Preface

This volume contains the papers presented at ICALP 2017, the 44th edition of the International Colloquium on Automata, Languages and Programming, held in Warsaw, Poland during July 10–14, 2017. ICALP is a series of annual conferences of the European Association for Theoretical Computer Science (EATCS), which first took place in 1972. This year, the ICALP program consisted of three tracks:

- Track A: Algorithms, Complexity, and Games,
- Track B: Logic, Semantics, Automata and Theory of Programming,
- Track C: Foundations of Networked Computation: Models, Algorithms, and Information Management.

In response to the call for papers, a total 459 submissions were received: 296 for track A, 108 for track B, and 55 for track C. Each submission was reviewed by at least three Program Committee members, aided by many subreviewers. Out of these, the committee decided to accept 137 papers for inclusion in the scientific program: 88 papers for Track A, 32 for Track B, and 17 for Track C. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper for each of the three tracks, selected by the Program Committees.

The best paper awards were given to the following papers:

- Track A: Andreas Björklund, Petteri Kaski and Ioannis Koutis. "Directed Hamiltonicity and Out-Branchings via Generalized Laplacians".
- Track B: Michael Benedikt, Pierre Bourhis and Michael Vanden Boom. "Characterizing Definability in Decidable Fixpoint Logics".
- Track C: Eyjólfur Ingi Ásgeirsson, Magnus M. Halldorsson and Tigran Tonoyan. "Universal Framework for Wireless Scheduling Problems".

The best student paper awards, for papers that are solely authored by students, were given to the following papers:

- Track A: Euiwoong Lee. "Improved Hardness for Cut, Interdiction, and Firefighter Problems".
- Track B: Fabian Reiter. "Asynchronous Distributed Automata: A Characterization of the Modal Mu-Fragment".

Apart from the contributed talks, ICALP 2017 included invited presentations by Mikołaj Bojańczyk, Monika Henzinger, Ronitt Rubinfeld and Mikkel Thorup. This volume of the proceedings contains all contributed papers presented at the conference together with the papers and abstracts of the invited speakers.

The program of ICALP 2017 also included presentation of the EATCS Award 2017 to Eva Tardos, the Presburger Award 2017 to Alexandra Silva and the EATCS Distinguished Dissertation Award to Vincent Cohen-Addad, Mika Göös and Steen Vester.

Three satellite events of ICALP were held on 14 July, 2017:

- SSG: Algorithms and Structure for Sparse Graphs
- AVeRTS: Algorithmic Verification of Real-Time Systems
- SP: Separability Problems

44th International Colloquium on Automata, Languages, and Programming (ICALP 2017).
Editors: Ioannis Chatzigiannakis, Piotr Indyk, Fabian Kuhn, and Anca Muscholl
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The Lipa Summer School was organized on topics connected to logic in computer science during 3–6 July, 2017.

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all referees who assisted the Program Committees in the evaluation process. We are also grateful to Mikołaj Bojańczyk, Piotr Sankowski, Bartek Klin and Filip Murlak for organizing ICALP 2017 and all the support staff of the Organizing Committee, especially Hanna Bargieł and Alicja Kosińska from Global Congress.

We would like to thank Paul Spirakis, the president of EATCS, for his generous advice on the organization of the conference.

July 2017

Track A

Indyk Piotr	MIT, USA, Chair
Afshani Peyman	Aarhus University, Denmark
Agarwal Pankaj	Duke University, USA
Bringmann Karl	Max Planck Institute for Informatics, Germany
Chattopadhyay Arkadev	Tata Institute of Fundamental Research, India
Chechik Shiri	Tel-Aviv University, Israel
Ene Alina	Boston University, USA
Filmus Yuval	Technion – Israel Institute of Technology, Israel
Gopalan Parikshit	VMware Research, USA
Grossi Roberto	Universita' di Pisa, Italy
Gupta Anupam	Carnegie Mellon University, USA
Ishai Yuval	Technion, Israel
Kapralov Michael	EPFL, Switzerland
Kleinberg Robert	Cornell University, USA
Lu Pinyan	Shanghai University of Finance and Economics, China
Magniez Frederic	CNRS, Univ. Paris Diderot, France
Mahdian Mohammad	Google, USA
Marx Daniel	Computer and Automation Research Institute, Hungarian Academy of Sciences, Hungary
Nanongkai Danupon	KTH Royal Institute of Technology, Sweden, Sweden
Nelson Jelani	Harvard, USA
Pilipczuk Marcin	Institute of Informatics, University of Warsaw, Poland
Sankowski Piotr	University of Warsaw, Poland
Sauerwald Thomas	University of Cambridge, United Kingdom
Scheideler Christian	University of Paderborn, Germany
Sohler Christian	TU Dortmund, Germany
Telikepalli Kavitha	Tata Institute of Fundamental Research, Mumbai, India
Vaikuntanathan Vinod	University of Toronto, Canada
Vegh Laszlo A.	London School of Economics, United Kingdom
Venkatasubramanian Suresh	University of Utah, USA
Vidick Thomas	Caltech, USA
Wee Hoeteck	ENS, France
Weimann Oren	University of Haifa, Israel
Weinberg Seth	MIT, USA

44th International Colloquium on Automata, Languages, and Programming (ICALP 2017).
Editors: Ioannis Chatzigiannakis, Piotr Indyk, Fabian Kuhn, and Anca Muscholl
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B

Muscholl Anca	LaBRI, Universite Bordeaux, France, Chair
Barcelo Pablo	Universidad de Chile, Chile
Blumensath Achim	Masaryk University, Brno, Czech Republic
Brihaye Thomas	Université de Mons, Belgium
Chatterjee Krishnendu	Institute of Science and Technology (IST), Austria
Coquand Thierry	Chalmers University, Sweden
Dawar Anuj	University of Cambridge, United Kingdom
Endrullis Jörg	Vrije Universiteit Amsterdam, Netherlands
Fisman Dana	University of Pennsylvania, USA
Hofmann Martin	LMU Munich, Germany
Jagadeesan Radha	DePaul University, USA
Kiefer Stefan	University of Oxford, United Kingdom
Kieronski Emanuel	University of Wroclaw, Poland
Kreutzer Stephan	Technical University Berlin, Germany
La Torre Salvatore	Dipartimento di Informatica, Università degli studi di Salerno, Italy
Lin Anthony Widjaja	Department of Computer Science, University of Oxford, United Kingdom
Martens Wim	University of Bayreuth, Germany
Mellies Paul-André	CNRS, Université Paris Diderot, France
Padovani Luca	Università di Torino, Italy
Palamidessi Catuscia	INRIA, France
Pighizzini Giovanni	Dipartimento di Informatica, Università degli Studi di Milano, Italy
Pin Jean-Éric	LIAFA, CNRS and University Paris 7, France
Silva Alexandra	University College London, United Kingdom
Talbot Jean-Marc	LIF, Universite d'Aix-Marseille, France
Viswanathan Mahesh	University of Illinois, Urbana-Champaign, USA
Wilke Thomas	University of Kiel, Germany
Worell James	Oxford University, United Kingdom

Track C

Kuhn Fabian	University of Freiburg, Germany, Chair
Abraham Ittai	VMware Research, USA
Anta Antonio Fernandez	IMDEA Networks Institute, Spain
Aspnes James	Yale, USA
Censor-Hillel Keren	Technion, Israel
Emek Yuval	Technion, Israel
Ghaffari Mohsen	ETH Zurich, Switzerland
Giakkoupis George	INRIA Rennes, France
Gilbert Seth	N/A, Singapore
Haeupler Bernhard	CMU, USA
Korman Amos	CNRS and Université Paris Diderot - Paris 7, France
Kosowski Adrian	IRIF (LIAFA) / Inria Paris, France
Lenzen Christoph	MPI for Informatics, Germany
Masuzawa Toshimitsu	Osaka University, Japan
Panagiotou Konstantinos	University of Munich (LMU), Germany
Panconesi Alessandro	Sapienza University of Rome, Italy
Parter Merav	MIT, CSAIL, USA
Patt-Shamir Boaz	Tel Aviv University, Israel
Pigonlet Yvonne-Anne	ABB Corporate Research, Switzerland

Orbit-Finite Sets and Their Algorithms*†

Mikołaj Bojańczyk

University of Warsaw, Warsaw, Poland
bojan@mimuw.edu.pl

Abstract

An introduction to *orbit-finite sets*, which are a type of sets that are infinite enough to describe interesting examples, and finite enough to have algorithms running on them. The notion of orbit-finiteness is illustrated on the example of register automata, an automaton model dealing with infinite alphabets.

1998 ACM Subject Classification F.1.1 Models of Computation

Keywords and phrases Orbit-finite sets, sets with atoms, data words, register automata

Digital Object Identifier 10.4230/LIPIcs.ICALP.2017.1

1 Introduction

An orbit-finite set is a set that is constructed using some infinite logical structure, such as $(\mathbb{N}, =)$ or $(\mathbb{Q}, <)$, and which is finite up to automorphisms of that structure. For example, if the structure is $(\mathbb{N}, =)$, then

$$\{X : X \subseteq \mathbb{N} \text{ and } |X| \leq 3\}$$

is an orbit-finite set, because automorphisms of the structure (i.e. permutations of $\mathbb{N}$) can be used to map any subset $X \subseteq \mathbb{N}$ to any other subset of same cardinality, and therefore the set has four elements (cardinalities 0, 1, 2, 3) up to automorphisms.

The goal of this paper is to give a gentle introduction to orbit-finite sets, in particular to explain how they can be represented and manipulated using algorithms. As a running example we use register automata over infinite alphabets. A more detailed description can be found in the lecture notes [5].

2 The running example: register automata

As our running example for describing orbit-finite sets, we consider register automata over data words, and their associated decision problems such as emptiness or minimisation.

Typically, formal language theory uses finite alphabets. Here is an example which uses an infinite alphabet.

▶ **Running Example.** *Let $\mathbb{A}$ be some infinite set. As our running example, consider the language*

$$\{w \in \mathbb{A}^* : \textit{ at most two distinct letters appear in } w\}. \tag{1}$$

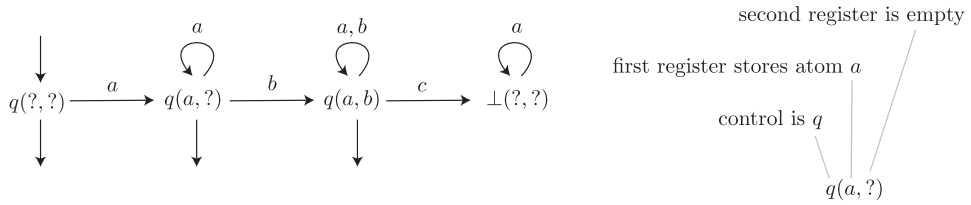

Figure 1 There are two possible values for the control state, q and $\bot$. A configuration of the automaton consists of a value for the control plus a valuation of the registers. Dangling arrows indicate initial and accepting configurations. The variables a, b, c range over distinct atoms, i.e. to get the automaton one should instantiate the picture for every triple $(a, b, c) \in \mathbb{A}^3$ of distinct atoms.

In our running example, the letters are only compared with respect to equality. Words as in the example are called languages of *data words*. The most common type of alphabet for data words is of the form $\Sigma \times \mathbb{A}$, where Σ is a finite set and $\mathbb{A}$ is an infinite set whose elements can only be compared for equality. We will use the name *atoms* for $\mathbb{A}$; to underline that they have no structure except for equality. Automata that process data words (and more complicated objects, such as data trees) are a popular model in database theory (e.g. an XML document is conveniently described as a type of data tree) or in the theory of verification. See the survey [25] for more on such automata.

One of the most basic automata models for data words is register automata (introduced in [17] under the name of *finite memory automata*). This is a type of automaton which uses finitely many registers to store some of the atoms that have been seen so far. We will use register automata as our running example of orbit-finite sets.

▶ **Running Example.** *This language in the running example, namely "at most two letters (atoms) appear" is recognised by a register automaton with two registers. The registers are used to store the at most two distinct atoms in the input. Once the two registers are filled up and a fresh third atom appears, the automaton enters a rejecting sink state. The automaton is shown in Figure 1.*

In general, the space of configurations of a register automaton is defined by giving a finite set of control states and a set of register names. A configuration is then a pair: (control state, partial function from register names to atoms). For the precise syntax of the transition relation (and notions of initial and final configurations), we refer to [17]; for the purposes of this paper it suffices to say that the syntax is designed so that transitions depend on the atoms in a way which only uses equality. Register automata, and especially deterministic register automata, are one of the simplest automaton models for data words, e.g. they are not expressive enough to recognise the language "all input letters are different". For more expressive models, see [25].

3 Mild extensions of register automata

To motivate the introduction of orbit-finite and definable sets, which are the topic of this paper, we present three mild requirements for extending the model of register automata. We will then show that these requirements can be met by automata with definable (or equivalently, orbit-finite) descriptions.

3.1 Minimisation

One natural thing to do with (deterministic) register automata is to minimise them. As we will see, the register mechanism is not well suited to this task.

▶ **Running Example.** *Consider the automaton from Figure 1, which uses two registers to recognise words with at most two distinct atoms. This automaton has different configurations after reading inputs ab and ba, because its configuration implicitly remembers which letter was read first. A minimal automaton, on the other hand, should have the same configuration after reading these two inputs, because the language is commutative. In a minimal automaton, the set of reachable configurations should be something like:*

$$\underbrace{\{\epsilon, \bot\}}_{\text{initial state and rejecting sink}} \cup \underbrace{\{a : a \in \mathbb{A}\}}_{\text{words that have exactly one atom}} \cup \underbrace{\{\{a, b\} : a \neq b \in \mathbb{A}\}}_{\text{word that have exactly two atoms}} .$$

Such a configuration set cannot be achieved with the register mechanism.

A workaround for the problems described above would be to allow registers which store unordered sets of atoms. Here is another example language, where the workaround with unordered sets of atoms fails.

▶ **Example 1.** Consider the following language

$$\{wv : w, v \in \mathbb{A}^3 \text{ are equal up to cyclic shift}\}. \tag{2}$$

For this language, the set of configurations of a minimal automaton reachable after reading three letters should be

$$\{ \underbrace{\{abc, bca, cab\}}_{\substack{\text{equivalence class of a} \\ \text{three letter word up} \\ \text{to cyclic shifts}}} : a, b, c \in \mathbb{A}\}.$$

Example 1 and the running example essentially exhaust the possible problems with miminisation: to minimise register automata it suffices to consider a model where each control state has a varying number of registers, and there might be some group acting on the registers (e.g. so that the registers form an unordered set, or can be shifted cyclically, etc.), see [8, Section 6]. The idea to use groups acting on registers dates back to [23].

Why is it so important to minimise automata? A minimal automaton is not just small – with the obvious efficiency advantages – but more importantly it is a canonical representation of its recognised language.

One use for canonical automata is that for the correctness of certain algorithms, it is useful to assume that the input is a canonical automaton. An example is learning algorithms, whose running time bounds and correctness proofs are based on minimal automata, see e.g. [20] for a variant of the Angluin algorithm for register automata. Another example is algorithms which input an automaton and decide if its recognised language is definable in some logic, see [2, 6]; here non-definability is typically equivalent to some kind of forbidden pattern in the canonical automaton.

Another use for canonical automata is that they can be useful when trying to better understand "regularity" for languages over infinite an alphabet. There is a multitude of automata models for infinite alphabets, see [22, 25], most of them with different expressive powers, and one naturally asks [4]: which model defines the "regular languages"? Over finite

alphabets, the Myhill-Nerode theorem gives a convincing machine independent characterisation of regular languages in terms of minimisation: a language is regular if and only if it has finitely many equivalence classes in their syntactic congruence (and these equivalence classes form the states of the canonical minimal automaton). Therefore, a natural idea is to study the syntactic congruences of languages such as the one in the running example, and try to find devices which store the information from the syntactic congruence and nothing else. This idea was pursued for monoids (corresponding to a two-sided syntactic congruence) in [6], for deterministic automata (corresponding to a one-sided syntactic congruence, which is different from the two-side one in the presence of infinite alphabets) in [8], and for deterministic timed automata in [3, 10]. In all of these cases the straightforward register mechanism (without group actions and other features) is insufficient to allow minimisation. See also [21] for algorithmic aspects of minimising register automata.

3.2 More general input alphabets

In data words and register automata, the input alphabet is typically assumed to be of the form $\Sigma \times \mathbb{A}$ for some finite set Σ. Why not allow slightly more general input alphabets, such as pairs of atoms $\mathbb{A}^2$ or unordered pairs of atoms $\binom{\mathbb{A}}{2}$? At first sight this seems like a needless generalisation, but it turns out that some interesting theoretical issues appear only for the more general alphabets. As an example [18, Example 2.5], which admittedly goes far beyond register automata because it uses Turing machines, consider the following set:

$$\{\{\{a, b, c\}, \{d, e, f\}\} : a, b, c, d, e, f \in \mathbb{A} \text{ are pairwise different}\}.$$

Suppose that the input alphabet Σ is the above set, and consider the language:

$$\{wv : w, v \in \Sigma^* \text{ are such that } \pi(w) = v \text{ for some permutation of the atoms } \pi\}.$$

In [18] it is shown that the above language witnesses that deterministic and nondeterministic Turing machines (in a suitable generalisation for infinite alphabets using atoms) have different expressive powers, and simpler alphabets (e.g. alphabets which talk about less than six atoms) do not witness this. This result builds on [9], which in turn builds on the seminal Cai-Fürer-Immermann [27] construction. The readers familiar with [27] will recognise the use of six atoms in the alphabet Σ.

3.3 Atoms with more structure than just equality

In our definition of data words and register automata, the atoms $\mathbb{A}$ had equality as the only available structure. Why not allow for more structure? Data words with additional structure, such as a total order, have long been present in the literature on data words. For example, [13] shows that emptiness is decidable for register automata where the input alphabet is $(\mathbb{N}, <)$ and the register operations can compare letters with respect to the order. Another important example is timed automata [1], which can be viewed as a special kind of register automata where the atoms are $(\mathbb{Q}, <, +1)$, see [10] and [14, 15] for the case of pushdown automata. Other examples come from modelling programs interacting with a database, see e.g. [26, 11]; in these applications the atoms might have e.g. an arbitrary graph structure.

4 Definable sets

In Section 2 we described register automata, and in Section 3 we discussed three requirements for a more general model: it should minimise (Section 3.1); it should allow more general

input alphabets than only the atoms (Section 3.2); and it should allow more structure on the atoms than just equality (Section 3.3). In this section we present such a model, using the notion of definable sets. The general idea is that definable sets are those that can be constructed using set-builder notation. Before giving the precise definition, consider some examples.

▶ **Example 2.** Here are some of the sets that we have seen so far:

atoms	$\mathbb{A}$
ordered pairs of atoms	$\mathbb{A}^2$
unordered pairs of atoms	$\{\{a,b\} : a,b \in \mathbb{A}\}$
states in the minimal automaton from the running example	$\{\epsilon, \bot\} \cup \{a : a \in \mathbb{A}\} \cup \{\{a,b\} : a \neq b \in \mathbb{A}\}$
triples of atoms modulo cyclic shift	$\{\{abc, bca, cab\} : a,b,c \in \mathbb{A}\}$
input alphabet for a language which witnesses that Turing machines with atoms do not determinise	$\{\{\{a,b,c\},\{d,e,f\} :$ $a,b,c,d,e,f \in \mathbb{A}$ are distinct$\}$

The above examples used only equality. In the spirit of Section 3.3, let us consider some examples which assume that the atoms are equipped with structure other than equality.

▶ **Example 3.** Assume that the atoms are equipped with a total order, and assume that 5 is one of the atoms. Here are some examples of sets defined using set builder notation:

atoms smaller than 5	$\{a : a \in \mathbb{A} \text{ with } a < 5\}$
all closed intervals	$\{\{c : c \in \mathbb{A} \text{ with } a \leq c \leq b\} : a,b \in \mathbb{A} \text{ with } a < b\}$

We now give a more formal description of set-builder notation and sets defined by it. A parameter is an underlying logical structure $\mathbb{A}$, i.e. a universe equipped with some relations and functions (equality is for free), which will be referred to as the *atoms*.

▶ **Example 4.** Here are some examples of logical structures that we will use as atoms:

$$\underbrace{\mathbb{A} = (\mathbb{N}, =)}_{\text{equality only}} \qquad \underbrace{\mathbb{A} = (\mathbb{Q}, <)}_{\text{ordered rationals}} \qquad \underbrace{\mathbb{A} = (\mathbb{N}, +)}_{\text{Presburger arithmetic}} \qquad \underbrace{\mathbb{A} = (\mathbb{N}, +, \times)}_{\text{arithmetic}}$$

In the first structure, we write the equality symbol (which is implicitly assumed to be always available) just to underline that it is the only structure available.

Given a logical structure $\mathbb{A}$, we define *set-builder expressions over* $\mathbb{A}$ by induction as follows. Fix some infinite set of variables $\{a, b, c, \ldots\}$, which will be used in the set-builder expressions, and which are intended to range over atoms, i.e. elements of the universe of $\mathbb{A}$. Subexpressions in set-builder expression can have free variables, but in the end we are interested in an outermost expression with no free variables. There are four constructions: each element of $\mathbb{A}$ is an expression (constant expression); each variable is an expression (variable expression); and expressions can be combined using binary union and set comprehension. These constructions are illustrated in Figure 2.

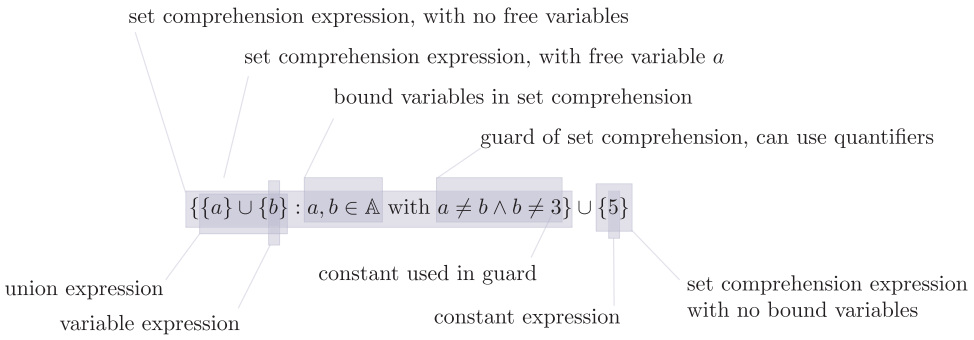

Figure 2 A set-builder expression over $\mathbb{A} = (\mathbb{N}, =)$.

The semantics of a set-builder expression is a function which inputs a valuation of its free variables (i.e. a function from the free variables to the universe of $\mathbb{A}$) and outputs an atom, a set, a set of sets, etc. defined in the obvious way. A *definable set over* $\mathbb{A}$ is the semantics of a set-builder expression without free variables. The reader will readily see that all sets mentioned in Example 2 are definable regardless of the choice of $\mathbb{A}$ (see the running example below for an explanation of how pairing and elements such as $\bot$ are encoded) and the sets mentioned in Example 3 are definable as long as the vocabulary of $\mathbb{A}$ contains a binary relation $<$ and the universe contains an element 5.

Our proposed solution to the requirements raised in Section 3 is to consider automata where all components (the input alphabet, the states, the transition relation, the initial and accepting states) are definable over some structure $\mathbb{A}$. Call these *definable automata* over some structure $\mathbb{A}$ [8, 11].

▶ **Running Example.** *Assume that the atoms are $\mathbb{A} = (\mathbb{N}, =)$, i.e. some countably infinite set with equality only. Here is a deterministic automaton which recognises the language from our running example, i.e. words in $\mathbb{A}^*$ with at most two distinct letters. The input alphabet is $\mathbb{A}$, which is clearly a definable set, as defined by the set-builder expression $\{a : a \in \mathbb{A}\}$. The set of states Q is*

$$\{\emptyset, \bot\} \cup \{a : a \in \mathbb{A}\} \cup \{\{a, b\} : a \neq b \in \mathbb{A}\},$$

which is also definable as long as we assume that $\bot$ is syntactic sugar for some definable set like $\{\emptyset\}$. The initial state is $\emptyset$, which is clearly definable, and all states states are final except $\bot$. Here is the set of transitions, which happens to be a total function of type $Q \times \mathbb{A} \to Q$ as required in a deterministic automaton:

$$\{(\emptyset, a, \{a\}) : a \in \mathbb{A}\} \cup$$
$$\{(\{a\}, b, \{a, b\}) : a, b \in \mathbb{A}\} \cup$$
$$\{(\{a, b\}, a, \{a, b\}) : a, b \in \mathbb{A}\} \cup$$
$$\{(\{a, b\}, c, \bot) : a, b, c \in \mathbb{A} \text{ with } a \neq b \wedge a \neq c \wedge b \neq c\} \cup$$
$$\{(\bot, a, \bot) : a \in \mathbb{A}\}$$

The above description uses ordered triples, which are formally not part of the syntax of set-builder expressions. However, triples and other tuples can encoded in sets using Kuratowski pairing:

$$(x, y) \stackrel{\text{def}}{=} \{x, \{x, y\}\} \qquad (x, y, z) \stackrel{\text{def}}{=} ((x, y), z).$$

Under the above encoding of triples as sets, it is clear that the transition relation defined above is an example of a definable set.

Based on the above example, it is easy to see that definable automata generalise register automata. What is more, the added flexibility of definable automata is sufficient to satisfy the requirements mentioned in Section 3, in particular minimisation, i.e. for every deterministic definable automaton there exists a unique (up to isomorphism of automata) minimal deterministic definable automaton which recognises the same language [8, Theorem 3.8]. (This minimisation requires an additional assumption on the atoms, called oligomorphism, which will be discussed in Section 6.)

Without further restrictions on the atoms $\mathbb{A}$, definable automata are too general to be useful, as shown in the following example.

▶ **Example 5.** Assume that the atoms are Presburger arithmetic $\mathbb{A} = (\mathbb{N}, +)$. Consider an automaton where the input alphabet has one letter only, say the input alphabet is $\{\emptyset\}$, and the set of states is the definable set of all atoms (i.e. natural numbers). Assume that there is only one final state, namely the natural number 0. Since there is only one input letter, the transition function can be viewed as a function $\mathbb{A} \to \mathbb{A}$. As the transition function, consider the function

$$a \mapsto \begin{cases} a/2 & \text{if } a \text{ is even} \\ 3a+1 & \text{otherwise} \end{cases}$$

which is a definable set as witnessed by the following set-builder expression for its graph:

$$\{(a,b) : a, b \in \mathbb{A} \text{ with } a = b + b\} \quad \cup$$
$$\{(a,b) : a, b \in \mathbb{A} \text{ with } \neg(\exists c\ a = c + c) \wedge b = a + a + a + 1\}.$$

The transition function is based on the famous Collatz conjecture, which in the terminology of this example says: for every choice of initial state, at least one input word is accepted. In fact, all decision problems, such as emptiness or equivalence, are going to be undecidable for this particular choice of atoms (Presburger arithmetic, or even $(\mathbb{N}, <)$ or $(\mathbb{N}, +1)$), which follows from the fact that Minsky machines are a special case of definable automata.

▶ **Example 6.** Assume that the atoms are arithmetic $\mathbb{A} = (\mathbb{N}, +, \times)$, and consider a set-builder expression of the form

$$\{a : a \in \mathbb{A} \text{ with } \varphi(a)\}.$$

The above set is empty if and only if $\varphi(a)$ is unsatisfiable. Since satisfiability in arithmetic is undecidable, it follows that one cannot even decide if a set-builder expression describes an empty set. (This is in contrast with Presburger arithmetic from Example 5, where at least emptiness for set-builder expressions is definable, by virtue of Presburger arithmetic having a decidable theory, see [19, Proposition 2].) Other problems, such as nonemptiness or equivalence for automata are clearly also going to be undecidable when the atoms are arithmetic.

5 Graph reachability for definable sets

In the previous section, we introduced definable sets, and discussed definable automata, i.e. automata where all components are definable sets. In Examples 5 and 6 we argued

```
input V, E, s, t given by set-builder expressions

R := {s}
repeat
 for v in R do
  for w in V do
    if {v,w} in E then
      R += {w}
until R does not grow

if t in R then
 print "reachable"
else
 print "unreachable"
```

Figure 3 A naive algorithm for reachability.

that emptiness for automata is undecidable when the atoms are $(\mathbb{N}, +)$ or $(\mathbb{N}, +, \times)$. In this section, we discuss algorithmic problems like emptiness of automata in more detail. Instead of automata emptiness, we will discuss the essentially equivalent but more fundamental problem of graph reachability. We formalise the problem and present a condition on the atom structure $\mathbb{A}$ which guarantees the graph reachability problem is decidable. This condition is going to be violated for atoms like $(\mathbb{N}, <)$, $(\mathbb{N}, +)$ and $(\mathbb{N}, +, \times)$ but it is going to be satisfied for atoms like $(\mathbb{N}, =)$ or $(\mathbb{Q}, <)$.

The graph reachability problem

For a logical structure $\mathbb{A}$, define *reachability for definable graphs over* $\mathbb{A}$ to be the following decision problem:

- **Input.** A graph (V, E) where V, E are definable sets and two vertices $s, t \in V$.
- **Question.** Is there a path from s to t?

In the decision problem above, the inputs are represented by set-builder expressions. This representation assumes that there is some way of representing the universe of $\mathbb{A}$, which is the case for all atom structures we have discussed so far, where the universe consists of natural or rational numbers. We are mainly interested in decidability and not in the precise complexity of the decision problem.

▶ **Example 7.** Assume that the atoms $\mathbb{A}$ are $(\mathbb{N}, +)$. A valid input for the reachability problem for definable graphs over $\mathbb{A}$ is

$$V = \mathbb{N} \quad E = \{(a, b) : a, b \in \mathbb{A} \text{ with } a = b + b \vee a + 1 = b\} \quad s = 7 \quad t = 2.$$

For this particular input the answer is "yes" because one can go from 7 to 2 by doing several steps of the form "divide by two or add one". For the same reason as discussed in Example 5, i.e. encoding Minsky machines, reachability is undecidable for definable graphs over Presburger arithmetic $(\mathbb{N}, +)$. Actually, the undecidability holds already for atoms $(\mathbb{N}, <)$, since Minsky machines use only increments and decrements on the counters, and these can be defined in first-order logic using only the order. Note that to get undecidability for $(\mathbb{N}, <)$ it is important that formulas in the guards of definable sets are allowed to use

quantifiers. If only quantifier-free formulas would be allowed in the guards, then graph reachability for $(\mathbb{N}, <)$ would be decidable [13].

Example 7 shows that the reachability problem is undecidable when the atoms are natural numbers with order, or any other richer structure such as addition or multiplication. What about definable graphs over atoms with equality only, or atoms such as $(\mathbb{Q}, <)$? It turns out that for these atoms, reachability is decidable, and the algorithm is quite straightforward. Define R_n to be the vertices which can be reached from the source by path of at most n edges. A naive algorithm to solve graph reachability (see Figure 3) would be to simply compute the sequence $R_0 \subseteq R_1 \subseteq R_2 \subseteq \cdots$ until it stabilises, and then test if the target vertex is in the stable set. Here is a key property of the program in Figure 3. Assuming that the atoms have decidable first-order theory (which assumption is true Presburger arithmetic $(\mathbb{N}, +)$ but not for general arithmetic $(\mathbb{N}, +, \times)$), then at least each step (both for loops) of the naive algorithm can be carried out in finite time, but the number of steps (repeat loop) might be unbounded:

need not terminate

```
repeat
 for v in R do
  for w in V do
   if {v,w} in E then
    R += {w}
until R does not grow
```

will always terminate, assuming $\mathbb{A}$ has decidable first-order theory

A more formal statement is in the following lemma.

▶ **Lemma 8.** *Let $\mathbb{A}$ be a logical structure. Suppose that $E \subseteq V \times V$ and $R \subseteq V$ are given by set-builder expressions over $\mathbb{A}$. Then one can compute a set-builder expression representing*

$$R \cup \{v \in V : \{v, w\} \in E \text{ for some } w \in R\}.$$

Assume furthermore that $\mathbb{A}$ has decidable first-order theory. Then one can decide, given R' and R represented using set-builder expressions, if $R' \subseteq R$.

The above lemma can be shown using [19, Proposition 2]; but it is mainly interesting as part of a more general framework, namely programming languages that deal with definable sets. There are currently two programming languages: a functional one [7], with an implementation as a Haskell library [20]; and an imperative one [12] with an implementation as a C++ library [19]. The example reachability program in Figure 3 is based on the imperative approach. The original version of the imperative programming language [12] assumed that the atoms were oligomorphic (see below), but the version from [19] relaxed this assumption to having a decidable first-order theory (which captures additional examples such as Presburger arithmetic). The semantics of both languages are designed so that one does not need to prove results like Lemma 8 by hand; but one can simply use more general principles like the following: every program without `repeat` can be simulated in finite time, assuming the inputs (i.e. program state before) and outputs (i.e. program state after) are represented using set-builder expressions.

As follows from Example 7, decidability of the first-order theory of $\mathbb{A}$ alone does not guarantee that the repeat loop in the program from Firgure 3 will terminate in finitely many steps. Remarkably, when the atoms have equality only, or they are $(\mathbb{Q}, <)$, then the repeat loop necessarily terminates. The reason is that atoms with equality only or $(\mathbb{Q}, <)$ are examples of *oligomorphic* structures. In the next two sections, we discuss oligomorphic structures and prove this termination (Theorem 13). The assumption that the atoms are oligomorphic is what makes the theory of definable sets robustly well behaved.

6 Oligomorphism and orbit-finiteness

In this section we describe what it means for a logical structure to be oligomorphic. The main use of this assumption is that it allows us to use relaxed notion of finiteness for sets, called *orbit-finiteness*; in particular all definable sets will turn out to be orbit-finite.

Definition of oligomorphism

If $\mathbb{A}$ is a logical structure, then an *automorphism* is defined to be any permutation of its universe which is consistent with all the relations and functions in the vocabulary of $\mathbb{A}$. For example, when $\mathbb{A}$ has only equality in its signature then an automorphism is any permutation; while if $\mathbb{A}$ is $(\mathbb{Q}, <)$ then an automorphism is any order-preserving permutation. The structures $(\mathbb{N}, <)$ and $(\mathbb{N}, +)$ have no automorphisms, while $(\mathbb{Z}, <)$ has only translations as automorphisms.

▶ **Definition 9** (Oligomorphism)**.** Consider a logical structure $\mathbb{A}$. We say that two tuples $\bar{a}, \bar{b} \in \mathbb{A}^k$ are *in the same orbit* if there exists an automorphism of $\mathbb{A}$ which takes $\bar{a}$ to $\bar{b}$ componentwise. The structure $\mathbb{A}$ is called *oligomorphic* if for every k, the "same orbit" equivalence relation on $\mathbb{A}^k$ has finitely many equivalence classes.

The notion of oligomorphism made its appearance in model theory in 1959, thanks to a theorem proved independently by Engeler, Ryll-Nardzewski and Svenonius: for a countable structure, being oligomorphic is equivalent to having an ω-categorical theory, see [16, Theorem 7.3.1]. One important corollary of this theorem (and its proof) is that in an oligomorphic structure, every orbit of $\mathbb{A}^k$ can be defined by a formula of first-order logic with k free variables; we will use this property later on.

▶ **Example 10.** Here are some examples and non-examples of oligormophic structures.

- Assume that $\mathbb{A} = (\mathbb{N}, <)$. This structure has no automorphisms, and therefore the "same orbit" equivalence relation on $\mathbb{A}$ has infinitely many equivalence classes (which are singletons). Therefore $\mathbb{A}$ is not oligomorphic.
- Assume that $\mathbb{A} = (\mathbb{Z}, <)$. The automorphisms are translations, and hence the "same orbit" equivalence relation has one equivalence class on $\mathbb{A}$. However, there are infinitely many equivalence classes for $\mathbb{A}^2$, because

  $$(a_1, a_2), (b_1, b_2) \text{ are in the same orbit} \qquad \text{iff} \qquad a_1 - a_2 = b_1 - b_2.$$

  Therefore $\mathbb{A}$ is not oligomorphic.
- Assume that $\mathbb{A} = (\mathbb{N}, =)$, i.e. a countably infinite set with equality only. For every k, tuples in $\mathbb{A}^k$ are in the same orbit if and only if they have the same equality types, and there are finitely many equality types. Therefore, $\mathbb{A}$ is oligomorphic.
- Assume that $\mathbb{A} = (\mathbb{Q}, <)$. It is not difficult to see that for every k, tuples $\bar{a}, \bar{b}$ satisfy $\bar{a} \sim \bar{b}$ if and only if they have the same order types, and there are finitely many order types. Therefore, $\mathbb{A}$ is oligomorphic.
- Every structure over a finite vocabulary without functions that is homogeneous is oligomorphic. This covers Fraïssé limits of classes of finite relational structures, such as the previous two items, or the countable random graph. For more on homogeneous structures, the Fraïssé limit and the random graph, see [16, Section 7].

Orbit-finiteness

Oligomorphic structures turn out to be exceptionally well-behaved with respect to definable sets. The reason for this is that in an oligomorphic structure one can distinguish a relaxed notion of finiteness, called *orbit-finiteness*, which is well behaved and can be used to prove results such as the termination of the algorithm Figure 3.

To define orbit-finiteness, we need to introduce a little set terminology. Fix a logical structure $\mathbb{A}$. Define the *cumulative hierarchy over* $\mathbb{A}$ to be objects that are built using atoms (i.e. elements of $\mathbb{A}$) and set brackets in a well-founded way. More precisely, for an ordinal number we define the rank α objects of the the cumulative hierarchy as follows: for $\alpha = 0$ the rank α objects are the empty set and every atom; for $\alpha > 0$ the rank α objects sets whose elements are objects of rank $< \alpha$. The cumulative hierarchy is the union of all ranks. For example, every definable set over $\mathbb{A}$ is in the cumulative hierarchy, but there are many more sets in the cumulative hierarchy (e.g. the cumulative hierarchy is closed under taking arbitrary subsets, unlike definable sets).

If π is an automorphism of $\mathbb{A}$ (actually, any function of type $\mathbb{A} \to \mathbb{A}$), then one can apply π to an object x in the cumulative hierarchy, by simply applying to the atoms that are used in x; the result is a new object $\pi(x)$ in the cumulative hierarchy with the same rank.

▶ **Definition 11** (Finite support and orbit-finiteness)**.** Let $\mathbb{A}$ be a logical structure. For x in the cumulative hierarchy over $\mathbb{A}$, we say that x is *finitely supported* if there exists a tuple of atoms $\bar{a}$ (which is called a *support* of x) such that

$$\pi(\bar{a}) = \sigma(\bar{a}) \quad \text{implies} \quad \pi(y) = \sigma(y) \qquad \text{for every automorphisms } \pi, \sigma \text{ of } \mathbb{A}.$$

We say that x is *orbit-finite* if the following equivalence relation on elements of x has finitely many equivalence classes:

$$y \sim z \quad \text{if } y = \pi(z) \qquad \text{for some automorphism } \pi \text{ of } \mathbb{A}.$$

The notion of finite supports is fundamental to set theories such as Fraenkel-Mostowski, and more recently to the theory of nominal sets [24]. To the author's best knowledge, the notion of orbit-finiteness was first explicitly proposed in [6]. In the terminology of the above definition, $\mathbb{A}$ is oligomorphic if and only if $\mathbb{A}^k$ is orbit-finite for every k. The following theorem shows that, under the assumption that the atoms are oligomorphic, then the notion of orbit-finiteness is well behaved and definable sets are the same as sets which are hereditarily orbit-finite. For a proof of the following theorem, see [5].

▶ **Theorem 12.** *Let $\mathbb{A}$ be a logical structure which is oligomorphic, and let x be in the cumulative hierarchy over $\mathbb{A}$.*

1. *x is orbit-finite if and only if for every tuple of atoms $\bar{a}$, the following equivalence relation has finitely many equivalence classes:*

$$y \sim_{\bar{a}} z \quad \text{if } y = \pi(z) \text{ for some automorphism } \pi \text{ of } \mathbb{A} \text{ which satisfies } \pi(\bar{a}) = \bar{a}.$$

2. *x is definable if and only if it is hereditarily orbit-finite (i.e. x finitely supported and orbit-finite, and both these properties also hold for elements of x, their elements, and so on recursively).*

The equivalence in item 2 of the above theorem is very useful for computation: in some cases it is more convenient to use definable sets (e.g. to represent sets in a finite way), and in some cases it is more convenient to use orbit-finite sets (e.g. in termination proofs). We now show an example of this usefulness.

Termination of the reachability algorithm

In Figure 3 from Section 5, we presented a naive reachability algorithm for definable graphs. We also remarked that, as long as the atoms have decidable first-order theory, then each iteration of the repeat loop could be evaluated in finite time. We are now ready to show that, as long as the atoms are oligomorphic, then the repeat loop will be be performed finitely often.

▶ **Theorem 13.** *Assume that $\mathbb{A}$ is oligomorphic. Then the reachability algorithm in Figure 3 terminates on every input.*

Proof. Assume that the input to is a graph with distinguished source and target, and that each part of the input (vertices, edges, source and target) is a definable set represented by a set-builder expression. By item 2 in Theorem 12, each part of the input has a finite support. By combining these finite supports into a single tuple, we can conclude there is some tuple of atoms $\bar{a}$ which supports all parts of the input, i.e. $\bar{a}$ supports the vertices, the edges and the source and target vertices. For $n \in \{0, 1, \ldots\}$ define R_n to be the vertices which are reachable from the source vertex by a path with at most n edges. Recall the equivalence relation $\sim_{\bar{a}}$ mentioned in item 1 of Theorem 12. Using induction on n and the assumption that $\bar{a}$ supports the source vertex and the edges, we get the following observation:

(*) each set R_n is a union of equivalence classes of the $\sim_{\bar{a}}$.

By item 1 of Theorem 12, there are finitely many equivalence classes. By (*) each step of the reachability algorithm adds some new equivalence classes, and therefore the algorithm must terminate in a finite number of steps. ◀

The goal of the above proof was to illustrate the interplay between definability (as a way of representing infinite inputs) and orbit-finiteness (as a way of proving termination for algorithms). Other examples of this interplay include algorithms which uses a fixpoint computation, such as the standard algorithm for emptiness of a context-free grammar (which works if the grammar is definable over oligomorphic atoms) or the Moore minimisation algorithm for deterministic automata (which works for definable automata over oligomorphic atoms).

Efficient Algorithms for Graph-Related Problems in Computer-Aided Verification

Monika Henzinger

Faculty of Computer Science, University of Vienna, Vienna, Austria
monika.henzinger@univie.ac.at

Abstract

Fundamental algorithmic problems that lie in the core of many application in formal verification and analysis of systems can be described as graph-related algorithmic problems. Nodes in these problems are of one of two (or three) types, giving rise to a game-theoretic viewpoint: *Player one* nodes are under the control of the algorithm that wants to accomplish a goal, *player two* nodes are under the control of a worst-case adversary that tries to keep player one to achieve her goal, and *random* nodes are under the control of a random process that is oblivious to the goal of player one. A graph containing only player one and random nodes is called a Markov Decision Process, a graph containing only player one and player two nodes is called a game graph. A variety of goals on these graphs are of interest, the simplest being whether a fixed set of nodes can be reached. The algorithmic question is then whether there is a strategy for player one to achieve her goal from a given starting node. In this talk we give an overview of a variety of goals that are interesting in computer-aided verification and present upper and (conditional) lower bounds on the time complexity for deciding whether a winning strategy for player one exists.

Local Computation Algorithms

Ronitt Rubinfeld

Abstract

Consider a setting in which inputs to and outputs from a computational problem are so large, that there is not time to read them in their entirety. However, if one is only interested in small parts of the output at any given time, is it really necessary to solve the entire computational problem? Is it even necessary to view the whole input? We survey recent work in the model of *local computation algorithms* which for a given input, supports queries by a user to values of specified bits of a legal output. The goal is to design local computation algorithms in such a way that very little of the input needs to be seen in order to determine the value of any single bit of the output. In this talk, we describe results on a variety of problems for which sublinear time and space local computation algorithms have been developed – we will give special focus to finding maximal independent sets and sparse spanning graphs.

Fast and Powerful Hashing Using Tabulation*†

Mikkel Thorup

Department of Computer Science, University of Copenhagen, Copenhagen, Denmark
mikkel2thorup@gmail.com

Abstract

Randomized algorithms are often enjoyed for their simplicity, but the hash functions employed to yield the desired probabilistic guarantees are often too complicated to be practical. Here we survey recent results on how simple hashing schemes based on tabulation provide unexpectedly strong guarantees.

Simple tabulation hashing dates back to Zobrist [1970]. Keys are viewed as consisting of c characters and we have precomputed character tables $h_1, ..., h_q$ mapping characters to random hash values. A key $x = (x_1, ..., x_c)$ is hashed to $h_1[x_1] \oplus h_2[x_2] ..... \oplus h_c[x_c]$. This schemes is very fast with character tables in cache. While simple tabulation is not even 4-independent, it does provide many of the guarantees that are normally obtained via higher independence, e.g., linear probing and Cuckoo hashing.

Next we consider *twisted tabulation* where one character is "twisted" with some simple operations. The resulting hash function has powerful distributional properties: Chernoff-Hoeffding type tail bounds and a very small bias for min-wise hashing.

Finally, we consider *double tabulation* where we compose two simple tabulation functions, applying one to the output of the other, and show that this yields very high independence in the classic framework of Carter and Wegman [1977]. In fact, w.h.p., for a given set of size proportional to that of the space consumed, double tabulation gives fully-random hashing.

While these tabulation schemes are all easy to implement and use, their analysis is not.

This keynote talk surveys results from the papers in the reference list.

Abstract

We study the problem of testing unateness of functions $f : \{0,1\}^d \to \mathbb{R}$. We give an $O(\frac{d}{\varepsilon} \cdot \log \frac{d}{\varepsilon})$-query nonadaptive tester and an $O(\frac{d}{\varepsilon})$-query adaptive tester and show that both testers are optimal for a fixed distance parameter ε. Previously known unateness testers worked only for Boolean functions, and their query complexity had worse dependence on the dimension both for the adaptive and the nonadaptive case. Moreover, no lower bounds for testing unateness were known. We generalize our results to obtain optimal unateness testers for functions $f : [n]^d \to \mathbb{R}$.

Our results establish that adaptivity helps with testing unateness of real-valued functions on domains of the form $\{0,1\}^d$ and, more generally, $[n]^d$. This stands in contrast to the situation for monotonicity testing where there is no adaptivity gap for functions $f : [n]^d \to \mathbb{R}$.

1998 ACM Subject Classification F.2.2 Nonnumerical Algorithms and Problems

Keywords and phrases Property testing, unate and monotone functions

Digital Object Identifier 10.4230/LIPIcs.ICALP.2017.5

1 Introduction

We study the problem of testing whether a given real-valued function f on domain $[n]^d$, where $n, d \in \mathbb{N}$, is unate. A function $f : [n]^d \to \mathbb{R}$ is *unate* if for every coordinate $i \in [d]$, the function is either nonincreasing in the coordinate i or nondecreasing in the coordinate i. Unate functions naturally generalize monotone functions, which are nondecreasing in all

* A preliminary full version of this paper appears in ECCC [2], https://eccc.weizmann.ac.il/report/2017/049/.

† The authors R.B., R.P. and S.R. were partially supported by NSF award CCF-1422975. This work was done while D.C. was at Microsoft Research, India.

coordinates, and **b**-monotone functions, which have a particular direction in each coordinate (either nonincreasing or nondecreasing), specified by a bit-vector $\mathbf{b} \in \{0,1\}^d$. More precisely, a function is **b**-monotone if it is nondecreasing in coordinates i with $\mathbf{b}_i = 0$ and nonincreasing in the other coordinates. Observe that a function f is unate iff there exists some $\mathbf{b} \in \{0,1\}^d$ for which f is **b**-monotone.

A *tester* [33, 25] for a property $\mathcal{P}$ of a function f is an algorithm that gets a distance parameter $\varepsilon \in (0,1)$ and query access to f. It has to accept with probability at least $2/3$ if f has property $\mathcal{P}$ and reject with probability at least $2/3$ if f is ε-far (in Hamming distance) from $\mathcal{P}$. We say that f is ε-far from $\mathcal{P}$ if at least an ε fraction of values of f must be modified to make f satisfy $\mathcal{P}$. A tester has *one-sided error* if it always accepts a function satisfying $\mathcal{P}$, and has *two-sided error* otherwise. A *nonadaptive* tester makes all its queries at once, while an *adaptive* tester can make queries after seeing answers to the previous ones.

Testing of various properties of functions, including monotonicity (see, e.g., [24, 19, 20, 31, 22, 21, 26, 1, 27, 3, 8, 7, 10, 13, 9, 6, 14, 15, 12, 17, 16, 29, 4, 5, 18] and recent surveys [32, 11]), the Lipschitz property [28, 13, 9, 16], bounded-derivative properties [12], and unateness [24, 30], has been studied extensively over the past two decades. Even though unateness testing was initially discussed in the seminal paper by Goldreich et al. [24] that gave first testers for properties of functions, relatively little is known about testing this property. All previous work on unateness testing focused on the special case of Boolean functions on domain $\{0,1\}^d$. The domain $\{0,1\}^d$ is called the *hypercube* and the more general domain $[n]^d$ is called the *hypergrid*. Goldreich et al. [24] provided a $O(\frac{d^{3/2}}{\varepsilon})$-query nonadaptive tester for unateness of Boolean functions on the hypercube. Recently, Khot and Shinkar [30] improved the query complexity to $O(\frac{d \log d}{\varepsilon})$, albeit with an adaptive tester.

In this paper, we improve upon both these works, and our results hold for a more general class of functions. Specifically, we show that unateness of real-valued functions on hypercubes can be tested nonadaptively with $O(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon})$ queries and adaptively with $O(\frac{d}{\varepsilon})$ queries. More generally, we describe a $O(\frac{d}{\varepsilon} \cdot (\log \frac{d}{\varepsilon} + \log n))$-query nonadaptive tester and a $O(\frac{d \log n}{\varepsilon})$-query adaptive tester of unateness of real-valued functions over hypergrids.

In contrast to the state of knowledge for unateness testing, the complexity of testing monotonicity of real-valued functions over the hypercube and the hypergrid has been resolved. For constant distance parameter ε, it is known to be $\Theta(d \log n)$. Moreover, this bound holds for all *bounded-derivative* properties [12], a large class that includes **b**-monotonicity and some properties quite different from monotonicity, such as the Lipschitz property. Amazingly, the upper bound for all these properties is achieved by the same simple and, in particular, nonadaptive, tester. Even though proving lower bounds for adaptive testers has been challenging in general, a line of work, starting from Fischer [21] and including [8, 14, 12], has established that adaptivity does not help for this large class of properties. Since unateness is so closely related, it is natural to ask whether the same is true for testing unateness.

We answer this in the negative: we prove that any non-adaptive tester of real valued functions over the hypercube (for some constant distance parameter) must make $\Omega(d \log d)$ queries. More generally, it needs $\Omega(d(\log d + \log n))$ queries for the hypergrid domain. These lower bounds complement our algorithms, completing the picture for unateness testing of real-valued functions. From a property testing standpoint, our results establish that unateness is different from monotonicity and, more generally, any derivative-bounded property.

1.1 Formal Statements and Technical Overview

Our upper bounds are summarized in the following theorem, stated for functions over the hypergrid domains. (Recall that the hypercube is a special case of the hypergrid with $n = 2$.)

▶ **Theorem 1.1.** *Consider functions $f : [n]^d \to \mathbb{R}$ and a distance parameter $\varepsilon \in (0, 1/2)$.*
1. *There is a nonadaptive unateness tester that makes $O(\frac{d}{\varepsilon}(\log \frac{d}{\varepsilon} + \log n))$ queries*[1].
2. *There is an adaptive unateness tester that makes $O(\frac{d \log n}{\varepsilon})$ queries.*

Both testers have one-sided error.

Our main technical contribution is the proof that the extra $\Omega(\log d)$ is needed for nonadaptive testers. This result demonstrates a gap between adaptive and nonadaptive unateness testing.

▶ **Theorem 1.2.** *Any nonadaptive unateness tester (even with two-sided error) for real-valued functions $f : \{0,1\}^d \to \mathbb{R}$ with distance parameter $\varepsilon = 1/8$ must make $\Omega(d \log d)$ queries.*

The lower bound for adaptive testers is an easy adaptation of the monotonicity lower bound in [14]. We state this theorem for completeness and prove it in the full version [2].

▶ **Theorem 1.3.** *Any unateness tester for functions $f : [n]^d \to \mathbb{R}$ with distance parameter $\varepsilon \in (0, 1/4)$ must make $\Omega\left(\frac{d \log n}{\varepsilon} - \frac{\log 1/\varepsilon}{\varepsilon}\right)$ queries.*

Theorems 1.2 and 1.3 directly imply that our nonadaptive tester is optimal for constant ε, even for the hypergrid domain. All missing proofs and details from the technical sections appear in the full version of this paper [2].

1.1.1 Overview of Techniques

We first consider the hypercube domain. For each $i \in [d]$, an *i-edge* of the hypercube is a pair (x, y) of points in $\{0,1\}^d$, where $x_i = 0, y_i = 1$, and $x_j = y_j$ for all $j \in ([d] \setminus \{i\})$. Given an input function $f : \{0,1\}^d \to \mathbb{R}$, we say an i-edge (x, y) is *increasing* if $f(x) < f(y)$, *decreasing* if $f(x) > f(y)$, and *constant* if $f(x) = f(y)$.

Our nonadaptive unateness tester on the hypercube uses the work investment strategy from [6] (also refer to Section 8.2.4 of Goldreich's book [23]) to "guess" a good dimension where to look for violations of unateness (specifically, both increasing and decreasing edges). For all $i \in [d]$, let α_i be the fraction of the i-edges that are decreasing, β_i be the fraction of the i-edges that are increasing, and $\mu_i = \min(\alpha_i, \beta_i)$. The dimension reduction theorem from [12] implies that if the input function is ε-far from unate, then the average of μ_i over all dimensions is at least $\frac{\varepsilon}{4d}$. If the tester knew which dimension had $\mu_i = \Omega(\varepsilon/d)$, it could detect a violation with high probability by querying the endpoints of $O(1/\mu_i) = O(d/\varepsilon)$ uniformly random edges. However, the tester does not know which μ_i is large and, intuitively, nonadaptively checks the following $\log d$ different scenarios, one for each $k \in [\log d]$: exactly 2^k different μ_i's are $\varepsilon/2^k$, and all others are 0. This leads to the query complexity of $O(\frac{d \log d}{\varepsilon})$.

With adaptivity, this search through $\log d$ different scenarios is not required. A pair of queries in each dimension detects influential coordinates (i.e., dimensions with many non-constant edges), and the algorithm focuses on finding violations among those coordinates. This leads to the query complexity of $O(d/\varepsilon)$, removing the $\log d$ factor.

It is relatively easy to extend (both adaptive and nonadaptive) testers from hypercubes to hypergrids by incurring an extra factor of $\log n$ in the query complexity. The role of i-edges is now played by *i-lines*. An i-line is a set of n domain points that differ only on coordinate i. The domain $[n]$ is called a line. Monotonicity on the line (a.k.a. sortedness) can be tested with $O(\frac{\log n}{\varepsilon})$ queries, using, for example, the classical *tree tester* from [20].

[1] For many properties, when the domain is extended from the hypercube to the hypergrid, testers incur an extra multiplicative factor of $\log n$ in the query complexity. This is the case for our adaptive tester. However, note that the complexity of nonadaptive unateness testing (for constant ε) is $\Theta(d(\log d + \log n))$ rather than $\Theta(d \log d \log n)$.

Instead of sampling a random i-edge, we sample a random i-line ℓ and run the tree tester on the restriction $f_{|\ell}$ of function f to the line ℓ. This is optimal for adaptive testers, but, interestingly, not for nonadaptive testers. We show that for each function f on the line that is ε-far from unateness, one of the two scenarios happen: (1) the tree tester is likely to find a violation of unateness; (2) function f is increasing (and also decreasing) on a constant fraction of pairs in $[n]$. This new angle on the classical tester allows us to replace the factor $(\log d)(\log n)$ with $\log d + \log n$ in the query complexity. Thus, the nonadaptive complexity becomes $O(d(\log d + \log n))$, which we show is optimal.

The nonadaptive lower bound. Our most significant finding is the $\log d$ gap in the query complexity between adaptive and nonadaptive testing of unateness. By previous work [21, 14], it suffices to prove lower bounds for *comparison-based* testers, i.e., testers that can only perform comparisons of the function values at queried points, but cannot use the values themselves. Our main technical contribution is the $\Omega(d \log d)$ lower bound for nonadaptive comparison-based testers of unateness on hypercube domains.

Intuitively, we wish to construct $K = \Theta(\log d)$ families of functions where, for each $k \in [K]$, functions in the k^{th} family have 2^k dimensions i with $\mu_i = \Theta(1/2^k)$, while $\mu_i = 0$ for all other dimensions. What makes the construction challenging is the existence of a *single, universal* nonadaptive $O(d)$-tester for all $\mathbf{b}$-monotonicity properties, proven in [12]. In other words, there is a single distribution on $O(d)$ queries that defines a nonadaptive property tester for $\mathbf{b}$-monotonicity, regardless of $\mathbf{b}$. Since unateness is the union of all $\mathbf{b}$-monotonicity properties, our construction must be able to fool such algorithms. Furthermore, nonadaptivity must be critical, since we obtained a $O(d)$-query adaptive tester for unateness.

Another obstacle is that once a tester finds a non-constant edge in each dimension, the problem reduces to testing $\mathbf{b}$-monotonicity for a vector $\mathbf{b}$ determined by the directions (increasing or decreasing) of the non-constant edges. That is, intuitively, most edges in our construction must be constant. This is one of the main technical challenges. The previous lower bound constructions for monotonicity testing [8, 14] crucially used the fact that all edges in the hard functions were non-constant.

We briefly describe how we overcome the problems mentioned above. By Yao's minimax principle, it suffices to construct **Yes** and **No** distributions that a deterministic nonadaptive tester cannot distinguish. First, for some parameter m, we partition the hypercube into m subcubes based of the first $\log_2 m$ most significant coordinates. Both distributions, **Yes** and **No**, sample a uniform k from $[K]$, where $K = \Theta(\log d)$, and a set $R \subseteq [d]$ of cardinality 2^k. Furthermore, each subcube $j \in [m]$ selects an "action dimension" $r_j \in R$ uniformly at random. For both distributions, in any particular subcube j, the function value is completely determined by the coordinates *not in* R, and the random coordinate $r_j \in R$. Note that all the i-edges for $i \in (R \setminus \{r_j\})$ are constant. Within the subcube, the function is a linear function with exponentially increasing coefficients. In the **Yes** distribution, any two cubes j, j' with the same action dimension orient the edges in that dimension the same way (both increasing or both decreasing), while in the **No** distribution each cube decides on the orientation independently. The former correlation maintains unateness while the latter independence creates distance to unateness. We prove that to distinguish the distributions, any comparison-based nonadaptive tester must find two distinct subcubes with the same action dimension r_j and, furthermore, make a specific query (in both) that reveals the coefficient of r_j. We show that, with $o(d \log d)$ queries, the probability of this event is negligible.

Algorithm 1: The Nonadaptive Unateness Tester over Hypercubes

input : distance parameter $\varepsilon \in (0, 1/2)$; query access to a function $f : \{0,1\}^d \to \mathbb{R}$.

for $r = 1$ *to* $\lceil 3 \log(4d/\varepsilon) \rceil$ **do**
  repeat $s_r = \lceil \frac{16d \ln 4}{\varepsilon \cdot 2^r} \rceil$ **times**
    Sample a dimension $i \in [d]$ uniformly at random.
    Sample $3 \cdot 2^r$ i-edges uniformly and independently at random and **reject** if there exists an increasing edge and a decreasing edge among the sampled edges.
accept

2 Upper Bounds

In this section, we prove parts 1–2 of Theorem 1.1, starting from the hypercube domain.

Recall the definition of i-edges and i-lines from Section 1.1.1 and what it means for an edge to be increasing, decreasing, and constant.

The starting point for our algorithms is the dimension reduction theorem from [12]. It bounds the distance of $f : [n]^d \to \mathbb{R}$ to monotonicity in terms of average distances of restrictions of f to one-dimensional functions.

▶ **Theorem 2.1** (Dimension Reduction, Theorem 1.8 in [12]). *Fix a bit vector $\mathbf{b} \in \{0,1\}^d$ and a function $f : [n]^d \to \mathbb{R}$ which is ε-far from $\mathbf{b}$-monotonicity. For all $i \in [d]$, let μ_i be the average distance of $f_{|\ell}$ to $\mathbf{b}_i$-monotonicity over all i-lines ℓ. Then $\sum_{i=1}^{d} \mu_i \geq \varepsilon/4$.*

For the special case of the hypercube domains, i-lines become i-edges, and the average distance μ_i to $\mathbf{b}_i$-monotonicity is the fraction of i-edges on which the function is not $\mathbf{b}_i$-monotone.

2.1 The Nonadaptive Tester over the Hypercube

We now describe Algorithm 1, the nonadaptive tester for unateness over the hypercubes.

It is evident that Algorithm 1 is a nonadaptive, one-sided error tester. Furthermore, its query complexity is $O\left(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon}\right)$. It suffices to prove the following.

▶ **Lemma 2.2.** *If f is ε-far from unate, Algorithm 1 rejects with probability at least $2/3$.*

Proof. Recall that α_i is the fraction of i-edges that are decreasing, β_i is the fraction of i-edges that are increasing and $\mu_i = \min(\alpha_i, \beta_i)$.

Define the d-dimensional bit vector $\mathbf{b}$ as follows: for each $i \in [d]$, let $\mathbf{b}_i = 0$ if $\alpha_i < \beta_i$ and $\mathbf{b}_i = 1$ otherwise. Observe that the average distance of f to $\mathbf{b}_i$-monotonicity over a random i-edge is precisely μ_i. Since f is ε-far from being unate, f is also ε-far from being $\mathbf{b}$-monotone. By Theorem 2.1, $\sum_{i \in [d]} \mu_i \geq \frac{\varepsilon}{4}$. Hence, $\mathbf{E}_{i \in [d]}[\mu_i] \geq \frac{\varepsilon}{4d}$. We now apply the work investment strategy due to Berman et al. [6] to get an upper bound on the probability that Algorithm 1 fails to reject.

▶ **Theorem 2.3** ([6]). *For a random variable $X \in [0,1]$ with $\mathbf{E}[X] \geq \mu$ for $\mu < \frac{1}{2}$, let $p_r = \Pr[X \geq 2^{-r}]$ and $\delta \in (0,1)$ be the desired error probability. Let $s_r = \frac{4 \ln 1/\delta}{\mu \cdot 2^r}$. Then,*

$$\prod_{r=1}^{\lceil 3 \log(1/\mu) \rceil} (1 - p_r)^{s_r} \leq \delta.$$

Algorithm 2: The Adaptive Unateness Tester over Hypercubes

input : distance parameter $\varepsilon \in (0, 1/2)$; query access to a function $f : \{0,1\}^d \to \mathbb{R}$.

1 **repeat** $10/\varepsilon$ **times**
2 **for** $i = 1$ *to* d **do**
3 Sample an i-edge e_i uniformly at random.
4 **if** e_i *is non-constant (i.e., increasing or decreasing)* **then**
5 Sample i-edges uniformly at random till we obtain a non-constant edge e_i'.
6 **reject** if one of the edges e_i, e_i' is increasing and the other is decreasing.
7 **accept**

Consider running Algorithm 1 on a function f that is ε-far from unate. Let $X = \mu_i$ where i is sampled uniformly at random from $[d]$. Then $\mathbf{E}[X] \geq \frac{\varepsilon}{4d}$. Applying the work investment strategy (Theorem 2.3) on X with $\mu = \frac{\varepsilon}{4d}$, we get that the probability that, in some iteration, Step 3 samples a dimension i such that $\mu_i \geq 2^{-r}$ is at least $1-\delta$. We set $\delta = 1/4$. Conditioned on sampling such a dimension, the probability that Step 4 fails to obtain an increasing edge and a decreasing edge among its $3 \cdot 2^r$ samples is at most $2\left(1 - 1/2^r\right)^{3 \cdot 2^r} \leq 2e^{-3} < 1/9$, as the fraction of both increasing and decreasing edges is at least $1/2^r$. Hence, the probability that Algorithm 1 rejects f is at least $\frac{3}{4} \cdot \frac{8}{9} = \frac{2}{3}$. This completes the proof of Lemma 2.2. ◀

2.2 The Adaptive Tester over the Hypercube

We now describe Algorithm 2, an adaptive tester for unateness over the hypercube domain with good expected query complexity. The final tester is obtained by repeating this tester and accepting if the number of queries exceeds a specified bound.

▶ **Claim 2.4.** *The expected number of queries made by Algorithm 2 is* $40d/\varepsilon$.

Proof. Consider one iteration of the **repeat**-loop in Step 1. We prove that the expected number of queries in this iteration is $4d$. The number of queries in Step 3 is $2d$, as 2 points per dimension are queried. Let E_i be the event that edge e_i is non-constant and T_i be the random variable for the number of i-edges sampled in Step 5. Then $\mathbf{E}[T_i] = \frac{1}{\alpha_i + \beta_i} = \frac{1}{\Pr[E_i]}$. Therefore, the expected number of all edges sampled in Step 5 is $\sum_{i=1}^{d} \Pr[E_i] \cdot \mathbf{E}[T_i] = \sum_{i=1}^{d} \Pr[E_i] \cdot \frac{1}{\Pr[E_i]} = d$. Hence, the expected number of queries in Step 5 is $2d$. Since there are $10/\varepsilon$ iterations in Step 1, the expected number of queries in Algorithm 2 is $40d/\varepsilon$. ◀

▶ **Claim 2.5.** *If f is ε-far from unate, Algorithm 2 accepts with probability at most* $1/6$.

Proof. First, we bound the probability that a violation of unateness is detected in some dimension $i \in [d]$ in one iteration of the **repeat**-loop. Consider the probability of finding a decreasing i-edge in Step 3, and an increasing i-edge in Step 5. The former is exactly α_i, and the latter is $\beta_i/(\alpha_i + \beta_i)$. Therefore, the probability we detect a violation from dimension i is $2\alpha_i\beta_i/(\alpha_i + \beta_i) \geq \min(\alpha_i, \beta_i) = \mu_i$. The probability that we fail to detect a violation in any of the d dimensions is at most $\prod_{i=1}^{d}(1 - \mu_i) \leq \exp\left(-\sum_{i=1}^{d} \mu_i\right)$, which is at most $e^{-\varepsilon/4}$ by Theorem 2.1 (Dimension Reduction). By Taylor expansion of $e^{-\varepsilon/4}$, the probability of finding a violation in one iteration is at least $1 - e^{-\varepsilon/4} \geq \frac{\varepsilon}{4} - \frac{\varepsilon^2}{32} \geq \frac{\varepsilon}{5}$. The probability that Algorithm 2 does not reject in any iteration is at most $(1 - \varepsilon/5)^{10/\varepsilon} < 1/6$. ◀

Proof of Theorem 1.1, part 2 (the special case of the hypercube domain). We run Algorithm 2, aborting and accepting if we ever make more than $240d/\varepsilon$ queries. By Markov's

Algorithm 3: Tree Tester

input : Query access to a function $h : [n] \mapsto \mathbb{R}$.

Pick $x \in [n]$ uniformly at random.
Let $Q_x \subseteq [n]$ be the set of points visited in a binary search for x. Query h on all points in Q_x.
If there is an increasing pair in Q_x, set $\mathsf{dir} \leftarrow \{\uparrow\}$; otherwise, $\mathsf{dir} \leftarrow \emptyset$.
If there is a decreasing pair in Q_x, update $\mathsf{dir} \leftarrow \mathsf{dir} \cup \{\downarrow\}$.
Return dir.

Algorithm 4: The Adaptive Unateness Tester over Hypergrids

input : distance parameter $\varepsilon \in (0, 1/2)$; query access to a function $f : [n]^d \to \mathbb{R}$.

repeat $10/\varepsilon$ **times**
  for $i = 1$ *to* d **do**
    Sample an i-line ℓ_i uniformly at random.
    Let dir_i be the output of Algorithm 3 on $f_{|\ell_i}$.
    if $\mathsf{dir}_i \neq \emptyset$ **then**
      Sample i-lines uniformly at random and run Algorithm 3 on f restricted to each line until it returns a non-empty set. Call it dir_i'.
      If $\mathsf{dir}_i \cup \mathsf{dir}_i' = \{\uparrow, \downarrow\}$, **reject**.
accept

inequality, the probability of aborting is at most 1/6. By Claim 2.5, if f is ε-far from unate, Algorithm 2 accepts with probability at most 1/6. The theorem follows by a union bound. ◀

2.3 Extension to Hypergrids

We start by establishing terminology for lines and pairs. Consider a function $f : [n]^d \to \mathbb{R}$. Recall the definition of i-lines from Section 1.1.1. A pair of points that differ only in coordinate i is called an i-pair. An i-pair (x, y) with $x_i < y_i$ is called *increasing* if $f(x) < f(y)$, *decreasing* if $f(x) > f(y)$, and *constant* if $f(x) = f(y)$.

The main tool for extending Algorithms 1 and 2 to work on hypergrids is the *tree tester*, designed by Ergun et al. [20] to test monotonicity of functions $h : [n] \to \mathbb{R}$. We modify the tree tester to return information about directions it observed instead of just accepting or rejecting. See Algorithm 3. We call a function $h : [n] \to \mathbb{R}$ *antimonotone* if $f(x) \geq f(y)$ for all $x < y$. The following lemma summarizes the guarantee of the tree tester.

▶ **Lemma 2.6** ([20, 12]). *If $h : [n] \mapsto \mathbb{R}$ is ε-far from monotone (respectively, antimonotone), then the output of Algorithm 3 on h contains $\downarrow$ (respectively, $\uparrow$) with probability at least ε.*

Our hypergrid testers are stated in Algorithms 4 and 5. Next, we explain how Lemma 2.6 and Theorem 2.1 are used in the analysis of the adaptive tester. For a dimension $i \in [d]$, let α_i and β_i denote the average distance of $f_{|\ell}$ to monotonicity and antimonotonicity, respectively, over all i-lines ℓ. Then $\mu_i := \min(\alpha_i, \beta_i)$ is the average fraction of points per i-line that needs to change to make f unate. Define the $\mathbf{b}$-vector with $\mathbf{b}_i = 0$ if $\alpha_i < \beta_i$, and $\mathbf{b}_i = 1$ otherwise. By Theorem 2.1, if f is ε-far from unate, and thus ε-far from $\mathbf{b}$-monotone, then $\sum_{i=1}^{d} \mu_i \geq \varepsilon/4$. By Lemma 2.6, the probability that the output of Algorithm 3 on $f_{|\ell}$ contains

Algorithm 5: The Nonadaptive Unateness Tester over Hypergrids

input : distance parameter $\varepsilon \in (0, 1/2)$; query access to a function $f : [n]^d \to \mathbb{R}$.

repeat $220/\varepsilon$ **times**
  for $i = 1$ *to* d **do**
    Sample an i-line ℓ uniformly at random.
    Reject if Algorithm 3, on input $f_{|\ell}$, returns $\{\uparrow, \downarrow\}$.
for $r = 1$ *to* $\lceil 3 \log(200d/\varepsilon) \rceil$ **do**
  repeat $s_r = \lceil \frac{800d \ln 4}{\varepsilon \cdot 2^r} \rceil$ **times**
    Sample a dimension $i \in [d]$ uniformly at random.
    Sample $3 \cdot 2^r$ i-pairs uniformly and independently at random.
    If we find an increasing and a decreasing pair among the sampled pairs, **reject**.
accept

$\downarrow$ (respectively, $\uparrow$), where ℓ is a uniformly random i-line, is at least α_i (respectively, β_i). The rest of the analysis of Algorithm 4 is similar to that in the hypercube case.

To analyze the nonadaptive tester, we prove Lemma 2.7, which demonstrates the power of the tree tester and may be of independent interest.

▶ **Lemma 2.7.** *Consider a function $h : [n] \to \mathbb{R}$ which is ε-far from monotone (respectively, antimonotone). At least one of the following holds:*

1. $\Pr[$*Algorithm 3, on input h, returns* $\{\uparrow, \downarrow\}] \geq \varepsilon/25$.
2. $\Pr_{u,v \in [n]}[(u, v)$ *is a decreasing (respectively, increasing) pair*$] \geq \varepsilon/25$.

3 The Lower Bound for Nonadaptive Testers over Hypercubes

In this section, we prove Theorem 1.2, which gives a lower bound for nonadaptive unateness testers for functions over the hypercube.

Previous work of [14] on lower bounds for monotonicity testing shows that, for a special class of properties, which includes unateness, it is sufficient to prove lower bounds for *comparison-based testers*. Comparison-based testers base their decisions only on the *order* of the function values at queried points, and not on the values themselves.

We first state the reduction to comparison-based testers from [14]. Let a (t, ε, δ)-tester for a property $\mathcal{P}$ be a 2-sided error t-query tester, with distance parameter ε, that errs with probability at most δ. Consider functions of the form $f : D \to \mathbb{R}$, where D is an arbitrary partial order (in particular the hypergrid/hypercube). A property $\mathcal{P}$ is invariant under monotone transformations if, for all strictly increasing maps $\phi : \mathbb{R} \to \mathbb{R}$ and all functions f, it holds that $\mathsf{dist}(f, \mathcal{P}) = \mathsf{dist}(\phi \circ f, \mathcal{P})$. In particular, unateness is invariant under monotone transformations. The following theorem is implicitly proven in [14]. Specifically, Theorem 2.1 of [14] is stated for monotonicity, but the proof only uses the fact that monotonicity is a property invariant under monotone transformations, so it applies to all such properties.

▶ **Theorem 3.1** (implicit in [21, 14])**.** *Let $\mathcal{P}$ be a property invariant under monotone transformations. Suppose there exists a nonadaptive (resp., adaptive) (t, ε, δ)-tester for $\mathcal{P}$. Then there exists a nonadaptive (resp., adaptive) comparison-based $(t, \varepsilon, 2\delta)$-tester for $\mathcal{P}$.*

Our main lower bound theorem is stated next. In the light of the previous discussion, it implies Theorem 1.2.

▶ **Theorem 3.2.** *Any nonadaptive comparison-based tester for unateness of functions* $f : \{0,1\}^d \to \mathbb{R}$ *must make* $\Omega(d \log d)$ *queries.*

By Theorem 3.1 and Yao's minimax principle [34], it suffices to prove the lower bound for deterministic, nonadaptive, comparison-based testers over a known distribution of functions. It may be useful for the reader to recall the sketch of the main ideas given in Section 1.1.1. For convenience, assume d is a power of 2 and let $d' := d + \log_2 d$. We will focus on proving the lower bound for functions $h : \{0,1\}^{d'} \to \mathbb{R}$, as $d \log d = \Theta(d' \log d')$.

3.1 The Hard Distributions

We partition $\{0,1\}^{d'}$ into d subcubes based on the $\log_2 d$ most significant bits. Specifically, for $i \in [d]$, the i^{th} subcube is defined as $C_i := \{x \in \{0,1\}^{d'} : \mathsf{val}(x_{d'} x_{d'-1} \cdots x_{d+1}) = i-1\}$, where $\mathsf{val}(z_p z_{p-1} \dots z_1) := \sum_{i=1}^{p} z_i 2^{i-1}$ is the integer equivalent of the binary string $z_p z_{p-1} \dots z_1$.

Let $m := d$. We denote the set of indices of the subcube by $[m]$ and the set of dimensions by $[d]$. We use $i, j \in [m]$ to index subcubes and $a, b \in [d]$ to index dimensions. We define a series of random variables, where each subsequent variable may depend on the previous ones:

- k: a number picked uniformly at random from $\{1, 2, \dots, \frac{1}{2}\log_2 d\}$.
- R: a uniformly random subset of $[d]$ of size 2^k.
- r_i: for each $i \in [m]$, r_i is picked from R uniformly and independently at random.
- α_b: for each $b \in [d]$, α_b is picked from $\{-1, +1\}$ uniformly and independently at random.
- β_i: for each $i \in [m]$, β_i is picked from $\{-1, +1\}$ uniformly and independently at random.

We denote by $\boldsymbol{S}$ the tuple $(k, R, \{r_i\})$, also referred to as the *shared randomness*. We use $\boldsymbol{T}$ to refer to the entire set of random variables. Given $\boldsymbol{T}$, define the following functions:

$$f_{\boldsymbol{T}}(x) := \sum_{b \in [d'] \setminus R} x_b 3^b + \alpha_{r_i} \cdot x_{r_i} 3^{r_i}, \text{ where } i \text{ is the subcube with } x \in C_i.$$

$$g_{\boldsymbol{T}}(x) := \sum_{b \in [d'] \setminus R} x_b 3^b + \beta_i \cdot x_{r_i} 3^{r_i}, \text{ where } i \text{ is the subcube with } x \in C_i.$$

The distribution **Yes** generates $f_{\boldsymbol{T}}$ and the distribution **No** generates $g_{\boldsymbol{T}}$.

In all cases, the function restricted to any subcube C_i is linear. Consider some dimension $b \in R$. There can be numerous r_i's that are equal to b. For $f_{\boldsymbol{T}}$, in all of these subcubes, the coefficient of x_{r_i} has the same sign, namely α_{r_i}. For $g_{\boldsymbol{T}}$, the coefficient β_i is potentially different, as it depends on the actual subcube. We write $f \sim \mathcal{D}$ to denote that f is sampled from distribution $\mathcal{D}$.

▶ **Claim 3.3.** *Every function* $f \in \mathsf{supp}(\mathbf{Yes})$ *is unate. A function* $g \sim \mathbf{No}$ *is* $\frac{1}{8}$*-far from unate with probability at least* $9/10$.

3.2 From Functions to Signed Graphs that are Hard to Distinguish

For convenience, denote $x \prec y$ if $\mathsf{val}(x) < \mathsf{val}(y)$. Note that $\prec$ forms a total ordering on $\{0,1\}^{d'}$. Given $x \prec y \in \{0,1\}^{d'}$ and a function $h : \{0,1\}^{d'} \to \mathbb{R}$, define $\mathsf{sgn}_h(x, y)$ to be 1 if $h(x) < h(y)$, 0 if $h(x) = h(y)$, and -1 if $h(x) > h(y)$.

Any deterministic, nonadaptive, comparison-based tester is defined as follows: It makes a set of queries Q and decides whether or not the input function h is unate depending on the $\binom{|Q|}{2}$-comparisons in Q. More precisely, for every pair $(x, y) \in Q \times Q$, $x \prec y$, we insert an edge labelled with $\mathsf{sgn}_h(x, y)$. Let this signed graph be called G_h^Q. Any nonadaptive,

comparison-based algorithm can be described as a partition of the universe of all signed graphs over Q into $\mathcal{G}_Y$ and $\mathcal{G}_N$. The algorithm accepts the function h iff $G_h^Q \in \mathcal{G}_Y$.

Let $\boldsymbol{G}_Y^Q$ be the distribution of the signed graphs G_h^Q when $h \sim \mathbf{Yes}$. Similarly, define $\boldsymbol{G}_N^Q$ when $h \sim \mathbf{No}$. Our main technical theorem is Theorem 3.4, which is proved in Section 3.3.

▶ **Theorem 3.4.** *For small enough $\delta > 0$ and large enough d, if $|Q| \leq \delta d \log d$, then $\|\boldsymbol{G}_Y^Q - \boldsymbol{G}_N^Q\|_{\mathrm{TV}} = O(\delta)$.*

The proof of Theorem 3.4 is naturally tied to the behavior of sgn_h. Ideally, we would like to say that $\mathsf{sgn}_h(x, y)$ is almost identical regardless of whether $h \sim \mathbf{Yes}$ or $h \sim \mathbf{No}$. Towards this, we determine exactly the set of pairs (x, y) that potentially differentiate **Yes** and **No**.

▶ **Claim 3.5.** *For all $h \in \mathsf{supp}(\mathbf{Yes}) \cup \mathsf{supp}(\mathbf{No})$, for all $x \in C_i$ and $y \in C_j$ such that $i < j$, we have $\mathsf{sgn}_h(x, y) = 1$.*

Thus, comparisons between points in different subcubes reveal no information about which distribution h was generated from. Thus the "interesting" pairs that can distinguish whether $h \sim \mathbf{Yes}$ or $h \sim \mathbf{No}$ must lie in the same subcube. The next claim shows a further criterion that is needed for a pair to be interesting. We first define another notation.

▶ **Definition 3.6.** For any setting of the shared randomness $\boldsymbol{S}$, subcube C_i, and points $x, y \in C_i$, we define $t^i_{\boldsymbol{S}}(x, y)$ to be the most significant coordinate of difference (between x, y) in $([d] \setminus R) \cup \{r_i\}$.

Note that $\boldsymbol{S}$ determines R and $\{r_i\}$. For any $\boldsymbol{T}$ that extends $\boldsymbol{S}$ and any function, the restriction to C_i is unaffected by the coordinates in $R \setminus r_i$. Thus, $t^i_{\boldsymbol{S}}(x, y)$ is the first coordinate of difference that is influential in C_i.

▶ **Claim 3.7.** *Fix some $\boldsymbol{S}$, subcube C_i, and points $x, y \in C_i$. Let $c = t^i_{\boldsymbol{S}}(x, y)$, and assume $x \prec y$. For any $\boldsymbol{T}$ that extends $\boldsymbol{S}$:*

- *If $c \neq r_i$, then $\mathsf{sgn}_{f_{\boldsymbol{T}}}(x, y) = \mathsf{sgn}_{g_{\boldsymbol{T}}}(x, y) = 1$.*
- *If $c = r_i$, $\mathsf{sgn}_{f_{\boldsymbol{T}}}(x, y) = \alpha_c$ and $\mathsf{sgn}_{g_{\boldsymbol{T}}}(x, y) = \beta_i$.*

3.3 Proving Theorem 3.4: Good and Bad Events

For a given Q, we first identify certain "bad" values for $\boldsymbol{S}$, on which Q could potentially distinguish between $f_{\boldsymbol{S}}$ and $g_{\boldsymbol{S}}$. We will prove that the probability of a bad $\boldsymbol{S}$ is small for a given Q. Furthermore, we show that Q cannot distinguish between $f_{\boldsymbol{S}}$ and $g_{\boldsymbol{S}}$ for any good $\boldsymbol{S}$. We set up some definitions.

▶ **Definition 3.8.** Given a pair (x, y), define $\mathsf{cap}(x, y)$ to be the 5 most significant coordinates[2] in which they differ. We say (x, y) *captures* these coordinates. For any set $S \subseteq \{0, 1\}^{d'}$, define $\mathsf{cap}(S) := \bigcup_{x,y \in S} \mathsf{cap}(x, y)$ to be the coordinates captured by the set S.

Fix any Q. We set $Q_i := Q \cap C_i$. We define two bad events for $\boldsymbol{S}$.

- Abort Event $\mathcal{A}$: There exist $x, y \in Q$ with $\mathsf{cap}(x, y) \subseteq R$.
- Collision Event $\mathcal{C}$: There exist $i, j \in [d]$ with $r_i = r_j$, $r_i \in \mathsf{cap}(Q_i)$ and $r_j \in \mathsf{cap}(Q_j)$.

If the abort event doesn't occur, then for any pair (x, y), the sign $\mathsf{sgn}_h(x, y)$ is determined by $\mathsf{cap}(x, y)$ for any $h \in \mathsf{supp}(\mathbf{Yes}) \cup \mathsf{supp}(\mathbf{No})$. The heart of the analysis lies in Theorem 3.9, which states that the bad events happen rarely. Theorem 3.9 is proved in Section 3.4.

[2] There is nothing special about the constant 5. It just needs to be sufficiently large.

▶ **Theorem 3.9.** *If* $|Q| \leq \delta d \log d$*, then* $\Pr[\mathcal{A} \cup \mathcal{C}] = O(\delta)$.

When neither the abort nor the collision events happen, we say $\boldsymbol{S}$ is good for Q. Next, we show that conditioned on a good $\boldsymbol{S}$, the set Q cannot distinguish $f \sim \mathbf{Yes}$ from $g \sim \mathbf{No}$.

▶ **Lemma 3.10.** *For any signed graph* G *over* Q*,*

$$\Pr_{f \sim \mathbf{Yes}}[G_f^Q = G | \boldsymbol{S} \text{ is good}] = \Pr_{g \sim \mathbf{No}}[G_g^Q = G | \boldsymbol{S} \text{ is good}].$$

Proof Sketch. As stated above, when the abort event doesn't happen, the sign $\mathsf{sgn}_h(x, y)$ is determined by $\mathsf{cap}(x, y)$ for any $h \in \mathsf{supp}(\mathbf{Yes}) \cup \mathsf{supp}(\mathbf{No})$. Furthermore, a pair (x, y) has a possibility of distinguishing (that is, the pair is interesting) only if $x, y \in C_i$ and $r_i \in \mathsf{cap}(x, y)$. Focus on such interesting pairs. For such a pair, both $\mathsf{sgn}_{f_{\boldsymbol{T}}}(x, y)$ and $\mathsf{sgn}_{g_{\boldsymbol{T}}}(x, y)$ are equally likely to be $+1$ or -1. Therefore, to distinguish, we would need two interesting pairs, $(x, y) \in C_i$ and $(x', y') \in C_j$ with $i \neq j$. Note that, when $g \sim \mathbf{No}$, the signs $\mathsf{sgn}_{g_{\boldsymbol{T}}}(x, y)$ and $\mathsf{sgn}_{g_{\boldsymbol{T}}}(x', y')$ are independently set, whereas when $f \sim \mathbf{Yes}$, the signs are either the same when $r_i = r_j$, or independently set. But if the collision event doesn't occur, we have $r_i \neq r_j$ for interesting pairs in different subcubes. Therefore, the probabilities are the same. ◀

Now, we are armed to prove Theorem 3.4.

Proof of Theorem 3.4. Given any subset of signed graphs, $\mathcal{G}$, it suffices to upper bound

$$\left| \Pr_{f \sim \mathbf{Yes}}[G_f^Q \in \mathcal{G}] - \Pr_{f \sim \mathbf{No}}[G_f^Q \in \mathcal{G}] \right| \leq sum_{\text{good } \boldsymbol{S}} \left| \Pr[\boldsymbol{S}] \cdot \left(\Pr_{f \sim \mathbf{Yes}}[G_f^Q \in \mathcal{G} | \boldsymbol{S}] - \Pr_{f \sim \mathbf{No}}[G_f^Q \in \mathcal{G} | \boldsymbol{S}] \right) \right|$$
$$+ \sum_{\text{bad } \boldsymbol{S}} \left| \Pr[\boldsymbol{S}] \cdot \left(\Pr_{f \sim \mathbf{Yes}}[G_f^Q \in \mathcal{G} | \boldsymbol{S}] - \Pr_{f \sim \mathbf{No}}[G_f^Q \in \mathcal{G} | \boldsymbol{S}] \right) \right|.$$

The first term of the RHS is 0 by Lemma 3.10. The second term is at most the probability of bad events, which is $O(\delta)$ by Theorem 3.9. ◀

3.4 Bounding the Probability of Bad Events: Proof of Theorem 3.9

We prove Theorem 3.9 by individually bounding $\Pr[\mathcal{A}]$ and $\Pr[\mathcal{C}]$.

▶ **Lemma 3.11.** *If* $|Q| \leq \delta d \log d$*, then* $\Pr[\mathcal{A}] \leq d^{-1/4}$.

Proof. Fix any choice of k (in $\boldsymbol{S}$). For any pair of points $x, y \in Q$, we have $\Pr[\mathsf{cap}(x, y) \subseteq R] \leq (\frac{2^k}{d-5})^5$. Since $d - 5 \geq d/2$ for all $d \geq 10$ and $k \leq (\log_2 d)/2$, the probability is at most $32d^{-5/2}$. For a large enough d, a union bound over all pairs in $Q \times Q$, which are at most $d^2 \log^2 d$ in number, completes the proof. ◀

The collision event is more challenging to bound. Bounding it is the heart of the lower bound. We start by showing that, if each Q_i captures few coordinates, then the collision event has low probability. A critical point is the appearance of $d \log d$ in this bound.

▶ **Lemma 3.12.** *If* $\sum_i |\mathsf{cap}(Q_i)| \leq M$*, then* $\Pr[\mathcal{C}] = O\left(\frac{M}{d \log d}\right)$.

Proof. For any $r \in [d]$, define $A_r := \{j : r \in \mathsf{cap}(Q_j)\}$ to be the set of indices of Q_j's that capture coordinate r. Let $a_r := |A_r|$. Define $n_\ell := |\{r : a_r \in (2^{\ell-1}, 2^\ell]\}|$. Observe that $\sum_{\ell \leq \log_2 d} n_\ell 2^\ell \leq 2 \sum_{r \in [d]} a_r \leq 2M$.

Fix k. For $r \in [d]$, we say the event $\mathcal{C}_r$ occurs if (a) $r \in R$, and (b) there exists $i, j \in [d]$ such that $r_i = r_j = r$, and $r_i \in \mathtt{cap}(Q_i)$ and $r_j \in \mathtt{cap}(Q_j)$. By the union bound, $\Pr[\mathcal{C}|k] \leq \sum_{r=1}^{d} \Pr[\mathcal{C}_r|k]$.

Let us now compute $\Pr[\mathcal{C}_r|k]$. Only sets Q_j's with $j \in A_r$ are of interest, since the others do not capture r. Event $\mathcal{C}_r$ occurs if at least two of these sets have $r_i = r_j = r$. Hence,

$$\begin{aligned}\Pr[\mathcal{C}_r|k] &= \Pr[r \in R] \cdot \Pr[\exists i, j \in A_r : r_i = r_j = r \mid r \in R] \\ &= \frac{2^k}{d} \cdot \sum_{c \geq 2} \binom{a_r}{c} \left(\frac{1}{2^k}\right)^c \left(1 - \frac{1}{2^k}\right)^{a_r - c}. \end{aligned} \tag{1}$$

A fixed r is in R with probability $\binom{d-1}{2^k-1}/\binom{d}{2^k} = \frac{2^k}{d}$. Given that $|R| = 2^k$, the probability that $r_i = r$ is precisely 2^{-k}.

If $a_r \geq \frac{2^k}{4}$, then we simply upper bound (1) by $\frac{2^k}{d}$. For $a_r < \frac{2^k}{4}$, we upper bound (1) by

$$\frac{2^k}{d}\left(1 - \frac{1}{2^k}\right)^{a_r} \sum_{c \geq 2} \left(a_r \cdot \frac{1}{2^k} \cdot \left(1 - \frac{1}{2^k}\right)^{-1}\right)^c \leq \frac{2^k}{d} \sum_{c \geq 2} \left(\frac{a_r}{2^{k-1}}\right)^c \leq \frac{8a_r^2}{2^k d}.$$

Summing over all r and grouping according to n_ℓ, we get

$$\Pr[\mathcal{C}|k] \leq \sum_{r=1}^{d} \Pr[\mathcal{C}_r|k] \leq \sum_{r: a_r \geq 2^{k-2}} \frac{2^k}{d} + \frac{8}{d} \sum_{r: a_r < 2^{k-2}} \frac{a_r^2}{2^k} \leq \frac{2^k}{d} \sum_{\ell > k-2} n_\ell + \frac{8}{d} \sum_{\ell=1}^{k-2} n_\ell 2^{2\ell - k}.$$

Averaging over all k, we get

$$\begin{aligned}\Pr[\mathcal{C}] = \frac{2}{\log_2 d} \sum_{k=1}^{(\log_2 d)/2} \Pr[\mathcal{C}|k] \quad &\leq \quad \frac{16}{d \log_2 d} \sum_{k=1}^{(\log_2 d)/2} \left(\sum_{\ell=1}^{k-2} n_\ell 2^{2\ell - k} + \sum_{\ell > k-2} n_\ell 2^k\right) \\ &= \frac{16}{d \log_2 d} \left(\sum_{\ell=1}^{(\log_2 d)/2} n_\ell \sum_{k \geq \ell+2} 2^{2\ell - k} + \sum_{\ell=1}^{\log_2 d} n_\ell \sum_{k < \ell+2} 2^k\right). \end{aligned} \tag{2}$$

Now, $\sum_{k \geq \ell+2} 2^{2\ell-k} \leq 2^\ell$ and $\sum_{k < \ell+2} 2^k \leq 4 \cdot 2^\ell$. Substituting, $\Pr[\mathcal{C}] \leq \frac{80}{d \log_2 d} \sum_{\ell=1}^{\log_2 d} n_\ell 2^\ell \leq \frac{160M}{d \log_2 d}$, proving the lemma. ◀

We are now left to bound $\sum_i |\mathtt{cap}(Q_i)|$. This is done by the following combinatorial lemma.

▶ **Lemma 3.13.** *Let V be a set of vectors over an arbitrary alphabet and any number of dimensions. For any natural number c and $x, y \in V$, let $\mathtt{cap}_c(x, y)$ denote the (set of) first c coordinates at which x and y differ. Then $|\mathtt{cap}_c(V)| \leq c(|V| - 1)$.*

Proof. We construct c different edge-coloured graphs $G_1, \ldots, G_c$ over the vertex set V. For every coordinate $i \in \mathtt{cap}_c(V)$, there must exist at least one pair of vectors x, y such that $i \in \mathtt{cap}_c(x, y)$. Thinking of each $\mathtt{cap}_c(x, y)$ as an ordered set, find a pair (x, y) where i appears "earliest" in $\mathtt{cap}_c(x, y)$. Let the position of i in this $\mathtt{cap}_c(x, y)$ be denoted t. We add edge (x, y) to G_t, and colour it i. Note that the same edge (x, y) cannot be added to G_t with multiple colours, and hence all G_t's are simple graphs. Furthermore, observe that each colour is present only once over all G_t's.

We claim that each G_t is acyclic. Suppose not. Let there be a cycle C and let (x, y) be the edge in C with the smallest colour i. Clearly, $x_i \neq y_i$ since $i \in \mathtt{cap}_c(x, y)$. There must exist another edge (u, v) in C such that $u_i \neq v_i$. Furthermore, the colour of (u, v) is $j > i$. Thus, j is the t^{th} entry in $\mathtt{cap}_c(u, v)$. Note that $i \in \mathtt{cap}_c(u, v)$ and must be the s^{th} entry for some $s < t$. But this means that the edge (u, v) coloured i should be in G_s, contradicting the presence of $(x, y) \in G_t$. ◀

We wrap up the bound now.

▶ **Lemma 3.14.** *If* $|Q| \leq \delta d \log d$, *then* $\Pr[\mathcal{C}] = O(\delta)$.

Proof. Lemma 3.13 applied to each Q_i, yields $\sum_i |\mathtt{cap}(Q_i)| \leq 5|Q_i| = 5|Q|$. An application of Lemma 3.12 completes the proof. ◀

Abstract

We consider the problem of sampling from a distribution on graphs, specifically when the distribution is defined by an evolving graph model, and consider the time, space and randomness complexities of such samplers.

In the standard approach, the whole graph is chosen randomly according to the randomized evolving process, stored in full, and then queries on the sampled graph are answered by simply accessing the stored graph. This may require prohibitive amounts of time, space and random bits, especially when only a small number of queries are actually issued. Instead, we propose to generate the graph on-the-fly, in response to queries, and therefore to require amounts of time, space, and random bits which are a function of the actual number of queries.

We focus on two random graph models: the Barabási-Albert Preferential Attachment model (BA-graphs) [3] and the random recursive tree model [24]. We give on-the-fly generation algorithms for both models. With probability $1 - 1/\text{poly}(n)$, each and every query is answered in $\text{polylog}(n)$ time, and the increase in space and the number of random bits consumed by any single query are both $\text{polylog}(n)$, where n denotes the number of vertices in the graph.

Our results show that, although the BA random graph model is defined by a sequential process, efficient random access to the graph's nodes is possible. In addition to the conceptual contribution, efficient on-the-fly generation of random graphs can serve as a tool for the efficient simulation of sublinear algorithms over large BA-graphs, and the efficient estimation of their performance on such graphs.

1 Introduction

Consider a Markov process in which a sequence $\{S_t\}_t$ of states, $S_t \in \mathcal{S}$, evolves over time $t \geq 1$. Suppose there is a set $\mathcal{P}$ of predicates defined over the state space $\mathcal{S}$. Namely, for every predicate $P \in \mathcal{P}$ and state $S \in \mathcal{S}$, the value of $P(S)$ is well defined. A query is a pair

* Research supported in part by ANR projet RDAM.

(P, t) and the answer to the query is $P(S_t)$. In the general case, answering a query (P, t) requires letting the Markov process run for t steps until S_t is generated. In this paper we are interested in ways to reduce the dependency, on t, of the computation time time, the memory space, and the number of used random bits, required to answer a query (P, t).

We focus on the case of generative models for random graphs, and in particular, on the Barabási-Albert Preferential Attachment model [3] (which we call BA-graphs), on the equivalent linear evolving copying model of Kumar et al. [10], and on the random recursive tree model [24]. The question we address is whether one can design a randomized *on-the-fly* graph generator that answers adjacency list queries of BA-graphs (or random recursive trees), without having to generate the complete graph. Such a generator outputs answers to adjacency list queries as if it first selected the whole graph at random (according the appropriate distribution) and then answered the queries based on the samples graph.

We are interested in the following resources of a graph generator: (1) the number of random bits consumed per query, (2) the running time per query, and (3) the increase in memory space per query.

Our main result is a randomized on-the-fly graph generator for BA-graphs over n vertices that answers adjacency list queries. The generated graph is sampled according to the distribution defined for BA-graphs over n vertices, and the complexity upper bounds that we prove hold with probability $1 - 1/\text{poly}(n)$. That is, with probability $1 - 1/\text{poly}(n)$ each and every query is answered in $\text{polylog}(n)$ time, and the increase in space, and the number of random bits consumed during that query are $\text{polylog}(n)$. Our result refutes (definitely for $\text{polylog}(n)$ queries) the recent statement of Kolda et al. [9] that: "The majority of graph models add edges one at a time in a way that each random edge influences the formation of future edges, making them inherently serial and therefore unscalable. The classic example is Preferential Attachment, but there are a variety of related models..."

We remark that the entropy of the edges in BA-graphs is $\Theta(\log n)$ per edge in the second half of the graph [23]. Hence it is not possible to consume a sublogarithmic number of random bits per query in the worst case if one wants to sample according to the BA-graph distribution. Similarly, to insure consistency (i.e., answer the same query twice in the same way) one must use $\Omega(\log n)$ space per query.

From a conceptual point of view, the main ingredient of our result are techniques to "invert" the sequential process where each new vertex randomly selects its "parent" in the graph among the previous vertices. Instead, vertices randomly select their "children" among the "future" vertices, while maintaining the same probability distribution as if each child picked "in the future" its parent. We apply these techniques in the related model of random recursive trees [24] (also used within the evolving copying model [10]), and use them as a building block for our main result for BA-graphs.

Due to space limitations, some of the proofs are omitted from this extended abstract.

Related work. A linear time randomized algorithm for efficiently generating BA-graphs is given in Betagelj and Brandes [4]. See also Kumar et al. [10] and Nobari et al. [18]. A parallel algorithm is given in Alam et al. [1]. See also Yoo and Henderson [25]. An external memory algorithm was presented by Meyer and Peneschuck [16]. Generating huge random objects while using "small" amounts of randomness was studied by Goldreich, Goldwasser and Nussboim [8]. Mansour et al. [14] consider local generation of bipartite graphs in the context of local simulation of Balls into Bins online algorithms.

Applications. One reason for generating large BA-graphs is to simulate algorithms over them. Such algorithms often access only small portions of the graphs. In such instances, it is

wasteful to generate the whole graph. An interesting example is sublinear approximation algorithms [20, 26, 17, 19] which probe a constant number of neighbors. In addition, local computation algorithms probe a small number of neighbors to provide answers to optimization problems such as maximal independent sets and approximate maximum matchings [6, 7, 21, 22, 2, 14, 15, 11, 12, 13]. Support of adjacency list queries is especially useful for simulating (partial) DFS and BFS over graphs.

2 Preliminaries

Let $V_n \triangleq \{v_1, \ldots, v_n\}$. Let $G = (V_n, E)$ denote a directed graph on n nodes.[1] We refer to the endpoints of a directed edge (u, v) as the *head* v and the *tail* u. Let $\deg(v_i, G)$ denote the *degree* of the vertex v_i in G (both incoming and outgoing edges). Similarly, let $deg_{in}(v_i, G)$ and $deg_{out}(v_i, G)$ denote the in-degree and out-degree, respectively, of the vertex v_i in G.

In the sequel, when we say that an event occurs *with high probability* (or *w.h.p*) we mean that it occurs with probability at least $1 - \frac{1}{n^c}$, for some constant c.

For ease of presentation, we extensively use in the algorithms arrays of size n. However, in order to keep the space complexity low, we implement these arrays by means of balanced search trees, with keys in $[1, n]$. Thus, the space used by the "arrays" is the number of keys stored. The time complexities that we give are therefore to be multiplied by a factor of $O(\log n)$.

3 Queries and On-the-Fly Generators

Consider an undirected graph $G = (V_n, E)$, where $V_n = \{v_1, \ldots, v_n\}$. Slightly abusing notation, we sometimes consider and denote node v_i as the integer number i and so we have a natural order on the nodes. The access to the graph is done by means of a user-query `BA-next-neighbor` : $[1, n] \to [1, n + 1]$, where $n + 1$ denotes "no additional neighbor". We number the queries according to the order they are issued, and call this number the *time* of the query. Let q_t be the node on which the query at time t was issued, i.e, at time t the query `BA-next-neighbor`(q_t) is issued by the user. For each node $v \in V$ and any time t, let $last_t(j)$ be the largest numbered node which was previously returned as the value of `BA-next-neighbor`(j), or 0 if no such query was issued before time t. That is, $last_t(v) = \min\{0, \min_{t' < t}\{\texttt{BA-next-neighbor}(q_{t'}) | q_{t'} = v\}$. At time t the query `BA-next-neighbor`(v) returns $\arg\min_{i > last_t(j)}\{(i, j) \in E\}$, or $n+1$ if no such i exists. When the implementation of the query has access to a data structure holding the whole of E, then the implementation of `BA-next-neighbor` is straightforward just by accessing this data structure.

An on-the-fly graph generator is an algorithm that gives access to a graph by means of the `BA-next-neighbor` query defined above, but itself does not have access to a data structure that encodes the whole graph. Instead, in response to the queries issued by the user, the generator modifies its internal data structure (a.k.a state), which is initially some empty (constant) state. The generator must ensure however that its answers are consistent with some graph G. An on-the-fly graph generator for a given distribution on a family of graphs (such as the family of Preferential Attachment graphs on n nodes) must in addition

[1] Preferential attachment graphs are usually presented as undirected graphs. For convenience of discussion we orient each edge from the high index vertex to the low index vertex, but the graphs we consider remain undirected graphs.

ensure that it samples the graphs according to the required distribution. That is, its answers to a sequence of queries must be *distributed identically* to those returned when a graph was first sampled (according to the desired distribution), stored, and then accessed (See Definition 16 and Theorem 17).

4 Random Graph Models

Preferential attachment [3]. We restrict our attention to the case in which each vertex is connected to the previous vertices by a single edge (i.e., $m = 1$ in the terminology of [3]). We thus denote the random process that generates a graph over V_n according to the preferential attachment model by BA_n. The random process BA_n generates a sequence of n directed edges $E_n \triangleq \{e_1, \ldots, e_n\}$, where the tail of e_i is v_i, for every $i \in [1, n]$. (We abuse notation and let $BA_n = (V_n, E_n)$ also denote the graph generated by the random process.) We refer to the head of e_i as the *parent* of v_i.

The process BA_n draws the edges sequentially starting with the self-loop $e_1 = (v_1, v_1)$. Suppose we have selected BA_{j-1}, namely, we have drawn the edges $e_1, \ldots, e_{j-1}$, for $j > 1$. The edge e_j is drawn such its head is node v_i with probability $\frac{\deg(v_i, G)}{2(j-1)}$.

Note that the out-degree of every vertex in (the directed graph representation of) BA_n is exactly one, with only one self-loop in v_1. Hence BA_n (without the self-loop) is an in-tree rooted at v_1.

Evolving copying model [10]. Let Z_n denote the evolving copying model with out-degree $d = 1$ and copy factor $\alpha = 1/2$. As in the case of BA_n, the process Z_n selects the edges $E'_n = \{e'_1, \ldots, e'_n\}$ one-by-one starting with a self-loop $e'_1 = (v_1, v_1)$. Given the graph $Z_{n-1} = (V_n, E'_n)$, the next edge e'_n emanates from v_n. The head of edge e'_n is chosen as follows. Let $b_n \in \{0, 1\}$ be an unbiased random bit. Let $u(n) \in [1, n-1]$ be a uniformly distributed random variable (the random variables $b_1, \ldots, b_n$ and $u(1), \ldots, u(n)$ are all pairwise independent.) The head v_i of e'_n is determined as follows: $head(e'_n) \triangleq u(n)$, if $b_n = 1$; and $head(e'_n) \triangleq head(e_{u(n)})$, if $b_n = 0$.

Random recursive tree model [24]. If we eliminate from the evolving copying model the bits b_i and the "copying effect" we get a model where each new node n is connected to one of the previous nodes, chosen uniformly at random. This is the extensively studied (random) recursive tree model [24].

We now relate the various models. Proof omitted from this extended abstract.

▶ **Claim 1** ([1]). *The random graphs BA_n and Z_n are identically distributed.*

We use the following claim in the sequel.

▶ **Claim 2** (cf. [5], Thm. 6.12 and Thm. 6.32). *Let T be a rooted directed tree on n nodes denoted $1, \ldots, n$, and where node 1 is the root of the tree. If the head of the edge emanating from node $j > 1$ is uniformly distributed among the nodes in $[1, j-1]$, then, with high probability, the following two properties hold:*

1. *The maximum in-degree of a node in the tree is $O(\log n)$.*
2. *The height of the tree is $O(\log n)$.*

5 The Pointers Tree

We now consider a graph inspired by the the random recursive tree model [24] and the evolving copying model [10]. Each vertex i has a variable $u(i)$ that is uniformly distributed

over $[1, i-1]$, and can be viewed as a directed edge (or pointer) from i to $u(i)$. We denote this random rooted directed in-tree by UT. Let $u^{-1}(j)$ denote the set $\{i : u(i) = j\}$. We refer to the set $u^{-1}(i)$ as the *u-children* of i and to $u(i)$ as the *u-parent* of i. In conjunction with each pointer, we keep a flag indicating whether this pointer is to be used as a `dir` (direct) pointer or as a `rec` (recursive) pointer. We thus use the directed pointer tree to represent a graph in the evolving copying model (which is equivalent, when the flag of each pointer is equality distributed between `rec` and `dir`, to the BA model).

In this section we consider the subtask of giving access to a random UT, together with the flags of each pointer. Ignoring the flags, this section thus gives an on-the-fly random access generator for the extensively studied model of random recursive trees (cf. [24]). We define the following queries.

- $(i, flag) \leftarrow$ `parent`(j): i is the parent of j in the tree, and $flag$ is the associated flag.
- $i \leftarrow$ `next-child-tp`$(j, k, type)$, where $k \geq j$: i is the least numbered node $i > k$ such that the parent of i is j and the flag of that pointer is of type "type". If no such node exists then i is $n + 1$.

The "ideal" way to implement this task is to go over all n nodes, and for each node j (1) uniformly at random choose its parent in $[1, j-1]$, (2) uniformly at random chose the associated flag in $\{$`dir`, `rec`$\}$. Then store the pointers and flags, and answer the queries by accessing this data structure.

In this section we give an *on-the-fly* generator that answers the above queries. We start with some notations. We say that j is *exposed* if $u(j) \neq$ nil (initially all pointers $u(j)$ are set to nil). We denote the set of all exposed vertices by F. We say that j is *directly* exposed if $u(j)$ was set during an invocation of `next-child-tp`$(i, \cdot, \cdot)$. We say that j is *indirectly* exposed if $u(j)$ was determined during an invocation of `parent`(j). As a result of answering and processing `next-child-tp` and `parent` queries, the on-the-fly generator commits to various decisions (e.g., prefixes of adjacency lists). These commitments include edges but also non-edges (i.e., vertices that can no longer serve as $u(j)$ for a certain j). For a node i, $front(i)$ denotes the largest value (node) $k \in [1, n+1]$ such that k was returned by a `next-child-tp`$(i, \cdot, \cdot)$ query, and nil if no such returned value exists. Observe that $front(i) = k$ implies that (1) $u(k) = i$; and (2) we know already for each node $j \in [j+1, k-1]$ if $u(j) = i$ or not. We denote - roughly speaking - the set of vertices that cannot serve as u-parents of j by $not\text{-}u\text{-}parent\text{-}candidate(j)$, the nodes that can still be u-parents of j by $\Phi(j)$, and their number by $\varphi(j) = |\Phi(j)|$. The formal definitions are:

$$
\begin{aligned}
not\text{-}u\text{-}parent\text{-}candidate(j) &\triangleq \{i \in [1, j-1] : front(i) \geq j\} \ , \\
\Phi(j) &\triangleq [1, j-1] \setminus not\text{-}u\text{-}parent\text{-}candidate(j) \ , \\
\varphi(j) &\triangleq |\Phi(j)| \ .
\end{aligned}
$$

5.1 An efficient implementation of `next-child`

We first shortly discuss the challenges on the way to an efficient implementation of `next-child`. Observe that before the first `next-child`(j) query, for a given j, is issued, the probability for any $x > j$ to be a u-child of j is $1/\varphi(x)$, because all nodes $x' < x$ can still be the u-parent of x. But once `next-child`$(\cdot)$ queries are issued, this may no longer be the case. For example, if $x > front(j')$, then, even if the u-parent of x is not yet determined, j' is no longer an option to be the u-parent of x. This renders the calculation of $\mathbf{Pr}[u(x) = j]$ more complicated and more computation-time consuming, which renders the process of selecting the next child of a node j non-efficient. In the rest of this section we show how to overcome these

difficulties and give a procedure that selects the next child, with the appropriate probability distribution, using polylog(n) random bits and in polylog(n) time, and while increasing the space by polylog(n). This procedure will be at the heart of our efficient implementation of `next-child`.

The efficient implementation of `next-child` (and of `parent`) makes use of the following data structures.

- An array of length n, $u(j)$
- An array of length n, *type*(j)
- An array of length n, *front*(j) (We also maintain an array $front^{-1}(i)$ with the natural definition.)
- An array of n balanced search trees, called `child`(j), each holding a set of nodes $i > j$ such that $u(i) = j$ (not necessarily all such nodes). For technical reasons we initiate all trees `child`(j) with $n + 1 \in$ `child`(j).
- A number of additional data structures that are implicit in the listing, described and analyzed in the sequel.

In the implementation we maintain the following two invariant.

▶ **Invariant 3.** *For every node j, the first* ***next-child-tp***$(j, \cdot, \cdot)$ *query is always preceded by a* ***parent***(j) *query.*

We will use this invariant to infer that *front*$(j) \neq$ nil implies that $u(j) \neq$ nil. One can easily maintain this invariant by introducing a `parent`(j) query as the first step of the implementation of the `next-child-tp`$(j, \cdot, \cdot)$ query (for technical reasons we do that in a lower-level procedure `next-child`.)

▶ **Invariant 4.** *For every vertex j, front*$(j) \neq$ nil *implies that front*$(front(j)) \neq$ nil*.*

The second invariant is maintained by issuing an "internal" `next-child`$(front(j), front(j))$ query whenever *front*(j) is updated. This is done recursively, the base of the recursion being node $n+1$. Let $front^{-1}(j)$ denote the vertex i such that *front*$(i) = j$, if such a vertex i exists; otherwise $front^{-1}(j) =$ nil. We get that if $front^{-1}(j) \neq$ nil, then $u(j) \neq$ nil.

▶ **Definition 5.** At a given time t, and for any node j, let $\Phi(j)$ and $\phi(j)$ be defined as follows: $\Phi(j) \triangleq \{i \mid i < j$ `and` (*front*$(i) < j$ `or` *front*$(i) =$ nil$)\}$, and $\phi(j) = |\Phi(j)|$.

The following lemma gives properties of the series $\{\Phi(x)\}_x$. Proof omitted.

▶ **Lemma 6.** *For every $x \in [1, n-1]$:*

1. $\Phi(x) \subseteq \Phi(x+1) \subseteq \Phi(x) \cup \{x, front^{-1}(x)\}$.
2. $\Phi(x+1) = \Phi(x)$ *iff* $x \in K$.
3. $\varphi(x+1) - \varphi(x) \leq 1$.

We now describe the implementation of `next-child-tp`$(j, k, type)$ and `next-child`(j). `next-child-tp`$(j, k, type)$ is a loop of `next-child-from`(j, k) until the right type is found, and `next-child-from`(j, k) is essentially a call to `next-child`(j) (see Figure 1). Note that if j does not have children larger than k, then `next-child-from`(j, k) returns $n + 1$.

If *front*$(j) > k$ when `next-child-from`(j, k) is called, then the next child is already fixed and it is just extracted from the data structures. Otherwise, an interval $I = [a, b]$ is defined, and it will contain the answer of `next-child`(j). Let $a =$ *front*$(j) + 1$ if *front*$(j) \neq$ nil; otherwise $a = j + 1$. Let b denote the smallest, larger than *front*(j), indirectly exposed child of j if one exists (i.e., if *front*$(j) \neq$ nil then $b = \min\{\ell > front(j) \mid u(\ell) = j\}$); if no such b

exists then $b = n+1$. By the definition of K, $K \subseteq F$, and no vertex $x \in F \cap [a,b)$ can satisfy $u(x) = j$. Hence, the answer is in $I \setminus (F \setminus \{b\})$.

The next child can be sampled according to the desired distribution in a straightforward way by going sequentially over the vertices in $I \setminus F \setminus \{b\}$, and tossing for each vertex x a coin that has probability $1/\varphi(x)$ to be 1, until indeed one of those coins comes out 1, or all vertices are exhausted (in which case node b is taken as the next child). However, this procedure takes linear time. We denote by $D(x)$, $x \in I \setminus F$, the probability that x is chosen according to the above procedure. In order to start building our efficient implementation for `next-child` we consider the same process, with the same probabilities $1/\varphi(x)$, but this time for $[a,b) \setminus K$, rather than $[a,b) \setminus F$. The vertex on which we stop, denote is x, is a *candidate next u-child*. If $x \in F \setminus K$, then x cannot be a child of j so we proceed in the same way, but with the interval $[x+1, b]$.

We now build our efficient procedure that selects the candidate, without sequentially going over the nodes. To this end, observe that the sequence of probabilities of the coins tossed in the last-described process behaves "nicely". Namely, the probabilities $1/\varphi(x)$, for $x \in [a,b)\setminus K$, form the harmonic sequence starting from $1/\varphi(a)$ and ending in $1/(\varphi(a) + |[a,b) \setminus K| - 1)$. Indeed, Lemma 6 implies that if vertex i is the smallest vertex in $I \setminus K$, then $\varphi(i) = \varphi(a)$ and an increment between $\varphi(x)$ and $\varphi(x+1)$ occurs if and only if $x \notin K$. Let $s = |I \setminus K|$ and let P_q, $0 \leq q \leq s-1$ be the probability that the node of rank q in $I \setminus K$ is chosen as candidate in the sequential procedure defined above. Since $\varphi(x)$ form the harmonic sequence for $x \in [a,b) \setminus K$, we can calculate in $O(1)$ time, for any $0 \leq i \leq s-1$, the probability $P'_i = \sum_{q<i} P_q$ (i.e., a node of some rank q, $q < i$, is chosen). Indeed, for $i = 0$, $P_i = \frac{1}{\varphi(a)}$; for $0 < i < s-1$, $P_i = \frac{1}{\varphi(a)+i} \cdot \prod_{\ell=0}^{i-1} \left(1 - \frac{1}{\varphi(a)+\ell}\right) = \frac{\varphi(a)-1}{(\varphi(a)+i-1)(\varphi(a)+i)}$; and for $i = s-1$, $P_{s-1} = \prod_{\ell=0}^{s-2} \left(1 - \frac{1}{\varphi(a)+\ell}\right) = \frac{\varphi(a)-1}{\varphi(a)+s-2}$. Hence, for $0 \leq i \leq s-1$, $P'_i = 1 - \frac{\varphi(a)-1}{\varphi(a)+(i-1)}$, and for $i = s$, $P'_s = 1$. This allows us to simulate one iteration (i.e., choosing the next *candidate next u-child*) by choosing uniformly at random a single number in $[0,1]$, and then performing a binary search over 0 to $s-1$ to decide what rank h this number "represents". After we randomly chose a rank $h \in [0, s-1]$, h is then mapped to the vertex of rank h in $I \setminus K$, denote it x, and this is the *candidate next u-child*. As before, if $x \in (F \setminus K)$, then x cannot be a child of j so we ignore it and proceed in the same way, this time with the interval $[x+1, b]$. See the pseudo code of of `next-child` and `toss` (Figure 1). We denote by $\hat{D}(x)$, $x \in I \setminus F$ the probability that x is chosen according to this third procedure. See Figure 1 for a formal definition of this procedure.

Observe that this procedure takes $O(\log s)$ time (see Section 5.2 for a formal statement of the time and randomness complexities). We note that we cannot perform this selection procedure in the same time complexity for the set $[a,b) \setminus F$, because we do not have a way to calculate each and every probability P'_i, $i \in [a,b) \setminus F$, in $O(1)$ time.

To conclude the description of the implementation of `next-child`, we give the following lemma which states that the probability distribution on the next child is the same for all three processes described above. The (technical) proof is omitted.

▶ **Lemma 7.** *For all $x \in I \setminus F$, $\hat{D}(x) = D(x)$.*

The implementation of `parent` is straightforward (see Figure 1). However, note that updating the various data structures, while implicit in the listing, is accounted for in the time analysis.

Figure 1 Pseudo code of the pointers tree generator.

5.2 Analysis of the pointer tree generator

We first give the following claim that we later use a number of times.

▶ **Lemma 8.** *With high probability, for each and every invocation of* `next-child`*, the size of the recursion tree of that invocation for calls to* `next-child` *is* $O(\log n)$.

Proof. Consider the recursive invocation tree that results from a call to `next-child`. Observe that (1) by the code of `next-child` this tree is in fact a path; and (2) this path corresponds to a path in the pointers tree, where each edge of this tree-path is "discovered" by the corresponding call to `next-child`. That is, the maximum size of an invocation tree of a call of `next-child` is bounded from above by the height of the pointers tree. By Claim 2, with high probability, this is $O(\log n)$. ◀

5.2.1 Data structures and space complexity

The efficient implementation of `next-child` makes use of the following data structures.

- A number of arrays of length n, $u(j)$ and $type(j)$, $front(j)$ and $front^{-1}(j)$, used to store various values for nodes j. Since we implement arrays by means of search trees, the space complexity of each array is $O(m)$, where m is the maximum number of distinct keys stored with a non-null value in that array, at any given time. The time complexity for each operation is $O(\log m) = O(\log n)$.
- For each node j, a balanced binary search tree called $\texttt{child}(j)$, where $\texttt{child}(j)$ stores (some of the known) children of node j. (for technical reasons we define $\texttt{child}(j)$ to always include node $n+1$.) Observe that for each child i stored in one of these trees, $u(i)$ is already determined. Thus, the increase, during a given period, in the space used by the `child` trees is bounded from above by the the number of nodes i for which $u(i)$ got determined during that period. For the time complexity of the operations on these trees we use a coarse standard upper bound of $O(\log n)$.

The listings of the implementations of the various procedures leave *implicit* the maintenance of two data structures, related to the set K and to the computation of $\varphi(\cdot)$:

- A data structure that allows one to retrieve the value of $\varphi(a)$ for a given vertex a. This data structure is implemented by retrieving the cardinality of *not-u-parent-candidate*(a) for a given node a. The latter is equivalent to counting how many nodes $i < a$ have $front(i) \neq \mathsf{nil}$ and $front(i) \geq a$. We use two balanced binary search trees (or order statistics trees) in a specific way and have that by standard implementations of balanced search trees the space complexity is $O(k)$ (and all operations are done in time $O(\log k) = O(\log n)$). Here k denotes the number of nodes i such that $front(i) \neq \mathsf{nil}$. The details of the implementation are omitted from this extended abstract.
- A data structure that allows one to find the vertex of rank h in the ordered set $[a, n+1] \setminus K$. This data structure is implemented by a balanced binary search tree storing the nodes in K, augmented with the queries $rank_K(i)$ (as in an order-statistics tree) as well as $rank_{\bar{K}}(i)$ and $select_{\bar{K}}(s)$, i.e., finding the element of rank s in the complement of K. To find the vertex of rank h in $[a, n+1] \setminus K$ we use the query $select_{\bar{K}}(rank_{\bar{K}}(a) + h)$. The space complexity of this data structure is $O(k)$, and all operations are done in time $O(\log k) = O(\log n)$ or $O(\log^2 k) = O(\log^2 n)$ (for the $select_{\bar{K}}(i)$ query). Here k denotes the number of nodes in K, which is upper bounded by the number of nodes i such that $front(i) \neq \mathsf{nil}$. The details of the implementation are omitted from this extended abstract.

5.2.2 Time complexity

Time complexity of `toss`(φ, s). The time complexity of this procedure is $O(1)$ regardless of whether or not the `if` condition holds or not.

Time complexity of "$x \leftarrow$ the vertex of rank h in $[a, n+1] \setminus K$". This operation is implemented using the data structure defined above, and takes $O(\log^2 n)$ time.

Time complexity of `parent`(j). Examining the listing (Figure 1), one observes that the number of operations is constant. However, though implicit in the listing, one should take into account the update of the data structures `child`(j) as well as the data structure that stores the set K, each taking $O(\log n)$ time.

Time complexity of `next-child`. First consider the time complexity of a single invocation of `next-child`, involving the update of the various data structures: The call to `parent` takes $O(\log n)$ time. Therefore, until the start of the repeat loop, the time is $O(\log n)$ (the time complexity of `succ` is $O(\log n)$). Now, the time complexity of a single iteration of the loop (without taking into account recursive calls to `next-child`) is $(O \log^2 n)$ because:

- The call to `toss` takes O(1) time.
- Finding the vertex of rank h in $[a, n+1] \setminus K$ takes $O(\log^2 n)$ time.
- Each of the $O(1)$ updates of $front(\cdot)$ or $front^{-1}(\cdot)$ may change the set K, and therefore may take $O(\log n)$ time to update the data structure involving K.
- Each update of a pointer $u(\cdot)$ results also in an (implicit) update in a certain `child` search tree, taking $O(\log n)$ time.

We now examine the number of iterations of the loop.

▶ **Claim 9.** *With high probability, the number of iterations of the loop in a single invocation of `next-child` is $O(\log n)$.*

Proof. We consider a process where the iterations continue until the selected node is node b. A random variable, R, depicting this number dominates a random variable that depicts the actual number of iterations. For each iteration, an additional node is selected by `toss`. By Lemma 7 the probability that a node $j < b$ is selected by `toss` is $1/\varphi(j)$, and we have that $1/\varphi(j) \leq \frac{1}{j-1}$. Thus, $R = 1 + \sum_{j=a}^{b-1} X_j$, where X_j is 1 iff node j was selected, 0 otherwise. Since $\mu = \sum_{j=a}^{b-1} \frac{1}{\varphi(j)} \leq \log n$, using Chernoff bound we have, for any constant $c > 6$, $P[R > c \cdot \log n] \leq 2^{-c \cdot \log n} = n^{-\Omega(1)}$. ◀

We thus have the following.

▶ **Lemma 10.** *For any given invocation of `next-child`, with high probability, the time complexity is $O(\log^3 n)$.*

5.2.3 Randomness complexity

In procedure `parent` we use $O(\log n)$ random bits whenever, for a given j, this procedure is called with parameter j for the first time.

In procedure `toss` the `if` condition holds with probability $1 - 1/n^{c-1}$ (where c is the constant used in that procedure). Therefore, given an invocation of `toss`, with probability $1 - 1/n^{c-1}$ this procedure uses $O(\log n)$ bits. By Claim 9, in each invocation of `next-child` the number of times that `toss` is called is, w.h.p., $O(\log n)$. We thus have the following.

▶ **Lemma 11.** *During a given call to* `next-child`*, w.h.p.,* $O(\log^2 n)$ *random bits are used.*

The following lemma states the time, space, and randomness complexities of the queries.

▶ **Lemma 12.** *The complexities of* `next-child-tp` *and* `parent` *are as follows.*

- *Given an invocation of* `parent` *the following hold for this invocation:*
  1. *The increase, during that invocation, of the space used by our algorithm is* $O(1)$*.*
  2. *The number of random bits used during that invocation is* $O(\log n)$*.*
  3. *The time complexity of that invocation is* $O(\log n)$*.*
- *Given an invocation of* `next-child-tp`*, with high probability, all of the following hold for this invocation:*
  1. *The increase, during that invocation, of the space used by our algorithm is* $O(\log^2 n)$*.*
  2. *The number of random bits used during that invocation is* $O(\log^4 n)$*.*
  3. *The time complexity of that invocation is* $O(\log^5 n)$*.*

Proof.

`parent`. During an invocation of `parent`(j) the size of the used space increases when a pointer $u(j)$ becomes non-nul or when additional values are stored in `child`$(u(j))$. To select $u(j)$, $O(\log n)$ random bits are used, and $O(\log n)$ time is consumed to insert j in `child`$(u(j))$ and to update the data structure for the set K (this is implicit in the listing).

`next-child-tp`. We first consider `next-child`. Observe that by Lemma 8, w.h.p., each and every root (non-recursive) invocation of `next-child` has a recursion tree of size $O(\log n)$. In each invocation of `next-child`, $O(1)$ variables *front*(j) and $u(j)$ may be updated. Therefore, w.h.p., for all root (non-recursive) calls to `next-child` it holds that the increase in space during this invocation is $O(\log n)$ (see Section 5.2.1). Using Lemmas 11 and 8 we have that, w.h.p., each root invocation of `next-child` uses $O(\log^3 n)$ random bits. Using Lemmas 10 and 8, we have that, w.h.p., the time complexity of each root invocation of `next-child` is $O(\log^4 n)$.

Because the types of the pointers are uniformly distributed in {`dir`, `rec`}, each call to `next-child-tp` results, w.h.p., in $O(\log n)$ calls to `next-child`. The above complexities are thus multiplied by an $O(\log n)$ factor to get the (w.h.p.) complexities of `next-child-tp`. ◀

6 On-the-fly Generator for BA-Graphs

Our on-the-fly generator for BA-graphs is called `O-t-F-BA`, and simply calls `BA-next-neighbor`(v) for each query on node v. We present an implementation for the `BA-next-neighbor` query, and prove its correctness, as well as analyze its time, space, and randomness complexities. The on-the-fly BA generator maintains n standard `heaps`, one for each node. The heaps store nodes, where the order is the natural order of their serial numbers. The heap of node j stores some of the nodes already known to be neighbors of j.

- *For the first* `BA-next-neighbor`(v) *query*, for a given v, we proceed as follows. We find the parent of v in the BA-graph, which is done by following, in the pointers tree, the pointers of the ancestors of v until we find an ancestor pointed to by a `dir` pointer (and not a `rec` pointer). See Figure 2. In addition, we initialize the process of finding neighbors of v to its right (i.e., with a bigger serial number) by inserting into the heap of v the "final node" $n+1$ as well as the first child of v.
- Observe that any *subsequent* `BA-next-neighbor`(v) *query* is to return a *child* of v in the BA-graph. The children x of v in the BA-graph have, in the pointers tree, a path of $u(\cdot)$ pointers starting at x and ending at v with all pointers, except the last one, being `rec`

```
1: procedure BA-NEXT-NEIGHBOR(v)
2:     if first_query(v) = true then
3: /* first query for v */
4:         first_query(v) ← false
5:         heap-insert(heap_v, n + 1)
6:         heap-insert(heap_v, next-child-tp(v, v, dir))
7:         return BA-parent(v)
8:     else
9: /* all subsequent queries for v */
10:        r ← heap-extract-min(heap_v)
11:        if r = n + 1 then
12:            heap-insert(heap_v, n + 1)
13:            return n + 1
14:        else
15:            if type(r) = dir then
16:                heap-insert(heap_v, next-child-tp(v, r, dir))
17:                heap-insert(heap_v, next-child-tp(r, r, rec))
18:            else
19:                (q, type) ← parent(r)
20:                heap-insert(heap_v, next-child-tp(q, r, rec))
21:            end if
22:            return r
23:        end if
24:    end if
25: end procedure
```

```
1: procedure BA-PARENT(v)
2:     (i, flag) ← parent(v)
3:     if flag = dir then
4:         return i
5:     else
6:         return BA-parent(i)
7:     end if
8: end procedure
```

Figure 2 Pseudo code of the on-the-fly BA generator.

(the last being `dir`). The query has to report the children in increasing index number. To this end the `heap` of v is used; it stores some of the children of v, *not yet returned by a* `BA-next-neighbor`(v) *query*. This heap is also updated so that `BA-next-neighbor`(v) will continue to return the next child according to the index order. To do so, whenever a node, r, is extracted from the heap, the heap is updated to include the following:

- If r has a `dir` pointer to v, then we add to the heap (1) the next, after r, node with a `dir` pointer to v, and (2) the first node that has a `rec` pointer to r.
- If r has a `rec` pointer to a node r', then we add to the heap the first, after r, node with a `rec` pointer to r'.

The proof of the next lemma, by induction on the number of queries, is omitted.

▶ **Lemma 13.** *The procedure `BA-next-neighbor` returns the next neighbor of v.*

Since the flags in the pointers tree are uniformly distributed, and by Lemma 12, we have:

▶ **Lemma 14.** *For any given root (non-recursive) invocation of `BA-parent`, with high probability, that invocation takes $O(\log^2 n)$ time.*

The next theorem follows from the code, standard heap implementation, and Lemma 12.

▶ **Theorem 15.** *For any given invocation of `BA-next-neighbor`, with high probability, all of the following hold for that invocation:*

1. *The increase, during that invocation, of the space used by our algorithm $O(\log^2 n)$.*
2. *The number of random bits used during that invocation is $O(\log^4 n)$.*
3. *The time complexity of that invocation is $O(\log^5 n)$.*

We now state the properties of our on-the-fly graph generator for BA-graphs.

▶ **Definition 16.** For a number of queries $T > 0$ and a sequence of `BA-next-neighbor` queries $Q = (q_1, \ldots, q_T)$, let $A(Q)$ be the sequence of answers returned by an algorithm A on Q. If A is randomized then $A(Q)$ is a probability distribution on sequences of answers.

Let $\texttt{Opt-BA}_n$ be the (randomized) algorithm that first runs the Markov process to generate a graph G on n nodes according to the BA model, stores G, and then answers queries by accessing the stored G. Let $\texttt{O-t-F-BA}_n$ be the algorithm `O-t-F-BA` run with graph-size n.

▶ **Theorem 17.** *For any sequence of queries Q, $\texttt{Opt-BA}_n(Q) = \texttt{O-t-F-BA}_n(Q)$.*

▶ **Theorem 18.** *For any $T > 0$ and any sequence of queries $Q = (q_1, \ldots, q_T)$, when using $\texttt{O-t-F-BA}_n$ it holds w.h.p. that, for all $1 \leq t \leq T$:*

1. *The increase in the used space, while processing query t, is $O(\log^2 n)$.*
2. *The number of random bits used while processing query t is $O(\log^4 n)$.*
3. *The time complexity for processing query t is $O(\log^5 n)$.*

Proof. A query $\texttt{BA-next-neighbor}(v)$ at time t is a *trivial* if at some $t' < t$ a query $\texttt{BA-next-neighbor}(v)$ returns $n+1$. Observe that trivial queries take $O(\log n)$ *deterministic* time, do not use randomness, and do not increase the used space. Since there are less than n^2 *non-trivial* queries, the theorem follows from Theorem 15 and a union bound. ◀

Acknowledgments. We thank Yishay Mansour for raising the question of whether one can locally generate preferential attachment graphs, and Dimitri Achlioptas and Matya Katz for useful discussions. We further thank an anonymous ICALP reviewer for a comment that helped us simplify one of the data structure implementations.

Abstract

We revisit the classic problem of estimating the degree distribution moments of an undirected graph. Consider an undirected graph $G = (V, E)$ with n (non-isolated) vertices, and define (for $s > 0$) $\mu_s = \frac{1}{n} \cdot \sum_{v \in V} d_v^s$. Our aim is to estimate μ_s within a multiplicative error of $(1+\varepsilon)$ (for a given approximation parameter $\varepsilon > 0$) in sublinear time. We consider the sparse graph model that allows access to: uniform random vertices, queries for the degree of any vertex, and queries for a neighbor of any vertex. For the case of $s = 1$ (the average degree), $\widetilde{O}(\sqrt{n})$ queries suffice for any constant ε (Feige, SICOMP 06 and Goldreich-Ron, RSA 08). Gonen-Ron-Shavitt (SIDMA 11) extended this result to all integral $s > 0$, by designing an algorithms that performs $\widetilde{O}(n^{1-1/(s+1)})$ queries. (Strictly speaking, their algorithm approximates the number of star-subgraphs of a given size, but a slight modification gives an algorithm for moments.)

We design a new, significantly simpler algorithm for this problem. In the worst-case, it exactly matches the bounds of Gonen-Ron-Shavitt, and has a much simpler proof. More importantly, the running time of this algorithm is connected to the *degeneracy* of G. This is (essentially) the maximum density of an induced subgraph. For the family of graphs with degeneracy at most α, it has a query complexity of $\widetilde{O}\left(\frac{n^{1-1/s}}{\mu_s^{1/s}}\left(\alpha^{1/s} + \min\{\alpha, \mu_s^{1/s}\}\right)\right) = \widetilde{O}(n^{1-1/s}\alpha/\mu_s^{1/s})$. Thus, for the class of bounded degeneracy graphs (which includes all minor closed families and preferential attachment graphs), we can estimate the average degree in $\widetilde{O}(1)$ queries, and can estimate the variance of the degree distribution in $\widetilde{O}(\sqrt{n})$ queries. This is a major improvement over the previous worst-case bounds. Our key insight is in designing an estimator for μ_s that has low variance when G does not have large dense subgraphs.

1 Introduction

Estimating the mean and moments of a sequence of n integers $d_1, d_2, \ldots, d_n$ is a classic problem in statistics that requires little introduction. In the absence of any knowledge of the moments of the sequence, it is not possible to prove anything non-trivial. But suppose these integers formed the degree sequence of a graph. Formally, let $G = (V, E)$ be an undirected graph over n vertices, and let d_v denote the degree of vertex $v \in V$, where we assume that $d_v \geq 1$ for every v.[1] Feige proved that $O^*(\sqrt{n})$ uniform random vertex degrees (in expectation) suffice to provide a $(2+\varepsilon)$-approximation to the average degree [23]. (We use $O^*(\cdot)$ to suppress $\text{poly}(\log n, 1/\varepsilon)$ factors.) The variance can be as large as n for graphs of constant average degree (simply consider a star), but the constraints of a degree distribution allow for non-trivial approximations. Classic theorems of Erdős-Gallai and Havel-Hakimi characterize such sequences [29, 21, 27].

Again, the star graph shows that the $(2+\varepsilon)$-approximation cannot be beaten in sublinear time through pure vertex sampling. Suppose we could also access random neighbors of a given vertex. In this setting, Goldreich and Ron showed it is possible to obtain a $(1+\varepsilon)$-approximation to the average degree in $O^*(\sqrt{n})$ expected time [24].

In a substantial (and complex) generalization, Gonen, Ron, and Shavitt (henceforth, GRS) gave a sublinear-time algorithm that estimates the higher moments of the degree distribution [25]. Technically, GRS gave an algorithm for approximating the number of stars in a graph, but a simple modification yields an algorithm for moments estimation. For precision, let us formally define this problem. The *degree distribution* is the distribution over the degree of a uniform random vertex. The *s-th moment* of the degree distribution is $\mu_s \triangleq \frac{1}{n} \cdot \sum_{v \in V} d_v^s$.

The Degree Distribution Moment Estimation (DDME) Problem. *Let $G = (V, E)$ be a graph over n vertices, where n is known. Access to G is provided through the following queries. We can (i) get the id (label) of a uniform random vertex, (ii) query the degree d_v of any vertex v, (iii) query a uniform random neighbor of any vertex v. Given $\varepsilon > 0$ and $s \geq 1$, output a $(1+\varepsilon)$-multiplicative approximation to μ_s with probability[2] $> 2/3$.*

The DDME problem has important connections to network science, which is the study of properties of real-world graphs. There have been numerous results on the significance of heavy-tailed/power-law degree distributions in such graphs, since the seminal results of Barabási-Albert [5, 10, 22]. The degree distribution and its moments are commonly used to characterize and model graphs appearing in varied applications [7, 36, 14, 37, 8]. On the theoretical side, recent results provide faster algorithms for graphs where the degree distribution has some specified form [6, 9]. Practical algorithms for specific cases of DDME have been studied by Dasgupta et al and Chierichetti et al. [17, 13]. (These results requires bounds on the mixing time of the random walk on G.)

1.1 Results

Let m denote the number of edges in the graph (where m is not provided to the algorithm). For the sake of simplicity, we restrict the discussion in the introduction to case when $\mu_s \leq n^{s-1}$.

[1] The assumption on there being no isolated vertices is made here only for the sake of simplicity of the presentation, as it ensures a basic lower bound on the moments.

[2] The constant $2/3$ is a matter of convenience. It can be increased to at least $1-\delta$ by taking the median value of $\log(1/\delta)$ independent invocations.

As observed by GRS, the complexity of the DDME problem is smaller when μ_s is significantly larger. GRS designed an (expected) $O^*\left(n^{1-1/(s+1)}/\mu_s^{1/(s+1)} + n^{1-1/s}\right)$-query algorithm for DDME and proved this expression was optimal up to $\text{poly}(\log n, 1/\varepsilon)$ dependencies. (Here $O^*(\cdot)$ also suppresses additional factors that depend only on s). Note that for a graph without isolated vertices, $\mu_s \geq 1$ for every $s > 0$, so this yields a worst-case $O^*(n^{1-1/(s+1)})$ bound. The $s = 1$ case is estimating the average degree, so this recovers the $O^*(\sqrt{n})$ bounds of Goldreich-Ron. We mention a recent result by Aliakbarpour et al. [1] for DDME, in a stronger model that assumes additional access to uniform random edges. They get a better bound of $O^*(m/(n\mu_s)^{1/s})$ in this stronger model, for $s > 1$ (and $\mu_s \leq n^{s-1}$). Note that the main challenge of DDME is in measuring the contribution of high-degree vertices, which becomes substantially easier when random edges are provided. In the DDME problem without such samples, it is quite non-trivial to even detect high degree vertices.

All the bounds given above are known to be optimal, up to $\text{poly}(\log n, 1/\varepsilon)$ dependencies, and at first blush, this problem appears to be solved. We unearth a connection between DDME and the *degeneracy* of G. The degeneracy of G is (up to a factor 2) the maximum density over all subgraphs of G. We design an algorithm that has a nuanced query complexity, depending on the degeneracy of G. Our result subsumes all existing results, and provides substantial improvements in many interesting cases. Furthermore, our algorithm and its analysis are significantly simpler and more concise than in the GRS result.

We begin with a convenient corollary of our main theorem. A tighter, more precise bound appears as Theorem 3.

▶ **Theorem 1.** *Consider the family of graphs with degeneracy at most α. The DDME problem can be solved on this family using $O^*\left(\frac{n^{1-1/s}}{\mu_s^{1/s}}\left(\alpha^{1/s} + \min\{\alpha, \mu_s^{1/s}\}\right)\right)$ queries in expectation. The running time is linear in the number of queries.*

Consider the case of *bounded degeneracy* graphs, where $\alpha = O(1)$. This is a rich class of graphs. *Every* minor-closed family of graphs has bounded degeneracy, as do graphs generated by the Barabási-Albert preferential attachment process [5]. There is a rich theory of *bounded expansion graphs*, which spans logic, graph minor theory, and fixed-parameter tractability [32]. All these graph classes have bounded degeneracy. For every such class of graphs, we get a $(1+\varepsilon)$-estimate of μ_s in $O^*(n^{1-1/s}/\mu_s^{1/s})$ time. We stress that bounded degeneracy does not imply any bounds on the maximum degree or the moments. The star graph has degeneracy 1, but has extremely large moments due to the central vertex.

Consider any bounded degeneracy graph without isolated vertices. We can accurately estimate the average degree ($s = 1$) in $\text{poly}(\log n)$ queries, and estimate the variance of the degree distribution ($s = 2$) in $\sqrt{n} \cdot \text{poly}(\log n)$ queries. Contrast this with the (worst-case optimal) $\sqrt{n}$ bounds of Feige and Goldreich-Ron for average degree, and the $O^*(n^{2/3})$ bound of GRS for variance estimation. For general s, our bound is a significant improvement over the $O^*(n^{1-1/(s+1)}/\mu_s^{1/(s+1)})$ bound of GRS.

The algorithm attaining Theorem 1 requires an upper bound on the degeneracy of the graph. When an degeneracy bound is not given, the algorithm recovers the bounds of GRS, with an improvement on the extra $\text{poly}(\log n)/\varepsilon$ factors. More details are in Theorem 3. We note that the degeneracy-dependent bound in Theorem 1 cannot be attained by an algorithm that is only given n as a parameter. In particular, if an algorithm is only provided with n and must work on all graphs with n vertices, then it must perform $\Omega(\sqrt{n})$ queries in order to approximate the average degree even for graphs of constant degeneracy (and constant average degree). Details are given in Subsection 7.1 in the full version of the paper.

The bound of Theorem 1 may appear artificial, but we prove that it is optimal when $\mu_s \leq n^{s-1}$. (For the general case, we also have optimal upper and lower bounds.) This construction is an extension of the lower bound proof of GRS.

▶ **Theorem 2.** *Consider the family of graphs with degeneracy α and where $\mu_s \leq n^{s-1}$. Any algorithm for the DDME problem on this family requires $\Omega\Big(\frac{n^{1-1/s}}{\mu_s^{1/s}} \cdot \Big(\alpha^{1/s} + \min\{\alpha, \mu_s^{1/s}\}\Big)\Big)$ queries.*

1.2 From degeneracy to moment estimation

We begin with a closer look at the lower bound examples of Feige, Goldreich-Ron, and GRS. The core idea is quite simple: DDME is hard when the overall graph is sparse, but there are small dense subgraphs. Consider the case of a clique of size $100\sqrt{n}$ connected to a tree of size n. The small clique dominates the average degree, but any sublinear algorithm with access only to random vertices pays $\Omega(\sqrt{n})$ for a non-trivial approximation. GRS use more complex constructions to get an $\Omega(n^{1-1/(s+1)})$ lower bound for general s. This also involves embedding small dense subgraphs that dominate the moments.

Can we prove a converse to these lower bound constructions? In other words, prove that the *non-existence* of dense subgraphs must imply that DDME is easier? A convenient parameter for this non-existence is the *degeneracy*.

But the degeneracy is a global parameter, and it is not clear how a sublinear algorithm can exploit it. Furthermore, DDME algorithms are typically very local; they sample random vertices, query the degrees of these vertices and maybe also query the degrees of some of their neighbors. We need a local property that sublinear algorithms can exploit, but can also be linked to the degeneracy. We achieve this connection via the *degree ordering* of G. Consider the DAG obtained by directing all edges from lower to higher degree vertices. Chiba-Nishizeki related the properties of the *out-degree* distribution to the degeneracy, and exploited this for clique counting [12]. Nonetheless, there is no clear link to DDME. (Nor do we use any of their techniques; we state this result merely to show what led us to use the degree ordering).

Our main insight is the construction of an estimator for DDME whose variance depends on the degeneracy of G. This estimator critically uses the degree ordering. Our proof relates the variance of this estimator to the density of subgraphs in G, which can be bounded by the degeneracy. We stress that our algorithm is quite simple, and the technicalities are in the analysis and setting of certain parameters.

1.3 Designing the algorithm

Designate the *weight* of an edge (u, v) to be $d_u^{s-1} + d_v^{s-1}$. A simple calculation yields that the sum of the weights of all edges is exactly $M_s \triangleq \sum_v d_v^s = n \cdot \mu_s$. Suppose we could sample uniform random *edges* (and knew the total number of edges). Then we could hope to estimate M_s through uniform edge sampling. The variance of the edge weights can be bounded, and this yields an $O^*(m/(n\mu_s)^{1/s}) = O^*(n^{1-1/s})$ algorithm (when no vertex is isolated). Indeed, this is very similar to the approach of Aliakbarpour et al. [1]. Such variance calculations were also used in the classic Alon-Matias-Szegedy result of frequency moment estimation [3].

Our approach is to simulate uniform edge samples using uniform vertex samples. Suppose we sampled a set R of uniform random vertices. By querying the degrees of all these vertices, we can select vertices in R with probability proportional to their degrees, which allows us to uniformly sample edges that are incident to vertices in R. Now, we simply run the uniform

edge sampling algorithm on these edges. This algorithmic structure was recently used for sublinear triangle counting algorithms by Eden et al. [19].

Here lies the core technical challenge. How to bound the number of random vertices that is sufficient for effectively simulating the random edge algorithm? This boils down to the behavior of the variance of the "vertex weight" distribution. Let the weight of a vertex be the sum of weights of its incident edges. The weight distribution over vertices can be extremely skewed, and this approach would require a forbiddingly large R.

A standard technique from triangle counting (first introduced by Chiba-Nishizeki [12]) helps reduce the variance. Direct all edges from lower degree to higher degree vertices, breaking ties consistently. Now, set the weight of a vertex to be the sum of weights on incident *out-edges*. Thus, a high-degree vertex with lower degree neighbors will have a significantly reduced weight, reducing overall variance. In the general case (ignoring degeneracy), a relatively simple argument bounds the maximum weight of a vertex, which enables us to bound the variance of the weight distribution. This yields a much simpler algorithm and proof of the GRS bound.

In the case of graphs with bounded degeneracy, we need a more refined approach. Our key insight is an intimate connection between the variance and the existence of dense subgraphs in G. We basically show that the main structure that leads to high variance is the existence of dense subgraphs. Formally, we can translate a small upper bound on the density of any subgraph to a bound on the variance of the vertex weights. This establishes the connection to the graph degeneracy.

1.4 Simplicity of our algorithm

Our viewpoint on DDME is quite different from GRS and its precursor [24], which proceed by bucketing the vertices based on their degree. This leads to a complicated algorithm, which essentially samples to estimate the size of the buckets, and also the number of edges between various buckets (and "sub-buckets"). We make use of buckets in out analysis, in order to obtain the upper bound that depends on the degeneracy α (in order to achieve the GRS upper bound, our analysis does not use bucketing).

As explained above, our main DDME procedure, **Moment-estimator** is simple enough to present in a few lines of pseudocode (see Figure 1). We feel that the structural simplicity of **Moment-estimator** is an important contribution of our work.

Moment-estimator takes two sampling parameters r and q. The main result Theorem 3 follows from running **Moment-estimator** with a standard geometric search for the right setting of r and q. In **Moment-estimator** we use $id(v)$ to denote the label of a vertex v, where vertices have unique ids and there is a complete order over the ids.

1.5 Other related work

As mentioned at the beginning of this section, Aliakbarpour et al. [1] consider the problem of approximating the number of s-stars for $s \geq 2$ when given access to uniformly selected edges. Given the ability to uniformly select edges, they can select vertices with probability proportional to their degree (rather than uniformly). This can be used to get an unbiased estimator of μ_s (or the s-star count) with low variance. This leads to an $O(m/(n\mu_s)^{1/s})$ bound, which is optimal (for $\mu_s \leq n^{s-1}$).

Dasgupta, Kumar, and Sarlos give practical algorithms for average degree estimation, though they assume bounds on the mixing time of the random walk on the graph [17]. A recent paper of Chierichetti et al. build on these methods to sample nodes according to

Moment-estimator$_s(r, q)$

1. Select r vertices, uniformly, independently, at random and let the resulting multi-set be denoted by R. Query the degree of each vertex in R, and let $d_R = \sum_{v \in R} d_v$.
2. For $i = 1, \ldots, q$ do:
   a. Select a vertex v_i with probability proportional to its degree (i.e., with probability d_{v_i}/d_R), and query for a random neighbor u_i of v_i.
   b. If $d_{v_i} < d_{u_i}$ or $d_{v_i} = d_{u_i}$ and $id(v_i) < id(u_i)$, set $X_i = (d_{v_i}^{s-1} + d_{u_i}^{s-1})$. Else, set $X_i = 0$.
3. Return $X = \frac{1}{r} \cdot \frac{d_R}{q} \cdot \sum_{i=1}^{q} X_i$.

Figure 1 Algorithm **Moment-estimator$_s$** for approximating μ_s.

powers of their degree (which is closely related to DDME) [13]. Simpson, Seshadhri, and McGregor give practical algorithms to estimate the entire cumulative degree distribution in the streaming setting [38]. This is different from the sublinear query model we consider, and the results are mostly empirical.

In [19], Eden et al. present an algorithm for approximating the number of triangles in a graph. Although this is a very different problem than DDME, there are similar challenges regarding high-degree vertices. Indeed, as mentioned earlier, the approach of sampling random edges through a set of random vertices was used in [19].

The degeneracy is closely related to other "density" notions, such as the arboricity, thickness, and strength of a graph [4]. There is a rich history of algorithmic results where run time depends on the degeneracy [31, 12, 2, 20].

Other sublinear algorithms for estimating various graph parameters include: approximating the size of the minimum-weight spanning tree [11, 16, 15], maximum matching [33, 39] and of the minimum vertex cover [35, 33, 30, 39, 28, 34].

A Comment regarding this extended abstract

We defer some of the details of the analysis of the algorithm, as well as the lower bound proof, to the accompanying full version of the paper.

2 The main theorem

▶ **Theorem 3.** *For every graph G, there exists an algorithm that returns a value Z such that $Z \in [(1-\varepsilon)\mu_s(G), (1+\varepsilon)\mu_s(G)]$ with probability at least $2/3$. Assume that algorithm is given α, an upper bound on the degeneracy of G. (If no such bound is provided, the algorithm assumes a trivial bound of $\alpha = \infty$.) The expected running time is the minimum of the following two expressions.*

$$O\left(2^s \cdot n^{1-1/s} \cdot \log^2 n \cdot \left(\frac{\alpha}{\mu_s}\right)^{1/s} + \min\left\{\frac{n^{1-1/s} \cdot \alpha}{\mu_s^{1/s}}, \frac{n^{s-1} \cdot \alpha}{\mu_s}\right\}\right) \cdot \frac{s \log n \cdot \log(s \log n)}{\varepsilon^2} \quad (1)$$

$$O\left(\frac{n^{1-1/(s+1)}}{\mu_s^{1/(s+1)}} + \min\left\{n^{1-1/s}, \frac{n^{s-1-1/s}}{\mu_s^{1-1/s}}\right\}\right) \cdot \frac{s \log n \cdot \log(s \log n)}{\varepsilon^2} \quad (2)$$

Equation (2) is essentially the query complexity of GRS (albeit with a better dependence on $s, \log n$, and $1/\varepsilon$). Thus, our algorithm is guaranteed to be at least as good as that. If α is

exactly the degeneracy of G, then we can prove that Equation (1) is less than Equation (2). Within each expression, there is a min of two terms. The first term is smaller iff $\mu_s \leq n^{s-1}$.

The mechanism of deriving this rather cumbersome running time is the following. The algorithm of Theorem 3 runs **Moment-estimator** for geometrically increasing values of r and q, which is in turn derived from a geometrically decreasing guess of μ_s. It uses this guess to set r and q. There is a setting of values depending on α, and a setting independent of it. The algorithm simply picks the minimum of these settings to achieve the smaller running time.

3 Sufficient conditions for r and q in Moment-estimator

In this section we provide sufficient conditions on the parameters r and q that are used by **Moment-estimator** (Figure 1), in order for the algorithm to return a $(1+\varepsilon)$ estimate of μ_s. First we introduce some notations. For a graph $G = (V, E)$ and a vertex $v \in V$, let $\Gamma(v)$ denote the set of neighbors of v in G (so that $d_v = |\Gamma(v)|$). For any (multi-)set R of vertices, let E_R be the (multi-)set of edges incident to the vertices in R. We will think of the edges in E_R as ordered pairs; thus (v, u) is distinct from (u, v), and so $E_R \triangleq \{(v, u) : v \in R, u \in \Gamma(v)\}$. Observe that d_R, as defined in Step 1 of **Moment-estimator** equals $|E_R|$. Let $M_s = M_s(G) \triangleq \sum_{v \in V} d_v^s$, so that $\mu_s = M_s/n$. In the analysis of the algorithm, it is convenient to work with M_s instead of μ_s.

A critical aspect of our algorithm (and proof) is the *degree ordering on vertices*. Formally, we set $u \prec v$ if $d_u < d_v$ or, $d_u = d_v$ and $id(u) < id(v)$. Given the degree ordering, we let $\Gamma^+(v) \triangleq \{u \in \Gamma(v) : v \prec u\}$, $d_v^+ \triangleq |\Gamma^+(v)|$, and $E^+ \triangleq \{(v, u) : v \in V, u \in \Gamma^+(v)\}$. Here and elsewhere, we use $\sum_v$ as a shorthand for $\sum_{v \in V}$.

▶ **Definition 4.** We define the weight of an edge $e = (v, u)$ as follows: if $v \prec u$ define $\mathrm{wt}(e) \triangleq (d_v^{s-1} + d_u^{s-1})$. Otherwise, $\mathrm{wt}(e) \triangleq 0$.
For a vertex $v \in V$, $\mathrm{wt}(v) \triangleq \sum_{u \in \Gamma(v)} \mathrm{wt}((v, u)) = \sum_{u \in \Gamma^+(v)} \mathrm{wt}((v, u))$, and for a (multi-)set of vertices R, $\mathrm{wt}(R) \triangleq \sum_{v \in R} \mathrm{wt}(v)$.

Observe that given the above notations and definition, **Moment-estimator** selects uniform edges from E_R and sets each X_i (in Step 2b) to $\mathrm{wt}((v_i, u_i))$. The next two claims readily follow from Definition 4 (and the description of the algorithm).

▶ **Claim 5.** $\sum_v \mathrm{wt}(v) = M_s$.

▶ **Claim 6.** $\mathrm{Ex}[X] = \mu_s$, *where* X *is as defined in Step 3 of the algorithm.*

3.1 Conditions on the parameters r and q

We next state two conditions on the parameters r and q, which are used in the algorithm, and then establish several claims, based on the conditions holding. The conditions are stated in terms of properties of the graph as well as the approximation parameter ε and a confidence parameter δ.

1. **The vertex condition:** $r \geq (120 \cdot n \cdot \sum_v \mathrm{wt}(v)^2)/(\varepsilon^2 \cdot \delta \cdot M_s^2)$,
2. **The edge condition:** $q \geq 2000 \cdot m \cdot M_{2s-1}/(\varepsilon^2 \cdot \delta^3 \cdot M_s^2)$.

▶ **Lemma 7.** *If Condition 1 holds, then with probability at least* $1 - \delta/2$*, all the following hold.*

1. $\mathrm{wt}(R) \in \left[\left(1 - \frac{\varepsilon}{2}\right) \cdot \frac{r}{n} \cdot M_s, \left(1 + \frac{\varepsilon}{2}\right) \cdot \frac{r}{n} \cdot M_s\right]$.
2. $|E_R| \leq \frac{12}{\delta} \cdot \frac{r}{n} \cdot m$.
3. $\sum_{(v,u) \in E_R^+} \mathrm{wt}\left((v,u)\right)^2 \leq \frac{18}{\delta} \cdot \frac{r}{n} \cdot M_{2s-1}$.

The proof of the first item in Lemma 7 follows from Chebyshev's inequality (using $\mathrm{Var}[\mathrm{wt}(R)] \leq \frac{r}{n} \cdot \sum_v \mathrm{wt}(v)^2$), and the proofs of the other two items follow from Markov's inequality (as well as the definition of M_{2s-1}).

▶ **Theorem 8.** *If Conditions 1 and 2 hold, then* $X \in [(1-\varepsilon)\mu_s, (1+\varepsilon)\mu_s]$ *with probability at least* $1 - \delta$*.*

Proof. Condition on any choice of R. We have $\mathrm{Ex}[X|R] = (1/r)\mathrm{wt}(R)$. Turning to the variance, since the edges (v_i, u_i) are chosen from E_R uniformly at random, it is not hard to verify that

$$\mathrm{Var}[X|R] = \left(\frac{1}{r}\right)^2 \cdot \left(\frac{|E_R|}{q}\right)^2 \cdot \mathrm{Var}\left[\sum_{i=1}^{q} X_i \;\middle|\; R\right] = \frac{1}{q} \cdot \frac{|E_R|}{r} \cdot \frac{\sum_{(v,u) \in E_R^+} \mathrm{wt}\left((v,u)\right)^2}{r} \,.$$

Let us now condition on R such that the bounds of Lemma 7 hold. Note that such an R is chosen with probability at least $1 - \delta/2$. We get $\mathrm{Var}[X|R] \leq \frac{250}{\delta^2} \cdot \frac{1}{q} \cdot \frac{m}{n} \cdot \frac{M_{2s-1}}{n}$. We apply Chebyshev's inequality and invoke Condition 2:

$$\Pr\left[\left|(X|R) - \mathrm{Ex}[X|R]\right| \leq \frac{\varepsilon}{2} \cdot \mu_s\right] \;\leq\; \frac{4 \cdot \mathrm{Var}[X|R]}{\varepsilon^2 \cdot \mu_s^2} \leq \frac{1}{q} \cdot \frac{4 \cdot (250/\delta^2) \cdot m \cdot M_{2s-1}}{\varepsilon^2 \cdot M_s^2} \leq \frac{\delta}{2} \,.$$

By Lemma 7, $\mathrm{Ex}[X|R] = (1/r)\mathrm{wt}(R) \in [(1-\varepsilon/2)\mu_s, (1+\varepsilon/2)\mu_s]$. The theorem follows by applying the union bound. ◀

4 Satisfying Conditions 1 and 2 in general graphs

We show how to set r and q to satisfy Conditions 1 and 2 in general graphs. Our setting of r and q will give us the same query complexity as [25] (up to the dependence on $1/\varepsilon$ and $\log n$, on which we improve, and the exponential dependence on s in [25], which we do not incur). In the next section we show how the setting of r and q can be improved using a degeneracy bound.

For c_r and c_q that are sufficiently large constants, we set

$$r = \frac{c_r}{\varepsilon^2 \cdot \delta} \cdot \frac{n}{M_s^{1/(s+1)}} \,, \qquad q = \frac{c_q}{\varepsilon^2 \cdot \delta^3} \cdot \min\left\{n^{1-1/s}, \frac{n^{s-1/s}}{M_s^{1-1/s}}\right\} \,. \tag{3}$$

This setting of parameters requires the knowledge of M_s, which is exactly what we are trying to approximate (up to the normalization factor of n). A simple geometric search argument alleviates the need to know M_s. For details see Section 6.

In order to assert that r as set in Equation (3) satisfies Condition 1, it suffices to establish the next lemma.

▶ **Lemma 9** (Condition 1 holds)**.** $\sum_v \mathrm{wt}(v)^2 \leq 4M_s^{2-\frac{1}{s+1}}$.

Proof. Let $\theta = M_s^{1/(s+1)}$ be a degree threshold. We define $H \triangleq \{v : d_v > \theta\}$, $L \triangleq V \setminus H$. This partition into "high-degree" vertices (H) and "low-degree" vertices (L) will be useful in upper bounding the maximum weight $\mathrm{wt}(v)$ of a vertex v, and hence upper bounding $\sum_v \mathrm{wt}(v)^2$. Details follow.

We first observe that $|H| \leq M_s^{1/(s+1)}$. This is true since otherwise, $\sum_{v\in H} d_v^s > M_s^{1/(s+1)} \cdot M_s^{\frac{s}{s+1}} = M_s$, which is a contradiction. We claim that this upper bound on $|H|$ implies that

$$\max_v d_v^+ \leq M_s^{1/(s+1)} \ . \tag{4}$$

To verify this, assume, contrary of the claim, that for some v, $d_v^+ > M_s^{1/(s+1)}$. But then there are at least $M_s^{1/(s+1)}$ vertices u such that $d_u \geq d_v \geq d_v^+ > M_s^{1/(s+1)}$. This contradicts the bound on $|H|$.

It will also be useful to bound $\sum_{u\in H} d_u^{s-1}$. By Hölder's inequality with conjugates s and $s/(s-1)$ (a statement of Hölder's inequality can be found in the full version of the paper) and the bound on $|H|$,

$$\sum_{u\in H} d_u^{s-1} = \sum_{u\in H} 1 \cdot d_u^{s-1} \leq |H|^{1/s} \left(\sum_{u\in H} d_u^s\right)^{\frac{s-1}{s}} \leq M_s^{\frac{1}{s(s+1)}} \cdot M_s^{\frac{s-1}{s}} \leq M_s^{\frac{s}{s+1}} \ . \tag{5}$$

We now turn to bounding $\max_v\{\mathrm{wt}(v)\}$. By the definition of $\mathrm{wt}(v)$ and the degree ordering,

$$\mathrm{wt}(v) = \sum_{u\in\Gamma^+(v)} (d_v^{s-1} + d_u^{s-1}) \leq 2 \sum_{u\in\Gamma^+(v)} d_u^{s-1} = 2 \sum_{u\in\Gamma^+(v)\cap L} d_u^{s-1} + 2 \sum_{u\in\Gamma^+(v)\cap H} d_u^{s-1} \ . \tag{6}$$

For the first term on the right-hand-side of Equation (6), recall that $d_u \leq M_s^{1/(s+1)}$ for $u \in L$. Thus, by Equation (4),

$$\sum_{u\in\Gamma^+(v)\cap L} d_u^{s-1} \leq d_v^+ \cdot M_s^{\frac{s-1}{s+1}} \leq M_s^{\frac{s}{s+1}} \ . \tag{7}$$

For the second term, using $\Gamma^+(v) \cap H \subseteq H$ and applying Equation (5),

$$\sum_{u\in\Gamma^+(v)\cap H} d_u^{s-1} \leq \sum_{u\in H} d_u^{s-1} \leq M_s^{\frac{s}{s+1}} \ . \tag{8}$$

Finally,

$$\sum_v \mathrm{wt}(v)^2 \leq \max_v\{\mathrm{wt}(v)\} \cdot \sum_v \mathrm{wt}(v) \leq M_s^{2-1/(s+1)} \ ,$$

where the second inequality follows by combining Equations (6)–(8) to get an upper bound on $\max_v\{\mathrm{wt}(v)\}$ and applying Claim 5. ◀

The next lemma implies that Condition 2 holds for q as set in Equation (3).

▶ **Lemma 10** (Condition 2 holds). $\min\left\{n^{1-1/s}, \frac{n^{s-1/s}}{M_s^{1-1/s}}\right\} \geq 2m \cdot \frac{M_{2s-1}}{M_s^2}$.

Proof. We can bound M_{2s-1} in two ways. First, by a standard norm inequality, since $s \geq 1$,

$$M_{2s-1} = \sum_v d_v^{2s-1} \leq \left(\sum_v d_v^s\right)^{(2s-1)/s} = M_s^{2-1/s} \ . \tag{9}$$

We can also use the trivial bound $d_v \leq n$ and get $M_{2s-1} \leq n^{s-1} \cdot M_s$. Thus, $M_{2s-1} \leq \min\{M_s^{2-1/s}, n^{s-1} \cdot M_s\}$. By applying Hölder's inequality with conjugates $s/(s-1)$ and s we get that

$$2m = \sum_v 1 \cdot d_v \leq n^{(s-1)/s} \cdot \left(\sum_v d_v^s \right)^{1/s} = n^{1-1/s} \cdot M_s^{1/s} \,. \tag{10}$$

We multiply the bound by M_{2s-1} to complete the proof. ◀

5 The Degeneracy Connection

The degeneracy, or the coloring number, of a graph $G = (V, E)$ is the maximum value, over all subgraphs G' of G, of the minimum degree in G'. In this definition, we can replace "minimum" by "average" to get a 2-factor approximation to the degeneracy (refer to [26]; Theorem 2.4.4 and Corollary 5.2.3 of [18]). Abusing notation, it will be convenient for us to define $\alpha(G) = \max_{S \subseteq V} \left\{ \frac{|E(S)|}{|S|} \right\}$.

We also make the following observation regarding the relation between $\alpha(G)$ and $M_s(G)$.

▶ **Claim 11.** *For every graph G, $\alpha(G) \leq M_s(G)^{\frac{1}{s+1}}$.*

In this section, we show that the following setting of parameters for **Moment-estimator**$_s$ satisfies Conditions 1 and 2, for every graph G with degeneracy at most α (i.e., $\alpha(G) \leq \alpha$), and for appropriate constants c_r and c_q.

$$r = \frac{c_r}{\varepsilon^2 \cdot \delta} \cdot \min \left\{ \frac{n}{M_s^{1/(s+1)}} \,,\; 2^s \cdot n \cdot \log^2 n \cdot \left(\frac{\alpha}{M_s} \right)^{1/s} \right\} , \tag{11}$$

$$q = \frac{c_q}{\varepsilon^2 \cdot \delta^3} \cdot \min \left\{ \frac{n \cdot \alpha}{M_s^{1/s}}, \frac{n^s \cdot \alpha}{M_s}, n^{1-1/s}, \frac{n^{s-1/s}}{M_s^{1-1/s}} \right\} . \tag{12}$$

Clearly the setting of r and q in Equation (11) and Equation (12) respectively, can only improve on the setting of r and q for the general case in Equation (3) (Section 4).

Our main challenge is in proving that Condition 1 holds for r as set in Equation (11) (when the graph has degeneracy at most α). Here too, the goal is to upper bound $\sum_v \mathrm{wt}(v)^2$. However, as opposed to the proof of Lemma 9 in Section 4, where we simply obtained an upper bound on $\max_v\{\mathrm{wt}(v)\}$ (and bounded $\sum_v \mathrm{wt}(v)^2$ by $\max_v\{\mathrm{wt}(v)\} \cdot M_s$), here the analysis is more refined, and uses the degeneracy bound. For details see the proof of our main lemma, stated next.

▶ **Lemma 12** (Condition 1 holds). *For a sufficiently large constant c, $\sum_v \mathrm{wt}(v)^2 \leq c \cdot 2^s \cdot \alpha^{1/s} \cdot M_s^{2-1/s} \cdot \log^2 n$.*

Proof Sketch. In this extended abstract we only provide the high-level structure of the proof. By the definition of $\mathrm{wt}(v)$, and since $d_v \leq d_u$ for every v and $u \in \Gamma^+(v)$,

$$\sum_v \mathrm{wt}(v)^2 = \sum_v \Big(\sum_{u \in \Gamma^+(v)} \left(d_v^{s-1} + d_u^{s-1} \right) \Big)^2 \;\leq\; 4 \cdot \sum_v \Big(\sum_{u \in \Gamma^+(v)} d_u^{s-1} \Big)^2 . \tag{13}$$

In order to bound the expression on the right-hand-side of Equation (13) we partition the vertices (with degree at least 1) according to their degree. Let $U_i \triangleq \{u \in V : d_u \in$

$(2^{i-1}, 2^i]\}$ for $0 \le i \le \lceil \log n \rceil$, and let $\Gamma_i^+(v)$ be a shorthand for $\Gamma^+(v) \cap U_i$. By considering each U_i separately and applying Hölder's inequality we get the following bound for every v.

$$\sum_{u \in \Gamma_i^+(v)} 1 \cdot d_u^{s-1} \le |\Gamma_i^+(v)|^{1/s} \cdot \Big(\sum_{u \in \Gamma_i^+(v)} d_u^s \Big)^{(s-1)/s} \le |\Gamma_i^+(v)|^{1/s} \cdot M_s^{(s-1)/s} \,. \tag{14}$$

For each i, we also partition the vertices in V according to the number of outgoing edges that they have to U_i. Specifically, for $1 \le j \le \lceil \log(n/\alpha) \rceil$, define $V_{i,j} \triangleq \Big\{ v \in V : |\Gamma_i^+(v)| \in \big(2^{j-1}\alpha, 2^j\alpha\big] \Big\}$. Also define $V_{i,0} \triangleq \Big\{ v \in V : |\Gamma_i^+(v)| \le \alpha \Big\}$. Hence, $\{V_{i,j}\}_{j=0}^{\lceil \log(n/\alpha) \rceil}$ is a partition of V for each i.

For a vertex u, let $\Gamma^-(u) \triangleq \{v : u \in \Gamma^+(v)\}$. For two sets of vertices S and T (which are not necessarily disjoint), let $E^+(S,T) \triangleq \{(u,v) : (u,v) \in E^+, u \in S, v \in T\}$. By applying Equation (14) (to one term of the square $\Big(\sum_{u \in \Gamma_i^+(v)} d_u^{s-1}\Big)^2$), and by the definition of $V_{i,j}$, it can be shown that

$$\sum_v \Big(\sum_{u \in \Gamma_i^+(v)} d_u^{s-1} \Big)^2 \le M_s^{(s-1)/s} \cdot \sum_{j=0}^{\lceil \log n \rceil} \Big(\sum_{u \in U_i} d_u^{s-1} \cdot \sum_{v \in \Gamma^-(u) \cap V_{i,j}} |\Gamma_i^+(v)|^{1/s} \Big) \,. \tag{15}$$

For $j < 2$ we can show that $\sum_{u \in U_i} d_u^{s-1} \sum_{v \in \Gamma^-(u) \cap V_{i,j}} |\Gamma_i^+(v)|^{1/s} \le 2 \cdot \alpha^{1/s} \cdot M_s$. Turning to $j \ge 2$, since all vertices in U_i have degree at most 2^i, we get:

$$\sum_{u \in U_i} d_u^{s-1} \cdot \sum_{v \in \Gamma^-(u) \cap V_{i,j}} |\Gamma_i^+(v)|^{1/s} \le 2^{j/s} \cdot \alpha^{1/s} \cdot 2^{i(s-1)} \cdot |E^+(V_{i,j}, U_i)| \,. \tag{16}$$

Since G has degeneracy at most α and by the definition of $V_{i,j}$, it can be shown that $|E^+(V_{i,j}, U_i)| \le 2\alpha \cdot |U_i|$, where $U_i = U_i \cap \Big(\bigcup_{v \in V_{i,j}} \Gamma^+(v) \Big)$. Furthermore, the definition of U_i (together with the degeneracy bound and the definition of M_s) implies that $|U_i| \le M_s \cdot 2^{-((i-1)(s-1)+j)} \cdot \alpha^{-1}$. The lemma follows by combining Equation (13) with Equation (15) and the above bounds for $j < 2$ and $j \ge 2$. ◀

The next lemma, which establishes Condition 2, can be proved similarly to Lemma 10.

▶ **Lemma 13** (Condition 2 holds).

$$\min \left\{ \frac{n \cdot \alpha}{M_s^{1/s}}, \frac{n^s \cdot \alpha}{M_s}, n^{1-1/s}, \frac{n^{s-1/s}}{M_s^{1-1/s}} \right\} \ge m \cdot \frac{M_{2s-1}}{M_s^2} \,.$$

6 Wrapping things up

The proof of our final result, Theorem 3, follows by combining Theorem 8, Lemma 9, Lemma 12 and Lemma 13, with a geometric search for a factor-2 estimate of M_s (which determines the correct setting of r and q in the algorithm).

Abstract

We investigate the problem of testing the equivalence between two discrete histograms. A k-*histogram* over $[n]$ is a probability distribution that is piecewise constant over some set of k intervals over $[n]$. Histograms have been extensively studied in computer science and statistics. Given a set of samples from two k-histogram distributions p, q over $[n]$, we want to distinguish (with high probability) between the cases that $p = q$ and $\|p - q\|_1 \geq \epsilon$. The main contribution of this paper is a new algorithm for this testing problem and a nearly matching information-theoretic lower bound. Specifically, the sample complexity of our algorithm matches our lower bound up to a logarithmic factor, improving on previous work by polynomial factors in the relevant parameters. Our algorithmic approach applies in a more general setting and yields improved sample upper bounds for testing closeness of other structured distributions as well.

1 Introduction

In this work, we study the problem of testing equivalence (closeness) between two discrete *structured* distributions. Let $\mathcal{D}$ be a family of univariate distributions over $[n]$ (or $\mathbb{Z}$). The problem of *closeness testing for* $\mathcal{D}$ is the following: Given sample access to two unknown distribution $p, q \in \mathcal{D}$, we want to distinguish between the case that $p = q$ versus $\|p - q\|_1 \geq \epsilon$. (Here, $\|p-q\|_1$ denotes the ℓ_1-distance between the distributions p, q.) The sample complexity of this problem depends on the underlying family $\mathcal{D}$.

For example, if $\mathcal{D}$ is the class of *all* distributions over $[n]$, then it is known [13] that the optimal sample complexity is $\Theta(\max\{n^{2/3}/\epsilon^{4/3}, n^{1/2}/\epsilon^2\})$. This sample bound is best possible only if the family $\mathcal{D}$ includes all possible distributions over $[n]$, and we may be able to obtain significantly better upper bounds for most natural settings. For example, if both p, q are promised to be (approximately) log-concave over $[n]$, there is an algorithm to test

equivalence between them using $O(1/\epsilon^{9/4})$ samples [25]. This sample bound is independent of the support size n, and is dramatically better than the worst-case tight bound [13] when n is large.

More generally, [25] described a framework to obtain sample-efficient equivalence testers for various families of structured distributions over both continuous and discrete domains. While the results of [25] are sample-optimal for *some* families of distributions (in particular, over continuous domains), it was not known whether they can be improved for natural families of discrete distributions. In this paper, we work in the framework of [25] and obtain new nearly-matching algorithms and lower bounds.

Before we state our results in full generality, we describe in detail a concrete application of our techniques to the case of *histograms* – a well-studied family of structured discrete distributions with a plethora of applications.

Testing Closeness of Histograms. A *k-histogram* over $[n]$ is a probability distribution $p : [n] \to [0, 1]$ that is piecewise constant over some set of k intervals over $[n]$. The algorithmic difficulty in testing properties of such distributions lies in the fact that the location and "size" of these intervals is a priori unknown. Histograms have been extensively studied in statistics and computer science. In the database community, histograms [37, 14, 46, 33, 35, 36, 1] constitute the most common tool for the succinct approximation of data. In statistics, many methods have been proposed to estimate histogram distributions [44, 32, 45, 40, 21, 48, 38] in a variety of settings.

In recent years, histogram distributions have attracted renewed interested from the theoretical computer science community in the context of learning [18, 10, 11, 12, 23, 2, 3, 27] and testing [36, 17, 26, 8, 9]. Here we study the following testing problem: Given sample access to two distributions p, q over $[n]$ that are promised to be (approximately) k-histograms, distinguish between the cases that $p = q$ versus $\|p - q\|_1 \geq \epsilon$. As the main application of our techniques, we give a new testing algorithm and a nearly-matching information-theoretic lower bound for this problem.

We now provide a summary of previous work on this problem followed by a description of our new upper and lower bounds. We want to ϵ-test closeness in ℓ_1-distance between two k-histograms over $[n]$, where $k \leq n$. Our goal is to understand the optimal sample complexity of this problem as a function of $k, n, 1/\epsilon$. Previous work is summarized as follows:

- In [25], the authors gave a closeness tester with sample complexity $O(\max\{k^{4/5}/\epsilon^{6/5}, k^{1/2}/\epsilon^2\})$.
- The best known sample lower bound is $\Omega(\max\{k^{2/3}/\epsilon^{4/3}, k^{1/2}/\epsilon^2\})$. This straightforwardly follows from [13], since k-histograms can simulate *any* support k distribution.

Notably, none of the two bounds depends on the domain size n. Observe that the upper bound of $O(\max\{k^{4/5}/\epsilon^{6/5}, k^{1/2}/\epsilon^2\})$ cannot be tight for the entire range of parameters. For example, for $n = O(k)$, the algorithm of [13] for testing closeness between arbitrary support n distributions has sample size $O(\max\{k^{2/3}/\epsilon^{4/3}, k^{1/2}/\epsilon^2\})$, matching the above sample complexity lower bound, up to a constant factor.

This simple example might suggest that the $\Omega(\max\{k^{2/3}/\epsilon^{4/3}, k^{1/2}/\epsilon^2\})$ lower bound is tight in general. We prove that this is not the case. The main conceptual message of our new upper bound and nearly-matching lower bound is the following:

> *The sample complexity of ϵ-testing closeness between two k-histograms over $[n]$ depends in a subtle way on the relation between the relevant parameters k, n and $1/\epsilon$.*

We find this fact rather surprising because such a phenomenon does *not* occur for the sample complexities of closely related problems. Specifically, testing the identity of a k-histogram

over $[n]$ to a *fixed* distribution has sample complexity $\Theta(k^{1/2}/\epsilon^2)$ [26]; and learning a k-histogram over $[n]$ has sample complexity $\Theta(k/\epsilon^2)$ [11]. Note that both these sample bounds are independent of n and are known to be tight for the entire range of parameters $k, n, 1/\epsilon$.

Our main positive result is a new closeness testing algorithm for k-histograms over $[n]$ with sample complexity $O\big(k^{2/3} \cdot \log^{4/3}(2 + n/k) \log(k)/\epsilon^{4/3}\big)$. Combined with the known upper bound of [25], we obtain the sample upper bound of

$$O\big(\max\big(\min(k^{4/5}/\epsilon^{6/5}, k^{2/3}\log^{4/3}(2+n/k)\log(k)/\epsilon^{4/3}), k^{1/2}\log^2(k)\log\log(k)/\epsilon^2\big)\big).$$

As our main negative result, we prove a lower bound of $\Omega(\min(k^{2/3}\log^{1/3}(2+n/k)/\epsilon^{4/3}, k^{4/5}/\epsilon^{6/5}))$. The first term in this expression shows that the "$\log(2 + n/k)$" factor that appears in the sample complexity of our upper bound is in fact necessary, up to a constant power. In summary, these bounds provide a nearly-tight characterization of the sample complexity of our histogram testing problem for the entire range of parameters.

A few observations are in order to interpret the above bounds:

- When n goes to infinity, the $O(k^{4/5}/\epsilon^{6/5})$ upper bound of [25] is tight for k-histograms.
- When $n = \mathrm{poly}(k)$ and ϵ is not too small (so that the $k^{1/2}/\epsilon^2$ term does not kick in), then the right answer for the sample complexity of our problem is $(k^{2/3}/\epsilon^{4/3})\mathrm{polylog}(k)$.
- The terms "$k^{4/5}/\epsilon^{6/5}$" and "$k^{2/3}\log^{4/3}(2 + n/k)\log(k)/\epsilon^{4/3}$" appearing in the sample complexity become equal when n is exponential in k. Therefore, our new algorithm has better sample complexity than that of [25] for all $n \leq 2^{O(k)}$.

In the following subsection, we state our results in a general setting and explain how the aforementioned applications are obtained from them.

1.1 Our Results and Comparison to Prior Work

For a given family $\mathcal{D}$ of discrete distributions over $[n]$, we are interested in designing a closeness tester for distributions in $\mathcal{D}$. We work in the general framework introduced by [26, 25]. Instead of designing a different tester for any given family $\mathcal{D}$, the approach of [26, 25] proceeds by designing a generic equivalence tester under a *different metric* than the ℓ_1-distance. This metric, termed $\mathcal{A}_k$-distance [20], where $k \geq 2$ is a positive integer, interpolates between Kolmogorov distance (when $k = 2$) and the ℓ_1-distance (when $k = n$). It turns out that, for a range of structured distribution families $\mathcal{D}$, the $\mathcal{A}_k$-distance can be used as a proxy for the ℓ_1-distance for a value of $k \ll n$ [11]. For example, if $\mathcal{D}$ is the family of k-histograms over $[n]$, the $\mathcal{A}_{2k}$ distance between them is tantamount to their ℓ_1 distance. We can thus obtain an ℓ_1 closeness tester for $\mathcal{D}$ by plugging in the right value of k in a general $\mathcal{A}_k$ closeness tester.

To formally state our results, we will need some terminology.

Notation. We will use p, q to denote the probability mass functions of our distributions. If p is discrete over support $[n] := \{1, \ldots, n\}$, we denote by p_i the probability of element i in the distribution. For two discrete distributions p, q, their ℓ_1 and ℓ_2 distances are $\|p-q\|_1 = \sum_{i=1}^n |p_i - q_i|$ and $\|p-q\|_2 = \sqrt{\sum_{i=1}^n (p_i - q_i)^2}$. Fix a partition of the domain I into disjoint intervals $\mathcal{I} := (I_i)_{i=1}^{\ell}$. For such a partition $\mathcal{I}$, the *reduced distribution* $p_r^{\mathcal{I}}$ corresponding to p and $\mathcal{I}$ is the discrete distribution over $[\ell]$ that assigns the i-th "point" the mass that p assigns to the interval I_i; i.e., for $i \in [\ell]$, $p_r^{\mathcal{I}}(i) = p(I_i)$. Let $\mathfrak{J}_k$ be the collection of all partitions of the domain I into k intervals. For $p, q : I \to \mathbb{R}_+$ and $k \in \mathbb{Z}_+$, we define the $\mathcal{A}_k$-distance between p and q by $\|p-q\|_{\mathcal{A}_k} \stackrel{\mathrm{def}}{=} \max_{\mathcal{I}=(I_i)_{i=1}^k \in \mathfrak{J}_k} \sum_{i=1}^k |p(I_i) - q(I_i)| = \max_{\mathcal{I}\in\mathfrak{J}_k} \|p_r^{\mathcal{I}} - q_r^{\mathcal{I}}\|_1$.

In this context, [25] gave a closeness testing algorithm under the $\mathcal{A}_k$-distance using $O(\max\{k^{4/5}/\epsilon^{6/5}, k^{1/2}/\epsilon^2\})$ samples. It was also shown that this sample bound is information–theoretically optimal (up to constant factors) for some adversarially constructed continuous distributions, or discrete distributions of support size n sufficiently large as a function of k. These results raised two natural questions: (1) What is the *optimal* sample complexity of the $\mathcal{A}_k$-closeness testing problem as a function of $n, k, 1/\epsilon$? (2) Can we obtain tight sample lower bounds for *natural* families of structured distributions?

We resolve both these open questions. Our main algorithmic result is the following:

▶ **Theorem 1.** *Given sample access to distributions p and q on $[n]$ and $\epsilon > 0$ there exists an algorithm that takes*

$$O\left(\max\left(\min\left(k^{4/5}/\epsilon^{6/5}, k^{2/3}\log^{4/3}(2+n/k)\log(2+k)/\epsilon^{4/3}\right), k^{1/2}\log^2(k)\log\log(k)/\epsilon^2\right)\right)$$

samples from each of p and q and distinguishes with $2/3$ probability between the cases that $p = q$ and $\|p-q\|_{\mathcal{A}_k} \geq \epsilon$.

As explained in [26, 25], using Theorem 1 one can obtain testing algorithms for the ℓ_1 closeness testing of various distribution families $\mathcal{D}$, by using the $\mathcal{A}_k$ distance as a "proxy" for the ℓ_1 distance:

▶ **Fact 2.** *For a univariate distribution family $\mathcal{D}$ and $\epsilon > 0$, let $k = k(\mathcal{D}, \epsilon)$ be the smallest integer such that for any $f_1, f_2 \in \mathcal{D}$ it holds that $\|f_1 - f_2\|_1 \leq \|f_1 - f_2\|_{\mathcal{A}_k} + \epsilon/2$. Then there exists an ℓ_1 closeness testing algorithm for $\mathcal{D}$ with the sample complexity of Theorem 1.*

Applications

Our upper bound for ℓ_1-testing of k-histogram distributions follows from the above by noting that for any k-histograms p, q we have $\|p-q\|_1 = \|p-q\|_{\mathcal{A}_{2k}}$. Also note that our upper bound is *robust*: it applies even if p, q are $O(\epsilon)$-close in ℓ_1-norm to being k-histograms.

Finally, we remark that our general $\mathcal{A}_k$ closeness tester yields improved upper bounds for various other families of structured distributions. Consider for example the case that $\mathcal{D}$ consists of all k-mixtures of some simple family (e.g., discrete Gaussians or log-concave), where the parameter k is large. The algorithm of [25] leads to a tester whose sample complexity scales with $O(k^{4/5})$, while Theorem 1 implies a $\tilde{O}(k^{2/3})$ bound.

On the lower bound side, we show:

▶ **Theorem 3.** *Let p and q be distributions on $[n]$ and let $\epsilon > 0$ be less than a sufficiently small constant. Any tester that distinguishes between $p = q$ and $\|p-q\|_{\mathcal{A}_k} \geq \epsilon$ for some $k \leq n$ must use $\Omega(m)$ samples for $m = \min(k^{2/3}\log^{4/3}(2+n/k)/\epsilon^{4/3}, k^{4/5}/\epsilon^{6/5})$.*

Furthermore, for $m = \min(k^{2/3}\log^{1/3}(2+n/k)/\epsilon^{4/3}, k^{4/5}/\epsilon^{6/5})$, any tester that distinguishes between $p = q$ and $\|p-q\|_{\mathcal{A}_k} \geq \epsilon$ must use $\Omega(m)$ samples even if p and q are both guaranteed to be piecewise constant distributions on $O(k+m)$ pieces.

Note that a lower bound of $\Omega(\sqrt{k}/\epsilon^2)$ straightforwardly applies even for p and q being k-histograms. This dominates the above bounds for $\epsilon < k^{-3/8}$.

We also note that our general lower bound with respect to the $\mathcal{A}_k$ distance is somewhat stronger, matching the term "$\log^{4/3}(2+n/k)$" in our upper bound.

1.2 Related Work

During the past two decades, *distribution property testing* [5] – whose roots lie in statistical hypothesis testing [41, 39] – has received considerable attention by the computer science community, see [43, 7] for two recent surveys. The majority of the early work in this field has focused on characterizing the sample size needed to test properties of arbitrary distributions of a given support size. After two decades of study, this "worst-case" regime is well-understood: for many properties of interest there exist sample-optimal testers (matched by information-theoretic lower bounds) [42, 13, 47, 26, 24, 22].

In many settings of interest, we know a priori that the underlying distributions have some "nice structure" (exactly or approximately). The problem of *learning* a probability distribution under such structural assumptions is a classical topic in statistics, see [4] for a classical book, and [34] for a recent book on the topic, that has recently attracted the interest of computer scientists [18, 19, 10, 16, 11, 12, 1, 30, 31, 28, 15, 3, 27, 29].

On the other hand, the theory of *distribution testing* under structural assumptions is less fully developed. More than a decade ago, Batu, Kumar, and Rubinfeld [6] considered a specific instantiation of this question – testing the equivalence between two unknown discrete monotone distributions – and obtained a tester whose sample complexity is poly-logarithmic in the domain size. A recent sequence of works [17, 26, 25] developed a framework to leverage such structural assumptions and obtained more efficient testers for a number of natural settings. However, for several natural properties of interest there is still a substantial gap between known sample upper and lower bounds.

1.3 Overview of Techniques

To prove our upper bound, we use a technique of iteratively reducing the number of bins (domain elements). In particular, we show that if we merge bins together in consecutive pairs, this does not significantly affect the $\mathcal{A}_k$ distance between the distributions, unless a large fraction of the discrepancy between our distributions is supported on $O(k)$ bins near the boundaries in the optimal partition. In order to take advantage of this, we provide a novel identity tester that requires few samples to distinguish between the cases where $p = q$ and the case where p and q have a large ℓ_1 distance supported on only k of the bins. We are able to take advantage of the small support essentially because having a discrepancy supported on few bins implies that the ℓ_2 distance between the distributions must be reasonably large.

Our new lower bounds are somewhat more involved. We prove them by exhibiting explicit families of pairs of distributions, where in one case $p = q$ and in the other p and q have large $\mathcal{A}_k$ distance, but so that it is information-theoretically impossible to distinguish between these two families with a small number of samples. In both cases, p and q are explicit piecewise constant distributions with a small number of pieces. In both cases, our domain is partitioned into a small number of bins and the restrictions of the distributions to different bins are independent, making our analysis easier. In some bins we will have $p = q$ each with mass about $1/m$ (where m is the number of samples). These bins will serve the purpose of adding "noise" making harder to read the "signal" from the other bins. In the remaining bins, we will have either that $p = q$ being supported on some interval, or p and q will be supported on consecutive, non-overlapping intervals. If three samples are obtained from any one of these intervals, the order of the samples and the distributions that they come from will provide us with information about which family we came from. Unfortunately, since triple collisions are relatively uncommon, this will not be useful unless $m \gg \max(k^{4/5}/\epsilon^{6/5}, k^{1/2}/\epsilon^2)$. Bins from which we have one or zero samples will tell us nothing, but bins from which we have exactly two samples may provide information.

For these bins, it can be seen that we learn nothing from the ordering of the samples, but we may learn something from their spacing. In particular, in the case where p and q are supported on disjoint intervals, we would suspect that two samples very close to each other are far more likely to be taken from the same distribution rather than from opposite distributions. On the other hand, in order to properly interpret this information, we will need to know something about the scale of the distributions involved in order to know when two points should be considered to be "close". To overcome this difficulty, we will stretch each of our distributions by a random exponential amount. This will effectively conceal any information about the scales involved so long as the total support size of our distributions is exponentially large.

2 A Near-Optimal Closeness Tester over Discrete Domains

2.1 Warmup: A Simpler Algorithm

We start by giving a simpler algorithm establishing a basic version of Theorem 1 with slightly worse parameters:

▶ **Proposition 4.** *Given sample access to distributions p and q on $[n]$ and $\epsilon > 0$ there exists an algorithm that takes*

$$O\left(k^{2/3}\log^{4/3}(3+n/k)\log\log(3+n/k)/\epsilon^{4/3} + \sqrt{k}\log^2(3+n/k)\log\log(3+n/k)/\epsilon^2\right)$$

samples from each of p and q and distinguishes with $2/3$ probability between the cases that $p = q$ and $\|p-q\|_{\mathcal{A}_k} \geq \epsilon$.

The basic idea of our algorithm is the following: From the distributions p and q construct new distributions p' and q' by merging pairs of consecutive buckets. Note that p' and q' each have much smaller domains (of size about $n/2$). Furthermore, note that the $\mathcal{A}_k$ distance between p and q is $\sum_{I\in\mathcal{I}}|p(I)-q(I)|$ for some partition $\mathcal{I}$ into k intervals. By using essentially the same partition, we can show that $\|p'-q'\|_{\mathcal{A}_k}$ should be almost as large as $\|p-q\|_{\mathcal{A}_k}$. This will in fact hold unless much of the error between p and q is supported at points near the endpoints of intervals in $\mathcal{I}$. If this is the case, it turns out there is an easy algorithm to detect this discrepancy. We require the following definitions:

▶ **Definition 5.** For a discrete distribution p on $[n]$, the merged distribution obtained from p is the distribution p' on $\lceil n/2\rceil$, so that $p'(i) \stackrel{\text{def}}{=} p(2i)+p(2i+1)$. For a partition $\mathcal{I}$ of $[n]$, define the *divided partition* $\mathcal{I}'$ of domain $\lceil n/2\rceil$, so that $I'_i \in \mathcal{I}'$ has the points obtained by point-wise gluing together odd points and even points.

Note that one can simulate a sample from p' given a sample from p by letting $p' = \lceil p/2\rceil$.

▶ **Definition 6.** Let p and q be distributions on $[n]$. For integers $k \geq 1$, let $\|p-q\|_{1,k}$ be the sum of the largest k values of $|p(i)-q(i)|$ over $i \in [n]$.

We begin by showing that either $\|p'-q'\|_{\mathcal{A}_k}$ is close to $\|p-q\|_{\mathcal{A}_k}$ or $\|p-q\|_{1,k}$ is large.

▶ **Lemma 7.** *For any two distributions p and q on $[n]$, let p' and q' be the merged distributions. Then,*

$$\|p-q\|_{\mathcal{A}_k} \leq \|p'-q'\|_{\mathcal{A}_k} + 2\|p-q\|_{1,k}\ .$$

Proof. Let $\mathcal{I}$ be the partition of $[n]$ into k intervals so that $\|p-q\|_{\mathcal{A}_k} = \sum_{I\in\mathcal{I}} |p(I)-q(I)|$. Let $\mathcal{I}'$ be obtained from $\mathcal{I}$ by rounding each upper endpoint of each interval except for the last down to the nearest even integer, and rounding the lower endpoint of each interval up to the nearest odd integer. Note that

$$\sum_{I\in\mathcal{I}'} |p(I)-q(I)| = \sum_{I\in\mathcal{I}'} |p'(I/2)-q'(I/2)| \le \|p'-q'\|_{\mathcal{A}_k} .$$

The partition $\mathcal{I}'$ is obtained from $\mathcal{I}$ by taking at most k points and moving them from one interval to another. Therefore, the difference

$$\left| \sum_{I\in\mathcal{I}} |p(I)-q(I)| - \sum_{I\in\mathcal{I}'} |p(I)-q(I)| \right| ,$$

is at most twice the sum of $|p(i)-q(i)|$ over these k points, and therefore at most $2\|p-q\|_{1,k}$. Combing this with the above gives our result. ◀

Next, we need to show that if two distributions have $\|p-q\|_{1,k}$ large that this can be detected easily.

▶ **Lemma 8.** *Let p and q be distributions on $[n]$. Let $k>0$ be a positive integer, and $\epsilon>0$. There exists an algorithm which takes $O(k^{2/3}/\epsilon^{4/3}+\sqrt{k}/\epsilon^2)$ samples from each of p and q and, with probability at least $2/3$, distinguishes between the cases that $p=q$ and $\|p-q\|_{1,k}>\epsilon$.*

Note that if we needed to distinguish between $p=q$ and $\|p-q\|_1>\epsilon$, this would require $\Omega(n^{2/3}/\epsilon^{4/3}+\sqrt{n}/\epsilon^2)$ samples. However, the optimal testers for this problem are morally ℓ_2-testers. That is, roughly, they actually distinguish between $p=q$ and $\|p-q\|_2>\epsilon/\sqrt{n}$. From this viewpoint, it is clear why it would be easier to test for discrepancies in $\|-\|_{1,k}$-distance, since if $\|p-q\|_{1,k}>\epsilon$, then $\|p-q\|_2>\epsilon/\sqrt{k}$, making it easier for our ℓ_2-type tester to detect the difference.

Our general approach will be by way of the techniques developed in [24]. We begin by giving the definition of a split distribution coming from that paper:

▶ **Definition 9.** Given a distribution p on $[n]$ and a multiset S of elements of $[n]$, define the *split distribution* p_S on $[n+|S|]$ as follows: For $1\le i\le n$, let a_i denote 1 plus the number of elements of S that are equal to i. Thus, $\sum_{i=1}^n a_i = n+|S|$. We can therefore associate the elements of $[n+|S|]$ to elements of the set $B=\{(i,j): i\in[n], 1\le j\le a_i\}$. We now define a distribution p_S with support B, by letting a random sample from p_S be given by (i,j), where i is drawn randomly from p and j is drawn randomly from $[a_i]$.

We now recall two basic facts about split distributions:

▶ **Fact 10** ([24])**.** *Let p and q be probability distributions on $[n]$, and S a given multiset of $[n]$. Then:*

(i) *We can simulate a sample from p_S or q_S by taking a single sample from p or q, respectively.*

(ii) *It holds $\|p_S-q_S\|_1 = \|p-q\|_1$.*

▶ **Lemma 11** ([24])**.** *Let p be a distribution on $[n]$. Then:*

(i) *For any multisets $S\subseteq S'$ of $[n]$, $\|p_{S'}\|_2 \le \|p_S\|_2$, and*

(ii) *If S is obtained by taking m samples from p, then $\mathbb{E}[\|p_S\|_2^2] \le 1/m$.*

We also recall an optimal ℓ_2 closeness tester under the promise that one of the distributions has smal ℓ_2 norm:

▶ **Lemma 12** ([13]). *Let p and q be two unknown distributions on $[n]$. There exists an algorithm that on input n, $b \geq \min\{\|p\|_2, \|q\|_2\}$ and $0 < \epsilon < \sqrt{2}b$, draws $O(b/\epsilon^2)$ samples from each of p and q and, with probability at least $2/3$, distinguishes between the cases that $p = q$ and $\|p - q\|_2 > \epsilon$.*

Proof of Lemma 8: We begin by presenting the algorithm:

Algorithm `Small-Support-Discrepancy-Tester`
Input: sample access to pdf's $p, q : [n] \to [0,1]$, $k \in \mathbb{Z}_+$, and $\epsilon > 0$.
Output: "YES" if $q = p$; "NO" if $\|q - p\|_{1,k} \geq \epsilon$.

1. Let $m = \min(k^{2/3}/\epsilon^{4/3}, k)$.
2. Let S be the multiset obtained by taking m independent samples from p.
3. Use the ℓ_2 tester of Lemma 12 to distinguish between the cases that $p_S = q_S$ and $\|p_S - q_S\|_2^2 \geq k^{-1}\epsilon^2/2$ and return the result.

The analysis is simple. By Lemma 11, with 90% probability $\|p_S\|_2 = O(m^{-1/2})$, and therefore the number of samples needed (using the ℓ_2 tester from Lemma 12) is $O(m + km^{-1/2}/\epsilon^2) = O(k^{2/3}/\epsilon^{4/3} + \sqrt{k}/\epsilon^2)$. If $p = q$, then $p_S = q_S$ and the algorithm will return "YES" with appropriate probability. If $\|q - p\|_{1,k} \geq \epsilon$, then $\|p_S - q_S\|_{1,k+m} \geq \epsilon$. Since $k + m$ elements contribute to total ℓ_1 error at least ϵ, by Cauchy-Schwarz, we have that $\|p_S - q_S\|_2^2 \geq \epsilon^2/(k+m) \geq k^{-1}\epsilon^2/2$. Therefore, in this case, the algorithm returns "NO" with appropriate probability. ◀

Proof of Proposition 4: The basic idea of our algorithm is the following: By Lemma 8, if $\|p - q\|_{\mathcal{A}_k}$ is large, then so is either $\|p - q\|_{1,k}$ or $\|p' - q'\|_{\mathcal{A}_k}$. Our algorithm then tests whether $\|p - q\|_{1,k}$ is large, and recursively tests whether $\|p' - q'\|_{\mathcal{A}_k}$ is large. Since p', q' have half the support size, we will only need to do this for $\log(n/k)$ rounds, losing only a poly-logarithmic factor in the sample complexity. We present the algorithm here:

Algorithm `Small-Domain-`$\mathcal{A}_k$`-tester`
Input: sample access to pdf's $p, q : [n] \to [0,1]$, $k \in \mathbb{Z}_+$, and $\epsilon > 0$.
Output: "YES" if $q = p$; "NO" if $\|q - p\|_{\mathcal{A}_k} \geq \epsilon$.

1. For $i := 0$ to $t \stackrel{\text{def}}{=} \lceil \log_2(n/k) \rceil$, let $p^{(i)}, q^{(i)}$ be distributions on $[\lceil 2^{-i} n \rceil]$ defined by $p^{(i)} = \lceil 2^{-i} p \rceil$ and $q^{(i)} = \lceil 2^{-i} q \rceil$.
2. Take $Ck^{2/3} \log^{4/3}(3 + n/k) \log\log(3 + n/k)/\epsilon^{4/3}$ samples, for C sufficiently large, and use these samples to distinguish between the cases $p^{(i)} = q^{(i)}$ and $\|p^{(i)} - q^{(i)}\|_{1,k} > \epsilon/(4\log_2(3+n/k))$ with probability of error at most $1/(10\log_2(3+n/k))$ for each i from 0 to t, using the same samples for each test.
3. If any test yields that $p^{(i)} \neq q^{(i)}$, return "NO". Otherwise, return "YES".

We now show correctness. In terms of sample complexity, we note that by taking a majority over $O(\log\log(3 + n/k))$ independent runs of the tester from Lemma 8 we can run this algorithm with the stated sample complexity. Taking a union bound, we can also assume that all tests performed in Step 2 returned the correct answer. If $p = q$ then $p^{(i)} = q^{(i)}$ for all i and thus, our algorithm returns "YES". Otherwise, we have that $\|p - q\|_{\mathcal{A}_k} \geq \epsilon$. By repeated application of Lemma 7, we have that

$$\|p - q\|_{\mathcal{A}_k} \leq \sum_{i=0}^{t-1} 2\|p^{(i)} - q^{(i)}\|_{1,k} + \|p^{(t)} - q^{(t)}\|_{\mathcal{A}_k} \leq 2\sum_{i=0}^{t} \|p^{(i)} - q^{(i)}\|_{1,k} \,,$$

where the last step was because $p^{(t)}$ and $q^{(t)}$ have a support of size at most k and so $\|p^{(t)} - q^{(t)}\|_{\mathcal{A}_k} = \|p^{(t)} - q^{(t)}\|_1 = \|p^{(t)} - q^{(t)}\|_{1,k}$. Therefore, if this is at least ϵ, it must be the case that $\|p^{(i)} - q^{(i)}\|_{1,k} > \epsilon/(4\log_2(3+n/k))$ for some $0 \leq i \leq t$, and thus our algorithm returns "NO". This completes our proof. ◀

2.2 Full Algorithm

The improvement to Proposition 4 is somewhat technical. The key idea involves looking into the analysis of Lemma 8. Generally speaking, choosing a larger value of m (up to the total sample complexity), will decrease the ℓ_2 norm of p, and thus the final complexity. Unfortunately, taking $m > k$ might lead to problems as it will subdivide the k original bins on which the error is supported into $\omega(k)$ bins. This in turn could worsen the lower bounds on $\|p - q\|_2$. However, this will only be the case if the total mass of these bins carrying the difference is large. Thus, we can obtain an improvement to Lemma 8 when the mass of bins on which the error is supported is small. The details are deferred to the full version.

3 Nearly Matching Information-Theoretic Lower Bound

We give a lower bound for k-histograms (k-flat distributions), postponing our slightly stronger construction to the full version. Before moving to the discrete setting, we first establish a lower bound for continuous histogram distributions. Our bound on discrete distributions will follow from taking the adversarial distribution from this example and rounding its values to the nearest integer. In order for this to work, we will need ensure to that our adversarial distribution does not have its $\mathcal{A}_k$-distance decrease by too much when we apply this operation. To satisfy this requirement, we will guarantee that our distributions will be piecewise constant with all the pieces of length at least 1.

▶ **Proposition 13.** *Let $k \in \mathbb{Z}_+$, $\epsilon > 0$ sufficiently small, and $W > 2$. Fix*

$$m = \min(k^{2/3}\log^{1/3}(W)/\epsilon^{4/3}, k^{4/5}/\epsilon^{6/5}) .$$

There exist distributions $\mathcal{D}, \mathcal{D}'$ over pairs of distributions p and q on $[0, 2(m+k)W]$, where p and q are $O(m+k)$-flat with pieces of length at least 1, so that: (a) when drawn from $\mathcal{D}$, we have $p = q$ deterministically, (b) when drawn from $\mathcal{D}'$, we have $\|p - q\|_{\mathcal{A}_k} > \epsilon$ with 90% probability, and so that $o(m)$ samples are insufficient to distinguish whether or not the pair is drawn from $\mathcal{D}$ or $\mathcal{D}'$ with better than 2/3 probability.

At a high-level, our lower bound construction proceeds as follows: We will divide our domain into $m+k$ bins so that no information about which distributions had samples drawn from a given bin or the ordering of these samples will help to distinguish between the cases of $p = q$ and otherwise, unless at least three samples are taken from the bin in question. Approximately k of these bins will each have mass ϵ/k and might convey this information if at least three samples are taken from the bin. However, the other m bins will each have mass approximately $1/m$ and will be used to add noise. In all, if we take s samples, we expect to see approximately $s^3\epsilon^3/k^2$ of the lighter bins with at least three samples. However, we will see approximately s^3/m^2 of our heavy bins with three samples. In order for the signal to overwhelm the noise, we will need to ensure that we have $(s^3\epsilon^3/k^2)^2 > s^3/m^2$.

The above intuitive sketch assumes that we cannot obtain information from the bins in which only two samples are drawn. This naively should not be the case. If $p = q$, the distance between two samples drawn from that bin will be independent of whether or not they are

drawn from the same distribution. However, if p and q are supported on disjoint intervals, one would expect that points that are close to each other should be far more likely to be drawn from the same distribution than from different distributions. In order to disguise this, we will scale the length of the intervals by a random, exponential amount, essentially making it impossible to determine what is meant by two points being close to each other. In effect, this will imply that two points drawn from the same bin will only reveal $O(1/\log(W))$ bits of information about whether $p = q$ or not. Thus, in order for this information to be sufficient, we will need that $(s^2\epsilon^2/k)^2/\log(W) > (s^2/m)$. We proceed with the formal proof below.

Proof of Proposition 13: We use ideas from [24] to obtain this lower bound using an information theoretic argument.

We may assume that $\epsilon > k^{1/2}$, because otherwise we may employ the standard lower bound that $\Omega(\sqrt{k}/\epsilon^2)$ samples are required to distinguish two distributions on a support of size k.

First, we note that it is sufficient to take $\mathcal{D}$ and $\mathcal{D}'$ be distributions over pairs of non-negative, piecewise constant distributions with total mass $\Theta(1)$ with 90% probability so that running a Poisson process with parameter $o(m)$ is insufficient to distinguish a pair from $\mathcal{D}$ from a pair from $\mathcal{D}'$ [24].

We construct these distributions as follows: We divide the domain into $m + k$ bins of length $2W$. For each bin i, we independently generate a random ℓ_i, so that $\log(\ell_i/2)$ is uniformly distributed over $[0, 2\log(W)/3]$. We then produce an interval I_i within bin i of total length ℓ_i and with random offset. In all cases, we will have p and q supported on the union of the I_i's.

For each i with probability $m/(m+k)$, we have the restrictions of p and q to I_i both uniform with $p(I_i) = q(I_i) = 1/m$. The other $k/(m + k)$ of the time we have $p(I_i) = q(I_i) = \epsilon/k$. In this latter case, if p and q are being drawn from $\mathcal{D}$, p and q are each constant on this interval. If they are being drawn from $\mathcal{D}'$, then $p + q$ will be constant on the interval, with all of that mass coming from p on a random half and coming from q on the other half.

Note that in all cases p and q are piecewise constant with $O(m + k)$ pieces of length at least 1. It is easy to show that with high probability the total mass of each of p and q is $\Theta(1)$, and that if drawn from $\mathcal{D}'$ that $\|p - q\|_{\mathcal{A}_k} \gg \epsilon$ with at least 90% probability.

We will now show that if one is given m samples from each of p and q, taken randomly from either $\mathcal{D}$ or $\mathcal{D}'$, that the shared information between the samples and the source family will be small. This implies that one is unable to consistently guess whether our pair was taken from $\mathcal{D}$ or $\mathcal{D}'$.

Let X be a random variable that is uniformly at random either 0 or 1. Let A be obtained by applying a Poisson process with parameter $s = o(m)$ on the pair of distributions p, q drawn from $\mathcal{D}$ if $X = 0$ or from $\mathcal{D}'$ if $X = 1$. We note that it suffices to show that the shared information $I(X : A) = o(1)$. In particular, by Fano's inequality, we have:

▶ **Lemma 14.** *If X is a uniform random bit and A is a correlated random variable, then if f is any function so that $f(A) = X$ with at least 51% probability, then $I(X : A) \geq 2 \cdot 10^{-4}$.*

Let A_i be the samples of A taken from the i^{th} bin. Note that the A_i are conditionally independent on X. Therefore, we have that $I(X : A) \leq \sum_i I(X : A_i) = (m + k)I(X : A_1)$. We will proceed to bound $I(X : A_1)$.

We note that $I(X : A_1)$ is at most the integral over pairs of multisets a (representing a set of samples from q and a set of samples from p), of

$$O\left(\frac{(\Pr(A_1 = a|X = 0) - \Pr(A_1 = a|X = 1))^2}{\Pr(A_1 = a)}\right).$$

Thus,

$$I(X : A_1) = \sum_{h=0}^{\infty} \int_{|a|=h} O\left(\frac{(\Pr(A_1 = a|X = 0) - \Pr(A_1 = a|X = 1))^2}{\Pr(A_1 = a)}\right).$$

We will split this sum up based on the value of h.

For $h = 0$, we note that the distributions for $p + q$ are the same for $X = 0$ and $X = 1$. Therefore, the probability of selecting no samples is the same. Therefore, this contributes 0 to the sum.

For $h = 1$, we note that the distributions for $p + q$ are the same in both cases, and conditioning on I_1 and $(p+q)(I_1)$ that $\mathbb{E}[p]$ and $\mathbb{E}[q]$ are the same in each of the cases $X = 0$ and $X = 1$. Therefore, again in this case, we have no contribution.

For $h \geq 3$, we note that $I(X : A_1) \leq I(X : A_1, I_1) \leq I(X : A_1|I_1)$, since I_1 is independent of X. We note that $\Pr(A_1 = a|X = 0, p(I_1) = 1/m) = \Pr(A_1 = a|X = 1, p(I_1) = 1/m)$. Therefore, we have that

$$\begin{aligned}\Pr(A_1 = a|X = 0) - \Pr(A_1 = a|X = 1)\\ = \Pr(A_1 = a|X = 0, p(I_1) = \epsilon/k) - \Pr(A_1 = a|X = 1, p(I_1) = \epsilon/k).\end{aligned}$$

If $p(I_1) = \epsilon/k$, the probability that exactly h elements are selected in this bin is at most $k/(m+k)(2s\epsilon/k)^h/h!$, and if they are selected, they are uniformly distributed in I_1 (although which of the sets p and q they are taken from is non-uniform). However, the probability that h elements are taken from I_1 is at least $\Omega(m/(m+k)(sm)^{-h}/h!)$ from the case where $p(I_1) = 1/m$, and in this case the elements are uniformly distributed in I_1 and uniformly from each of p and q. Therefore, we have that this contribution to our shared information is at most $k^2/(m(m+k))O(s\epsilon^2 m/k^2)^h/h!$. We note that $\epsilon^2 m/k^2 < 1$. Therefore, the sum of this over all $h \geq 3$ is $k^2/(m(m+k))O(s\epsilon^2 m/k^2)^3$. Summing over all $m + k$ bins, this is $k^{-4}\epsilon^6 s^3 m^2 = o(1)$.

It remains to analyze the case where $h = 2$. Once again, we have that ignoring which of p and q elements of A_1 came from, A_1 is identically distributed conditioned on $p(I_1) = 1/m$ and $|A_1| = 2$ as it is conditioned on $p(I_1) = \epsilon/k$ and $|A_1| = 2$. Since once again, the distributions $\mathcal{D}$ and $\mathcal{D}'$ are indistinguishable in the former case, we have that the contribution of the $h = 2$ terms to the shared information is at most

$$\begin{aligned}O\left(\frac{(k/(k+m)(\epsilon s/k)^2)^2}{m/(k+m)(s/m)^2}\right) d_{\mathrm{TV}}((A_1|X = 0, p(I_1)\epsilon/k, |A_1| = 2),\\ (A_1|X = 1, p(I_1) = \epsilon/k, |A_1| = 2))\end{aligned}$$

or

$$\begin{aligned}O\left(s^2 m k^{-2}\epsilon^4/(k+m)\right) d_{\mathrm{TV}}((A_1|X = 0, p(I_1) = \epsilon/k, |A_1| = 2),\\ (A_1|X = 1, p(I_1) = \epsilon/k, |A_1| = 2)) .\end{aligned}$$

It will suffice to show that conditioned upon $p(I_1) = \epsilon/k$ and $|A_1| = 2$ that

$$d_{\mathrm{TV}}((A_1|X = 0), (A_1|X = 1)) = O(1/\log(W)).$$

Let f be the order preserving linear function from $[0, 2]$ to I_1. Notice that conditional on $|A_1| = 2$ and $p(I_1) = \epsilon/k$ that we may sample from A_1 as follows:

- Pick two points $x > y$ uniformly at random from $[0, 2]$.
- Assign the points to p and q as follows:

- If $X = 0$ uniformly randomly assign these points to either distribution p or q.
- If $X = 1$ randomly do either:
  - Assign points in $[0, 1]$ to q and other points to p.
  - Assign points in $[0, 1]$ to p and other points to q.
- Randomly pick I_1 and apply f to x and y to get outputs $z = f(x), w = f(y)$.

Notice that the four cases:

(i) both points coming from p,
(ii) both points coming from q,
(iii) a point from p preceding a point from q,
(iv) a point from q preceding a point from p,

are all equally likely conditioned on either $X = 0$ or $X = 1$. However, we will note that this ordering is no longer independent of the choice of x and y.

Therefore, we can sample from A_1 subject to $X = 0$ and from A_1 subject to $X = 1$ in such a way that this ordering is the same deterministically. We consider running the above sampling algorithm to select (x, y) while sampling from $X = 0$ and (x', y') when sampling from $X = 1$ so that we are in the same one of the above four cases. We note that

$$d_{\mathrm{TV}}((A_1|X = 0), (A_1|X = 1)) \leq \mathbb{E}_{x,y,x',y'}[d_{\mathrm{TV}}((f(x), f(y)), (f(x'), f(y')))] \, ,$$

where the variation distance is over the random choices of f.

To show that this is small, we note that $|f(x) - f(y)|$ is distributed like $\ell_1(x - y)$. This means that $\log(|f(x) - f(y)|)$ is uniform over $[\log(f(x) - f(y)), \log(f(x) - f(y)) + 2\log(W)/3]$. Similarly, $\log(|f'(x') - f'(y')|)$ is uniform over $[\log(f(x') - f(y')), \log(f(x') - f(y')) + 2\log(W)/3]$. These differ in total variation distance by

$$O\left(\frac{|\log(f(x) - f(y))| + |\log(f(x') - f(y'))|}{\log(W)}\right) \, .$$

Taking the expectation over x, y, x', y' we get $O(1/\log(W))$. Therefore, we may further correlate the choices made in selecting our two samples, so that $z - w = z' - w'$ except with probability $O(1/\log(W))$. We note that after conditioning on this, z and z' are both uniformly distributed over subintervals of $[0, 2W]$ of length at least $2(W - W^{2/3})$. Therefore, the distributions on z and z' differ by at most $O(W^{-1/3})$. Hence, the total variation distance between A_1 conditioned on $|A_1| = 2, p(I_1) = \epsilon/k, X = 0$ and conditioned on $|A_1| = 2, p(I_1) = \epsilon/k, X = 1$ is at most $O(1/\log(W)) + O(W^{-1/3}) = O(1/\log(W))$. This completes our proof. ◀

We can now turn this into a lower bound for testing $\mathcal{A}_k$ distance on discrete domains.

Proof of second half of Theorem 3: Assume for sake of contradiction that this is not the case, and that there exists a tester taking $o(m)$ samples. We use this tester to come up with a continuous tester that violates Proposition 13.

We begin by proving a few technical bounds on the parameters involved. Firstly, note that we already have a lower bound of $\Omega(k^{1/2}/\epsilon^2)$, so we may assume that this is much less than m. We now claim that $m = O(\min(k^{2/3}\log^{1/3}(3 + n/(m + k))/\epsilon^{4/3}, k^{4/5}/\epsilon^{6/5})$. If $m \leq k$, there is nothing to prove. Otherwise,

$$k^{2/3}\log^{1/3}(3 + n/(m + k))/\epsilon^{4/3} \geq m(m/k)^{-1/3}\log(3 + n/(m + k))^{1/3}.$$

Thus, there is nothing more to prove unless $\log(3 + n/(m + k)) \gg m/k$. But, in this case, $\log(3 + n/(m + k)) \gg \log(m/k)$ and thus $\log(3 + n/(m + k)) = \Theta(\log(3 + n/k))$, and we are done.

We now let $W = n/(6(m+k))$, and let $\mathcal{D}$ and $\mathcal{D}'$ be as specified in Proposition 13. We claim that we have a tester to distinguish a p, q from $\mathcal{D}$ from ones taken from $\mathcal{D}'$ in $o(m)$ samples. We do this as follows: By rounding p and q down to the nearest third of an integer, we obtain p',q' supported on set of size n. Since p and q were piecewise constant on pieces of size at least 1, it is not hard to see that $\|p' - q'\|_{\mathcal{A}_k} \geq \|p - q\|_{\mathcal{A}_k}/3$. Therefore, a tester to distinguish $p' = q'$ from $\|p' - q'\|_{\mathcal{A}_k} \geq \epsilon$ can be used to distinguish $p = q$ from $\|p - q\|_{\mathcal{A}_k} \geq 3\epsilon$. This is a contradiction and proves our lower bound. ◀

Abstract

Analyzing multi-dimensional data is a fundamental problem in various areas of computer science. As the amount of data is often huge, it is desirable to obtain sublinear time algorithms to understand local properties of the data.

We focus on the natural problem of testing *pattern freeness*: given a large d-dimensional array A and a fixed d-dimensional pattern P over a finite alphabet Γ, we say that A is *P-free* if it does not contain a copy of the forbidden pattern P as a consecutive subarray. The distance of A to P-freeness is the fraction of the entries of A that need to be modified to make it P-free.

For any $\epsilon > 0$ and any large enough pattern P over any alphabet – other than a very small set of exceptional patterns – we design a *tolerant tester* that distinguishes between the case that the distance is at least ϵ and the case that the distance is at most $a_d\epsilon$, with query complexity and running time $c_d\epsilon^{-1}$, where $a_d < 1$ and c_d depend only on the dimension d. These testers only need to access uniformly random blocks of samples from the input A.

To analyze the testers we establish several combinatorial results, including the following d-dimensional *modification lemma*, which might be of independent interest: For any large enough d-dimensional pattern P over any alphabet (excluding a small set of exceptional patterns for the binary case), and any d-dimensional array A containing a copy of P, one can delete this copy by modifying one of its locations without creating new P-copies in A.

Our results address an open question of Fischer and Newman, who asked whether there exist efficient testers for properties related to tight substructures in multi-dimensional structured data.

1 Introduction

Pattern matching is the algorithmic problem of finding occurrences of a fixed pattern in a given string. This problem appears in many settings and has applications in diverse domains such as computational biology, computer vision, natural language processing and web search. There has been extensive research concerned with developing algorithms that search for patterns in strings, resulting with a wide range of efficient algorithms [12, 24, 19, 14, 26, 25]. Higher-dimensional analogues where one searches for a d-dimensional pattern in a d-dimensional

array have received attention as well. For example, the 2D case arises in analyzing aerial photographs [7, 8] and the 3D case has applications in medical imaging.

Given a string S of length n and a pattern P of length $k \leq n$, any algorithm which determines whether P occurs in S has running time $\Omega(n)$ [13, 29] and a linear lower bound carries over to higher dimensions. For the 2D case, when an $n \times n$ image is concerned, algorithms whose run time is $O(n^2)$ are known [8]. These algorithms have been generalized to the 3D case to yield running time of $O(n^3)$ [18] for $n \times n \times n$ arrays. Finally it is also known (e.g., [21]) that for the d-dimensional case it is possible to solve the pattern matching problem in time $O(d^2 n^d \log m)$ (where the pattern is an array of size m^d). It is natural to ask which tasks of this type can be performed in sublinear (namely $o(n^d)$) time for d-dimensional arrays.

The field of *property testing* [20, 30] deals with decision problems regarding discrete objects (e.g., graphs, functions, images) that either satisfy a certain property $\mathcal{P}$ or are *far* from satisfying $\mathcal{P}$. Here, the property $\mathcal{P}$ consists of all d-dimensional arrays that avoid a predetermined pattern P. *Tolerant* property testing [27] is a useful extension of the standard notion, in which the tester needs to distinguish between objects that are *close* to satisfying the property and those that are *far* from satisfying it.

A d-dimensional $k_1 \times \ldots \times k_d$ array A over an alphabet Γ is a function from $[k_1] \times \ldots \times [k_d]$ to Γ, where for an integer $k > 0$ we let $[k]$ denote the set $\{0, \ldots, k-1\}$ and write $[k]^d = [k] \times \ldots \times [k]$. For simplicity of presentation, all results in this paper are presented for *square* arrays in which $k_1 = \ldots = k_d$, but they generalize to non-square arrays in a straightforward manner. We consider the (tolerant) *pattern-freeness problem*. An (ϵ_1, ϵ_2)-tester Q for this problem is a randomized algorithm that is given access to a d-dimensional array A, as well as its size and proximity parameters $0 \leq \epsilon_1 < \epsilon_2 < 1$. Q needs to distinguish with probability at least $2/3$ between the case that A is ϵ_1-close to being P-free and the case that A is ϵ_2-far from being P-free. The query complexity of Q is the number of queries it makes in A.

Our interest in the pattern-freeness problem stems from several applications. In certain scenarios of interest, we might be interested in identifying quickly that an array is far from not containing a given pattern. In the one dimensional case, being far from not containing a given text may indicate a potential anomaly which requires attention (e.g., an offensive word in social network media), hence such testing algorithms may provide useful in anomaly detection. Many computer vision methods for classifying images are feature based; being far from not containing a certain pattern associated with a feature may be useful in rejection methods that enable us to quickly discard images that do not possess a certain visual property.

Beyond practical applications, devising property testing algorithms for the pattern freeness problem is of theoretical interest. In the first place, it leads to a combinatorial characterization of the distance from being P-free. Such a characterization has proved fruitful in graph property testing [3, 4] where celebrated graph removal lemmas were developed en route of devising algorithms for testing subgraph freeness. We encounter a similar phenomena in studying patterns and arrays: at the core of our approach for testing pattern freeness lies a *modification lemma* for patterns which we state next. We believe that this lemma may be of independent interest and find applications beyond testing algorithms.

For a pattern P of size $k \times k \times \ldots \times k$, an entry whose location in $\mathcal{P}$ is in $\{0, k-1\} \times \ldots \times \{0, k-1\}$ is said to be a *corner* of P. We say that P is *almost homogeneous* if all of its entries but one are equal, and the different entry lies in a corner of P. Finally, P is *removable* (with respect to the alphabet Γ) if for any d-dimensional array A over Γ and any copy of P in A, one can destroy the copy by modifying one of its entries without creating new P-copies in A. The modification lemma states that for any d, and any large enough pattern P, when the

alphabet is binary it holds that P is removable *if and only if* it is not almost homogeneous, and when the alphabet is not binary, P is removable provided that it is large enough.

Recent works [10, 11] have obtained tolerant testers for visual properties. As observed in these works, tolerance is an attractive property for testing visual properties as real-world images are often noisy. With the modification lemma at hand, we show that when P is removable, the (relative) *hitting number* of P in A, which is the minimal size of a set of entries that intersects all P-copies in A divided by $|A|$, differs from the distance of A from P-freeness by a multiplicative factor that depends only on the dimension d of the array. This relation allows us to devise very fast $(5^{-d}\epsilon, \epsilon)$-tolerant testers for P-freeness, as the hitting number of P in A can be well approximated using only a very small sample of blocks of entries from A. The query complexity of our tester is c_d/ϵ, where c_d is a positive constant depending only on d. Note that our characterization in terms of the hitting number is crucial: Merely building on the fact that A contains many occurrences of P (as can be derived directly from the modification lemma) and randomly sampling $O(1/\epsilon)$ possible locations in A, checking whether the sub-array starting at these locations equals P, would lead to query complexity of $O(k^d/\epsilon)$. Note that our tester is optimal (up to a multiplicative factor that depends on d), as any tester for this problem must make $\Omega(1/\epsilon)$ queries.

The one dimensional setting, where one seeks to determine quickly whether a string S is ϵ-far from being P-free is of particular interest. We are able to leverage the modification lemma and show that the distance of a string S from being P-free for a fixed pattern P (that is not almost homogeneous) is *exactly equal* to the hitting number of P in A. For an arbitrary constant $0 < c < 1$, this characterization allows us to devise a $((1-c)\epsilon, \epsilon)$-tolerant tester making $O_c(1/\epsilon)$ queries for this case. For the case of almost homogeneous patterns, and an arbitrary constant $c > 0$, we devise a $((1/(16+c))\epsilon, \epsilon)$-tolerant tester that makes $O_c(1/\epsilon)$ queries. Whether tolerant testers exist for almost homogenous patterns of dimension larger than 1 is an open question.

2 Related Work

The problem of testing pattern freeness is related to the study of testing subgraph freeness (see, for example, [1, 4, 2]). This line of work examines how one can test quickly whether a given graph G is H-free or ϵ-far from being H-free, where H is a fixed subgraph. In this problem, a graph is ϵ-far from being H-free if at least an ϵ-fraction of its edges and non-edges need to be altered in order to ensure that the resulting graph does not contain H as a (not necessarily induced) subgraph. A key component in these works are removal lemmas: typically such lemmas imply that if G is ϵ-far from being H-free, then it contains a large number of copies of H. For example, the *triangle removal lemma* asserts that for every $\epsilon > 0$, there exists $\delta = \delta(\epsilon) > 0$ such that if an n-vertex graph G is ϵ-far from being triangle free, then G contains at least δn^3 triangles (see, e.g., [6] and the references within).

Alon *et. al.* [3] studied the problem of testing regular languages. Testing pattern-freeness (1-dimensional, binary alphabet, constant pattern length k) is a special case of the former, since the language L of all strings avoiding a fixed pattern is regular. The query complexity of their tester is $O\left(\frac{s^3}{\epsilon} \cdot \ln^3(\frac{1}{\epsilon})\right)$, where s is the minimal size of a DFA that accepts the regular language L. In the case of the regular language considered here a simple pumping-lemma inspired argument shows that $s \geq \Omega(k)$. Hence the upper bound on testing pattern freeness implied by their algorithm is $O\left(\frac{k^3}{\epsilon} \cdot \ln^3(\frac{1}{\epsilon})\right)$. Our 1D tester solves a very restricted case of the problem the tester of [3] deals with, but it achieves a query complexity of $O(1/\epsilon)$ in this setting. Moreover, our tester is much simpler and can be applied in the more general high

dimensional setting, or when the pattern length k is allowed to grow as a function of the string length n.

The problem of testing *submatrix freeness* is investigated in [15, 16, 5, 17, 2]. As opposed to our case, which is concerned with *tight* submatrices, all of these results deal with submatrices that are not necessarily tight (i.e. the rows and the columns need not be consecutive). Quantitatively, the submatrix case is very different from our case: in our case P-freeness can be testable using $O(\epsilon^{-1})$ queries, while in the submatrix case, for a binary submatrix of size $k \times k$ a lower bound of $\epsilon^{-\Omega(k^2)}$ on the needed number of queries is easy to obtain, and in the non-binary case there exist 2×2 matrices for which there exists a super polynomial lower bound of $\epsilon^{-\Omega(\log 1/\epsilon)}$.

The 2D part of our work adds to a growing literature concerned with testing properties of images [28, 31, 10]. Ideas and techniques from the property testing literature have recently been used in the fields of computer vision and pattern recognition [22, 23].

3 Notation and definitions

An (n, d)-*array* A over an alphabet Γ is a function from $[n]^d$ to Γ. The $x = (x_1, \ldots, x_d)$ *entry* of A, denoted by A_x, is the value of the function A at location x. Let P be a (k, d)-array over an alphabet Γ of size at least two. We say that a d-dimensional array A *contains* a copy of P (or a P-copy) *starting in location* $x = (x_1, \ldots, x_d)$ if for any $y \in [k]^d$ we have $A_{x+y} = P_y$. Finally, A is P-free if it does not contain copies of P.

A property $\mathcal{P}$ of d-dimensional arrays is simply a family of such arrays over an alphabet Γ. For an array A and a property $\mathcal{P}$, the *absolute distance* $d_{\mathcal{P}}(A)$ of A to $\mathcal{P}$ is the minimal number of entries that one needs to change in A to get an array that satisfies $\mathcal{P}$. The *relative distance* of A to $\mathcal{P}$ is $\delta_{\mathcal{P}}(A) = d_{\mathcal{P}}(A)/|A|$, where clearly $0 \leq \delta_{\mathcal{P}}(A) \leq 1$ for any nontrivial $\mathcal{P}$ and A. We say that A is ϵ-close to $\mathcal{P}$ if $\delta_{\mathcal{P}}(A) \leq \epsilon$, and ϵ-far if $\delta_{\mathcal{P}}(A) \geq \epsilon$. In this paper we consider the property of P-freeness, which consists of all P-free arrays. The absolute and relative distance to P-freeness are denoted by $d_P(A)$ and $\delta_P(A)$, respectively.

For an array A and a pattern P, a *deletion set* is a set of entries in A whose modification can turn it to be P-free, and $d_P(A)$ is called the *deletion number*, since it is the size of a minimal deletion set. Similarly, a given set of entries in A is a *hitting set* if every P-copy in A contains at least one of these entries. The *hitting number* $h_P(A)$ is the size of the minimal hitting set for P in A. For all notation here and above, in the 1-dimensional case we replace A by S (for String).

We use several definitions from [27]. Let $\mathcal{P}$ be a property of arrays and let $h_1, h_2 : [0, 1] \to [0, 1]$ be two monotone increasing functions. An (h_1, h_2)-*distance approximation* algorithm for $\mathcal{P}$ is given query access to an unknown array A. The algorithm outputs an estimate $\hat{\delta}$ to $\delta_P(A)$, such that with probability at least $2/3$ it holds that $h_1(\delta_P(A)) \leq \hat{\delta} \leq h_2(\delta_P(A))$. For a property $\mathcal{P}$ and for $0 \leq \epsilon_1 < \epsilon_2 \leq 1$, an (ϵ_1, ϵ_2)-*tolerant tester* for $\mathcal{P}$ is given query access to an array A. The tester *accepts* with probability at least $2/3$ if A is ϵ_1-close to $\mathcal{P}$, and *rejects* with probability at least $2/3$ if A is ϵ_2-far from $\mathcal{P}$. In the "standard" notion of property testing, $\epsilon_1 = 0$. Thus, any tolerant tester is also a tester in the standard notion. Finally, we define the additive (multiplicative) *tolerance* of the tester above as $\epsilon_2 - \epsilon_1$ (ϵ_2/ϵ_1 respectively).

Table 1 Summary of results. $0 < \tau < 1$ and $c > 0$ are arbitrary constants. α_c is a constant that depends only on c. $\beta_{d,\tau}$ is a constant that depends only on d and τ. 'modification lemma' specifies if patterns are classified as removable or not. The 'tester tolerance' is multiplicative.

dim.	template type	modification lemma	tester tolerance	query complexity
1D	general	removable for any k	$1/(1-\tau)$	$O(1/\epsilon\tau^3)$
	almost homog.	not removable for any k	$16+c$	α_c/ϵ
2^+D	general	removable for $k > 3 \cdot 2^d$	$(1-\tau)^{-d}\alpha_d$	$\beta_{d,\tau}/\epsilon$
	almost homog.	not removable for any k	–	–

4 Main Results

The modification lemma presented is central in the study of minimal deletion sets. It classifies the possible patterns into ones that are removable and ones that are not. The result that the vast majority of patterns are removable is used extensively throughout the paper in the design and proofs of algorithms for efficient testing of pattern freeness (in 1 and higher dimensions).

Our 1-dimensional modification lemma (Lemma 1) gives the following full characterization of 1-dimensional patterns (i.e. strings). A binary pattern is removable *if and only if* it is not almost homogeneous, while *any* pattern over a larger alphabet is removable. The multidimensional version of the lemma (Lemma 2) makes the exact same classification, but for (k,d)-arrays for which $k \geq 3 \cdot 2^d$.

The fact that most patterns are removable is very important for analyzing the deletion number. For example, observe that a removable pattern appears at least $d_P(A)$ times (possibly with overlaps) in the array A, so an ϵ-tester can simply check for the presence of the d-dimensional pattern in $1/\epsilon$ random locations in the array, using $O(k^d/\epsilon)$ queries.

Another important part of our work makes explicit connections between the deletion number and the hitting number for both 1 and higher dimensions. These are needed in order to get improved testers (e.g. for getting rid of k in the sample complexity) in d-dimensions.

In the 1-dimensional removable case we show that the deletion number $d_P(S)$ equals the hitting number $h_P(S)$. We derive a $((1-\tau)\epsilon,\epsilon)$-tolerant tester for any fixed $\tau > 0$ and any $0 < \epsilon \leq 1$, whose number of queries and running time are $O(\epsilon^{-1}\tau^{-3})$ (Corollary 13).

For higher dimensions, we show (Lemma 11) that $h_P(A) \leq d_P(A) \leq \alpha_d h_P(A) \leq \alpha_d k^{-d}$, where $\alpha_d = 4^d + 2^d$ depends only on the dimension d. This bound gives a $((1-\tau)^d\alpha_d^{-1}\epsilon,\epsilon)$-tolerant tester making $C_\tau\epsilon^{-1}$ queries, where $C_\tau = O(1/\tau^d(1-(1-\tau)^d)^2)$ (Theorem 15). The running time here is $C'_\tau\epsilon^{-1}$ where C'_τ depends only on τ.

In the full version of the paper [9], for the 1-dimensional setting we also provide dedicated algorithms to handle the almost homogeneous (non-removable) patterns, obtaining an $O(n)$ algorithm for computing the deletion number as well as an $(\epsilon/(16+c),\epsilon)$-tolerant tester, for any constant $c > 0$, using $\alpha_c\epsilon^{-1}$ queries, where α_c depends only on c.

Finally, we provide a lower bound of $\Omega(1/\epsilon)$ (full proof in can be found in [9]) for any general tester of pattern freeness. Our main results are summarized in Table 1.

A natural question is what happens if one is concerned with pattern freeness with respect to several patterns simultaneously. Namely, testing quickly whether an array satisfies the property of not containing a fixed set of patterns $P_1,\ldots,P_r$ with $r > 1$, or is far from satisfying this property. Our results do not apply to this setting, with the main obstacle being our modification lemmas. Namely, the difficulty is that for several distinct patterns $P_1 \ldots P_r$, modifying an occurrence of P_i may create an new occurrence of P_j (where $i \neq j$).

5 Modification Lemma

We begin with the proof of the 1-dimensional modification lemma. The main strategy here is to consider the longest streaks of zeros and ones (0s and 1s) in the pattern - a strategy that cannot be used in higher dimensions.

▶ **Theorem 1** (1D Modification Lemma). *For a 1-dimensional pattern P over an alphabet Γ:*

1. *If $|\Gamma| = 2$ then P is removable if and only if it is not almost homogeneous.*
2. *If $|\Gamma| \geq 3$ then P is removable.*

▶ Remark. The second statement of the theorem can be easily derived from the first statement. If P does not contain all letters in Γ then it is clearly removable, as changing any of its entries to any of the missing letters cannot create new P-copies. Otherwise, we can reduce the problem to the binary case: let σ_1, σ_2 be the letters in Γ that appear the smallest number of times in P (specifically, if P is of length 3 and has exactly three different letters, we pick σ_1 and σ_2 to be the first letter and the last letter in P, respectively). Consider the following pattern P' over $\{0,1\}$: $P'_x = 0$ if $P_x \in \{\sigma_1, \sigma_2\}$ and $P'_x = 1$ otherwise. Observe that P' is not almost homogeneous, implying that it is removable. It is not hard to verify now that P is removable as well.

Proof of Theorem 1. As discussed above, it is enough to consider the binary case. Let $P = P_0 \dots P_{k-1}$ be a binary pattern of length k that is not almost homogeneous, and let S be an arbitrary binary string containing P. We need to show that one can flip one of the bits of P without creating a new P-copy in S. We assume that P contains both 0s and 1s (i.e. it is not homogeneous) otherwise flipping any bit would work. We may assume that $k \geq 3$ (since for $k = 1, 2$ all patterns are homogeneous or almost homogeneous). Let us also assume that P starts with a 1, i.e. $P_0 = 1$ and let $t \leq k-1$ be the length of the longest 0-streak (sub-string of consecutive 0s) in P. Let $i > 0$ be the leftmost index in which such a 0-streak of length t begins. Clearly, $P_{i-1} = 1$ and $P_i = \dots = P_{i+t-1} = 0$.

If $i + t \leq k - 1$ (i.e. the streak is not at the end of P) then $P_{i+t} = 1$ and in such a case if we modify P_{i+t} to 0, the copy of P is removed without creating new P-copies in S. To see this, observe that a new copy cannot start at the bit flip location $i + t$ or within the 0-streak at any of its locations $i, \dots, i + t - 1$ since the bits in these locations are 0 while the starting bit of P is 1. Note that flipping P_{i+t} does not create new P-copies starting after the location of P_{i+t} in S. Furthermore, no new copy starting before P_i is created since otherwise it would contain a 0-streak of length $t + 1$.

Thus, we may assume that P contains exactly one 0-streak of length t, lying at its last t locations, so $P_{k-1} = 0$. Denote by s the length of the longest 1-streak in P; a symmetric reasoning shows that P begins with its only 1-streak of length s. If P is *not* of the form 1^s0^t, it can be verified that flipping P_s (the leftmost 0 in P) to 1 does not create any P-copy. The only case left is $P = 1^s0^t$, where $s, t \geq 2$ since P is not almost homogeneous. Consider the bit of the string S that is to the left of P. If it is a 0 then we flip P_1 to 0 and otherwise, we flip P_0 to 0, where in both cases no new copy is created. ◀

We now turn to proving the high dimensional version of the modification lemma. Here, as opposed to the 1-dimensional case, there exist patterns that are neither removable nor almost-homogeneous. However, we show that if a pattern is large enough and not almost homogeneous then it is removable.

▶ **Theorem 2** (Modification Lemma). *Let $d > 1$ and let P be a (k, d)-array over the alphabet Γ where $k \geq 3 \cdot 2^d$.*

1. *If $|\Gamma| = 2$ then P is removable if and only if it is not almost homogeneous.*
2. *If $|\Gamma| \geq 3$ then P is removable.*

▶ Remark. Theorem 2 states that any large enough binary pattern which is not almost homogeneous is removable. The requirement that the pattern is large enough is crucial, as can be seen from the following 2-dimensional example. The 2×2 pattern $P = [01; 01]$ is in the center of the 4×4 matrix $A = [0101; 0011; 0011; 0101]$. Flipping any bit in P creates a new P-copy in A. This example easily generalizes to a $2 \times \ldots \times 2$ pattern in a $4 \times \ldots \times 4$ array, while the dependence of k on d is exponential in the statement of Theorem 2. It will be interesting to understand what is the correct order of magnitude of this dependence.

Proof of Theorem 2. The reduction from a general alphabet to a binary one, described after the statement of Theorem 1, can be used here as well. Thus, it is enough to prove the first statement of the theorem. If P is binary and almost homogeneous then it is not removable: Without loss of generality $P_{(0,\ldots,0)} = 1$ and $P_x = 0$ for any $x \neq (0, \ldots, 0)$. Consider a $(2k, d)$-array A such that $M_{(0,\ldots,0)} = M_{(1,\ldots,1)} = 1$ and $A = 0$ elsewhere. Modifying any bit of the P-copy starting at $(1, \ldots, 1)$ creates a new P-copy in A, hence P is not removable.

The rest of the proof is dedicated to the other direction. Suppose that P is a binary (k, d)-array that is not removable. We would like to show that P must be almost homogeneous. As P is not removable, there exists a binary array A containing a copy of P such that flipping any single bit in this copy creates a new copy of P in A. This copy of P will be called the *template* of P in A.

Clearly, all of the new copies created by flipping bits in the template must intersect the template, so we may assume that A is of size $(3k - 2)^d$ and that the template starts in location $\tilde{k} = (k - 1, \ldots, k - 1)$. For convenience, let $I = [k]^d$ denote the set of indices of P. For any $x \in I$ let $\bar{x} = x + \tilde{k}$; $\bar{x}$ is the location in A of bit x of the template.

Roughly speaking, our general strategy for the proof is to show that there exist at most two "special" entries in P such that when we flip a bit in the template (creating a new copy of P in A) the flipped bit usually plays the role of one of the special entries in the new copy. We then show that in fact, there must be exactly one special entry, which must lie in a corner of P, and that all non-special entries are equal while the special entry is equal to their negation. This will finish the proof that P is almost homogeneous.

▶ **Definition 3.** Let $i \leq d$ and let δ be positive integers. Let $x = (x_1, \ldots, x_d)$ and $y = (y_1, \ldots, y_d)$ be d-dimensional points. The pair (x, y) is (i, δ)-*related* if $y_i - x_i = \delta$ and $y_j = x_j$ for any $j \neq i$. An (i, δ)-related pair (x, y) is said to be an (i, δ)-*jump* in P if $P_x \neq P_y$.

In other words, (x, y) is (i, δ)-*related* if there is an increasing path of length δ along coordinate i in the hypergrid graph on $[n]^d$.

▶ **Lemma 4.** *For any $1 \leq i \leq d$ there exists $0 < \Delta_i < k/3$ such that at most two of the (i, Δ_i)-related pairs of points from I are (i, Δ)-jumps in P.*

Proof. Recall that, by our assumption, flipping any of the $K = k^d$ bits of the template creates a new copy of P in A. Consider the following mapping $m : I \to [2k-1]^d$. $m(x_1, \ldots, x_d)$ is the starting location of a new copy of P created in A as a result of flipping bit $x = (x_1, \ldots, x_d)$ of the template (which is bit $\bar{x}$ of A). If more than one copy is created by this flip, then we choose the starting location of one of the copies arbitrarily.

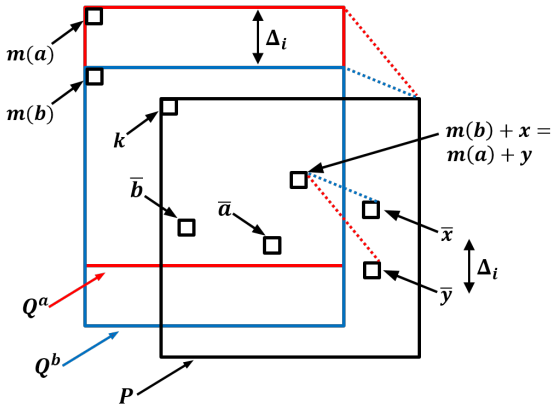

Figure 1 Illustration for Lemma 4. A 2-dimensional example, where i is the vertical coordinate: Flipping the bit (of the template P) at location $\bar{a}$ creates the P-copy Q^a at location $m(a)$. Similarly, the copy Q^b is created at location $m(b)$. Note that the pair of points $(\bar{x}, \bar{y})$ (which is (x, y) in P) and the copy locations pair $(m(a), m(b))$ are both (i, Δ_i)-related. The values P_x and P_y ($M_{\bar{x}}$ and $M_{\bar{y}}$) must be equal.

Observe that m is injective, and let S be the image of m, where $|S| = K$. Let $1 \leq i \leq d$ and consider the collection of (1-dimensional) lines

$$\mathcal{L}_i = \big\{\{x_1\} \times \ldots \times \{x_{i-1}\} \times [2k-1] \times \{x_{i+1}\} \times \ldots \times \{x_d\} \quad | \quad \forall j \neq i : x_j \in [2k-1]\big\}.$$

Clearly $\sum_{\ell \in \mathcal{L}_i} |S \cap \ell| = K$. On the other hand, $|\mathcal{L}_i| = \prod_{j \neq i}(2k-1) < 2^{d-1} \prod_{j \neq i} k = 2^{d-1}K/k$, so there exists a line $\ell \in \mathcal{L}_i$ for which $|S \cap \ell| > k/2^{d-1} \geq 6$. Hence $|S \cap \ell| \geq 7$. Let $\alpha_1 < \ldots < \alpha_7$ be the smallest i-indices of elements in $S \cap \ell$. Since $\alpha_7 - \alpha_1 < 2k-1$ there exists some $1 \leq l \leq 6$ such that $\alpha_{l+1} - \alpha_l < k/3$. That is, S contains an (i, Δ_i)-related pair with $0 < \Delta_i < k/3$. In other words, there are two points $a, b \in I$ such that flipping $\bar{a}$ ($\bar{b}$) would create a new P-copy, denoted by Q^a (Q^b respectively), which starts in location $m(a)$ ($m(b)$ respectively) in A, and $(m(a), m(b))$ is an (i, Δ_i)-related pair.

The following claim finishes the proof of the lemma and will also be useful later on.

▶ **Claim 5.** *For a and b as above, let (x, y) be a pair of points from I that are (i, Δ_i)-related and suppose that $y \neq \bar{a} - m(a)$ and that $x \neq \bar{b} - m(b)$. Then $P_x = P_y$.*

Proof. The bits that were flipped in A to create Q^a and Q^b are $\bar{a}, \bar{b}$ respectively. Since $y + m(a) \neq \bar{a}$, the entry $M_{y+m(a)}$ serves as the entry of the P-copy Q^a in location y, so $P_y = M_{y+m(a)}$. Similarly, since $x + m(b) \neq \bar{b}$, we have $P_x = M_{x+m(b)}$. But since both pairs (x, y) and $(m(a), m(b))$ are (i, Δ_i)-related, we get that $m(b) - m(a) = y - x$, implying that $x + m(b) = y + m(a)$, and therefore $P_x = M_{x+m(b)} = M_{y+m(a)} = P_y$, as desired. ◀

Clearly, the number of (i, Δ_i)-related pairs that do not satisfy the conditions of the claim is at most two, finishing the proof of Lemma 4. ◀

Let $\Delta = (\Delta_1, \ldots, \Delta_d)$ where for any $1 \leq i \leq d$, we take Δ_i that satisfies the statement of Lemma 4 (its specific value will be determined later).

▶ **Definition 6.** Let $x \in I$. The set of Δ-*neighbours* of x is

$$N_x = \big\{y \in I \quad | \quad \exists i : (x, y) \text{ is } (i, \Delta_i)\text{-related or } (y, x) \text{ is } (i, \Delta_i)\text{-related}\big\}$$

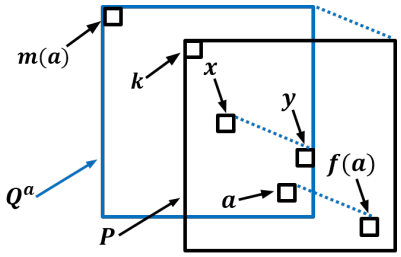

Figure 2 Illustration for Definition 8. Recall that flipping a bit $\bar{a}$ in A creates a new P-copy Q^a (which contains $\bar{a}$), located at the point $m(a)$ in the coordinates of A. The bits x and a are *mapped* to y and $f(a)$ respectively.

and the number of Δ-neighbours of x is $n_x = |N_x|$, where $d \leq n_x \leq 2d$. We say that x is a Δ-*corner* if $n_x(\Delta) = d$ and that it is Δ-*internal* if $n_x(\Delta) = 2d$. Furthermore, x is (Δ, P)-*isolated* if $P_x \neq P_y$ for any $y \in N_x$, while it is (Δ, P)-*generic* if $P_x = P_y$ for any $y \in N_x$.

When using the above notation, we sometimes omit the parameters (e.g. simply writing *isolated* instead of (Δ, P)-isolated) as the context is usually clear.

The definition imposes a symmetric neighborhood relation, that is, $x \in N_y$ holds if and only if $y \in N_x$. If $x \in N_y$ we say that x and y are Δ-neighbours. Note that a point $x = (x_1, \ldots, x_d) \in I$ is a Δ-corner if $x_i < \Delta_i$ or $x_i \geq k - \Delta_i$ for any $1 \leq i \leq d$, and that x is Δ-internal if $\Delta_i \leq x_i < k - \Delta_i$ for any $1 \leq i \leq d$.

▶ **Claim 7.** *Two (Δ, P)-isolated points in I cannot be Δ-neighbors.*

Proof. Suppose towards contradiction that $x = (x_1, \ldots, x_d)$ and $y = (y_1, \ldots, y_d)$ are two distinct (Δ, P)-isolated points and that (x, y) is (i, Δ_i)-related for some $1 \leq i \leq d$. Since $\Delta_i < k/3$, at least one of x or y participates in two different (i, Δ_i)-related pairs: if $x_i < k/3$ then $y_i + \Delta_i = x_i + 2\Delta_i < k$ so y is in two such pairs, and otherwise $x_i \geq \Delta_i$, meaning that x participates in two such pairs. Assume without loss of generality that the two (i, Δ_i)-related pairs are (t, x) and (x, y), then $P_t \neq P_x$ and $P_x \neq P_y$ as x is isolated. By Lemma 4, these are the only (i, Δ_i)-jumps in P.

Choose an arbitrary $j \neq i$ and take $v = (v_1, \ldots, v_d)$ where $v_j = \Delta_j$ and $v_l = 0$ for any $l \neq j$. Recall that $\Delta_j < k/3$, implying that either $x_j + v_j < k$ or $x_j - v_j \geq 0$. Without loss of generality assume the former, and let $x' = x + v$ and $y' = y + v$. Since x and y are (Δ, P)-isolated, and since $x' \in N_x$ and $y' \in N_y$, we get that $P_{x'} \neq P_x \neq P_y \neq P_{y'}$, and thus $P_{x'} \neq P_{y'}$ (as the alphabet is binary). Therefore, (x', y') is also an (i, Δ_i)-jump in P, a contradiction. ◀

▶ **Definition 8.** For three points $x, y, a \in I$, we say that x is *mapped* to y as a result of the flipping of a if $\bar{x} = m(a) + y$. Moreover, define the function $f : I \to I$ as follows: $f(x) = \bar{x} - m(x)$ is the location to which x is mapped as a result of flipping x.

In other words, x is mapped to y as a result of flipping the bit a if bit $\bar{x}$ of A "plays the role" of bit y in the new P-copy Q_a that is created by flipping a. Note that

- If $\bar{x} - m(a) \notin I$ then x is not mapped to any point. However, this cannot hold when $x = a$, so the function f is well defined.

- For a fixed a, the mapping as a result of flipping a is linear: if x and y are mapped to x' and y' respectively, then $y - x = y' - x'$. In particular, if (x, y) is (i, Δ_i)-related for some $1 \leq i \leq d$ then (x', y') is also (i, Δ_i)-related.
- If x is mapped to y as a result of flipping a and $x \neq a$, then $P_x = P_y$.
- On the other hand, we always have $P_x \neq P_{f(x)}$.
- If x is Δ-internal and (Δ, P)-generic, then $f(x)$ must be (Δ, P)-isolated.

The first four statements are easy to verify. To verify the last one, suppose that x is internal and generic and let $z \in N_{f(x)}$; we will show that $P_{f(x)} \neq P_z$. Since x is internal, there exists $y \in N_x$ such that $y - x = z - f(x)$. Then y is mapped to z as a result of flipping x, since $\bar{y} = y + \tilde{k} = z + (x + \tilde{k}) - f(x) = z + \bar{x} - f(x) = z + m(x)$. Therefore $P_y = P_z$. On the other hand, $P_x = P_y$ as x is generic and $P_x \neq P_{f(x)}$, and we conclude that $P_z \neq P_{f(x)}$.

▶ **Lemma 9.** *There is exactly one (Δ, P)-isolated point in I.*

Proof. Let $\mathcal{S}$ be the set of isolated points; our goal is to show that $|\mathcal{S}| = 1$. Consider the set

$$C = \{(x, y) : x, y \in I, (x, y) \text{ is an } (i, \Delta_i)\text{-jump for some } 1 \leq i \leq d\}.$$

Clearly, each point in $\mathcal{S}$ is contained in at least d pairs from C. By claim 7 no pair of isolated points are Δ-neighbours and therefore every pair in C contains at most one point from $\mathcal{S}$. By Lemma 4, $|C| \leq 2d$ which implies that $|\mathcal{S}| \leq 2$. On the other hand we have $|\mathcal{S}| \geq 1$. To see this, observe that the number of (Δ, P)-internal points in I is greater than $\prod_{i=1}^{d} k/3 \geq 2^{d^2}$, while the number of non-Δ-generic points is at most $2|C| \leq 4d$, implying that at least $2^{d^2} - 4d > 0$ of the internal points are generic. Therefore, pick an internal generic point $z \in I$. As we have seen before, $f(z)$ must be isolated.

To complete the proof it remains to rule out the possibility that $|\mathcal{S}| = 2$. If two different (Δ, P)-isolated points $a = (a_1, \ldots, a_d)$ and $b = (b_1, \ldots, b_d)$ exist, each of them must participate in exactly d pairs in C. This implies that both of them are Δ-corners with d neighbors. It follows that every Δ-internal point z must be generic (since an internal point and a corner point cannot be neighbours), implying that either $f(z) = a$ or $f(z) = b$.

Let $1 \leq i \leq d$ and define $\delta_i > 0$ to be the smallest integer such that there exists an (i, δ_i)-related pair (x, y) of generic internal points with $f(x) = f(y)$. For this choice of x and y we have $m(y) - m(x) = \bar{y} - f(y) - (\bar{x} - f(x)) = \bar{y} - \bar{x} = y - x$, so $(m(x), m(y))$ is also (i, δ_i)-related. In particular, we may take $\Delta_i = \delta_i$ (Recall that until now, we only used the fact that $\Delta_i < k/3$, without committing to a specific value). Without loss of generality we may assume that $f(x) = f(y) = a$. By Claim 5, any pair (s, t) of (i, Δ_i)-related points for which $s \neq \bar{y} - m(y) = f(y) = a$ and $t \neq \bar{x} - m(x) = f(x) = a$ is not an (i, Δ_i)-jump. Since b is not a Δ-neighbour of a, it does not participate in any (i, Δ_i)-jump, contradicting the fact that it is (Δ, P)-isolated. This finishes the proof of the lemma. ◀

Finally, we are ready to show that P is almost homogeneous. Let $a = (a_1, \ldots, a_d)$ be the single (Δ, P)-isolated point in I. Consider the set

$$J = \{x = (x_1, \ldots, x_d) \in I : \Delta_i \leq x_i < \Delta_i + 2^d \text{ for any } 1 \leq i \leq d\}$$

and note that all points in J are Δ-internal. Let $1 \leq i \leq d$ and partition J into $(i, 1)$-related pairs of points. There are $2^{d^2-1} \geq 4d$ pairs in the partition. On the other hand, the number of non-generic points in J is at most $2|C| - (d - 1) < 4d$ (to see it, count the number of elements in pairs from C and recall that a is contained in at least d pairs). Therefore, there exists a pair (x, y) in the above partition such that x and y are both generic. As before,

$f(x)$ and $f(y)$ must be isolated, and thus $f(x) = f(y) = a$, implying that $\Delta_i = \delta_i = 1$. We conclude that $\Delta = (1, \ldots, 1)$.

Claim 5 now implies that any pair (s, t) of $(i, 1)$-related points for which $s \neq \bar{y} - m(y) = f(y) = a$ and $t \neq \bar{x} - m(x) = f(x) = a$ is not an $(i, 1)$-jump. That is, for any two neighbouring points $s, t \neq a$ in I, $P_s = P_t$, implying that $P_x = P_y$ for any $x, y \neq a$ (since $\Delta = (1, \ldots, 1)$, a Δ-neighbour is a neighbour in the usual sense). To see this, observe that for any two points $x, y \neq a$ there exists a path $x_0 x_1 \ldots x_t$ in I where x_j and x_{j+1} are neighbours for any $0 \leq j \leq t-1$, the endpoints are $x_0 = x$ and $x_t = y$, and $x_j \neq a$ for any $0 < j < t$. Since a is isolated, it is also true that $P_a \neq P_x$ for any $x \neq a$.

To finish the proof that P is almost homogeneous, it remains to show that a is a corner. Suppose to the contrary that $0 < a_i < k - 1$ for some $1 \leq i \leq d$ and let $b, c \in I$ be the unique points such that (a, b) and (c, a) are $(i, 1)$-related, respectively. Clearly $f(b) = a$, so a is mapped to $\bar{a} - m(b) = \bar{a} - \bar{b} + f(b) = c - a + a = c$ as a result of flipping b, which is a contradiction - as $P_a \neq P_c$ and $b \neq a, c$. This finishes the proof. ◀

6 From Deletion to Testing

We use the modification lemmas of Section 5 to investigate combinatorial characterizations of the deletion number, which in turn allow efficient approximation and testing of pattern freeness for removable patterns. In particular, we prove that minimal deletion sets and minimal hitting sets are closely related. Due to space considerations, the proofs of all results in this Section do not appear here, and are given in the full version of this paper [9].

The characterizations for almost homogeneous 1-dimensional patterns are also given in the full version of the paper [9], along with an optimal tester for pattern freeness in that case. The rest of this section deals with removable patterns, for both the 1-dimensional and multi-dimensional settings.

In the 1-dimensional case, we show that for any removable pattern there exist certain minimal hitting sets which are in fact minimal deletion sets. These are sets where none of the flips create new occurrences. Our constructive proof shows how to build such a set.

▶ **Theorem 10** ($d_P(S)$ equals $h_P(S)$)**.** *For a binary string S of length n and a binary pattern P of length k that is removable, the deletion number $d_P(S)$ equals the hitting number $h_P(S)$.*

For the multidimensional case, we show that when P is removable, the hitting number $h_P(A)$ of A approximates the deletion number up to a multiplicative constant that depends only on the dimension d. This is done in two stages, the first of which involves the analysis of a procedure that proves the existence of a large collection of P-copies with small pairwise overlaps, among the set of all P-copies in A. This procedure heavily relies on the fact that P is removable. The second stage shows that since these copies have small overlaps, their hitting number cannot be much different than their deletion number. The result is summarized in Lemma 11.

▶ **Lemma 11** (Relation between distance and hitting number)**.** *Let P be a removable (k, d)-array over an alphabet Γ, and let A be an (n, d)-array over Γ. Let $\alpha_d = 4^d + 2^d$. It holds that: $h_P(A) \leq d_P(A) \leq \alpha_d h_P(A) \leq \alpha_d (n/k)^d$.*

We describe efficient distance approximation algorithms and testers for both the 1-dimensional and the d-dimensional removable patterns. The tolerance of the testers depends only on d, and the query complexity is linear in ϵ^{-1} where the constant depends only on d (and not on k; using a completely naive tester, it can be seen that the tolerance and the query

complexity depend on k). The distance approximation algorithms and the testers essentially estimate the hitting number by sampling a small set of $O(k) \times \ldots \times O(k)$ uniformly chosen consecutive subarrays of the input array, and calculating the hitting number of the pattern P in each of these samples.

▶ **Theorem 12** (Approximating the deletion number in 1-dimension). *Let P be a removable string of length k and fix constants $0 < \tau < 1, 0 < \delta < 1/k$. Let $h_1, h_2 : [0,1] \to [0,1]$ be defined as $h_1(\epsilon) = (1-\tau)\epsilon - \delta$ and $h_2(\epsilon) = \epsilon + \delta$. There exists an (h_1, h_2)-distance approximation algorithm for P-freeness with query complexity and running time of $O(1/k\tau\delta^2)$.*

Note that $d_P(S) = h_P(S) \leq n/k$ always holds, so having an additive error parameter of $\delta \geq 1/k$ is pointless. The proof of Theorem 12 can be adapted to derive an (ϵ_1, ϵ_2)-tolerant tester for any $0 \leq \epsilon_1 < \epsilon_2 \leq 1$, yielding the following multiplicative-error tester.

▶ **Corollary 13** (Multiplicative tolerant tester for pattern freeness in 1-dimension). *Fix $0 < \tau < 1$. For any $0 < \epsilon \leq 1$ there exists a $((1-\tau)\epsilon, \epsilon)$-tolerant tester whose number of queries and running time are $O(\epsilon^{-1}\tau^{-3})$.*

For the multidimensional case, our distance approximation algorithm and tolerant tester for P-freeness are given in Theorems 14 and 15.

▶ **Theorem 14** (Approximating the deletion number in multidimensional arrays). *Let P be a removable (k,d)-array and fix constants $0 < \tau \leq 1, 0 \leq \delta \leq 1/k^d$. Let $h_1, h_2 : [0,1] \to [0,1]$ be defined as $h_1(\epsilon) = (1-\tau)^d \alpha_d^{-1}\epsilon - \delta$ and $h_2(\epsilon) = \epsilon + \delta$. There exists an (h_1, h_2)-distance approximation algorithm for P-freeness making at most $\gamma/k^d\tau^d\delta^2$ queries, where $\gamma > 0$ is an absolute constant, and has running time $\zeta_\tau/k^d\delta^2$ where ζ_τ is a constant depending only on τ.*

▶ **Theorem 15** (Multiplicative tolerant tester for pattern freeness in multidimensional arrays). *Fix $0 < \tau \leq 1$ and let P be a removable (k,d)-array. For any $0 < \epsilon \leq 1$ there exists a $((1-\tau)^d \alpha_d^{-1}\epsilon, \epsilon)$-tolerant tester making $C_\tau \epsilon^{-1}$ queries, where $C_\tau = O(1/\tau^d(1-(1-\tau)^d)^2)$. The running time is $C'_\tau \epsilon^{-1}$ where C'_τ depends only on τ.*

7 Discussion and Open Questions

We have provided efficient algorithms for testing whether high-dimensional arrays do not contain P for any fixed removable pattern P. The results suggest several interesting open questions on the problem of pattern-freeness and more generally, on local properties - where we say that a property $\mathcal{P}$ is k-local (for $k \ll n$) if for any array A not satisfying $\mathcal{P}$, there exists a consecutive subarray of A of size at most $k \times \ldots \times k$ which does not satisfy $\mathcal{P}$ as well. That is, a property is local if any array not satisfying $\mathcal{P}$ contains a small 'proof' for this fact. Note that P-freeness is indeed k-local where k is the side length of P, and that a property $\mathcal{P}$ is k-local if and only if there exists a *family* $\mathcal{F}$ of arrays of size at most $k \times \ldots \times k$ each, such that A satisfies $\mathcal{P}$ if and only if it does not contain any consecutive sub-array from $\mathcal{F}$. That is, to understand the general problem of testing local properties of arrays we will need to understand the testing of $\mathcal{F}$-freeness, where $\mathcal{F}$ is a family of forbidden patterns (rather than a single forbidden pattern). As mentioned, it is not clear how to apply our methods to develop testers for families of patterns. Devising testers for this case is an interesting open question.

The problem of approximate pattern matching is of interest as well. The family of forbidden patterns for this problem might consist of a pattern and all patterns that are close enough to it, and the distance measures between patterns might also differ from the Hamming distance (e.g., ℓ_1 distance for grey-scale patterns).

Finally, it is desirable to settle the problem of testing pattern freeness for the almost homogenous case by either finding an efficient tester for the almost homogeneous multi-dimensional case, or proving that an efficient tester cannot exist for such patterns. It is also of interest to examine which of the $[k]^d$ patterns with $k < 3 \cdot 2^d$ are removable.

Abstract

People tend to behave inconsistently over time due to an inherent present bias. As this may impair performance, social and economic settings need to be adapted accordingly. Common tools to reduce the impact of time-inconsistent behavior are penalties and prohibition. Such tools are called commitment devices. In recent work Kleinberg and Oren [5] connect the design of a prohibition-based commitment device to a combinatorial problem in which edges are removed from a task graph G with n nodes. However, this problem is NP-hard to approximate within a ratio less than $\sqrt{n}/3$ [2]. To address this issue, we propose a penalty-based commitment device that does not delete edges, but raises their cost. The benefits of our approach are twofold. On the conceptual side, we show that penalties are up to $1/\beta$ times more efficient than prohibition, where $\beta \in (0, 1]$ parameterizes the present bias. On the computational side, we improve approximability by presenting a 2-approximation algorithm for allocating penalties. To complement this result, we prove that optimal penalties are NP-hard to approximate within a ratio of 1.08192.

1 Introduction

Most people make long term plans. They intend to eat healthy, save money, prepare for exams, exercise regularly and so on. Curiously, the same people often change their plans at a later point in time. They indulge in fast food, squander their money, fail to study and skip workouts. Although change may be necessary due to unforeseen events, people often change their plans even if the circumstances stay the same. This type of *time-inconsistent behavior* is a well-known phenomenon in behavioral economics and might impair a person's performance in social or economic domains [1, 8].

A sensible explanation for time-inconsistent behavior is that people are *present biased* and assign disproportionately greater value to the present than to the future. Consider, for instance, a scenario in which a student named Alice attends a course over several weeks. To pass the course, Alice either needs to solve a homework exercise each week or give a

presentation once. The presentation incurs a onetime effort of 3, whereas each homework exercise incurs an effort of 1. Furthermore, we assume that Alice immediately fails if she misses a homework assignment before she has given a presentation. If the course lasts for more than 3 weeks, she clearly minimizes her effort by giving a presentation in the first week. Paradoxically, if Alice is present biased, she may solve all homework exercises instead. The reason for this is the following:

Suppose Alice perceives present effort accurately, but discounts future effort by a factor of $\beta = 1/3$. In the first week Alice must decide between solving the homework exercise or giving a presentation. Remember that she automatically fails if she does neither of the two. Clearly, the homework incurs less immediate effort than the presentation. Furthermore, Alice can still give a presentation later on. Her perceived effort for doing the homework this week and giving the presentation the week after is $1 + \beta 3 = 2$. To Alice this plan appears more convenient than giving the presentation right away. Consequently, she does the homework. However, come next week she changes this plan and postpones the presentation once more. Her reasoning is the same as in the first week. Due to her time-inconsistent behavior, Alice continues to postpone the presentation and ends up doing all the homework assignments.

Previous Work. Time-inconsistent behavior has been studied extensively in behavioral economics. For an introduction to the topic refer for example to [1]. Alice's scenario demonstrates how time-inconsistency arises whenever people are present biased. Alice evaluates her preferences based on a well-established discounting model called *quasi-hyperbolic-discounting* [7]. As her story shows, quasi-hyperbolic-discounting tempts people to make poor decisions. To prevent poor decisions, social and economic settings need to be adapted accordingly. Depending on the domain, such adaptations might be implemented by governments, companies, teachers or people themselves. We call these entities *designers* and their motivation can be benevolent or self-serving. In either case, the designer's objective is to commit people to a certain goal. Their tools are called *commitment devices* and may include rewards, penalty fees and strict prohibition [3, 9].

Until recently, the study of time-inconsistent behavior lacked a unifying and expressive framework. However, groundbreaking work by Kleinberg and Oren closed this gap by reducing the behavior of a quasi-hyperbolic-discounting person to a simple planning problem in task graphs [5]. Their framework has helped to identify various structural properties of social and economic settings that affect the performance of present biased individuals [5, 10]. It has also been extended to people whose present bias varies over time [4] as well as people who are aware of their present bias and act accordingly [6]. We will formally introduce the framework in Section 2. A significant part of Kleinberg and Oren's work is concerned with the study of a simple yet powerful commitment device based on prohibition [5]. In particular, they demonstrate how performance can be improved by removing a strategically chosen set of edges from the task graph. The drawback of their approach is its computational complexity. As it turns out, an optimal commitment device is NP-hard to approximate within a ratio less than $\sqrt{n}/3$, where n denotes the number nodes in the task graph [2]. Currently, the only known polynomial-time algorithms achieve approximation ratios of $1/\beta$ and $1 + \beta/n$, which in combination yields a $1 + \sqrt{n}$ approximation [2]. It should be mentioned that Kleinberg and Oren's framework has also been used to analyze reward-based commitment devices [2, 10]. Unfortunately, the computational complexity of such commitment devices does not permit a polynomial-time approximation within a finite ratio unless P = NP [2].

Our Contribution. To circumvent the theoretical limitations mentioned above, we propose a natural generalization of Kleinberg and Oren's work. Instead of prohibition, our commitment

device is based on penalty fees, a standard tool in the economic literature [3, 9]. This means that the designer is free to raise the cost of arbitrary edges in the task graph. We call such an assignment of penalties a *cost configuration*. The designer's objective is to construct cost configurations that are as efficient as possible.

In Section 3 we conduct a quantitative comparison between the efficiency of penalty fees and prohibition. Assuming that optimal commitment devices can be computed, we show that penalties are strictly more powerful than prohibition. In particular, we show that penalties may outperform prohibition by a factor of $1/\beta$ where β parameterizes the present bias. This result is tight. In Section 4 we investigate the computational complexity of our commitment device. Using a reduction from 3-SAT, we argue that the construction of an efficient cost configuration is NP-hard when posed as a decision problem. A generalization of this reduction proves NP-hardness for approximations within a ratio of 1.08192. Unless P = NP, this dismisses the existence of a polynomial-time approximation scheme. While analyzing the complexity of our commitment device we also point to a remarkable structural property. More specifically, we show that every cost configuration admits another cost configuration of comparable efficiency that assigns its cost entirely along a single path. Assuming that the path is known in advance, we provide an algorithm for constructing such a cost configuration in polynomial-time. This result is important for the design of exact algorithms as it reduces the search space to the set of paths through the task graph. Finally, Section 5 introduces a 2-approximation algorithm for our commitment device. This is our main result and a considerable improvement to the $\sqrt{n}/3$ approximability of the prohibition-based commitment device [2]. It is interesting to note that the $1/\beta$ approximation algorithm of [2] can also be applied to penalty fees. As a result, our penalty-based approach is particularly interesting for highly present biased agents with $\beta < 1/2$.

2 The Formal Framework

In the following, we introduce Kleinberg and Oren's framework [5]. Let $G = (V, E)$ be a directed acyclic graph with n nodes that models a given long-term project. The edges of G correspond to the tasks of the project and the nodes represent the states. In particular, there exists a start state s and a target state t. Each path from s to t corresponds to a valid sequence of tasks to complete the project. The effort of a specific task is captured by a non-negative cost $c(e)$ assigned to the associated edge e.

To complete the project, an agent with a *present bias* of $\beta \in (0, 1]$ incrementally constructs a path from s to t as follows: At any node v different from t, the agent evaluates her *lowest perceived cost*. For this purpose she considers all paths P leading from v to t. However, she only anticipates the cost of the first edge of P correctly; all other edges of P are discounted by her present bias. More formally, let $d(w)$ denote the cost of a cheapest path from node w to t. The agent's lowest perceived cost at v is defined as $\zeta(v) = \min\{c(v, w) + \beta d(w) \mid (v, w) \in E\}$. We assume that she only traverses edges (v, w) that minimize her anticipated cost, i.e. edges for which $c(v, w) + \beta d(w) = \zeta(v)$. Ties are broken arbitrarily. For convenience, we define the perceived cost of (v, w) as $\eta(v, w) = c(v, w) + \beta d(w)$. The agent is motivated by an intrinsic or extrinsic reward r collected at t. As she receives this reward in the future, she perceives its value as βr at each node different from t. When located at v, she compares her lowest perceived cost to the anticipated reward and continues moving if and only if $\zeta(v) \leq \beta r$. Otherwise, if $\zeta(v) > \beta r$, we assume she abandons the project. We call G *motivating* if she does not abandon while constructing her path from s to t. Note that in some graphs the agent can take several paths from s to t due to ties between incident edges. In this case, G is considered motivating if she does not abandon on any of these paths.

For the sake of a clear presentation, we will assume throughout this work that each node of G is located on a path from s to t. This assumption is sensible for the following reason: Clearly, the agent can only visit nodes that are reachable from s. Furthermore, she is not willing to enter nodes that do not lead to the reward. Consequently, only nodes that are on a path from s to t are relevant to her behavior. Note that all nodes that do not satisfy this property can be removed from G in a simple preprocessing step.

To illustrate the model, we revisit Alice's scenario from Section 1. Assume that the course takes m weeks. We represent each week i by a distinct node v_i and set $s = v_1$. Furthermore, we introduce a target node t that marks the passing of the course. Each week $i < m$ Alice can either give a presentation or proceed with the homework. We model the first case by an edge (v_i, t) of cost 3 and the latter case by an edge (v_i, v_{i+1}) of cost 1. In the last week, i.e. $i = m$, Alice's only sensible choice is to do the homework. Therefore, edge (v_m, t) is of cost 1. Recall that Alice's present bias is $\beta = 1/3$. Moreover, assume that her intrinsic reward for passing is $r = 6$. For $i < m$ her perceived cost of the edges (v_i, t) is $\eta(v_i, t) = c(v_i, t) = 3$. As this is less than her perceived reward, which is $\beta 6 = 2$, she is never motivated to give a presentation right away. However, her perceived cost of the edges (v_i, v_{i+1}) is at most $\eta(v_i, v_{i+1}) \leq c(v_i, v_{i+1}) + \beta c(v_{i+1}, t) \leq 2$. This matches her perceived reward. As a result, she walks from v_1 to v_m along the edge (v_i, v_{i+1}). Once she reaches v_m she traverses the only remaining edge for a perceived cost of $\eta(v_m, t) = c(v_m, t) = 1$ and passes the course. This matches our analysis from Section 1.

3 Prohibition versus Penalties

In this section we demonstrate how the *designer* can modify a given project to help the agent reach t. For this purpose, the designer may have several commitment devices at her disposal. A straightforward approach is to increase the reward that the agent collects at t. Although this may keep the agent from abandoning the project prematurely, it has no influence on the path taken by the agent. Furthermore, increasing the reward may be costly for the designer. As a result, the designer has two conflicting objectives. On the one hand, she must ensure that the agent reaches t. On the other hand, she needs to minimize the resources spent. To deal with this dilemma, Kleinberg and Oren allow the designer to prohibit a strategically chosen set of tasks [5]. This commitment device is readily implemented in their framework. In fact, it is sufficient to remove all edges of prohibited tasks. The result is a subgraph G' that may significantly reduce the reward required to motivate the agent. Unfortunately, an optimal subgraph G' is NP-hard to approximate within a ratio less than $\sqrt{n}/3$ [2].

To circumvent this theoretical limitation, we propose a different approach. Instead of prohibiting certain tasks we allow the designer to charge penalty fees. Such fees could be implemented in several ways; for instance in the form of donations to charity. Our only assumption is that the designer does not benefit from the fees, i.e. there is no incentive to maximize the fees payed by the agent. Similar to the prohibition-based commitment device, our commitment device is readily implemented in Kleinberg and Oren's framework. The designer simply assigns a positive extra cost $\tilde{c}(e)$ to the desired edges e. The new cost of e is equal to $c(e) + \tilde{c}(e)$. We call $\tilde{c}$ a *cost configuration*. Applying a cost configuration to G yields a new task graph with increased edge cost. All concepts of the original framework carry over immediately. Sometimes it will be necessary to compare different commitment devices with each other. To clarify which commitment device we are talking about, we use the following notation whenever necessary: If we consider a subgraph G', we write $d_{G'}$, $\eta_{G'}$ and $\zeta_{G'}$. Similarly, if we consider a cost configuration $\tilde{c}$, we write $d_{\tilde{c}}$, $\eta_{\tilde{c}}$ and $\zeta_{\tilde{c}}$. Moreover, we denote the trivial cost configuration, i.e. the one that assigns no extra cost, by $\tilde{0}$.

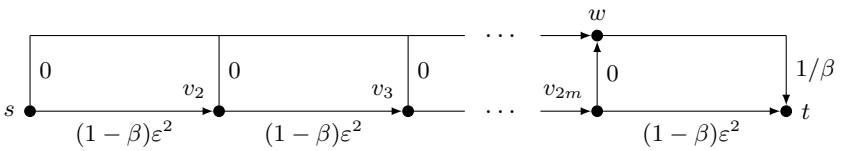

Figure 1 Graph maximizing the ratio between the efficiency of subgraphs and cost configurations.

It is interesting to think of penalty fees as a natural generalization of prohibition. This becomes particularly apparent in the context of Kleinberg and Oren's framework as we can recreate the properties of any subgraph G' by a cost configuration $\tilde{c}$. For this purpose, it is sufficient to assign an extra cost of $\tilde{c}(e) = r + 1$ to any edge e not contained in G'. As a result, the agent's perceived cost of paths along e certainly exceeds her perceived reward. However, this means that e is irrelevant to the agent's planning and could be deleted from G altogether. Consequently, penalties are at least as powerful as prohibition. But how much more efficient are penalties in the best case? As the following theorem suggests, cost configurations may outperform subgraphs by a factor of almost $1/\beta$.

▶ **Theorem 1.** *The ratio between the minimum reward r that admits a motivating subgraph and the reward q of a motivating cost configuration is at most $1/\beta$. This bound is tight.*

Proof. To see that $r/q \leq 1/\beta$, let G be an arbitrary task graph and consider a subgraph G' whose only edges are those of a cheapest path P from s to t. Recall that $d(s)$ denotes the cost of P. In G' the agent's only choice is to follow P. Because her perceived cost is a discounted version of the actual cost, she never perceives a cost greater than $d(s)$ in G'. Consequently, $d(s)/\beta$ is an upper bound on r. Next, consider an arbitrary cost configuration $\tilde{c}$. As $\tilde{c}$ only increases edge cost, the agent's lowest perceived cost at s is at least $\beta d(s)$. We conclude that q must be at least $d(s)$ to be motivating. This yields the desired ratio.

It remains to show the tightness of the result. For this purpose, we construct a task graph G such that: (a) The minimum reward that admits a motivating subgraph is $1/\beta^2$. (b) There exists a cost configuration that is motivating for a reward of $(1+\varepsilon)/\beta$, where ε is a positive value strictly less than 1. Our construction is a modified version of Alice's task graph. Let $m = \lceil \beta^{-2}(1-\beta)^{-1}\varepsilon^{-2} \rceil$ and assume that G contains a path $v_1, \ldots, v_{2m+1}$ whose edges are all of cost $(1-\beta)\varepsilon^2$. We call this the *main path* and set $s = v_1$ and $t = v_{2m+1}$. In addition to the main path, each v_i with $i \leq 2m$ has a *shortcut* to t via a common node w. The edges (v_i, w) are free, whereas (w, t) is of cost $1/\beta$. Figure 1 illustrates the structure of G. Note that the drawing merges some of the edges (v_i, w) for a concise representation.

We proceed to argue that G satisfies (a). For the sake of contradiction, assume the existence of a subgraph G' that is motivating for a reward $r < 1/\beta^2$. In this case the agent must not take shortcuts as her perceived cost at w exceeds her perceived reward. Therefore, she must follow the main path. In particular, she must visit each node v_i on the first half of the path, i.e. $i \leq m+1$. At each of these nodes, her lowest perceived cost is realized along the edge (v_i, v_{i+1}). Essentially, there are two ways she can come up with this cost. First, she might plan to take a shortcut at a later point in time. As a result, we get $\eta_{G'}(v_i, v_{i+1}) \geq c(v_i, v_{i+1}) + \beta c(w, t) > 1$. Secondly, she might plan to stay on the main path. In this case she must traverse at least m edges, each of which contributes $\beta(1-\beta)\varepsilon^2$ or more to $\eta_{G'}(v_i, v_{i+1})$. Consequently, we get $\eta_{G'}(v_i, v_{i+1}) \geq m\beta(1-\beta)\varepsilon^2 \geq 1/\beta \geq 1$. Either way her perceived cost for taking the main path is at least 1. As this tempts her to take the shortcut at v_i, all of the first $m+1$ shortcuts must be interrupted in G'. This means she must walk along at least m edges of the main path before taking the first shortcut. As a

Algorithm 1: PathAndFence

Input: Task graph G, present bias β, path $P = v_1, \dots, v_m$, positive value ε
Output: Cost configuration $\tilde{c}$

```
1 c̃ ← 0̃;
2 for i from m − 1 to 1 do
3     foreach w ∈ {w′ | (v_i, w′) ∈ E} do
4         if w ≠ v_{i+1} then c̃(v_i, w) ← max{0, η_c̃(v_i, v_{i+1}) − η_c̃(v_i, w) + βε/(m − 2)};
5 return c̃;
```

result, her lowest perceived cost at v_1 is at least $\zeta_{G'}(v_1) \geq m\beta(1-\beta)\varepsilon^2 \geq 1/\beta$. This is a contradiction to the assumption that r is motivating.

Next we show how to construct a cost configuration $\tilde{c}$ that satisfies (b). For this purpose it is sufficient to add an extra cost of ε to all edges (v_i, w). To upper bound the agent's perceived cost of (v_i, v_{i+1}), assume she plans to take a shortcut in the next step, i.e. at v_{i+1}. For $i < 2m$ we get $\eta_{\tilde{c}}(v_i, v_{i+1}) \leq c(v_i, v_{i+1}) + \beta(\tilde{c}(v_{i+1}, w) + c(w, t)) = (1-\beta)\varepsilon^2 + \beta\varepsilon + 1 < 1 + \varepsilon$. In the special case of $i = 2m$, the inequality $\eta_{\tilde{c}}(v_i, v_{i+1}) < 1 + \varepsilon$ is still satisfied, this time via the direct edge (v_{2m}, t). In contrast, the agent's perceived cost of an immediate shortcut is $\eta_{\tilde{c}}(v_i, t) = \varepsilon + \beta c(w, t) = 1 + \varepsilon$ for all $i \leq 2m$. Therefore, she is never tempted to divert from the main path. Furthermore, a reward of $q = (1+\varepsilon)/\beta$ is sufficient to keep her motivated. ◀

4 Computing Motivating Cost Configurations

We now turn our attention to the computational aspects of designing efficient penalty fees. In this section, we assume that the agent's reward is fixed to some value $r > 0$. Our goal is to compute cost configurations that are motivating for r whenever they exist. Similar to the prohibition-based commitment device [2], this task is NP-hard whenever the agent is present biased, i.e. $\beta \neq 1$. We will prove this claim at the end of the section. But first, assume that we already have partial knowledge of the solution. More precisely, assume we know one of the paths the agent might take in a motivating cost configuration provided a motivating cost configuration exists. We call this path P. Based on P, Algorithm 1 constructs a cost configuration $\tilde{c}$ that is motivating for a slightly larger reward $r + \varepsilon$.

The basic idea of Algorithm 1 is simple. Starting with v_{m-1}, it considers all nodes v_i of P in reverse order. For each v_i it assigns an extra cost of $\max\{0, \eta_{\tilde{c}}(v_i, v_{i+1}) - \eta_{\tilde{c}}(v_i, w) + \beta\varepsilon/(m-2)\}$ to the edges (v_i, w) that leave P, i.e. edges different from (v_i, v_{i+1}). As a result, the agent's perceived cost of (v_i, w) is greater than that of (v_i, v_{i+1}) by at least $\beta\varepsilon/(m-2)$. Consequently, she has no incentive to divert from P at v_i. Since the algorithm runs in reverse order, extra cost assigned in iteration i has no effect on the agent's behavior at later nodes, i.e. nodes v_j with $j > i$. Figuratively speaking, the algorithm builds a fence of penalty fees along P preventing the agent from leaving P. For this reason, we call the algorithm PathAndFence. As the next proposition suggests, cost configurations of this particular fence structure can achieve almost the same efficiency as any other cost configuration. Due to space constraints, refer to the full version of this work for a proof.

▶ **Proposition 2.** *Let P be the agent's path from s to t with respect to a cost configuration $\tilde{c}^*$ that is motivating for a reward r.* PathAndFence *constructs a cost configuration $\tilde{c}$ that is motivating for a reward of $r + \varepsilon$, where ε is an arbitrary small but positive quantity.*

Proposition 2 has some interesting implications. The first one is of conceptual nature.

Note that PathAndFence constructs a cost configuration that never actually charges the agent any extra cost. This suggests the existence of an efficient penalty-based commitment device that does not require the designer to enforce penalties. The mere threat of repercussions appears to be sufficient. The second implication is computational. Clearly, PathAndFence runs in polynomial-time with respect to n. In particular, the number of iterations does not depend on the choice of ε. Consequently, PathAndFence can be combined with an exhaustive search algorithm that considers all paths from s to t to search for a motivating cost configuration. Although the number of such paths can be exponential in n, this approach still reduces the size of the search space considerably. Finally, it should be noted that a similar result for the prohibition-based commitment device is unlikely to exist. The reason is that subgraphs remain hard to approximate even if the agent's optimal path is known [2], indicating a favorable computational complexity for the design of penalty fees. Of course there is another potential source of hardness: the computation of P. To prove that this is a limiting factor, we introduce the decision problem MOTIVATING COST CONFIGURATION:

▶ **Definition 3** (MCC)**.** Given a task graph G, a reward $r > 0$ and a present bias $\beta \in (0, 1]$, decide the existence of a motivating cost configuration.

We propose a reduction from 3-SAT to show that MCC is NP-complete for arbitrary $\beta \in (0, 1)$. At a later point we will use the same reduction to establish a hardness of approximation result.

▶ **Theorem 4.** *MCC is NP-complete for any present bias $\beta \in (0, 1)$.*

Proof. According to [2], whether or not a given task graph is motivating for a fixed reward can be verified in polynomial-time. Of course, this remains valid if the edges are assigned extra cost. Consequently, any motivating cost configuration is a suitable certificate for a "yes"-instance of MCC. We conclude that MCC is in NP. In the following, we present a reduction from 3-SAT to show that MCC is also NP-hard. This establishes the theorem.

Let $\mathcal{I}$ be an arbitrary instance of 3-SAT consisting of ℓ clauses $c_1, \ldots, c_\ell$ over m variables $x_1, \ldots, x_m$. We construct a MCC instance $\mathcal{J}$ such that its task graph G admits a motivating cost configuration for a reward of $r = 1/\beta$ if and only if $\mathcal{I}$ has a satisfying variable assignment. Figure 2 depicts G for a small sample instance of $\mathcal{I}$. In general, G consists of a source s, a target t and five nodes $u_1, \ldots, u_5$. Depending on $\mathcal{I}$, G also contains some extra nodes. For each variable x_k, there are two *variable nodes* $w_{k,T}$ and $w_{k,F}$. The idea is to interpret x_k as true whenever the agent visits $w_{k,T}$ and as false whenever she visits $w_{k,F}$. As a result, the agent's walk through G yields a variable assignment τ. Furthermore, for each clause c_i there is a *literal node* $v_{i,j}$ corresponding to the j-th literal of c_i. Our goal is to construct G in such a way that every motivating cost configuration guides the agent along literal nodes that are satisfied with respect to τ.

All nodes $v_{i,j}$ and $w_{k,y}$ are connected via so-called *forward edges*. More specifically, for all $1 \leq i < \ell$ and $1 \leq j, j' \leq 3$ there is a forward edge from $v_{i,j}$ to $v_{i+1,j'}$. Similarly, there is a forward edge from $w_{k,y}$ to $w_{k+1,y'}$ for all $1 \leq k < m$ and $y, y' \in \{T, F\}$. We also have forward edges from s to each $v_{1,j}$, from each $v_{\ell,j}$ to u_1, from u_2 to each $w_{1,y}$ and from each $w_{m,y}$ to u_3. For the sake of readability, some forward edges are merged in Figure 2. The price of each forward edge is $(1-\beta)^3 - \varepsilon$, where the encoding length of β is assumed to be polynomial in $\mathcal{I}$. Furthermore, ε denotes a small but positive quantity such that

$$\varepsilon < \min\left\{(1-\beta)^2, \frac{\beta(1-\beta)^3}{1+\beta}, \frac{\beta(1-\beta)^2}{1+\beta}\right\}.$$

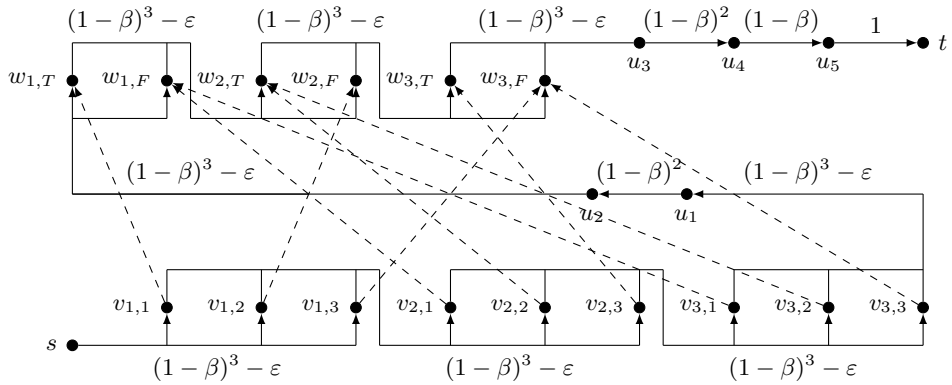

Figure 2 Reduction from the 3-SAT instance: $(\bar{x}_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \bar{x}_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$.

In addition to the forward edges, there are three types of *shortcuts*. The first type, which is depicted as dashed edges in Figure 2, connects each literal node $v_{i,j}$ to a distinct variable node via a single edge of cost $(1-\beta)^2$. If the j-th literal of c_i is equal to x_k, the shortcut goes to $w_{k,F}$. Otherwise, if the literal is negated, i.e. $\bar{x}_k$, the shortcut goes to $w_{k,T}$. The second type of shortcut goes from u_2 to t along a single edge of cost $2-\beta$. For clear representation, this shortcut is omitted in Figure 2. The third type of shortcut connects each variable node $w_{k,y}$ to t via a distinct intermediate node. The first edge is free while the second costs $2-\beta$. Again, shortcuts of this type are omitted in Figure 2 to keep the drawing simple. Finally, there are four more edges (u_1, u_2), (u_3, u_4), (u_4, u_5) and (u_5, t) of cost $(1-\beta)^2$, $(1-\beta)^2$, $1-\beta$ and 1 respectively. Note that G is acyclic and its encoding length is polynomial in $\mathcal{I}$.

To establish the theorem, we must show that $\mathcal{I}$ has a satisfying variable assignment if and only if $\mathcal{J}$ has a motivating cost configuration. A detailed argument is described in the full version of this work. At this point we only sketch the main ideas. For this purpose let $\tilde{c}$ be a cost configuration that is motivating for a reward of $1/\beta$ and let P be the agent's path through G with respect to $\tilde{c}$. Note that P cannot contain shortcuts of the second or third type as their edges are too expensive. Furthermore, P cannot contain a shortcut of the first type because the agent either perceives it as too expensive or is tempted to enter a shortcut of the third type immediately afterwards. As a result, P contains exactly one of the two nodes $w_{k,T}$ and $w_{k,F}$ for each variable x_k. Let $\tau : \{x_1, \dots, x_m\} \to \{T, F\}$ be the corresponding variable assignment. To keep the agent on P, $\tilde{c}$ must assign extra cost to all shortcuts that start at a variable node satisfied by τ. However, this raises the perceived cost of all paths via literal nodes not satisfied by τ to values that are not motivating. Consequently, P cannot contain such literal nodes. But P must contain exactly one literal node of each clause because P takes no shortcuts. This means that τ satisfies at least one literal in each clause and is therefore a feasible solution of $\mathcal{I}$. Conversely, whenever $\mathcal{I}$ has a feasible solution τ, we can construct a motivating cost configuration $\tilde{c}$ as follows: First, assign an appropriate extra cost, e.g. $(1-\beta)^2$, to the shortcuts of type three starting at the variable nodes $w_{k,\tau(x_k)}$. Secondly, block the forward edges into the variable nodes $w_{k,\tau(\bar{x}_k)}$ with high extra cost of e.g. 1. ◀

5 Approximating Motivating Cost Configurations

The previous section suggests that an optimal assignment of penalty fees is NP-hard to compute. This section therefore focuses on an optimization version of the problem. Our goal is to construct cost configurations that require the designer to raise the reward at t as little

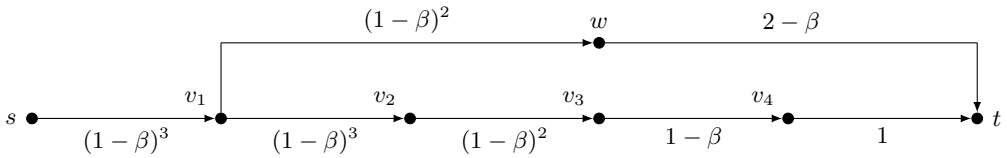

Figure 3 Task graph with no optimal cost configuration.

Algorithm 2: MinMaxPathApprox

Input: Task graph G, present bias β
Output: Cost configuration $\tilde{c}$

```
P ← minmax path from s to t with respect to η_{c̃0};
ϱ ← max{η_{c̃0}(e) | e ∈ P};
foreach v ∈ V \ {t} do
    ς(v) ← successor node of v on a cheapest path from v to t;
foreach (v, w) ∈ E do
    if (v, w) ∈ P ∨ (ς(v) = w ∧ v ∉ P) then c̃(v, w) ← 0;
    else if (v, w) ≠ P ∧ ς(v) ≠ w then c̃(v, w) ← 3ϱ/β;
    else
        P' ← v, ς(v), ς(ς(v)), ..., t;
        u ← first node of P' different from v that is also a node of P;
        e ← most expensive edge of P', between v and u;
        c̃(v, w) ← c(e);
return c̃;
```

as possible. However, before we provide a formal definition of the problem we should consider a curious technical detail; namely, not all task graphs admit an optimal cost configuration.

Consider, for instance, the task graph in Figure 3. At v_1 the agent is indifferent between the edges (v_1, v_2) and (v_1, w). In both cases her perceived cost is 1. If she chooses (v_1, w), she faces a perceived cost of $2 - \beta$ at w. Conversely, if she chooses (v_1, v_2), she perceives a cost of 1 at v_2, v_3 and v_4. Assuming that $\beta < 1$, (v_1, v_2) is the better choice. To break the tie between (v_1, w) and (v_1, v_2) we must place a positive extra cost of ε onto the upper path. However, when located at s the agent's perceived cost of the upper path is $1 + \beta\varepsilon$. In contrast, her perceived cost of the lower path is $1 + \beta(1-\beta)^3$. Assuming that $\varepsilon < (1-\beta)^3$, she prefers the upper path. Consequently, we can construct a cost configuration that is motivating for a reward arbitrarily close to $1/\beta$, but no cost configuration is motivating for a reward of exactly $1/\beta$. To account for the potential lack of an optimal solution, we compare our results to the infimum of all rewards that admit a motivating cost configuration. The optimization problem MCC-OPT is defined accordingly:

▶ **Definition 5** (MCC-OPT). Given a task graph G and a present bias $\beta \in (0, 1)$, determine the infimum of all rewards for which a motivating cost configuration exists.

We are now ready to introduce Algorithm 2. This algorithm enables us to construct cost configurations that approximate MCC-OPT within a factor of 2. At a high level, the algorithm proceeds in two phases. First, it computes a value ϱ such that ϱ/β is a lower bound for any reward that admits a motivating cost configuration. Secondly, it constructs a cost configuration $\tilde{c}$ that is motivating for a reward of $2\varrho/\beta$. This yields the promised approximation ratio of 2.

For a more detailed discussion of Algorithm 2 assume that each edge e is labeled with its perceived cost $\eta_{\tilde{0}}(e)$. Furthermore, let $\tilde{c}'$ be an arbitrary cost configuration and P' the agent's corresponding path from s to t. Our goal is to lower bound the minimum reward that is motivating for $\tilde{c}'$ by some value ϱ/β. For this purpose, it is instructive to observe that any motivating reward must be at least $\max\{\eta_{\tilde{c}'}(e) \mid e \in P'\}/\beta \geq \max\{\eta_{\tilde{0}}(e) \mid e \in P'\}/\beta$. Since P' can be an arbitrary path from s to t, we set

$$\varrho = \min\big\{\max\{\eta_{\tilde{0}}(e) \mid e \in P\} \;\big|\; P \text{ is a path from } s \text{ to } t\big\}.$$

In other words, ϱ is the maximum edge cost of a *minmax path* P from s to t with respect to $\eta_{\tilde{0}}$. Note that P can be computed in polynomial-time by adding the edges of G in non-decreasing order of perceived cost to an initially empty set E' until s and t become connected for the first time. Any path from s to t that only uses edges of E' is a suitable minmax path.

We continue with the construction of $\tilde{c}$. To facilitate this task, Algorithm 2 sets up a cheapest path successor relation ς. More precisely, it assigns a distinct successor node $\varsigma(v)$ to each $v \in V \setminus \{t\}$. The successor is chosen in such a way that $(v, \varsigma(v))$ is the initial edge of a cheapest path from v to t. Since we may assume that t is reachable from each node of G, all $v \neq t$ must have at least one suitable successor. By construction of ς, any path $P' = v, \varsigma(v), \varsigma(\varsigma(v)), \ldots, t$ is a cheapest path from v to t. We call P' the *ς-path* of v.

Once ς has been created, Algorithm 2 starts to assign an appropriate extra cost to all edges of G. The idea behind this assignment is to either keep the agent on P or guide her along a suitable ς-path. For this reason, we also call the algorithm MinMaxPathApprox. While iterating through the edges (v, w) of G the algorithm distinguishes between three types of edges: First, (v, w) might be an edge of P or an edge of a ς-path. In the latter case v must not be a node of P. Any (v, w) that satisfies these requirements is an edge we want the agent to traverse or use in her plans. Consequently, (v, w) is assigned no extra cost. Secondly, (v, w) might neither be an edge of P nor of a ς-path. Since we do not want the agent to traverse or plan along such an edge, the algorithm assigns an extra cost of $3\varrho/\beta$ to (v, w). This is sufficiently expensive for the agent to lose interest in (v, w) provided that the reward is $2\varrho/\beta$. Thirdly, (v, w) might not be an edge of P but of a ς-path such that v is a node of P. This is the most involved case. To find an appropriate cost for (v, w), the algorithm considers the ς-path P' of v. Let u be the first common node between P and P' that is different from v. Because P and P' both end in t, such a node must exist. Moreover, let e be the most expensive edge of P' between v and u. The algorithm assigns an extra cost of $c(e)$ to (v, w). As we will show in Theorem 6, this cost is either high enough to keep the agent on P or she travels to u along P' without encountering edges that are too expensive.

Clearly, Algorithm 2 can be implemented to run in polynomial-time with respect to the size of G. It remains to show that the algorithm returns a cost configuration $\tilde{c}$ that approximates MCC-OPT within a factor of 2.

▶ **Theorem 6.** MinMaxPathApprox *has an approximation ratio of* 2*.*

Proof. Recall that ϱ denotes the maximum perceived edge cost along the minmax path P. From the above description of MinMaxPathApprox, it should be evident that ϱ/β is a lower bound on the minimum motivating reward of any cost configuration. To prove the theorem, we need to show that the algorithm returns a cost configuration $\tilde{c}$ that is motivating for a reward of $2\varrho/\beta$.

As our first step we argue that the cost of a cheapest path from any node v to t with respect to $\tilde{c}$ is at most twice the cost of a cheapest path with respect to $\tilde{0}$. More formally, we prove that $d_{\tilde{c}}(v) \leq 2d_{\tilde{0}}(v)$. For this purpose let P' be the ς-path of v. By construction

of ς, P' is a cheapest path from v to t. It is crucial to observe that MinMaxApprox only assigns extra cost to an edge $(v', \varsigma(v'))$ of P' if v' is located on P. Consequently, there is at most one edge with extra cost between any two consecutive intersections of P and P'. Furthermore, this extra cost is equal to the cost of an edge on P' between v' and the next intersection of P and P'. Therefore, each edge of P' can contribute at most once to the total extra cost assigned to P'. This means that the price of P' with respect to $\tilde{c}$ is at most twice the price of P' with respect to $\tilde{0}$. Because the price of P' is an upper bound for $d_{\tilde{c}}(v)$, we have shown that $d_{\tilde{c}}(v) \leq 2d_{\tilde{0}}(v)$.

We proceed to investigate the agent's walk through G. Our goal is to show that her lowest perceived cost is at most 2ϱ at every node v on her way. This establishes the theorem. Our analysis is based on the following case distinction: First, assume that v is located on P. The immediate successor of v on P is denoted by w. Remember that $\tilde{c}$ assigns no extra cost to (v, w). Using the result from the previous paragraph, we get

$$\begin{aligned}\zeta_{\tilde{c}}(v) &\leq \eta_{\tilde{c}}(v,w) = c(v,w) + \beta d_{\tilde{c}}(w) \leq c(v,w) + \beta 2 d_{\tilde{0}}(w) \leq 2\big(c(v,w) + \beta d_{\tilde{0}}(w)\big) \\ &= 2\eta_{\tilde{0}}(v,w) \leq 2\varrho.\end{aligned}$$

The last inequality is valid by definition of ϱ.

Secondly, assume that v is not located on P and consider the last node v' on P the agent visited before v. Because she traversed $(v', \varsigma(v'))$ to get to v, we know that $\eta_{\tilde{c}}(v', \varsigma(v')) \leq 2\varrho$ and $d_{\tilde{c}}(\varsigma(v')) \leq 2\varrho/\beta$. We also know that she faces an extra cost of $3\varrho/\beta$ whenever she tries to leave the ς-path P' of v' before the next intersection of P and P'. Since she is not willing to pay this much, v must be located on P'. In particular, all paths from $\varsigma(v')$ to t either visit $\varsigma(v)$ or cross an edge that charges an extra cost of $3\varrho/\beta$. Consequently, a cheapest path from $\varsigma(v')$ to t with respect to $\tilde{c}$ costs at least $d_{\tilde{c}}(\varsigma(v')) \geq \min\{3\varrho/\beta, d_{\tilde{c}}(\varsigma(v))\}$. As $d_{\tilde{c}}(\varsigma(v')) \leq 2\varrho/\beta$, this implies that $d_{\tilde{c}}(\varsigma(v')) \geq d_{\tilde{c}}(\varsigma(v))$. Our proof is almost complete. For the final part, recall that $(v, \varsigma(v))$ is located on P' between v' and the next intersection of P and P'. By construction of $\tilde{c}$ we have $\tilde{c}(v', \varsigma(v')) \geq c(v, \varsigma(v))$. Furthermore, $(v, \varsigma(v))$ has no extra cost. Putting all the pieces together we get

$$\begin{aligned}\zeta_{\tilde{c}}(v) &\leq \eta_{\tilde{c}}(v, \varsigma(v)) = c(v, \varsigma(v)) + \beta d_{\tilde{c}}(\varsigma(v)) \leq \tilde{c}(v', \varsigma(v')) + \beta d_{\tilde{c}}(\varsigma(v')) \\ &\leq c(v', \varsigma(v')) + \tilde{c}(v', \varsigma(v')) + \beta d_{\tilde{c}}(\varsigma(v')) = \eta_{\tilde{c}}(v', \varsigma(v')) \leq 2\varrho.\end{aligned}$$

◀

To complement this result, we argue that MCC-OPT is NP-hard to approximate within any ratio of $1 + \beta(1-\beta)^4$ or less. Choosing $\beta = 1/5$ maximizes this term and yields inapproximability for constant ratios of 1.08192 or less. In particular, assuming that P $\neq$ NP this rules out the existence of a polynomial-time approximation scheme.

▶ **Theorem 7.** *MCC-OPT is NP-hard to approximate within a ratio less or equal to* 1.08192.

Proof. To establish the theorem, a reduction similar to the one from Theorem 4 can be used. In fact, given a 3-SAT instance $\mathcal{I}$ we can construct the corresponding MCC-OPT instance $\mathcal{J}$ the same way as in the proof of Theorem 4. The only difference is that our choice of ε is slightly more restrictive as we require

$$\varepsilon < \min\Big\{\beta(1-\beta)^3, \beta(1-\beta)^2(2-\beta), \frac{\beta^2(1-\beta)^3}{1+\beta}, \frac{\beta^2(1-\beta)^2(2-\beta)}{1+\beta}\Big\}.$$

The proof can be structured around the following properties of $\mathcal{J}$: (a) If $\mathcal{I}$ has a solution, $\mathcal{J}$ admits a motivating cost configuration for a reward of $1/\beta$. (b) If $\mathcal{I}$ has no solution, $\mathcal{J}$ admits no motivating cost configuration for a reward of $(1+\beta(1-\beta)^4)/\beta$ or less. Consequently,

any algorithm that approximates MCC-OPT within a ratio of $1+\beta(1-\beta)^4$ or less must also solve $\mathcal{I}$. To maximize this ratio we choose $\beta = 1/5$ and obtain the desired approximability bound, namely $1 + (1 - 1/5)^4/5 = 1.08192$. All that remains to show is that $\mathcal{J}$ indeed satisfies (a) and (b). The correctness of (a) is an immediate consequence of the proof of Theorem 4. A detailed proof of (b) can be found in the full version of this work. ◀

6 Conclusion

In this work we have used Kleinberg and Oren's graph theoretic framework [5] to provide a systematic analysis of a penalty-based commitment device. We have shown that penalty fees are strictly more powerful than prohibition. In particular, we have shown that penalties may outperform prohibition by a factor of up to $1/\beta$. We have also been able to obtain some of the first positive computational results for the algorithmic design of commitment devices. We have given a polynomial-time algorithm to construct penalty fees that match an optimal solution by a factor of 2. This is significant progress when compared to the prohibition-based commitment device, whose approximation is known to be NP-hard within a factor less than $\sqrt{n}/3$ [2]. Due to its versatility, expressiveness and favorable computational properties, we believe that our penalty-based commitment device will prove to be a valuable tool for addressing time-inconsistent behavior in complex social and economic settings.

Abstract

The *dispersion* problem has been widely studied in computational geometry and facility location, and is closely related to the packing problem. The goal is to locate n points (e.g., facilities or persons) in a k-dimensional polytope, so that *they are far away from each other and from the boundary of the polytope.* In many real-world scenarios however, the points arrive and depart at different times, and decisions must be made without knowing future events. Therefore we study, for the first time in the literature, the *online dispersion* problem in Euclidean space.

There are two natural objectives when time is involved: the *all-time worst-case* (ATWC) problem tries to maximize the minimum distance that ever appears at any time; and the *cumulative distance* (CD) problem tries to maximize the integral of the minimum distance throughout the whole time interval. Interestingly, the online problems are highly non-trivial even on a segment. For cumulative distance, this remains the case even when the problem is time-dependent but offline, with all the arriving and departure times given in advance.

For the online ATWC problem on a segment, we construct a deterministic polynomial-time algorithm which is $(2\ln 2+\epsilon)$-competitive, where $\epsilon > 0$ can be arbitrarily small and the algorithm's running time is polynomial in $\frac{1}{\epsilon}$. We show this algorithm is actually *optimal*. For the same problem in a square, we provide a 1.591-competitive algorithm and a 1.183 lower-bound. Furthermore, for arbitrary k-dimensional polytopes with $k \geq 2$, we provide a $\frac{2}{1-\epsilon}$-competitive algorithm and a $\frac{7}{6}$ lower-bound. All our lower-bounds come from the structure of the online problems and hold even when computational complexity is not a concern. Interestingly, for the offline CD problem in arbitrary k-dimensional polytopes, we provide a polynomial-time black-box reduction to the online ATWC problem, and the resulting competitive ratio increases by a factor of at most 2. Our techniques also apply to online dispersion problems with different boundary conditions.

1 Introduction

The problem of assigning elements to locations in a given area comes up only too often in real life: where to seat the customers in a restaurant, where to put certain facilities in a city, where to build nuclear power stations in a country, etc. Different problems have different features and constraints, but one common feature that appears in many of them is *not to locate the elements too close to each other*: for people's privacy, for environmental safety, and/or for serving more users. Another feature is also common in many applications: that is, *not to locate the elements too close to the boundary of the area.* Indeed, for security reasons, important national industrial facilities in many countries are built at a safe distance away from the border. Such problems have been widely studied in computational geometry and facility location; see, e.g., [32, 3, 2, 4]. In particular, in the *dispersion* problem defined by [2], there is a k-dimensional polytope P and an integer n, and the goal is to locate n points in P so as to maximize *the minimum distance among them and from them to the boundary of* P.

However, there is another important feature in all the scenarios mentioned above and many other real-world scenarios: the presence of elements is *time-dependent* and decisions need to be made along time, without knowing when the elements will come and go in the future. Indeed, it may be hard to move an element once it is located, making it infeasible for the decision maker to relocate all the present elements according to the optimal static solution when an arrival/departure event occurs. Online dispersion and facility location problems have been studied when the underlying locations are vertices of a graph [28, 17, 27]. In this paper we consider, for the first time in the literature, the online dispersion problem in Euclidean space. The arriving and departure times of points are chosen by an adversary who knows everything and works adaptively. An online dispersion algorithm decides where to locate a point upon its arrival, without any knowledge about future events.

1.1 Main Results

We focus on two natural objectives for the online problem: the *all-time worst-case* (ATWC) problem, which aims at maximizing the minimum distance that ever appears at any time; and the *cumulative distance* (CD) problem, which aims at maximizing the integral of the minimum distance throughout the whole time interval. Although polynomial-time constant approximations have been given when time is not involved [2, 4], nothing was known about the online problem. As we will show, solutions for the online problem are already complex even on a segment. For cumulative distance, even when the problem is time-dependent but offline, with all the arriving and departure times given in advance, it remains unclear how to efficiently compute the optimal solution. We formally define the problem in Section 2 and summarize our results in Table 1 below.

The most technical parts are the online ATWC problem and the offline time-dependent CD problem. Interestingly, we provide an efficient reduction from the offline CD problem to the online ATWC problem, and show that in order to solve the former, one can use an algorithm for the latter as a black-box. For the online ATWC problem, it is not hard to see that a natural greedy algorithm provides a 2-competitive ratio. Our main contributions for this problem are to provide an efficient algorithm that is optimal for the 1-dimensional case, improve the competitive ratio and prove a lower-bound for squares, and provide an efficient implementation of the greedy algorithm for the general case. We also prove a simple lower-bound for the general case.

To establish our results, we show interesting new connections between dispersion and ball-packing – both *uniform* packing (i.e., with balls of identical radius) and *non-uniform*

Table 1 Online and offline time-dependent dispersion problems in a k-dimensional polytope P.

	Online	Offline time-dependent
ATWC	$k = 1$: a $2\ln 2$ (≈ 1.386) lower-bound and an optimal algorithm; see Theorems 5 and 8. $k = 2$: a 1.183 lower-bound and a 1.591-competitive algorithm for squares; see Theorems 11 and 12. $k \geq 2$: a $\frac{7}{6}$ lower-bound and a $\frac{2}{1-\epsilon}$-competitive algorithm for arbitrary polytopes P; see Theorems 13 and 14.	Equivalent to dispersion without time; see Claim 2.
CD	No constant competitive algorithm even when $k = 1$; see Claim 1.	A black-box reduction to online ATWC for arbitrary k and P, with the competitive ratio scaling up by at most 2; see Theorem 15.

packing (i.e., with balls of different radii). All our algorithms are deterministic and of polynomial time. Some of them take an arbitrarily small constant ϵ as a parameter and the running time is polynomial in $\frac{1}{\epsilon}$. All inapproximability results hold even when running time is not a concern. Due to lack of space, most proofs are given in the full version [8].

Discussion and future directions. An algorithm for high-dimensional polytopes may not be directly applicable in dimension 1, because all locations are on the boundary when a segment is treated as a high-dimensional polytope, and the minimum distance is always 0. Accordingly, we do not know whether the lower-bound for dimension 1 carries through to higher dimensions, and proving better lower-bounds will be an interesting problem for future studies. In [8], we consider online dispersion without the boundary constraint, where the lower-bound for dimension 1 indeed carries through. We show all our algorithms can be adapted for this setting. Another important future direction is to understand the role of randomized algorithms in the online dispersion problem. Finally, improving the (deterministic or randomized) algorithms' competitive ratios in various classes of polytopes is certainly a long-lasting theme for the online dispersion problem. Special classes such as regular polytopes and uniform polytopes may be reasonable starting points. Given the connections between dispersion and ball-packing, it is conceivable that new competitive algorithms for online dispersion may stem from and also imply new findings on ball-packing.

1.2 Related Work

Dispersion without time. In dispersion problems in general, the possible locations can be either a *continuous* region or a set of *discrete* candidates. Two objectives have been studied in the literature: the *max-min distance* as considered in this paper, and the *maximum total distance*. In continuous settings, the authors of [2] consider the max-min distance with the boundary condition. Under L_∞-norm, they give a polynomial-time 1.5-approximation in rectilinear polygons[1] and show that a $\frac{14}{13}$-approximation in arbitrary polygons is NP-hard. Moreover, they show there is no PTAS under any norm unless P=NP. [4] considers a similar boundary condition under L_2-norm and provides a 1.5-approximation in polygons with

[1] A rectilinear polygon is a 2-dimensional polytope whose edges are axis-parallel.

obstacles. [11] considers the problem of selecting n points in n given unit-disks, one per disk, and the objective is to maximize the minimum distance.

In discrete settings, [32, 5] show that, if the distances among the candidate locations do not satisfy triangle inequality, then there is no polynomial-time constant approximation for either objective, unless P=NP; while if triangle inequality is satisfied, then there are efficient 2-approximations for both objectives. If the goal is to maximize total distance and the candidate locations are in a k-dimensional space, [15] gives a PTAS under L_1-norm; and [6, 7] provide PTASes when locations need to satisfy matroid constraints. Finally, [3, 31, 25, 1] consider various dispersion problems in obnoxious facility allocation.

Packing without time. It is well known that dispersion and packing are "dual" problems of each other [26]. In this paper we show interesting new connections between them and use several important results for packing in our analysis. Thus we briefly introduce this literature. Indeed, the packing problem is one of the most extensively studied problems in geometric optimization, and a huge amount of work has been done on different variants of the problem; see [30, 21] for surveys on this topic.

One important problem is to *pack circles with identical radius, as many as possible, in a bounded region.* [18] shows this problem to be strongly NP-hard and [22] gives a PTAS for it. An APTAS for the *circle bin packing* problem is given in [29]. The *dispersal packing* problem tries to maximize the radius of a given number of circles packed in a square. A lot of effort has been made in finding the optimal radius and the corresponding packing when the number of circles is a small constant; see [36, 35, 37, 30]. Heuristic methods have also been used in finding approximations when the number of circles gets large [24, 41]. Finally, an important packing problem is to understand the *packing density*: that is, the maximum fraction of an infinite space covered by a packing of unit circles/spheres. The packing density is solved for dimension 2 in [14] and for dimension 3 in [20]. Very recently, [42] and [9] solve it for dimensions 8 and 24, respectively. Asymptotic lower bounds (as the dimension grows) for the density of the densest packing are provided in [33].

Online geometric optimization. Many important geometric optimization problems have been studied in online settings, although the settings and objectives are quite different from ours. In particular, the seminal work of [38] provides a nearly-optimal competitive algorithm for the classic *online bin-packing* problem. Algorithms for variants of the problem have been considered ever since, such as a constant competitive ratio for packing circles in square bins [23], and constant competitive ratios for bin-packing in higher dimensions [12, 13].

In *online facility location* [28], it is the demands rather than the facilities that come along time. The facilities have open costs and the goal is to minimize the total open cost and the total distance between demands and facilities. As shown in [28], when the demands arrive adversarially, there is a randomized polynomial-time $O(\log n)$-competitive algorithm, and a constant competitive ratio is impossible. A deterministic $O(\frac{\log n}{\log \log n})$-competitive algorithm and a matching lower-bound are provided in [17]. In *incremental facility location* [16], the facilities can be opened, closed or merged, depending on the arriving demands. In [27, 34], there is a cost for each location configuration and the goal is to minimize the cost when the facilities arrive online. A constant competitive algorithm for this problem is provided in [27], and [34] gives a reduction from the online problem to the offline version of the problem.

Dynamic resource division. Fair resource division is an important problem in economics [39, 10, 40]. When the resource is 1-dimensional and homogenous, dynamic fair division

is in some sense the "dual" of online dispersion: locating n points as far as possible from each other and from the boundary is the same as partitioning the segment into $n+1$ pieces as evenly as possible. [19] provides an optimal d-disruptive mechanism for 1-dimensional homogenous resource. Interestingly, our algorithm for the 1-dimensional case provides an optimal mechanism when $d = 1$, although the techniques are quite different. Optimal mechanisms for heterogenous or high-dimensional resource remain unknown. It would be interesting to see if our techniques for dispersion can be used in resource division in general.

2 The Online Dispersion Problem

Given a k-dimensional polytope P, the *dispersion* problem [2] takes as input a positive integer n and outputs n locations, $X_1, \ldots, X_n \in P$, for n points. For each point i, let $dis(X_i, \partial P)$ be the distance from X_i to ∂P, the boundary of P, measured by L_2-norm. Also, let $dis(X_i, X_j)$ be the distance between X_i and X_j for any $i \neq j$. The objective is

$$Disp(n; P) \triangleq \max_{X_1,\ldots,X_n \in P} \min_{i,j\in[n]} \{dis(X_i, \partial P), dis(X_i, X_j)\}.$$

In [8], we also consider the dispersion problem where the distances to the boundary are not taken into consideration. Most of our techniques can be applied there.

We now define the *online dispersion* problem, where each point i arrives at time s_i and departs at time d_i, with $d_i > s_i$. Without loss of generality, $0 = s_1 \leq s_2 \leq \cdots \leq s_n$. An online algorithm is notified upon an arrival/departure event. It must decide the location X_i for i upon its arrival, knowing neither the future events nor the number n. An adversary knows how the algorithm works and chooses future events after seeing the algorithm's output so far. In the *time-dependent offline* version of the problem, the times of all events, denoted by a vector $S = ((s_1, d_1), \ldots, (s_n, d_n))$, is given to the algorithm in advance.

Given such a vector S, let $T = \max_{i\in[n]} d_i$ be the last departure time. Moreover, given locations $X = (X_1, \ldots, X_n)$, for any $t \leq T$, let

$$d_{min}(t; X) = \min_{i,j\in[n]: s_i \leq t \leq d_i, s_j \leq t \leq d_i} \{dis(X_i, \partial P), dis(X_i, X_j)\}$$

be the minimum distance corresponding to the points that are present at time t. When X is clear from the context, we may write $d_{min}(t)$ for short. We consider two natural objectives: the *all-time worst-case* (ATWC) problem, where the objective is

$$OPT_A(S; P) \triangleq \max_{X_1,\ldots,X_n} \min_{t\leq T} d_{min}(t);$$

and the *cumulative distance* (CD) problem, where the objective is

$$OPT_C(S; P) \triangleq \max_{X_1,\ldots,X_n} \int_0^T d_{min}(t)dt.$$

Note that both objectives are defined to be the optimum of the corresponding *offline* problems, the same as the *ex-post* optimum for the online problems. Below we provide two simple observations about the objectives.

▶ **Claim 1.** *For the CD problem, even when $k = 1$ and P is the unit segment, no (randomized) online algorithm achieves a competitive ratio to OPT_C better than $\Omega(n)$.*

Next, given any ex-post instance $S = ((s_1, d_1), \ldots, (s_n, d_n))$, let m be the maximum number of points simultaneously present at any time t: that is, $m = \max_{t\leq T} |\{i : s_i \leq t \leq d_i\}|$.

▶ **Claim 2.** *$\forall\ S = ((s_1, d_1), \ldots, (s_n, d_n))$, letting $m = \max_{t \le T} |\{i : s_i \le t \le d_i\}|$, we have $OPT_A(S; P) = Disp(m; P)$.*

In light of the claims above, the online CD problem is highly inapproximable and the offline ATWC problem is equivalent to the dispersion problem without time. Thus we will focus on the online ATWC problem and the offline CD problem, especially the former. Our results imply a simple $O(n)$-competitive algorithm for the online CD problem (see [8]), matching the lower-bound in Claim 1.

Below we point out some connections between dispersion and ball-packing: they are not hard to show, and similar results for the dispersion problem without the boundary condition have been pointed out in [26]. More precisely, the *(uniform) ball-packing* problem [22] in a polytope P takes as input a non-negative value r and outputs an integer n, the maximum number of balls of radius r that can be packed non-overlappingly in P, together with a corresponding packing. We denote the solution by $Pack(r; P)$. The *dispersal packing* problem [2] is a "mixture" of dispersion and packing: it takes as input an integer n and outputs the maximum radius for n balls with identical radius that can be packed in P, together with a corresponding packing. That is, $DP(n; P) \triangleq \max\{r : Pack(r; P) \ge n\}$.

Recall that a k-dimensional convex polytope P has an *insphere* if the largest ball contained wholly in P is tangent to *all* the facets (i.e., $(k-1)$-faces) of P. Such a ball, if it exists, is unique. It is referred to as *the* insphere of P. The center of the insphere maximizes the minimum distance for any point in P to its facets, and has the same distance to all facets – the radius of the insphere. We have the following two claims.

▶ **Claim 3.** *For any $k \ge 1$ and any k-dimensional convex polytope P with an insphere, letting x be the radius of the insphere, we have $Disp(n; P) = \frac{2xDP(n;P)}{x+DP(n;P)}$.*

▶ **Claim 4.** *For any $k \ge 1$ and any k-dimensional convex polytope P with an insphere, given the radius of the insphere,*
(1) *any polynomial-time algorithm for $Disp(n; P)$ implies such an algorithm for $Pack(r; P)$;*
(2) *any polynomial-time algorithm for $Pack(r; P)$ implies an FPTAS for $Disp(n; P)$.*

To the best of our knowledge, it is still unknown whether ball-packing in regular polytopes (which is a special case of convex polytopes with an insphere) is NP-hard or not. Therefore the complexity of dispersion in regular polytopes remains open. Note that ball-packing in arbitrary polytopes is NP-hard [18], so is a $\frac{14}{13}$-approximation for dispersion in rectilinear polygons [2]. Moreover, a claim similar to Claim 4 applies to $DP(n; P)$ and $Pack(r; P)$ in arbitrary polytopes. The relation between dispersion and packing in arbitrary polytopes is not so clear and worth further investigation: for example, it would be interesting to know if there exists a counterpart of Claim 4 when the polytope does not have an insphere.

Finally, the *insert-only* model, where all points have the same departure time, is a special case of our general model. Interestingly, as will become clear in our analysis, the difficulty of the general online ATWC problem is captured by the problem under this special model. The insert-only model was also considered by [27, 34] in settings different from ours and with a different objective function. We further discuss this model in [8].

3 The 1-Dimensional Online All-Time Worst-Case Problem

Note that a 1-dimensional polytope is simply a segment. Without loss of generality, we consider the unit segment $P = [0, 1]$. Below we first provide a lower bound for the competitive ratio of any algorithm, even computationally unbounded ones.

Figure 1 The pre-fixed positions in Q for dimension 1.

3.1 The Lower Bound

▶ **Theorem 5.** *No online algorithm achieves a competitive ratio better than* $2\ln 2$ *(*≈ 1.386*) for the 1-dimensional ATWC problem.*

Proof Ideas. Letting $\sigma'_r = \sum_{i=r+1}^{2r} \frac{1}{i}$ for any positive integer r, we show that no algorithm achieves a competitive ratio better than $2\sigma'_r$. Roughly speaking, we construct an instance (i.e., an adversary) for the online ATWC problem with three stages. In the first stage, $r-1$ points arrive simultaneously; in the second stage, r new points arrive one by one; and finally, all $2r-1$ points depart simultaneously. If an algorithm $\mathcal{A}$ is α-competitive to OPT_A with $\alpha < 2\sigma'_r$, it must be α-competitive after the arrival of each point, as it does not know the total number of points. Thus for each arriving point, there must exist an interval long enough such that putting the new point inside the interval does not violate the competitive ratio. We show that in order for $\mathcal{A}$ to do so, the segment must be longer than P itself, a contradiction. Theorem 5 holds by setting $r \to \infty$. The complete proof is in [8]. ◀

3.2 A Polynomial-Time Online Algorithm

Next, we provide a deterministic polynomial-time online algorithm whose competitive ratio to OPT_A can be arbitrarily close to $2\ln 2$. Intuitively, a good algorithm should disperse the points as evenly as possible. However, if at some point of time with m points present, the resulting $m+1$ intervals on the segment have almost the same length, then the next arriving point will force the minimum distance to drop by a factor of 2, while the optimum only changes from $\frac{1}{m+1}$ to $\frac{1}{m+2}$, causing the competitive ratio to drop by almost 2. To overcome this problem, the algorithm must find a balance between two consecutive points, choosing a sub-optimal solution for the former so as to leave enough space for the latter. The difficulty, as for online algorithms in general, is that this balance needs to be kept for arbitrarily many pairs of consecutive point, as the sequence of points is chosen by an adversary who observes the algorithm's output. Inspired by our lower bound, roughly speaking, our algorithm uses a parameter r to pre-fix the locations of the first r points and the resulting $r+1$ intervals, and then inserts the next $r+1$ points in the middle of these intervals. The idea is that, when done properly, after these $2r+1$ points, the resulting configuration is almost the same as if the algorithm has used parameter $2r+1$ to pre-fix the first $2r+2$ intervals: then the procedure can repeat for arbitrary sequences.

More specifically, given a positive integer r, let $Q = \{q_1, \ldots, q_r\}$ be a set of positions on the segment, such that the length ratios of the $r+1$ intervals sliced by them are $\frac{1}{r+1} : \frac{1}{r+2} : \cdots : \frac{1}{2r+1}$. That is, letting $\sigma_r = \sum_{i=r+1}^{2r+1} \frac{1}{i}$, the lengths of the intervals are $\frac{1}{\sigma_r(r+1)}$, $\frac{1}{\sigma_r(r+2)}$, $\cdots$, $\frac{1}{\sigma_r(2r+1)}$, and $q_i = \frac{1}{\sigma_r} \sum_{j=r+1}^{r+i} \frac{1}{j}$ for each $i \in [r]$, as illustrated by Figure 1, with $q_0 = 0$ and $q_{r+1} = 1$. Note that σ_r differs from σ'_r in Theorem 5 by $\frac{1}{2r+1}$. Also, σ_r is strictly decreasing in r and $\lim_{r\to\infty} \sigma_r = \ln 2$. Moreover, for any two intervals (q_{j-1}, q_j) and $(q_{j'-1}, q_{j'})$ with $j < j' \le r+1$, we have $|(q_{j'-1}, q_{j'})| < |(q_{j-1}, q_j)| < 2|(q_{j'-1}, q_{j'})|$.

Our algorithm, Algorithm 1, also takes as parameter an ordering for the positions in Q, denoted by $\tau = (\tau_1, \tau_2, \ldots, \tau_r)$. We have the following two lemmas, whose main ideas are sketched below. Recall that, given $S = ((s_1, d_1), \ldots, (s_n, d_n))$, m is the maximum number of points simultaneously present at any time t.

Algorithm 1. A polynomial-time algorithm for the 1-dimensional online ATWC problem.

Parameter: A positive integer r, the corresponding set $Q = \{q_1, \ldots, q_r\}$, and an ordering τ for Q.

Input: A sequence of points arriving and departing along time.

Denote by $\hat{Q}$ the set of positions ever occupied by a point. At any point of time, a position in $\hat{Q}$ is labeled *occupied* if currently there is a point there and *vacant* otherwise. Initially $\hat{Q} = \emptyset$.
When a point i leaves, change the label of its position in $\hat{Q}$ from *occupied* to *vacant*.
When a point i arrives:
if $\hat{Q} = \emptyset$ or all positions in $\hat{Q}$ are labelled *occupied* **then**
  if $Q \not\subseteq \hat{Q}$ **then**
    Choose the first position q according to τ with $q \in Q \setminus \hat{Q}$, add it to $\hat{Q}$ and label it *occupied*.
    Put i at position q.
  else
    Find position q which is the middle of the largest interval created by the positions in $\hat{Q}$.
    Put i at position q, add q to $\hat{Q}$ and label it *occupied*.
  end if
else
  Arbitrarily choose a vacant position q from $\hat{Q}$ and label it *occupied*.
  Put i at position q.
end if

▶ **Lemma 6.** *$\forall$ r and τ, Algorithm 1 is $2\sigma_r$-competitive to OPT_A for any S with $m > r$.*

Proof Ideas. Since Algorithm 1 only creates a new position when the number of points simultaneously present on the line increases, for any time t, the number of positions created is exactly the maximum number of points that has appeared simultaneously on the line. Thus only m positions is created for instance S. We prove that when $m > r$, the minimum distance produced by our algorithm, denoted by $d_{min}(m)$, is $\frac{1}{2^{l+1}\sigma_r(r+i)}$, where l, i are the unique integers such that $l \geq 0, 0 \leq i \leq r+1$ and $2^l(r+1) + 2^l(i-1) \leq m < 2^l(r+1) + 2^l i$. Note that the minimum distance only depends on m. By comparing OPT_A with $d_{min}(m)$, we show that the competitive ratio $2\sigma_r$ holds for all $m > r$. ◀

▶ **Lemma 7.** *For any integer $l > 0$ and $r = 2^l - 1$, there exists an ordering τ for the corresponding set Q, s.t. Algorithm 1 is $2\sigma_r$-competitive to OPT_A for any S with $m \leq r$.*

Proof Ideas. Interestingly, due to the structure of Algorithm 1, we only need to consider the instance $S = ((1, r+1), (2, r+1), \ldots, (r, r+1))$. We construct an ordering $\tau = \{\tau_d\}_{d \in [r]}$ for Q such that the competitive ratio at any time $d \in [r]$ is smaller than $2\sigma_r$. To do so, we fill in a complete binary tree with r nodes as in Figure 2, and τ is obtained by traversing the tree in a breadth-first manner starting from the root. Given any $d = 2^i + s$ with $i \in \{0, 1, \ldots, l-1\}$ and $s \in \{0, 1, \ldots, 2^i - 1\}$, we have $\tau_d = q_{2^{l-i-1}(2s+1)}$. Denoting the competitive ratio at time d by $apx(d)$, we prove that

$$apx(d) = \frac{\sigma_r}{(2^i + s + 1) \cdot \sum_{j=2^l+2^{l-i-1}(2s+1)}^{2^l-1+2^{l-i-1}(2s+2)} \frac{1}{j}}.$$

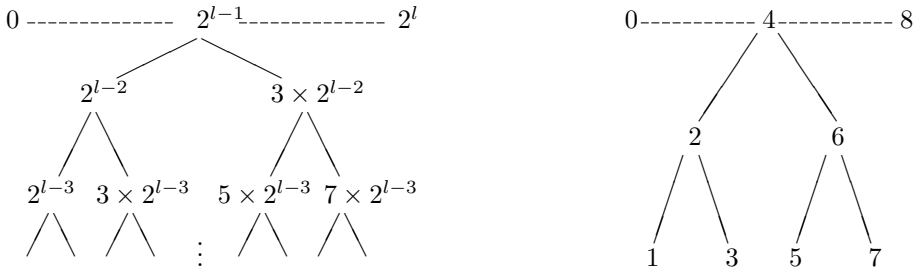

Figure 2 The left-hand side shows the top three levels of the binary tree for a general l, with $\tau = (q_{2^{l-1}}, q_{2^{l-2}}, q_{3\times 2^{l-2}}, q_{2^{l-3}}, q_{3\times 2^{l-3}}, q_{5\times 2^{l-3}}, q_{7\times 2^{l-3}}, \dots)$. The right-hand side shows the complete binary tree for $l = 3$, with $\tau = (q_4, q_2, q_6, q_1, q_3, q_5, q_7)$.

Writing $apx(d)$ as $apx(i, s)$, we prove that, fixing i, $apx(i, s)$ is strictly increasing in s; and letting $s = 2^i - 1$, $apx(i, s)$ is strictly increasing in i. Thus the worst competitive ratio occurs at $i = l-1$ and $s = 2^{l-1} - 1$. As $apx(l-1, 2^{l-1}-1) = (2 - \frac{1}{2^l})\sigma_r < 2\sigma_r$, Lemma 7 holds. ◀

The theorem below follows easily from the above two lemmas.

▶ **Theorem 8.** *There exists a deterministic polynomial-time online algorithm for the ATWC problem, whose competitive ratio can be arbitrarily close to* $2\ln 2$. *Moreover, the running time is polynomial in* $\frac{1}{\epsilon}$ *for competitive ratio* $2\ln 2 + \epsilon$.

Remark. When the number of points is large but the maximum number m of simultaneously present points is small, the running time of the algorithm for each arriving point is polynomial in m and can be much faster than being polynomial in the size of the input.

Following Theorem 5, Algorithm 1 is essentially optimal. Inspired by our constructions of Q and τ, we actually characterize the optimal solution for the online ATWC problem, whose competitive ratio is exactly $2\ln 2$: see Theorem 9. However, this solution involves irrational numbers and cannot be exactly computed in polynomial time.

▶ **Theorem 9.** *For any integer* $d = 2^i + s$ *with* $i \geq 0$ *and* $0 \leq s \leq 2^i - 1$, *let* $\tau_d = \log_2(1 + \frac{2s+1}{2^{i+1}})$. *If Algorithm 1 creates the d-th new position in* $\hat{Q}$ *to be* τ_d, *the competitive ratio is* $2\ln 2$.

4 The 2-Dimensional Online All-Time Worst-Case Problem

We now consider the 2-dimensional online ATWC problem in a square – without loss of generality, $P = [0, 1]^2$. One difficulty is that, different from the 1-dimensional problem where it is trivial to have $Disp(n; P) = \frac{1}{n+1}$ for any $n \geq 1$, here neither $Disp(n; P)$ nor $Pack(r; P)$ has a known closed-form optimal solution (whether polynomial-time computable or not). Accordingly, our lower-bound and our competitive algorithm must rely on some proper upper- and lower-bounds for $Disp(n; P)$, which is part of the reason why the resulting bounds are not tight. In particular, we have the following.

▶ **Lemma 10.** *For any* $n \geq 1$, $\frac{2}{5+\sqrt{2\sqrt{3}n}} \leq Disp(n; P) \leq \frac{2}{2+\sqrt{2\sqrt{3}n}}$.

4.1 The Lower Bound

Interestingly, not only the dispersion problem is closely related to *uniform* packing (i.e., the disks all have the same radius) as we have seen in Section 2, but we also obtain a lower bound for the online ATWC problem by carefully fitting a *non-uniform* packing into the square.

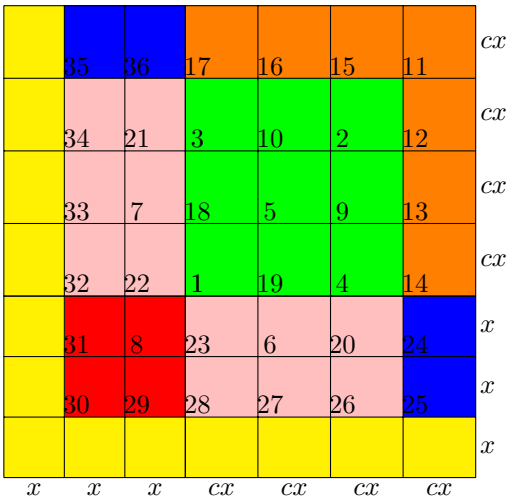

Figure 3 The set of pre-fixed positions, $Q = \{q_1, \ldots, q_{36}\}$, and the grid created by Q. A grid point labelled by i indicates the position q_i. The colored areas are used in the algorithm's description. More specifically, denoting a rectangle by the position in Q at its lower-left corner, the green area is $(3, 10, 2; 18, 5, 9; 1, 19, 4)$; the two pink areas are $(23, 6, 20; 28, 27, 26)$ and $(34, 21; 33, 7; 32, 22)$; the red area is $(31, 8; 30, 29)$; the two blue areas are $(35, 36)$ and $(24, 25)$; the orange area is $(17, 16, 15, 11, 12, 13, 14)$; and finally the yellow area contains all the remaining rectangles: that is, rectangles adjacent to the left boundary and the bottom boundary.

The idea is to imagine each position created in an online algorithm as a disk centered at that position. The radius of each disk is a function of the algorithm's competitive ratio and the optimal solutions to specific dispersion problems without time. Note that the area covered by the disks is upper-bounded by the area of the square containing them. Combining these relations together gives us the following theorem.

▶ **Theorem 11.** *No online algorithm achieves a competitive ratio better than 1.183 for the 2-dimensional ATWC problem in a square.*

4.2 A Polynomial-Time Online Algorithm

Now we provide a deterministic polynomial-time online algorithm which is 1.591-competitive to OPT_A. Similar to Algorithm 1, we construct a set Q of pre-fixed positions. However, it is unclear how to define Q of arbitrary size in the square, and we construct a set of 36 positions, denoted by $Q = \{q_1, \ldots, q_{36}\}$. It depends on a parameter $1 < c < \sqrt{2}$ and $x = \frac{1}{3+4c}$, as in Figure 3. The q_i's indices specify the order according to which they should be occupied, thus we do not need an extra ordering τ. Note these positions create a grid in P and split it into multiple rectangles. The choice of c (and x, Q) will become clear in the analysis.

Whenever a new position needs to be created, we pick the first position in Q that has never been occupied yet. When all positions in Q are occupied, we may (1) create a new position in the center of a current rectangle with the largest area, split this rectangle into four smaller ones accordingly, and add the vertices of the new rectangles into the grid; or (2) create a new position at a grid point that has never been occupied yet. The main Algorithm 2 is similar to Algorithm 1. It uses in Step 8 a sub-routine to implement (1) and (2) above: the *Position Creation Phase,* as defined in [8], where we further provide some intuition on the choices of Q, x, and c. Setting $c = 1.271$, we have the following.

Algorithm 2. A polynomial-time online algorithm for the ATWC problem in a square.

Parameter: c such that $1 < c < \sqrt{2}$, the corresponding $x = \frac{1}{3+4c}$, and Q.
Input: A sequence of points arriving and departing along time.

Denote by $\hat{Q}$ the set of positions ever occupied by a point. At any point of time, a position in $\hat{Q}$ is labeled *occupied* if currently there is a point there and *vacant* otherwise. Initially $\hat{Q} = \emptyset$.
When a point w leaves, change the label of its position in $\hat{Q}$ from *occupied* to *vacant*.
When a point w arrives:
if $\hat{Q} = \emptyset$ or all positions in $\hat{Q}$ are labelled *occupied* **then**
  if $|\hat{Q}| < 36$ **then**
    Put w at position $q_{|\hat{Q}|+1}$, add this position to $\hat{Q}$ and label it *occupied*.
  else
    Compute a position q according to the Position Creation Phase defined in [8].
    Put w at position q, add q to $\hat{Q}$ and label it *occupied*.
  end if
else
  Arbitrarily choose a vacant position q from $\hat{Q}$ and label it *occupied*.
  Put w at position q.
end if

▶ **Theorem 12.** *Algorithm 2 runs in polynomial time and is* 1.591*-competitive for the 2-dimensional online ATWC problem in a square.*

Note that the upper-bound for $Disp(n; P)$ in Lemma 10 is not tight when n is small. With better upper-bounds for $Disp(n; P)$, better competitive ratios for our algorithm can be directly obtained via a similar analysis. Moreover, we believe the competitive ratio can be improved by using a larger set Q and the best ordering for positions in Q. Such a Q and a rigorous analysis based on it are left for future studies. Finally, similar techniques can be used when P is a rectangle, but the gap between the lower- and upper-bounds will be even larger, and the analysis will be more complicated without adding much new insight to the problem. Thus we leave a thorough study on rectangles for the future.

5 The General k-Dimensional Online ATWC Problem

Although the literature gives us little understanding about the optimal dispersion/packing problem in an arbitrary k-dimensional polytope P with $k \geq 2$, we are still able to provide a simple lower-bound and a simple polynomial-time algorithm for the online ATWC problem. Below we only state the theorems.

▶ **Theorem 13.** *For any $k \geq 2$, no online algorithm achieves a competitive ratio better than $\frac{7}{6}$ for the ATWC problem for arbitrary polytopes.*

For any polytope P, letting the *covering rate* be the ratio between the edge-lengths of the maximum inscribed cube and the minimum bounding cube, we have the following theorem. Note that, although a natural greedy algorithm provides a 2-competitive ratio, the exact greedy solution may not be computable in polynomial time. Here we show the greedy algorithm can be efficiently approximated arbitrarily closely. The geometric problems of finding the minimum bounding cube, deciding whether a position is in P, and finding the distance between a point in P and the boundary of P are given as oracles.

Algorithm 3. Algorithm $\mathcal{A}_{\mathcal{I}}$ for computing $\mathcal{I} = \{\mathcal{I}_1, \mathcal{I}_2\}$ satisfying properties Φ.1 and Φ.2.

Input: A sequence $S = ((s_1, d_1), \ldots, (s_n, d_n))$.

Let $\mathcal{I}_1 = \mathcal{I}_2 = \emptyset$, $s = -1$, $d = 0$ and $T = \max_{i\in[n]} d_i$. (s and d are end-points of a "sliding window" for the arriving times under consideration.)
Let $index = 1$.
while d $\neq T$ **do**
  Let $\hat{S} = \{i | i \in S, s_i > s, s_i \leq d, d_i > d\}$.
  if $\hat{S} \neq \emptyset$ **then**
    Arbitrarily choose $j \in \arg\max_{i\in\hat{S}} d_i$ and add j to $\mathcal{I}_{index}$; $s = d$; then $d = d_j$.
  else
    $s = d$; then $d = \min_{i\in S, s_i > d} s_i$.
  end if
  $index = 3 - index$.
end while
Output $\mathcal{I} = \{\mathcal{I}_1, \mathcal{I}_2\}$.

▶ **Theorem 14.** *For any constants $\gamma, \epsilon > 0$, integer $k \geq 2$ and k-dimensional polytope P with covering rate at least γ, there exists a deterministic polynomial-time online algorithm for the ATWC problem, with competitive ratio $\frac{2}{1-\epsilon}$ and running time polynomial in $\frac{1}{(\gamma\epsilon)^k}$.*

6 The General k-Dimensional Offline CD Problem

By Claim 1, no online algorithm provides a good competitive ratio for the CD problem, thus we focus on the offline problem. Given an input sequence $S = ((s_1, d_1), \ldots, (s_n, d_n))$, we first slice the whole time interval $[0, T]$ into smaller ones by the arriving time s_i and the departure time d_i of each point $i \in [n]$. Thus the set of present points only changes at the end-points of the intervals and stays the same within an interval. Our algorithm will be such that, *in each time interval,* the minimum distance is a good approximation to the optimal dispersion problem without time, for the points present in this interval.

Interestingly, this is achieved by reducing the offline CD problem to the online ATWC problem, for any dimension k and polytope P. To carry out this idea, we first provide a polynomial-time algorithm $\mathcal{A}_{\mathcal{I}}$ (Algorithm 3) that, given a sequence S, selects a subset $\mathcal{I}$ of points from S. The set $\mathcal{I}$ satisfies the following properties, as proved in [8].

(Φ.1) $\mathcal{I}$ can be partitioned into two groups $\mathcal{I}_1$ and $\mathcal{I}_2$ such that the points in the same group have disjoint time intervals.

(Φ.2) For any time $0 \leq t \leq T$, if there are points in S present at time t, then at least one of them is selected to $\mathcal{I}$.

The offline CD algorithm $\mathcal{A}_{CD}$ uses algorithm $\mathcal{A}_{\mathcal{I}}$ to select $\mathcal{I}$ from its input S, eliminates the selected points from S, and repeats on the remaining S. Recall that m is the maximum number of points simultaneously present at any time. By property Φ.2, this procedure ends in at most m iterations. Based on the partitions constructed by $\mathcal{A}_{\mathcal{I}}$, $\mathcal{A}_{CD}$ constructs an instance of the online ATWC problem and uses any online algorithm $\mathcal{A}_{ATWC}$ for the latter as a black-box, so as to decide how to locate the points. Algorithm $\mathcal{A}_{CD}$ is defined in Algorithm 4 and we have the following theorem. Below we sketch the main ideas.

Algorithm 4. $\mathcal{A}_{CD}$

Input: A sequence $S = ((s_1, d_1), \ldots, (s_n, d_n))$.

1: Let $r = 0$.
2: **while** $S \neq \emptyset$ **do**
3: Run $\mathcal{A}_{\mathcal{I}}$ on S to obtain two disjoint sets $\mathcal{I}_{2r+1}, \mathcal{I}_{2r+2} \subseteq S$.
4: $S = S \setminus (\mathcal{I}_{2r+1} \cup \mathcal{I}_{2r+2})$.
5: $r = r + 1$.
6: **end while**
7: Run $\mathcal{A}_{ATWC}$ on the following online sequence of $2r$ points: for all $i \in \{0, 1, \ldots, r-1\}$, points $2i+1$ and $2i+2$ arrive at time i. All points depart at time r.
8: Letting x_{2i+1}, x_{2i+2} be the two positions returned by $\mathcal{A}_{ATWC}$ at time i, assign all points in $\mathcal{I}_{2i+1}$ to x_{2i+1} and all points in $\mathcal{I}_{2i+2}$ to x_{2i+2}.

▶ **Theorem 15.** *$\forall\ k \geq 1$ and k-dimensional polytope P, given any polynomial-time σ-competitive online algorithm $\mathcal{A}_{ATWC}$ for ATWC, there is a polynomial-time offline algorithm $\mathcal{A}_{CD}$ for CD with competitive ratio $\sigma \max_{i \geq 1} \frac{Disp(i;P)}{Disp(2i;P)} \leq 2\sigma$, using $\mathcal{A}_{ATWC}$ as a black-box.*

Proof Ideas. Given an input sequence S, we slice the whole time interval $[0, T]$ into smaller ones according to the arriving time and the departure time of each point. Denote these small intervals by $T_1, \ldots, T_l$, where l is the number of small intervals created. For each interval T_i, let S_i be the set of points that overlap with T_i and $n_i = |S_i|$. By properties $\Phi.1$ and $\Phi.2$, all points in S_i are eliminated from S in the first n_i iterations of $\mathcal{A}_{\mathcal{I}}$, thus are located at the first $2n_i$ positions created by $\mathcal{A}_{ATWC}$. The minimum distance among points in T_i (and to the boundary) is at least $\frac{Disp(2n_i;P)}{\sigma}$, since algorithm $\mathcal{A}_{ATWC}$ has competitive ratio σ. Thus, within each T_i, the competitive ratio to the optimal solution is upper-bounded by $\frac{\sigma Disp(n_i;P)}{Disp(2n_i;P)}$. Taking summation over all T_i's, the competitive ratio is upper-bounded by $\sigma \max_{i \geq 1} \frac{Disp(i;P)}{Disp(2i;P)}$. Finally, we prove $\max_{i \geq 1} \frac{Disp(i;P)}{Disp(2i;P)} \leq 2$, finishing the proof of Theorem 15. ◀

Abstract

We consider fractional online covering problems with ℓ_q-norm objectives. The problem of interest is of the form $\min\{f(x) : Ax \geq 1, x \geq 0\}$ where $f(x) = \sum_e c_e \|x(S_e)\|_{q_e}$ is the weighted sum of ℓ_q-norms and A is a non-negative matrix. The rows of A (i.e. covering constraints) arrive online over time. We provide an online $O(\log d + \log \rho)$-competitive algorithm where $\rho = \frac{\max a_{ij}}{\min a_{ij}}$ and d is the maximum of the row sparsity of A and $\max |S_e|$. This is based on the online primal-dual framework where we use the dual of the above convex program. Our result expands the class of convex objectives that admit good online algorithms: prior results required a monotonicity condition on the objective f which is not satisfied here. This result is nearly tight even for the linear special case. As direct applications we obtain (i) improved online algorithms for non-uniform buy-at-bulk network design and (ii) the first online algorithm for throughput maximization under ℓ_p-norm edge capacities.

1 Introduction

The online primal-dual approach is a widely used approach for online problems. This involves solving a discrete optimization problem online as follows (i) formulate a linear programming relaxation and obtain a primal-dual online algorithm for it; (ii) obtain an online rounding algorithm for the resulting fractional solution. While this is similar to a linear programming (LP) based approach for offline optimization problems, a key difference is that solving the LP relaxation in the online setting is highly non-trivial. (Recall that there are general polynomial time algorithms for solving LPs offline.) So there has been a lot of effort in obtaining good online algorithms for various classes of LPs: see [1, 13, 23] for pure covering LPs, [13] for pure packing LPs and [5] for certain mixed packing/covering LPs. Such online LP solvers have been useful in obtaining online algorithms for various problems, eg. set cover [2], facility location [1], machine scheduling [5], caching [8] and buy-at-bulk network design [21].

Recently, [6] initiated a systematic study of online fractional covering and packing with *convex* objectives; see also the full versions [7, 11, 15]. These papers obtained good online algorithms for a large class of fractional convex covering problems. They also demonstrated the utility of this approach via many applications that could not be solved using just online LPs. However these results were limited to convex objectives $f : \mathbb{R}^n_+ \to \mathbb{R}_+$ satisfying a

monotone gradient property, i.e. $\nabla f(z) \geq \nabla f(y)$ pointwise for all $z, y \in \mathbb{R}^n$ with $z \geq y$. There are however many natural convex functions that do not satisfy such a gradient monotonicity condition. Note that this condition requires the Hessian $\nabla^2 f(x)$ to be pointwise non-negative in addition to convexity which only requires $\nabla^2 f(x)$ to be positive semidefinite.

In this paper, we focus on convex functions f that are sums of different ℓ_q-norms. This is a canonical class of convex functions with non-monotone gradients and prior results are not applicable; see Section 1.1 for a more detailed comparison. We show that sum of ℓ_q-norm functions admit a logarithmic competitive online algorithm. This result is nearly tight because there is a logarithmic lower bound even for online covering LPs (which corresponds to an ℓ_1 norm objective). We also provide two applications of our result (i) improved competitive ratios (by two logarithmic factors) for some online non-uniform buy-at-bulk problems studied in [21], and (ii) the first online algorithm for throughput maximization with ℓ_p-norm edge capacities (the competitive ratio is logarithmic which is known to be best possible even in the special case of individual edge capacities).

Given that we achieve log-competitive online algorithms for sums of ℓ_q-norms, a natural question is whether such a result holds for all norms. Recall that any norm is a convex function. It turns out that a log-competitive algorithm is not possible for general norms. This follows from a result in [7] which shows an $\Omega(q \log d)$ lower bound for minimizing the objective $\|Bx\|_q$ under covering constraints (where B is a non-negative matrix). It is still an interesting open question to identify the correct competitive ratio for general norm functions.

1.1 Our Results and Techniques

We consider the online covering problem

$$\min \left\{ \sum_{e=1}^{r} c_e \|x(S_e)\|_{q_e} \,:\, Ax \geq \mathbf{1},\, x \in \mathbb{R}^n_+ \right\}, \tag{1}$$

where each $S_e \subseteq [n] := \{1, 2, \cdots n\}$, $q_e \geq 1$, $c_e \geq 0$ and A is a non-negative $m \times n$ matrix. For any $S \subseteq [n]$ and $q \geq 1$ we use the standard notation $\|x(S)\|_q = \left(\sum_{i \in S} x_i^q\right)^{1/q}$. We also consider the dual of this convex program, which is the following packing problem:

$$\max \left\{ \sum_{k=1}^{m} y_k \,:\, A^T y = \mu,\, \sum_{e=1}^{r} \mu_e = \mu,\, \|\mu_e(S_e)\|_{p_e} \leq c_e \,\forall e \in [r],\, y \geq 0 \right\}. \tag{2}$$

The values p_e above satisfy $\frac{1}{p_e} + \frac{1}{q_e} = 1$; so $\|\cdot\|_{p_e}$ is the dual norm of $\|\cdot\|_{q_e}$. This dual can be derived from (1) using Lagrangian duality.

Our framework captures the classic setting of packing/covering LPs when $r = n$ and for each $e \in [n]$ we have $S_e = \{e\}$ and $q_e = 1$. Our main result is:

▶ **Theorem 1.** *There is an $O(\log d + \log \rho)$-competitive online algorithm for (1) and (2) where the covering constraints in (1) and variables y in (2) arrive over time. Here d is the maximum of the row-sparsity of A and $\max_{e=1}^{r} |S_e|$ and $\rho = \frac{\max\{a_{ij}\}}{\min\{a_{ij}\}}$.*

We note that this bound is also the best possible, even in the linear case [13]. For just the covering problem, a better $O(\log d)$ bound is known in the linear case [23] as well as for convex functions with monotone gradients [6].

The algorithm in Theorem 1 is the natural extension of the primal-dual approach for online LPs [13]. We use the gradient $\nabla f(x)$ at the current primal solution x as the cost function, and use this to define a multiplicative update for the primal. Simultaneously, the

dual solution y is increased additively. This algorithm is in fact identical to the one in [6] for convex functions with monotone gradients. See Algorithm 1 for the formal description. The contribution of this paper is in the analysis of this algorithm, which requires new ideas to deal with non-monotone gradients.

Limitations of previous approaches [6]

Recall that the general convex covering problem is

$$\min \left\{ f(x) \,:\, Ax \geq \mathbf{1},\, x \in \mathbb{R}^n_+ \right\},$$

where $f : \mathbb{R}^n_+ \to \mathbb{R}_+$ is a convex function. Its dual is:

$$\max \left\{ \sum_{k=1}^{m} y_k - f^*(\mu) \,:\, A^T y = \mu,\, y \geq 0 \right\},$$

where $f^*(\mu) = \max_{x \in \mathbb{R}^n_+} \{\mu^T x - f(x)\}$ is the Fenchel conjugate of f. When f is the sum of ℓ_q-norms, these primal-dual convex programs reduce to (1) and (2).

We restrict the discussion of prior techniques to functions f with $\max_{x \in \mathbb{R}^n_+} \frac{x^T \nabla f(x)}{f(x)} \leq 1$ because this condition is satisfied by sums of ℓ_q norms.[1] At a high level, the analysis in [6] uses the gradient monotonicity to prove a *pointwise upper bound* $A^T y \leq \nabla f(\bar{x})$ where $\bar{x}$ is the final primal solution. This allows them to lower bound the dual objective by $\sum_{k=1}^{m} y_k$ because $f^*(\nabla f(\bar{x})) \leq 0$ for any $\bar{x}$ (see Lemma 4(d) in [6]). Moreover, proving the pointwise upper bound $A^T y \leq \nabla f(\bar{x})$ is similar to the task of showing dual feasibility in the *linear* case [13, 23] where $\nabla f(\bar{x})$ corresponds to the (fixed) primal cost coefficients.

Below we give a simple example with an ℓ_q-norm objective where the pointwise upper bound $A^T y \leq \nabla f(\bar{x})$ is not satisfied by the online primal-dual algorithm unless the dual solution y is scaled down by a large (i.e. polynomial) factor. This means that one cannot obtain a sub-polynomial competitive ratio for (1) using this approach directly.

Consider an instance with objective function $f(x) = \|x\|_2 = \sqrt{\sum_{i=1}^{n} x_i^2}$. There are $m = \sqrt{n}$ covering constraints, where the k^{th} constraint is $\sum_{i=k(m-1)+1}^{km} x_i \geq 1$. Note that each variable appears in only one constraint. Let P be the value of primal objective and D be the value of dual objective at any time. Suppose that the rate of increase of the primal objective is at most α times that of the dual; α corresponds to the competitive ratio in the online primal-dual algorithm. Upon arrival of any constraint k, it follows from the primal updates that all the variables $\{x_i\}_{i=k(m-1)+1}^{km}$ increase from 0 to $\frac{1}{m}$. So the increase in P due to constraint k is $(\sqrt{k} - \sqrt{k-1})\frac{1}{\sqrt{m}}$ for iteration k. This means that the increase in D is at least $\frac{1}{\alpha}(\sqrt{k} - \sqrt{k-1})\frac{1}{\sqrt{m}}$, and so $y_k \geq \frac{1}{\alpha}(\sqrt{k} - \sqrt{k-1})\frac{1}{\sqrt{m}}$. Finally, since $\bar{x} = \frac{1}{m}\mathbf{1}$, we know that $\nabla f(\bar{x}) = \frac{1}{m}\mathbf{1}$ (recall $n = m^2$). On the other hand, $(A^T y)_1 = y_1 \geq \frac{1}{\alpha\sqrt{m}}$. Therefore, in order to guarantee $A^T y \leq \nabla f(\bar{x})$ we must have $\alpha \geq \sqrt{m} = n^{1/4}$.

Our approach

First, we show that by duplicating variables and using an online separation oracle approach (as in [1]) one can ensure that the sets $\{S_e\}_{e=1}^{r}$ are disjoint. This allows for a simple

[1] The result in [6] also applies to other convex functions with monotone gradients, but the competitive ratio depends exponentially on $\max_{x \in \mathbb{R}^n_+} \frac{x^T \nabla f(x)}{f(x)}$.

expression for ∇f which is useful in the later analysis. Then we utilize the specific form of the primal-dual convex programs (1) and (2) and an explicit expression for ∇f to show that the dual y is approximately feasible. In particular we show that $\|y^T A(S_e)\|_{p_e} \leq O(\log d\rho) \cdot c_e$ for each $e \in [r]$; here $A(S_e)$ denotes the submatrix of A with columns from S_e. Note that this is a weaker requirement than upper bounding $A^T y$ pointwise by $\nabla f(\bar{x})$.

In order to bound $\|y^T A(S_e)\|_{p_e}$, we analyze each $e \in [r]$ separately. We partition the steps of the algorithm into *phases* where phase j corresponds to steps where $\Phi_e = \sum_{i \in S_e} x_i^{q_e} \approx \theta^j$; here $\theta > 1$ is a parameter that depends on q_e. The number of phases can be bounded using the fact that Φ_e is monotonically increasing. By triangle inequality we upper bound $\|y^T A(S_e)\|_{p_e}$ by $\sum_j \|y_{(j)}^T A(S_e)\|_{p_e}$ where $y_{(j)}$ denotes the dual variables that arrive in phase j. And in each phase j, we can upper bound $\|y_{(j)}^T A(S_e)\|_{p_e}$ using the differential equations for the primal and dual updates.

Applications

We also provide two applications of Theorem 1.

Non-uniform multicommodity buy-at-bulk. This is a well-studied network design problem in the offline setting [16, 17]. For its online version, the first poly-logarithmic competitive ratio was obtained recently in [21]. A key step in this result was a fractional online algorithm for a certain mixed packing-covering LP. We improve the competitive ratio of this step from $O(\log^3 n)$ to $O(\log n)$ which leads to a corresponding improvement in the final result of [21]. See Theorem 6.

Throughput maximization with ℓ_p-norm capacities. The online problem of maximizing throughput subject to edge capacities is well studied and a tight logarithmic competitive ratio is known [4, 13]. We consider the generalization where instead of individual edge capacities, we can have capacity constraints on subsets as follows. A ℓ_p-norm capacity of c for some subset S of edges means that the ℓ_p-norm of the loads on edges of S must be at most c. We show that one can obtain a randomized log-competitive algorithm even in this setting, which generalizes the case with edge-capacities. See Theorem 7.

1.2 Related Work

The online primal-dual framework for linear programs [14] is fairly well understood. Tight results are known for the class of packing and covering LPs [13, 23], with competitive ratio $O(\log d)$ for covering LPs and $O(\log d\rho)$ for packing LPs; here d is the row-sparsity and ρ is the ratio of the maximum to minimum entries in the constraint matrix. Such LPs are very useful because they correspond to the LP relaxations of many combinatorial optimization problems. Combining the online LP solver with suitable online rounding schemes, good online algorithms have been obtained for many problems, eg. set cover [2], group Steiner tree [1], caching [8] and ad-auctions [12]. Online algorithms for LPs with mixed packing and covering constraints were obtained in [5]; the competitive ratio was improved in [6]. Such mixed packing/covering LPs were also used to obtain an online algorithm for capacitated facility location [5]. A more complex mixed packing/covering LP was used recently in [21] to obtain online algorithms for non-uniform buy-at-bulk network design: as an application of our result, we obtain a simpler and better (by two log-factors) online algorithm for this problem.

There have also been a number of results utilizing the online primal-dual framework with *convex* objectives for specific problems, eg. matching [19], caching [25], energy-efficient scheduling [18, 22] and welfare maximization [10, 24]. All of these results involve separable convex/concave functions. Recently, [6] considered packing/covering problems with general (non-separable) convex objectives, but (as discussed previously) this result requires a monotone gradient assumption on the convex function. The sum of ℓ_q-norm objectives considered in this paper does not satisfy this condition. While our primal-dual algorithm is identical to [6], we need new techniques in the analysis.

All the results above (as well as ours) involve convex objectives and linear constraints. We note that [20] obtained online primal-dual algorithms for certain semidefinite programs (i.e. involving non-linear constraints). While both our result and [20] generalize packing/covering LPs, they are not directly comparable.

We also note that online algorithms with ℓ_q-norm objectives have been studied previously for many scheduling problems, eg. [3, 9]. These results use different approaches and are not directly comparable to ours. More recently [7] used ideas from the online primal-dual approach in an online algorithm for unrelated machine scheduling with ℓ_p-norm objectives as well as startup costs. However, the algorithm in [7] was tailored to their scheduling setting and we do not currently see a connection between our result and [7].

2 Preliminaries

Recall the primal covering problem (1) and its dual packing problem (2). In the online setting, the constraints in the primal and variables in the dual arrive over time. We need to maintain monotonically increasing primal (x) and dual (y) solutions. The following lemma shows that one can assume that the sets $\{S_e\}_{e=1}^r$ are *disjoint* without loss of generality. We defer the proof of the lemma to the full version. This leads to a much simpler expression for ∇f that will be used in Section 3.

▶ **Lemma 2.** *If there is a poly-time α-competitive algorithm for instances with disjoint S_e, then there is a poly-time $O(\alpha)$-competitive algorithm for general instances.*

Henceforth we will assume that the sets $\{S_e\}_{e=1}^r$ are disjoint. The dual program (2) in this case reduces to:

$$\max \left\{ \sum_{k=1}^{m} y_k \;:\; A^T y = \mu,\ \|\mu(S_e)\|_{p_e} \le c_e \ \forall e \in [r],\ y \ge 0 \right\}. \tag{3}$$

It is easy to see that weak duality holds (Lemma 3). Strong duality also holds because (1) satisfies Slater's condition; however we do not use this fact.

▶ **Lemma 3.** *For any pair of feasible solutions x to (1) and (y, μ) to (3), we have*

$$\sum_{e=1}^{r} c_e \|x(S_e)\|_{q_e} \ge \sum_{k=1}^{m} y_k.$$

Proof. This follows from the following inequalities:

$$\sum_{k=1}^{m} y_k = y^T \mathbf{1} \le y^T A x = \mu^T x \le \sum_{e=1}^{r} \sum_{i \in S_e} \mu_i \cdot x_i \le \sum_{e=1}^{r} \|\mu(S_e)\|_{p_e} \cdot \|x(S_e)\|_{q_e} \le \sum_{e=1}^{r} c_e \cdot \|x(S_e)\|_{q_e}.$$

The first inequality is by primal feasibility; the second and last are by dual feasibility; the fourth is by Hölder's inequality. ◀

When the k^{th} request $\sum_{i=1}^{n} a_{ki}x_i \geq 1$ arrives
Let τ be a continuous variable denoting the current time.;
while *the constraint is unsatisfied, i.e.,* $\sum_{i=1}^{n} a_{ki}x_i < 1$ **do**
  For each i with $a_{ki} > 0$, increase x_i at rate $\frac{\partial x_i}{\partial \tau} = \frac{a_{ki}x_i + \frac{1}{d}}{\nabla_i f(x)} = \frac{a_{ki}x_i + \frac{1}{d}}{c_e x_i^{q_e - 1}} \|x(S_e)\|_{q_e}^{q_e - 1}$;
  Increase y_k at rate $\frac{\partial y_k}{\partial \tau} = 1$;
  Set $\mu = A^T y$;
end

Algorithm 1: Algorithm for ℓ_q-norm packing/covering.

3 Algorithm and analysis

Let $f(x) = \sum_{e=1}^{r} c_e \|x(S_e)\|_{q_e}$ denote the primal objective in (1).

In order to ensure that the gradient ∇f is positive, the primal solution x starts off as $\delta \cdot \mathbf{1}$ where $\delta > 0$ is arbitrarily small. So we assume that the initial primal value is zero.

It is clear that the algorithm maintains a feasible and monotonically non-decreasing primal solution x. The dual solution (y, μ) is also monotonically non-decreasing, but not necessarily feasible. We will show that (y, μ) is $O(\log \rho d)$-approximately feasible, i.e. the packing constraints in (3) are violated by at most an $O(\log \rho d)$ factor.

▶ **Lemma 4.** *The primal objective $f(x)$ is at most twice the dual objective $\sum_{k=1}^{m} y_k$.*

Proof. We will show that the rate of increase of the primal is at most twice that of the dual. Consider the algorithm upon the arrival of some constraint k. Then

$$\frac{df(x)}{d\tau} = \sum_{i:a_{ki}>0} \nabla_i f(x) \cdot \frac{\partial x_i}{\partial \tau} = \sum_{i:a_{ki}>0} (a_{ki}x_i + \frac{1}{d}) \leq 2.$$

The inequality comes from the fact that (i) the process for the kth constraint is terminated when $\sum_i a_{ki}x_i = 1$ and (ii) the number of non-zeroes in constraint k is at most d. Also it is clear that the dual objective increases at rate one, which finishes the proof. ◀

▶ **Lemma 5.** *The dual solution (y, μ) is $O(\log \rho d)$-approximately feasible, i.e.*

$$\|\mu(S_e)\|_{p_e} \;\leq\; O(\log \rho d) \cdot c_e, \qquad \forall e \in [r].$$

Proof. Fix any $e \in [r]$. When $q_e = 1$ the analysis is simple (details are deferred to the full version). Here we only consider $q_e > 1$ which is the main part of the analysis. In order to prove the desired upper bound on $\|\mu(S_e)\|_{p_e}$ we use a potential function $\Phi = \sum_{i \in S_e} (x_i^{q_e})$. Let phase zero denote the period where $\Phi \leq \zeta := (\frac{1}{\max\{a_{ij}\} \cdot d^2})^{q_e}$, and for each $j \geq 1$, phase j is the period where $\theta^{j-1} \cdot \zeta \leq \Phi < \theta^j \cdot \zeta$. Here $\theta > 1$ is a parameter depending on q_e that will be determined later. Note that $\Phi \leq d(\frac{1}{\min\{a_{ij}\}})^{q_e}$ as variable x_i will never be increased beyond $1/\min_{j=1}^{m} a_{ij}$. So the number of phases is at most $3q_e \cdot \log(d\rho)/\log\theta$. Next, we bound the increase in $\|\mu(S_e)\|_{p_e}$ for each phase separately.

For any phase, we have the following equalities

$$\frac{\partial x_i}{\partial \tau} = \frac{a_{ki}x_i + \frac{1}{d}}{c_e x_i^{q_e - 1}} \|x(S_e)\|_{q_e}^{q_e - 1}, \quad \frac{\partial y_k}{\partial \tau} = 1, \quad \frac{\partial \mu_i}{\partial \tau} = a_{ki}$$

$$\Rightarrow d\mu_i = \frac{c_e\, a_{ki}\, x_i^{q_e - 1}}{(\sum_{j \in S_e} x_j^{q_e})^{1 - \frac{1}{q_e}} (a_{ki}x_i + \frac{1}{d})} dx_i \tag{4}$$

Phase zero. Suppose that each x_i increases to α_i in phase zero. From (4) we have

$$d\mu_i \leq \frac{d\, c_e\, a_{ki}\, x_i^{q_e-1}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}}} dx_i \qquad \Rightarrow \qquad \frac{1}{d\, c_e\, a_{ki}} d\mu_i \leq \frac{x_i^{q_e-1}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}}} dx_i.$$

This means that the increase $\Delta\mu_i$ in μ_i can be bounded as:

$$\frac{1}{d\, c_e\, a_{ki}} \Delta\mu_i \leq \int_{\delta}^{\alpha_i} \frac{x_i^{q_e-1}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}}} dx_i \leq \int_0^{\alpha_i} 1 dx_i \leq \alpha_i.$$

Since in phase zero, $\Phi \leq (\frac{1}{\max\{a_{ij}\}\cdot d^2})^{q_e}$, we know that each $\alpha_i \leq \frac{1}{\max\{a_{ij}\}\cdot d^2}$. So $\Delta\mu_i \leq \frac{c_e}{d}$ and at the end of phase zero, we have $\|\mu(S_e)\|_{p_e} \leq \|\mu(S_e)\|_1 \leq c_e$. The last inequality is because $d \geq \max_e |S_e|$.

Phase $j \geq 1$. Let Φ_0 and Φ_1 be the value of Φ at the beginning and end of this phase respectively. In phase j, suppose that each x_i increases from s_i to t_i. Then,

$$d\mu_i = \frac{c_e\, a_{ki}\, x_i^{q_e-1}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}} (a_{ki} x_i + \frac{1}{d})} dx_i \leq \frac{c_e x_i^{q_e-2}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}}} dx_i\,.$$

So the increase $\Delta\mu_i$ in μ_i during this phase is:

$$\Delta\mu_i \leq \int_{s_i}^{t_i} \frac{c_e x_i^{q_e-2}}{(\sum_{j\in S_e} x_j^{q_e})^{1-\frac{1}{q_e}}} dx_i.$$

Note that variables $x_{i'}$ for $i' \neq i$ can also increase in this phase: so we cannot directly bound the above integral. This is precisely where the potential Φ is useful. We know that throughout this phase, $\sum_{i\in S_e} x_i^{q_e} \geq \Phi_0$. So,

$$\Delta\mu_i \leq c_e \int_{s_i}^{t_i} \frac{x_i^{q_e-2}}{\Phi_0^{1-\frac{1}{q_e}}} dx_i = c_e \frac{t_i^{q_e-1} - s_i^{q_e-1}}{(q_e-1)\Phi_0^{1-\frac{1}{q_e}}} = c_e \frac{t_i^{q_e-1} - s_i^{q_e-1}}{(q_e-1)\Phi_0^{\frac{1}{p_e}}}.$$

Above we used the assumption that $q_e > 1$ in evaluating the integral. Now,

$$\begin{aligned}(\Delta\mu_i)^{p_e} &\leq \frac{c_e^{p_e}}{(q_e-1)^{p_e}\,\Phi_0} \cdot \left(t_i^{q_e-1} - s_i^{q_e-1}\right)^{p_e} \leq \frac{c_e^{p_e}}{(q_e-1)^{p_e}\,\Phi_0} \cdot \left(t_i^{(q_e-1)p_e} - s_i^{(q_e-1)p_e}\right) \\ &= \frac{c_e^{p_e}}{(q_e-1)^{p_e}\,\Phi_0} \cdot (t_i^{q_e} - s_i^{q_e})\,.\end{aligned}$$

The first inequality above uses the fact that $(z_1+z_2)^{p_e} \geq z_1^{p_e} + z_2^{p_e}$ for any $p_e \geq 1$ and $z_1, z_2 \geq 0$, with $z_1 = s_i^{q_e-1}$ and $z_2 = t_i^{q_e-1} - s_i^{q_e-1}$. The last equality uses $\frac{1}{p_e} + \frac{1}{q_e} = 1$.

We can now bound

$$\sum_{i\in S_e} (\Delta\mu_i)^{p_e} \leq \frac{c_e^{p_e}}{(q_e-1)^{p_e}\,\Phi_0} \cdot \sum_{i\in S_e} (t_i^{q_e} - s_i^{q_e}) = \frac{c_e^{p_e}}{(q_e-1)^{p_e}\,\Phi_0} (\Phi_1 - \Phi_0) \leq \frac{c_e^{p_e}}{(q_e-1)^{p_e}} (\theta - 1)\,.$$

Let $\mu_j \in \mathbb{R}^{|S_e|}$ denote the increase in $\mu(S_e)$ during phase j. It follows from the above that $\|\mu_j\|_{p_e} \leq \frac{c_e}{q_e-1}(\theta-1)^{1/p_e}$.

Combining across phases. Note that $\mu = \sum_{j\geq 0} \mu_j$. By triangle inequality, we have

$$\|\mu\|_{p_e} \leq \sum_{j\geq 0} \|\mu_j\|_{p_e} \leq c_e + \sum_{j\geq 1} \|\mu_j\|_{p_e} \leq c_e \left(1 + \frac{3q_e(\theta-1)^{1/p_e}}{(q_e-1)\log\theta} \cdot \log(d\rho)\right). \tag{5}$$

To complete the proof we show next that for any $q_e > 1$, there is some choice of $\theta > 1$ such that the right-hand-side above is $O(\log(d\rho)) \cdot c_e$.

- If $q_e \geq 2$ then setting $\theta = 2$, we have $\frac{3q_e}{(q_e-1)}(\theta-1)^{1/p_e}/\log\theta \leq 6$.
- If $1 < q_e < 2$ then set $\theta = 1 + (q_e-1)^{-\epsilon p_e}$, where $\epsilon = \frac{1}{-\log(q_e-1)} > 0$. We have

$$\frac{(\theta-1)^{\frac{1}{p_e}}}{\log\theta} \leq \frac{(\theta-1)^{\frac{1}{p_e}}}{\log(q_e-1)^{-\epsilon p_e}} = \frac{(q_e-1)^{-\epsilon}}{\log(q_e-1)^{-\epsilon p_e}} = \frac{(q_e-1)^{-\epsilon}}{-\epsilon p_e \log(q_e-1)} = \frac{(q_e-1)^{-\epsilon}}{p_e} = \frac{2}{p_e}.$$

The first inequality above uses that $\theta - 1 = (q_e-1)^{-\epsilon p_e} > 1$. Thus we have

$$\frac{3q_e(\theta-1)^{1/p_e}}{(q_e-1)\log\theta} \leq \frac{6q_e}{(q_e-1)p_e} = 6,$$

where the last equality uses $\frac{1}{p_e} + \frac{1}{q_e} = 1$.

So in either case we have that the right-hand-side of (5) is at most $(1+6\log(d\rho)) \cdot c_e$. ◀

Combining Lemmas 3, 4 and 5, we obtain Theorem 1.

4 Applications

4.1 Online Buy-at-Bulk Network Design

In the non-uniform buy-at-bulk problem, we are given a directed graph $G = (V, E)$ with a monotone subadditive cost function $g_e : \mathbb{R}_+ \to \mathbb{R}_+$ on each edge $e \in E$ and a collection $\{(s_i, t_i)\}_{i=1}^m$ of m source/destination pairs. The goal is to find an $s_i - t_i$ path P_i for each $i \in [m]$ such that the objective $\sum_{e\in E} g_e(load_e)$ is minimized; here $load_e$ is the number of paths using e. An equivalent view of this problem involves two costs c_e and ℓ_e for each edge $e \in E$ and the objective $\sum_{e\in\cup P_i} c_e + \sum_{e\in E} \ell_e \cdot load_e$. In the online setting, the pairs (s_i, t_i) arrive over time and we need to decide on the path P_i immediately after the i^{th} pair arrives. Recently, [21] gave a modular online algorithm for non-uniform buy-at-bulk with competitive ratio $O(\alpha\beta\gamma \cdot \log^5 n)$ where:

- α is the "junction tree" approximation ratio,
- β is the integrality gap of the natural LP for single-sink instances,
- γ is the competitive ratio of an online algorithm for single-sink instances.

See [21] for more details. One of the main components in this result was an $O(\log^3 n)$-competitive fractional online algorithm for a certain mixed packing/covering LP. Here we show that Theorem 1 can be used to provide a better (and tight) $O(\log n)$-competitive ratio. This leads to the following improvement:

▶ **Theorem 6.** *There is an $O(\alpha\beta\gamma \cdot \log^3 n)$-competitive ratio for non-uniform buy-at-bulk, where α, β, γ are as above.*

The LP relaxation. Let $\mathcal{T} = \{s_i, t_i : i \in [m]\}$ denote the set of all sources/destinations. For each $i \in [m]$ and root $r \in V$ variable z_{ir} denotes the extent to which both s_i and t_i route to/from r. For each $r \in V$ and $e \in E$, variable x_{er} denotes the extent to which edge e is used in the routing to root r. For each $r \in V$ and $u \in \mathcal{T}$, variables $\{f_{r,u,e} : e \in E\}$ represent a flow between r and u. [21] relied on solving the following LP:

$$\begin{aligned}
\min \quad & \sum_{r\in V}\sum_{e\in E} c_e \cdot x_{e,r} \;+\; \sum_{r\in V}\sum_{e\in E} \ell_e \cdot \sum_{u\in\mathcal{T}} f_{r,u,e} \\
\text{s.t.} \quad & \sum_{r\in V} z_{ir} \geq 1, \qquad \forall i \in [m] \\
& \{f_{r,s_i,e} : e \in E\} \text{ is a flow from } s_i \text{ to } r \text{ of } z_{ir} \text{ units}, \qquad \forall r \in V,\, i \in [m] \\
& \{f_{r,t_i,e} : e \in E\} \text{ is a flow from } r \text{ to } t_i \text{ of } z_{ir} \text{ units}, \qquad \forall r \in V,\, i \in [m] \\
& f_{r,u,e} \leq x_{e,r}, \qquad \forall u \in \mathcal{T},\, e \in E \\
& x, f, z \geq 0
\end{aligned}$$

The online algorithm in [21] for this LP has competitive ratio $O(D \cdot \log n)$ w.r.t. the optimal integral solution; here D is an upper bound on the length of any $s_i - t_i$ path (note that D can be as large as n). Using a height reduction operation, they could ensure that $D = O(\log n)$ while incurring an additional $O(\log n)$-factor loss in the objective. This lead to the $O(\log^3 n)$ factor for the fractional online algorithm. Here we provide an improved $O(\log n)$-competitive algorithm for this LP which does not require any bound on the path-lengths.

For any $r \in V$ and $u \in \mathcal{T}$, let $\mathsf{MC}(r, u)$ denote the $u - r$ (resp. $r - u$) minimum cut in the graph with edge capacities $\{f_{r,u,e} : e \in E\}$ if u is a source (resp. destination). By the max-flow min-cut theorem, it follows that $z_{ir} \leq \min\{\mathsf{MC}(r, s_i), \mathsf{MC}(r, t_i)\}$. Using this, we can combine the first three constraints of the above LP into the following:

$$\sum_{r\in V} \min\{\mathsf{MC}(r, s_i), \mathsf{MC}(r, t_i)\} \;\geq\; 1, \qquad \forall i \in [m].$$

For a fixed $i \in [m]$, this constraint is equivalent to the following. For each $r \in V$, pick either an $s_i - r$ cut (under capacities $f_{r,s_i,\star}$) or an $r - t_i$ cut (under capacities $f_{r,t_i,\star}$), and check if the total cost of these cuts is at least 1. This leads to the following reformulation that eliminates the x and z variables.

$$\begin{aligned}
\min \quad & \sum_{r\in V}\sum_{e\in E} c_e \cdot \left(\max_{u\in\mathcal{T}} f_{r,u,e}\right) \;+\; \sum_{r\in V}\sum_{e\in E} \ell_e \cdot \sum_{u\in\mathcal{T}} f_{r,u,e} \\
\text{s.t.} \quad & \sum_{r\in R_s} f_{r,s_i}(S_r) \;+\; \sum_{r\in R_t} f_{r,t_i}(T_r) \geq 1, \qquad \forall i \in [m],\; \forall (R_s, R_t) \text{ partition of } V, \\
& \qquad \forall S_r : s_i - r \text{ cut}, \forall r \in R_s,\; \forall T_r : r - t_i \text{ cut}, \forall r \in R_t \\
& f \geq 0.
\end{aligned}$$

Note that $\ell_{\log(n)}$-norm is a constant approximation for ℓ_∞. Therefore we can reformulate the above objective function (at the loss of a constant factor) as the sum of $\ell_{\log(n)}$ and ℓ_1 norms. Our fractional solver applies to this convex covering problem, and yields an $O(\log n)$-competitive ratio (note that $\rho = 1$ for this instance). In order to get a polynomial running time, we can use the natural "separation oracle" approach to produce violated covering constraints.

Each iteration above runs in polynomial time since the minimum cuts can be computed in polynomial time. In order to bound the number of iterations, consider the potential $\psi = \sum_{e\in E}(f_{r,s_i,e} + f_{r,t_i,e})$. Note that $0 \leq \psi \leq 2|E|$ and each iteration increases ψ by at least $\frac{1}{2}$. So the number of iterations is at most $4|E|$.

When the i^{th} request (s_i, t_i) arrives
repeat
  For each $r \in V$, compute $\mathsf{MC}(r, s_i)$ and $\mathsf{MC}(r, t_i)$ and the respective cuts S_r and T_r;
  Let $R_s = \{r \in V : \mathsf{MC}(r, s_i) \leq \mathsf{MC}(r, t_i)\}$ and $R_t = V \setminus R_s$;
  Run Algorithm 1 with constraint $\sum_{r \in R_s} f_{r,s_i}(S_r) + \sum_{r \in R_t} f_{r,t_i}(T_r) \geq 1$;
until $\sum_{r \in V} \min\{\mathsf{MC}(r, s_i), \mathsf{MC}(r, t_i)\} \geq \frac{1}{2}$;

Algorithm 2: Separation Oracle Based Algorithm for Buy-at-Bulk.

4.2 Throughput Maximization with ℓ_p-norm Capacities

The online problem of maximizing multicommodity flow was studied in [4, 13]. In this problem, we are given a directed graph with edge capacities $u(e)$. Requests (s_i, t_i) arrive in an online fashion. The algorithm should choose a path between s_i and t_i and allocate a bandwidth of 1 on the path to serve request i. The total bandwidth allocated on any edge is not allowed to exceed its capacity. This is the simplest version of the multicommodity routing problem. Here we consider an extension with ℓ_p-norm capacity constraints on subsets of edges. This can be used to model situations where edges are provided by multiple agents. Each agent j owns a subset S_j of edges and it requires the ℓ_{p_j}-norm of the bandwidths of these edges to be at most c_j. In this section we assume the S_j are disjoint. Our result also applies to general S_j via a reduction to disjoint instances.

▶ **Theorem 7.** *Assume that $c_j = \Omega(\log m) \cdot |S_j|^{1/p_j}$ for each j. Then there is a randomized $O(\log m)$-competitive online algorithm for throughput maximization with ℓ_p-norm capacities, where m is the number of edges in the graph.*

We note that a similar "high capacity" assumption is also needed in the linear special case [4, 13] where each $|S_j| = 1$.

In a fractional version of the problem, a request can be satisfied by several paths and the allocation of bandwidth can be in range $[0, 1]$ instead of being restricted from $\{0, 1\}$. For request (s_i, t_i), let $\mathcal{P}_i$ be the set of simple paths between s_i and t_i. Variable $f_{i,P}$ is defined to be the amount of flow on the path P for request (s_i, t_i). The total profit of algorithm is the (fractional) number of requests served and the performance is measured with respect to the maximum number of requests that could be served if the requests are known beforehand. We describe the problem as a packing problem:

$$\max \quad \sum_i \sum_{P \in \mathcal{P}_i} f_{i,P} \tag{6}$$

$$\text{s.t.} \quad \sum_{P \in \mathcal{P}_i} f_{i,P} \leq 1, \qquad \forall i \tag{7}$$

$$\sum_i \sum_{P \in \mathcal{P}_i : e \in P} f_{i,P} = \mu_e, \qquad \forall e \tag{8}$$

$$\|\mu(S_j)\|_{p_j} \leq c_j, \qquad \forall j \tag{9}$$

$$f \in \mathbb{R}^n_+$$

Note that single edge capacity is a special case of (9) with $|S_j| = 1$ and any p_j. The corresponding primal problem is the following.

$$\min \quad \sum_j c_j \|x(S_j)\|_{q_j} + \sum_i z_i \tag{10}$$

$$\text{s.t.} \quad z_i + \sum_{e \in P} x_e \geq 1, \qquad \forall i,\ P \in \mathcal{P}_i \tag{11}$$

$$x, z \in \mathbb{R}^n_+$$

where z is the dual variable of constraints (7) and x is the dual variable of constraints (8) to (9). This formulation falls in the form of (1). Combining our algorithm with online rounding techniques, we can prove Theorem 7. A formal proof appears in the full version.

Abstract

In this paper, we construct a deterministic 4-competitive algorithm for the online file migration problem, beating the currently best 20-year old, 4.086-competitive MTLM algorithm by Bartal et al. (SODA 1997). Like MTLM, our algorithm also operates in phases, but it adapts their lengths dynamically depending on the geometry of requests seen so far. The improvement was obtained by carefully analyzing a linear model (factor-revealing LP) of a single phase of the algorithm. We also show that if an online algorithm operates in phases of fixed length and the adversary is able to modify the graph between phases, no algorithm can beat the competitive ratio of 4.086.

1 Introduction

Consider the problem of managing a shared data item among sets of processors. For example, in a distributed program running in a network, nodes want to have access to shared files, objects or databases. Such a file can be stored in the local memory of one of the processors and when another processor wants to access (read from or write to) this file, it has to contact the processor holding the file. Such a transaction incurs a certain cost. Moreover, access patterns to this file may change frequently and unpredictably, which renders any static placement of the file inefficient. Hence, the goal is to minimize the total cost of communication by moving the file in response to such accesses, so that the requesting processors find the file "nearby" in the network.

The *file migration* problem serves as the theoretical underpinning of the application scenario described above. The problem was coined by Black and Sleator [13] and was initially called *page migration*, as the original motivation concerned managing a set of memory pages

in a multiprocessor system. There the data item was a single memory page held at a local memory of a single processor.

Most subsequent work referred to this problem as *file migration* and we will stick to this convention in this paper. The file migration problem assumes the *non-uniform model*, where the shared file is much larger than a portion accessed in a single time step. This is typical when in one step a processor wants to read a single unit of data from a file or a record from a database. On the other hand, to reduce the maintenance overhead, it is assumed that the shared file is indivisible, and can be migrated between nodes only as a whole. This makes the file migration much more expensive than a single access to the file. As the knowledge of future accesses is either partial or completely non-existing, the accesses to the file can be naturally modeled as an online problem, where the input sequence consists of processor identifiers, which sequentially try to access pieces of the shared file.

1.1 The Model

The studied network is modeled as an edge-weighted graph or, more generally, as a metric space $(\mathcal{X}, d)$ whose point set $\mathcal{X}$ corresponds to processors and d defines the distances between them. There is a large indivisible *file* (historically called *page*) of size D stored at a point of $\mathcal{X}$. An input is a sequence of space points $r_1, r_2, r_3, \ldots$ denoting processors requesting access to the file. This sequence is presented in an online manner to an algorithm. More precisely, we assume that the time is slotted into steps numbered from 1. Let ALG_t denote the position of the file at the end of step t and ALG_0 be the initial position of the file. In step $t \geq 1$, the following happens:

1. A requesting point r_t is presented to the algorithm.
2. The algorithm pays $d(\text{ALG}_{t-1}, r_t)$ for serving the request.
3. The algorithm chooses a new position ALG_t for the file (possibly $\text{ALG}_t = \text{ALG}_{t-1}$) and moves the file to ALG_t paying $D \cdot d(\text{ALG}_{t-1}, \text{ALG}_t)$.

After the t-th request, the algorithm has to make its decision (where to migrate the file) exclusively on the basis of the sequence up to step t. To measure the performance of an online strategy, we use the standard competitive ratio metric [14]: an online deterministic algorithm Alg is *c-competitive* if there exists a constant γ, such that for any input sequence $\mathcal{I}$, it holds that $C_{\text{ALG}}(\mathcal{I}) \leq c \cdot C_{\text{OPT}}(\mathcal{I}) + \gamma$, where C_{ALG} and C_{OPT} denote the costs of Alg and Opt (optimal *offline* algorithm) on $\mathcal{I}$, respectively. The minimum c for which Alg is c-competitive is called the *competitive ratio* of Alg.

1.2 Previous Work

The problem was stated by Black and Sleator [13], who gave 3-competitive deterministic algorithms for uniform metrics and trees and conjectured that 3-competitive deterministic algorithms were possible for any metric space.

Westbrook [26] constructed randomized strategies: a 3-competitive algorithm against adaptive-online adversaries and a $(1 + \phi)$-competitive algorithm (for D tending to infinity) against oblivious adversaries, where $\phi \approx 1.618$ denotes the golden ratio. By the result of Ben-David et al. [10] this asserted *the existence* of a deterministic algorithm with the competitive ratio at most $3 \cdot (1 + \phi) \approx 7.854$.

The first explicit deterministic construction was the 7-competitive algorithm Move-To-Min (Mtm) by Awerbuch et al. [2]. Mtm operates in phases of length D, during which the algorithm *remains at a fixed position*. In the last step of a phase, Mtm migrates the file to

a point that minimizes the sum of distances to all requests $r_1, r_2, \ldots, r_D$ presented in the phase, i.e., to a minimizer of the function $f_{\text{MTM}}(x) = \sum_{i=1}^{D} d(x, r_i)$.

The ratio has been subsequently improved by the algorithm Move-To-Local-Min (Mtlm) by Bartal et al. [8]. Mtlm works similarly to Mtm, but it changes the phase duration to $c_0 \cdot D$ for a constant c_0, and when computing the new position for the file, it also takes the migration distance into consideration. Namely, it chooses to migrate the file to a point that minimizes the function

$$f_{\text{MTLM}}(x) = D \cdot d(v_{\text{MTLM}}, x) + \tfrac{c_0+1}{c_0} \sum_{i=1}^{c_0 \cdot D} d(x, r_i) \ ,$$

where v_{MTLM} denotes the point at which Mtlm keeps its file during the phase. The algorithm is optimized by setting $c_0 \approx 1.841$ being the only positive root of the equation $3c^3 - 8c - 4 = 0$. For such c, the competitive ratio of Mtlm is $R_0 \approx 4.086$, where R_0 is the largest (real) root of the equation $R^3 - 5R^2 + 3R + 3 = 0$. Their analysis is tight.

It is worth noting that most of the competitive ratios given above hold when D tends to infinity. In particular, for Mtlm we assume that $c_0 \cdot D$ is an integer and the ratio of $1 + \phi$ of Westbrook's algorithm [26] is achieved only in the limit.

Better deterministic algorithms are known only for some specific graph topologies. There are 3-competitive algorithms for uniform metrics and trees [13], and $(3 + 1/D)$-competitive strategies for three-point metrics [23]. Chrobak et al. [15] showed $2 + 1/(2D)$-competitive strategies for continuous trees and products of trees, e.g., for $\mathbb{R}^n$ with ℓ_1 norm. Furthermore, a $(1 + \phi)$-competitive algorithm for $\mathbb{R}^n$ under any norm was also given in [15].

A straightforward lower bound of 3 for deterministic algorithms was given by Black and Sleator [13] and later adapted to randomized algorithms against adaptive-online adversaries by Westbrook [26]. The currently best lower bound for deterministic algorithms is due to Matsubayashi [22], who showed a lower bound of $3 + \varepsilon$ that holds for any value of D, where ε is a constant that does not depend on D. This renders the file migration problem one of the few natural problems, where a known lower bound on the competitive ratio of any deterministic algorithm is strictly larger than the competitive ratio of a randomized algorithm against an adaptive-online adversary.

Finally, improved results were given for a simplified model where $D = 1$: the competitive ratio for deterministic algorithms is then known to be between 3.164 and 3.414 [21].

1.3 Our Contribution

We propose a new deterministic algorithm that dynamically decides on the length of the phase based on the geometry of requests received in the initial part of each phase. This improves the 20-years old result of Bartal et al. [8].

The improvement was obtained by carefully analyzing a linear model (factor revealing LP) of a single phase of the algorithm. It allowed us to identify some key tight examples for the previous analysis, suggested a nontrivial construction of the new algorithm, and facilitated a systematic search within the design parameter space.

More precisely, for a fixed algorithm Alg (from a relatively broad class), we create a maximization LP with the following property: if the competitive ratio of Alg is at least R, then so is the value of LP. A solution to the LP contains a succinct description of a metric space along with a short description of a single-phase input, both constituting a lower bound for Alg. Hence, the value of LP is an upper bound on Alg's competitiveness. We discuss the details of the LP approach in Section 4.

The way the algorithm was obtained is perhaps unintuitive. Nevertheless, the final algorithm is an elegant construction involving only essentially integral constants. By studying

the dual solution, we managed to extract a compact, human-readable, combinatorial upper bound based on path-packing arguments and to obtain the following result.

▶ **Theorem 1.** *There exists a deterministic 4-competitive algorithm for the file migration problem.*

We also show that improvement of MTLM would not be possible by just selecting different parameters for a phase-based algorithm operating with a fixed phase length. Our construction shows that an analysis that treats each phase separately (e.g., the one employed for MTLM [8]) cannot give better bounds on the competitive ratio than 4.086. (A weaker lower bound of 3.847 for algorithms that use fixed phase length was given by Bartal et al. [8].)

▶ **Theorem 2.** *Fix any algorithm* ALG *that operates in phases of fixed length. Assume that between the phases, the adversary can arbitrarily modify the graph while keeping the distance between the files of* OPT *and* ALG *unchanged. Then, the competitive ratio of* ALG *is at least R_0 (for D tending to infinity), where $R_0 \approx 4.086$ is the competitive ratio of algorithm* MTLM*.*

1.4 Other Related Work

The file migration problem has been generalized in a few directions. When we lift the restriction that the file can only be migrated and not copied, the resulting problem is called *file allocation* [9, 2, 18]. It makes sense especially when we differentiate read and write requests to the file; for the former, we need to contact only one replica of the file; for the latter all copies need to be updated. The attainable competitive ratios become then worse: the best deterministic algorithm is $O(\log n)$-competitive [2]; the lower bound of $\Omega(\log n)$ holds even for randomized algorithms and follows by a reduction from the online Steiner tree problem [9, 17].

The file migration problem has been also extended to accommodate memory capacity constraints at nodes (when more than one file is used) [1, 3, 4, 6], dynamically changing networks [4, 12], and different objective functions (e.g., minimizing congestion) [19, 25]. For a more systematic treatment of the file migration and related problems, see surveys [7, 11]. For more applied approaches, see the survey [16] and the references therein.

2 4-Competitive Algorithm Dynamic-Local-Min

We start with an insight concerning the hard inputs for the MTLM algorithm [8]. We identified two classes of tight instances for MTLM: *bipartite* and *linear* (cf. Figure 1). It can be shown that if the algorithm knew in advance on which instance it was run, it could improve its performance by changing the phase length. Namely, for bipartite instances a longer phase would help the algorithm, whereas a shorter phase would be beneficial for linear instances.

To decide the length of the phase, we need to measure the level of request concentration as compared to the distance from the current position of an algorithm to the center of requests. Intuitively, observing that (from some time) requests are concentrated around a certain point motivates the algorithm to shorten the phase and quickly move to the "center of the requests". If, on the other hand, requests are scattered and the current algorithm's position is essentially in the middle of the observed requests, it appears reasonable to wait longer before moving the file. This rule agrees with the desired behavior of the algorithm on linear and bipartite instances.

Turning the above intuition into an effective phase extension rule is not trivial. We present an algorithm based on a rule that we have extracted from an optimization process

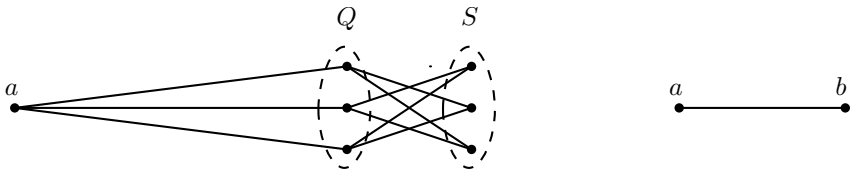

Figure 1 The geometries of selected tight instances for MTLM. In both cases, the algorithm starts at point a. In the *linear* instance (on the right), the requests are initially given at a and then later at b, and the algorithm is expected to migrate the file to point b. In the *bipartite* instance (on the left) the requests are given at nodes from set S and the algorithm is expected to migrate the file to one of the nodes from set Q.

using a natural linear model of the amortized phase-based analysis. This linear model is quite complex and we present it in Section 4. It can be seen as an alternative (computer-based) proof for the performance guarantee of our algorithm. Such proof technique might be interesting on its own and useful for analyzing other online games played on metric spaces.

2.1 Notation

For succinctness, we introduce the following notions. For any two points $v_1, v_2 \in \mathcal{X}$, let $[v_1, v_2] = D \cdot d(v_1, v_2)$. We extend this notation to sequences of points, i.e., $[v_1, v_2, \ldots, v_j] = [v_1, v_2] + [v_2, v_3] + \ldots + [v_{j-1}, v_j]$. Moreover, if $v \in \mathcal{X}$ is a point and $S \subseteq \mathcal{X}$ is a multiset of points, then

$$[v, S] = [S, v] = D \cdot \tfrac{1}{|S|} \textstyle\sum_{x \in S} d(v, x) \ ,$$

i.e., $[v, S]$ is the average distance from v to a point of S times D. We extend the sequence notation introduced above to sequences of points and multisets of points, e.g., $[v, S, u, T] = [v, S] + [S, u] + [u, T]$. The symbol $[S, T]$ is not defined for multisets S, T; we will only use this notation for sequences that do not contain two consecutive multisets.

Observe that the sequence notation allows for easy expressing of the triangle inequality: $[v_1, v_2] \leq [v_1, v_3, v_2]$; we will extensively use this property. Note that the following "multiset" version of the triangle inequality also holds: $[v_1, v_2] \leq [v_1, S, v_2]$.

2.2 Algorithm definition

We propose a new phase-based algorithm that dynamically decides on the length of the current phase, which we call Dynamic-Local-Min (DLM). DLM operates in phases, but it chooses their lengths depending on the geometry of requests seen in the initial part of the phase. Roughly speaking, when it recognizes that the currently seen requests more closely resemble a linear tight example for MTLM, it ends the phase after $1.75\,D$ steps. Otherwise, it assumes that the presented graph is more in the flavor of the bipartite construction, and ends the phase only after $2.25\,D$ steps.

For any step t, we denote the position of DLM's file at the end of step t by DLM_t and that of OPT by OP_t. We identify the requests with the points where they are issued.

Assume a phase starts in step $t+1$; that is, DLM_t is the position of DLM at the very beginning of a phase. Within the phase, DLM waits $1.75\,D$ steps and at step $t + 1.75\,D$, it finds a node v_g that minimizes the function

$$g(v) = [\text{DLM}_t, v, \mathcal{R}_1, v, \mathcal{R}_2] = [\text{DLM}_t, v] + 2 \cdot [v, \mathcal{R}_1] + [v, \mathcal{R}_2] \ ,$$

where $\mathcal{R}_1$ is the multiset of the requests from steps $t+1,\ldots,t+D$ and $\mathcal{R}_2$ is the multiset of the subsequent requests from steps $t+D+1,\ldots,t+1.75\,D$.

If $g(v_g) \le 1.5 \cdot [\textsc{dlm}_t, \mathcal{R}_2]$, the algorithm moves its file to v_g, and ends the current phase. Intuitively, this condition corresponds to detecting if there exists a point that is substantially closer to the first $1.75\,D$ requests of the phase than the current position. The condition is constructed in a way to be conclusive for each of the possible outcomes. If indeed such point exists, then by moving the file to this point, we get much closer to the file of Opt. If there is no such good point, then also the optimal solution is experiencing some request related costs. Then, we may afford to wait a little longer and meanwhile get a more accurate estimation of the possible location of the file of Opt.

That is, if $g(v_g) > 1.5 \cdot [\textsc{dlm}_t, \mathcal{R}_2]$, Dlm waits the next $0.5\,D$ steps and (in step $t+2.25\,D$) it moves its file to the point v_h, where v_h is the minimizer of the function

$$h(v) = [\textsc{dlm}_t, v] + [v, \mathcal{R}_1] + 1.25 \cdot [v, \mathcal{R}_2] + 0.75 \cdot [v, \mathcal{R}_3] \ .$$

$\mathcal{R}_3$ is the multiset of the last $0.5\,D$ requests from the prolonged phase (from steps $t+1.75\,D+1,\ldots,t+2.25\,D$). Also in this case, the next phase starts right after the file movement.

Note that the *short phase* consists of D requests denoted $\mathcal{R}_1$ followed by $0.75\,D$ requests denoted $\mathcal{R}_2$, while the *long phase* consists additionally of $0.5\,D$ requests denoted $\mathcal{R}_3$. We will say that the short phase consists of *two parts*, $\mathcal{R}_1$ and $\mathcal{R}_2$, and the long phase consists of *three parts*, $\mathcal{R}_1$, $\mathcal{R}_2$ and $\mathcal{R}_3$.

2.3 DLM Analysis

We start with a lower bound on Opt. The following bound is an extension of the bound given implicitly in [8]; its proof is given in the full version of the paper.

▶ **Lemma 3.** *Let $\mathcal{R}$ be a subsequence of at most $2D$ consecutive requests from the input issued at steps $t+1, t+2, \ldots, t+|\mathcal{R}|$. Then, $4 \cdot C_{\mathrm{OPT}}(\mathcal{R}) \ge (2|\mathcal{R}|/D) \cdot [\textsc{op}_t, \mathcal{R}, \textsc{op}_{t+|\mathcal{R}|}] + (4 - 2|\mathcal{R}|/D) \cdot [\textsc{op}_t, \textsc{op}_{t+|\mathcal{R}|}]$.*

We define a potential function at (the end of) step t as $\Phi_t = 3 \cdot [\textsc{dlm}_t, \textsc{op}_t]$. It suffices to show that in any (short or long) phase consisting of steps $t+1, t+2, \ldots, t+\ell$, during which requests $\mathcal{R}$ are given, it holds that

$$C_{\mathrm{ALG}}(\mathcal{R}) + \Phi_{t+\ell} \le 4 \cdot C_{\mathrm{OPT}}(\mathcal{R}) + \Phi_t \ . \tag{1}$$

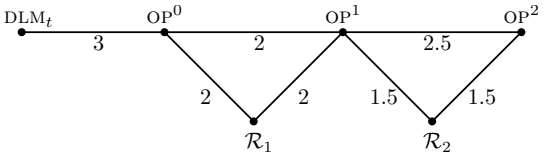
Theorem 1 follows immediately by summing the above bound over all phases of the input.

2.3.1 Proof for a short phase

We consider any short phase $\mathcal{R}$ consisting of part $\mathcal{R}_1$, spanning steps $t+1,\ldots,t+D$, and part $\mathcal{R}_2$, spanning steps $t+D+1,\ldots,t+1.75\,D$. For succinctness, we define $\textsc{op}^0 = \textsc{op}_t$, $\textsc{op}^1 = \textsc{op}_{t+D}$ and $\textsc{op}^2 = \textsc{op}_{t+1.75\,D}$. By Lemma 3 applied to $\mathcal{R}_1$ and $\mathcal{R}_2$,

$$\begin{aligned} 4 \cdot C_{\mathrm{OPT}}(\mathcal{R}) + \Phi_t \ &= \ 3 \cdot [\textsc{dlm}_t, \textsc{op}^0] + 4 \cdot C_{\mathrm{OPT}}(\mathcal{R}_1) + 4 \cdot C_{\mathrm{OPT}}(\mathcal{R}_2) \\ &\ge \ 3 \cdot [\textsc{dlm}_t, \textsc{op}^0] + 2 \cdot [\textsc{op}^0, \textsc{op}^1] + 2 \cdot [\textsc{op}^0, \mathcal{R}_1, \textsc{op}^1] \\ &\quad + 2.5 \cdot [\textsc{op}^1, \textsc{op}^2] + 1.5 \cdot [\textsc{op}^1, \mathcal{R}_2, \textsc{op}^2] \ . \end{aligned} \tag{2}$$

We treat the amount (2) as our budget. This is illustrated below; the coefficients are written as edge weights.



Budget = 4 OPT
+ initial potential
(short phase case)

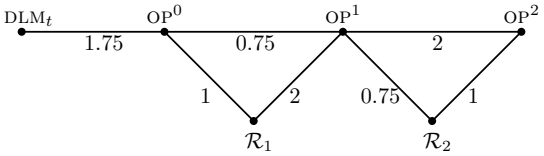
Now, we bound $C_{\text{ALG}}(\mathcal{R}) + \Phi_{t+1.75\,D}$ using the definition of ALG and the triangle inequality.

$$\begin{aligned}
&C_{\text{ALG}}(\mathcal{R}) + \Phi_{t+1.75\,D} \\
&\quad = C_{\text{ALG}}(\mathcal{R}_1) + C_{\text{ALG}}(\mathcal{R}_2) + 3[v_g, \text{OP}^2] \\
&\quad \le [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + [\text{DLM}_t, v_g] + 3 \cdot [v_g, \text{OP}^2] \\
&\quad \le [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + [\text{DLM}_t, v_g] + 2 \cdot [v_g, \mathcal{R}_1, \text{OP}^2] + [v_g, \mathcal{R}_2, \text{OP}^2] \\
&\quad = [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 2 \cdot [\text{OP}^2, \mathcal{R}_1] + [\text{OP}^2, \mathcal{R}_2] \\
&\qquad\quad + [\text{DLM}_t, v_g] + 2 \cdot [v_g, \mathcal{R}_1] + [v_g, \mathcal{R}_2] \\
&\quad = [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 2 \cdot [\text{OP}^2, \mathcal{R}_1] + [\text{OP}^2, \mathcal{R}_2] + g(v_g)\ . \qquad (3)
\end{aligned}$$

The first four summands of (3) can be bounded as

$$\begin{aligned}
&[\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 2 \cdot [\text{OP}^2, \mathcal{R}_1] + [\text{OP}^2, \mathcal{R}_2] \qquad (4) \\
&\quad \le [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \text{OP}^0, \text{OP}^1, \mathcal{R}_2] + 2 \cdot [\text{OP}^2, \text{OP}^1, \mathcal{R}_1] + [\text{OP}^2, \mathcal{R}_2]\ ,
\end{aligned}$$

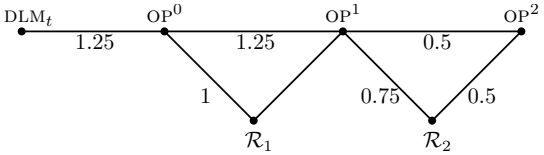
and their total weights in the final expression are depicted below.



DLM cost
+ final potential
(part 1, short phase)

For the last summand of (3), $g(v_g)$, we use the fact that v_g is a minimizer of the function g (and hence $g(v_g) \le g(\text{OP}^0)$), and the property of the short phase ($g(v_g) \le 1.5 \cdot [\text{DLM}_t, \mathcal{R}_2]$). Therefore,

$$\begin{aligned}
g(v_g) \ &\le\ 0.5 \cdot g(\text{OP}^0) + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] \\
&\le\ 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1, \text{OP}^0, \mathcal{R}_2] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] \qquad (5) \\
&\le\ 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1, \text{OP}^0, \text{OP}^1, \text{OP}^2, \mathcal{R}_2] + 0.75 \cdot [\text{DLM}_t, \text{OP}^0, \text{OP}^1, \mathcal{R}_2]\ .
\end{aligned}$$



DLM cost
+ final potential
(part 2, short phase)

By combining (3), (4) and (5) (or simply adding the edge coefficients on the last two figures) we observe that the budget ((2), i.e., the edge coefficients on the first figure) is not exceeded. This implies 4-competitiveness, i.e., that (1) holds for any short phase.

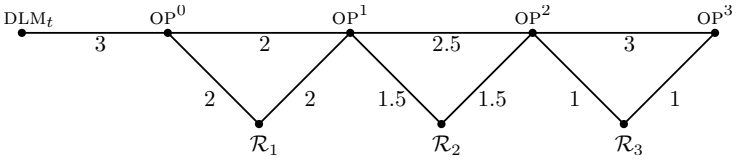
2.3.2 Proof for a long phase

We consider any long phase $\mathcal{R}$ consisting of part $\mathcal{R}_1$, spanning steps $t+1, \ldots, t+D$; part $\mathcal{R}_2$, spanning steps $t+D+1, \ldots, t+1.75 \cdot D$; and part $\mathcal{R}_3$, spanning steps $t+1.75 \cdot D+1, \ldots, t+2.25 \cdot D$. Similarly to the proof for a short phase, we define $\text{OP}^0 = \text{OP}_t$, $\text{OP}^1 = \text{OP}_{t+D}$,

$\text{OP}^2 = \text{OP}_{t+1.75\,D}$, and $\text{OP}^3 = \text{OP}_{t+2.25\,D}$. We emphasize that the positions of Opt in a long and a short phase can be completely different.

By Lemma 3, we obtain a bound very similar to that for a short phase; again, we treat it as a budget and depict its coefficients as edge weights.

$$\begin{aligned} 4 \cdot C_{\text{OPT}}(\mathcal{R}) + \Phi_t &= 3 \cdot [\text{DLM}_t, \text{OP}^0] + 4 \cdot C_{\text{OPT}}(\mathcal{R}_1) + 4 \cdot C_{\text{OPT}}(\mathcal{R}_2) + 4 \cdot C_{\text{OPT}}(\mathcal{R}_3) \\ &\geq 3 \cdot [\text{DLM}_t, \text{OP}^0] + 2 \cdot [\text{OP}^0, \text{OP}^1] + 2 \cdot [\text{OP}^0, \mathcal{R}_1, \text{OP}^1] \\ &\quad + 2.5 \cdot [\text{OP}^1, \text{OP}^2] + 1.5 \cdot [\text{OP}^1, \mathcal{R}_2, \text{OP}^2] \\ &\quad + 3 \cdot [\text{OP}^2, \text{OP}^3] + [\text{OP}^2, \mathcal{R}_3, \text{OP}^2] \ . \end{aligned} \tag{6}$$



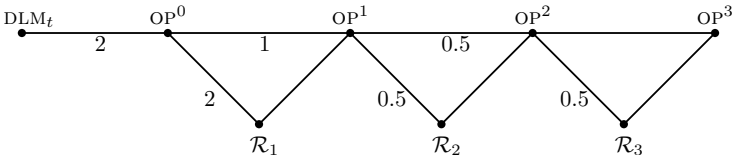
Budget = 4 OPT + initial potential (long phase case)

Now, we bound $C_{\text{ALG}}(R) + \Phi_{t+2.25\,D}$, using the definition of Alg and the triangle inequality.

$$\begin{aligned} &C_{\text{ALG}}(\mathcal{R}) + \Phi_{t+2.25\,D} \\ &\quad = C_{\text{ALG}}(\mathcal{R}_1) + C_{\text{ALG}}(\mathcal{R}_2) + C_{\text{ALG}}(\mathcal{R}_3) + 3 \cdot [v_h, \text{OP}^3] \\ &\quad = [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 0.5 \cdot [\text{DLM}_t, \mathcal{R}_3] + [\text{DLM}_t, v_h] + 3 \cdot [v_h, \text{OP}^3] \\ &\quad \leq [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 0.5 \cdot [\text{DLM}_t, \mathcal{R}_3] + [\text{DLM}_t, v_h] \\ &\qquad + [v_h, \mathcal{R}_1, \text{OP}^3] + 1.25 \cdot [v_h, \mathcal{R}_2, \text{OP}^3] + 0.75 \cdot [v_h, \mathcal{R}_3, \text{OP}^3] \\ &\quad = [\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 0.5 \cdot [\text{DLM}_t, \mathcal{R}_3] \\ &\qquad + [\text{OP}^3, \mathcal{R}_1] + 1.25 \cdot [\text{OP}^3, \mathcal{R}_2] + 0.75 \cdot [\text{OP}^3, \mathcal{R}_3] + h(v_h) \ . \end{aligned} \tag{7}$$

Since Dlm has not migrated the file after the first two parts, $g(v) \geq 1.5 \cdot [\text{DLM}_t, \mathcal{R}_2]$ for any node v. Therefore $0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] \leq 0.5 \cdot g(\text{OP}^0) = 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1, \text{OP}^0, \mathcal{R}_2] \leq 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1, \text{OP}^0, \text{OP}^1, \mathcal{R}_2]$. Using this and the triangle inequality, the first three summands of (7) can be bounded and depicted as follows:

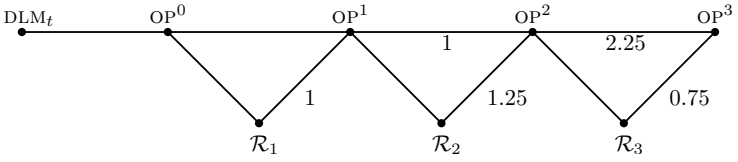
$$\begin{aligned} &[\text{DLM}_t, \mathcal{R}_1] + 0.75 \cdot [\text{DLM}_t, \mathcal{R}_2] + 0.5 \cdot [\text{DLM}_t, \mathcal{R}_3] \\ &\quad \leq [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1] + 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \mathcal{R}_1, \text{OP}^0, \text{OP}^1, \mathcal{R}_2] \\ &\qquad + 0.5 \cdot [\text{DLM}_t, \text{OP}^0, \text{OP}^1, \text{OP}^2, \mathcal{R}_3] \ . \end{aligned} \tag{8}$$



DLM cost + final potential (part1, long phase)

The next three summands of (7) can be also bounded appropriately:

$$\begin{aligned} &[\text{OP}^3, \mathcal{R}_1] + 1.25 \cdot [\text{OP}^3, \mathcal{R}_2] + 0.75 \cdot [\text{OP}^3, \mathcal{R}_3] \\ &\quad \leq [\text{OP}^3, \text{OP}^2, \text{OP}^1, \mathcal{R}_1] + 1.25 \cdot [\text{OP}^3, \text{OP}^2, \mathcal{R}_2] + 0.75 \cdot [\text{OP}^3, \mathcal{R}_3] \ . \end{aligned} \tag{9}$$

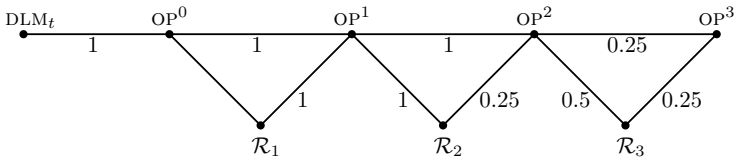


DLM cost + final potential (part 2, long phase)

Lastly, for bounding $h(v_h)$, we use the fact that v_h is a minimizer of h, and hence

$$\begin{aligned} h(v_h) &\leq h(\text{OP}^1) \\ &= [\text{OP}^1, \text{DLM}_t] + [\text{OP}^1, \mathcal{R}_1] + 1.25 \cdot [\text{OP}^1, \mathcal{R}_2] + 0.75 \cdot [\text{OP}^1, \mathcal{R}_3] \\ &\leq [\text{OP}^1, \text{OP}^0, \text{DLM}_t] + [\text{OP}^1, \mathcal{R}_1] + [\text{OP}^1, \mathcal{R}^2] + 0.25 \cdot [\text{OP}^1, \text{OP}^2, \mathcal{R}_2] \\ &\qquad + 0.5 \cdot [\text{OP}^1, \text{OP}^2, \mathcal{R}_3] + 0.25 \cdot [\text{OP}^1, \text{OP}^2, \text{OP}^3, \mathcal{R}_3] \ . \end{aligned} \tag{10}$$

Note that in (10) we split some of the paths and choose the longer ones, so that the budgets on edges are not violated. Bound (10) is depicted on the figure below.



DLM cost
+ final potential
(part 3, long phase)

By combining (7), (8), (9) and (10) (or simply adding edge coefficients on the last three figures), we observe that the budget ((6), i.e., the edge coefficients on the first figure) is not exceeded. This implies 4-competitiveness, i.e., that (1) holds for any long phase and concludes the proof of Theorem 1.

3 Lower Bound for Phase-Based Algorithms

A *fixed-phase algorithm* chooses phase length $c \cdot D$ and after every $c \cdot D$ requests it makes a migration decision solely on the basis of its current position and the last $c \cdot D$ requests. We now proceed to argue that no fixed-phase algorithm ALG can beat the competitive ratio $R_0 \approx 4.086$ achieved by MTLM [8] (cf. Theorem 2). As already stated in the introduction, to ensure that the algorithm cannot base its choices on the previous phases, we will give the adversary an additional power: it may modify the graph between the phases of ALG, as long as the distance between nodes keeping the files of ALG and OPT (v_{ALG} and v_{OPT}, respectively) is preserved. We emphasize that the analysis of MTLM [8] essentially uses this model: each phase is analyzed completely separately from others. The full proof is given in the full version of the paper; here we informally highlight its key ideas.

The adversarial construction consists of many epochs, each consisting of some number of phases. At the beginning and at the end of an epoch, ALG and OPT keep their files at the same node. We define three adversarial strategies, called *plays*: *linear*, *bipartite*, and *finishing*. Each play consists of one or more phases. A prerequisite for each given play is a particular distance between v_{ALG} and v_{OPT}. Each play will have some properties: it will incur some cost on ALG and OPT and will end with v_{ALG} and v_{OPT} in a specific distance.

In the first phase of an epoch, when initially $v_{\text{ALG}} = v_{\text{OPT}}$, the adversary uses the *linear* play (the generated graph is a single edge of length 1), so that at the end of the phase, $d(v_{\text{ALG}}, v_{\text{OPT}}) = 1$. For such phase P, we have $C_{\text{ALG}}(P) \geq R_0 \cdot C_{\text{OPT}}(P) - (1/(1-2\alpha)) \cdot D$, where $\alpha = 1/(R_0 - 1)$. Note that in this phase alone, the adversary does not enforce the desired competitive ratio of R_0, but it increases the distance between v_{OPT} and v_{ALG}.

In each of the next L phases, the adversary employs the *bipartite* play; the graph used corresponds to a tight bipartite example for MTLM, cf. Figure 1). Let f be the value of $d(v_{\text{ALG}}, v_{\text{OPT}})$ at the beginning of a phase. If the algorithm plays well, then at the end of the phase this distance decreases to $2\alpha \cdot f$. Furthermore, neglecting lower order terms, for such phase P, it holds that $C_{\text{ALG}}(P) \geq R_0 \cdot C_{\text{OPT}}(P) + f \cdot D$, i.e., the inequality $C_{\text{ALG}}(P) \geq R_0 \cdot C_{\text{OPT}}(P)$ holds with the slack $f \cdot D$. The sum of these slacks over L phases

is $\sum_{i=0}^{L-1}(2\alpha)^i \cdot D$, which tends to $(1/(1-2\alpha)) \cdot D$ when L grows. Hence, after one linear and L bipartite phases (for a large L and neglecting lower order terms again), the cost paid by Alg is at least R_0 times the cost paid by Opt and the distance between their files is negligible.

Finally, to decrease the distance between v_{ALG} and v_{OPT} to zero, the adversary uses a third type of play, the *finishing* one. This play incurs a negligible cost and it forces the positions of Alg and Opt files to coincide, which ends an epoch.

4 Linear Program for File Migration

In this section, we present a linear programming model for the analysis of both algorithm Mtlm by Bartal et al. [8] and our algorithm Dlm.

4.1 LP analysis of MTLM-like algorithms

In our approach, we analyze any Mtlm-like algorithm Alg. We use our notion of distances from Section 2.1. Alg will be a variant of Mtlm parameterized with two values β and δ. The length of its phase is $\delta \cdot D$ and the initial point of Alg is denoted by A_0. We denote the set of requests within a phase by $\mathcal{R}$. At the end of a phase, Alg migrates the file to a point A_1 that minimizes the function

$$f(x) = [A_0, x] + \beta \cdot [x, \mathcal{R}] \ .$$

As in the amortized analysis of the algorithm Mtlm [8], we will use a potential function equal to ϕ times the distance between the files of Alg and Opt, where ϕ is a parameter used in the analysis. We let O_0 and O_1 denote the initial and final position of Opt during the studied phase, respectively. Then, the amortized cost of Alg in a single phase is $C_{\text{ALG}} = \delta \cdot [A_0, \mathcal{R}] + [A_0, A_1] + \phi([A_1, O_1] - [A_0, O_0])$.

The following factor-revealing LP mimics the proof given in [8]. Namely, it encodes inequalities that are true for any phase and a graph on which Alg can be run. Its goal is to maximize the ratio between C_{ALG} and C_{OPT}: as an instance can be scaled, we set $C_{\text{OPT}} = 1$ and we maximize C_{ALG}. Let $V = \{A_0, A_1, O_0, O_1\}$ and $V' = V \cup \{\mathcal{R}\}$.

maximize C_{ALG}

subject to:

$$C_{\text{ALG}} = \delta \cdot [A_0, \mathcal{R}] + [A_0, A_1] + \phi \cdot ([A_1, O_1] - [A_0, O_0])$$
$$C_{\text{OPT}} = 1$$
$$C_{\text{OPT}} = C^{\text{req}}_{\text{OPT}} + C^{\text{move}}_{\text{OPT}}$$
$$C^{\text{move}}_{\text{OPT}} \geq [O_0, O_1]$$
$$2 \cdot C^{\text{req}}_{\text{OPT}} + \delta \cdot C^{\text{move}}_{\text{OPT}} \geq \delta \cdot [O_0, \mathcal{R}] + \delta \cdot [O_1, \mathcal{R}]$$
$$f(A_1) \leq f(v) \qquad \text{for all } v \in V$$
$$0 \leq [v_1, v_3] \leq [v_1, v_2] + [v_2, v_3] \qquad \text{for all } v_1, v_2, v_3 \in V'$$

As $\mathcal{R}$ is a set of requests, it does not necessarily correspond to a single point in the studied metric. Nevertheless, our notion of average distances (i.e., $[v_1, v_2]$) allows us to write the triangle inequalities for any pair of objects from set $V \cup \{\mathcal{R}\}$.

In the LP above, $C^{\text{req}}_{\text{OPT}}$, $C^{\text{move}}_{\text{OPT}}$ denote the cost of Opt for serving the request and the cost of Opt for migrating the file, respectively. The inequality $2 \cdot C^{\text{req}}_{\text{OPT}} + \delta \cdot C^{\text{move}}_{\text{OPT}} \geq \delta \cdot [O_0, \mathcal{R}] + \delta \cdot [O_1, \mathcal{R}]$ is a counterpart of the relation guaranteed by Lemma 3.

For any choice of parameters β, δ, and ϕ, the LP above finds an instance that maximizes the competitive ratio of Alg. Note that such instance is not necessarily a certificate that Alg indeed performs poorly: in particular, inequalities that lower-bound the cost of Opt might not be tight. However, the opposite is true: if the value of C_{ALG} returned by the LP is ξ, then for any possible instance the ratio is at most ξ.

Let $c_0 = 1.841$ be the phase length of Mtlm. Setting $\delta = c_0$ and $\beta = \phi = 1 + c_0$ yields that the optimal value of the LP is $R_0 \approx 4.086$, which can be interpreted as a numerical counterpart of the original analysis in [8]. To obtain a formal mathematical proof, one may take a dual solution to the LP. It gives the coefficients that multiplied by the corresponding LP inequalities and summed over all inequalities yield a proof that the amortized cost of Mtlm in any phase is at most R_0 times the cost of Opt. Summed over all phases, this implies that Mtlm is R_0-competitive.

Among other advantages, this approach allows us to numerically find the instances that are tight for the current analysis (cf. Section 2 and Figure 1): linear and bipartite instances can be obtained this way.

4.2 LP analysis of DLM-like algorithms

Now we show how to adapt the LP from the previous section to analyze Dlm-type algorithms. Recall that after $1.75\,D$ requests, Dlm evaluates the geometry of the so-far-received requests and decides whether to continue this phase or not. Although the final parameters of Dlm are elegant numbers (multiplicities of 1/4), they were obtained by a tedious optimization process using the LP we present below. Furthermore, the LP below does not give us an explicit rule for continuing the phase; it only tells that Dlm is successful either in a short or in a long phase.

Recall that in a phase, Dlm considers three groups of consecutive $\delta_i \cdot D$ requests: $\mathcal{R}_1$, $\mathcal{R}_2$, and $\mathcal{R}_3$, where δ_1, δ_2, and δ_3 are parameters of Dlm. First, assume that Dlm always processes three parts and afterwards it moves the file to a point A_3 that minimizes the function

$$h(x) = [A_0, x] + \beta_1 \cdot [x, \mathcal{R}_1] + \beta_2 \cdot [x, \mathcal{R}_2] + \beta_3 \cdot [x, \mathcal{R}_3] \ ,$$

where β_i are parameters that we choose later. We denote the strategy of an optimal algorithm by OptL (short for Opt-Long). Let O_0^L, O_1^L, O_2^L and O_3^L denote the trajectory of OptL (O_0^L is the initial position of the OptL's file at the beginning of the phase, and O_i^L is its position right after the i-th part of the phase). Analogously to the previous section, we obtain the following LP.

maximize C_{ALGL}

subject to:

$$C_{\text{ALGL}} = [A_0, A_3] + \textstyle\sum_{i=1,2,3} \delta_i \cdot [A_0, \mathcal{R}_i] + \phi \cdot ([A_3, O_3^L] - [A_0, O_0^L])$$

$$C_{\text{OPTL}} = 1$$

$$C_{\text{OPTL}} = \textstyle\sum_{i=1,2,3} (C^{\text{req}}_{\text{OPTL}}(i) + C^{\text{move}}_{\text{OPTL}}(i))$$

$$C^{\text{move}}_{\text{OPTL}}(i) \geq [O_{i-1}^L, O_i^L] \qquad \text{for } i = 1, 2, 3$$

$$2 \cdot C^{\text{req}}_{\text{OPTL}}(i) + \delta \cdot C^{\text{move}}_{\text{OPTL}}(i) \geq \delta_i \cdot [O_{i-1}^L, \mathcal{R}_i] + \delta_i \cdot [O_i^L, \mathcal{R}_i] \qquad \text{for } i = 1, 2, 3$$

$$h(A_3) \leq h(v) \qquad \text{for all } v \in V$$

$$0 \leq [v_1, v_3] \leq [v_1, v_2] + [v_2, v_3] \qquad \text{for all } v_1, v_2, v_3 \in V'$$

This time $V = \{A_0, A_3, O_0^L, O_1^L, O_2^L, O_3^L\}$ and $V' = V \cup \{\mathcal{R}_1, \mathcal{R}_2, \mathcal{R}_3\}$.

We note that such parameterization alone does not improve the competitive ratio, i.e., for any choice of parameters δ_i and β_i, the objective value of the LP above is at least $R_0 \approx 4.086$.

However, as stated in Section 2.1, DLM verifies if after two parts it can migrate its file to a node A_2 being the minimizer of the function

$$g(x) = [A_0, x] + \beta'_1 \cdot [x, \mathcal{R}_1] + \beta'_2 \cdot [x, \mathcal{R}_2] \ ,$$

where β'_i are parameters that we choose later.

In our analysis, we gave an explicit rule whether the migration to A_2 should take place. However, for our LP-based approach, we follow a slightly different scheme. Namely, if the migration to A_2 guarantees that the amortized cost in the short phase (the first two parts) is at most 4 times the cost of *any* strategy for the short phase, then DLM may move to A_2 and we immediately achieve competitive ratio 4 on the short phase. Otherwise, we may add additional constraints to the LP, stating that the competitive ratio of an algorithm which moves to A_2 is at least 4 (against any chosen strategy OPTS). Analogously to OPTL, the trajectory of OPTS is described by three points: O_0^S, O_1^S, and O_2^S. This allows us to strengthen our LP by adding the following inequalities:

$$\begin{aligned}
&C_{\text{ALGS}} = [A_0, A_2] + \textstyle\sum_{i=1,2} \delta_i \cdot [A_0, \mathcal{R}_i] + \phi \cdot ([A_2, O_2^S] - [A_0, O_0^S]) \\
&C_{\text{OPTS}} = \textstyle\sum_{i=1,2} (C^{\text{req}}_{\text{OPTS}}(i) + C^{\text{move}}_{\text{OPTS}}(i)) \\
&C^{\text{move}}_{\text{OPTS}}(i) \geq [O_{i-1}^S, O_i^S] && \text{for } i = 1, 2 \\
&2 \cdot C^{\text{req}}_{\text{OPTS}}(i) + \delta \cdot C^{\text{move}}_{\text{OPTS}}(i) \geq \delta_i \cdot [O_{i-1}^S, \mathcal{R}_i] + \delta_i \cdot [O_i^S, \mathcal{R}_i] && \text{for } i = 1, 2 \\
&g(A_2) \leq g(v) && \text{for all } v \in V \\
&C_{\text{ALGS}} \geq 4 \cdot C_{\text{OPTS}}
\end{aligned}$$

We also change V to $\{A_0, A_3, O_0^L, O_1^L, O_2^L, O_3^L, O_0^S, O_1^S, O_2^S\}$, both in new and in old inequalities.

When we choose $\phi = 3$, fix phase length parameters to be $\delta_1 = 1$, $\delta_2 = 0.75$, $\delta_3 = 0.5$ and parameters for functions g and h to be $\beta'_1 = 2$, $\beta'_2 = 1$, $\beta_1 = 1, \beta_2 = 0.25$ and $\beta_3 = 0.75$, we obtain that the value of the above LP is 4. Again, this can be interpreted as a numerical argument that DLM is indeed a 4-competitive algorithm.

5 Conclusions

While in the last decade factor-revealing LPs became a standard tool for analysis of approximation algorithms, their application to online algorithms so far have been limited to online bipartite matching and its variants (see, e.g., [24, 20]) and for showing lower bounds [5]. In this paper, we successfully used the factor-revealing LP to bound the competitive ratio of an algorithm for an online problem defined on an arbitrary metric space. We believe that similar approaches could yield improvements also for other online graph problems.

Abstract

We study a variant of the k-server problem, the infinite server problem, in which infinitely many servers reside initially at a particular point of the metric space and serve a sequence of requests. In the framework of competitive analysis, we show a surprisingly tight connection between this problem and the (h, k)-server problem, in which an online algorithm with k servers competes against an offline algorithm with h servers. Specifically, we show that the infinite server problem has bounded competitive ratio if and only if the (h, k)-server problem has bounded competitive ratio for some $k = O(h)$. We give a lower bound of 3.146 for the competitive ratio of the infinite server problem, which implies the same lower bound for the (h, k)-server problem even when $k/h \to \infty$ and holds also for the line metric; the previous known bounds were 2.4 for general metric spaces and 2 for the line. For weighted trees and layered graphs we obtain upper bounds, although they depend on the depth. Of particular interest is the infinite server problem on the line, which we show to be equivalent to the seemingly easier case in which all requests are in a fixed bounded interval away from the original position of the servers. This is a special case of a more general reduction from arbitrary metric spaces to bounded subspaces. Unfortunately, classical approaches (double coverage and generalizations, work function algorithm, balancing algorithms) fail even for this special case.

1 Introduction

The k-server problem is a fundamental well-studied online problem [19, 16]. In this problem k servers serve a sequence of requests. The servers reside at k points of a metric space M and requests are simply points of M. Serving a request entails moving one of the servers to the request. The objective is to minimize the total distance traveled by the servers. The most interesting variant of the problem is its online version, in which the requests appear one-by-one and the online algorithm must decide how to serve a request without knowing the future requests. It is known that the deterministic k-server problem has competitive ratio between k and $2k - 1$ for every metric space with at least $k + 1$ distinct points [19, 17].

In this paper, we study the *infinite server problem*, the variant of the k-server problem in which there are infinitely many servers, all of them initially residing at a given point, the

source[1]. At first glance it may appear that the lower bound of k for the k-server problem would imply an unbounded competitive ratio for the infinite server problem. But consider, for example, the version of the k-server problem on uniform metric spaces (i. e. the distance between any two points is 1), and observe that the infinite server problem has competitive ratio 1 for this case.

The infinite server problem is closely related to the (h, k)-server problem, the resource augmentation version of the k-server problem in which the online algorithm has k servers and competes against an offline algorithm for $h \leq k$ servers. This model is also known as *weak adversaries* [2, 15]. One major open problem in competitive analysis is whether the (h, k)-server problem has bounded competitive ratio when $k \gg h$. Here we show a, perhaps surprising, tight connection between the infinite server problem and the (h, k)-server problem, which also allows us to improve lower bounds for the latter.

The infinite server problem is also a considerable generalization of the ski-rental problem, since the ski-rental problem is essentially a special case of the infinite server problem when the metric space is an isosceles triangle.

Besides its theoretical appeal, our three main reasons for investigating the infinite server problem are the following. First, the competitive ratio of the k-server problem goes to infinity as $k \to \infty$, but for $k = \infty$ it goes back to a small constant at least on some metric spaces. This suggests that the high competitive ratio of the k-server problem is somewhat artificial. Second, the problem allows to model applications where the number of servers is so high that it is not a limitation in practice, or where more servers can be bought. A price for buying new servers can be modeled easily by appropriate placement of the source in the metric space. Third, the relationship between the infinite server problem and the (h, k)-server problem allows for new ways to tackle the latter.

1.1 Previous Work

The k-server problem was first formulated by Manasse et al. [19], to generalize a variety of online settings whose stepwise cost had a 'metric'-like structure. They built on previous work by Sleator and Tarjan [20], the genesis of competitive analysis, on the paging problem. This problem can be easily recast as a k-server instance for the uniform metric and was already known to be k-competitive.

Manasse et al. [19] also showed that the competitive ratio of the k-server problem is at least k on any metric space with more than k points. They then proposed the renowned k-server conjecture, stating that this bound is tight. This has been shown to be true for $k = 2$ [19] and for several special metric spaces [6, 7, 18, 19, 20]. A stream of refinements [12, 3] led to better competitive ratios for general metric spaces until [17] showed that a competitive ratio of $2k - 1$ can be achieved on any metric space. Chasing the competitive ratio for the deterministic (and randomized) k-server problem has been pivotal for the development of competitive analysis. For a more in depth view on the history of the k-server problem and further related work, we refer to [16].

In the weak adversaries setting, significantly less is known. For the (h, k)-server problem, the exact competitive ratio is $\frac{k}{k-h+1}$ on uniform metrics (equivalent to paging) [20] and weighted stars (equivalent to weighted paging) [21]. Bansal et al. [1] showed recently for weighted trees that the competitive ratio as $k/h \to \infty$ is bounded by a constant depending on the depth of the tree. On general metrics, the (h, k)-server problem is still poorly understood.

[1] We first learned about this problem from Kamal Jain [14].

No algorithm is known for general metrics that performs better than disabling the $k-h$ extra servers and using h servers only. In fact, for the line it was shown [2, 1] that the Double Coverage Algorithm and the Work Function Algorithm – despite achieving the optimal competitive ratio of h if $k=h$ [6, 4] – perform strictly worse in the resource augmentation setting than disabling the $k-h$ extra servers and applying the same algorithm to h servers only. For the case that h is not fixed, the Work Function Algorithm was shown to be $2h$-competitive simultaneously against any number $h \leq k$ of offline servers [15].

In terms of lower bounds, it is known that unlike for (weighted) paging, the competitive ratio does not converge to 1 on general metrics even as $k/h \to \infty$. Prior to this work, the best known lower bounds were 2 on the line, due to Bar-Noy and Schieber (see [5, p. 175]), and 2.4 for general metrics as shown recently by Bansal et al. [1].

The closest publication to this work is by Csirik et al. [10], which studies a problem that is essentially the special case of the infinite server problem on the uniform metric space augmented by a far away source. It is cast as a paging problem where new cache slots can be bought at a fixed price per unit and gives matching upper and lower bounds of ≈ 3.146 on the competitive ratio.

1.2 Our Results

Our main result is an equivalence theorem between the infinite server problem and the (h,k)-server problem, presented in Section 2. It states that the infinite server problem is competitive on every metric space if and only if the (h,k)-server problem is $O(1)$-competitive on every metric space as $k/h \to \infty$. We show further that it is not even necessary to let k/h tend to infinity because in the positive case, there must also exist some $k = O(h)$. The theorem holds also if "every metric space" is replaced by "the real line".

In Section 3 we present upper and lower bounds on the competitive ratio of the infinite server problem on a variety of metric spaces. Extending the work in [10], we present a tight lower bound for non-discrete spaces, which is then turned into a 3.146 lower bound for the (h,k) setting. To our knowledge, this is the largest bound on the weak adversaries setting for any metric space, as $k/h \to \infty$. We show how recent work by Bansal et al. [1] can be adapted to give an upper bound on the competitive ratio of the infinite server problem on bounded-depth weighted trees. We also consider layered graph metrics, which are equivalent (up to a factor of 2) to general graph metrics. We have not settled the case for their competitive ratio, but we present a natural algorithm with tight analysis and pose challenges for further research. The main open problem is whether there exists a metric space on which the infinite server problem is not competitive.

In Section 4 we show how a variety of known algorithms such as the work function and balancing algorithms fail for the infinite server problem, even on the real line. We focus in particular on a class of speed-adjusted variants of the well-known double coverage algorithm.

Finally, we present a useful reduction from arbitrary metric spaces to bounded subspaces in Section 5. In particular, the infinite server problem on the line is competitive if and only if it is competitive for the special case where requests are restricted to some bounded interval further away from the source.

1.3 Preliminaries

Let $M=(M,d)$ be a metric space and let s be a point of M. In the *infinite server problem on* (M,s), an unbounded number of servers starts at point s and serves a finite sequence

$\sigma = (\sigma_0 = s, \sigma_1, \sigma_2, \ldots, \sigma_m)$ of requests $\sigma_i \in M$. Serving a request entails moving one of the servers to it. The goal is to minimize the total distance traveled by the servers.

We drop s in the notation if the location of the source is not relevant or understood. We refer to the action of moving a server from the source to another point as *spawning*. Throughout this work we use the letter d for the metric associated with the metric space.

In the online setting, the requests are revealed one by one and need to be served immediately without knowledge of future requests. All algorithms considered in this paper are deterministic. An algorithm is called *lazy* if it moves only one server to serve a request at an unoccupied point and moves no server if the requested point is already covered. An algorithm is called *local* [9] if it moves a server from a to b only if there is no server at some other point c on a shortest path from a to b, i. e. with $d(a, b) = d(a, c) + d(c, b)$. It is easy to see that any algorithm can be turned into a lazy and local algorithm without increasing its cost (i. e. the total distance traveled by all servers).

For an algorithm ALG, we denote by $ALG(\sigma)$ its cost on the request sequence σ. Similarly, we write $OPT(\sigma)$ for the optimal (offline) cost.

An online algorithm ALG is *ρ-competitive* for $\rho \geq 1$ if $ALG(\sigma) \leq \rho OPT(\sigma) + c$ for all σ, where c is a constant independent of σ. The *competitive ratio* of an algorithm is the infimum of all such ρ. We say that an algorithm is *competitive* if it is ρ-competitive for some ρ. We also call an online problem itself (ρ-)competitive if it admits such an algorithm. If the additive term c in the definition is 0, then the algorithm is also called *strictly ρ-competitive* [11].

The *(h, k)-server problem on M* is defined like the infinite server problem except that the number of servers is k for the online algorithm and h for the optimal (offline) algorithm against whom it is compared in the definition of competitiveness. For this problem, the servers are not required to start at the same point, although a different initial configuration would only affect the additive term c. The problem is interesting only when $k \geq h$. The case $h = k$ is the standard k-server problem and the case $k \geq h$ is known as the *weak adversaries* model. One major open problem is to determine the competitive ratio of the (h, k)-server problem as k tends to infinity.

We will sometimes write OPT_h and OPT_∞ for the optimal offline algorithm, where the index specifies the number of servers available.

The following two propositions will be useful later in the paper.

▶ **Proposition 1.** *If for every metric space there exists a competitive algorithm for the infinite server problem, then there exists a universal competitive ratio ρ such that the infinite server problem is* strictly *ρ-competitive on every metric space.*

Proof. We first show the existence of ρ such that the infinite server problem is ρ-competitive (strictly or not) on every metric space. Suppose such ρ does not exist, then for every $n \in \mathbb{N}$ we can find a metric space M_n containing some point s_n such that the infinite server problem on (M_n, s_n) is not n-competitive. Consider the metric space obtained by taking the disjoint union of all spaces M_n and gluing all the points s_n together. The infinite server problem would not be competitive on this metric space, in contradiction to the assumption.

Analogously we can also find a universal constant c that works for all metric spaces as additive constant in the definition of ρ-competitiveness. A scaling argument shows that also $c = 0$ works. ◀

With a very similar argument we get:

▶ **Proposition 2.** *Let $k = k(h)$ be a function of h. Suppose that for every metric space M and for all h there exists an $O(1)$-competitive algorithm for the (h, k)-server problem on M. Then there exists a universal competitive ratio ρ such that the (h, k)-server problem is strictly ρ-competitive on every metric space if all servers start at the same point.*

2 Equivalence of Infinite Servers and Weak Adversaries

The main result of this section is the following tight connection between the infinite server problem and the weak adversaries model.

▶ **Theorem 3.** *The following are equivalent:*
1. *The infinite server problem is competitive.*
2. *The (h, k)-server problem is $O(1)$-competitive as $k/h \to \infty$.*
3. *For each h there exists $k = O(h)$ so that the (h, k)-server problem is $O(1)$-competitive.*

The three statements above are also equivalent if we fix the metric space to be the real line.

The implication "3 $\Longrightarrow$ 2" is trivial. The proof of the equivalence theorem consists in its core of two reductions. Theorem 4 contains the easier of the two reductions, which is from the infinite server problem to the k-server problem against weak adversaries ("2 $\Longrightarrow$ 1"). By Propositions 1 and 2, it suffices to consider only strictly competitive algorithms. Theorem 5 proves essentially the inverse for general metric spaces, and Theorem 8 specializes it to the line ("1 $\Longrightarrow$ 3").

As a corollary of the theorem we get the non-trivial implication "2 $\Longrightarrow$ 3", a potentially useful statement towards resolving the major open problem about weak adversaries: "Is Statement 2 true?" This highlights the importance of the infinite server problem.

▶ **Theorem 4.** *Fix a metric space M and consider algorithms with all servers starting at some $s \in M$. If for every h there exists $k = k(h)$ such that the (h, k)-server problem on M is strictly ρ-competitive, for some constant ρ, then there exists a strictly ρ-competitive online strategy for the infinite server problem on M.*

Proof. Let $ALG_{k(h)}$ denote an online algorithm with $k(h)$ servers that is strictly ρ-competitive against an optimal algorithm OPT_h for h servers, i. e.

$$ALG_{k(h)}(\sigma) \leq \rho OPT_h(\sigma) \tag{1}$$

for every request sequence σ. Without loss of generality, algorithm $ALG_{k(h)}$ is lazy.

For every request sequence σ, consider the equivalence relation $\equiv_\sigma$ on natural numbers in which $h \equiv_\sigma h'$ if and only if $ALG_{k(h)}(\sigma)$ and $ALG_{k(h')}(\sigma)$ serve σ in exactly the same way (i. e. , make exactly the same moves). To every σ, we associate an equivalence class $H(\sigma)$ of $\equiv_\sigma$ that satisfies
- $H(\sigma)$ is infinite,
- $H(\sigma r) \subseteq H(\sigma)$, for every request r.

This is done inductively in the length of σ (in a manner reminiscent of König's lemma) as follows: For the base case when σ is the empty request sequence, $H(\sigma) = \mathbb{N}$. For the induction step, suppose that we have defined $H(\sigma)$. Consider the equivalence classes of $\equiv_{\sigma r}$, a refinement of the equivalence classes of $\equiv_\sigma$. Since there are only finitely many possible ways to serve r, they partition $H(\sigma)$ into finitely many parts. At least one of these parts is infinite and we select it to be $H(\sigma r)$; if there is more than one such sets, we select one arbitrarily, say the lexicographically first.

Given such a mapping H, we define the online algorithm ALG_∞ which serves every σ in the same way as all the online algorithms $ALG_{k(h)}$ for $h \in H(\sigma)$. The second property of H guarantees that ALG_∞ is a well-defined online algorithm.

By construction, $ALG_\infty(\sigma) = ALG_{k(h)}(\sigma)$ for every $h \in H(\sigma)$. To finish the proof, observe that since $H(\sigma)$ is infinite, it contains some h greater than the length of σ, and for such an h we have $OPT_\infty(\sigma) = OPT_h(\sigma)$. Substituting these to (1), we see that ALG_∞ is strictly ρ-competitive. ◀

We now show the reduction from the k-server problem against weak adversaries to the infinite server problem on general metric spaces.

▶ **Theorem 5.** *If the infinite server problem on general metric spaces is strictly $\tilde{\rho}$-competitive, then there exists a constant ρ such that the (h,k)-server problem is ρ-competitive, for $k = O(h)$. In particular, for every $\epsilon > 0$, we can take $\rho = (3+\epsilon)\tilde{\rho}$ and any $k \geq (1+1/\epsilon)\tilde{\rho}h$.*

Proof. Fix some metric space M and a point $s \in M$. We will describe a strictly ρ-competitive algorithm for the (h,k)-server problem on M for the case that all servers start at s. This implies a (not necessarily strictly) ρ-competitive algorithm for any initial configuration.

The idea is to simulate a strictly $\tilde{\rho}$-competitive infinite server algorithm, but whenever it would spawn a $(k+1)$-st server, we bring all servers back to the origin and restart the algorithm. The problem is that the overhead cost for returning the servers to the origin, may be very high. To compensate for this, we assume that every time the servers return to the origin, they pretend to start from a different point further away from the origin. This motivates the following notation:

▶ **Definition 6.** Given a metric M, a point $s \in M$, and a value $w \geq 0$, we will use the notation $M_{s \oplus w}$ to denote the metric derived from M when we increase the distance of s from every other point by w; we will also denote the relocated point by $s \oplus w$.

Let ALG_∞ denote a strictly $\tilde{\rho}$-competitive online algorithm for the infinite server problem. We now define an online algorithm ALG_k for k servers (all starting at s). We will make use of the notation $A(\sigma; s)$ to denote the cost of algorithm A to serve the request sequence σ when all servers start at s.

▶ **Definition 7** (ALG_k derived from ALG_∞)**.** Algorithm ALG_k runs in phases with the initial phase being the 0th phase. At the beginning of every phase, all servers of ALG_k are at s. In every phase i, the algorithm simulates the infinite server algorithm ALG_∞, whose servers start at $s \oplus w_i$ for some $w_i \geq 0$. The parameters w_i are determined online, and initially $w_0 = 0$. Whenever ALG_∞ spawns a server from $s \oplus w_i$, algorithm ALG_k spawns a server from s.

The phase ends just before ALG_∞ spawns its $(k+1)$-st server or when the request sequence ends. In the former case, all servers of ALG_k return to s to start the $(i+1)$-st phase. To determine the starting point of the simulated algorithm of the next phase, we set

$$w_{i+1} = \epsilon \, \frac{OPT_h(\sigma_i; s)}{h}\,, \tag{2}$$

where σ_i is the sequence of requests during phase i.

Let n be the number of phases. The cost of ALG_k for the requests in phase $i < n$ is $ALG_\infty(\sigma_i; s \oplus w_i) - kw_i$; the last term is subtracted because the k servers do not have to actually travel the distance between $s \oplus w_i$ and s. However for the last phase no such term can be subtracted since we do not know how many servers are spawned during the phase, and we can only bound the cost from above by $ALG_\infty(\sigma_n; s \oplus w_n)$. The cost of returning the servers to s at the end of a phase can at most double the cost during the phase.

From this, we see that the total cost of ALG_k in phase i is

$$cost_i \leq \begin{cases} 2\left(ALG_\infty(\sigma_i; s \oplus w_i) - kw_i\right) & \text{for } i < n \\ ALG_\infty(\sigma_n; s \oplus w_n) & \text{for } i = n\,. \end{cases}$$

Since ALG_∞ is strictly $\tilde{\rho}$-competitive, we have

$$\begin{aligned} ALG_\infty(\sigma_i; s \oplus w_i) &\leq \tilde{\rho}\, OPT_\infty(\sigma_i; s \oplus w_i) \\ &\leq \tilde{\rho}\, OPT_h(\sigma_i; s \oplus w_i) \\ &\leq \tilde{\rho}\, (OPT_h(\sigma_i; s) + hw_i) \end{aligned}$$

and substituting this in the expression for the cost, we can bound the total cost by

$$\begin{aligned} ALG_k(\sigma; s) = \sum_{i=0}^{n} cost_i &\leq 2 \sum_{i=0}^{n-1} (\tilde{\rho}(OPT_h(\sigma_i; s) + hw_i) - kw_i) + \tilde{\rho}(OPT_h(\sigma_n; s) + hw_n) \\ &= 2 \sum_{i=0}^{n-1} (\tilde{\rho} OPT_h(\sigma_i; s) - (k - \tilde{\rho}h)w_i) + \tilde{\rho} OPT_h(\sigma_n; s) + \tilde{\rho} h w_n \,. \end{aligned}$$

The parameters w_i and k were selected so that the summation telescopes, and we are left with

$$\begin{aligned} ALG_k(\sigma; s) &\leq 2\,\tilde{\rho}\, OPT_h(\sigma_{n-1}; s) + \tilde{\rho}\, OPT_h(\sigma_n; s) + \tilde{\rho}\,\epsilon\, OPT_h(\sigma_{n-1}; s) \\ &\leq (3 + \epsilon)\,\tilde{\rho}\, OPT_h(\sigma; s)\,. \end{aligned}$$

◀

The previous reduction requires the infinite server problem to be competitive on *every* metric space. The following variant only requires the infinite server problem to be competitive on the line.

▶ **Theorem 8.** *If the infinite server problem on the line is ρ-competitive, then for every $h \in \mathbb{N}$ and $\epsilon > 0$, the (h, k)-server problem on the line is $(3 + \epsilon)\rho$-competitive, when $k \geq 2\lceil(1 + 1/\epsilon)\rho h\rceil$.*

Proof. A straightforward adaptation of the proof of the previous lemma, shows the existence of a $(3 + \epsilon)\rho$-competitive algorithm for the interval $[0, \infty)$, when $k \geq 2(1 + 1/\epsilon)\rho h$. By doubling the number of online servers so that half of them are used in each half-line, we get a $(3 + \epsilon)\rho$-competitive algorithm for the entire line, when $k \geq 2\lceil(1 + 1/\epsilon)\rho h\rceil$.

Note that the proof assumes strictly competitive algorithms. But, by a straightforward scaling argument, if the infinite server problem on the line is ρ-competitive, then it is also strictly ρ-competitive. This in turn implies a strictly ρ-competitive online algorithm for $M_{0 \oplus w}$, since this space is isometric to the subspace $\{-w\} \cup (0, \infty)$ of the line. ◀

In the next section we look at some particular metric spaces and give upper and lower bounds on the competitive ratio.

3 Upper and Lower Bounds

Unlike the k-server problem, which is 1-competitive if and only if the metric spaces has at most k points and conjectured k-competitive otherwise, the situation is more diverse for the infinite server problem. For example, on uniform metric spaces (where all distances are the same) the problem is trivially 1-competitive even if the metric space consists of uncountably many points. This is because an optimal strategy in this case is to spawn a server to every requested point. More generally, this strategy achieves a finite competitive ratio on any metric space where distances are bounded from below and above by positive constants. This suggests that statements about the competitive ratio for the infinite server problem cannot be as simple as the (conjectured) dichotomy for the k-server problem, which depends only on the number of points of the metric space. In this section we derive bounds on the competitive ratio for particular classes of metric spaces.

3.1 Weighted Trees

We consider the infinite server problem on metric spaces that can be modeled by edge-weighted trees. The points of the metric space are the nodes of the tree, and the distance between two nodes is the sum of edge weights along their connecting path. We choose the source of the metric space as the root of the tree, and define the depth of the tree as the maximal number of edges from the root to a leaf. The number of nodes can be infinite (otherwise the infinite server problem is trivially 1-competitive), but we assume the depth to be finite.

An upper bound on the competitive ratio of such trees follows easily from an upper bound for the (h, k)-server on such trees [1] and the equivalence theorem:

▶ **Theorem 9.** *The competitive ratio of the infinite server problem on trees of depth d is at most $O(2^d \cdot d)$.*

Proof. Bansal et al. [1, Theorem 1.3] showed that the competitive ratio of the (h, k)-server problem on trees of depth d is at most $O(2^d \cdot d)$ provided that k/h is large enough. Inspection of the proof in [1] shows that if all servers start at the root, it is in fact strictly $O(2^d \cdot d)$-competitive. Thus, Theorem 4 implies the result for the infinite server problem. ◀

3.2 Non-Discrete Spaces and Spaces with Small Infinite Subspaces

The following theorem gives a lower bound of 3.146 on the competitive ratio of the infinite server problem on any metric space containing an infinite subspace of a diameter that is small compared to the subspace's distance from the source. For example, every non-discrete metric space has this property (unless the source is the only non-discrete point), since non-discrete metric spaces contain infinite subspaces of arbitrarily small diameter. The theorem is a generalization of such a lower bound established in [10] for a variant of the paging problem where cache cells can be bought. Crucial parts of the subsequent proof are as in [10].

▶ **Theorem 10.** *Let M be a metric space containing an infinite subspace $M_0 \subset M$ of finite diameter δ and a point $s \in M \setminus M_0$ such that the infimum Δ of distances between s and points in M_0 is positive. Let $\lambda > 3.146$ be the largest real solution to*

$$\lambda = 2 + \ln \lambda \,. \tag{3}$$

The competitive ratio of any deterministic online algorithm for the infinite server problem on (M, s) is bounded from below by a value that converges to λ as $\Delta/\delta \to \infty$. In particular, the competitive ratio is at least λ if $M \setminus \{s\}$ contains a non-discrete part.

Proof. By scaling the metric, we can assume that $\delta = 1$. Let $p_1, p_2, p_3, \ldots$ be infinitely many distinct points in M_0.

Fix some lazy deterministic online algorithm ALG. We consider the request sequence that always requests the point p_i with i minimal such that p_i is not occupied by a server of ALG. We call a move of a server between two points in M_0 *local* (i. e. every move that does not spawn is local). Let f_j be the cumulative cost of local moves incurred to ALG until it spawns its jth server. Let σ_k be this request sequence that is stopped right after ALG spawns its kth server, for some large k. The total online cost is

$$ALG(\sigma_k) \geq k\Delta + f_k \,. \tag{4}$$

Let $h = \lceil k/\lambda \rceil$. We consider several offline algorithms that start behaving the same way, so we think of it as one algorithm initially that is forked into several algorithms later. The

offline algorithms make use of only h servers and they begin by spawning them to the points $p_1, \dots, p_h$. They do not need to move any servers until ALG spawns its hth server. Whenever ALG spawns its jth server for some $j \geq h$, every offline algorithm is forked to h distinct algorithms: Each of them moves a different server to p_{j+1} (to prepare for the next request, which will be at p_{j+1}). We will keep the invariant that each offline algorithm already has a server at the next request. To this end, whenever ALG does a local move from p to p', every offline algorithm that does not have a server at p moves a server from p' to p; note that the algorithm had a server at p' by the invariant, and the next request will be at p.

When ALG has j spawned servers ($j \geq h$), the offline algorithms are in $\binom{j}{h-1}$ different configurations, each of which occurs equally often among them. If ALG does a local move from p to p', there are $\binom{j-1}{h-1}$ different offline configurations for which a local move is made in the opposite direction. Thus, for each local move by ALG while having j servers in total, a portion $\binom{j-1}{h-1}/\binom{j}{h-1} = \frac{j-h+1}{j}$ of the offline algorithms move a server in the opposite direction for the same cost.

We use the average cost of all offline algorithms we considered as an upper bound on the optimal cost. The cost of spawning h servers is at most $h(\Delta+1)$, and the average cost while ALG has j spawned servers (for $j = h, \dots, k-1$) is at most $\frac{j-h+1}{j}(f_{j+1} - f_j) + 1$ (with the "+1" coming from the move when offline algorithms fork). Hence,

$$\begin{aligned} OPT(\sigma_k) &\leq h(\Delta+1) + k - h + \sum_{j=h}^{k-1} \frac{j-h+1}{j}(f_{j+1} - f_j)\,, \\ &\leq h\Delta + k + \frac{k-h}{k-1} f_k - \frac{f_h}{h} - \sum_{j=h+1}^{k-1} \frac{h-1}{j(j-1)} f_j\,, \end{aligned}$$

Note that $\frac{f_k}{k}$ is bounded from above because otherwise ALG would not be competitive, and it is bounded from below by 0. Thus, $L = \liminf_{k\to\infty} \frac{f_k}{k}$ exists. In the following we use the asymptotic notation $o(1)$ for terms that disappear as $k \to \infty$. We can choose arbitrarily large values of k such that $\frac{f_k}{k} = L + o(1)$. Since $h = \lceil k/\lambda \rceil$, we have $\frac{f_j}{j} \geq L + o(1)$ for all $j \geq h$. Moreover, $\sum_{j=h+1}^{k-1} \frac{1}{j-1} = \ln(\lambda) + o(1)$. This allows us to simplify the previous bound to

$$\begin{aligned} OPT(\sigma_k) &\leq \frac{k}{\lambda}\Big(\Delta + \lambda + \big(\lambda - 1 - \ln(\lambda)\big)L + o(1)\Big) \\ &= \frac{k}{\lambda}\big(\Delta + L + \lambda + o(1)\big)\,, \end{aligned}$$

where the last step uses equation (3).

The competitive ratio is at least

$$\begin{aligned} \frac{ALG(\sigma_k) + O(1)}{OPT(\sigma_k)} &\geq \frac{k\Delta + f_k + O(1)}{\frac{k}{\lambda}\big(\Delta + L + \lambda + o(1)\big)} \\ &= \lambda \cdot \frac{\Delta + L}{\Delta + L + \lambda} + o(1)\,. \end{aligned}$$

The fraction in the last term tends to 1 as $\Delta \to \infty$. ◀

This bound is tight due to a matching upper bound in [10] that shows (translated to the terminology of the infinite server problem) that a competitive ratio of λ can be achieved on metric spaces where all pairwise distances are 1 except that the source is at some larger distance Δ from the other points.

The previous theorem together with the equivalence theorem also allows us to obtain a new lower bound for the k-server problem against weak adversaries.

▶ **Corollary 11.** *For sufficiently large h, there is no* 3.146*-competitive algorithm for the (h, k)-server problem on the line, even if $k \to \infty$.*

Proof. By a scaling argument it is easy to see that if the infinite server problem on the line is ρ-competitive, then it is also *strictly* ρ-competitive. Thus, the statement follows from Theorems 4 and 10. ◀

This improves upon both the previous best known lower bounds of 2 for this problem on the line [5, p. 175] and 2.4 on general metric spaces [1].

3.3 Layered Graphs

A *layered graph of depth D* is a graph whose (potentially infinitely many) nodes can be arranged in layers $0, 1, \ldots, D$ so that all edges run between adjacent layers and each node – except for a single node in layer 0 – is connected to at least one node of the previous layer. The induced metric space is the set of nodes with the distance being the minimal number of edges of a connecting path. For the purposes of the infinite server problem, the single node in layer 0 is the source. We assume $D \geq 2$ to avoid trivial cases.

Note that a connected graph is layered if and only if it is bipartite. Moreover, any graph can be embedded into a bipartite graph by adding a new node in the middle of each edge. So essentially, layered graphs capture *all* graph metrics.

Let *Move Only Outwards (MOO)* be some lazy and local algorithm for the infinite server problem on layered graphs that moves servers along edges only in the direction away from the source. Not surprisingly, the competitive ratio of this simple algorithm is quite bad and we show that it is exactly $D - 1/2$. Nonetheless, at least for $D \leq 3$ this is actually the optimal competitive ratio.

▶ **Theorem 12.** *The competitive ratio of MOO is exactly $D - \frac{1}{2}$.*

▶ **Theorem 13.** *The competitive ratio of the infinite server problem on layered graphs of depth D is exactly* 1.5 *for $D = 2$, exactly* 2.5 *for $D = 3$ and at least* 3 *for $D \geq 4$.*

Both theorems are proved in the full version of this paper. It remains an open problem to close the gap between the lower bound of 3 and the upper bound of 3.5 for $D = 4$. More importantly, we are interested in the question whether an algorithm better than MOO exists for large D, achieving a competitive ratio of less than $D - 1/2$ on any layered graph of depth D. Note that if no algorithm with a competitive ratio of $O(1)$ as $D \to \infty$ exists, then the infinite server problem on general metric spaces would not be competitive.

For large D, the lower bound of 3 is certainly not tight: Consider a layered graph where each layer contains one node except that the bottom layer contains infinitely many nodes. By Theorem 10 (and a matching upper bound shown in [10]), the competitive ratio on this graph converges to $\lambda \approx 3.146$ as $D \to \infty$.

4 Algorithms with Unbounded Competitive Ratio

We examine the performance of classical algorithms known for the k-server problem when applied to the infinite server problem, focusing on the line as a particularly appealing metric space. We also consider a generalization of the Double Coverage algorithm for the line with adjusted server speeds. This idea has proved successful for the (h, k)-server problem (and hence the infinite server problem) on weighted trees [1]. However, neither of these algorithms is competitive for the infinite server problem on the line. Proofs of the results of this section

as well as the definitions of the algorithms of the following theorem can be found in the full version of this paper.

▶ **Theorem 14.** *The Work Function Algorithm [8, 17], Balance [19] and Balance2 [13] are not competitive for the infinite server problem on the line.*

Perhaps more surprising than for the above three algorithms is that a class of algorithms extending the Double Coverage (DC) algorithm [6] is also not competitive for the infinite server problem. The basic DC algorithm on the line serves each request by an adjacent server. If the request lies between two servers, both servers move towards it at equal speed until one of them reaches the request. A sensible extension of this algorithm seems to be to give different speeds to servers, so that they move away from the source faster than towards it.

We consider here only the half-line $[0, \infty)$ with the source at the left border 0. Let x_i be the position of the ith server from the right. We use the notation x_i both for its position and for the server itself. As servers do not overtake each other, x_i is the ith spawned server. Let $\mathcal{S} = \{s_i \geq 1 \mid i \in \mathbb{N} \text{ and } i \geq 2\}$ for a monotonic (non-decreasing or non-increasing) sequence of speeds s_i. The algorithm $\mathcal{S}$-DC is defined as follows:

- If there exist servers x_{i+1} and x_i to the left and right of the request, move them towards it with speeds s_{i+1} and 1 respectively until one of the two reaches it.
- If a request does not have a server to its right, move the rightmost server to the request.

If $s_i = 1$ for all i, this is precisely the original DC algorithm.

▶ **Theorem 15.** *Algorithm $\mathcal{S}$-DC is not competitive for any $\mathcal{S}$.*

The intuitive reason is that servers move to the right either too slowly or too fast: Imagine repeatedly requesting the same n points in some small interval away from the source, until $\mathcal{S}$-DC covers all n points. One case is that $\mathcal{S}$-DC spawns too slowly and is therefore defeated by an adversary covering these n positions immediately with n servers. In the other case, the adversary will also use n servers to cover the initial group of requests and then shift its group of servers slowly towards the source, always making requests at the new positions of these offline servers. As $\mathcal{S}$-DC tries to cover the new requests, it is tricked into spawning too many servers. Both cases lead to an unbounded competitive ratio.

5 Reduction to Bounded Spaces

In this section we show a reduction from the infinite server problem on general metric spaces to bounded subspaces. Specifically, a metric space can be partitioned into "rings" of points whose distance from the source is between r^n and r^{n+1}, where $r > 1$ is fixed and $n \in \mathbb{Z}$. We show that if the infinite server problem is strictly ρ-competitive on each ring, then it is competitive on the entire metric space.

▶ **Theorem 16.** *Let M be a metric space and $s \in M$ and let $r > 1$. For $n \in \mathbb{Z}$ let $M_n = \{s\} \cup \{p \in M \mid d(s,p) \in [r^n, r^{n+1})\}$. If for each n the infinite server problem on (M_n, s) is strictly ρ-competitive, then on (M, s) it is strictly $\frac{4r-1}{r-1}\rho$-competitive.*

Proof. Let ALG_n be a ρ-competitive algorithm for the infinite server problem on (M_n, s).

For a request sequence σ, let σ_n be the subsequence of requests in M_n. Let ALG be the algorithm for (M, s) that uses different servers for each of the subsequences σ_n and serves them independently according to ALG_n.

The total online cost is $ALG(\sigma) = \sum_n ALG_n(\sigma_n) \le \rho \sum_n OPT(\sigma_n)$. To finish the proof, it suffices to show that

$$\sum_n OPT(\sigma_n) \le \frac{4r-1}{r-1} OPT(\sigma)\,. \tag{5}$$

Thus, we only need to analyze the offline cost. We do this for each offline server separately. Fix some offline server x. Let N_0 and N_1 be the minimal and maximal values of n such that x visits M_n. We can assume without loss of generality (by adding virtual points to the metric space) that whenever x moves from M_n to $M_{n'}$ for some $n < n'$, it travels across points $p_{n+1}, p_{n+2}, \ldots, p_{n'}$ with $d(s, p_i) = r^i$, and similarly for $n > n'$.

The movements of server x can be tracked by many servers, one server x_n in every set M_n for $N_0 \le n \le N_1$. When server x is in M_n, server x_n is exactly at the same position tracking the movement of x. When server x exits M_n at some point p at the boundary to M_{n-1} or M_{n+1}, server x_n freezes at p. The movement cost of x_n can be partitioned into the cost of deploying x_n at the first point visited in M_n, the tracking cost within M_n, and the cost of of relocating x_n whenever x re-enters M_n at a location different from the last exiting location.

The total tracking cost of all servers x_n is bounded by the distance traveled by x. The cost of deploying all servers x_n is $\sum_{n=N_0}^{N_1} r^n \le \sum_{n=-\infty}^{N_1} r^n = r^{N_1+1}/(r-1)$, which is at most $\frac{r}{r-1}$ times the total movement of server x, because the latter is at least r^{N_1}.

To bound the relocating cost, say x exits M_n at p and re-enters it at p'. Then p and p' are at the boundary of M_n and M_{n+u} for $u \in \{-1, +1\}$. Let b be the distance traveled by x in M_{n+u} between the times when it is entered at p and when it is next exited. If this exiting is at p', then the relocating cost $d(p, p')$ is at most b by the triangle inequality. Otherwise, x exits M_{n+u} at a point p'' at the boundary of M_{n+u} and M_{n+2u}. If $u = 1$, then $d(p, p') \le d(s, p) + d(s, p') = 2r^{n+1}$ and $b \ge d(p, p'') \ge d(s, p'') - d(s, p) = r^{n+2} - r^{n+1} = (r-1)r^{n+1}$. If $u = -1$, then $d(p, p') \le d(s, p) + d(s, p') = 2r^n$ and $b \ge d(p, p'') \ge d(s, p) - d(s, p'') = r^n - r^{n-1} = \frac{r-1}{r} r^n$. In both cases, the relocating cost $d(p, p')$ is at most $\frac{2r}{r-1} b$. Thus, the total relocating cost of all servers x_n is at most $\frac{2r}{r-1}$ times the total distance traveled by x.

Thus, the sum of deployment, tracking and relocating cost of the servers x_n is at most $\frac{4r-1}{r-1}$ times the distance traveled by x. This shows (5), giving the statement of the theorem. ◀

The last theorem can also be slightly generalized to the case where instead of *strict* ρ-competitiveness, an additive term proportional to r^n is allowed. It is not difficult to show the following specialization for the line, where the premise can be weakened to require competitiveness only on a single interval:

▶ **Corollary 17.** *Let $0 < a < b$. The infinite server problem is competitive on the line if and only if it is competitive on $(\{0\} \cup [a, b], 0)$.*

6 Open Problems

The most obvious open problem is whether the infinite server problem is competitive on general metric spaces. A challenging special case is to resolve the question for the real line. Similarly, improving the MOO algorithm and settling the question for layered graphs remains open. It would also be interesting to find a metric space with a competitive ratio greater than 3.146 for the infinite server problem or the (h, k)-server problem when $k \gg h$. Another possible line of research is to consider randomized algorithms.

Abstract

Aaronson and Drucker (2011) asked whether there exists a quantum finite automaton that can distinguish fair coin tosses from biased ones by spending significantly more time in accepting states, on average, given an infinite sequence of tosses. We answer this question negatively.

1 Introduction

In a 2011 work, Aaronson and Drucker [2] investigated the ability of a finite automaton to distinguish, given an infinite sequence of coin tosses, whether the coins are fair or $(\frac{1}{2} \pm \epsilon)$-biased. There are several axes of consideration discussed in [2], three of which we state here:

1. Whether the automaton is classical (and probabilistic), or quantum.
2. Whether $\epsilon > 0$ is "known" or not; i.e., whether the automaton can depend on ϵ.
3. The mechanism by which the automaton makes its decision. One possibility is that the automaton guesses "biased" by halting, and guesses "fair" by running forever. A laxer possibility is that the automaton always runs forever, with each of its states designated "biased" or "fair"; its final decision is based on the limiting time-average it spends in "biased" vs. "fair" states. We refer to the two mechanisms as "one-sided halting" and "limiting acceptance".

For example, an old result of Hellman and Cover [5] is that even when ϵ is known and limiting acceptance is allowed, a classical automaton needs $\Omega(1/\epsilon)$ states to solve the problem. On the other hand, Aaronson and Drucker made the interesting observation that for every fixed known ϵ, there's a quantum automaton with just 2 states that solves the problem using one-sided halting. They also showed no quantum automaton with a fixed number of states can solve the problem for every *unknown* ϵ, if the decision mechanism is one-sided halting.

Aaronson and Drucker asked whether the same negative result holds even if the automaton is allowed to use the limiting acceptance decision mechanism. Indeed, for the 48 different variations of the problem they considered, this was the only variant that remained unsolved.

In 2014, Aaronson called this question one of the "Ten Most Annoying Problems in Quantum Computing" [1].

In this work, we make the world of quantum computing 10% less annoying by resolving the problem in the negative. Stated informally, our main theorem is the following (a precise phrasing appears below after we give some formal definitions):

▶ **Theorem 1.** *There is no quantum finite automaton that has the following property, simultaneously for every* $\epsilon \in [-\frac{1}{2}, \frac{1}{2}] \setminus \{0\}$*: Given access to an infinite sequence of coin tosses, if the coin is* $(\frac{1}{2} + \epsilon)$*-biased then the automaton spends at least* $2/3$ *of its time guessing "biased", and if the coin is fair then the automaton spends at least* $2/3$ *of its time guessing "fair".*

Proving this theorem involves a careful understanding of the fixed points of quantum channels.

2 Classical and quantum automata

In this section we review the definitions of probabilistic and quantum finite state automata. Although we are ultimately only concerned with quantum automata, we feel it is instructive to also discuss probabilistic automata at the same time. All of our automata will have input alphabet $\Sigma = \{0, 1\}$, which may be thought of as $\{\text{tails}, \text{heads}\}$.

A classical deterministic automaton on alphabet $\Sigma = \{0, 1\}$ has some d *basic-states*,[1] an initial basic-state $i_0 \in [d]$, and transition rules $f_0, f_1 : [d] \to [d]$. Given a sequence of input symbols $w_1, w_2, w_3, \cdots \in \{0, 1\}$, the automaton operates as follows: It starts in basic-state i_0 at time 0. Then, if it is in basic-state i_t at time $t \in \mathbb{N}$, it transitions to basic-state $f_{w_{t+1}}(i_t)$ at time $t+1$. Automata also typically have their basic-states classified as "accept" or "reject"; we discuss this more later.

One can also consider classical *probabilistic* automata. These have randomized transitions, which can be encoded by a pair of $d \times d$ *stochastic matrices* S_0, S_1. Now at any time t the automaton can be in a "probabilistic-state", represented by a length-d probability vector π_t. (An initial probabilistic-state π_0 is also specified.) On reading symbol w_{t+1}, the automaton transitions to the probabilistic-state $\pi_{t+1} = S_{w_{t+1}} \pi_t$.

Finally, the setting for a *quantum* automaton is a d-dimensional Hilbert space $\mathcal{H}$ (which we may think of as having an orthonormal basis of "basic-state vectors" $|1\rangle, \ldots, |d\rangle$). At any time t, the automaton has a "quantum-state", which is a density operator $\rho_t \in \mathcal{B}(\mathcal{H})$. Here $\mathcal{B}(\mathcal{H})$ denotes the set of linear operators on $\mathcal{H}$, and a density operator means a positive semidefinite operator of trace 1. (Probabilistic-states are the special case of quantum-states in which ρ_t is diagonal with respect to $|1\rangle, \ldots, |d\rangle$.) The transition rules are now any two allowable quantum transformations Φ_0, Φ_1; i.e., they are *quantum channels (superoperators)* on $\mathcal{B}(\mathcal{H})$. Here a quantum channel means a linear map $\Phi : \mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H})$ that is completely positive and trace-preserving; an equivalent condition is that there exist (non-unique) *Kraus operators* $K_1, \ldots, K_r \in \mathcal{B}(\mathcal{H})$ with $\sum_{i=1}^r K_i^\dagger K_i = \mathbb{1}$ such that $\Phi(\rho) = \sum_{i=1}^r K_i \rho K_i^\dagger$. (For more on quantum channels, see e.g. [7].) Again, an initial quantum-state ρ_0 is given, and on reading symbol w_{t+1}, the automaton transitions from quantum-state ρ_t to quantum-state $\rho_{t+1} = \Phi_{w_{t+1}}(\rho_t)$.

[1] There is an unfortunate terminology clash involving the word "state" – in automata theory, "states" are the basic vertices in automaton graphs, whereas in quantum mechanics a "state" usually means the "mixed quantum state" or "density operator" of a given system. Throughout we'll refer to the former as "basic-states" and the latter as "quantum-states".

Automata with random inputs

This paper is concerned with automata whose inputs are infinite sequences of p-biased coin tosses, $p \in [0,1]$. More formally, we always assume the input symbols $w_1, w_2, w_3, \cdots \in \{0,1\}$ are chosen independently at random with $\mathbf{Pr}[w_t = 1] = p$. Because of this assumption, we can give a simplified formalization of probabilistic and quantum automata. In the case of probabilistic automata, at each time step (independently) we apply S_1 with probability p and S_0 with probability $1-p$. It is clear that this is equivalent to simply applying the stochastic matrix $S_p \coloneqq pS_1 + (1-p)S_0$ at each time step. In other words, the probabilistic-state of a probabilistic automaton after t time steps is simply $S_p^t \pi_0$. The setup is precisely equivalent to a Markov chain on $[d]$ with transition matrix S_p.

Similarly for quantum automata, at each time step we apply Φ_1 with probability p and Φ_0 with probability $1-p$; this is physically equivalent to simply applying the channel $\Phi_p \coloneqq p\Phi_1 + (1-p)\Phi_0$ at each time step. (This is ultimately because being in quantum-state ρ with probability p and quantum-state ρ' with probability $1-p$ is physically equivalent to being in quantum-state $p\rho + (1-p)\rho'$.) Thus the quantum-state of a probabilistic automaton after t time steps is simply $\Phi_p^t(\rho_0)$; we have here the quantum analogue of a Markov chain.

Automaton acceptance probability

As discussed in Section 1, we will be considering "limiting acceptance", the most relaxed possible notion for automaton acceptance. We first define this in the context of probabilistic automata. Here, each basic-state in $[d]$ is classified as either guessing "Fair" or "Biased". We write $e_{\text{fair}} \in \mathbb{R}^d$ for the 0-1 indicator of the Fair states. Thus if the automaton is in probabilistic-state $\pi \in \mathbb{R}^d$, the probability it is in a Fair basic-state is $\langle e_{\text{fair}}, \pi \rangle$. We then consider, for a sequence of T coin tosses, the *average* probability with which the automaton is in a Fair basic-state:

$$f_T(p) \coloneqq \frac{1}{T}\sum_{t=1}^{T} \langle e_{\text{fair}}, S_p^t \pi_0 \rangle = \Big\langle e_{\text{fair}}, \Big(\frac{1}{T}\sum_{t=1}^{T} S_p^t\Big)\pi_0 \Big\rangle.$$

Finally, we consider the limiting value of this probability:

$$f(p) \coloneqq \lim_{T\to\infty} f_T(p) = \langle e_{\text{fair}}, S_p^\infty \pi_0 \rangle, \quad \text{where } S_p^\infty \coloneqq \lim_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} S_p^t.$$

Here we relied on the well-known fact that the limiting matrix S_p^∞ exists. (In fact, S_p^∞ is also a stochastic matrix, and it acts by projection onto the 1-eigenspace of S_p; we discuss this further in Section 3.) One may then say that the probabilistic automaton "guesses Fair in the limit" if $f(p) \geq \frac{2}{3}$, and "guesses Biased in the limit" if $f(p) \leq \frac{1}{3}$. (It may be considered "indecisive" otherwise.)

The definitions for a quantum automaton are extremely similar. The automaton is assumed to come equipped with an "acceptance POVM", $\{E_{\text{fair}}, \mathbb{1} - E_{\text{fair}}\}$. (Here $E_{\text{fair}} \in \mathcal{B}(\mathcal{H})$ is any operator satisfying $0 \preceq E_{\text{fair}} \preceq \mathbb{1}$, and $\mathbb{1}$ denotes the identity operator.) If the automaton is in quantum-state ρ, the probability of it measuring "Fair" is $\langle E_{\text{fair}}, \rho \rangle \coloneqq \text{tr}(E_{\text{fair}}^\dagger \rho)$. We can then again define the limiting average probability of guessing "Fair" via

$$f_T(p) \coloneqq \frac{1}{T}\sum_{t=1}^{T} \langle E_{\text{fair}}, \Phi_p^t \pi_0 \rangle = \Big\langle E_{\text{fair}}, \Big(\frac{1}{T}\sum_{t=1}^{T} \Phi_p^t\Big)\pi_0 \Big\rangle,$$

$$f(p) \coloneqq \lim_{T\to\infty} f_T(p) = \langle E_{\text{fair}}, \Phi_p^\infty \pi_0 \rangle, \quad \text{where } \Phi_p^\infty \coloneqq \lim_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} \Phi_p^t. \tag{1}$$

Again, it is known that the limiting operator Φ_p^∞ exists; this is explicitly discussed in Section 3. As before, one may say that the quantum automaton "guesses Fair in the limit" if $f(p) \geq \frac{2}{3}$, and "guesses Biased in the limit" if $f(p) \leq \frac{1}{3}$.

We may now state the main theorem of this paper:

▶ **Theorem 2.** *In the setting of quantum automata reading p-biased bits (as described above), the function f from* (1) *is a continuous function of $p \in (0,1)$.*

This theorem is a formal strengthening of Theorem 1, our negative result for coin distinguishing stated in Section 1. For example, it implies that if an automaton guesses "Fair" in the limit" for $p = \frac{1}{2}$, then for all sufficiently small ϵ it *cannot* guess "Biased" in the limit for $p = \frac{1}{2} \pm \epsilon$. In fact, we get the inability of quantum automata to distinguish p-biased and $(p \pm \epsilon)$-biased coins with limiting acceptance for any fixed $p \in (0,1)$. As noted in [2], this is sharp in the sense that there is a trivial 2-state deterministic classical automaton that distinguishes a 0-biased coin from any ϵ-biased coin, even with one-sided halting.

3 Outline of the proof

Here we give an outline of the proof of Theorem 2. At the same time, it will be instructive to outline the analogous proof in the special case of probabilistic automata. To prove that the limiting acceptance probability $f(p)$ from (1) is continuous for $p \in (0,1)$, it is enough to prove the following:

▶ **Theorem 3.** *Φ_p^∞ is continuous for $p \in (0,1)$.*

Here for definiteness we can take the metric on channels induced by the operator norm on $\mathcal{B}(\mathcal{H})$; Theorem 2 then follows because matrix multiplication and inner product are continuous.

Now is a good time to review the properties of Φ_p^∞. In general, let Φ denote any channel on $\mathcal{B}(\mathcal{H})$. Then the following are known [7, Prop. 6.3] (and easy) facts: First, $\Phi^\infty := \lim_{T\to\infty} \frac{1}{T} \sum_{t=1}^{T} \Phi^t$ exists and is itself a channel. Second, as an operator, Φ^∞ acts as projection onto the fixed points $V_1(\Phi)$ of Φ. Here we are using the following notation:

▶ **Notation 4.** *For any operator A we write $V_1(A)$ for the eigenspace of A with eigenvalue* 1*, i.e., the* invariant *subspace for A.*

As mentioned earlier, the analogous statements are true regarding S^∞, when S is a stochastic operator. (In both the probabilistic and quantum cases, the essential point is that the operator in question has spectral radius 1.)

Returning to Theorem 3, certainly $\Phi_p = p\Phi_1 + (1-p)\Phi_0$ varies continuously for $p \in [0,1]$. But what we need to prove is that the *invariant subspace* $V_1(\Phi_p)$ of Φ_p varies continuously for $p \in (0,1)$. There is one obvious potential obstruction: the *dimension* of $V_1(\Phi_p)$ might change as p varies. (As we will see, this is actually the only obstruction.) Now in general, slightly perturbing a matrix *can* change the dimension of its 1-eigenspace. However we are not concerned with completely general perturbations: we are just considering all the convex combinations of two fixed channels Φ_0, Φ_1. The main technical theorem in our paper will be the following:

▶ **Theorem 5.** *For any channels Φ_0, Φ_1, the dimension $\dim V_1(\Phi_p)$ is the same for all $p \in (0,1)$.*

We will discuss the intuition for this theorem below. But first we will observe that Theorem 3 is an elementary linear-algebraic consequence of Theorem 5. This deduction of Theorem 3 from Theorem 5 is a little more familiar if we consider $\mathbb{1} - \Phi_p$ rather than Φ_p. Then Φ_p^∞ is the projection onto the kernel of $\mathbb{1} - \Phi_p$, and it is elementary that, given a continuously-parameterized family of matrices like $p \mapsto \mathbb{1} - \Phi_p$, the kernel varies continuously wherever the nullity (in this case, $\dim V_1(\Phi_p)$) is locally constant. For a simple explicit proof see, e.g., [6].

Thus all that remains in this work is to prove Theorem 5. We will do this in Section 4, but first we provide some intuition and introduce a key definition, that of *combinatorially equivalent channels*.

3.1 Intuition for Theorem 5

All of our discussion so far applies equally to probabilistic automata defined by stochastic matrices S_0, S_1. So let us first consider the analogue of Theorem 5 in this case. Here we have a family of Markov chains defined by $S_p = pS_1 + (1-p)S_0$ and we want to consider the dimension of their invariant subspaces. It is well known that the invariant subspace $V_1(S)$ of the Markov chain defined by S is spanned by a linearly independent set of invariant *probabilistic-states*. Thus $\dim V_1(S)$ is equal to the number of linearly independent ("fundamentally different", one might say) invariant distributions.

In the study of Markov chains, it's popular to focus on the irreducible case, in which case there is a unique invariant probability distribution; i.e., $\dim V_1(S) = 1$. However in general we must consider reducible Markov chains (the "mathematically annoying case", as Hellman and Cover [5] put it). Fortunately, the theory of reducible Markov chains is well developed, and it is known that there is one linearly independent invariant distribution per every *communication class* of the Markov chain. Here the "communication classes" of the Markov chain defined by S are precisely the strongly connected components of the underlying digraph on $[d]$; i.e., the graph which has a directed edge (i, j) whenever $S_{ij} \neq 0$. Given this theory, it is easy to deduce the analogue of Theorem 5; the point is that for any fixed S_0, S_1, *the underlying digraph of S_p is the same for all $p \in (0, 1)$*. Since $S_p = pS_1 + (1-p)S_0$, an edge (i, j) is present in S_p if and only if it is present in either S_0 or S_1. Thus S_p has the same set (hence number) of communication classes for all $p \in (0, 1)$, as needed.

In this paper, we show there is an analogous sequence of ideas in the quantum case, using some of the recently developed theory of fixed points of quantum channels. Given a quantum channel Φ, it is known [7, Cor. 6.5] that $V_1(\Phi)$ is always spanned by linearly independent *quantum-states*. The analogous notion to communication classes is that of *minimal enclosures*. Further, similar to how the communication classes of a Markov chain are determined only by the nonzero pattern of its transition matrix, the minimal enclosures of a quantum channel are determined only by its Kraus operators. We then make use of the fact that all the convex combinations Φ_p of two channels Φ_0, Φ_1 have related Kraus operators. Specifically, we introduce the following notion:

▶ **Definition 6.** We will say that two channels Φ and $\widehat{\Phi}$ (with the same Hilbert space $\mathcal{H}$) are *combinatorially equivalent* if there are Kraus operators $K_1, \dots, K_r$ for Φ and $\widehat{K}_1, \dots, \widehat{K}_{\widehat{r}}$ for $\widehat{\Phi}$ such that each K_i is proportional to some $\widehat{K}_{i'}$ and vice versa.

Given channels Φ_0, Φ_1 with Kraus operators $\{K_i^{(0)} : i \in [r_0]\}, \{K_j^{(1)} : j \in [r_1]\}$ respectively, the channel $\Phi_p = p\Phi_1 + (1-p)\Phi_0$ has Kraus operators $\{\sqrt{1-p}K_i^{(0)} : i \in [r_0]\} \cup \{\sqrt{p}K_j^{(1)} : j \in [r_1]\}$. Thus the channels Φ_p are all pairwise combinatorially equivalent for $p \in (0, 1)$

(though not necessarily for $p \in \{0, 1\}$). To show Theorem 5, it therefore suffices to show the following more general result:

▶ **Theorem 7.** *Suppose* Φ *and* $\widehat{\Phi}$ *are combinatorially equivalent. Then* $\dim V_1(\Phi) = \dim V_1(\widehat{\Phi})$.

4 The last step: proof of Theorem 7

To prove Theorem 7, we use some known results concerning the decomposition of a quantum channel into irreducible components, and the structure of its invariant quantum-states. We will specifically use the key decomposition theorem appearing variously as [7, Theorem 6.14], [3, Theorem 7], [4, Theorem 7.2].

Let Φ denote a quantum channel on $\mathcal{B}(\mathcal{H})$ with Kraus operators $K_1, \ldots, K_r$. We are interested in $m = \dim V_1(\Phi)$, the dimension of the space of Φ's fixed points. As Φ is a quantum channel, it is known [7, Prop. 6.1] that its spectral radius is 1 and that it has at least one eigenvalue equal to 1; thus $m \geq 1$. As mentioned, it is also known [7, Cor. 6.5] that $V_1(\Phi)$ is always spanned by some m linearly independent *quantum-states*.

If ρ is a quantum-state, its *support* $\mathrm{supp}(\rho)$ is simply the range of ρ as a subspace of $\mathcal{H}$. The *recurrent subspace* for Φ is the subspace of $\mathcal{H}$ defined by

$$\mathcal{R} = \mathrm{span}\{\mathrm{supp}(\rho) : \rho \text{ is an invariant quantum-state}\}.$$

The orthogonal complement of $\mathcal{R}$ in $\mathcal{H}$ is denoted $\mathcal{D}$; this is the *decaying* (or *transient*) subspace. A subspace $\mathcal{V} \subseteq \mathcal{H}$ is called an *enclosure* if $\mathrm{supp}(\rho) \subseteq \mathcal{V} \implies \mathrm{supp}(\Phi(\rho)) \subseteq \mathcal{V}$ for all quantum-states ρ. We can relate this concept to Kraus operators via the following equivalence:

▶ **Fact 8** ([4, Proposition 4.4]). *$\mathcal{V}$ is an enclosure if and only if $K_i\mathcal{V} \subseteq \mathcal{V}$ for all Kraus operators K_i.*

An enclosure $\mathcal{V}$ is called *minimal* if it is nonzero and all enclosures $\mathcal{V}' \subseteq \mathcal{V}$ are equal to either $\{0\}$ or $\mathcal{V}$. It is also known [3, Prop. 15] that a subspace of $\mathcal{H}$ is a minimal enclosure if and only if it is the support of an extremal invariant quantum-state, meaning one that cannot be written as a nontrivial convex combination of two distinct invariant quantum-states. One consequence is that

$$\begin{aligned}\mathcal{R} &= \mathrm{span}\{\mathrm{supp}(\rho) : \rho \text{ is an extremal invariant quantum-state}\} \\ &= \mathrm{span}\{\mathcal{V} : \mathcal{V} \text{ is a minimal enclosure}\}. \end{aligned} \tag{2}$$

The theorems [7, Theorem 6.14], [3, Theorem 7], [4, Theorem 7.2] characterize $V_1(\Phi)$ and the quantum-states therein in slightly different ways. To explain, we make some definitions.

▶ **Definition 9.** (In this definition, k, $m_1, \ldots, m_k$, $d_1, \ldots, d_k$ denote positive integers.)

Given Φ, we define a *minimal enclosure decomposition* to be an orthogonal decomposition of $\mathcal{H}$ into subspaces

$$\mathcal{H} = \mathcal{D} \oplus \bigoplus_{i=1}^{k} \mathcal{W}_i, \quad \text{where } \mathcal{W}_i = \bigoplus_{j=1}^{m_i} \mathcal{V}_{i,j} \tag{3}$$

for which the following properties hold:

1. $\mathcal{D}$ is the decaying subspace for Φ.
2. Each $\mathcal{V}_{i,j}$ is a minimal enclosure.
3. Each $\dim \mathcal{V}_{i,j} = d_i$ for all $1 \le j \le m_i$.
4. For any minimal enclosure $\mathcal{X}$ of Φ and any $1 \le i \le k$, if $\mathcal{X}$ is not orthogonal to $\mathcal{W}_i$ then $\mathcal{X} \subseteq \mathcal{W}_i$. (In particular, if $m_i = 1$ then $\mathcal{X}$ must equal $\mathcal{W}_i$.)
5. The decomposition (3) is maximal, in the sense that it is not possible to increase k.

▶ Remark. In fact, one can show there is always a *unique* minimal enclosure decomposition. However, we have not found this exact statement appearing in the literature, and in this paper we will prefer to simply cite known results.

▶ **Definition 10.** Suppose we have a minimal enclosure decomposition for Φ as above. Fix any ordered orthogonal basis for $\mathcal{H}$ compatible with (3) (meaning the first $\dim \mathcal{D}$ elements span $\mathcal{D}$, the next $m_1 d_1$ elements come in m_1 groups of d_1 spanning $\mathcal{V}_{1,1}, \dots, \mathcal{V}_{1,m_1}$ respectively, etc.). Let $X \in \mathcal{B}(\mathcal{H})$, and think of X in its matrix form with respect to the ordered basis.

Then we say that X *respects the minimal enclosure decomposition* if X is block-diagonal with blocks corresponding to $\mathcal{D}, \mathcal{W}_1, \dots, \mathcal{W}_k$, and furthermore X is 0 on the $\mathcal{D}$-block and is of the form $A_i \otimes \rho_i$ on the $\mathcal{W}_i$-block for some $A_i \in \mathbb{C}^{m_i \times m_i}$ and some strictly positive density matrix $\rho_i \in \mathbb{C}^{d_i \times d_i}$. In symbols,

$$X = 0 \oplus \bigoplus_{i=1}^{k} A_i \otimes \rho_i.$$

(We remark that the property of respecting the minimal enclosure decomposition does not depend on the choice of the compatible orthogonal basis.)

In combination, [7, Theorem 6.14], [3, Theorem 7] state the following:[2]

▶ **Theorem 11.** *Given any channel Φ, there exists a minimal enclosure decomposition as in* (3) *such that $V_1(\Phi)$ consists precisely of* all *$X \in \mathcal{B}(\mathcal{H})$ that respect the decomposition. (An immediate consequence is that $m = \dim V_1(\Phi) = \sum_i m_i^2$.) Finally, the quantum-states that are invariant are precisely all such X with $A_i = \lambda_i \sigma_i$, where $\sigma_1, \dots, \sigma_k$ are density matrices and $\lambda_1, \dots, \lambda_k$ are nonnegative reals summing to* 1.

The statement of [4, Theorem 7.2] is slightly different:[3]

▶ **Theorem 12.** *Given any channel Φ, at least one minimal enclosure decomposition exists. Furthermore, given* any *minimal enclosure decomposition*

$$\mathcal{H} = \mathcal{D} \oplus \bigoplus_{i=1}^{\widehat{k}} \widehat{\mathcal{W}}_i, \quad \text{where } \widehat{\mathcal{W}}_i = \bigoplus_{j=1}^{\widehat{m}_{\widehat{k}}} \widehat{\mathcal{V}}_{i,j},$$

every invariant quantum-state for Φ respects it. (As an immediate consequence, we have $m = \dim V_1(\Phi) \le \sum_i \widehat{m}_i^2$.)

[2] [7] deals with the invariant subspace whereas [3] deals with the invariant quantum-states. The fact that the ρ_i's are strictly positive is in [7]. Finally, [3] does not explicitly show that the minimal enclosure decomposition satisfies condition (4) in Definition 9. However, it's implicit and it's easy to deduce: we know that any minimal enclosure $\mathcal{X}$ is the support of some extremal invariant quantum-state ρ, and it's clear that if this support is not entirely within a single $\mathcal{W}_i$-block then ρ would not be extremal.

[3] The first statement of this theorem is [4, Proposition 7.1], except that that Proposition does not include either condition (4) of Definition 9 for those i with $m_i = 1$. However it is evident from the proof that this is an oversight; a personal communication from the authors confirmed this. Also, [4, Proposition 7.1] does not explicitly state condition (5) of Definition 9, but it is obtained by the proof, and is in fact needed for correctness of the proof.

We are now able to give the proof of Theorem 7.

Proof of Theorem 7. Write $m = \dim V_1(\Phi)$ and $\widehat{m} = \dim V_1(\widehat{\Phi})$. Since Φ and $\widehat{\Phi}$ play symmetric roles, it suffices to show $\widehat{m} \leq m$. Apply Theorem 11 to Φ, obtaining a minimal enclosure decomposition as in (3). We have $m = \sum_{i=1}^{k} m_i^2$. We claim that this decomposition is also a minimal enclosure decomposition for $\widehat{\Phi}$. This will finish the proof of $\widehat{m} \leq m$, by Theorem 12.

To see the claim, we first observe that every enclosure $\mathcal{V}$ for Φ is an enclosure for $\widehat{\Phi}$ (and vice versa). This follows from Fact 8: $\mathcal{V}$ satisfies $K_i\mathcal{V} \subseteq \mathcal{V}$ for each Kraus operator K_i of Φ, and hence the same is true for the Kraus operators $\widehat{K}_{i'}$ of $\widehat{\Phi}$, by combinatorial equivalence of Φ and $\widehat{\Phi}$. It then follows by definition that every *minimal* enclosure for Φ is also a minimal enclosure for $\widehat{\Phi}$ (and vice versa). Finally, the claim now follows because Φ and $\widehat{\Phi}$ have the same decaying subspace (by (2)) and because Definition 9 of minimal enclosure decompositions depends *only* on which subspaces of $\mathcal{H}$ are minimal enclosures. ◀

A New Holant Dichotomy Inspired by Quantum Computation*†

Miriam Backens

School of Mathematics, University of Bristol, Bristol, UK
m.backens@bristol.ac.uk

Abstract

Holant problems are a framework for the analysis of counting complexity problems on graphs. This framework is simultaneously general enough to encompass many counting problems on graphs and specific enough to allow the derivation of dichotomy results, partitioning all problems into those which are in FP and those which are #P-hard. The Holant framework is based on the theory of holographic algorithms, which was originally inspired by concepts from quantum computation, but this connection appears not to have been explored before.

Here, we employ quantum information theory to explain existing results in a concise way and to derive a dichotomy for a new family of problems, which we call Holant$^+$. This family sits in between the known families of Holant*, for which a full dichotomy is known, and Holant^c, for which only a restricted dichotomy is known. Using knowledge from entanglement theory – both previously existing work and new results of our own – we prove a full dichotomy theorem for Holant$^+$, which is very similar to the restricted Holant^c dichotomy and may thus be a stepping stone to a full dichotomy for that family.

1 Introduction

Quantum computation (QC) provided the inspiration for holographic algorithms [30], which in turn inspired the Holant framework [11]. While Holant problems are an area of active research, so far there appear to have been no attempts to apply knowledge from quantum information theory (QIT) or QC to their analysis. Yet, as we show in the following, QIT and QC offer promising new avenues of research into Holant problems.

The Holant framework encompasses a wide range of counting complexity problems on graphs, parameterised by sets of functions $\mathcal{F}$. Here, we consider functions of Boolean inputs taking values in the set of algebraic complex numbers. Each vertex in the graph is assigned a function from $\mathcal{F}$, with each edge incident on the vertex corresponding to an input of the function. This structure is associated with a complex number, the *Holant*, computed by multiplying the function values together and summing over all possible input assignments for each edge (for the full definition, see Section 2). The associated counting problem Holant $(\mathcal{F})$ is the following: given a graph and an assignment of functions from $\mathcal{F}$ to

vertices, find the value of the Holant [11]. From a QIT perspective, each function can be considered as a tensor with one index for each input, making $\text{Holant}(\mathcal{F})$ the evaluation of a tensor network contraction.

The Holant framework is general enough to include problems such as counting matchings or perfect matchings, counting vertex covers [11], or counting Eulerian orientations [21]. It also encompasses other counting complexity frameworks like counting constraint satisfaction problems (#CSP) or counting graph homomorphisms [11]. On the other hand, the Holant framework is specific enough to allow the derivation of dichotomy theorems, which state that for function sets $\mathcal{F}$ within certain classes, the Holant problem is either in FP or it is #P-hard. By an analogue of Ladner's Theorem about NP-intermediate problems [23], such a dichotomy is not expected to hold for general counting problems [6].

One example of such a dichotomy is that for Holant^*. The problem $\text{Holant}^*(\mathcal{F})$ is equal to $\text{Holant}(\mathcal{F} \cup \mathcal{U})$, where $\mathcal{U}$ is the set of all unary functions [6]. Another example is the dichotomy for symmetric Holant^c, where all function sets considered must contain the unary functions pinning edges to values 0 or 1, respectively. Additionally, all functions are required to be *symmetric*, meaning their value depends only on the Hamming weight of the input [10]. Further dichotomies exist, but these, too, assume the availability of certain functions [12] or restrict the function sets, e.g. to symmetric or real-valued functions only [9, 27]. A full dichotomy for all Holant problems, as well as a full dichotomy for Holant^c, have so far remained elusive.

Here, we use knowledge from QC and QIT to make a step towards a full dichotomy for Holant^c. First, we analyse existing dichotomies in quantum terms, finding natural characterisations of the Holant^* and symmetric Holant^c dichotomies. The former can be described in terms of the entanglement classes of the allowed functions. Entanglement is a core concept in quantum theory: a quantum state of multiple systems is entangled if it cannot be written as a tensor product of states of subsystems. For states of more than two systems, there are different classes of entanglement which can be used for different QIT tasks [28]; their classification is an area of ongoing research [15, 31, 24, 25, 2]. We also find that the tractable class of *affine functions* arising in the dichotomy for symmetric Holant^c (see Section 3.2) is well-known in QIT as *stabilizer states* [20].

Motivated by this, we define a new class of Holant problems, which we call Holant^+. This class encompasses Holant problems where function sets are required to contain four specific unary functions, including the two that are available in Holant^c. In this way, Holant^+ fits between Holant^*, for which there is a full dichotomy, and Holant^c, for which there is no full dichotomy. These four unary functions enable the use of a known result from entanglement theory about producing two-system entangled states from many-system ones via projections [29, 18]: this corresponds to the ability to produce non-degenerate binary functions via gadgets. In fact, we prove an extension of that result about constructing three-qubit entangled states, or equivalently ternary functions. Using this, we derive our dichotomy theorem for Holant^+, whose tractable classes are very similar to those of the dichotomy for symmetric Holant^c [11]. Our dichotomy is the first full Holant dichotomy with no restrictions on the type of functions and where only a finite number of functions are assumed available, except for the dichotomy for $\#\text{R}_3$-CSP [12].

In the following, Section 2 contains a more detailed introduction to the Holant problem and associated concepts. In Section 3, we recap the relevant existing dichotomies and results. The quantum perspective on Holant problems, together with important notions from entanglement theory, is introduced in Section 4. We define and motivate the new family of Holant problems, called Holant^+, and prove the dichotomy theorem in Section 5.

2 Holant problems

Holant problems are a framework for counting complexity problems on graphs, introduced by Cai *et al.* [11], and based on the theory of holographic algorithms developed by Valiant [30]. Let $\mathcal{F}$ be a set of complex-valued functions with Boolean inputs, also called *signatures*, and let $G = (V, E)$ be an undirected graph with vertices V and edges E. Throughout, graphs are allowed to have parallel edges and self-loops. All complex numbers are assumed to be algebraic [7]. A *signature grid* is a tuple $\Omega = (G, \mathcal{F}, \pi)$ where π is a function that assigns to each n-ary vertex $v \in V$ a function $f_v : \{0,1\}^n \to \mathbb{C}$ in $\mathcal{F}$, specifying which edge corresponds to which input. The Holant for a signature grid Ω is:

$$\text{Holant}_\Omega = \sum_{\sigma : E \to \{0,1\}} \prod_{v \in V} f_v(\sigma|_{E(v)}), \tag{1}$$

where σ is an assignment of Boolean values to each edge and $\sigma|_{E(v)}$ is the restriction of σ to the edges incident on v.

▶ **Definition 1.** The Holant problem for a set of signatures $\mathcal{F}$, denoted by $\text{Holant}(\mathcal{F})$, is defined as follows:

- *Input*: a signature grid $\Omega = (G, \mathcal{F}, \pi)$ over the signature set $\mathcal{F}$,
- *Output*: Holant_Ω.

A *symmetric signature* is a function that depends only on the Hamming weight of the input. An n-ary symmetric signature is often written as $f = [f_0, f_1, \ldots, f_n]$, where f_k is the value f takes on inputs of Hamming weight k for $k \in \{0, \ldots, n\}$. A signature is called *degenerate* if it is a product of unary signatures. Any signature that cannot be expressed as a product of unary signatures is called *non-degenerate*. Multiplying a signature by a non-zero constant does not change the complexity of evaluating the Holant, so we will usually identify functions that are equal up to non-zero scalar factor.

Given a bipartite graph, we can define a *bipartite signature grid* by specifying two signature sets $\mathcal{F}$ and $\mathcal{G}$ and assigning signatures from $\mathcal{F}$ ($\mathcal{G}$) to vertices from the first (second) partition. A bipartite signature grid is denoted by a tuple $(G, \mathcal{F} \mid \mathcal{G}, \pi)$. The corresponding *bipartite Holant problem* is $\text{Holant}(\mathcal{F} \mid \mathcal{G})$. Any signature grid can be made bipartite by inserting a new vertex carrying the binary equality signature in the middle of each edge.

2.1 Signature grids in terms of vectors

As noted in [8], any signature $f : \{0,1\}^n \to \mathbb{C}$ can be considered as a complex vector of 2^n components indexed by $\{0,1\}^n$. Let $\{|x\rangle\}_{x \in \{0,1\}^n}$ be an orthonormal basis[1] for $\mathbb{C}^{2^n}$. The vector corresponding to the signature f is then denoted by $|f\rangle = \sum_{x \in \{0,1\}^n} f(x) |x\rangle$.

Suppose $\Omega = (G, \mathcal{F} \mid \mathcal{G}, \pi)$ is a bipartite signature grid, where $G = (V, W, E)$ has vertex partitions V and W. Then the Holant for Ω can be written as:

$$\text{Holant}_\Omega = \left(\bigotimes_{w \in W} (|g_w\rangle)^T \right) \left(\bigotimes_{v \in V} |f_v\rangle \right) = \left(\bigotimes_{v \in V} (|f_v\rangle)^T \right) \left(\bigotimes_{w \in W} |g_w\rangle \right), \tag{2}$$

where the tensor products are assumed to be ordered such that, in each inner product, two systems associated with the same edge meet.

[1] In using this notation for vectors, called *Dirac notation* and common in QC and QIT, we anticipate the interpretation of the vectors associated with signatures as quantum states, cf. Section 4.

2.2 Reductions

Holographic transformations are the origin of the name 'Holant problems'. Let M be a 2 by 2 complex matrix. For any $f : \{0,1\}^n \to \mathbb{C}$, write $M \circ f$ for the function corresponding to the vector $M^{\otimes n} |f\rangle$. Furthermore, for any signature set $\mathcal{F}$, write $M \circ \mathcal{F} := \{M \circ f \mid f \in \mathcal{F}\}$.

▶ **Theorem 2** (Valiant's Holant Theorem, [30]). *Suppose $\mathcal{F}$ and $\mathcal{G}$ are two sets of signatures, M an invertible 2 by 2 complex matrix, and $\Omega = (G, \mathcal{F} \mid \mathcal{G}, \pi)$ a signature grid. Let $\Omega' = (G, M \circ \mathcal{F} \mid (M^{-1})^T \circ \mathcal{G}, \pi')$ be the signature grid resulting from Ω by replacing each f_v or g_w by $M \circ f_v$ or $(M^{-1})^T \circ g_w$, respectively. Then $\text{Holant}_\Omega = \text{Holant}_{\Omega'}$ and therefore $\text{Holant}(\mathcal{F} \mid \mathcal{G}) \equiv_T \text{Holant}\left(M \circ \mathcal{F} \mid (M^{-1})^T \circ \mathcal{G}\right)$.*

Here, $\equiv_T$ means the two problems have the same complexity. For non-bipartite signature grids, Theorem 2 implies that $\text{Holant}(\mathcal{F}) \equiv_T \text{Holant}(O \circ \mathcal{F})$, where O is any orthogonal 2 by 2 complex matrix [30]. Going from a signature set $\mathcal{F} \mid \mathcal{G}$ to $M \circ \mathcal{F} \mid (M^{-1})^T \circ \mathcal{G}$ or from $\mathcal{F}$ to $O \circ \mathcal{F}$ is a *holographic reduction*.

A *gadget* over a signature set $\mathcal{F}$ (also called $\mathcal{F}$-gate) is a fragment of a signature grid with some 'dangling' edges. Any gadget can be assigned an effective signature g. If g is the effective signature of some gadget over $\mathcal{F}$, g is said to be *realisable over* $\mathcal{F}$.

▶ **Lemma 3** ([6]). *Suppose $\mathcal{F}$ is some signature set and g is realisable over $\mathcal{F}$. Then $\text{Holant}(\mathcal{F} \cup \{g\}) \equiv_T \text{Holant}(\mathcal{F})$.*

Following [27], we define for any signature set $\mathcal{F}$, $S(\mathcal{F}) = \{g \mid g \text{ is realisable over } \mathcal{F}\}$. Then Lemma 3 implies that $\text{Holant}(S(\mathcal{F})) \equiv_T \text{Holant}(\mathcal{F})$.

If $g \notin S(\mathcal{F})$, in certain cases it is nevertheless possible to show a result like Lemma 3 by analysing a family of signature grids that differ in specific ways. This process is called *polynomial interpolation* and will not be used here, though it is a crucial ingredient in some of the results we build upon. The interested reader can find a discussion of polynomial interpolation in [11].

3 Existing results about the Holant problem

We now introduce the existing families of Holant problems and the associated dichotomy results. Gadget constructions, which are at the heart of many reductions, are easier the more signatures are known to be available. As a result, several families of Holant problems have been defined, in which certain sets of signatures are freely available – i.e. have to be included in any set $\mathcal{F}$ – and can thus be used in gadget constructions and polynomial interpolation.

3.1 Holant*

The Holant problem in which all unary signatures are freely available is $\text{Holant}^*(\mathcal{F}) = \text{Holant}(\mathcal{F} \cup \mathcal{U})$, where $\mathcal{U}$ is the set of all unary signatures [11, 6].

We begin with some definitions. Given a bit string x, let $\bar{x}$ be its bit-wise complement. Denote by $\langle \mathcal{F} \rangle$ the closure of a signature set $\mathcal{F}$ under tensor products. Furthermore, let:

- $\mathcal{T}$ be the set of all binary signatures,
- $\mathcal{E}$ the set of signatures which are non-zero only on two inputs x and $\bar{x}$, and
- $\mathcal{M}$ the set of signatures which are non-zero only on inputs of Hamming weight at most 1.

Finally, define $K = \left(\begin{smallmatrix} 1 & 1 \\ i & -i \end{smallmatrix}\right)$ and $X = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. The matrix K satisfies $K^T K \doteq X$, where $\doteq$ denotes equality up to non-zero scalar factor. In fact, up to multiplication by a diagonal matrix or by X itself, K is the only solution to this equation (see the full version of this paper at [1]).

▶ **Theorem 4** ([6]). *Let $\mathcal{F}$ be any set of complex valued functions in Boolean variables. The problem* $\#\mathrm{HOLANT}^*(\mathcal{F})$ *is polynomial time computable if:*

- $\mathcal{F} \subseteq \langle \mathcal{T} \rangle$, *or*
- $\mathcal{F} \subseteq \langle O \circ \mathcal{E} \rangle$, *where O is a complex orthogonal 2 by 2 matrix, or*
- $\mathcal{F} \subseteq \langle K \circ \mathcal{E} \rangle$, *or*
- $\mathcal{F} \subseteq \langle K \circ \mathcal{M} \rangle$ *or* $\mathcal{F} \subseteq \langle KX \circ \mathcal{M} \rangle$.

In all other cases, $\#\mathrm{HOLANT}^*(\mathcal{F})$ *is #P-hard. The dichotomy is still valid even if the inputs are restricted to planar graphs.*

3.2 Holant^c

$\#\mathrm{HOLANT}^c$ is the Holant problem in which only the unary signatures pinning edges to 0 or 1 are freely available [11, 10], i.e. $\#\mathrm{HOLANT}^c(\mathcal{F}) = \#\mathrm{HOLANT}(\mathcal{F} \cup \{\delta_0, \delta_1\})$ with $\delta_0 = [1, 0]$ and $\delta_1 = [0, 1]$. There is no full dichotomy for $\#\mathrm{HOLANT}^c$ yet, though there is a dichotomy that applies to sets of symmetric signatures only. This dichotomy features a new family of tractable signatures, which do not appear in the $\#\mathrm{HOLANT}^*$ dichotomy.

▶ **Definition 5.** A signature $f : \{0,1\}^n \to \mathbb{C}$ is called *affine* if it has the form:

$$f(x) = ci^{l(x)}(-1)^{q(x)}\chi_{Ax=b}(x), \tag{3}$$

where $c \in \mathbb{C}$, $i^2 = -1$, $l : \{0,1\}^n \to \mathbb{Z}_2$ is a linear function, $q : \{0,1\}^n \to \mathbb{Z}_2$ is a quadratic function, A is an m by n matrix with Boolean entries for some $0 \leq m \leq n$, $b \in \{0,1\}^m$, and χ is an indicator function which takes value 1 on inputs satisfying $Ax = b$, and 0 otherwise.

The set of all affine signatures is denoted by $\mathcal{A}$; this is already closed under tensor products. For the reader familiar with quantum information theory, the affine signatures correspond – up to a scalar factor – to stabilizer states (cf. Section 4.2).

▶ **Theorem 6** ([10]). *Let $\mathcal{F}$ be a set of complex symmetric signatures.* $\#\mathrm{HOLANT}^c(\mathcal{F})$ *is #P-hard unless $\mathcal{F}$ satisfies one of the following conditions, in which case it is in FP:*

- $\#\mathrm{HOLANT}^*(\mathcal{F})$ *is polynomial-time computable (cf. Theorem 4), or*
- *there exists a $T \in \mathcal{I}$ such that $\mathcal{F} \subseteq T \circ \mathcal{A}$, where:*

$$\mathcal{I} = \left\{ T \,\middle|\, \left(T^{-1}\right)^{\otimes T} \circ \{=_2, \delta_0, \delta_1\} \subset \mathcal{A} \right\}. \tag{4}$$

3.3 Other Holant problems

Complex-weighted Boolean #CSP (the counting constraint satisfaction problem) corresponds to a Holant problem in which equality functions of any arity are freely available. Formally, $\#\mathrm{CSP}(\mathcal{F}) = \#\mathrm{HOLANT}(\mathcal{F} \cup \mathcal{G})$, where $\mathcal{G} = \{=_1, =_2, =_3, \ldots\}$ with $=_1$ being the function that is equal to 1 on both inputs [11, 10, 12].

▶ **Theorem 7** ([12]). *Suppose $\mathcal{F}$ is a class of functions mapping Boolean inputs to complex numbers. If $\mathcal{F} \subseteq \mathcal{A}$ or $\mathcal{F} \subseteq \langle \mathcal{E} \rangle$, then* $\#\mathrm{CSP}(\mathcal{F})$ *is computable in polynomial time. Otherwise,* $\#\mathrm{CSP}(\mathcal{F})$ *is #P-hard.*

The same dichotomy also holds for $\#\mathrm{R}_3$-CSP, which corresponds to the bipartite Holant problem $\#\mathrm{HOLANT}(\mathcal{F} \mid \{=_1, =_2, =_3\})$ [12]. This dichotomy follows immediately from that for #CSP if $\mathcal{F}$ contains the binary (or indeed any non-unary) equality function, but it is non-trivial if $\mathcal{F}$ does not contain any non-unary equality functions.

In the case of $\#\mathrm{HOLANT}$ with no free signatures, there exists a dichotomy for complex-valued symmetric signatures [9] and a dichotomy for (not necessarily symmetric) signatures taking non-negative real values [27]. We will not explore those results in any detail here.

3.4 Results about ternary symmetric signatures

The hardness of problems of the form $\text{Holant}\,(\{[y_0,y_1,y_2]\} \mid \{[x_0,x_1,x_2,x_3]\})$ has been fully determined. If $[x_0,x_1,x_2,x_3]$ is degenerate, the problem is tractable by the first case of Theorem 4. If $[x_0,x_1,x_2,x_3]$ is non-degenerate, it can always be mapped to $[1,0,0,1]$ or $[1,1,0,0]$ by a holographic transformation [10]. By Theorem 2, it thus suffices to consider the cases $\{[y_0,y_1,y_2]\} \mid \{[1,0,0,1]\}$ and $\{[y_0,y_1,y_2]\} \mid \{[1,1,0,0]\}$.

There are holographic transformations which leave the signature $[1,0,0,1]$ invariant: in particular, $\left(\begin{smallmatrix}1 & 0\\ 0 & \omega\end{smallmatrix}\right) \circ [1,0,0,1] = [1,0,0,1]$ if $\omega^3 = 1$ [10]. Thus, by Theorem 2:

$$\text{Holant}\,(\{[y_0,y_1,y_2]\} \mid \{[1,0,0,1]\}) \equiv_T \text{Holant}\left(\{[y_0,\omega y_1,\omega^2 y_2]\} \mid \{[1,0,0,1]\}\right). \quad (5)$$

This relationship can be used to reduce the number of symmetric binary signatures to be considered. Following [10], a signature of the form $[y_0,y_1,y_2]$ is called *ω-normalised* if $y_0 = 0$, or there does not exist a primitive $(3t)$-th root of unity λ, where $gcd(t,3) = 1$, such that $y_2 = \lambda y_0$. Similarly, a unary signature $[a,b]$ is ω-normalised if $a = 0$, or there does not exist a primitive $(3t)$-th root of unity λ, where $gcd(t,3) = 1$, such that $b = \lambda a$.

▶ **Theorem 8** ([10]). *Let $\mathcal{G}_1, \mathcal{G}_2$ be two sets of signatures and let $[y_0,y_1,y_2]$ be a ω-normalised and non-degenerate signature. In the case of $y_0 = y_2 = 0$, further assume that $\mathcal{G}_1$ contains a unary signature $[a,b]$ which is ω-normalised and satisfies $ab \neq 0$. Then:*

$$\text{Holant}\,(\{[y_0,y_1,y_2]\} \cup \mathcal{G}_1 \mid \{[1,0,0,1]\} \cup \mathcal{G}_2) \equiv_T \#\text{CSP}(\{[y_0,y_1,y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2). \quad (6)$$

More specifically, $\text{Holant}\,(\{[y_0,y_1,y_2]\} \cup \mathcal{G}_1 \mid \{[1,0,0,1]\} \cup \mathcal{G}_2)$ *is #P-hard unless:*

- $\{[y_0,y_1,y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2 \subseteq \langle \mathcal{E} \rangle$, *or*
- $\{[y_0,y_1,y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2 \subseteq \mathcal{A}$,

in which cases the problem is in FP.

▶ **Theorem 9** ([10]). $\text{Holant}\,(\{[y_0,y_1,y_2]\} \mid \{[x_0,x_1,x_2,x_3]\})$ *is #P-hard unless $[y_0,y_1,y_2]$ and $[x_0,x_1,x_2,x_3]$ satisfy one of the following conditions, in which case the problem is in FP:*

- $[x_0,x_1,x_2,x_3]$ *is degenerate, or*
- *there is a 2 by 2 matrix M such that:*
  - $[x_0,x_1,x_2,x_3] = M \circ [1,0,0,1]$ *and* $M^T \circ [y_0,y_1,y_2]$ *is in* $\mathcal{A} \cup \langle \mathcal{E} \rangle$,
  - $[x_0,x_1,x_2,x_3] = M \circ [1,1,0,0]$ *and* $[y_0,y_1,y_2] = (M^{-1})^T \circ [0,a,b]$ *for some* $a,b \in \mathbb{C}$.

4 The quantum state perspective on signature grids

In Section 2.1, we introduced the idea of considering signatures as complex vectors. This perspective is useful for proving Valiant's Holant Theorem, which is at the heart of the theory of Holant problems. It also gives a connection to the theory of QC.

In QC and QIT, the basic system of interest is a *qubit* (quantum bit), which takes the place of the usual bit in standard computer science. The state of a qubit is described by a vector[2] in $\mathbb{C}^2$. State spaces compose by tensor product, i.e. the state of n qubits is described by a vector in $\left(\mathbb{C}^2\right)^{\otimes n}$, which is isomorphic to $\mathbb{C}^{2^n}$. Thus, the vector associated with an n-ary signature can be considered to be an (unnormalised) quantum state of n qubits.

[2] Strictly speaking, vectors only describe *pure* quantum states: there are also *mixed* states, which need to be described differently; but we do not consider those here.

Let $\{|0\rangle, |1\rangle\}$ be an orthonormal basis for $\mathbb{C}^2$. We call this the *computational basis*. The induced basis on $\left(\mathbb{C}^2\right)^{\otimes n}$ is labelled by $\{|x\rangle\}_{x\in\{0,1\}^n}$ as a short-hand, e.g. we write $|00\ldots0\rangle$ instead of $|0\rangle\otimes|0\rangle\otimes\ldots\otimes|0\rangle$. This is exactly the same as the basis introduced in Section 2.1.

Holographic transformations also have a natural interpretation in quantum information theory: going from an n-qubit state $|f\rangle$ to $M^{\otimes n}|f\rangle$, where M is some invertible 2 by 2 matrix, is a 'stochastic local operation with classical communication' (SLOCC) [4, 15]. These are physical operations that can be applied locally (without needing access to more than one qubit at a time) using classical (i.e. non-quantum) communication between the sites where the different qubits are held, and which succeed with non-zero probability. Unlike holographic transformations, SLOCC operations do not need to be symmetric under interchange of the qubits: the most general SLOCC operation on an n-qubit state is given by $M_1\otimes M_2\otimes\ldots\otimes M_n$, where $M_1, M_2, \ldots M_n$ are invertible complex 2 by 2 matrices [15].

From now on, we will use standard Holant terminology (or notation) and quantum terminology (or notation) interchangeably, and sometimes mix the two.

4.1 Entanglement and its classification

One major difference between quantum theory and preceding theories of physics (known as 'classical physics') is the possibility of *entanglement* in states of multiple systems.

▶ **Definition 10.** A state of multiple systems is *entangled* if it cannot be written as a tensor product of states of individual systems.

Where a state involves more than two systems, it is possible for some of the systems to be entangled with each other and for other systems to be in a product state with respect to the former. We sometimes use the term *genuinely entangled state* to refer to a state in which no subsystem is in a product state with the others. The term *multipartite entanglement* refers to entangled states in which more than two qubits are mutually entangled. Non-degenerate signatures correspond to (not necessarily genuinely) entangled states.

Entanglement is an important resource in QC, where it has been shown that quantum speedups are impossible without the presence of unboundedly growing amounts of entanglement [22]. Similarly, it is a resource in QIT [28], featuring in protocols such as quantum teleportation [3] and quantum key distribution [16]. Many QIT protocols have the property that two quantum states can be used to perform the same task if one can be transformed into the other by SLOCC, motivating the following equivalence relation.

▶ **Definition 11.** Two n-qubit states are *equivalent under SLOCC* if one can be transformed into the other using SLOCC. More formally: suppose $|f\rangle$ and $|g\rangle$ are two n-qubit states. Then $|f\rangle \sim_{SLOCC} |g\rangle$ if and only if there exist invertible complex 2 by 2 matrices $M_1, M_2, \ldots, M_n$ such that $(M_1\otimes M_2\otimes\ldots\otimes M_n)|f\rangle = |g\rangle$.

The equivalence classes of this relation are called *entanglement classes* or *SLOCC classes*.

For two qubits, there is only one class of entangled states, i.e. all entangled two-qubit states are equivalent to $|00\rangle + |11\rangle$ under SLOCC. For three qubits, there are two classes of genuinely entangled states [15], called the GHZ class and the W class. The former contains states that are equivalent under SLOCC to the GHZ state $|\mathrm{GHZ}\rangle := |000\rangle + |111\rangle$, the latter those equivalent to the W state $|W\rangle := |001\rangle + |010\rangle + |100\rangle$. Given an arbitrary three-qubit state expressed in the computational basis, it is straightforward to determine its entanglement class [26]. For more than three qubits, there are infinitely many SLOCC classes. It is possible to partition these into families which share similar properties. Yet, so

far, there is no consensus on how to partition the classes: there are different schemes for partitioning even the four-qubit entanglement classes, yielding different families [31, 25, 2].

It is sometimes useful to generalise the definitions of GHZ and W states to n-qubit states. The generalised GHZ state on n qubits is $|\mathrm{GHZ}_n\rangle := |0\rangle^{\otimes n} + |1\rangle^{\otimes n}$, i.e. it is the state corresponding to the n-ary equality signature. The generalised W state on n qubits is defined as $|W_1\rangle := |1\rangle$ and $|W_n\rangle := |1\rangle \otimes |0\rangle^{\otimes n-1} + |0\rangle \otimes |W_{n-1}\rangle$ for $n > 1$, i.e. $|W_n\rangle$ corresponds to the n-ary indicator function for inputs of Hamming weight 1. We sometimes drop the word 'generalised' when talking about generalised GHZ or W states. It should be clear from context whether or not we mean the three-qubit state specifically.

4.2 The existing results in the quantum picture

Several of the existing dichotomies have straightforward descriptions in the quantum picture. The tractable cases of the Holant* dichotomy (cf. Section 3.1) can be described as follows:

- either there is no multipartite entanglement – this corresponds to the case $\mathcal{F} \subseteq \langle \mathcal{T} \rangle$, or
- there is GHZ-type multipartite entanglement but it is impossible to realise W-type multipartite entanglement – this corresponds to the cases $\mathcal{F} \subseteq \langle O \circ \mathcal{E} \rangle$ or $\mathcal{F} \subseteq \langle K \circ \mathcal{E} \rangle$, or
- there is W-type multipartite entanglement and it is impossible to realise GHZ-type multipartite entanglement – this corresponds to the case $\mathcal{F} \subseteq \langle K \circ \mathcal{M} \rangle$ or $\mathcal{F} \subseteq \langle KX \circ \mathcal{M} \rangle$.

By GHZ-type entanglement we mean states that are equivalent to generalised GHZ states under SLOCC, and similarly for W-type entanglement.

The tractable case of Holant^c (cf. Section 3.2) that does not appear in Holant* also has a natural description: in QIT, the states corresponding to affine signatures are known as *stabilizer states* [13]. These states and the associated operations play an important role in the context of quantum error-correcting codes [20] and are thus at the core of most attempts to build large-scale quantum computers [14]. The fragment of quantum theory consisting of stabilizer states and operations that preserve the set of stabilizer states can be efficiently simulated on a classical computer [20]; this result is known as the Gottesman-Knill theorem.

Thus, the Holant problem and QIT are linked not only by quantum algorithms being an inspiration for holographic ones: instead, the known tractable signature sets of various Holant problems correspond to state sets that are of independent interest in QC and QIT.

The restriction to algebraic numbers is not a problem from the quantum perspective, not even when considering the question of universal QC: there exist (approximately) universal sets of quantum operations where each operation can be described using algebraic complex coefficients. One such example is the Clifford+T gate set [5, 19].

5 Holant$^+$

Our new family of Holant problems, called Holant$^+$, sits in between Holant* and Holant^c. It has a small number of freely available signatures, which are all unary. Yet, using results from QIT, these can be shown to be sufficient for constructing the gadgets required to reduce to the dichotomies in Section 3.4. Formally:

$$\text{Holant}^+ (\mathcal{F}) = \text{Holant} (\mathcal{F} \cup \{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}), \tag{7}$$

where $|+\rangle := |0\rangle + |1\rangle$ corresponds to the 'unary equality function' and $|-\rangle := |0\rangle - |1\rangle$ is a vector that is orthogonal to $|+\rangle$. In quantum theory, the set $\{|+\rangle, |-\rangle\}$ is known as the *Hadamard basis*, since they are related to the computational basis vectors by a Hadamard transformation (up to scalar factor): $\{|+\rangle, |-\rangle\} \doteq H \circ \{|0\rangle, |1\rangle\}$, where $H = \frac{1}{\sqrt{2}} \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$.

5.1 Why these free signatures?

The definition of $\#\text{HOLANT}^+$ is motivated by the following result from quantum theory.

▶ **Theorem 12** ([29],[18]). *Let $|\Psi\rangle$ be an n-system entangled state. For any two of the n systems, there exists a projection, onto a tensor product of states of the other $(n-2)$ systems, that leaves the two systems in an entangled state.*

Here, 'projection' means a (partial) inner product between $|\Psi\rangle$ and the tensor product of single-system states. The original proof of this statement in [29] was flawed but it was recently corrected [18]. The following corollary is not stated explicitly in either paper, but can be seen to hold by inspecting the proof in [18].

▶ **Corollary 13.** *Let $|\Psi\rangle$ be an n-qubit entangled state. For any two of the n qubits, there exists a projection of the other $(n-2)$ qubits onto a tensor product of computational and Hadamard basis states that leaves the two qubits in an entangled state.*

In other words, Theorem 12 holds when the systems are restricted to qubits and the projectors are restricted to products of computational and Hadamard basis states. Here, it is crucial to have projectors taken from two bases that are linked by the Hadamard transformation: the corollary works only in that case. We extend this result as follows.

▶ **Theorem 14.** *Let $|\Psi\rangle$ be an n-qubit entangled state with $n \geq 3$. There exists some choice of three of the n qubits and a projection of the other $(n-3)$ qubits onto a tensor product of computational and Hadamard basis states that leaves the three qubits in a genuinely entangled state.*

Proof (Sketch). If $n = 3$, $|\Psi\rangle$ itself is the desired state. For larger n, the theorem is proved inductively: we show that, given an n-qubit entangled state with $n > 3$, it is possible to project $(n-3)$ qubits in the desired way, assuming the same holds for all k-qubit genuinely entangled states with $3 \leq k \leq n$. The induction step is then proved by contradiction, employing the assumption that Theorem 14 does not hold for $(n+1)$-qubit states while Theorem 12 does. The full proof can be found in [1]. ◀

This result, which was not previously known in the QIT literature, is stronger than Theorem 12 in that we construct entangled three-qubit states rather than two-qubit ones. On the other hand, our result may not hold for all choices of three qubits: all we show is that there exists some choice of three qubits for which it does hold. The original proof of Theorem 14 in an earlier version of this paper was long and involved; this new shorter proof was suggested by Gachechiladze and Gühne [17].

5.2 The dichotomy theorem

Using Theorem 14, as well as Theorems 8 and 9, we prove our main result: a dichotomy for $\#\text{HOLANT}^+$ applying to complex, not necessarily symmetric signatures.

▶ **Theorem 15.** *Let $\mathcal{F}$ be a set of complex signatures. $\#\text{HOLANT}^+(\mathcal{F})$ is in FP if $\mathcal{F}$ satisfies one of the following conditions:*

- *$\#\text{HOLANT}^*(\mathcal{F})$ is in FP, or*
- *$\mathcal{F} \subseteq \mathcal{A}$.*

In all other cases, the problem is #P-hard.

The tractable cases are almost the same as those for symmetric Holant^c (Theorem 6), now without the symmetry restriction. The only difference is that the holographic transformations allowed in the affine case of the Holant^c dichotomy are trivial in the case of Holant$^+$: any transformation that maps $\{|=_2\rangle, |0\rangle, |1\rangle, |+\rangle, |-\rangle\}$ to a subset of $\mathcal{A}$ must itself be in $\mathcal{A}$.

The tractability proof follows immediately by reduction to Holant* or #CSP, respectively. For the hardness proof, we use Theorem 14 to construct signatures corresponding to three-qubit entangled states. We then show that, unless we are in one of the tractable cases, it is possible to construct ternary gadgets with non-degenerate symmetric signatures. If the ternary symmetric signature is in the GHZ class, Theorem 8 applies. If the ternary symmetric signature is in the W class but not in $K \circ \mathcal{M}$ or $KX \circ \mathcal{M}$, we use Theorem 9. Finally, if the ternary symmetric signature is contained in $K \circ \mathcal{M}$, then by assumption the set of available signatures $\mathcal{F}$ must contain some signature that is not in $K \circ \mathcal{M}$ – otherwise, the problem is already known to be tractable. We show how to use such a signature to construct a binary symmetric signature that is not in $K \circ \mathcal{M}$. Then the desired result follows by Theorem 9. An analogous result holds with $KX \circ \mathcal{M}$ instead.

The gadget constructions for ternary symmetric signatures are given in Section 5.3. The gadget construction for a symmetric binary signature that is not in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$) follows in Section 5.4. Section 5.5 contains the hardness proof itself.

5.3 Symmetrising ternary signatures

The dichotomies given in Section 3.4 apply to symmetric ternary entangled signatures. The signatures constructed according to Theorem 14 are ternary and entangled, but they are not generally symmetric. Yet, these general ternary entangled signatures can be used to realise symmetric ones, possibly with the help of an additional binary non-degenerate signature. We prove this by distinguishing cases according to whether the ternary entangled signature constructed using Theorem 14 is in the GHZ or the W entanglement class.

First, consider a general GHZ-class state $|\psi\rangle$. By definition, there exist invertible complex 2 by 2 matrices A, B, C such that $|\psi\rangle = (A \otimes B \otimes C) |\mathrm{GHZ}\rangle$. We can draw the signature associated with $|\psi\rangle$ as the 'virtual gadget' shown in Figure 1a. The 'boxes' denoting the matrices are non-symmetric to indicate that A, B, C are not in general symmetric. The white dot represents the GHZ state. This notation is not meant to imply that the signatures A, B, C or the ternary equality signature are available on their own. Thinking of the signature as such a composite will simply make future arguments more straightforward. A similar argument can be applied if $|\psi\rangle$ is a W-class state, in which case the white dots in Figure 1 should be thought of as having signature $|W\rangle$.

In both cases, three vertices with the same ternary entangled signature can be connected to form the rotationally symmetric gadget shown in Figure 1b. In fact, the signature for that gadget is fully symmetric: its value depends only on the Hamming weight of the inputs. On the other hand, it may not be entangled or it may have the all-zero signature. For a general non-symmetric $|\psi\rangle$ there are three such symmetric gadgets that can be constructed by permuting the roles of A, B, and C in Figure 1b – in particular, which of the three ends up on the external edge of the gadget. This idea leads to the following lemmas.

▶ **Lemma 16.** *Let $|\psi\rangle$ be a three-qubit GHZ-class state, i.e. $|\psi\rangle = (A \otimes B \otimes C) |\mathrm{GHZ}\rangle$ for some invertible 2 by 2 matrices A, B, C. Then at least one of the three possible symmetric gadgets resulting from permutations of A, B, C in Figure 1b is non-degenerate unless $|\psi\rangle \in K \circ \mathcal{E}$ and is furthermore already symmetric.*

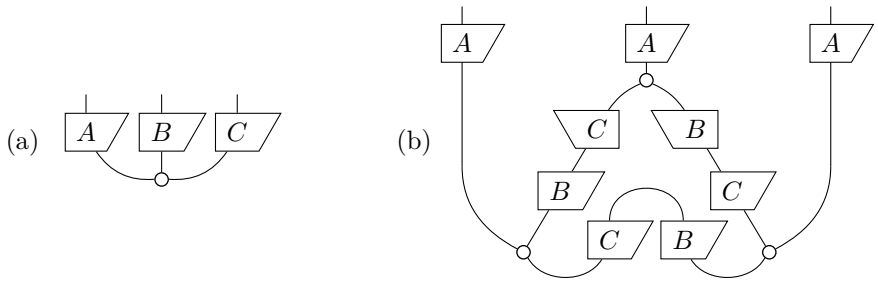

Figure 1 (a) A 'virtual gadget' for an entangled ternary signature based on the idea of SLOCC classes. (b) A symmetric gadget constructed from three copies of that ternary signature.

▶ **Lemma 17.** *Let $|\psi\rangle$ be a three-qubit W-class state, i.e. $|\psi\rangle = (A \otimes B \otimes C)|W\rangle$ for some invertible 2 by 2 matrices A, B, C. If $|\psi\rangle \in K \circ \mathcal{M}$ (or $|\psi\rangle \in KX \circ \mathcal{M}$), assume that we also have a two-qubit entangled state $|\phi\rangle$ that is not in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$, respectively). Then we can realise a symmetric three-qubit entangled state.*

5.4 Constructing binary signatures

We have shown in the previous section that it is possible to realise a non-degenerate ternary symmetric signature under some mild assumptions. Now, we show that if the full signature set $\mathcal{F}$ is not a subset of $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$), it is possible to construct a symmetric binary gadget over $\mathcal{F} \cup \{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}$ whose signature is not in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$, respectively). This signature can be used in Lemma 17, and a symmetric signature realised from it can also be used for a hardness proof according to Theorem 9.

▶ **Lemma 18.** *Suppose $|\psi\rangle$ is a genuinely entangled n-qubit state with $n \geq 2$, and $|\psi\rangle \notin K \circ \mathcal{M}$. Then there exists a non-degenerate binary gadget over $\{|\psi\rangle, |0\rangle, |1\rangle, |+\rangle, |-\rangle\}$ with signature $|\varphi\rangle \notin K \circ \mathcal{M}$.*

The binary signature required in Lemma 17 is not required to be symmetric, only non-degenerate. The one in Theorem 9, on the other hand, does need to be symmetric.

▶ **Lemma 19.** *Suppose $|\psi\rangle \in K \circ \mathcal{M}$ is a three-qubit symmetric entangled state and $|\phi\rangle \notin K \circ \mathcal{M}$ is a two-qubit entangled state. Then there exists a gadget over $\{|\psi\rangle, |\phi\rangle, |0\rangle, |1\rangle, |\pm\rangle\}$ such that its signature $|\varphi\rangle$ is a two-qubit symmetric entangled state and $|\varphi\rangle \notin K \circ \mathcal{M}$.*

An analogous argument holds with KX instead of K. Hence, we can construct a non-degenerate symmetric binary signature satisfying the required properties whenever needed.

5.5 Sketch of the hardness proof

Suppose $\mathcal{F}$ is not in one of the tractable cases. Then, in particular, $\mathcal{F} \not\subseteq \langle \mathcal{T} \rangle$, i.e. $\mathcal{F}$ must contain multipartite entanglement (cf. Section 3.1). We can therefore use Theorem 14 to realise a ternary entangled signature. The quantum state associated with this signature must be in either the GHZ or the W SLOCC class.

In the GHZ case, either the state is already symmetric or it is possible to realise a non-degenerate symmetric ternary signature by Lemma 16. In the W case, if the ternary signature is not in $K \circ \mathcal{M}$ or $KX \circ \mathcal{M}$, it can be used to realise a non-degenerate ternary symmetric signature by Lemma 17. If the ternary signature is in $K \circ \mathcal{M}$, by Lemma 18, we can realise a binary signature that is not in $K \circ \mathcal{M}$ since by assumption $\mathcal{F} \not\subseteq K \circ \mathcal{M}$; and

similarly with KX instead of K. This then enables the use of Lemma 17. Hence if $\mathcal{F}$ is not one of the tractable sets, it is always possible to realise a non-degenerate symmetric ternary signature. Again, the quantum state associated with this signature must be in either the GHZ or the W SLOCC class.

If it is a GHZ class state, use the following lemma and corollary to reduce the problem to Theorem 8. This theorem yields #P-hardness unless $\mathcal{F}$ is a subset of $\langle O \circ \mathcal{E} \rangle$ or $\mathcal{A}$, which we assumed it was not.

▶ **Lemma 20.** *Let f be a signature and $\mathcal{G}$ a set of signatures. Then:*

$$\text{Holant}(\{f\} \cup \mathcal{G}) \equiv_T \text{Holant}(\{f, [1,0,1]\} \mid \mathcal{G} \cup \{[1,0,1]\}). \tag{8}$$

▶ **Corollary 21.** *Let f be a signature and $\mathcal{G}$ a set of signatures, and let M be an invertible 2 by 2 matrix. Then:*

$$\text{Holant}(\{M \circ f\} \cup \mathcal{G}) \equiv_T \text{Holant}\left(\left\{f, M^{-1} \circ [1,0,1]\right\} \,\middle|\, (\mathcal{G} \cup \{[1,0,1]\}) \circ M^T\right). \tag{9}$$

The corollary follows immediately from Lemma 20 and Theorem 2.

If the non-degenerate symmetric ternary signature $|\psi\rangle$ realised according to Section 5.3 is in the W class, then, by Theorem 9, the problem is #P-hard unless the signature is in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$). In the latter case, as by assumption $\mathcal{F} \not\subseteq K \circ \mathcal{M}$ (or $\mathcal{F} \not\subseteq KX \circ \mathcal{M}$), we can use Lemmas 18 and 19 to construct a symmetric binary signature $|\varphi\rangle$ that is not in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$, respectively).

Now, $\text{Holant}(\{|\varphi\rangle\} \mid \{|\psi\rangle\}) \leq_T \text{Holant}(\{|\varphi\rangle, |\psi\rangle\} \cup \mathcal{G})$ for any set $\mathcal{G}$. But if $|\psi\rangle \in K \circ \mathcal{M}$ and $|\varphi\rangle \notin K \circ \mathcal{M}$, then $\text{Holant}(\{|\varphi\rangle\} \mid \{|\psi\rangle\})$ is #P-hard by Theorem 9, and similarly with KX instead of K. Thus $\text{Holant}^+(\mathcal{F})$ is #P-hard whenever such $|\psi\rangle$ and $|\varphi\rangle$ are realisable over $\mathcal{F}$.

This concludes the investigation of all cases. We have therefore shown that Holant^+ is #P-hard in all but the listed cases. A full proof of this result can be found in [1].

6 Conclusions

Applying knowledge from QIT to Holant problems, we find that several tractable classes of existing dichotomies have concise descriptions in the framework of quantum entanglement. Motivated by this and by existing results in entanglement theory, we define a new Holant family, Holant^+, fitting between the known families Holant^* and Holant^c. We derive a full dichotomy for this family, which is closely related to the dichotomy for symmetric Holant^c [10]. It may therefore be a useful stepping stone towards a full Holant^c dichotomy, and thus to a full dichotomy for all Holant problems.

We also prove a new result in entanglement theory: given any n-qubit genuinely entangled state, it is possible to find some subset of $(n-3)$ qubits and a projector which is a tensor product of $(n-3)$ computational and Hadamard basis states such that the projection leaves the remaining three qubits in a genuinely entangled state. This is a generalisation of a similar result about constructing two-qubit entangled states [29, 18], though our result is slightly weaker in some aspects, which it may be possible to strengthen in future work.

We expect that further analysis of Holant problems using methods from QIT and QC will lead to further new insights, both into the complexity of Holant problems and into entanglement or other areas of quantum theory.

Acknowledgements. I would like to thank Ashley Montanaro, both for introducing me to Holant problems and for helpful comments on earlier drafts of this paper. I would also like to thank Mariami Gachechiladze and Otfried Gühne for pointing out a significantly shorter and more elegant proof of Theorem 14, and for letting me use it here.

Abstract

We consider the natural generalization of the Schrödinger equation to *Markovian open system dynamics*: the so-called the Lindblad equation. We give a quantum algorithm for simulating the evolution of an n-qubit system for time t within precision ϵ. If the Lindbladian consists of $\text{poly}(n)$ operators that can each be expressed as a linear combination of $\text{poly}(n)$ tensor products of Pauli operators then the gate cost of our algorithm is $O(t\,\text{polylog}(t/\epsilon)\text{poly}(n))$. We also obtain similar bounds for the cases where the Lindbladian consists of local operators, and where the Lindbladian consists of sparse operators. This is remarkable in light of evidence that we provide indicating that the above efficiency is impossible to attain by first expressing Lindblad evolution as Schrödinger evolution on a larger system and tracing out the ancillary system: the cost of such a *reduction* incurs an efficiency overhead of $O(t^2/\epsilon)$ even before the Hamiltonian evolution simulation begins. Instead, the approach of our algorithm is to use a novel variation of the "linear combinations of unitaries" construction that pertains to channels.

1 Introduction

The problem of simulating the evolution of closed systems (captured by the Schrödinger equation) was proposed by Feynman [12] in 1982 as a motivation for building quantum computers. Since then, several quantum algorithms have appeared for this problem (see section 1.1 for references to these algorithms). However, many quantum systems of interest are not closed but are well-captured by the Lindblad Master equation [21, 13]. Examples exist in quantum physics [20, 32], quantum chemistry [25, 27], and quantum biology [11, 14, 26]. Lindblad evolution also arises in quantum computing and quantum information in the

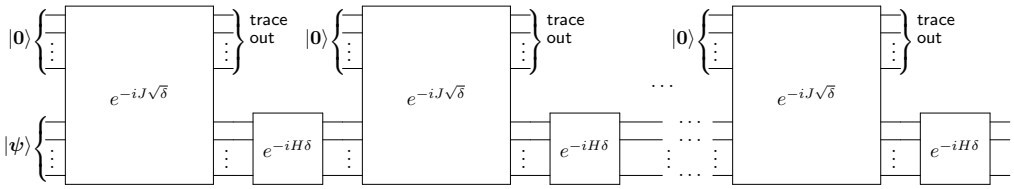

Figure 1 Lindblad evolution for time t approximated by unitary operations. There are N iterations and $\delta = t/N$. This converges to Lindblad evolution as $N \to \infty$.

context of entanglement preparation [19, 16, 29], thermal state preparation [15], quantum state engineering [31], and studying the noise of quantum circuits [24].

We consider the computational cost of simulating the evolution of an n-qubit quantum state for time t under the Lindblad Master equation

$$\dot{\rho} = -i[H, \rho] + \sum_{j=1}^{m} \Big(L_j \rho L_j^\dagger - \frac{1}{2} L_j^\dagger L_j \rho - \frac{1}{2} \rho L_j^\dagger L_j \Big), \tag{1}$$

(representing Markovian open system dynamics), where H is a Hamiltonian and $L_1, \ldots, L_m$ are linear operators. By *simulate the evolution*, we mean: provide a quantum circuit that computes the quantum channel corresponding to evolution by Eq. (1) for time t within precision ϵ. The quantum circuit must be independent of the input state, which is presumed to be unknown. When $L_1 = \cdots = L_m = 0$, Eq. (1) is the Schrödinger equation.

Eq. (1) can be viewed as an idealization of the frequently occurring physical scenario where a quantum system evolves jointly with a large external environment in a manner where information dissipates from the system into the environment. In quantum information theoretic terms, Lindblad evolution is a continuous-time process that, for any evolution time, is a quantum channel. Moreover, Lindblad evolution is *Markovian* in the sense that, for any $\delta > 0$, the state at time $t + \delta$ is a function of the state at time t alone (i.e., is independent of the state before time t).

Lindblad evolution can be intuitively thought of as Hamiltonian evolution in a larger system that includes an ancilla register, but where the ancilla register is being continually reset to its initial state. To make this more precise, consider a time interval $[0, t]$, and divide it into N subintervals of length $\frac{t}{N}$ each. At the beginning of each subinterval, reset the state of the ancilla register to its initial state, and then let the joint system-ancilla evolve under a Hamiltonian J and the system itself evolve under H. Let the evolution time for J be $\sqrt{t/N}$ and the evolution time for H be t/N. This process, illustrated in Fig. 1, converges to true Lindblad evolution as N approaches ∞.

For the specific evolution described by Eq. (1), it suffices to set the ancilla register to $\mathbb{C}^{m+1}$ and the Hamiltonian J to the block matrix

$$J = \begin{pmatrix} 0 & L_1^\dagger & \cdots & L_m^\dagger \\ L_1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ L_m & 0 & \cdots & 0 \end{pmatrix}. \tag{2}$$

A remarkable property of this way of representing Lindblad evolution is that the rate at which the Hamiltonian J evolves is effectively infinite: Lindblad evolution for time t/N is simulated by a process that includes evolution by J for time $\sqrt{t/N}$, so the rate of the

evolution scales as

$$\frac{\sqrt{t/N}}{t/N} = \sqrt{\frac{N}{t}}, \tag{3}$$

which diverges as $N \to \infty$. Moreover, the total Hamiltonian evolution time of J in Fig. 1 is $N\sqrt{t/N} = \sqrt{Nt}$, which also diverges. In the Appendix A we prove that, in general, the above scaling phenomenon is necessary for simulating time-independent Lindblad evolution in terms of time-independent Hamiltonian evolution along the lines of the overall structure of Fig. 1. In this sense, *exact* Lindblad evolution for finite time does not directly correspond to Hamiltonian evolution for *any* finite time. On the other hand, it can be shown that if the scaling of N is at least t^3/ϵ^2 then the final state is an *approximation* within ϵ. Note that then the corresponding total evolution time for J scales as $\sqrt{(t^3/\epsilon^2)t} = t^2/\epsilon$. Therefore, quantum algorithms that simulate Lindblad evolution by first applying the above reduction to Hamiltonian evolution and then efficiently simulating the Hamiltonian evolution are likely to incur scaling that is at least t^2/ϵ.

Here we are interested in whether much more efficient simulations of Lindblad evolution are possible, such as $O(t \operatorname{polylog}(t/\epsilon))$.

1.1 Previous work

Simulating Hamiltonian evolution. Hamiltonian evolution (a.k.a. Schrödinger evolution) is the special case of Eq. (1) where $L_j = 0$ for all j. This simulation problem has received considerable attention since Feynman [12] proposed this as a motivation for building quantum computers; see for example [22, 1, 8, 2, 3, 5, 4, 18, 23, 28, 6]. Some of the recent methods obtain a scaling that is $O(t \operatorname{polylog}(t/\epsilon)\operatorname{poly}(n))$, thereby exceeding what can be accomplished by the longstanding Trotter-Suzuki methods [30].

Simulating Lindblad evolution. The natural generalization from closed systems to Markovian open systems in terms of the Lindblad equation has received much less attention. Kliesch *et al.* [17] give a quantum algorithm for simulating Lindblad evolution in the case where each of $H, L_1, \ldots, L_m$ can be expressed as a sum of local operators (i.e., which act on a constant number of qubits). The cost of this algorithm with respect to t and ϵ (omitting factors of $\operatorname{poly}(n)$) is $O(t^2/\epsilon)$. Childs and Li [9] improve this to $O(t^{1.5}/\sqrt{\epsilon})$ and also give an $O((t^2/\epsilon)\operatorname{polylog}(t/\epsilon))$ query algorithm for the case where the operators in Eq. (1) are sparse and represented in terms of an oracle. Another result in [9] is an $\Omega(t)$ lower bound for the query complexity for time t when Eq. (1) has $H = 0$ and $m = 1$.

As far as we know, none of the previous algorithms for simulating Lindblad evolution has cost $O(t \operatorname{polylog}(t/\epsilon)\operatorname{poly}(n))$, which is the performance that we attain. Our results are summarized precisely in the next subsection (subsection 1.2).

We note that there are simulation algorithms that solve problems that are related to but different from ours, such as [7], which does not produce the final state; rather it simulates the expectation of an observable applied to the final state. We do not know how to adapt these techniques to produce the unmeasured final state instead.

Finally, we note that there are interesting classical algorithmic techniques for simulating Lindblad evolution that are feasible when the dimension of the Hilbert space (which is 2^n, for n qubits) is not too large—but these do not carry over to the context of quantum algorithms (where n can be large). In the classical setting, since the state is known (and stored) explicitly, various "unravellings" of the process that are state-dependent can be simulated. For example, the random variable corresponding to "the next jump time" (which is highly state-dependent)

can be simulated. In the context of quantum algorithms, the input state is unknown and cannot be measured without affecting it.

1.2 New results

Eq. (1) can be written as $\dot{\rho} = \mathcal{L}[\rho]$, where $\mathcal{L}$ is a *Lindbladian*, defined as a mapping of the form

$$\mathcal{L}[\rho] = -i[H,\ \rho] + \sum_{j=1}^{m}\Big(L_j \rho L_j^\dagger - \frac{1}{2}L_j^\dagger L_j \rho - \frac{1}{2}\rho L_j^\dagger L_j\Big), \tag{4}$$

for operators $H, L_1, \ldots, L_m$ on the Hilbert space $\mathcal{H} = \mathbb{C}^{2^n}$ (n qubits) with H Hermitian. Evolution under Eq. (1) for time t corresponds to the quantum map $e^{\mathcal{L}t}$ (which is a channel for any $t \geq 0$).

Each of the operators $H, L_1, \ldots, L_m$ corresponds to a $2^n \times 2^n$ matrix. The simulation algorithm is based on a succinct specification of these matrices. Our succinct specification is as a *linear combination of q Paulis*, defined as

$$H = \sum_{k=0}^{q-1} \beta_{0k} V_{0k} \tag{5}$$

$$L_j = \sum_{k=0}^{q-1} \beta_{jk} V_{jk}, \tag{6}$$

where, for each $j \in \{0, \ldots, m\}$ and $k \in \{0, \ldots, q-1\}$, V_{jk} is an n-fold tensor product of Paulis (I, σ_x, σ_y, σ_z) and a scalar phase $e^{i\theta}$ ($\theta \in [0, 2\pi]$), and $\beta_{jk} \geq 0$.

In the evolution $e^{\mathcal{L}t}$, it is possible to scale up $\mathcal{L}$ by some factor while reducing t by the same factor, i.e., $e^{\mathcal{L}t}[\rho] = e^{(c\mathcal{L})\frac{t}{c}}[\rho]$ for any $c > 0$[1]. This reduces the simulation time but transfers the cost into the magnitude of $\mathcal{L}$. To normalize this cost, we define a norm based on the specification of $\mathcal{L}$.

Define the norm[2] of a specification of a Lindbladian $\mathcal{L}$ as a linear product of Paulis as

$$\|\mathcal{L}\|_{\mathsf{pauli}} = \sum_{k=0}^{q-1} \beta_{0k} + \sum_{j=1}^{m}\Big(\sum_{k=0}^{q-1} \beta_{jk}\Big)^2. \tag{7}$$

Our main result is the following theorem.

▶ **Theorem 1.** *Let $\mathcal{L}$ be a Lindbladian presented as a linear combination of q Paulis. Then, for any $t > 0$ and $\epsilon > 0$, there exists a quantum circuit of size*

$$O\left(m^2 q^2 \tau \frac{(\log(mq\tau/\epsilon) + n)\log(\tau/\epsilon)}{\log\log(\tau/\epsilon)}\right) \tag{8}$$

that implements a quantum channel $\mathcal{N}$, such that $\left\|\mathcal{N} - e^{\mathcal{L}t}\right\|_\diamond \leq \epsilon$, where $\tau = t\,\|\mathcal{L}\|_{\mathsf{pauli}}$.

---

[1] $c\mathcal{L}$ denotes the mapping obtained from $\mathcal{L}$ with H multiplied by c and each L_j multiplied by $\sqrt{c}$.

[2] For simplicity we use the terminology $\|\mathcal{L}\|_{\mathsf{pauli}}$ even though the quantity is not directly a function of the mapping $\mathcal{L}$. However, $\|c\mathcal{L}\|_{\mathsf{pauli}} = c\|\mathcal{L}\|_{\mathsf{pauli}}$ if $c\mathcal{L}$ denotes the expression in Eq. (4) with the factor c multiplied through.

Remarks

1. The proof of Theorem 1 is sketched in section 4 and is shown in the full version of this paper [10]. A main novel ingredient of the proof is Lemma 3, concerning a variant of the "linear combination of unitaries" construction that is suitable for channels (explained in sections 2 and 3).
2. The factor $\|\mathcal{L}\|_{\mathsf{pauli}}$ corresponding to the coefficients of the specification as a linear combination of Paulis is a natural generalization to the case of Lindbladians of a similar factor for Hamiltonians that appears in [3].
3. When $m, q \in \mathrm{poly}(n)$, the gate complexity in Theorem 1 simplifies to

$$O\left(\tau \frac{\log(\tau/\epsilon)^2}{\log\log(\tau/\epsilon)} \mathrm{poly}(n)\right). \tag{9}$$

4. A Lindbladian $\mathcal{L}$ is *local* if

$$H = \sum_{j=1}^{m'} H_j, \tag{10}$$

where $H_1, \ldots, H_{m'}$ and also $L_1, \ldots, L_m$ are local (i.e., they each act on a constant number of qubits). A *local* specification of $\mathcal{L}$ is as $H_1, \ldots, H_{m'}, L_1, \ldots, L_m$ and we define its norm as

$$\|\mathcal{L}\|_{\mathsf{local}} = \sum_{j=1}^{m'} \|H_j\| + \sum_{j=1}^{m} \|L_j\|^2. \tag{11}$$

For local Lindbladians, Theorem 1 reduces to the following.

▶ **Corollary 2.** *If $\mathcal{L}$ is a local Lindbladian then the gate complexity for simulating $e^{\mathcal{L}t}$ with precision ϵ is*

$$O\left((m+m')\,\tau \frac{\log((m+m')\tau/\epsilon)\log(\tau/\epsilon)}{\log\log(\tau/\epsilon)}\right), \tag{12}$$

where $\tau = t\,\|\mathcal{L}\|_{\mathsf{local}}$.

5. We also consider *sparse* Lindbladians (see [9] for various definitions, extending definitions and specifications of sparse Hamiltonians [1]). Here, we define a Lindbladian to have d-sparse operators if $H, L_1, \ldots, L_m$ each have at most d non-zero entries in each row/column. A *sparse specification* of such a Lindbladian $\mathcal{L}$ is as a black-box that provides the positions and values of the non-zero entries of each row/column of $H, L_1, \ldots, L_m$ via queries. Define the norm of any specification of a Lindbladian in terms of operators $H, L_1, \ldots, L_m$ as

$$\|\mathcal{L}\|_{\mathsf{ops}} = \|H\| + \sum_{j=1}^{m} \|L_j\|^2. \tag{13}$$

The query complexity and gate complexity for simulating d-sparse Lindbladians $\mathcal{L}$ are

$$O\big(\tau\,\mathrm{polylog}(mq\tau/\epsilon)\mathrm{poly}(d,n)\big), \tag{14}$$

where $\tau = t\|\mathcal{L}\|_{\mathsf{ops}}$. We sketch the analysis in the full version of this paper [10].
6. We expect some of the methodologies in [3, 4, 23, 28] to be adaptable to the Lindblad evolution simulation problem (in conjunction with our variant of the LCU construction and oblivious amplitude amplification), but have not investigated this.

2 Brief summary of novel techniques

As noted in subsection 1.1, for the case of Hamiltonian evolution, a series of recent quantum algorithms whose scaling is $O(t\,\mathrm{polylog}(t/\epsilon))$ have been discovered which improve on what has been accomplished using the longstanding Trotter-Suzuki decomposition. One of the main tools that these algorithms employ is a remarkable circuit construction that is based on a certain decomposition of *unitary* operations (or *near-unitary* operations) into a linear combination of unitaries. We refer to this construction as the *standard LCU method*.

For the case of Lindblad evolution, the operations that arise are *channels* that are not generally unitary. Some channels are *mixed unitary*, which means that they can be expressed as a randomly chosen unitary (say with probabilities $p_0, \ldots, p_{m-1}$ on the unitaries $U_0, \ldots, U_{m-1}$). For such channels, the standard LCU method can be adapted along the lines of first randomly sampling $j \in \{0, \ldots, m-1\}$ and then applying the standard LCU method to the unitary U_j. However, there exist channels that are *not* mixed unitary—and such channels can arise from the Lindblad equation. A different reductionist approach is to express these channels in the Stinespring form, as unitary operations that act on a larger system, and then apply the standard LCU method to *those* unitaries; however, as we explain in subsection 2.1, this approach performs poorly. We take a different approach that does not involve a reduction to the unitary case: we have developed a new variant of the LCU method that is for channels. This is explained in section 3.

Another new technique that we employ is an Oblivious Amplitude Amplification algorithm for isometries (as opposed to unitaries), which is noteworthy because a reductionist approach based on extending isometries to unitaries does not work. Roughly speaking, this is because our LCU construction turns out to produce an isometry (corresponding to a purification of the channel); however, it does not produce a unitary extension of that isometry.

2.1 The standard LCU method performs poorly on Stinespring dilations

Here we show in some technical detail why the standard LCU method performs poorly for Stinespring dilations of channels. The standard LCU method (explained in detail in Sec. 2.1 of [18]) for a unitary V expressible as a linear combination of unitaries as $V = \alpha_0 U_0 + \cdots + \alpha_{m-1} U_{m-1}$ is a circuit construction W that has the property

$$W|0\rangle|\psi\rangle = \sqrt{p}|0\rangle V|\psi\rangle + \sqrt{1-p}|\Phi^{\perp}\rangle \tag{15}$$

where $|\Phi^{\perp}\rangle$ has zero amplitude in states with first register $|0\rangle$ (i.e., $(|0\rangle\langle 0| \otimes I)|\Phi^{\perp}\rangle = 0$) and

$$p = \frac{1}{(\sum_{j=0}^{m-1} \alpha_j)^2} \tag{16}$$

is the success probability (that arises if the first indicator register is measured).

Consider the *amplitude damping channel*, which has two Kraus operators with the following LCU decompositions

$$A_0 = \begin{bmatrix} 1 & 0 \\ 0 & \sqrt{1-\delta} \end{bmatrix} = \alpha_{00} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \alpha_{01} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

$$A_1 = \begin{bmatrix} 0 & \sqrt{\delta} \\ 0 & 0 \end{bmatrix} = \alpha_{10} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} + \alpha_{11} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix},$$

where $\alpha_{00} = \frac{1+\sqrt{1-\delta}}{2}$, $\alpha_{01} = \frac{1-\sqrt{1-\delta}}{2}$, $\alpha_{10} = \frac{\sqrt{\delta}}{2}$, $\alpha_{11} = \frac{\sqrt{\delta}}{2}$. Evolving an amplitude damping process for time t yields this channel with $\delta = 1 - e^{-t}$. When $t \ll 1$, $\delta \approx t$, $\alpha_{00} \approx 1 - t/4$, and $\alpha_{01} \approx t/4$.

A Stinespring dilation of V and its LCU decomposition can be derived from the above LCU decompositions of A_0 and A_1 as

$$V = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \sqrt{1-\delta} & -\sqrt{\delta} & 0 \\ 0 & \sqrt{\delta} & \sqrt{1-\delta} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \alpha_{00} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} + \alpha_{01} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$
$$+ \alpha_{10} \begin{bmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} + \alpha_{11} \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}.$$

Applying the standard LCU method here results in a success probability (computed from Eq. (16)) of

$$\frac{1}{\left(\alpha_{00}+\alpha_{01}+\alpha_{10}+\alpha_{11}\right)^2} = \frac{1}{\left(1+\sqrt{\delta}\right)^2} = 1 - 2\sqrt{\delta} + \Theta(\delta).$$

For small time evolution t, the failure probability is $\Theta(\sqrt{t})$, which is prohibitively expensive. It means that the process can be repeated at most $\Theta(1/\sqrt{t})$ times until the cumulative failure probability becomes a constant. The amount of evolution time (of the amplitude damping process) that this corresponds to is

$$\Theta\Big(\frac{1}{\sqrt{t}}\Big) \cdot t = \Theta(\sqrt{t}),$$

which is subconstant as $t \to 0$. This creates a problem in the general Lindblad simulation.

Our new LCU method for channels (explained in section 3) achieves the higher success probability

$$\frac{1}{\left(\alpha_{00}+\alpha_{01}\right)^2 + \left(\alpha_{10}+\alpha_{11}\right)^2} = \frac{1}{1+\delta} = 1 - \delta + \Theta(\delta^2).$$

For small time evolution t, the failure probability is $\Theta(t)$. Now, the process can be repeated $\Theta(1/t)$ times until the cumulative failure probability becomes a constant, which corresponds to evolution time

$$\Theta\Big(\frac{1}{t}\Big) \cdot t = \Theta(1),$$

which is constant as $t \to 0$. Since this is consistent with what arises in the algorithm of simulating Hamiltonian evolution in [2, 3], the methodologies used therein, with various adjustments, can be used to obtain the simulation bounds.

3 New LCU method for channels and completely positive maps

Let $A_0, \ldots, A_{m-1}$, linear operators on $\mathbb{C}^{2^n}$ (n-qubit states), be the Kraus operators of a channel. Suppose that, for each $j \in \{0, \ldots, m-1\}$, we have a decomposition of A_j as a linear combination of unitaries in the form

$$A_j = \sum_{k=0}^{q-1} \alpha_{jk} U_{jk}, \tag{17}$$

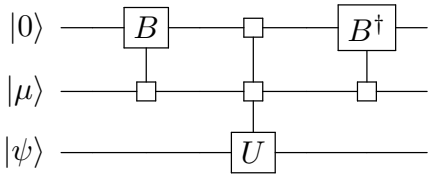

Figure 2 The circuit W for simulating a channel using the new LCU method.

where, for each $j \in \{0, \ldots, m-1\}$ and $k \in \{0, \ldots, q-1\}$, $\alpha_{jk} \geq 0$ and U_{jk} is unitary.

The objective is to implement the channel in terms of the implementations of U_{jk}'s. We will describe a circuit W and fixed state $|\mu\rangle$ such that, for any n-qubit state $|\psi\rangle$,

$$W|0\rangle|\mu\rangle|\psi\rangle = \sqrt{p}|0\rangle \left(\sum_{j=0}^{m-1} |j\rangle A_j|\psi\rangle \right) + \sqrt{1-p}|\Phi^{\perp}\rangle, \tag{18}$$

where $(|0\rangle\langle 0| \otimes I \otimes I)|\Phi^{\perp}\rangle = 0$ and

$$p = \frac{1}{\sum_{j=0}^{m-1} (\sum_{k=0}^{q-1} \alpha_{jk})^2} \tag{19}$$

is called the success probability parameter (which is realized if the first register is measured). Note that the isometry $|\psi\rangle \mapsto \sum_{j=0}^{m-1} |j\rangle A_j|\psi\rangle$ is the channel in purified form.

The circuit W is in terms of two gates. One gate is a *multiplexed-U gate*, denoted by multi-U such that, for all $j \in \{0, \ldots, m-1\}$ and $k \in \{0, \ldots, q-1\}$,

$$\text{multi-}U|k\rangle|j\rangle|\psi\rangle = |k\rangle|j\rangle U_{jk}|\psi\rangle. \tag{20}$$

The other gate is a *multiplexed-B gate*, denoted by multi-B, such that, for all $j \in \{0, \ldots, m-1\}$,

$$\text{multi-}B|0\rangle|j\rangle = \left(\frac{1}{\sqrt{s_j}} \sum_{k=0}^{q-1} \sqrt{\alpha_{jk}}|k\rangle \right) |j\rangle, \tag{21}$$

where

$$s_j = \sum_{k=0}^{q-1} \alpha_{jk}. \tag{22}$$

Define the state $|\mu\rangle$ (in terms of $s_0, \ldots, s_{m-1}$ from Eq. (22))

$$|\mu\rangle = \frac{1}{\sqrt{\sum_{j=1}^{m-1} s_j^2}} \sum_{j=0}^{m-1} s_j|j\rangle. \tag{23}$$

Define the circuit W (acting on $\mathbb{C}^q \otimes \mathbb{C}^m \otimes \mathbb{C}^{2^n}$) as

$$W = (\text{multi-}B^{\dagger} \otimes I)\text{multi-}U(\text{multi-}B \otimes I). \tag{24}$$

The LCU construction with the circuit W with its initial state $|0\rangle \otimes |\mu\rangle \otimes |\psi\rangle$ is illustrated in Fig. 2.

In this figure, we refer to the first register as the *indicator register* (as it indicates whether the computation succeeds at the end of this operation), the second register as the *purifier*

register (as it is used to purify the channel when the computation succeeds), and the third register as the *system register* (as it contains the state being evolved).

In the following lemma, Eq. (18) is shown to apply where $A_0, \ldots, A_{m-1}$ are arbitrary linear operators (i.e., Kraus operators of a completely positive map that is not necessarily trace preserving). If the map is also trace preserving then $\sum_{j=0}^{m-1} |j\rangle A_j|\psi\rangle$ and $|\Phi^{\perp}\rangle$ are normalized states and the success probability parameter p is the actual success probability realized if the first register is measured; otherwise, these need not be the case. In subsequent sections, we will apply this lemma in a context where the trace preserving condition is *approximately* satisfied.

▶ **Lemma 3.** *Let $A_0, \ldots, A_{m-1}$ be the Kraus operators of a completely positive map. Suppose that each A_j can be written in the form of Eq.* (17)*. Let multi-U, multi-B, W, and $|\mu\rangle$ be defined as above. Then applying the unitary operator W on any state of the form $|0\rangle|\mu\rangle|\psi\rangle$ produces the state*

$$\sqrt{p}|0\rangle \left(\sum_{j=0}^{m-1} |j\rangle A_j|\psi\rangle \right) + \sqrt{1-p}|\Phi^{\perp}\rangle,$$

where $(|0\rangle\langle 0| \otimes I \otimes I)|\Phi^{\perp}\rangle = 0$, and

$$p = \frac{1}{\sum_{j=0}^{m-1} \left(\sum_{k=0}^{q-1} \alpha_{jk} \right)^2}.$$

Proof. First consider the state $|0\rangle|j\rangle|\psi\rangle$ for any $j \in \{0, \ldots, m-1\}$. Applying W on this state is the standard LCU method [18]:

$$\begin{aligned}
W|0\rangle|j\rangle|\psi\rangle =& (\text{multi-}B^{\dagger} \otimes I)\text{multi-}U(\text{multi-}B \otimes I)|0\rangle|j\rangle|\psi\rangle && (25)\\
=& \frac{1}{\sqrt{s_j}}(\text{multi-}B^{\dagger} \otimes I)\text{multi-}U \left(\sum_{k=0}^{q-1} \sqrt{\alpha_{jk}}|k\rangle \right) |j\rangle|\psi\rangle && (26)\\
=& \frac{1}{\sqrt{s_j}}(\text{multi-}B^{\dagger} \otimes I) \left(\sum_{k=0}^{q-1} \sqrt{\alpha_{jk}}|k\rangle|j\rangle U_{jk}|\psi\rangle \right) && (27)\\
=& \frac{1}{s_j}|0\rangle|j\rangle \left(\sum_{k=0}^{q-1} \alpha_{jk} U_{jk}|\psi\rangle \right) + \sqrt{\gamma_j}|\Phi_j^{\perp}\rangle && (28)\\
=& \frac{1}{s_j}|0\rangle|j\rangle A_j|\psi\rangle + \sqrt{\gamma_j}|\Phi_j^{\perp}\rangle, && (29)
\end{aligned}$$

where $|\Phi_j^{\perp}\rangle$ is a state satisfying $(|0\rangle\langle 0| \otimes I \otimes I)|\Phi_j^{\perp}\rangle = 0$ and γ_j is some normalization factor.

Up to this point, if the indicator register were measured and $|0\rangle$ were observed as the "success" case as in the standard LCU method, then the state of the purifier and the system register collapses to $|j\rangle A_j|\psi\rangle$. However, this is not a meaningful quantum sate, as it only captures one Kraus operator of a quantum map. Now we use this specially designed quantum state $|\mu\rangle$ to obtain the desired purification state. We use the superposition $|\mu\rangle$ instead of $|j\rangle$ in the second register then, by linearity, we have

$$W|0\rangle|\mu\rangle|\psi\rangle = \sqrt{p}|0\rangle \left(\sum_{j=0}^{m-1} |j\rangle A_j|\psi\rangle \right) + \sqrt{1-p}|\Phi^{\perp}\rangle, \quad (30)$$

where $(|0\rangle\langle 0| \otimes I \otimes I)|\Phi^{\perp}\rangle = 0$ and $p = \frac{1}{\sum_{j=0}^{m-1} s_j^2}$. ◀

4 Overview of the main result, Theorem 1

In this section we briefly sketch how to apply our new LCU method in order to prove our main result, Theorem 1. The overall structure is similar to that in [2] and [3], with the main novel ingredient being our variant of the LCU construction (explained in section 3) and also a variant of oblivious amplitude amplification for isometries. For clarity, the details are organized into section 4 of the full version of this paper [10], whose content is summarized as:

1. In Sec. 4.1 of [10], we describe a simple mapping $\mathcal{M}_\delta$ in terms of Kraus operators that are based on the operators in $\mathcal{L}$. For small δ, $\mathcal{M}_\delta$ is a good approximation of $e^{\mathcal{L}\delta}$.
2. In Sec. 4.2 of [10], we show how to simulate the mapping $\mathcal{M}_\delta$ in the sense of Lemma 3, with success probability parameter $1 - O(\delta)$.
3. In Sec. 4.3 of [10], we show how to combine r simulations of $\mathcal{M}_{O(1/r)}$ so as to obtain cumulative success probability parameter $1/4$. Conditional on success, this produces a good approximation of constant-time Lindblad evolution.
4. In Sec. 4.4 of [10], we show how to apply a modified version of oblivious amplitude amplification to unconditionally simulate an approximation of constant-time Lindblad evolution.
5. In Sec. 4.5 of [10], we show how to reduce the number of multiplexed Pauli gates by a concentration bound on the amplitudes associated with nontrivial Pauli gates.
6. In Sec. 4.6 of [10], we bound the total number of gates and combine the simulations for segments in order to complete the proof of Theorem 1.

Acknowledgments. We thank Andrew Childs, Patrick Hayden, Martin Kliesch, Tongyang Li, Hans Massen, Barry Sanders, and Rolando Somma for helpful discussions.

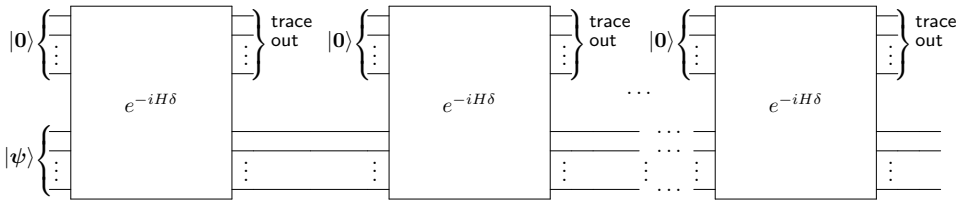

Figure 3 N-stage ϵ-precision discretization of the trajectory resulting from $\mathcal{L}$. For each $k \in \{1, \ldots, N\}$, after k stages, the channel should be within ϵ of $\exp\left(\frac{kT}{N}\mathcal{L}\right)$.

A Cost of expressing Lindblad evolution as Hamiltonian evolution

Let $\mathcal{L}$ be a Lindbladian acting on an n-qubit register $\mathcal{H}$ over a time interval $[0, T]$. For each initial state, $\mathcal{L}$ associates a *trajectory*, consisting of a density operator $\rho(t)$ for each $t \in [0, T]$. Here we show that if this is simulated by Hamiltonian evolution in a larger system with an ancillary register that is continually reset (expressed as a limiting case when $N \to \infty$ in the process illustrated in Figure 3) then the total evolution time for this Hamiltonian can be necessarily infinite.

▶ **Definition 4.** Define an *N-stage ϵ-precision discretization of $\mathcal{L}$ for interval* $[0, T]$ as an ancillary register $\mathcal{K}$, a Hamiltonian H (with $\|H\| = 1$) acting on the joint system $\mathcal{K} \otimes \mathcal{H}$, and $\delta \geq 0$ such that the channel $\mathcal{N}_{H\delta}$ defined as

$$\mathcal{N}_{H\delta}[\rho] = \mathrm{Tr}_{\mathcal{K}}\left(e^{-iH\delta}(|0\rangle\langle 0| \otimes \rho)e^{iH\delta}\right) \tag{31}$$

has the following property. $\mathcal{N}_{H\delta}$ approximates evolution under $\mathcal{L}$ in the sense that, for each $j \in \{1, \ldots, N\}$,

$$\left\|(\mathcal{N}_{H\delta})^k - \exp\left(\tfrac{kT}{N}\mathcal{L}\right)\right\|_\diamond \leq \epsilon. \tag{32}$$

That is, the N points generated by $\mathcal{N}_{H\delta}, (\mathcal{N}_{H\delta})^2, \ldots, (\mathcal{N}_{H\delta})^N$ approximate the corresponding points on the trajectory determined by $\mathcal{L}$.

Our lower bound is for the *amplitude damping process* on a 1-qubit system is the time-evolution described by the Lindbladian $\mathcal{L}$, where

$$\mathcal{L}[\rho] = L\rho L^\dagger - \tfrac{1}{2}(L^\dagger L\rho + \rho L^\dagger L), \tag{33}$$

and $L = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$.

▶ **Theorem 5.** *Any $\frac{1}{4}$-precision N-stage approximation of the amplitude damping process over the time interval $[0, \ln 2]$ has the property that the total evolution time of H is $\Omega(\sqrt{N})$. (Note that this lower bound is independent of the dimension of the ancillary system.)*

To prove Theorem 5, we first prove the following *Local Hamiltonian Approximation* lemma. This concerns a scenario where H is a Hamiltonian acting on a joint system of two registers, a system register $\mathcal{H}$ and an ancillary register $\mathcal{K}$, and where $\mathcal{K}$ is traced out after this evolution. Informally, the lemma states that, if the initial state is a product state and the evolution time is short, then this process can be approximated by the evolution of another Hamiltonian G that acts on $\mathcal{H}$ alone. This is illustrated in figure 4.

Figure 4 The Local Hamiltonian Approximation Lemma. The first register is d-dimensional, the second register contains n qubits, and the approximation is within $O(\delta^2)$ (independent of d and n).

▶ **Lemma 6** (Local Hamiltonian approximation). *Let $\mathcal{H}$ be an n-qubit register and $\mathcal{K}$ a d-dimensional register. Let H be a Hamiltonian (with $\|H\| = 1$) acting on the joint system $\mathcal{K} \otimes \mathcal{H}$. Define the n-qubit channel $\mathcal{N}_{H\delta}$ as*

$$\mathcal{N}_{H\delta}[\rho] = \mathrm{Tr}_{\mathcal{K}}\big(e^{-iH\delta}(|0\rangle\langle 0| \otimes \rho)e^{iH\delta}\big). \tag{34}$$

Then there exists a Hamiltonian G (with $\|G\| = 1$), acting on $\mathcal{H}$ alone, such that $\mathcal{N}_{G\delta}$ defined as

$$\mathcal{N}_{G\delta}[\rho] = e^{-iG\delta}\rho\, e^{iG\delta} \tag{35}$$

satisfies $\|\mathcal{N}_{H\delta} - \mathcal{N}_{G\delta}\|_1 \in O(\delta^2)$. (The notation $\|\cdot\|_1$ indicates the trace-induced norm, which is sufficient for our purposes because our application is a lower bound.)

Proof. Viewing H as a $d \times d$ block matrix, we have

$$H = \sum_{j=0}^{d-1}\sum_{k=0}^{d-1} |j\rangle\langle k| \otimes H_{jk} \tag{36}$$

and we refer to H_{jk} as the (j,k) *block*. Define D as the diagonal blocks of H, namely

$$D = \sum_{j=0}^{d-1} |j\rangle\langle j| \otimes H_{jj}, \tag{37}$$

and set $J = H - D$ (the off-diagonal blocks). Note that $\|D\|, \|J\| \leq 1$ and $\|e^{-iH\delta} - e^{-iD\delta}e^{-iJ\delta}\| \leq \delta^2$, for $\delta > 0$, which permits us to consider the effect of J and D separately.

Now consider the state $e^{-iJ\delta}|0\rangle\otimes|\psi\rangle$. We will show that, if the measurement corresponding to projectors $|0\rangle\langle 0|$ and $I - |0\rangle\langle 0|$ is performed on register $\mathcal{K}$, then the residual state has trace distance $O(\delta^2)$ from $|0\rangle \otimes |\psi\rangle$. Since the $(0,0)$ block of J is 0,

$$J\delta\,|0\rangle \otimes |\psi\rangle = \delta'|\Psi^{\perp}\rangle, \tag{38}$$

where $|\Psi^{\perp}\rangle$ is a state such that $(|0\rangle\langle 0| \otimes I)|\Psi^{\perp}\rangle = 0$ and $0 \leq \delta' \leq \delta$. Therefore,

$$e^{-iJ\delta}|0\rangle \otimes |\psi\rangle = \sum_{r=0}^{\infty} \frac{(-iJ\delta)^r}{r!}|0\rangle \otimes |\psi\rangle \tag{39}$$

$$= |0\rangle \otimes |\psi\rangle - i\delta'|\Psi^{\perp}\rangle + \delta''|\Phi\rangle, \tag{40}$$

where $0 \leq \delta'' \leq e^{\delta} - 1 - \delta \in O(\delta^2)$. It follows that, if the above measurement is performed on register $\mathcal{K}$, then the probability of measurement outcome $I - |0\rangle\langle 0|$ is at most $(\delta')^2 + (\delta'')^2 \in O(\delta^2)$. This implies that the state when register $\mathcal{K}$ of $e^{-iJ\delta}|0\rangle \otimes |\psi\rangle$ is traced out, namely

$$\mathrm{Tr}_{\mathcal{K}}\big(e^{-iJ\delta}(|0\rangle\langle 0| \otimes |\psi\rangle\langle\psi|)e^{iJ\delta}\big), \tag{41}$$

has trace distance $O(\delta^2)$ from the original state $|\psi\rangle\langle\psi|$.

Therefore, for states of the form $|0\rangle \otimes |\psi\rangle$, the operation $e^{-iH\delta}$ can be approximated by $e^{-iD\delta}$ at the cost of an error of $O(\delta^2)$ in trace distance. The result follows by setting $G = H_{00}$ (the $(0,0)$ block of D). ◀

Proof of Theorem 5. It is straightforward to check that, starting with the initial state $|1\rangle\langle 1|$ and evolving by the amplitude damping process for time $T = \ln 2$ produces the maximally mixed state.

Consider any $\frac{1}{4}$-precision N-stage discretization of this process, with Hamiltonian H and $\delta > 0$. We can apply the Local Hamiltonian Approximation Lemma (Lemma 6) to approximate each of the N evolutions of H with evolution by a Hamiltonian G that is local to the qubit. The result is unitary evolution of the qubit that approximates the amplitude damping process within trace distance error at most $O(N\delta^2)$.

Unitary evolution applied to $|1\rangle\langle 1|$ results in a pure state, and the trace distance between any pure state and the maximally mixed state is $\frac{1}{2}$. Therefore, to avoid a contradiction, we must have $N\delta^2 \in \Omega(1)$, which implies that $\delta \in \Omega(1/\sqrt{N})$. Therefore, the total evolution time of H is $N\delta \in \Omega(\sqrt{N})$. ◀

Controlled Quantum Amplification*

Abstract

We propose a new framework for turning quantum search algorithms that decide into quantum algorithms for finding a solution. Consider we are given an abstract quantum search algorithm A that can determine whether a target g exists or not. We give a general construction of another operator U that both determines and finds the target, whenever one exists. Our amplification method at most doubles the cost over using A, has little overhead, and works by controlling the evolution of A. This is the first known general framework to the open question of turning abstract quantum search algorithms into quantum algorithms for finding a solution.

We next apply the framework to random walks. We develop a new classical algorithm and a new quantum algorithm for finding a unique marked element. Our new random walk finds a unique marked element using H update operations and $1/\epsilon$ checking operations. Here H is the hitting time, and ϵ is the probability that the stationary distribution of the walk is in the marked state. Our classical walk is derived via quantum arguments. Our new quantum algorithm finds a unique marked element using $\sqrt{H}$ update operations and $\sqrt{1/\epsilon}$ checking operations, up to logarithmic factors. This is the first known quantum algorithm being simultaneously quadratically faster in both parameters. We also show that the framework can simulate Grover's quantum search algorithm, amplitude amplification, Szegedy's quantum walks, and quantum interpolated walks.

1 Introduction

Grover's search algorithm [15], amplitude amplification [8], and quantum walks [3, 30] are highly successful methodologies for searching in quantum algorithms. They are used in search problems in which we are given some unitary operator W as a black-box. We start in some initial state $|\text{init}\rangle$ which is a $(+1)$-eigenvector of the unitary W. Our goal is to produce some unknown target state $|g\rangle$. We are given a reflection[1] operator $\mathsf{G} = 1 - 2|g\rangle\langle g|$ that permits us to distinguish the target state $|g\rangle$ from any other orthogonal state. Our task is to construct an algorithm that evolves the initial state $|\text{init}\rangle$ into a state that has constant overlap with

the target state $|g\rangle$, using the operator W. The standard approach in quantum algorithmics for doing so is to use operator $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$ [5].

Much work on search problems on quantum computers has been specifically developed within quantum walks. The operator W is often derived from a random walk, in which case it is referred to as the *walk* or *update* operator. The cost of the quantum search algorithm is then typically phrased in terms of the spectral gap δ or the hitting time of the associated random walk.

The study of quantum walks has been a highly successful and active line of research, with recent results such as a quantum algorithm for triangle finding [13] using only $O(n^{5/4})$ queries. Other applications of quantum walks include verification of matrix products [9], testing group commutativity [27], formula evaluation [4], subgraph finding [10], triangle finding [26, 13, 14], and 3-distinctness [7].

These and other applications were found after the seminal works of Ambainis [3] and Szegedy [30]. Ambainis [3] gave a quantum walk for element distinctness, and Szegedy [30] gave a general method for obtaining an quantum search algorithm from any symmetric random walk [30]. Magniez et al. [25] gave a quantum algorithm that finds a unique marked element for any reversible random walk[2] of cost in the order of $\mathsf{S} + \sqrt{1/(\epsilon\delta)}\mathsf{U} + \sqrt{1/\epsilon}\mathsf{C}$. Here S, U, and C are the setup, update and checking costs of the quantum walk, δ the spectral gap of the walk, and ϵ the probability that the stationary state is in the marked state [29, 28].

Magniez et al. [23] gave a quantum algorithm that finds a unique marked element for any state-transitive random walk of cost in the order of $\mathsf{S} + \sqrt{H}\mathsf{U} + \sqrt{H}\mathsf{C}$. Here H is the hitting time of the random walk. Krovi et al. [22] introduced the novel idea of interpolating walks. Krovi et al. show in [20, 21] that interpolated walks can find a marked element for any reversible random walk. Their algorithm works for multiple marked elements and has cost in the order of $\mathsf{S} + \sqrt{H^+}\mathsf{U} + \sqrt{H^+}\mathsf{C}$, where H^+ is a quantity introduced in [21] and referred to as the extended hitting time. When there is a unique marked element, the extended hitting time and hitting time coincide, $H^+ = H$. When there are multiple marked elements, the extended hitting time is bounded by $H \leq H^+ \leq \frac{1}{\epsilon\delta}$. Excellent surveys on quantum walks, their history and applications, include [2, 18, 29, 32, 28].

In this work, we propose a new framework for the general setting of search problems. Our framework does *not* require that the operator W is derived from a random walk and it makes no explicit use of properties of quantum walks or random walks. The most obvious application of our framework is naturally to random walks, but is not limited to such cases. We will assume that W has only real entries, and that our target $|g\rangle$ has real coordinates in a canonical orthogonal basis for the space acted upon by W. This assumption is fulfilled in all the applications we consider here, including quantum walks.

Our framework consists of several parts. We give a new generic quantum algorithm for solving search problems. Our algorithm is based on a circuit U which controls the search, and we refer to this process as *controlled quantum amplification*. We prove that whenever the operator $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$ determines whether a target $|g\rangle$ exists or not, in some number of iterations T, with constant success probability, then our circuit U both determines and finds the target using at most $2T$ iterations, with constant success probability.

We apply our analysis to quantum walks and prove that we can obtain a quadratic speedup for reversible random walks. We show that our framework can simulate quantum interpolated

[2] A Markov chain P with a unique stationary distribution $\pi = (\pi_x)$ is said to be *reversible* if $\pi_x P_{y,x} = \pi_y P_{x,y}$ for all states x, y. All Markov chains obtained from a random walk on undirected graphs are reversible. We will below use the wording "random walk" and "Markov chain" interchangeably.

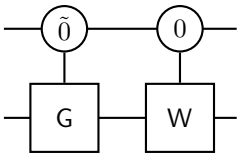

Figure 1 Our circuit U for controlled quantum amplification, expressed in terms of the reflection operator G and the unitary W, here given in its simplest form. We apply circuit U successively to the initial state $|0\rangle|\overline{\text{init}}\rangle$, say T times, thus producing the final state $\mathsf{U}^T|0\rangle|\overline{\text{init}}\rangle$, which we measure. If the outcome of the measurement is $|\tilde{1}\rangle|g\rangle$, the circuit has successfully found the marked state g.

walks [21], thus eliminating the need for running an interpolation of a random walk and its absorbing analog. We prove a relation between the operator W and the operator A, and we use this relation to construct a new quantum algorithm that, up to a logarithmic factor, finds a unique marked element in cost $\mathsf{S}+\sqrt{H}\mathsf{U}+\sqrt{1/\epsilon}\mathsf{C}$. This is superior to the existing algorithms. We also use this relation to construct a new *classical* algorithm that finds a unique marked element in cost $\mathsf{S}+H\mathsf{U}+1/\epsilon\mathsf{C}$. Our classical walk is derived using quantum arguments.

2 Controlled quantum amplification

In a quantum search problem, we are given an arbitrary unitary operator W, through which we would like to extract some unknown target state $|g\rangle$. The operator W can be given as a black box, which we can apply to any state $|\psi\rangle$, producing the state $\mathsf{W}|\psi\rangle$. An application of W has some cost, which is called the *update cost*.

We are also given a reflection operator $\mathsf{G}=1-2\Pi_G$, where $\Pi_G=|g\rangle\langle g|$ is a projection on the target state $|g\rangle$. Operator G permits us to distinguish the target state $|g\rangle$ from any other orthogonal state. The operator G can be given as a black box as well. An application of G has some cost, which is called the *checking cost*.

Our first step is to prepare the initial state $|\text{init}\rangle$. Preparing this state has a cost, which is called the *setup cost*. We then measure whether the initial state contains the target state or not by applying the measurement $\{\Pi_G, 1-\Pi_G\}$. The probability by which we measure $|g\rangle$ is some $\epsilon=\sin^2(\theta)$ where $\sin(\theta)=\langle g|\text{init}\rangle$. Let $|g\rangle$ and this initial angle θ be so that $0\le\theta\le\pi/2$. If $\theta=0$, our initial success probability is zero and the quantum search algorithm $\mathsf{A}=\mathsf{W}\cdot\mathsf{G}$ will not amplify this. If $\theta=\pi/2$, our initial state *is* the target state and there is nothing to be amplified. We shall therefore assume that $0<\theta<\pi/2$. Typically θ is very close to zero, corresponding to that the non-amplified success probability ϵ is small.

If our initial measurement yields the outcome $|g\rangle$, we terminate the algorithm as we have produced our target state $|g\rangle$. Otherwise, our initial state becomes $|\overline{\text{init}}\rangle=\frac{1}{\cos(\theta)}(|\text{init}\rangle-\sin(\theta)|g\rangle)$, which is orthogonal to $|g\rangle$ by construction. Thus starting with $|\overline{\text{init}}\rangle$, we then want to produce a state with large overlap with $|g\rangle$. To achieve this, we propose the following circuit U.

The circuit U acts on two registers. The first register contains a qubit which we use to control the evolution in the second register. The circuit is comprised of two operators, both of which are controlled on the state in the first register. We fix an angle $0<\tilde{\theta}<\pi/2$ and use the rotated orthogonal basis $|\tilde{0}\rangle=\cos(\tilde{\theta})|0\rangle+\sin(\tilde{\theta})|1\rangle$ and $|\tilde{1}\rangle=-\sin(\tilde{\theta})|0\rangle+\cos(\tilde{\theta})|1\rangle$. The first operator $|\tilde{0}\rangle\langle\tilde{0}|\otimes\mathsf{G}+|\tilde{1}\rangle\langle\tilde{1}|\otimes 1$ in our circuit reflects about the target state $|g\rangle$ conditional on that the control qubit is in state $|\tilde{0}\rangle$. The second operator $|0\rangle\langle 0|\otimes\mathsf{W}+|1\rangle\langle 1|\otimes 1$ applies the update W conditional on that the control qubit is in state $|0\rangle$.

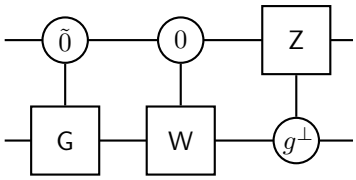

Figure 2 W with reflection.

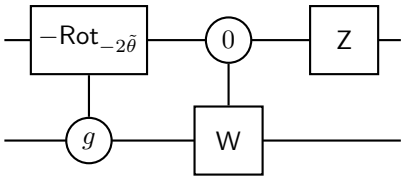

Figure 3 W with rotation.

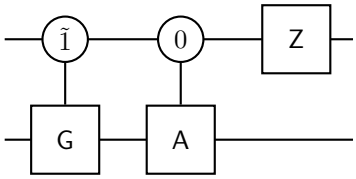

Figure 4 $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$ with reflection.

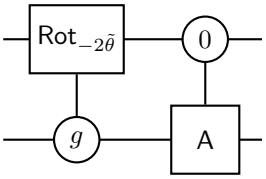

Figure 5 A with rotation.

The circuit U is parameterized by the angle $\tilde{\theta}$. The choice of $\tilde{\theta}$ has some algorithmic consequences, which we may handle by exponential searching similar to past work [8, 23]. The framework applies with no increase in asymptotic cost if we are given a multiplicatively approximate value for the initial success amplitude $\sin(\theta)$. We apply circuit U successively to the initial state $|0\rangle|\overline{\text{init}}\rangle$, say T times, thus producing the final state $\mathsf{U}^T|0\rangle|\overline{\text{init}}\rangle$, which we measure. We prove here that for an appropriately chosen value of T, the final measurement yields the target $|g\rangle$ with probability at least a constant, and we thus refer to this process as *controlled quantum amplification*.

The circuit has multiple interpretations and forms which both provide us with flexibility in terms of implementations as well as a foundation for proving properties on quantum amplification processes. We give here four circuits, all of which act equivalently to U. In Figure 2, the third gate $\mathsf{Z} \otimes (1 - |g\rangle\langle g|) + 1 \otimes |g\rangle\langle g|)$ applies the phase gate $\mathsf{Z} = |0\rangle\langle 0| - |1\rangle\langle 1|$ on the control qubit conditional on that the search space does not contain the target state $|g\rangle$. In Figures 3 and 5, the first gate rotates the ancilla qubit by an angle of $\pi - 2\tilde{\theta}$ and $-2\tilde{\theta}$, respectively, conditional on the search space contains the target state $|g\rangle$.

One of our aims is to compare our new controlled amplification circuit U with the operator $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$. The operator A has been used extensively in quantum walks and, when applied to random walks, it corresponds to an absorbing random walk [30, 3, 5]. The main limitation of the operator A is that it does not necessarily produce the target state, even when one exists. Significant research has been put into understanding when the operator A does and does not produce the target state. Our proposed controlled circuit circumvents this barrier in all generality. We prove that whenever the operator A determines whether a unique target exists or not, in some number of iterations, then our circuit U both determines and finds the target in the same asymptotic number of iterations.

Controlled quantum computations have been successfully applied in quantum computing dating back to at least the notion of phase kick-back [11]. Tulsi used a quantum walk with controlled operators for the problem of finding a unique target $|g\rangle$ on a grid [31]. His algorithm finds a unique target in cost $O(\sqrt{n \log n})$, which is quadratically smaller than the classical hitting time of $\Theta(n \log n)$ [1]. The grid graph is a two-dimensional torus of size $\sqrt{n} \times \sqrt{n}$ and has been a notoriously hard case for quantum searching because all of its edges are local. Magniez, Nayak, Richter, and Santha [23] extended this and gave a controlled operator that finds a unique target $|g\rangle$ for any state-transitive graph.

Our controlled amplifier does not rely on any graph-theoretic properties. We prove the general statement that whenever A determines whether a unique target state exists or not, our controlled amplifier finds the target state in asymptotically the same cost.

3 Quantum hitting times

The hitting time is a notion used in the analysis of stochastic processes such as random walks. It is the expected number of steps some stochastic process U uses to reach the target state g, starting from some appropriately defined initial distribution π. The choice of an appropriate corresponding definition of quantum hitting time is non-trivial.

Let U be any real unitary, and let $|w\rangle$ be any normalized target state with real coordinates in a canonical orthogonal basis for the space acted upon by U. The possible eigenvalues for U are $+1$, -1, and conjugated pairs $(e^{i\alpha}, e^{-i\alpha})$ for some eigenphase $0 < \alpha < \pi$. Each such pair of eigenvalues corresponds to a distinct two-dimensional subspace acted upon by U by a rotation of angle α. We order these non-trivial eigenphases of U as $0 < \alpha_1 \leq \alpha_2 \leq \cdots \leq \alpha_m < \pi$, for some $m \geq 0$. Let $|U_j^+\rangle$ and $|U_j^-\rangle$ be the conjugated eigenvectors of U corresponding to the eigenvalues $e^{i\alpha_j}$ and $e^{-i\alpha_j}$, for each $1 \leq j \leq m$. We decompose $|w\rangle$ into this ordered eigenbasis of U, as $w_0|U_0\rangle + \sum_{j=1}^{m} \left(w_j^+|U_j^+\rangle + w_j^-|U_j^-\rangle\right) + w_{-1}|U_{-1}\rangle$. Here we group all $(+1)$-eigenvectors of U into $|U_0\rangle$, and all the (-1)-eigenvectors into $|U_{-1}\rangle$. Since U and $|w\rangle$ have real components, we can choose the scalars of the eigenvectors of U such that $w_j^+ = w_j^- = w_j \in \mathbb{R}$. Given this basis, we define the quantum hitting time as follows.

▶ **Definition 1.** The *quantum hitting time* of U on $|w\rangle = w_0|U_0\rangle + \sum_{j=1}^{m} w_j\left(|U_j^+\rangle + |U_j^-\rangle\right) + w_{-1}|U_{-1}\rangle$ is

$$\mathsf{QHT}_\alpha(\mathsf{U}, |w\rangle) = \sqrt{2\sum_{j=1}^{m} |w_j|^2 \frac{1}{\alpha_j^2}}. \tag{1}$$

Since our proofs use the specifics of this definition, we mention that our definition differs from the more commonly used quantity $\mathsf{QHT}_1(\mathsf{U}, |w\rangle) = 2\sum_{j=1}^{m} |w_j|^2 \frac{1}{\alpha_j} + |w_{-1}|$. Our notion of quantum hitting time QHT_α is quadratically smaller than the classical hitting time for reversible random walks, by Szegedy's correspondence [30]. Thus, if a quantum algorithm has cost in the order of QHT_α, then it has cost quadratically smaller than the classical hitting time. For technical reasons, we need to introduce a second notion of quantum hitting time, which we refer to as the *cotangent quantum hitting time* and define as $\mathsf{QHT}_{\cot}(\mathsf{U}, |w\rangle) = \sqrt{2\sum_{j=1}^{m} |w_j|^2 \cot^2(\frac{\alpha_j}{2})}$. Our two notions of quantum hitting times QHT_α and $\mathsf{QHT}_{\cot}$ are asymptotically of the same order, as shown in Lemma 9 in the appendix. We use QHT as a shorthand for QHT_α.

4 Finding in the quantum hitting time

Our goal is to prove that the circuit U finds a target state in the quantum hitting time, stated as Corollary 6 below. We first identify the principal eigenvector of the circuit U.

▶ **Lemma 2.** *The unnormalized state* $|v_0\rangle = \sin(\tilde{\theta})\,|0, \overline{\text{init}}\rangle - \frac{\sin(\theta)}{\cos(\theta)}\,|\tilde{1}, g\rangle$ *is a* $(+1)$*-eigenvector of circuit* U.

Proof. The proof follows be considering the action of the circuit U given in Figure 1.

The first operator in the circuit reflects the state $|\tilde{0}, g\rangle$. The first term in the state $|v_0\rangle$ is orthogonal to this reflection state since $|\overline{\text{init}}\rangle$ is orthogonal to $|g\rangle$ by definition. The second term in $|v_0\rangle$ is also orthogonal to the reflection state since $|\tilde{0}\rangle$ and $|\tilde{1}\rangle$ constitute an orthonormal basis. The reflection operator thus acts trivially on $|v_0\rangle$.

The second operator in the circuit applies the operator W on the search register conditional on that the control qubit is in state $|0\rangle$. Rewrite $|v_0\rangle$ on the form

$$\frac{\sin(\tilde{\theta})}{\cos(\theta)}|0, \text{init}\rangle - \frac{\sin(\theta)}{\cos(\theta)}\cos(\tilde{\theta})\,|1, g\rangle.$$

Then each of the two terms is again invariant, and we conclude that the second operator similarly acts trivially on $|v_0\rangle$. ◀

We want this principal eigenvector to be an equally weighted superposition of our initial state $|0, \overline{\text{init}}\rangle$ and our target state $|\tilde{1}, g\rangle$. We therefore choose and fix the angle $\tilde{\theta}$ such that $0 < \tilde{\theta} < \pi/2$ and $\sin(\tilde{\theta}) = \frac{\sin(\theta)}{\cos(\theta)}$, and write the principal eigenvector on the normalized form $|U_0\rangle = \frac{1}{\sqrt{2}}\big(|0, \overline{\text{init}}\rangle - |\tilde{1}, g\rangle\big)$.

When considering quantum search problems, it is commonly assumed that the walk operator W has a unique $(+1)$-eigenvector (up to scalars), which we adapt here for convenience. The purpose of a quantum search problem is to produce a state that has large overlap with the target state $|g\rangle$. Our proposed algorithm for doing so, is to apply our circuit U successively a number of T times on the initial state $|0, \overline{\text{init}}\rangle$, producing the final state $\mathsf{U}^T|0, \overline{\text{init}}\rangle$. We show that it suffices to pick the number of iterations T to be in the order of the quantum hitting time $\mathsf{QHT}(\mathsf{U}, |\tilde{1}, g\rangle)$ of U. We divide the proof up into two cases. When W is a reflection, our circuit emulates amplitude amplification. For general operators W, we use that the principal $(+1)$-eigenvector of U has large overlap with both the initial state and the target state $|\tilde{1}, g\rangle$.

Consider first that $\mathsf{W} = 2|\text{init}\rangle\langle\text{init}| - 1$ is a reflection about the initial state. In amplitude amplification [8], we apply the operator $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$ a number of T times, thus constructing the state $|\text{final}\rangle = (\mathsf{W} \cdot \mathsf{G})^T|\text{init}\rangle$. By picking $T = \lceil \frac{\pi}{4\theta} \rceil \in \Theta(\frac{1}{\sqrt{\epsilon}})$, a measurement of the final state $|\text{final}\rangle$ yields the target state $|g\rangle$ with probability at least $1 - \epsilon$, where $\epsilon = \sin^2(\theta) = \langle g|\text{init}\rangle^2$ is the initial success probability. Amplitude amplification thus amplifies quadratically faster than classical repetition.

Now consider circuit U given in Figure 1 when $\mathsf{W} = 2|\text{init}\rangle\langle\text{init}| - 1$ is a reflection about the initial state. Then U is the product of two reflections and effectively implements a rotation in the two-dimensional subspace spanned by $|\tilde{0}, g\rangle$ and $|0, \overline{g}\rangle$, where $|\overline{g}\rangle = \frac{1}{\cos(\theta)}(|g\rangle - \sin(\theta)|\text{init}\rangle)$ is defined analogously to $|\overline{\text{init}}\rangle$. The rotational angle is 2φ, where φ is given by the inner product $\cos(\varphi) = \langle 0, \overline{g}|\tilde{0}, g\rangle = \cos(\tilde{\theta})\cos(\theta) = \sqrt{\cos(2\theta)}$. This gives us that $2\varphi \approx 2\sqrt{2}\theta$. The initial state is $|0, \overline{\text{init}}\rangle = \frac{1}{\sqrt{2}}(|U_0\rangle + |U_{\text{rot}}\rangle)$, where $|U_{\text{rot}}\rangle$ belongs to the two-dimensional rotational subspace. We pick $T = \lceil \frac{\pi}{2\sqrt{2}\theta} \rceil$, and produce the final state $\mathsf{U}^T|0, \overline{\text{init}}\rangle$, a measurement of which yields the target $|\tilde{1}, g\rangle = \frac{1}{\sqrt{2}}(|U_0\rangle - |U_{\text{rot}}\rangle)$ with probability at least $1 - O(\epsilon)$.

4.1 Finding in the quantum hitting time for general A

When W is a reflection about the initial state $|\text{init}\rangle$, the previous subsection implies that it suffices to choose T to be in the order of $\frac{1}{\theta}$, just as in amplitude amplification. For arbitrary operators W, it suffices to choose T to be in the order of the quantum hitting time $\mathsf{QHT}(\mathsf{U}, |0, \overline{\text{init}}\rangle)$ of U on the initial state $|0, \overline{\text{init}}\rangle$.

▶ **Theorem 3.** *There is an algorithm that applies* U *an expected number of order* $\mathsf{QHT}(\mathsf{U}, |0,\overline{\text{init}}\rangle)$ *times to the initial state* $|0,\overline{\text{init}}\rangle$*, and produces a final state with constant overlap with* $|\tilde{1},g\rangle$*.*

The proof is as follows. By Lemma 2, the initial state $|0,\overline{\text{init}}\rangle$ can be written as an equal superposition of the principal eigenvector $|U_0\rangle$ of U and the state $|U_{\text{rot}}\rangle = \frac{1}{\sqrt{2}}\big(|0,\overline{\text{init}}\rangle + |\tilde{1},g\rangle\big)$. The state $|U_0\rangle$ has constant overlap with the target state $|\tilde{1},g\rangle$. The state $|U_0\rangle$ is an eigenvector of U with eigenphase 0, whereas the state $|U_{\text{rot}}\rangle$ is a superposition of states with non-zero eigenphases. Following a standard argument via phase estimation [19, 11, 8, 24, 23], we can determine which is the case by successive (controlled) U applications. The primary observations are that the success probability in phase estimation can be expressed naturally in terms of our quantum hitting time QHT_α, and the controls on U can be dropped.

The theorem remains true if we replace the quantum hitting time with the effective quantum hitting time, at the expense of a drop in the overlap by at most a small constant. Here the effective quantum hitting time is the smallest number of applications of (controlled) U required to produce a final state with constant overlap with $|\tilde{1},g\rangle$. By Markov's inequality, the effective quantum hitting time is at most in the order of the quantum hitting time.

Theorem 3 provides us with an expression of the cost of U in terms of the quantum hitting time of U itself. We next relate the quantum hitting time of U to the quantum hitting times of quantum search operators A and W. Let $\epsilon = \sin^2(\theta)$ be the initial success probability, where angle $0 < \theta < \pi/2$ is so that $\sin(\theta) = |\langle g|\text{init}\rangle|$, and set angle $0 < \tilde{\theta} < \pi/2$ so that $\sin(\tilde{\theta}) = \frac{\sin(\theta)}{\cos(\theta)}$.

▶ **Theorem 4.**

$$\mathsf{QHT}(\mathsf{U}, |0,\overline{\text{init}}\rangle) = \mathsf{QHT}(\mathsf{U}, |\tilde{1},g\rangle) = \Theta\left(\frac{1}{\sqrt{\epsilon}}\mathsf{QHT}(\mathsf{W}, |\bar{g}\rangle)\right) = \Theta\big(\mathsf{QHT}(\mathsf{A}, |\overline{\text{init}}\rangle)\big).$$

Consider Theorem 4. The first equality follows since the principal $(+1)$-eigenvector $|U_0\rangle = \frac{1}{\sqrt{2}}(|0,\overline{\text{init}}\rangle - |\tilde{1},g\rangle)$ of the controlled amplifier U is an equal superposition of the starting state and the target state. To prove the remaining two equalities, we relate the computational quantity QHT to a structural quantity, an inner product.

▶ **Lemma 5.** *Let* V *be any real unitary, and let* $|w\rangle$ *be a real state that does not overlap the* $(+1)$*-eigenspace* V_+ *of* V*. Then the operator* $\mathsf{S} = \mathsf{V}\cdot(1-2|w\rangle\langle w|)$ *has a unique* $(+1)$*-eigenvector* $|+S\rangle$ *orthogonal to* V_+*, and it satisfies that* $\mathsf{QHT}(\mathsf{V}, |w\rangle) = \Theta\big(\frac{1}{|\langle w|+S\rangle|}\big)$*.*

Proof. We first decompose $|w\rangle$ into the eigenbasis of V as $|w\rangle = \sum_j w_j(|V_j^+\rangle + |V_j^-\rangle) + w_{-1}|V_{-1}\rangle$, where $w_j \in \mathbb{R}$ for all j. The states $|V_j^+\rangle$ and $|V_j^-\rangle$ are the two conjugated eigenstates for the j^{th} rotational subspace of V with eigenphases $\pm\varphi_j$. The state $|V_{-1}\rangle$ is the normalized projection of $|w\rangle$ onto the (-1)-eigenspace of V (when it exists). Then S has a $(+1)$-eigenvector on the form $|+w\rangle = |w\rangle + i|w^\perp\rangle = |w\rangle + i\sum_j w_j \cot\left(\frac{\varphi_j}{2}\right)\big(|V_j^-\rangle - |V_j^+\rangle\big)$, and it is the unique $(+1)$-eigenvector orthogonal to the trivial $(+1)$-eigenspace V_+. The norm $\|+w\|$ of $|+w\rangle$ is

$$\sqrt{1+\||w^\perp\rangle\|^2} = \sqrt{1+2\sum_j w_j^2\cot^2\left(\frac{\varphi_j}{2}\right)} = \Theta(\mathsf{QHT}_{\cot}(\mathsf{V}, |w\rangle)) = \Theta(\mathsf{QHT}(\mathsf{V}, |w\rangle)),$$

where the last equality follows by Lemma 9 given in the appendix. The normalized eigenvector is then $|+S\rangle = \frac{1}{\Theta(\mathsf{QHT}(\mathsf{V},|w\rangle))}\left(|w\rangle + i|w^\perp\rangle\right)$. ◀

Note that in Theorem 4, the last two vectors are orthogonal to the $(+1)$-eigenspaces of the respective operators, and hence Lemma 5 applies. Since the corresponding inner products

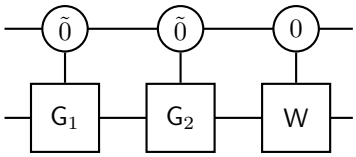

Figure 6 The circuit U rewritten to permit an analysis of its action when there are multiple targets.

are of the same order and also of the same order as the quantity $\mathsf{QHT}(\mathsf{U}, |\tilde{1}, g\rangle)$, we deduce the four quantum hitting times are of the same order, implying Theorem 4.

Theorem 4 implies that the quantum hitting time of U on $|0, \overline{\text{init}}\rangle$ is asymptotically the same as the quantum hitting time of A on $|\overline{\text{init}}\rangle$.

▶ **Corollary 6.** *There is an algorithm that applies circuit* U *an expected number in the order of* $\mathsf{QHT}(\mathsf{A}, |\overline{\text{init}}\rangle)$ *times to the initial state* $|0, \overline{\text{init}}\rangle$ *and produces a final state with constant overlap with* $|\tilde{1}, g\rangle$.

When A is a quantum walk derived from a reversible random walk P using Szegedy's construction [30], then A can detect the presence of a unique target in cost in the order of $\mathsf{QHT}(\mathsf{A}, |\overline{\text{init}}\rangle) \in O(\sqrt{\mathsf{HT}(\mathsf{P}, \{m\})})$, which is quadratically less than the hitting time of P [23, 28]. The corollary thus implies that U finds a unique target quadratically faster than classically.

5 Finding with multiple targets

We have analyzed our circuit U given in Figure 1 for a single target state $|g\rangle$. Consider now we have t targets. Let $|g_1\rangle, \ldots, |g_t\rangle$ be a set of t orthogonal states spanning this target subspace $\mathcal{G}$, and let Π_G be the projection onto $\mathcal{G}$. In our circuit U in Figure 1, consider we now have $\mathsf{G} = 1 - 2\Pi_G$. Let $|g_\pi\rangle$ be the normalized projection of $|\text{init}\rangle$ onto the target subspace. Then $\epsilon_\pi = \sin^2(\theta) = |\langle g_\pi|\text{init}\rangle|^2$ is the total probability that a measurement of the initial state would successfully produce any of the target states.

To analyze the circuit U when there are multiple targets, we again rewrite the circuit. Set $\mathsf{G}_1 = 1 - 2|g_\pi\rangle\langle g_\pi|$ and let $\mathsf{G}_2 = 1 - 2(\Pi_G - |g_\pi\rangle\langle g_\pi|)$. We can then write our circuit U on the form given in Figure 6. The rewritten circuit differs in form from our original circuit by the second gate $|\tilde{0}\rangle\langle\tilde{0}| \otimes \mathsf{G}_2 + |\tilde{1}\rangle\langle\tilde{1}| \otimes 1$. In general, this second gate changes the quantum hitting time of the circuit. For some classes of operators W, though, the second gate has no impact. In particular, for quantum walks on reversible graphs when the operator W is comprised of a reflection and a swap operator [30], we can compute an explicit expression of the complexity.

▶ **Theorem 7.** *Let* W *be a reversible quantum walk with multiple marked elements. There is an algorithm that applies* U *an expected number in the order of* $\frac{1}{\sqrt{\epsilon_\pi}} \cdot \mathsf{QHT}(\mathsf{W}, |\overline{g_\pi}\rangle)$ *times on the initial state* $|0, \overline{\text{init}}\rangle$ *and produces a final state with constant overlap with* $|\tilde{1}, g_\pi\rangle$.

Note that in this theorem, $|g_\pi\rangle$ is the normalized projection of $|\text{init}\rangle$ onto the marked subspace and ϵ_π is the total probability a measurement of $|\text{init}\rangle$ yields a marked element. The state $|\overline{g_\pi}\rangle$ is the normalized projection of $|g_\pi\rangle$ onto the subspace orthogonal to $|\text{init}\rangle$. The theorem follows by observing that the quantum hitting times on the input $|0, \overline{\text{init}}\rangle$ with or without the second gate are the same.

6 Faster algorithms for a unique marked element

Consider there is a unique marked element g. By Theorem 4, we can write $\mathsf{QHT}^2(\mathsf{A}, |\overline{\text{init}}\rangle)$ as a product of the two factors $\frac{1}{\epsilon}$ and $\mathsf{QHT}^2(\mathsf{W}, |\overline{g}\rangle)$. This decomposition permits us to device a new quantum algorithm for finding a unique marked element with constant success probability of cost in the order of

$$\mathsf{S} + \sqrt{H}\mathsf{U} + \frac{1}{\sqrt{\epsilon}}\mathsf{C}. \tag{2}$$

Here $H \in \widetilde{O}(\mathsf{QHT}^2(\mathsf{A}, |\overline{\text{init}}\rangle))$ is in the order of the square of the quantum hitting time, up to logarithmic factors. When A is the quantum walk derived from a reversible random walk P using Szegedy's construction, then $\mathsf{QHT}^2(\mathsf{A}, |\overline{\text{init}}\rangle) \in O(\mathsf{HT}(\mathsf{P}, \{g\}))$ is in the order of the hitting time of P with unique marked element g.

Since the hitting time $\mathsf{HT}(\mathsf{P}, \{g\})$ is upper bounded by $\frac{1}{\epsilon\delta}$, the cost of our algorithm is, up to logarithmic factors, upper bounded by the cost of the existing algorithms in [25, 23, 21]. Our algorithm is derived by using Theorem 4 and is based on recursive amplitude amplification [17, 16, 25]. In terms of the checking cost C, our algorithm has the same cost as amplitude amplification would have, which offers a quadratic speed-up over any classical algorithm.

We also obtain a new *classical* algorithm that has cost of order

$$\mathsf{S} + H\mathsf{U} + \frac{1}{\epsilon}\mathsf{C}. \tag{3}$$

Here $H \in O(\mathsf{HT}(\mathsf{P}, \{g\}))$ is the hitting time of the reversible walk P with unique marked element g, without logarithmic factors. This combines the best of two natural choices of random walks having cost in the order of $\mathsf{S}+H(\mathsf{U}+\mathsf{C})$ and $\mathsf{S}+\frac{1}{\epsilon}(\frac{1}{\delta}\mathsf{U}+\mathsf{C})$ (see e.g. Santha [29] for a discussion on classical search algorithms). The main structure in our classical algorithm is as follows.

1. Sample an initial vertex x according to the stationary distribution π.
2. Repeat the following of order H/E times
   a. Let x denote the current state.
   b. Check if x is marked. If so, halt and output x.
   c. Else apply the random walk P a number of E times, starting from x.
3. If the current state x is marked, output x. Otherwise output "no marked element found."

The proof is by showing that $\mathsf{QHT}^2(\mathsf{W}(\mathsf{P}^E), \{g\})$ is upper bounded by a constant when E is of order $\mathsf{QHT}^2(\mathsf{W}(\mathsf{P}), \{g\})$. This statement is effectively an example of a classical theorem derived via quantum arguments. We have not been able to find this classical algorithm discussed in the literature before, and it is to the best of our knowledge new. We neither know of a way to prove that this classical algorithm finds a marked element in cost in the order of the expression in Eq. 3 without explicitly or implicitly applying arguments resembling the arguments introduced in this paper. It is, as far as we know, the first known random walk derived through the notion of quantum walks. We refer the reader to the excellent survey by Drucker and de Wolf [12] for further examples on quantum proofs for classical theorems.

7 Simulation of quantum interpolated walks

Our controlled amplifier can be applied to arbitrary real operators W, and we prove a general bound on the cost of the amplifier given in terms of the quantum hitting time QHT_α. We

now consider operators W derived from reversible random walks. This is the broadest class of random walks for which quantum algorithms of costs in the order of the quantum hitting time have been derived. The general problem is given by a state space X on which we defined a reversible random walk P. A subset $\mathcal{M}$ of the states of X are marked (the elements of $\mathcal{M}$ correspond to the solutions to some computational problem). Our goal is to find an element of $\mathcal{M}$.

Szegedy gives a general method for constructing a quantum walk $\mathsf{W}(\mathsf{P})$ from a reversible random walk P [30, 23]. Krovi et al. give in [21] a notion of interpolation between a reversible random walk P and its corresponding absorbing walk P', which is obtained from P by replacing all the transitions from marked vertices with self-loops. The interpolation $\mathsf{P}(s)$ is between two classical walks, where we transition according to P' with some fixed probability s, and transition according to P with complementary probability $1-s$. The resulting walk $\mathsf{P}(s)$ then yields a quantum walk $\mathsf{W}(\mathsf{P}(s))$ by Szegedy's construction. We use W and $\mathsf{W}(s)$ as shorthands for $\mathsf{W}(\mathsf{P})$ and $\mathsf{W}(\mathsf{P}(s))$, respectively. Let $\mathsf{HT}(\mathsf{P}(s),\mathcal{M})$ denote the classical hitting time of $\mathsf{P}(s)$. The quantum interpolated walk introduced in [21] finds a marked element. It takes a number of steps that is in the order of $\mathsf{HT}^+(\mathsf{P},\mathcal{M})$, where $\mathsf{HT}^+(\mathsf{P},\mathcal{M})$ is defined as $\mathsf{HT}^+(\mathsf{P},\mathcal{M}) = \lim_{s\to 1}\mathsf{HT}(\mathsf{P}(s),\mathcal{M})$. This limit is well-defined and referred to as the extended hitting time [21]. We use HT and HT^+ as shorthands for $\mathsf{HT}(\mathsf{P},\mathcal{M})$ and $\mathsf{HT}^+(\mathsf{P},\mathcal{M})$ when both P and $\mathcal{M}$ are fixed.

We show that controlled quantum amplifiers can simulate quantum interpolated walks. We do so by giving a constructive embedding E_s of $\mathsf{W}(s)$ into our framework. For a given parameter s, we choose the angle $\tilde{\theta}$ so that it satisfies that $0 \le \tilde{\theta} \le \pi/2$ and that

$$\sin\tilde{\theta} = \sqrt{1-s}, \tag{4}$$

obtaining the circuit $\mathsf{U} = \mathsf{U}(\tilde{\theta})$ (see Figure 1).

Let $\mathcal{H}_{\mathcal{M}}$ be the subspace of $\mathcal{H}_{\mathsf{W}}$ with marked items in the first register. Denote by $\epsilon = \sin^2(\theta)$ the initial success probability, namely the probability that we obtain a marked state in the first register by measuring $|\mathrm{init}\rangle$ according to $\{\Pi(\mathcal{H}_{\mathcal{M}}), 1-\Pi(\mathcal{H}_{\mathcal{M}})\}$. The optimal value for $\tilde{\theta}$, which is $\tilde{\theta} = \arcsin\left(\frac{\sin(\theta)}{\cos(\theta)}\right)$, corresponds to the optimal value of s, which is given by $s = 1 - \frac{\epsilon}{1-\epsilon}$.

Denote by $\mathcal{H}_{\mathsf{W}(s)}$ the space on which the quantum walk $\mathsf{W}(s)$ acts non-trivially (which is the same as the space on which W acts non-trivially), and let $\mathcal{H}_{\mathsf{U}}$ denote the space on which $\mathsf{U}(\tilde{\theta})$ acts. We define an embedding E_s from $\mathcal{H}_{\mathsf{W}(s)}$ to a subspace of $\mathcal{H}_{\mathsf{U}}$. We define E_s on a spanning set of $\mathcal{H}_{\mathsf{W}(s)}$ and then extend it by linearity,

$$\mathsf{E}_s \begin{cases} |u, p(s)_u\rangle & \mapsto & |0\rangle|u, p_u\rangle \\ |p(s)_u, u\rangle & \mapsto & |0\rangle|p_u, u\rangle \\ |m, p(s)_m\rangle & \mapsto & -|\tilde{1}\rangle|m, p_m\rangle \\ |p(s)_m, m\rangle & \mapsto & \sin\tilde{\theta}|0\rangle|p_m, m\rangle - \cos\tilde{\theta}|1\rangle|m, p_m\rangle. \end{cases} \tag{5}$$

The state $|p_x\rangle$ is a superposition of the neighbors of x and is defined by $\langle y|p_x\rangle$ being the square-root of the probability of transition from state x to state y in the random walk P. The states $|p(s)_x\rangle$ are defined similarly the random walk $\mathsf{P}(s)$.

By direct inspection, the embedding preserves inner products and is thus well-defined. Consider the following two maps from $\mathcal{H}_{\mathsf{W}(s)}$ to $\mathcal{H}_{\mathsf{U}}$ given by $\mathsf{E}_s\mathsf{W}(s)$ and $\mathsf{U}(\tilde{\theta})\mathsf{E}_s$. The first map first applies the quantum interpolated walk and then the embedding. The second map first applies the embedding and then our controlled quantum walk $\mathsf{U}(\tilde{\theta})$. These two operators act identically on each of the states given on the left hand sides in Eq. 5, and we thus conclude that $\mathsf{E}_s\mathsf{W}(s) = \mathsf{U}(\tilde{\theta})\mathsf{E}_s$, implying Theorem 8.

▶ **Theorem 8.** *Fix any* $0 \leq s < 1$. *There is an inner-product preserving map* E_s *from* $\mathcal{H}_\mathsf{W}$ *to a subspace of* $\mathcal{H}_\mathsf{U}$ *such that* $\mathsf{E}_s\mathsf{W}(s) = \mathsf{U}(\tilde{\theta})\mathsf{E}_s$.

Theorem 8 readily implies that controlled quantum walks can simulate quantum interpolated walks. Instead of running a quantum interpolated walk on its initial state $|\overline{\text{init}}\rangle$, we run a controlled quantum walk on the initial state $|0\rangle|\overline{\text{init}}\rangle = \mathsf{E}_s|\overline{\text{init}}\rangle$. Instead of measuring whether we have produced the state $|m, p(s)_m\rangle$ in a quantum interpolated walk, we run a controlled quantum walk and measure whether we have produced the state $|\tilde{1}\rangle|m, p_m\rangle = -\mathsf{E}_s|m, p(s)_m\rangle$.

By combining Theorems 7 and 8, we obtain that the extended hitting time $\mathsf{HT}^+(\mathsf{P}, \mathcal{M})$ of a reversible walk P on a marked subset $\mathcal{M}$ is in the order of $\frac{1}{\epsilon_\pi}\mathsf{QHT}^2(\mathsf{W}(\mathsf{P}), |\overline{g_\pi}\rangle)$. Further, we also re-derive the following result already shown by Ambainis and Kokainis [6]. Since $\mathsf{QHT}(\mathsf{W}, |\overline{g_\pi}\rangle) \leq \frac{1}{\sqrt{\delta}}$, we get that the extended hitting time is never more than a factor of $1/\delta$ larger than the hitting time, and that the extended hitting time $\mathsf{HT}^+(\mathsf{P}, \mathcal{M})$ is in the order of $\frac{1}{\epsilon_\pi \delta}$ for all marked subsets $\mathcal{M}$. Here δ is the spectral gap of the random walk P.

8 Concluding remarks

An quantum search algorithm takes two ingredients: an operator W and a reflection operator G. The standard method in quantum search algorithms is to apply the composed operator $\mathsf{A} = \mathsf{W} \cdot \mathsf{G}$. This method permits one to distinguish between the case when there is a marked state and the case when there are none. It does not in general produce a marked state, even when one exists.

We have here proposed a general method for amplifying the success probability of quantum search algorithms. The method applies readily to arbitrary (real) operators W, including operators derived from random walks. Our circuit U can be based equally well on either of the two operators W or A, depending on the application in mind. We prove that the controlled amplifier U finds a unique marked element in the same asymptotic cost as the standard circuit A determines whether one exists or not. We then prove and use properties of the controlled amplifier U to simulate amplitude amplification and interpolated walks, and to derive a new quantum and classical algorithm. Up to logarithmic factors, the costs are in the order of $\mathsf{S} + \sqrt{H}\mathsf{U} + 1/\sqrt{\epsilon}\mathsf{C}$ and $\mathsf{S} + H\mathsf{U} + 1/\epsilon\mathsf{C}$, respectively. Both algorithms improve upon the best known quantum and classical algorithms.

A A lemma

The following lemma, referenced in Section 3, shows that the two quantum hitting times, $\mathsf{QHT}_{\cot}$ and QHT_{α} are of the same asymptotic order.

▶ **Lemma 9.** *For any real unitary* U *and any real state* $|w\rangle$,

$$\mathsf{QHT}_{\cot}(\mathsf{U},|w\rangle) \le 2\,\mathsf{QHT}_{\alpha}(\mathsf{U},|w\rangle) \le \sqrt{2} + \mathsf{QHT}_{\cot}(\mathsf{U},|w\rangle).$$

Proof. Since $\sin x < x < \tan x$ for any $x \in (0,\pi/2)$,

$$\cot^2 x < \frac{1}{x^2} < 1 + \cot^2 x. \tag{6}$$

By the first inequality in Eq. 6,

$$\mathsf{QHT}_{\cot}(\mathsf{U},|w\rangle) = \sqrt{2\sum_{j=1}^{m} |w_j|^2 \cot^2\left(\frac{\alpha_j}{2}\right)} \le \sqrt{2\sum_{j=1}^{m} |w_j|^2 \left(\frac{4}{\alpha_j^2}\right)} = 2\,\mathsf{QHT}_{\alpha}(\mathsf{U},|w\rangle),$$

proving the first inequality. Since the eigenphases α_j of U belong to $(0,\pi)$, the half angles $\alpha_j/2$ belong to the interval $(0,\pi/2)$. By the second inequality in Eq. 6, then

$$\begin{aligned}\mathsf{QHT}_{\alpha}(\mathsf{U},|w\rangle) &= \frac{1}{\sqrt{2}}\sqrt{\sum_{j=1}^{m} |w_j|^2 \left(\frac{4}{\alpha_j^2}\right)} \le \frac{1}{\sqrt{2}}\sqrt{\sum_{j=1}^{m} |w_j|^2 \left(1+\cot^2\left(\frac{\alpha_j}{2}\right)\right)} \\ &= \frac{1}{\sqrt{2}}\sqrt{1+\frac{1}{2}\mathsf{QHT}^2_{\cot}(\mathsf{U},|w\rangle)}.\end{aligned}$$

We obtain the second inequality in the lemma by applying the inequality $\sqrt{a+b} \le \sqrt{a}+\sqrt{b}$, for positive reals a and b. ◀

Approximating Language Edit Distance Beyond Fast Matrix Multiplication: Ultralinear Grammars Are Where Parsing Becomes Hard!*

Abstract

In 1975, a breakthrough result of L. Valiant showed that parsing context free grammars can be reduced to Boolean matrix multiplication, resulting in a running time of $O(n^\omega)$ for parsing where $\omega \leq 2.373$ is the exponent of fast matrix multiplication, and n is the string length. Recently, Abboud, Backurs and V. Williams (FOCS 2015) demonstrated that this is likely optimal; moreover, a combinatorial $o(n^3)$ algorithm is unlikely to exist for the general parsing problem[1]. The language edit distance problem is a significant generalization of the parsing problem, which computes the minimum edit distance of a given string (using insertions, deletions, and substitutions) to any valid string in the language, and has received significant attention both in theory and practice since the seminal work of Aho and Peterson in 1972. Clearly, the lower bound for parsing rules out any algorithm running in $o(n^\omega)$ time that can return a nontrivial multiplicative approximation of the language edit distance problem. Furthermore, combinatorial algorithms with cubic running time or algorithms that use fast matrix multiplication are often not desirable in practice.

To break this n^ω hardness barrier, in this paper we study *additive* approximation algorithms for language edit distance. We provide two explicit combinatorial algorithms to obtain a string with minimum edit distance with performance dependencies on either the number of *non-linear productions*, k^*, or the number of *nested non-linear production*, k, used in the optimal derivation. Explicitly, we give an additive $O(k^*\gamma)$ approximation in time $O(|G|(n^2 + \frac{n^3}{\gamma^3}))$ and an additive $O(k\gamma)$ approximation in time $O(|G|(n^2 + \frac{n^3}{\gamma^2}))$, where $|G|$ is the grammar size and n is the string length. In particular, we obtain tight approximations for an important subclass of context free grammars known as *ultralinear* grammars, for which k and k^* are naturally bounded. Interestingly, we show that the same conditional lower bound for parsing context free grammars holds for the class of ultralinear grammars as well, clearly marking the boundary where parsing becomes hard!

1 Introduction

Introduced by Chomsky in 1956 [11], context-free grammars (CFG) play a fundamental role in the development of formal language theory [2, 22], compiler optimization [16, 42], natural language processing [27, 31], with diverse applications in areas such as computational biology [39], machine learning [33, 20, 41] and databases [23, 14, 34]. Parsing CFG is a basic computer science question, that given a CFG G over an alphabet Σ, and a string $x \in \Sigma^*$, $|x| = n$, determines if x belongs to the language $\mathcal{L}(G)$ generated by G. The canonical parsing algorithms such as Cocke-Younger-Kasimi (CYK) [2], Earley parser, [12] etc. are based on a natural dynamic programming, and run in $O(n^3)$ time[2]. In 1975, in a theoretical breakthrough, Valiant gave a reduction from parsing to Boolean matrix multiplication, showing that the parsing problem can be solved in $O(n^\omega)$ time [38]. Despite decades of efforts, these running times have remain completely unchanged.

Nearly three decades after Valiant's result, Lee came up with an ingenious reduction from Boolean matrix multiplication to CFG parsing, showing for the first time why known parsing algorithms may be optimal [25]. A remarkable recent result of Abboud, Backurs and V. Williams made her claims concrete [1]. Based on a conjecture of the hardness of computing large cliques in graphs, they ruled out any improvement beyond Valiant's algorithm; moreover they showed that there can be no combinatorial algorithm for CFG parsing that runs in truly subcubic $O(n^{3-\epsilon})$ time for $\epsilon > 0$ [1]. However combinatorial algorithms with cubic running time or algorithms that use fast matrix multiplication are often impractical. Therefore, a long-line of research in the parsing community has been to discover subclasses of context free grammars that are sufficiently expressive yet admit efficient parsing time [26, 24, 17]. Unfortunately, there still exist important subclasses of the CFG's for which neither better parsing algorithms are known, nor have conditional lower bounds been proven to rule out the possibility of such algorithms.

Language Edit Distance

A generalization of CFG parsing, introduced by Aho and Peterson in 1972 [3], is *language edit distance* (LED) which can be defined as follows.

▶ **Definition 1** (Language Edit Distance (LED))**.** Given a formal language $\mathcal{L}(G)$ generated by a grammar G over alphabet Σ, and a string $\overline{x} \in \Sigma^*$, compute the minimum number of edits (insertion, deletion and substitution) needed on $\overline{x}$ to convert it to a valid string in $\mathcal{L}(G)$.

LED is among the most fundamental and best studied problems related to strings and grammars [3, 30, 34, 35, 8, 1, 32, 6, 21], and generalizes two basic problems in computer science: parsing and string edit distance computation. Aho and Peterson presented a dynamic programming algorithm for LED that runs in $O(|G|^2 n^3)$ time [3], which was improved to $O(|G|n^3)$ by Myers in 1985 [30]. Only recently these bounds have been improved by Bringmann, Grandoni, Saha, and V. Williams to give the first truly subcubic $O(n^{2.8244})$ algorithm for LED [8]. When considering approximate answers, a *multiplicative* $(1+\epsilon)$-approximation for LED has been presented by Saha in [35], that runs in $O(\frac{n^\omega}{\text{poly}(\epsilon)})$ time.

These subcubic algorithms for LED crucially use fast matrix multiplication, and hence are not practical. Due to the hardness of parsing [25, 1], LED cannot be approximated

[2] Dependency on the grammar size if not specified is either $|G|$ as in most combinatorial algorithms, or $|G|^2$ as in most algebraic algorithms. In this paper the algorithms will depend on $|P|$, the number of productions in the grammar. In general we assume $|P| \in \Theta(|G|)$.

with any multiplicative factor in time $o(n^\omega)$. Moreover, there cannot be any combinatorial multiplicative approximation algorithm that runs in $O(n^{3-\epsilon})$ time for any $\epsilon > 0$ [1]. LED provides a very generic framework for modeling problems with vast applications [23, 20, 41, 28, 33, 31, 15]. A fast exact or approximate algorithm for it is likely to have tangible impact, yet there seems to be a bottleneck in improving the running time beyond $O(n^\omega)$, or even in designing a truly subcubic combinatorial approximation algorithm. Can we break this n^ω barrier?

One possible approach is to allow for an *additive approximation*. Since the hardness of multiplicative approximation arise from the lower bound of parsing, it is possible to break the n^ω barrier by designing a purely combinatorial algorithm for LED with an additive approximation. Such a result will have immense theoretical and practical significance. Due to the close connection of LED with matrix products, all-pairs shortest paths and other graph algorithms [35, 8], this may imply new algorithms for many other fundamental problems. In this paper, we make a significant progress in this direction by providing the first nontrivial additive approximation for LED that runs in quadratic time. Let $G = (Q, \Sigma, P, S)$ denote a context free grammar, where Q is the set of nonterminals, Σ is the alphabet or set of terminals, P is the set of productions, and S is the starting non-terminal.

▶ **Definition 2.** Given $G = (Q, \Sigma, P, S)$, a production $A \to \alpha$ is said to be *linear* if there is at most one non-terminal in α where $A \in Q$ and $\alpha \in (Q \cup \Sigma)^*$. Otherwise, if α contains two or more non-terminals, then $A \to \alpha$ is said to be *non-linear*.

The performance of our algorithms depends on either the total number of *non-linear productions* or the maximum number of *nested non-linear productions* (depth of the parse tree after condensing every consecutive sequence of linear productions, see the full version for more details) in the derivation of string with optimal edit distance, where the latter is often substantially smaller. Explicitly, we give an additive $O(k^*\gamma)$ approximation in time $O(|G|(n^2 + \frac{n^3}{\gamma^3}))$ and an additive $O(k\gamma)$ approximation in time $O(|G|(n^2 + \frac{n^3}{\gamma^2}))$, where k^* is the number of non-linear productions in the derivation of the optimal string, and k is the maximum number of nested non-linear productions in the derivation of the optimal string (each minimized over all possible derivations). Our algorithms will be particularly useful for an important subclass of CFGs, known as the *ultralinear grammars*, for which these values are tightly bounded for all derivations [43, 10, 26, 7, 29].

▶ **Definition 3** (ultralinear)**.** A grammar $G = (Q, \Sigma, P, S)$ is said to be **k-ultralinear** if there is a partition $Q = Q_1 \cup Q_1 \cup \cdots \cup Q_k$ such that for every $X \in Q_i$, the productions of X consist of *linear productions* $X \to \alpha A | A\alpha | \alpha$ for $A \in Q_j$ with $j \leq i$ and $\alpha \in \Sigma$, or *non-linear productions* of the form $X \to w$, where $w \in (Q_1 \cup Q_2 \cup \cdots \cup Q_{i-1})^*$.

The parameter k places a built-in upper bound on the number of nested non-linear productions allowed in any derivation. Thus for simplicity we will use k both to refer to the parameter of an ultralinear grammar, as well as the maximum number of nested non-linear productions. Furthermore, if d is the maximum number of non-terminals on the RHS of a production, then d^k is a built-in upper bound on the total number of non-linear productions in any derivation. In all our algorithms, without loss of generality, we use a standard normal form where $d = 2$ for all non-linear productions. As we will see later, given any CFG G and any $k \geq 1$, we can create a new grammar G' by making k copies $Q_1, \ldots, Q_k$ of the set of non-terminals Q of G, and forcing every nonlinear production in Q_i to go to non-terminals in Q_{i-1}. Thus G' has non-terminal set $Q_1 \cup Q_2 \cup \cdots \cup Q_k$, and size $O(k|G|)$. In this way we can restrict any CFG to a k-ultralinear grammar which can produce any string in $\mathcal{L}(G)$

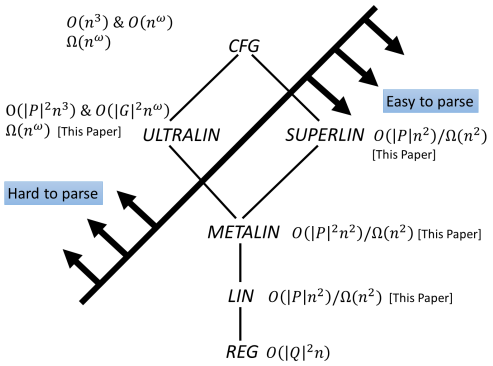

Figure 1 CFG Hierarchy: Upper bounds shown first followed by lower bounds for each class of grammars. Here $|P|$ is the number of productions in the grammar [38] [1] [40].

requiring no more than k nested non-linear productions. It is precisely this procedure of creating a k-ultralinear grammar from a CFG G that we use in our proof of hardness for parsing ultralinear languages (see the full version).

For example, if G is the well-known *Dyck Languages* [34, 6], the language of well-balanced parenthesis, $\mathcal{L}(G')$ contains the set of all parentheses strings with at most k levels of nesting. Note that a string consisting of n open parenthesis followed by n matching closed parenthesis has zero levels of nesting, whereas the string "((())())" has one level. As an another example, consider RNA-folding [8, 39, 44] which is a basic problem in computational biology and can be modeled by grammars. The restricted language $\mathcal{L}(G')$ for RNA-folding denotes the set of all RNA strings with at most k nested folds. In typical applications, we do not expect the number of nested non-linear productions used in the derivation of a valid string to be too large [14, 23, 4].

Among our other results, we consider exact algorithms for several other notable subclasses of the CFG's. In particular, we develop exact quadratic time language edit distance algorithms for the linear, metalinear, and superlinear languages. Moreover, we show matching lower bound assuming the Strong Exponential Time Hypothesis [18, 19]. The figure to the right displays the hierarchical relationship between these grammars, where all upwards lines denote strict containment. Interestingly, till date there exists no parsing algorithm for the ultralinear grammars that runs in time $o(n^\omega)$, while a $O(n^2)$ algorithm exists for the metalinear grammars. In addition, there is no combinatorial algorithm that runs in $o(n^3)$ time. In this paper, we derive conditional lower bound exhibiting why a faster algorithm has so far been elusive for the ultralinear grammars, clearly demarking the boundary where parsing becomes hard!

1.1 Results & Techniques

Lower Bounds. Our first hardness result is a lower bound for the problem of linear language edit distance. We show that a truly subquadratic time algorithm for linear language edit distance would refute the Strong Exponential Time Hypothesis (SETH). This further builds on a growing family of "SETH-hard" problems – those for which lower bounds can be proven conditioned on SETH. We prove this result by reducing binary string edit distance, which has been shown to be SETH-hard [9, 5], to linear language edit distance.

▶ **Theorem** (Linear Grammar Hardness of Parsing). *There exists no algorithm to compute the minimum edit distance between a string $\overline{x}$, $|\overline{x}| = n$, and a linear language $\mathcal{L}(G)$ in $o(n^{2-\epsilon})$ time for any constant $\epsilon > 0$, unless SETH is false.*

Our second, and primary hardness contribution is a conditional lower bound on the recognition problem for ulralinear languages. Our result builds closely off of the work of Abboud, Backurs and V. Williams [1], who demonstrate that finding an $o(n^3)$-time combinatorial algorithm or any $o(n^\omega)$-algorithm for context free language recognition would result in faster algorithms for the k-clique problem and falsify a well-known conjecture in graph algorithms. We modify the grammar in their construction to be ultralinear, and then demonstrate that the same hardness result holds for our grammar. See the full version for details.

▶ **Theorem** (Ultralinear Grammar Hardness of Parsing). *There is a ultralinear grammar $\mathcal{G}_U$ such that if we can solve the membership problem for a string of length n in time $O(|\mathcal{G}_U|^\alpha n^c)$ for any fixed constant $\alpha > 0$, then we can solve the $3k$-clique problem on a graph with n nodes in time $O(n^{c(k+3)+3\alpha})$.*

Upper Bounds. We provide the first quadratic time algorithms for linear (Theorem 7), superlinear (in full version), and metalinear language edit distance (in full version), running in $O(|P|n^2)$, $O(|P|n^2)$ and $O(|P|^2n^2)$ time respectively. This exhibits a large family of grammars for which edit distance computation can be done faster than for general context free grammars, as well as for other well known grammars such as the Dyck grammar [1]. Along with our lower bound for the ultralinear language parsing, this demonstrates a clear division between those grammars for which edit distance can be efficiently calculated, and those for which the problem is likely to be fundamentally hard. Our algorithms build progressively off the construction of a *linear language edit distance graph*, reducing the problem of edit distance computation to computing shortest path on a graph with $O(|P|n^2)$ edges (Section 2).

Our main contribution is an additive approximation for language edit distance. We first present a cubic time exact algorithm, and then show a general procedure for modifying this algorithm, equivalent to forgetting states of the underlying dynamic programming table, into a family of *amnesic* dynamic programming algorithms. This produces *additive approximations* of the edit distance, and also provides a tool for proving general bounds on any such algorithm. In particular, we provide two explicit procedures for forgetting dynamic programming states: *uniform* and *non-uniform* grid approximations achieving the following approximation-running time trade-off. See Section 4, and the full version for missing proofs.

▶ **Theorem 4.** *If $\mathcal{A}$ is a γ-uniform grid approximation, then the edit distance computed by $\mathcal{A}$ satisfies $|OPT| \leq |\mathcal{A}| \leq |OPT| + O(k^*\gamma)$ and it runs in $O(|P|(n^2 + (\frac{n}{\gamma})^3))$ time.*

▶ **Theorem 5.** *Let $\mathcal{A}$ be any γ-non-uniform grid approximation, then the edit distance computed by $\mathcal{A}$ satisfies $|OPT| \leq |\mathcal{A}| \leq |OPT| + O(k\gamma)$and it runs in $O\big(|P|\big(n^2 + \frac{n^3}{\gamma^2}\big)\big)$ time.*

We believe that our amnesic technique can be applied to wide range of potential dynamic programming approximate algorithms, and lends itself particularly well to randomization.

2 Linear Grammar Edit Distance in Quadratic Time

We first introduce a graph-based exact algorithm for linear grammar, that is a grammar $G = (Q, \Sigma, P, S)$ where every production has one of the following forms: $A \to \alpha B$, $A \to B\alpha$, $A \to \alpha B\beta$, or $A \to \alpha$ where $A, B \in Q$, and $\alpha, \beta \in \Sigma$. Given G and a string $\overline{x} = x_1x_2 \dots x_n \in \Sigma^*$, we give an $O(|P|n^2)$ algorithm to compute edit distance between $\overline{x}$ and G in this section. The algorithm serves as a building block for the rest of the paper.

Note that if we only have productions of the form $A \to \alpha B$ (or $A \to B\alpha$ but not both) then the corresponding language is regular, and all regular languages can be generated in

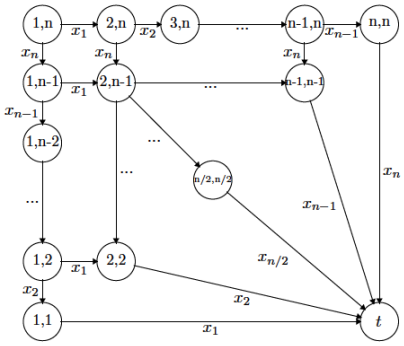

Figure 2 Clouds corresponding to Linear Grammar Edit Distance Graph Construction. Each cloud contains a vertex for every nonterminal.

this manner. However, there are linear languages that are not regular. For instance, the language $\{0^n1^n \mid n \in \mathbb{N}\}$ can be produced by the linear grammar $S \to 0S1 \mid \epsilon$, but cannot be produced by any regular grammar [37]. Therefore, regular languages are a strict subclass of linear languages. Being a natural extension of the regular languages, the properties and applications of linear languages are of much interest[13, 36].

Algorithm. Given inputs G and $\overline{x}$, we construct a weighted digraph $\mathcal{T} = \mathcal{T}(G, \overline{x})$ with a designated vertex $S^{1,n}$ as the source and t as the sink such that the weight of the shortest path between them will be the minimum language edit distance of $\overline{x}$ to G.

Construction. The vertices of $\mathcal{T}$ consist of $\binom{n}{2}$ *clouds*, each corresponding to a unique substring of $\overline{x}$. We use the notation (i, j) to represent the cloud, $1 \leq i \leq j \leq n$, corresponding to the substring $x_ix_{i+1}....x_j$. Each cloud will contain a vertex for every nonterminal in Q. Label the nonterminals $Q = \{S = A_1, A_2, \ldots, A_q\}$ where $|Q| = q$, then we denote the vertex corresponding to A_k in cloud (i, j) by $A_k^{i,j}$. We will add a new sink node t, and use $S^{1,n}$ as the source node s. Thus the vertex set of $\mathcal{T}$ is $V(\mathcal{T}) = \{A_k^{i,j} \mid 1 \leq i \leq j \leq n,\ 1 \leq k \leq q\} \cup \{t\}$. The edges of $\mathcal{T}$ will correspond to the productions in G. Each path from a nonterminal $A_k^{i,j}$ in (i, j) to t corresponds to the production of a legal string w, that is a string that can be derived starting from A_k and following the productions of P, and a sequence of editing procedures to edit w to $x_ix_{i+1} \ldots x_j$. For any cloud (i, j), edges will exist between two nonterminals in (i, j), and from nonterminals in (i, j) to nonterminals in $(i + 1, j)$ and $(i, j - 1)$. Our goal will be to find the shortest path from $S^{1,n}$, the starting nonterminal S in cloud $(1, n)$, to the sink t.

Adding the edges. Each edge in $\mathcal{T}$ is directed, has a weight in $\mathbb{Z}^+$ and a label from $\{x_1, x_2, .., x_n, \epsilon\} \cup \{\epsilon(\alpha) \mid \alpha \in \Sigma\}$, where $\epsilon(\alpha)$ corresponds to the deletion of α. If u, v are two vertices in $\mathcal{T}$, then we use the notation $u \xrightarrow[w(u,v)]{\ell} v$ to denote the existence of an edge from u to v with weight $w(u, v)$ and edge label ℓ. For any nonterminal $A \in Q$, define $null(A)$ to be the length of the shortest string in Σ^* derivable from A, which can be precomputed in $O(|Q||P| \log(|Q|))$ time for all $A \in Q$ (see full version for details). This is the minimum cost of deleting a whole string produced by A. Given input $x_1x_2 \ldots x_n$, for all nonterminals A_k, A_r and every $1 \leq i \leq j \leq n$, the construction is as follows:

- **Legal Productions:** For $i \neq j$, then if $A_k \to x_i A_r$ is a production, add the edge $A_k^{i,j} \xrightarrow[0]{x_i} A_r^{i+1,j}$ to $\mathcal{T}$. If $A_k \to A_r x_j$ is a production, add the edge $A_k^{i,j} \xrightarrow[0]{x_j} A_r^{i,j-1}$ to $\mathcal{T}$.
- **Completing Productions:** If $A_k \to x_i$ is a production, add the edge $A_k^{i,i} \xrightarrow[0]{x_i} t$ to $\mathcal{T}$. If $A_k \to x_i A_r$ or $A_k \to A_r x_i$ is a production, add the edge $A_k^{i,i} \xrightarrow[null(A_r)]{x_i} t$ to $\mathcal{T}$.
- **Insertion:** If $A_k \to x_i A_k$ is *not* a production, add the edge $A_k^{i,j} \xrightarrow[1]{x_i} A_k^{i+1,j}$ to $\mathcal{T}$. If $A_k \to A_k x_j$ is *not* a production, add $A_k^{i,j} \xrightarrow[1]{x_j} A_k^{i,j-1}$. *{these are called insertion edges.}*
- **Deletion:** For every production $A_k \to \alpha A_r$ or $A_k \to A_r \alpha$, add the edge $A_k^{i,j} \xrightarrow[1]{\epsilon(\alpha)} A_r^{i,j}$. *{these are called deletion edges.}*
- **Replacement:** For every production $A_k \to \alpha A_r$, if $\alpha \neq x_i$, then add the edge $A_k^{i,j} \xrightarrow[1]{x_i} A_r^{i+1,j}$ to T. For every production $A_k \to A_r \alpha$, if $\alpha \neq x_j$, add $A_k^{i,j} \xrightarrow[1]{x_j} A_r^{i,j-1}$ to $\mathcal{T}$. For any A_k such that $A_k \to x_i$ is not a production, but $A_k \to \alpha$ is a production with $\alpha \in \Sigma$, add the edge $A_k^{i,i} \xrightarrow[1]{x_i} t$ to $\mathcal{T}$.*{these are called substitution or replacement edges.}*

▶ **Theorem 6.** *For every $A_k \in Q$ and every $1 \leq i \leq j \leq n$, the cost of the shortest path of from $A_k^{i,j}$ to the sink $t \in \mathcal{T}$ is d if and only if d is the minimum edit distance between the string $x_i \dots x_j$ and the set of strings which can be derived from A_k.*

▶ **Theorem 7.** *The cost of the shortest path from $S^{1,n}$ to t in the graph $\mathcal{T}$ is the minimum edit distance which can be computed in $O(|P|n^2)$ time.*

3 Context Free Language Edit Distance

In this section, we develop an exact algorithm which utilizes the graph construction presented in Section 2 to compute the language edit distance of a string $\overline{x} = x_1 \dots x_n$ to any context free grammar (CFG) $G = (Q, \Sigma, P, S)$. We use a standard normal form for G, which is Chomsky normal form except we also allow productions of the form $A \to Aa|aA$, where $A \in Q, a \in \Sigma$. For us, the important property of this normal form is that every non-linear production must be of the form $A \to BC$, with exactly two non-terminals on the right hand side. Any CFG can be reduced to this normal form (see full version for more details).

Let $P_L, P_{NL} \subset P$ be the subsets of (legal) linear and non-linear productions respectively. Then for any nonterminal $A \in Q$, the grammar $G_L = (Q, \Sigma, P_L, A)$ is linear, and we denote the corresponding linear language edit distance graph by $\mathcal{T}(G_L, \overline{x}) = \mathcal{T}$, as constructed in Section 2. Let L_i be the set of clouds in $\mathcal{T}$ which correspond to substrings of length i (so $L_i = \{(k, j) \in \mathcal{T} \mid j - k + 1 = i\}$). Then $L_1, \dots, L_n$ is a *layered partition* of $\mathcal{T}$. Let t be the sink of $\mathcal{T}$. We write $\mathcal{T}^R$ to denote the graph $\mathcal{T}$ where the direction of each edge is reversed. Let L_i^R denote the edge reversed subgraph of L_i. In other words, L_i^R is the subgraph of $\mathcal{T}^R$ with the same vertex set as L_i. Our algorithm will add some additional edges within L_i^R, and some additional edges from t to L_i^R, for all $1 \leq i \leq n$, resulting in an augmented subgraph which we denote $\overline{L}_i^R$. We then compute single source shortest path from t to $\overline{L}_i^R \cup \{t\}$ in phase i. Our algorithm will maintain the property that, after phase $q - p + 1$, if $A^{p,q}$ is any nonterminal in cloud (p, q) then the weight of the shortest path from t to $A^{p,q}$ is precisely the minimum edit distance between the string $x_p x_{p+1} \dots x_q$ and the set of strings that are legally derivable from A. The algorithm is as follows:

Algorithm: Context Free-Exact

1. **Base Case: strings of length 1.** For every non-linear production $A \to BC$, and every $1 \leq \ell \leq n$, add the edges $A^{\ell,\ell} \xleftarrow[null(B)]{} C^{\ell,\ell}$ and $A^{\ell,\ell} \xleftarrow[null(C)]{} B^{\ell,\ell}$ to L_1^R. Note that the direction of the edges are reversed because we are adding edges to L_1^R and not L_1. Call the resulting augmented graph $\overline{L_1^R}$.
2. Solve single source shortest path from t to every vertex in $\overline{L_1^R} \cup \{t\}$. Store the value of the shortest path from t to every vertex in $\overline{L_1^R}$, and an encoding of the path itself. For any $1 \leq p \leq q \leq n$ and $A^{p,q} \in L_{q-p+1}$, we write $T_{p,q}(A)$ to denote the weight of the shortest path from t to $A^{p,q}$. After having computed shortest paths from t to every vertex in the subgraphs $\overline{L}_1^R, \ldots, \overline{L}_{i-1}^R$, we now consider L_i^R.
3. **Induction: strings of length i.** For every edge from a vertex $A^{p,q}$ in L_i to a vertex $B^{p+1,q}$ or $B^{p,q-1}$ in L_{i-1} with cost $\gamma \in \{0,1\}$, add an edge from t to $A^{p,q} \in L_i^R$ with cost $T_{p+1,q}(B) + \gamma$ or $T_{p,q-1}(B) + \gamma$, respectively. These are the linear production edges created in the linear grammar edit distance algorithm.
4. For every non-linear production $A \to BC$ and every vertex $A^{p,q} \in L_i^R$, add an edge from t to $A^{p,q}$ in L_i^R with cost c where $c = \min_{p \leq \ell < q} T_{p,\ell}(B) + T_{\ell+1,q}(C)$. The indices $p \leq \ell < q$ are called *splitting points,* as they specify where the string $x_p, \ldots, x_q$ is split by the production $A \to BC$. To later recover the derivation, we store the specific ℓ which yields the minimum value of the above equation.
5. For every non-linear production $A \to BC$, add the edge $A^{p,q} \xleftarrow[null(B)]{} C^{p,q}$ and $A^{p,q} \xleftarrow[null(C)]{} B^{p,q}$ to L_i^R.
6. After adding the edges in steps 3-5, we call the resulting graph $\overline{L}_i^R$. Then compute shortest path from t to every vertex in the subgraph $\overline{L}_i^R \cup \{t\}$, and store the values of the shortest paths, along with an encoding of the paths themselves.
7. Repeat for $i = 1, 2, \ldots, n$. Return the value $T_{1,n}(S)$.

▶ **Theorem 8.** *For any nonterminal $A \in Q$ and $1 \leq p \leq q \leq n$, the weight of the shortest path from $A^{p,q} \in \overline{L}_i$ to t is the minimum edit distance between the substring $x_p \ldots x_q$ and the set of strings which can be legally produced from A, and the overall time required to compute the language edit distance is $O(|P|n^3)$.*

4 Context Free Language Edit Distance Approximation

Now this cubic time algorithm itself is not an improvement on that of Aho and Peterson [3]. However, by strategically modifying the construction of the subgraphs L_i by **forgetting** to compute some of the non-linear edge weights (and taking the minimum over fewer splitting points for those that we do compute), we can obtain an additive approximation of the minimum edit distance. We introduce a family of approximation algorithms which do just this, and prove a strong general bound on their behavior. Our results give bounds for the performance of our algorithm for any CFG. Additionally, for any k-ultralinear language, our results also give explicit $O(k\sqrt{n})$ and $O(2^k n^{1/3})$ additive approximations from this family which run in quadratic time. Note that, as shown in our construction in the proof of hardness of parsing ultralinear grammars, for any k we can restrict any context free grammar G to a k-ultralinear grammar G' such that $\mathcal{L}(G') \subseteq \mathcal{L}(G)$ contains all words that can be derived using fewer than $\leq k$ nested non-linear productions (see full version for a more formal definition of k and hardness proofs).

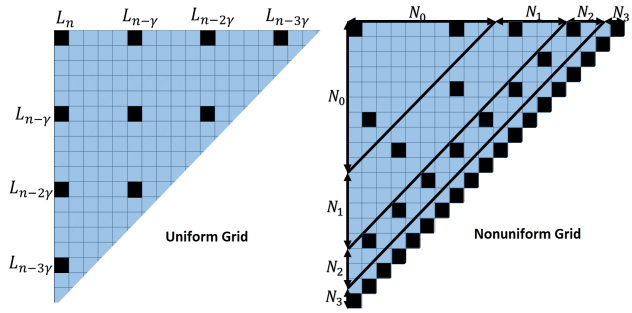

Figure 3 Non-uniform edges are computed only for a subset of the clouds (colored black). Only a subset of the splitting points are considered while computing the weights.

▶ **Definition 9.** For any Context Free Language edit distance approximation algorithm $\mathcal{A}$, we say that $\mathcal{A}$ is in the family $\mathcal{F}$ if it follows the same procedure as in the exact algorithm with the following modifications:

1. **Subset of non-linear productions.** $\mathcal{A}$ constructs the non-linear production edges in step 4 for the vertices in some subset of the total set of clouds $\{(p,q) \mid 1 \leq p \leq q \leq n\}$.
2. **Subset of splitting points.** For every cloud (p,q) that $\mathcal{A}$ computes non-linear production edges for, in step 4 of the algorithm when computing the weight c of any edge in this cloud it takes minimum over only a subset of the possible splitting points $p, \ldots, q$ (where this subset is the same for every non-linear edge weight computed in (p,q)).

By forgetting to construct all non-linear production edges, and by taking a minimum over fewer values when we do construct non-linear production edges, the time taken by our algorithm to construct new edges can be substantially reduced. Roughly, the intuition for how we can still obtain an additive approximation is as follows. If the shortest path to the sink in the exact algorithm uses a non-linear edge from a vertex $A^{p,q}$ in cloud (p,q), then naturally our approximation algorithm would also use such an edge if it existed. However, it is possible that nonlinear edges were not constructed for cloud (p,q) by the approximation. Still, what we can do is find the closest cloud (p',q'), with $p \leq p' \leq q' \leq q$, such that nonlinear edges were constructed in (p',q'), and then follow the insertion edges $A^{p,q} \to A^{p+1,q} \to \cdots \to A^{p',q'}$, and take the desired non-linear production edge from $A^{p',q'}$. The additional incurred cost is at most $|p-p'| + |q-q'|$, or the distance to the nearest cloud with non-linear edges, and this cost is incurred at most once for every non-linear production in an optimal derivation.

We now give two explicit examples of how steps 1 and 2 can be implemented. We later prove explicit bounds on the approximations of these examples in Theorems 4 and 5. In both examples a *sensitivity parameter*, γ, is first chosen. We use $|OPT|$ to denote the optimum language edit distance, and $|\mathcal{A}|$ to denote the edit distance computed by an approximation algorithm $\mathcal{A}$.

▶ **Definition 10.** An approximation algorithm $\mathcal{A} \in \mathcal{F}$ is a γ-*uniform grid* approximation if for $i = n, (n-\gamma), (n-2\gamma), \ldots, (n - \lfloor \frac{n}{\gamma} \rfloor \gamma)$ (see Figure 3).

1. $\mathcal{A}$ constructs non-linear production edges only for an evenly-spaced $1/\gamma$ fraction of the clouds in L_i, and no others, where γ is a specified sensitivity parameter.
2. Furthermore, for every non-linear edge constructed, $\mathcal{A}$ considers only an evenly-spaced $1/\gamma$ fraction of the possible break points.

Here if i or $(n-i+1)$ (the number of substrings of length i) is not evenly divisible by γ, we evenly space the clouds/breakpoints until no more will fit.

We will later see that the running time of such a γ-uniform grid approximation is $O(|P|(n^2 + (\frac{n}{\gamma})^3))$, and in particular for any k-ultralinear grammar G it gives an additive approximation of $O(2^k\gamma)$. Thus by setting $\gamma = n^{1/3}$, we get an $O(2^k n^{1/3})$-approximation in $O(|P|n^2)$ time (Theorem 4).

▶ **Definition 11.** For $i = 0, 1, \ldots, \log(n)$, set $N_i = \{L_j \mid \frac{n}{2^{i+1}} < j \leq \frac{n}{2^i}\}$. Let $N_i' \subset N_i$ be an evenly-spaced $\min\{\frac{2^i}{\gamma}, 1\}$-fraction of the L_j's in N_i (subset of diagonals). Then, an approximation algorithm $\mathcal{A} \in \mathcal{F}$ is a γ-*non-uniform grid* approximation if, for every $L_j \in N_i'$, $\mathcal{A}$ computes non-linear production edges only for a $\min\{\frac{2^i}{\gamma}, 1\}$-evenly-spaced fraction of the clouds in L_j. Furthermore, for any of these clouds in N_i' for which $\mathcal{A}$ does compute non-linear production edges, $\mathcal{A}$ considers only an evenly-spaced $\min\{\frac{2^i}{\gamma}, 1\}$ -fraction of all possible break points (see Figure 3 (right)).

We will see that the running time of a γ-non-uniform grid approximation is $O(|P|(n^2 + \frac{n^3}{\gamma^2}))$, and in particular for any k-ultralinear grammar, or if k is the maximum number of nested non-linear productions, it gives an additive approximation of $O(k\gamma)$. Hence setting $\gamma = \sqrt{n}$, we get an additive approximation of $O(k\sqrt{n})$ in quadratic time (Theorem 5).

4.1 Analysis

The rest of this section will be devoted to proving bounds on the performance of approximation algorithms in $\mathcal{F}$. We use $\mathcal{T}^{OPT}$ to denote the graph which results from adding all the edges specified in the exact algorithm to $\mathcal{T}$. Recall that $\mathcal{T}$ is the graph constructed from the linear productions in G. For $\mathcal{A} \in \mathcal{F}$, we write $\mathcal{T}^{\mathcal{A}}$ to denote the graph which results from adding the edges specified by the approximation algorithm $\mathcal{A}$. Note that since $\mathcal{A}$ functions by forgetting to construct a subset of the non-linear edges created by the exact algorithm, we have that the edge sets satisfy $E(\mathcal{T}) \subseteq E(\mathcal{T}^{\mathcal{A}}) \subseteq E(\mathcal{T}^{OPT})$. We now introduce the primary structure which will allow us to analyze the execution of our language edit distance algorithms.

Binary Production-Edit Trees

▶ **Definition 12.** A *production-edit tree* (PET) $\mathbb{T}$ for grammar G and input string $\overline{x}$ is a binary tree which satisfies the following properties:

1. Each node of $\mathbb{T}$ stores a path in the linear grammar edit distance graph $\mathcal{T} = \mathcal{T}(G_L, \overline{x})$ (see Section 2 and 3). The path given by the root of $\mathbb{T}$ must start at the source vertex $S^{1,n}$ of $\mathcal{T}$.
2. For any node $v \in \mathbb{T}$, let $A^{p,q}, B^{r,s}$ be the starting and ending vertices of the corresponding path. If $B^{r,s}$ is not the sink t of $\mathcal{T}$, then v must have two children, v_R, v_L, such that there exists a production $B \to CD$ and the starting vertices of the paths in v_L and v_R are $C^{r,\ell}$ and $D^{\ell+1,s}$ respectively, where ℓ is some splitting point $r - 1 \leq \ell \leq s$. If $\ell = r - 1$ or $\ell = s$, then one of the children will be in the same cloud (r, s) as the ending cloud of the path given by v, and the other will be called a *nullified node*. This corresponds to the case where one of the *null* edges created in step 5 of the exact algorithm is taken.
3. If the path in $v \in \mathbb{T}$ ends at the sink of $\mathcal{T}$, then v must be a leaf in $\mathbb{T}$. If $A^{p,q}$ is the starting vertex of the path, this means that the path derives the entire substring $x_p \ldots x_q$ using only linear productions. Thus a node v is a leaf of $\mathbb{T}$ if and only if it either ends at the sink or is a nullified node. It follows from 2. and 3. that every non-leaf node has exactly 2 children.

Notation: To represent a node in $\mathbb{T}$ that is a path of cost c from $A^{p,q}$ to either $B^{r,s}$, or t, we will use the notation $[A^{p,q}, B^{r,s}, c]$, or $[A^{p,q}, t, c]$, respectively. If one of the arguments is either unknown or irrelevant, we write $\cdot$ as a placeholder. In the case of a nullified node, corresponding to the nullification of $A \in Q$, we write $[A, t, null(A)]$ to denote the node. Note, since we are now dealing with two *types* of graphs, to avoid confusion whenever we are talking about a vertex $A^{p,q}$ in any of the edit-distance graphs (such as $\mathcal{T}, \mathcal{T}^{\mathcal{A}}, \mathcal{T}^{OPT}$, ect), we will use the term *vertex*. When referring to the elements of a PET $\mathbb{T}$ we will use the term *node*. Also note that all error productions are linear.

We can now represent any sequence of edits produced by a language edit distance algorithm by such a PET, where the edit distance is given by the sum of the costs stored in the nodes of the tree. To be precise, if $[\cdot, \cdot, c_1], \ldots, [\cdot, \cdot, c_k]$ is the set of all nodes in $\mathbb{T}$, then the associated total cost $\|\mathbb{T}\| = \sum_{i=1}^{k} c_i$. Let $\mathcal{D}_{\mathcal{A}}$ be the set of PET's $\mathbb{T}$ compatible with a fixed approximation algorithm $\mathcal{A} \in \mathcal{F}$.

▶ **Definition 13** (PET's compatible with $\mathcal{A}$)**.** For an approximation algorithm $\mathcal{A} \in \mathcal{F}$, let $\mathcal{D}_{\mathcal{A}} \subset \mathcal{F}$ be the set of PET's $\mathbb{T}$ which satisfy the following constraints:

1. If $[A^{p,q}, B^{r,s}, \cdot]$ is a node in $\mathbb{T}$, where $A, B \in Q$, then $\mathcal{A}$ must compute non-linear edges for the cloud $(r, s) \in \mathcal{T}^{\mathcal{A}}$.
2. If $[C^{r,\ell}, \cdot, \cdot], [D^{\ell+1,s}, \cdot, \cdot]$ are the left and right children of a node $[A^{p,q}, B^{r,s}, \cdot]$ respectively, then $\mathcal{A}$ must consider the splitting point $\ell \in [p, q)$ when computing the weights of the non-linear edges in the cloud $(r, s) \in \mathcal{T}^{\mathcal{A}}$.

The set $\mathcal{D}_{\mathcal{A}}$ is then the set of all PET's which utilize only the non-linear productions and splitting points which correspond to edges that are actually constructed by the approximation algorithm $\mathcal{A}$ in $\mathcal{T}^{\mathcal{A}}$. Upon termination, any $\mathcal{A} \in \mathcal{F}$ will return the value $\|\mathbb{T}_{\mathcal{A}}\|$ where $\mathbb{T}_{\mathcal{A}} \in \mathcal{D}_{\mathcal{A}}$ is the tree corresponding to the shortest path from t to $S^{1,n}$ in $\mathcal{T}^{\mathcal{A}}$. The following theorem is not difficult to show.

▶ **Theorem 14.** *Fix any $\mathcal{A} \in \mathcal{F}$, and let c be the edit distance returned after running the approximation algorithm $\mathcal{A}$. Then if $\mathbb{T}$ is any PET in $\mathcal{D}_{\mathcal{A}}$, we have $c \leq \|\mathbb{T}\|$.*

Note that since the edges of $\mathcal{T}^{\mathcal{A}}$ are a subset of the edges of $\mathcal{T}^{OPT}$ considered by an exact algorithm OPT, we also have $c \geq \|\mathbb{T}_{OPT}\|$, where $\mathbb{T}_{OPT}$ is the PET given by the exact algorithm. To prove an upper bound on c, it then suffices to construct a explicit $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$, and put a bound on the size of $\|\mathbb{T}\|$. Thus, in the remainder of our analysis our goal will be to construct such a $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$. We now introduce our precision functions.

▶ **Definition 15** (Precision Functions)**.** For any cloud $(p, q) \in \mathcal{T}^{\mathcal{A}}$, let $\alpha(p, q)$ be any upper bound on the minimum distance $d^*((p, q), (r, s)) = (r - p) + (q - s)$ such that $p \leq r \leq s \leq q$ and $\mathcal{A}$ computes non-linear edge weights for the cloud (r, s) . Let $\beta(p, q)$ be an upper bound on the maximum distance between any two splitting points which are considered by $\mathcal{A}$ in the construction of the non-linear production edges originating in a cloud (r, s) such that $\mathcal{A}$ computes non-linear edge weights for (r, s) and $d^*((p, q), (r, s)) \leq \alpha(p, q)$. Furthermore, the precision functions must satisfy $\alpha(p, q) \geq \alpha(p', q')$ and $\beta(p, q) \geq \beta(p', q')$ whenever $(q - p) \geq (q' - p')$.

While the approximation algorithms presented in this paper are deterministic, the definitions of $\alpha(p, q)$ and $\beta(p, q)$ allow the remaining theorems to be easily adapted to algorithms which *randomly forget* to compute non-linear edges. While our paper considers only two explicit approximation algorithms, stating our results in this full generality substantially

easies the analysis. Both Theorems 4 and 5 will follow easily once general bounds are proven, and without the generality two distinct proofs would be necessary.

Constructing a PET $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$ similar to $\mathbb{T}_{OPT}$

Our goal is now to construct a PET $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$ with bounded cost. We do this by considering each node v of $\mathbb{T}_{OPT}$ and constructing a corresponding node u in $\mathbb{T}$ such that the path stored in u *imitates* the path in v as closely as possible. A perfect imitation may not be feasible if the path at v uses a non-linear production edge in a cloud that $\mathcal{A}$ does not compute non-linear edges for. Whenever this happens, we will need to move to the closest cloud which $\mathcal{A}$ does consider before making the *same* non-linear production that the exact algorithm did. Afterwards, the ending cloud of our path will deviate from that of the optimal, so we will need to bound the total deviation that can occur throughout the construction of our tree in terms of $\alpha(p,q)$ and $\beta(p,q)$. The following lemma will be used crucially in this regard for the proof of our construction in Theorem 17. The lemma takes as input a node $[A^{p,q}, B^{r,s}, c] \in \mathbb{T}_{OPT}$ and a cloud (p',q') such that $x_p,\dots,x_q$ is not disjoint from $x_{p'},\dots,x_{q'}$, and constructs a path $[A^{p',q'}, B^{r',s'}, c']$ of bounded cost that is compatible with a PET $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$.

▶ **Lemma 16.** *Let $[A^{p,q}, B^{r,s}, c]$ be any non-leaf node in $\mathbb{T}_{OPT}$, and let $\mathcal{A} \in \mathcal{F}$ be an approximation algorithm with precision functions $\alpha(p,q), \beta(p,q)$. If p', q' satisfy $p \le q'$ and $p' \le q$, then there is a path from $A^{p',q'}$ to $B^{r',s'}$, where $r \le r' \le s' \le s$, of cost $c' \le c + (|p'-p| + |q'-q|) - (|r'-r| + |s'-s|) + 2\alpha(r,s)$ such that $\mathcal{A}$ computes non-linear production edges for cloud (r',s'). Furthermore, for any leaf node $[A^{p,q}, t, c] \in \mathbb{T}_{OPT}$, we can construct a path from $A^{p',q'}$ of cost at most $c' \le c + (|p'-p| + |q'-q|)$ to the sink.*

We will now iteratively apply Lemma 16 to each node $v \in \mathbb{T}_{OPT}$ from the root down, transforming it into a new node $\psi(v) \in \mathbb{T}$. Here ψ will be a surjective function $\psi : V(\mathbb{T}_{OPT}) \to V(\mathbb{T})$. Lemma 16 will guarantee that the cost of $\psi(v)$ is not too much greater than that of v. If during the construction of $\mathbb{T}$, the substrings corresponding to v and $\psi(v)$ become disjoint, then we will transform the *entire* subtree rooted at v into a single node $\psi(v) \in \mathbb{T}$, thus the function may not be injective.

Let v be any node in $\mathbb{T}_{OPT}$, and u its parent node if v is not the root. Let $(p,q),(r,s) \in \mathcal{T}$ and $(p_v,q_v),(r_v,s_v) \in \mathcal{T}$ be the starting and ending clouds of u and v respectively. Similarly let $(p',q'),(r',s')$ and $(p'_v,q'_v),(r'_v,s'_v)$ be the starting and ending clouds of $\psi(u)$ and $\psi(v)$ respectively. Furthermore, let (p_X,q_X) and (p'_X,q'_X), where $X = L$ for left child and $X = R$ for right child, be the starting clouds of the left and right children of u and $\psi(u)$ respectively. Let c_v be the cost of v, and let $\overline{c_v}$ be the cost of v plus the cost of all the descendants of v. Finally, let c'_v be the cost of $\psi(v)$. An abbreviated version of Theorem 17 (see the full version for extended statement) relates the cost of v with $\psi(v)$ in terms of the starting and ending clouds by defining ψ inductively from the root of $\mathbb{T}_{OPT}$ down. The theorem uses Lemma 16 repeatedly to construct the nodes of $\mathbb{T}$.

▶ **Theorem 17.** *For any approximation algorithm $\mathcal{A} \in \mathcal{F}$ with precision functions α, β, there exists a PET $\mathbb{T} \in \mathcal{D}_{\mathcal{A}}$ and a PET mapping $\psi : V(\mathbb{T}_{OPT}) \to V(\mathbb{T})$ such that $\mathbb{T}_{OPT}$ can be partitioned into disjoint sets $U^1_{NL} \cup U^2_{NL} \cup U^1_L \cup U^2_L \cup X$ with the following properties. For $v \in \mathbb{T}_{OPT}$, if $v \in U^1_{NL} \cup U^2_{NL}$ then v satisfies (Non-leaf), and if $v \in U^1_L \cup U^2_L$ then v satisfies (Leaf):*

$$c'_v \le c_v + \big(|p'_v - p_v| + |q'_v - q_v|\big) - \big(|r'_v - r_v| + |s'_v - s_v|\big) + 2\alpha(r_v, s_v) \qquad \text{(Non-leaf)}$$

$$c'_v \le \overline{c_v} + |p'_v - p_v| + |q'_v - q_v| + \beta(r,s) \qquad \text{(Leaf)}$$

$$\textit{Furthermore } (|p'_L - p_L| + |q'_L - q_L|) + (|p'_R - p_R| + |q'_R - q_R|) \le |r'-r| + |s'-s| + 2\beta(r,s) \quad (*)$$

Let $\mathbb{T}'_{OPT} \subset \mathbb{T}_{OPT}$ be the subgraph of nodes v in the tree for which either v is the only node mapped to $\psi(v) \in \mathbb{T}$, or v is the node closest to the root that is mapped to $\psi(v)$. In the previous theorem, the set X corresponds to the nodes v for which $\psi(v) = \psi(u)$ such that u is an ancestor of v in $\mathbb{T}_{OPT}$. So $\mathbb{T}'_{OPT} = \mathbb{T}_{OPT} \setminus X$. The final theorem is the result of summing over the bounds from Theorem 17 for all $v_j \in \mathbb{T}'_{OPT}$, applying the appropriate bound depending on the set v_j belongs to.

▶ **Theorem 18.** *For any $\mathcal{A} \in \mathcal{F}$ with precision functions α, β, let $\mathbb{T}_{OPT}$ be the PET of any optimal algorithm. Label the nodes of $\mathbb{T}'_{OPT} \subset \mathbb{T}_{OPT}$ by $v_1 \dots v_K$. For $1 \leq i \leq K$, let $(p_i, q_i), (r_i, s_i)$ be the starting and ending clouds of the path v_i in $\mathcal{T}$, then*

$$|OPT| \leq |\mathcal{A}| \leq |OPT| + \sum_{v_j \in \mathbb{T}'_{OPT}} \Big(2\alpha(r_j, s_j) + 3\beta(r_j, s_j)\Big).$$

As an illustration of Theorem 18, consider the γ-uniform grid approximation of Theorem 4. In this case, we have the upper bound $\alpha(r_j, s_j) = \beta(r_j, s_j) = 2\gamma$ for all $v_j \in \mathbb{T}_{OPT}$. Since there are k^* total vertices in $\mathbb{T}_{OPT}$, we get $|OPT| \leq |\mathcal{A}| \leq |OPT| + 10\gamma k^*$. To analyze the running time, note that we only compute non-linear production edges for $(n/\gamma)^2$ clouds, and in each cloud that we compute non-liner edges for we consider at most n/γ break-points. Thus the total runtime is $O(|P|(\frac{n}{\gamma})^3)$ to compute non-linear edges, and $O(|P|n^2)$ to a shortest path algorithm on $\mathcal{T}^{\mathcal{A}}$, for a total runtime of $O(|P|(n^2 + (\frac{n}{\gamma})^3))$.

Our second illustration of Theorem 18 is the γ-non-uniform grid approximation of Theorem 5. Here we obtain a $O(k\gamma)$ additive approximation in time $O(|P|(n^2 + \frac{n^3}{\gamma^2}))$. A detailed analysis can be found in the full version.

Abstract

We provide evidence that computing the maximum flow value between every pair of nodes in a directed graph on n nodes, m edges, and capacities in the range $[1..n]$, which we call the All-Pairs Max-Flow problem, cannot be solved in time that is faster significantly (i.e., by a polynomial factor) than $O(n^2m)$. Since a single maximum st-flow in such graphs can be solved in time $\tilde{O}(m\sqrt{n})$ [Lee and Sidford, FOCS 2014], we conclude that the all-pairs version might require time equivalent to $\tilde{\Omega}(n^{3/2})$ computations of maximum st-flow, which strongly separates the directed case from the undirected one. Moreover, if maximum st-flow can be solved in time $\tilde{O}(m)$, then the runtime of $\tilde{\Omega}(n^2)$ computations is needed. This is in contrast to a conjecture of Lacki, Nussbaum, Sankowski, and Wulf-Nilsen [FOCS 2012] that All-Pairs Max-Flow in general graphs can be solved faster than the time of $O(n^2)$ computations of maximum st-flow.

Specifically, we show that in sparse graphs $G = (V, E, w)$, if one can compute the maximum st-flow from every s in an input set of sources $S \subseteq V$ to every t in an input set of sinks $T \subseteq V$ in time $O((|S||T|m)^{1-\varepsilon})$, for some $|S|$, $|T|$, and a constant $\varepsilon > 0$, then MAX-CNF-SAT (maximum satisfiability of conjunctive normal form formulas) with n' variables and m' clauses can be solved in time ${m'}^{O(1)}2^{(1-\delta)n'}$ for a constant $\delta(\varepsilon) > 0$, a problem for which not even $2^{n'}/\mathsf{poly}(n')$ algorithms are known. Such runtime for MAX-CNF-SAT would in particular refute the Strong Exponential Time Hypothesis (SETH). Hence, we improve the lower bound of Abboud, Vassilevska-Williams, and Yu [STOC 2015], who showed that for every fixed $\varepsilon > 0$ and $|S| = |T| = O(\sqrt{n})$, if the above problem can be solved in time $O(n^{3/2-\varepsilon})$, then some incomparable (and intuitively weaker) conjecture is false. Furthermore, a larger lower bound than ours implies strictly super-linear time for maximum st-flow problem, which would be an amazing breakthrough.

In addition, we show that All-Pairs Max-Flow in *uncapacitated* networks with every edge-density $m = m(n)$, cannot be computed in time significantly faster than $O(mn)$, even for acyclic networks. The gap to the fastest known algorithm by Cheung, Lau, and Leung [FOCS 2011] is a factor of $O(m^{\omega-1}/n)$, and for acyclic networks it is $O(n^{\omega-1})$, where ω is the matrix multiplication exponent.

1 Introduction

The maximum flow problem is one of the most fundamental problems in combinatorial optimization. This classic problem and its variations such as minimum-cost flow, integral flow, and minimum-cost circulation, were studied extensively over the past decades, and have become key algorithmic tools with numerous applications, in theory and in practice. Moreover, techniques developed for flow problems were generalized or adapted to other problems, see for example [6, 3, 5]. The maximum st-flow problem, which we shall denote Max-Flow, asks to ship the maximum amount of flow from a source node s to a sink node t in a directed edge-capacitated graph $G = (V, E, w)$, where throughout, we denote $n = |V|$ and $m = |E|$, and assume integer capacities bounded by U. After this problem was introduced in 1954 by Harris and Ross (see [22] for a historical account), Ford and Fulkerson [12] devised the first algorithm for Max-Flow, which runs in time $O((n+m)F)$, where F is the maximum value of a feasible flow. Ever since, a long line of generalizations and improvements was studied, and the current fastest algorithm for Max-Flow with arbitrary capacities is by Lee and Sidford [20], which takes $O(m\sqrt{n}\log U)$ time. For the case of small capacities and sufficiently sparse graphs, the fastest algorithm, due to Mądry [21], has a running time $\tilde{O}(m^{10/7}U^{1/7})$. Here and throughout, $\tilde{O}(f)$ denotes $O(f \log^c f)$ for unspecified constant $c > 0$.

A very natural problem is to compute the maximum st-flow for multiple source-sink pairs in the same graph G. The seminal work of Gomory and Hu [14] shows that in undirected graphs, Max-Flow for all $\binom{n}{2}$ source-sink pairs requires at most $n-1$ executions of Max-Flow (see also [15], where the $n-1$ computations are all on the input graph), and a lot of research aimed to extend this result to directed graphs, with several partial successes, see details in Section 1.1. However, it is still not known how to solve Max-Flow for multiple source-sink pairs faster than solving it separately for each pair, even in special cases like a single source and all possible sinks. We shall consider the following problems involving multiple source-sink pairs, where the goal is always to report the value of each flow (and not an actual flow attaining it).

▶ **Definition 1.1.** (Single-Source Max-Flow) Given a directed edge-capacitated graph $G = (V, E, w)$ and a source node $s \in V$, output, for every $t \in V$, the maximum flow that can be shipped in G from s to t.

▶ **Definition 1.2.** (All-Pairs Max-Flow) Given a directed edge-capacitated graph $G = (V, E, w)$, output, for every pair of nodes $u, v \in V$, the maximum flow that can be shipped in G from u to v.

▶ **Definition 1.3.** (ST-Max-Flow) Given a directed edge-capacitated graph $G = (V, E, w)$ and two subsets of nodes $S, T \subseteq V$, output, for every pair of nodes $s \in S$ and $t \in T$, the maximum flow that can be shipped in G from s to t.

▶ **Definition 1.4.** (Global Max-Flow) Given a directed edge capacitated graph $G = (V, E, w)$, output the maximum among all pairs $u, v \in V$, of the maximum flow value that can be shipped in G from u to v.

▶ **Definition 1.5.** (Maximum Local Edge Connectivity) Given a directed graph $G = (V, E)$, output the maximum among all pairs $u, v \in V$, of the maximum number of edge-disjoint uv-paths in G.

Note that in a graph with all edge capacities equal to 1, the problem of finding the maximum local edge connectivity is equivalent to finding the global maximum flow.

Table 1 Known algorithms for multiple-pairs Max-Flow. In this table, $T(n,m)$ is the fastest time to compute maximum st-flow in an undirected graph, ω is the matrix multiplication exponent, and $\gamma = \gamma(G)$ is a topological property of the input network that varies between 1 and $\Theta(n)$. In planar graphs, γ is the minimum number of faces required to cover all the nodes (i.e., every node is adjacent to at least one such face) over all possible planar embeddings [13].

Directed	Class	Problem	Runtime	Reference
No	General	All-Pairs (G-H Tree)	$(n-1)T(n,m)$	[14]
No	Uncapacitated Networks	All-Pairs (G-H Tree)	$\tilde{O}(mn)$	[7]

Yes	Planar	Single-Source	$O(n \log^3 n)$	[19]

1.1 Prior Work

We start with undirected graphs, where the All-Pairs Max-Flow values can be represented in a very succint manner, called nowdays *a Gomory-Hu* tree [14]. In addition to being very succint, it allows the flow values and the corresponding cuts (vertex partitions) to be quickly retrieved. See Table 1 for a list of previous algorithms for multiple pairs maximum st-flow, see Table 1. For directed graphs, no current algorithm computes the maximum flow between any $k = \omega(1)$ given pairs of nodes faster than the time of $O(k)$ separate Max-Flow computations. However, some results are known in special settings. It is possible to compute Max-Flow for $O(n)$ pairs in the time it takes for a single Max-Flow computation [16] and this result is used to find a global minimum cut. However, these pairs cannot be specified in the input.

For directed planar graphs, there is an $O(n \log^3 n)$ time algorithm for the Single-Source Max-Flow problem [19], which immediately yields an $O(n^2 \log^3 n)$ time algorithm for the All-Pairs version, that is much faster than the time of $O(n^2)$ computations of planar Max-Flow, a problem that can be solved in time $O(n \log n)$ [9]. Based on these results, it was conjectured in [19] that also in general graphs, All-Pairs Max-Flow can be solved faster than the time required for computing $O(n^2)$ separate maximum st-flows.

Several hardness results are known for multiple-pairs variants of Max-Flow [2]. For ST-Max-Flow in sparse graphs ($m = O(n)$) and $|S| = |T| = O(\sqrt{n})$, there is an $n^{3/2-o(1)}$ lower bound assuming at least one of the Strong Exponential Time Hypothesis (SETH), 3SUM, and All-Pairs Shortest-Paths (APSP) conjectures is correct (for a comprehensive survey on them, see [23]). In addition, they show that Single-Source Max-Flow on sparse graphs requires $n^{2-o(1)}$ time, unless MAX-CNF-SAT can be solved in time $2^{(1-\delta)n}\mathsf{poly}(m)$ for some fixed $\delta > 0$, and in particular SETH is false.

We will mostly rely on SETH, a conjecture introduced by [17], and on some weaker assumption related to its maximization version, MAX-CNF-SAT. In more detail, SETH states that for every fixed $\varepsilon > 0$ there is an integer $k \geq 3$ such that k-SAT on n variables and m clauses cannot be solved in time $2^{(1-\varepsilon)n}\mathsf{poly}(m)$, where $\mathsf{poly}(m)$ refers to $O(m^c)$ for unspecified constant c. By the sparsification lemma [18], in order to refute SETH it can be assumed that the number of clauses is $O(n)$. The MAX-CNF-SAT problem asks for the maximum number of clauses that can be satisfied in an input CNF formula. Most

of our conditional lower bounds are based on the assumption that for every fixed $\delta > 0$, MAX-CNF-SAT cannot be solved in time $2^{(1-\delta)n}\mathsf{poly}(m)$, where currently even $2^n/\mathsf{poly}(n)$ algorithms are not known for this problem [2]. Note that this is a weaker assumption than SETH, since a faster algorithm for MAX-CNF-SAT would imply a faster algorithm for CNF-SAT and refute SETH. Different assumptions regarding the hardness of CNF-SAT have been the basis for many lower bounds, including for the runtime of solving NP-hard problems exactly, parametrized complexity, and problems in P. See the Introduction in [1] and the references therein.

1.2 Our Contribution

We present conditional runtime lower bounds for both uncapacitated and capacitated networks. The proofs appear in sections 2 and 3, respectively, where the order reflects increasing level of complication. All our lower bounds hold even when the input G is a DAG and has a constant diameter, and in the case of general capacities, they can be easily modified to apply also for graphs with constant maximum degree. In addition, for integer $k \geq 1$ we use the notation $[k]$ to denote the range $\{1, ..., k\}$.

Capacitated Networks

Our main result is that for every set sizes $|S|$ and $|T|$, the ST-Max-Flow cannot be solved significantly faster than $O(|S||T|m)$ (i.e., polynomially smaller runtime), unless a breakthrough in MAX-CNF-SAT is achieved, and consequently in SETH.

▶ **Theorem 1.6.** *If for some fixed $\varepsilon > 0$ and some (possibly functions of n) set sizes $|S|$ and $|T|$, ST-Max-Flow can be solved in graphs with n nodes, $m = O(n)$ edges and capacities in $[n]$ in time $O((|S||T|m)^{1-\varepsilon})$, then for some $\delta(\varepsilon) > 0$, MAX-CNF-SAT on n' variables and $O(n')$ clauses can be solved in time $2^{(1-\delta)n'}\mathsf{poly}(n')$, and in particular SETH is false.*

This result improves the aforementioned $n^{3/2-o(1)}$ lower bound of [2], as for their setting of $|S| = |T| = O(\sqrt{n})$ our lower bound is $n^{2-o(1)}$, although their lower bound is based on an incomparable (and intuitively weaker) conjecture, that at least one of the SETH, 3SUM, and APSP conjectures is correct. In fact, if there was a reduction from SETH that implied a larger runtime lower bound for ST-Max-Flow, then the (single-pair) Max-Flow problem would require a strictly super-linear time under it, but such a reduction is not possible unless the non-deterministic version of SETH (abbreviated NSETH) is false [10]. And anyway, such a lower bound for Max-Flow would be an amazing breakthrough.

The next theorem is an immediate corollary of Theorem 1.6, by assigning $|S|, |T| = \Theta(n)$.

▶ **Theorem 1.7.** *If for some fixed $\varepsilon > 0$, All-Pairs Max-Flow in graphs with n nodes, $m = O(n)$ edges, and capacities in $[n]$ can be solved in time $O((n^2m)^{1-\varepsilon})$, then for some $\delta(\varepsilon) > 0$, MAX-CNF-SAT on n' variables and $O(n')$ clauses can be solved in time $2^{(1-\delta)n'}\mathsf{poly}(n')$, and in particular SETH is false.*

This conditional lower bound (see Figure 1) shows that All-Pairs Max-Flow requires time that is equivalent to $\Omega(n^{3/2})$ computations of Max-Flow, which strongly separates the directed case from the undirected one (where a Gomory-Hu tree can be constructed in the time of $n-1$ computations). If Max-Flow takes $\tilde{O}(m)$ time, which is currently open but plausible, then the running time of $\tilde{\Omega}(n^2)$ computations of Max-Flow is needed. This is in contrast to the aforementioned conjecture of Lacki, Nussbaum, Sankowski, and Wulf-Nilsen [19] that All-Pairs Max-Flow in general graphs can be solved faster than the time of $O(n^2)$ computations of maximum st-flow.

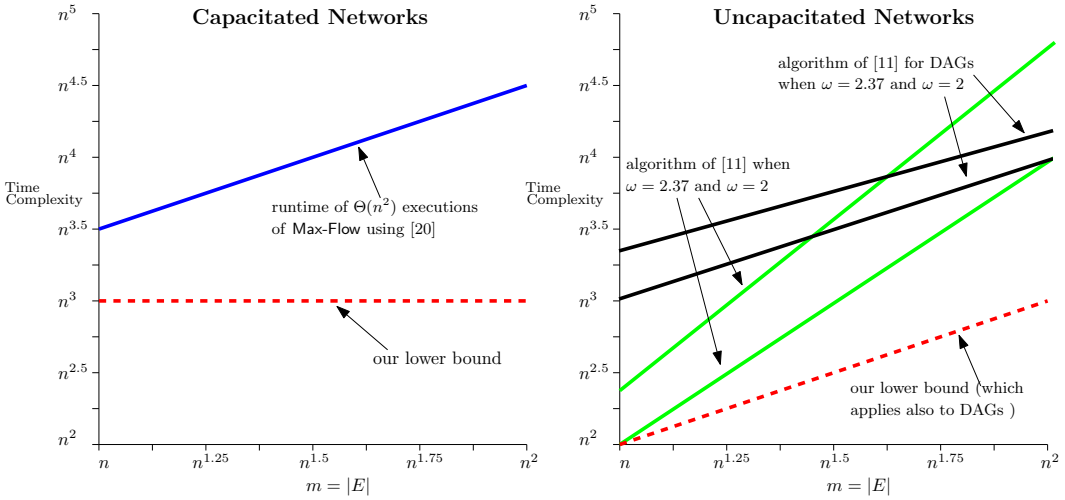

Figure 1 State of the art bounds for All-Pairs Max-Flow in directed networks. Conditional lower bounds are depicted in dashed lines, and known algorithms in solid lines.

Uncapacitated Networks

For the case of uncapacitated networks, we show that for every $m = m(n)$, All-Pairs Max-Flow cannot be solved significantly faster than $O(mn)$. Here we introduce a new technique to design reductions from SETH to graphs with varying edge densities, rather than the usual reductions that only deal with sparse graphs. Our technique is based on partitioning the variables set of CNF-SAT to different sizes.

▶ **Theorem 1.8.** *If for some fixed $\varepsilon > 0$ and some $m = m(n) \in [n, n^2]$, All-Pairs Max-Flow in uncapacitated graphs with n nodes and m edges can be solved in time $O((nm)^{1-\varepsilon})$, then for some $\delta(\varepsilon) > 0$, MAX-CNF-SAT on n' variables and $O(n')$ clauses can be solved in time $2^{(1-\delta)n'}\mathsf{poly}(n')$, and in particular SETH is false.*

Hence, a certain additional improvement to the $O(m^\omega)$ time algorithm of [11] (and similarly to the $O(n^\omega m)$ time for DAGs, where our lower bounds apply too) is not likely. We now present conditional lower bounds for ST-Max-Flow, which are functions of $|S|$ and $|T|$.

▶ **Theorem 1.9.** *If for some fixed $\varepsilon > 0$ and some (possibly functions of n) set sizes $|S|$ and $|T|$, ST-Max-Flow on uncapacitated graphs with n nodes and $O((|S| + |T|)n)$ edges can be solved in time $O((|S||T|n)^{1-\varepsilon})$, then for some $\delta(\varepsilon) > 0$, MAX-CNF-SAT on n' variables and $O(n')$ clauses can be solved in time $2^{(1-\delta)n'}\mathsf{poly}(n')$, and in particular SETH is false.*

Finally, we present a conditional lower bound for computing the Maximum Local Edge Connectivity of a sparse graph, which is the same as Global Max-Flow if all the capacities are 1, which is indeed the case in our reduction. In the Orthogonal Vectors problem the input is two sets U and V, each of n vectors from $\{0,1\}^d$, and the goal is to determine whether there are $u \in U$ and $v \in V$ such that $\sum_{i=1}^{d} u_i \cdot v_i = 0$. An equivalent version of the problem has $U = V$. For $d = \omega(\log n)$, Williams [24] proved that SETH implies the non-existence of a truly subquadratic (in n) algorithm for the problem. The next result, proved in Section 4, was obtained together with Bundit Laekhanukit and Rajesh Chitnis, and we thank them for their permission to include it here.

▶ **Theorem 1.10.** *If for some fixed $\varepsilon > 0$, the Maximum Local Edge Connectivity in graphs with n nodes and $\tilde{O}(n)$ edges can be found in time $O(n^{2-\varepsilon})$, then for some $\delta(\varepsilon) > 0$, the Orthogonal Vectors problem on n' vectors and every $d = \mathsf{polylog}(n')$ can be solved in time $O(n'^{2-\delta})$, and in particular SETH is false.*

2 Reduction to Multiple-Pairs Max-Flow with Unit Capacity

In this section we prove Theorems 1.8 and 1.9. We start with a general lemma which is the heart of the proofs.

▶ **Lemma 2.1.** *Let $a \in [0,1]$ and $b \in [0, 1-a]$. Then MAX-CNF-SAT on n variables and m clauses can be reduced to $O(m)$ instances of ST-Max-Flow with $|S| = 2^{an}$ and $|T| = 2^{bn}$ in graphs with $\Theta(2^{an} + 2^{(1-a-b)n}m + 2^{bn})$ nodes, $\Theta((2^{an} + 2^{bn}) \cdot 2^{(1-a-b)n}m)$ edges, and capacities in $\{0,1\}$.*

Proof. Given a CNF-formula F on n variables and m clauses $\{C_i\}_{i\in[m]}$ as input for MAX-CNF-SAT, $a \in [0,1]$, and $b \in [0, 1-a]$, we split the variables into three sets U_1, U_2, and U_3, where U_1 is of size an, U_2 is of size $(1-a-b)n$, and U_3 is of size bn, and enumerate all their 2^{an}, $2^{(1-a-b)n}$, and 2^{bn} partial assignments (with respect to F), respectively, when the objective is to find a triple α, β, γ of assignments to U_1, U_2, and U_3 respectively, that satisfies the maximal number of clauses. We will have an instance G_p of ST-Max-Flow for each value $p \in [m]$, in which by one call to ST-Max-Flow we check if there exists a triple α, β, and γ that satisfies at least p clauses, as follows.

We construct a graph G_p for every $p \in [m]$ on N nodes $V_1 \cup V_2 \cup V_3$, where V_1 contains a node α for every assignment α to U_1, V_2 contains $2m + 1 + (p-1) = 2m + p$ nodes for every assignment β to U_2, that are β_i^l and β_i^r for every $i \in [m]$, β', and the set $\{\beta'^i\}_{i\in[p-1]}$, and V_3 contains a node γ for every assignment γ to U_3. We use the notation α for nodes in V_1 and for assignments to U_1, β for assignments to U_2, and γ for nodes in V_3 and assignments to U_3. However, it will be clear from the context. Now, we have to describe the edges in the network. In order to simplify the reduction, we partition the edges into blue and red colors, as follows.

For every α, β, and $i \in [m]$, we add a blue edge from α to β_i^l if both of α and β do not satisfy the clause C_i (do not set any of the literals to true), and otherwise we add a red edge from α to β_i^r. We further add, for every β, γ, and $i \in [m]$, a blue edge from β_i^l to γ if γ does not satisfy C_i. For every β, γ, and $j \in [p-1]$, we add a red edge from every β'^j to every γ. For every β and $i \in [m]$, we add a red edge from β_i^l to β_i^r and from β_i^r to β', and finally for every β and $j \in [p-1]$, we add a red edge from β' to β'^j, where all edges are of capacity 1.

The graph we built has $2^{an} + 2 \cdot 2^{(1-a-b)n}m + 2^{(1-a-b)n} + 2^{(1-a-b)n}(p-1) + 2^{bn} = \Theta(2^{an} + 2^{(1-a-b)n}m + 2^{bn})$ nodes, $2^{an} \cdot 2^{(1-a-b)n}m + 2^{bn} \cdot 2^{(1-a-b)n}m + 2 \cdot 2^{(1-a-b)n}m + (p-1)2^{(1-a-b)n} + 2^{bn} \cdot (p-1)2^{(1-a-b)n} = \Theta((2^{an} + 2^{bn}) \cdot 2^{(1-a-b)n}m)$ edges, with capacities in $\{0,1\}$ (see Figure 2), and its construction time is asymptotically the same as the time it takes to construct its edges set.

For every α, β, and γ, we denote by $G_p^{\alpha,\beta,\gamma}$ the graph induced from G_p on the nodes

$$(\alpha, \beta', \gamma) \cup \left(\bigcup_{\substack{y\in\{l,r\} \\ i\in[m]}} \beta_i^y \right) \cup \left(\bigcup_{j\in[p-1]} \beta'^j \right).$$

We claim that for every α and γ, the maximum flow from α to γ can be bounded by the sum, over all β, of the maximum flow between them in $G_p^{\alpha,\beta,\gamma}$. This claim follow easily

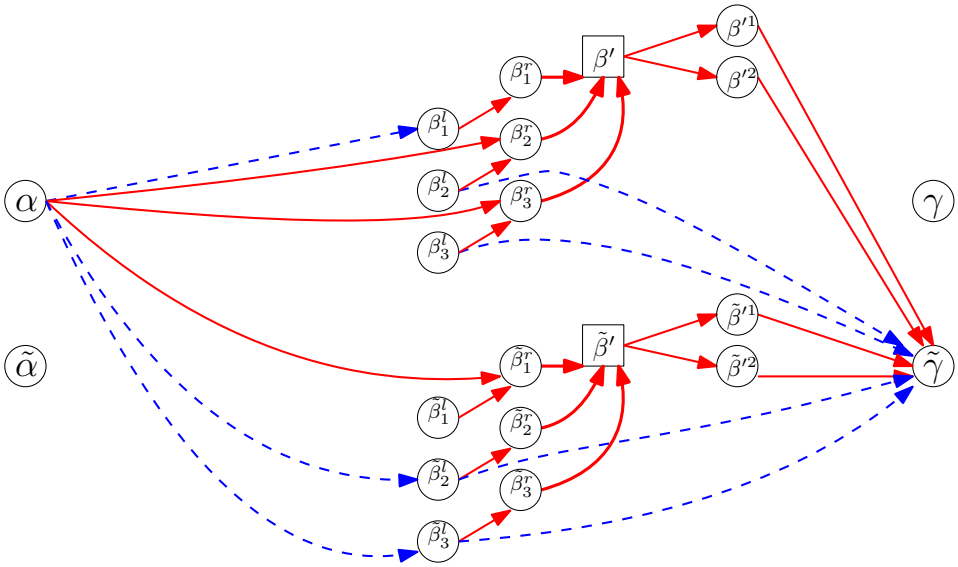

Figure 2 An illustration of part of the reduction. Here, U_1, U_2, and U_3 have 2 assignments each, α and $\tilde{\alpha}$ to U_1, β and $\tilde{\beta}$ to U_2, and γ and $\tilde{\gamma}$ to U_3. Blue edges are dashed. For simplicity, only the edges of $G_3^{\alpha,\beta,\tilde{\gamma}} \cup G_3^{\alpha,\tilde{\beta},\tilde{\gamma}}$ are presented. In this illustration, α does not satisfy anything, β satisfies C_2 and C_3, $\tilde{\beta}$ satisfies C_1, and $\tilde{\gamma}$ satisfies C_1. Note that the assignment comprised of α, β, and $\tilde{\gamma}$ satisfies all the clauses, and indeed the maximum flow from α to γ is $2 \cdot 3 - 1 = 5$.

because the intersection $G_p^{\alpha,\beta_1,\gamma} \cap G_p^{\alpha,\beta_2,\gamma}$ for $\beta_1 \neq \beta_2$ is exactly the source and the sink $\{\alpha, \gamma\}$, no edge passes between these two graphs, and $\left(\bigcup_\beta G_i^{\alpha,\beta,\gamma}\right)$ consists of all nodes that are both reachable from α and γ is reachable from them.

We now prove that if there is an assignment to F that satisfies at least p clauses then the graph G_p we built has a triple α, β, γ with maximum flow from α to γ in $G_p^{\alpha,\beta,\gamma}$ at most $m-1$. Since for every $\tilde{\beta}$, m is the number of outgoing edges from α in $G_p^{\alpha,\tilde{\beta},\gamma}$, m is also an upper bound for the maximum flow from α to γ in it, and hence in G_p it is at most $2^{(1-a-b)n}m - 1$. Otherwise, we will show that every triple α, β, γ has a maximum flow from α to γ in $G_p^{\alpha,\beta,\gamma}$ of size at least m, and so in G_p it is at least $2^{(1-a-b)n}m$. Hence, by simply picking the maximal $j \in [m]$ such that the maximum flow in G_j of some pair α, γ is at most $2^{(1-a-b)n}m - 1$, and then iterating over all assignments β to U_2 with α and γ fixed as the assignments to U_1 and U_3, we can also find the required triple α, β, γ.

For the first direction, assume that F has an assignment that satisfies at least p clauses, and denote such assignment by Φ. Let α_Φ, β_Φ, and γ_Φ be the assignments to U_1, U_2, and U_3, respectively, that are induced from Φ. Since a blue path from α_Φ through $\beta_{\Phi_i}^l$ for some $i \in [m]$ to γ_Φ corresponds to α_Φ, β_Φ, and γ_Φ all do not satisfy C_i, in $G_p^{\alpha_\Phi,\beta_\Phi,\gamma_\Phi}$ there are at most $m - p$ (internally) disjoint blue paths from α to γ. As the only way to ship flow in $G_p^{\alpha_\Phi,\beta_\Phi,\gamma_\Phi}$ that is not through a blue path is through the node β'_Φ, and the total number of edges going out of this node is $p-1$, we conclude that the total maximum flow in $G_p^{\alpha_\Phi,\beta_\Phi,\gamma_\Phi}$ from α_Φ to β_Φ is bounded by $m - p + (p-1) = m - 1$. Since for every β, the maximum amount of flow that can be shipped in $G_p^{\alpha_\Phi,\beta,\gamma_\Phi}$ from α_Φ to γ_Φ is at most m, summing over all β we get that the total flow in G_p from α_Φ to γ_Φ is bounded by $(2^{(1-a-b)n} - 1)m + (m-1) \leq 2^{(1-a-b)n}m - 1$, as required.

For the second direction, assume that every assignment to F satisfies at most $p-1$ clauses. In order to show that the maximum flow from every α to every γ is at least $2^{(1-a-b)n}m$,

we first fix α, β, and γ. Then, by passing flow in two phases we show that m units of flow can be passed in $G_p^{\alpha,\beta,\gamma}$ from α to γ. As this argument applies for every β, we can add up the respective flows without violating capacities, concluding the proof. By the assumption, there exist $m-(p-1)=m-p+1$ i's, such that α, β, and γ do not satisfy C_i, and we denote a set with this amount of such i's by I_β. Each of these i's induces a blue path $(\alpha \to \beta_i^l \to \gamma)$ from α to γ in $G_p^{\alpha,\beta,\gamma}$, and so we ship a unit of flow through every one of them according to I_β, in what we call the first phase. In the second phase, we ship additional $m-(m-p+1)=p-1$ units in the following way. Let $A_1 := \{i \in [m] \setminus I_\beta : \alpha \nvDash C_i \wedge \beta \nvDash C_i\}$, and $A_2 := ([m] \setminus I_\beta) \setminus A_1 = \{i \in [m] \setminus I_\beta : \alpha \vDash C_i \vee \beta \vDash C_i\}$, where $\alpha \vDash C_i$ denotes that the assignment α satisfies C_i (as defined earlier), and $\alpha \nvDash C_i$ denotes that it does not satisfy C_i. Let $f : A_1 \cup A_2 \to [m-|I_\beta|]$ be a bijective function such that the range of A_1 is $[|A_1|]$ and the range of A_2 is $[m-|I_\beta|] \setminus [|A_1|]$. Clearly, there exists such bijection and it is easy to find one. For every $i \in A_1$ we ship flow through the path $(\alpha \to \beta_i^l \to \beta_i^r \to \beta' \to \beta'^j \to \gamma)$, and for every $i \in A_2$ through the path $(\alpha \to \beta_i^r \to \beta' \to \beta'^j \to \gamma)$, in both cases with $j = f(i)$.

Since we defined the flow in paths, we only need to show that the capacity requirements hold, and we start with blue edges. Indeed, edges of the form (α, β_i^l) are used in the first phase, with flow that is determined uniquely by β and $i \in I_\beta$, and in the second phase uniquely according to β and $i \in [m] \setminus I_\beta$, and so they cannot be used twice. Edges of the form (β_i^l, γ) are only used in the first phase, and their flow is uniquely determined according to β and $i \in I_\beta$, and so are good too. We now proceed to red edges, which were used only in the second phase.

Edges of the forms (α, β_i^r), (β_i^l, β_i^r) and (β_i^r, β') have flow that is uniquely determined by β and $i \in [m] \setminus I_\beta$, and so are not used more than once. Edges of the form (β', β'^j) have flow that is uniquely determined by β and $j = f(i) \in [p-1]$, and since f is a bijection, every j has at most one i such that $f(i) = j$, and so these edges are also used at most once. As a byproduct, and since every edge of the form (β'^j, γ) has only the edge (β', β'^j) as its source for flow, edges of the form (β'^j, γ) are also used at most once. Altogether, we have bounded the total flow in all edges that were used in both phases, and so the capacity requirements follow, which completes the proof of the second direction and of Lemma 2.1. ◀

Proof of Theorem 1.8. We apply Lemma 2.1 in the following way. By setting $a = b \in [1/3, 1/2]$ we get graphs $G = (V, E, w)$ with $|V| = \Theta(2^{an})$ ($|V| = \Theta(2^{an})m$ if $a = 1/3$) and $|E| = 2^{(1-a)n}m$. Hence, $|E| = O(|V|^{1/a-1})$ and we get our desired bound for every $|E|$ between $|V|$ and $|V|^2$ and Theorem 1.8 follows. ◀

Proof of Theorem 1.9. Here we apply Lemma 2.1 a bit differently. By setting $a, b \leq 1/3$ we get graphs $G = (V, E, w)$ with $|V| = \Theta(2^{(1-a-b)n}m)$ and $|E| = \Theta((2^{an} + 2^{bn})2^{(1-a-b)n}m)$. By setting $|S| = |V|^{a/(1-a-b)}$ and $|T| = n^{b/(1-a-b)}$ we get our lower bound for $|E| = O((|S| + |T|)|V|)$ and Theorem 1.9 follows. ◀

3 Reduction to Multiple-Pairs Max-Flow in Capacitated Networks

In this section we prove Theorems 1.6 and 1.7. We proceed to prove our main technical lemma.

▶ **Lemma 3.1.** *MAX-CNF-SAT on n variables and m clauses $\{C_i\}_{i\in[m]}$ can be reduced to $O(m)$ instances of ST-Max-Flow, each with the property that $S \cap T = \emptyset$, and all of them are in graphs with $N = \Theta(2^{n/3}m)$ nodes, $O(2^{n/3}m) = O(N)$ edges, and with capacities in $[N]$.*

Proof. Given a CNF-formula F on n variables and m clauses as input for MAX-CNF-SAT, we split the variables into three sets U_1, U_2, and U_3 of size $n/3$ each and enumerate all $2^{n/3}$ partial assignments (with respect to F) to each of them, when the objective is to find a triple (α, β, γ) of assignments to U_1, U_2, and U_3, that satisfy the maximal number of clauses. We will have an instance G_p of ST-Max-Flow with the mentioned property for each value $p \in [m]$, in which by one call to ST-Max-Flow we check if there exists a triple (α, β, γ) that satisfies at least p clauses, as follows.

We construct the graph G_p on N nodes $V_1 \cup V_2 \cup V_3 \cup A \cup B \cup \{v_B\}$, where V_1 contains a node α for every assignment α to U_1, V_2 contains $3m+1$ nodes for every assignment β to U_2, that are β_i^l, β_i^c, β_i^r, for every $i \in [m]$, and β', V_3 contains a node γ for every assignment γ to U_3, A contains two nodes $C_i^{\models}$ and $C_i^{\not\models}$ for every clause C_i, and B contains a node C_i for every clause C_i. We use the notation α for nodes in V_1 and assignments to U_1, β to assignments to U_2, γ for nodes in V_3 and assignments to U_3, and C_i for nodes in B and clauses. However, it will be clear from the context. Now, we have to describe the edges in the network. In order to simplify the reduction, we partition the edges into red and blue colors, as follows.

For every α and $i \in [m]$ we add a red edge of capacity $2^{n/3}$ from α to $C_i^{\models}$ if $\alpha \models C_i$, and a blue edge of the same capacity from α to $C_i^{\not\models}$ otherwise. We further add, for every β, a red edge of capacity 1 from $C_i^{\models}$ to β_i^c, a blue edge of capacity 1 from $C_i^{\not\models}$ to β_i^l, a blue edge of capacity 1 from β_i^l to β_i^r if $\beta \not\models C_i$, a red edge of capacity 1 from β_i^c to β', and a blue edge of capacity 1 from β_i^r to C_i. For every β we add a red edge of capacity $p-1$ from β' to v_B. For every γ we add a red edge of capacity $2^{n/3}(p-1)$ from v_B to $\gamma \in V_3$, and finally, for every γ and $i \in [m]$ we add a blue edge of capacity $2^{n/3}$ from C_i to γ if $\gamma \not\models C_i$.

The graph we built has $N = 2^{n/3} + 2m + 2^{n/3} \cdot 3m + 2^{n/3} + 1 + m + 2^{n/3} = \Theta(2^{n/3}m)$ nodes, at most $2^{n/3}m + 2^{n/3} \cdot 2m + 2^{n/3} \cdot 2m + 2^{n/3}m + 2^{n/3} + 1 + 2^{n/3}m + 2^{n/3}m = O(2^{n/3}m)$ edges, all of its capacities are in $[N]$, and its construction time is $O(Nm)$ (see Figure 3).

We proceed to prove that if there is an assignment to F that satisfies at least p clauses then the graph G_p we built has a pair α, γ with maximum flow from α to γ at most $2^{n/3}m - 1$, and otherwise, every α, γ has a maximum flow of size at least $2^{n/3}m$. Hence, by simply picking the maximal $j \in [m]$ such that the maximum flow in G_j of some pair α, γ is at most $2^{n/3}m - 1$, and then iterating over all assignments β to U_2 with α and γ fixed as the assignments to U_1 and U_3, we can also find the required triple α, β, γ.

For the first direction, assume that F has an assignment that satisfies at least p clauses, and denote such assignment by Φ. Let α_Φ, β_Φ, and γ_Φ be the assignments to U_1, U_2, and U_3, respectively, that are induced from Φ. We will show that there exists an $(\alpha_\Phi, \gamma_\Phi)$ cut whose capacity is at most $2^{n/3}m - 1$, hence by the Min-Cut Max-Flow theorem, the maximum flow from α_Φ to γ_Φ is bounded by this number, concluding the proof of the first direction. We define the cut in a way that for every $\beta \neq \beta_\Phi$, the cut will have m cut edges that are contributed from nodes related to β, and nodes related to β_Φ will be carefully added to either side of the cut so that they will contribute capacity of only $m-1$ to the cut. To be more precise, we define a suitable cut as follows.

$$S = \{\alpha_\Phi, \beta'_\Phi\} \cup \{C_i^{\models} : \alpha_\Phi \models C_i\} \cup \{C_i^{\not\models} : \alpha_\Phi \not\models C_i\} \cup \{{\beta_\Phi}_i^c : i \in [m]\}$$
$$\cup \{C_i, {\beta_\Phi}_i^l, {\beta_\Phi}_i^r : \gamma_\Phi \models C_i\} \cup \{{\beta_\Phi}_i^l : \gamma_\Phi \not\models C_i \wedge \beta_\Phi \models C_i\}$$

▶ **Claim 3.2.** *The cut $(S, V \setminus S) = (S, T)$ has capacity $2^{n/3}m - 1$.*

Proof of Claim. We will go over all the nodes in S, and count the total capacity leaving to nodes in T for each of them. $\alpha_\Phi \in S$ and all nodes $C_i^{\models}$ and $C_i^{\not\models}$ that are adjacent to it are in S too, hence it does not contribute anything. For every $i \in [m]$, we have two cases for

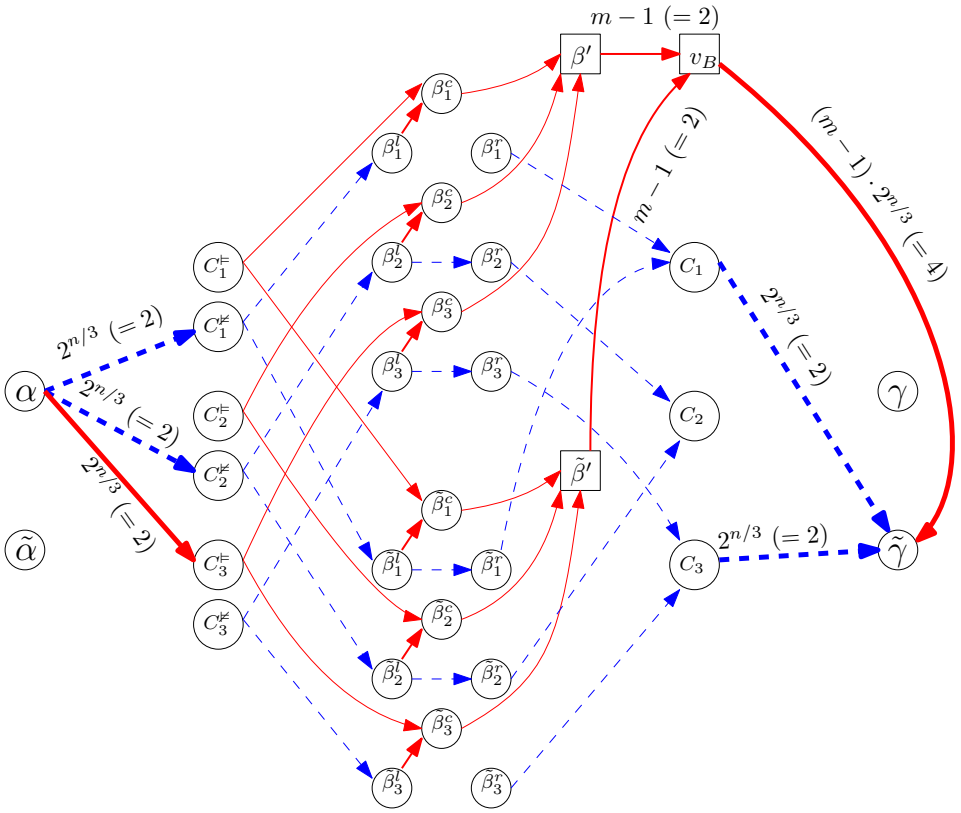

Figure 3 An illustration of part of the reduction, with $p = m$. Here, U_1, U_2, and U_3 have 2 assignments each; α and $\tilde{\alpha}$ to U_1, β and $\tilde{\beta}$ to U_2, γ and $\tilde{\gamma}$ to U_3. Bolder edges correspond to edges of higher capacity (specified wherever they are bigger than 1), and blue edges are dashed. For simplicity, only the edges relevant to α and $\tilde{\gamma}$ are presented. In this illustration, α satisfies C_3, β satisfies C_1, $\tilde{\beta}$ satisfies C_3, and $\tilde{\gamma}$ satisfies C_2. Note that the assignment comprised of α, β, and $\tilde{\gamma}$ satisfies all the clauses, and indeed the maximum flow from α to γ is $2 \cdot 3 - 1 = 5$.

nodes in A. If $\alpha_\Phi \vDash C_i$ then $C_i^{\nvDash} \in T$ and hence $C_i^{\nvDash}$ does not contribute anything. However, $C_i^{\vDash}$ has $2^{n/3}$ outgoing edges, where all except ${\beta_\Phi}_i^c$ are in T. Hence, it contributes $2^{n/3} - 1$ to the cut. Else, if $\alpha_\Phi \nvDash C_i$ then $C_i^{\vDash} \in T$ and hence $C_i^{\vDash}$ does not contribute anything. But $C_i^{\nvDash}$ has $2^{n/3}$ outgoing edges, of which $2^{n/3} - 1$ are cut edges as their targets are in T, and the one incoming to ${\beta_\Phi}_i^l$ is a cut edge if and only if ${\beta_\Phi}_i \nvDash C_i$ and also $\gamma_\Phi \nvDash C_i$ (equivalently, ${\beta_\Phi}_i^l \in T$), and in our current case it means that $\Phi \nvDash C_i$. Hence, for every $i \in [m]$, the nodes in $\{C_i^{\vDash}, C_i^{\nvDash}\}$ contribute $2^{n/3} - 1$ to the cut if $\Phi \vDash C_i$, and $2^{n/3}$ otherwise. Since there are at most $m - p$ clauses that are not satisfied by Φ, summing over all $i \in [m]$ would yield a total of at most $p(2^{n/3} - 1) + (m - p)(2^{n/3}) = 2^{n/3}m - p$ cut edges for vertices with origin in A.

For every $\beta \neq \beta_\Phi$, all nodes in V_2 that are associated with β, v_B, and γ_Φ, are in T and hence will not contribute anything to the cut. However, the node ${\beta_\Phi}'$ is always in S, with v_B its sole target, and hence the edge $({\beta_\Phi}', v_B)$ is in the cut and ${\beta_\Phi}'$ contributes an additional amount of $p - 1$, to a current total of at most $2^{n/3}m - p + (p - 1) = 2^{n/3}m - 1$. In addition, ${\beta_\Phi}'$ is the only target of ${\beta_\Phi}_i^c$, and thus ${\beta_\Phi}_i^c$ will not contribute to the cut.

We will show that the rest of the nodes, i.e., nodes in V_2 that are associated with β_Φ, and the nodes in B, contribute nothing to the cut. For every $i \in [m]$, ${\beta_\Phi}_i^l \in S$ if and only if either $\beta_\Phi \vDash C_i$ or $\gamma_\Phi \vDash C_i$. It always happens that ${\beta_\Phi}_i^c \in S$, and ${\beta_\Phi}_i^r \in T$ if and only if

$\gamma_\Phi \nvDash C_i$, but in such case it must be that $\beta_\Phi \vDash C_i$, which implies that the edge $(\beta_{\Phi_i}^{\ l}, \beta_{\Phi_i}^{\ r})$ is not in the graph, thus the total contribution of $\beta_{\Phi_i}^{\ l}$ is zero.

For every $i \in [m]$, it is easy to verify that each of the following four implies the rest. $\beta_{\Phi_i}^{\ r} \in S$, $\gamma_\Phi \vDash C_i$, $C_i \in S$, and the edge (C_i, γ_Φ) is not in the graph. In the case where C_i and $\beta_{\Phi_i}^{\ r}$ are in T it is clear that they do not contribute anything, so we will focus on the other case. Since C_i is the only target of $\beta_{\Phi_i}^{\ r}$, $\beta_{\Phi_i}^{\ r}$ will not increase the cut capacity. In addition, since the edge (C_i, γ_Φ) is not in the graph, C_i does not increase the capacity of the cut either. Altogether we have bounded the total capacity of the cut by $2^{n/3}m - 1$, finishing the proof of Claim 3.2. ◀

Proceeding with the proof of Lemma 3.1, we now focus on the second direction. Assume that every assignment to F satisfies at most $p-1$ clauses. We remind that we need to prove that the maximum flow from every α to every γ is at least $2^{n/3}m$, and to do this we first fix α and γ. By the assumption, for every β there exist $m-(p-1) = m-p+1$ i's, such that α, β, and γ do not satisfy C_i, and we denote a set with this amount of such i's by I_β. Each of these i's induces a blue path $(\alpha \to C_i^{\nvDash} \to \beta_i^l \to \beta_i^r \to C_i \to \gamma)$ from α to γ, and so we pass a unit of flow through every one of them according to I_β, and for all β, in what we call the first phase. We note that so far, the flow sums up to $2^{n/3}(m-p+1)$, and so we carry on with shipping the second phase of flow through paths that are not entirely blue.

We claim that for every β, we can pass an additional amount of $m-(m-p+1) = p-1$ units through β', which would add up to a total flow of $2^{n/3}(m-p+1)+2^{n/3}(p-1) = 2^{n/3}m$, concluding the proof. Indeed, for every β, we ship flow in the following way. For every $i \in [m] \setminus I_\beta$, if $\alpha \nvDash C_i$ then send a unit through $(\alpha \to C_i^{\nvDash} \to \beta_i^l \to \beta_i^c \to \beta' \to v_B \to \gamma)$, and otherwise send a unit through $(\alpha \to C_i^{\vDash} \to \beta_i^c \to \beta' \to v_B \to \gamma)$.

Since we defined the flow in paths, we only need to show that the capacity constraints are satisfied, starting with edges of color blue. Edges of the forms (β_i^l, β_i^r), (β_i^r, C_i), and (C_i, γ) are only used in the first phase, where the flow in the first two is uniquely determined by β and $i \in I_\beta$, and so at most 1 unit of flow is passed through them, and the flow in the latter kind is determined by $i \in I_\beta$, and the same $i \in I_\beta$ can have at most $|\{\beta_i^r\}_\beta| = 2^{n/3}$ units of flow passing in (C_i, γ), and so the flow in it is also bounded. The flow in edges of the form $(C_i^{\nvDash}, \beta_i^l)$ in the first phase is uniquely determined by β and $i \in I_\beta$, and in the second phase uniquely according to β and $i \in [m] \setminus I_\beta$, and so will not be used twice, and the flow in edges of the form $(\alpha, C_i^{\nvDash})$ is determined in the first phase by $i \in I_\beta$ and in the second phase by $i \in [m] \setminus I_\beta$, and so will be used at most $\sum_\beta |I_\beta \cap \{i\}| + \sum_\beta |([m] \setminus I_\beta) \cap \{i\}| \leq 2^{n/3}$ times.

We now proceed to prove that red edges too do not have more flow than their capacity, and for this we only need to consider the second phase. Edges of the forms $(C_i^{\vDash}, \beta_i^c)$, (β_i^l, β_i^c), and (β_i^c, β') has flow that is uniquely determined by β and $i \in [m] \setminus I_\beta$ and so are not used more than once, edges of the form (β', v_B) has flow that is determined by β and thus have flow $|\{\beta_i^c\}_{i \in [m] \setminus I_\beta}| = |[m] \setminus I_\beta| = p-1$ and hence are properly bounded, and edges of the form (v_B, γ) have flow of size $(p-1)|\{\beta'\}_\beta|2^{n/3} = (p-1)2^{n/3}$. Finally, edges of the form $(\alpha, C_i^{\vDash})$ have flow that is determined by $i \in [m] \setminus I_\beta$ and so are used at most $|\{\beta_i^c\}_\beta| = 2^{n/3}$ times. Altogether, we have bounded the total flow in all the edges that were used in both phases, and so the capacity requirements follow, which completes the proof of the second direction and of Lemma 3.1. ◀

Proof of Theorem 1.6. We use Lemma 3.1 in the following way. Assume that for some $|S'|$ and $|T'|$ there is an algorithm for ST-Max-Flow that runs in time $O((|S'||T'|m)^{1-\varepsilon})$, and consider the version of ST-Max-Flow with S'' and T'' such that $S'' \cap T'' = \emptyset$. Applying such an algorithm repeatedly with S' and T' iterate over respective partitions of S'' and T'' of sizes

$|S''|/|S'|$ and $|T''|/|T'|$, respectively, would solve S'' and T'''s version of ST-Max-Flow and take time $(|S''|/|S'|)(|T''|/|T'|)O(|S'||T'|m)^{1-\varepsilon}) = O((|S''||T''|m)^{1-\varepsilon'})$ for some $\varepsilon' = \varepsilon'(\varepsilon)$, and Theorem 1.6 follows. ◀

4 Global Max-Flow

Proof of Theorem 1.10. Let U and V be an instance of the Orthogonal Vectors problem, where $|U| = |V| = n'$, and all the vectors are from $\{0,1\}^d$ for some $d = \mathsf{polylog}(n')$. We construct a graph $G = (U', V', D)$ as follows. U' contains a node u for every vector $u \in U$, V' contains a node v for every $v \in V$, and D contains three nodes $c_{0,0}$, $c_{0,1}$, and $c_{1,0}$ for every coordinate $c \in [d]$. For every $u \in U'$ and $c \in D$, we add an edge from u to $c_{0,0}$ and $c_{0,1}$ if $u[c] = 0$, and an edge from u to $c_{1,0}$ otherwise. Similarly, for every $v \in U'$ and $c \in D$, we add an edge from v to $c_{0,0}$ and $c_{1,0}$ if $v[c] = 0$, and an edge from v to $c_{0,1}$ otherwise. This graph has $n = n' + n' + 3d = O(n')$ nodes and at most $n' \cdot 2d + n' \cdot 2d = \tilde{O}(n')$ edges. For every $u \in U'$, $v \in V'$, and $c \in [d]$, there is exactly one path (of length 2) from u to v through nodes associated with c if and only if $u[c] \cdot v[c] = 0$, and no paths through them otherwise. Hence, the number of edge disjoint paths from u to v is d if their inner product is 0, and less than d otherwise, and so an algorithm for Maximum Local Edge Connectivity with strictly subquadratic runtime implies an algorithm for the Orthogonal Vectors problem with similar runtime, completing the proof. ◀

Abstract

In this paper, we investigate the complexity of *one-dimensional dynamic programming*, or more specifically, of the Least-Weight Subsequence (LWS) problem: Given a sequence of n data items together with weights for every pair of the items, the task is to determine a subsequence S minimizing the total weight of the pairs adjacent in S. A large number of natural problems can be formulated as LWS problems, yielding obvious $\mathcal{O}(n^2)$-time solutions.

In many interesting instances, the $\mathcal{O}(n^2)$-many weights can be succinctly represented. Yet except for near-linear time algorithms for some specific special cases, little is known about when an LWS instantiation admits a subquadratic-time algorithm and when it does not. In particular, no lower bounds for LWS instantiations have been known before. In an attempt to remedy this situation, we provide a general approach to study the fine-grained complexity of succinct instantiations of the LWS problem: Given an LWS instantiation we identify a highly parallel *core* problem that is subquadratically *equivalent*. This provides either an explanation for the apparent hardness of the problem or an avenue to find improved algorithms as the case may be.

More specifically, we prove subquadratic equivalences between the following pairs (an LWS instantiation and the corresponding core problem) of problems: a low-rank version of LWS and minimum inner product, finding the longest chain of nested boxes and vector domination, and a coin change problem which is closely related to the knapsack problem and $(\min, +)$-CONVOLUTION. Using these equivalences and known **SETH**-hardness results for some of the core problems, we deduce tight conditional lower bounds for the corresponding LWS instantiations. We also establish the $(\min, +)$-CONVOLUTION-hardness of the knapsack problem. Furthermore, we revisit some of the LWS instantiations which are known to be solvable in near-linear time and explain their easiness in terms of the easiness of the corresponding core problems.

1 Introduction

Dynamic programming (DP) is one of the most fundamental paradigms for designing algorithms and a standard topic in textbooks on algorithms. Scientists from various disciplines have developed DP formulations for basic problems encountered in their applications. However, it is not clear whether the existing (often simple and straightforward) DP formulations are in fact optimal or nearly optimal. Our lack of understanding of the optimality of the DP formulations is particularly unsatisfactory since many of these problems are computational primitives.

Interestingly, there have been recent developments regarding the optimality of standard DP formulations for some specific problems, most importantly, conditional lower bounds assuming the Strong Exponential Time Hypothesis (**SETH**) [26]. Let us consider the longest common subsequence (LCS) problem as an illustrative example. It is defined as follows: Given two strings x and y of length at most n, compute the length of the longest string z that is a subsequence of both x and y. The standard DP formulation for the LCS problem involves computing a two-dimensional table requiring $\mathcal{O}(n^2)$ steps. This algorithm is slower than the fastest known algorithm due to Masek and Paterson [33] only by a polylogarithmic factor. However, there has been no progress in finding more efficient algorithms for this problem since the 1980s, which prompted attempts as early as in 1976 [5] to understand the barriers for efficient algorithms and to prove lower bounds. Unfortunately, there have not been any nontrivial unconditional lower bounds for this or any other problem in general models of computation. This state of affairs prompted researchers to consider *conditional* lower bounds based on conjectures such as 3-Sum conjecture [18] and more recently based on **ETH** [27] and **SETH** [26]. Researchers have found **ETH** and **SETH** to be useful to explain the exact complexity of several **NP**-complete problems (see the survey paper [32]). Surprisingly, Ryan Williams [39] has found a simple reduction from the CNF-SAT problem to the orthogonal vectors problem which under **SETH** leads to a matching quadratic lower bound for the orthogonal vectors problem. This in turn led to a number of conditional lower bound results for problems in **P** (including LCS and related problems) under **SETH** [6, 1, 10, 2, 22]. Also see [37] for a recent survey.

The DP formulation of the LCS problem is perhaps the conceptually simplest example of a *two-dimensional* DP formulation. In the standard formulation, each entry of an $n \times n$ table is computed in constant time. This property is typical for *alignment problems* which, for example, are used to model similarity between gene or protein sequences and for which LCS and Edit distance are the most prominent examples. Tight conditional lower bounds have recently been proved for a number of alignment problems [8, 6, 1, 10, 3].

In contrast, there are many problems for which natural quadratic-time DP formulations compute a *one-dimensional* table of length n by spending $\mathcal{O}(n)$-time per entry. The question arises: Can similar optimality results as for alignment problems be obtained for this fundamentally different setting? In pursuit of an answer, we investigate the optimality of one-dimensional DP formulations and obtain new (conditional) lower bounds which match the complexity of these standard DP formulations.

1-dimensional DP: The Least-Weight Subsequence (LWS) Problem. In this paper, we investigate the optimality of the standard DP formulation of the LWS problem. A classic example of an LWS problem is airplane refueling [24]: Given airport locations on a line, and a preferred distance per hop k (in miles), we define the penalty for flying k' miles as $(k - k')^2$. The goal is then to find a sequence of airports terminating at the last airport that minimizes the sum of the penalties. We now define the LWS problem formally.

▶ **Problem 1.1** (LWS). *We are given weights* $w_{i,j} \in \{-W, \dots, W\} \cup \{\infty\}$ *for every pair* $0 \le i < j \le n$ *and an arbitrary function* $g : \mathbb{Z} \to \mathbb{Z}$. *The* LWS *problem is to determine* $F[n]$ *which is defined by the following DP formulation.*

$$F[0] = 0,$$
$$F[j] = \min_{0 \le i < j} g(F[i]) + w_{i,j} \qquad \text{for } j = 1, \dots, n. \tag{1}$$

In the above definition, we did not specify the precise encoding of the problem. We typically consider *succinct instantiations* of LWS, where the input has subquadratic size (typically $\tilde{\mathcal{O}}(n)$) and the weights are a function of the input. In many cases, the input is a list of data items $x_0, \dots, x_n$ and $w_{i,j}$ is a function of x_i and x_j. For example, to formulate airplane refueling as an LWS problem, we let x_i be the location of the i'th airport, g be the identity function, and $w_{i,j} = (x_j - x_i - k)^2$.

The generality of the LWS definition captures a large variety of problems: it not only encompasses classical problems such as the pretty printing problem due to Knuth and Plass [30], the airplane refueling problem [24] and the longest increasing subsequence (LIS) [17], but also the unbounded subset sum problem [36, 9], a more general coin change problem that is effectively equivalent to the unbounded knapsack problem, 1-dimensional k-means clustering problem [23], finding longest R-chains (for an arbitrary binary relation R), and many others (for a more detailed overview and problem definitions, see the full version [31]).

Under mild assumptions on the encoding of the data items and weights, any instantiation of the LWS problems can be solved in time $\mathcal{O}(n^2)$ using (1) for determining the values $F[j], j = 1, \dots, n$ in time $\mathcal{O}(n)$ each. However, the best known algorithms for the LWS problems differ quite significantly in their time complexity. Some problems including the pretty printing problem, the airline refueling problem and LIS turn out to be solvable in near-linear time, while no subquadratic algorithms are known for the unbounded knapsack problem or for finding the longest R-chain.

The main goal of the paper is to investigate the optimality of the LWS DP formulation for various problems by proving conditional lower bounds.

Succinct LWS instantiations. In the extremely long presentation of an LWS problem, the weights $w_{i,j}$ are given explicitly. This is, however, not a very interesting case from a computational point of view, as the standard DP formulation takes linear time (in the size of the input) to compute $F[n]$. In the example of the airplane refueling problem, the size of the input is only $\mathcal{O}(n)$ assuming that the values of the data items are bounded by some polynomial in n. For such succinct representations, we ask if the quadratic-time algorithm based on the standard LWS DP formulation is optimal. Our approach is to study several natural succinct versions of the LWS problem (by specifying the type of data items and the weight function[1]) and determine their complexity.

Our Contributions and Results. The main contributions of our paper include a general framework for reducing succinct LWS instantiations to what we call the *core* problems and proving subquadratic equivalences between them. Such subquadratic equivalences are interesting for two reasons. First, they allow us to conclude conditional lower bounds for certain LWS instantiations, where previously no lower bounds are known. Second,

[1] In all our applications, the function g is the trivial identity function.

subquadratic (or more general fine-grained) equivalences are more useful since they let us translate *easiness* in addition to hardness results.

Our results include tight (up to subpolynomial factors) conditional lower bounds for several LWS instantiations with succinct representations. These instantiations include the coin change problem, low-rank versions of the LWS problem, and the longest subchain problems. Our results are somewhat more general. We propose a *factorization* of the LWS problem into a *core* problem and a fine-grained reduction from the LWS problem to the core problem. The idea is that core problems (which are often well-known problems) capture the hardness of the LWS problem and act as a potential barrier for more efficient algorithms. While we do not formally define the notion of a core problem, we identify several core problems which share several interesting properties. For example, they do not admit natural DP formulations and are easy to parallelize. In contrast, the quadratic-time DP formulation of LWS problems requires the entries $F[i]$ to be computed in order, suggesting that the general problem might be inherently sequential.

The reductions between LWS problems and core problems involve a natural intermediate problem, which we call the Static-LWS problem. We first reduce the LWS problem to the Static-LWS problem in a general way and then reduce the Static-LWS problem to a core problem. The first reduction is divide-and-conquer in nature and is inherently sequential. The latter reduction is specific to the instantiation of the LWS problem. The Static-LWS problem is easy to parallelize and does not have a natural DP formulation. However, the problem is not necessarily a natural problem. The Static-LWS problem can be thought of as a generic core problem, but it is output-intensive.

In the other direction, we show that many of the core problems can be reduced to the corresponding LWS instantiations thus establishing an equivalency between LWS instantiations and their core problems. This equivalence enables us to translate both the hardness and easiness results (i.e., the subquadratic-time algorithms) for the core problems to the corresponding LWS instantiations.

The first natural succinct representation of the LWS problem we consider is the low-rank LWS problem, where the weight matrix $\mathbf{W} = (w_{i,j})$ is of low rank and thus representable as $\mathbf{W} = L \cdot R$ where L and R^{T} are $(n \times n^{o(1)})$-matrices. For this low-rank LWS problem, we identify the minimum inner product problem (MinInnProd) as a suitable core problem. It is only natural and not particularly surprising that MinInnProd can be reduced to the low-rank LWS problem which shows the **SETH**-hardness of the low-rank LWS problem. The other direction is more surprising: Inspired by an elegant trick of Vassilevska Williams and Williams [40], we are able to show a subquadratic-time reduction from the (highly sequential) low-rank LWS problem to the (highly parallel) MinInnProd problem. Thus, the very compact problem MinInnProd problem captures exactly the complexity of the low-rank LWS problem (under subquadratic reductions).

We also show that the coin change problem is subquadratically equivalent to the $(\min, +)$-convolution problem. In the coin change problem, the weight matrix $\mathbf{W}$ is succinctly given as a Toeplitz matrix. At this point, the conditional hardness of the $(\min, +)$-convolution problem is unknown. Only very recently and independent of our work, a detailed treatment of Cygan et al. [13] considers quadratic-complexity of $(\min, +)$-convolution as a hardness assumption and discusses its relation to more established assumptions. The quadratic-time hardness of the $(\min, +)$-convolution problem would be very interesting, since it is known that the $(\min, +)$-convolution problem is reducible to the 3-Sum problem and the APSP problem (see also [13]). However, recent results give surprising subquadratic-time algorithms for special cases of $(\min, +)$-convolution [12]. If these subquadratic-time

algorithms extend to the general $(\min,+)$-CONVOLUTION problem, our equivalence result also provides a subquadratic-time algorithm for the coin change problem and the closely related unbounded knapsack problem. Our reductions also give, as a corollary, a quadratic-time $(\min,+)$-CONVOLUTION-based lower bound for the bounded case of knapsack. We remark that independently of our results, [13] gave randomized subquadratic equivalences of $(\min,+)$-CONVOLUTION to unbounded knapsack (while we give deterministic reductions) and bounded Knapsack (where we only give a $(\min,+)$-CONVOLUTION-based lower bound).

We next consider the problem of finding longest chains: here, we search for the longest subsequence (chain) in the input sequence such that all adjacent pairs in the subsequence are contained in some binary relation R. We show that for any binary relation R satisfying certain conditions the chaining problem is subquadratically equivalent to a corresponding (highly parallel) selection problem. As corollaries, we get equivalences between finding the longest chain of nested boxes (NESTEDBOXES) and VECTORDOMINATION as well as between finding the longest subset chain (SUBSETCHAIN) and the orthogonal vectors (OV) problem. Interestingly, these results have algorithmic implications: known algorithms for low-dimensional vector domination and low-dimensional orthogonal vectors translate to faster algorithms for low-dimensional NESTEDBOXES and SUBSETCHAIN for small universe size.

Table 1 lists the LWS succinct instantiations (as discussed above) and their corresponding core problems. For a detailed treatment of all LWS instantiations and core problems considered in this work, see the full version of this paper [31].

Finally, we revisit classic problems including the longest increasing subsequence problem, the unbounded subset sum problem and the concave LWS problem and analyze the STATIC-LWS instantiations to immediately infer that the corresponding core problem can be solved in near-linear time. Table 2 gives an overview of some of the problems we look at in this context.

Related Work. LWS has been introduced by Hirschberg and Larmore [24]. If the weight function satisfies the *quadrangle inequality* formalized by Yao [41], one obtains the *concave LWS* problem (CONCLWS), for which they give an $\mathcal{O}(n \log n)$-time algorithm. Subsequently, improved algorithms solving CONCLWS in time $\mathcal{O}(n)$ were given [38, 20]. This yields a fairly large class of weight functions (including, e.g., the pretty printing and airplane refueling problems) for which linear-time solutions exist. To generalize this class of problems, further

works address convex weight functions[2] [19, 35, 29] as well as certain combinations of convex and concave weight functions [15] and provide near-linear time algorithms. For a more comprehensive overview over these algorithms and further applications of the LWS problem, we refer the reader to Eppstein's PhD thesis [16].

Apart from these notions of concavity and convexity, results on succinct LWS problems are typically more scattered and problem-specific (see, e.g., [17, 30, 9, 23]; furthermore, a closely related recurrence to (1) pops up when solving bitonic TSP [14]). An exception to this rule is a study of the parallel complexity of LWS [21].

Organization. After setting up notation and conventions in Section 2, Section 3 gives a general reduction from LWS instantiations to STATIC-LWS that is independent of the representation of the weight matrix. Section 4 contains the result on low-rank LWS. Section 5 proves the subquadratic equivalence of the coin change problem and $(\min, +)$-CONVOLUTION, while Section 6 discusses chaining problems and their corresponding selection (core) problem. Due to space constraints, most proofs and our discussion of near-linear time algorithms are deferred to the full version of this article [31].

2 Preliminaries

In this section, we state our notational conventions and list the main problems considered in this work.

Notation and Conventions. Problem A *subquadratically reduces* to problem B, denoted $A \leq_2 B$, if for any $\varepsilon > 0$ there is a $\delta > 0$ such that the existence of a $\mathcal{O}(n^{2-\varepsilon})$-time algorithm for B implies a $\mathcal{O}(n^{2-\delta})$-time algorithm for A. We call the two problems subquadratically equivalent, denoted $A \equiv_2 B$, if there are subquadratic reductions both ways.

We let $[n] := \{1, \ldots, n\}$. When stating running time, we use the notation $\tilde{\mathcal{O}}(\cdot)$ to hide polylogarithmic factors. For a problem P, we write T^P for its time complexity. We generally assume the word-RAM model of computation with word size $w = \Theta(\log n)$. For most problems defined in this paper, we consider inputs to be integers in the range $\{-W, \ldots, W\}$ where W fits in a constant number of words[3]. For vectors, we use d for the dimension and generally assume $d = n^{o(1)}$.

[2] A weight function is convex if it satisfies the inverse of the quadrangle inequality.

[3] For the purposes of our reductions, even values up to $W = 2^{n^{o(1)}}$ would be fine.

Succinct LWS Instantiations. In the definition of LWS (Problem 1.1) we did not fix the encoding of the problem (in particular the representation of the weights $w_{i,j}$ and the function g). Assuming that g and the weights can be determined in $\tilde{\mathcal{O}}(1)$ and that $W = \texttt{poly}(n)$, this problem can naturally be solved in time $\tilde{\mathcal{O}}(n^2)$, by evaluating the central recurrence (1) for each $j = 1, \ldots, n$ – this takes $\tilde{\mathcal{O}}(n)$ time for each j, since we take the minimum over at most n expressions that can be evaluated in time $\tilde{\mathcal{O}}(1)$ by accessing the previously computed entries $F[0], \ldots, F[j-1]$ as well as computing g. We assume from now on that g is the identity function, as this is the case for all our applications. Thus it suffices to define the type of data items and the corresponding weight matrix to specify an LWS instantiation. Throughout this paper, whenever we fix a representation of the weight matrix $\mathbf{W} = (w_{i,j})_{i,j}$, we denote the corresponding problem LWS($\mathbf{W}$).

3 Static LWS

Our reductions from LWS instantiations to core problems go through intermediate problems that share some of the characteristics of core problems, as well as some of the characteristics of LWS. In particular, these problems are naturally parallelizable and their brute-force algorithm is already quadratic time, similar to core problems. On the other hand their definitions are closely related to the definition of LWS. Other than core problems, our intermediate problems are not decision problems but ask to compute some linear sized output. Towards making this notion more precise, we define a generic intermediate problem called Static-LWS.

▶ **Problem 3.1** (Static-LWS($\mathbf{W}$)). *Fix an instance of* LWS($\mathbf{W}$). *Given intervals of indices* $I := \{a+1, \ldots, a+N\}$ *and* $J := \{a+N+1, \ldots, a+2N\}$ *with* a, N *such that* $I, J \subseteq [n]$, *together with the values* $F[a+1], \ldots, F[a+N]$, *the Static Least-Weight Subsequence Problem (*Static-LWS*) asks to determine*

$$F'[j] := \min_{i \in I} F[i] + w_{i,j} \qquad \text{for all } j \in J.$$

The main purpose of this section is to give a reduction from LWS($\mathbf{W}$) to Static-LWS($\mathbf{W}$) that is independent of the weight matrix $\mathbf{W}$ and therefore independent of the succinct LWS instantiations we consider throughout this paper. This reduction is a key step in our reductions from LWS to their corresponding core problems.

The reduction is a divide-and-conquer scheme that divides the LWS problem into two subproblems of half the size each and Static-LWS to combine the two. Crucially, the two subproblems have to be solved sequentially. The reduction therefore captures the sequential nature of the LWS problem, while Static-LWS captures a parallelizable part of the problem.

In a certain sense, this reduction has appeared implicitly in previous work on LWS [24]. In particular, the reduction of ConcLWS to the SMAWK problem by Galil and Park [20] can be thought of as a variant of this reduction specialized to the concave case to avoid log-factors.

▶ **Lemma 3.2** (LWS($\mathbf{W}$) $\leq_2$ Static-LWS($\mathbf{W}$)). *For any choice of* $\mathbf{W}$, *if* Static-LWS($\mathbf{W}$) *can be solved in time* $\mathcal{O}(N^{2-\varepsilon})$ *for some* $\varepsilon > 0$, *then* LWS($\mathbf{W}$) *can be solved in time* $\tilde{\mathcal{O}}(n^{2-\varepsilon})$.

Proof. In what follows, we fix LWS as LWS($\mathbf{W}$) and Static-LWS as Static-LWS($\mathbf{W}$).

We define the subproblem $S(\{i, \ldots, j\}, (f_i, \ldots, f_j))$ that given an interval spanned by $1 \leq i \leq j \leq n$ and values $f_k = \min_{0 \leq k' < i} F[k'] + w_{k',k}$ for each point $k \in \{i, \ldots, j\}$, computes all values $F[k]$ for $k \in \{i, \ldots, j\}$. Note that a call to $S([n], (w_{0,1}, \ldots, w_{0,n}))$ solves the LWS problem, since $F[0] = 0$ and thus the values of $f_k, k \in [n]$ are correctly initialized.

Algorithm 1 Reducing LWS to Static-LWS

1: **function** $S(\{i,\dots,j\},(f_i,\dots,f_j))$
2: **if** $i=j$ **then**
3: **return** $F[i]\leftarrow f_i$
4: $m\leftarrow\lceil\frac{j-i}{2}\rceil$
5: $(F[i],\dots,F[i+m-1])\leftarrow S(\{i,\dots,i+m-1\},(f_i,\dots,f_{i+m-1}))$
6: solve Static-LWS on the subinstance given by $I:=\{i,\dots,i+m-1\}$ and $J:=\{i+m,\dots,i+2m-1\}$:
7: ▷ obtains values $F'[k]=\min_{i\le k'<i+m}F[k']+w_{k',k}$ for $k=i+m,\dots,i+2m-1$.
8: $f'_k\leftarrow\min\{f_k,F'[k]\}$ for all $k=i+m,\dots,i+2m-1$.
9: $(F[i+m],\dots,F[i+2m-1])\leftarrow S(\{i+m,\dots,i+2m-1\},(f'_{i+m},\dots,f'_{i+2m-1}))$
10: **if** $j=i+2m$ **then**
11: $F[j]:=\min\{f_j,\min_{i\le k<j}F[k]+w_{k,j}\}$.
12: **return** $(F[i],\dots,F[j])$

We solve S using Algorithm 1.

We briefly argue correctness, using the invariant that $f_k=\min_{0\le k'<i}F[k']+w_{k',k}$ in every call to S. If S is called with $i=j$, then the invariant yields $f_i=\min_{0\le k'<i}F[k']+w_{k',i}=F[i]$, thus $F[i]$ is computed correctly. For the call in Line 5, the invariant is fulfilled by assumption, hence the values $(F[i],\dots,F[i+m-1])$ are correctly computed. For the call in Line 9, we note that for $k=i+m,\dots,i+2m-1$, we have that f'_k equals

$$\min\{f_k,F'[k]\}=\min\{\min_{0\le k'<i}F[k']+w_{k',k},\min_{i\le k'<i+m}F[k']+w_{k',k}\}=\min_{0\le k'<i+m}F[k']+w_{k',k}.$$

Hence the invariant remains satisfied. Thus, the values $(F[i+m],\dots,F[i+2m-1])$ are correctly computed. Finally, if $j=i+2m$, we compute the remaining value $F[j]$ correctly, since $f_j=\min_{0\le k<i}F[k]+w_{k,j}$ by assumption.

To analyze the running time $T^S(n)$ of S on an interval of length $n:=j-i+1$, note that each call results in two recursive calls of interval lengths at most $n/2$. In each call, we need an additional overhead that is linear in n and $T^{\text{Static-LWS}}(n/2)$. Solving the corresponding recursion $T^S(n)\le 2T^S(n/2)+T^{\text{Static-LWS}}(n/2)+\mathcal{O}(n)$, we obtain that an $\mathcal{O}(N^{2-\varepsilon})$-time algorithm Static-LWS, with $0<\varepsilon<1$ yields $T^{\text{LWS}}(n)\le T^S(n)=\mathcal{O}(n^{2-\varepsilon})$. Similarly, an $\mathcal{O}(N\log^c N)$-time algorithm for Static-LWS would result in an $\mathcal{O}(n\log^{c+1}n)$-time algorithm for LWS. ◀

4 LowRankLWS

In this section we prove the first equivalence between an instantiation of LWS and a core problem. Specifically, we first analyze the following canonical succinct representation of a low-rank weight matrix $\mathbf{W}=(w_{i,j})_{i,j}$: If $\mathbf{W}$ is of rank $d\ll n$, we can write it more succinctly as $\mathbf{W}=L\cdot R$, where L and R are $(n\times d)$- and $(d\times n)$ matrices, respectively. We can express the resulting natural LWS problem equivalently as follows.

▶ **Problem 4.1** (LowRankLWS). *We define the* LWS *instantiation* LowRankLWS $=$ LWS($\mathbf{W}_{\text{LowRank}}$) *as follows.*
Data: *out-vectors* $\mu_0,\dots,\mu_{n-1}\in\{-W,\dots,W\}^d$, *in-vectors* $\sigma_1,\dots,\sigma_n\in\{-W,\dots,W\}^d$
Weights: $w(i,j)=\langle\mu_i,\sigma_j\rangle$ *for* $0\le i<j\le n$

In this section, we show that this problem is equivalent, under subquadratic reductions, to the following *non-sequential* problem.

▶ **Problem 4.2** (MinInnProd). *Given $a_1, \dots, a_n, b_1, \dots, b_n \in \{-W, \dots, W\}^d$ and a natural number $r \in \mathbb{Z}$, determine if there is a pair i, j satisfying $\langle a_i, b_j \rangle \leq r$.*

This is interesting for a number of reasons. For one, MinInnProd is a fairly natural problem and, as opposed to LowRankLWS it is not inherently sequential in its definition. We understand MinInnProd comparably well both from an upper and from a lower bound perspective. Using ray shooting data structures [34] we can solve MinInnProd in strongly subquadratic time if d is constant. At the same time, if $d = \omega(\log n)$, the problem is quadratic-time **SETH**-hard. By showing subquadratic equivalence between MinInnProd and LowRankLWS, we can conclude both these results, as well as any future improvements, for LowRankLWS.

There is a simple reduction from MinInnProd to LowRankLWS that along the way proves quadratic-time **SETH**-hardness of LowRankLWS.

▶ **Lemma 4.3.** *It holds that $T^{\text{MinInnProd}}(n, d, W) \leq T^{\text{LowRankLWS}}(2n+1, d+2, dW) + \mathcal{O}(nd)$.*

To prove the other direction, we will use the quite general approach to compute the sequential LWS problem by reducing to Static-LWS (Lemma 3.2). In particular, for the special case of LowRankLWS, it is not difficult to see that its static version boils down to the following natural reformulation.

▶ **Problem 4.4** (AllInnProd). *Given vectors $a_1, \dots, a_n \in \{-W, \dots, W\}^d$ and $b_1, \dots, b_n \in \{-W, \dots, W\}^d$, determine* for all $j \in [n]$, *the value* $\min_{i \in [n]} \langle a_i, b_j \rangle$.

▶ **Lemma 4.5** (Static-LWS($\mathbf{W}_{\text{LowRank}}$) $\leq_2$ AllInnProd). *We have*

$$T^{\text{Static-LWS}(\mathbf{W}_{\text{LowRank}})}(n, d, W) \leq T^{\text{AllInnProd}}(n, d+1, nW) + \mathcal{O}(nd).$$

Finally, inspired by an elegant trick of [40], we reduce AllInnProd to MinInnProd.

▶ **Lemma 4.6** (AllInnProd $\leq_2$ MinInnProd). *We have*

$$T^{\text{AllInnProd}}(n, d, W) \leq \mathcal{O}(n \cdot T^{\text{MinInnProd}}(\sqrt{n}, d+3, ndW^2) \cdot \log^2 nW).$$

By the sequence of lemmas above and Lemma 3.2, we obtain our subquadratic equivalence of LowRankLWS to its core problem.

▶ **Theorem 4.7.** *We have* LowRankLWS $\equiv_2$ MinInnProd.

5 Coin Change and Knapsack Problems

In this section, we focus on the following problem related to Knapsack: Assume we are given coins of denominations $d_1, \dots, d_m$ with corresponding weights $w_1, \dots, w_m$ and a target value n, determine a way to represent n using these coins (where each coin can be used arbitrarily often) minimizing the total sum of weights of the coins used. Since without loss of generality $d_i \leq n$ for all i, we can assume that $m \leq n$ and think of n as our problem size. In particular, we describe the input by weights $w_1, \dots, w_n$ where w_i denotes the weight of the coin of denomination i (if no coin with denomination i exists, we set $w_i = \infty$). It is straightforward to see that this problem is an LWS instance LWS($\mathbf{W}_{\text{cc}}$), where the weight matrix $\mathbf{W}_{\text{cc}}$ is a Toeplitz matrix.

▶ **Problem 5.1** (CC). *We define the following* LWS *instantiation* $\mathrm{CC} = \mathrm{LWS}(\mathbf{W}_{\mathrm{cc}})$.
Data: *weight sequence* $w = (w_1, \ldots, w_n)$ *with* $w_i \in \{-W, \ldots, W\} \cup \{\infty\}$
Weights: $w_{i,j} = w_{j-i}$ *for* $0 \leq i < j \leq n$

Translated into a Knapsack-type formulation (i.e., denominations are weights, weights are profits, and the objective becomes to maximize the profit), the problem differs from UnboundedKnapsack only in that it searches for the most profitable multiset of items of weight *exactly* n, instead of *at most* n.

▶ **Problem 5.2** (UnboundedKnapsack). *We are given a sequence of profits* $p = (p_1, \ldots, p_n)$ *with* $p_i \in \{0, 1, \ldots, W\}$*, that is, the item of size* i *has profit* p_i*. Find the total profit of the multiset of indices* I *such that* $\sum_{i \in I} i \leq n$ *and the total profit* $\sum_{i \in I} p_i$ *is maximized.*

The purpose of this section is to show that both CC and UnboundedKnapsack are subquadratically equivalent to the $(\min, +)$-convolution problem. Along the way, we also prove quadratic-time $(\min, +)$-convolution-hardness of Knapsack. Recall the definition of $(\min, +)$-convolution.

▶ **Problem 5.3** ($(\min, +)$-convolution). *Given* n*-dimensional vectors* $a = (a_0, \ldots, a_{n-1})$*,* $b = (b_0, \ldots, b_{n-1}) \in \{-W, \ldots, W\}^n$*, determine its* $(\min, +)$-convolution $a * b$ *defined by*

$$(a * b)_k = \min_{0 \leq i,j < n : i+j=k} a_i + b_j \qquad \text{for all } 0 \leq k \leq 2n-2.$$

As opposed to the classical convolution, solvable in time $\mathcal{O}(n \log n)$ using FFT, no strongly subquadratic algorithm for $(\min, +)$-convolution is known. Compared to the popular orthogonal vectors problem, we have less support for believing that no $\mathcal{O}(n^{2-\varepsilon})$-time algorithm for $(\min, +)$-convolution exists. In particular, interesting special cases can be solved in subquadratic time [12] and there are subquadratic-time co-nondeterministic and nondeterministic algorithms [7, 11]. At the same time, breaking this long-standing quadratic-time barrier is a prerequisite for progress on refuting the 3SUM and APSP conjectures (see also [13]). This makes it an interesting target particularly for proving subquadratic *equivalences*, since both positive and negative resolutions of this open question appear to be reasonable possibilities.

To obtain our result, we address two issues: (1) We show an equivalence between the problem of determining only the value $F[n]$, i.e., the best way to give change only for the target value n, and to determine *all values* $F[1], \ldots, F[n]$, which we call the *output-intensive version*. (2) We show that the output-intensive version is subquadratic equivalent to $(\min, +)$-convolution.

▶ **Problem 5.4** (oiCC). *The output-intensive version of* CC *is to determine, given an input to* CC*, all values* $F[1], \ldots, F[n]$.

We first consider issue (2) and prove $(\min, +)$-convolution-hardness of oiCC.

▶ **Lemma 5.5** ($(\min, +)\mathrm{conv} \leq_2$ oiCC). *We have* $T^{(\min,+)\mathrm{conv}}(n, W) \leq T^{\mathrm{oiCC}}(6n, 4(2W + 1)) + \mathcal{O}(n)$.

Using the notion of Static-LWS, the other direction is straight-forward.

▶ **Lemma 5.6.** *We have* $\mathrm{oiCC} \leq_2 \text{Static-LWS}(\mathbf{W}_{\mathrm{cc}}) \leq_2 (\min, +)\mathrm{conv}$.

The last two lemmas resolve issue (2). We proceed to issue (1) and show that the output-intensive version is subquadratically equivalent to both CC and UnboundedKnapsack that only ask to determine a single output number.

It is trivial to see that UnboundedKnapsack $\leq_2$ oiCC. Furthermore, there is a simple reduction from CC to UnboundedKnapsack.

▶ **Oberservation 5.7** (CC $\leq_2$ UnboundedKnapsack $\leq_2$ oiCC)**.** *We have* $T^{\mathrm{CC}}(n,W) \leq T^{\textsc{UnboundedKnapsack}}(n,nW) + \mathcal{O}(n)$ *and* $T^{\textsc{UnboundedKnapsack}}(n,W) \leq T^{\mathrm{oiCC}}(n,W) + \mathcal{O}(n)$.

The remaining part is similar in spirit to Lemma 4.6: Somewhat surprisingly, the same general approach works despite the much more sequential nature of Knapsack and CC – this sequentiality can be taken care of by a more careful treatment of appropriate subproblems that involves solving them in a particular order and feeding them with information gained during the process.

▶ **Lemma 5.8** (oiCC $\leq_2$ CC)**.** *We have* $T^{\mathrm{oiCC}}(n,W) \leq \mathcal{O}(\log(nW)\cdot n \cdot T^{\mathrm{CC}}(24\sqrt{n}, 3n^2W))$.

The lemmas above and their underlying reductions prove the following theorem.

▶ **Theorem 5.9.** *We have* $(\min,+)$conv $\equiv_2$ CC $\equiv_2$ UnboundedKnapsack*. Furthermore, the bounded version of* Knapsack *admits no strongly subquadratic-time algorithm unless* $(\min,+)$-convolution *can be solved in strongly subquadratic time.*

6 Chain LWS

In this section we consider a special case of Least-Weight Subsequence problems called the Chain Least-Weight Subsequence (ChainLWS) problem. This captures problems in which edge weights are given implicitly by a relation R that determines which pairs of data items we are allowed to chain. The aim is to find the longest chain.

An example of a Chain Least-Weight Subsequence problem is the NestedBoxes problem. Given n boxes in d dimensions, given as non-negative, d-dimensional vectors $b_1,\ldots,b_n$, find the longest chain such that each box fits into the next (without rotation). We say box that box a fits into box b if for all dimensions $1 \leq i \leq d$, $a_i \leq b_i$.

NestedBoxes is not immediately a Least-Weight Subsequence problem, as for Least-Weight subsequence problems we are given a sequence of data items, and require any sequence to start at the first item and end at the last. However, we can easily convert NestedBoxes into a LWS problem by sorting the vectors by the sum of the entries and introducing two special boxes, one very small box $\bot$ such that $\bot$ fits into any box b_i and one very large box $\top$ such that any b_i fits into $\top$.

We define the Chain Least-Weight Subsequence problem with respect to any relation R and consider a weighted version where data items are given weights. To make the definition consistent with the definition of LWS the output is the weight of the sequence that minimizes the sum of the weights.

▶ **Problem 6.1** (ChainLWS)**.** *Fix a set of objects* D *and a relation* $R \subseteq D \times D$*. We define the following* LWS *instantiation* $\textsc{ChainLWS}(R) = \mathrm{LWS}(\mathbf{W}_{\textsc{ChainLWS}(R)})$.
Data: *sequence of objects* $d_0,\ldots,d_n \in D$ *with weights* $w_1,\ldots,w_n \in \{-W,\ldots,W\}$.
Weights: $w_{i,j} = \begin{cases} w_j & \text{if } (x_i,x_j) \in R, \\ \infty & \text{otherwise,} \end{cases}$ *for* $0 \leq i < j \leq n$.

The input to the (weighted) Chain Least-Weight Subsequence problem is a *sequence* of data items, and not a set. Finding the longest chain in a *set* of data items is **NP**-complete in general. For example, consider the box overlap problem: The input is a set of boxes in two dimensions, given by the top left corner and the bottom right corner, and the relation

consists of all pairs such that the two boxes overlap. This problem is a generalization of the Hamiltonian path problem on induced subgraphs of the two-dimensional grid, which is an **NP**-complete problem [28].

We relate ChainLWS(R) to the class of *selection* problems with respect to the same relation R.

▶ **Problem 6.2** (Selection Problem). *Let D be a set of objects, let $R \subseteq D \times D$ be a relation and let $D_1, D_2 \subseteq D^n$. Given two sequences of inputs $(a_1, \ldots, a_n) \in D_1$ and $(b_1, \ldots, b_n) \in D_2$, determine if there is i, j satisfying $R(a_i, b_j)$. We denote this selection problem with respect to the relation R and sets D_1, D_2 by* Selection(R^{D_1,D_2}). *If $D_1 = D_2 = D^n$, we denote the problem by* Selection(R).

The class of selection problems includes several well-studied problems including MinInnProd, OV [39, 4] and VectorDomination [25].

We give a subquadratic reduction from ChainLWS(R) to Selection(R), independently of R. The proof is again based on Static-LWS and a variation on a trick of [40].

▶ **Theorem 6.3.** *For all relations R such that R can be computed in time subpolynomial in the number of data items n,* ChainLWS(R) $\leq_2$ Selection(R).

For the other direction, we do not have a reduction that is independent of the relation R. Instead, we give sufficient conditions for the existence of such subquadratic reductions.

▶ **Theorem 6.4.** *Let D be a set of objects and $D_1, D_2 \subseteq D^n$ be a set of possible sequences. Consider any relation $R \subseteq D \times D$ satisfying the following properties.*

- *There is a data item $\perp$ such that $(\perp, d) \in R$ for all $d \in D$.*
- *There is a data item $\top$ such that $(d, \top) \in R$ for all $d \in D$.*
- *For all $a \in \{1, 2\}$ and any set of data items $(d_1, \ldots, d_n) \in D_a$ there is a permutation of indices $i_1, \ldots, i_n$ such that for any $j < k$, $(d_{i_j}, d_{i_k}) \notin R$. This ordering can be computed in time $\mathcal{O}(n^{2-\delta})$ for $\delta > 0$. We call this ordering the natural ordering.*

Then Selection(R^{D_1,D_2}) $\leq_2$ ChainLWS(R).

We call a relation satisfying the conditions above a *topological* relation. An immediate corollary is that if we can subquadratically reduce Selection(R) to Selection(R') for some topological relation R', then Selection(R) $\leq_2$ ChainLWS(R').

We conclude by providing interesting instantiations of the subquadratic equivalence of Selection and ChainLWS.

▶ **Corollary 6.5** (NestedBoxes $\equiv_2$ VectorDomination). *The weighted* NestedBoxes *problem on $d = c \log n$ dimensions can be solved in time $n^{2-(1/\mathcal{O}(c \log^2 c))}$. For $d = \omega(\log n)$, the (unweighted)* NestedBoxes *problem cannot be solved in time $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$ assuming* **SETH**.

If we restrict NestedBoxes and VectorDomination to Boolean vectors, then we get SubsetChain and SetContainment, respectively. In this case the upper bound improves to $n^{2-1/\mathcal{O}(\log c)}$ [4]. Note that SetContainment $\equiv_2$ OV, hence SubsetChain $\equiv_2$ OV.

7 Open Problems

We discuss the complexity of some succinct LWS instantiations both from an upper bound and a lower bound perspective by proving equivalences with a number of comparably well-studied core problems. The succinct instantiations we study include natural problems

such as LowRankLWS, CC, ChainLWS including NestedBoxes and SubsetChain, as well as previously studied instantiations such as ConcLWS and LIS. A number of open questions remain. Our results do not generalize to arbitrary instantiations of LWS. In particular, Static-LWS does not seem to reduce subquadratically to the problem of finding the minimum element in a succinctly descibed matrix. With LowRankLWS and CC we do provide instances for which we can identify equivalent core problems, and it will be interesting to find further examples or even sufficient conditions for which we can reduce LWS to other problems and vice versa.

For the case of ChainLWS, we are able to generalize the reduction from LWS to Selection problems. However, the reduction, while preserving subquadratic algorithms, does not preserve near-linear time algorithms. For some cases, such as LIS, we are able to reconstruct a near-linear time algorithm, which raises the question of what conditions are necessary to do that. Similarly, we give sufficient conditions to reduce from Selection to ChainLWS, and other sufficient or even necessary conditions should be explored for both black-box as well as white-box reductions.

Acknowledgments. We would like to thank Karl Bringmann and Russell Impagliazzo for helpful discussions and comments.

Abstract

In the recent years, significant progress has been made in explaining apparent hardness of improving over naive solutions for many fundamental polynomially solvable problems. This came in the form of conditional lower bounds – reductions from a problem assumed to be hard. These include 3SUM, All-Pairs Shortest Paths, SAT and Orthogonal Vectors, and others.

In the $(\min,+)$-convolution problem, the goal is to compute a sequence $(c[i])_{i=0}^{n-1}$, where $c[k] = \min_{i=0,\ldots,k}\{a[i] + b[k-i]\}$, given sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$. This can easily be done in $\mathcal{O}(n^2)$ time, but no $\mathcal{O}(n^{2-\varepsilon})$ algorithm is known for $\varepsilon > 0$. In this paper we undertake a systematic study of the $(\min,+)$-convolution problem as a hardness assumption.

As the first step, we establish equivalence of this problem to a group of other problems, including variants of the classic knapsack problem and problems related to subadditive sequences. The $(\min,+)$-convolution has been used as a building block in algorithms for many problems, notably problems in stringology. It has also already appeared as an ad hoc hardness assumption. We investigate some of these connections and provide new reductions and other results.

1 Introduction

1.1 Hardness in P

For many problems there exist ingenious algorithms that significantly improve upon the naive approach in terms of time complexity. On the other hand, for some fundamental problems, the naive algorithms are still the best known, or have been improved upon only slightly. To some extent this has been explained by the P≠NP conjecture. However, for many problems even the naive approaches lead to polynomial algorithms, and the P≠NP conjecture does not seem to be particularly useful for proving polynomial lower bounds.

* This work is part of a project TOTAL that has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 677651).

In the recent years, significant progress has been made in establishing such bounds, conditioned on conjectures other than P≠NP, each of them claiming time complexity lower bounds for a different problem. And so, conjecture that there is no $\mathcal{O}(n^{2-\epsilon})$ algorithm for 3SUM problem[1] implies hardness for problems in computational geometry [22] and dynamic algorithms [33]. The conjecture that All-Pairs Shortest Paths (APSP) is hard implies hardness of finding graph radius, graph median and some dynamic problems (see [38] for survey). Finally, the Strong Exponential Time Hypothesis (SETH) introduced in [25, 26] that has been used extensively to prove hardness of parametrized problems, recently lead to polynomial lower bounds via the intermediate Orthogonal Vectors problem (see [36]). These include bounds for Edit Distance [3], Longest Common Subsequence [9, 2], and other [38].

It is worth noting that in many cases the results mentioned are not only showing the hardness of the problem in question, but also that it is computationally equivalent to the underlying hard problem. This leads to clusters of equivalent problems being formed, each cluster corresponding to a single hardness assumption (see [38, Figure 1]).

As Christos H. Papadimitriou is quoted to say „*There is nothing wrong with trying to prove that P=NP by developing a polynomial-time algorithm for an NP-complete problem. The point is that without an NP-completeness proof we would be trying the same thing without knowing it!*" [32]. In the same spirit, these new conditional hardness results have cleared the polynomial landscape by showing that there really are not that many hard problems.

1.2 Hardness of MinConv

In this paper we propose yet another hardness assumption in the MinConv problem.

MinConv
Input: Sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$
Task: Output sequence $(c[i])_{i=0}^{n-1}$, such that $c[k] = \min_{i+j=k}(a[i] + b[j])$

This problem has been used as a hardness assumption before for at least two specific problems [29, 4], but to the best of our knowledge no attempts have been made to systematically study the neighborhood of this problem in the polynomial complexity landscape. To be more precise, we consider the following.

▶ **Conjecture 1.** *There is no $\mathcal{O}(n^{2-\varepsilon})$ algorithm for* MinConv*, for $\varepsilon > 0$.*

Let us first look at the place occupied by MinConv in the landscape of established hardness conjectures. Figure 1 shows known reductions between these conjectures and includes MinConv. Bremner et al. [7] showed reduction from MinConv to APSP. It is also known [4, 1] that MinConv can be reduced to 3SUM (to the best of our knowledge no such reduction has been published before, and we provide the details in the full version of this paper [18]). Note that a reduction from 3SUM or APSP to MinConv would imply a reduction between 3SUM and APSP, which is a major open problem in the area [38]. No relation is known between MinConv and SETH or OV.

In this paper we study three broad categories of problems. The first category consists of the classic 0/1 Knapsack and its variants, which we show to be essentially equivalent to MinConv. This is perhaps somewhat surprising, given recent progress of Bringmann [8] for SubsetSum, which is a special case of 0/1 Knapsack. However, note that Bringmann's

[1] We included all problem definitions together with known results concerning these problems in Section 2. This is to keep the introduction relatively free of technicalities.

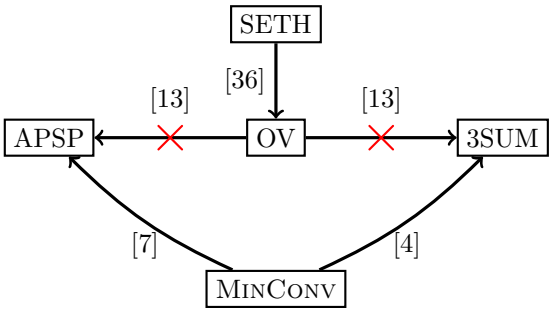

Figure 1 The relationship between popular conjectures. A reduction from OV to 3SUM or APSP contradicts the nondeterministic version of SETH [13, 38] (these arrows are striked-out).

algorithm [8] (as well as in other efficient solutions for SubsetSum) is built upon the idea of composing solutions using the $(\vee, \wedge)$-convolution, which can implemented efficiently using Fast Fourier Transform (FFT). The corresponding composition operation for 0/1 Knapsack is MinConv (see the full version of this paper for details [18]).

The second category consists of problems directly related to MinConv. This includes decision versions of MinConv, and problems related to the notion of subadditivity. Any subadditive sequence a with $a[0] = 0$ is an idempotent of MinConv, so it is perhaps natural that these problems turn out to be equivalent to MinConv.

Finally, we investigate problems that have previously been shown to be related to MinConv, and contribute some new reductions, or simplify existing ones.

2 Problem definitions and known results

2.1 3SUM

3sum
Input: Sets of integers A, B, C, each of size n
Task: Decide whether there exist $a \in A$, $b \in B$, $c \in C$ such that $a + b = c$

The 3sum problem is the first problem that was considered as a hardness assumption in P. It admits a simple $\mathcal{O}(n^2 \log n)$ algorithm but the existence of an $\mathcal{O}(n^{2-\epsilon})$ algorithm remains a big open problem. The first lower bounds based on hardness of 3sum appeared in 1995 [22] and some other examples can be found in [5, 33, 39]. The current best algorithm for 3sum runs in slightly subquadratic expected time $\mathcal{O}\left((n^2/\log^2 n)(\log\log n)^2\right)$ [5]. An $\mathcal{O}\left(n^{1.5}\text{polylog}(n)\right)$ algorithm is possible on the nondeterministic[2] Turing machine [13]. The 3sum problem is known to be subquadratically equivalent to its convolution version in the randomized setting [33].

3sumConv
Input: Sequences a, b, c, each of length n
Task: Decide whether there exist i, j such that $a[i] + b[j] = c[i + j]$

Both problems are sometimes considered with real weights but in this work we restrict only to the integer setting.

[2] We say that decision problem L admits a nondeterministic algorithm in time $T(n)$ if $L \in \text{NTIME}(T(n)) \cap \text{co-NTIME}(T(n))$.

2.2 MinConv

We have already defined the MinConv problem in Subsection 1.2. Note that it is equivalent (just by negating elements) to the analogous MaxConv problem.

MaxConv
Input: Sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$
Task: Output sequence $(c[i])_{i=0}^{n-1}$, such that $c[k] = \max_{i+j=k}(a[i] + b[j])$

We describe our contribution in terms of MinConv as this version has been already been heavily studied. However, in the theorems and proofs we use MaxConv, as it is easier to work with. We will also work with a decision version of the problem.

MaxConv UpperBound
Input: Sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$, $(c[i])_{i=0}^{n-1}$
Task: Decide whether $c[k] \geq \max_{i+j=k}(a[i] + b[j])$ for all k

If we replace the latter condition with $c[k] \leq \max_{i+j=k}(a[i]+b[j])$ we obtain a similar problem MaxConv LowerBound. Yet another statement of a decision version asks whether a given sequence is a self upper bound with respect to MaxConv, i.e., if it is superadditive. From the perspective of MinConv we may ask an analogous question about being subadditive (again equivalent by negating elements). As far as we know, the computational complexity of these problems has not been studied yet.

SuperAdditivity Testing
Input: A sequence $(a[i])_{i=0}^{n-1}$
Task: Decide whether $a[k] \geq \max_{i+j=k}(a[i] + a[j])$ for all k

In the standard $(+, \cdot)$ ring, convolution can be computed in $\mathcal{O}(n \log n)$ time by the FFT. A natural line of attacking MinConv would be to design an analogue of FFT in the $(\min, +)$-semiring, also called a *tropical semiring*[3]. However, due to the lack of inverse for the min-operation it is unclear if such a transform exists for general sequences. When restricted to convex sequences, one can use a tropical analogue of FFT, namely the Legendre-Fenchel transform [19], which can be performed in linear time [30]. Also, [24] considered sparse variants of convolutions and connection with 3sum.

There has been a long line of research dedicated to improve $\mathcal{O}(n^2)$ algorithm for MinConv. Bremner et al. [7] gave an $\mathcal{O}(n^2/\log n)$ algorithm for MinConv, and gave a reduction from MinConv to APSP [7, Theorem 13]. Williams [37] gave an $\mathcal{O}(n^3/2^{\Omega(\log n)^{1/2}})$ algorithm for APSP, which implies the best known $\mathcal{O}(n^2/2^{\Omega(\log n)^{1/2}})$ algorithm for MinConv [15].

Truly subquadratic algorithms for MinConv exist for monotone increasing sequences with integer values bounded by $\mathcal{O}(n)$. Chan and Lewenstein [15] presented an $\mathcal{O}(n^{1.859})$ randomized algorithm and an $\mathcal{O}(n^{1.864})$ deterministic algorithm for that case. They exploited ideas from additive combinatorics. Bussieck et al. [12] showed that for random input, MinConv can be computed in $\mathcal{O}(n \log n)$ expected and $\Theta(n^2)$ worst case time.

If we are satisfied with computing c with a relative error $(1 + \epsilon)$ then general MinConv admits a nearly-linear algorithm [4, 40]. It could be called an FPTAS (fully polynomial-time

[3] In this setting MinConv is often called $(\min, +)$-convolution, inf-convolution or epigraphic sum.

approximation schema) with a remark that usually this name is reserved for single-output problems for which decision versions are NP-hard.

Using techniques of Carmosino et al. [13] and reduction from MaxConv UpperBound to 3sum one can construct an $\mathcal{O}\left(n^{1.5}\text{polylog}(n)\right)$ algorithm working on nondeterministic Turing machines for MaxConv UpperBound (see the full version of this paper [18]). This running time matches the $\mathcal{O}(n^{1.5})$ algorithm for MinConv in the nonuniform decision tree model [7]. This result is based on the techniques of Fredman [21, 20]. It remains unclear how to transfer these results to the word-RAM model [7].

2.3 Knapsack

0/1 Knapsack
Input: A set of items $\mathcal{I}$ with given weights and values $((w_i, v_i))_{i\in\mathcal{I}}$, capacity t
Task: Find the maximal total value of the items subset $\mathcal{I}' \subseteq \mathcal{I}$ such that $\sum_{i\in\mathcal{I}'} w_i \leq t$

If we are allowed to take multiple copies of a single item then we obtain the Unbounded Knapsack problem. The decision versions of both problems are known to be NP-hard [23] but there are classical algorithms based on dynamic programming with a pseudo-polynomial running time $\mathcal{O}(nt)$ [6]. In fact they solve more general problems, i.e., 0/1 Knapsack$^+$ and Unbounded Knapsack$^+$, where we are asked to output answers for each $0 < t' \leq t$. There is also a long line of research on FPTAS for Knapsack with the current best running times respectively $\mathcal{O}(n \log \frac{1}{\epsilon} + \frac{1}{\epsilon^3} \log^2 \frac{1}{\epsilon})$ for 0/1 Knapsack [28] and $\mathcal{O}(n + \frac{1}{\epsilon^2} \log^3 \frac{1}{\epsilon})$ for Unbounded Knapsack [27].

2.4 Other problems related to MinConv

Tree Sparsity
Input: A rooted tree T with a weight function $x : V(T) \to \mathbb{N}_{\geq 0}$, parameter k
Task: Find the maximal total weight of rooted subtree of size k

The Tree Sparsity problem admits an $\mathcal{O}(nk)$ algorithm, which was at first invented for restricted case of balanced trees [14] and generalised later [4]. There is also a nearly-linear FPTAS based on the FPTAS for MinConv [4]. It is known that an $\mathcal{O}(n^{2-\epsilon})$ algorithm for Tree Sparsity entails a subquadratic algorithm for MinConv [4].

MCSP
Input: A sequence $(a[i])_{i=0}^{n-1}$
Task: Output the maximal sum of k consecutive elements for each k

There is a trivial $\mathcal{O}(n^2)$ algorithm for MCSP and a nearly-linear FPTAS based on the FPTAS for MinConv [16]. To the best of our knowledge, this is the first problem to have been explicitly proven to be subquadratically equivalent with MinConv [29]. Our reduction to SuperAdditivity Testing allows us to significantly simplify the proof (see Section 6.1).

l_p-Necklace Alignment
Input: Sequences $(x[i])_{i=0}^{n-1}$, $(y[i])_{i=0}^{n-1}$ describing locations of beads on a circle
Task: Output the cost of the best alignment in p-norm, i.e., $\sum_{i=0}^{n-1} d\left(x[i] + c, y[\pi(i)]\right)^p$ where c is a circular shift, π is a permutation, and d is a distance function on a circle

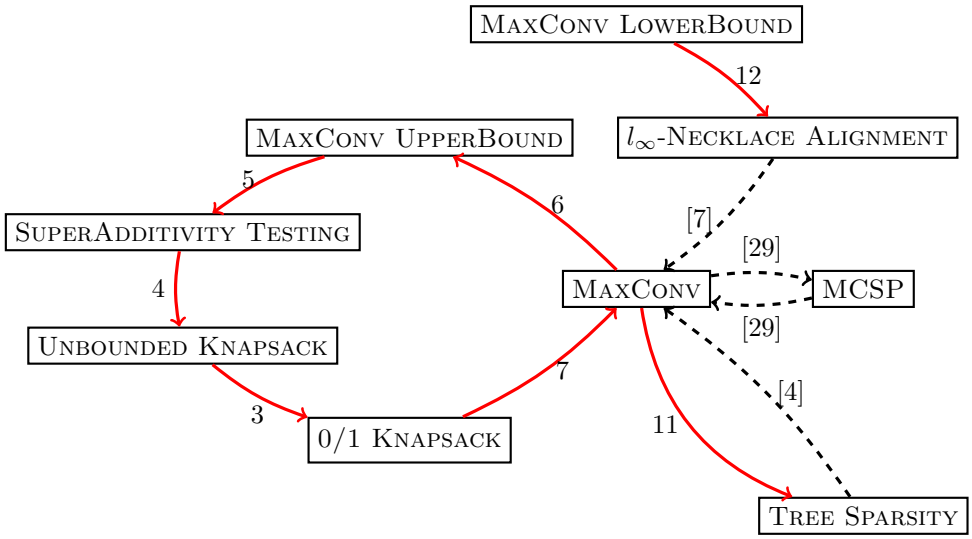

Figure 2 Summary of reductions in the MinConv complexity class. An arrow from problem A to B denotes a reduction from A to B. Black dashed arrows were previously known, red arrows are new results. Numbers next to red arrows point to the corresponding theorems. The only randomized reduction is in the proof of Theorem 7.

For $p = \infty$ we are interested in bounding the maximal distance between any two matched beads. The problem initially emerged for $p = 1$ during the research on geometry of musical rhythm [35]. The family of Necklace Alignment problems has been systematically studied by Bremner et al. [7] for various values of p, in particular $1, 2, \infty$. For $p = 2$ they presented an $\mathcal{O}(n \log n)$ algorithm based on Fast Fourier Transform. For $p = \infty$ the problem was reduced to MinConv which led to a slightly subquadratic algorithm.

Although it is more natural to state the problem with inputs from $[0, 1)$, we find it more convenient to work with integer sequences that describe a necklace after scaling.

Fast $o(n^2)$ algorithms for MinConv have also found applications in text algorithms. Moosa and Rahman [31] reduced the *Indexed Permutation Matching* to MinConv and obtained $o(n^2)$ algorithm. Burcsi et al. [10] used MinConv to get faster algorithms for *Jumbled Pattern Matching* and described how finding dominating pairs can be used to solve MinConv. Later Burcsi et al. [11] showed that fast MinConv can also be used to get faster algorithms for a decision version of the *Approximate Jumbled Pattern Matching* over binary alphabets.

3 New results summary

Figure 2 illustrates the technical contributions of this paper. The long ring of reductions on the left side of the Figure 2 is summarized below.

▶ **Theorem 2.** *The following statements are equivalent:*

1. *There exists an* $\mathcal{O}(n^{2-\varepsilon})$ *algorithm for* MaxConv *for some* $\varepsilon > 0$.
2. *There exists an* $\mathcal{O}(n^{2-\varepsilon})$ *algorithm for* MaxConv UpperBound *for some* $\varepsilon > 0$.
3. *There exists an* $\mathcal{O}(n^{2-\varepsilon})$ *algorithm for* SuperAdditivity Testing *for some* $\varepsilon > 0$.
4. *There exists an* $\mathcal{O}((n+t)^{2-\varepsilon})$ *algorithm for* Unbounded Knapsack *for some* $\varepsilon > 0$.
5. *There exists an* $\mathcal{O}((n+t)^{2-\varepsilon})$ *algorithm for* 0/1 Knapsack *for some* $\varepsilon > 0$.

We allow randomized algorithms.

Theorem 2 is split into five implications, presented separately as Theorems 3,4,5,6 and 7 in Section 5. While Theorem 2 has a relatively short and simple statement, it is not the strongest possible version of the equivalence. In particular, one can show analogous implications for subpolynomial improvements, such as the $\mathcal{O}(n^2/2^{\Omega(\log n)^{1/2}})$ algorithm for MinConv of Williams [37]. The theorems listed above contain stronger versions of the implications.

Section 6 is devoted to the remaining arrows in Figure 2. In Subsection 6.1, we show that by using Theorem 2 we can obtain an alternative proof of the equivalence of MCSP and MaxConv (and so also MinConv), much simpler than the one presented in [29]. In Subsection 6.2, we show that Tree Sparsity reduces to MaxConv, complementing the opposite reduction showed in [4]. Finally in Subsection 6.3 we provide some observations on the possible equivalence between l_∞-Necklace Alignment and MaxConv.

4 Preliminaries

We present a series of results of the following form: if a problem $\mathcal{A}$ admits an algorithm with running time $T(n)$, then a problem $\mathcal{B}$ admits an algorithm with running time $T'(n)$, where function T' depends on T and n is the length of the input. Our main interest is in showing that $T(n) = \mathcal{O}(n^{2-\epsilon}) \Rightarrow T'(n) = \mathcal{O}(n^{2-\epsilon'})$. Some problems, in particular Knapsack, have no simple parameterization and we allow function T to take multiple arguments.

We assume that for all studied problems the input consists of a list of integers within $[-W, W]$. For the sake of readability we omit W as a running time parameter and we allow function T to hide polylog(W) factors. As sometimes the size of the input grows in the reduction, we restrict ourselves to a class of functions satisfying $T(cn) = \mathcal{O}(T(n))$ for a constant c. This is justified as we mainly focus on functions of the form $T(n) = n^\alpha$. In some reductions the integers in the new instance may increase to $\mathcal{O}(nW)$. In that case we multiply the running time by polylog(n) to take into account the overhead of performing arithmetic operations. All logarithms are base 2.

5 Main reductions

▶ **Theorem 3** (Unbounded Knapsack $\to$ 0/1 Knapsack). *A $T(n,t)$ algorithm for* 0/1 Knapsack *implies an $\mathcal{O}(T(n,t)\log t)$ algorithm for* Unbounded Knapsack.

Proof. Consider an instance of Unbounded Knapsack with the capacity t and the set of items given as weight-value pairs $((w_i, v_i))_{i\in\mathcal{I}}$. Construct an equivalent 0/1 Knapsack instance with the same t and the set of items $\left((2^j w_i, 2^j v_i)\right)_{\in\mathcal{I}, 0\le j\le \log t}$. Let $X = (x_i)_{\in\mathcal{I}}$ be the list of multiplicities of items chosen in a solution to the Unbounded Knapsack problem. Of course $x_i \le t$. Define $(x_i^j)_{0\le j\le \log t}$, $x_i^j \in \{0,1\}$ to be the binary representation of x_i. Then the vector $(x_i^j)_{\in\mathcal{I}, 0\le j\le \log t}$ induces a solution to 0/1 Knapsack with the same total weight and value. The described mapping can be reverted what implies the equivalence between the instances and proves the claim. ◀

▶ **Theorem 4** (SuperAdditivity Testing $\to$ Unbounded Knapsack). *If* Unbounded Knapsack *can be solved in time $T(n,t)$ then* SuperAdditivity Testing *admits an algorithm with running time $\mathcal{O}(T(n,n)\log n)$.*

Proof. Let $(a[i])_{i=0}^{n-1}$ be a non-negative monotonic sequence.[4] Set $D = \sum_{i=0}^{n-1} a[i] + 1$ and construct an Unbounded Knapsack instance with the set of items $((i, a[i]))_{i=0}^{n-1} \cup$

[4] For a technical reduction of SuperAdditivity Testing to this case see the full version of this paper [18].

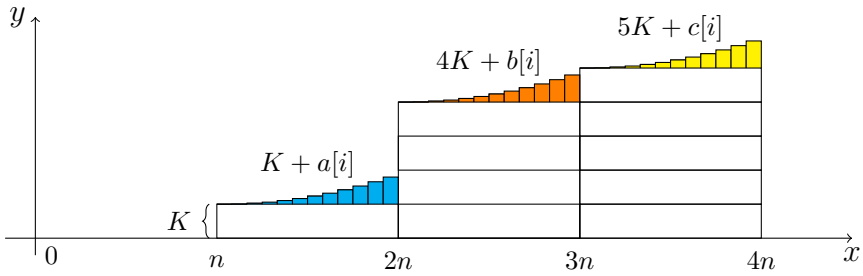

Figure 3 Graphical interpretation of the sequence e in Theorem 5. The height of rectangles equals K.

$((2n-1-i, D-a[i]))_{i=0}^{n-1}$ and $t = 2n-1$. It is always possible to gain D by taking two items $(i, a[i]), (2n-1-i, D-a[i])$ for any i. We will claim that the answer to the constructed instance equals D if and only if a is superadditive.

If a is not superadditive, then there are i, j such that $a[i] + a[j] > a[i+j]$. Choosing $((i, a[i]), (j, a[j]), (2n-1-i-j, D-a[i+j]))$ gives a solution of value exceeding D.

Now assume that a is superadditive. Observe that any feasible knapsack solution may contain at most one item with weight exceeding $n-1$. On the other hand, the optimal solution has to include one such item because the total value of the lighter ones is less than D. Therefore the optimal solution contains an item $(2n-1-k, D-a[k])$ for some $k < n$. The total weight of the rest of the solution is at most k. As a is superadditive, we can replace any pair $(i, a[i]), (j, a[j])$ with the item $(i+j, a[i+j])$ without decreasing the value of the solution. By repeating this argument, we end up with a single item lighter than n. The sequence a is monotonic so it is always profitable to replace this item with a heavier one, as long as the load does not exceed t. We conclude that the optimal solution must be of form $((k, a[k]), (2n-1-k, D-a[k]))$, which completes the proof. ◀

▶ **Theorem 5** (MaxConv UpperBound → SuperAdditivity Testing). *If* SuperAdditivity Testing *can be solved in time* $T(n)$ *then* MaxConv UpperBound *admits an algorithm with running time* $\mathcal{O}(T(n)\log n)$.

Proof. We start with reducing the instance of MaxConv UpperBound to the case of non-negative monotonic sequences. Observe that condition $a[i] + b[j] \le c[i+j]$ can be rewritten as $(C + a[i] + Di) + (C + b[j] + Dj) \le 2C + c[i+j] + D(i+j)$ for any constants C, D. Hence, replacing sequences $(a[i])_{i=0}^{n-1}$, $(b[i])_{i=0}^{n-1}$, $(c[i])_{i=0}^{n-1}$ with $a'[i] = C + a[i] + Di$, $b'[i] = C + b[i] + Di$, $c'[i] = 2C + c[i] + Di$ leads to an equivalent instance. We can thus pick C, D of magnitude $\mathcal{O}(W)$ to ensure that all elements are non-negative and do not exceed the successor. The values in the new sequences may rise up to $\mathcal{O}(nW)$.

From now we can assume the given sequences to be non-negative and monotonic. Define K to be the maximal value occurring in any sequence. Construct a sequence e of length $4n$ as follows. For $i \in [0, n-1]$ set $e[i] = 0$, $e[n+i] = K + a[i]$, $e[2n+i] = 4K + b[i]$, $e[3n+i] = 5K + c[i]$. If there is $a[i] + b[j] > c[i+j]$ for some i, j, then $e[n+i] + e[2n+j] > e[3n+i+j]$ and therefore e is not superadditive. We now show that otherwise e must be superadditive.

Assume w.l.o.g. $i \le j$. The case $i < n$ can be ruled out because it implies $e[i] = 0$ and $e[i] + e[j] \le e[i+j]$ for any j as e is monotonic. If $i \ge 2n$, then $i + j \ge 4n$, so we can restrict to $i \in [n, 2n-1]$. We can also clearly assume $j < 3n$. If $j \in [n, 2n-1]$, then $e[i] + e[j] \le 4K \le e[i+j]$. Finally, $j \in [2n, 3n-1]$ corresponds to the original condition. ◀

▶ **Theorem 6** (MaxConv → MaxConv UpperBound). *A $T(n)$ algorithm for* MaxConv UpperBound *implies an $\mathcal{O}(T(\sqrt{n})n\log n)$ algorithm for* MaxConv.

The proof of the reduction from MaxConv to MaxConv UpperBound has been independently given recently in [4]. For completeness we give our proof in the full version of this paper [18].

▶ **Theorem 7** (0/1 Knapsack → MaxConv). *A $T(n)$ algorithm for* MaxConv *implies an $\mathcal{O}(T(t\log t)\log^3(n/\delta)\log n)$ for* 0/1 Knapsack *that outputs the correct answer with probability at least $1-\delta$.*

▶ **Corollary 8.** *The $\mathcal{O}((n+t)^{2-\epsilon})$ time algorithm for* 0/1 Knapsack *implies the randomized $\mathcal{O}(t^{2-\epsilon'}+n)$ time algorithm for* 0/1 Knapsack$^+$.

The proof follows the approach of Bringmann [8], and we present it in the full version of this paper [18].

6 Other problems related to MinConv

6.1 Maximum consecutive subsums problem

The Maximum Consecutive Subsums Problem (MCSP) is to the best of our knowledge the first problem that has been explicitly proven to be subquadratically equivalent with MinConv [29]. The reduction from MCSP to MaxConv is only shown for completeness, but the reduction in the opposite direction is much simpler than the original one.

▶ **Theorem 9** (MCSP → MaxConv). *If* MaxConv *can be solved in time $T(n)$ then* MCSP *admits an algorithm with running time $\mathcal{O}(T(n))$.*

Proof. Let $(a[i])_{i=0}^{n-1}$ be the input sequence. Construct sequences of length $2n$ as follows: $b[k]=\sum_{i=0}^{k}a[i]$ for $k<n$, $c[k]=-\sum_{i=0}^{n-k-1}a[i]$ for $k\le n$ (empty sum equals 0) and otherwise $b[k]=c[k]=-D$, where D is two times larger than any partial sum. Observe that

$$(b\oplus^{\max}c)[n+k-1]=\max_{\substack{0\le j<n\\ 0\le n+k-j-1\le n}}\sum_{i=0}^{j}a[i]-\sum_{i=0}^{j-k}a[i]=\max_{k-1\le j<n}\sum_{i=j-k+1}^{j}a[i], \tag{1}$$

so we can read the maximum consecutive sum for each length k after performing MaxConv. ◀

▶ **Theorem 10** (SuperAdditivity Testing → MCSP). *If* MCSP *can be solved in time $T(n)$ then* SuperAdditivity Testing *admits an algorithm with running time $\mathcal{O}(T(n))$.*

Proof. Let $(a[i])_{i=0}^{n-1}$ be the input sequence and $b[i]=a[i+1]-a[i]$. The superadditivity condition $a[k]\le a[k+j]-a[j]$ (for all possible k,j) can be translated into $a[k]\le\min_{0\le j<n-k}\sum_{i=j}^{k+j-1}b[i]$ (for all k), so computing MCSP vector on $(-b[i])_{i=0}^{n-2}$ suffices to check if the above condition holds. ◀

6.2 Tree Sparsity

▶ **Theorem 11** (Tree Sparsity → MaxConv). *If* MaxConv *can be solved in time $T(n)$ and the function T is superadditive then* Tree Sparsity *admits an algorithm with running time $\mathcal{O}\left(T(n)\log^2 n\right)$.*

Proof. We take advantage of the heavy-light decomposition introduced by Sleator and Tarjan [34]. This technique has been utilized by Backurs et al. [4] in order to transform a nearly-linear PTAS for MaxConv to a nearly-linear PTAS for Tree Sparsity. The reduction for exact subquadratic algorithms is different in the second phase though.

We construct a *spine* with a *head* s_1 at the root of the tree. We define s_{i+1} to be the child of s_i with the larger subtree (in case of draw we choose any child) and the last node in the spine is a leaf. The remaining children of nodes s_i become heads for analogous spines so the whole tree gets covered. Note that every path from a leaf to the root intersects at most $\log n$ spines because each spine transition doubles the subtree size.

For a node v with a subtree of size m we define the sparsity vector $(x^v[0], x^v[1], \ldots, x^v[m])$ with the weights of the heaviest subtrees rooted at v with fixed sizes. We are going to compute sparsity vectors for all heads of spines in the tree recursively. Let $(s_i)_{i=1}^{\ell}$ be a spine with a head v and let u^i indicate the sparsity vector for the child of s_i being a head (i.e., the child with the smaller subtree). If s_i has less than two children we treat u^i as a vector (0).

For an interval $[a, b] \subseteq [1, \ell]$ let $u^{a,b} = u^a \oplus^{\max} u^{a+1} \oplus^{\max} \cdots \oplus^{\max} u^b$ and $y^{a,b}[k]$ be the maximum weight of a subtree of size k rooted at s_a and not containing s_{b+1}. Let $c = \left\lfloor \frac{a+b}{2} \right\rfloor$. The $\oplus^{\max}$ operator is associative so $u^{a,b} = u^{a,c} \oplus^{\max} u^{c+1,b}$. To compute the second vector we consider two cases: whether the optimal subtree contains s_{c+1} or not.

$$\begin{aligned} y^{a,b}[k] &= \max\left[y^{a,c}[k], \quad \sum_{i=a}^{c} x(s_i) + \max_{k_1+k_2=k-(c-a+1)} \left(u^{a,c}[k_1] + y^{c+1,b}[k_2] \right) \right] \\ &= \max\left[y^{a,c}[k], \quad \sum_{i=a}^{c} x(s_i) + \left(u^{a,c} \oplus^{\max} y^{c+1,b} \right)[k-(c-a+1)] \right] \end{aligned}$$

Using the presented formulas we reduce the problem of computing $x^v = y^{1,\ell}$ to subproblems for intervals $[1, \frac{\ell}{2}]$ and $[\frac{\ell}{2}+1, \ell]$ and results are merged with two $(\max, +)$-convolutions. Proceeding further we obtain $\log \ell$ levels of recursion, where the sum of convolution sizes on each level is $\mathcal{O}(m)$, what results in the total running time $\mathcal{O}(T(m) \log m)$ (recall that T is superadditive).

The second type of recursion comes from the spine decomposition. There are at most $\log n$ levels of recursion with the cumulative sum of subtrees bounded by n on each level, what proves the claim. ◀

6.3 l_∞-Necklace Alignment

In this section we study the l_∞-Necklace Alignment alignment problem that was proved to reduce to MinConv [7]. We are unable to reduce any of the problems equivalent to MinConv to this problem, but we do reduce a related problem - MaxConv LowerBound. We also elaborate on why obtaining a full reduction is difficult.

▶ **Theorem 12** (MaxConv LowerBound $\to$ l_∞-Necklace Alignment)**.** *If* l_∞-Necklace Alignment *can be solved in time* $T(n)$ *then* MaxConv LowerBound *admits an algorithm with running time* $\mathcal{O}(T(n) \log n)$.

Proof. Let a, b, c be the input sequences to MaxConv LowerBound. We call a sum of form $e_1[k_1] + e_2[k_2] + \cdots + e_m[k_m]$, where $e_i \in \{a, b, c\}$, a *combination*, and we define its order as $\sum_{i=1}^{m} k_i$. If an element $e_i[k_i]$ occurs with minus, we subtract k_i.

We can assume the following properties of the input sequences w.l.o.g.

1. *We may assume the sequences are non-negative and* $a[i] \le c[i]$ *for all* i. Just add C_1 to a, $C_1 + C_2$ to b, and $2C_1 + C_2$ to c for appropriate positive constants C_1, C_2.

2. *We can artificially append an element $b[n]$ larger than value of any combination of order n and length bounded by a constant L.* Alternatively, we can say that combinations of order 0 with a positive coefficient at $b[n]$ have positive value. Initially, we enforce this property by setting $b[n]$ as the maximum absolute value of an element times L.
3. *Any combination of positive order and length bounded by L has a non-negative value.* Add a linear function Di to all sequences. As the order of combination is positive, the factors at D sum up to a positive value. It suffices to choose D equal to the maximum absolute value of an element times L. Note that previous inequalities compare combinations of the same order so they stay unaffected.

The values of the elements might increase to $\mathcal{O}(nWL^2)$. For the rest of this proof we will use $L = 10$. Let $B = b[n]$, $B_1 = b[n-1]$, $B_2 = b[n] - b[1]$. We define necklaces x, y of length $2B$ with $2n$ beads each. The property (3) implies monotonicity of the sequences so the beads are given in the right order. We allow two beads to lie in the same place (in particular the first one and the last one in y).

$$\begin{array}{lccccccccc} x = (& a[0], & a[1], & \dots, & a[n-1], & B + c[0], & B + c[1], & \dots, & B + c[n-2], & B + c[n-1] \ ), \\ y = (& B_1 - b[n-1], & B_1 - b[n-2], & \dots, & B_1 - b[0], & B + B_2 - b[n-1], & B + B_2 - b[n-2], & \dots, & B + B_2 - b[1], & 2B \ ). \end{array}$$

Bremner et al. [7] pointed out that the optimal solution for l_∞-Necklace Alignment must be non-crossing, so we can consider only matchings of form $(x[i], y[j])$ where $j = i + k \bmod 2n$ and k is fixed. Let $d(x[i], y[j])$ be the forward distance between $x[i]$ and $y[j]$, i.e., $y[j] - x[i]$ plus the length of the necklaces if $j < i$. Define M_k to be $\max_{i\in[0,N)} d\big(x[i], y[k + i \bmod 2n]\big) - \min_{i\in[0,N)} d\big(x[i], y[k + i \bmod 2n]\big)$. In this setting [7, Fact 5] says that for a fixed k the optimal shift provides solution of value $\frac{M_k}{2}$.

We want to show that for $k \in [0, n)$ it holds

$$\begin{aligned} \min_{i\in[0,2n)} d\big(x[i], y[k + i \bmod 2n]\big) &= B_1 - \max_{i+j=n-k-1} (a[i] + b[j]), \\ \max_{i\in[0,2n)} d\big(x[i], y[k + i \bmod 2n]\big) &= B - c[n-k-1]. \end{aligned}$$

There are five types of connections between beads.

$$d\big(x[i], y[k + i \bmod 2n]\big) = \begin{cases} B_1 - a[i] - b[n-k-1-i] & i \in [0, n-k-1], \quad \text{(I)} \\ B + B_2 - a[i] - b[2n-k-1-i] & i \in [n-k, n-1], \quad \text{(II)} \\ B_2 - b[2n-k-1-i] - c[i-n] & i \in [n, 2n-k-2], \quad \text{(III)} \\ B - c[n-k-1] & i = 2n-k-1, \quad \text{(IV)} \\ B + B_1 - b[3n-k-1-i] - c[i-n] & i \in [2n-k, 2n-1]. \quad \text{(V)} \end{cases}$$

All formulas form combinations of length bounded by 5 so we can apply the properties (2,3). Observe that the order of each combination equals k, except for $i = 2n-k-1$ where the order is $k+1$. Using the property (3) we reason that $B - c[n-k-1]$ is indeed the maximal forward distance. It remains to show that the minimum lies within the group (I). Note that these are the only combinations that lack $b[n]$. By the property (2) each distance from the group (I) compares less with any other distance because the combinations have the same order (except for the maximal one) and only the latter contains $b[n]$.

For $k < n$ the condition $M_k < B - B_1$ is equivalent to $c[n-k-1] > \max_{i+j=n-k-1}(a[i] + b[j])$. If there is such a k, i.e., the answer to MaxConv LowerBound for sequences a, b, c is NO, then $\min_k M_k < B - B_1$ and the return value is less than $\frac{1}{2}(B - B_1)$.

Finally, we need to prove that otherwise $M_k \geq B - B_1$ for all k. We have already acknowledged that for $k < n$. Each matching for $k \geq n$ can be represented as swapping sequences a and c inside the necklace x, composed with the index shift by $k - n$. The two halves of the necklace x are analogous so all the prior observations on the matching structure remain valid.

If the answer to MaxConv LowerBound for sequences a, b, c is YES, then $\forall_{k\in[0,n)}\exists_{i+j=k} a[i]+b[j] \geq c[k]$. The property (1) guarantees that $a \leq c$ so we conclude that $\forall_{k\in[0,n)}\exists_{i+j=k} c[i]+b[j] \geq a[i]+b[j] \geq c[k] \geq a[k]$, and by the same argument as before the cost of the solution is at least $\frac{1}{2}(B-B_1)$. ◀

Observe that both l_∞-Necklace Alignment and MaxConv LowerBound admit simple linear nondeterministic algorithms. For MaxConv LowerBound it is enough to either assign each k a single condition $a[i]+b[k-i] \geq c[k]$ that is satisfied, or guess a k for which none inequality holds. For l_∞-Necklace Alignment we define a decision version of the problem by asking if there is an alignment of value bounded by K (the problem is self-reducible via binary search). For positive instances the algorithm just guesses k inducing an optimal solution. For negative instances it must hold $M_k > 2K$ for all k. Therefore, it suffices to guess for each k a pair i, j such that $d\big(x[i], y[k+i \bmod n]\big) - d\big(x[j], y[k+j \bmod n]\big) > 2K$.

We remind that MaxConv UpperBound reduces to 3sum which admits an $\mathcal{O}\left(n^{1.5}\text{polylog}(n)\right)$ nondeterministic algorithm [13] so in fact there is no obstacle for a subquadratic reduction from MaxConv LowerBound to MaxConv UpperBound to exist (see the full version of this paper [18]). However, the nondeterministic algorithm for 3sum exploits techniques significantly different from ours, including modular arithmetic, and a potential reduction would probably need to rely on some different structural properties of MaxConv.

7 Conclusions and future work

In this paper we undertake a systematic study of MinConv as a hardness assumption, and prove subquadratic equivalence of MinConv with SuperAdditivity Testing, Unbounded Knapsack, 0/1 Knapsack, and Tree Sparsity. An intriguing open problem is to establish the relation between the MinConv conjecture and SETH.

One consequence of our results is a new lower bound on 0/1 Knapsack. It is known that an $\mathcal{O}(t^{1-\epsilon}n^{\mathcal{O}(1)})$ algorithm for 0/1 Knapsack contradicts the SetCover conjecture [17]. Here, we show that an $\mathcal{O}((n+t)^{2-\epsilon})$ algorithm contradicts the MinConv conjecture. This does not rule out an $\mathcal{O}(t+n^{\mathcal{O}(1)})$ algorithm, which leads to another interesting open problem.

Finally, it is open whether MaxConv LowerBound is equivalent to MinConv, which would imply an equivalence between l_∞-Necklace Alignment and MinConv.

Abstract

We initiate the study of finding the Jaccard center of a given collection N of sets. For two sets X, Y, the Jaccard index is defined as $|X \cap Y|/|X \cup Y|$ and the corresponding distance is $1 - |X \cap Y|/|X \cup Y|$. The Jaccard center is a set C minimizing the maximum distance to any set of N.

We show that the problem is NP-hard to solve exactly, and that it admits a PTAS while no FPTAS can exist unless $P = NP$. Furthermore, we show that the problem is fixed parameter tractable in the maximum Hamming norm between Jaccard center and any input set. Our algorithms are based on a compression technique similar in spirit to coresets for the Euclidean 1-center problem.

In addition, we also show that, contrary to the previously studied median problem by Chierichetti et al. (SODA 2010), the continuous version of the Jaccard center problem admits a simple polynomial time algorithm.

1 Introduction

The Jaccard index is a widely used similarity measure on item sets. Given two sets X and Y over a base set U, the similarity is defined as $J(X, Y) = |X \cap Y|/|X \cup Y|$ and the distance is $D(X, Y) = 1 - J(X, Y) = |X \triangle Y|/|X \cup Y|$, where $X \triangle Y$ denotes the symmetric difference of X and Y. In this paper we study the problem of finding the center of a given set of item sets under the Jaccard distance, i.e. for a given collection of sets $N = \{X_1, \ldots, X_n\}$ finding a set $C \subset U$ such that $\max_{X \in N} D(X, C)$ is minimized.

The Jaccard index is arguably the oldest [25] and best known similarity measure on binary data. It has found a wide range of applications such as plagiarism detection [7], association rule mining [12], collaborative filtering [13], web compression [9], biogeographical analysis [34], and chemical similarity searching [39]. Most theoretical computer science research dealing with the Jaccard index focuses on hashing algorithms for nearest neighbor problems, which was pioneered by Broder [6], though a number of publications also deal with clustering tasks on the Jaccard metric, see, for instance, Guha et al [22]. most closely related to this paper addresses the Jaccard median problem, i.e. finding an item set that minimizes the sum of Jaccard distances, see [35, 37].Only recently did Chierichetti et al. [10] show that the Jaccard median problem is NP-hard but also admits a PTAS.

From a more general perspective, the task of finding a single center in a metric space has been studied in various forms dating back to the 19th century [36]. In constant Euclidean space, linear time algorithms exist [30, 38]. In higher dimensions, approximate algorithms based on (weak) coresets have been proposed [3, 4, 11, 26, 40]. Hardness for the 1-center problem in certain finite metrics have been established, including permutation metrics such as Kendall tau and Cayley distances [2, 5, 33], the edit distance on strings [14, 32], and the Hamming metric on strings [16, 27]. The latter problem, also known as the *closest string problem*, is one of the most widely studied center problems in computer science with numerous results on fixed parameter algorithms [15, 21, 29] and approximation algorithms [18, 27, 28]. The more general k-center problem admits a tight 2-approximation in any metric space [19, 23], though some improvements are possible in restricted metrics such as Euclidean space [4].

Our Contribution

We show that the problem is NP-hard to solve exactly, even when the input item sets have cardinality 2. Since the Jaccard distance is a metric, any input point is a trivial 2-approximate solution, and it is easy to see that this bound is tight. We propose two algorithms for the problem. The first algorithm is a PTAS with running time $|N|^{O(\varepsilon^{-6})}|U|^2$. The second one is an FPT algorithm with parameter $k = \max_{X \in N} |X \triangle C|$, i.e. the maximum Hamming norm of input points and Jaccard center C and running time $2^{O(k^3)} \cdot |N| \cdot |U|^3$. As a consequence of our hardness result, we show that under the exponential time hypothesis [24] no FPT algorithm with parameter k and running time $2^{o(k)}$ and no PTAS with running time $2^{o(\sqrt{1/\varepsilon})}$ can exist.

Lastly, we also briefly remark on the continuous version of the problem. Here the input points are non-negative d-dimensional real vectors and $J_c(X,Y) = \frac{\sum_{i=1}^{d} \min(X_i,Y_i)}{\sum_{i=1}^{d} \max(X_i,Y_i)}$. While the Jaccard median problem remains NP-hard for the continuous setting [10, 35], the center problem becomes solvable in polynomial time.

Our Techniques

Our algorithms are based on the existence of a small subset of input points we call *core-covers*. Informally, the union of items of all sets in the *core-cover* contains the (majority of) items of some optimal center C. Specifically, the intersection of the union of items with C yields an α-approximate solution. An *anchored core-cover* further restricts the possible solutions by always containing the items in the intersection of all sets of the core-cover. Crucially, we show that the size of an appropriate (anchored) core-cover is independent of the input when aiming for a $(1+\varepsilon)$-approximation, and dependent only on the parameter k in the context of the FPT algorithm.

In an approximate variant, a core-cover is similar to but weaker than a weak coreset for the Euclidean minimum enclosing ball problem, which requires that the expansion of the minimum enclosing ball computed on the coreset by an $(1+\varepsilon)$-factor contains the entire point set. The existence of constant size weak coresets has been widely studied and utilized [3, 4, 11, 26, 40]. Though the Jaccard distance can be isometrically embedded into (high dimensional) squared Euclidean space, see Gower and Legendre [20], the weak coreset results do not seem to be applicable to the constrained set of solutions corresponding to

embedded item sets. Stronger coreset guarantees extending to arbitrary centers require an exponential dependency on the dimension [1] and therefore also do not seem to be feasible for our purposes.

For the PTAS, we proceed as follows. It turns out that a natural LP relaxation can be efficiently rounded for a large fraction of inputs, namely when for all input sets $X \in N$, we have $\mathrm{OPT} \cdot |X| \in \Omega(\log n/\varepsilon^2)$, where OPT denotes the objective value of the optimum center. If the LP cannot be efficiently rounded, the symmetric difference between any two input sets as well as the optimum set is bounded by $O(\log n/\varepsilon^4)$. A QPTAS now immediately follows by choosing an arbitrary set X, iterating over all subsets S of the base set U with $|S| \in O(\log n/\varepsilon^4)$, and determining the best solution among all candidate centers $X \triangle S$. If we choose multiple sets $X_1, \dots, X_m$ then the number of candidate subsets S will be reduced. In fact, if $X_1, \dots, X_m$ is an anchored core-cover then the dependency on the size of the base set $|U|$ can be replaced by some constant depending only on m and ε. Since there exist anchored core-covers of size $O(1/\varepsilon)$, we obtain a polynomial running time for any fixed ε.

For the FPT-algorithm, the main technical difficulties are to show (1) that the size of an appropriate core-cover can be bounded in terms of the parameter k and (2) that we can efficiently construct an anchored core-cover. As was the case for the PTAS, for a given preliminary anchored core-cover M, we can compute an induced optimum via complete enumeration. If the induced optimum has distance at most OPT to all sets $X \in N$, we are done. Otherwise, any set violating this bound can be added to M. The improvement rate of each added set matches the non-constructive bounds used to show the existence of core-covers, ensuring that the algorithm terminates quickly.

2 Preliminaries

Let $U = \{u_1, \dots u_d\}$ be a base set containing d elements and let $N \subset \mathcal{P}(U)$ be a collection of n subsets of U. Denote the symmetric difference of two sets by $X \triangle Y = (X \setminus Y) \cup (Y \setminus X)$.

▶ **Definition 1** (Binary Jaccard Measures)**.** Given $X, Y \subseteq U$, the *Jaccard similarity* is defined as

$$J(X,Y) = \begin{cases} \frac{|X \cap Y|}{|X \cup Y|} & \text{if } X \cup Y \neq \emptyset \\ 1 & \text{if } X \cup Y = \emptyset, \end{cases}$$

and the *Jaccard distance* is defined as $D(X,Y) = 1 - J(X,Y)$.

It is convenient to refer to specific elements of a set X by the characteristic vector $X \in \{0,1\}^d$ where $X_i = 1$ if $u_i \in X$ and $X_i = 0$ otherwise. The extension of the Jaccard measure to vectors with non-negative but otherwise arbitrary entries is as follows.

▶ **Definition 2** (Continuous Jaccard Measures)**.** Given two d dimensional vectors X, Y with non-negative real entries, the *continuous Jaccard similarity* is defined as

$$J_c(X,Y) = \begin{cases} \frac{\sum_{i=1}^d \min(X_i,Y_i)}{\sum_{i=1}^d \max(X_i,Y_i)} & \text{if } \sum_{i=1}^n \max(X_i,Y_i) > 0 \\ 1 & \text{if } \sum_{i=1}^d \max(X_i,Y_i) = 0, \end{cases}$$

and the *continuous Jaccard distance* is defined as $D_c(X,Y) = 1 - J_c(X,Y)$.

In both cases the Jaccard distance is a metric. We say that the *Jaccard center* of a collection N is the set $C \subseteq U$ (resp. a non-negative real vector $C \in \mathbb{R}^n_{\geq 0}$ for the continuous case) such that $\max_{X \in N} D(X,C)$ is minimized. Throughout this paper we denote by OPT the

value of $\min_{C \subseteq U} \max_{X \in N} D(X, C)$. We always assume $\emptyset \notin N$, i.e. the empty set is not part of the input, as otherwise $\emptyset$ is a trivial optimal solution with maximum distance 1 if there exists at least one further set in N, and maximum distance 0 if $N = \{\emptyset\}$. Lastly, we will frequently use the following easily verifiable facts throughout the paper.

▶ **Fact 3.** *Let $X, Y \subseteq U$ be two item sets. Then the following statements hold:*
- $|X \cap Y| = (1 - D(X, Y)) \cdot |X \cup Y|$,
- $|X| \geq (1 - D(X, Y)) \cdot |Y|$,
- $|X \setminus Y| \leq D(X, Y) \cdot |X|$.

3 Hardness of Binary Jaccard Center

We reduce the problem of finding the optimum Jaccard center from vertex cover defined as follows.

▶ **Definition 4.** Given a graph $G(V, E)$, a vertex cover is a set $K \subset V$ such that $e \cap K \neq \emptyset$ for any $e \in E$. The minimum vertex cover is the vertex cover of smallest cardinality.

It is well known that computing the minimum vertex cover is NP-hard [17]. We will use instances with a minor constraint added for technical reasons. The minimum vertex cover will always have cardinality at most $\frac{|V|}{2} - 2$. It is easy to see that this does not affect the hardness of the vertex cover problem, for instance by adding an isolated star with one central node and $|V| + 5$ remaining nodes.

▶ **Theorem 5.** *Computing the optimum Jaccard center is NP-hard even if every $X \in N$ has cardinality at most 2.*

Proof. Let K be a minimum vertex cover of cardinality at most $\frac{|V|}{2} - 2$ in a graph $G(V, E)$ with no isolated nodes. Consider now the instance of the Jaccard center problem where the input item sets are E, the base set is V, and the center is some subset of V. We claim that a collection of vertexes C is an optimum Jaccard center if and only if C is a minimum vertex cover.

For every collection of vertices C and any edge $e \in E$, we have the following three cases:

$$D(e, C) = \begin{cases} 1 & \text{if } |C \cap e| = 0 \\ \frac{|C|}{|C|+1} & \text{if } |C \cap e| = 1 \\ \frac{|C|-2}{|C|} & \text{if } |C \cap e| = 2. \end{cases}$$

Note that the distance for some edge is 1 if and only if C is not a vertex cover. Note also that $\frac{|C|}{|C|+1} > \frac{|C|-2}{|C|}$, i.e. if $C \neq V$ then $\max_{e \in E} D(e, C) = \frac{|C|}{|C|+1}$. Now for any collection of vertices C that is a vertex cover with $|C| > |K|$, we have two cases. If $C \neq V$, then

$$\max_{e \in E} D(e, C) = \frac{|C|}{|C|+1} \geq \frac{|K|+1}{|K|+2} > \frac{|K|}{|K|+1} = \max_{e \in E} D(e, K).$$

If $C = V$, then

$$\max_{e \in E} D(e, V) = \frac{|V|-2}{|V|} = \frac{\frac{|V|}{2}-1}{\frac{|V|}{2}} \geq \frac{|K|+1}{|K|+2} > \frac{|K|}{|K|+1} = \max_{e \in E} D(e, K). \qquad \blacktriangleleft$$

▶ **Corollary 6.** *There exists no FPTAS for the binary Jaccard center problem unless P=NP.*

Proof. Two non-equal distances are at least apart by $\frac{1}{d^2}$. If an FPTAS were to exist, we could compute determine a $(1+\frac{1}{d^2})$ approximation in polynomial time. This approximation however would coincide with the optimal solution. ◀

Assuming the exponential time hypothesis (ETH), we can give stronger time bounds for PTAS and FPT. ETH, formulated by Impagliazzio, Paturi and Zane [24] assumes that there exists some positive real number s such that 3-SAT with n variables and m clauses cannot be decided in time $2^{s\cdot n}(n+m)^{O(1)}$.

▶ **Corollary 7.** *Let N be a collection of subsets over a base set U and let $C \subset U$ be the optimal Jaccard center. Assuming ETH, no FPT algorithm with parameter $k = \max_{X\in N} |C \triangle X|$, can run in time $2^{o(k)}poly(N,d)$. Further, no PTAS for the Jaccard Center problem can run in time $2^{o(\sqrt{1/\varepsilon})}poly(N,d)$.*

Proof. Under ETH, no FPT algorithm for vertex cover with parameter $|K|$, the minimal size of the vertex cover, can run in time $2^{o(|K|)}\text{poly}(N)$, see Cai and Juedes [8]. Since $k = \max_{X\in N} |C \triangle X| \in \Theta(|K|)$, the first claim follows. For the second claim, recall any PTAS approximating the Jaccard center problem beyond a factor of $(1+\frac{1}{d^2})$ recovers the optimal solution. ◀

4 Core-Covers

Our algorithms are based on the existence of a small collection M of input sets such that a high-quality center can be extracted from M. Informally, the items of an optimal center are well represented by the items of the sets contained in M. The construction is somewhat inspired by coresets for the Euclidean minimum enclosing ball problem, albeit with a weaker guarantee.

▶ **Definition 8** (Core-Covers)**.** Let N be a collection of subsets of a base set U, let OPT be the maximum distance of an optimal Jaccard center to any subset in N, and let $\alpha \geq 1$ be a parameter. A collection $M \subseteq N$ is called an *α-core-cover* if there exists an optimal center C with

$$\max_{X\in N} D\left(X, \left(\bigcup_{X\in M} X\right) \cap C\right) \leq \alpha \cdot \text{OPT}.$$

A collection $M \subseteq N$ with $A_M = \bigcap_{X\in M} X$ and $O_M = \bigcup_{X,Y\in M} X \triangle Y$ is called an *anchored α-core-cover* if there exists an optimal center C with

$$\max_{X\in N} D(X, A_M \cup (O_M \cap C)) \leq \alpha \cdot \text{OPT}.$$

We are especially interested in the size of core-covers with $\alpha = 1$ or $\alpha = 1+\varepsilon$. Core-covers are useful when the supports, i.e. the sets X are small, in which case we can find the solution by enumerating over all possible subsets of $\bigcup_{X\in M} X$. Anchored core-covers are more useful if the supports are large while the optimum value is small. For the remainder of this section, we will give (non-constructive) upper and lower bounds on the number of points required to satisfy both guarantees. Our proofs are essentially based on the following observation.

▶ **Observation 1.** *For any three sets $C, K, X \subseteq U$*

$$D(X,K) \leq D(X, K\cap C) + \frac{|K\setminus C| - 2|(X\cap K)\setminus C)|}{|X\cup K|}.$$

Proof.

$$\begin{aligned} D(X,K) &= \frac{|X \triangle K|}{|X \cup K|} = \frac{|X \triangle (K \cap C)| + |K \setminus C \setminus X| - |X \cap (K \setminus C)|}{|X \cup (K \cap C)| + |K \setminus C \setminus X|} \\ &\leq \frac{|X \triangle (K \cap C)|}{|X \cup (K \cap C)|} + \frac{|K \setminus C \setminus X| - |X \cap (K \setminus C)|}{|X \cup K|} \\ &= D(X, K \cap C) + \frac{|K \setminus C| - 2|X \cap (K \setminus C)|}{|X \cup K|} \end{aligned}$$ ◀

If X is an arbitrary input point, K is our possible solution, and C is an optimal center, this observation implies that it is sufficient to show that $D(X, K \cap C)$ is a good approximation to $D(X, C)$ and $\frac{|K \setminus C| - 2|(X \cap K) \setminus C)|}{|X \cup K|}$ is small or negative.

▶ **Lemma 9.** *For any collection of subsets N, there exists an α-core-cover M of size $\lceil 1/\varepsilon \rceil + 1$ if $\alpha = 1 + \varepsilon$ with $\varepsilon > 0$ and $\min\left\{\frac{\log(OPT \cdot |C|)}{\log(2 - OPT)} + 1, |C|\right\}$ if $\alpha = 1$.*

Proof. We show the existence of the collection M by proving that we can iteratively add a set to M such that either K is already a good approximate solution or the added set contains many elements from $C \setminus K$. Thus, finally we either have C covered by $\bigcup_{X \in M} X$ or no set violates the approximation guarantee. Let $M^{(0)} = \{X\}$ for an arbitrary $X \in N$. We denote by $K^{(i)} = C \cap \left(\bigcup_{X \in M^{(i)}} X\right)$ our solution after the i-th iteration. Note that due to Fact 3, we can assume $|C \setminus K^{(i)}| \leq \mathrm{OPT} \cdot |C|$ as $M^{(i)}$ is non-empty. In the following derivations, we assume that $\alpha \cdot \mathrm{OPT} < 1$, which is always the case for $\alpha = 1$ and always the case for $\alpha = 1 + \varepsilon$ and $\mathrm{OPT} \leq \frac{1}{1+\varepsilon}$. The latter assumption is justified by observing that otherwise any single input point already satisfies the $(1 + \varepsilon)$-core-cover guarantee.

Let $X \in N$ be a set such that $D\left(X, K^{(i)}\right) > \alpha \cdot \mathrm{OPT}$. Then

$$\begin{aligned} |X \cap (C \setminus K^{(i)})| &\overset{K^{(i)} \subseteq C}{=} |X \cap C| - |X \cap K^{(i)}| \\ &\geq (1 - \mathrm{OPT}) \cdot |X \cup C| - (1 - D(X, K^{(i)})) \cdot |X \cup K^{(i)}| \\ &> (1 - \mathrm{OPT}) \cdot |X \cup C| - \\ &\quad (1 - \alpha \cdot \mathrm{OPT}) \cdot (|X \cup C| - |C \setminus K^{(i)}| + |X \cap (C \setminus K^{(i)})|) \\ &\geq (\alpha - 1) \cdot \mathrm{OPT} \cdot |C| + \\ &\quad (1 - \alpha \cdot \mathrm{OPT}) \cdot (|C \setminus K^{(i)}| - |X \cap (C \setminus K^{(i)})|) \end{aligned}$$

For for $\alpha = 1 + \varepsilon$, we have the lower bound $|X \cap (C \setminus K^{(i)})| \geq \varepsilon \cdot \mathrm{OPT} \cdot |C|$. Since $|C \setminus K^{(0)}| \leq \mathrm{OPT} \cdot |C|$, after adding at most $s = \lceil 1/\varepsilon \rceil$ sets to $M^{(0)}$, we have $K^{(s)} = C$, or no set X with $D\left(X, K^{(s)}\right) > (1 + \varepsilon) \cdot \mathrm{OPT}$ exists.

If $\alpha = 1$, we have

$$|X \cap (C \setminus K^{(i)})| \geq \frac{1 - \mathrm{OPT}}{2 - \mathrm{OPT}} \cdot |C \setminus K^{(i)}|$$

which implies that X covers at least $\frac{1-\mathrm{OPT}}{2-\mathrm{OPT}}$ items from $C \setminus K^{(i))}$ in iteration i. Thus, $|C \setminus K^{(i)}| \leq (1 - \frac{1-\mathrm{OPT}}{2-\mathrm{OPT}})^i |C \setminus K^{(0)}| \leq (\frac{1}{2-\mathrm{OPT}})^i \cdot \mathrm{OPT} \cdot |C|$ which is smaller than 1 if $i > \frac{\log(\mathrm{OPT} \cdot |C|)}{\log(2-\mathrm{OPT})}$. Note that $|X \cap (C \setminus K^{(i)})| \geq 1$ if $D(X, K^{(i)}) > OPT$ which concludes the proof. ◀

With the space bound for core-covers, we can prove the main result of this section.

▶ **Lemma 10.** *For any collection of subsets N, there exists an anchored α-core-cover $M \subset N$ of size $O(1/\varepsilon)$ if $\alpha = 1 + \varepsilon$ with $\varepsilon > 0$ and of size $\min\{\frac{\log(OPT \cdot |C|)}{\log(2 - OPT)} + 1, |C|\} + \log \frac{OPT \cdot |C|}{1 - OPT}$ if $\alpha = 1$.*

Proof. Assume we have some optimal center C. Lemma 9 gives a set M such that $K \cap C$ is an α-approximate solution where we can represent K as $K = A_M \cup (O_M \cap C)$. Using Observation 1, the distance between K and some arbitrary set X is

$$\begin{aligned} D(X,K) &\leq D(X, K\cap C) + \frac{|K \setminus C| - 2\cdot|(X\cap K)\setminus C)|}{|X\cup K|} \\ &= D(X, K\cap C) + \frac{|A_M \setminus C| - 2\cdot|X\cap(A_M\setminus C)|}{|X\cup K|} \\ &\leq \alpha\cdot\mathrm{OPT} + \frac{|A_M \setminus C| - 2\cdot|X\cap(A_M\setminus C)|}{|X\cup K|} \end{aligned}$$

If for every $X \in N$, we have $2\cdot|X\cap(A_M\setminus C)| > |A_M\setminus C|$ then the ratio is negative and $D(X,K) \leq D(X, K\cap C) \leq \alpha\cdot\mathrm{OPT}$. Otherwise, there exists an X such that $|X\cap(A_M\setminus C)| = |(X\cap A_M)\setminus C| \leq |A_M\setminus C|/2$. We iteratively augment the collection M satisfying the space and approximation bounds of Lemma 9 with additional sets X. In each iteration, $|A_M\setminus C|$ is halved.

If $\alpha = 1$ and after adding $i > \log|A_M\setminus C|$ sets, we have $A_M\setminus C = \emptyset$. For a more precise bound on i let $Y \in M$. Then due to Fact 3,

$$|A_M\setminus C| \leq |Y\setminus C| \leq \mathrm{OPT}\cdot|Y\cup C| \leq \frac{\mathrm{OPT}\cdot|C|}{1-\mathrm{OPT}}.$$

For the case $\alpha = 1+\varepsilon$, we assume $\mathrm{OPT} < 1/(1+\varepsilon)$ as otherwise any point is a $(1+\varepsilon)$ approximation. Let $X \in N$. Again due to Fact 3 we have

$$\begin{aligned} |A_M\setminus C| &\leq \mathrm{OPT}\cdot\frac{|C|}{1-\mathrm{OPT}} \leq \mathrm{OPT}\cdot\frac{|X|}{(1-\mathrm{OPT})^2} \\ &\leq \mathrm{OPT}\cdot\frac{(1+\varepsilon)^2\cdot|X|}{\varepsilon^2} \leq \mathrm{OPT}\cdot\frac{4}{\varepsilon^2}\cdot|X|, \end{aligned}$$

where the last inequality follows for $\varepsilon \leq 1$. After adding $\log\frac{4}{\varepsilon^3}$ sets such that $|A_M\setminus C|$ is halved with each sets, we have $|A_M\setminus C|/|X\cup K| \leq \varepsilon\cdot\mathrm{OPT}\cdot|X|/|X\cup K| \leq \varepsilon\cdot\mathrm{OPT}$. Our approximation factor is therefore $\alpha\cdot\mathrm{OPT} + \varepsilon\cdot\mathrm{OPT} = (1+2\varepsilon)\cdot\mathrm{OPT}$. Rescaling ε by a factor of 2 completes the proof. ◀

We would like to remark that the bound on the number of sets required to satisfy the $(1+\varepsilon)$-core-cover guarantee is tight, and that the bound on the number of sets to satisfy the anchored $(1+\varepsilon)$-core-cover guarantee is tight up to constant multiplicative factors. Note that M is constrained to using only input sets. Better bounds are possible when we lift this restriction on M (for instance, if M consists of only an optimum center C then all guarantees are met). It is unclear whether improved guarantees not using input sets can be feasibly used in an algorithm.

▶ **Lemma 11.** *There exists a collection of subsets N such that for any $(1+\varepsilon)$-core-cover $M \subseteq N$, we have $|M| \geq 1/\varepsilon - 1$.*

Proof. For a given $\varepsilon > 0$ and assuming $1/\varepsilon$ to be an integer, we consider the following instance of vertex cover. We are given $1/\varepsilon - 1$ stars, each with at least two leaves. The optimum vertex cover and the optimum Jaccard center consists of the internal nodes, with an optimum objective value for the Jaccard center of $\frac{1/\varepsilon-1}{1/\varepsilon}$. If M does not consist of at least one edge from each star, corresponding to a set containing the element contained in the optimal Jaccard center, any center computed using only the entries of the picked edges will not intersect with at least one star, i.e. have distance 1 to the edges of the omitted star. Since $\frac{1/\varepsilon-1}{1/\varepsilon}\cdot(1+\varepsilon) = 1-\varepsilon^2 < 1$, M has to hit every star. ◀

Algorithm 1: PTAS for the Jaccard center problem

Input : Collection N of subsets, Parameter $\varepsilon > 0$
Output : $(1+\varepsilon)$-approximate Jaccard center C

1 Let $D = \{\frac{i}{j} \mid 1 \leq j \leq d \text{ and } 0 \leq i < j\}$.
2 Initialize list $C = \emptyset$.
3 **foreach** $\widehat{OPT} \in D$ **do**
4 **if** $\exists X \in N : \ \widehat{OPT} \cdot |X| < \frac{27 \ln(4n)}{\varepsilon^2}$ **then**
5 **foreach** $M \subseteq N$ with $|M| = \lceil \frac{5}{\varepsilon} + 5 \rceil$ **do**
6 Compute optimal solution $K_{\widehat{\text{OPT}}} = A_M \cup S$ with $S \subseteq O_M$ (cf. Lemma 10).
7 Add $K_{\widehat{\text{OPT}}}$ to C
8 **else**
9 Obtain non-integral solution $K'_{\widehat{\text{OPT}}}$ by solving the set of linear equations given by Equation 1
10 Obtain $K_{\widehat{\text{OPT}}}$ by rounding each entry of $K'_{\widehat{\text{OPT}}}$
11 Add $K_{\widehat{\text{OPT}}}$ to C
12 **return** $\underset{\widehat{\text{OPT}} \in D}{\text{argmin}} \{K_{\widehat{\text{OPT}}} \in C\}$

5 A PTAS for Binary Jaccard Center

This section mainly consists of the proof of the following theorem.

▶ **Theorem 12.** *Given a collection N of n subsets from a base set U of cardinality d and any $\varepsilon > 0$, there exists an algorithm computing a $(1+\varepsilon)$-approximation to the optimal Jaccard center. The algorithm runs in time $d^2 \cdot (n^{O(\varepsilon^{-6})} + LP(n,d))$, where $LP(n,d)$ is the time required to solve a linear program with n constraints and d variables.*

The algorithm (see also Algorithm 1) consists of two main steps. Let OPT be the optimal objective value. Since there are $O(d^2)$ distinct objective values for the Jaccard center problem with a base set of size d, we can try to a find solution for each value (cf. line 3 Algorithm 1). Recall that $C_i = \begin{cases} 0 & \text{if } i \notin C \\ 1 & \text{if } i \in C \end{cases}$ and that $D(X,C) \leq \text{OPT}$ holds for all $X \in N$. By multiplying both sides of the inequality with $|X \cup C|$, we obtain

$$|X \triangle C| \leq \widehat{\text{OPT}} \cdot |X \cup C|. \tag{1}$$

Observe that $|X \triangle C| = \sum_{i=1}^{d} X_i - 2X_iC_i + C_i$ and $|X \cup C| = \sum_{i=1}^{d} X_i - X_iC_i + C_i$. Hence, we obtain a set of linear inequalities which we can test for feasibility by relaxing the integrality constraints on C. Denote a feasible non-integral solution by C'. The existence of a feasible integral solution of Equation 1 implies a feasible relaxed solution C'. We interpret the C'_i as probabilities, i.e. we obtain a binary vector C by rounding each C'_i to 1 with probability C'_i. Using Chernoff bounds, this approach yields a good solution if $\text{OPT} \cdot |X| > s \cdot \log n/\varepsilon^2$ for all X and some constant s (cf. lines 4–7 of Algorithm 1).

If $\text{OPT} \cdot |Y|$ is smaller than this threshold for at least one $Y \in N$ then we could employ a naive brute force algorithm by iterating over all $\binom{d}{s \cdot \log n/\varepsilon} \in O(d^{s \cdot \log n/\varepsilon})$ subsets S and outputting the best $Y \triangle S$. To eliminate the dependency on d, we first show that a bound on $\text{OPT} \cdot |Y|$ implies that $|X_1 \triangle X_2|$ for any two sets $X_1, X_2 \in N$ is bounded. Then we compute an anchored core-cover M by enumerating all collections of $O(1/\varepsilon)$ input sets.

Having determined M, computing the optimum $A_M \cup S$ with $S \subseteq O_M$ becomes feasible (cf. lines 9–11 of Algorithm 1).

Proof of Theorem 12. In the following, we always assume that $\mathrm{OPT} < 1/(1+\varepsilon)$, as otherwise any solution is a $(1+\varepsilon)$ approximation.

To round the set of linear Equations 1, we first recall and apply the following probabilistic bounds.

▶ **Theorem 13** (Multiplicative Chernoff-Bounds [31]). *Let $B_1, \dots B_d$ be independent binary random variables with $\mu = \mathbb{E}[\sum_{i=1}^{d} B_i]$. Then for any $0 < \delta < 1$:*

$$\mathbb{P}\left[\sum_{i=1}^{d} B_i > (1+\delta)\cdot\mu\right] \leq \exp\left(-\frac{\delta^2\cdot\mu}{3}\right) \quad \textit{and} \quad \mathbb{P}\left[\sum_{i=1}^{d} B_i < (1-\delta)\cdot\mu\right] \leq \exp\left(-\frac{\delta^2\cdot\mu}{2}\right).$$

▶ **Lemma 14.** *Let S be a random binary vector obtained by rounding a fractional feasible solution of the set of Equations 1 and let $\varepsilon > 0$ be a constant. Assume that $OPT\cdot|X| \geq \frac{27\ln(4n)}{\varepsilon^2}$ for all $X \in N$. Then with probability at least $1/2$, the rounding procedure produces a binary solution S with $\max_{X\in N} D(X,S) \leq (1+\varepsilon)\cdot OPT$.*

Proof. Observe that $\mathbb{E}[|X\cup S|] \geq |X|$. We first derive concentration bounds on $|X \triangle S|$ and $|X \cup S|$. For any $X \in N$, Theorem 13 yields

$$\mathbb{P}\left[|X\cup S| < (1-\varepsilon/3)\cdot\mathbb{E}[|X\cup S|]\right] \leq \exp\left(-\frac{\varepsilon^2\cdot\mathbb{E}[|X\cup S|]}{18}\right) \leq \exp\left(-\frac{\varepsilon^2\cdot|X|}{18}\right) \leq \frac{1}{4n}$$

and

$$\begin{aligned}
& \mathbb{P}\left[|X\triangle S| > \mathbb{E}[|X\triangle S|] + \varepsilon/3\cdot\mathrm{OPT}\cdot\mathbb{E}[|X\cup S|]\right] \\
= \;& \mathbb{P}\left[|X\triangle S| > \left(1+\frac{\varepsilon\cdot\mathrm{OPT}\cdot\mathbb{E}[|X\cup S|]}{3\cdot\mathbb{E}[|X\triangle S|]}\right)\cdot\mathbb{E}[|X\triangle S|]\right] \\
\leq \;& \exp\left(-\frac{\varepsilon^2\cdot\mathrm{OPT}^2\cdot\mathbb{E}[|X\cup S|]^2}{27\cdot\mathbb{E}[|X\triangle S|]^2}\cdot\mathbb{E}[|X\triangle S|]\right) \\
\leq \;& \exp\left(-\varepsilon^2\cdot\mathrm{OPT}\cdot\mathbb{E}[|X\cup S|]/27\right) \leq \exp\left(-\varepsilon^2\cdot\mathrm{OPT}\cdot|X|/27\right) \leq \frac{1}{4n}.
\end{aligned}$$

Combining these two bounds, we have

$$\frac{|X\triangle S|}{|X\cup S|} \leq \frac{\mathbb{E}[|X\triangle S|] + \varepsilon/3\cdot\mathrm{OPT}\cdot\mathbb{E}[|X\cup S|]}{(1-\varepsilon/3)\cdot\mathbb{E}[|X\cup S|]} \leq \frac{\mathrm{OPT}+\varepsilon/3\cdot\mathrm{OPT}}{1-\varepsilon/3} \leq (1+\varepsilon)\cdot\mathrm{OPT}$$

with probability at least $1 - 1/2n$. Applying the union bound, we then obtain

$$\begin{aligned}
& \mathbb{P}\left[\max_{X\in N} D(X,S) \leq (1+\varepsilon)\cdot\mathrm{OPT}\right] \\
& = 1 - \mathbb{P}\left[\exists X\in N:\ \frac{|X\triangle S|}{|X\cup S|} > (1+\varepsilon)\cdot\mathrm{OPT}\right] \geq 1 - \frac{n}{2n} = 1/2.
\end{aligned}$$

◀

If $\mathrm{OPT}\cdot|X| > \frac{27\ln(4n)}{\varepsilon^2}$ for all $X \in N$, we can use the LP-based rounding scheme analyzed in Lemma 14 (cf. lines 4–7 of Algorithm 1). For the other cases, we will utilize Lemma 10 as follows. There exists at least one set Y with $\mathrm{OPT}\cdot|Y| \leq \frac{27\ln(4n)}{\varepsilon^2}$. With Fact 3, we have

$\mathrm{OPT} \cdot |C| \leq \mathrm{OPT} \cdot |Y|/(1-\mathrm{OPT}) \leq \frac{27\cdot(1+\varepsilon)\cdot\ln(4n)}{\varepsilon^3}$. For any two sets $X_1, X_2 \in N$, we then have

$$\begin{aligned} |X_1 \triangle X_2| &\leq 2 \cdot \mathrm{OPT} \cdot |X_1 \cup X_2| \leq 2 \cdot \mathrm{OPT} \cdot (|X_1| + |X_2|) \\ &\leq 4 \cdot \mathrm{OPT} \frac{|C|}{1-\mathrm{OPT}} \leq \frac{108 \cdot (1+\varepsilon)^2 \cdot \ln(4n)}{\varepsilon^4}. \end{aligned}$$

Let M now be a collection of sets satisfying the guarantee of Lemma 10 with $A_M = \bigcap_{X\in M} X$ and $O_M = \bigcup_{X,Y\in M} X \triangle Y$. Such a collection can be determined in time $n^{O(\varepsilon^{-1})}$ by iterating through all subsets of N of cardinality $O(\varepsilon^{-1})$. Since $|O_M| \leq \sum_{X_i\in M}\sum_{X_j\in M} |X_i \triangle X_j| \leq |M|^2 \cdot \max_{X_i,X_j\in M} |X_i \triangle X_j| \in O(\log n \cdot \varepsilon^{-6})$, we can compute an optimal solution of $\max_{X\in N} \min_{S\subseteq O_M} D(X, A_M \cup S)$ in time $2^{|O_M|} = 2^{O(\log n\cdot\varepsilon^{-6})}$.

The total running time amounts to d^2 calls to the LP given via Equations 1 or d^2 applications of Lemma 10 with a running time of $2^{O(\log n\cdot\varepsilon^{-6})} = n^{O(\varepsilon^{-6})}$. ◀

6 An FPT Algorithm for Binary Jaccard Center

Our second application of core-covers is an FPT algorithm in the parameter $k = \max_{X\in N} |X \triangle C|$ where C is an arbitrary optimal solution. The main technical difficulty is to efficiently construct a core-cover without enumerating all possible core-covers. We first bound the size of an anchored 1-core-cover given by Lemma 10 in terms of k.

▶ **Lemma 15.** *For any collection N of subsets and an optimal center C with cost $OPT < 1$, let $k = \max_{X\in N} |X \triangle C|$. Then*

$$\min\left\{\frac{\log(OPT\cdot|C|)}{\log(2-OPT)} + 1, |C|\right\} \leq 2k \text{ and } \log\frac{OPT\cdot|C|}{1-OPT} \leq 3\log k.$$

Proof. There exists an $X \in N$ such that $k \geq |X \triangle C| = \mathrm{OPT} \cdot |X \cup C| \geq \mathrm{OPT} \cdot |C|$. We first note that both terms are increasing with OPT, hence we assume $\mathrm{OPT} > 1/2$. Then $|X \triangle C|/|X \cup C| = \mathrm{OPT}$ for some $X \in N$ implying

$$(1-\mathrm{OPT}) = \mathrm{OPT} \cdot |X \cap C|/|X \triangle C| \geq \frac{1}{2|X \triangle C|} \geq \frac{1}{2k}.$$

Therefore, we have $1/(1-\mathrm{OPT})) \leq 2k$,

$$\log(2-\mathrm{OPT}) = \log(1+1-\mathrm{OPT}) = \frac{\ln(1+1-\mathrm{OPT})}{\ln 2} \geq \frac{1-\mathrm{OPT}}{2\ln 2} \geq \frac{1}{4k\ln 2},$$

and

$$\min\left\{\frac{\log(\mathrm{OPT}\cdot|C|)}{\log(2-\mathrm{OPT})} + 1, |C|\right\} \leq |C| \leq 2k \text{ and } \log\frac{\mathrm{OPT}\cdot|C|}{1-\mathrm{OPT}} \leq 1 + 2\log k.$$ ◀

For a given estimate of OPT, the algorithm initially chooses two arbitrary sets to be included in the anchored core-cover M. If the optimal solution $A_M \cup S$ with $S \subseteq O_M$ satisfies $\max_{X\in N} D(X, A_M \cup S) < \mathrm{OPT}$ then we can reduce our estimate of OPT. Otherwise, we add any set X at distance greater than OPT to M. The set X improves the core-cover, either by increasing $|C \cap (A_M \cup O_M)|$ or by decreasing $|A_M \setminus C|$ for some optimal center C. Lemma 15 allows us to bound the number of times this happens before M satisfies the anchored core-cover guarantee, upon which we can recover the optimum solution.

Algorithm 2: FPT-algorithm for the Jaccard center problem

Input : Collection N of subsets, Parameter $k = \max_{X \in N} |X \triangle C|$
Output : Optimal Jaccard center C

1 Let $D = \{\frac{i}{j} \mid 1 \leq j \leq d \text{ and } 0 \leq i < j\}$.
2 Initialize list $C = \emptyset$.
3 **foreach** $\widehat{OPT} \in D$ **do**
4 Initialize $M = \{X, Y\}$ with arbitrary $X, Y \in N$ and $X \neq Y$.
5 **for** $i = 1$ **to** $5k$ **do**
6 Compute optimal solution $K_{\widehat{\text{OPT}}} = A_M \cup S$ with $S \subseteq O_M$ (cf. Lemma 10).
7 **if** $\exists X \in N : D(X, K_{\widehat{OPT}}) > \widehat{OPT}$ **then**
8 $M = M \cup \{X\}$
9 **else**
10 Add $K_{\widehat{\text{OPT}}}$ to C
11 **break**
12 **return** $\operatorname{argmin}_{\widehat{\text{OPT}} \in D} \{K_{\widehat{\text{OPT}}} \in C\}$

▶ **Theorem 16.** *Algorithm 2 computes an optimal Jaccard center C satisfying $\max_{X \in N} |X \triangle C| = k$ in time $2^{O(k^3)} \cdot n \cdot d^3$.*

Proof. Let $\widehat{\text{OPT}} \in D$ be a guess for our optimal value OPT. If $\widehat{\text{OPT}} < \text{OPT}$ then the loop terminates without finding a center. Let $\widehat{\text{OPT}} \geq \text{OPT}$. Using Observation 1, we know that

$$D(X, K_{\widehat{\text{OPT}}}) \leq D(X, K_{\widehat{\text{OPT}}} \cap C) + \frac{|K_{\widehat{\text{OPT}}} \setminus C| - 2 \cdot |(X \cap K_{\widehat{\text{OPT}}}) \setminus C)|}{|X \cup K_{\widehat{\text{OPT}}}|}.$$

If $D(X, K_{\widehat{\text{OPT}}}) > \widehat{\text{OPT}}$ then we distinguish between two cases:

Case $|K_{\widehat{\text{OPT}}} \setminus C| - 2 \cdot |(X \cap K_{\widehat{\text{OPT}}}) \setminus C)| \leq 0$:
Then $D(X, K_{\widehat{\text{OPT}}} \cap C) > \widehat{\text{OPT}}$ and we can apply the analysis of Lemma 9. Thus, we add at most $2k$ sets to M until this case can no longer occur (Lemma 15).

Case $|K_{\widehat{\text{OPT}}} \setminus C| - 2 \cdot |(X \cap K_{\widehat{\text{OPT}}}) \setminus C)| > 0$:
Then $|(X \cap K_{\widehat{\text{OPT}}}) \setminus C)| \leq |K_{\widehat{\text{OPT}}} \setminus C|/2$ and we can apply the analysis of Lemma 10. Thus, we add at most $3 \log k$ points to M until this case can no longer occur (Lemma 15).

The computation of $K_{\widehat{\text{OPT}}}$ can be done in time $2^{O(k^3)}$ by an exhaustive search over all possible subsets of O_M since

$$|O_M| \leq |M^2| \cdot \max_{X,Y \in N} |X \triangle Y| \leq O(k^2) \cdot \max_{X,Y \in N} (|X \triangle C| + |Y \triangle C|) = O(k^3).$$

We perform the exhaustive search $O(k)$ times and for each solution we evaluate the objective value for each set. Since $|D| = O(d^2)$ and we examine every set in line 7 of Algorithm 2, the algorithm terminates in time $2^{O(k^3)} \cdot n \cdot d^3$. ◀

7 A Note on Continuous Jaccard Center

We conclude by briefly describing how to find the continuous Jaccard center. We will formulate the decision problem of finding a center with distance at most *dist* as an LP. The

optimum center can thereafter be determined in polynomial time using binary search over the possible values of $dist$. In the following let $X^j \in N$ be the jth point of N w.r.t. some arbitrary ordering. We use the variable $c_i \geq 0$ to denote the ith entry of the Jaccard center. We further use the variables $a_{i,j}$ and $b_{i,j}$ for all $i \in \{1, \ldots, d\}$ and $j \in \{1, \ldots n\}$ to denote the maximum and minimum of X_i^j and c_i. We then use the constraints

$$\sum_{i=1}^{d} b_{i,j} \geq (1 - dist) \cdot \sum_{i=1}^{d} a_{i,j} \qquad \text{for all } j \in \{1, \ldots n\}$$

$$b_{i,j} \leq c_i, X_i^j \leq a_{i,j} \qquad \text{for all } j \in \{1, \ldots n\}, i \in \{1, \ldots d\}$$

$$a_{i,j}, b_{i,j}, c_i \geq 0 \qquad \text{for all } j \in \{1, \ldots n\}, i \in \{1, \ldots d\}.$$

Note that the top most equation $\sum_{i=1}^{d} \min(c_i, X_i^j) \geq (1 - dist) \cdot \sum_{i=1}^{d} \max(c_i, X_i^j)$ is equal to $1 - \frac{\sum_{i=1}^{d} \min(X_i, Y_i)}{\sum_{i=1}^{d} \max(X_i, Y_i)} \leq dist$.

Abstract

The *Orbit Problem* consists of determining, given a matrix $\mathcal{A} \in \mathbb{R}^{d\times d}$ and vectors $x, y \in \mathbb{R}^d$, whether there exists $n \in \mathbb{N}$ such that $\mathcal{A}^n = y$. This problem was shown to be decidable in a seminal work of Kannan and Lipton in the 1980s. Subsequently, Kannan and Lipton noted that the Orbit Problem becomes considerably harder when the *target* y is replaced with a subspace of $\mathbb{R}^d$. Recently, it was shown that the problem is decidable for vector-space targets of dimension at most three, followed by another development showing that the problem is in **PSPACE** for polytope targets of dimension at most three.

In this work, we take a dual look at the problem, and consider the case where the *initial* vector x is replaced with a polytope P_1, and the target is a polytope P_2. Then, the question is whether there exists $n \in \mathbb{N}$ such that $\mathcal{A}^n P_1 \cap P_2 \neq \emptyset$. We show that the problem can be decided in **PSPACE** for dimension at most three. As in previous works, decidability in the case of higher dimensions is left open, as the problem is known to be hard for long-standing number-theoretic open problems.

Our proof begins by formulating the problem as the satisfiability of a parametrized family of sentences in the existential first-order theory of real-closed fields. Then, after removing quantifiers, we are left with instances of simultaneous positivity of sums of exponentials. Using techniques from transcendental number theory, and separation bounds on algebraic numbers, we are able to solve such instances in **PSPACE**.

1 Introduction

Given a linear transformation $\mathcal{A}$ over the vector space $\mathbb{R}^d$, together with a starting point x, the *orbit* of x under $\mathcal{A}$ is the infinite sequence $x, \mathcal{A}x, \mathcal{A}^2x, \ldots$. A natural decision problem in discrete linear dynamical systems is whether the orbit of x ever hits a particular target set V (assuming suitable, effective representations of $\mathcal{A}$, x, and V). An early instance of

this problem was raised by Harrison in 1969 [12] for the special case in which V is simply a point in $\mathbb{R}^d$. Decidability remained open for over ten years, and was finally settled in a seminal paper of Kannan and Lipton, who moreover gave a polynomial-time decision procedure [13]. In subsequent work [14], Kannan and Lipton noted that the Orbit Problem becomes considerably harder when the target V is replaced by a subspace of $\mathbb{R}^d$: indeed, if V has dimension $d-1$, the problem is equivalent to the *Skolem Problem*, known to be **NP-Hard** but whose decidability has remained open for over 80 years [21]. However, for low-dimensional target spaces, the Orbit Problem becomes more tractable. Indeed, it was recently shown in [7] that the problem is decidable for vector-space targets of dimension at most three, with polynomial-time complexity for one-dimensional targets, and complexity in $\mathbf{NP}^{\mathbf{RP}}$ for two- and three-dimensional targets. Another development followed in [8], where the authors consider more intricate target sets, namely polytopes. It is shown in [8] that up to dimension three, the problem can be solved in **PSPACE**. In addition, it is shown that for higher dimensions, the problem becomes hard with respect to long-standing number-theoretic open problems.

A key motivation for studying the Orbit Problem comes from program verification, particularly the problem of determining whether a simple while loop with affine assignments and guards will terminate or not. Similar reachability questions were considered and left open by Lee and Yannakakis in [15] for what they termed "real affine transition systems". Similarly, decidability for the case of a single-halfspace target was mentioned as an open problem by Braverman in [5].

An important aspect of termination problems for linear loops is the quantification of the initial point. Traditionally, the 'Termination problem' in the program-verification literature (see, e.g. [4]) refers to termination of while loops for *all* possible initial starting points. In [17] the traditional Termination Problem is solved over the integers for while loops, assuming diagonalisability of the associated linear transformation. To our knowledge, very little else is known on the general problem of universally quantified inputs. In contrast, the works in [7, 8] study the termination problem where the input is fixed (but the target space is complicated). This corresponds to verifying the termination of a concrete run of a linear loop. It should be noted that the techniques used for analyzing the latter differ significantly from the former.

In this work, we take a dual look at the problem, and study the case where the input is existentially quantified. Thus, we are given a set $P_1 \subseteq \mathbb{R}^d$, and a target set P_2, and the problem is to decide whether there exists $x \in P_1$ and $n \in \mathbb{N}$ such that $\mathcal{A}^n x \in P_2$. In practice, this corresponds to deciding *safety* properties of linear loops: we think of P_2 as some error set, and the problem is to decide whether there exists an input that would cause the program to reach the error set.

Specifically, the focus of this paper is the **3D Polytope-Collision Problem** (**3DPCP**, for short): Given two polytopes P_1 and P_2 in $\mathbb{R}^3$ (represented as an intersection of halfspaces) and a matrix with real-algebraic entries[1] $\mathcal{A} \in (\mathbb{A} \cap \mathbb{R})^{3\times 3}$, determine whether there exists a point $x \in P_1$ and a natural number n such that $\mathcal{A}^n x \in P_2$.

We present the following effectiveness result on the 3D Polytope-Collision Problem.

▶ **Theorem 1.** *3DPCP is decidable in* ***PSPACE****.*

Note that as proved in [8], when the dimension is at least four, the polytope-collision problem becomes hard with respect to number-theoretic open problems.

[1] We denote by $\mathbb{A}$ the set of algebraic numbers.

Before describing our approach, we explain why this result is somewhat surprising. Consider a simplification of 3DPCP, where the initial polytope P is a segment between points x and y, and we wish to decide whether the orbit of P under the matrix $\mathcal{A}$ collides with another polytope R. We can represent P as the single point (x, y) in $\mathbb{R}^6$, and extend $\mathcal{A}$ to a matrix $\mathcal{B} \in \mathbb{R}^{6\times 6}$ that has two copies of $\mathcal{A}$ on its diagonal. Then, the orbit of P under $\mathcal{A}$ corresponds to the orbit of (x, y) under $\mathcal{B}$. However, the respective target space in $\mathbb{R}^6$ becomes the set of all points (u, v) such that the line between u and v in $\mathbb{R}^3$ intersects R. While this is a semi-algebraic set, it is quite complicated, and recall that the polytope hitting problem is already hard in dimension four. Thus, this approach suggests that the problem may be as hard as the hitting problem in $\mathbb{R}^6$.

Technically, the above intricacy prevents us from using the techniques previously employed on fixed-input orbit problems, e.g. [8]. There, describing the dominant behavior of the orbit is relatively straightforward, and the difficulty is reasoning about hitting the target. In our setting, merely describing the orbit involves symbolic quantifier elimination, as described next, and reasoning about hitting the target therefore involves symbolic analysis.

Our approach to proving Theorem 1 is as follows. Observe that 3DPCP can be formulated as the problem of deciding whether there exists $n \in \mathbb{N}$ such that $\mathcal{A}^n P_1$ intersects P_2 (where $\mathcal{A}^n P_1 = \{\mathcal{A}^n x : x \in P_1\}$). In Section 3 we reduce this formulation of 3DPCP to the problem of solving a system of inequalities, as we now describe.

In Section 3.1 we identify two types of intersection of 3D polytopes, namely (1) where a vertex of one polytope lies in the other polytope, and (2) where an edge of one polytope intersects a face of the other polytope. We show that under a certain representation, an intersection of polytopes is always of one of these types. Note that while each of these types seems symmetric with respect to the two polytopes, in our setting the polytopes have an inherent asymmetry, as $\mathcal{A}^n P_1$ is dependent on n whereas P_2 is not.

In order to overcome this asymmetry, in Section 3.2 we reduce 3DPCP to the case where the matrix $\mathcal{A}$ is invertible. Then, considering $\mathcal{A}^n P_1$ and P_2 is symmetric to considering P_1 and $(\mathcal{A}^{-1})^n P_2$.

Next, in Section 3.3 we observe that intersections of Type (1) can be decided using the work in [8], and we are left to address intersections of Type (2). We formulate this type of intersection as $\exists n \in \mathbb{N}\ \Phi(\alpha^n, \overline{\alpha}^n, \rho^n)$, where Φ is a sentence in the existential first-order theory of real-closed fields, and $\alpha, \overline{\alpha}$, and ρ are the eigenvalues of the matrix $\mathcal{A}$, with $\alpha \in \mathbb{A}\setminus\mathbb{R}$ and $\rho \in \mathbb{A} \cap \mathbb{R}$ (the case where $\mathcal{A}$ has only real eigenvalues is simpler, and we handle it in the full version). Moreover, Φ contains only linear expressions (with respect to its variables, where n is treated as a constant), and at most three real variables. We proceed by eliminating the quantifiers from Φ. We use the fact that the expressions in $\Phi(n)$ are linear to apply the simple Fourier-Motzkin quantifier-elimination algorithm [11]. We note that while other quantifier-elimination algorithms (e.g., [20]) offer better asymptotic complexity, since the number of variables in Φ is constant, Fourier-Motzkin elimination takes polynomial time. Moreover, its simplicity allows us to keep track of the expressions in the quantifier free equivalent of $\Phi(n)$. Specifically, we show that this output consists of a disjunction of systems, where each system is a conjunction of expressions of the form

$$A\alpha^{2n} + \overline{A}\overline{\alpha}^{2n} + B\alpha^n\rho^n + \overline{B}\overline{\alpha}^n\rho^n + C\rho^{2n} + D|\alpha|^{2n} + E\alpha^n + \overline{E}\overline{\alpha}^n + F\rho^n + G \bowtie 0 \qquad (1)$$

where $\bowtie \in \{>, =\}$.

Finally, Section 4 is the heart of our technical contribution, in which we show how to solve such systems. Intuitively, we normalize Expression (1) such that the maximal modulus of its terms is 1, thus obtaining an expression of the form $A\gamma^{2n} + \overline{A}\overline{\gamma}^{2n} + B\gamma^n + \overline{B}\overline{\gamma}^n + C + r(n) \bowtie 0$

with $|\gamma| = 1$ and $r(n)$ tending exponentially fast to 0. We then consider two cases, depending on whether γ is a root of unity or not. If γ is a root of unity, we show that it is enough to consider polynomially many expressions with only real elements, which can be handled using relatively standard techniques. If γ is not a root of unity, things are more involved. Then, by utilizing consequences of the Baker-Wüstholz theorem [2], we are able to show that the expression $|A\gamma^{2n} + \overline{A}\overline{\gamma}^{2n} + B\gamma^n + \overline{B}\overline{\gamma}^n + C|$ is bounded away from 0 by an inverse polynomial in n. Then, using a separation bound due to Mignotte [16], we show that $r(n)$ decays fast enough to obtain a bound $N \in \mathbb{N}$ such that $r(n)$ does not affect the sign of $A\gamma^{2n} + \overline{A}\overline{\gamma}^{2n} + B\gamma^n + \overline{B}\overline{\gamma}^n + C$ for all $n > \mathbb{N}$. Finally, since γ is not a root of unity, it is dense in the unit circle, and we can replace the analysis of the former expression by analysis of the simpler function $f(z) = Az^2 + \overline{A}\overline{z}^2 + Bz + \overline{B}\overline{z} + C$ on the unity circle, from which we obtain our main result.

2 Mathematical Tools

In this section we introduce the key technical tools used in this paper.

2.1 Algebraic numbers

For $p \in \mathbb{Z}[x]$ a polynomial with integer coefficients we denote by $\|p\|$ the bit length of its representation as a list of coefficients encoded in binary. Note that the *degree* of p, denoted $\deg(p)$ is at most $\|p\|$, and the *height* of p – i.e., the maximum of the absolute values of its coefficients, denoted $H(p)$ – is at most $2^{\|p\|}$.

We begin by summarising some basic facts about algebraic numbers (denoted $\mathbb{A}$) and their (efficient) manipulation. The main references include [3, 9, 20]. A complex number α is *algebraic* if it is a root of a single-variable polynomial with integer coefficients. The *defining polynomial* of α, denoted p_α, is the unique polynomial of least degree, and whose coefficients do not have common factors, which vanishes at α. The *degree* and *height* of α are respectively those of p, and are denoted $\deg(\alpha)$ and $H(\alpha)$. A standard representation[2] for algebraic numbers is to encode α as a tuple comprising its defining polynomial together with rational approximations of its real and imaginary parts of sufficient precision to distinguish α from the other roots of p_α. More precisely, α can be represented by $(p_\alpha, a, b, r) \in \mathbb{Z}[x] \times \mathbb{Q}^3$ provided that α is the unique root of p_α inside the circle in $\mathbb{C}$ of radius r centred at $a + bi$. A separation bound due to Mignotte [16] asserts that for roots $\alpha \neq \beta$ of a polynomial $p \in \mathbb{Z}[x]$, we have

$$|\alpha - \beta| > \frac{\sqrt{6}}{d^{(d+1)/2} H^{d-1}} \tag{2}$$

where $d = \deg(p)$ and $H = H(p)$. Thus if r is required to be less than a quarter of the root-separation bound, the representation is well-defined and allows for equality checking. Given a polynomial $p \in \mathbb{Z}[x]$, it is well-known how to compute standard representations of each of its roots in time polynomial in $\|p\|$ [3, 9, 19]. Thus given an algebraic number α for which we have (or wish to compute) a standard representation, we write $\|\alpha\|$ to denote the bit length of this representation. From now on, when referring to computations on algebraic numbers, we always implicitly refer to their standard representations.

Note that Equation 2 can be used more generally to separate arbitrary algebraic numbers: indeed, two algebraic numbers α and β are always roots of the polynomial $p_\alpha p_\beta$ of degree

[2] Note that this representation is not unique.

at most $\deg(\alpha) + \deg(\beta)$, and of height at most $H(\alpha)H(\beta)$. Given algebraic numbers α and β, one can compute $\alpha + \beta$, $\alpha\beta$, $1/\alpha$ (for $\alpha \neq 0$), $\overline{\alpha}$, and $|\alpha|$, all of which are algebraic, in time polynomial in $\|\alpha\| + \|\beta\|$. Likewise, it is straightforward to check whether $\alpha = \beta$. Moreover, if $\alpha \in \mathbb{R}$, deciding whether $\alpha > 0$ can be done in time polynomial in $\|\alpha\|$. Efficient algorithms for all these tasks can be found in [3, 9].

2.2 First-order theory of the reals

Let $\overrightarrow{x} = x_1, \ldots, x_m$ be a list of m real-valued variables, and let $\sigma(\overrightarrow{x})$ be a Boolean combination of atomic predicates of the form $g(\overrightarrow{x}) \bowtie 0$, where each $g(\overrightarrow{x}) \in \mathbb{Z}[x]$ is a polynomial with integer coefficients over these variables, and $\bowtie \in \{>, =\}$. A *sentence of the first-order theory of the reals* is of the form $Q_1 x_1 Q_2 x_2 \cdots Q_m x_m \sigma(\overrightarrow{x})$, where each Q_i is one of the quantifiers $\exists$ or $\forall$. Let us denote the above formula by τ , and write $\|\tau\|$ to denote the bit length of its syntactic representation. Tarski famously showed that the first-order theory of the reals is decidable [22]. His procedure, however, has non-elementary complexity. Many substantial improvements followed over the years, starting with Collins' technique of cylindrical algebraic decomposition [10], and culminating with the fine-grained analysis of Renegar [20]. In this paper, we focus exclusively on the situation in which the number of variables is uniformly bounded.

▶ **Theorem 2** (Renegar). *Let $M \in \mathbb{N}$ be fixed, let τ be of the form $Q_1 x_1 Q_2 x_2 \cdots Q_m x_m \sigma(\overrightarrow{x})$. Assume that the number of variables in τ is bounded by M (i.e., $m \leq M$). Then the truth value of τ can be determined in time polynomial in $\|\tau\|$.*

An important property of the first-order theory of the reals is that it admits *quantifier elimination*. That is, consider two lists of variables $\overrightarrow{x}$, $\overrightarrow{y}$ and a sentence $Q_1 x_1 \cdots Q_m x_m \sigma(\overrightarrow{x}, \overrightarrow{y})$ with the variables of $\overrightarrow{y}$ being free, then there exists an (unquantified) sentence $\sigma'(\overrightarrow{y})$ such that for every assignment π to the variables in $\overrightarrow{y}$ it holds that $\sigma'(\pi)$ is true iff $Q_1 x_1 \cdots Q_m x_m \sigma(\overrightarrow{x}, \pi)$ is true.

When the polynomials in σ are all linear and the quantifiers are all existential, then quantifier elimination can be performed using the Fourier-Motzkin quantifier-elimination algorithm [11] (see the full version for details). The benefit of this algorithm is its simplicity, which allows us to remove quantifiers symbolically.

We remark that algebraic constants can also be incorporated as coefficients in the first-order theory of the reals, as follows. Consider a polynomial $g(x_1, \ldots, x_m)$ with algebraic coefficients $c_1, \ldots, c_k$. We replace every c_i with a new, existentially-quantified variable y_i, and add to the sentence the predicates $p_{c_i}(y_i) = 0$ and $(y_i - (a + bi))^2 < r^2$, where (p_{c_i}, a, b, r) is the representation of c_i. Then, in any evaluation of this formula to True, it must hold that y_i is assigned value c_i.

2.3 Polytopes and their representation

A *polytope* P in $\mathbb{R}^3$ is an intersection of finitely many halfspaces in $\mathbb{R}^3$: $P = \{x \in \mathbb{R}^3 : v_1^T x \geq c_1 \wedge \ldots \wedge v_k^T x \geq c_k\}$ for vectors $v_1, \ldots, v_k \in \mathbb{R}^3$ and numbers $c_1, \ldots, c_k \in \mathbb{R}$. The *halfspace description* of P is then $(v_1, c_1), \ldots, (v_k, c_k)$. When all entries are algebraic, we denote by $\|P\|$ the description length.

The *dimension* of a polytope P, denoted $\dim(P)$, is the dimension of the subspace of $\mathbb{R}^3$ spanned by P. The dimension of P can be computed in time polynomial in $\|P\|$ by solving polynomially many linear programs. In $\mathbb{R}^3$, the dimension of a polytope is in $\{0, \ldots, 3\}$. A 2D boundary of a 3D polytope is a 2D polytope called a *face*. Similarly, the boundries of 2D

polytopes (and in particular of faces) are called *edges*, and the boundries of edges are *vertices*. Every 3D polytope, except the trivial $\mathbb{R}^3$ and $\emptyset$, has at least one face (but not necessarily edges or vertices). Since vertices and edges are crucial for our algorithms, we present the following lemma from [8].

▶ **Lemma 3** ([8] Lemma A.1). *Suppose $P \subseteq \mathbb{R}^3$ is a 2D polytope. Then $P = \bigcup_{i=1}^{m} A_i$, where m is finite and each A_i is of the form $A_i = \{u_i + \alpha v_i + \beta w_i : T_i(\alpha, \beta)\}$ where $u_i, v_i, w_i \in \mathbb{R}^3$ and the predicates $T_i(\alpha, \beta)$ are from the following:*

- $T_i(\alpha, \beta) \equiv \alpha \geq 0 \wedge \beta \geq 0$ *(A_i is an infinite cone)*
- $T_i(\alpha, \beta) \equiv \alpha \geq 0 \wedge \beta \geq 0 \wedge \alpha + \beta \leq 1$ *(A_i is a triangle)*
- $T_i(\alpha, \beta) \equiv \alpha \geq 0 \wedge \beta \geq 0 \wedge \beta \leq 1$ *(A_i is an infinite strip)*

Furthermore, if we are given a halfspace description of P with length $\|P\|$, the size of the representation of each vector u_i, v_i, w_i is at most $\|P\|^{O(1)}$.

Note that since the representation of u_i, v_i, and w_i is polynomial, it follows that m is at most exponential in $\|P\|$, and moreover, that iterating over the sets A_i can be done in **PSPACE**.

3 From 3DPCP to a System of Inequalities

In this section we reduce 3DPCP to the problem of solving a system of inequalities. More precisely, we show how to solve 3DPCP by solving an exponential number of systems of equalities and inequalities, and that iterating over these systems can be done in **PSPACE**. In Section 4 we tackle the main technical challenge of solving each such system in **PSPACE**, thus concluding the proof of Theorem 1.

As mentioned in Section 1, we start by studying the intersection of polytopes.

3.1 Intersection of polytopes

Consider two intersecting polytopes Q_1 and Q_2 in $\mathbb{R}^3$. In this section, we characterize the intersection of Q_1 and Q_2, which would later simplify the solution of 3DPCP. To illustrate the idea, assume that both Q_1 and Q_2 are bounded 3D polytopes. In this case, we can assume w.l.o.g. that Q_1 and Q_2 are both tetrahedra. Indeed, every bounded 3D polytope with d vertices can be decomposed into a union of at most $\binom{d}{4}$ tetrahedra, and two such decompositions intersect iff two of the tetrahedra in the respective decompositions intersect. Under this assumption, there are two possible "types" of intersections: either Q_1 is contained in Q_2 (or vice-versa), or an edge of Q_1 intersects a face of Q_2 (or vice-versa). When the polytopes are bounded, we can relax the first requirement, and require instead that a vertex of Q_1 lies in Q_2 (or vice-versa).

In general, however, Q_1 or Q_2 may be unbounded. In this case we need to be slightly more careful. Indeed, as stated in Section 2.3, unbounded polytopes might have no vertices or edges, but only faces (unless the polytope is $\mathbb{R}^3$ or $\emptyset$, in which case the problem is trivial). For example, consider the case where Q_1 and Q_2 are infinite prisms. Then, it is possible that $Q_1 \cap Q_2 \neq \emptyset$ and neither are contained in each other, but no edge of Q_1 intersects a face of Q_2 (and vice-versa).

Therefore, to get the above characterization for unbounded polytopes, we need to add "fictive" edges. Since we assume the input polytopes are non trivial, then each of them has at least one face, and recall that the faces of a 3D polytope are 2D polytopes. By employing Lemma 3 on the faces of the polytopes, we get that each face of Q_1 and of Q_2 can be written as $\bigcup_{i=1}^{m} A_i$ as per Lemma 3. Observe that every set A_i in the decomposition of Lemma 3

has at least two edges and one vertex, and that a non-empty intersection $A_i \cap A'_j$ in such decompositions also intersects an edge of at least one of the two sets (the only involved case is the intersection of two infinite strips, where one should notice that the strips are only infinite to one side).

We conclude that the above characterization of the intersection of polytopes is correct also for unbounded ones. In the following, when we refer to a vertex/edge of an unbounded polytope, we mean the vertices and edges of the sets in the decomposition of Lemma 3.

Thus, we have that Q_1 intersects Q_2 if at least one of the following holds:

1. There exists a vertex of Q_1 that is in Q_2.
2. There exists a vertex of Q_2 that is in Q_1.
3. An edge of Q_1 intersects a face of Q_2.
4. An edge of Q_2 intersects a face of Q_1.

3.2 Reduction to the invertible case

In the notations of Section 3.1, we wish to check the intersection of $Q_1 = \mathcal{A}^n P_1$ and $Q_2 = P_2$ for an existentially quantified $n \in \mathbb{N}$. As mentioned in Section 1, if $\mathcal{A}$ is invertible, then the problem is symmetric with respect to Q_1 and Q_2. Indeed, $\mathcal{A}^n P_1$ intersects P_2 iff P_1 intersects $(\mathcal{A}^{-1})^n P_2$. However, if $\mathcal{A}$ is not invertible, the problem is not clearly symmetric. In this section, we reduce 3DPCP to the case where $\mathcal{A}$ is an invertible matrix.

Consider polytopes $P, R \subseteq \mathbb{R}^3$, and let $\mathcal{A} \in (\mathbb{A} \cap \mathbb{R})^{3\times 3}$ be a singular matrix, so 0 is an eigenvalue of $\mathcal{A}$. Consider first the case where the multiplicity of 0 is 1. Thus, we can write $\mathcal{A} = D^{-1} \begin{pmatrix} 0 & 0 \\ 0 & B \end{pmatrix} D$ where D is an invertible matrix with real-algebraic entries, and $B \in (\mathbb{A} \cap \mathbb{R})^{2\times 2}$. Indeed, if $\mathcal{A}$ has only real eigenvalues then this is achieved by converting $\mathcal{A}$ to Jordan form, and if $\mathcal{A}$ has complex eigenvalues α and $\overline{\alpha}$, then this is achieved by setting $D = (v, u, w)$ where v is an eigenvector corresponding to 0, and $u + iw$ is an eigenvector corresponding to α. In addition, B is invertible, since its eigenvalues are the nonzero eigenvalues of $\mathcal{A}$.

In the full version, we show that in this case, there exist polytopes $P', R' \subseteq \mathbb{R}^2$ such that for every $n \geq 2$ the following holds: there exists $x \in P$ such that $\mathcal{A}^n x \in R$ iff there exists $x' \in P'$ such that $B^{n-1} x' \in R'$. Thus, it is enough to consider the polytopes P', R' and the invertible matrix B. Moreover, we show that computing P' and R' can be done in polynomial time. We also show a similar approach can be taken when 0 has multiplicity 2 or 3 (with the latter being trivial, since $\mathcal{A}$ is then nilpotent).

It should be noted that in the reduction above, even if the input had only rational entries, the output may still require a real-algebraic description. However, the degree and height of the algebraic numbers involved in the description of the output polytopes remain polynomial in the size of the input.

Finally, we note that we can always *increase* the dimension of the problem while maintaining an invertible matrix. Indeed, Given a invertible matrix $B \in (\mathbb{A} \cap \mathbb{R})^{2\times 2}$, we can consider the invertible matrix $\begin{pmatrix} 1 & 0 \\ 0 & B \end{pmatrix}$, and change $P, R \subseteq \mathbb{R}^2$ to $\{1\} \times P, \{1\} \times R \subseteq \mathbb{R}^3$ (and a similar approach when $B \in (\mathbb{A} \cap \mathbb{R})^{1\times 1}$). Thus, it is enough to solve the problem in the invertible case in dimension 3.

3.3 From the invertible case to an equation system

In this section we focus on solving 3DPCP in the invertible case.

Let P_1, P_2 be the input polytopes (whose description may contain algebraic numbers, as per the reduction of Section 3.2), and let $\mathcal{A} \in (\mathbb{A} \cap \mathbb{R})^{3\times 3}$ be an invertible matrix. By Section 3.1, and since $\mathcal{A}$ is invertible, it suffices to decide whether there exists a number $n \in \mathbb{N}$ such that either there exists a vertex x of P_1 with $\mathcal{A}^n x \in P_2$, or there exists an edge e of P_1 such that $\mathcal{A}^n e$ intersects a face of P_2. Note that we may need to reverse the roles of P_1 and P_2, and use $\mathcal{A}^{-1}$ instead of $\mathcal{A}$. We remark that $\left\|\mathcal{A}^{-1}\right\|$ is polynomial in $\|\mathcal{A}\|$, and moreover – since the eigenvalues of $\mathcal{A}^{-1}$ are inverses of those of $\mathcal{A}$ – the description length of the eigenvalues of $\mathcal{A}^{-1}$ is equal to that of $\mathcal{A}$.

In [8], the authors show that the problem of deciding, given a polyhedron P in $\mathbb{R}^3$, a vector $x \in \mathbb{R}^3$, and a matrix $\mathcal{A} \in (\mathbb{A} \cap \mathbb{R})^{3\times 3}$, whether there exists $n \in \mathbb{N}$ such that $\mathcal{A}^n x \in P$ is solvable in **PSPACE**. This solves the former case. It remains to solve the latter.

We thus assume that we are given as input a matrix $\mathcal{A} \in (\mathbb{A} \cap \mathbb{R})^{3\times 3}$, an edge $E = \{u + \lambda v : \lambda \in J\}$ where $u, v \in \mathbb{R}^3$ and J is either $[0, 1]$ or $[0, \infty)$, and a face $F = \{s + \mu t + \nu r : T(\mu, \nu)\}$, where $s, t, r \in \mathbb{R}^3$ and $T(\mu, \nu)$ is one of the following predicates (as per Lemma 3):

- $T(\mu, \nu) \equiv \mu \geq 0 \wedge \nu \geq 0$,
- $T(\mu, \nu) \equiv \mu \geq 0 \wedge \nu \geq 0 \wedge \mu + \nu \leq 1$,
- $T(\mu, \nu) \equiv \mu \geq 0 \wedge \nu \geq 0 \wedge \nu \leq 1$.

We wish to determine whether there exists a number n and $x \in E$ such that $\mathcal{A}^n x \in F$. In the following, we will treat the case where $E = \{u + \lambda v : \lambda \in [0, 1]\}$ and $F = \{s + \mu t + \nu r : \mu \geq 0 \wedge \nu \geq 0 \wedge \mu + \nu \leq 1\}$. The other cases are slightly simpler, and can be solved *mutatis-mutandis*.

Consider the eigenvalues of $\mathcal{A}$. Since $\mathcal{A}$ is a 3×3 invertible matrix, either all the eigenvalues are real, or there is one real eigenvalue ρ, and two complex, conjugate eigenvalues, α and $\overline{\alpha}$. In the latter case, $\mathcal{A}$ is also diagonalizable. We consider here the latter case. In the full version we show how to handle the former case, which is easier.

Thus, let us assume that the eigenvalues of $\mathcal{A}$ are $\rho \in \mathbb{A}\cap\mathbb{R}$ and $\alpha, \overline{\alpha} \in \mathbb{A}$. We can compute an invertible matrix $B \in \mathbb{A}^{3\times 3}$ such that $A = B^{-1} \begin{pmatrix} \rho & 0 & 0 \\ 0 & \alpha & 0 \\ 0 & 0 & \overline{\alpha} \end{pmatrix} B$, and the rows of B are the respective eigenvectors. Note that if w_α is an eigenvector of α, then $\overline{w_\alpha}$ is eigenvector of $\overline{\alpha}$, so we can write $B = \begin{pmatrix} w_\rho & w_\alpha & \overline{w_\alpha} \end{pmatrix}^T$. We now have that $\mathcal{A}^n = B^{-1} \begin{pmatrix} \rho^n & 0 & 0 \\ 0 & \alpha^n & 0 \\ 0 & 0 & \overline{\alpha}^n \end{pmatrix} B$ for every $n \in \mathbb{N}$. By analyzing the structure of B and B^{-1}, it is not hard to verify that every entry of $\mathcal{A}^n$ is a linear combination of $\alpha^n, \overline{\alpha}^n$ and ρ^n such that the coefficients of α^n and $\overline{\alpha}^n$ are conjugates, and the coefficient of ρ^n is real. That is, for every $1 \leq i, j \leq 3$ it holds that $(\mathcal{A}^n)_{i,j} = c_{i,j}\alpha^n + \overline{c_{i,j}}\,\overline{\alpha}^n + d_{i,j}\rho^n$ for coefficients $c_{i,j} \in \mathbb{A}$ and $d_{i,j} \in \mathbb{A} \cap \mathbb{R}$ (independent of n).

Consider a vector $x = u + \lambda v \in E$. We can write $\mathcal{A}^n x = \mathcal{A}^n u + \lambda \mathcal{A}^n v$, and observe that for $1 \leq i \leq 3$ we have $(\mathcal{A}^n u)_i = (c_{i,1}u_1 + c_{i,2}u_2 + c_{i,3}u_3)\alpha^n + \left(\overline{c_{i,1}u_1 + c_{i,2}u_2 + c_{i,3}u_3}\right)\overline{\alpha}^n + (d_{i,1}u_1 + d_{i,2}u_2 + d_{i,3}u_3)\rho^n$, and a similar structure holds for $\mathcal{A}^n v$. By renaming the coefficients, we can write $(\mathcal{A}^n u + \lambda \mathcal{A}^n v)_i = f_i\alpha^n + \overline{f_i}\,\overline{\alpha}^n + g_i\rho^n + \lambda(h_i\alpha^n + \overline{h_i}\,\overline{\alpha}^n + k_i\rho^n)$ where $f_i, h_i \in \mathbb{A}$ and $g_i, k_i \in \mathbb{A} \cap \mathbb{R}$ for $1 \leq i \leq 3$.

We can now formulate the problem as follows: does there exist a number $n \in \mathbb{N}$ such that the following first-order sentence is true: $\exists \lambda, \mu, \nu : 0 \leq \lambda, \mu, \nu \leq 1 \wedge \mu + \nu \leq 1 \wedge$

$$\bigwedge_{i=1}^{3} \left(f_i\alpha^n + \overline{f_i}\,\overline{\alpha}^n + g_i\rho^n + \lambda(h_i\alpha^n + \overline{h_i}\,\overline{\alpha}^n + k_i\rho^n) = s_i + \mu t_i + \nu r_i\right) . \tag{3}$$

As mentioned in Section 2.2, we can convert (3) to an equivalent, quantifier-free sentence. Since our reasoning requires this equivalent sentence to have a special structure, we must explicitly remove the quantifiers. This is done in the full version using Fourier-Motzkin quantifier elimination [11], where we conclude the following.

▶ **Theorem 4.** *There exist constants M, M' such that the sentence (3) is equivalent to a disjunction $\bigvee_{i=1}^{M} \mathrm{Sys}_i$ where for every $1 \leq i \leq M$, Sys_i is a conjunction of at most M' expressions of the form*

$$A\alpha^{2n} + \overline{A}\overline{\alpha}^{2n} + B\alpha^n\rho^n + \overline{B}\overline{\alpha}^n\rho^n + C\rho^{2n} + D|\alpha|^{2n} + E\alpha^n + \overline{E}\overline{\alpha}^n + F\rho^n + G \bowtie 0\,, \quad (4)$$

where $\bowtie \in \{>, =\}$, $A, B, E \in \mathbb{A}$, and $C, D, F, G \in \mathbb{A} \cap \mathbb{R}$. Moreover, the description of Sys *is polynomial in $\|I\|$ (the description length of the input).*

4 Solving the System

This section constitutes the main technical challenge of the paper, namely to decide whether there exists $n \in \mathbb{N}$ such that the disjunction presented in Theorem 4 is true. We refer to such an n as a *solution* for the disjunction.

We first note that it is enough to consider each system in the disjunction separately. Indeed, since the number of systems is bounded, independent of the input, we can try to solve each one separately. Our goal is then to decide, given a system Sys of expressions as per Theorem 4, whether there exists a solution $n \in \mathbb{N}$ that satisfies all the expressions simultaneously.

We divide our analysis to two cases. First we handle the (straightforward) case where $\frac{\alpha}{|\alpha|}$ is a root of unity. We then proceed to consider the more involved case, where $\frac{\alpha}{|\alpha|}$ is not a root of unity.

4.1 The case where $\frac{\alpha}{|\alpha|}$ is a root of unity

Suppose that $\frac{\alpha}{|\alpha|}$, denoted γ, is a root of unity. We can now treat (4) as

$$|\alpha|^{2n}A\gamma^{2n} + |\alpha|^{2n}\overline{A}\overline{\gamma}^{2n} + |\alpha|^n B\gamma^n\rho^n + |\alpha|^n\overline{B}\overline{\gamma}^n\rho^n + C\rho^{2n} + D|\alpha|^{2n} + |\alpha|^n E\gamma^n + |\alpha|^n\overline{E}\overline{\gamma}^n + F\rho^n + G \bowtie 0\,.$$

Let d be the order of γ, then γ^2 is also a root of unity of order at most d. Thus, there are at most d^2 possible values for (γ^n, γ^{2n}), determined by the pair $(n \bmod d, 2n \bmod d)$. We can now treat the expression as d^2 expressions of real-algebraic sums of exponentials. We show that $d \leq \deg(\gamma)^2$, so these can be solved in **PSPACE** using standard techniques of asymptotic analysis, by considering the coefficients and the moduli of α and ρ (see the full version for details).

4.2 The case where $\frac{\alpha}{|\alpha|}$ is not a root of unity

When $\gamma = \frac{\alpha}{|\alpha|}$ is not a root of unity, things are more involved. Nonetheless, we prove the following theorem.

▶ **Theorem 5.** *The problem of deciding whether a system* Sys *of expressions of the form* (4) *has a solution, is in **PSPACE**.*

Before proving the theorem, we need some definitions. In the following, we assume w.l.o.g. that $\rho > 0$. Indeed, if $\rho < 0$ then we can divide into two cases according to the parity of n, and solve each separately (note that $\rho \neq 0$ since the matrix $\mathcal{A}$ is invertible).

For an expression of the form (4), we obtain its *normalized expression* by dividing it by $(\max\{|\alpha|^2, |\alpha|\rho, \rho^2, |\alpha|, |\rho|\})^n$ (and such that the coefficient of the element we divide by is nonzero). Thus, the normalized expression is of the form

$$A\gamma^{2n} + \overline{A}\overline{\gamma}^{2n} + B\gamma^n + \overline{B}\overline{\gamma}^n + C + r(n) \bowtie 0, \tag{5}$$

with $\gamma \in \mathbb{A}$ such that $|\gamma| = 1$ and γ is not a root of unity, $A, B \in \mathbb{A}$ and $C \in \mathbb{A} \cap \mathbb{R}$ are not all 0, and $r(n) = \sum_{l=1}^{m} D_l \beta_l^n + \overline{D_l \beta_l}^n$, where $|\beta_l| < 1$ for every $1 \leq l \leq m$, and $0 \leq m \leq 4$ (note that for uniformity we treat real numbers in $r(n)$ as a sum of complex conjugates). For every $1 \leq l \leq m$, β_l is a quotient of two elements from the set $\{\alpha, \alpha^2, \rho, \rho^2, \alpha\rho\}$. Since α and ρ are eigenvalues of $\mathcal{A}$, $\deg(\alpha), \deg(\rho)$ are $\|\mathcal{A}\|^{O(1)}$. Thus, by Section 2.1, $\deg(\beta_l) = \|\mathcal{A}\|^{O(1)}$, and $H(\beta_l) = 2^{\|\mathcal{A}\|^{O(1)}}$.

Since γ is not a root of unity, then $\{\gamma^n : n \in \mathbb{N}\}$ is dense in the unit circle. With this motivation in mind, we define, for a normalized expression, its *dominant function* $f : \mathbb{C} \to \mathbb{R}$ as $f(z) = Az^2 + \overline{A}\overline{z}^2 + Bz + \overline{B}\overline{z} + C$. Observe that (5) is now equivalent to $f(\gamma^n) + r(n) \bowtie 0$.

The following lemma is our main technical tool in proving Theorem 5.

▶ **Lemma 6.** *Consider a normalized expression as in* (5)*. Let $\|I\|$ be its encoding length, and let f be its dominant function. Then there exists $N \in \mathbb{N}$ computable in polynomial time in $\|I\|$ with $N = 2^{\|I\|^{O(1)}}$ such that for every $n > N$ it holds that*

1. $f(\gamma^n) \neq 0$,
2. $f(\gamma^n) > 0$ *iff* $f(\gamma^n) + r(n) > 0$,
3. $f(\gamma^n) < 0$ *iff* $f(\gamma^n) + r(n) < 0$.

In particular, the lemma implies that if $f(n) + r(n) = 0$, then $n \leq N$. The proof of Lemma 6 relies on the following lemma from [18], which is itself a consequence of the Baker-Wüstholz Theorem [2].

▶ **Lemma 7** ([18])**.** *There exists $D \in \mathbb{N}$ such that for all algebraic numbers ζ, ξ of modulus 1, and for every $n \geq 2$, if $\zeta^n \neq \xi$, then $|\zeta^n - \xi| > \frac{1}{n^{(\|\zeta\| + \|\xi\|)^D}}$.*

We now turn to prove Lemma 6. The following synopsis contains the main ideas. The full proof can be found in the full version.

Proof (Synopsis). Since $\{\gamma^n : n \in \mathbb{N}\}$ is dense on the unit circle, we consider $f(z)$ for z in the unit circle. In the full proof, we show that $\{z : f(z) = 0 \wedge |z| = 1\}$ contains at most four points $\{z_1, \ldots, z_4\}$, whose coordinates are algebraic. Since γ is not a root of unity, it holds that $\gamma^{n_1} \neq \gamma^{n_2}$ for every $n_1 \neq n_2 \in \mathbb{N}$. Thus, there exists $N_1 \in \mathbb{N}$ such that $\gamma^n \notin \{z_1, \ldots, z_4\}$ for every $n > N_1$. Moreover, by Lemma D.1 in [6], we have that $N_1 = k^{O(1)}$, where $k = \|\gamma\| + \sum_{j=1}^{4} \|z_j\|$, and N_1 can be computed in polynomial time in k. Then, by Lemma 7, there exists a constant $D \in \mathbb{N}$ such that for every $n \geq N_1$ and $1 \leq j \leq 4$ we have that $|\gamma^n - z_j| > \frac{1}{n^{(k^D)}}$. Intuitively, for $n > N_1$ we have that γ^n does not get close to any z_i "too quickly" as a function of n. In particular, for $n > N_1$ we have $f(\gamma^n) \neq 0$. It thus remains to show that for large enough n, $r(n)$ does not affect the sign of $f(\gamma^n) + r(n)$. Intuitively, this is the case because $r(n)$ decreases exponentially, while $|f(\gamma^n)|$ is bounded from below by an inverse polynomial. While proving that this holds in general is not very difficult, note that we also need the bound on N in the statement of the Lemma to be effectively computable and to be $2^{\|I\|^{O(1)}}$, which complicates things significantly.

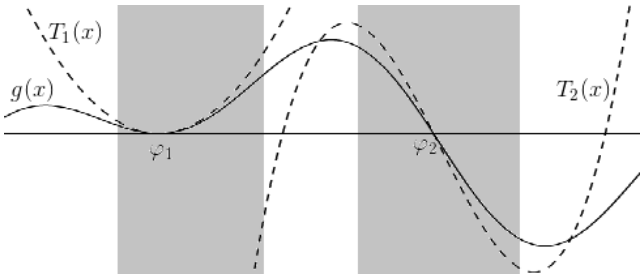

Figure 1 $g(x)$ and two Taylor polynomials: $T_1(x)$ around φ_1 and $T_2(x)$ around φ_2. The shaded regions show where requirements (1)–(3) hold, which determine ϵ_1. Observe that for T_1, the most restrictive requirement is $|g(x) - T_1(x)| \leq \frac{1}{2}T_1(x)$, whereas for T_2 the restriction is the requirement that $T_2(x)$ is monotone.

We consider the function $g : (-\pi, \pi] \to \mathbb{R}$ defined by $g(x) = f(e^{ix})$. Explicitly, we have $g(x) = 2|A|\cos(2x + \theta_A) + 2|B|\cos(x + \theta_B) + C$ where $\theta_A = \arg(A)$ and $\theta_B = \arg(B)$. By the above, g has at most four roots, denoted $\varphi_1, \ldots, \varphi_4$. We now show that there exist $N_2 \in \mathbb{N}$ and a non-negative polynomial $p(n)$ such that $f(\gamma^n) = g(\arg(\gamma^n)) > \frac{1}{p(n)}$ for every $n > N_2$. For every $1 \leq j \leq 4$ consider the first non-zero Taylor polynomial T_j of g around φ_j. In the full version we show that the degree of such approximations is at most 3. We show that there exists $\epsilon_1 > 0$ such that for every $x \in (\varphi_j - \epsilon_1, \varphi_j + \epsilon)$ it holds that (1) $|g(x) - T_j(x)| \leq \frac{1}{2}|T_j(x)|$, (2) g is monotone on either side of φ_j, and (3) T is monotone with the same tendency of g (see Figure 1 for an illustration). In the full version we also show that crucially, we can require ϵ_1 to be efficiently computable and $\frac{1}{\epsilon} = 2^{n^{O(1)}}$.

Consider $n \in \mathbb{N}$ such that $\gamma^n \in \bigcup_{j=1}^{4}(\varphi_j - \epsilon_1, \varphi_j + \epsilon_1)$ and such that $n > N_1$, then as we have seen above, $\frac{1}{n^{(k^D)}} < |\gamma^n - z_j|$. But $|\gamma^n - z_j| < |\arg(\gamma^n) - \varphi_j|$ (since the euclidean distance is smaller than the arc length), so $|\arg(\gamma^n) - \varphi_j| > \frac{1}{n^{(k^D)}}$. From requirements (1) and (2) of ϵ_1, we get that $|g(\arg(\gamma^n))| \geq \frac{1}{2}|T_j(\gamma^n)|$ and from the monotonicity of T_j in the neighbourhood of φ_j (requirement (3)), we have that $\frac{1}{2}|T_j(\gamma^n)| > \frac{1}{2}\min\left\{|T_j(\varphi_j + \frac{1}{n^{(k^D)}})|, |T_j(\varphi_j - \frac{1}{n^{(k^D)}})|\right\}$, from which we conclude that $|g(\arg(\gamma^n))| > \frac{1}{p(n)}$ for some non-negative polynomial p. Moreover, we can compute the representation of p in polynomial time.

Finally, for $x \notin \bigcup_{j=1}^{4}(\varphi_j - \epsilon_1, \varphi_j + \epsilon_1)$, we have that $|g(x)|$ is bounded from below by a constant. Our careful accounting of $\|\epsilon_1\|$ in the full version allows us to compute this bound, and show that it is not too small.

The last step in the proof is to show that $r(n)$ decreases fast enough such that $r(n) < \frac{1}{p(n)}$ for every $n > N_3$ for some large enough $N_3 \in \mathbb{N}$. Clearly this holds eventually, since $r(n)$ decreases exponentially. However, we also need a bound on the size of N_3, which requires more effort. Recall that $r(n) = \sum_{l=1}^{m} D_l\beta_l^n + \overline{D_l\beta_l}^n$. By applying The root separation bound (2) from Section 2.1 to $1 - |\beta_l|$, we compute $\epsilon \in (0, 1)$ and $N_3 \in \mathbb{N}$ such that $\frac{1}{\epsilon}$ and N_3 are $2^{\|I\|^{O(1)}}$, and for every $n > N_3$ it holds that $|r(n)| < (1 - \epsilon)^n$. Using this, we can find $N_4 \in \mathbb{N}$ such that $N_4 = 2^{\|I\|^{O(1)}}$ and $|r(n)| < \frac{1}{p(n)}$ for all $n > N_4$, from which we can conclude the proof. ◀

We are now ready to prove Theorem 5

Proof. For every expression in Sys, let f be the corresponding function as per Lemma 6, and compute its respective bound N. If $\bowtie$ is "=", then by Lemma 6, if the equation is satisfiable for $n \in \mathbb{N}$, then $n < N$.

If all the $\bowtie$ are ">", then for each such inequality compute $\{z : f(z) > 0\}$. If the intersection of these sets is empty, then if n is a solution for the system, it must hold that $n < N$. If the intersection is non-empty, then it is an open set. Since γ is not a root of unity, then $\{\gamma^n : n \in \mathbb{N}\}$ is dense in the unit circle. Thus, there exists $n > N$ such that γ^n is in the above intersection, so the system has a solution. Checking the emptiness of the intersection can be done in polynomial time using Theorem 2.

Thus, it remains to check whether there exists a solution $n < N$. Recall that $N = 2^{\|I\|^{O(1)}}$. Thus, in order to check whether the system is solved for $n < N$, we need to compute, e.g., α^{2n}, whose representation is exponential in $\|I\|$, so a naive implementation would take exponential space.

Instead, we take a similar approach to [8]: by representing numbers as arithmetic circuits, deciding the positivity (or testing for 0 equality) can be done using an oracle to **PosSLP**, which by [1] is in the counting hierarchy. By first guessing $n < N$, the problem can be solved in $\mathbf{NP}^{\mathbf{PosSLP}}$, which is contained in **PSPACE**. ◀

5 Conclusions

5.1 Proof of Theorem 1

We conclude by giving an explicit proof of Theorem 1: Given polytopes P_1 and P_2 and a matrix $\mathcal{A}$, if $\mathcal{A}$ is singular, we first apply (in polynomial time) the reduction in Section 3.2. Thus, we can assume $\mathcal{A}$ is invertible. Next, if P_1 or P_2 are unbounded, for each unbounded face F we proceed as follows: decompose F as per Lemma 3, so $F = \bigcup_{i=1}^{m} A_i$, and recall that iterating over the A_i's can be done in **PSPACE**. In each iteration, consider an edge E of P_1 and a face F of P_2 (both of which may belong to sets A_i as above). Formulate the first-order sentence (3) in Section 3.3, and apply Theorem 4 to obtain an equivalent disjunction of systems $\bigvee_{i=1}^{M} \mathrm{Sys_i}$, where M is constant. Then, for each system $\mathrm{Sys_i}$, check in **PSPACE** whether it has a solution, using either Section 4.1 or Theorem 5. If no solution was found, check in **PSPACE** whether a vertex of P_1 collides with P_2, using the algorithm in [8]. Then, if still no solution is found, repeat the same procedure by interchanging the roles of P_1 and P_2, and considering the matrix $\mathcal{A}^{-1}$ instead of $\mathcal{A}$. The correctness and complexity of this procedure follow from the proofs of the respective theorems.

5.2 Discussion

This paper studies an extension of the Orbit Problem, in which the input is existentially quantified over a polytope, and the target is a polytope. The importance of this work is twofold: from a practical perspective, we provide an algorithm for deciding the termination of linear while loops with affine guards, up to dimension three, when the input is not fixed. From a more theoretical perspective, and as already pointed out by Kannan and Lipton in [14], the Orbit Problem and its variants are closely related to long-standing open problems such as the *Skolem Problem*, and various number-theoretic problems. It is therefore useful and compelling to push the borders of decidability, in order to identify the core of the remaining difficulties, and to eventually hopefully overcome them.

Finally, as discussed in Section 1, the problem at hand can be viewed as a particular case of the Orbit Problem in dimension six where the target is a semi-algebraic set. As the general problem is known to be hard even in dimension four, our work here suggests that interesting and useful fragments are tractable even in high dimensions.

Abstract

Dynamic Time Warping (DTW) and Geometric Edit Distance (GED) are basic similarity measures between curves or general temporal sequences (e.g., time series) that are represented as sequences of points in some metric space (X, dist). The DTW and GED measures are massively used in various fields of computer science and computational biology, consequently, the tasks of computing these measures are among the core problems in P. Despite extensive efforts to find more efficient algorithms, the best-known algorithms for computing the DTW or GED between two sequences of points in $X = \mathbb{R}^d$ are long-standing dynamic programming algorithms that require quadratic runtime, even for the one-dimensional case $d = 1$, which is perhaps one of the most used in practice.

In this paper, we break the nearly 50 years old quadratic time bound for computing DTW or GED between two sequences of n points in $\mathbb{R}$, by presenting deterministic algorithms that run in $O\left(n^2 \log\log\log n / \log\log n\right)$ time. Our algorithms can be extended to work also for higher dimensional spaces $\mathbb{R}^d$, for any constant d, when the underlying distance-metric dist is polyhedral (e.g., L_1, L_∞).

1 Introduction

Searching for optimal algorithms is a standard routine in the study of algorithm design. Among the most popular basic problems in P are those that have standard algorithms that run in $O(n^c)$ time, where $c = 2$ or 3. For $c = 3$ (cubic time), we can find many kinds of combinatorial matrix multiplication algorithms, and for $c = 2$ (quadratic time), we can find many fundamental problems, such as 3SUM, and many basic matching problems between strings, curves, and point-sequences, such as Edit Distance, Geometric Edit Distance (GED), Dynamic Time Warping (DTW), Discrete Fréchet Distance, and Longest Common Subsequence (LCS). These problems are usually referred to as "quadratic problems".

Motivated to find optimal algorithms for these basic problems, researchers have come up with time bounds of the form $O(n^c/\operatorname{polylog}(n))$, where $\operatorname{polylog}(n)$ stands for $\log^k n$, for some constant $k > 0$. By now, many classical quadratic problems have upper bounds of the form $O(n^2/\operatorname{polylog}(n))$, including all of the problems mentioned above, except for DTW and GED; see [3, 29, 18, 21] for such upper bounds. Among the very few archetypal quadratic problems for which no $o(n^2)$-time algorithm is known, DTW and GED seem to be prominent examples, considering the decades of extensive efforts to break the quadratic barrier.

Motivation. Complementary to the standard theoretical interest in finding optimal algorithms for basic problems in P, a significant progress has been made in recent years towards a better understanding these problems, by proving conditional lower bounds via reductions from basic problems, such as 3SUM and CNF-SAT. Assuming that CNF-SAT takes $\Omega\left(2^{(1-o(1))n}\right)$ time (the so-called *Strong Exponential Time Hypothesis* (SETH) [22, 23]), has led to recent lower bounds for a growing list of problems, including most of the quadratic problems mentioned above. Specifically, assuming SETH, there is no $O\left(n^{2-\Omega(1)}\right)$-time algorithm for Discrete Fréchet Distance [8], Edit Distance [6], LCS [1, 9], and DTW [1, 9].

A recent seminal work by Abboud *et al.* [2] shows that even an improvement by a sufficient polylogarithmic factor for any of these basic problems would lead to major consequences, such as faster Formula-SAT algorithms, and new circuit lower bounds. Hence, the work of Abboud *et al.* highly motivates and revives the study of polylogarithmic-factor improvements for these basic problems, since it may be the only way to push the efficiency of the solution "to the limit".

Problem Statement. Let $A = (p_1, \ldots, p_n)$ and $B = (q_1, \ldots, q_m)$ be two sequences of points (also referred to as curves) in some metric space (X, dist). A *coupling* $C = (c_1, \ldots, c_k)$ between A and B is an ordered sequence of distinct pairs of points from $A \times B$, such that $c_1 = (p_1, q_1)$, $c_k = (p_n, q_m)$, and

$$c_r = (p_i, q_j) \Rightarrow c_{r+1} \in \big\{(p_{i+1}, q_j),\ (p_i, q_{j+1}),\ (p_{i+1}, q_{j+1})\big\},$$

for $r < k$. The DTW-distance between A and B is

$$\mathsf{dtw}(A, B) = \min_{C:\, coupling} \sum_{(p_i, q_j) \in C} \mathsf{dist}(p_i,\, q_j). \tag{1}$$

The coupling C for which the above sum is minimized is called the *optimal coupling*. The DTW problem is to compute $\mathsf{dtw}(A, B)$, and sometimes also the optimal coupling C.

A *monotone matching* $\mathcal{M} = \{m_1, \ldots, m_k\}$ between A and B is a set of pairs of points from $A \times B$, such that any two pairs (p_i, q_j), $(p_{i'}, q_{j'}) \in \mathcal{M}$ satisfy that $i \leq i'$ iff $j \leq j'$, and each point in A is matched with at most one point in B and vice versa (possibly some points in $A \cup B$ do not appear in any pair of the matching); Note the difference from coupling (defined above), which covers all points of $A \cup B$ and a point can appear in multiple pairs of the coupling. The cost of $\mathcal{M}$ is defined to be the sum of all the distances between the points of each pair in $\mathcal{M}$, plus a *gap* penalty parameter $\rho \in \mathbb{R}$, for each point in $A \cup B$ that does not appear in any pair of $\mathcal{M}$.

The Geometric Edit Distance (GED) between A and B is

$$\mathsf{ed}(A, B) = \min_{\mathcal{M}} \sum_{(p_i, q_j) \in \mathcal{M}} \mathsf{dist}(p_i,\, q_j) + \rho\left(n + m - 2|\mathcal{M}|\right), \tag{2}$$

where the minimum is taken over all sets $\mathcal{M}$ of monotone matchings in the complete bipartite graph $A \times B$. The monotone matching $\mathcal{M}$ for which the above sum is minimized is called

the *optimal matching*. The GED problem is to compute $\mathsf{ed}(A, B)$, and sometimes also the optimal matching. More sophisticated gap penalty functions have been proposed [14], but for this presentation, we focus on the standard linear gap penalty function, although our presented algorithm supports more complex gap penalty, such as taking ρ to be a linear function in the coordinates of the points $A \cup B$. By tuning ρ correctly, meaningful matchings can be computed even when faced with outlier points that arise from measurement errors or short deviations in otherwise similar trajectories.

The DTW-distance and GED are massively used in dozens of applications, such as speech recognition, geometric shape matching, DNA and protein sequences, protein backbones, matching of time series data, GPS, video and touch screen authentication trajectories, music signals, and countless data mining applications; see [11, 13, 15, 28, 27, 25, 30, 32, 26] for some examples.

The best-known worst-case running times for solving DTW or GED are given by long-standing dynamic programming algorithms that require $\Theta(nm)$ time. We review the standard quadratic-time DTW and GED algorithms in the full version of this paper [19].

DTW was perhaps first introduced as a speech discrimination method [33] back in the 1960's. GED is a natural extension of the well-known string version of Edit Distance, however, the subquadratic-time algorithms for the string version do not seem to extend to GED (see below).

A popular setting in both theory and practice is the one-dimensional case $X = \mathbb{R}$ (under the standard distance $\mathsf{dist}(x, y) = |x - y|$). Even for this special case, no subquadratic-time algorithms have been known. We mainly consider this case throughout the paper.

Prior Results. Since no subquadratic-time algorithm is known for computing DTW, a number of heuristics were designed to speed up its exact computation in practice; see Wang *et al.* [34] for a survey. Very recently, Agarwal *et al.* [4] gave a near-linear approximation scheme for computing DTW or GED for a restricted, although quite large, family of curves.

Recently, Bringmann and Künnemann [9] proved that DTW on one-dimensional point sequences whose elements are taken from $\{0, 1, 2, 4, 8\} \subset \mathbb{R}$ has no $O(n^{2-\Omega(1)})$-time algorithm, unless SETH fails. They proved a similar hardness result also for Edit Distance between two binary strings, improving the conditional lower bound of Backurs and Indyk [6]. This line of work was extended in a very recent work by Abboud *et al.* [2], mentioned above, where they show that even a sufficiently large polylog(n)-factor improvement over the quadratic time upper bound for Edit Distance or DTW, will lead to major consequences.

Masek and Paterson [29] showed that Edit Distance between two strings of length at most n over an $O(1)$-size alphabet can be solved in $O(n^2/\log n)$ time. More recent works [7, 20] managed to lift the demand for $O(1)$-size alphabet and retain a subquadratic-time bound by making a better use of the word-RAM model. However, these works do not seem to extend to GED, especially not when taking sequences of points with arbitrary real coordinates. In the string version, the cost of replacing a character is fixed (usually 1), hence, we only need to detect that two characters are not identical in order to compute the replacement cost, unlike in GED, where the analogous cost for two matched points is taken to be their distance, under some metric.

Our Results and Related Work. Efforts for breaking the quadratic time barrier for basic similarity measures between curves and point-sequences were recently stimulated by the result of Agarwal *et al.* [3] who showed that the discrete Fréchet distance can be computed in $O(n^2/\log n)$ time. Their algorithm for (discrete) Fréchet distance does not extend to DTW

or GED, as the recursive formula for the (discrete) Fréchet distance uses the max function, while the formula for DTW and GED involves the sum. As a result, the Fréchet distance is effectively determined by a single pair of sequence elements, which fits well into the use of the Four-Russians technique [5], while the DTW and GED are determined by many pairs of elements. This makes our algorithms much more subtle, involving a combination and extension of techniques from computational geometry and graph shortest paths.

To simplify the presentation, we present our results only for the "balanced" case $m = n$; extending them to the general case $m \leq n$ is easy. The standard $\Theta(mn)$-time algorithm is superior only when m is subpolynomial in n.

▶ **Theorem 1.** *Given two sequences $A = (p_1, \ldots, p_n)$ and $B = (q_1, \ldots, q_n)$, each of n points in $\mathbb{R}$, the* DTW*-distance* $\mathsf{dtw}(A, B)$ *(and optimal coupling), or the* GED $\mathsf{ed}(A, B)$ *(and optimal matching) can be computed by a deterministic algorithm in $O(n^2 \log\log\log n / \log\log n)$ time.*

Theorem 1 gives the very first subquadratic-time algorithm for solving DTW, breaking the nearly 50 years old $\Theta(n^2)$ time bound. In the full version of this paper [19], we extend our algorithm to give a more general result, which supports high-dimensional polyhedral metric spaces, as stated in Theorem 2. Additionally, in [19], we extend our algorithm for solving GED.

▶ **Theorem 2.** *Let $A = (p_1, \ldots, p_n)$ and $B = (q_1, \ldots, q_n)$ be two sequences of n points in a polyhedral metric space*[1] *($\mathbb{R}^d$, dist). Then* $\mathsf{dtw}(A, B)$ *(and optimal coupling), or* $\mathsf{ed}(A, B)$ *(and optimal matching) can be computed by a deterministic algorithm in $O(n^2 \log\log\log n / \log\log n)$ time, for any constant d.*

2 Preliminaries

Throughout the paper, we view matrices with rows indexed in increasing order from bottom to top and columns indexed in increasing order from left to right, so, for example, $M[1, 1]$ the leftmost-bottom cell of a matrix M.

In Fredman's classic 1976 articles on the decision tree complexity of $(\min, +)$-matrix multiplication [17], and on sorting $X + Y$ [16], he often uses the simple observation that $a + b < a' + b'$ iff $a - a' < b' - b$. This observation is usually referred to as *Fredman's trick*. In our algorithm, we will often use the following extension of Fredman's trick.

$$\begin{aligned} a_1 - b_1 + \cdots + a_r - b_r < a'_1 - b'_1 + \cdots + a'_t - b'_t \\ \textit{if and only if} \\ a_1 + \cdots + a_r - a'_1 - \cdots - a'_t < b_1 + \cdots + b_r - b'_1 - \cdots - b'_t. \end{aligned} \tag{3}$$

Our algorithm uses the following geometric domination technique, based on an algorithm by Chan [12]. Given a finite set Q of red points and blue points in $\mathbb{R}^d$, the *bichromatic dominating pairs reporting* problem is to report all the pairs $(p, q) \in Q^2$ such that p is red, q is blue, and p dominates q, i.e., p is greater than or equal to q at each of the d coordinates. A natural divide-and-conquer algorithm [31, p. 366] runs in $O(|Q| \log^d |Q| + K)$ time, where K is the output size. Chan [12] provided an improved *strongly* subquadratic time bound (excluding the cost of reporting the output) when $d = O(\log |Q|)$, with a sufficiently small constant of proportionality.

[1] That is, the underlying metric is induced by a norm, whose unit ball is a symmetric convex polytope with $O(1)$ facets (e.g., L_1, L_∞).

▶ **Lemma 3** (Chan [12]). *Given a finite set $Q \subset \mathbb{R}^d$ of red and blue points, one can compute all bichromatic dominating pairs $(p, q) \in Q^2$ in time $O(c_\varepsilon^d |Q|^{1+\varepsilon} + K)$, where K is the output size, $\varepsilon \in (0, 1)$ is an arbitrary prespecified parameter, and $c_\varepsilon = 2^\varepsilon/(2^\varepsilon - 1)$.*

Throughout the paper, we invoke Lemma 3 many times, with $\varepsilon = 1/2, c_\varepsilon \approx 3.42$, and $d = \delta \log n$, where $\delta > 0$ is a sufficiently small constant, chosen to make the overall running time of all the invocations dominated by the total output size; see below for details.

We denote by $[N] = \{1, \ldots, \lceil N \rceil\}$, the set of the first $\lceil N \rceil$ natural numbers, for any $N \in \mathbb{R}^+$.

Throughout the paper, we sometimes refer to a square matrix as a *box*.

Our model of computation is a simplified Real RAM model, in which "truly real" numbers are subject to only two unit-time operations: addition and comparison. In all other respects, the machine behaves like a $w = O(\log n)$-bit word RAM with the standard repertoire of unit-time AC^0 operations, such as bitwise Boolean operations, and left and right shifts.

3 Dynamic Time Warping in Subquadratic Time

As above, the input consists of two sequences $A = (p_1, \ldots, p_n)$ and $B = (q_1, \ldots, q_n)$ of n points in $\mathbb{R}$. Our algorithm can easily be modified to support the case where A and B have different lengths.

Preparations. We fix some (small) parameter g, whose value will be specified later; for simplicity, we assume that $\frac{n}{g-1}$ is an integer. We decompose A and B into $s = \frac{n}{g-1}$ subsequences $A_1, \ldots, A_s$, and $B_1, \ldots, B_s$, such that for each $i, j \in \{2, \ldots, s\}$, each of A_i and B_j consists of $g - 1$ consecutive elements of the corresponding sequence, prefixed by the last element of the preceding subsequence. We have that A_1 and B_1 are both of size $g - 1$, each A_i and B_j is of size g, for each $i, j \in \{2, \ldots, s\}$, and each consecutive pairs A_i, A_{i+1} or B_j, B_{j+1} have one common element.

For each $i, j \in [s]$, denote by $D_{i,j}$ the *all-pairs-distances matrix* between points from A_i and points from B_j; specifically, $D_{i,j}$ is a $g \times g$ matrix (aka *box*) (see below for the cases $i = 1$ or $j = 1$) such that for every $\ell, m \in [g]$,

$$D_{i,j}[\ell, m] = \big|A_i(\ell) - B_j(m)\big|.$$

For all $i \in [s]$, we add a leftmost column with ∞ values to each box $D_{i,1}$, and similarly, we add a bottommost row with ∞ values to each box $D_{1,i}$. In particular, $D_{1,1}$ is augmented by both new leftmost column and new bottommost row. The common element $D_{1,1}[0, 0]$ of this row and column is set to 0. Overall, we have $s^2 = \left(\frac{n}{g-1}\right)^2$ boxes $D_{i,j}$, all of size $g \times g$.

We define a *staircase path* P on a $g \times g$ matrix $D_{i,j}$ as a sequence of positions from $[g] \times [g]$ that form a monotone staircase structure, starting from a cell on the left or bottom boundary and ending at the right or top boundary, so that each subsequent position is immediately either to the right, above, or above-right of the previous one. Formally, by enumerating the path positions as $P(0), \ldots, P(t^*)$, we have $P(t+1) \in \{P(t)+(0,1), P(t)+(1,0), P(t)+(1,1)\}$, for each $t = 0, \ldots, t^* - 1$. The path starts at some point $P(0) = (\cdot, 1)$ or $(1, \cdot)$, which lies on either the left or the bottom boundary, and ends at some t^* (not necessarily the first such index) for which $P(t^*) = (\cdot, g)$ or $(g, \cdot)$; that is, P ends on either the right or the top boundary. Note that t^* can have any value in $[2g - 2]$. The number of possible monotone

staircase paths in a box $D_{i,j}$ is trivially bounded by $O(g^2 3^{2g-2})$, and by observing more carefully, we can bound it by $O(3^{2g})$, as is easily checked.[2]

We define the *cost* of a staircase path P in a box $D_{i,j}$ by

$$\mathrm{cost}_{i,j}(P) = \sum_{t=1}^{t^*} D_{i,j}(P(t)).$$

(For technical reasons, that will become clear in the sequel, we generally do not include the first position $P(0)$ of the path in evaluating its cost, except in the boxes $D_{i,1}$ and $D_{1,j}$ for all $i, j \in [s]$.) In the algorithm that follows, we want to assume (or ensure) that no two distinct paths in a box $D_{i,j}$ have the same cost. This will be the case if we assume that the input sequences are in sufficiently general position. We omit in this study perturbation techniques that can handle degenerate situations.

We denote by L the set of *positions* in the left and bottom boundaries of *any* box $D_{i,j}$, and by R the set of positions in the right and top boundaries (note that L and R have two common positions). Given a starting position $v \in L$, and an ending position $w \in R$, we denote by $S(v, w)$ the set of all staircase paths $P_{v,w}$ that start at v and end at w (if there is no staircase path between v and w, then $S(v, w) = \emptyset$). We say that $P^*_{v,w} \in S(v, w)$ is the *shortest path* between v and w in $D_{i,j}$ iff

$$\mathrm{cost}_{i,j}\left(P^*_{v,w}\right) = \min_{P_{v,w} \in S(v,w)} \left\{\mathrm{cost}_{i,j}\left(P_{v,w}\right)\right\}.$$

Note that according to our general position assumption, the shortest path between v and w, within a given box, is *unique*.

First Stage: Preprocessing. The first stage of our algorithm is to construct a data structure in subquadratic time (and storage), such that for each box $D_{i,j}$, and for each pair of positions $(v, w) \in L \times R$, we can retrieve the shortest path $P^*_{v,w}$ and $\mathrm{cost}_{i,j}(P^*_{v,w})$ in $O(1)$ time, when such a path exists (i.e., when $S(v, w)$ is nonempty).

The algorithm enumerates all $(2g-1)^2$ pairs of positions (v, w) in a $g \times g$ matrix (box) such that $v \in L$ and $w \in R$, discarding pairs that cannot be connected by a monotone staircase path, and referring to the surviving pairs as *admissible*. Again, we simplify the notation by upper bounding this quantity by $4g^2$. For each such admissible pair $(v, w) \in L \times R$, we enumerate *every* possible staircase path in $S(v, w)$ as $P_{v,w} : [t^*] \to [g] \times [g]$, where we write $P_{v,w} = \left(P^{\mathrm{r}}_{v,w}, P^{\mathrm{c}}_{v,w}\right)$ as a pair of row and column functions $P^{\mathrm{r}}_{v,w}$, $P^{\mathrm{c}}_{v,w} : [t^*] \to [g]$, so that $P_{v,w}(k) = \left(P^{\mathrm{r}}_{v,w}(k), P^{\mathrm{c}}_{v,w}(k)\right)$, for each $k \in [t^*]$. (Note that t^* is a path-dependent parameter, determined by v, w and the number of diagonal moves in the path.) There are $O(3^{2g})$ possible staircase paths $P_{v,w}$ (for all admissible pairs $(v, w) \in L \times R$ combined), so in total, we enumerate $O(3^{2g})$ staircase paths. These enumerations can be done in a natural lexicographic order, so that they induce an order on the $< 4g^2$ admissible pairs of positions of $L \times R$, and for each such pair (v, w), an order on all possible staircase paths $P_{v,w} \in S(v, w)$.

Given two staircase paths $P_{v,w}$ and $P'_{v,w}$ with the same starting and ending positions in a box $D_{i,j}$, we want to use the extended Fredman's trick (as in (3)) to compare $\mathrm{cost}_{i,j}\left(P_{v,w}\right)$ with $\mathrm{cost}_{i,j}\left(P'_{v,w}\right)$, by comparing two expressions such that one de-

[2] Each staircase path can be encoded by its first position, followed by its sequence of moves, where each move is in one of the directions up/right/up-right. Thus, the number of staircase paths that start in some position $(r, 1)$ (resp. $(1, r)$) on the left (resp. bottom) boundary is bounded by 3^{2g-1-r}. Thus, the total number of staircase paths that start in the left or the bottom boundary is bounded by $2\sum_{r=1}^{g} 3^{2g-1-r} = O(3^{2g})$.

pends on points from A_i only and the other depends on points from B_j only. Suppose that $P_{v,w} = ((\ell_1, m_1), \ldots, (\ell_r, m_r))$ and $P'_{v,w} = ((\ell'_1, m'_1), \ldots, (\ell'_t, m'_t))$ (note that $(\ell_r, m_r) = (\ell'_t, m'_t) = w$, since both paths end at w, and that we ignore the starting positions $(\ell_0, m_0) = (\ell'_0, m'_0) = v$). We have

$$\text{cost}_{i,j}(P_{v,w}) = \big|A_i(\ell_1) - B_j(m_1)\big| + \cdots + \big|A_i(\ell_r) - B_j(m_r)\big|,$$

and

$$\text{cost}_{i,j}\left(P'_{v,w}\right) = \big|A_i(\ell'_1) - B_j(m'_1)\big| + \cdots + \big|A_i(\ell'_t) - B_j(m'_t)\big|,$$

and we want to test whether, say, $\text{cost}_{i,j}(P_{v,w}) < \text{cost}_{i,j}\left(P'_{v,w}\right)$ (recall that we assume that equalities do not arise), that is, testing whether

$$\big|A_i(\ell_1)-B_j(m_1)\big|+\cdots+\big|A_i(\ell_r)-B_j(m_r)\big| < \big|A_i(\ell'_1)-B_j(m'_1)\big|+\cdots+\big|A_i(\ell'_t)-B_j(m'_t)\big|. \quad (4)$$

The last term in each side of (4) is actually unnecessary, since they are equal. In order to transform this inequality into a form suitable for applying the extended Fredman's trick (3), we need to replace each absolute value $|x|$ by either $+x$ or $-x$, as appropriate. To see what we are after, assume first that the expressions $A_i(\ell_k) - B_j(m_k)$ and $A_i(\ell'_k) - B_j(m'_k)$ are all positive, so that (4) becomes

$$A_i(\ell_1) - B_j(m_1) + \cdots + A_i(\ell_r) - B_j(m_r) < A_i(\ell'_1) - B_j(m'_1) + \cdots + A_i(\ell'_t) - B_j(m'_t).$$

By (3) we can rewrite this inequality as

$$A_i(\ell_1)+\cdots+A_i(\ell_r)-A_i(\ell'_1)-\cdots-A_i(\ell'_t) < B_j(m_1)+\cdots+B_j(m_r)-B_j(m'_1)-\cdots-B_j(m'_t),$$

which can be written as

$$A_i(P^{\mathrm{r}}_{v,w}(1)) + \cdots + A_i(P^{\mathrm{r}}_{v,w}(r)) - A_i(P'^{\,\mathrm{r}}_{v,w}(1)) - \cdots - A_i(P'^{\,\mathrm{r}}_{v,w}(t)) \quad (5)$$

$$< B_j(P^{\mathrm{c}}_{v,w}(1)) + \cdots + B_j(P^{\mathrm{c}}_{v,w}(r)) - B_j(P'^{\,\mathrm{c}}_{v,w}(1)) - \cdots - B_j(P'^{\,\mathrm{c}}_{v,w}(t)). \quad (6)$$

If $P_{v,w} = P^*_{v,w}$ (i.e., if $P_{v,w}$ is the shortest path from v to w) in $D_{i,j}$ then the inequality above holds for all pairs $(P_{v,w}, P'_{v,w})$, where $P'_{v,w} \in S(v,w)$ is any other staircase path between v and w.

For each admissible pair of positions $(v,w) \in L \times R$, we guess a staircase path $P_{v,w}$ as a candidate for being the shortest path from v to w. The overall number of such guesses is fewer than $(3^{2g})^{4g^2} = 3^{8g^3}$. For a fixed choice of paths, one for each admissible pair $(v,w) \in L \times R$, we want to test whether all the $< 4g^2$ guessed paths are the shortest paths between the corresponding pairs of positions. As unfolded next, we will apply this test for all boxes $D_{i,j}$, and output those boxes at which the outcome is positive (for the current guessed set of shortest paths). We will repeat the procedure for all $< 3^{8g^3}$ possible sets of guessed paths $P_{v,w}$.

Testing a fixed guess of shortest paths. For each group A_i, we create a (blue) point α_i, and for each group B_j we create a (red) point β_j, such that, for every admissible pair $(v,w) \in L \times R$, we have one coordinate for each path $P'_{v,w} \in S(v,w)$, different from the guessed path. The value of α_i (resp., β_j) at that coordinate is the corresponding expression (5) (resp., (6)). The points α_i and β_j are embedded in $\mathbb{R}^{d_g}$, where $d_g = \sum_{(v,w)} \Gamma_{v,w}$ is the sum over all admissible pairs $(v,w) \in L \times R$, and $\Gamma_{v,w}$ is the number of monotone staircase paths from v to w minus 1. As discussed earlier, $d_g = O(3^{2g})$.

We have that a (blue) point

$$\alpha_i = \left(\dots, A_i(P^{\mathrm{r}}_{v,w}(1)) + \dots + A_i(P^{\mathrm{r}}_{v,w}(r)) - A_i(P'^{\mathrm{r}}_{v,w}(1)) - \dots - A_i(P'^{\mathrm{r}}_{v,w}(t)), \dots\right)$$

is dominated by a (red) point

$$\beta_j = \left(\dots, B_j(P^{\mathrm{c}}_{v,w}(1)) + \dots + B_j(P^{\mathrm{c}}_{v,w}(r)) - B_j(P'^{\mathrm{c}}_{v,w}(1)) - \dots - B_j(P'^{\mathrm{c}}_{v,w}(t)), \dots\right),$$

if and only if each of the paths that we guessed (a path for every admissible pair $(v, w) \in L \times R$) are the shortest paths between the corresponding positions v, w in box $D_{i,j}$. The number of points is $2s = \Theta(n/g)$, and the time to prepare the points, i.e., to compute all their coordinates, is $O(2s \cdot 3^{2g} \cdot g) = O(3^{2g}n)$.

By Lemma 3, we can report all pairs of points (α_i, β_j) such that α_i is dominated by β_j, in $O\left(c_\varepsilon^{3^{2g}}(n/g)^{1+\varepsilon} + K\right)$ time, where K is the number of boxes at which the test of our specific guesses comes out positive. As mentioned earlier, we use $\varepsilon = 1/2$, with $c_\varepsilon \approx 3.42$.

This runtime is for a specific guess of a set of shortest paths between all admissible pairs in $L \times R$. As already mentioned, we repeat this procedure at most 3^{8g^3} times. Overall, we will report exactly $s^2 = \Theta\left((n/g)^2\right)$ dominating pairs (red on blue), because the set of shortest paths between admissible pairs in $L \times R$ in each box $D_{i,j}$ is unique (recall, we assumed that any pair of distinct staircase paths in a box do not have the same cost). Since the overall number of guesses is bounded by 3^{8g^3}, the overall runtime for all invocations of the bichromatic dominance reporting algorithm (including preparing the points) is

$$O\left(3^{8g^3}\left(3^{2g}n + c_\varepsilon^{3^{2g}}(n/g)^{1+\varepsilon}\right) + (n/g)^2\right).$$

Recall that, so far, we have assumed that all the differences within the absolute values $D_{i,j}[\ell, m] = \left|A_i(\ell) - B_j(m)\right|$ are positive, which allowed us to drop the absolute values, and write $D_{i,j}[\ell, m] = A_i(\ell) - B_j(m)$, for every $i, j \in [s]$, and $\ell, m \in [g]$, thereby facilitating the use of (the extended) Fredman's trick (3). Of course, in general this will not be the case, so, in order to still be able to drop the absolute values, we also have to guess the signs of all these differences.

For each box $D_{i,j}$, there is a *unique* sign assignment $\sigma^* : [g] \times [g] \to \{-1, 1\}$ such that

$$D_{i,j}[\ell, m] = \left|A_i(\ell) - B_j(m)\right| = \sigma^*(\ell, m)(A_i(\ell) - B_j(m)),$$

for every $\ell, m \in [g]$ (our "general position" assumption implies that each difference is nonzero). Thus for any staircase path $P = (P^{\mathrm{r}}, P^{\mathrm{c}})$ in $D_{i,j}$, of length t^*, we have

$$\mathrm{cost}_{i,j}(P) = \sum_{t=1}^{t^*} \sigma^*(P(t))\left(A_i(P^{\mathrm{r}}(t)) - B_j(P^{\mathrm{c}}(t))\right).$$

Now we proceed as before, guessing sets of paths, but now we also guess the sign assignment of the box, by trying *every* possible assignment $\sigma : [g] \times [g] \to \{-1, 1\}$, and modify the points α_i and β_j, defined earlier, by (i) adding sign factors to each term, and (ii) adding coordinates that enable us to test whether σ is the correct assignment σ^* for the corresponding boxes $D_{i,j}$.

Denote by P the guessed shortest path for some admissible pair of positions $(v, w) \in L \times R$, and let σ be the guessed sign assignment. Then, for every other path $P' \in S(v, w)$, we have the following modified coordinates for α_i and β_j respectively.

$$\left(\dots, \sigma(P(1))A_i(P^{\mathrm{r}}(1)) + \dots + \sigma(P(r))A_i(P^{\mathrm{r}}(r)) - \sigma(P'(1))A_i(P'^{\mathrm{r}}(1)) - \dots - \sigma(P'(t))A_i(P'^{\mathrm{r}}(t)), \dots\right),$$
$$\left(\dots, \sigma(P(1))B_j(P^{\mathrm{c}}(1)) + \dots + \sigma(P(r))B_j(P^{\mathrm{c}}(r)) - \sigma(P'(1))B_j(P'^{\mathrm{c}}(1)) - \dots - \sigma(P'(t))B_j(P'^{\mathrm{c}}(t)), \dots\right),$$

where we use the same notations as in (4), (5), and (6). In addition, to validate the correctness of σ, we extend α_i and β_j by adding the following g^2 coordinates to each of them. For every pair $(\ell, m) \in [g] \times [g]$, we add the following coordinates to α_i and β_j respectively.

$$(\ldots, -\sigma(\ell, m)A_i(\ell), \ldots),$$
$$(\ldots, -\sigma(\ell, m)B_j(m), \ldots).$$

This ensures that a point α_i is dominated by a point β_j if and only if $D_{i,j}[\ell, m] = \sigma(\ell, m)\left(A_i(\ell) - B_j(m)\right)$, for every $\ell, m \in [g]$, and all the $< 4g^2$ paths that we guessed are indeed shortest paths in box $D_{i,j}$.

The runtime analysis is similar to the preceding one, but now we increase the number of guesses by a factor of 2^{g^2} for the sign assignments, and the dimension of the space where the points are embedded increases by g^2 additional coordinates. We now have $2s = \Theta(n/g)$ points in $\mathbb{R}^{d_g+g^2}$ ($d_g = O(3^{2g})$ is as defined earlier), and the time to prepare them (computing the value of each coordinate) is $O((n/g)(d_g + g^2)g) = O(3^{2g}n)$. There are at most 3^{8g^3} sets of paths to guess, and for each set, there are at most 2^{g^2} sign assignment guesses, so in total, we invoke the bichromatic dominance reporting algorithm at most $2^{g^2}3^{8g^3} < 3^{8g^3+g^2}$ times, for an overall runtime (including preparing the points) of

$$O\left(3^{8g^3+g^2}\left(3^{2g}n + c_\varepsilon^{3^{2g}+g^2}(n/g)^{1+\varepsilon}\right) + (n/g)^2\right).$$

By setting $\varepsilon = 1/2$ and $g = \delta \log\log n$, for a suitable sufficiently small constant δ, the first two terms become negligible (strongly subquadratic), and the runtime is therefore dominated by the output size, that is $O\left((n/g)^2\right) = O\left(n^2/(\log\log n)^2\right)$. Each reported pair (α_i, β_j) certifies that the current set of $< 4g^2$ guessed paths are all shortest paths in box $D_{i,j}$. Each of the $s^2 = \Theta\left((n/g)^2\right)$ sets of shortest paths is represented by $O(g^3) = O((\log\log n)^3)$ bits (there are $< 4g^2$ shortest paths connecting admissible pairs, each of length at most $2g-1$, and each path can be encoded by its first position, followed by the sequence of its at most $2g-2$ moves, where each move is in one of the three directions up/right/up-right), and thus it can easily be stored in one machine word (for sufficiently small δ). Moreover, we have an order on the pairs (v, w) (induced by our earlier enumeration), so for each set, we can store its shortest paths in this order, and therefore, accessing a specific path (for some admissible pair) from the set takes $O(1)$ time.

Note, however, that we obtain only the *positions* that the paths traverse and not their *cost*. In later stages of our algorithm we will also need to compute, on demand, the cost of certain paths, but doing this naively would take $O(g)$ time per path, which is too expensive for us. To handle this issue, when we guess a sign assignment σ, and a set S of the $< 4g^2$ paths as candidates for the shortest paths, we also compute and store, for each path $P \in S$ that we have not yet encountered, the *rows-value* of P in A_i,

$$V_i^{\mathrm{r}}(P, \sigma) = \sigma(P(1))A_i(P^{\mathrm{r}}(1)) + \cdots + \sigma(P(t^*))A_i(P^{\mathrm{r}}(t^*)),$$

for every $i \in [s]$, and the *columns-value* of P in B_j,

$$V_j^{\mathrm{c}}(P, \sigma) = \sigma(P(1))B_j(P^{\mathrm{c}}(1)) + \cdots + \sigma(P(t^*))B_j(P^{\mathrm{c}}(t^*)),$$

for every $j \in [s]$, where t^* is the length of P. Observe that, for the correct sign assignment σ^* of box $D_{i,j}$,

$$\mathrm{cost}_{i,j}(P) = V_i^{\mathrm{r}}(P, \sigma^*) - V_j^{\mathrm{c}}(P, \sigma^*). \tag{7}$$

We do not compute $V_i^{\mathrm{r}}(P,\sigma) - V_j^{\mathrm{c}}(P,\sigma)$ yet, but only compute and store (if not already stored) the separate quantities $V_i^{\mathrm{r}}(P,\sigma)$ and $V_j^{\mathrm{c}}(P,\sigma)$, for each $P \in S$, for every guessed set S, and sign assignment σ. We store the values $V_i^{\mathrm{r}}(P,\sigma)$ and $V_j^{\mathrm{c}}(P,\sigma)$ in arrays, ordered by the earlier enumeration of all staircase paths, so that given a staircase path P, and indices $\kappa, \kappa' \in \left[\frac{n}{g-1}\right]$, we can retrieve, upon demand, the values $V_\kappa^{\mathrm{r}}(P,\sigma^*)$ and $V_{\kappa'}^{\mathrm{c}}(P,\sigma^*)$, and compute $\mathrm{cost}_{\kappa,\kappa'}(P)$ by using (7), in $O(1)$ time. In total, over all our guessed paths and sign assignments, this takes $O(2^{g^2}3^{2g} \cdot (n/g) \cdot g) = O(3^{g^2+2g}n)$ time and space, which is already subsumed by the time (and space) bound for reporting dominances from the previous stage.

To summarize this stage of the algorithm, we presented a subquadratic-time preprocessing procedure, which runs in $O\left((n/g)^2\right) = O\left(n^2/(\log\log n)^2\right)$ time, such that for any box $D_{i,j}$, and an admissible pair of positions $(v,w) \in L \times R$, we can retrieve the shortest path $P^*_{v,w}$ in $O(1)$ time, as well as compute $\mathrm{cost}_{i,j}(P^*_{v,w})$ in $O(1)$ time. This will be useful in the next stage of our algorithm.

Second Stage: Compact Dynamic Programming. Our approach is to view the $(n+1) \times (n+1)$ matrix M from the dynamic programming algorithm as decomposed into $s^2 = \left(\frac{n}{g-1}\right)^2$ boxes $M_{i,j}$, each of size $g \times g$, so that each box $M_{i,j}$ occupies the same positions as does the corresponding box $D_{i,j}$. That is, the indices of the rows (resp., columns) of $M_{i,j}$ are those of A_i (resp., B_j). In particular, for each $i,j \in [s]$, the positions $(\cdot, g)$ on the right boundary of each box $M_{i,j}$ coincide with the corresponding positions $(\cdot, 1)$ on the left boundary of $M_{i,j+1}$, and the positions $(g,\cdot)$ on the top boundary of $M_{i,j}$ coincide with the corresponding positions $(1,\cdot)$ on the bottom boundary of $M_{i+1,j}$. Formally, $M_{i,j}[\ell,m] = M\left[(i-1)(g-1)+\ell, (j-1)(g-1)+m\right]$, for each position $(\ell,m) \in [g] \times [g]$. See Figure 1 for an illustration.

Our strategy is to traverse the boxes, starting from the leftmost-bottom one $M_{1,1}$, where we already have the values of M at the positions of its left and bottom boundaries L, and we compute the values of M on its top and right boundaries R. We then continue to the box on the right, $M_{1,2}$, now having the values on its L-boundary (where its left portion overlaps with the R-boundary of $M_{1,1}$ and its bottom portion is taken from the already preset bottom boundary), and we compute the values of M on its R-boundary. We continue in this way until we reach the rightmost-bottom box $M_{1,s}$. We then continue in the same manner in the next row of boxes, starting at $M_{2,1}$ and ending at $M_{2,s}$, and keep going through the rows of boxes in order. The process ends once we compute the values of M on the R-boundary of the rightmost-top box $M_{s,s}$, from which we obtain the desired entry $M[n,n]$.

For convenience, we enumerate the positions in L as $L(1), \ldots, L(2g-1)$ in "clockwise" order, so that $L(1)$ is the rightmost-bottom position $(1,g)$, and $L(2g-1)$ is the leftmost-top position $(g,1)$. Similarly, we enumerate the positions of R by $R(1), \ldots, R(2g-1)$ in "counterclockwise" order, with the same starting and ending locations. Let $M_{i,j}(L) = \{M_{i,j}[L(1)], \ldots M_{i,j}[L(2g-1)]\}$ and $M_{i,j}(R) = \{M_{i,j}[R(1)], \ldots M_{i,j}[R(2g-1)]\}$, for $i,j \in [s]$.

By definition, for each position $(\ell,m) \in [n+1] \times [n+1]$, $M[\ell,m]$ is the minimal cost of a staircase path from $(0,0)$ to (ℓ,m). It easily follows, by construction, that for each box $D_{i,j}$, and for each $w \in R$, we have

$$M_{i,j}[w] = \min_{\substack{u \in L \\ (u,w) \text{ admissible}}} \Big\{ M_{i,j}[u] + \mathrm{cost}_{i,j}(P^*_{u,w}) \Big\}. \tag{8}$$

(Note that, by definition, the term $D_{i,j}[u]$ is included in $M_{i,j}[u]$ and not in $P^*_{u,w}$, so it is not doubly counted.) For each box $M_{i,j}$ and each position $w \in R$, our goal is thus to compute

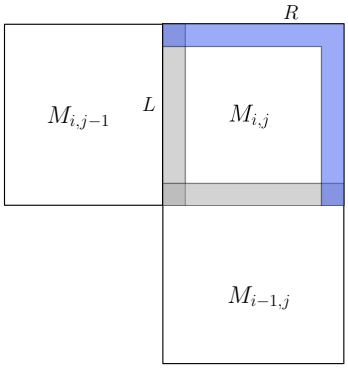

Figure 1 The L-boundary (shaded in gray) of box $M_{i,j}$ overlaps with the top boundary of $M_{i-1,j}$ and the right boundary of $M_{i,j-1}$. Once we have the values of M at the positions of the L-boundary of $M_{i,j}$, our algorithm computes the values of M at the positions of its R-boundary (shaded in blue).

the position $u \in L$ that attains the minimum in (8). We call such (u, w) the *minimal pair* for w in $M_{i,j}$.

For each box $D_{i,j}$, and each admissible pair $(v, w) \in L \times R$, we refer to the value $M_{i,j}[v] + \text{cost}_{i,j}(P^*_{v,w})$ as the *cumulative cost* of the pair (v, w), and denote it by c-cost(v, w).

We can rewrite (8), for each $w \in R$, as

$$M_{i,j}[w] = \min\{M^L_{i,j}[w],\ M^B_{i,j}[w]\},$$

where $M^B_{i,j}[w]$ is the minimum in (8) computed only over $u \in \{L(1), \ldots, L(g)\}$, which is the portion of L that overlaps the R-boundary of the bottom neighbor $M_{i-1,j}$ (when $i > 1$), and $M^L_{i,j}[w]$ is computed over $u \in \{L(g), \ldots, L(2g-1)\}$, which overlaps the R-boundary of the left neighbor $M_{i,j-1}$ (when $j > 1$). See Figure 1 for a schematic illustration. (Recall that the bottommost row and the leftmost column of M are initialized with ∞ values, except their shared cell $M[0, 0]$ that is initialized with 0.) The output of the algorithm is $M_{s,s}[R(g)] = M_{s,s}[g, g] = M[n, n]$. We can also return the optimal coupling, by using a simple backward pointer tracing procedure.

Computing minimal pairs. We still have to explain how to compute the minimal pairs (u, w) in each box $M_{i,j}$. Our preprocessing stage produces, for every box $D_{i,j}$, the set of all its shortest paths $S_{i,j} = \{P^*_{v,w} \mid (v, w) \in L \times R\}$ (ordered by the earlier enumeration of $L \times R$ and including only admissible pairs), and we can also retrieve the cost of each of these paths in $O(1)$ time (as explained earlier in the preprocessing stage). The cumulative cost (defined above) of each such pair (v, w) can also be computed in $O(1)$ time, assuming we have already computed $M_{i,j}[v]$. A naive, brute-force technique for computing the minimal pairs is to compute all the cumulative costs c-cost$_{i,j}(v, w)$, for all admissible pairs $(v, w) \in L \times R$, and select from them the minimal pairs. This however would take $O(g^2)$ time for each of the s^2 boxes, for a total of $\Theta(g^2 s^2) = \Theta(n^2)$ time, which is what we want to avoid.

Luckily, we have the following important lemma, which lets us compute all the minimal pairs within a box, significantly faster than in $O(g^2)$ time.

▶ **Lemma 4.** *For a fixed box $D_{i,j}$, and for any two distinct positions $w, w' \in R$, let $u, u' \in L$ be the positions for which (u, w) and (u', w') are minimal pairs in $M_{i,j}$. Then their corresponding shortest paths $P^*_{u,w}$ and $P^*_{u',w'}$ can partially overlap but can never cross each other. Formally, assuming that $w > w'$ (in the counterclockwise order along R), we have that for any*

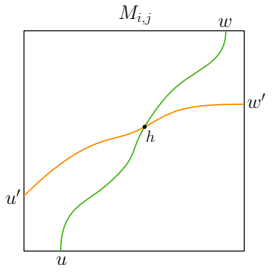

Figure 2 By Lemma 4, if (u, w) and (u', w') are minimal pairs in $M_{i,j}$, then the illustrated scenario is impossible, since the path $P^*_{u,w}$ (in green) is a portion of the shortest path from $M[0, 0]$ to $M_{i,j}[w]$, and the path $P^*_{u',w'}$ (in orange) is a portion of the shortest path from $M[0, 0]$ to $M_{i,j}[w']$. The illustrated intersection implies that one of the latter paths can decrease its cumulative cost by replacing its portion that ends at h by the respective portion that ends in h of the other path, which contradicts the fact that both of these paths are shortest paths.

$\ell, \ell', m \in [g]$, if $(\ell, m) \in P^*_{u,w}$ and $(\ell', m) \in P^*_{u',w'}$ then $\ell \geq \ell'$. That is, $P^*_{u,w}$ lies fully above $P^*_{u',w'}$ (partial overlapping is possible). In particular, we also have $u \geq u'$ (in the clockwise order along L)

Lemma 4 asserts the so-called *Monge property* of shortest-path matrices (see, e.g., [10, 24]). See Figure 2 for an illustration (of an impossible crossing) and a sketch of a proof.

We can therefore use the following divide-and-conquer paradigm for computing the minimal pairs within a box $D_{i,j}$. We start by setting the median index $k = \lfloor |R|/2 \rfloor$ of $|R|$, and compute the minimal pair $(u, R(k))$ and c-cost$(u, R(k))$, naively, in $O(g)$ time, as explained above. The path $P^*_{u,R(k)}$ decomposes the box $D_{i,j}$ into two parts, so that one part, X, consists all the positions in $D_{i,j}$ that are (weakly) *above* $P^*_{u,R(k)}$, and the other part, Y, consists all the positions in $D_{i,j}$ that are (weakly) *below* $P^*_{u,R(k)}$, so that X and Y are disjoint, except for the positions along the path $P^*_{u,R(k)}$ which they share. By Lemma 4, the shortest paths between any other minimal pair of positions in $L \times R$ can never cross $P^*_{u,R(k)}$. Thus, we can repeat this process separately in X and in Y. Note that the input to each recursive step is just the sequences of positions of X and Y along L and R, respectively (and we encode each sequence simply by its first and last elements); there is no need to keep track of the corresponding portion of $D_{i,j}$ itself.

Denote by $T(a, b)$ the maximum runtime for computing all the minimal pairs (u, w), within any box $M_{i,j}$, for u in some contiguous portion L' of a entries of L, and w in some contiguous portion R' of b entries of R. Clearly, $T(1, b) = O(b)$, and $T(a, 1) = O(a)$. In general, the runtime is bounded by the recurrence

$$T(a, b) = \max_{k \in [a]} \Big\{ T(k,\, b/2) + T(a - k + 1,\, b/2) \Big\} + O(a).$$

It is an easy exercise to show that the solution of this recurrence satisfies $T(a, b) = O\left((a + b) \log b\right)$. Thus, the runtime of the divide-and-conquer procedure described above, for a fixed box $M_{i,j}$, is $O\left((|R| + |L|) \log |R|\right) = O(g \log g)$.

The runtime of computing $M_{i,j}(R)$ for all $s^2 = \Theta\left((n/g)^2\right)$ boxes is thus $O\left((n/g)^2 g \log g\right) = O\left(n^2 \log g/g\right)$. Overall, including the preprocessing stage, the total runtime of the algorithm is $O\left((n/g)^2 + n^2 \log g/g\right) = O\left(n^2 \log g/g\right)$. As dictated by the preprocessing stage, we need to choose $g = \Theta(\log \log n)$, so the overall runtime is $O\left(n^2 \log \log \log n / \log \log n\right)$. This completes the proof of Theorem 1 for DTW. ◀

Abstract

In this paper we describe an algorithm that embeds a graph metric (V, d_G) on an undirected weighted graph $G = (V, E)$ into a distribution of tree metrics (T, D_T) such that for every pair $u, v \in V$, $d_G(u, v) \leq d_T(u, v)$ and $\mathbf{E}_T[d_T(u, v)] \leq O(\log n) \cdot d_G(u, v)$. Such embeddings have proved highly useful in designing fast approximation algorithms, as many hard problems on graphs are easy to solve on tree instances. For a graph with n vertices and m edges, our algorithm runs in $O(m \log n)$ time with high probability, which improves the previous upper bound of $O(m \log^3 n)$ shown by Mendel et al. in 2009.

The key component of our algorithm is a new approximate single-source shortest-path algorithm, which implements the priority queue with a new data structure, the *bucket-tree structure*. The algorithm has three properties: it only requires linear time in the number of edges in the input graph; the computed distances have a distance preserving property; and when computing the shortest-paths to the k-nearest vertices from the source, it only requires to visit these vertices and their edge lists. These properties are essential to guarantee the correctness and the stated time bound.

Using this shortest-path algorithm, we show how to generate an intermediate structure, the approximate dominance sequences of the input graph, in $O(m \log n)$ time, and further propose a simple yet efficient algorithm to converted this sequence to a tree embedding in $O(n \log n)$ time, both with high probability. Combining the three subroutines gives the stated time bound of the algorithm.

We also show a new application of probabilistic tree embeddings: they can be used to accelerate the construction of a series of approximate distance oracles.

1 Introduction

The idea of probabilistic tree embeddings [4] is to embed a finite metric into a distribution of tree metrics with a minimum expected distance distortion. A distribution $\mathcal{D}$ of trees of a metric space (X, d_X) should minimize the expected stretch ψ so that:

1. dominating property: for each tree $T \in \mathcal{D}$, $d_X(x, y) \leq d_T(x, y)$ for every $x, y \in X$, and
2. expected stretch bound: $\mathbf{E}_{T\sim\mathcal{D}}[d_T(x, y)] \leq \psi \cdot d_X(x, y)$ for every $x, y \in X$,

where $d_T(\cdot, \cdot)$ is the tree metric, and $\mathbf{E}_{T\sim\mathcal{D}}$ draws a tree T from the distribution $\mathcal{D}$. After a sequence of results [2, 3, 4], Fakcharoenphol, Rao and Talwar [17] eventually proposed an elegant and asymptotically optimal algorithm (FRT-embedding) with $\psi = O(\log n)$.

Probabilistic tree embeddings facilitate many applications. They lead to practical algorithms to solve a number of problems with good approximation bounds, for example, the k-median problem, buy-at-bulk network design [8], and network congestion minimization [30]. A number of network algorithms use tree embeddings as key components, and such applications include generalized Steiner forest problem, the minimum routing cost spanning tree problem, and the k-source shortest paths problem [22]. Also, tree embeddings are used in solving symmetric diagonally dominant (SDD) linear systems. Classic solutions use spanning trees as the preconditioner, but recent work by Cohen et al. [14] describes a new approach to use trees with Steiner nodes (e.g. FRT trees).

In this paper we discuss yet another remarkable application of probabilistic tree embeddings: constructing of approximate distance oracles (ADOs)—a data structure with compact storage ($o(n^2)$) which can approximately and efficiently answer pairwise distance queries on a metric space. We show that FRT trees can be used to accelerate the construction of some ADOs [24, 34, 10].

Motivated by these applications, efficient algorithms to construct tree embeddings are essential, and there are several results on the topic in recent years [12, 22, 8, 25, 21, 19, 6]. Some of these algorithms are based on different parallel settings, e.g. share-memory setting [8, 19, 6] or distributed setting [22, 21]. As with this paper, most of these algorithms [12, 22, 25, 21, 6] focus on graph metrics, which most of the applications discussed above are based on. In the sequential setting, i.e. on a RAM model, to the best of our knowledge, the most efficient algorithm to construct optimal FRT-embeddings was proposed by Mendel and Schwob [25]. It constructs FRT-embeddings in $O(m \log^3 n)$ expected time given an undirected positively weighted graph with n vertices and m edges. This algorithm, as well as the original construction in the FRT paper [17], works hierarchically by generating each level of a tree top-down. However, such a method can be expensive in time and/or coding complexity. The reason is that the diameter of the graph can be arbitrarily large and the FRT trees may contain many levels, which requires complicated techniques, such as building sub-trees based on quotient graphs.

Our results. The main contribution of this paper is an efficient construction of the FRT-embeddings. Given an undirected positively weighted graph $G = (V, E)$ with n vertices and m edges, our algorithm builds an optimal tree embedding in $O(m \log n)$ time. In our algorithm, instead of generating partitions by level, we adopt an alternative view of the FRT algorithm in [22, 8], which computes the potential ancestors for each vertex using ***dominance sequences*** of a graph (first proposed in [12], and named as least-element lists in [12, 22]). The original algorithm to compute the dominance sequences requires $O(m \log n + n \log^2 n)$ time [12]. We then discuss a new yet simple algorithm to convert the dominance sequences to an FRT tree only using $O(n \log n)$ time. A similar approach was taken by Khan et al. [22] but their output is an implicit representation (instead of an tree) and under the distributed

setting and it is not work-efficient without using the observations and tree representations introduced by Blelloch et al. in [8].[1]

Based on the algorithm to efficiently convert the dominance sequences to FRT trees, the time complexity of FRT-embedding construction is bottlenecked by the construction of the dominance sequences. Our efficient approach contains two subroutines:

- An efficient (approximate) single-source shortest-path algorithm, introduced in Section 3. The algorithm has three properties: linear complexity, distance preservation, and the ordering property (full definitions given in Section 3). All three properties are required for the correctness and efficiency of constructing FRT-embedding. Our algorithm is a variant of Dijkstra's algorithm with the priority queue implemented by a new data structure called *bucket-tree structure*.
- An algorithm to integrate the shortest-path distances into the construction of FRT trees, discussed in Section 4. When the diameter of the graph is $n^{O(1)}$, we show that an FRT tree can be built directly using the approximate distances computed by shortest-path algorithm. The challenge is when the graph diameter is large, and we proposed an algorithm that computes the approximate dominance sequences of a graph by concatenating the distances that only use the edges within a relative range of $n^{O(1)}$. Then we show why the approximate dominance sequences still yield valid FRT trees.

With these new algorithmic subroutines, we show that the time complexity of computing FRT-embedding can be reduced to $O(m \log n)$ w.h.p. for an undirected positively weighted graph with arbitrary edge weight.

In addition to the efficient construction of FRT trees, this paper also discuss a new application. We show that FRT trees are intrinsically Ramsey partitions (definition given in Section 5) with asymptotically tight bound, and can achieve even better (constant) bounds on distance approximation. Previous construction algorithms of optimal Ramsey partitions are based on hierarchical CKR partitions, namely, on each level, the partition is individually generated with an independent random radius and new random priorities. In this paper, we present a new proof to show that the randomness in each level is actually unnecessary, so that only one single random permutation is enough and the ratio of radii in consecutive levels can be fixed as 2. Our FRT-tree construction algorithm therefore can be directly applied to a number of different distance oracles that are based on Ramsey partitions and accelerates the construction of these distance oracles.

2 Preliminaries and Notations

Let $G = (V, E)$ be a weighted graph with edge lengths $l : E \to \mathbb{R}_+$, and $d(u, v)$ denote the shortest-path distance in G between nodes u and v. Throughout this paper, we assume that $\min_{x \neq y} d(x, y) = 1$. Let $\Delta = \frac{\max_{x,y} d(x,y)}{\min_{x \neq y} d(x,y)} = \max_{x,y} d(x, y)$, the diameter of the graph G.

In this paper, we use the single source shortest paths problem (SSSP) as a subroutine for a number of algorithms. Consider a weighted graph with n vertices and m edges, Dijkstra's algorithm [15] solves the SSSP in $O(m + n \log n)$ time if the priority queue of distances is maintained using a Fibonacci heap [18].

A premetric (X, d_X) defines on a set X and provides a function $d : X \times X \to \mathbb{R}$ satisfying $d(x, x) = 0$ and $d(x, y) \geq 0$ for $x, y \in X$. A metric (X, d_X) further requires $d(x, y) = 0$ iff $x = y$, symmetry $d(x, y) = d(y, x)$, triangle inequality $d(x, y) \leq d(x, z) + d(z, y)$ for

[1] A simultaneous work by Friedrichs et al. proposed an $O(n \log^3 n)$ algorithm of this conversion (Lemma 7.2 in [19]).

$x, y, z \in X$. The shortest-path distances on a graph is a metric and is called the graph metric and denoted as d_G.

We assume all intermediate results of our algorithm have word size $O(\log n)$ and basic algorithmic operations can be finished within a constant time. Then within the range of $[1, n^k]$, the integer part of natural logarithm of an integer and floor function of an real number can be computed in constant time for any constant k. This can be achieved using standard table-lookup techniques (similar approaches can be found in Thorup's algorithm [32]). The time complexity of the algorithms are measured using the random-access machine (RAM) model.

A result holds *with high probability* (**w.h.p.**) for an input of size n if it holds with probability at least $1 - n^{-c}$ for any constant $c > 0$, over all possible random choices made by the algorithm.

Let $[n] = \{1, 2, \cdots, n\}$ where n is a positive integer.

We recall a useful fact about random permutations [31]:

▶ **Lemma 1.** *Let $\pi : [n] \to [n]$ be a permutation selected uniformly at random on $[n]$. The set $\{i \mid i \in [n], \pi(i) = \min\{\pi(j) \mid j = 1, \cdots, i\}\}$ contains $O(\log n)$ elements both in expectation and with high probability.*

3 An Approximate SSSP Algorithm

In this section we introduce a variant of Dijkstra's algorithm. This is an efficient algorithm for single-source shortest paths (SSSP) with linear time complexity $O(m)$. The computed distances are α-distance preserving:

▶ **Definition 2** (α-distance preserving)**.** For a weighted graph $G = (V, E)$, the single-source distances $d(v)$ for $v \in V$ from the source node s is α-distance preserving, if there exists a constant $0 \leq \alpha \leq 1$ such that $\alpha\, d_G(s, u) \leq d(u) \leq d_G(s, u)$, and $d(v) - d(u) \leq d_G(u, v)$, for every $u, v \in V$.

α-distance preserving can be viewed as the triangle inequality on single-source distances (i.e. $d(u) + d_G(u, v) \geq d(v)$ for $u, v \in V$), and is required in many applications related to distances. For example, in Corollary 4 we show that using Gabow's scaling algorithm [20] we can compute a $(1+\epsilon)$-approximate SSSP using $O(m \log \epsilon^{-1})$ time. Also in many metric problems including the contruction of optimal tree embeddings, distance preservation is necessary in the proof of the expected stretch, and such an example is Lemma 11 in Section 4.3.

The preliminary version we discussed in Section 3.1 limits edge weights in $[1, n^k]$ for a constant k, but with some further analysis in the full version of this paper we can extend the range to $[1, n^{O(m)}]$. This new algorithm also has two properties that are needed in the construction of FRT trees, while no previous algorithms achieve them all:

1. (α-distance preserving) The computed distances from the source $d(\cdot)$ is α-distance preserving.
2. (Ordering property and linear complexity) The vertices are visited in order of distance $d(\cdot)$, and the time to compute the first k distances is bounded by $O(m')$ where m' is the sum of degrees from these k vertices.

The algorithm also works on directed graphs, although this is not used in the FRT construction.

Approximate SSSP algorithms are well-studied [32, 23, 13, 29, 26]. In the sequential setting, Thorup's algorithm [32] compute single-source distances on undirected graphs with

integer weights using $O(n+m)$ time. Nevertheless, Thorup's algorithm does not obey the ordering property since it uses a hierarchical bucketing structure and does not visit vertices in an order of increasing distances, and yet we are unaware of a simple argument to fix this. Other algorithms are either not work-efficient (i.e. super-linear complexity) in sequential setting, and / or violating distance preservation.

▶ **Theorem 3.** *For a weighted directed graph $G=(V,E)$ with edge weights between 1 and $n^{O(1)}$, a $(1/4)$-distance preserving single-source shortest-path distances $d(\cdot)$ can be computed, such that the distance to the k-nearest vertices v_1 to v_k by $d(\cdot)$requires $O(\sum_{i=1}^{k}\text{degree}(v_i))$ time.*

The algorithm also has the two following properties. Since they are not used in the construction of FRT trees, we review them in the full version of this paper. We discuss how to (1) extend the range of edge weights to $n^{O(m)}$, and the cost to compute the k-nearest vertices is $O(\log_n d(v_k)+\sum_{i=1}^{k} degree(v_i))$ where v_1 to v_k are the k nearest vertices; and (2) compute $(1+\epsilon)$-distance-preserving shortest-paths for an arbitrary $\epsilon>0$:

▶ **Corollary 4.** *$(1+\epsilon)$-distance-preserving shortest-paths for all vertices can be computed by repeatedly using Theorem 3 $O(\log \epsilon^{-1})$ times.*

3.1 Algorithm Details

The key data structure in this algorithm is a bucket-tree structure shown in Figure 1 that implements the priority queue in Dijkstra's algorithm. With the bucket-tree structure, each Decrease-Key or Extract-Min operation takes constant time. Given the edge range in $[1,n^k]$, this structure has $l=\lceil(1+k)\log_2 n\rceil$ levels, each level containing a number of buckets corresponding to the distances to the source node. In the lowest level (level 1) the difference between two adjacent buckets is 2.

At anytime only one of the buckets in each level can be non-empty: there are in total l active buckets to hold vertices, one in each level. The active bucket in each level is the left-most bucket whose distance is larger than that of the current vertex being visited in our algorithm. We call these active buckets the **frontier** of the current distance, and they can be computed by the **path string**, which is a 0/1 bit string corresponding to the path from the current location to higher levels (until the root), and 0 or 1 is decided by whether the node is the left or the right child of its parent. For clarity, we call the buckets on the frontier **frontier buckets**, and the ancestors of the current bucket **ancestor buckets** (can be traced using the path string). For example, as the figure shows, if the current distance is 4, then the available buckets in the first several levels are the buckets corresponding to the distances $6,5,11,7$, and so on. The ancestor bucket and the frontier bucket in the same level may or may not be the same, depending on whether the current bucket is the left or right subtree of this bucket. For example, the path string for the current bucket with label 4 is 0100 and so on, and ancestor buckets correspond to $4,5,3,7$ and so on. It is easy to see that given the current distance, the path string, the ancestor buckets, and the frontier buckets can be computed in $O(l)$ time—constant time per level.

Note that since only one bucket in each level is non-empty, the whole structure need not to be build explicitly: we store one linked list for each level to represent the only active bucket in the memory (l lists in total), and use the current distance and path string to retrieve the location of the current bucket in the structure.

With the bucket-tree structure acting as the priority queue, we can run standard Dijkstra's algorithm. The only difference is that, to achieve linear cost for an SSSP query, the operations of Decrease-Key and Extract-Min need to be redefined on the bucket-tree structure.

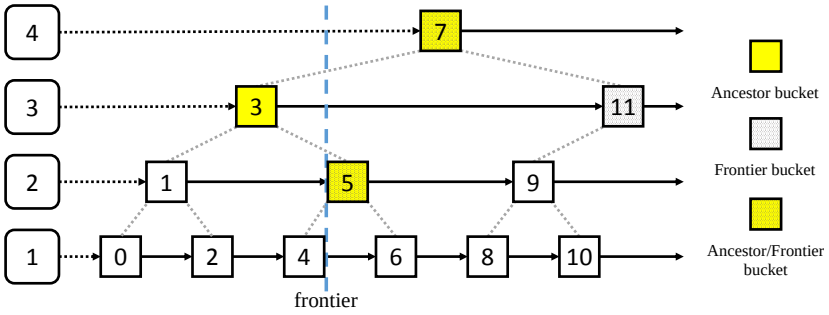

Figure 1 An illustration of a bucket-tree structure with the lowest 4 levels, and the current visiting bucket has distance 4. Notice that our algorithm does not insert vertices to the same level as the current bucket (i.e. bucket 6).

Once the relaxation of an edge succeeds, a DECREASE-KEY operation for the corresponding vertex will be applied. In the bucket-tree structure it is implemented by a DELETE (if the vertex is added before) followed by an INSERT on two frontier buckets respectively. The deletion is trivial with a constant cost, since we can maintain the pointer from each vertex to its current location in the bucket tree. We mainly discuss how to insert a new tentative distance into the bucket tree. When vertex u successfully relaxes vertex v with an edge e, we first round down the edge weight w_e by computing $r = \lfloor \log_2 (w_e + 1) \rfloor$. Then we find the appropriate frontier bucket B that the difference of the distances w'_e between this bucket B and the current bucket is the closest to (but no more than) $w_r = 2^r - 1$, and insert the relaxed vertex into this bucket. The constant approximation for this insertion operation holds due to the following lemma:

▶ **Lemma 5.** *For an edge with length w_e, the approximated length w'_e, which is the distance between the inserted bucket B and the current bucket, satisfies the following inequality: $w_e/4 \leq w'_e \leq w_e$.*

Proof. After the rounding, $w_r = 2^r - 1 = 2^{\lfloor \log_2 (w_e+1) \rfloor} - 1$ falls into the range of $[w_e/2, w_e]$. We now show that there always exists such a bucket B on the frontier that the approximated length w'_e is in $[w_r/2, w_r]$.

We use Algorithm 1 to select the appropriate bucket for a certain edge, given the current bucket level and the path string. The first case is when b, the current level, is larger than r. In this case all the frontier buckets on the bottom r levels form a left spine of the corresponding subtree rooted by the right child of the current bucket, so picking bucket in the r-th level leads to $w'_e = 2^{r-1}$, and therefore $w_e/4 < w'_e \leq w_e$ holds. The second case is when $b \leq r$, and the selected bucket is decided based on the structure on the ancestor buckets from the $(r+1)$-th level to $(r-1)$-th level, which is one of the three following cases.

- The simplest case ($b < r$, line 9) is when the ancestor bucket in the $(r-1)$-th level is the right child of the bucket in the r-th level. In this case when we pick the bucket in level r since the distance between two consecutive buckets in level r is 2^r, and the distance from the current bucket to the ancestor bucket in r-th level is at most $\sum_{i=1}^{r-1} 2^{i-1} < 2^{r-1}$. The distance thus between the current bucket and the frontier bucket in level r is $w'_e > 2^r - 2^{r-1} = 2^{r-1} > w_e/4$.
- The second case is when either $b = r$ and the current bucket is the left child (line 5), or $b < r$ and the ancestor bucket in level $r-1$ is on the left spine of the subtree rooted at the ancestor bucket in level $r+1$ (line 11). Similar to the first case, picking the frontier

Algorithm 1: Finding the appropriate bucket

Input: Current bucket level b, rounded edge length $2^r - 1$ and path string.
Output: The bucket in the frontier (the level is returned).

```
Let r' be the lowest ancestor bucket above level r that is a left child
if b > r then
    return r
else if b = r then
    if current bucket is left child then return r + 1
    else return r' + 1
else
    switch the branches from (r + 1)-th level to (r − 1)-th level in the path string do
        case left-then-right or right-then-right do
            return r
        case left-then-left do
            return r + 1
        case right-then-left do
            return r' + 1
```

bucket in the $(r+1)$-th level (which is also an ancestor bucket) skips the right subtree of the bucket in r-th level, which contains $2^{r-1} - 1 \geq w_e/4$ nodes.

- The last case is the same as the second case expect that the level-r ancestor bucket is the right child of level-$(r+1)$ ancestor bucket. In this case we will pick the frontier bucket that has distance 2^{r-1} to the ancestor bucket in level r, which is the parent of the lowest ancestor bucket that is a left child and above level r. In this case the approximated edge distance is between 2^{r-1} and $2^r - 1$.

Combining all these cases proves the lemma. ◀

We now explain ehe Extract-Min operation on the bucket tree. We will visit vertex in the current buckets one by one, so each Extract-Min has a constant cost. Once the traversal is finished, we need to find the next closest non-empty frontier.

▶ **Lemma 6.** Extract-Min *and* Decrease-Key *on the bucket tree require* $O(1)$ *time.*

Proof. We have shown that the modification on the linked list for each operation requires $O(1)$ time. A naïve implementation to find the bucket in Decrease-Key and Extract-Min takes $O(l) = O(\log n)$ time, by checking all possible frontier buckets. We can accelerate this look-up using the standard table-lookup technique. The available combinations of the input of Decrease-Key are n^{k+1} (total available current distance) by $l = O(k \log n)$ (total available edge distance after rounding), and the input combinations of Extract-Min are two $\lceil \log_2 n^{k+1} \rceil$ bit strings corresponding to the path to the root and the emptiness of the buckets on the frontier. We therefor partition the bucket tree into several parts, each containing $\lfloor (1-\epsilon')(\log_2 n)/2 \rfloor$ consecutive levels (for any $0 < \epsilon' < 1$). We now precompute the answer for all possible combinations of path strings and edge lengths, and (1) the sizes of look-up tables for both operations to be $O((2^{\lfloor (1-\epsilon')(\log_2 n)/2 \rfloor})^2) = o(n)$, (2) the cost for brute-force preprocessing to be $O((2^{\lfloor (1-\epsilon')(\log_2 n)/2 \rfloor})^2 \log n) = o(n)$, and (3) the time of either operation of Decrease-Key and Extract-Min to be $O(k)$, since each operation requires to look up at most $l/\lfloor (1-\epsilon')(\log_2 n)/2 \rfloor = O(k)$ tables. Since k is a constant, each of the two operations as well takes constant time. The update of path string can be computed similarly using this

table-lookup approach. As a result, with $o(n)$ preprocessing time, finding the associated bucket for DECREASE-KEY or EXTRACT-MIN operation uses $O(1)$ time. ◀

We now show the three properties of the new algorithm: linear complexity, triangle inequality, and the ordering property.

Proof of Theorem 3. Here we show the algorithm satisfies the properties in Theorem 3. Lemma 6 proves the linear cost of the algorithm. Lemma 5 shows that the final distances is α-distance preserving. Lastly, since this algorithm is actually a variant of Dijkstra's algorithm with the priority implemented by the bucket-tree structure, the ordering property is met, although here the k-nearest vertices are based on the approximate distances instead of real distances. ◀

In the full version we discuss how to extend the range of edge weight to $[1, n^{O(m)}]$.

4 The Dominance Sequence

In this section we review and introduce the notion of dominance sequences for each point of a metric space and describe the algorithm for constructing them on a graph. The basic idea of dominance sequences was previously introduced in [12] and [8]. Here we name the structure as the dominance sequence since the "dominance" property introduced below is crucial and related to FRT construction. In the next section we show how they can easily be converted into an FRT tree.

4.1 Definition

▶ **Definition 7** (Dominance)**.** Given a premetric (X, d_X) and a permutation π, for two points $x, y \in X$, x *dominates* y if and only if

$$\pi(x) = \min\{\pi(w) \mid w \in X, d_X(w, y) \leq d_X(x, y)\}.$$

Namely, x dominates y iff x's priority is greater (position in the permutation is earlier) than any point that is closer to y.

The dominance sequence for a point $x \in X$, is the sequence of all points that dominate x sorted by distance. More formally:

▶ **Definition 8** (Dominance Sequence[2])**.** For each $x \in X$ in a premetric (X, d_X), the *dominance sequence* of a point x with respect to a permutation $\pi : X \to [n]$ (denoted as $\chi_\pi^{(x)}$), is the sequence $\langle p_i \rangle_{i=1}^k$ such that $1 = \pi(p_1) < \pi(p_2) < \cdots < \pi(p_k) = \pi(x)$, and p_i is in $\chi_\pi^{(x)}$ iff p_i dominates x.

We use χ_π to refer to all dominance sequences for a premetric under permutation π. It is not hard to bound the size of the dominance sequence:

▶ **Lemma 9** ([13])**.** *Given a premetric (X, d_X) and a random permutation π, for each vertex $x \in X$, with w.h.p.*

$$\left|\chi_\pi^{(x)}\right| = O(\log n)$$

[2] Also called as "least-element list" in [12]. We rename it since in later sections we also consider many other variants of it based on the dominance property.

Algorithm 2: Efficient FRT tree construction

1 Pick a uniformly random permutation $\pi : V \to [n]$.
2 Compute the dominance sequences χ_π.
3 Pick $\beta \in [1, 2]$ with the probability density function $f_B(x) = 1/(x \ln 2)$.
4 Convert the dominance sequence χ_π to the compressed partition sequence $\bar{\sigma}_{\pi,\beta}$.
5 Generate the FRT tree based on $\bar{\sigma}_{\pi,\beta}$.

and hence overall, with w.h.p.

$$|\chi_\pi| = \sum_{x \in X} \left|\chi_\pi^{(x)}\right| = O(n \log n)$$

Since the proof is fairly straight-forward, for completeness we also provide it in the full version of this paper.

Now consider a graph metric (V, d_G) defined by an undirected positively weighted graph $G = (V, E)$ with n vertices and m edges, and $d_G(u, v)$ is the shortest distance between u and v on G. The dominance sequences of this graph metric can be constructed using $O(m \log n + n \log^2 n)$ time w.h.p. [12]. This algorithm is based on Dijkstra's algorithm.

4.2 Efficient FRT tree construction based on the dominance sequences

We now consider the construction of FRT trees based on a pre-computed dominance sequences of a given metric space (X, d_X). We assume the weights are normalized so that $1 \le d_X(x, y) \le \Delta = 2^\delta$ for all $x \neq y$, where δ is a positive integer.

The FRT algorithm [17] generates a top-down recursive low-diameter decomposition (LDD) of the metric, which preserves the distances up to $O(\log n)$ in expectation. It first chooses a random β between 1 and 2, and generates $1 + \log_2 \Delta$ levels of partitions of the graph with radii $\{\beta\Delta, \beta\Delta/2, \beta\Delta/4, \cdots\}$. This procedure produces a laminar family of clusters, which are connected based on set-inclusion to generate the FRT tree. The weight of each tree edge on level i is $\beta\Delta/2^i$.

Instead of computing these partitions directly, we adopt the idea of a point-centric view proposed in [8]. We use the intermediate data structure "dominance sequences" as introduced in Section 4.1 to store the useful information for each point. Then, an FRT tree can be retrieved from this sequence with very low cost:

▶ **Lemma 10.** *Given β and the dominance sequences χ_π of a metric space with associated distances to all elements, an FRT tree can be constructed using $O(n \log n)$ time w.h.p.*

The difficulty in this process is that, since the FRT tree has $O(\log \Delta)$ levels and Δ can be large (i.e. $\Delta > 2^{O(n)}$), an explicit representation of the FRT tree can be very costly. Instead we generate the compressed version with nodes of degree two removed and their incident edge weights summed into a new edge. The algorithm is outlined in Algorithm 2.

Proof. We use the definition of partition sequence and compressed partition sequence from [8]. Given a permutation π and a parameter β, the *partition sequence* of a point $x \in X$, denoted by $\sigma_{\pi,\beta}^{(x)}$, is the sequence $\sigma_{\pi,\beta}^{(x)}(i) = \min\{\pi(y) \mid y \in X, d(x, y) \le \beta \cdot 2^{\delta - i}\}$ for $i = 0, \ldots, \delta$, i.e. point y has the highest priority among vertices up to level i. We note that a trie (radix tree) built on the partition sequence is the FRT tree, but as mentioned we cannot build this explicitly. The compressed partition sequence, denoted as $\bar{\sigma}_{\pi,\beta}^{(x)}$, replaces consecutive

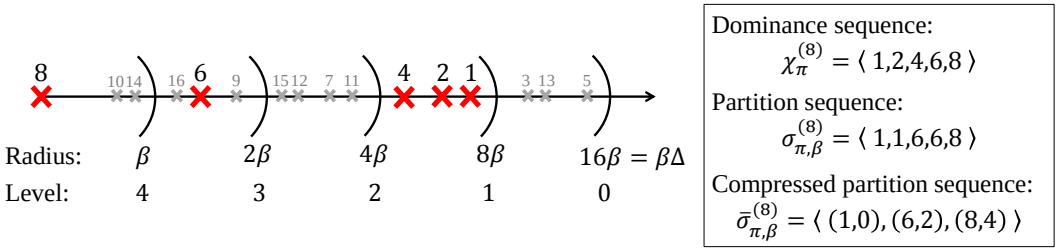

Figure 2 An illustration for dominance sequence, partition sequence and compressed partition sequence for vertex 8. Here we assume that the label of each vertex corresponds to its priority. The left part shows the distances of all vertices to vertex 8 in log-scale, and the red vertices dominate vertex 8.

equal points in the partition sequence $\sigma_{\pi,\beta}^{(x)}$ by the pair (p_i, l_i) where p_i is the vertex and l_i is the highest level p_i dominates x in the FRT tree. Figure 2 gives an example of a partition sequence, a compressed partition sequence, and their relationship to the dominance sequence.

To convert the dominance sequences χ_π to the compressed partition sequences $\bar{\sigma}_{\pi,\beta}$ note that for each point x the points in $\bar{\sigma}_{\pi,\beta}^{(x)}$ are a subsequence of $\chi_\pi^{(x)}$. Therefore, for $\bar{\sigma}_{\pi,\beta}^{(x)}$, we only keep the highest priority vertex in each level from $\chi_\pi^{(x)}$ and tag it with the appropriate level. Since there are only $O(\log n)$ vertices in $\chi_\pi^{(x)}$ w.h.p., the time to generate $\bar{\sigma}_{\pi,\beta}^{(x)}$ is $O(\log n)$ w.h.p., and hence the overall construction time is $O(n \log n)$ w.h.p.

The compressed FRT tree can be easily generated from the compressed partition sequences $\bar{\sigma}_{\pi,\beta}$. Blelloch et. al. [8] describe a parallel algorithm that runs in $O(n^2)$ time (sufficient for their purposes) and polylogarithmic depth. Here we describe a similar version to generate the FRT tree sequentially in $O(n \log n)$ time w.h.p. The idea is to maintain the FRT as a patricia trie [27] (compressed trie) and insert the compressed partition sequences one at a time. Each insertion just needs to follow the path down the tree until it diverges, and then either split an edge and create a new node, or create a new child for an existing node. Note that a hash table is required to trace the tree nodes since the trie has a non-constant alphabet. Each insertion takes time at most the sum of the depth of the tree and the length of the sequence, giving the stated bounds. ◀

We note that for the same permutation π and radius parameter β, it generates exactly the same tree as the original algorithm in [17].

4.3 Expected Stretch Bound

In Section 4.2 we discussed the algorithm to convert the dominance sequences to a FRT tree. When the dominance sequences is generated from a graph metric (G, d_G), the expected stretch is $O(\log n)$, which is optimal, and the proof is given in many previous papers [17, 8]. Here we show that any distance function $\hat{d}_G$ in Lemma 11 is sufficient to preserve this expected stretch. As a result, we can use the approximate shortest-paths computed in Section 3 to generate the dominance sequences and further convert to optimal tree embeddings.

▶ **Lemma 11.** *Given a graph metric (G, d_G) and a distance function $\hat{d}_G(u, v)$ such that for $u, v, w \in V$, $|\hat{d}_G(u, v) - \hat{d}_G(u, w)| \leq 1/\alpha \cdot d_G(v, w)$ and $d_G(u, v) \leq \hat{d}_G(u, v) \leq 1/\alpha \cdot d_G(u, v)$ for some constant $0 < \alpha \leq 1$, then the dominance sequences based on $(G, \hat{d}_G)$ can still yield optimal tree embeddings.*

Proof Outline. Since the overestimate distances hold the dominating property of the tree embeddings, we show the expected stretch is also not affected. We now show the expected stretch is also held.

Recall the proof of the expected stretch by Blelloch et al. in [8] (Lemma 3.4). By replacing d_G by $\hat{d}_G$, the rest of the proof remains unchanged except for Claim 3.5, which upper bounds the expected cost of a common ancestor w of $u, v \in V$ in u and v's dominance sequences. The original claim indicates that the probability that u and v diverges in a certain level centered at vertex w is $O(|d_G(w,u) - d_G(w,v)|/d_G(u,w)) = O(d_G(u,v)/d_G(u,w))$ and the penalty is $O(d_G(u,w))$, and therefore the contribution of the expected stretch caused by w is the product of the two, which is $O(d_G(u,v))$ (since there are at most $O(\log n)$ of such w (Lemma 9), the expected stretch is thus $O(\log n)$). With the distance function $\hat{d}_G$ and α as a constant, the probability now becomes $O(|\hat{d}_G(w,u) - \hat{d}_G(w,v)|/\hat{d}_G(u,w)) = O(d_G(u,v)/d_G(u,w))$, and the penalty is $O(\hat{d}_G(u,w)) = O(d_G(u,w))$. As a result, the expected stretch asymptotically remains unchanged. ◀

4.4 Efficient construction of approximate dominance sequences

Assume that $\hat{d}_G(u,v)$ is computed as $d_u(v)$ by the shortest-path algorithm in Section 3 from the source node u. Notice that $d_u(v)$ does not necessarily to be the same as $d_v(u)$, so $(G, \hat{d}_G(u,v))$ is not a metric space. Since the computed distances are distance preserving, it is easy to check that Lemma 11 is satisfied, which indicate that we can generate optimal tree embeddings based on the distances. This leads to the main theorem of this paper.

▶ **Theorem 12** (Efficient optimal tree embeddings). *There is a randomized algorithm that takes an undirected positively weighted graph $G = (V, E)$ containing $n = |V|$ vertices and $m = |E|$ edges, and produces an tree embedding such that for all $u, v \in V$, $d_G(u,v) \leq d_T(u,v)$ and $\mathbf{E}[d_T(u,v)] \leq O(\log n) \cdot d_G(u,v)$. The algorithm w.h.p. runs in $O(m \log n)$ time.*

The algorithm computes approximate dominance sequences $\hat{\chi}_\pi$ by the approximate SSSP algorithm introduced in Section 3. Then we apply Lemma 10 to convert $\hat{\chi}_\pi$ to an tree embedding. Notice that this tree embedding is an FRT-embedding based on $\hat{d}_G$. We still call this an FRT-embedding since the overall framework to generate hierarchical tree structure is similar to that in the original paper [17].

The advantage of our new SSSP algorithm is that the Decrease-Key and Extract-Min operation only takes constant time when the relative edge range (maximum divided by minimum) is no more than $n^{O(1)}$. To handle arbitrary weight edges we adopt a similar idea to [23] to solve the subproblems on specific edge ranges, and concatenate the results to form the final output. This requires pre-processing to restrict the edge range.

The high-level idea of the algorithm is as follows. In the pre-processing, the goal is to use $O(m \log n)$ time to generate a list of subproblems: the i-th subproblem has edge range in the interval $[n^{i-1}, n^{i+1}]$ and we compute the elements in the dominance sequences with values falling into the range from n^i to n^{i+1}. All the edge weights less than the minimum value of this range are treated as 0. Namely, the vertices form some components in one subproblem and the vertex distances within each component is 0.

After the subproblems are computed, we run the shortest-path algorithm on each subproblem, and the i-th subproblem generates the entries in the approximate dominance sequences in the range of $[n^i, n^{i+1})$. Finally, we solve an extra subproblem that only contains edges with weight less than n to generate the elements in dominance sequences whose distances fall in range $[1, n)$.

Due to page limit, the details of the algorithm, the proofs of the correctness and time bound are given in the full version of this paper.

5 An Application of FRT-Embedding: Ramsey Partitions and Distance Oracles

In this section we show a new application of FRT-embedding, which with our efficient construction, accelerates the construction of some existing approximate distance oracles [34, 10]. The bridge is to show that the FRT trees are Ramsey partitions [24]. It is interesting to point out that, the construction of FRT trees is not only much faster and simpler than the previous best-known approach [25] to generate Ramsey partitions, but the stretch factor of k, which is 18.5, is also smaller than the previous constants of 128 [24] and 33 [28].

We start with the definition of Ramsey partitions. Let (X, d_X) be a metric space. A hierarchical partition tree of X is a sequence of partitions $\{\mathcal{P}_k\}_{k=0}^{\infty}$ of X such that $\mathcal{P}_0 = \{X\}$, the diameter of the partitions in each level decreases by a constant $c > 1$, and each level $\mathcal{P}_{k+1}$ is a refinement of the previous level $\mathcal{P}_k$. A Ramsey partition [24] is a distribution of hierarchical partition trees such that each vertex has a lower-bounded probability of being sufficiently far from the partition boundaries in all partitions k, and this gap is called the *padded range* of a vertex. More formally:

▶ **Definition 13.** An (α, γ)-Ramsey partition of a metric space (X, d_X) is a probability distribution over hierarchical partition trees $\mathcal{P}$ of X such that for every $x \in X$:

$$\Pr\left[\forall k \in \mathbb{N}, B_X\left(x, \alpha \cdot c^{-k}\Delta\right) \subseteq \mathcal{P}_k(x)\right] \geq |X|^{-\gamma}.$$

An asymptotically tight construction of Ramsey partition where $\alpha = \Omega(\gamma)$ is provided by Mendel and Naor [24] using the Calinescu-Karloff-Rabani partition [9] for each level.

▶ **Theorem 14.** *The probability distribution over FRT trees is an asymptotically tight Ramsey Partition with $\alpha = \Omega(\gamma)$ (shown in the appendix) with fixed $c = 2$. More precisely, for every $x \in X$,*

$$\Pr\left[\forall i \in \mathbb{N}, B_X\left(x, \left(1 - 2^{-1/2a}\right)2^{-i}\Delta\right) \subseteq \mathcal{P}_i(x)\right] \geq \frac{1}{2}|X|^{-\frac{2}{a}}$$

for any positive integer $a > 1$.

The details of the proof are provided in the full version of this paper.

Ramsey Partitions are used in generating approximate distance oracles (ADOs), which supports efficient approximate pairwise shortest-distance queries. ADOs are well-studied by many researchers (e.g. [33, 5, 1, 16, 11, 24, 34, 10]), and a (P, S, Q, D)-distance oracle on a finite metric space (X, d_X) is a data structure that takes expected time P to preprocess from the given metric space, uses S storage space, and answers distance query between points x and y in X in time Q satisfying $d_X(x, y) \leq d_O(x, y) \leq D \cdot d_X(x, y)$, where $d_O(x, y)$ is the pairwise distance provided by the distance oracle, and D is called the stretch.

▶ **Corollary 15.** *With Theorem 14, we can accelerate the time to construct the Ramsey-partitions-based Approximate Distance Oracle in [24] to*

$$O\left(n^{1/k}(m + n\log n)\log n\right)$$

on a graph with n vertices and m edges, improving the stretch to $18.5k$, while maintaining the same storage space and constant query time.

This can be achieved by replacing the original hierarchical partition trees in the distance oracles by FRT trees (and some other trivial changes). The construction time can further reduce to $O\big(n^{1/k}m\log n\big)$ using the algorithm introduced in Section 4.4 while the oracle still has a constant stretch factor. Accordingly, the complexity to construct Christian Wulff-Nilsen's Distance Oracles [34] and Shiri Chechik's Distance Oracles [10] can be reduced to

$$O\Big(kmn^{1/k} + kn^{1+1/k}\log n + n^{1/ck}m\log n\Big)$$

since they all use Mendel and Naor's Distance Oracle to obtain an initial distance estimation. The acceleration is from two places: first, the FRT tree construction is faster; second, FRT trees provide better approximation bound, so the c in the exponent becomes smaller.

Abstract

We study the complexity of approximate counting Constraint Satisfaction Problems (#CSPs) in a bounded degree setting. Specifically, given a Boolean constraint language Γ and a degree bound Δ, we study the complexity of $\#\mathsf{CSP}_\Delta(\Gamma)$, which is the problem of counting satisfying assignments to CSP instances with constraints from Γ and whose variables can appear at most Δ times. Our main result shows that: (i) if every function in Γ is affine, then $\#\mathsf{CSP}_\Delta(\Gamma)$ is in FP for all Δ, (ii) otherwise, if every function in Γ is in a class called IM_2, then for all sufficiently large Δ, $\#\mathsf{CSP}_\Delta(\Gamma)$ is equivalent under approximation-preserving (AP) reductions to the counting problem $\#\mathsf{BIS}$ (the problem of counting independent sets in bipartite graphs) (iii) otherwise, for all sufficiently large Δ, it is NP-hard to approximate the number of satisfying assignments of an instance of $\#\mathsf{CSP}_\Delta(\Gamma)$, even within an exponential factor. Our result extends previous results, which apply only in the so-called "conservative" case.

1 Introduction

Constraint Satisfaction Problems (CSPs), which originated in Artificial Intelligence [18] provide a general framework for modelling decision, counting and approximate counting problems. The paradigm is sufficiently general that applications from diverse areas such as database theory, scheduling and graph theory can all be captured (see, for example, [14, 15, 17]). Moreover, all graph homomorphism decision and counting problems [12] can be re-cast in the CSP framework and partition function problems from statistical physics [21] can be represented as counting CSPs. Given the usefulness of CSPs, the study of the complexity

of CSPs is a an extremely active area in computational complexity (for example, see [2] and the references therein).

In this paper, we are concerned with Boolean counting CSPs. An instance $I = (V, \mathcal{C})$ of a Boolean counting CSP consists of a set V of *variables* and a set $\mathcal{C}$ of constraints. An assignment $\sigma : V \to \{0, 1\}$ assigns a Boolean value called a "spin" to each variable. Each constraint associates a tuple $(v_1, \ldots, v_k)$ of variables with a Boolean relation which constrains the spins that can be assigned to $v_1, \ldots, v_k$. The assignment σ is said to "satisfy" the constraint if the tuple $(\sigma(v_1), \ldots, \sigma(v_k))$ is in the corresponding relation. An assignment is said to be "satisfying" if it satisfies all constraints. A Constraint Satisfaction Problem comes with two important parameters – the constraint language Γ is the set of all relations that may be used in constraints and the degree Δ is the maximum number of times that any variable $v \in V$ may be used in constraints in any instance. The number of satisfying assignments is denoted Z_I. The computational problem $\#\mathsf{CSP}_\Delta(\Gamma)$ is the problem of computing Z_I, given a CSP instance I with constraints in Γ and degree at most Δ. We use $\#\mathsf{CSP}(\Gamma)$ to denote the version of the problem in which the degree of instances is unconstrained.

Although constraints are supported by Boolean relations, they can be used to code up weighted interactions such as those that arise in statistical physics. For example, let R be the "not-all-equal" relation of arity 3. Then consider the conjunction of $R(x, a, b)$ and $R(y, a, b)$. There are two satisfying assignments with $\sigma(x) = 0$ and $\sigma(y) = 1$ since $\sigma(a)$ and $\sigma(b)$ must differ. Similarly, there are two satisfying assignments with $\sigma(x) = 1$ and $\sigma(y) = 0$. On the other hand, there are three satisfying assignments with $\sigma(x) = \sigma(y) = 1$ and there are three satisfying assignments with $\sigma(x) = \sigma(y) = 0$. Thus, the induced interaction on the variables x and y is the same as the interaction of the ferromagnetic Ising model (at an appropriate temperature) – an assignment in which x and y have the same spin has weight 3, whereas an assignment where they have different spins has weight 2.

For every $\Delta \geq 3$, the work of Cai, Lu and Xia [5] completely classifies the complexity of exactly solving $\#\mathsf{CSP}_\Delta(\Gamma)$, depending on the parameter Γ. If every relation in Γ is affine, then $\#\mathsf{CSP}_\Delta(\Gamma)$ is solvable in polynomial time (so the problem in the complexity class FP). Otherwise, it is $\#\mathsf{P}$-complete. The term "affine" will be defined in § 2. Roughly, it means that the tuples in the relation are solutions to a linear system, so Gaussian elimination gives an appropriate polynomial-time algorithm. The characterisation of Cai, Lu and Xia is exactly the same classification that was obtained for the unbounded problem $\#\mathsf{CSP}(\Gamma)$ by Creignou and Hermann [6]. Thus, as far as exact counting is concerned, the degree-bound Δ does not affect the complexity as long as $\Delta \geq 3$. As Cai, Lu and Xia point out, the dichotomy is false for $\Delta = 2$, where $\#\mathsf{CSP}_2(\Gamma)$ is equivalent to the Holant problem $\mathsf{Holant}(\Gamma)$ – see the references in [5] for more information about Holant problems.

Much less is known about the complexity of *approximately* solving $\#\mathsf{CSP}_\Delta(\Gamma)$. In fact, even the *decision problem* is still open. While Schaefer [19] completely classified the complexity of the decision problem $\mathsf{CSP}(\Gamma)$ – where the goal is to determine whether or not Z_I is 0 for an instance of $\#\mathsf{CSP}(\Gamma)$ – the complexity of the corresponding decision problem $\mathsf{CSP}_\Delta(\Gamma)$, where the instance has degree at most Δ, is still not completely resolved. For $\Delta \geq 3$, Dalmau and Ford [7] have solved the special case where Γ includes both of the relations $R_{\delta_0} = \{0\}$ and $R_{\delta_1} = \{1\}$. This special case is known as the "conservative case" in the CSP literature. For $\Delta \geq 6$, Dyer et al. [9] have classified the difficulty of the approximation problem:

- If every relation in Γ is affine, then $\#\mathsf{CSP}_\Delta(\Gamma \cup \{R_{\delta_0}, R_{\delta_1}\})$ is in FP.
- Otherwise, if every relation in Γ is in a class called IM_2 (a class defined in § 2) then $\#\mathsf{CSP}_\Delta(\Gamma \cup \{R_{\delta_0}, R_{\delta_1}\})$ is equivalent under approximation-preserving (AP) reductions to the counting problem $\#\mathsf{BIS}$ (the problem of counting independent sets in bipartite graphs).
- Otherwise, there is no FPRAS for $\#\mathsf{CSP}_\Delta(\Gamma \cup \{R_{\delta_0}, R_{\delta_1}\})$ unless $\mathsf{NP} = \mathsf{RP}$.

Dyer et al. made only partial progress on the cases where $\Delta \in \{3, 4, 5\}$. We refer the reader to [9, 16] for a discussion of the partial classification. However, it is worth noting here that the complexity of $\#\mathsf{CSP}_\Delta(\Gamma \cup \{R_{\delta_0}, R_{\delta_1}\})$ is closely related to the complexity of counting satisfying assignments of so-called read-d Monotone CNF Formulas. Crucial progress was made by Liu and Lu [16], who completely resolved the complexity of the latter problem. Given the work of Liu and Lu, a complete classification of $\#\mathsf{CSP}_\Delta(\Gamma \cup \{R_{\delta_0}, R_{\delta_1}\})$ for $\Delta \in \{3, 4, 5\}$ may be in reach.

The restriction that R_{δ_0} and R_{δ_1} are contained in Γ is a severe one because it does not apply to many natural applications. On the other hand, we are a long way from a precise understanding of the complexity of $\#\mathsf{CSP}_\Delta(\Gamma)$ without this restriction because there are specific, relevant parameters that we do not understand. For example, for a positive integer k, let Γ be the singleton set containing only the arity-k "not-all-spin-1" relation. Then satisfying assignments of an instance of $\#\mathsf{CSP}_\Delta(\Gamma)$ correspond to independent sets of a k-uniform hypergraph with maximum degree Δ. It is known that there is an FPRAS for $\Delta = O(2^{k/2})$ [13] and that the problem is NP-hard to approximate for $\Delta = \Omega(2^{k/2})$ [1]; the implicit constants in these bounds do not currently match and thus, for big k, there is a large range of Δ's where we do not yet know the complexity of approximating $\#\mathsf{CSP}_\Delta(\Gamma)$. If Γ instead contains (only) the arity-k "at-least-one-spin-0" relation then satisfying assignments of an instance of $\#\mathsf{CSP}_\Delta(\Gamma)$ correspond to the so-called "strong" independent sets of a k-uniform hypergraph. Song, Yin and Zhao [20] have presented a barrier for hardness results, showing why current technology is unsuitable for resolving the cases where $\Delta \in \{4, 5\}$ (roughly, these cases are in "non-uniqueness", but this is not realisable by finite gadgets).

The purpose of the present paper is to remove the severe restriction that R_{δ_0} and R_{δ_1} are contained in Γ in the approximate counting classification of $\#\mathsf{CSP}_\Delta(\Gamma)$ from [9]. Since pinning down precise thresholds seems a long way out of reach, we instead focus on whether there is a "barrier" value Δ_0 such that, for all $\Delta \geq \Delta_0$, approximation is intractable. Since we wish to get the strongest possible inapproximability results (showing the hardness of approximating Z_I even within an exponential factor), we define the following computational problem, which has an extra parameter $c > 1$ that captures the desired accuracy.

Name $\#\mathsf{CSP}_{\Delta,c}(\Gamma)$.
Instance An n-variable instance I of a CSP with constraint language Γ and degree at most Δ.
Output A number $\widehat{Z}$ such that $c^{-n} Z_I \leq \widehat{Z} \leq c^n Z_I$.

Although we have not yet defined all of the terms, we can now at least state (a weak version of) our result.

▶ **Theorem 1.** *Let Γ be a Boolean constraint language. Then,*
1. *If every relation in Γ is affine then $\#\mathsf{CSP}(\Gamma)$ is in FP.*
2. *Otherwise, if every relation in Γ is in the class IM_2, then there exists an integer Δ_0 such that for all $\Delta \geq \Delta_0$, $\#\mathsf{CSP}_\Delta(\Gamma)$ is $\#\mathsf{BIS}$-equivalent under AP-reductions.*
3. *Otherwise, there exists an integer Δ_0 such that for all $\Delta \geq \Delta_0$, there exists a real number $c > 1$ such that $\#\mathsf{CSP}_{\Delta,c}(\Gamma)$ is NP-hard.*

After defining all of the terms, we will state a stronger theorem, Theorem 6, which immediately implies Theorem 1. The stronger version applies to the #CSP problems that we have already introduced, but it also applies to other restrictions of these problems, which have even more applications.

We now explain the restriction. Note that in the CSP framework, as we have defined it, the variables that are constrained by a given constraint need not be distinct. Thus, if the arity-4 relation R is present in a constraint language Γ, then an instance of $\#\mathsf{CSP}(\Gamma)$

with variables x and y may contain a constraint such as $R(x, x, y, x)$. This ability to repeat variables is equivalent to assuming that equality relations of all arities are present in Γ. This feature of the CSP definition is inconvenient for two reasons: (1) It does not fit well with some spin-system applications, and (2) In many settings, it obscures the nuanced complexity classification that arise.

As an example of (1), recall the application where Γ is the singleton set containing only the arity-k "not-all-spin-1" relation. As we noted earlier, satisfying assignments of a $\#\mathsf{CSP}(\Gamma)$ instance correspond to independent sets of a k-uniform hypergraph. Here, hyperedges are size-k subsets of vertices and it does not make sense to allow repeated vertices!

The point (2) is well-known. In fact, the "equality is always present" assumption is the main feature that separates #CSPs from the more general Holant framework [3].

In our current setting, it turns out that adding equality functions to Γ does not change the complexity classification, but this is a result of our theorems rather than an a priori assumption – indeed, determining which constraint languages Γ can appropriately simulate equality functions is one of the difficulties – thus, throwing equalities in "for free" would substantially weaken our results! Our main result, Theorem 6, which will be presented in § 2, applies both to the #CSPs that we have already defined, and to more refined versions, in which constraints may not repeat variables.

We wish now to discuss an important special case in which both the #CSPs and the refined versions have already been studied. This is the special case in which Γ consists of a single relation which is symmetric in its arguments. A symmetric relation that is not affine is not in IM_2. Therefore, Item 2 in the statement of Theorem 1 never arises in this special case. Our earlier paper [11] shows that, in this case (where Γ consists of a single, symmetric, non-affine relation) there is an integer Δ_0 such that for all $\Delta \geq \Delta_0$, there exists a real number $c > 1$ such that $\#\mathsf{CSP}_{\Delta,c}(\Gamma)$ is NP-hard.

While the work of [11] is important for this paper, note that the special case is far from general – in particular, it is easy to induce asymmetric constraints using symmetric ones. For example, suppose that R_1 is the (symmetric) arity-2 "not-all-spin-1" constraint, R_2 is the (symmetric) arity-2 "not the same spin" constraint and $R_3 = \{(0,0),(0,1),(1,1)\}$ is the (asymmetric) arity-2 "Implies" constraint. Then the conjunction of $R_1(x, a)$ and $R_2(a, y)$ induces $R_3(x, y)$.

It is interesting that Theorem 1 is exactly the same classification that was obtained for the *unbounded* problem $\#\mathsf{CSP}(\Gamma)$ by Dyer et al. [10]. In particular, they showed

1. If every relation in Γ is affine then $\#\mathsf{CSP}(\Gamma)$ is in FP.
2. Otherwise, if every relation in Γ is in the class IM_2, then $\#\mathsf{CSP}(\Gamma)$ is $\#\mathsf{BIS}$-equivalent under AP-reductions.
3. Otherwise, $\#\mathsf{CSP}(\Gamma)$ is $\#\mathsf{SAT}$-equivalent under AP-reductions, where $\#\mathsf{SAT}$ is the problem of counting the satisfying assignments of a Boolean formula.

The inapproximability that we demonstrate in Item 3 of Theorem 1 is stronger than what was known in the unbounded case, both (obviously) because of the degree bound, but also because we show that it is hard to get within an exponential factor. (This strong kind of inapproximability was also missing from the results of [9]).

2 Definitions and Statement of Main Result

Before giving formal definitions of the problems that we study, we introduce some notation. We use boldface letters to denote Boolean vectors. A *pseudo-Boolean* function is a function of the form $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ for some positive integer k, which is called the *arity* of f.

▶ **Definition 2.** Given a pseudo-Boolean function $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$, we use the notation R_f to denote the relation $R_f = \{\mathbf{x} \in \{0,1\}^k \mid f(\mathbf{x}) > 0\}$, which is the relation underlying f.

If the range of f is $\{0,1\}$ then f is said to be a *Boolean function* and of course in that case $R_f = \{\mathbf{x} \in \{0,1\}^k \mid f(\mathbf{x}) = 1\}$.

In order to allow consistency with obvious generalisations, our formal definition of the Boolean Constraint Satisfaction Problem is in terms of Boolean functions (rather than, equivalently, using the underlying relations).

A *Constraint language* Γ is a set of pseudo-Boolean functions. It is a *Boolean constraint language* if all of the functions in it are Boolean functions. An instance $I = (V, \mathcal{C})$ of a CSP with constraint language Γ consists of a set V of variables and a set $\mathcal{C}$ of constraints. Each constraint $C_i \in \mathcal{C}$ is of the form $f_i(v_{i,1}, \ldots, v_{i,k_i})$ where f_i is an arity-k_i function in Γ and $(v_{i,1}, \ldots, v_{i,k_i})$ is a tuple of (not necessarily distinct) variables in V. The constraint C_i is said to be "Repeat-Free" if all of the variables are distinct. Each *assignment* $\sigma : V \to \{0,1\}$ of Boolean values to the variables in V has a weight $w_I(\sigma) := \prod_{f_i(v_{i,1},\ldots,v_{i,k_i}) \in \mathcal{C}} f_i(\sigma(v_{i,1}), \ldots, \sigma(v_{i,k_i}))$. The *partition function* maps the instance I to the quantity $Z_I := \sum_{\sigma:V\to\{0,1\}} w_I(\sigma) = \sum_{\sigma:V\to\{0,1\}} \prod_{f_i(v_{i,1},\ldots,v_{i,k_i}) \in \mathcal{C}} f_i(\sigma(v_{i,1}), \ldots, \sigma(v_{i,k_i}))$.

If Γ is a Boolean constraint language then it is easy to see that $w_I(\sigma) = 1$ if the assignment is satisfying and $w_I(\sigma) = 0$, otherwise. Thus, Z_I is the number of satisfying assignments of I.

When $Z_I > 0$, we will use $\mu_I(\cdot)$ to denote the Gibbs distribution corresponding to Z_I. This is the probability distribution on the set of assignments $\sigma : V \to \{0,1\}$ such that $\mu_I(\sigma) = w_I(\sigma)/Z_I$ for all $\sigma : V \to \{0,1\}$.

The *degree* $d_v(C)$ of a variable v in a constraint C is the number of times that the variable v appears in the tuple corresponding to C and the degree d_v of the variable is $d_v = \sum_{C\in\mathcal{C}} d_v(C)$. Finally, the degree of the instance I is $\max_{v\in V} d_v$.

▶ **Definition 3.** $\#\mathsf{CSP}_\Delta(\Gamma)$ is the problem of computing Z_I, given a CSP instance I with constraints in Γ and degree at most Δ. $\#\mathsf{CSP}(\Gamma)$ is the version of the problem in which the degree of instances is unconstrained. $\#\mathsf{CSP}_{\Delta,c}(\Gamma)$ has an extra parameter $c > 1$ that captures the desired accuracy. The problem is to compute a number $\widehat{Z}$ such that $c^{-n} Z_I \leq \widehat{Z} \leq c^n Z_I$, where n is the number of variables in the instance I. The problems $\#\mathsf{NoRepeatCSP}_\Delta(\Gamma)$, $\#\mathsf{NoRepeatCSP}(\Gamma)$ and $\#\mathsf{NoRepeatCSP}_{\Delta,c}(\Gamma)$ are defined similarly, except that inputs are restricted so that all constraints are Repeat-Free.

▶ **Definition 4.** A Boolean function $f : \{0,1\}^k \to \{0,1\}$ is *affine* if there is a $k \times k$ Boolean matrix $\mathbf{A}$ and a length-k Boolean vector $\mathbf{b}$ such that R_f is equal to the set of solutions $\mathbf{x}$ of $\mathbf{Ax} = \mathbf{b}$ over GF(2).

▶ **Definition 5** (The set of functions IM_2)**.** A Boolean function $f : \{0,1\}^k \to \{0,1\}$ is in IM_2 if $f(x_1, \ldots, x_k)$ is logically equivalent to a conjuction of (any number of) predicates of the form x_i, $\neg x_i$ or $x_i \Rightarrow x_j$.

We have now defined all of the terms in our main theorem apart from some well-known concepts from complexity theory, which we discuss next. FP is the class of computational problems (with numerical output) that can be solved in polynomial time. An FPRAS is a randomised algorithm that produces approximate solutions within specified relative error with high probability in polynomial time. For two counting problems #A and #B, we say that #A is #B-easy if there is an approximation-preserving (AP)-reduction from #A to #B. The formal definition of an AP-reduction can be found in [8]. It is a randomised Turing reduction that yields close approximations to #A when provided with close approximations to #B. The definition of AP-reduction meshes with the definition of FPRAS in the sense

that the existence of an FPRAS for #B implies the existence of an FPRAS for #A. We say that #A is #B-hard if there is an AP-reduction from #B to #A. Finally, we say that #A is #B-equivalent if #A is both #B-easy and #B-hard.

The problem of counting satisfying assignments of a Boolean formula is denoted by #SAT. Every counting problem in #P is AP-reducible to #SAT, so #SAT is said to be complete for #P with respect to AP-reductions. It is known that there is no FPRAS for #SAT unless RP = NP. The problem of counting independent sets in a bipartite graph is denoted by #BIS. The problem #BIS appears to be of intermediate complexity: there is no known FPRAS for #BIS (and it is generally believed that none exists) but there is no known AP-reduction from #SAT to #BIS. Indeed, #BIS is complete with respect to AP-reductions for a complexity class $\#\mathsf{RH}\Pi_1$.

Given all of these definitions, we now formally state the stronger version of Theorem 1 promised in the introduction. The proof can be found in full version.

▶ **Theorem 6.** *Let Γ be a Boolean constraint language. Then,*

1. *If every function in Γ is affine then $\#\mathsf{CSP}(\Gamma)$ and $\#\mathsf{NoRepeatCSP}(\Gamma)$ are both in FP.*
2. *Otherwise, if $\Gamma \subseteq IM_2$, then there exists an integer Δ_0 such that for all $\Delta \geq \Delta_0$, $\#\mathsf{CSP}_\Delta(\Gamma)$ and $\#\mathsf{NoRepeatCSP}_\Delta(\Gamma)$ are both #BIS-equivalent under AP-reductions, and*
3. *Otherwise, there exists an integer Δ_0 such that for all $\Delta \geq \Delta_0$, there exists a real number $c > 1$ such that $\#\mathsf{CSP}_{\Delta,c}(\Gamma)$ and $\#\mathsf{NoRepeatCSP}_{\Delta,c}(\Gamma)$ are both NP-hard.*

3 Overview of the Proof of Theorem 6

In this section, we give a non-technical overview of the proof of Theorem 6. Our objective is to illustrate the main ideas and obstacles without delving into the more detailed definitions. A more technical overview can be found in § 5. Our focus in this section will be on the case where Γ consists of a single Boolean function $f : \{0,1\}^k \to \{0,1\}$. This case is the main ingredient in the proof of the theorem.

A typical approach for showing that a counting CSP is intractable is to use an instance of the CSP to build a "gadget" which simulates an intractable binary 2-spin constraint. This was the approach used in [11], which proved the intractability of $\#\mathsf{NoRepeatCSP}_\Delta(\{f\})$ for any *symmetric* non-affine Boolean function f. There, an instance I of $\#\mathsf{NoRepeatCSP}_\Delta(\{f\})$ was constructed, along with variables x and y, such that for all spins $s_x \in \{0,1\}$ and $s_y \in \{0,1\}$ the marginal distribution $\mu_I(x,y)$ satisfies

$$\mu_I(\sigma(x) = s_x, \sigma(y) = s_y) = g(s_x, s_y)/(g(0,0) + g(0,1) + g(1,0) + g(1,1)), \tag{1}$$

where g is a binary function that codes up the interaction of an intractable anti-ferromagnetic 2-spin system. We will not need to give detailed definitions of 2-spin systems in this paper. Instead, we give a sufficient condition for intractability.

▶ **Definition 7.** A binary function $g : \{0,1\}^2 \to \mathbb{R}_{\geq 0}$ is said to be "*hard*" if all of the following hold: $g(0,0)+g(1,1) > 0$, $\min\{g(0,0), g(1,1)\} < \sqrt{g(0,1)g(1,0)}$, and $\max\{g(0,0), g(1,1)\} \leq \sqrt{g(0,1)g(1,0)}$.

It was established in [11] that the ability to "simulate" a hard function g in the sense of (1) ensures that $\#\mathsf{NoRepeatCSP}_\Delta(\{f\})$ is NP-hard to approximate, even within an exponential factor.

A key feature of *symmetric* Boolean functions f which facilitated such simulation in [11] was the fact that the class of relevant hard functions g is well-behaved, and it turned out that

it suffices to encode such a hard binary function with only ϵ-accuracy, for some sufficiently small $\epsilon > 0$, and this was enough to ensure the NP-hardness of $\#\mathsf{CSP}_{\Delta,c}(\{f\})$.

The main obstacle in adapting the approach of [11] to the case where f need not be symmetric in its arguments arises when f is in IM_2. It is unlikely that such a function f can simulate a hard function g in the sense of (1) – indeed such a simulation would prove the (very surprising) result that #BIS does not have an FPRAS (unless NP = RP). Thus, for $f \in IM_2$, we need instead to encode a binary function which will allow us to connect the problem $\#\mathsf{NoRepeatCSP}_{\Delta}(\{f\})$ to #BIS.

Now consider the binary Boolean function Implies whose underlying relation $R_{\mathsf{Implies}} = \{(0,0),(0,1),(1,1)\}$ contains all (x,y) satisfying $x \Rightarrow y$. Obviously, Implies is not symmetric, and it is not hard according to Definition 7. On bipartite instances, however, the symmetry can be restored by interpreting differently the spins 0 and 1 on the two parts of the graph, and this leads to a connection with #BIS. In particular, it is well-known [10] that $\#\mathsf{CSP}(\{\mathsf{Implies}\})$ is equivalent to #BIS under AP-reductions. This connection was extended to the bounded-degree setting by [4].

Unfortunately, the symmetrisation which connects $\#\mathsf{CSP}(\{\mathsf{Implies}\})$ to #BIS is not very robust. For example, suppose that a (non-symmetric) Boolean function f can be used to simulate, in the sense of (1), a binary function g which is very close to Implies. In particular, suppose that for some $\epsilon > 0$ and $\epsilon_1, \epsilon_2, \epsilon_3, \epsilon_4$ satisfying $|\epsilon_i| \leq \epsilon$ for $i = 1, 2, 3, 4$, we have $g(0,0) = 1+\epsilon_1$, $g(0,1) = 1+\epsilon_2$, $g(1,0) = \epsilon_3$, and $g(1,1) = 1+\epsilon_4$. Such a close approximation is about the best that can be expected using the kind of approximate encodings that are available. However, the complexity of asymmetric 2-spin systems is not sufficiently well understood to exploit such a simulation. Surprisingly, for *any* arbitrarily small constant $\epsilon > 0$, it is not known even whether the unbounded degree version $\#\mathsf{CSP}(\{g\})$ is #BIS-hard, and certainly nothing is known in our bounded-degree setting! The trouble is that the symmetrisation that works for Implies (i.e., when $\epsilon_i = 0$ for $i = 1, 2, 3, 4$) is no longer guaranteed to symmetrise the imperfect version with the ϵ_i's, so the swapping of spin-0 and spin-1 values on one side of the bipartite graph leads to an *asymmetric* 2-spin system on bipartite graphs and this does not fall into the scope of known results [4] concerning bounded-degree bipartite 2-spin systems.

Our approach to handle this problem for $f \in IM_2$ is to carefully ensure that there is no accuracy error ϵ in encoding the function Implies. In other words, we show that, using $f \in IM_2$, we can encode Implies *perfectly*, a task which is surprisingly intricate in the repeat-free setting. Our main technical theorem, Theorem 17, achieves this goal. Namely, it shows that, for every non-affine Boolean function f, either f simulates a hard function (with arbitrarily small accuracy-error ϵ, which leads to the desired intractability of $\#\mathsf{NoRepeatCSP}_{\Delta}(\{f\})$) or else f "supports perfect equality" – a concept which will be defined later, but essentially means that f can be used to perfectly simulate the binary function EQ with underlying relation $R_{\mathsf{EQ}} = \{(0,0),(1,1)\}$. Using EQ, it is possible to simulate repeated variables in constraints, so the #BIS-hardness of $\#\mathsf{CSP}_{\Delta}(\{f\})$ follows from [10]. When $f \notin IM_2$ but f supports perfect equality, instead of reducing to the work in [10], we work somewhat harder to make sure that we also get the strong (exponential factor) inapproximability given in Theorem 6.

4 Pinning, equality and simulating functions

An important case in our proof is the case where Γ contains a single function $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$. In this case, we can we simplify the notation because the constraints in an instance I are in one-to-one correspondence with k-tuples of variables (there is no need to repeat the name of the function f in each constraint). So, for convenience, we make the following definitions.

A *k-tuple hypergraph* $H = (V, \mathcal{F})$ consists of a set V of vertices, together with a set $\mathcal{F}$ of *hyperarcs*, where every hyperarc in $\mathcal{F}$ is a k-tuple of distinct vertices in V. The degree of H is the maximum, over all vertices $v \in V$, of the number of hyperarcs that contain v. Given a function $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$, we let $I_f(H)$ denote the instance of $\#\mathsf{NoRepeatCSP}(\{f\})$ whose constraints correspond to the hyperarcs of H. Given an assignment $\sigma\colon V \to \{0,1\}$ we define $w_{f;H}(\sigma) := \prod_{(v_1,\ldots,v_k)\in\mathcal{F}} f(\sigma(v_1),\ldots,\sigma(v_k))$ and $Z_{f;H} := \sum_{\sigma:V\to\{0,1\}} w_{f;H}(\sigma)$, so $Z_{I_f(H)} = Z_{f;I_f(H)}$. By analogy to the Gibbs distribution on satisfying assignments, when $Z_{f;H} > 0$, we use $\mu_{f;H}(\cdot)$ to denote the probability distribution in which, for all assignments $\sigma : V \to \{0,1\}$, $\mu_{f;H}(\sigma) = w_{f;H}(\sigma)/Z_{f;H}$.

Given a function $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ and a positive integer Δ, we define $\#\mathsf{Multi2Spin}_\Delta(f)$ to be the problem of computing $Z_{f;H}$, given as input a k-tuple hypergraph H with degree at most Δ. The name $\#\mathsf{Multi2Spin}_\Delta(f)$ indicates that the problem is to compute the partition function of a 2-spin system with multi-body interactions specified by f and degree-bound Δ. Given a real number $c > 1$, the problem $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ has the same input, and the goal, when the input has n vertices, is to compute a number $\widehat{Z}$ such that $c^{-n}Z_{f;H} \leq \widehat{Z} \leq c^n Z_{f;H}$. Clearly, $\#\mathsf{Multi2Spin}_\Delta(f)$ is equivalent to $\#\mathsf{NoRepeatCSP}_\Delta(\{f\})$ and $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ is equivalent to $\#\mathsf{NoRepeatCSP}_{\Delta,c}(\{f\})$.

4.1 Supporting pinning and equality

Let k be a positive integer and let $H = (V, \mathcal{F})$ be a k-tuple hypergraph. Given a configuration $\sigma : V \to \{0,1\}$ and a subset $T \subseteq V$, we will use σ_T to denote the restriction of σ to vertices in T. For a vertex $v \in V$, we will also use σ_v to denote the spin $\sigma(v)$ of vertex v in σ. The following definitions are generalisations of definitions from [11].

▶ **Definition 8.** Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$. Suppose that $\epsilon \geq 0$ and $s \in \{0,1\}$. The k-tuple hypergraph H is an *ϵ-realisation of pinning-to-s* if there exists a vertex v of H such that $\mu_{f;H}(\sigma_v = s) \geq 1 - \epsilon$.

▶ **Definition 9.** Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ and $s \in \{0,1\}$. We say that f supports *pinning-to-s* if, for every $\epsilon > 0$, there is a k-tuple hypergraph which is an ϵ-realisation of pinning-to-s. We say that f supports *perfect* pinning-to-s if there is a k-tuple hypergraph which is a 0-realisation of pinning-to-s.

We now define what it means for a function f to support (perfect) equality (cf. § 3).

▶ **Definition 10.** Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ and $\epsilon \geq 0$. The k-tuple hypergraph H is an *ϵ-realisation of equality* if there exist distinct vertices v_1 and v_2 of H such that, for each $s \in \{0,1\}$, $\mu_{f;H}(\sigma_{v_1} = \sigma_{v_2} = s) \geq (1-\epsilon)/2$.

▶ **Definition 11.** Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$. The function f *supports equality* if, for every $\epsilon > 0$, there is a k-tuple hypergraph which is an ϵ-realisation of equality. The function f *supports perfect equality* if there is a k-tuple hypergraph which is a 0-realisation of equality.

4.2 Realising conditional distributions induced by pinning and equality

Given a set S of vertices, we write $\sigma_S = \mathbf{0}$ to denote the event that all vertices in S are assigned the spin 0 under the assignment σ. We similarly write $\sigma_S = \mathbf{1}$ to denote the event that all vertices in S are assigned the spin 1 under the assignment σ. Finally, we use use σ_S^{eq} to denote the event that all vertices in S have the same spin under σ (the spin could be 0 or 1). The following definition is a generalisation of Definition 16 of [11] except that we have changed the notation slightly for convenience.

▶ **Definition 12** ([11, Definition 16]). Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$. Let $H = (V, \mathcal{F})$ be a k-tuple hypergraph. Let $\mathcal{V} = (V_{\mathsf{pin0}}, V_{\mathsf{pin1}}, \mathcal{V}_{\mathsf{eq}})$ where V_{pin0} and V_{pin1} are disjoint subsets of V and $\mathcal{V}_{\mathsf{eq}}$ is a (possibly empty) set of disjoint subsets of $V \backslash (V_{\mathsf{pin0}} \cup V_{\mathsf{pin1}})$. Suppose that: (i) $V_{\mathsf{pin0}} = \emptyset$ if f does not support pinning-to-0, (ii) $V_{\mathsf{pin1}} = \emptyset$ if f does not support pinning-to-1, (iii) $\mathcal{V}_{\mathsf{eq}} = \emptyset$ if f does not support equality, (iv) it holds that $\mu_{f;H}(\sigma_{V_{\mathsf{pin0}}} = \mathbf{0}, \sigma_{V_{\mathsf{pin1}}} = \mathbf{1}, \bigcap_{W \in \mathcal{V}_{\mathsf{eq}}} \sigma^{\mathsf{eq}}_W) > 0$. We will then say that "$\mathcal{V}$ is *admissible* for H with respect to f" and we will denote by $\mu^{\mathrm{cond}(\mathcal{V})}_{f;H}$ the probability distribution $\mu_{f;H}(\cdot \mid \sigma_{V_{\mathsf{pin0}}} = \mathbf{0}, \sigma_{V_{\mathsf{pin1}}} = \mathbf{1}, \bigcap_{W \in \mathcal{V}_{\mathsf{eq}}} \sigma^{\mathsf{eq}}_W)$.

4.3 Simulating hard functions and inapproximability results

We can now give a formal definition of "simulation", along the lines that was informally discussed in § 3 (Equation (1)).

▶ **Definition 14.** Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ and $g : \{0,1\}^t \to \mathbb{R}_{\geq 0}$. The function f simulates the function g if there is a k-tuple hypergraph H, an admissible set $\mathcal{V}$ for H with respect to f, and t vertices $v_1, v_2, \ldots, v_t$ of H such that, for all $(s_1, s_2, \ldots, s_t) \in \{0,1\}^t$,

$$\mu^{\mathrm{cond}(\mathcal{V})}_{f;H}(\sigma(v_1) = s_1, \sigma(v_2) = s_2, \ldots, \sigma(v_t) = s_t) = \frac{g(s_1, s_2, \ldots, s_t)}{\sum_{(s'_1, s'_2, \ldots, s'_t) \in \{0,1\}^t} g(s'_1, s'_2, \ldots, s'_t)}.$$

If $\mathcal{V} = (\emptyset, \emptyset, \emptyset)$, then we say that f *perfectly simulates* g. More generally, we say that f simulates a set of functions $\mathcal{G}$ if f simulates every $g \in \mathcal{G}$.

The connection betweeen "hard" as defined in Definition 7 and intractability is given in the following lemma. The lemma is stated for symmetric functions in [11], but the proof also works for asymmetric functions.

▶ **Lemma 15** ([11, Lemma 18]). *Let $f : \{0,1\}^k \to \mathbb{R}_{\geq 0}$. If f simulates a hard function, then for all sufficiently large Δ, there exists $c > 1$ such that $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ is NP-hard.* ◀

5 Proof Sketch

In this section, for a Boolean function $f : \{0,1\}^k \to \{0,1\}$, we consider the complexity of the problems $\#\mathsf{Multi2Spin}_{\Delta}(f)$ and $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$. Classifying the complexity of these problems is the most important step in the proof of Theorem 6. Namely, to obtain Theorem 6, it suffices to show that for every non-affine function f, we have that:

- If f is in IM_2, then for all sufficiently large Δ, $\#\mathsf{Multi2Spin}_{\Delta}(f)$ is $\#\mathsf{BIS}$-equivalent.
- If f is not in IM_2, then for all sufficiently large Δ, there exists a real number $c > 1$ such that $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ is NP-hard.

Our main technical theorem to prove this is the following classification of Boolean functions, which asserts that every non-affine function either supports perfect equality or simulates a hard function. A proof sketch is provided later.

▶ **Theorem 17.** *Let $k \geq 2$ and let $f : \{0,1\}^k \to \{0,1\}$ be a Boolean function. Then at least one of three following propositions is true:*

1. *f is affine;*
2. *f supports perfect equality;*
3. *f simulates a hard function.*

When f simulates a hard function, using Lemma 15, we can immediately conclude that for all sufficiently large Δ, there exists $c > 1$ such that $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ is NP-hard. As

we already discussed in § 3, it is important that, in the case where f does not simulate a hard function, Theorem 17 guarantees that f supports *perfect* equality (rather than simple imperfect equality); this allows us to recover the connection to #BIS for those $f \in IM_2$. In fact, when f supports perfect equality, we can effectively carry out (a strengthening of) the program in [10] to obtain the following classification which perfectly aligns with Theorem 6.

▶ **Theorem 18.** *Let $f : \{0,1\}^k \to \{0,1\}$ be a Boolean function that is not affine. Suppose that f supports perfect equality.*

1. *If f is in IM_2, then for all sufficiently large Δ, $\#\mathsf{Multi2Spin}_\Delta(f)$ is $\#\mathsf{BIS}$-equivalent.*
2. *If f is not in IM_2, then for all sufficiently large Δ, there exists a real number $c > 1$ such that $\#\mathsf{Multi2Spin}_{\Delta,c}(f)$ is NP-hard.*

Theorems 17 and 18 together achieve the desired classification of $\#\mathsf{Multi2Spin}_\Delta(f)$ when $f \in IM_2$ as well as the strong inapproximability results when $f \notin IM_2$. Before presenting a more elaborate sketch of the proof of Theorem 17, it will be instructive to give the main ideas behind both proofs.

To prove Theorem 17, our proof departs from the previous approaches in the related works [10] and [11]. In these works, f was used to directly encode a binary function which was feasible because of the presence of equality in [10] and the symmetry of f in [11]. Instead, we take a much more painstaking combinatorial approach by using induction on the arity of the function f.

The base case of the induction (proving Theorem 17 for arity-2 functions) is fairly simple to handle, so let us focus on the induction step. The rough idea, to put the induction hypothesis to work, is to study whether f supports pinning-to-0 or pinning-to-1; then, provided that at least one these pinnings is available, we need to pin appropriately some arguments of f to obtain a function h of smaller arity. Our goal is then to ensure that h is non-affine; then, we can invoke the induction hypothesis and obtain that h either supports perfect equality or simulates a hard function. From there, since h was obtained by pinning some arguments of f, we will obtain by a transitivity argument (cf. Lemma 33 in the full version) that f either supports perfect equality or f simulates the same hard function as h. (Note, in the case where h supports perfect equality, to conclude that f supports perfect equality, we need to ensure that the pinnings of f used to obtain h were perfect.)

Determining which arguments of f need to be pinned is the most challenging aspect of this scheme. Our method for reducing the number of functions under consideration is to symmetrise f in a natural way and obtain a new function f^* which is now symmetric (see definitions in § 6). Then, it turns out that there are seven possibilities for the function f^* which we need to consider in detail. That is, when the symmetrisation of f is one of these seven functions, we have to figure out whether f supports perfect equality and, if not, work out the combinatorial structure of f and pinpoint which arguments are suitable to be pinned. The details of the argument can be found in the full version of this paper.

The proof of Theorem 18, where f supports perfect equality, basically follows the approach of [10]. However, to get the stronger inapproximability results, we have to take a detour studying self-dual functions (functions whose value does not change when we complement their arguments). We show that if f is self-dual then it simulates a hard function (Theorem 46 of the full version). The problem with self-dual functions is that they do not support pinning-to-0 or pinning-to-1, so we are not able to use the relevant results from [10]. After proving Theorem 46 and demonstrating (Lemma 42) that "implementations in CSPs" work in the repeat-free setting when f supports perfect equality, the techniques of [10] can be adapted to get Theorem 18.

6 A partial sketch of the proof of Theorem 17

Let $f : \{0,1\}^k \to \{0,1\}$ be a Boolean function. For $S \subseteq [k]$, χ_S denotes the characteristic vector of S, which is the length-k Boolean vector such that, for all $i \in [k]$, the i-th bit of χ_S is 1 iff $i \in S$. $\Omega_f = \{S \subseteq [k] \mid \chi_S \in R_f\}$. The function f is said to be *semi-trivial* iff there is a set S such that $\Omega_f = \{T \mid S \subseteq T \subseteq [k]\}$ or $\Omega_f = \{T \mid T \subseteq S\}$. Every semi-trivial Boolean function is affine. Let P_k denote the set of all permutations $\pi : [k] \to [k]$. Then the symmetrisation f^* of f is the function $f^* : \{0,1\}^k \to \mathbb{R}_{\geq 0}$ defined by $f^*(x_1, \ldots, x_k) = \prod_{\pi \in P_k} f(x_{\pi(1)}, \ldots, x_{\pi(k)})$. For $s \in \{0,1\}$, let $\delta_s : \{0,1\} \to \{0,1\}$ be the Boolean function defined by $\delta_s(s) = 1$ and $\delta_s(1 \oplus s) = 0$. Define $f_{i \to s}$ to be the function obtained from f by pinning the i-th argument of f to s, i.e. $f_{i \to s}(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_k) = \sum_{x_i \in \{0,1\}} f(x_1, \ldots, x_k) \cdot \delta_s(x_i)$. Similarly, for $S, T \subseteq [k]$, let $f_{S \to 0, T \to 1}$ be the $(k - |S \cup T|)$-ary function obtained from f by pinning the arguments in S to 0 and the arguments in T to 1. So if $\mathbf{x}'$ denotes the $|S \cup T|$-ary vector containing all x_i with $i \in S \cup T$ and $\mathbf{x}''$ denotes the $k - |S \cup T|$-ary vector containing all x_i with $i \in [k] \setminus S \cup T$, $f_{S \to 0, T \to 1}(\mathbf{x}'') = \sum_{\mathbf{x}' \in \{0,1\}^{|S \cup T|}} f(x_1, \ldots, x_k) \cdot \prod_{i \in S} \delta_0(x_i) \cdot \prod_{j \in T} \delta_1(x_j)$. If $S = \emptyset$ or $T = \emptyset$, we will omit $S \to 0$ or $T \to 1$ from the notation.

Partial Proof Sketch. We prove the theorem by induction on the arity of f. The base case, $k = 2$, is covered in the full version. For the induction step, assume $k \geq 3$. The inductive hypothesis is that for all $2 \leq k' < k$, all k'-ary functions f' satisfy at least one of the three propositions in the statement of the theorem. We now prove that an arbitrary $f : \{0,1\}^k \to \{0,1\}$ also satisfies at least one of the propositions. The easy case is when f^* is not affine. In this case, the work of [11] shows that f^* either simulates a hard function (in which case f simulates the hard function as well) or f^* supports perfect equality (in which case f does as well). The bulk of the proof deals with the case where f^* is affine. It turns out that there are seven possible symmetric affine functions f^*. To illustrate the ideas, we consider just one of them here. So from now on (to cover this special case), suppose that, for all $\mathbf{x} \in \{0,1\}^k$, $f^*(\mathbf{x}) = 0$.

We prove in the full version that either f supports perfect equality or f supports both perfect pinning-to-0 and perfect pinning-to-1. If f supports perfect equality, then we are done, so suppose from now on that f supports both perfect pinning-to-0 and perfect pinning-to-1.

We will show below that at least one of the following items holds. (1) f is affine (so we are finished), (2) there exist $S, T \subseteq [k]$ such that $f_{S \to 0, T \to 1}$ is not affine, (3) f supports perfect equality (so we are finished), or (4) f simulates a hard function (so we are finished). In situation (2), since $f_{S \to 0, T \to 1}$ is not affine, it must support perfect equality or simulate a hard function g by the induction hypothesis. So we finish by showing (Lemma 33) that f either supports perfect equality or simulates the same hard function g. We now discuss how to show that at least one of the four items holds.

We prove in the full version (Lemma 39) that for all $W \in \Omega_f$, $f_{\overline{W} \to 0}$ is semi-trivial (otherwise one of the items holds). Choose $S \in \Omega_f$ such that $|S|$ is as large as possible. Let $h = f_{\overline{S} \to 0}$. Since h is semi-trivial (by taking $W = S$ above), we claim that there is a T satisfying $\emptyset \subset T \subseteq S$ such that $\Omega_h = \{U \mid T \subseteq U \subseteq S\}$. (To see this, note that the definition of semi-trivial implies that there is a subset T of S such that either $\Omega_h = \{U \mid U \subseteq T\}$ or $\Omega_h = \{U \mid T \subseteq U \subseteq S\}$. The former is impossible since $\emptyset \notin \Omega_h$ since $h(\mathbf{0}) = f(\mathbf{0}) = f^*(\mathbf{0}) = 0$. Also, in the latter case, T is not empty because, once again, $\emptyset \notin \Omega_h$.)

Case 1. *Suppose that* $\forall X \in \Omega_f$, $T \subseteq X$: Recall that T is non-empty. Also, for every $i \in T$, $\{i\} \cup \Omega_{f_{i \to 1}} = \Omega_f$ so either f is affine (item (1)) or $f_{i \to 1}$ is not affine (item (2)).

Now, if Case 1 does not hold then there is an $X \in \Omega_f$ such that $T \setminus X$ is non-empty. Since $\Omega_h = \{U \mid T \subseteq U \subseteq S\}$ we conclude that $X \notin \Omega_h$. Since $h = f_{\overline{S} \to 0}$ we conclude that $X \setminus S$ is non-empty. Thus, the only other case to consider is as follows.

Case 2. *Suppose that there is an $X \in \Omega_f$ such that $T \setminus X$ and $X \setminus S$ are both non-empty:* Let $\Psi = \{X \in \Omega_f \mid T \setminus X \neq \emptyset \text{ and } X \setminus S \neq \emptyset\}$, $a = \min\{|T \setminus X| : X \in \Psi\}$, and $b = \min\{|X \setminus S| : X \in \Psi \text{ and } |T \setminus X| = a\}$. Choose $R \in \Psi$ with $|T \setminus R| = a$ and $|R \setminus S| = b$. Now before proceeding, we use the sets S, T and R to partition $[k]$. Specifically, let $A = \{i \in [k] \mid i \in S, i \in T, i \notin R\}$, $B = \{i \in [k] \mid i \in S, i \in T, i \in R\}$, $C = \{i \in [k] \mid i \in S, i \notin T, i \notin R\}$, $D = \{i \in [k] \mid i \in S, i \notin T, i \in R\}$, $E = \{i \in [k] \mid i \notin S, i \notin T, i \notin R\}$ and $F = \{i \in [k] \mid i \notin S, i \notin T, i \in R\}$. It is clear from the definitions that the sets A, B, C, D, E and F are disjoint. Also, since $T \subseteq S$, they partition $[k]$. From the definitions, $A = T \setminus R$ and $F = R \setminus S$ so, by the choice of R, A and F are non-empty. Let $g = f_{C \cup E \to 0, B \cup D \to 1}$.

By definition, every element of Ω_g is a subset of $A \cup F$. Also, for $Y \subseteq A \cup F$, "$Y \in \Omega_g$" means the same thing as "$Y \cup B \cup D \in \Omega_f$". We establish some facts before dividing the analysis into sub-cases.

Fact 1: $A \in \Omega_g$. We have $\Omega_h = \{U \mid T \subseteq U \subseteq S\}$ and $T = A \cup B$ so $A \cup B \cup D \in \Omega_h$. Since $A \cup B \cup D \subseteq S$, this means $A \cup B \cup D \in \Omega_f$. Equivalently, $A \in \Omega_g$.

Fact 2: $F \in \Omega_g$. From the definition of R, $R \in \Omega_f$. Also, $R = B \cup D \cup F$ so $F \cup B \cup D \in \Omega_f$. Equivalently, $F \in \Omega_g$.

Fact 3: If $Y \in \Omega_g$ then either $Y \cap A \in \{\emptyset, A\}$ or $Y \cap F = \emptyset$ (or both). Suppose for contradiction that $\emptyset \subset Y \cap A \subset A$ and $Y \cap F$ is non-empty. Note that $R = B \cup D \cup F$. Let $R' = B \cup D \cup Y$. Note that $T \setminus R = A$ and $T \setminus R' = A \setminus Y \subset A$ so $|T \setminus R'| < |T \setminus R|$. We will show a contradiction to the choice of R by showing that $R' \in \Psi$. First, since $Y \in \Omega_g$, $R' \in \Omega_f$. Also, $T \setminus R' = A \setminus Y$ is non-empty and $R' \setminus S = Y \cap F$ is non-empty.

Fact 4: If $Y \in \Omega_g$ and $Y \cap A = \emptyset$ then $Y \in \{\emptyset, F\}$. Suppose for contradiction that $\emptyset \subset Y \subset F$. As in the proof of Fact 3, let $R' = B \cup D \cup Y$. Note that $T \setminus R = T \setminus R' = A$. Also, $R \setminus S = F$ and $R' \setminus S = Y$ so $|R \setminus S| > |R' \setminus S|$. Once again, we will show a contradiction to the choice of R by showing that $R' \in \Psi$. As in the proof of Fact 3, since $Y \in \Omega_g$, $R' \in \Omega_f$. Also, $T \setminus R'$ is non-empty since $T \setminus R$ is. Finally, $R' \setminus S = Y$, which is non-empty.

Fact 5: If $Y \in \Omega_g$ and $Y \cap F = \emptyset$ then $Y = A$. Since $Y \in \Omega_g$, we have $Y \cup B \cup D \in \Omega_f$. But since $Y \subseteq A$, we have $Y \cup B \cup D \subseteq S$, so $Y \cup B \cup D \in \Omega_h$. Since $\Omega_h = \{U \mid T \subseteq U \subseteq S\}$ we have $T \subseteq Y \cup B \cup D$ so $A \subseteq Y$.

Given Facts 1–5, we have only the following sub-cases.

Case 2a: $\Omega_g = \{A, F\}$. In this case, we will show that f supports perfect equality. Let H_0 be a k-tuple hypergraph, with a vertex u_0 such that $\mu_{f;H_0}(\sigma_{u_0} = 0) = 1$. Let H_1 be a k-tuple hypergraph, with a vertex u_1 such that $\mu_{f;H_1}(\sigma_{u_1} = 0) = 1$. We have already noted that A is non-empty. Suppose, without loss of generality, that $1 \in A$ (otherwise, we simply re-order the arguments of $[k]$). Now let H' be the k-tuple hypergraph with vertices $v_0, v_1, \ldots, v_k$ and hyperarcs $(v_0, v_2, \ldots, v_k)$ and $(v_1, v_2, \ldots, v_k)$. Construct H from H' by doing the following:

- For every $i \in C \cup E$, take a new copy of H_0 and identify vertex u_0 with v_i.
- For every $i \in B \cup D$, take a new copy of H_1 and identify vertex u_1 with v_i.

Now since $\Omega_g = \{A, F\}$, $\mu_{f;H}(\sigma(v_0) = \sigma(v_1) = 0) = \mu_{f;H}(\sigma(v_0) = \sigma(v_1) = 1) = 1/2$. Thus, f supports perfect equality, so item (3) holds.

Case 2b: $\exists Y \in \Omega_g$ such that $Y \cap A = A$ and $Y \cap F$ is non-empty. We show in the full version that $f_{t \to 1}$ is not affine for some $t \in A$ (so item (2) holds). ◀

Abstract

We study the problem of approximately evaluating the independent set polynomial of bounded-degree graphs at a point λ. Equivalently, this problem can be reformulated as the problem of approximating the partition function of the hard-core model with activity λ on graphs G of maximum degree Δ. For $\lambda > 0$, breakthrough results of Weitz and Sly established a computational transition from easy to hard at $\lambda_c(\Delta) = (\Delta-1)^{(\Delta-1)}/(\Delta-2)^{\Delta}$, which coincides with the tree uniqueness phase transition from statistical physics.

For $\lambda < 0$, the evaluation of the independent set polynomial is connected to the problem of checking the conditions of the Lovász Local lemma (LLL) and applying its algorithmic consequences. Shearer described the optimal conditions for the LLL and identified the threshold $\lambda^*(\Delta) = (\Delta-1)^{\Delta-1}/\Delta^{\Delta}$ as the maximum value p such that every family of events with failure probability at most p and whose dependency graph has maximum degree Δ has nonempty intersection. Very recently, Patel and Regts, and Harvey et al. have independently designed FPTASes for approximately computing the partition function whenever $|\lambda| < \lambda^*(\Delta)$.

Our main result establishes for the first time a computational transition at the Shearer threshold. Namely, we show that for all $\Delta \geq 3$, for all $\lambda < -\lambda^*(\Delta)$, it is NP-hard to approximate the partition function on graphs of maximum degree Δ, even within an exponential factor. Thus, our result, combined with the algorithmic results for $\lambda > -\lambda^*(\Delta)$, establishes a phase transition for negative activities. In fact, we now have a complete picture for the complexity of approximating the partition function for all $\lambda \in \mathbb{R}$ and all $\Delta \geq 3$, apart from the critical values.

1. For $-\lambda^*(\Delta) < \lambda < \lambda_c(\Delta)$, there exists an FPTAS for approximating the partition function with activity λ on graphs G of maximum degree Δ.
2. For $\lambda < -\lambda^*(\Delta)$ or $\lambda > \lambda_c(\Delta)$, it is NP-hard to approximate the partition function with activity λ on graphs G of maximum degree Δ, even within an exponential factor.

Rather than the tree uniqueness threshold of the positive case, the phase transition for negative activities corresponds to the existence of zeros for the partition function of the tree below $-\lambda^*(\Delta)$.

1 Introduction

The independent set polynomial is a fundamental object in computer science which has been studied with various motivations. From an algorithmic viewpoint, the evaluation of this polynomial is crucial for determining the applicability of the Lovász Local Lemma and thus obtaining efficient algorithms for both finding [14] and approximately counting [6, 12] combinatorial objects with specific properties.

The independent set polynomial also arises in statistical physics, where it is called the hard-core partition function. Given a graph G, the value of the independent set polynomial of G at a point λ is equal to the value of the partition function of the hard-core model where the so-called "activity parameter" is equal to λ. We use the following notation. Given a graph G, let $\mathcal{I}_G$ denote the set of independent sets in G. The weight of an independent set $I \in \mathcal{I}_G$ is given by $\lambda^{|I|}$. The hard-core partition function with parameter λ is defined as $Z_G(\lambda) := \sum_{I \in \mathcal{I}_G} \lambda^{|I|}$.

The hard-core model has attracted significant interest in computer science during recent years, due to the pioneering results by Weitz and Sly which established that the computational complexity of approximating the partition function undergoes a transition that coincides with the uniqueness phase transition in statistical physics. Namely, for $\Delta \geq 3$, let $\lambda_c(\Delta) := (\Delta-1)^{\Delta-1}/(\Delta-2)^{\Delta}$. Weitz [22] designed an FPTAS for approximating the partition function on graphs G of maximum degree Δ when the activity parameter λ is in the range $0 < \lambda < \lambda_c(\Delta)$. On the other hand, Sly [19] showed that approximating the partition function for $\lambda > \lambda_c(\Delta)$ is NP-hard (see [20] for the refinement stated here). The threshold $\lambda_c(\Delta)$ coincides with the uniqueness threshold of the infinite Δ-regular tree and it captures whether root-to-leaf correlations persist, or decay exponentially, as the height of the tree goes to infinity. This beautiful connection between computational complexity and phase transitions has lead to a classification of the complexity of approximating the partition function of general antiferromagnetic 2-spin systems on graphs of maximum degree Δ (see [11, 18] for the algorithmic side and [20, 3] for the hardness side).

Our goal in this paper is to determine whether a computational transition takes place for negative activities as well, i.e., when $\lambda < 0$. Interestingly, the evaluation of the independent set polynomial for $\lambda < 0$ has significant algorithmic interest due to its connection with the Lovász Local Lemma (LLL) and, more precisely, to the problem of checking when the LLL applies. We will review this well-known connection shortly; prior to that, we introduce the Shearer threshold, which is relevant for our work.

Shearer, as part of his work [17] on the LLL, implicitly established that for every $\Delta \geq 2$, there is a threshold $\lambda^*(\Delta)$, given by $\lambda^*(\Delta) = (\Delta-1)^{\Delta-1}/\Delta^{\Delta}$, such that

1. for all $\lambda \geq -\lambda^*(\Delta)$, for all graphs G of maximum degree Δ, it holds that $Z_G(\lambda) > 0$.
2. for all $\lambda < -\lambda^*(\Delta)$, there exists a graph G of maximum degree Δ such that $Z_G(\lambda) \leq 0$.

We refer to the point $-\lambda^*(\Delta)$ as the *Shearer threshold*. Similarly to the positive case, the Δ-regular tree plays a role in determining the location of the Shearer threshold, in the sense that for all $\lambda < -\lambda^*(\Delta)$, the truncation of the tree at an appropriate height yields a (finite) tree T of maximum degree Δ such that $Z_T(\lambda) \leq 0$. Scott and Sokal [16] were the first to realise the relevance of Shearer's work to the phase transitions of the hard-core model, and to make explicit Shearer's contribution in this context. They further developed these ideas to study the analyticity of the logarithm of the partition function in the complex plane.

From an algorithmic viewpoint, the Shearer threshold is tacitly present in most, if not all, applications of the (symmetric) LLL. In particular, Shearer [17] proved that $\lambda^*(\Delta)$ is the maximum value p such that every family of events, with failure probability at most p and

with a dependency graph of maximum degree Δ, has nonempty intersection. This simple characterisation is a corollary of far more elaborate conditions formulated in the same work that determine whether a dependency graph falls into the scope of the LLL. To date, no polynomial-time algorithm has been presented that, given as input a dependency graph G of maximum degree Δ, decides whether Shearer's conditions are satisfied when the failure probabilities of some events exceed the threshold $\lambda^*(\Delta)$ and it is very plausible that none exists (see for example [8, Section 4] for results in this direction).

Very recently, there have been two independent works that study the Shearer threshold from an approximate counting perspective. In particular, Patel and Regts [15] and Harvey, Srivastava, and Vondrák [8] (see also [21]) designed FPTASes, using different techniques, that approximate $Z_G(\lambda)$ on graphs G of maximum degree Δ when $-\lambda^*(\Delta) < \lambda < 0$ (and also for complex values λ with $|\lambda| < \lambda^*(\Delta)$). Thus, not only is it trivial to decide whether $Z_G(\lambda)$ is positive above the Shearer threshold, but also it is computationally easy to approximate $Z_G(\lambda)$ within an arbitrarily small polynomial relative error (see [8] for extensions to the multivariate partition function). Apart from partial results in [8] which we shall review shortly, these works left open the regime $\lambda < -\lambda^*(\Delta)$. In light of their results, it is natural to ask whether the Shearer threshold has a computational complexity significance for the problem of approximating $Z_G(\lambda)$ when $\lambda < 0$, analogous to the role that the tree uniqueness threshold has for $\lambda > 0$.

In this work, we answer this question by showing that, for all $\Delta \geq 3$, for all $\lambda < -\lambda^*(\Delta)$, it is NP-hard to approximate $|Z_G(\lambda)|$, even within an exponential factor. To formally state our result, we define the following problem which has three parameters–the activity λ, a degree bound Δ, and a value $c > 1$ which specifies the desired accuracy of the approximation.

Name $\#\mathsf{HardCore}(\lambda, \Delta, c)$.
Instance An n-vertex graph G with maximum degree at most Δ.
Output A number $\widehat{Z}$ such that $c^{-n}|Z_G(\lambda)| \leq \left|\widehat{Z}\right| \leq c^n|Z_G(\lambda)|$.

We now formally state our result.

▶ **Theorem 1.** *Let $\Delta \geq 3$ and $\lambda < -\lambda^*(\Delta)$. Then there exists a constant $c > 1$ such that $\#\mathsf{HardCore}(\lambda, \Delta, c)$ is NP-hard, i.e., it is NP-hard to approximate $|Z_G(\lambda)|$ on graphs G of maximum degree at most Δ, even within an exponential factor.*

The previous known result for the inapproximability of the partition function for $\lambda < 0$ was given in [8, Theorem 4.4] which applies for $\Delta \geq 62$ and $\lambda < -39/\Delta$. Theorem 1 therefore vastly tightens that result, by showing a strong inapproximability result all the way to the Shearer threshold for all degree bounds $\Delta \geq 3$.

To elucidate the content of Theorem 1, we remark that, combined with the algorithmic results of [8, 15], it establishes for the first time a sharp computational transition at the Shearer threshold for negative activities. In fact, we now have a complete picture for the complexity of approximating $Z_G(\lambda)$ for all $\lambda \in \mathbb{R}$ apart from the critical values $-\lambda^*(\Delta)$ and $\lambda_c(\Delta)$.

1. For $-\lambda^*(\Delta) < \lambda < \lambda_c(\Delta)$, there exists an FPTAS for approximating $Z_G(\lambda)$ on graphs G of maximum degree Δ; this follows by [8, 15] for $-\lambda^*(\Delta) < \lambda < 0$ and by [22] for $0 < \lambda < \lambda_c(\Delta)$. (The case $\lambda = 0$ is trivial since $Z_G(\lambda) = 1$ for all graphs G.)
2. For $\lambda < -\lambda^*(\Delta)$ or $\lambda > \lambda_c(\Delta)$, it is NP-hard to approximate $|Z_G(\lambda)|$ on graphs G of maximum degree Δ, even within an exponential factor; this follows by Theorem 1 for $\lambda < -\lambda^*(\Delta)$ and by [20] for $\lambda > \lambda_c(\Delta)$.

While both of the thresholds $-\lambda^*(\Delta)$ and $\lambda_c(\Delta)$ come from the infinite Δ-regular tree, they are of different nature: the Shearer threshold marks the point where the partition function of the tree of appropriate height eventually becomes negative, while the uniqueness threshold

marks the point where correlations between the root and the leaves persist, as the height of the tree grows.

The interplay between the zeros of graph polynomials and the complexity of approximating partition functions has appeared before in the approximate counting literature, see for example [4, 5]. However, one of the main differences in our present setting is the constant degree bound Δ, which significantly restricts the power of "thickening". One might then think that perhaps Sly's technique for establishing inapproximability above the uniqueness threshold might be relevant; this would entail analysing the partition function of random bipartite Δ-regular graphs for negative activities using moment analysis, which, to say the least, quickly runs into severe problems. Working around these difficulties for degrees as low as $\Delta = 3$ is one the technical contributions of our work–see Section 1.1 for a high-level outline.

We conclude this introductory section by outlining very briefly the series of works that have established the Shearer threshold as an algorithmic benchmark. Beck [2] gave the first algorithmic application of the LLL, albeit with significantly worse guarantees than the non-constructive version; three decades later, Moser [13] and Moser and Tardos [14] succeeded in giving elegant, constructive analogues of the vanilla LLL; Shearer's conditions were finally used in full generality to give a constructive proof of the LLL by Kolipaka and Szegedy [10], which yielded as a corollary efficient algorithms up to the Shearer threshold. See also [1, 7, 9] for recent algorithmic extensions of the LLL (and a more thorough overview of the LLL literature) and see [6, 12] for new applications of the LLL in approximate counting.

1.1 Proof outline and organisation

At a very high level, to prove Theorem 1 for an activity $\lambda < -\lambda^*(\Delta)$, our strategy is to transform λ into a "nicer" activity. Our key technical lemma, stated as Lemma 4 in Section 2, shows how to simulate a dense set of activities on the real line using graphs of maximum degree Δ as gadgets. As we shall explain later in detail, this lemma crucially uses the assumption that $\lambda < -\lambda^*(\Delta)$ by utilising trees of appropriate depth and combining them in suitable graph constructions that respect the degree bound Δ. Once Lemma 4 is in place, some extra care is needed to obtain the inapproximability results for $\Delta = 3$. Our approach is to construct binary gadgets and use inapproximability results for antiferromagnetic 2-spin systems on 3-regular graphs.

The paper is organised in two parts. In the first part, which is in Section 2, we state our key Lemma 4 and then show how to use it to conclude the inapproximability results of Theorem 1. In the second part, which is in Section 3, we present an overview of the proof of Lemma 4 and then give, in more detail, the proofs of some indicative lemmas.

2 Proof of Theorem 1

To give some rough intuition for our main proof technique of Theorem 1, suppose that we are given a degree bound $\Delta \geq 3$ and an activity $\lambda < -\lambda^*(\Delta)$. We will pursue the freedom to "change" the activity λ to a "nicer" activity λ' by using a suitable graph of maximum degree Δ. We will refer to this construction as *implementing* the activity λ' (cf. Definition 3 for the formal notion that is used throughout the paper). Our reduction for the proof of Theorem 1 is designed so that we need to implement just two well-chosen values of λ'. Using these two activities carefully so that we do not increase the degree Δ, we will construct binary gadgets (i.e., gadgets acting on edges) that will allow us to get our NP-hardness results by reducing from an appropriate (antiferromagnetic) 2-spin model on 3-regular graphs.

To illustrate more precisely the relevant ideas, we will need a few quick definitions. Let $\lambda \in \mathbb{R}$ and $G = (V, E)$ be an arbitrary graph. For a vertex $v \in V$, we will denote

$$Z^{\mathsf{in}}_{G,v}(\lambda) := \sum_{I \in \mathcal{I}_G;\, v \in I} \lambda^{|I|}, \quad Z^{\mathsf{out}}_{G,v}(\lambda) := \sum_{I \in \mathcal{I}_G;\, v \notin I} \lambda^{|I|}.$$

Thus, $Z^{\mathsf{in}}_{G,v}(\lambda)$ is the contribution to the partition function $Z_G(\lambda)$ from those independent sets $I \in \mathcal{I}_G$ such that $v \in I$; similarly, $Z^{\mathsf{out}}_{G,v}(\lambda)$ is the contribution to $Z_G(\lambda)$ from those $I \in \mathcal{I}_G$ such that $v \notin I$. We can now formalise the notion of implementation.

▶ **Definition 2.** Let $\lambda \in \mathbb{R}_{\neq 0}$. We say that the graph G implements the activity $\lambda' \in \mathbb{R}$ with accuracy $\epsilon > 0$ if there is a vertex v in G such that $Z^{\mathsf{out}}_{G,v}(\lambda) \neq 0$ and

1. the degree of vertex v in G is 1,
2. it holds that $\left| \dfrac{Z^{\mathsf{in}}_{G,v}(\lambda)}{Z^{\mathsf{out}}_{G,v}(\lambda)} - \lambda' \right| \leq \epsilon$.

We will refer to the vertex v as the terminal of G. When Item 2 holds with $\epsilon = 0$, then we will just say that G implements the activity λ'.

▶ **Definition 3.** Let $\Delta \geq 2$ be an integer and $\lambda \in \mathbb{R}_{\neq 0}$. We say that (Δ, λ) *implements* the activity $\lambda' \in \mathbb{R}$ if there is a graph G of maximum degree at most Δ which implements the activity λ'.

More generally, we say that (Δ, λ) implements a set of activities $S \subseteq \mathbb{R}$, if for every $\lambda' \in S$ it holds that (Δ, λ) implements λ'.

Our main lemma to prove Theorem 1 is the following, whose proof is given in Section 3 (there, we also give an overview of the proof).

▶ **Lemma 4.** *Let $\Delta \geq 3$ and $\lambda < -\lambda^*(\Delta)$. Then, for every $\lambda' \in \mathbb{R}$, for every $\epsilon > 0$, there exists a graph G of maximum degree at most Δ that implements λ' with accuracy ϵ. In other words, (Δ, λ) implements a set of activities S which is dense in $\mathbb{R}$.*

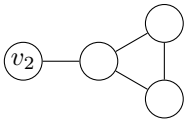
We remark here that Lemma 4 fails for $\lambda > -\lambda^*(\Delta)$. For example, for $\lambda \geq 0$, it is not hard to see that $0 \leq Z^{\mathsf{in}}_{G,v}(\lambda)/Z^{\mathsf{out}}_{G,v}(\lambda) \leq \lambda$ for all graphs G and all vertices v in G. Moreover, in the regime $\lambda > -\lambda^*(\Delta)$, Scott and Sokal [16] have shown that $Z^{\mathsf{in}}_{G,v}(\lambda)/Z^{\mathsf{out}}_{G,v}(\lambda) > -1$ for all graphs G of maximum degree Δ (and all vertices v in G). This lower bound (in various forms) was also a key ingredient in the approximation algorithms of [8, 15].

We also remark that Lemma 4 does not give any quantitative guarantees on the dependence of the size of the graph G with respect to $\lambda, \lambda', 1/\epsilon$. This is by design: such estimates will not be important for us since our reduction for Theorem 1 invokes Lemma 4 for just two constant values of λ' with some small constant $\epsilon > 0$ (the particular values depend on λ but not on the input). In particular, for our applications of Lemma 4 in the proof of Theorem 1, the sizes of the relevant graphs G will be bounded by a constant (depending on λ).

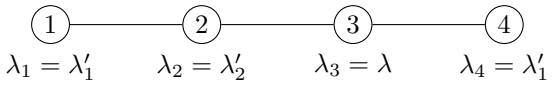
2.1 The hard-core model with non-uniform activities

Implementing activities can be thought of as constructing unary gadgets that allow modification of the activity at a particular vertex v. We will use the implemented activities to simulate a more general version of the hard-core model with non-uniform activities. In particular, let $G = (V, E)$ be a graph and $\boldsymbol{\lambda} = \{\lambda_v\}_{v \in V}$ be a real vector; we associate to every vertex $v \in V$ the activity λ_v. The hard-core partition function with activity vector $\boldsymbol{\lambda}$ is defined as $Z_G(\boldsymbol{\lambda}) = \sum_{I \in \mathcal{I}_G} \prod_{v \in I} \lambda_v$. Note that the standard hard-core model with activity λ is obtained from this general version by setting all vertex activities equal to λ. For a vertex

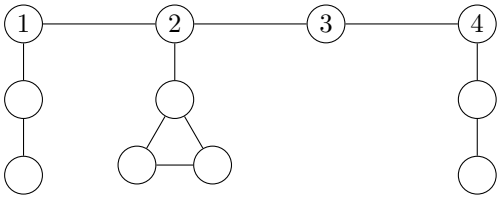
(a) The graph G_1 with terminal v_1 implementing an activity λ_1'



(b) The graph G_2 with terminal v_2 implementing an activity λ_2'



(c) The graph G with activity vector $\boldsymbol{\lambda}$



(d) The graph G' with uniform activity λ

Figure 1 An illustrative depiction of the construction in the statement of Lemma 5. The graphs G_1, G_2 in Figures 1a, 1b implement the activities λ_1', λ_2', respectively, i.e., $\frac{Z^{\mathsf{in}}_{G_1,v_1}(\lambda)}{Z^{\mathsf{out}}_{G_1,v_1}(\lambda)} = \lambda_1'$ and $\frac{Z^{\mathsf{in}}_{G_2,v_2}(\lambda)}{Z^{\mathsf{out}}_{G_2,v_2}(\lambda)} = \lambda_2'$ for some $\lambda_1', \lambda_2' \in \mathbb{R}$. In Figure 1c, we have a graph G with non-uniform activities $\{\lambda_i\}_{i\in[4]}$ such that $\lambda_i \in \{\lambda, \lambda_1', \lambda_2'\}$ for $i \in [4]$. By sticking onto G the graphs G_1, G_2 as in Figure 1d, we obtain the graph G'. Note that the vertex whose activity was equal to λ was not modified.

$v \in V$, we define $Z^{\mathsf{in}}_G(\boldsymbol{\lambda})$ and $Z^{\mathsf{out}}_G(\boldsymbol{\lambda})$ for the non-uniform model analogously to $Z^{\mathsf{in}}_G(\lambda)$ and $Z^{\mathsf{out}}_G(\lambda)$ for the uniform model, respectively.

The following lemma connects the partition function $Z_G(\boldsymbol{\lambda})$ with non-uniform activities to the hard-core partition function with uniform activity λ. Roughly, whenever all the activities in the activity vector $\boldsymbol{\lambda}$ can be implemented, we can just stick graphs on the vertices of G which implement the corresponding activities in $\boldsymbol{\lambda}$ (if a vertex activity equals λ, no action is required).

▶ **Lemma 5.** *Let $\lambda \in \mathbb{R}_{\neq 0}$, let $t \geq 1$ be an arbitrary integer, and let $\lambda_1', \ldots, \lambda_t' \in \mathbb{R}$. Suppose that, for $j \in [t]$, the graph G_j with terminal v_j implements the activity λ_j', and let $C_j := Z^{\mathsf{out}}_{G_j,v_j}(\lambda)$. Then, the following holds for every graph $G = (V, E)$ and every activity vector $\boldsymbol{\lambda} = \{\lambda_v\}_{v\in V}$ such that $\lambda_v \in \{\lambda, \lambda_1', \ldots, \lambda_t'\}$ for every $v \in V$.*

For $j \in [t]$, let $V_j := \{v \in V \mid \lambda_v = \lambda_j'\}$. Consider the graph G' obtained from G by attaching, for every $j \in [t]$ and every vertex $v \in V_j$, a copy of the graph G_j to the vertex v and identifying the terminal v_j with the vertex v (see Figure 1). Then, for $C := \prod_{j=1}^{t} C_j^{|V_j|}$, it holds that $Z_{G'}(\lambda) = C \cdot Z_G(\boldsymbol{\lambda})$.

▶ Remark. Note that, in the construction of Lemma 5, every vertex $v \in G$ with $\lambda_v = \lambda$ maintains its degree in G' (in fact, the neighbourhood of such a vertex v is the same in G and G'). The degree of every other vertex v in G gets increased by one. This observation will ensure in later applications of Lemma 5 that we do not blow up the degree.

2.2 Antiferromagnetic 2-spin systems on Δ-regular graphs

In our setting, where every vertex has degree at most Δ, an implementation consumes one of the Δ slots that a vertex has available to connect to other vertices. This is particularly problematic for the case where $\Delta = 3$. In the following we circumvent this problem by constructing suitable binary gadgets, so that we can use inapproximability results for computing the partition function of antiferromagnetic 2-spin systems on Δ-regular graphs.

Recall, an antiferromagnetic 2-spin system (without external field) is specified by two parameters $\beta, \gamma > 0$ such that $\beta\gamma < 1$. Let $\mathbf{M} = \{M_{ij}\}_{i,j\in\{0,1\}}$ be the matrix $\left[\begin{smallmatrix}\beta & 1\\ 1 & \gamma\end{smallmatrix}\right]$. For a graph $H = (V, E)$, configurations of the 2-spin system are assignments $\sigma : V \to \{0, 1\}$ and the weight of a configuration σ is given by $w_{H,\beta,\gamma}(\sigma) = \prod_{\{u,v\}\in E} M_{\sigma(u),\sigma(v)}$. The partition function of H is then given by

$$Z_{H,\beta,\gamma} = \sum_{\sigma:V\to\{0,1\}} w_{H,\beta,\gamma}(\sigma) = \sum_{\sigma:V\to\{0,1\}} \prod_{\{u,v\}\in E} M_{\sigma(u),\sigma(v)}.$$

For positive parameters β, γ and $c > 1$, we consider the following computational problem, where the input is a 3-regular graph H.

Name #2Spin(β, γ, c).
Instance An n-vertex graph H which is 3-regular.
Output A number $\hat{Z}$ such that $c^{-n} Z_{H,\beta,\gamma} \le \hat{Z} \le c^n Z_{H,\beta,\gamma}$.

The case $\beta = \gamma < 1$ corresponds to the well-known (antiferromagnetic) Ising model. As a corollary of results of Sly and Sun [20] (see also [3]), it is known that, for $0 < \beta = \gamma < 1/3$, there exists $c > 1$ such that #2Spin(β, β, c) is NP-hard, i.e., approximating the partition function $Z_{G,\beta,\beta}$ of the Ising model on 3-regular graphs H is NP-hard, even within an exponential factor. The following lemma is somewhat less known but follows easily from the results of [20].

▶ **Lemma 7.** *Let $\Delta = 3$ and β, γ be such that $0 < \beta, \gamma < 1/3$. Then, there exists $c > 1$ such that* #2Spin(β, γ, c) *is* NP*-hard.*

The following lemma will be used in the proof of Theorem 1 to specify the activities that we need to implement to utilise the inapproximability result of Lemma 7. It allows us to use the graph in Figure 2 as a binary gadget to simulate a 2-spin system with parameters β, γ.

▶ **Lemma 8.** *Let $\lambda < 0$. Then, there exist λ'_1, λ'_2 such that*

$$-1 - \frac{1}{6}|\lambda|^{1/3} < \lambda'_1 < -1, \qquad -1 - 2\lambda < \lambda'_2 < -1 - 2\lambda + \frac{\lambda'_1\lambda}{1 + \lambda'_1 + 3|\lambda|^{1/3}}. \tag{1}$$

For all λ'_1, λ'_2 satisfying (1)*, the following parameters β, γ (defined in terms of $\lambda, \lambda'_1, \lambda'_2$)*

$$\beta = \frac{(1+\lambda'_1)\Big((1+\lambda'_1)(1+\lambda'_2+2\lambda) - 2\lambda'_1\lambda\Big)}{|\lambda|^{1/3}\Big(\lambda'_1\lambda - (1+\lambda'_1)(1+\lambda'_2+2\lambda)\Big)}, \quad \gamma = \frac{|\lambda|^{1/3}(1+\lambda'_2+2\lambda)}{\lambda'_1\lambda - (1+\lambda'_1)(1+\lambda'_2+2\lambda)}. \tag{2}$$

satisfy $0 < \beta, \gamma < 1/3$.

2.3 The reduction & Proof of Theorem 1

The reduction to obtain Theorem 1 uses a binary gadget to simulate an antiferromagnetic 2-spin system on 3-regular graphs, i.e., we will replace every edge of a 3-regular graph H with a suitable graph B which has two special vertices to encode the edge. The gadget B is given in Figure 2, the two special vertices are v_1, v_2. Note that the gadget B has nonuniform activities but this will be compensated for later by invoking Lemma 5. We thus obtain the following lemma (whose proof is in the full version).

▶ **Lemma 9.** *Let $\lambda < 0$ and $\lambda'_1, \lambda'_2 \in \mathbb{R}$ satisfy* (1)*. Then, for β, γ as in* (2)*, the following holds. For every 3-regular graph $H = (V_H, E_H)$ we can construct in linear time a graph $G = (V_G, E_G)$ of maximum degree 3 and specify an activity vector $\boldsymbol{\lambda} = \{\lambda_v\}_{v\in V}$ on G such that*

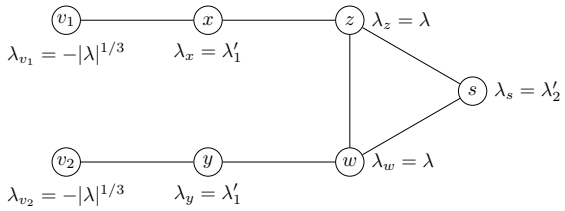


Figure 2 The binary gadget $B = (U, F)$ used in Lemma 9 to simulate an antiferromagnetic 2-spin system on 3-regular graphs. The gadget B is used to encode the edges of a 3-regular graph H. In particular, every edge $e = \{h_1, h_2\}$ of H gets replaced by a distinct copy of B, with the vertices v_1, v_2 of B getting identified with the vertices h_1, h_2 of H, respectively.

1. $Z_{H,\beta,\gamma} = Z_G(\boldsymbol{\lambda})/C^{|E_H|}$, *where* $C := |\lambda|^{1/3}\big(\lambda_1'\lambda - (1+\lambda_1')(1+\lambda_2'+2\lambda)\big) > 0$.
2. *For every vertex* v *of* G, *it holds that* $\lambda_v \in \{\lambda, \lambda_1', \lambda_2'\}$. *Moreover, if* $\lambda_v \neq \lambda$, *then* v *has degree two in* G.

Now, we are ready to prove Theorem 1.

Proof of Theorem 1 (Sketch). By Lemma 4, there are graphs G_1, G_2 of max degree Δ with terminals v_1, v_2 which implement activities λ_1', λ_2' satisfying the condition (1) of Lemma 8. For later use, set $C_1 := Z^{\mathsf{out}}_{G_1,v_1}(\lambda)$, $C_2 := Z^{\mathsf{out}}_{G_2,v_2}(\lambda)$ and note that C_1, C_2 are explicitly computable constants. Let β, γ be the parameters given by (2). By Lemma 8, it holds that $0 < \beta, \gamma < 1/3$. Thus, by Lemma 7, there exists $c > 1$ such that $\#\mathsf{2Spin}(\beta, \gamma, c)$ is NP-hard. We will use Lemmas 5 and 9 to reduce $\#\mathsf{2Spin}(\beta, \gamma, c)$ to $\#\mathsf{HardCore}(\lambda, \Delta, c')$ for some constant $c' > 1$.

Let H be a 3-regular graph which is an input graph to the problem $\#\mathsf{2Spin}(\beta, \gamma, c)$. By Lemma 9, we can construct in linear time a graph G of maximum degree 3 and specify an activity vector $\boldsymbol{\lambda} = \{\lambda_v\}_{v \in V}$ on G such that

1. $Z_{H,\beta,\gamma} = Z_G(\boldsymbol{\lambda})/C^{|E_H|}$, where $C := |\lambda|^{1/3}\big(\lambda_1'\lambda - (1+\lambda_1')(1+\lambda_2'+2\lambda)\big) > 0$.
2. For every vertex v of G, $\lambda_v \in \{\lambda, \lambda_1', \lambda_2'\}$. Also, if $\lambda_v \neq \lambda$, then v has degree two in G.

Using the graphs G_1, G_2 that implement λ_1', λ_2' respectively, we obtain from Lemma 5 that we can construct in linear time a graph $G' = (V_{G'}, E_{G'})$ of maximum degree at most Δ such that $Z_{G'}(\lambda) = C_1^{n_1} C_2^{n_2} \cdot Z_G(\boldsymbol{\lambda})$, where n_1, n_2 are the number of vertices in G whose activity equals λ_1', λ_2', respectively. Note, the fact that the maximum degree of G' is at most Δ follows from the construction of Lemma 5 and Item 2 (cf. the Remark after Lemma 5).

It follows that $Z_{H,\beta,\gamma} = Z_{G'}(\lambda)/\big(C^{|E_H|} C_1^{n_1} C_2^{n_2}\big)$. Since the size of G' exceeds the size of H only by a constant factor, there is a constant $c' > 1$ (depending only on λ) such that an approximation to $|Z_{G'}(\lambda)|$ within a factor $(c')^{|V_{G'}|}$ yields an estimate to $|Z_{H,\beta,\gamma}| = Z_{H,\beta,\gamma}$ within a factor $c^{|V_H|}$. It follows that $\#\mathsf{HardCore}(\lambda, \Delta, c')$ is NP-hard. ◀

3 Proof of Lemma 4

In this final section, we give a proof overview of Lemma 4, which is the last missing ingredient used in the proof of Theorem 1. Let us fix a degree bound $\Delta \geq 3$. Our goal is to show that for any fixed $\lambda < -\lambda^*(\Delta)$, we can implement a dense set of activities using graphs of maximum degree Δ. At a very rough level, the proof of Lemma 4 splits into two regimes:

1. when $\lambda < -\lambda^*(2) = -1/4$,
2. when $-1/4 \leq \lambda < -\lambda^*(\Delta)$.

Roughly, in regime 1, we will be able to use *paths* to implement a dense set of activities. In regime 2, we will first use a $(\Delta - 1)$-ary tree to implement an activity $\lambda' < -1/4$. Then,

using the activity λ', we will be able to use the path construction of the first regime to implement a dense set of activities.

Unfortunately, the actual proof is more intricate, since as it turns out there is a set $\mathcal{B} \subset \mathbb{R}$, dense in $(-\infty, -1/4)$, such that, if $\lambda \in \mathcal{B}$, paths exhibit a periodic behaviour in terms of implementing activities (and thus can only be used to implement a finite set of activities). The following lemma will be important in specifying the set $\mathcal{B}$ and understanding this periodic behaviour. The proof is a manipulation with trigonometric identities and can be found in Section 3.2 of the full version.

▶ **Lemma 10.** *Let $\lambda < -1/4$ and $\theta \in (0, \pi/2)$ be such that $\lambda = -1/(2\cos\theta)^2$. Then, the partition function of the path P_n with n vertices is given by*

$$Z_{P_n}(\lambda) = \frac{\sin((n+2)\theta)}{2^n(\cos\theta)^n \sin(2\theta)}.$$

The "bad" set $\mathcal{B}$ of activities (for which paths exhibit a periodic behaviour) can be read off from Lemma 10. To make this precise, let

$$\mathcal{B} := \left\{\lambda \in \mathbb{R} \mid \lambda = -\frac{1}{4(\cos\theta)^2} \text{ for some } \theta \in (0, \pi/2) \text{ which is a } \textit{rational multiple} \text{ of } \pi\right\}. \quad (3)$$

Note, for example, that $-1, -1/2, -1/3 \in \mathcal{B}$ (set $\theta = \pi/3, \pi/4, \pi/6$, respectively). For $\lambda < -1/4$, it is not hard to infer from Lemma 10 that the ratio $\frac{Z^{\mathsf{in}}_{P_n,v}(\lambda)}{Z^{\mathsf{out}}_{P_n,v}(\lambda)}$ is equal to $-\frac{1}{2\cos\theta}\frac{\sin(n\theta)}{\sin((n+1)\theta)}$. Therefore, when $\lambda \in \mathcal{B}$ or equivalently θ is a rational multiple of π, the ratio is periodic in terms of the number of vertices n in the path. On the other hand, when $\lambda < -1/4$ and $\lambda \notin \mathcal{B}$, then we can show that the ratio is dense in $\mathbb{R}$ as n varies (this follows essentially from the fact that $\{n\theta \bmod 2\pi \mid n \in \mathbb{Z}\}$ is dense on the circle when θ is irrational) and hence we can use paths to implement a dense set of activities. This is the scope of the next lemma, which is proved in Section 3.2 of the full version.

▶ **Lemma 11.** *Let $\lambda < -1/4$ be such that $\lambda \notin \mathcal{B}$. Let P_n denote a path with n vertices and let v be one of the endpoints of P_n. Then, for every $\lambda' \in \mathbb{R}$, for every $\epsilon > 0$, there exists n such that $|\frac{Z^{\mathsf{in}}_{P_n,v}(\lambda)}{Z^{\mathsf{out}}_{P_n,v}(\lambda)} - \lambda'| \le \epsilon$.*

When $\lambda \in \mathcal{B}$, we can no longer use paths to implement a dense set of activities, as we explained earlier, and we need to use a more elaborate argument. A key observation is that, for $\lambda \in \mathcal{B}$, the partition function of a path of appropriate length is equal to 0. In particular, we have the following simple corollary of Lemma 10.

▶ **Corollary 12.** *Let $\lambda < -1/4$ be such that $\lambda \in \mathcal{B}$. Denote by P_n the path with n vertices. Then, there is an integer $n \ge 1$ such that the partition function of the path P_n is zero, i.e., $Z_{P_n}(\lambda) = 0$.*

Having a path P whose partition function is 0 allows us to implement the activity -1: indeed, for an endpoint v of the path P, we have that $Z^{\mathsf{in}}_{P,v}(\lambda) + Z^{\mathsf{out}}_{P,v}(\lambda) = Z_P(\lambda) = 0$, and hence P, with terminal v, implements $\frac{Z^{\mathsf{in}}_{P,v}(\lambda)}{Z^{\mathsf{out}}_{P,v}(\lambda)} = -1$ (note, we will later ensure that P is such that $Z^{\mathsf{out}}_{P,v}(\lambda) \neq 0$). A somewhat ad-hoc gadget allows us to also implement the activity $+1$. Using these two implemented activities, -1 and $+1$, we then show how to implement *all* rational numbers using graphs whose structure resembles a caterpillar (the proof is inspired by the "ping-pong" lemma in group theory, used to establish free subgroups). We carry out this scheme in a more general setting where, instead of a path, we have a tree whose partition function is zero (this will also be relevant in the regime $\lambda > -1/4$). More precisely, we have the following lemma, whose proof is given in Section 3.1.

▶ **Lemma 13.** *Suppose that $\lambda \in \mathbb{R}_{\neq 0}$ and that T is a tree with $Z_T(\lambda) = 0$. Let d be the maximum degree of T and let $\Delta = \max\{d, 3\}$. Then, (Δ, λ) implements a dense set of activities in $\mathbb{R}$.*

We thus obtain the following throughout the regime 1 ($\lambda < -1/4$).

▶ **Lemma 14.** *Let $\lambda < -1/4$. For $\Delta = 3$, (Δ, λ) implements a dense set of activities in $\mathbb{R}$.*

Proof. We may assume that $\lambda \in \mathcal{B}$, otherwise the result follows directly from Lemma 11. For $\lambda \in \mathcal{B}$, we have by Corollary 12 a path P such that $Z_P(\lambda) = 0$. Since P has maximum degree 2, applying Lemma 13 gives the desired conclusion. ◀

Note, Lemma 14 applies only for values of λ which are far from the threshold $-\lambda^*(\Delta)$ for any $\Delta \geq 3$ and thus it should not be surprising that we can implement a dense set of activities using graphs of maximum degree 3. This highlights the next obstacle that we have to address: for general degree bounds $\Delta \geq 3$, to get all the way to the threshold $-\lambda^*(\Delta)$ we need to use graphs with maximum degree Δ (rather than just 3) to have some chance of implementing interesting activities.

Analyzing more complicated graphs for $\Delta \geq 3$ and $-1/4 \leq \lambda < -\lambda^*(\Delta)$ might sound daunting given the story for $\lambda < -1/4$, but it turns out that all we need to do is construct a graph G of maximum degree Δ that implements an activity $\lambda' < -1/4$. Then, to show that (Δ, λ) implements a dense set of activities, we only need to consider whether $\lambda' \in \mathcal{B}$. If $\lambda' \notin \mathcal{B}$, we can argue by decorating the paths from Lemma 11 using the graph G. Otherwise, if $\lambda' \in \mathcal{B}$, we can first construct a tree T of maximum degree Δ such that $Z_T(\lambda) = 0$ (by decorating the path from Lemma 12), and then invoke Lemma 13. Thus, we are left with the task of implementing an activity $\lambda' < -1/4$. For that, we combine appropriately $(\Delta - 1)$-ary trees of appropriate depth, which can be analysed relatively simply using a recursion. (A technical detail here is that, initially, we are not able to implement this boosted activity λ' in the sense of Definition 3 since the terminal of the relevant tree has degree bigger than 1; nevertheless, the degree of the terminal is at most $\Delta - 2$, so it can be combined with the paths without overshooting the degree bound Δ.) Putting together these pieces yields the following lemma (see Section 3.5 of the full version).

▶ **Lemma 15.** *Let $\Delta \geq 3$ and $-1/4 \leq \lambda < -\lambda^*(\Delta)$. Then, (Δ, λ) implements a dense set of activities in $\mathbb{R}$.*

Using Lemmas 14 and 15, the proof of Lemma 4 is immediate.

3.1 The case where the partition function of some tree is zero

In this section, we prove Lemma 13 which is an ingredient in both Lemmas 14 and 15.

We start with the following lemma, whose full proof is given in the full version. Roughly, in the proof, the implementation of -1 uses as a gadget the tree T with a leaf as the terminal; the implementation of $+1$ uses an ad-hoc gadget.

▶ **Lemma 19.** *Let $\lambda \in \mathbb{R}_{\neq 0}$ and $d \geq 2$ be a positive integer. Suppose that there exists a tree T with maximum degree d such that $Z_T(\lambda) = 0$. Then, for $\Delta = \max\{d, 3\}$, we have that (Δ, λ) implements the activities -1 and $+1$.*

The following functions f_+ and f_- will be important in what follows:

$$f_+ : \mathbb{R}\backslash\{-1\} \mapsto \mathbb{R}\backslash\{0\}, \text{ given by } f_+(x) = \frac{1}{1+x} \text{ for all } x \neq -1,$$

$$f_- : \mathbb{R}\backslash\{+1\} \mapsto \mathbb{R}\backslash\{0\}, \text{ given by } f_-(x) = \frac{1}{1-x} \text{ for all } x \neq +1.$$

▶ **Definition 20.** Let $S \subseteq \mathbb{R}$ be the set of real numbers defined as follows: $z \in S$ iff for some integer $n \geq 0$, there exists a sequence $x_0, \ldots, x_n$ such that $x_0 = 0$, $x_n = z$ and for all $i = 0, \ldots, n-1$ it holds that either $x_{i+1} = f_+(x_i)$ or $x_{i+1} = f_-(x_i)$.

The set S in Definition 20 is obtained by the following recursive procedure. Set $S_0 = \{0\}$. For $h = 0, 1, \ldots$, define S_{h+1} by first letting $S^+_{h+1} = f_+(S_h)$ and $S^-_{h+1} = f_-(S_h)$ and then setting $S_{h+1} = S^+_{h+1} \cup S^-_{h+1}$. S can then be recovered by taking the union of the sets S_h, i.e., $S = \cup^\infty_{h=0} S_h$. Our interest in the set S is due to the following lemma (proof in the full version).

▶ **Lemma 21.** *Let $\Delta \geq 3$ and $\lambda < 0$. Suppose that (Δ, λ) implements the activities -1 and $+1$. Then, (Δ, λ) also implements the set of activities $\{\lambda z \mid z \in S\}$.*

It is simple to see that all numbers in the set S of Definition 20 are rationals. Somewhat surprisingly, the following lemma asserts that S is in fact the set $\mathbb{Q}$ of all rational numbers.

▶ **Lemma 22.** *Let $S \subseteq \mathbb{R}$ be the set in Definition 20. Then, $S = \mathbb{Q}$.*

Proof. Recall that $S \subseteq \mathbb{Q}$, so we only need to argue that $\mathbb{Q} \subseteq S$. Since $0 \in S$ (by taking $n = 0$ in Definition 20) and $f_+(0) = 1$, we have that $0, 1 \in S$. Note that

$$f_-(f_-(f_+(x))) = -x \text{ for } x \neq -1, 0. \tag{4}$$

It follows that $-1 \in S$. Also, $1/2, 2 \in S$ since $f_+(f_+(0)) = 1/2$ and $f_-(f_+(f_+(0))) = 2$. Let $T := \{-1, 0, 1/2, 1, 2\}$; the arguments above established that $T \subseteq S$. Consider an arbitrary $\rho \in \mathbb{Q}$ such that $\rho \notin T$. To prove the lemma, we need to show that $\rho \in S$.

We will show that, for some integer $n \geq 0$, there is a sequence $\{\rho_i\}^n_{i=0}$ such that

(i) $\rho_0 = \rho$, $\rho_n = -1$.
(ii) $\rho_i \notin \{0, 1/2, 1\}$ for $i = 0, \ldots, n-1$.
(iii) $\rho_{i+1} = f_+(\rho_i)$ or $\rho_{i+1} = f_-(\rho_i)$ for $i = 0, \ldots, n-1$.

Before proving the existence of such a sequence, we first show how to conclude that $\rho \in S$. To do this, let $x_i := \rho_{n-i}$ for $i = 0, \ldots, n$. Properties (i)–(iii) of the sequence $\{\rho_i\}^n_{i=0}$ translate into the following properties of the sequence $\{x_i\}^n_{i=0}$:

(a) $x_0 = -1$, $x_n = \rho$.
(b) $x_i \notin \{0, 1/2, 1\}$ for $i = 1, 2, \ldots, n$.
(c) $x_i = f^{-1}_+(x_{i-1})$ or $x_i = f^{-1}_-(x_{i-1})$ for $i = 1, 2, \ldots, n$.

We show by induction on i that $x_i \in S$ for all $i = 0, \ldots, n$, which for $i = n$ gives that $\rho \in S$ (since by Item (a) we have $x_n = \rho$). For the base case $i = 0$, we have that $x_0 = -1$ by Item (a) and hence $x_0 \in S$. For the induction step, assume that $x_i \in S$ for some integer $0 \leq i \leq n-1$, our goal is to show that $x_{i+1} \in S$. The main observation is that the inverses of the functions f_- and f_+ can be obtained by composing appropriately the functions f_- and f_+. Namely, we have that

$$f^{-1}_-(x) = \frac{x-1}{x} = f_-(f_-(x)) \text{ for } x \neq 0, 1, \tag{5}$$

$$f^{-1}_+(x) = \frac{1-x}{x} = f_-(f_-(f_+(f_-(f_-(x)))))) \text{ for } x \neq 0, \tfrac{1}{2}, 1. \tag{6}$$

(5) is proved by just making the substitutions. (6) is obtained from (4) and (5), and checking when $f_-(f_-(x)) = \frac{x-1}{x}$ equals -1 and 0. Since by Items (a) and (b) we have that $x_j \neq 0, 1/2, 1$ for all $0 \leq j \leq n$ and $x_i \in S$ by the induction hypothesis, it follows by Item (c) and (5), (6) that $x_{i+1} \in S$, as wanted.

It remains to establish the existence of the sequence $\{\rho_i\}^n_{i=0}$ with the properties (i)–(iii). Consider the following set S_ρ, which is defined analogously to the set S with the only

difference that the starting point for S_ρ is the point ρ (instead of 0 that was used in the definition of S). Formally, $z \in S_\rho$ iff for some integer $n \geq 0$, there exists a sequence $\{\rho_i\}_{i=0}^n$ such that $\rho_0 = \rho$, $\rho_n = z$ and for all $i = 0, \ldots, n-1$ it holds that either $\rho_{i+1} = f_+(\rho_i)$ or $x_{i+1} = f_-(\rho_i)$. For convenience, we will call such a sequence a certificate that $z \in S_\rho$ and we will refer to n as the length of the certificate. We will show that, for any $\rho \in \mathbb{Q}$ such that $\rho \notin T = \{-1, 0, 1/2, 1, 2\}$, it holds that

$$0, 1 \notin S_\rho, \qquad -1 \in S_\rho. \tag{7}$$

By considering a certificate of smallest length that $-1 \in S_\rho$ (existence is guaranteed by (7)), we obtain a sequence $\{\rho_i\}_{i=0}^n$ that has all of the required properties (i), (ii), and (iii), see the full version for the details. Thus, in the following we focus on establishing (7). First, we show that $0, 1 \notin S_\rho$. Observe that $\rho \neq 0, 1$, so any certificate that $0, 1 \in S_\rho$ must have nonzero length. Further, the range of the functions f_+, f_- excludes 0, which implies that $0 \notin S_\rho$. Moreover, the only way that we can have $1 \in S_\rho$ is if for some $x \in S_\rho$ it holds that $f_+(x) = 1$ or $f_-(x) = 1$. Both of these mandate that $x = 0$, but $0 \notin S_\rho$ as we just showed.

The remaining bit of (7), i.e., that $-1 \in S_\rho$, will require more effort to prove. As a starting point, note that from $\rho \in \mathbb{Q}$, we have that $S_\rho \subseteq \mathbb{Q}$. Also, S_ρ is nonempty since $\rho \in S_\rho$. Thus, there exists $z^* \in S_\rho$ such that $z^* = p/q$ where p, q are integers such that $|p| + |q|$ is minimum. Since $|p| + |q|$ is minimum, it must be the case that $\gcd(p, q) = 1$.

We first prove that $z^* \in T$; note, we already know that $z^* \neq 0, 1$ since $0, 1 \notin S_\rho$ and $z^* \in S_\rho$, but keeping the values $0, 1$ into consideration will be convenient for the upcoming argument. Namely, for the sake of contradiction, assume that $z^* \notin T$, which implies in particular that $z^* \neq 0, -1$. Since $z^* \in S_\rho$, by (4), we obtain that $-z^* \in S_\rho$ as well. By switching to $-z^*$ if necessary, we may thus assume that z^* is positive and hence that $p, q > 0$, i.e., that both p, q are positive integers. Since $z^* \neq 1$ (from $z^* \notin T$), we have that $p \neq q$. For each of the cases $p > q$ and $p < q$, we obtain a contradiction to the minimality of $p + q$ by constructing $z' = p'/q' \in S_\rho$ with p', q' positive integers such that $0 < p' + q' < p + q$.

Case 1. $p > q$. Since $z^* \neq 1, 2$ (from $z^* \notin T$), we have that $p/q \neq 1$ and $f_-(p/q) = \frac{q}{q-p} \neq 0, -1$, so by (4) we have that $f_-(f_-(f_+(f_-(p/q)))) = \frac{q}{p-q}$. Thus, letting $p' = q$ and $q' = p - q$ yields $z' = p'/q' \in S_\rho$ with $p' > 0, q' > 0$ and $0 < p' + q' < p + q$.

Case 2. $p < q$. Since $z^* \neq 0, 1/2, 1$ (from $z^* \notin T$), we obtain from (6) that $f_-(f_-(f_+(f_-(f_-(p/q))))) = \frac{q-p}{p}$. Thus, letting $p' = q - p$ and $q' = p$ yields $z' = p'/q' \in S_\rho$ with $p' > 0, q' > 0$ and $0 < p' + q' < p + q$.

This concludes the proof that $z^* \in T$. In fact, we can now deduce easily that $-1 \in S_\rho$. As noted earlier, we have that $z^* \neq 0, 1$ as a consequence of $0, 1 \notin S_\rho$, so in fact $z^* \in \{-1, 1/2, 2\}$. If $z^* = -1$, then we automatically have that $-1 \in S_\rho$ since z^* was chosen to be in S_ρ. If $z^* = 2$, then we have that $2 \in S_\rho$ and hence $f_-(2) = -1 \in S_\rho$ as well. Finally, if $z^* = 1/2$, we have that $1/2 \in S_\rho$ and hence $f_-(f_-(1/2)) = -1 \in S_\rho$. Thus, it holds that $-1 \in S_\rho$, which completes the proof of (7) and hence the proof of Lemma 22. ◀

Combining Lemmas 19, 21 and 22, we obtain Lemma 13.

Abstract

Holant problem is a general framework to study the computational complexity of counting problems. We prove a complexity dichotomy theorem for Holant problems over the Boolean domain with non-negative weights. It is the first complete Holant dichotomy where constraint functions are not necessarily symmetric.

Holant problems are indeed read-twice #CSPs. Intuitively, some #CSPs that are #P-hard become tractable when restricted to read-twice instances. To capture them, we introduce the Block-rank-one condition. It turns out that the condition leads to a clear separation. If a function set $\mathcal{F}$ satisfies the condition, then $\mathcal{F}$ is of affine type or product type. Otherwise (a) Holant($\mathcal{F}$) is #P-hard; or (b) every function in $\mathcal{F}$ is a tensor product of functions of arity at most 2; or (c) $\mathcal{F}$ is transformable to a product type by some real orthogonal matrix. Holographic transformations play an important role in both the hardness proof and the characterization of tractability.

1 Introduction

There has been considerable interest in several frameworks to study the complexity of counting problems. One natural framework is the counting Constraint Satisfaction Problem (#CSP) [18, 2, 19, 4, 22, 3, 8, 7, 1]. Another is Graph Homomorphism (GH) [30, 27, 21, 5, 20, 25, 6, 9], which can be seen as a special case of #CSP. Such frameworks express a large class of counting problems in the Sum-of-Product form. It is known that if P $\neq$ NP, then there exists a problem that is neither in P nor NP-complete [29]. And there is an analogue of Ladner's Theorem for the class #P. However, for these frameworks, various beautiful dichotomy theorems have been proved, classifying all problems in the broad class into those which are computable in polynomial time (in P) and those which are #P-hard. A natural question is: For how broad a class of counting problems can one prove a dichotomy theorem?

While GH can express many interesting graph parameters, Freedman, Lovász and Schrijver [24] showed that the number of perfect matchings of a graph cannot be represented as a homomorphism function. Inspired by holographic algorithms [32, 31], Cai, Lu and Xia [14] proposed a more refined framework called Holant Problems. Here we give a brief introduction. In this paper, constraint functions are defined over the Boolean domain, if not specified. Let $\mathcal{F}$ denote a set of algebraic complex-valued functions. A *signature grid* Ω is a tuple $(G, \mathcal{F}, \pi)$ where $G = (V, E)$ is an undirected graph, and π is a map that maps each vertex $v \in V$ to some function $f_v \in \mathcal{F}$ and its incident edges $E(v)$ to the input variables of f_v. The counting problem on Ω is to compute

$$\text{Holant}_\Omega = \sum_{\sigma: E \to \{0,1\}} \prod_{v \in V} f_v(\sigma|_{E(v)}),$$

where $\sigma|_{E(v)}$ is the restriction of σ to $E(v)$. All such signature grids constitute the set of instances of the problem Holant($\mathcal{F}$). For example, consider the problem of counting perfect matchings (#PM) on graph G. In a perfect matching, every vertex is saturated by exactly one edge. Such constraint on a vertex of degree n can be expressed as an Exact-One function $f : \{0,1\}^n \to \{0,1\}$, which takes the value 1 if and only if its input has Hamming weight 1. If every vertex is assigned such a function, then the value Holant_Ω is exactly the number of perfect matchings. Let $\mathcal{F}$ denote the set of all Exact-One functions, then Holant($\mathcal{F}$) represents the problem #PM.

The Holant framework is general enough: #CSPs can be viewed as special Holant problems where all equality functions are available [14]. However, the very generality makes it more difficult to prove a dichotomy. A function is *symmetric* if the function values only depend on the Hamming weights of inputs, like the Exact-One functions. Satisfactory progress has been made in the complexity classification of Holant problems specified by sets of symmetric functions [13, 28, 26, 11, 10]. And in the process, some unexpected tractable classes were discovered. They give many deep insights into both tractability and hardness.

It still remains open whether a complete dichotomy exists, since the definition of Holant problems does not require that constraint functions be symmetric. Such restriction is stringent and generally it is not imposed in #CSP. Cai, Lu and Xia [16] proved a dichotomy without symmetry for a special family of Holant problems, called Holant*, where all unary functions are assumed to be available. But without this assumption, as in [11], more tractable classes will be released, which makes the hardness proof very different.

We prove a dichotomy theorem for Holant problems with non-negative algebraic real weights. It is the first complete Holant dichotomy where constraint functions are not necessarily symmetric and no auxiliary function is assumed to be available. This generalizes the results on Boolean #CSP in [18, 19], and the dichotomies in [28, 11] restricted to non-negative case. Our proof starts with an infinitary condition, but finally obtains an explicit criterion (Theorem 19).

A simple observation is that, Holant problems are indeed *read-twice* #CSPs where every variable in an instance appears exactly twice (see subsection 2.4). Intuitively, some #CSPs that are #P-hard become tractable when restricted to read-twice instances. To capture them, we need insights into what makes a problem hard in #CSP. Inspired by dichotomy theorems over general domains [5, 23, 8, 7], we introduce the Block-rank-one condition for Holant problems (see subsection 7.1). It is known that non-block-rank-one structures imply hardness in #CSP. So our condition is necessary for tractability since it is imposed on the functions defined by read-twice instances. Surprisingly, on the Boolean domain, the Block-rank-one condition is also *sufficient* and leads to a clear separation:

I. **Function set $\mathcal{F}$ satisfies the condition**. Then #CSP($\mathcal{F}$) is in P, and hence its subproblem Holant($\mathcal{F}$) is also in P.
II. **Function set $\mathcal{F}$ violates the condition**. Then (a) Holant($\mathcal{F}$) is #P-hard or (b) #CSP($\mathcal{F}$) is #P-hard but Holant($\mathcal{F}$) is tractable.

First we discuss Part II. We can prove #P-hardness directly, or further induce an orthogonal holographic transformation. After performing the transformation, we have to handle real-valued functions. Luckily, we can even prove a dichotomy theorem for a family of *complex-valued* Holant problems (Theorem 9). And towards this theorem, we prove a lemma (Lemma 6) on how to "extract" a function from its tensor powers. The proof is non-constructive and the idea can simplify some existing proofs. For example, it can be shown directly that the two problems #CSP$^d(\mathcal{F} \cup \{[1,0]^{\otimes d}, [0,1]^{\otimes d}\})$ and #CSP$^d(\mathcal{F} \cup \{[1,0],[0,1]\})$ in [28] are equivalent under polynomial-time Turing reduction.

Now consider Part I. It can be derived that $\mathcal{F}$ is of affine type or $\mathcal{F}$ is of product type, exactly the criterion given by Dyer, Goldberg and Jerrum [19]. Dichotomies for #CSP over general domains [1, 23, 3, 8] are very different from those over the Boolean domain [18, 19]. Our proof builds a connection between them.

The Block-rank-one condition is a little conceptual. To obtain the structure of $\mathcal{F}$, we introduce an equivalent notion, called *balance*, for Holant problems (see subsection 7.2). The equivalence is simply built on the concept of *vector representation* in [8], which was used to design a polynomial-time algorithm for #CSP. Back to non-negative #CSP, we find that actually the notions of weak balance and balance (different from our version for Holant) in [8] are equivalent, without assuming FP $\neq$ #P. Therefore, to decide the complexity of a problem #CSP($\mathcal{F}$), we only need to decide whether $\mathcal{F}$ is of weak balance.

2 Preliminaries

2.1 Functions and Signatures

Let $\mathbb{C}$ and $\mathbb{R}_+$ denote the set of algebraic complex numbers and the set of algebraic non-negative real numbers, respectively. Throughout this paper, we refer to them simply as complex and non-negative numbers.

Given a function $f : \{0,1\}^n \to \mathbb{C}$, we will often write it as a vector of dimension 2^n whose entries are the function values, indexed by $\mathbf{x} \in \{0,1\}^n$ lexicographically. This vector is called a *signature*. If the values of an n-ary function only depend on the Hamming weights of inputs, then the function is called *symmetric* and can be expressed as $[f_0, f_1, ..., f_n]$ where f_k is the function value for inputs of Hamming weight k. For example, the ternary logic OR function has the signature $[0,1,1,1]$.

Generally, given a function f of arity n, we can express it as a $2^r \times 2^{n-r}$ matrix $(1 \leq r \leq n)$, denoted by $M_{[r]}(f)$. The rows and columns are indexed by $\mathbf{x} \in \{0,1\}^r$ and $\mathbf{y} \in \{0,1\}^{n-r}$ respectively, and $f(\mathbf{x}, \mathbf{y})$ is the $(\mathbf{x}, \mathbf{y})^{\text{th}}$ entry of the matrix. And the matrices $\{M_{[r]}(f) \,|\, r \in [n]\}$ are called the *signature matrices* of f. When the integer r is clear from the context, we simply write M_f.

In most cases, if not confused, we identify functions, signatures and signature matrices. But in section 7, we shall distinguish a function from its matrix representations.

Given an n-ary function f and a permutation π on $[n]$, we define the function f_π : For $x_1, x_2, ..., x_n \in \{0,1\}$, $f_\pi(x_1, x_2, ..., x_n) = f(x_{\pi(1)}, x_{\pi(2)}, ..., x_{\pi(n)})$.

A function F is *reducible* if F_π is a tensor product of two functions (of arity ≥ 1) for some permutation π. Otherwise F is called *irreducible*. A function is called *degenerate* if it is a tensor product of some unary functions. Otherwise we call it *non-degenerate*.

Given a positive integer k, we use $=_k$ to denote the k-ary *equality* function $[1, 0, ..., 0, 1]$. And we use $\neq_2$ to denote the binary *disequality* function $[0, 1, 0]$.

In the following, we define three classes of complex-valued functions. Let $\mathcal{T}$ denote the set of functions that can be expressed as a tensor product of functions of arity at most 2.

The *support* of an n-ary function f, denoted by $\text{supp}(f)$, is the set $\{\mathbf{x} \in \mathbb{Z}_2^n \mid f(\mathbf{x}) \neq 0\}$. A Boolean relation is *affine* if it is the set of solutions to a system of linear equations over the field $\mathbb{Z}_2$. We say that f has affine support if its support is affine.

▶ **Definition 1.** A function f of arity n is *affine* if its support is affine and there is a constant $\lambda \in \mathbb{C}$ such that for all $\mathbf{x} \in \text{supp}(f)$, $f(\mathbf{x}) = \lambda \cdot i^{Q(\mathbf{x})}$, where $i = \sqrt{-1}$ and Q is a quadratic polynomial $Q(x_1, ..., x_n) = \sum_{i=1}^{n} a_i x_i^2 + 2\sum_{1 \leq i < j \leq n} b_{ij} x_i x_j$ with $a_i \in \mathbb{Z}_4$ and $b_{ij} \in \{0, 1\}$. We use $\mathcal{A}$ to denote the set of all affine functions.

▶ **Definition 2.** A function f is of *product type* if it can be expressed as a product of unary functions, binary functions of the form $=_2$ and $\neq_2$ (on not necessarily disjoint subsets of variables). We use $\mathcal{P}$ to denote the set of all functions of product type.

2.2 Holographic Reductions

To introduce the holographic reductions, we define bipartite Holant problems. $\text{Holant}(\mathcal{F} \mid \mathcal{G})$ denotes the Holant problem on bipartite graphs $H = (U, V, E)$ where each vertex in U (V) is assigned a function from $\mathcal{F}$ ($\mathcal{G}$). A Holant problem $\text{Holant}(\mathcal{F})$ can seen as the bipartite problem $\text{Holant}(=_2 \mid \mathcal{F})$.

Let T be a 2×2 matrix and let $\mathcal{F}$ be a function set. Whenever we write $T\mathcal{F}$, the functions in $\mathcal{F}$ are viewed as column vectors and, $T\mathcal{F} = \{T^{\otimes n} f \mid f \in \mathcal{F} \text{ and } n = \text{arity}(f)\}$. Similarly, $\mathcal{F}T = \{fT^{\otimes n} \mid f \in \mathcal{F} \text{ and } n = \text{arity}(f)\}$ where the functions in $\mathcal{F}$ are expressed as row vectors.

Let T be a matrix in $GL_2(\mathbb{C})$. We say there is a *holographic reduction* defined by T from $\text{Holant}(\mathcal{F} \mid \mathcal{G})$ to $\text{Holant}(\mathcal{F}' \mid \mathcal{G}')$, if $\mathcal{F}T \subseteq \mathcal{F}'$ and $T^{-1}\mathcal{G} \subseteq \mathcal{G}'$. The holographic reduction maps a signature grid $\Omega = (G, \mathcal{F} \mid \mathcal{G}, \pi)$ to $\Omega' = (G, \mathcal{F}' \mid \mathcal{G}', \pi')$: For each vertex v of G, π' assigns the function $f_v T$ or $T^{-1} f_v$ to v, depending on which part v belongs to.

▶ **Theorem 3** (Valiant's Holant Theorem [32])**.** *Let T be any matrix in $GL_2(\mathbb{C})$. Suppose that the holographic reduction defined by T maps a signature grid Ω to Ω'. Then* $\text{Holant}_\Omega = \text{Holant}_{\Omega'}$.

We will use $\leq_{\mathsf{T}}$ to denote polynomial-time Turing reductions and use $\equiv_{\mathsf{T}}$ to denote the equivalence relation under polynomial-time Turing reductions.

▶ **Theorem 4.** *Let F be a function set and let H be an orthogonal matrix ($H^{\mathsf{T}}H = I$). Then* $\text{Holant}(H\mathcal{F}) \equiv_{\mathsf{T}} \text{Holant}(\mathcal{F})$.

2.3 Realizability

Let $\mathcal{F}$ be a set of functions. An $\mathcal{F}$-gate [15] Γ is a tuple $(G, \mathcal{F}, \pi)$ where $G = (V, E, D)$ is a graph with regular edges E and some dangling edges D. Other than these dangling edges, the gate Γ is the same as a signature grid: π maps each vertex $v \in V$ to some function $f_v \in \mathcal{F}$ and it incident edges (including the dangling ones) to the input variables of f_v. We denote the edges in E by $1, 2, ..., m$ and the dangling edges in D by $m+1, m+2, ..., m+n$. Then we can define a function f for Γ:

$$f(y_1, y_2, ..., y_n) = \sum_{x_1, x_2, ..., x_m \in \{0,1\}} F(x_1, x_2, ..., x_m, y_1, y_2, ..., y_n)$$

where $(y_1, y_2, ..., y_n) \in \{0,1\}^n$ is an assignment on the dangling edges and $F(\mathbf{x}, \mathbf{y})$ denotes the product of evaluations at all vertices of V. We say the function f is *realizable* from the function set $\mathcal{F}$. We use $\mathsf{S}(\mathcal{F})$ to denote the set of functions realizable from $\mathcal{F}$.

Given a function f, we use $f^{x_i=c}$ to denote the function obtained by pinning the ith input variable of f to $c \in \{0,1\}$.

2.4 Weighted Counting CSP

Let $\mathcal{F}$ be a set of complex-valued functions. Then the problem #CSP($\mathcal{F}$) is defined as follows. An input instance I of the problem consists of a finite set of variables $V = \{x_1, ..., x_n\}$ and a finite set of constraints $\{C_1, ..., C_m\}$. Each C_i has the form $(F_i, \mathbf{x}_i)$ where $F_i \in \mathcal{F}$ and $\mathbf{x}_i$ is a tuple of (not necessarily distinct) variables from V. The instance I *defines* a function F_I over $\mathbf{x} = (x_1, ..., x_n) \in \{0,1\}^n$: $F_I(\mathbf{x}) = \prod_{i=1}^m F_i(\mathbf{x}_i)$ for $\mathbf{x} \in \{0,1\}^n$. The output is the sum: $Z(I) = \sum_{\mathbf{x} \in \{0,1\}^n} F_I(\mathbf{x})$.

Holant problems are indeed read-twice #CSPs. Given a signature grid, we assume that the numbering of its vertices and edges is also given. If these edges are viewed as variables, then the signature grid is a #CSP instance where every variable appears exactly twice. So we also say that a signature grid defines a function. And the concept of realizability can be defined in the CSP language.

Cai, Lu and Xia [17] proved a dichotomy for complex-weighted #CSP over the Boolean domain.

▶ **Theorem 5** ([17]). *Let $\mathcal{F}$ be a set of complex-valued functions. Then the problem* #CSP($\mathcal{F}$) *is computable in polynomial time if $\mathcal{F} \subseteq \mathcal{A}$ or $\mathcal{F} \subseteq \mathcal{P}$. Otherwise* #CSP($\mathcal{F}$) *is* #P*-hard.*

3 Decomposition

In Holant problems, sometimes we are able to realize a function $F = f \otimes g$, but do not know how to realize the function f directly, which can be technically beneficial. Fortunately, under certain conditions, if F is realizable, then we may assume that f is freely available.

In this section, we prefer to prove the lemmas in the CSP language. If not specified, the functions we discussed are over a fixed finite domain and take complex values.

Let m be a positive integer. We use $f^{\otimes m}$ to denote the m-th tensor power of f. $f^{\otimes m}$ can be seen as m copies of f: $f^{\otimes m}(\mathbf{x}_1, ..., \mathbf{x}_m) = f(\mathbf{x}_1) \cdots f(\mathbf{x}_m)$. Let I be a #CSP instance that contains m constraints: $(f, \mathbf{x}_1), (f, \mathbf{x}_2), ..., (f, \mathbf{x}_m)$. We replace these m tuples by one tuple $(f^{\otimes m}, \mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_m)$ and then obtain a new instance I'. It is easy to see that $Z(I) = Z(I')$.

▶ **Lemma 6.** *For any function set $\mathcal{F}$ and function f,* Holant($\mathcal{F} \cup \{f\}$) $\leq_{\mathsf{T}}$ Holant($\mathcal{F} \cup \{f^{\otimes d}\}$) *for all $d \geq 1$.*

Proof. Impose induction on d. Let n denote the arity of f.

The base case, $d = 1$, is trivial. Now suppose that the conclusion holds for all $d < k$ ($k \geq 2$). In the problem Holant($\mathcal{F} \cup \{f^{\otimes k}\}$), we may assume that the functions $f^{\otimes (mk)}$ are freely available for integers $m > 0$. There are two cases to consider:

- There exists an instance I of Holant($\mathcal{F} \cup \{f\}$) such that $Z(I) \neq 0$ and f appears p times where $p = qk + r$ ($q \geq 0, 0 < r < k$). Let $C_1, ..., C_p$ be the p constraints that have the form $(f, \mathbf{x}_i)$. We replace the first qk constraints by one tuple $C_1' = (f^{\otimes (qk)}, \mathbf{x}_1, ..., \mathbf{x}_{qk})$, and the last r constraints by one tuple $C_2' = (f^{\otimes k}, \mathbf{x}_{qk+1}, ..., \mathbf{x}_p, \mathbf{y})$ where $\mathbf{y}$ denotes a list of new distinct variables, of length $(k - r)n$. After the substitution, we get a function

$F(\mathbf{x}, \mathbf{y})$ where $\mathbf{x}$ denotes the variables of the original instance I. Every variable in $\mathbf{x}$ occurs twice, so by summing on them we can realize the following function:

$$\sum_{\mathbf{x}} F(\mathbf{x}, \mathbf{y}) = \sum_{\mathbf{x}} F_I(\mathbf{x}) f^{\otimes(k-r)}(\mathbf{y}) = Z(I) f^{\otimes(k-r)}(\mathbf{y}).$$

Because $Z(I) \neq 0$, we have $\text{Holant}(\mathcal{F} \cup \{f^{\otimes(k-r)}\}) \leq_{\mathsf{T}} \text{Holant}(\mathcal{F} \cup \{f^{\otimes k}\})$. And by the induction hypothesis, $\text{Holant}(\mathcal{F} \cup \{f\}) \leq_{\mathsf{T}} \text{Holant}(\mathcal{F} \cup \{f^{\otimes(k-r)}\})$. Therefore, the conclusion holds.

- For all I with $Z(I) \neq 0$, f appears a multiple of k times. Given an instance I of $\text{Holant}(\mathcal{F} \cup \{f\})$, we show how to compute $Z(I)$ with the help of the oracle for $\text{Holant}(\mathcal{F} \cup \{f^{\otimes k}\})$. First we check whether the number p of constraints containing f is a multiple of k. If not, we simply output 0. Otherwise we replace all such constraints by one tuple $(f^{\otimes p}, \mathbf{x})$ as in case (1), and then obtain an instance I' of $\text{Holant}(\mathcal{F} \cup \{f^{\otimes k}\})$. Clearly $Z(I) = Z(I')$, and we can compute $Z(I')$ by accessing the oracle.

In either case, there exists a polynomial-time Turing reduction. This completes the induction. ◀

Note that our proof only shows the *existence* of polynomial-time Turing reductions, but does not produce such reductions *constructively* for given function sets. Based on Lemma 6, we can prove a more general one.

▶ **Lemma 7.** *Let $\mathcal{F}$ be a set of functions, and f, g be two functions. Suppose that there exists an instance I of* $\text{Holant}(\mathcal{F} \cup \{f, g\})$ *such that $Z(I) \neq 0$, and the number of occurrences of g in I is greater than that of f. Then* $\text{Holant}(\mathcal{F} \cup \{f, f \otimes g\}) \leq_{\mathsf{T}} \text{Holant}(\mathcal{F} \cup \{f \otimes g\})$.

4 When A Non-trivial Equality Function Appears

Let $\text{Holant}^c(\mathcal{F})$ denote the problem $\text{Holant}(\mathcal{F} \cup \{[1,0],[0,1]\})$. We have the following theorem:

▶ **Theorem 8.** *Let λ be any nonzero complex number that is not a root of unity. For any set $\mathcal{F}$ of complex-valued functions,* $\text{Holant}^c(\mathcal{F} \cup \{[1,0,\lambda]\})$ *is computable in polynomial time if $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq \mathcal{P}$. Otherwise the problem is #P-hard.*

The conclusion still holds if we remove the unary functions $[1,0]$ and $[0,1]$:

▶ **Theorem 9.** *Let λ be any nonzero complex number that is not a root of unity. For any set $\mathcal{F}$ of complex-valued functions,* $\text{Holant}(\mathcal{F} \cup \{[1,0,\lambda]\})$ *is computable in polynomial time if $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq \mathcal{P}$. Otherwise the problem is #P-hard.*

Proof. We can interpolate $[1,0]^{\otimes 2}$ and $[0,1]^{\otimes 2}$ using $[1,0,\lambda]$. Then by Lemma 6, $\text{Holant}^c(\mathcal{F} \cup \{[1,0,\lambda]\}) \leq_{\mathsf{T}} \text{Holant}(\mathcal{F} \cup \{[1,0,\lambda]\})$. ◀

Intuitively, we can interpolate all functions of the form $[a,0,b]$, using the binary function $[1,0,\lambda]$. By connecting with these binary funtions, a function f may range arbitrarily. To avoid #P-hardness, the structure of the support of f must be simple enough.

5 $\mathcal{P}$-transformability

We start with some simple facts from linear algebra. Let $M = \begin{bmatrix} a_1 & a_2 & \cdots & a_n \\ b_1 & b_2 & \cdots & b_n \end{bmatrix}$ $(n \geq 2)$ be a non-negative matrix of rank 2. Then $A = MM^{\mathsf{T}} = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$ satisfying $a, c > 0$. Moreover, by Cauchy-Schwarz inequality, $\det A = ac - b^2 > 0$.

▶ **Lemma 10.** *If $a \neq c$ or $b \neq 0$, then A has two distinct positive eigenvalues α and β.*

The following lemma is a simple case of the Spectral Theorem for real symmetric matrices.

▶ **Lemma 11.** *There is an orthogonal matrix H such that $HAH^{\mathsf{T}} = \begin{bmatrix} \alpha & 0 \\ 0 & \beta \end{bmatrix}$, where α and β are the eigenvalues of A.*

Let f be a non-negative binary function. If f is non-degenerate and affine, then $f = a[1,0,1]$ or $f = a[0,1,0]$ for some $a > 0$.

▶ **Lemma 12.** *Let $f = (a,b,c,d)$ be a non-negative function. Suppose that f is non-degenerate and $f \notin \mathcal{A}$. Then for any function set $\mathcal{F}$ with $f \in \mathsf{S}(\mathcal{F})$, $\mathrm{Holant}(\mathcal{F})$ is #P-hard or $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq H\mathcal{P}$ for some orthogonal matrix H.*

Proof. Since $f \in \mathsf{S}(\mathcal{F})$, the symmetric matrix

$$A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} a & c \\ b & d \end{bmatrix} = \begin{bmatrix} a^2+b^2 & ac+bd \\ ac+bd & c^2+d^2 \end{bmatrix}$$

is also realizable. Because f is non-degenerate, $a^2+b^2, c^2+d^2 > 0$ and $ac+bd \geq 0$. We claim that $ac+bd \neq 0$ or $a^2+b^2 \neq c^2+d^2$. Suppose $ac+bd = 0$, then $ac = bd = 0$ since f is non-negative. So $f = \begin{bmatrix} a & 0 \\ 0 & d \end{bmatrix}$ or $f = \begin{bmatrix} 0 & b \\ c & 0 \end{bmatrix}$. In both cases, as $f \notin \mathcal{A}$, $a^2+b^2 \neq c^2+d^2$.

By Lemma 10 and Lemma 11, there is some orthogonal matrix H such that $HAH^{\mathsf{T}} = \begin{bmatrix} \alpha & 0 \\ 0 & \beta \end{bmatrix}$, where α and β are the two distinct positive eigenvalues of A. Now we perform the transformation H and obtain the following equivalence:

$$\mathrm{Holant}(\{[\alpha,0,\beta]\} \cup H\mathcal{F}) \equiv_{\mathsf{T}} \mathrm{Holant}(\{A\} \cup \mathcal{F}) \equiv_{\mathsf{T}} \mathrm{Holant}(\mathcal{F}).$$

The latter equivalence follows from the fact $A \in \mathsf{S}(f) \subseteq \mathsf{S}(\mathcal{F})$. β/α is nonzero and not a root of unity, so if $H\mathcal{F} \not\subseteq \mathcal{T}$ and $H\mathcal{F} \not\subseteq \mathcal{P}$, the problem is #P-hard by Theorem 9. ◀

6 On Special Functions of Arity 4

In this section, we consider some special functions of arity 4, and complete the preparation for the hardness part of our dichotomy.

▶ **Lemma 13.** *Let f be a function of arity 4, whose signature matrix has the form*

$$M_f = \begin{bmatrix} f_{0000} & f_{0001} & f_{0010} & f_{0011} \\ f_{0100} & f_{0101} & f_{0110} & f_{0111} \\ f_{1000} & f_{1001} & f_{1010} & f_{1011} \\ f_{1100} & f_{1101} & f_{1110} & f_{1111} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & a \\ 0 & b & c & 0 \\ 0 & c & b & 0 \\ a & 0 & 0 & 1 \end{bmatrix}$$

where $a,b,c \geq 0$ and at least two of them are positive. Then $\mathrm{Holant}(f)$ is #P-hard if $f \neq [1,0,1,0,1]$.

We prove a dichotomy for function sets that contain certain functions of arity 4.

▶ **Lemma 14.** *Let f be a non-negative function of arity 4. And $\begin{bmatrix} f_{0000} & f_{0011} \\ f_{1100} & f_{1111} \end{bmatrix} = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$ where $b \neq 0$ and $ac > b^2$. Then for any function set $\mathcal{F}$ containing f, $\mathrm{Holant}(\mathcal{F})$ is #P-hard or $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq H\mathcal{P}$ for some orthogonal matrix H.*

Proof. We can show that $\mathrm{Holant}(\mathcal{F})$ is #P-hard by Theorem 5 and Lemma 13, or there is some non-negative binary function $f \notin \mathcal{A} \cup \mathcal{P}$ such that $\mathrm{Holant}(\mathcal{F} \cup \{f\}) \leq_{\mathsf{T}} \mathrm{Holant}(\mathcal{F})$. Then the conclusion follows from Lemma 12. ◀

7 The Dichotomy

7.1 The Block-rank-one Condition Captures the Dichotomy

Given a function f of arity n, we use $f^{[t]}$, for each $t \in [n]$, to denote the function

$$f^{[t]}(x_1, ..., x_t) = \sum_{x_{t+1},...,x_n \in \{0,1\}} f(x_1, ..., x_t, x_{t+1}, ..., x_n).$$

Recall that Holant problems are read-twice #CSPs and every #CSP instance *defines* a function (subsection 2.4). We adopt the notation in [7], defining the following set of functions for a given $\mathcal{F}$:

$$\mathcal{W}_{\mathcal{F}} = \{F^{[t]} \mid F \text{ is a function defined by an instance of Holant}(\mathcal{F}) \text{ and } 1 \le t \le \text{arity of } F\}.$$

Note that the functions in $\mathcal{W}_{\mathcal{F}}$ are not necessarily realizable from $\mathcal{F}$. The following two lemmas show how $\mathcal{W}_{\mathcal{F}}$ and $\mathsf{S}(\mathcal{F})$ are related:

▶ **Lemma 15.** *Let $f \in \mathcal{W}_{\mathcal{F}}$ be a function of arity n. Then there is a function $g \in \mathsf{S}(\mathcal{F})$ of arity $2n$, such that for all $x_1, x_2, ..., x_n \in \{0, 1\}$, $f(x_1, x_2, ..., x_n) = g(x_1, x_1, x_2, x_2, ..., x_n, x_n)$.*

▶ **Lemma 16.** *For $f \in \mathsf{S}(\mathcal{F})$, $f^2 \in \mathcal{W}_{\mathcal{F}}$.*

Let M be a non-negative matrix. We say M is *block-rank-one* if every two rows of it are linearly dependent or orthogonal. Given a non-negative function f of arity n, we say f is *block-rank-one* if either $n = 1$ or the matrix $M_{[n-1]}(f)$ is block-rank-one.

Now we impose a condition on $\mathcal{W}_{\mathcal{F}}$:

Block-rank-one: All functions in $\mathcal{W}_{\mathcal{F}}$ are block-rank-one.

We can classify those function sets that do not satisfy this condition:

▶ **Lemma 17.** *Let $\mathcal{F}$ be a set of non-negative functions. If $\mathcal{F}$ does not satisfy the Block-rank-one condition, then* Holant$(\mathcal{F})$ *is #P-hard or $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq H\mathcal{P}$ for some orthogonal matrix H.*

Proof. Let $f \in \mathcal{W}_{\mathcal{F}}$ be a function of arity n. Then by Lemma 15, there is a function $g \in \mathsf{S}(\mathcal{F})$ of arity $2n$, such that for all $x_1, x_2, ..., x_n \in \{0, 1\}$, $f(x_1, x_2, ..., x_n) = g(x_1, x_1, x_2, x_2, ..., x_n, x_n)$.

Now suppose that f is not block-rank-one. By definition, $n \ge 2$ and the two columns of $M_{[n-1]}(f)$ are linearly independent but not orthogonal. Then the first and the last columns of the matrix $M = M_{[2n-2]}(g)$, $g^{x_{2n-1}=x_{2n}=0}$ and $g^{x_{2n-1}=x_{2n}=1}$, are also linearly independent but not orthogonal. Let h denote the 4×4 matrix $M^{\mathsf{T}}M$. Then $h_{0011} = h_{1100} > 0$ and $h_{0000}h_{1111} > h_{0011}^2$. Since $g \in \mathsf{S}(\mathcal{F})$, h is also realizable. Thus Holant$(\mathcal{F} \cup \{h\}) \le_{\mathsf{T}}$ Holant$(\mathcal{F})$. By Lemma 14, Holant$(\mathcal{F})$ is #P-hard or $\mathcal{F} \subseteq \mathcal{T}$ or $\mathcal{F} \subseteq H\mathcal{P}$ for some orthogonal H. ◀

Surprisingly, the Block-rank-one condition has *captured* the dichotomy. We have the crucial lemma below:

▶ **Lemma 18.** *Let $\mathcal{F}$ be a set of non-negative functions. If $\mathcal{F}$ satisfies the Block-rank-one condition, then $\mathcal{F} \subseteq \mathcal{A}$ or $\mathcal{F} \subseteq \mathcal{P}$.*

Therefore, if $\mathcal{F}$ satisfies the Block-rank-one condition, then Holant$(\mathcal{F})$ is in polynomial time. So our dichotomy is quite simple and it is decidable in polynomial time [12]:

▶ **Theorem 19.** *Let $\mathcal{F}$ be a set of non-negative functions. The problem* Holant($\mathcal{F}$) *is computable in polynomial time if $\mathcal{F}$ satisfies one of the following three conditions:*

- $\mathcal{F} \subseteq \mathcal{T}$;
- $\mathcal{F} \subseteq \mathcal{A}$;
- $\mathcal{F} \subseteq H\mathcal{P}$ *for some real orthogonal matrix* H.

Otherwise Holant($\mathcal{F}$) *is* #P*-hard.*

The remaining is to prove Lemma 18. To obtain the structure of $\mathcal{F}$, it is more convenient to consider directly the set $\mathcal{F}$ and the functions realizable from it. So in the next subsection, we will introduce a notion equivalent to the Block-rank-one condition. This notion restricts the function set $\mathsf{S}(\mathcal{F})$.

7.2 Balance

We define the notion of *balance* for non-negative Holant problems. The notion was introduced for non-negative #CSP by Cai, Chen and Lu [8].

▶ **Definition 20** (Balance)**.** Let $\mathcal{F}$ be a set of non-negative functions. $\mathcal{F}$ is called *balanced* if for any function $f \in \mathsf{S}(\mathcal{F})$, every signature matrix in $\{M_{[r]}(f) \mid 1 \leq r \leq \text{arity}(f)\}$ is block-rank-one. A non-negative function f is *balanced* if the set $\{f\}$ is balanced.

Note that in the definition above, when $r = \text{arity}(f)$, the matrix $M_{[r]}(f)$ is a column vector and hence trivially block-rank-one.

Balanced sets satisfy the Block-rank-one condition. Generally, we have the following lemma.

▶ **Lemma 21.** *Let $\mathcal{F}$ be a set of non-negative functions. Suppose that $\mathcal{F}$ is balanced. Then for any $f \in \mathcal{W}_{\mathcal{F}}$, every matrix in $\{M_{[r]}(f) \mid 1 \leq r \leq \text{arity}(f)\}$ is block-rank-one.*

Proof. Let $f \in \mathcal{W}_{\mathcal{F}}$ be a function of arity n. Then by Lemma 15, there exists a function $g \in \mathsf{S}(\mathcal{F})$ of arity $2n$, such that for all $x_1, x_2, ..., x_n \in \{0, 1\}$,

$$f(x_1, x_2, ..., x_n) = g(x_1, x_1, x_2, x_2, ..., x_n, x_n).$$

Therefore, for any $r \in [n]$, $M_{[r]}(f)$ is a submatrix of $M_{[2r]}(g)$. Because $\mathcal{F}$ is balanced, $M_{[2r]}(g)$ is block-rank-one. Hence so is $M_{[r]}(f)$. ◀

Let f be a non-negative function of arity n. And let $s_1, ..., s_n$ be n non-negative unary functions. We call $(s_1, ..., s_n)$ a *vector representation* of f if for all $\mathbf{x} \in \{0, 1\}^n$, either $f(\mathbf{x}) = 0$ or $f(\mathbf{x}) = s_1(x_1) \cdots s_n(x_n)$.

▶ **Lemma 22** ([8])**.** *Let f be a non-negative function of arity n. If $f^{[t]}$ is block-rank-one for all $t \in [n]$, then f has a vector representation.*

▶ **Lemma 23.** *Let $\mathcal{F}$ be a set of non-negative functions that satisfies the Block-rank-one condition. Then every function in $\mathsf{S}(\mathcal{F})$ has a vector representation.*

Proof. Let f be a function in $\mathsf{S}(\mathcal{F})$ of arity n. By Lemma 16, $f^2 \in \mathcal{W}_{\mathcal{F}}$. Then f^2 has a vector representation $(s_1, ..., s_n)$ by Lemma 22. Let $(s'_1, ..., s'_n)$ be n non-negative unary functions such that for all $i \in [n]$, $s'_i(a) = \sqrt{s_i(a)}$ for $a \in \{0, 1\}$. Then $(s'_1, ..., s'_n)$ is a vector representation of the function f. ◀

Now we are able to prove the equivalence between the notion of balance and the Block-rank-one condition.

▶ **Lemma 24.** *Let $\mathcal{F}$ be a set of non-negative functions. $\mathcal{F}$ is balanced if and only if $\mathcal{F}$ satisfies the Block-rank-one condition.*

Proof. The necessity follows directly from Lemma 21. We only need to show the sufficiency.

Let f be an n-ary function in $\mathsf{S}(\mathcal{F})$, with $n \geq 2$. And suppose that $M = M_{[r]}(f)$ is not block-rank-one for some $r \in [n]$. Then there exist two rows of M, indexed by some $\mathbf{x}, \mathbf{y} \in \{0,1\}^r$, which are linearly independent but not orthogonal. So we can realize a signature $g = MM^{\mathsf{T}}$. Its submatrix

$$h = \begin{bmatrix} g(\mathbf{x},\mathbf{x}) & g(\mathbf{x},\mathbf{y}) \\ g(\mathbf{y},\mathbf{x}) & g(\mathbf{y},\mathbf{y}) \end{bmatrix} = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$$

is of full rank and $a, b, c > 0$. But by Lemma 23, g has a vector representation $(s_1, ..., s_{2r})$, such that for all $\mathbf{u} \in \mathrm{supp}(g)$, $g(\mathbf{u}) = s_1(u_1) \cdots s_{2r}(u_{2r})$. Let $s = s_1 \otimes \cdots \otimes s_r$ and $t = s_{r+1} \otimes \cdots \otimes s_{2r}$. Then

$$h = \begin{bmatrix} s(\mathbf{x})t(\mathbf{x}) & s(\mathbf{x})t(\mathbf{y}) \\ s(\mathbf{y})t(\mathbf{x}) & s(\mathbf{y})t(\mathbf{y}) \end{bmatrix},$$

which is singular. A contradiction. ◀

Having shown the equivalence, we turn to consider some properties of balanced sets. There are two basic facts about balance. Later we will often use them but without explicit reference.

▶ **Lemma 25.** *If $\mathcal{F} \subseteq \mathcal{G}$ and $\mathcal{G}$ is balanced, then $\mathcal{F}$ is also balanced.*

▶ **Lemma 26.** *If $f \in \mathsf{S}(\mathcal{F})$ and $\mathcal{F}$ is balanced, then $\mathcal{F} \cup \{f\}$ is also balanced.*

In Boolean #CSP, the two unary functions $[1, 0]$ and $[0, 1]$ can be simulated [19]. And the function $[1, 1]$ is the unary equality function, which is freely available. These unary functions make it more convenient to construct certain functions. But in Holant problems, generally we do not know how to realize or simulate them. Fortunately, we can circumvent this difficulty by the lemma below. It follows from Lemma 28 and Lemma 30.

▶ **Lemma 27.** *If $\mathcal{F}$ is balanced, then the set $\mathcal{F} \cup \{[1, 0], [0, 1], [1, 1]\}$ is balanced.*

▶ **Lemma 28.** *If $\mathcal{F}$ is balanced, then $\mathcal{F} \cup \{[1, 0], [0, 1]\}$ is balanced.*

▶ **Lemma 29.** *Suppose that $\mathcal{F}$ is a balanced set of non-negative functions. Let f be an n-ary function in $\mathsf{S}(\mathcal{F})$ and let F denote the function f^2. Then for each $t \in [n]$, there exists a constant $\lambda_t > 0$ such that $F^{[t]} = \lambda_t (f^{[t]})^2$.*

Proof. Impose induction on t. The base case $t = n$ is trivial where $\lambda_n = 1$.

Suppose that $F^{[t]} = \lambda_t (f^{[t]})^2$ for $t = k + 1 \leq n$. Consider the case $t = k$. For all $\mathbf{x} \in \{0,1\}^k$,

$$F^{[k]}(\mathbf{x}) = F^{[k+1]}(\mathbf{x}, 0) + F^{[k+1]}(\mathbf{x}, 1) = \lambda_{k+1} \left[\left(f^{[k+1]}(\mathbf{x}, 0) \right)^2 + \left(f^{[k+1]}(\mathbf{x}, 1) \right)^2 \right].$$

Note that the function $F^{[k+1]} \in \mathcal{W}_{\mathcal{F}}$ since $F = f^2 \in \mathcal{W}_{\mathcal{F}}$. Because $\mathcal{F}$ is balanced, $F^{[k+1]}$ is block-rank-one by Lemma 24. Thus the function $f^{[k+1]} = \sqrt{F^{[k+1]}/\lambda_{k+1}}$ is also block-rank-one, which implies that the two column vectors of the matrix $M_{[k]}(f^{[k+1]})$, denoted by $\mathbf{v}_0$ and $\mathbf{v}_1$, are orthogonal or linearly dependent:

- $\mathbf{v}_0$ and $\mathbf{v}_1$ are orthogonal. Then for all $\mathbf{x} \in \{0,1\}^k$,

$$F^{[k]}(\mathbf{x}) = \lambda_{k+1}\left[\left(f^{[k+1]}(\mathbf{x},0)\right)^2 + \left(f^{[k+1]}(\mathbf{x},1)\right)^2\right]$$
$$= \lambda_{k+1}\left(f^{[k+1]}(\mathbf{x},0) + f^{[k+1]}(\mathbf{x},1)\right)^2 = \lambda_{k+1}\left(f^{[k]}(\mathbf{x})\right)^2.$$

- $\mathbf{v}_0$ and $\mathbf{v}_1$ are linearly dependent. Without loss of generality, we assume that $\mathbf{v}_1 = \lambda\mathbf{v}_0$ for some $\lambda \geq 0$. Then for all $\mathbf{x} \in \{0,1\}^k$,

$$F^{[k]}(\mathbf{x}) = \lambda_{k+1}(1+\lambda^2)\left(f^{[k+1]}(\mathbf{x},0)\right)^2 = \lambda_{k+1}\frac{1+\lambda^2}{(1+\lambda)^2}\left(f^{[k]}(\mathbf{x})\right)^2.$$

In either case, the conclusion holds. This completes the induction. ◀

▶ **Lemma 30.** *If $\mathcal{F}$ is balanced, then $\mathcal{F} \cup \{[1,1]\}$ is balanced.*

Proof. Suppose that $[1,1] \notin \mathsf{S}(\mathcal{F})$, otherwise we are done. Let g be an n-ary function in $\mathsf{S}(\mathcal{F} \cup \{[1,1]\})$. We need to show that all the matrices in $\{M_{[r]}(g) \mid 1 \leq r \leq \text{arity}(g)\}$ are block-rank-one.

Let Γ denote the gate that realizes g. If there is an isolated vertex with a dangling edge in Γ, assigned the function $[1,1]$, then we remove this vertex; If there are two adjacent vertices, both assigned the function $[1,1]$, then we delete the pair. Repeat removing until no such vertices. Finally we obtain a new gate Γ'. If Γ' has no dangling edges, then we are done. Suppose not. Let h denote the function that Γ' realizes. And for all $x_1, ..., x_n \in \{0,1\}$, $g(x_1, ..., x_n) = 2^s h(x_{i_1}, ..., x_{i_t})$ where $1 \leq i_1 < \cdots < i_t \leq n$ and s denotes the number of pairs we delete. It suffices to prove that the signature matrices of h are all block-rank-one.

Note that $h = f^{[t]}$ for some $f \in \mathsf{S}(\mathcal{F})$ and $1 \leq t \leq \text{arity}(f)$. Let F denote the function f^2. Then by Lemma 29, there is a constant $\lambda_t > 0$ such that $F^{[t]} = \lambda_t (f^{[t]})^2$. Therefore, for any $r \in [t]$, the two matrices $M_{[r]}(f^{[t]})$ and $M_{[r]}(F^{[t]})$ are both block-rank-one or neither. Since $F^{[t]} \in \mathcal{W}_{\mathcal{F}}$, all of its signature matrices are block-rank-one by Lemma 21. Thus every matrix in $\{M_{[r]}(f^{[t]}) \mid 1 \leq r \leq t\}$ is block-rank-one. ◀

With these unary functions, we are able to prove two more lemmas:

▶ **Lemma 31.** *Let $\mathcal{F}$ be a set of non-negative functions and let $g = [1,0,1,0]$. If $\mathcal{F} \cup \{g\}$ is balanced, then $\mathcal{F} \subseteq \mathcal{A}$.*

▶ **Lemma 32.** *Let $\mathcal{F}$ be a set of non-negative functions and let $g = [a,0,...,0,b]$ be a general equality function where $\text{arity}(g) \geq 3$ and $a, b > 0$. If $\mathcal{F} \cup \{g\}$ is balanced, then $\mathcal{F} \subseteq \mathcal{A}$ or $\mathcal{F} \subseteq \mathcal{P}$.*

7.3 Proof Sketch of Lemma 18

Suppose that a function set $\mathcal{F}$ satisfies the Block-rank-one condition. Then the set $\mathcal{G} = \mathcal{F} \cup \{[1,0],[0,1],[1,1]\}$ is balanced. So it suffices to prove that $\mathcal{G} \subseteq \mathcal{A}$ or $\mathcal{G} \subseteq \mathcal{P}$.

First we consider the case $\mathcal{G} \subseteq \mathcal{T}$. In this case, every nondegenerate binary function in $\mathsf{S}(\mathcal{G})$ has the form $[a,0,b]$ or $(0,a,b,0)$. Thus all of them are of product type. Since the set $\mathcal{P}$ is closed under tensor product, $\mathcal{G} \subseteq \mathcal{P}$.

Now suppose that $\mathcal{G} \not\subseteq \mathcal{T}$. Then there is an irreducible function $f \in \mathsf{S}(\mathcal{G})$ of arity $n \geq 3$. For $1 \leq i < j \leq n$ and $a, b \in \{0,1\}$, we use f_{ij}^{ab} denote the column vector $M_{[n-2]}(f^{x_i=a, x_j=b})$. And we define the $2^{n-2} \times 2^2$ matrices $M_{ij} = (f_{ij}^{00}, f_{ij}^{01}, f_{ij}^{10}, f_{ij}^{11})$.

Since f is irreducible and $\mathcal{G}$ is balanced, any two elements of the support of f differ at two or more bits. Thus we have:

$$\langle f_{ij}^{00}, f_{ij}^{01} \rangle = 0, \ \langle f_{ij}^{00}, f_{ij}^{10} \rangle = 0,$$
$$\langle f_{ij}^{11}, f_{ij}^{01} \rangle = 0, \ \langle f_{ij}^{11}, f_{ij}^{10} \rangle = 0,$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product. Therefore, for every pair (i, j), the 4×4 matrix $B_{ij} = (M_{ij})^{\mathsf{T}} M_{ij}$ has the form

$$\begin{bmatrix} a & 0 & 0 & b \\ 0 & x & y & 0 \\ 0 & y & z & 0 \\ b & 0 & 0 & c \end{bmatrix}.$$

By Cauchy-Schwarz inequality, $ac \geq b^2$ and $xz \geq y^2$. If for all $1 \leq i < j \leq n$, B_{ij} is diagonal, then there exists a function $g = [a, 0, ..., 0, b] \in \mathsf{S}(\mathcal{G})$ where arity$(g) \geq 3$ and $a, b > 0$. If some B_{ij} is not diagonal, then $B_{ij} = a[1, 0, 1, 0, 1]$ for some $a > 0$ due to the balance of $\mathcal{G}$. In this case, we can further realize the function $a[1, 0, 1, 0]$. According to Lemma 32 or Lemma 31, $\mathcal{G} \subseteq \mathcal{A}$ or $\mathcal{G} \subseteq \mathcal{P}$.

8 Conclusion

To determine the complexity of a problem Holant$(\mathcal{F})$, the proofs of previous Holant dichotomies often start with a non-trivial function in $\mathcal{F}$. This works well for symmetric functions, but the structure of an asymmetric one can be very intricate. In [16], we have already seen that asymmetry poses great challenges in arity reduction and gadget construction, even assuming the presence of all unary functions. In fact, similar difficulty arises on higher domains, where it is tough to obtain an explicit dichotomy. The #CSP dichotomies over general domains [23, 8, 7] are more abstract than those over the Boolean domain, but they offer great insights into sum-of-product computation. Inspired by them, we introduce the Block-rank-one condition for Holant problems, which leads to a clear classification. At the beginning of our work, we were not sure whether the condition is sufficient for tractability. Lemma 24 and Lemma 27 make it possible to absorb the results in [19] and reach the destination.

Polynomial-Time Rademacher Theorem, Porosity and Randomness

Alex Galicki

The University of Auckland, Auckland, New Zealand
agal629@aucklanduni.ac.nz

Abstract

The main result of this paper is a polynomial time version of Rademacher's theorem. We show that if $z \in \mathbb{R}^n$ is p-random, then every polynomial time computable Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$ is differentiable at z. This is a generalization of the main result of [19].

To prove our main result, we introduce and study a new notion, p-porosity, and prove several results of independent interest. In particular, we characterize p-porosity in terms of polynomial time computable martingales and we show that p-randomness in $\mathbb{R}^n$ is invariant under polynomial time computable linear isometries.

1 Introduction

The topic of interactions between algorithmic randomness [11, 18] and computable analysis [17, 27] has been extensively studied in the recent years. The general idea is that classical theorems about properties holding almost everywhere in $\mathbb{R}^n$ have effective variants formulated in terms of algorithmic randomness. Differentiability of well-behaved functions is a sub-area that attracted particular interest of researchers (see [8, 13]). Most of results in this area are concerned with computable real functions of one variable. Less is known about functions of several variables (however, see [20, 15, 14]) and still less is known about differentiability and randomness in resource bounded settings [19].

The randomness notion this paper is concerned about is *p-randomness*, first studied by Wang [26]. It is usually defined in terms of polynomial time computable betting strategies.

In [19], Nies characterized p-randomness in terms of differentiability of polynomial time computable real-valued monotone functions of one variable. He showed that $z \in [0, 1]$ is p-random if and only if every polynomial time computable monotone function $f : [0, 1] \to \mathbb{R}$ is differentiable at z. Note that if $f : \mathbb{R} \to \mathbb{R}$ is a $K-$Lipschitz function, then $x \to f(x) + Kx$ is a monotone function. Hence the $\Rightarrow$ direction of this result also shows that polynomial time computable Lipschitz functions are differentiable at p-random reals.

The following classical result by Hans Rademacher [23] shows that Lipschitz real valued functions on $\mathbb{R}^n$ are almost everywhere differentiable.

▶ **Theorem 1** (Rademacher, 1919). *If $f : \mathbb{R}^n \to \mathbb{R}$ is Lipschitz, then it is differentiable at almost every $x \in \mathbb{R}^n$ (with respect to the Lebesgue measure).*

In this paper we prove the following polynomial time version of Rademacher's theorem:

▶ **Theorem 2** (Polynomial time Rademacher). *If $f : \mathbb{R}^n \to \mathbb{R}$ is Lipschitz and polynomial time computable, then it is differentiable at every p-random $x \in \mathbb{R}^n$.*

The notion of porosity, which originated in works of Denjoy, is crucial for this paper. Informally, x is a porosity point of $S \subseteq \mathbb{R}^n$ if it is possible to find relatively large balls disjoint from S (called *holes in* S) arbitrarily close to x. Most proofs of Rademacher's theorem, as well as our proof of the Theorem 1, have two distinct steps:

- The "one-dimensional" step, showing that directional derivatives (of a given Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$) exist almost everywhere. This part can be seen as concerned with differentiability of real functions of one variable.
- The step which shows that the set of points where the full derivative does not exist despite existence of some of the directional derivatives is negligible too.

Porosity can be observed and exploited in both steps. For real functions of one variable, porosity appears in sets where different types of derivatives disagree (see [9, 25] and [1]). In a polynomial time setting this phenomenon has been exploited by Nies in [19]. In the second step porosity appears in sets witnessing failures of linearity of directional derivatives (that is, when the directional derivative at a point as a function of direction is not a linear function). This particular phenomenon has been observed and studied for functions exhibiting Lipschitz-like regularity (for example, see [22] and [7]).

Since our main goal is to prove a polynomial-time version of Rademacher's theorem, we need a polynomial-time version of porosity. In the Section 3 we define a suitable notion, which we call *p-porosity*. It is worth mentioning that at least one effective version of porosity and its connections to algorithmic randomness has been studied before (see [6, 16]). We will briefly explain the difference between this notion of porosity and ours later in the paper.

The paper is structured as follows: in the Section 2 we review the relevant basic notions and define the notation used in the paper. In the Section 3 we define and study the notion of p-porosity. In the Section 4 we outline the proof of the Theorem 2.

2 Preliminaries and notation

In this paper we often have to go back and forth between the Cantor space and $\mathbb{R}^n$. Mostly, we use the standard notation (for notation related to the Cantor space and strings of finite length, please consult [18]). However, for the sake of readability and expressiveness, we will introduce some custom notation which is described below.

2.1 Dyadic cubes in $\mathbb{R}^n$, 1/3-shift trick

Let $\mathcal{D}^n$ denote the collection of half-open basic dyadic cubes in $\mathbb{R}^n$. That is

$$\mathcal{D}^n = \left\{2^{-k}([m_1, m_1+1) \times \cdots \times [m_n, m_n+1)) : \ k \in \mathbb{Z},\ m_1, \ldots, m_n \in \mathbb{Z}\right\}.$$

For $k \in \mathbb{Z}$, let $\mathcal{D}^n(k)$ denote the collection of basic dyadic cubes in $\mathbb{R}^n$ with its side length equal to 2^{-k}. If $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ is a linear isometry, let $\mathcal{D}_\Omega$ denote the set of images of elements of $\mathcal{D}^n$ under Ω. Analogously, let $\mathcal{D}_\Omega(k)$ be the collection of images of elements of $\mathcal{D}^n(k)$ under Ω. For $x \in \mathbb{R}^n$ and $i \in \mathbb{N}$, define $\mathcal{D}^n(x, i)$ (respectively, $\mathcal{D}_\Omega(x, i)$) to be the unique element of $\mathcal{D}^n(i)$ (respectively, $D_\Omega(i)$) containing x.

By $B(x, r)$ we denote the open ball in $\mathbb{R}^n$ with radius r and centered at x. The following proposition is known as the "$1/3-$shift trick" in $\mathbb{R}^n$.

▶ **Proposition 3** (cf. Theorem 3.8 in [24]). *For any ball $B = B(x, r) \subset \mathbb{R}^n$, there exists $k \in \mathbb{Z}$, $Q \in \mathcal{D}^n(k)$ and $t \in \{0, 1/3, 2/3\}^n$ such that $B \subset (Q + t)$ and $6r < 2^{-k} \leq 12r$.*

2.2 Binary expansion of elements in $\mathbb{R}^n$

Each real number $r \in [0,1)$ can be written in the form $r = \sum_{i\geq 0} r_i 2^{-i-1}$ where $r_i \in \{0,1\}$. We say $r_0 r_1 ...$ is the binary expansion of r. The binary expansion of r is unique unless r is a dyadic rational.

Let $x \in \mathbb{R}^n$. For every $1 \leq i \leq n$, let X_i denote the binary expansion of x_i, the $i-$th component of x. Then $X \in 2^\omega$ is the binary expansion of x if for all $1 \leq i \leq n$ and all j, $X(nj+i-1) = X_i(j)$.

Fix a positive $m \in \mathbb{N}$. Let $A \in 2^\omega$. We denote by $0._m A$ an element of $\mathbb{R}^m$, whose binary expansion is A. We omit the m subscript, when it is clear from the context.

Let $\sigma \in 2^{<\omega}$ with $|\sigma| = nk + m$ for some natural numbers n, k, m with $n > 0$ and $m < n$. Define $\{\sigma\}_n$ by $\{\sigma\}_n = \sigma\restriction_{nk}$. By $[\sigma]_n$ we denote the basic (open) dyadic cube (in $\mathbb{R}^n$) corresponding to $\{\sigma\}_n$.

2.3 Polynomial time computability and p-randomness

Intuitively, a function $f : \mathbb{R}^n \to \mathbb{R}$ is computable in polynomial time if for any $s \in \mathbb{N}$ and $x \in \mathbb{R}^n$, we can compute, uniformly in s and x, an approximate value e to $f(x)$ within an error 2^{-s} in time $O(s^k)$ for some constant k. For the rigorous definition, please see the Section 2.5 in [17]. This approach is equivalent to the one used in [19].

A *martingale* is a function $M\colon 2^{<\omega} \to \mathbb{R}_0^+$ such that $2M(\sigma) = M(\sigma 0) + M(\sigma 1)$ for all $\sigma \in 2^{<\omega}$. This notion of martingales is meant to formalize the intuitive notion of a betting strategy:

- $M(\sigma)$ represents the capital available after betting on bits of σ, which is always positive,
- betting the amount $\alpha \leq M(\sigma)$ on the next bit being 0, will result in losing α in the case when the next bit is 1 ($M(\sigma 1) = M(\sigma) - \alpha$) and winning α otherwise ($M(\sigma 0) = M(\sigma) + \alpha$).

We say that M *succeeds* on Z if $\limsup_n M(Z\restriction_n) = \infty$. For more details, please see [18].

▶ **Definition 4.** A martingale M is called *polynomial time computable* if from a string σ and $i \in \mathbb{N}$ we can in time polynomial in $|\sigma| + i$ compute an approximate value $(M(\sigma))_i$ to $M(\sigma)$ with $|M(\sigma) - (M(\sigma))_i| \leq 2^{-i}$.

▶ **Definition 5.** We say that $Z \in 2^\omega$ is *p-random* if no polynomial time martingale succeeds on Z. An element of $\mathbb{R}^n$ is said to be p-random if its binary expansion is p-random.

p-randomness is a polynomial time variant of *computable randomness* (see [18]). Computable randomness is usually defined in terms of succeeding of computable martingales. However, it is known that in the context of computable randomness, succeeding can be replaced with *divergence*. That is, $Z \in 2^\omega$ is not computably random iff there exists a computable martingale M with $\liminf_i M(Z\restriction_i) < \limsup_i M(Z\restriction_i)$. An analogous result holds for p-randomness and a somewhat stronger proposition will be shown later in this paper.

2.4 Martingales-measures correspondence and derivatives

We denote the Lebesgue measure (both on $\mathbb{R}^n$ and on 2^ω) by λ. By $\mathcal{M}_\lambda$ we denote the class of measures μ on $\mathbb{R}^n$ for which $\mu(A) \leq k \cdot \lambda(A)$ holds for some k and all Borel A.

Most of martingales considered in this paper are bounded. We will use repeatedly the following correspondence between measures from $\mathcal{M}_\lambda$ and bounded martingales.

▶ **Definition 6.** Let M be a martingale bounded from above. For all $\sigma \in 2^{<\omega}$ define

$$\mu_0([\sigma]_n) = M(\{\sigma\}_n)\lambda([\sigma]_n).$$

This defines a pre-measure on $[0,1]^n$. We can extend μ_0 to a measure $\mu \in \mathcal{M}_\lambda$ on $\mathbb{R}^n$ supported on a subset of the unit cube. We say μ is *a corresponding (to M) measure.*

For the other direction, let $\mu \in \mathcal{M}_\lambda$. We define *the corresponding (to μ) martingale M* by setting

$$M(\sigma) = \frac{\mu([\sigma]_n)}{\lambda([\sigma]_n)}.$$

Clearly, M is a bounded martingale.

▶ **Notation 7.** *Let μ be a measure on $\mathbb{R}^n$. Let $x \in \mathbb{R}^n$ and let $i \in \mathbb{N}$. Define*

$$\frac{\partial_2 \mu}{\partial_2 \lambda}(x,i) = \frac{\mu(\mathcal{D}^n(x,i))}{\lambda(\mathcal{D}^n(x,i))}$$

and

$$\frac{\partial_2 \mu}{\partial_2 \lambda}(x) = \lim_{i \to +\infty} \frac{\partial_2 \mu}{\partial_2 \lambda}(x,i).$$

If $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ is a linear isometry, we define

$$\frac{\partial_\Omega \mu}{\partial_\Omega \lambda}(x,i) = \frac{\mu(\mathcal{D}_\Omega(x,i))}{\lambda(\mathcal{D}_\Omega(x,i))}$$

and

$$\frac{\partial_\Omega \mu}{\partial_\Omega \lambda}(x) = \lim_{i \to +\infty} \frac{\partial_\Omega \mu}{\partial_\Omega \lambda}(x,i).$$

▶ **Notation 8.** *Let $n \geq 1$. By $e_1, \ldots, e_n$ we denote the unit vectors of the standard basis for $\mathbb{R}^n$.*

Let $f : \mathbb{R}^n \to \mathbb{R}$ be a function and let $v, x \in \mathbb{R}^n$. By $D_1 f(x), \ldots, D_n f(x)$ we denote the partial derivatives of f. We denote the directional derivative (in the direction of v) of f at x by $D_v f(x)$.

3 p-porosity

Let (X,d) be a metric space. $x \in X$ is said to be a *porosity point* of $S \subseteq X$ if

$$\mathbf{por}(x,S) = \limsup_{r \to 0} \gamma(x,r,S)/r > 0,$$

where $\gamma(x,r,S)$ is defined for any $r > 0$ as

$$\sup\{r' > 0 : \quad \text{for some } z \in X,\ B(z,r') \subseteq B(x,r) \text{ and } B(z,r') \cap S = \emptyset\}.$$

A set S is said to be *porous* if all its points are porosity points of S. A set is said to be *$\sigma-$porous* if it is a countable union of porous sets.

The following definitions are meant to formalize an efficient version of the above notion of porosity.

▶ **Definition 9.** Let C be a subset of 2^ω and let $Z \in C$. Define

$$\mathbf{por}_2(Z, C) = \liminf_{i\to\infty}\{|\sigma| - i \ : \ \sigma \succ Z\restriction_i \wedge \ [\sigma] \cap C = \emptyset\}.$$

If $\mathbf{por}_2(Z, C) < \infty$, then we say that Z is a *dyadic porosity point of* C.

Since we are interested in polynomial time computable betting strategies, we need to restrict our attention to subsets of 2^ω for which finding holes can be done in polynomial time.

▶ **Definition 10.** Let $A \subseteq 2^\omega$ be a Σ^0_1 set. We say A is *polynomial time computable* if there is a function $p : 2^{<\omega} \to \{0, 1\}$ computable in polynomial time such that $p(\sigma) = 1 \iff [\sigma] \subset A$ for all σ. Let $B \subseteq 2^\omega$ be a Π^0_1 set. We say it is polynomial time computable in if its complement is polynomial time computable.

▶ **Definition 11.** Let $X \in 2^\omega$. We say X is a *polynomial time porosity point (p-porosity point)* if there exists a polynomial time computable Π^0_1 set $A \subseteq 2^\omega$ such that X is a dyadic porosity point of A. If $C \subseteq A$ and $X \in C$, we say X is a p-porosity point of C.

We say $X \in 2^\omega$ is a *p-nonporosity point* if it is not a p-porosity point.

To show that $Z \in 2^\omega$ is a p-porosity point, it is sufficient to describe a polynomial-time algorithm for locating holes in some $S \subset 2^\omega$ arbitrarily close to Z. That is, to exhibit a function $p : 2^{<\omega} \to \{0, 1\}$ computable in polynomial time, such that

1. $p(\sigma) = 1 \iff [\sigma] \cap S = \emptyset$ and
2. Z is a dyadic porosity point of the complement of $\bigcup_{p(\sigma)=1}[\sigma]$.

▶ Remark. While our definitions admit straightforward generalizations to $\mathbb{R}^n$, for the sake of simplicity, we have defined our notion of p-porosity in terms of the Cantor space.

▶ Remark. As was mentioned in the introduction, one other effective version of porosity has been studied in the context of algorithmic randomness [6, 16]. $X \in 2^\omega$ is said to be a *porosity point* if there exists a Π^0_1 set $S \subseteq 2^\omega$ such that X is a dyadic porosity point of S. The main difference between this notion and p-porosity is that the latter requires a polynomial time algorithm for finding holes, while holes in a Π^0_1 set in general can only be enumerated.

3.1 p-porosity and polynomial time computable martingales

Since out main result, Theorem 2, is concerned with p-randomness, and we plan to use the notion of p-porosity extensively in the proof of it, we need to characterize the notion of p-porosity in terms of success sets of polynomial time computable martingales. This subsection is devoted to this task.

▶ Remark. A closely related notion, *p-genericity*, has been studied extensively (see [3], [2]). $Z \in 2^\omega$ is said to be *p-generic* if it does not belong to the boundary of any polynomial time computable Σ^0_1 subset of 2^ω. Since every p-porosity point belongs to the boundary of some polynomial time computable Σ^0_1 set, p-genericy implies p-nonporosity. Moreover, it is known that p-randomness implies p-genericity (see [4]). Hence, p-randomness implies p-nonporosity.

▶ **Definition 12.** Let μ be a measure on $\mathbb{R}^n$ and let $\epsilon > 0$. We say $x \in \mathbb{R}^n$ is *an $\epsilon-$oscillation point of μ* if for infinitely many $i \in \mathbb{N}$,

$$\left|\frac{\partial_2\mu}{\partial_2\lambda}(x, i) - \frac{\partial_2\mu}{\partial_2\lambda}(x, i + 1)\right| \geq \epsilon.$$

We say $x \in \mathbb{R}^n$ is *an oscillation point of μ* if x is an $\epsilon-$oscillation point of μ for some $\epsilon > 0$.

Analogously, we say $X \in 2^\omega$ is *an $\epsilon-$oscillation point of a martingale M* if for infinitely many $i \in \mathbb{N}$,

$$|M(X\restriction_i) - M(X\restriction_{i+1})| \geq \epsilon.$$

Let M be a martingale and let $\epsilon > 0$. By $\mathbf{Osc}(M, \epsilon)$ we denote the set of $\epsilon-$oscillation points of M. Finally, we let

$$\mathbf{Osc}(M) = \bigcup_{\epsilon > 0} \mathbf{Osc}(M, \epsilon).$$

▶ **Definition 13.** For $A, B \subseteq \mathbb{R}^n$ we say A and B are *$\epsilon-$separated by μ* if

$$\left| \frac{\mu(A)}{\lambda(A)} - \frac{\mu(B)}{\lambda(B)} \right| \geq \epsilon.$$

The following proposition provides a characterization of p-randomness in terms of $\epsilon-$oscillation points of polynomial time computable martingales.

▶ **Proposition 14.** *Let $Z \in 2^\omega$. The following are equivalent:*
1. *Z is p-random and*
2. *$Z \notin \boldsymbol{Osc}(M)$ for every bounded from above polynomial time computable martingale M.*

Proof Sketch. The (1) $\Rightarrow$ (2) direction is a polynomial time version of the Doob martingale convergence theorem. A straightforward adaptation of the proof of Theorem 7.1.3 from [10] suffices.

For the (2) $\Rightarrow$ (1) direction, suppose M is a polynomial time computable martingale succeeding on $Z \in 2^\omega$. We may assume M has the *saving property*, that is $M(\sigma\nu) \geq M(\sigma) - 1$ and $M(\sigma) > 1$ for all $\sigma, \nu \in 2^{<\omega}$. (See the proof of the Proposition 5.3.8 in [10])

Our proof is a suitable modification of the construction found in the proof of Theorem 4.2 from [13]. There, given a computable martingale M with the saving property, succeeding on Z, authors construct a computable martingale B that diverges on Z and for all $\sigma \in 2^{<\omega}$, $1 \leq B(\sigma) \leq 4$. It is easy to verify, that when M is polynomial time computable, B is polynomial time computable too. The construction turns the success of M into oscillations of B. It does so by having B alternating between two "phases": in the *up phase* B adds the capital that M risks, until $B(\sigma)$ reaches 3, while in the *down phase*, B subtracts the capital that M risks, until $B(\sigma)$ reaches 2. The required modification is following: the last bet of every up phase is a $1/4-$bet. It can be verified that for all $\sigma \in 2^{<\omega}$, $1 - 1/4 \leq B(\sigma) \leq 4 + 1/4$ and $Z \in \mathbf{Osc}(B, 1/4)$. ◀

▶ **Definition 15.** Let M be a martingale. We define $\mathcal{E}_{\geq}(M)$ to be the set of those X such that M does not make any losses while betting on X. More formally,

$$\mathcal{E}_{\geq}(M) = \{Z \ : \ \forall_i \ M(Z\restriction_{i+1}) \geq M(Z\restriction_i)\}.$$

The following proposition provides a characterization of p-porosity points in terms of martingales: p-porosity points are precisely those X for which there exists a martingale computable in polynomial time that succeeds on X without making any losses and places infinitely many ϵ-bets in the process.

▶ **Proposition 16.** *Let $Z \in 2^\omega$. The following two are equivalent:*
1. *Z is a p-porosity point, and*
2. *$Z \in \boldsymbol{Osc}(M) \cap \mathcal{E}_{\geq}(M)$ for some computable in polynomial time martingale M.*

Proof 1 ⇒ 2. Let A be a polynomial time computable Σ^0_1 set and let $p : 2^{<\omega} \to \{0,1\}$ be as in the Definition 10. Suppose Z is a dyadic porosity point of $2^\omega \setminus A$. Let $s = \mathbf{por}_2(Z, 2^\omega \setminus A)$. We define a martingale M in the following way. Let $M(\emptyset) = 1$ (by $\emptyset$ we denote the empty string). For all strings $\sigma \in 2^{<\omega}$ with $l = |\sigma| = k(s+1)$ for some $k > 1$, we let $M(\sigma) = M(\sigma\restriction_{l-1})$. Suppose $M(\sigma)$ has been defined, where $l = |\sigma| = k(s+1)$. If there is a string $\tau \succ \sigma$ of length $l+s$ such that $p(\tau) = 1$, then let $M(\tau) = 0$ and let $M(\sigma_1) = M(\sigma)\frac{2^s}{2^s-1}$ for all $\sigma_1 \succ \sigma$ with $\sigma_1 \neq \tau$ and $|\sigma_1| = s + l$. Otherwise, if such string τ does not exist, let $M(\sigma_1) = M(\sigma)$ for all $\sigma_1 \succ \sigma$ with $|\sigma_1| < (k+1)(s+1)$. M is clearly computable in polynomial time. Since Z is a dyadic porosity point of $2^\omega \setminus A$, for infinitely many i, we have

$$M(Z\restriction_{i+s}) - M(Z\restriction_i) \geq \frac{1}{2^s - 1}.$$

It follows that $Z \in \mathbf{Osc}\left(M, \frac{1}{s(2^s-1)}\right) \cap \mathcal{E}_{\geq}(M)$. ◀

Proof 2 ⇒ 1. Suppose $Z \in \mathbf{Osc}(M, \epsilon) \cap \mathcal{E}_{\geq}(M)$, where M is a computable in polynomial time martingale and $\epsilon > 0$. Let $s \in \mathbb{N}$ be such that $\epsilon > 2^{-s}$. For every $\sigma \in 2^{<\omega}$ with $\sigma \neq \emptyset$, let $\overline{\sigma}$ denote the string obtained from σ by flipping the last bit.

Define $p : 2^{<\omega} \to \{0,1\}$ by letting

- $p(\emptyset) = 0$ and
- for all $\sigma \neq \emptyset$, if $\left(M(\sigma) - M(\sigma\restriction_{|\sigma|-1})\right)_s > 0$, then $p(\overline{\sigma}) = 1$. Otherwise, let $p(\overline{\sigma}) = 0$.

Since $\left(M(\sigma) - M(\sigma\restriction_{|\sigma|-1})\right)_s > 0$ is decidable in polynomial time, p is computable in polynomial time too. Hence the set $A = 2^\omega \setminus \bigcup_{p(\sigma)=1}[\sigma]$ is polynomial time computable. For infinitely many i, we have $M(Z\restriction_{i+1}) - M(Z\restriction_i) > 2^{-s}$ and hence $p\left(\overline{Z\restriction_{i+1}}\right) = 1$. It follows that Z is a dyadic porosity point of A. ◀

4 Polynomial-time Rademacher's theorem

4.1 Overview of the proof

Let $f : \mathbb{R}^n \to \mathbb{R}$ be a Lipschitz function. Let us denote by $N(f)$ the set of points where f is not differentiable. Classical Rademacher's theorem asserts that it is a Lebesgue nullset. This can be proven in two steps.

1. Firstly, fix a countable set of unit vectors $V \subset \mathbb{R}^n$. Let $N(V, f) \subset \mathbb{R}^n$ denote the set where $D_v f(x)$ does not exist for at least one $v \in V$. A.e. differentiability of real-valued Lipschitz functions of one variable in conjunction with Fubini's theorem implies that this set is a Lebesgue nullset.
2. Secondly, consider the set $N(f) \setminus N(V, f)$. It can be proven that this set is $\sigma-$porous provided V is not empty (for example, see Theorem 3.1 in [5] and Theorem 2 in [21]). This concludes the proof, since $\sigma-$porous sets are Lebesgue nullsets.

Our proof of Theorem 2 follows a similar path. Firstly, let V_p be the set of polynomial time computable unit vectors in $\mathbb{R}^n$. Suppose $f : \mathbb{R}^n \to \mathbb{R}$ is a polynomial time computable Lipschitz function. We need to show that $N(f)$ contains no p-random elements. Just like in the classical case outlined above, we show this by splitting $N(f)$ in two parts - $N(f) \setminus N(V_p, f)$ and $N(V_p, f)$ - and then showing that neither of them contains a p-random element.

The proof has three nontrivial and relatively self-contained parts:

- Firstly, we show a result of independent interest. In the subsection 4.2 we prove that p-randomness in $\mathbb{R}^n$ is invariant under linear isometries computable in polynomial time.

It is worth mentioning that the one-dimensional version of this result follows from results in [12]. Higher dimensional result in this paper, requires, however, quite a different approach.

- Then, we show that p-randomness of z is sufficient for existence of partial derivatives of f at z. This is an adaptation of the one-dimensional proof from [19]. Existence of directional derivatives $D_v f(z)$ where $v \in V_p$ follows the preservation property mentioned in the previous point. This concludes the proof that $N(V_p, f)$ contains no p-random elements.
- Finally, we demonstrate that $N(f) \setminus N(V_p, f)$ contain no p-random points. This is accomplished by a careful analysis of structural properties of $N(f) \setminus N(V_p, f)$ and showing that binary expansions of elements of this set are p-porosity points.

Due to size limitations, this paper contains the full proof of the first part only (bar the proof of the technical lemma from the Section 4.2.2).

4.2 Invariance of p-randomness under linear isometries computable in polynomial time

In this subsection we will use the following notational convention.

▶ **Notation 17.** *Let μ be a measure on $\mathbb{R}^n$, and let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a linear isometry. By μ_Ω we denote the measure defined by $\mu_\Omega(A) = \mu(\Omega(A))$ for all Borel A.*

If M is a martingale corresponding to μ, by M_Ω we denote the martingale corresponding to μ_Ω.

The main result of this subsection is that p-randomness is invariant under polynomial time computable linear isometries. Let us examine how an analogous result can be shown for computable randomness. Suppose $z \in \mathbb{R}^n$ be not computably random and let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a computable linear isometry. We want to show that $\Omega^{-1}(z)$ is not computably random. Let M be a bounded computable martingale diverging on Z (where $z = 0.Z$) and let μ be a corresponding measure on $\mathbb{R}^n$. Define $y = \Omega^{-1}(z)$ and let Y be the binary expansion of y. Observe that M_Ω is also a bounded computable martingale. There are two possibilities:
(A) Either M_Ω diverges on Y, in which case Y is not computably random, or
(B) M_Ω converges on Y and then y belongs to the set

$$A = \left\{ x : \ \frac{\partial_2 \mu_\Omega}{\partial_2 \lambda}(x) \text{ exists and } \frac{\partial_\Omega \mu_\Omega}{\partial_\Omega \lambda}(x) \text{ does not exist} \right\}.$$

In this case it is possible to show that y is a porosity point of some subset of A and use this information to conclude that y is not computably random.

A similar argument can be made about p-randomness. However, there are two additional obstacles. Firstly, it is not clear what (additional) conditions on M and Ω ensure that M_Ω is polynomial time computable. Secondly, the porosity mentioned in (B) would have to be replaced with p-porosity. A significant portion of this section is dedicated to address those two problems. The plan is following:

- In the Subsection 4.2.1 we show that $\epsilon-$oscillation points of M_Ω are not p-random, even if it is not known whether M_Ω is computable in polynomial time;
- In the Subsection 4.2.2 we prove a technical lemma related to linear transformations and $\epsilon-$oscillation;
- Finally, in the Subsection 4.2.3 we combine those ideas to prove our main invariance theorem.

4.2.1 Betting on ϵ-oscillation points of M_Ω

▶ **Lemma 18.** *Let $A, B \subseteq \mathbb{R}^n$ be Borel with $A \subseteq B$ and $\lambda(B) > 0$. Let μ be a measure on $\mathbb{R}^n$ such that for some $k \in \mathbb{N}$, $\mu(C) \leq k\lambda(C)$ for all C. Suppose $\frac{\lambda(B\setminus A)}{\lambda(A)} \leq \epsilon$ for some $\epsilon \in \mathbb{R}$. Then*

$$\left|\frac{\mu(B)}{\lambda(B)} - \frac{\mu(A)}{\lambda(A)}\right| \leq 2k \cdot \epsilon.$$

Proof.

$$\begin{aligned}\left|\frac{\mu(B)}{\lambda(B)} - \frac{\mu(A)}{\lambda(A)}\right| &= \left|\frac{\mu(B)\lambda(A) - \mu(B)\lambda(B) + \mu(B\setminus A)\lambda(B)}{\lambda(B)\,\lambda(A)}\right| \\ &= \left|\frac{\mu(B)}{\lambda(B)}\frac{\lambda(B)-\lambda(A)}{\lambda(A)} + \frac{\mu(B\setminus A)}{\lambda(A)}\right| \\ &\leq 2k \cdot \epsilon.\end{aligned}$$

◀

▶ **Lemma 19** (Approximation lemma)**.** *Let M be a computable in polynomial time martingale bounded above by some $k \in \mathbb{N}$. Let μ be a corresponding measure on $\mathbb{R}^n$. Let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a computable in polynomial time linear isometry. Fix $s \in \mathbb{N}$. There exists function $M_{\Omega,s} : 2^{<\omega} \to \mathbb{R}$ computable in polynomial time such that for all σ*

$$|M_{\Omega,s}(\sigma) - M_\Omega(\sigma)| \leq 2^{-s}.$$

Proof. This is a consequence of Lemma 18. For a given σ, we can find in polynomial time a finite collection of dyadic basic cubes $(D(\sigma)_i)_{i\in\mathbb{N}}$ such that

$$\frac{\lambda(\Omega([\sigma]_n) \setminus \bigcup_i D(\sigma)_i)}{\lambda(\bigcup_i D(\sigma)_i)} \leq \frac{2^{-s-1}}{k},$$

so that

$$\left|\frac{\mu(\Omega([\sigma]_n))}{\lambda(\Omega([\sigma]_n))} - \frac{\mu(\bigcup_i D(\sigma)_i)}{\lambda(\bigcup_i D(\sigma)_i)}\right| \leq 2^{-s}.$$

Define $M_{\Omega,s}(\sigma) = \frac{\mu(\bigcup_i D(\sigma)_i)}{\lambda(\bigcup_i D(\sigma)_i)}$. This function is computable in polynomial time and the following holds for every σ:

$$|M_\Omega(\sigma) - M_{\Omega,s}(\sigma)| = \left|\frac{\mu(\Omega([\sigma]_n))}{\lambda(\Omega([\sigma]_n))} - \frac{\mu(\bigcup_i D(\sigma)_i)}{\lambda(\bigcup_i D(\sigma)_i)}\right| \leq 2^{-s}.$$

◀

▶ **Lemma 20.** *Let M be a polynomial time computable martingale bounded above by some $k \in \mathbb{N}$ and let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a polynomial time computable linear isometry. For every $\epsilon > 0$, there exists a polynomial time computable martingale H_ϵ such that every $\epsilon-$oscillation point of M_Ω is an $\epsilon/2-$oscillation point of H_ϵ.*

Proof. Let s be such that $2^{-s+1} < \epsilon$. By Lemma 19, there exists a polynomial time computable function $M_{\Omega,s}$ such that for all σ

$$|M_{\Omega,s}(\sigma) - M_\Omega(\sigma)| \leq 2^{-s}.$$

We define H_ϵ as following. We let $H_\epsilon(\emptyset) = M_{\Omega,s}(\emptyset)$. For any σ, suppose $H_\epsilon(\sigma)$ has been defined. We define $\alpha(\sigma) = H_\epsilon(\sigma) - \frac{1}{2}(M_{\Omega,s}(\sigma 0) + M_{\Omega,s}(\sigma 1))$ and we let

$$H_\epsilon(\sigma 0) = M_{\Omega,s}(\sigma 0) + \alpha(\sigma), \text{ and } H_\epsilon(\sigma 1) = M_{\Omega,s}(\sigma 1) + \alpha(\sigma).$$

It is easy to verify that H_ϵ is a polynomial time computable martingale. Now suppose $|M_\Omega(\sigma) - M_\Omega(\sigma 1)| \geq \epsilon$. We have

$$|H_\epsilon(\sigma) - H_\epsilon(\sigma 1)| = \frac{1}{2}\,|M_{\Omega,s}(\sigma 1) - M_{\Omega,s}(\sigma 0)| \geq \frac{1}{2}(2\epsilon - 2^{-s+1}) > \epsilon/2.$$

The case when $|M_\Omega(\sigma) - M_\Omega(\sigma 0)| \geq \epsilon$ is handled analogously. ◀

4.2.2 A technical lemma

Let M be a martingale computable in polynomial time, bounded from above, and let μ be a corresponding measure on $\mathbb{R}^n$. Suppose $y \in \mathbb{R}^n$ is an $\epsilon-$oscillation point of μ. It can be easily shown that for any $k > 0$ and for infinitely many i, $\mathcal{D}^n(y, i)$ contains two dyadic cubes from $\mathcal{D}^n(i + k)$, that are $\epsilon-$ separated by μ.

Now consider a linear isometry $\Omega : \mathbb{R}^n \to \mathbb{R}^n$. Suppose that for some $k > 0$, $\epsilon > 0$ and for infinitely many i, $D = \mathcal{D}^n(y, i)$ contains two cubes $D_1, D_2 \in \mathcal{D}_\Omega(i + k)$, that are $\epsilon-$separated by μ. In general, this does not imply that y is an oscillation point of μ. However, the following technical lemma shows that if y is not an oscillation point of μ, then it is a p-porosity point.

▶ **Lemma 21.** *Let M be a martingale computable in polynomial time, bounded from above. Let μ be a corresponding measure on $\mathbb{R}^n$. Let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a linear isometry. Let $y \in \mathbb{R}^n$ with $Y \in 2^\omega$ being its binary expansion. Suppose that for some $k > 0$, $\epsilon > 0$ and for infinitely many i, $D = \mathcal{D}^n(y, i)$ contains two cubes $D_1, D_2 \in \mathcal{D}_\Omega(i + k)$, that are $\epsilon-$separated by μ. If y is not an oscillation point of μ, then Y is a p-porosity point.*

4.2.3 Invariance theorems

▶ **Theorem 22.** *Let $z \in [0, 1]^n$ and let $r \in \mathbb{R}$ be a polynomial time computable real. Suppose z is not p-random. Then $z + re_i$ is not p-random for any $1 \leq i \leq n$.*

Proof. Since we are only interested in the question whether $z + re_i$ is p-random or not, we may assume that z and r are such that $z + re_i \in [0, 1]^n$.

Without loss of generality we may assume that every component of z is p-random and $n > 1$ (otherwise, the required result follows from preservation properties proven in [12]). Fix $i \in \mathbb{N}$ with $1 \leq i \leq n$ and define $\Phi, \Omega : \mathbb{R}^n \to \mathbb{R}^n$ by $\Omega(x) = x - re_i$ and $\Phi = \Omega^{-1}$. Let $y = \Phi(z)$. Let Z be the binary expansion of z and let Y be the binary expansion of y. Let M be the polynomial time computable martingale M from the (sketch of the)proof of the Proposition 14 such that Z is an $\epsilon-$oscillation point of M for some $\epsilon > 0$. M makes an infinite number of ϵ bets along Z. However, we need a modified version of M (which we also call M). First, let us introduce some notation. Let μ denote the measure corresponding to M. For every $\sigma \in 2^{<\omega}$ with $[\sigma]_n \in \mathcal{D}(j)$, let $D^1(\sigma), D^2(\sigma) \in \mathcal{D}_\Omega(j)$ be such that $[\sigma]_n \subseteq D^1(\sigma) \cup D^2(\sigma)$. $D^1(\sigma)$ and $D^2(\sigma)$ are not necessarily unique, but that does not matter. Our martingale M, instead of making an ϵ bet, waits until its input σ is such that $\frac{\lambda([\sigma]_n \cap D^1(\sigma))}{\lambda([\sigma]_n)} \geq 1/3$ and $\frac{\lambda([\sigma]_n \cap D^2(\sigma))}{\lambda([\sigma]_n)} \geq 1/3$ (this will occur sooner or later since all components of z are p-random). Once such input σ is found (with $[\sigma]_n \in \mathcal{D}(j)$ for some j), M places two $\epsilon/2$ bets on $\tau_1, \tau_2 \succ \sigma$ such that $[\tau_1]_n, [\tau_2]_n \in \mathcal{D}(j + 2)$, $[\tau_1]_n \subseteq [\sigma]_n \cap D^1(\sigma)$ and $[\tau_2]_n \subseteq [\sigma]_n \cap D^2(\sigma)$.

What is important in this construction is that for infinitely many i, both $D^1(Z{\restriction_i})$ and $D^2(Z{\restriction_i})$ contain two elements of $\mathcal{D}(i + 2)$ that are $\epsilon/2-$separated by μ and either $y \in \Phi(D^1(Z{\restriction_i}))$ or $y \in \Phi(D^2(Z{\restriction_i}))$.

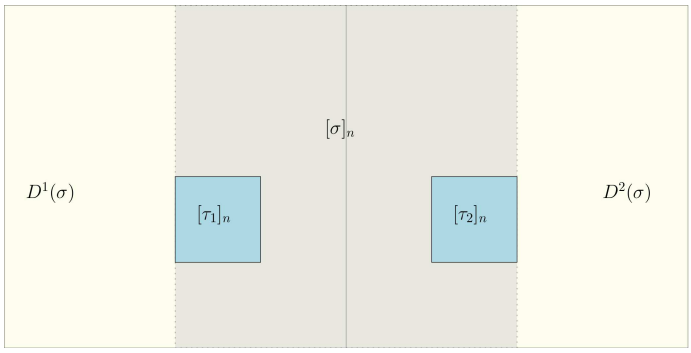

Figure 1 A particular betting pattern employed in the proof of the Theorem 22.

Clearly M is computable in polynomial time and Z is an $\epsilon/2-$oscillation point of M.

Consider the martingale M_Ω. By the Lemma 21, either $Y \in \mathbf{Osc}(M_\Omega)$ or Y is a p-porosity point. In both cases Y is not p-random. ◀

▶ Remark. There is an important implication of the above theorem. In those cases where we are only concerned whether some $x \in \mathbb{R}^n$ is p-random or not, we can always use the 1/3-shift trick freely. That is, since for every i, $x + 1/3e_i$ is p-random iff x is p-random, instead of x we can always consider a suitable shift of x. This will be used below, in the proof of our main result of this subsection.

▶ **Theorem 23.** *Let $\Omega : \mathbb{R}^n \to \mathbb{R}^n$ be a polynomial time computable linear isometry. Let $z \in [0,1]^n$. z is p-random iff $\Omega(z)$ is p-random.*

Proof. Since Ω^{-1} is polynomial time computable linear isometry as well, it is only required to show that if z is not p-random, then $\Omega^{-1}(z)$ is not p-random either. Again, we may assume $\Omega^{-1}(z) \in [0,1]^n$.

Let Z be the binary expansion of z. Let M be a bounded polynomial time computable martingale such that Z is an $\epsilon-$oscillation point of M for some $\epsilon > 0$. Define $\Phi = \Omega^{-1}$, let $y = \Phi(z)$ and let Y be the binary expansion of y.

Consider the martingale M_Ω and its corresponding measure μ_Ω. If y is an oscillation point of μ_Ω, Y is not p-random. Suppose y is not an oscillation point of μ_Ω.

There are infinitely many j, such that $\mathcal{D}_\Phi(j, y)$ and $\mathcal{D}_\Phi(j+1, y)$ are $\epsilon-$separated by μ_Ω. By the 1/3-shift trick and by Theorem 22, we may assume that for infinitely many such j's, $\mathcal{D}_\Phi(j, y)$ is contained in $\mathcal{D}^n(y, j - \hat{p})$ for some fixed $\hat{p}$. In that case, by the Lemma 21, Y is a p-porosity point and hence not p-random. ◀

4.3 Existence of directional derivatives

To prove our main result about directional derivatives, we need the following proposition:

▶ **Proposition 24.** *Let $f : \mathbb{R}^n \to \mathbb{R}$ be a polynomial time computable Lipschitz function. If $z \in \mathbb{R}^n$ is p-random, then $D_n f(z)$ exists.*

▶ Remark. The proof of the above proposition is a generalization of the proof of the $\Rightarrow$ direction of the Theorem 4 in [19]. The most technically challenging part required by the proof is the $\Leftarrow$ part of van Lambalgen's theorem for p-randomness. That is, we had to show that if there is an oracle martingale computable in polynomial time diverging on A while having an oracle access to B, then there is a martingale computable in polynomial time succeeding on $A \oplus_n B$.

▶ **Theorem 25.** *Let $f : \mathbb{R}^n \to \mathbb{R}$ be a Lipschitz function computable in polynomial time. Let $u \in V_p$ and let $x \in \mathbb{R}^n$ be p-random.*

The directional derivative $D_u f(x)$ exists.

Proof. Let $\Theta : \mathbb{R}^n \to \mathbb{R}^n$ be a change of basis map, such that $\Theta(e_1) = u$. We may assume it is computable in polynomial time. Define $z = \Theta^{-1}(x)$. By the Theorem 23, z is p-random too.

Define $g = f \circ \Theta$. g is a Lipschitz function computable in polynomial time. Then $D_u f(x) = D_1 g(z)$ and we know that $D_1 g(z)$ exists. ◀

4.4 Linearity of directional derivatives

Let $f : \mathbb{R}^n \to \mathbb{R}$ be a Lipschitz function computable in polynomial time. Recall that $N(f) \setminus N(V_p, f)$ is the set of points $x \in \mathbb{R}^n$ such that $D_v f(x)$ exists for all unit vectors v computable in polynomial time but f is not differentiable at x.

Let $u, v \in \mathbb{R}^n$. Define $D(f, u, v) \subseteq \mathbb{R}^n$ as the set of such x that $D_u f(x), D_v f(x)$ and $D_{u+v} f(x)$ exist, but

$$D_u f(x) + D_v f(x) \neq D_{u+v} f(x).$$

Since f is Lipschitz and V_p is dense in the set of unit vectors, it is known that

$$N(f) \setminus N(V_p, f) = \bigcup_{u,v \in V_p} D(f, u, v).$$

The following proposition is the last bit required to prove the Theorem 2:

▶ **Proposition 26.** *Let $f : \mathbb{R}^n \to \mathbb{R}$ be a Lipschitz function computable in polynomial time. Let $x \in \mathbb{R}^n$ with $X \in 2^\omega$ being its binary expansion. If $x \in N(f) \setminus N(V_p, f)$, then X is a p-porosity point.*

Abstract

The General Scheduling Problem (GSP) generalizes scheduling problems with sum of cost objectives such as weighted flow time and weighted tardiness. Given a set of jobs with processing times, release dates, and job dependent cost functions, we seek to find a minimum cost preemptive schedule on a single machine. The best known algorithm for this problem and also for weighted flow time/tardiness is an $O(\log \log P)$-approximation (where P denotes the range of the job processing times), while the best lower bound shows only strong NP-hardness. When release dates are identical there is also a gap: the problem remains strongly NP-hard and the best known approximation algorithm has a ratio of $e + \epsilon$ (running in quasi-polynomial time). We reduce the latter gap by giving a QPTAS if the numbers in the input are quasi-polynomially bounded, ruling out the existence of an APX-hardness proof unless $\mathsf{NP} \subseteq \mathsf{DTIME}(2^{\mathrm{polylog(n)}})$. Our techniques are based on the QPTAS known for the UFP-Cover problem, a particular case of GSP where we must pick a subset of intervals (jobs) on the real line with associated heights and costs. If an interval is selected, its height will help cover a given demand on any point contained within the interval. We reduce our problem to a *generalization* of UFP-Cover and use a sophisticated divide-and-conquer procedure with interdependent non-symmetric subproblems.

We also present a pseudo-polynomial time approximation scheme for two variants of UFP-Cover. For the case of agreeable intervals we give an algorithm based on a new dynamic programming approach which might be useful for other problems of this type. The second one is a resource augmentation setting where we are allowed to slightly enlarge each interval.

1 Introduction

The *General Scheduling Problem* (GSP) considers scheduling jobs with job dependent cost functions in a very general setting. We are given a single machine and a set of jobs J, where each job j has a release date $\rho_j \in \mathbb{N}$, a processing time $p_j \in \mathbb{N}$, and a cost function $f_j : \mathbb{N} \to \mathbb{N}_0 \cup \{\infty\}$ that is non-decreasing. The goal is to find a preemptive schedule on the machine that minimizes the total cost $\sum_{j \in J} f_j(C_j)$, where C_j is the completion time of job j in the computed schedule.

With arbitrary cost functions for the jobs, we have a lot of modeling power, which we believe makes the problem worth studying. In fact, we can model many scheduling objectives that were also studied separately, such as weighted flow time (each job j has weight w_j and $f_j(C_j) = w_j(C_j - \rho_j)$) or weighted tardiness (each job j additionally has a deadline d_j and $f_j(C_j) = \max\{w_j(C_j - d_j), 0\}$). The best known result for GSP is a $O(\log \log P)$-approximation [5] (where P denotes the range of the processing time) and no better polynomial time results are known for any of the mentioned special cases. The best known lower bound shows only strong NP-hardness [13] (even in the case without release dates), thus leaving a large gap compared to the $O(\log \log P)$-approximation. Even if all jobs have identical release dates there is a gap in our understanding: the best known results are a $(4 + \epsilon)$-approximation in polynomial time [11] and an $(e + \epsilon)$-approximation in quasi-polynomial time [12]. It is open whether this case is APX-hard. In this paper we settle the latter question: for GSP with identical release dates we present a QPTAS, i.e., a $(1 + \epsilon)$-approximation algorithm with a running time of $n^{\log(n)^{O(1)}}$ for any constant $\epsilon > 0$. This implies that the problem is *not* APX-hard, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(2^{\mathrm{poly}(\log n)})$.

In this extended abstract, many proofs and details had to be omitted due to space constraints.

1.1 General Scheduling Problem and UFP-Cover

For identical release dates, GSP is purely a sequencing problem, since a solution cannot profit from preempting jobs or leaving idle-time. Assuming that $\rho_j = 0$ for each j, the whole schedule finishes at time $T := \sum_j p_j$. Using the viewpoint from [5], we can see this problem as a covering problem. In any feasible solution, for each time t, we need that the total processing time of jobs finishing after time t is at least $D_t := T - t$. We can think of D_t as the *demand* of time point t. Now, we rephrase the problem as follows. For each job j select a completion time C_j such that for each t' the total processing time of the jobs unfinished at time t' is at least $D_{t'}$. We say that job j is *unfinished* or *active* during the interval $[0, C_j)$. An easy proof shows that, for each such choice of completion times, there exists a schedule in which every job j is finished by its completion time C_j [5].

An important special case arises when the cost function f_j of each job j attains only one of three values: zero in an interval $[0, r_j)$ (r_j should not to be confused with the release date $\rho_j = 0$), a job dependent value c_j in an interval $[r_j, d_j)$, and ∞ in $[d_j, \infty)$. In this setting, we can assume that the optimal solution selects either $[0, r_j)$ or $[0, d_j)$ to be the interval during which j is active. Moreover, we can simply remove p_j from the demand at each time $[0, r_j)$, which leaves as the only decision for j whether we pay c_j and cover p_j units of demand during $[r_j, d_j)$, or not. Thus, this special case can be reduced to the *Unsplittable Flow on a Path (UFP)-Cover* problem. In UFP-Cover, we are given a set of jobs J, each job described by a cost c_j, a size p_j, and the interval $[r_j, d_j)$ and, for each time point t, a demand D_t. The goal is to select a subset J' of the jobs such that, for each time point t, the total size of the jobs $j \in J'$ with $t \in [r_j, d_j)$ is at least D_t. Note that we do not

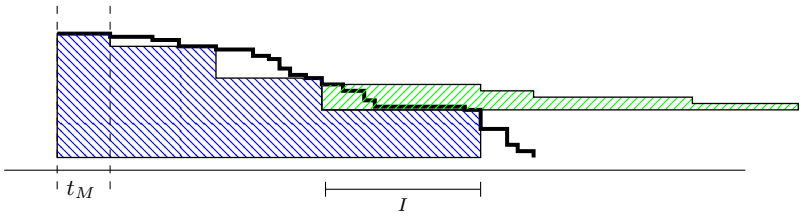

Figure 1 The bold curve denotes the size profile of job parts selected by the optimal solution that cross t_M. The blue step function shows an underestimating profile that approximates the former curve. The height of the green area (subprofile) is an (under-)estimation of the size of job parts in the optimal solution for all jobs that have a part covering t_M and whose right end point lies at interval I (i.e., the fourth step of the blue function).

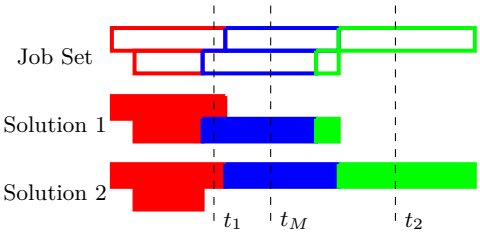
require that the demand function D_t is non-increasing (but by adding jobs of zero cost one could assume this w.l.o.g.). The best known results for UFP-Cover are a 4-approximation in polynomial time [6, 8] and a QPTAS which requires the input data to be quasi-polynomially bounded [12]. Since there is the QPTAS, it is natural to conjecture that also a PTAS exists. In this paper, we make progress towards this by presenting pseudo-polynomial time approximation schemes for the settings of agreeable intervals, i.e., when for any two jobs j, j' we have that $r_j \leq r_{j'} \Rightarrow d_j \leq d_{j'}$, and for a resource augmentation setting, where we are allowed to increase each given interval $[r_j, d_j)$ by a factor of $1 + \mu$ for an arbitrarily small $\mu > 0$ while the compared optimal solution cannot do this.

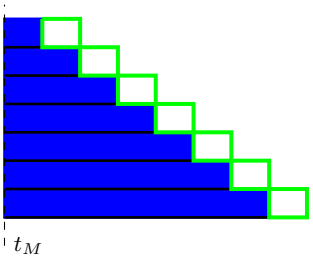
1.2 Our Contribution

Our first result is a QPTAS for GSP with identical release dates, assuming that all numbers in the input are quasi-polynomially bounded. We reduce GSP to a generalization of UFP-Cover. This *generalized UFP-Cover* problem is defined like regular UFP-Cover, but now each job j consists of K *parts*. More precisely, for each job j we are given an integral starting time r_j, a size p_j, up to K many integral end times $r_j < d_j^1 < d_j^2 < ... < d_j^K$, and corresponding accumulated costs $c_j^1, c_j^2, ..., c_j^K$. Jobs can be selected or not. If a job is not selected its cost is zero and it does not contribute to cover any demand. If job j is selected, we can choose to *extend it up to any part* $i \in \{1, \dots, K\}$, which means that then it is active during $[r_j, d_j^i)$. In this case we pay c_j^i for this job while it contributes to cover p_j units of demand to each time within $[r_j, d_j^i)$. The objective is to cover all demand D_t while minimizing the total cost. Notice that if $K = 1$ then we recover the UFP-Cover problem. On the other hand, we show that by losing a factor of $1 + \epsilon$ in the objective we can assume that $K = 1/\epsilon^2$.

Starting with this, we extend the known QPTAS for UFP-Cover, which works as follows. We consider the jobs crossing the middle time point t_M; denote them by J_M. They are split into $(\log n)^{O_\epsilon(1)}$ groups according to size and cost. For each group and each time t, we consider the total size of the jobs in the group crossing time point t in the optimal solution. This yields a function that is increasing from time 0 to time t_M, and decreasing from t_M to T. This function can be underestimated by a step-function (*profile*) with $O(1/\delta)$ (where $\delta = O_\epsilon(1)$) many steps (see the blue curve in Figure 1). One first guesses the step-function and then selects jobs that cover the demand given by this step-function greedily (which is essentially optimal). There is still some error due to the fact that the step-function underestimates the true amount that jobs in $\mathrm{OPT} \cap T_M$ cover on each time point. In the case of regular UFP-Cover, one can compensate this error by greedily selecting jobs that were not yet selected.



(a) Picking the blue part of the top job rules out Solution 1, while not picking it rules out Solution 2. Note that both solutions are incomparable since on t_1 and t_2 they cover different amounts of demand.



(b) Assume that the optimal solution selects all blue job parts (crossing t_M). Then there are still an exponential number of options for which jobs we should also select the green parts. Thus, we cannot take this decision immediately.

Figure 2 Locally Pareto-optimal choices.

In contrast to regular UFP-Cover, this approach fails for our generalization. We can think of each job as a collection of *parts* $[r_j, d_j^1), [d_j^1, d_j^2), ..., [d_j^{K-1}, d_j^K)$. The step function can only be guessed for the part that actually covers t_M. Yet, if we select that part, we need to pick all preceding parts of that job as well. This influences our options on the left side of t_M. On the other hand, if we do not pick the part that covers t_M of a certain job, succeeding parts of that job cannot be picked. This influences our options on the right side of t_M (see Figure 2a).

To address these issues we guess more fine-grained underestimating profiles. We group the jobs further such that for each job in a group the same part crosses t_M. Assume that for the jobs in the considered group their respective i-th part, $[d_j^{i-1}, d_j^i)$, covers t_M. We guess a *right underestimating profile* that estimates the total size covered to the right of t_M by these i-th parts that are selected by OPT. This profile partitions the jobs into subgroups according to the "step" of the profile in which the i-th part ends (see the green curve in Figure 1). For each of these constantly many groups we create a *subprofile* which underestimates the additional demand covered by the $(i+1)$-th parts of those jobs in OPT, i.e., by the intervals $[d_j^i, d_j^{i+1})$. We continue recursively and create underestimating subprofiles for all parts of the jobs, which gives a tree structure. We refer to this construction as *tree profiling*.

The tree profiling yields constantly many subgroups of jobs. For each of them we guess the number of jobs that the optimal solution selects (recall that the jobs in the same group have essentially the same size and cost). Then we recurse *only on the left* subproblem in which we want to cover the demand of the interval $[0, t_M)$ subject to the new constraint that from each subgroup we select the previously guessed number of jobs. Once we have a solution to this left subproblem, ideally we would like to decide how many parts of the jobs crossing t_M we select, i.e., the parts laying in the interval $[t_M + 1, T)$. Unfortunately, there can still be very many Pareto-optimal choices for this (see Figure 2b for an example). This can even happen when taking into account the information from the tree profiling. Instead, at this point we select for each job only the part that crosses t_M and we decide later about the additional parts we want to select. We recurse on the interval $[t_M + 1, T)$ and the remaining problem is to cover the demand of the interval $[t_M + 1, T)$ while we can select additional parts from the jobs that we selected already. In each subproblem we recurse on the respective middle time point, which yields a recursion depth of $O(\log n)$ and thus quasi-polynomial running time overall.

UFP-Cover for agreeable deadlines. Our second result is a pseudo-polynomial time $(1+\epsilon)$-approximation for UFP-Cover with agreeable deadlines. We first present an exact pseudo-polynomial time dynamic program (DP) for the case that the interval of each job is of the form $[0, d_j)$ or $[r_j, T)$, i.e., $r_j = 0$ or $d_j = T$. Then, we generalize this to the case where there are $1/\epsilon$ intervals $[T_0, T_1)$, $[T_1, T_2)$, ..., $[T_{1/\epsilon-1}, T_{1/\epsilon})$ and for each job j we have that $[r_j, d_j) \cap [T_\ell, T_{\ell+1})$ equals either $[r_j, T_{\ell+1})$ or $[T_\ell, d_j)$. Using the fact that the job deadlines are agreeable we can show that the time axis can be partitioned into a possibly superconstant number of intervals $[T_\ell, T_{\ell+1})$ with this property. By losing only a factor $1+\epsilon$ in the objective, we can split those into groups of at most $1/\epsilon$ consecutive intervals, each of which then yields an independent subinstance of our problem on which we apply our DP. The backbone of the latter is that the agreeable-deadlines property yields an ordering to process the jobs such that we need to remember only little information about the previously chosen jobs. We believe that this ordering and the resulting DP technique might be useful for other problems on agreeable intervals as well. Note that the opposite case where the job intervals form a laminar family has a simple exact DP. Thus, we can now handle the two "extreme" cases of the problem.

PTAS under resource augmentation. For UFP-Cover we present a pseudopolynomial time PTAS for the setting where we can enlarge each job interval $[r_j, d_j)$ by a factor $1+\mu$ for some $\mu > 0$, i.e., replace it by the interval $[r_j - \frac{\mu}{2}(d_j - r_j), d_j + \frac{\mu}{2}(d_j - r_j))$, while the compared optimal solution does not have this privilege. We use this resource augmentation to discretize the begin and end points of the intervals of the jobs. As in a similar result for UFP-packing [3], we group the jobs by the lengths of their intervals. In UFP-packing, the grouping can be done such that two jobs in different groups have intervals whose lengths differ by a large factor. Then each group can be handled almost independently. In our case we cannot establish such a property, since it requires the removal of some jobs from the input, which in turn may make our instance of UFP-Cover infeasible. Instead, our DP needs to transfer a lot of information between groups. The key for our approach is to prove that for each group it is sufficient to remember information from *one* previous group.

1.3 Other related work

The General Scheduling Problem can model a vast class of well-studied objective functions. The known $O(\log \log P)$-approximation for it [5], is even the best known result for several important special cases. For example, for the weighted flow time objective there were previously algorithms known with approximation ratios of $O(\log^2 P)$, $O(\log W)$ and $O(\log nP)$ [4, 10], where P and W denote the ranges of the job processing times and weights, respectively. Also, there is a QPTAS with a running time of $n^{O_\epsilon(\log P \log W)}$ [9].

For GSP with identical release dates the first constant factor approximation is due to Bansal and Pruhs [5] and yields an approximation ratio of 16. This was later improved to $4+\epsilon$ [11] by adapting ideas from the 4-approximation algorithm for UFP-Cover [6, 8]. For UFP-Cover this is the best known polynomial time result, while for quasi-polynomially bounded input numbers the problem even admits a QPTAS, implying a quasi-polynomial time $(e+\epsilon)$-approximation for GSP with identical release dates [12]. The used techniques are based on a QPTAS for the packing version of UFP [3]. For the latter algorithm, one can even remove the assumption that the input data is quasi-polynomially bounded [7]. The best known polynomial time results for UFP-packing are a $(2+\epsilon)$-approximation [1] and PTASs for some special cases [7].

2 QPTAS for GSP with identical release dates

We present our QPTAS for the General Scheduling Problem with identical release dates. Throughout this section we assume that all input numbers are quasi-polynomially bounded integers, and that we are given an $\epsilon > 0$ such that $1/\epsilon$ is an integer. We assume as well that we are given the number $f_{\max} = \max\{f_j(t) : f_j(t) \neq \infty, t \leq T\}$ as part of the input. First, we simplify the input such that the job cost functions attain only values that are powers of $1+\epsilon$ or ∞.

▶ **Lemma 1.** *By losing a factor $1+\epsilon$ in the objective, we can assume for each job j and each t that $f_j(t) \in \{(1+\epsilon)^k | k \in \mathbb{N}_0\} \cup \{0, \infty\}$ and that f_j is a non-decreasing step function with $O_\epsilon(poly(\log n))$ steps. We can further assume that each f_j is given explicitly, even if in the input it was given via an oracle.*

As in [5] we interpret GSP as a covering problem. Given a demand D_t for each interval $[t, t+1)$ and a set of jobs J. Each job $j \in J$ is characterized by a size p_j, a set of parts with corresponding intervals $I_j^1 = [t_j^{(0)}, t_j^{(1)}), I_j^2 = [t_j^{(1)}, t_j^{(2)})$, ... for $t_j^{(0)} \leq t_j^{(1)} \leq t_j^{(2)} \leq \dots$ and cost values $0 \leq c_j^1 < c_j^2 < \dots$. The goal is to select for each job j a prefix of its parts, i.e., a value $\sigma(j) \in \mathbb{N}_0$ such that all parts $k \leq \sigma(j)$ are selected. The cost for j is then $c_j^{\sigma(j)}$. Possibly $\sigma(j) = 0$ and then no part is selected, and thus we define $c_j^0 := 0$ for each job j. For a solution σ we say that a job j is *active* at time t if $t \in \cup_{i=1}^{\sigma(j)} I_j^i$. We require that for each t the total size of the jobs active at t is at least D_t, i.e., $\sum_{j : t \in \cup_{i=1}^{\sigma(j)} I_j^i} p_j \geq D_t$. The objective is to minimize the total cost $\sum_{j \in J} c_j^{\sigma(j)}$. We call this problem the *generalized UFP-Cover problem* (regular UFP-Cover is the special case where each job has only one part).

Using a similar argumentation as in [5] we can prove the following lemma.

▶ **Lemma 2.** *For any instance of GSP with identical release dates in which each cost function attains only polynomially many different values, we can construct in polynomial time an instance of generalized UFP-Cover such that approximations are preserved, i.e., for any $\alpha \geq 1$ an α-approximate solution for the generalized UFP-Cover instance can be transformed in polynomial time to an α-approximate solution for the GSP instance.*

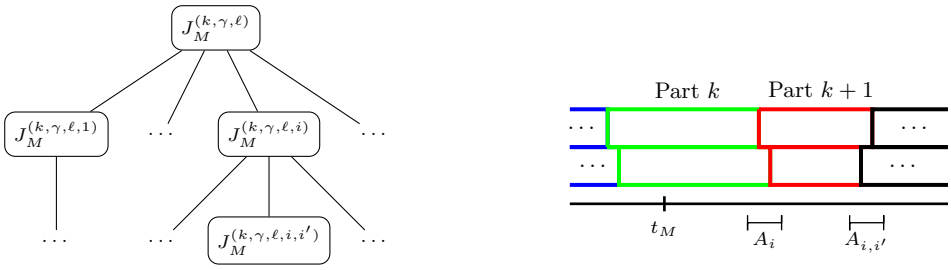
We apply Lemma 2 to reduce our given GSP instance to an instance of generalized UFP-Cover. Next, we ensure that each job has only $1/\epsilon^2$ parts.

▶ **Lemma 3.** *By losing a factor $1+\epsilon$ in the objective, we can assume that each job has at most $K := 1/\epsilon^2$ many parts, each value c_j^k is a power of $1+\epsilon$, and that $c_j^{k+1} = (1+\epsilon)c_j^k$ for each k.*

Assume w.l.o.g. that there is a value $T \leq \text{poly}(n)$ such that $I_j^k \subseteq [0, T)$ for each job j and each part k. Our algorithm is recursive. Let $t_M = \lceil \frac{T}{2} \rceil$ be the middle point of the interval $[0, T)$. The overall idea is to take a decision about the parts of jobs j that cover $[t_M, t_M + 1)$, i.e., such that $t_M \in I_j^k$ for some k, and then recursively decide on all job parts k' with $I_{j'}^{k'} \subseteq [0, t_M)$ (left subproblem) and k'' with $I_{j''}^{k''} \subseteq [t_M + 1, T)$ (right subproblem).

2.1 Tree profiling and grouping of jobs

Let $J_M \subseteq J$ denote the set of jobs j having a part k with $t_M \in I_j^k$. We partition J_M into a poly-logarithmic number of subsets according to their respective size, by the index of the



(a) Example of a tree $G^{(k,\gamma,\ell)}$. **(b)** Two jobs from group $J_M^{k,\gamma,\ell,i,i'}$.

Figure 3 Recursive partitioning of the jobs.

part that covers t_M, and by the cost of the latter. Formally, for numbers k, γ and λ we define sets

$$J_M^{(k,\gamma,\lambda)} := \{j \in J_M : t_M \in I_j^k,\ c_j^k = (1+\epsilon)^\gamma,\ \text{and } (1+\epsilon)^\lambda \le p_j < (1+\epsilon)^{\lambda+1}\}.$$

Consider one such group $J_M^{(k,\gamma,\lambda)}$. We want to partition it further. Let $\delta = \delta(\epsilon)$ be a small enough constant. First, we want to partition it into $O(1/\delta)$ subgroups $J_M^{(k,\gamma,\lambda,i)}$ such that: (i) OPT selects essentially the same number of jobs from each of these subgroups, and (ii) the k-th part of each job in the subgroup has a "similar" endpoint. Formally, we ensure the latter by partitioning the interval $[t_M, T)$ into subintervals $A_1, A_2, ...$ such that for each job j of a subgroup $J_M^{(k,\gamma,\lambda,i)}$ the k-th part ends in A_i (see Figure 3). Let $\bar{J}_M^{(k,\gamma,\lambda)}$ be the set of jobs $j \in J_M^{(k,\gamma,\lambda)} \cap OPT$ that OPT extends up to part k or further, i.e., for which OPT selects parts $I_j^1, ..., I_j^k$ and possibly more. To define our partition, we see that the respective k-th parts of the jobs in $\bar{J}_M^{(k,\gamma,\lambda)}$ cover some demand at each time point t, given by the function $\bar{f}_k(t) := \sum_{j \in \bar{J}_M^{(k,\gamma,\lambda)} : t \in I_j^k} p_j$. Observe that $\bar{f}_k$ is non-decreasing on $[0, t_M)$ and non-increasing on $[t_M, T)$. Ideally, we would like to guess $\bar{f}_k$ so that we have some idea about how much the k-th parts of the jobs in $J_M^{(k,\gamma,\lambda)}$ need to cover. Unfortunately, there are too many options on how $\bar{f}_k$ might look. Therefore, we guess $\left|\bar{J}_M^{(k,\gamma,\lambda)}\right|$ and a simpler underestimating function $\tilde{f}_k$ that approximates $\bar{f}_k$ sufficiently well, as given by the following lemma (see Figure 1). For our later purposes we need this function only on the interval $[t_M, T)$.

▶ **Lemma 4.** *There exists a function $\tilde{f}_k : [t_M, T) \to \{0, 1, ..., \sum_{j \in J} p_j\}$ such that $\tilde{f}_k$ is a step-function with at most $O(1/\delta)$ many steps, $\tilde{f}_k(t) \le \bar{f}_k(t) \le \tilde{f}_k(t) + \delta \cdot \left|\bar{J}_M^{(k,\gamma,\lambda)}\right| \cdot (1+\epsilon)^{\lambda+1}$, and $\tilde{f}$ is non-increasing.*

We use the function $\tilde{f}_k$ to split the set $J_M^{(k,\gamma,\lambda)}$ into subgroups, according to where the part k of each job $j \in J_M^{(k,\gamma,\lambda)}$ ends. Let $A_1, A_2, ...$ denote a partition of $[t_M, T)$ into $O(1/\delta)$ subintervals such that on each subinterval A_i the function $\tilde{f}_k$ is constant. For each such interval A_i we define $J_M^{(k,\gamma,\lambda,i)} \subseteq J_M^{(k,\gamma,\lambda)}$ to be the jobs $j \in J_M^{(k,\gamma,\lambda)}$ such that $(t_j^{(k)} - 1) \in A_i$ (recall that $I_j^k = [t_j^{(k-1)}, t_j^{(k)})$).

Subprofiles. It is convenient to think of a tree where $J_M^{(k,\gamma,\lambda)}$ forms the root node and the sets $J_M^{(k,\gamma,\lambda,i)}$ form the children of $J_M^{(k,\gamma,\lambda)}$. We take each such group $J_M^{(k,\gamma,\lambda,i)}$ and partition it further into $O(1/\delta)$ smaller subgroups $J_M^{(k,\gamma,\lambda,i,1)}, J_M^{(k,\gamma,\lambda,i,2)}, ...$ In the tree view, we can think of appending those as children to the node for the group $J_M^{(k,\gamma,\lambda,i)}$, see Figure 3. For

the subgroups, as before our goal is that OPT selects essentially the same number of jobs from each subgroup $J_M^{(k,\gamma,\lambda,i,i')}$ and that for each such subgroup the $(k+1)$-th part has a "similar" end point.

Recall that when we partitioned $J_M^{(k,\gamma,\lambda)}$ we estimated what the k-th part of the jobs in $J_M^{(k,\gamma,\lambda)} \cap OPT$ cover (via the function $\tilde{f}_k$) and obtained a grouping according to the steps of $\tilde{f}_k$. For the finer partitioning of $J_M^{(k,\gamma,\lambda,i)}$ we consider the jobs in $J_M^{(k,\gamma,\lambda,i)}$ for which OPT selects also the $(k+1)$-th part (and thus also the k-th part). Denote that set as $\bar{J}_M^{(k,\gamma,\lambda,i)}$. We define the function $\bar{f}_{k,i}(t)$ that models how much the k-th and the $(k+1)$-th parts of the jobs in $\bar{J}_M^{(k,\gamma,\lambda,i)} \cap OPT$ cover. Formally, $\bar{f}_{k,i}(t) := \sum_{j \in \bar{J}_M^{(k,\gamma,\lambda,i)} : t \in I_j^k \cup I_j^{k+1}} p_j$. We guess an underestimating function $\tilde{f}_{k,i}$ with the same properties as the function $\tilde{f}_k$ as given in Lemma 4, i.e., $\tilde{f}_{k,i}$ has $O(1/\delta)$ many steps, $\tilde{f}_{k,i}(t) \leq \bar{f}_{k,i}(t) \leq \tilde{f}_{k,i}(t) + O(\delta) \cdot |\bar{J}_M^{(k,\gamma,\lambda,i)}| \cdot (1+\epsilon)^{\lambda+1}$, and $\tilde{f}_{k,i}$ is non-increasing. Like before, the steps of $\tilde{f}_{k,i}$ yield a partition of $[t_M, T)$ into $O(1/\delta)$ many subintervals $A_{i,1}, A_{i,2}, \ldots$ such that $\tilde{f}_{k,i}$ is constant in each of them. Each such subinterval $A_{i,i'}$ yields a subgroup $J_M^{(k,\gamma,\lambda,i,i')}$ that contains all jobs $j \in J_M^{(k,\gamma,\lambda,i)}$ whose $(k+1)$-th part ends in $A_{i,i'}$, i.e., $(t_j^{(k+1)} - 1) \in A_{i,i'}$.

We continue recursively for K levels, expanding the tree accordingly. Analogous to before, we obtain for each node v in level k' of the tree (that is not a leaf), a subprofile function $\bar{f}_v$ and an approximate version $\tilde{f}_v$ such that $\tilde{f}_v(t) \leq \bar{f}_v(t) \leq \tilde{f}_v(t) + O(\delta) \cdot |\bar{J}_M^{(k,\gamma,\lambda,v)}| \cdot (1+\epsilon)^{\lambda+1}$, where $\bar{J}_M^{(k,\gamma,\lambda,v)}$ is the set of jobs in J_v that the optimum extends up to its $(k+k')$-th part. The leafs of the tree yield a partition of the job set, and the total number of nodes is $(1/\delta)^K$.

We can guess the whole partition in time $n^{(1/\delta)^{O(K)}}$ which will eventually be bounded by $n^{O_\epsilon(1)}$ (note that there are only $T \leq \text{poly}(n)$ options for each endpoint of an interval A_i or $A_{i,i'}$, etc.). In the same running time, we can guess for each arising group and subgroup the total number of jobs that OPT selects from these groups. More precisely, let $G^{(k,\gamma,\lambda)}$ be the resulting tree and for each node v denote by J_v the corresponding job group. For a node v on level k' we guess the value $N(v)$, the number of jobs in J_v that the optimum extends at least up to their respective $(k+k')$-th part.

We now bound the total demand deficit made by the underestimating functions. Let $f(t) = \sum_{j \in J_M^{(k,\gamma,\lambda)} : j \text{ active at } t \text{ in OPT}} p_j$ be the total size of jobs in $J_M^{(k,\gamma,\lambda)}$ that cover t in the optimal solution. We say that a solution is *concordant* with the tree $G^{(k,\gamma,\lambda)}$ and numbers $N(v)$ if, for each node v of each level k', the solution selects the $(k+k')$-th part of at least $(1+\epsilon)N(v)$ jobs in J_v, or of all jobs in J_v in case that $|J_v| < (1+\epsilon)N(v)$. As the next lemma shows, any tree concordant solution covers the demand at any point t almost as good as the optimal solution. The gap is bounded by $K \cdot \delta \cdot |\bar{J}_M^{(k,\gamma,\lambda)}| \cdot (1+\epsilon)^{\lambda+1}$ which is an upper bound on the sum of the deficits of all subprofiles relevant for a time point t. Here $\bar{J}_M^{(k,\gamma,\lambda)}$ is the subset of jobs in $J_M^{(k,\gamma,\lambda)}$ that OPT extends at least to the k-th part.

▶ **Lemma 5.** *Consider any solution concordant with tree $G^{(k,\gamma,\lambda)}$. The demand covered by such a solution at any time $t \in [t_M, T)$ is at least $f(t) - K \cdot \delta \cdot |\bar{J}_M^{(k,\gamma,\lambda)}| \cdot (1+\epsilon)^{\lambda+1}$.*

2.2 Fixing the demand deficit

We would like to recurse on the left and on the right subproblem, i.e., on $[0, t_M)$ and $[t_M + 1, T)$. We have guessed the correct number of jobs in each group but we have not decided yet which exact jobs from each group we want to select.

We deal with these issues as follows. Let us fix a tree $G^{(k,\gamma,\lambda)}$. We first consider any solution ALG that is concordant with the tree. By Lemma 5, this solution already covers almost all necessary demand, having a deficit of at most $\delta \cdot |\bar{J}_M^{(k,\gamma,\lambda)}| \cdot (1+\epsilon)^{\lambda+1}$ for every

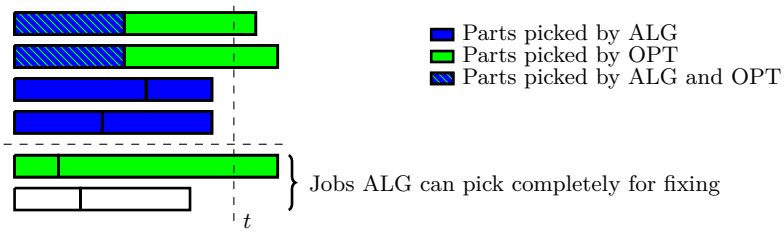


Figure 4 In contrast to the regular UFP-Cover Problem where selecting new jos is always sufficient, here this is not the case: even selecting all the new (bottom) jobs does not suffice to cover t! Instead, extending previously selected jobs is necessary.

time point in $[t_M, T]$. Even if we can fix this demand by adding more jobs (and we will, essentially, do so), picking an arbitrary concordant solution at this point will create issues for the left subproblem: nothing guarantees that the chosen solution we pick allows to cover the remaining demand within $[0, t_M)$ at a reasonable cost. To avoid this problem, we call the left subproblem recursively, giving the trees $G^{(k,\gamma,\lambda)}$ and numbers $N(v)$ for each node as input. We will require this problem to give us a solution ALG that is concordant with the tree for each group $J_M^{(k,\gamma,\lambda)}$ and that satisfies all demand at $[0, t_M)$. The exact way of solving this left subproblem is given in the next subsection. We call a solution constructed this way a *left-feasible* solution.

Consider now a left-feasible solution ALG and fix a tree $G^{(k,\gamma,\lambda)}$. The idea is to fix the deficit in $[t_M, T)$ by adding jobs picked greedily. As a first approach we could consider the following method: within all jobs in $J_M^{(k,\gamma,\lambda)}$ not active at t_M, pick the $\delta|\bar{J}_M^{(k,\gamma,\lambda)}|(1+\epsilon)$ ones that extend furthest to the right when all of their K parts are chosen. We denote by $H^{(k,\gamma,\lambda)}$ the set of these jobs. For any timepoint t that is covered by all these jobs, we will cover the whole deficit. Also, we can show that total incurred cost is at most an ϵ-fraction of the cost of $\mathrm{OPT} \cap \bar{J}_M^{(k,\gamma,\lambda)}$. One might be tempted to conclude that we are done: since we picked the jobs greedily, a time point t that is not covered by all jobs in $H^{(k,\gamma,\lambda)}$ cannot be covered by any other job that we did not make active at t_M. This is indeed enough to argue in the regular UFP-Cover problem [12]. However, the argument fails in our setting as we might still be able to further extend some jobs that our solution picks to cover t_M but not are not extended to cover t; see Figure 4.

To solve this issue we truncate ALG by removing for each group $J_M^{(k,\gamma,\lambda)}$ and each job $j \in J_M^{(k,\gamma,\lambda)}$ all parts that do not cover any point $t \in [0, t_M + 1)$. Let ALG_M be the truncated solution. We show that ALG_M plus all parts of all jobs in $H^{(k,\gamma,\lambda)}$ can be extended (by adding more parts, not necessarily like ALG) to a solution that covers all required demand and costs at most a $1+\epsilon$ factor more than OPT. The constructed solution covers all demand at times $[0, t_M + 1)$ and we will solve the remaining problem in the right subproblem.

To make this idea formal, denote by OPT_M the solution obtained by taking OPT and removing from it all parts I_j^k such that $I_j^k \subseteq [t_M + 1, T)$. For any left-feasible solution S we say that a solution S' is an *extension* of S if for each job j the solution S' extends j up to at least as many parts as S.

▶ **Lemma 6.** *Assume that $1/\delta = K \cdot \epsilon(1+\epsilon)^{O(K)}$. Suppose we are given the left-feasible truncated solution ALG_M. Then we can compute in polynomial time a set of jobs $H \subseteq J_M$ such that*

- *if we select all parts of each job in H this yields a total cost of at most $O(\epsilon) \cdot c(\mathrm{OPT}_M)$, and*
- *for the solution $ALG_M \cup H$ there is an extension ALG' such that $c(ALG') - c(ALG_M \cup H) \leq c(\mathrm{OPT}) - c(\mathrm{OPT}_M)$.*

Proof Sketch. Consider a set $J_M^{(k,\gamma,\lambda)}$. We consider all jobs of this set that are not covering t_M in ALG and sort them non-increasingly with respect to the right endpoint of I_j^K. Let $H^{(k,\gamma,\lambda)}$ be the set of the first $K \cdot \delta |\bar{J}_M^{(k,\gamma,\lambda)}|(1+\epsilon)$ such jobs and define $H = \cup_{k,\gamma,\lambda} H^{(k,\gamma,\lambda)}$. Notice that extending all parts of jobs in $H^{(k,\gamma,\lambda)}$ incurs a cost of at most $K \cdot \delta(1+\epsilon)^{K+1}(1+\epsilon)^{\gamma}|\bar{J}_M^{(k,\gamma,\lambda)}|$. By choosing the constants in the definition of δ appropriately we obtain that the cost is $O(\epsilon) \cdot c(\bar{J}_M^{(k,\gamma,\lambda)})$. Summing over all triplets k, γ, λ yields the desired bound on the total cost of H.

For a given set $H^{(k,\gamma,\lambda)}$, out of all right endpoints of jobs in the set, call τ_R the one most to the left. Inside the interval $[t_M, \tau_R)$ the jobs in $H^{(k,\gamma,\lambda)}$ cover at least $K(1+\epsilon)^{\lambda+1}\delta|\bar{J}_M^{(k,\gamma,\lambda)}|$, and thus they cover all deficit left by the solution ALG (or any other tree concordant solution). On the other hand, for any $t > \tau_R$ our greedy choice for $H^{(k,\gamma,\lambda)}$ guarantees that *all* jobs in $J_M^{(k,\gamma,\lambda)}$ that can be extended to cover t are taken at least up to their k-th part in $ALG_M \cup H$. This allows us to construct the claimed extension ALG' of $ALG_M \cup H$: we start with ALG and transform it step by step to make it resemble the optimal solution. Note that this is a purely existential result since we need to know the optimal solution for this procedure. ◀

2.3 Left subproblem

Suppose that via recursion we have computed a left-feasible solution ALG. Then, using Lemma 6 we compute the jobs H such that $c(H) \leq O(\epsilon) \cdot c(OPT_M)$ and such that the extension ALG' is guaranteed to exist. In order to compute (an approximation to) ALG' we recurse on the right subproblem, given by the interval $[t_M + 1, T)$.

For each $t \in [t_M + 1, T)$ we update the demand D_t to take into account that we already selected some job parts crossing t_M and the jobs in H. Formally, we define the new demands as $D'_t := D_t - \sum_{j:t\in\tilde{J}(t)} p_j$ where $\tilde{J}(t)$ denotes the set of jobs j such that $ALG_M \cup H$ contains a part of j that covers t. For each job j such that ALG_M selected the part I_j^k covering t_M, our subproblem only has the parts of j that lie completely within $[t_M + 1, T)$. We update their cost, taking into account that the left subproblem has already paid c_j^k for it, i.e., the cost value $\bar{c}_j^{\ell-k}$ for each new part $\ell - k$ is set to $\bar{c}_j^{\ell-k} = c_j^{\ell} - c_j^k$. This yields an instance of our problem on the interval $[t_M + 1, T)$ whose size is only half the size of the original interval $[0, T)$. Strictly speaking, the new costs might no longer be a power of $1 + \epsilon$. However, note that the adjustment of costs means that $\bar{c}_j^1 = c_j^{k+1} - c_j^k = \epsilon c_j^1$. Therefore, the costs of any two parts of a job still differ by at most a constant factor and the new cost values come from a set of size $O(\text{poly}(\log n))$ (which is important to bound the number of job groups $J_M^{(k,\gamma,\lambda)}$) . Moreover, this factor does not increase further in the recursion and hence we can recurse one the right subproblem with essentially the same routine as above.

It remains to describe how to recurse on the left subproblem for the interval $[0, t_M)$. Formally, this subproblem is defined as follows: we are given the interval $[0, t_M)$ together with the demand D'_t for each point $t \in [0, t_M)$ (the updated demand). Also, for each tree $G^{(k,\gamma,\lambda)}$ and each vertex v we are given a corresponding group of jobs J_v. Additionally we have to consider the set of all input jobs j such that no part of j crosses t_M - we refer to this set of jobs as J_L. Finally, for each group J_v we are given a value $N(v)$ that indicates that for at least $(1 + \epsilon)N(v)$ jobs in J_v we have to select the respective part that crosses t_M.

Our objective is to find a solution for jobs in $J_L \cup \bigcup_{k,\gamma,\lambda} J^{(k,\gamma,\lambda)}$ that covers all demand in $[0, t_M)$ and that is concordant for each tree. To have a cleaner subproblem, we observe that the leaves of $G^{(k,\gamma,\lambda)}$ imply a *partition* of the jobs of $J^{(k,\gamma,\lambda)}$ into subgroups. For each of them we guess how many jobs the optimal solution selects from the subset corresponding to that leaf. Then for each of them we require that the left subproblem selects either a factor

$1+\epsilon$ more jobs or all jobs from that subset. The resulting solution can easily be transformed into a concordant solution.

We consider the point $t'_M := \lceil \frac{t_M}{2} \rceil$. Like above, we partition the jobs into groups according to which part of them crosses t'_M. However, we do this separately for J_L and each subgroup of jobs crossing t_M. For each resulting separate group, we guess the profiles and recursive subprofiles as before. Once we have guessed this partition of the jobs together with the required number of jobs of each group, we recurse on the left-left problem, i.e., on the problem for the interval $[0, t'_M)$. When we obtained a solution for the left-left subproblem in the interval $[0, t'_M)$ we recurse further on the interval $[t'_M, t_M)$. For this left-right subproblem, we update the cost of the jobs whose respective parts crossing t'_M were selected by the left-left subproblem (like we did when we defined the right subproblem of the interval $[t_M + 1, T)$) and additionally impose the constraint that from each group J_v (as defined by the main subproblem for the interval $[0, T)$) for at least $(1+\epsilon)N(v)$ jobs we select the respective part crossing t_M.

Number of groups. We continue recursively in the same fashion. In the recursion, the number of job groups we pass to each subproblem increases since from the main subproblem for the interval $[0, T)$ we are given a partition into subgroups and whenever we recurse on a left subproblem these subgroups are partitioned further and also new subgroups are defined. However, we can show that in each step of the recursion the total number of arising subgroups is bounded by $(\frac{1}{\epsilon^2} \log n)^{O(K)}$.

▶ **Lemma 7.** *In the input of each subproblem arising in the recursion, the jobs are partitioned into at most* $(\frac{1}{\epsilon^2} \log n)^{O(K)}$ *different groups.*

Whenever we are given a subproblem on some interval I' then we guess subgroups and certain values with a quasi-polynomial number of options in total and we recurse on two subproblems, given by subintervals of I' whose size is half the size of I'. Thus, the recursion tree has a depth of $O(\log T) = O(\log n)$ and each internal node of the tree has at most quasi-polynomially many children. Hence, our algorithm has quasi-polynomial running time overall.

▶ **Theorem 8.** *There are quasi-polynomial time* $(1+\epsilon)$*-approximation algorithms for the general scheduling problem and for the generalized UFP-Cover problem, assuming that all input values are quasi-polynomially bounded integers.*

3 Agreeable Instances

In this section we present our pseudopolynomial-time $(1+\epsilon)$-approximation algorithm for the UFP-Cover problem on agreeable instances. We first show how to partition a given instance into smaller subinstances (Section 3.1). Then we then present our algorithm for a special type of subinstances (Section 3.2).

For simplicity of presentation, we will assume throughout this section w.l.o.g. that each integer timepoint t is associated with a demand D_t and that we only need to cover the demands at such timepoints. Furthermore, we assume w.l.o.g. that the the intervals defined by the release-time and deadline of each job are closed, i.e., have the form $[r_j, d_j]$. We also assume that all elements of the set $U := \cup_j \{r_j, d_j\}$ are disjoint. To simplify the presentation, we further assume w.l.o.g. that all elements of U are even integers.

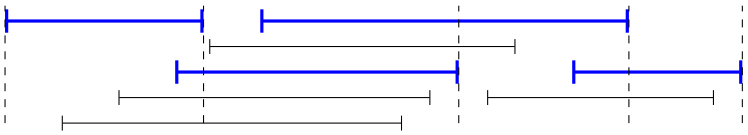

Figure 5 The thick blue jobs are the pivotal jobs, and the dashed vertical lines define the intervals. It is helpful to think of r_j for the first pivotal job j as the start point of the first interval.

3.1 Preprocessing & Preliminary Observations

We partition the time-horizon into intervals. We may assume that there is no timepoint throughout $[0, T]$ that is not covered by any job, since then we could easily seperate the instance at this timepoint into two independent subinstances. For our partitioning we inductively introduce a set of *pivotal jobs* P.

▶ **Definition 9.** The first pivotal job is the job with earliest start time r_j. We define the other pivotal jobs by induction. Assume that we have defined the first k pivotal jobs $j_1, ..., j_k$. Then the $(k+1)$-th pivotal job is the job with latest start time among all jobs j with $r_j \leq d_{j_k}$.

We use the end points of the pivotal jobs in order to partition the time horizon into intervals $\mathcal{I}$. More formally, we partition the time horizon into intervals at timepoints $X := \{d_j : j \in P\} \cup \{0\}$. Let $T_0, T_1, \cdots$ be the timepoints in X in increasing order. Then each interval in $\mathcal{I}$ is of the form $[T_k, T_{k+1}]$ for some $k \in \mathbb{N}$. See Figure 5 for an example.

▶ **Lemma 10.** *The $[r_j, d_j]$-interval of any non-pivotal job intersects at most one timepoint of X. The $[r_j, d_j]$-interval of any pivotal job intersects at most two timepoints of X.*

Next, we cut the instance into subinstances so that each subinstance contains at most q many intervals (in our final algorithm we will set $q = O(1/\epsilon)$). We do this in a randomized fashion but the procedure can be easily derandomized, similar to, e.g., [2]. Let x be a random variable that takes its value uniformly at random among the integers $\{0, 1, 2, \ldots, q-1\}$. We "cut" the instance into subinstances at timepoints $W := \{T_x, T_{x+q}, T_{x+2q}, \ldots\}$. Let each subinstance $I_i := [T_{x+iq}, T_{x+(i+1)q}]$ contain all jobs j whose interval $[r_j, d_j]$ intersects I_i. Jobs j whose intervals $[r_j, d_j]$ span two consecutive subinstances I_i and I_{i+1} are split into two jobs: a job j' with $r_{j'} := r_j, d_{j'} := T_{x+iq}, p_{j'} := p_j, c_{j'} := c_j$, and a job j'' with $r_{j''} := T_{x+iq}, d_{j''} := d_j, p_{j''} := p_j, c_{j''} := c_j$.

Note that the choice of x can be derandomized by trying out all q possible choices for x and selecting the best one. For the obtained division into subinstances we prove the following lemma.

▶ **Lemma 11.** *An exact algorithm with running time $O(f(n))$ for a subinstance containing at most q consecutive intervals from $\mathcal{I}$ yields a $(1 + 2/q)$-approximation algorithm for the original instance, with a running time of $O(n \cdot f(n))$.*

We give a pseudopolynomial-time exact algorithm for the problem on instances with $q = O(1/\epsilon)$ many consecutive intervals. The algorithm is based on dynamic programming. Due to space constraints in the main body of the paper we only present a simpler version of our DP for the case $q = 1$ in Subsection 3.2.

3.2 Solving a subinstance with only one interval

Assume that we are given a subinstance consisting of only one interval I_i. We form a partition $J_L \dot{\cup} J_R$ for the jobs whose $[r_j, d_j]$-interval intersects this interval I_i. The set J_L is the set of

all jobs j such that $d_j \in I_i$, and J_R is the set of such jobs j such that $r_j \in I_i$. By Lemma 10, $J_L \dot\cup J_R$ comprises the whole set of jobs j such that $[r_j, d_j] \cap I \neq \emptyset$. We now define a set of relevant timepoints M for our interval I_i as $M := (U \cap I_i)$, where $U := \{r_j, d_j | j \in J\}$ is the set of all globally relevant timepoints.

Let us consider this set ordered from left to right, so that $M = \{t_1, t_2 \dots t_k\}$. We fill out the table of our dynamic program in a bottom-up fashion by considering these timepoints in reverse order, that is from right to left. Each cell of the dynamic programming table has the form $T[t_z, b, i_L, c_L, c_R]$. Intuitively, it describes the subproblem of covering the demand on the subinterval $[t_z, t_k]$ by a set of jobs $J'_L \subseteq J_L$ having their respective deadline in $[t_z, t_k + 1]$ with $p(J'_L) := \sum_{j \in J'_L} p_j = i_L$ and $c(J'_L) := \sum_{j \in J'_L} c_j = c_L$, and by a set of jobs $J'_R \subseteq J_R$ having their respective release dates in $[t_z, t_k + 1]$ with $c(J'_R) = c_R$. The demand at each point $t \in [t_z, t_k]$ is $D_t - b$, i.e., the reader may imagine that some other routine of the global algorithm selects jobs with a total size of b that cover each point in $[t_z, t_k]$.

Formally, this DP cell is filled out with a "yes" if and only if there exist two sets $J'_L \subseteq J_L$ and $J'_R \subseteq J_R$, such that:

(i) for each job $j \in J'_R$, there holds $r_j \geq t_z$, and for each job $j \in J'_L$ there holds $d_j \geq t_z$,
(ii) $p(J'_L) = \sum_{j \in J'_L} p_j = i_L$ and $c(J'_L) = \sum_{j \in J'_L} c_j = c_L$,
(iii) $c(J'_R) = c_R$, and
(iv) $\forall \ell : z \leq \ell \leq k, \sum_{j \in J'_L \cup J'_R : [r_j, d_j] \ni t_\ell} p_j \geq D_{t_\ell} - b$.

Filling out the table. We fill out the table starting with all entries for the rightmost timepoint t_k. First, we fill in $T[t_k, b, i_L, c_L, c_R]$ for all possible values of $0 \leq i_L \leq \sum_j p_j$, $0 \leq c_L, c_R \leq \sum_j c_j$, and $0 \leq b \leq \sum_{j \in J_R} p_j$. Note that for such a cell only the pivotal job j_p of the interval is relevant since no other job can have its release date or deadline at t_k. For filling in the entry it suffices to consider the two possibilities of selecting j_p and not selecting j_p.

Assume now that we have filled in all cells corresponding to timepoints from t_{z+1} to t_k and we want to fill in the entries for t_z. The timepoint t_z is the start or the end point of a job j that either belongs to J_L or to J_R. The entries for t_z in our dynamic programming table depend on the set to which j belongs to, and on whether j is added to the solution. Formally, if $j \in J_R$, then $T[t_z, b, i_L, c_L, c_R]$ = "yes" if and only if $T[t_{z+1}, b, i_L, c_L, c_R]$ = "yes" and $i_L + b \geq D_{t_z}$ or if $T[t_{z+1}, b + p_j, i_L, c_L, c_R - c_j]$ = "yes" and $i_L + b + p_j \geq D_{t_z}$. So either we do not add j to the solution, and then we need to cover the demand at t_z with the jobs already selected for t_{z+1}, or we add j to the solution, and then we can add its size to the respective b-entry at t_{z+1}. Symmetrically, if $j \in J_L$, then $T[t_z, b, i_L, c_L, c_R]$ = "yes" if and only if we have that $T[t_{z+1}, b, i_L, c_L, c_R]$ = "yes" and $i_L + b \geq D_{t_z}$ or if $T[t_{z+1}, b, i_L - p_j, c_L - c_j, c_R]$ = "yes" and $i_L + b \geq D_{t_z}$.

By keeping track of the respective sets J_L and J_R in each cell we are able to reconstruct our solution starting from the cell of the form $T[t_1, 0, i_L, c_L, c_R]$ that minimizes $c_L + c_R$ among all such cells with a "yes"-entry. Our dynamic program requires pseudopolynomial running time, because the considered possible values for c_L, c_R, i_L and b are pseudopolynomial in the input size. It returns an exact solution to the given problem. We are able to generalize these ideas to subinstances with $O(1/\epsilon)$ many intervals, and thus prove the following theorem.

▶ **Theorem 12.** *There is a pseudopolynomial-time $(1 + \epsilon)$-approximation algorithm for the UFP-Cover problem on agreeable instances.*

Abstract

We consider the *MST-interdiction* problem: given a multigraph $G = (V, E)$, edge weights $\{w_e \geq 0\}_{e \in E}$, interdiction costs $\{c_e \geq 0\}_{e \in E}$, and an interdiction budget $B \geq 0$, the goal is to remove a set $R \subseteq E$ of edges of total interdiction cost at most B so as to maximize the w-weight of an MST of $G - R := (V, E \setminus R)$.

Our main result is a 4-approximation algorithm for this problem. This improves upon the previous-best 14-approximation [31]. Notably, our analysis is also significantly simpler and cleaner than the one in [31]. Whereas [31] uses a greedy algorithm with an involved analysis to extract a good interdiction set from an over-budget set, we utilize a generalization of knapsack called the *tree knapsack problem* that nicely captures the key combinatorial aspects of this "extraction problem." We prove a simple, yet strong, LP-relative approximation bound for tree knapsack, which leads to our improved guarantees for MST interdiction. Our algorithm and analysis are nearly tight, as we show that one cannot achieve an approximation ratio better than 3 relative to the upper bound used in our analysis (and the one in [31]).

Our guarantee for MST-interdiction yields an 8-approximation for *metric-TSP interdiction* (improving over the 28-approximation in [31]). We also show that *maximum-spanning-tree interdiction* is at least as hard to approximate as the minimization version of densest-k-subgraph.

1 Introduction

Interdiction problems are a broad class of optimization problems with a wide range of applications. They model the problem faced by an attacker, who given an underlying, say, minimization, problem, aims to destroy or *interdict* the elements involved in the optimization problem (e.g., nodes or edges in a network-optimization problem) without exceeding a given interdiction budget, so as to maximize the optimal value of the residual optimization problem (where one cannot use the interdicted elements). A classical example is the *minimum-spanning-tree (MST) interdiction* problem [22, 9, 31], which is the focus of this work: we are

* A full version of the paper is available at https://arxiv.org/abs/1706.00034.

given a multigraph $G = (V, E)$, edge weights $\{w_e \geq 0\}_{e \in E}$, interdiction costs $\{c_e \geq 0\}_{e \in E}$, and an interdiction budget $B \geq 0$; the goal is to interdict (i.e., remove) a set $R \subseteq E$ of edges of total interdiction cost at most B so as to maximize the w-weight of an MST of the multigraph $G - R := (V, E \setminus R)$. Note that G may have parallel edges, which can be useful in modeling partial-interdiction effects, wherein interdicting an edge causes an increase in its weight that depends on the interdiction cost incurred for the edge.

At a high level, interdiction problems can be seen as investigating the sensitivity of an underlying optimization problem with respect to the removal of a limited set of underlying elements. This type of sensitivity analysis may be utilized to identify vulnerable spots (e.g., regions in a network) either: (a) for possible reinforcement, or, (b) if the optimization problem models an undesirable process (e.g., the spread of infection, or nuclear-arms smuggling), for disruption, so as to maximally impair the underlying process. A variety of applications of interdiction problems ensue from these two perspectives, including infrastructure protection [5, 27], hospital-infection control [1], prevention of nuclear-arms smuggling [24], and military planning [11] (see also the references in [31]). Consequently, interdiction problems have been extensively studied, especially in the Operations Research literature; besides MST-interdiction, some well-studied interdiction problems include network-flow interdiction [25, 28, 2, 30, 13, 3], shortest s-t path interdiction [10, 14, 17, 20], and maximum-matching interdiction [29, 6]. All these problems, as well as MST-interdiction, are *NP*-hard.

Our results. Our main result is a 4-approximation algorithm for MST interdiction (Theorem 7), i.e., we compute in polytime a solution of value at least (optimum)/4. This is a substantial improvement over the previous-best approximation ratio of 14 obtained by Zenklusen [31].

Notably, and perhaps more importantly, our algorithm is simple, and its analysis is significantly simpler and cleaner than the one in [31]. The key ingredient (see also "Our techniques") of both our algorithm and the one in [31] is a procedure for extracting a good interdiction set from one that exceeds the interdiction budget. Whereas [31] uses a greedy algorithm with a rather involved analysis to achieve this, our simple and more-effective procedure is based on two chief insights. First, we discern that the key combinatorial aspects of this "extraction problem" can be captured quite nicely via a clean generalization of the knapsack problem called the *tree knapsack problem* [15] (Section 3). In particular, we argue that approximation guarantees for tree knapsack *relative to the natural LP for this problem* translate directly to guarantees for MST interdiction. Second, complementing the above insight, we show that the tree knapsack problem admits a simple *iterative-rounding* based algorithm that achieves a strong LP-relative guarantee (Theorem 4, Corollary 6). Our improved guarantee for MST interdiction then readily follows by combining these two ideas.

We also show a lower bound of 3 (Theorem 16) on the approximation ratio achievable relative to the upper bound used in our analysis (and the analysis in [31]), thereby showing that our algorithm and analysis are nearly tight.

Our MST-interdiction result also yields an improved guarantee for the *metric-TSP interdiction* problem (Section 5): given *metric* edge weights $\{w_e\}$, we now seek an interdiction set R with $\sum_{e \in R} c_e \leq B$ so as to maximize the minimum w-weight of a closed walk in $G - R$ that visits all nodes at least once. Since an α-approximation for MST interdiction yields a 2α-approximation for metric-TSP interdiction [31], we obtain an approximation factor of 8 for metric-TSP interdiction, which improves upon the previous-best factor of 28 [31].

In Section 6, we consider the *maximum-spanning-tree interdiction* problem, where the goal is to *minimize the maximum w-weight of a spanning tree of $G - R$*. We show that this problem is at least as hard to approximate as the minimization version of the *densest-k-subgraph* problem (MinDkS). MinDkS does not admit any constant-factor approximation under certain less-standard complexity assumptions [26] (and is believed to have a larger inapproximability threshold), so this highlights a stark contrast with the MST-interdiction problem.

Our techniques. We give an overview of our algorithm for MST interdiction. Let $\mathrm{val}(R)$ be the w-weight of an MST of $G - R$. Using standard arguments, we can reduce the problem to the following setting (see Section 2 and Theorem 3): we are given interdiction sets $R_1 \subseteq R_2$ with $c(R_1) < B < c(R_2)$ such that $a \cdot \mathrm{val}(R_1) + b \cdot \mathrm{val}(R_2) \geq OPT$, where OPT is the optimal value and $a, b \geq 0$ are such that $a + b = 1$ and $a \cdot c(R_1) + b \cdot c(R_2) = B$. These arguments resemble the ones in [31], but we do not need to assume that the w_e weights are powers of 2. (We emphasize however that this by itself is not the chief source of our improvement.) The technical meat of the algorithm, and where we diverge significantly from [31] to obtain our improved guarantee, is to show how to extract a good interdiction set from R_1, R_2. As mentioned earlier, we replace the greedy algorithm of [31] for extracting a good interdiction set from R_2, and its associated intricate analysis, by considering the tree-knapsack problem to capture the key aspects of this extraction problem, and devise a simple iterative-rounding algorithm that yields a strong LP-relative guarantee for tree knapsack. This conveniently translates to a much-improved 5-approximation algorithm for MST interdiction (Theorem 13). The further improvement to a 4-approximation arises by also leveraging R_1 to find a good interdiction set: instead of focusing solely on R_2 (as done in [31]), we return an interdiction set R such that $R_1 \subseteq R \subseteq R_2$ (see Section 4.1).

To arrive at the tree knapsack problem, observe that $\mathrm{val}(R)$ can be conveniently expressed as a weighted sum of the number of components of $(V, \{e \in E \setminus R : w_e \leq t\})$, where t ranges over some distinct edge weights, say, $0 \leq w_1 < \cdots < w_k$ (Lemma 2). Let $\mathcal{A}_0$ denote the components of $(V, E_{\leq 0} := \emptyset)$, and $\mathcal{A}_i$ denote the components of $(V, E_{\leq i} := \{e \in E \setminus R_2 : w_e \leq w_i\})$ for $i = 1, \ldots, k$. The multiset $\bigcup_{i=0}^{k} \mathcal{A}_i$ forms a laminar family, which can be viewed as a rooted tree. We seek to build our interdiction set R by selecting a suitable collection of sets from this laminar family, ensuring that if we pick a component $A \in \mathcal{A}_i$ then $\delta(A) \cap E_{\leq i}$ is included in R (so that A is a component of $(V, E_{\leq i} \setminus R)$). Whereas $\mathrm{val}(R)$ is nicely *decoupled* across the selected components, it is harder to decouple the interdiction cost incurred and account for it. For instance, summing $c\big(\delta(A) \cap E_{\leq i}\big)$ for the selected $A \in \mathcal{A}_i$ may grossly overestimate the interdiction cost, whereas summing $c\big(\delta(A) \cap \{e : w_e = w_i\}\big)$ for the selected $A \in \mathcal{A}_i$ *underestimates* the interdiction cost. A crucial insight is that, if we ensure that *whenever we pick $A \in \mathcal{A}_i$, we also pick its children in the laminar family*, then *summing $c\big(\delta(A) \cap \{e : w_e = w_i\}\big)$ for the selected $A \in \mathcal{A}_i$ is a good proxy for the interdiction cost incurred.*

This motivates the definition of the tree knapsack problem: given a rooted tree Γ with node values $\{\alpha_v\}$, node weights $\{\beta_v\}$, and budget B, we want to pick a maximum-value *downwards-closed* set of nodes (not containing the root) whose weight is at most B, where downwards-closed means that if we pick a node, then we also pick all its children. The standard knapsack problem is thus the special case where Γ is a star (rooted at its center). We consider the natural LP (TK-P) for tree knapsack, and generalizing a well-known result for knapsack, show that we can efficiently compute a solution of value at least $OPT_{\text{TK-P}} - \max_{\text{chains } C} \sum_{v \in C} \alpha_v$ (Theorem 4), where a chain is a subset of a root-leaf path.

Finally, we show that for the tree-knapsack instance derived (as above) from R_2, $OPT_{\text{TK-P}}$ is "large" (Lemma 10); combining this with the above bound yields our approximation ratio.

Related work. MST interdiction in its full generality seems to have been first considered by [22], who showed that the problem is *NP*-hard. The approximation question for MST interdiction was first investigated by [9]. They focused on the setting with unit interdiction costs, often called the *B-most-vital-edges* problem, showed that this special case remains *NP*-hard, and obtained an $O(\log B)$-approximation (which also yields an $O(\log |E|)$-approximation with general interdiction costs). This guarantee was improved only recently by Zenklusen [31],

who gave the first (and current-best) $O(1)$-approximation algorithm for (general) MST interdiction, achieving an approximation ratio of 14. The B-most-vital edges problem has been well studied for $B = 1$ and for $B = O(1)$, where it can be solved optimally; see, e.g., [21] and the references therein. The special case of MST interdiction where we have only two distinct edge weights captures the *budgeted graph disconnection* (BGD) problem [7] for which a 2-approximation is known [7]. As noted by [31], MST interdiction can be viewed as multilevel-BGD, which makes it much more challenging as it is difficult to control the interactions at the different levels. It is noteworthy that our approximation ratio of 4 for MST interdiction is quite close to the approximation ratio of 2 for BGD.

As with MST interdiction, until recently, there were wide gaps in our understanding of the approximability of the other classic *NP*-hard interdiction problems mentioned earlier. Maximum s-t flow interdiction, even on undirected graphs with unit interdiction costs, is now known to be at least as hard as MinDkS on λ-uniform hypergraphs. This follows from a recent hardness result for *k-route s-t cut* in [13], which turns out to be an equivalent problem.[1] This hardness result has been rediscovered (in a slightly weaker form) by [3], who also gave an $O(n)$-approximation algorithm. For shortest s-t path interdiction, very recently, Lee [20] proved a super-constant hardness result. For maximum-matching interdiction, [6] devised the first $O(1)$-approximation algorithm. Despite this recent progress, interdiction variants of common optimization problems are generally not well understood, especially from the viewpoint of approximability.

The tree knapsack problem was introduced by [15], and is a special case of the *partially-ordered knapsack* (POK) problem [18]. While an FPTAS can be obtained for tree knapsack and some special cases of POK [15, 18], and the natural LP for POK has been investigated [18], our LP-relative guarantee and rounding algorithm for tree knapsack are new.

2 Preliminaries

For any vector $d \in \mathbb{R}^E$ and any subset $F \subseteq E$ of edges, we use $d(F)$ to denote $\sum_{e \in F} d_e$. Given a subset $R \subseteq E$ of edges, we use $\mathrm{val}(R)$, which we call the *value* of R, to denote the w-weight of an MST in the multigraph $G - R$, i.e., $\mathrm{val}(R) := \min_{\text{spanning trees } T \text{ of } G-R} w(T)$. The *minimum-spanning-tree interdiction* problem can thus be restated as follows: $\max \big\{\mathrm{val}(R) : R \subseteq E,\ c(R) \leq B\big\}$.

If there is an interdiction set R with $c(R) \leq B$ such that $G - R$ is disconnected, then $\mathrm{val}(R) = \infty$, and so the MST-interdiction problem is unbounded. Note that this happens iff a min-cut $\delta(S)$ of G satisfies $c\big(\delta(S)\big) \leq B$, and we can efficiently detect this. So in the sequel, we assume that this is not the case. Let OPT denote the optimal value of the MST-interdiction problem (which is now finite). For $F \subseteq E$, let $\sigma(F)$ denote the number of connected components of (V, F).

Let $w_1, w_2, \ldots, w_M$ be the distinct weights in $\{w_e : e \in E\}$, where $0 \leq w_1 < w_2 < \cdots < w_M$. For $i = 1, \ldots, M$, define $E_i := \{e \in E : w_e = w_i\}$ and $E_{\leq i} := \{e \in E : w_e \leq w_i\}$. For notational convenience, we define $w_0 := 0$ and $E_0 = E_{\leq 0} := \emptyset$. (Note that E_0 is *not* necessarily $\{e \in E : w_e = w_0\}$, and $E_{\leq 0}$ is not necessarily $\{e \in E : w_e \leq w_0\}$.)

[1] In k-route s-t cut, the goal is to remove a min w-cost set of edges so as to reduce the s-t edge connectivity to at most $k-1$. This corresponds to taking all but the $k-1$ most-expensive edges of some cut. So we can rephrase this problem as follows: remove at most $k-1$ edges to minimize the (min-s-t-cut value = max-s-t-flow value) with capacities $\{w_e\}$; this is precisely the maximum s-t flow interdiction problem with unit interdiction costs and budget $k-1$.

Let $k \in \{1,\dots,M\}$ be the *smallest* index such that $c\big(\delta(S) \cap E_{\le k}\big) > B$ for every $\emptyset \neq S \subsetneq V$; that is, the multigraph $(V, E_{\le k} \setminus R)$ is connected for all R such that $c(R) \le B$. Note that k is well defined due to our earlier assumption. This implies the following properties, as also observed in [31]:

- **(i)** $OPT \ge w_k$ (since, by definition of k, there is a feasible interdiction set R whose removal disconnects $(V, E_{\le k-1})$);
- **(ii)** for any R with $c(R) \le B$, we have $\mathrm{val}(R) = \mathrm{val}(R \cap E_{\le k-1})$, and hence, there is an optimal solution that only interdicts edges from $E_{\le k-1}$; and
- **(iii)** given (ii), we may add additional edges of weight w_k without impacting the optimal value, so we may assume that (V, E_k) is connected.

We summarize these properties and assumptions below.

▶ **Claim 1.** *Let $k \in \{1,\dots,M\}$ be the smallest index such that $(V, E_{\le k} \setminus R)$ is connected for every $R \subseteq E$ with $c(R) \le B$. Assume that such a k exists. Then, (i) $OPT \ge w_k$, and (ii) there is an optimal solution R^* such that $R^* \subseteq E_{\le k-1}$. Moreover, we may assume that (iii) the multigraph (V, E_k) is connected.*

▶ **Lemma 2.** *Let $R \subseteq E$ be an edge-set such that $(V, E_{\le k} \setminus R)$ is connected. Then* $\mathrm{val}(R) = -w_k + \sum_{i=0}^{k-1} \sigma\left(E_{\le i} \setminus R\right)(w_{i+1} - w_i)$.

Proof. Consider, for example, running Kruskal's algorithm to obtain an MST of $G - R$. We include exactly $\sigma(E_{\le j-1} \setminus R) - \sigma(E_{\le j} \setminus R)$ edges of weight w_j for every $1 \le j \le M$, and this quantity is 0 for all $j > k$. It follows that

$$\begin{aligned}
\mathrm{val}(R) &= \sum_{j=1}^{M} \Big(\sigma\left(E_{\le j-1} \setminus R\right) - \sigma(E_{\le j} \setminus R)\Big) w_j = \sum_{j=1}^{k} \Big(\sigma(E_{\le j-1} \setminus R) - \sigma(E_{\le j} \setminus R)\Big) w_j \\
&= \sum_{j=1}^{k} \Big(\sigma\left(E_{\le j-1} \setminus R\right) - \sigma(E_{\le j} \setminus R)\Big) \sum_{i=0}^{j-1} (w_{i+1} - w_i) \\
&= \sum_{i=0}^{k-1} (w_{i+1} - w_i) \sum_{j=i+1}^{k} \Big(\sigma(E_{\le j-1} \setminus R) - \sigma(E_{\le j} \setminus R)\Big) \\
&= \sum_{i=0}^{k-1} \big(\sigma(E_{\le i} \setminus R) - 1\big)(w_{i+1} - w_i) = -w_k + \sum_{i=0}^{k-1} \sigma(E_{\le i} \setminus R)(w_{i+1} - w_i).
\end{aligned}$$

◀

Given Claim 1, we focus on interdiction sets $R \subseteq E_{\le k-1}$ and recast the MST-interdiction problem as: $\max \big\{\mathrm{val}(R) : R \subseteq E_{\le k-1},\ c(R) \le B\big\}$. As is common in the study of constrained optimization problems (see, e.g., [19, 12] and the references therein), we Lagrangify the budget constraint $c(R) \le B$, and consider the following Lagrangian problem (offset by $-\lambda B$), where $\lambda \ge 0$ is a parameter:

$$\max_{R \subseteq E_{\le k-1}} \quad f_\lambda(R) := \mathrm{val}(R) - \lambda c(R). \tag{P_λ}$$

The expression for $\mathrm{val}(R)$ in Lemma 2 holds for all $R \subseteq E_{\le k-1}$ as (V, E_k) is connected. Since $\sigma(E_{\le i} \setminus R)$ is a supermodular function of R, this implies that $\mathrm{val}(\cdot)$, and hence the objective function $f_\lambda(\cdot)$ of (P_λ), is *supermodular* over the domain $2^{E_{\le k-1}}$: for any $A_1, A_2 \subseteq E_{\le k-1}$, we have $f_\lambda(A_1) + f_\lambda(A_2) \le f_\lambda(A_1 \cap A_2) + f_\lambda(A_1 \cup A_2)$. Hence, (P_λ) can be solved exactly, which we crucially exploit.

Let $\mathcal{O}^*_\lambda$ denote the set of optimal solutions to (P_λ). Observe that for any $\lambda \ge 0$ and any $R \in \mathcal{O}^*_\lambda$, we have $\mathrm{val}(R) - \lambda c(R) \ge OPT - \lambda B$. So if we find some $\lambda \ge 0$ and $R \in \mathcal{O}^*_\lambda$ such

that $c(R) = B$, we have $\text{val}(R) \geq OPT$, so R is an optimal solution. In general, such a pair (λ, R) need not exist, or can be hard to find. However, by doing a binary search for λ, or alternatively, as noted in [31], via parametric submodular-function minimization [8, 23], we can obtain the following result; we include a self-contained proof in the full version.

▶ **Theorem 3** ([31]). *One can find in polytime: either (i) an optimal solution to the MST-interdiction problem, or (ii) a parameter $\lambda \geq 0$ and two optimal solutions R_1, R_2 to (P_λ) such that $R_1 \subseteq R_2$ and $c(R_1) < B < c(R_2)$.*

3 The tree knapsack problem

We now define the *tree knapsack problem*, and devise a simple, clean LP-based approximation algorithm for this problem (Theorem 4, Corollary 6). As we show in Section 4, the tree knapsack problem nicely abstracts the key combinatorial problem encountered in extracting a good interdiction set from an over-budget set R_2 in case (ii) of Theorem 3, and our LP-relative guarantees for tree knapsack readily yield improved approximation guarantees for MST interdiction.

In the tree knapsack problem [15], we have a tree $\Gamma = (\{r\} \cup N, A)$ rooted at node r. Each node $v \in N$ has a *value* $\alpha_v \geq 0$ and a *weight* $\beta_v \geq 0$, and we have a budget B. We say that a subset $S \subseteq N$ of nodes is *downwards-closed* if for every $v \in S$, all children of v are also in S. The goal is to find a maximum-value downwards-closed set $S \subseteq N$ (so $r \notin S$) such that $\sum_{v \in S} \beta_v \leq B$. Observe that the (standard) knapsack problem is precisely the special case of tree knapsack where the underlying tree is a star (rooted at its center). Throughout, we use v to index nodes in N. For $S \subseteq N$ and a vector $\rho \in \mathbb{R}^N$, we use $\rho(S)$ to denote $\sum_{v \in S} \rho_v$.

The following is a natural LP-relaxation for the tree knapsack problem involving variables x_v for all v. Let $\mathsf{ch}(v)$ denote the set of children of node v.

$$\max \quad \sum_v \alpha_v x_v \tag{TK-P}$$

$$\text{s.t.} \quad x_v \leq x_u \qquad \text{for all } v, \text{ for all } u \in \mathsf{ch}(v) \tag{1}$$

$$\sum_v \beta_v x_v \leq B, \qquad 0 \leq x_v \leq 1 \quad \text{for all } v.$$

Tree knapsack was first defined by [15] who devised an FPTAS for this problem via dynamic programming. However, for our purposes, we need an approximation guarantee relative to the above LP, which was not known previously.

The main result of this section is as follows. We say that $C \subseteq N$ is a *chain* if for every two distinct nodes in C, one is a descendant of the other.

▶ **Theorem 4.** *We can compute in polytime an integer solution to* (TK-P) *of value at least $OPT_{\text{TK-P}} - \max_{\text{chains } C \subseteq N} \alpha(C)$.*

Theorem 4 nicely generalizes a well-known result about the standard knapsack problem, namely, that we can always obtain a solution of value at least (LP-optimum)$-\max_v \alpha_v$. Notice that when Γ is a star (i.e., we have a knapsack instance), this is *precisely* the guarantee that we obtain above. The proof of Theorem 4 relies on the following structural result (which extends a similar result known for knapsack). Let $\Gamma(v)$ denote the subtree of Γ rooted at v.

▶ **Lemma 5.** *Let $\bar{x}$ be an extreme-point solution to the linear program* (TK-P). *Then there is at most one child v of r for which the subtree $\Gamma(v)$ contains a fractional node, i.e., some node w with $0 < \bar{x}_w < 1$.*

Proof of Theorem 4. We use *iterative rounding*, and the proof is by induction on the depth d of Γ, which is the maximum number of edges on a root-leaf path.

If $d = 0$, then $N = \emptyset$, and (TK-P) has no variables and constraints, so the statement is vacuously true. So suppose $d \geq 1$. Let x^* be an extreme-point optimal solution of (TK-P). If x^* is integral, then we obtain value $OPT_{\text{TK-P}}$, completing the induction step. Otherwise, by Lemma 5, there is exactly one child v of r such that the subtree $\Gamma(v)$ contains a fractional node.

Set $\tilde{x}' = x^*\big|_{N\setminus\Gamma(v)}$, i.e., x^* restricted to $N\setminus\Gamma(v)$, which is integral. We have $\sum_{u\in N\setminus\Gamma(v)} \alpha_u \tilde{x}'_u = OPT_{\text{TK-P}} - \sum_{w\in\Gamma(v)} \alpha_w x^*_w$. Now consider the tree knapsack instance defined by the tree $\Gamma(v)$ with root v, and budget $B - \sum_{u\in N\setminus\Gamma(v)} \beta_u \tilde{x}'_u$ (and values α_w and weights β_w for all $w \in \Gamma(v) \setminus \{v\}$). Observe that $x^*\big|_{\Gamma(v)\setminus\{v\}}$ is a fractional solution to the LP-relaxation (TK-P) corresponding to this tree knapsack problem, so the optimal value of this LP is at least $\sum_{w\in\Gamma(v)\setminus\{v\}} \alpha_w x^*_w$. (These objects are null if $\Gamma(v) = \{v\}$.) Thus, since $\Gamma(v)$ has depth at most $d - 1$, by our induction hypothesis, our rounding procedure applied to this tree knapsack instance yields an integer solution $\tilde{x}'' \in \{0,1\}^{\Gamma(v)\setminus\{v\}}$ of value at least $\sum_{w\in\Gamma(v)\setminus\{v\}} \alpha_w x^*_w - \max_{\text{chains } C\subseteq\Gamma(v)\setminus\{v\}} \alpha(C)$. Thus, taking $\tilde{x} = (\tilde{x}', \tilde{x}_v = 0, \tilde{x}'')$, we obtain a feasible integer solution to (TK-P) having value at least

$$\begin{aligned} OPT_{\text{TK-P}} - \sum_{w\in\Gamma(v)} \alpha_w x^*_w + \sum_{w\in\Gamma(v)\setminus\{v\}} \alpha_w x^*_w - \max_{\text{chains } C\subseteq\Gamma(v)\setminus\{v\}} \alpha(C) \\ \geq OPT_{\text{TK-P}} - \alpha_v - \max_{\text{chains } C\subseteq\Gamma(v)\setminus\{v\}} \alpha(C) \\ \geq OPT_{\text{TK-P}} - \max_{\text{chains } C\subseteq N} \alpha(C)\ . \end{aligned}$$

This completes the induction step, and hence the proof of the theorem. ◀

We remark that (as is standard) the iterative-rounding procedure in Theorem 4 is in fact combinatorial, since when we move to the subtree $\Gamma(v)$, we only need to move from $x^*\big|_{\Gamma(v)\setminus\{v\}}$ to an extreme-point of the LP of the smaller tree-knapsack instance of no smaller value (instead of obtaining an optimal LP solution), which can be done combinatorially.

We now state a stronger version of Theorem 4 that will be useful in Section 4, where we utilize tree knapsack to solve the MST-interdiction problem. This result follows from a more-careful scrutiny of the proof of Theorem 4. The depth of a node v is the number of edges on the (unique) r-v path of Γ. Let $L_i(\Gamma)$ be the set of nodes of Γ at depth i; we drop Γ if it is clear from the context. For a chain C of Γ, let C_i denote $C \cap L_i(\Gamma)$; note that $|C_i| \leq 1$.

▶ **Corollary 6.** *We can obtain in polytime an integer solution $\tilde{x}$ to* (TK-P) *of value at least* $OPT_{\text{TK-P}} - \max_{\text{chains } C\subseteq N} \{\sum_{i\geq 1:\tilde{x}(L_i)<|L_i|} \alpha(C_i)\}$.

4 MST interdiction

▶ **Theorem 7.** *There is a 4-approximation algorithm for MST interdiction.*

The above theorem is our main technical result. Our guarantee substantially improves the previous-best approximation ratio of 14 obtained by [31]. Also, notably and significantly, our algorithm and analysis, which are based on the tree knapsack problem introduced in Section 3, are noticeably simpler and cleaner than the one in [31]. Improved guarantees for MST interdiction readily follow from (Theorem 4 and) Corollary 6 and Lemma 14, yielding approximation ratios of 5 and 4 respectively for MST interdiction (see Theorem 13 and Section 4.1). The proof below shows a slightly worse guarantee of 5 but introduces the main underlying ideas. Section 4.1 discusses the refinement needed to obtain the 4-approximation.

Our algorithm follows the same high-level outline as the one in [31]. As mentioned earlier, we consider the Lagrangian problem (P_λ), $\max_{R\subseteq E_{\leq k-1}} f_\lambda(R) := \mathrm{val}(R) - \lambda c(R)$, obtained by dualizing the budget constraint $c(R) \leq B$. We then utilize Theorem 3. If this returns an optimal solution, then we are done. So assume in the sequel that Theorem 3 returns $\lambda \geq 0$ and two optimal solutions R_1 and R_2 to (P_λ) such that $R_1 \subseteq R_2$ and $c(R_1) < B < c(R_2)$.

For $R \subseteq E_{\leq k-1}$, define $h(R) := \sum_{i=0}^{k-1} \sigma\left(E_{\leq i} \setminus R\right)(w_{i+1} - w_i) = \mathrm{val}(R) + w_k$. Let $R^* \subseteq E_{\leq k-1}$ denote an optimal solution to the MST-interdiction problem, so $OPT = h(R^*) - w_k$. Let $a, b \geq 0$ such that $a + b = 1$ and $ac(R_1) + bc(R_2) = B$. Then, since $\mathrm{val}(R_1) - \lambda c(R_1) = \mathrm{val}(R_2) - \lambda c(R_2) \geq OPT - \lambda B$, we have $ah(R_1) + bh(R_2) \geq h(R^*)$. We establish our approximation guarantee by comparing the value of our solution against the upper bound $ah(R_1) + bh(R_2) - w_k$. The following claim shows that this upper bound is precisely the optimal value of the Lagrangian relaxation of the MST interdiction problem, which is $UB := \min_{\lambda'\geq 0}\big(\lambda' B + \max_{R\subseteq E_{\leq k-1}} f_{\lambda'}(R)\big)$. Complementing our 4-approximation, we prove a lower bound of 3 on the approximation ratio achievable relative to UB (Section 4.2).

▶ **Claim 8.** *We have $ah(R_1) + bh(R_2) - w_k = UB$.*

Translation to tree knapsack. We now describe how the problem of combining R_1 and R_2 to extract a good, feasible interdiction set can be captured by a suitable instance of the tree knapsack problem defined in Section 3.

For $i = 0, \ldots, k$, let $\mathcal{A}_i \subseteq 2^V$ be the partition of V induced by the connected components of the multigraph $(V, E_{\leq i} \setminus R_2)$. Thus, $\mathcal{A}_k = \{V\}$ and $\mathcal{A}_0 = \{\{v\} : v \in V\}$. The multiset $\bigcup_{i=0}^{k} \mathcal{A}_i$, where we include $S \subseteq V$ multiple times if it lies in multiple $\mathcal{A}_i$s, is a *laminar family* (i.e., any two sets in the collection are either disjoint or one is contained in the other). This laminar family can naturally be viewed as a rooted tree, which defines the tree Γ in the tree knapsack problem. Taking a cue from Lemma 2, we build our interdiction set R by selecting a suitable collection of sets from this laminar family, ensuring that if we pick some $A \in \mathcal{A}_i$, then we include all edges of $\delta(A) \cap E_{\leq i}$ in R and create A as a component of $(V, E_{\leq i} \setminus R)$ (and hence contribute $w_{i+1} - w_i$ to $h(R)$). Formally, the tree Γ has a node $v^{A,i}$ for every component $A \in \mathcal{A}_i$ and all $i = 0, \ldots, k$. For $i > 0$, the children of $v^{A,i}$ are the nodes $\{v^{S,i-1} : S \in \mathcal{A}_{i-1}, S \subseteq A\}$. Thus, Γ has depth k and root $r = v^{V,k}$. Recall that $L_i := L_i(\Gamma)$ denotes the set of nodes of Γ at depth i, which correspond to the components in $\mathcal{A}_{k-i}$ here. Let N be the set of non-root nodes of Γ.

For a node $v^{A,i} \in N$ (so $0 \leq i < k$), define its value $\alpha_{v^{A,i}} := w_{i+1} - w_i$. Let $R(v^{A,i}) := \delta(A) \cap E_i$ (which is $\emptyset$ for every leaf $v^{A,0}$). Define the weight of $v^{A,i}$ to be $\beta_{v^{A,i}} := c\big(R(v^{A,i})\big)$. For $N' \subseteq N$, let $R(N') := \bigcup_{q\in N'} R(q)$. Observe that $R(N) \subseteq R_2$. We set the budget of the tree-knapsack instance to B, the budget for MST interdiction.

The intuition is that we want to encode that picking node $v^{A,i}$ corresponds to creating component A in the multigraph $(V, E_{\leq i} \setminus R)$, where R is our interdiction set, in which case $\alpha_{v^{A,i}}$ gives the contribution from A to $h(R)$. However, in order to pay for the interdiction cost $c\big(\delta(A)\big)$ incurred, we need to take the β_q weights of all nodes q in the subtree rooted at $v^{A,i}$. Therefore, we insist that if we pick $v^{A,i}$ then we pick all its descendants (i.e., we pick a downwards-closed set of nodes), and then $\sum_{q\in\Gamma(v^{A,i})} \alpha_q$ gives the contribution from the components created to $h(R)$. Lemma 9 formalizes this intuition, and shows that if $N' \subseteq N$ is a downwards-closed set of nodes, then $\beta(N')$ and $\alpha(N')$ are good proxies (roughly speaking) for the interdiction cost $c\big(R(N')\big)$ incurred and $h\big(R(N')\big)$ respectively.

▶ **Lemma 9.** *Let $N' \subseteq N$ be downwards closed, and $R = R(N')$. Then*
(i) *$\beta(N')/2 \leq c(R) \leq \beta(N')$; and*
(ii) *$h(R) = \mathrm{val}(R) + w_k \geq \alpha(N') + \sum_{0\leq i\leq k-1 : L_{k-i}\setminus N' \neq \emptyset} (w_{i+i} - w_i)$.*

Proof. Each edge in R appears in at least one, and at most two, of the sets $\{R(q)\}_{q\in N'}$, so $\frac{1}{2}\sum_{q\in N'} c\big(R(q)\big) \le c(R) \le \sum_{q\in N'} c\big(R(q)\big)$. This yields part (i) since $\beta(N') = \sum_{q\in N'} c\big(R(q)\big)$.

For part (ii), consider an index $0 \le i \le k-1$. Since N' is downwards closed, for every node $v^{A,i} \in N'$, all descendants of $v^{A,i}$ are in N'; so $R \supseteq \delta(A) \cap E_{\le i}$ and A is a connected component of $(V, E_{\le i} \setminus R)$. Further, note that if $L_{k-i} \setminus N' \neq \emptyset$, then the sets $\{A : v^{A,i} \in N'\}$ do not cover V entirely, and so $(V, E_{\le i} \setminus R)$ must have at least one additional connected component. It follows that $(V, E_{\le i} \setminus R)$ always has at least $\min\big\{|N' \cap L_{k-i}| + 1, |L_{k-i}|\big\}$ connected components. Plugging this in Lemma 2 yields the result. ◀

▶ **Lemma 10.** *The vector* $\hat{x} := \big(\hat{x}_q = \frac{b}{2}\big)_{q\in N}$ *is a feasible solution to* (TK-P) *for the above tree-knapsack instance* $(\Gamma, \{\alpha_q\}, \{\beta_q\}, B)$. *Hence,* $OPT_{TK\text{-}P} \ge \frac{b}{2} \cdot h(R_2)$.

Proof. It is clear that $\hat{x}$ satisfies (1), and $0 \le \hat{x}_q \le 1$ for all $q \in N$. Applying Lemma 9 to $N' = N$ (which is indeed downwards-closed), we obtain $\beta(N) \le 2c\big(R(N)\big) \le 2c(R_2)$. So $\sum_{q\in N} \beta_q \hat{x}_q \le b \cdot c(R_2) \le a \cdot c(R_1) + b \cdot c(R_2) = B$. Finally, $OPT_{\text{TK-P}}$ is at least the objective value of $\hat{x}$, which is $\frac{b}{2} \cdot \alpha(N) = \frac{b}{2} \cdot h(R_2)$. ◀

Given this translation between tree knapsack and MST interdiction, it is easy to see that Corollary 6 (coupled with Lemmas 9 and 10) yields the following guarantee, which directly leads to an improved approximation guarantee of 5 for MST interdiction (see Claim 12).

▶ **Lemma 11** (Consequence of Corollary 6, Lemmas 9 and 10)**.** *We can obtain a feasible interdiction set* R *such that* $h(R) \ge \frac{b}{2} \cdot h(R_2)$.

▶ **Claim 12.** *We have* $\max\big\{w_k, h(R_1) - w_k, \frac{b}{2} \cdot h(R_2) - w_k\big\} \ge UB/5 \ge OPT/5$.

Proof. We have

$$\begin{aligned}\max\Big\{w_k, h(R_1) - w_k, \tfrac{b}{2} \cdot h(R_2) - w_k\Big\} &\ge \tfrac{2-b}{5-2b} \cdot w_k + \tfrac{1-b}{5-2b} \cdot \big(h(R_1) - w_k\big) \\ &\quad + \tfrac{2}{5-2b} \cdot \big(\tfrac{b}{2} \cdot h(R_2) - w_k\big) \\ &= \frac{1}{5-2b}\Big(ah(R_1) + bh(R_2) - w_k\Big) = \frac{UB}{5-2b} \ge UB/5 \ge OPT/5.\end{aligned}$$ ◀

▶ **Theorem 13.** *There is a* 5*-approximation algorithm for MST interdiction.*

Proof. If Theorem 3 returns an optimal solution, we are done. Otherwise, we return the best among a min-cut of $(V, E_{\le k-1})$, the set R_1, and the interdiction set returned by Lemma 11. The proof now follows from Claim 12. ◀

4.1 Improvement to the guarantee stated in Theorem 7

The improved approximation guarantee of 4 comes from the fact that instead of focusing only on R_2, we now *interpolate* between R_1 and R_2 to obtain our interdiction set R, i.e., we return R such that $R_1 \subseteq R \subseteq R_2$. Since we always include R_1, we change the definition of the tree-knapsack instance that we create accordingly. The tree Γ and the node weights $\{\alpha_q\}$ are unchanged; the weight of $v^{A,i}$ is now $\beta^{\text{new}}_{v^{A,i}} := c\big(R^{\text{new}}(v^{A,i})\big)$, where $R^{\text{new}}(v^{A,i}) := R(v^{A,i}) \setminus R_1 = \big(\delta(A) \setminus R_1\big) \cap E_i$, and our budget is $B^{\text{new}} := B - c(R_1)$. For $N' \subseteq N$, define $R^{\text{new}}(N') := R_1 \cup \bigcup_{q\in N'} R^{\text{new}}(q)$. Observe that $R^{\text{new}}(N) \subseteq R_2$.

Since $R_1 \subseteq R_2$, each component U of $(V, E_{\le i} \setminus R_1)$ is a union of components of $(V, E_{\le i} \setminus R_2)$, and hence, maps to a subset S of the nodes of Γ at depth $k-i$. We exploit the fact that since we include R_1 in our interdiction set, if we pick ℓ nodes from S, then we create $\min\{\ell+1, |S|\}$

components within U; this $+1$ term that we accrue (roughly speaking) from all components of $(V, E_{\le j} \setminus R)$ over all $j = 0, \ldots, k-1$ is the source of our improvement.

The following variant of Corollary 6 exploits the structure of the tree-knapsack instance obtained from the MST-interdiction problem, which we then utilize to obtain an interdiction set with an improved bound on $h(R)$ (Lemma 15).

▶ **Lemma 14.** *Let $\big(\Gamma, \{\alpha_v\}, \{\beta_v\}, B\big)$ be an instance of the tree knapsack problem such that $\alpha_v = \alpha^{(i)}$ for all $v \in L_i(\Gamma)$ and all $i \ge 1$. Let $\mathcal{S}_i$ be a partition of $L_i(\Gamma)$ for all $i \ge 1$. Let $\theta \in [0,1]$ be such that $(\hat{x}_q = \theta)_{q \in N}$ is a feasible solution to* (TK-P)*. We can obtain in polytime an integer solution $\tilde{x}$ to* (TK-P) *such that*

$$\sum_{i \ge 1} \sum_{S \in \mathcal{S}_i} \alpha^{(i)} \min\{\tilde{x}(S) + 1, |S|\} \ge \sum_{i \ge 1} \alpha^{(i)} |L_i| \theta + \sum_{i \ge 1 : |\mathcal{S}_i| > 1} \alpha^{(i)} \Big((1-\theta)|\mathcal{S}_i| - 1 \Big).$$

▶ **Lemma 15.** *Using Lemma 14, we can obtain a feasible interdiction set R such that $h(R) \ge \frac{a}{2} \cdot h(R_1) + \frac{b}{2} \cdot h(R_2) - \frac{a}{2} \cdot w_k$.*

Proof. For $i = 0, \ldots, k$, let $\mathcal{B}_i$ denote the partition of V induced by the connected components of $(V, E_{\le i} \setminus R_1)$. Since $R_1 \subseteq R_2$, the partition $\mathcal{A}_i$ refines (not necessarily strictly) the partition $\mathcal{B}_i$ for all $i = 0, \ldots, k$. The components in $\mathcal{B}_{k-i}$ therefore naturally induce a partition $\mathcal{S}_i$ of the nodes of Γ at depth i, consisting of the sets $\{v^{A,k-i} : A \in \mathcal{A}_{k-i}, A \subseteq S\}_{S \in \mathcal{B}_{k-i}}$.

We apply Lemma 14 to the tree-knapsack instance $\big(\Gamma, \{\alpha_q\}, \{\beta_q^{\mathsf{new}}\}, B^{\mathsf{new}}\big)$, taking $\alpha^{(i)} = w_{k-i+1} - w_{k-i}$ and $\mathcal{S}_i$ to be the partition defined above, for all $i = 1, \ldots, k$, and $\theta = \frac{b}{2}$. We show that $\hat{x} := (\hat{x}_q = \theta)_{q \in N}$ is a feasible solution to (TK-P) for this tree-knapsack instance. This follows because $\beta^{\mathsf{new}}(N) = 2c\big(\bigcup_{q \in N} R^{\mathsf{new}}(q)\big) \le 2\big(c(R_2) - c(R_1)\big)$ and $(1-b) \cdot c(R_1) + b \cdot c(R_2) = B$, so we have $\sum_q \beta_q^{\mathsf{new}} \hat{x}_q = \theta \beta^{\mathsf{new}}(N) \le b\big(c(R_2) - c(R_1)\big) = B - c(R_1) = B^{\mathsf{new}}$.

Let $\tilde{x}$ be the integer solution returned by Lemma 14, which specifies a downwards-closed set $N' \subseteq N$. Let $R = R^{\mathsf{new}}(N')$. We first show that, analogous to Lemma 9, R is feasible, and $h(R) \ge g(\tilde{x}) := \sum_{i \ge 1} \sum_{S \in \mathcal{S}_i} \alpha^{(i)} \min\{\tilde{x}(S) + 1, |S|\}$. We have

$$\begin{aligned} c(R) = c(R_1) + c\Big(\bigcup_{q \in N'} R^{\mathsf{new}}(q) \Big) &\le c(R_1) + \sum_{q \in N'} c\big(R^{\mathsf{new}}(q)\big) \\ &= c(R_1) + \beta^{\mathsf{new}}(N') \le c(R_1) + B^{\mathsf{new}} = B. \end{aligned}$$

Consider any index $0 \le i \le k-1$. As in the proof of part (ii) of Lemma 9, for every node $v^{A,i} \in N'$, we know that A is a component of $(V, E_{\le i} \setminus R)$. Consider any $S \in \mathcal{S}_{k-i}$, and let $U = \bigcup_{v^{A,i} \in S} A$. Note that if $S \setminus N' \ne \emptyset$, then $\bigcup_{v^{A,i} \in S \setminus N'} A$ is non-empty. So there are always at least $\min\big\{|N' \cap S| + 1, |S|\big\}$ components of $(V, E_{\le i} \setminus R)$ contained in U. Therefore, by Lemma 2 (and since $\mathcal{S}_i$ is a partition of L_i for each i), we obtain

$$h(R) = \mathrm{val}(R) + w_k \ge \sum_{i=0}^{k-1} \sum_{S \in \mathcal{S}_{k-i}} (w_{i+1} - w_i) \min\big\{|N' \cap S| + 1, |S|\big\} = g(\tilde{x}).$$

The guarantee in Lemma 14 then yields the following. Recall that $a = 1 - b$.

$$\begin{aligned} h(R) &\ge \sum_{i=0}^{k-1} (w_{i+1} - w_i) \sigma(E_{\le i} \setminus R_2) \cdot \tfrac{b}{2} + \sum_{\substack{i=0,\ldots,k-1: \\ \sigma(E_{\le i} \setminus R_1) > 1}} (w_{i+1} - w_i) \Big[\Big(1 - \tfrac{b}{2}\Big) \sigma(E_{\le i} \setminus R_1) - 1 \Big] \\ &\ge \tfrac{b}{2} \cdot h(R_2) + \sum_{\substack{i=0,\ldots,k-1: \\ \sigma(E_{\le i} \setminus R_1) > 1}} (w_{i+1} - w_i) \sigma(E_{\le i} \setminus R_1) \cdot \tfrac{a}{2} \end{aligned} \tag{2}$$

where inequality (2) follows since $t\big(1-\frac{b}{2}\big)-1 \geq t(1-b)/2$ for all $t \geq 2$. The RHS of (2) is

$$\tfrac{b}{2}\cdot h(R_2)+\tfrac{a}{2}\cdot h(R_1)-\sum_{\substack{i=0,\dots,k-1:\\ \sigma(E_{\leq i}\setminus R_1)=1}}(w_{i+1}-w_i)\cdot\tfrac{a}{2}\geq \tfrac{a}{2}\cdot h(R_1)+\tfrac{b}{2}\cdot h(R_2)-\tfrac{a}{2}\cdot w_k. \quad \blacktriangleleft$$

Proof of Theorem 7. We either return an optimal solution found by Theorem 3, or return the better of a min-cut of $(V, E_{\leq k-1})$ and the interdiction set returned by Lemma 15. We obtain a solution of value $\max\big\{w_k, \frac{a}{2}\cdot h(R_1)+\frac{b}{2}\cdot h(R_2)-\big(1+\frac{a}{2}\big)w_k\big\}$, which is at least

$$\frac{1+a}{3+a}\cdot w_k+\frac{2}{3+a}\cdot\Big(\tfrac{a}{2}\cdot h(R_1)+\tfrac{b}{2}\cdot h(R_2)-\big(1+\tfrac{a}{2}\big)w_k\Big)=\frac{UB}{3+a}\geq OPT/4. \quad \blacktriangleleft$$

4.2 Lower bound on the approximation ratio achievable relative to UB

We show that for every $\epsilon > 0$, there exist MST-interdiction instances, where $UB/OPT \geq 3-\epsilon$. This implies that one cannot achieve an approximation ratio better than 3 when comparing against the upper bound UB used in our analysis (and the one in [31]).

▶ **Theorem 16.** *For any $\epsilon > 0$, there exists an MST-interdiction instance with $\frac{UB}{OPT} \geq 3-\epsilon$.*

Proof. Our instance is a graph $G=(V,E)$, where $V := \{v_1,\dots,v_n\}$ with $n \geq \min\{4, 4/\epsilon\}$. The edge set is $E = E_1 \cup E_2$, where $E_1 := \{v_1v_2, v_2v_3, \dots, v_{n-2}v_{n-1}, v_{n-1}v_1\}$ is a simple cycle on $v_1,\dots,v_{n-1}$, and $E_2 := \{v_1v_n, v_2v_n, \dots, v_{n-1}v_n\}$ is a star rooted at v_n with leaves $v_1,\dots,v_{n-1}$. The edges in E_1 have weight $w_1 = 0$ and interdiction cost n, while the edges in E_2 have weight $w_2 = 1$ and interdiction cost $2n$. The interdiction budget is $B = 2n-2$.

Observe that the index k defined in Claim 1 is equal to 2. This also implies that $\mathrm{val}(R) \leq 1$ for any feasible interdiction set R: since $R \subseteq E_1$ and $|R \cap E_1| \leq 1$, we can construct a spanning tree of $G-R$ by taking $n-2$ edges from $E_1 \setminus R$ and any edge from E_2. So $OPT = 1$.

Now we proceed to compute the upper bound UB. For $R \subseteq E_{\leq 1}$, we have $f_\lambda(R) = 1$ if $R = \emptyset$, and $|R|(1-n\lambda)$ otherwise. Therefore, $\eta(\lambda) := \lambda B + \max_{R\subseteq E_{\leq 1}} f_\lambda(R) = \lambda B + \max\big\{1, (n-1)(1-n\lambda)\big\} = \max\big\{\lambda B+1, (n-1)-\lambda\big(n(n-1)-B\big)\big\}$, which is minimized at $\lambda = \frac{n-2}{n(n-1)}$. Therefore $UB := \min_{\lambda\geq 0}\eta(\lambda) = \frac{2(n-2)}{n}+1 = 3-\frac{4}{n} \geq (3-\epsilon)OPT$. $\blacktriangleleft$

5 Extension to metric-TSP interdiction

In the *metric-TSP interdiction* problem, we are given a complete graph $G=(V,E)$ with metric edge weights $\{w_e\}_{e\in E}$ and nonnegative interdiction costs $\{c_e\}_{e\in E}$, along with a nonnegative budget B. The goal is to find a set of edges $R \subseteq E$ such that $c(R) \leq B$ so as to maximize the minimum w-weight of a closed walk in the graph $G-R$ that visits each vertex at least once. Zenklusen [31] observed that an α-approximation algorithm for the MST interdiction problem yields a 2α-approximation algorithm for the metric-TSP interdiction problem. As a corollary to our Theorem 7, we therefore obtain the following result.

▶ **Theorem 17.** *There is an 8-approximation algorithm for metric-TSP interdiction.*

6 Maximum-spanning-tree interdiction

We now consider the *maximum-spanning-tree* (MaxST) *interdiction* problem, wherein the input $\big(G=(V,E), \{w_e \geq 0\}_{e\in E}, \{c_e \geq 0\}_{e\in E}, B\big)$ is the same as in the MST interdiction problem, but the goal is to remove a set $R \subseteq E$ of edges with $c(R) \leq B$ so as to *minimize* the

w-weight of a *maximum spanning tree* of $G-R$. We show that this problem is at least as hard as the minimization version of the *densest-k-subgraph* problem (MinDkS), wherein we seek a minimum-size set S of nodes in a given graph such that at least k edges have both endpoints in S. This shows a stark contrast between MST interdiction and MaxST interdiction.

▶ **Theorem 18.** *An $\alpha(m,n)$-approximation algorithm for the maximum-spanning-tree interdiction problem for instances with m edges, n nodes, yields a $2\alpha(m+n-1,n)$-approximation algorithm for* MinDkS *for instances with m edges and n nodes.*

Proof. Let $\mathcal{I} = \big(H=(N,F),k\big)$ be a MinDkS instance, with $|N|=n$, $|F|=m$. We may assume that $|F| \geq k$ as otherwise the instance is infeasible. We construct the following MaxST-interdiction instance $\mathcal{I}'$. The multigraph is $G=(N, E := E' \cup F)$, where E' is an arbitrary tree spanning N. Set $w_e = 0$, $c_e = m-k+1$ for all $e \in E'$, and $w_e = c_e = 1$ for all $e \in F$. We set the budget to $B = m-k$. Thus, if $R \subseteq E$ satisfies $c(R) \leq B$, we must have $R \subseteq F$, and so $G-R$ is connected and the interdiction problem has a finite optimal value.

We show that: (1) if $R \subseteq F$ is a feasible interdiction set, then the set S of non-isolated nodes of $(N, F \setminus R)$ is a feasible MinDkS solution of value at most $2 \cdot \mathsf{MaxST}(G-R)$, where $\mathsf{MaxST}(G-R)$ is the weight of a maximum spanning tree of $G-R$; (2) conversely, if $S \subseteq N$ is a feasible MinDkS solution, then $F \setminus F(S)$ is a feasible interdiction set with objective value at most $|S|$, where $F(S)$ is the set of edges in F having both endpoints in S.

These two statements imply the theorem as follows. Let $\mathcal{A}$ be the stated $\alpha = \alpha(m+n-1,n)$-approximation algorithm for maximum-spanning-tree interdiction. We run $\mathcal{A}$ to obtain a feasible interdiction set R, which yields a corresponding MinDkS solution S. Then,

$$|S| \leq 2 \cdot \mathsf{MaxST}(G-R) \leq 2\alpha\, OPT(\mathcal{I}') \leq 2\alpha\, OPT(\mathcal{I}) \ ,$$

where the first and last inequalities follow from statements (1) and (2) above.

We now prove statements (1) and (2). Let $R \subseteq F$ be such that $c(R) = |R| \leq B$. Let S denote the set of non-isolated vertices in the graph $(N, F \setminus R)$, so every node in S has at least one edge of $F \setminus R$ incident to it. First, we argue that S is a feasible MinDkS-solution. Since each vertex of $N \setminus S$ is isolated in the graph $(N, F \setminus R)$, it follows that $R \supseteq F \setminus F(S)$. Therefore, $|F| - |F(S)| \leq |R| \leq B = m-k$, and so $|F(S)| \geq k$. The weight of a maximum spanning tree in $G-R$ is equal to $|S| - \sigma$, where σ is the number of connected components of the graph $(S, F \setminus R)$. By the definition of S, this multigraph has no isolated vertices. So $\sigma \leq |S|/2$, and therefore $\mathsf{MaxST}(G-R) = |S| - \sigma \geq |S|/2$. This proves (1).

Conversely, suppose $S \subseteq N$ is such that $|F(S)| \geq k$. Then $R = F \setminus F(S)$ satisfies $c(R) = m - |F(S)| \leq B$, so is a feasible interdiction set. We have $\mathsf{MaxST}(G-R) = |S| - \sigma \leq |S|$, where σ is the number of connected components of $(S, F \setminus R)$. This proves (2). ◀

The above hardness result continues to hold with unit interdiction costs, since we can replace each edge e with $c_e = m-k+1$ in the above reduction with $m-k+1$ parallel unit-cost edges (of weight 0). Our reduction creates a MaxST-interdiction instance with two distinct edge weights $w_1 < w_2$. This interdiction problem can be seen as a special case of the following *matroid interdiction* problem (involving the graphic matroid on $\{e \in E : w_e = w_2\}$): given a matroid with ground set U and rank function rk, interdiction costs $c : U \mapsto \mathbb{R}_+$, and budget B, minimize $\mathrm{rk}(U \setminus R)$ subject to $c(R) \leq B$. Our hardness result for MaxST interdiction thus also implies that matroid interdiction is MinDkS-hard. A related rank-reduction problem—minimize $c(R)$ subject to $\mathrm{rk}(U \setminus R) \leq \mathrm{rk}(U) - k$—was considered by [16] and shown to be MinDkS-hard for transversal matroids (but not for graphic matroids, wherein this is essentially the min k-cut problem).

We remark that it is possible to achieve *bicriteria* approximation guarantees for MaxST interdiction: we can obtain a solution of weight $W \leq (1+\epsilon)OPT$ while violating the budget by a $\left(1+\frac{1}{\epsilon}\right)$ factor (and $W > OPT$ implies no budget violation). This follows by taking $\lambda = \epsilon OPT/B$ in the Lagrangian problem $\min_R\big(\mathsf{MaxST}(G-R)+\lambda c(R)\big)$, which is a submodular minimization problem that can be solved exactly; it also follows from the work of [4].

Abstract

In the reordering buffer management problem a sequence of requests arrive online in a finite metric space, and have to be processed by a single server. This server is equipped with a request buffer of size k and can decide at each point in time, which request from its buffer to serve next. Servicing of a request is simply done by moving the server to the location of the request. The goal is to process all requests while minimizing the total distance that the server is travelling inside the metric space.

In this paper we present a deterministic algorithm for the reordering buffer management problem that achieves a competitive ratio of $O(\log \Delta + \min\{\log n, \log k\})$ in a finite metric space of n points and aspect ratio Δ. This is the first algorithm that works for general metric spaces and has just a logarithmic dependency on the relevant parameters. The guarantee is memory-robust, i.e., the competitive ratio decreases only slightly when the buffer-size of the optimum is increased to $h = (1 + \epsilon)k$. For memory robust guarantees our bounds are close to optimal.

1 Introduction

In the reordering buffer management problem a sequence of requests arrive online in a finite metric space, and have to be processed by a single server. This server is equipped with a request buffer and can decide at each point in time, which request from its buffer to serve next. Servicing of a request is simply done by moving the server to the location of the request. The goal is to process all requests while minimizing the total distance that the server is traveling inside the metric space.

This simple, abstract model can be used for modeling context switching costs that occur in various applications in many different areas ranging from production engineering through computer graphics to information retrieval [7, 10, 17, 21]. In the online version of the problem the server does not see future requests but has to make its decision based on past requests and the requests it currently holds in the request buffer. The worst case ratio between the cost of the online algorithm and the cost of an optimal offline algorithm is called the *competitive ratio*.

We say a guarantee on the competitive ratio for the reordering buffer management problem is *memory robust* if the guarantee degrades gracefully as the buffer-size of the optimum algorithm is increased over the buffer-size of the online algorithm. More precisely, the ratio

between the cost of the online algorithm with a buffer-size of k, and the cost of an optimum offline algorithm with a buffer-size of $h \geq k$ should be at most $O(ch/k)$.

The main result of this paper is a deterministic algorithm for the reordering buffer management problem that achieves a competitive ratio of $O(h(\log \Delta + \min\{\log n, \log k\})/k)$ in a finite metric space of n points and aspect ratio Δ. The algorithm is also $O(h)$-competitive because any reasonable algorithm achieves this competitive ratio (see Lemma 13 in the appendix). This is the first algorithm that works for general metric spaces and has just a logarithmic dependency on the relevant parameters. The algorithm and its analysis are also very simple.

It has been shown that even on a uniform metric ($\Delta = 1$) the competitive ratio of an online algorithm (deterministic or randomized) must be $\Omega(\log k)$ against an optimum algorithm with buffer-size $h \geq (1+\epsilon)k$ [1, 12]. Hence, an $O(\log k)$ term in the competitive ratio is unavoidable for memory robust algorithms.

Biénkowski et al. [9] have shown that for a sub-linear dependency on the buffer-size there needs to be another term in the competitive ratio apart from k for memory-robust algorithms. In particular, they give an instance on a line metric with n equidistant points for which any online algorithm looses a factor of $\Omega(\min\{k, \log n\})$ against an optimum algorithm with slightly larger buffer ($h = (1+\epsilon)k$). For this instance the number of points n is equal to the aspect ratio Δ. So a logarithmic dependency on the aspect ratio seems reasonable.

Englert and Räcke [12] present a deterministic, memory-robust algorithm for tree metrics of hop-diameter D that obtains a competitive ratio of $O(\frac{h}{k}(\log D + \log k))$. They then use the technique of approximating arbitrary metrics by tree-metrics due to Fakcharoenphol, Rao, and Talwar [14] to obtain a randomized $O(\frac{h}{k} \log n \cdot \log h)$-competitive algorithm for general metrics.

As a whole these results are uncomparable to our results. There exist metrics where the aspect ratio Δ is very small, but there are a lot of points, resulting in very poor guarantees from the result by Englert and Räcke. However, if one considers a star with edges of different length, the aspect ratio could be very high, but the hop-diameter in the tree is just 2, which makes the guarantee given by the result in [12] stronger than ours. One advantage of our result is that for general metrics the dependency on our parameters is logarithmic, while Englert and Räcke have the product of two logarithms. This product cannot easily be removed as any (memory-robust) algorithm that relies on the FRT-approximation will loose one logarithm because of FRT, and another because an online solution on a tree will have a logarithmic competitive ratio.

In Section 5 we deal with the question whether it is possible to trade the dependency on $\log \Delta$ in our competitive ratio for something else, like e.g. $\log n$, which does not depend on the aspect ratio. Our algorithm is memory restricted in the sense that it makes its decisions only depending on the content of the buffer, and on the content of an additional memory that contains k bits. We show, that for such a scenario there exist instances with an aspect ratio Δ, on which every memory-restricted algorithm with k bits is $\Omega(\sqrt{\log \Delta})$-competitive. This extends a lower bound due to Khandekar and Pandit [20] for memoryless algorithms.

1.1 Further Related Work

Most previous work on the reordering buffer management problem considers the case of uniform metrics. Räcke et al. [22] introduced the problem and developed a deterministic algorithm with competitive ratio $O(\log^2 k)$, which was subsequently improved to $O(\log k)$ by Englert and Westermann [13]. The analysis of both these algorithms can be slightly modified to give a memory-robust guarantee.

The first paper that used an analysis technique that is not memory-robust (and can therefore beat the $\Theta(\log k)$-guarantee) was due to Avigdor-Elgrabli and Rabani, who presented a deterministic algorithm with competitive ratio $O(\log k/\log\log k)$. This in turn was improved to a guarantee of $O(\sqrt{\log k})$ by Adamaszek et al. [2], which is close to optimal due to a lower bound of $\Omega(\sqrt{\log k/\log\log k})$ shown in the same paper. For randomized algorithms Avigdor-Elgrabli and Rabani present an $O(\log\log k)$-competitive algorithm [6]. This is optimal due to a corresponding lower bound proved by Adamaszek et al. [2].

For star metric spaces the result by Englert and Westermann [13] obtains a deterministic competitive ratio of $O(\log k)$. The result by Adamaszek et al. [2] gives an $O(\sqrt{\log k})$ guarantee for the case that $\Delta = O(\text{poly}(k))$. A straightforward extension to arbitrary values of Δ gives a competitive ratio of $O(\sqrt{\log k + \log\Delta})$. For the randomized case Avigdor-Elgrabli et al. [4] give an $O((\log\log(k\Delta))^2)$-competitive algorithm, i.e., an algorithm with a slight dependency on the aspect ratio of the metric space.

Gamzu and Segev [15] analyze the reordering buffer problem for n points on a line as this can be used to model the disc scheduling problem. They present a deterministic algorithm with a competitive ratio of $O(\log n)$.

In the offline case it has been shown that finding an optimal solution to the problem is NP-hard even on uniform metrics [3, 11]. Avigdor-Elgrabli and Rabani have given a constant factor approximation [5]. Im and Moseley gave an $O(\log\log(k\Delta))$-approximation for the star-metric [18] and subsequently improved this to $O(\log\log\log(k\Delta))$ [19]. Barman et al. [8] gave a bicriteria approximation algorithm that achieves an approximation guarantee of $O(\log n)$ when the buffer of the online algorithm is a constant factor *larger* than the buffer of the optimum algorithm. This works in general metric spaces.

1.2 The Model

An input sequence σ of requests has to be processed, where each request σ_i corresponds to some point in a finite metric space $M = (V, d)$. We use $n = |V|$ to denote the number of distinct points in M, and Δ to denote its *aspect ratio*, i.e., the ratio between the largest and smallest distance between two points. We assume w.l.o.g. that the minimum non-zero distance between two points is 1.

A *reordering buffer* that can store k requests can be used to rearrange the input sequence into an output sequence σ' in the following way. Initially, the buffer contains the first k requests of σ. In every time step t an algorithm has to select a request r from the buffer and append it to the output sequence, i.e., the algorithm sets σ'_t to r. If there are still requests waiting in the input sequence, the next such request takes r's place in the buffer; otherwise this place stays empty. The process is repeated until all requests from σ have been appended to the output sequence.

An online algorithm ALG has to make its decision based on the requests in the buffer and on the requests previously seen, but not based on future requests that are still to come. Suppose an algorithm ALG generates a request sequence σ' when giving a request sequence σ as input. The (true) cost $\text{ALG}_{true}(\sigma)$ is defined as

$$\text{ALG}_{true}(\sigma) = \sum_{i=1}^{\ell-1} d(\sigma'_i, \sigma'_{i+1}) \ ,$$

where ℓ is the length of the input sequence. Note that this means that the server may start its processing at the first request without incurring any cost for traveling to this location.

Throughout the paper we use a slightly different notation w.r.t. the optimum algorithm OPT for processing σ. Firstly, we assume that OPT has a larger buffer-size $h \geq k$. Secondly,

we denote the (true) cost of this algorithm with $\mathrm{OPT}(\sigma) = \mathrm{OPT}_{true}(\sigma)$. The reason is that for an online algorithm we will introduce an approximate (simplified) version of $\mathrm{ALG}_{true}(\sigma)$, which will be denoted with $\mathrm{ALG}(\sigma)$. Hence, for the online algorithm we need the differentiation between $\mathrm{ALG}(\sigma)$ and $\mathrm{ALG}_{true}(\sigma)$, whereas this is not required for the optimum algorithm.

2 The Algorithm

A *block-oriented* algorithm for the reordering buffer management problem serves requests in blocks. Whenever the buffer gets full, the algorithm identifies a set S of requests from the buffer and serves these requests. Additional requests that arrive while serving requests in S are ignored, and will not be considered until all requests in S have been handled. We call such a set S of requests chosen by the algorithm a *block*. The process of choosing and servicing blocks of requests is repeated until the end of the input sequence is reached. The requests in the buffer at this time form the last *block* of the algorithm.

For a block-oriented algorithm we can write down the (approximate) cost of the algorithm just in terms of the sequence $S_1, S_2, S_3, \ldots$ of generated blocks. This is done as follows. For a block S_i, we use $C(S_i)$ to denote the *cost of the block*, which is defined as the length of a shortest path that connects all requests in S_i (note that computing $C(S_i)$ is NP-hard). For two blocks S_i and S_j, we define the *distance* $d(S_i, S_j)$ between the two blocks, by

$$d(S_i, S_j) = \min_{r_i \in S_i, r_j \in S_j} d(r_i, r_j) \ ,$$

i.e., the distance of the closest pair $(r_i, r_j) \in S_i \times S_j$.

Suppose that for a request sequence σ a block-oriented algorithm generates a sequence $S_1, S_2, \ldots, S_\ell$ of blocks. We define the *cost* $\mathrm{ALG}(\sigma)$ of the algorithm by

$$\mathrm{ALG}(\sigma) = \sum_{i=1}^{\ell} C(S_i) + \sum_{i=1}^{\ell-1} d(S_i, S_{i+1}) \ . \tag{1}$$

We refer to the first term in Equation 1 as the *block cost* $\mathrm{ALG}_{bc}(\sigma)$ of the algorithm, and to the second term as the *connection cost* $\mathrm{ALG}_{cc}(\sigma)$. The following lemma shows that this definition of cost is close to the true cost of the algorithm. The fact that we can specify the cost of the algorithm just in terms of the generated blocks will greatly simplifies our analysis.

▶ **Lemma 1.** *We can implement any block-oriented algorithm* ALG *such that* $\mathrm{ALG}(\sigma) \leq \mathrm{ALG}_{true}(\sigma) \leq 3\,\mathrm{ALG}(\sigma)$.

Proof. In the following we describe how to serve all requests in a block S_i, and how to move to the next block S_{i+1}. Suppose the server is initially located at a request from S_i (for the first block S_1 we can assume this because according to our model the server may start at an arbitrary location). Since the requests in block S_i are known completely before serving its first request, we can efficiently compute an MST that covers all requests in S_i. The cost of traversing the elements by following the edges of the MST is at most $2C(S_i)$. Let (r_i, r_{i+1}) denote the request pair in $S_i \times S_{i+1}$ with minimum distance. We move, from our current location (after serving the last request from S_i) along a shortest path to r_{i+1}. The cost for this step is at most $C(S_i) + d(r_i, r_{i+1})$.

Repeating the above step for all blocks gives a total true cost $\mathrm{ALG}_{true}(\sigma)$ of at most $3\,\mathrm{ALG}_{bc}(\sigma) + \mathrm{ALG}_{cc}(\sigma) \leq 3\,\mathrm{ALG}(\sigma)$. ◀

In order to complete the description of the algorithm we need to describe how to choose a *good* block of requests for service when the buffer becomes full. For this we need a few definitions. For a set S of requests, and a value δ, $0 \leq \delta \leq 1$ we define the δ-fraction cost $C_\delta(S)$ of S as the minimum cost for servicing a δ-fraction of the elements from S. Formally,

$$C_\delta(S) = \min_{U \subseteq S, |U| \geq \delta \cdot |S|} C(U) \ .$$

Our algorithm StableSet is based on the following notion of a *large, stable set*. Intuitively, the cost for servicing the elements of a stable set S does not reduce by too much even if a large fraction of elements from S is removed.

▶ **Definition 2.** A set S of requests is (α, β, γ)-stable if the following holds

1. $C_{1-\alpha}(S) \geq \beta \cdot C(S)$ (stability constraint),
2. $|S| \geq \gamma k$ (size constraint).

In Section 4 we prove the following lemma showing that we can efficiently find stable sets with good parameters.

▶ **Lemma 3.** *Let V denote a set of k requests covering at most $\ell \leq k$ distinct locations in a metric space with aspect ratio Δ. There exists a polynomial time algorithm that finds an (α, β, γ)-stable subset $S \subseteq V$ with $\alpha \geq 1/(1 + \log \Delta + \log \ell)$, $\beta \geq 1/8$, and $\gamma \geq 1/e$.*

With these definitions our algorithm StableSet becomes very simple. When the buffer becomes full, choose a stable subset S from the elements of the buffer according to the algorithm implicit in Lemma 3. Then service this block of requests according to the algorithm in Lemma 1. This is repeated until the end of the input sequence is reached. The elements that still remain in the buffer form the last block of the algorithm.

3 Analysis

In the following we first describe a general approach to obtain a lower bound on the cost $\mathrm{OPT}(\sigma)$ of the optimal solution. Let $X_1, \ldots, X_\ell$ denote subsets of requests from the input sequence. We say that a subset X_i is *partially scheduled* by OPT at time t, if the first t requests in OPT's output sequence contain at least one but not all elements from X_i. The following claim gives a lower bound on the optimum cost.

▶ **Claim 4.** *Let $X_1, \ldots, X_\ell$ denote (not necessarily disjoint) subsets of requests from the input sequence, and suppose that at each point in time there are at most s subsets X_i that are partially scheduled by* OPT. *Then* $\mathrm{OPT}(\sigma) \geq \frac{1}{s} \sum_i C(X_i)$.

Proof. We associate an interval $[start(i), end(i)]$ with each set X_i, where $start(i)$ denotes the position of the first element of X_i that appears in OPT's output sequence, and $end(i)$ denotes the position of the last such element. Clearly, the cost of OPT for serving elements that lie between $start(i)$ and $end(i)$ is at least $C(X_i)$.

We can color the intervals with s colors such that intervals with the same color do not intersect. This holds because the interval graph corresponding to the set of intervals has a maximum clique size of s. Such interval graphs can be colored with s colors by a Greedy algorithm. Since sets X_i from the same color class do not interleave in OPT's output sequence the cost for serving all elements of a color-class is at least $\sum_{i \in I} C(X_i)$, where I denotes the index set of the color-class. As there must exist a color-class with cost at least $\frac{1}{s} \sum_i C(X_i)$ the claim follows. ◀

3.1 Analyzing Block Cost

The following lemma gives the bound on the block cost induced by an algorithm that uses stable sets.

▶ **Lemma 5.** *Let $S_1, S_2, \ldots, S_\ell$ denote the sequence of blocks generated by a block-oriented algorithm, where all but the last block are (α, β, γ)-stable, where $k \geq \frac{6}{\alpha\gamma}$. Then* $\mathrm{ALG}_{bc}(\sigma) \leq \left(\frac{6h}{\alpha\beta\gamma k} + 1\right) \cdot \mathrm{OPT}(\sigma)$.

Proof. Let $z = \lceil \alpha\gamma k/3 \rceil$. We obtain a set X_i $(i < \ell)$ by taking S_i and removing the first z and the last z requests from it that appear in OPT's output sequence. Then the cardinality of X_i is at least

$$|X_i| = |S_i| - 2z = |S_i| - 2\lceil \alpha\gamma k/3 \rceil \geq |S_i| - 2\alpha\gamma k/3 - 2 \geq |S_i| - \alpha\gamma k \geq (1-\alpha)|S_i| \ ,$$

where the second inequality holds for $k \geq \frac{6}{\alpha\gamma}$, and the final inequality holds due to the size constraint for block S_i. The stability constraint for S_i gives us that $C(X_i) \geq \beta C(S_i)$.

We show that at most $(h+k)/z$ sets X_i can be partially scheduled by OPT at any given time. Fix a time t. We define a partially scheduled set X_i to be of Type I if not all of S_i has already appeared in the input sequence, otherwise, we define it to be of Type II. For sets of Type II, OPT must hold the last z requests of S_i (according to the order given by OPT's output sequence) in its buffer, as these have already appeared. For sets of Type I, ALG must hold the first z requests of S_i in its buffer, as these have already appeared but ALG only starts removing elements from S_i after all of S_i has appeared. This means there can at most be k/z partially scheduled sets of Type I, and at most h/z partially scheduled sets of Type II. Applying Claim 4 gives that

$$\mathrm{OPT}(\sigma) \geq \frac{z}{h+k} \sum_{i=1}^{\ell-1} C(X_i) \geq \frac{\alpha\beta\gamma k}{6h} \sum_{i=1}^{\ell-1} C(S_i) \ . \tag{2}$$

Combining the definition of block-cost, Equation 2, and the fact that $\mathrm{OPT}(\sigma) \geq C(S_\ell)$ gives

$$\mathrm{ALG}_{bc}(\sigma) = \sum_{i=1}^{\ell} C(S_i) \geq \left(\frac{6h}{\alpha\beta\gamma k} + 1\right) \cdot \mathrm{OPT}(\sigma) \ ,$$

as desired. ◀

3.2 Analyzing Connection Cost

▶ **Lemma 6.** *Let $S_1, S_2, \ldots, S_\ell$ denote the sequence of blocks generated by a block-oriented algorithm, where all but the last block have cardinality at least γk. Then* $\mathrm{ALG}_{cc}(\sigma) \leq \left(\frac{5h}{\gamma k} + 1\right) \cdot \mathrm{OPT}(\sigma)$.

Proof. We use $\mathrm{ALG}'_{cc}(\sigma)$ to denote the connection cost, where we ignore the cost for connecting the last two blocks $S_{\ell-1}$ and S_ℓ. For every pair of consecutive blocks S_i, S_{i+1}, $i \leq \ell - 2$ we generate $\lceil \gamma k \rceil$ request-pairs by matching $\lceil \gamma k \rceil$ requests from S_i to $\lceil \gamma k \rceil$ requests from S_{i+1} in an arbitrary manner. Let X_i^r, $i \in \{1, \ldots, \ell-2\}, r \in \{1, \ldots, \lceil \gamma k \rceil\}$ denote the request pairs generated this way. We have

▶ **Fact 7.** $\sum_{i,r} C(X_i^r) \geq \gamma k \cdot \mathrm{ALG}'_{cc}(\sigma)$.

To see this, observe that for a request-pair X_i^r we have $C(X_i^r) \geq d(S_i, S_{i+1})$, as the request pair connects sets S_i and S_{i+1}. Since for every i we have at least γk requests the fact holds. The following fact allows us to apply Claim 4.

▶ **Fact 8.** *At any given time, there exist at most* $5h$ *request pairs from sets* X_i^r *that are partially scheduled by* OPT.

Proof. Fix a time step t. Suppose we have a request pair that is partially scheduled by OPT at time t. We say that it is of Type I if it has not been scheduled by ALG at all (by time step t); it is of Type II if ALG has already scheduled both requests of the pair; and it is of Type III, otherwise.

There can be at most $2h$ request pairs of Type II, because OPT must hold the second request of such a pair in its buffer, and any request can belong to at most two pairs. There can be at most $2k$ request pairs of Type I, because ALG must hold the first request of such a pair in its buffer, as this request has already appeared but ALG has not scheduled it. Finally, observe that there are at most k pairs that are partially scheduled by ALG at any point in time. Hence, the total number of partially scheduled requests of Type III is at most k.

Altogether there exists at most $3k + 2h \leq 5h$ request pairs that are partially scheduled by OPT. ◀

Combining Claim 4 with the above fact gives $\mathrm{OPT}(\sigma) \geq \frac{1}{5h} \sum_{i,r} C(X_i^r)$. Together with Fact 7 we obtain

$$\mathrm{ALG}_{cc}(\sigma) \leq \mathrm{ALG}'_{cc}(\sigma) + \mathrm{OPT}(\sigma) \leq \frac{1}{\gamma k} \sum_{i,r} C(X_i^r) + \mathrm{OPT}(\sigma) \leq \left(\frac{5h}{\gamma k} + 1\right) \cdot \mathrm{OPT}(\sigma) \ ,$$

as desired. The first inequality uses the fact that the cost for connecting the two last blocks is at most $\mathrm{OPT}(\sigma)$. ◀

3.3 Proof of the Main Result

Combining the analysis of the block cost and the connection cost gives our main theorem.

▶ **Theorem 9.** *A block-oriented algorithm that only chooses* (α, β, γ)*-stable blocks is* $O(\frac{h}{k} \cdot (\alpha\beta\gamma)^{-1})$*-competitive, against an optimal algorithm with buffer size* $h \geq k$*. Using the stable set computation from Lemma 3 gives a competitive ratio of* $O(h(\log \Delta + \min\{\log n + \log k\})/k)$ *in a metric space of* n *points and aspect ratio* Δ*.*

Proof. For the case that $k \geq \frac{6}{\alpha\gamma}$ we can simply combine the bounds in Lemma 5 and Lemma 6. For the case that $k \leq \frac{6}{\alpha\gamma}$ we use the fact that any algorithm is $O(h)$-competitive which gives the result since $O(h) = O(\frac{h}{k} \cdot k) = O(\frac{h}{k}(\alpha\beta\gamma)^{-1})$. ◀

4 Finding Stable Sets

In this section we present an algorithm for finding stable sets.

▶ **Lemma 3.** *Let* V *denote a set of* k *requests covering at most* $\ell \leq k$ *distinct locations in a metric space with aspect ratio* Δ*. There exists a polynomial time algorithm that finds an* (α, β, γ)*-stable subset* $S \subseteq V$ *with* $\alpha \geq 1/(1 + \log \Delta + \log \ell)$*,* $\beta \geq 1/8$*, and* $\gamma \geq 1/e$*.*

Proof. Set $\beta' := 1/2$ and $\alpha := 1/(1 + \log_2 \Delta + \log_2 \ell)$. For a subset S of requests we define $\mathrm{MST}_{1\text{-}\alpha}(S)$ to be a minimum spanning tree among at least $\lceil (1-\alpha)|S| \rceil$ requests from S. It is NP-hard to find such an MST but there is a 2-approximation algorithm that returns a tree $T_{1-\alpha}$ that spans $\lceil (1-\alpha)|S| \rceil$ requests and has cost $\mathrm{cost}(T_{1-\alpha}) \leq 2\,\mathrm{cost}(\mathrm{MST}_{1\text{-}\alpha}(S))$ [16].

Our algorithm for finding a stable set proceeds as follows. Initially it sets $S := V$. Then it (approximately) checks whether S is stable. For this it computes an approximation

$T_{1-\alpha}$ to $\text{MST}_{1\text{-}\alpha}(S)$ according to the algorithm by Garg [16]. Then it checks whether $\text{cost}(T_{1-\alpha}) \geq \beta' \,\text{cost}(\text{MST}(S))$. If this is the case the set S is returned. Otherwise the algorithm sets $S := V(T_{1-\alpha})$, where $V(T_{1-\alpha})$ is the vertex set of tree $T_{1-\alpha}$, and repeats the process. In the following we prove that the set S returned by the algorithm fulfills the desired constraints. We start with the stability constraint:

▶ **Fact 10.** *For each subset $U \subseteq S$, $|U| \geq (1-\alpha)|S|$, we have $C(U) \geq \frac{1}{8} \cdot C(S)$.*

Proof. We have

$$C(U) \geq \text{cost}(\text{MST}_{1\text{-}\alpha}(S)) \geq \frac{1}{2}\,\text{cost}(T_{1-\alpha}) \geq \frac{\beta'}{2}\,\text{cost}(\text{MST}(S)) \geq \frac{1}{8}C(S) \ .$$

The first step follows because an optimum path for $C(U)$ is also a spanning tree on at least $\lceil(1-\alpha)|S|\rceil$ vertices. The second step holds because of the approximation guarantee of Garg's algorithm. The third step is due to the termination condition of our procedure for finding a stable set, and the last step holds because an MST is a 2-approximation for $C(S)$. ◀

It remains to prove the size constraint. For this we require a bound on the number of iterations.

▶ **Fact 11.** *The algorithm performs at most $r_{\max} \leq \log_2(\ell\Delta) + 1$ unsuccessful iterations.*

Proof. In every unsuccessful iteration the cost of the minimum spanning tree over the set S decreases by factor $\beta' = 1/2$. The cost can be at most $\ell\Delta$ at the start, and if the cost drops below one, all remaining requests are located at a single vertex, which leads to a stable set. ◀

In every unsuccessful iteration the cardinality of the set S decreases by a $(1-\alpha)$ factor. Hence, the final cardinality is at least $k(1-\alpha)^{r_{\max}} \geq k/e$. This completes the proof of the lemma. ◀

5 Lower Bound for Memory Restricted Algorithms

In [20] Khandekar and Pandit defined a memoryless reordering buffer management algorithm as an algorithm that bases its decisions only on the content of the buffer and not on some further information that may be stored in its memory. They showed that such algorithms are severely limited by giving a lower bounds of $\Omega(k)$ on the competitive ratio. In terms of the aspect ratio their lower bound example gives $\Omega(\log\Delta/\log\log(\Delta))$.

In this section we extend their result and show that an algorithm that only bases its decision on the buffer-content and on further k bits of memory may experience a competitive ratio of $\Omega(\sqrt{\log\Delta})$. This means, if the memory used by the algorithm does not depend on the aspect ratio, the aspect ratio must appear in the competitive ratio in some form (unless, of course, the competitive ratio is a trivial bound like $O(k)$).

Since our block-oriented algorithm only needs to mark all requests that belong to the current block, it can be implemented with k bits of memory. Hence, one reason that the aspect ratio appears in our competitive ratio is the structure of the algorithm that makes it memory-restricted.

▶ **Lemma 12.** *There exists an input sequence with aspect ratio $\Delta \leq (k(k+1)2^m)^k$, for which any deterministic reordering buffer management algorithm with m bits of memory has competitive ratio $\Omega(k)$. For $m = k$ this gives a lower bound of $\Omega(\sqrt{\log\Delta})$ on the competitive ratio.*

Proof. The instance consists of a metric space over $k+1$ vertices $\{v_0, \ldots, v_k\}$, where the distance between two distinct vertices v_i and v_j is $d(v_i, v_j) = \lambda^i + \lambda^j$. The vertices can be viewed as the leaves of a star, where the vertex v_i is connected to the center of the star via an edge of length λ^i. λ will be chosen later.

Let $\mathrm{ALG}_t \in \{v_0, \ldots, v_k\}$ denote the position of the online server in the metric space after the t-th request has been served. Initially, there is a request at every vertex v_i, $i \neq 0$, and we assume contrary to the definition of our model in Section 1.2 that the online algorithm has to start at vertex v_0 (i.e., $\mathrm{ALG}_0 = v_0$). This slight change in the model does not affect our asymptotic results. The input sequence is chosen adversarily: after serving the request at ALG_t a new request at ALG_{t-1} appears. This means that whenever the online algorithm is making a decision on the next request to serve, there is a request located at every vertex v_i different from the current position of the ALG-server.

There are $k+1$ possible states of the buffer; one state for every position of the online server. In addition, the m bits of memory give rise to 2^m memory-states. The state of the algorithm is a combination of the buffer-state and the memory-state. This means in total there are $z := (k+1)2^m$ different states that the algorithm may be in. Depending on its state $\mathcal{S}$ the algorithm deterministically chooses a vertex v_{next}, and serves the request located at this vertex. Then a new request appears at its previous position, and the algorithm is in some new state $\mathcal{S}'$.

We model the servicing of our adversarial sequence σ by a deterministic algorithm, as a path on a state graph G that contains one vertex for every possible state $\mathcal{S}$, and a directed edge $(\mathcal{S}, \mathcal{S}')$ if $\mathcal{S}'$ is the successor state to state $\mathcal{S}$. We assign a weight to every edge in G as follows. If $\mathcal{S}$ corresponds to a state where the server is located at v_i and $\mathcal{S}'$ corresponds to a state with the server at position v_j, we assign a length of $d(v_i, v_j)$ to edge $(\mathcal{S}, \mathcal{S}')$. By this definition the servicing of the request sequence corresponds to a path P on the state graph and the length of this path is the cost of the online algorithm. Note that the path will actually contain a cycle C, and asymptotically the cost of the online algorithm is determined by the cost for serving the cycle.

Let $v_{i_{\max}}$ denote the vertex with largest index that corresponds to some state along the cycle, let $n_{\max}$ denote the number of states along the cycle that correspond to this position, and let n_C denote the total number of vertices along the cycle. The cost of the online algorithm for serving the cycle is at least

$$\mathrm{cost}_{\mathrm{ALG}}(C) \geq 2n_{\max}\lambda^{i_{\max}} \ ,$$

as it enters and leaves the vertex $v_{i_{\max}}$ at least $n_{\max}$ times. An optimum algorithm can serve the cycle differently. It only holds requests at location $v_{i_{\max}}$ in its buffer. All other requests are served immediately as they arrive. Then it only has to pay for the edge to $v_{i_{\max}}$ every k-th time. Hence, the optimum (average) cost for serving the cycle is at most

$$\mathrm{cost}_{\mathrm{OPT}}(C) \leq 2n_C\lambda^{i_{\max}-1} + 2n_{\max}\lambda^{i_{\max}}/k \ .$$

This gives

$$\frac{\mathrm{cost}_{\mathrm{ALG}}(C)}{\mathrm{cost}_{\mathrm{OPT}}(C)} \geq \frac{n_{\max}\lambda^{i_{\max}}}{n_C\lambda^{i_{\max}-1} + n_{\max}\lambda^{i_{\max}}/k} \geq \frac{n_{\max}}{z/\lambda + n_{\max}/k} \geq \frac{n_{\max}}{1+n_{\max}}k = \Omega(k) \ .$$

Here, we use the fact that $n_C \leq z$ (the number of states) for the second inequality, and we choose $\lambda = kz$ for the third inequality. The ratio of the costs on the cycle gives an asymptotic bound on the competitive ratio, as the cycle dominates the cost. With our choice of λ we get that the aspect ratio Δ is $\Delta \leq \lambda^k = (k(k+1)2^m)^k$. ◀

Acknowledgments. We thank Matthias Englert for making us aware that the competitive ratio of a memory restricted algorithm should depend on the aspect ratio.

A Reasonable Algorithms

We define an algorithm for the reordering buffer management problem to be *reasonable* if at any point in time it chooses a request r from the buffer as the next request to be served, and then moves from its current location to r along a shortest path.

▶ **Lemma 13.** *Any reasonable algorithm for the reordering buffer management problem has competitive ratio* $2(h+k)$.

Proof. Suppose a reasonable online algorithm generates an output sequences $s_1, s_2, \ldots, s_\ell$. Its cost $\mathrm{ALG}_{true}(\sigma)$ is then $\sum_{i=1}^{\ell-1} d(s_i, s_{i+1})$. We define sets of consecutive requests: $X_i := \{s_i, s_{i+1}\}$. In the following we prove that at any point in time there can at most be $2(h+k)$ sets X_i that are partially scheduled by OPT. The result then follows by applying Claim 4.

Fix a time t. We order the elements within a request-pair X_j according to the order in which the elements are scheduled by OPT, and will refer to them as the first and second request, respectively. Suppose a request pair $X_j, j \leq t$ is partially scheduled by OPT at time t. This means that the second request of the pair must stay in OPT's buffer between steps t and $t+1$ because both requests have already appeared by time t. Note that this holds even for the case $j = t$, because the element s_{t+1} that is output by ALG at time $t+1$ must have appeared on or before time t. Any request is only contained in at most two pairs. Consequently, there can be at most $2h$ request pairs $X_j, j \leq t$, that are partially scheduled by OPT at time t.

Now, consider a request pair X_j, $j > t$ that is partially scheduled by OPT at time t. The first request of the pair is scheduled by OPT at time t or before, but ALG schedules both requests at time $t+1$ or later. Hence, the first request of the pair must be stored by ALG between steps t and $t+1$. This means we can have at most $2k$ request pairs $X_j, j > t$

that are partially scheduled by OPT at time t. In total we get at most $2(h+k)$ partially scheduled pairs. Applying Claim 4 gives

$$\mathrm{OPT}(\sigma) \geq \frac{1}{2(h+k)} \sum_i C(X_i) \ ,$$

and, hence, $\mathrm{ALG}_{true}(\sigma) \leq 2(h+k) \cdot \mathrm{OPT}(\sigma)$, as desired. ◀

Correlated Rounding of Multiple Uniform Matroids and Multi-Label Classification

Abstract

We introduce *correlated randomized dependent rounding* where, given multiple points $\mathbf{y}^1, \ldots, \mathbf{y}^n$ in some polytope $\mathcal{P} \subseteq [0,1]^k$, the goal is to simultaneously round each $\mathbf{y}^i$ to some integral $\mathbf{z}^i \in \mathcal{P}$ while preserving both marginal values and expected distances between the points. In addition to being a natural question in its own right, the correlated randomized dependent rounding problem is motivated by multi-label classification applications that arise in machine learning, *e.g.*, classification of web pages, semantic tagging of images, and functional genomics. The results of this work can be summarized as follows: (1) we present an algorithm for solving the correlated randomized dependent rounding problem in uniform matroids while losing only a factor of $O(\log k)$ in the distances (k is the size of the ground set); (2) we introduce a novel multi-label classification problem, the *metric multi-labeling* problem, which captures the above applications. We present a (true) $O(\log k)$-approximation for the general case of metric multi-labeling and a tight 2-approximation for the special case where there is no limit on the number of labels that can be assigned to an object.

1 Introduction

Randomized rounding [32] is a fundamental technique in approximation algorithms. In this approach, given a solution $\mathbf{y} \in \mathbb{R}^k$ to some linear program, each y_i is *independently* rounded

* Joseph (Seffi) Naor's work is supported in part by ISF grant 1585/15 and US-Israel BSF grant 2014414 (part of this work was done while visiting the Simons Institute for the Theory of Computing).
† Roy Schwart'z work is supported by ISF grant 1336/16.

into an integral value. Unfortunately, when constraints on the rounded solution are present, randomized rounding does not always produce a feasible solution. Hence, *dependent* rounding schemes were introduced [1, 2, 10, 12, 22, 26, 35]. In general, dependent rounding needs to solve the following problem: given a polytope $\mathcal{P} \subseteq [0,1]^k$ over ground set K of size k and $\mathbf{y} \in \mathcal{P}$, round $\mathbf{y}$ into $\mathbf{z} \in \mathcal{P} \cap \{0,1\}^k$ such that $\mathbb{E}[\mathbf{z}] = \mathbf{y}$. Intuitively, $\mathbf{z}$ has the following two properties: (1) $\mathbf{z}$ is always integral and feasible since $\mathbf{z} \in \mathcal{P} \cap \{0,1\}^k$; and (2) $\mathbf{z}$ preserves the marginal values given by $\mathbf{y}$ for each element in K since $\mathbb{E}[\mathbf{z}] = \mathbf{y}$. The above problem has been extensively studied and was solved for different types of polytopes $\mathcal{P}$, *e.g.*, bipartite matching and b-matching [22, 26], uniform matroids [35], spanning trees [2], and general matroids [12][1].

In this work we consider a natural extension of dependent rounding in which we are given many points in $\mathcal{P}$ and the goal is to round all the points, while preserving both marginal values and expected distances (up to some loss) between any pair of points. Formally, given a polytope $\mathcal{P} \subseteq [0,1]^k$ over ground set K of size k and $\mathbf{y}^1, \ldots, \mathbf{y}^n \in \mathcal{P}$, we need to round each $\mathbf{y}^i$ to some $\mathbf{z}^i$ such that the following hold: (1) $\mathbf{z}^i \in \mathcal{P} \cap \{0,1\}^k$ for every $i = 1, \ldots, n$; (2) $\mathbb{E}\left[\mathbf{z}^i\right] = \mathbf{y}^i$ for every $i = 1, \ldots, n$; and (3) there exists some loss factor α such that $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right] \leq \alpha ||\mathbf{y}^i - \mathbf{y}^j||_1$ for every $i, j = 1, \ldots, n$. We call this problem *correlated randomized dependent rounding*. Note that requirements (1) and (2) imply that each $\mathbf{z}^i$ is a feasible rounding of $\mathbf{y}^i$ that preserves marginal values, as in the standard dependent rounding setting. The novelty of our problem lies in requirement (3) which states that for all pairs of points the expected distance after the rounding, *i.e.*, $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right]$, is within a factor of α from the original distance between the points, *i.e.*, $||\mathbf{y}^i - \mathbf{y}^j||_1$. Additionally, it will be useful also to consider an extension of the above where each point $\mathbf{y}^i$ (and thus also $\mathbf{z}^i$) is required to be in a different polytope $\mathcal{P}_i$.

Our main reason for introducing the correlated randomized dependent rounding setting originates from multi-label classification problems. In classification problems, one must assign labels to objects given some observed data. In this work we consider classification problems where multiple labels can be assigned to each object. Such problems naturally arise in various settings, *e.g.*, classification of textual data such as web pages [38, 39], semantic tagging of images and videos [7, 30, 42], and functional genomics [4, 5].

The assignment of labels to objects should be done in a manner that is most consistent with the observed data, from which two important ingredients are derived. The first is an *assignment cost* for every (object,label) pair, reflecting a recommendation given by a local learning process which infers label preferences of objects. The second is similarity information on pairs of objects, giving rise to *separation costs* incurred once different label sets are assigned to a pair of similar objects. Our goal is to find a labeling that minimizes a global cost function, while taking into account both local and pairwise information.

To provide some intuition for the formal problem given below and the possible range of its parameters, we provide a concrete example. The objective in the example is that of assigning topics to web pages, where objects are the web pages and labels are the topics. Here, it is very natural for a web page to discuss more than one topic. The assignment cost of a (webpage,topic) pair can be derived from the features associated with a web page, *e.g.*, its words, or shingles, and the domain it is located in. However, consider information from search queries leading to the web page. A specific search query is typically observed only a

[1] In some of the above works, additional properties of $\mathbf{z}$ are required, *e.g.*, concentration of linear functions over $\mathbf{z}$. Since such concentration bounds are not required for the metric multi-labeling (MML) problem, the discussion on this topic is postponed to a full version of the paper.

handful of times, and though features can be extracted from it, a very natural way to use the latter information is by having pairwise similarity relations between web pages, if both were reached by the same search query.

We note that when assigning multiple labels to objects, it is often desirable to bound the number of labels assigned to objects. As a matter of fact, in most of the papers cited above the total number of labels can be in the thousands or even millions, while each object is expected to be assigned only a handful of labels. In particular, in the above example, we expect a single webpage to be assigned only a small fraction of all possible topics. This property imposes further constraints on our objective that we elaborate on below.

We are now ready to introduce the *metric multi-labeling* (MML) problem. In (MML) we are given a set of nodes V, where each node corresponds to an object, and a set of labels $K = \{1, 2, \ldots, k\}$. The pairwise relations are given in the form of an edge set E and a weight function $s : E \to \mathbb{R}^+$, capturing similarity between objects. Additionally, the bound function $b : V \to \mathbb{N}$ specifies how many labels can be assigned to each node. Finally, we are given an assignment cost function $c : V \times K \to \mathbb{R}$. Assignment costs may be either positive or negative, reflecting a recommendation given by a local learning process which infers the label preferences of objects. Intuitively, if $c(v, \ell) \geq 0$ (or $c(v, \ell) < 0$) we say that node v *dislikes* (or *likes*) label ℓ. A detailed explanation as to why assignment costs might be either positive or negative is deferred to a full version of the paper. The learning process determining assignment costs ignores pairwise relations between objects. Clearly, the labeling cost of completely agreeing with this recommendation is the minimum possible, and this is our *benchmark labeling*. We evaluate the assignment cost of a labeling by its deviation from the benchmark labeling.

A feasible multi-labeling $f : V \to 2^K \setminus \emptyset$ is an assignment of at least one label to every node, such that $|f(v)| \leq b_v$, *i.e.*, the number of labels assigned to v is at most b_v. For the special case where $b_v = k$ for every $v \in V$, *i.e.*, there is no upper bound on the number of labels that can be assigned to a node, we denote the problem by (Unbounded-MML).

The cost of a multi-labeling is measured by the sum of two terms: assignment costs and separation costs. Let us first focus on assignment costs, which measure the deviation of f from the benchmark labeling. Specifically, for every node v, the benchmark labeling assigns to v all labels it likes, *i.e.*, labels ℓ for which $c(v, \ell) < 0$, and does not assign to v any of the labels it dislikes, *i.e.*, labels ℓ for which $c(v, \ell) \geq 0$. Thus, focusing on a single label ℓ, f deviates from the benchmark labeling by $c(v, \ell)$ if $\ell \in f(v)$ and ℓ is a label v dislikes, *i.e.*, $c(v, \ell) \geq 0$. Similarly, f deviates from the benchmark labeling by $|c(v, \ell)|$ if $\ell \notin f(v)$ and ℓ is a label v likes, *i.e.*, $c(v, \ell) < 0$. Formally, denote by $K^+(v) \triangleq \{\ell \in K : c(v, \ell) \geq 0\}$ the collection of all labels v dislikes, and by $K^-(v) \triangleq \{\ell \in K : c(v, \ell) < 0\}$ the collection of all labels v likes. Then, the total assignment cost of node v with respect to f is: $\sum_{\ell \in K^+(v)} c(v, \ell) \mathbf{1}_{\{\ell \in f(v)\}} + \sum_{\ell \in K^-(v)} |c(v, \ell)| \, \mathbf{1}_{\{\ell \notin f(v)\}}$.

Let us now focus on the separation costs. The separation cost of edge (u, v) is the number of labels nodes u and v disagree on, *i.e.*, the ℓ_1 distance between the characteristic vectors of $f(u)$ and $f(v)$. Formally, a pair of nodes (u, v), given a multi-labeling f, incurs the following separation cost: $s(u, v) \cdot ||\mathbf{1}_{f(u)} - \mathbf{1}_{f(v)}||_1$. For any subset of labels $S \subseteq K$, $\mathbf{1}_S$ denotes the characteristic vector of S. Summing up over the above we are now ready to provide a formal

definition of the (MML) problem: find a feasible multi-labeling f that minimizes

$$\sum_{v\in V}\left(\sum_{\ell\in K^+(v)} c(v,\ell)\mathbf{1}_{\{\ell\in f(v)\}} + \sum_{\ell\in K^-(v)} |c(v,\ell)|\,\mathbf{1}_{\{\ell\notin f(v)\}}\right) + \sum_{(u,v)\in E} s(u,v)||\mathbf{1}_{f(u)} - \mathbf{1}_{f(v)}||_1\,. \tag{1}$$

Summarizing, (MML) is a novel classification model in which multiple labels can be assigned to objects. We emphasize that in (MML), obtaining a solution to the (global) optimization objective is decoupled from the local learning process for the objects, thus allowing us to view the output of these processes as part of the input to (MML), and treating them in a "black box" fashion.

Let us now focus on our results. We introduce the correlated randomized dependent rounding problem and the (MML) problem. We tackle the correlated dependent rounding problem for the case of multiple (possibly different) uniform matroids, as summarized in the following theorem.

▶ **Theorem 1.** *Let K be a ground set of size k and $M_1,\ldots,M_n$ be n uniform matroids over K, where $rank(M_i) = b_i$. Additionally, let $\mathbf{y}^i \in \{\mathbf{y}\in[0,1]^k : \sum_{\ell=1}^k y_\ell \le b_i\}$ for every $i=1,\ldots,n$. Then there is an efficient algorithm for sampling $\mathbf{z}^1,\ldots,\mathbf{z}^n$ s.t.: (1) $\mathbf{z}^i$ is the characteristic vector of an independent set of M_i for every $i=1,\ldots,n$; (2) $\mathbb{E}\left[\mathbf{z}^i\right] = \mathbf{y}^i$ for every $i=1,\ldots,n$; and (3) $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right] \le O(\log k)||\mathbf{y}^i - \mathbf{y}^j||_1$ for every $i,j=1,\ldots,n$.*

Note that the loss in the distance, *i.e.*, property (3) above, depends only on the size of the ground set k and not on the number of given matroids n.

We use the above to obtain a (true) approximation of $O(\log k)$ for (MML). For the special case of (Unbounded-MML) we present a tight 2-approximation.

▶ **Theorem 2.** *The (MML) problem admits a (true) approximation of $O(\log k)$.*

▶ **Theorem 3.** *The (Unbounded-MML) problem admits an approximation of 2.*

▶ **Theorem 4.** *Assuming the unique games conjecture, the (Unbounded-MML) problem does not admit an approximation better than $2\,(1-1/k)$.*

Let us now focus on our approach and techniques. Consider the correlated dependent rounding problem, we now elaborate as to why known techniques fail when applied to it. The problem of rounding of online paging [6] is closely related to correlated dependent rounding. Unfortunately, techniques developed in the paging context allow us to bound distances only between *some* of the pairs of points, *i.e.*, $\mathbb{E}\left[||\mathbf{z}^{i+1} - \mathbf{z}^i||_1\right]$ for every $i=1,\ldots,n-1$, as opposed to the desired $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right]$ for every $i,j=1,\ldots,n$. Therefore, a different approach is required.

We note that achieving requirements (1) and (2) alone, *i.e.*, $\mathbf{z}^i \in \mathcal{P}\cap\{0,1\}^k$ and $\mathbb{E}\left[\mathbf{z}^i\right] = \mathbf{y}^i$ for every $i=1,\ldots,n$, has already been achieved by any of the dependent rounding algorithms that can be applied to a uniform matroid, *e.g.*, [10, 12, 35] (just execute the algorithm independently for each $\mathbf{y}^i$). Obviously, this approach completely fails when considering requirement (3), *i.e.*, $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right] \le \alpha||\mathbf{y}^i - \mathbf{y}^j||_1$, as α might be unbounded. The reason for the latter is that if $\mathbf{y}^i = \mathbf{y}^j$ for some $i \ne j$, then $||\mathbf{y}^i - \mathbf{y}^j||_1 = 0$ but $\mathbb{E}\left[||\mathbf{z}^i - \mathbf{z}^j||_1\right] > 0$ (as the two executions of dependent rounding, one for $\mathbf{y}^i$ and the other for $\mathbf{y}^j$, are independent).

Our approach to solving the above is to correlate all n executions of dependent rounding, one for each $\mathbf{y}^1, \ldots, \mathbf{y}^n$. Specifically, we execute the randomized dependent rounding algorithm of [35] for each $\mathbf{y}^i$ separately, but use the *same* random bits as input for all n different executions. Remarkably, this simple approach suffices. However, we note that the analysis of our algorithm uses the specific inner-workings of the algorithm of [35]. Hence, it seems that correlated dependent rounding cannot be easily solved through a "black box" application of any dependent rounding algorithm, *e.g.*, [10, 12].

Let us now focus on the special case (Unbounded-MML) and illustrate why known algorithms and techniques fail when applied to it. (Unbounded-MML) is inspired by the *metric labeling* problem, first introduced in full generality by [25]. In the metric labeling problem we are given an edge weighted graph $G = (V, E)$, a collection K of k labels, a *non-negative* assignment cost function $c : V \times K \to \mathbb{R}^+$, and a metric d over K. The goal is to assign a *single* label to each node while minimizing the sum of assignment and separation costs. As in (Unbounded-MML), assignment costs are defined using c, whereas the separation cost of edge (u, v) is the distance in the metric d between the labels assigned to u and v. It is important to note that metric labeling differs from (Unbounded-MML) in two main points: (1) each object can be assigned exactly one label, as opposed to multiple labels in (Unbounded-MML), and (2) the assignment cost function c is non-negative, whereas in (Unbounded-MML) assignment costs may be either positive or negative.

Consider a further restricted special case of (Unbounded-MML) where all assignment costs are non-negative. If one applies the algorithm of [25] by expanding the label set K to $2^K \setminus \emptyset$ and considering the ℓ_1 metric on the expanded set[2], then this not only results in a large approximation guarantee of $O(k)$, but also the running time of the algorithm scales with 2^k and not k. More generally, we wish to claim that existing techniques and algorithms for the metric labeling problem cannot be directly applied to (Unbounded-MML). Consider a node v which has multiple labels ℓ it likes, *i.e.*, $c(v, \ell) < 0$. Since only a single label is allowed per node in metric labeling, it must be the case that whatever algorithm or technique we use, there is at least one label v likes that ultimately is not assigned to v. Thus, potentially incurring a huge loss in the objective.

We address the above difficulties by employing two approaches. First, we use a *global* charging argument over all labels in K when bounding the separation cost of an edge (u, v). Typically, such global arguments are avoided, *e.g.*, all known algorithm for metric labeling (either with a general or a specific metric) do not employ any type of global argument. Second, we *distort* the optimal marginal probabilities $x_{v,\ell}$ given by the linear programming relaxation for (Unbounded-MML). This enables us to balance both positive and negative assignment costs, along with separation costs.

Let us now mention some related work. An extensively studied topic is that of dependent rounding of fractional solution. A randomized variant of pipage rounding [1] was given by [22] who applied it to assignment polytopes (see also [26, 35]). An approach based on maximum entropy for dependent rounding was introduced by [3] in the context of max-min allocations, and was later extended to spanning trees by [2]. When considering general matroid independence polytopes, [10, 12] provided methods of conducting dependent rounding.

(MML) gets as input costs for assigning labels to objects and a similarity measure between objects. The labeling costs are based on a multi-label learning process (supervised learning) which is applied to a set of instances, each belonging potentially to multiple classes (labels),

[2] Only the general algorithm of [25] is known for the case of ℓ_1 distances over the k-dimensional hypercube, and it achieves an approximation of $O(k)$. This guarantee is tight as it based on tree metrics.

and predicts a set of class labels given a new instance. *Multi-label classification* has attracted much attention following various real world problems requiring usage of multiple labels [37], and thorough surveys in this area can be found in [34, 36]. The basic approach transforms the original problem into several instances of simpler binary classification problems, where each instance corresponds to a single label. This method is called *binary relevance*, and it assumes that labels are independent of each other, and thus one needs to solve k separate binary-label classification problems, where k denotes the number of labels. Approaches based on classifier chains have been adopted to model interdependencies between labels while maintaining acceptable computational complexity [33].

The *label power set* approach transforms the problem into a multi-class problem [14], where labels in the multi-class problem are a cross product of the original labels (and cover all possible combinations of these labels), resulting in the problem of mapping each data point to a binary vector. The main drawback of this approach is poor scaling in terms of the number of labels (e.g., vision problems where the number of categories may be large). A different approach addresses the problem directly, in its full generality, and is much harder than the traditional binary and multi-class problems, which in fact are special cases of multi-labeling. Some notable examples of multi-label algorithms, which are extensions based on binary problems, are adaptations of AdaBoost [21], the *ML-kNN* [41] based on kNN algorithm [20], and *Clare* which is an adapted decision tree algorithm for multi-label classification [31].

Another related machine learning approach is *kernel pairwise classification* [40]. Here, relations between pairs of samples are given using kernels. Supervised pairwise prediction aims to predict such pairwise relationships based on known relationships. Pairwise prediction takes a pair of instances as its input, and outputs the relationship between the two instances. The application of kernel methods to pairwise classification is based on a kernel function between two pairs of instances [24]. The main difference between this approach and our setting is that it does not consider single items, but rather focuses only on pairwise relations.

Metric labeling is an elegant and powerful mathematical model capturing a wide range of classification problems, where information about objects, as well as their pairwise relations, is given. Notice that such a scenario is not captured by neither known multi-class classification techniques, nor by existing pairwise kernel based techniques. The problem was first formulated in full generality by [25], and captures many classification problems that arise in various settings. Specifically, metric labeling has applications in important fields such as Markov theory [13, 27], image processing and computer vision [18, 8], as well as language modeling [29]. In [25], the authors gave an $O(\log k)$-approximation for any metric[3], and a 2-approximation for the uniform metric case. The latter is known to be tight assuming the unique games conjecture [28]. It is worth mentioning that metric labeling is of much importance in the combinatorial optimization setting, as it captures well studied problems such as multiway cut [9, 15, 16, 17, 23] and 0-extension [11, 19].

2 Preliminaries

We formulate the following natural linear programming relaxation for the (MML) problem (similarly to the relaxation given by [25] for uniform metric labeling). Variable $x_{v,\ell}$ is the (fractional) indicator for labeling node v with label ℓ. The first constraint guarantees that each node v receives between 1 and b_v labels. The following two constraints, along with the fact that the problem is a minimization problem, imply that $z_{u,v,\ell} = |x_{u,\ell} - x_{v,\ell}|$, i.e.,

[3] The metric over the labels determines their pairwise distances and can be arbitrary in general.

$z_{u,v,\ell}$ is the separation cost of nodes u and v with respect to label ℓ. Hence, the fourth constraint asserts that $d_{u,v}$ equals $||\mathbf{x}_u - \mathbf{x}_v||_1$, where $\mathbf{x}_u = (x_{u,1}, \ldots, x_{u,\ell})$ for every $u \in V$. The objective of the relaxation follows directly from the definition of (MML) (1).

$$
\begin{aligned}
\min \quad & \textstyle\sum_{v\in V}\left[\sum_{\ell\in K^+(v)} c(v,\ell)x_{v,\ell}+\sum_{\ell\in K^-(v)}|c(v,\ell)|(1-x_{v,\ell})\right]+\sum_{u,v\in V} s(u,v)d_{u,v} \\
s.t. \quad & 1 \le \sum_{\ell\in K} x_{v,\ell} \le b_v && \forall v \in V \\
& z_{u,v,\ell} \ge x_{u,\ell} - x_{v,\ell} && \forall u,v \in V \\
& z_{u,v,\ell} \ge x_{v,\ell} - x_{u,\ell} && \forall u,v \in V \\
& d_{u,v} = \sum_{\ell\in K} z_{u,v,\ell} && \forall u,v \in V \\
& 0 \le x_{v,\ell} \le 1 && \forall v \in V, \forall \ell \in K
\end{aligned}
$$

The following observation simplifies the analysis of the separation cost considerably.

▶ **Observation 5.** *Without loss of generality we can simply assume that any two adjacent nodes differ in only a single coordinate, by a value $\varepsilon > 0$, which can be made arbitrarily small. Specifically, given $(u,v) \in E$ we assume that $\mathbf{x}_u = (x_{u,1}, x_{u,2}, \ldots, x_{u,k})$ and $\mathbf{x}_v = (x_{u,1} + \varepsilon, x_{u,2}, \ldots, x_{u,k})$.*

3 Correlated Randomized Dependent Rounding

Denote by M_{K,b_v} the uniform matroid over K of rank b_v, and recall that $\mathcal{P}(M_{K,b_v}) = \{\mathbf{x} \in [0,1]^k : \sum_{\ell=1}^{k} x_\ell \le b_v\}$ is the standard independent set polytope corresponding to M_{K,b_v}. For completeness, we start by presenting the basic building block of [35] for rounding a single point in $\mathcal{P}_{M_{K,b_v}}$, as we later require its inner-workings.

Let us now focus on rounding a single point in the uniform matroid polytope. The basic building block (Algorithm 1) receives two marginal probabilities, $0 \le \alpha \le 1$ and $0 \le \beta \le 1$, for the i^{th} and j^{th} labels correspondingly, and randomly updates them. At least one of the updated marginal probabilities, denoted by α' and β', is "rounded" to either 0 or 1. This is done while deterministically preserving the sum of the marginal probabilities, and each of the marginal probabilities is preserved in expectation. Lemma 6 summarizes the above, and its proof is deferred to a full version of the paper.
It is important to note that $0 \le \alpha', \beta' \le 1$ always, *i.e.*, Algorithm 1 returns valid marginal probabilities.

▶ **Lemma 6.** *Upon the termination of Algorithm 1:*
1. $\mathbb{E}[\alpha'] = \alpha$ *and* $\mathbb{E}[\beta'] = \beta$.
2. $\alpha' + \beta' = \alpha + \beta$ *always.*
3. *One of i and j is declared* fixed *and its marginal value belongs to* $\{0,1\}$.

Define a *label tree* T of K to be a full binary tree with exactly k leaves, where each leaf corresponds to a distinct label of K. We now describe the rounding procedure which we denote by *label tree rounding*. It receives as input a label tree T, a point $\mathbf{x}_v \in \mathcal{P}(M_{K,b_v})$, a collection of independent random thresholds $\theta_z \sim Unif[0,1]$ for every non-leaf node z of T, and one additional independent random threshold $\theta \sim Unif[0,1]$. The label tree rounding procedure operates as follows:
1. Every leaf of T sends to its parent its label and its marginal value as given by the relaxation, *i.e.*, a leaf that corresponds to label $\ell \in K$ sends to its parent $(\ell, x_{v,\ell})$.

Algorithm 1 Resolve(i, α, j, β).

draw a threshold $\theta \sim Unif[0,1]$.
if (case (a)) $0 \leq \alpha + \beta \leq 1$ **then**
  if $\theta \leq {}^{\alpha}/_{(\alpha+\beta)}$ **then**
    $\alpha' \leftarrow \alpha + \beta$, $\beta' \leftarrow 0$, and $s \leftarrow j$.
  else
    $\alpha' \leftarrow 0$, $\beta' \leftarrow \alpha + \beta$, and $s \leftarrow i$.
  end if
end if
if (case (b)) $1 < \alpha + \beta \leq 2$ **then**
  if $\theta \leq {}^{(1-\beta)}/_{(2-\alpha-\beta)}$ **then**
    $\alpha' \leftarrow 1$, $\beta' \leftarrow \alpha + \beta - 1$, and $s \leftarrow i$.
  else
    $\alpha' \leftarrow \alpha + \beta - 1$, $\beta' \leftarrow 1$, and $s \leftarrow j$.
  end if
end if
return (i, α', j, β') and declare s as *fixed*.

2. Every non-leaf node z of T (that is not the root) receives from its two children (i, α) and (j, β); it executes Algorithm 1 with parameters (i, α, j, β) and θ_z as the random threshold to obtain (α', β'); updates the marginal probabilities of i and j to be α' and β' respectively; and sends to its parent in T the label that was *not* fixed from $\{i, j\}$ along with its newly updated marginal probability.
3. The root r of T operates exactly as any other non-leaf node of T with the following exception: instead of sending the label that was not fixed to its parent along with its newly updated marginal probability, r uses the given random threshold θ to round the label that was not fixed, *i.e.*, after the execution of Algorithm 1 by r if $s \in \{i, j\}$ denotes the label that is not fixed and the newly updated marginal probability of s equals γ, then r sets the marginal of s to be 1 if $\theta \leq \gamma$ and 0 otherwise.

The following lemma summarizes the desired properties of the label tree rounding procedure, and its proof is deferred to a full version of the paper.

▶ **Lemma 7.** *Let $v \in V$, $\mathbf{x}_v \in \mathcal{P}(M_{K,b_v})$, T a label tree of K, and denote by $\tilde{\mathbf{x}}_v$ the vector of marginal probabilities obtained by executing the label tree rounding procedure. Then,*
1. $\tilde{\mathbf{x}}_v \in \{0,1\}^k$.
2. *Let $B_v \triangleq \sum_{\ell \in K} x_{v,\ell}$, then $\lfloor B_v \rfloor \leq \sum_{\ell \in K} \tilde{x}_{v,\ell} \leq \lceil B_v \rceil$ always.*
3. *For every $\ell \in K$: $\Pr[\tilde{x}_{v,\ell} = 1] = x_{v,\ell}$.*

Let us now focus on rounding multiple points in the uniform matroid polytope. In this section we describe how to round multiple points in $\mathcal{P}(M_{K,b_v})$ while: (1) preserving marginal probabilities; and (2) being "faithful" to the original ℓ_1 distances between any pair of points in $\mathcal{P}(M_{K,b_v})$. Our correlated rounding procedure receives as input a fixed label tree T, along with n points $\{\mathbf{x}_v\}_{v \in V}$ in $\mathcal{P}(M_{K,b_v})$. Intuitively, it applies the label tree rounding procedure to all n points simultaneously, while using the same given tree T and the same random thresholds in all executions. A formal description appears in Algorithm 2. As before, we denote by $\tilde{\mathbf{x}}_v$ the output of Algorithm 2 for node $v \in V$.

Lemma 8 bounds the expected separation cost of neighbouring nodes u and v. Assuming $\mathbf{x}_u$ and $\mathbf{x}_v$ differ only in label 1 (as Observation 5 states without loss of generality), the

Algorithm 2 Correlated Rounding$\left(\{\mathbf{x}_v\}_{v\in V}, T\right)$.

For every non-leaf node z of T draw an independent threshold $\theta_z \sim Unif[0,1]$.
Draw an independent threshold $\theta \sim Unif[0,1]$ for the root r of T.
$\forall v \in V$: execute label tree rounding with input T, $\mathbf{x}_v$, $\{\theta_z\}_{z \text{ non-leaf node of } T}$, and θ.
Output the resulting $\{\tilde{\mathbf{x}}_v\}_{v\in V}$.

executions of Algorithm 1 can differ between u and v only at non-leaf nodes of T that lie on the (single) path from the leaf that represents label 1 and the root r of T. At the heart of the proof lies the following observation: the expected *additive* increase in $||\mathbf{x}_u - \mathbf{x}_v||_2$ is $O(\varepsilon)$ for each of the non-leaf nodes of T that lie on the above mentioned path.

▶ **Lemma 8.** *Let $u, v \in V$ be such that $\mathbf{x}_u$ and $\mathbf{x}_v$ satisfy Observation 5, let $\tilde{\mathbf{x}}_u$ and $\tilde{\mathbf{x}}_v$ be the output of Algorithm 2 for nodes u and v correspondingly, and let δ be the depth of T. Then,*

$$\mathbb{E}\left[||\tilde{\mathbf{x}}_u - \tilde{\mathbf{x}}_v||_1\right] \leq O(\delta)\varepsilon\,.$$

Proof. Recall that Observation 5 states that $\mathbf{x}_u$ and $\mathbf{x}_v$ are identical, except that $x_{v,1} = x_{u,1} + \varepsilon$. Hence, let P be the path from the leaf in T representing label 1 to the root r of T, and denote the sequence of nodes in this path by $z_1, z_2, z_3 \ldots, z_m$ (where z_1 is the leaf and z_m is the root r). We use the following two assumptions that can be made without loss of generality.

First, as the order of executions of Algorithm 1 at the nodes of T is irrelevant to the outcome of Algorithm 2, as long as execution of Algorithm 1 at some node z of T is performed after all executions of Algorithm 1 at all non-leaf nodes in the induced subtree of T that z is its root. Hence, let us assume without loss of generality that all executions of Algorithm 1 at nodes not in P are performed before any execution of Algorithm 1 at nodes $z_2, z_3, \ldots, z_m$.

Second, note that in every non-leaf node along P, *i.e.*, $z_2, z_3, \ldots, z_m$, exactly one execution of Algorithm 1 is performed for each of the nodes u and v. The execution of Algorithm 1 at some node z_p, $p = 2, \ldots, m$, receives exactly two labels as input, one from the child z_{p-1} (along the path P) and the other from the other child of z_p which we denote by w_{p-1} (not on the path P). It is important to note that each of these two inputs might be random, however, the input received from node w_{p-1} is *always identical* for both u and v. Therefore, let us denote for simplicity of presentation and without loss of generality that the input w_{p-1} sends to the execution of Algorithm 1 at node z_p is label number p with its updated marginal probability γ_p, *i.e.*, (p, γ_p). Thus, we can focus only on the first m labels of K since for labels $m+1, \ldots, k$ nodes u and v will always be identical and their contribution to $||\tilde{\mathbf{x}}_u - \tilde{\mathbf{x}}_v||_1$ will be always 0.

Denote by $\mathbf{x}_u^t \in [0,1]^m$ and $\mathbf{x}_v^t \in [0,1]^m$ the vector of marginal probabilities of the first m labels after performing the execution of Algorithm 1 at node z_t, for nodes u and v respectively. Thus, for example, $\mathbf{x}_u^1 = (u_1, \gamma_2, \gamma_3, \ldots, \gamma_m)$ and $\mathbf{x}_v^1 = (u_1 + \varepsilon, \gamma_2, \gamma_3, \ldots, \gamma_m)$, and $\mathbf{x}_u^m = (\tilde{x}_{u,1}, \tilde{x}_{u,2}, \tilde{x}_{u,3}, \ldots, \tilde{x}_{u,m})$ and $\mathbf{x}_v^m = (\tilde{x}_{v,1}, \tilde{x}_{v,2}, \tilde{x}_{v,3}, \ldots, \tilde{x}_{v,m})$. We prove that:

$$\mathbb{E}\left[||\mathbf{x}_u^t - \mathbf{x}_v^t||_1 - ||\mathbf{x}_u^{t-1} - \mathbf{x}_v^{t-1}||_1\right] \leq 2\varepsilon \qquad \forall t = 2, 3, \ldots, m. \tag{2}$$

The proof of the lemma is completed by summing (2) over all relevant values of t, and recalling that $||\mathbf{x}_u^1 - \mathbf{x}_v^1||_1 = ||\mathbf{x}_u - \mathbf{x}_v||_1 = \varepsilon$. Inequality (2) is proved by examining the joint distribution of Algorithm 1 at node z_t for both u and v. This computation is deferred to a full version of the paper. ◀

Algorithm 3 Single Threshold (ST).

draw a threshold $\theta \sim Unif[0,1]$.
for every $v \in V$ **do**
  $f_{ST}(v) \leftarrow \{\ell : \theta \leq h(x_{v,\ell})\}$.
end for
output f_{ST}.

Algorithm 4 Kleinberg-Tardos (KT).

while $V \neq \emptyset$ **do**
  independently draw a threshold $\theta \sim Unif[0,1]$ and a uniform label $\ell \in K$.
  for every $v \in V$ **do**
    if $\theta \leq x_{v,\ell}$ **then**
      $f_{KT}(v) \leftarrow \{\ell\}$ and $V \leftarrow V \setminus \{v\}$.
    end if
  end for
end while
output f_{KT}.

Proof (of Theorem 1). Apply Algorithm 2 to the given points $\mathbf{y}^1, \ldots, \mathbf{y}^n$ with a label tree T whose depth is $O(\log k)$. Lemmas 7 and 8 conclude the proof. ◀

4 $O(\log k)$-Approximation for MML

Proof (of Theorem 2). We apply Algorithm 2 to the fractional solution provided by the linear programming relaxation. Starting with assignment costs, Property (3) of Lemma 7 implies that all assignment costs are preserved in expectation. Considering separation costs, one can always choose a label tree T whose depth is $O(\log k)$, and thus Lemma 8 implies a multiplicative loss of $O(\log k)$ in the separation costs. Finally, Property (2) of Lemma 7 guarantees that every node $v \in V$ is assigned at most $\lceil B_v \rceil$ labels, but since $\lceil B_v \rceil \leq b_v$ our algorithm never deviates from the bound on the number of labels. Additionally, it is important to note that Property (2) of Lemma 7 also ensures that every node $v \in V$ is assigned at least one label since $\lfloor B_v \rfloor \geq 1$. ◀

5 A Tight Approximation for Unbounded MML

Let us now focus on the basic building blocks. We use the following two algorithms as basic building blocks for our final algorithm. The first is a simple single threshold algorithm. Let $h : [0,1] \to [0,1]$ be a monotone non-decreasing *distortion* function. The algorithm applies the distortion function h to each fractional value $x_{v,\ell}$, and then finds a multi-labeling $f_{ST}(v) : V \to 2^K$ by assigning to v all labels ℓ whose *distorted* fractional value is larger than a uniformly random threshold $\theta \in [0,1]$. The choice of an appropriate distortion function h plays a crucial role in obtaining the best possible approximation of 2 for (Unbounded-MML).

The second building block we use is due to [25]. It is the 2-approximation they provide for the uniform metric labeling problem.

Our algorithm is a simple "merge" of the two basic building blocks: Algorithms 3 and 4 are run independently and the union of their label assignments is returned.

Algorithm 5 Union.

independently run Algorithms 3 and 4 to obtain f_{ST} and f_{KT}.
for every $v \in V$ **do**
  $f(v) \leftarrow f_{ST}(v) \cup f_{KT}(v)$.
end for
output f.

Let us focus on the assignment costs. We denote by $\mathbf{x}_v \in [0,1]^k$ the vector corresponding to v, i.e., $(\mathbf{x}_v)_\ell = x_{v,\ell}$. First we start by stating two immediate observations regarding the assignment probabilities of labels to vertices by the basic building blocks (a full proof is deferred to a full version of the paper).

▶ **Lemma 9.** *For any $v \in V$ and $\ell \in K$ the following two claims hold:*
1. $\Pr[\ell \in f_{ST}(v)] = h(x_{v,\ell})$.
2. $\Pr[f_{KT}(v) = \{\ell\}] = \frac{x_{v,\ell}}{||\mathbf{x}_v||_1}$.

The following corollary states the probability that label ℓ is assigned to vertex v by the Union Algorithm (Algorithm 5), and is used to bound the total labeling cost of Algorithm 5. Its proof is deferred to a full version of the paper.

▶ **Corollary 10.** *For any $v \in V$ and $\ell \in K$,* $\Pr[\ell \in f(v)] = h(x_{v,\ell}) + \frac{x_{v,\ell}}{||\mathbf{x}_v||_1} - h(x_{v,\ell}) \cdot \frac{x_{v,\ell}}{||\mathbf{x}_v||_1}$.

We focus now on the separation cost of the Union Algorithm (Algorithm 5). Note that the expected separation cost of the Union Algorithm (Algorithm 5) equals:

$$\sum_{(u,v)\in E} s(u,v) \cdot \mathbb{E}\left[\left|\left|\mathbf{1}_{f(u)} - \mathbf{1}_{f(v)}\right|\right|_1\right] \ . \tag{3}$$

The next lemma provides all the ingredients required for bounding the expected separation cost (3), its proof is deferred to a full version of the paper.

▶ **Lemma 11.** *For any $u, v \in V$ such that $\mathbf{x}_u = (x_{u,1}, x_{u,2}, \ldots, x_{u,k})$ and $\mathbf{x}_v = (x_{u,1} + \varepsilon, x_{u,2}, \ldots, x_{u,k})$, the following hold:*
1. $\Pr[1 \in f(u), 1 \notin f(v)] = 0$.
2. $\Pr[1 \notin f(u), 1 \in f(v)] = \varepsilon \cdot \left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right) \cdot \left(\frac{h(x_{u,1}+\varepsilon) - h(x_{u,1})}{\varepsilon} + \frac{1 - h(x_{u,1}+\varepsilon)}{||\mathbf{x}_u|| + \varepsilon}\right)$.
3. $\Pr[\ell \in f(u), \ell \notin f(v)] = \varepsilon \cdot \frac{x_{u,\ell}(1 - h(x_{u,\ell}))}{||\mathbf{x}_u||_1 (||\mathbf{x}_u||_1 + \varepsilon)}$ *for every $\ell \neq 1$.*
4. $\Pr[\ell \notin f(u), \ell \in f(v)] = 0$ *for every $\ell \neq 1$.*

In order to bound the expected separation cost of an edge (u,v), as given by (3), we employ a *global* charging argument. Typically, if *local* charging works it is the case that the part of (3) that corresponds to a fixed label ℓ, *i.e.*, $\mathbb{E}\left[\mathbf{1}_{\{\ell \in f(u) \wedge \ell \notin f(v)\}} + \mathbf{1}_{\{\ell \notin f(u) \wedge \ell \in f(v)\}}\right]$ could be upper bounded by $\alpha \cdot z_{u,v,\ell}$ for some constant $\alpha > 0$. Unfortunately, this is not the case as can be seen from Lemma 11. Edge (u,v) satisfies Observation 5, *i.e.*, $\mathbf{x}_u$ and $\mathbf{x}_v$ differ only coordinate 1, and thus without loss of generality $z_{u,v,\ell} = 0$ for all $\ell \neq 1$. However, for example, case (3) of Lemma 11 implies that u and v have a non-zero probability of disagreeing on any label $\ell \neq 1$. Thus, a local charging argument as described above fails and we must resort to a global argument that sums over all possible labels ℓ. The following corollary provides exactly such a global guarantee, and its proof is deferred to a full version of the paper.

▶ **Corollary 12.** *Let* $\mathbf{x}_u = (x_{u,1}, x_{u,2}, \ldots, x_{u,k})$ *and* $\mathbf{x}_v = (x_{u,1} + \varepsilon, x_{u,2}, \ldots, x_{u,k})$ *for an edge* $(u, v) \in E$*. Then,*

$$\mathbb{E}\left[\left|\left|\mathbf{1}_{f(u)} - \mathbf{1}_{f(v)}\right|\right|_1\right] \leq \left(\frac{h(x_{u,1}+\varepsilon) - h(x_{u,1})}{\varepsilon} + \frac{2 - h(x_{u,1}+\varepsilon)}{||\mathbf{x}_u||_1 + \varepsilon}\right) \cdot \left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right) \cdot d_{u,v} \ .$$

Let us not focus on how to choose the distortion h. Given a specific choice of a distortion function $h : [0,1] \to [0,1]$, Corollaries 10 and 12 determine the approximation guarantee. Specifically, Corollary 10 determines the loss with respect to the labeling cost, and Corollary 12 determines the loss with respect to the separation cost.

The most natural distortion function is the identity, i.e., $h(x) = x$. The next theorem shows that this choice of h yields a 3-approximation for (Unbounded-MML).

▶ **Theorem 13.** *The Union Algorithm provides an approximation of* 3 *when* $h(x) = x$*.*

Proof. First, consider the labeling costs. Corollary 10, along with the fact that $||\mathbf{x}_v||_1 \geq 1$, imply:

$$\begin{cases} \Pr\left[\ell \in f(v)\right] = x_{v,\ell} + \frac{x_{v,\ell}}{||\mathbf{x}_v||_1} - \frac{x_{v,\ell}^2}{||\mathbf{x}_v||_1} \leq 2x_{v,\ell} \\ \Pr\left[\ell \notin f(v)\right] = (1 - x_{v,\ell}) \cdot \left(1 - \frac{x_{v,\ell}}{||\mathbf{x}_v||_1}\right) \leq 1 - x_{v,\ell} \end{cases}$$

Hence, the labeling costs incur a loss of at most a factor of 2. Second, consider the separation costs. Let $(u, v) \in E$ and assume without loss of generality that $\mathbf{x}_u = (x_{u,1}, x_{u,2}, \ldots, x_{u,k})$ and $\mathbf{x}_v = (x_{u,1} + \varepsilon, x_{u,2}, \ldots, x_{u,k})$. Corollary 12, along with the fact that $||\mathbf{x}_v||_1 \geq 1$, imply:

$$\mathbb{E}\left[\left|\left|\mathbf{1}_{f(u)} - \mathbf{1}_{f(v)}\right|\right|_1\right] \leq \left(\frac{\varepsilon}{\varepsilon} + \frac{2 - x_{u,1} - \varepsilon}{||\mathbf{x}_u||_1 + \varepsilon}\right)\left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right) d_{u,v} \leq 3d_{u,v} \ .$$

Thus, the separation costs incur a loss of at most a factor of 3, concluding the proof. ◀

We prove that choosing a quadratic distortion, i.e., $h(x) = x^2$, provides a tight approximation of 2 for (Unbounded-MML). We are now ready to prove Theorem 3.

Proof (of Theorem 3). For simplicity we prove the theorem in two phases. In the first phase we show that the quadratic distortion provides an approximation of $(2 + \varepsilon)$. In the second phase we show that, assuming $\varepsilon \leq (8k^4)^{-1}$, the approximation is in fact 2. This concludes the proof since ε can be chosen to be arbitrarily small.

Let us focus on the first phase. When considering the labeling costs, Corollary 10, along with the facts that $||\mathbf{x}_v||_1 \geq 1$ and $0 \leq x_{v,\ell} \leq 1$, imply:

$$\begin{cases} \Pr\left[\ell \in f(v)\right] = x_{v,\ell}^2 + \frac{x_{v,\ell}}{||\mathbf{x}_v||_1} - \frac{x_{v,\ell}^3}{||\mathbf{x}_v||_1} \leq x_{v,\ell} \cdot (1 - x_{v,\ell}) \leq 2x_{v,\ell} \\ \Pr\left[\ell \notin f(v)\right] = \left(1 - x_{v,\ell}^2\right) \cdot \left(1 - \frac{x_{v,\ell}}{||\mathbf{x}_v||_1}\right) \leq (1 - x_{v,\ell}^2) \leq 2(1 - x_{v,\ell}) \end{cases}$$

Hence, the labeling costs incur a loss of at most 2 in the approximation.

When considering the separation costs, let $(u, v) \in E$ and assume without loss of generality that $\mathbf{x}_u = (x_{u,1}, x_{u,2}, \ldots, x_{u,k})$ and $\mathbf{x}_v = (x_{u,1} + \varepsilon, x_{u,2}, \ldots, x_{u,k})$. Corollary (12) implies:

$$\begin{aligned} &\mathbb{E}\left[\sum_{\ell \in K}\left(\mathbf{1}_{\{\ell \in f(u) \wedge \ell \notin f(v)\}} + \mathbf{1}_{\{\ell \notin f(u) \wedge \ell \in f(v)\}}\right)\right] \leq \\ &\leq \left(\frac{(x_{u,1}+\varepsilon)^2 - x_{u,1}^2}{\varepsilon} + \frac{2 - (x_{u,1}+\varepsilon)^2}{||\mathbf{x}_u||_1 + \varepsilon}\right)\left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right) d_{u,v} \\ &= \left[\left(2x_{u,1} + \frac{2 - x_{u,1}^2}{||\mathbf{x}_u||_1 + \varepsilon}\right)\left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right) + \varepsilon\left(\frac{||\mathbf{x}_u||_1 - 2x_{u,1}}{|\mathbf{x}_u||_1 + \varepsilon}\right)\left(1 - \frac{x_{u,1}}{||\mathbf{x}_u||_1}\right)\right] d_{u,v} \ . \quad (4) \end{aligned}$$

Define the following function $L(z,t) : [0,1] \times [1,\infty) \to \mathbb{R}^+$, $L(z,t) \triangleq \left(2z + \frac{2-z^2}{t}\right) \cdot \left(1 - \frac{z}{t}\right)$. Clearly the maximum value of L upper bounds the left term of (4), when plugging $z = x_{u,1}$ and $t = ||\mathbf{x}_u||_1$. One can verify that $\max_{0\le z\le 1} \max_{t\ge 1} \{L(z,t)\} \le 2$ (details are deferred to a full version of the paper). Note that the right term of (4) is at most ε, hence the expected separation cost is at most $(2+\varepsilon)d_{u,v}$. This concludes the first phase. The proof of the second phase is deferred to a full version of the paper. ◀

The proof of Theorem 4 is deferred to a full version of the paper.

Abstract

Consider the following variant of the set cover problem. We are given a universe $U = \{1, ..., n\}$ and a collection of subsets $\mathcal{C} = \{S_1, ..., S_m\}$ where $S_i \subseteq U$. For every element $u \in U$ we need to find a set $\phi(u) \in \mathcal{C}$ such that $u \in \phi(u)$. Once we construct and fix the mapping $\phi : U \mapsto \mathcal{C}$ a subset $X \subseteq U$ of the universe is revealed, and we need to cover all elements from X with exactly $\phi(X) := \bigcup_{u \in X} \phi(u)$. The goal is to find a mapping such that the cover $\phi(X)$ is as cheap as possible.

This is an example of a universal problem where the solution has to be created before the actual instance to deal with is revealed. Such problems appear naturally in some settings when we need to optimize under uncertainty and it may be actually too expensive to begin finding a good solution once the input starts being revealed. A rich body of work was devoted to investigate such problems under the regime of worst case analysis, i.e., when we measure how good the solution is by looking at the worst-case ratio: universal solution for a given instance vs optimum solution for the same instance.

As the universal solution is significantly more constrained, it is typical that such a worst-case ratio is actually quite big. One way to give a viewpoint on the problem that would be less vulnerable to such extreme worst-cases is to assume that the instance, for which we will have to create a solution, will be drawn randomly from some probability distribution. In this case one wants to minimize the expected value of the ratio: universal solution vs optimum solution. Here the bounds obtained are indeed smaller than when we compare to the worst-case ratio.

But even in this case we still compare apples to oranges as no universal solution is able to construct the optimum solution for every possible instance. What if we would compare our approximate universal solution against an optimal universal solution that obeys the same rules as we do? We show that under this viewpoint, but still in the stochastic variant, we can indeed obtain better bounds than in the expected ratio model. For example, for the set cover problem we obtain H_n approximation which matches the approximation ratio from the classic deterministic offline setup. Moreover, we show this for all possible probability distributions over U that have a polynomially large carrier, while all previous results pertained to a model in which elements were sampled independently. Our result is based on rounding a proper configuration IP that captures the optimal universal solution, and using tools from submodular optimization.

The same basic approach leads to improved approximation algorithms for other related problems, including Vertex Cover, Edge Cover, Directed Steiner Tree, Multicut, and Facility Location.

1 Introduction

In a typical online problem part of the input is revealed gradually to an algorithm, which has to react to each new piece of the input by making irrevocable choices. In an online covering problem the online input consists of a sequence of *requests*, which have to be satisfied by the algorithm by buying *items* at minimum total cost.

Some online applications have severe resource constraints, typically in terms of time and/or computational power. Hence even making an online (non-trivial) choice might be too costly. In these settings it makes sense to consider universal algorithms. Roughly speaking, the goal of these algorithms is to pre-compute a reaction to each possible input, so that the online choice can then be made very quickly (say, looking at some pre-computed table). Since the adversary has a lot of power in the universal setting, typically one assumes a stochastic input. In particular, the input is sampled according to some probability distribution π, which is either given in input or that can be sampled multiple times at polynomial cost per sample (*oracle model*).

The most relevant prior work for this paper is arguably due to Grandoni et al. [21] (conference version in [20]). The authors consider the universal stochastic version of some classical NP-hard covering problems such as set cover, non-metric facility location, multicut etc. They provide polynomial-time approximation algorithms for those problems in the *independent activation model*, where each request u is independently sampled with some known probability p_u. Crucially, in their work the approximation ratio is obtained by comparing the expected cost of the approximate solution with the expected cost of the optimal offline solution (that knows the future sampled input). For example, in the set cover case they present a polynomial-time algorithm that computes a mapping of expected cost at most $O(\log(nm))\,\mathbb{E}[OPT_{\text{off}}(X)]$, where the expectation is taken over the sampling of X according to π and $OPT_{\text{off}}(X)$ is the minimum (offline) cost of a set cover of X. Here n is size of the universe and m the number of subsets. For $m \gg n$ this ratio becomes $O\left(\frac{\log m}{\log\log m}\right)$ and is tight. They also consider the universal (non-metric) facility location problem in the independent activation model, and provide a $O(\log n)$ approximation (in the above sense), where n is the total number of clients and facilities. We remark that their method seems not to lead to any improved approximation factor in the metric version of the problem. We finally mention their $O(\log^2 n)$ approximation for universal multicut in the independent activation model, where n is the number of nodes in the graph.

1.1 Our Results and Techniques

Comparing with the offline optimum as in [21] might be too pessimistic. And often when we need to optimize under uncertainty we cannot really find a better benchmark, flagship example of it would be online problems. However, stochastic two-stage [29, 42] and stochastic adaptive [38, 13, 12, 23] problems have proven that one can actually compare an approximate solution with an optimum algorithm that is not omnipotent but obeys the same rules of the model as the approximate one. This inspired us to ask the following question:

Is it also possible in a stochastic universal problem to compare our algorithm with an optimum solution that is restricted by the model in the same way as we are?

In this paper we show that we can do this indeed. In this way we manage to obtain tighter approximation ratios – which of course are compared to a weaker benchmark, but this benchmark itself can be interpreted as more fair and meaningful – and it also allows us to approach more general problems.

1.1.1 Universal Stochastic Set Cover

We shall describe carefully the Universal Stochastic Set Cover problem in this section so that we will fully present the model. For the remaining problems their full statements will appear in appropriate sections.

In the Universal Stochastic Set Cover problem we are given in input a universe $U = \{1, 2, ..., n\}$, and a collection $\mathcal{C} \subseteq 2^U$ of m subsets $S \subseteq U$, each one with an associated cost $c(S)$. We need to a priori map each element $u \in U$ into some set $\phi(u) \in \mathcal{C}$. Then a subset $X \subseteq U$ is sampled according to some probability distribution π (either given in input as a set of scenarios or only by accessing an oracle), and we have to buy the sets $\phi(X) = \bigcup_{u \in X} \phi(u)$ as the cover of X. Our goal is to minimize the expected value of the total cost, i.e., $\mathbb{E}_{X\sim\pi}[c(\phi(X))] = \mathbb{E}_{X\sim\pi}\left[\sum_{S\in\phi(X)} c(S)\right]$. One of the most important aspects in our model is that we do not compare ourselves against the expected value of an optimum offline solution for a given scenario, that is, not against $\mathbb{E}_{X\sim\pi}[OPT_{\text{off}}(X)]$, but what we compare ourselves with is

$$\min_{\phi:\forall_{u\in U} u\in\phi(u)} \mathbb{E}_{X\sim\pi}\left[\sum_{S\in\phi(X)} c(S)\right]$$

which is the expected outcome of an *optimal universal mapping*.

The results depend on the probability distribution with which we deal in an instance of the problem. Possible probability distributions are:

- **Scenario model:** Here we are given in input all the sets $X_1, ..., X_N \subseteq U$ such that $\mathbb{P}_{X\sim\pi}[X = X_i] > 0$ with the associated probability. This model allows for explicit use of all the scenarios in the computations. For the Universal Stochastic Set Cover we obtain $O(\log n)$-approximation in this case even in the weighted case.
- **Oracle model:** This is the most general model. We have a black-box access to an oracle Π from which we can sample a scenario from distribution π. We assume that taking a sample requires polynomial time. In this model we can find an $O(\log n)$-approximation for Universal Stochastic Set Cover in polynomial time only for the unweighted case; in the weighted case we achieve the same approximation factor in pseudo-polynomial time depending on $\max_{S\in\mathcal{C}} c(S)$.
- **Independent activation model:** In this model we assume that every element $u \in U$ is independently sampled with some given probability p_u. This model does not capture correlations of elements, and therefore sometimes it is not fully realistic. Though it cannot be represented by a polynomial number of scenarios, its nice properties allow one to develop good approximation algorithms for several problems. In this setting we are able to approximate Universal Stochastic Set Cover within a factor $O(\log n)$ in polynomial time even in the weighted case.

Our results are obtained by defining a proper configuration LP (with an exponential number of variables) that captures the optimal mapping. We are able to solve this LP via the ellipsoid

method using a separation oracle. Somehow interestingly, our separation oracle has to solve a submodular minimization problem. Then we can round the fractional solution in a standard way.

1.1.2 Overview of the results

The robustness of our framework allows us to address universal extensions of several covering problems. After expressing the goal as a true approximation task, we can adapt tools from the rich theory of approximation algorithms.

Here we give an overview of our results. Detailed statements of the theorems appear in appropriate sections.

Scenario model

In this setting, we are able to construct an LP-based polynomial-time $O(\log n)$-approximation to the universal stochastic version of Set Cover (Theorem 6), which generalizes to Non-Metric Facility Location and Constrained Set Multicover. In fact, the latter algorithm achieves an approximation guarantee of exactly H_n. Different rounding procedure leads to a 2-approximation for Universal Stochastic Vertex Cover. All these approximation ratios match the best guarantees obtained in the deterministic world. What is more, the exact polynomial time algorithm for Edge Cover extends to the scenario model. We also present an $O(\sqrt{k})$-approximation for Universal Stochastic Directed Steiner Tree on acyclic graphs, where k is the number of terminals. Except the Set Cover problem, proof of all of these Theorems will appear in the full version of the paper.

Independent activation model

In this setting, we are able to obtain several results in flavour of the $O(1)$-approximation for the Maybecast problem by Karger and Minkoff [33]. We present a 6.33-approximation for Universal Stochastic Metric Facility Location (Theorem 8) and an $O(\log n)$-approximation for Universal Stochastic Multicut (Theorem 12). As an intermediate result, we obtain a 4.75-approximation for Universal Stochastic Multicut on trees.

Oracle model

We can generalize most of our results for the scenario model to this setting, with the restriction that in the weighted case we get a pseudo-polynomial running time. This will be discussed in the full version.

1.2 Related work

Other universal-like problems have been addressed in the literature. For instance, in the universal TSP problem one computes a permutation of the nodes that is then used to visit a given subset of nodes. This problem has been studied both in the worst-case scenario for the Euclidean plane [39, 6] and general metrics [32, 22, 27], as well as in the average-case [31, 7, 43, 19, 45]. (For the related problem of universal Steiner tree, see [33, 32, 22, 19].) Jia et al. [32] introduced the universal set cover and universal facility location problems, and studied them in the worst-case: they show that the adversary is very powerful in such models, and give nearly-matching $\Omega(\sqrt{n})$ and $O(\sqrt{n \log n})$ bounds on the competitive factor. These problems have been later studied by Grandoni et al. in the independent activation model [21], as already mentioned before.

A somewhat related topic is *oblivious routing* [40, 28, 8] (see, e.g., [47, 49] for special cases). A tight logarithmic competitive result as well as a polynomial-time algorithm to compute the best routing is known in the worst case for undirected graphs [5, 41]. For *oblivious routing on directed graphs* in the worst case the lower bound of $\Omega(\sqrt{n})$ [5] nearly matches upper bounds in [24] but for the average case. The authors of [25] give an $O(\log^2 n)$-competitive oblivious routing algorithm when demands are chosen randomly from a known demand-distribution; they also use "demand-dependent" routings and show that these are necessary.

Another closely related notion is the one of *online problems*. These problems have a long history (see, e.g., [9, 16]), and there have been many attempts to relax the strict worst-case notion of competitive analysis: see, e.g., [14, 1, 19] and the references therein. Online problems with stochastic inputs (either i.i.d. draws from some distribution, or inputs arriving in random order) have been studied, e.g., in the context of optimization problems [36, 37, 19, 4], secretary problems [18], mechanism design [26], and matching problems in Ad-auctions [35].

Alon et al. [2] gave the first online algorithm for set cover with a competitive ratio of $O(\log m \log n)$; they used an elegant primal-dual-style approach that has subsequently found many applications (e.g., [3, 10]). This ratio is the best possible under complexity-theoretic assumptions [34]; even unconditionally, no deterministic online algorithm can do much better than this [2]. Online versions of *metric* facility location are studied in both the worst case [36, 17], the average case [19], as well as in the stronger *random permutation model* [36], where the adversary chooses a set of clients unknown to the algorithm, and the clients are presented to us in a random order. It is easy to show that for our problems, the random permutation model (and hence any model where elements are drawn from an *unknown* distribution) are as hard as the worst case.

One can of course consider the (offline) stochastic version of optimization problems. For example, k-stage stochastic set cover is studied in [29, 44], with an improved approximation factor (independent from k) later given in [46].

The result for the Oracle model are based on the Sample Average Approximation approach, see [11] for the application most relevant to our work.

As mentioned before, in two-stage stochastic problems [42, 29] and stochastic adaptive problems [13, 38, 12, 23] it is possible to compare our algorithms with an optimum algorithm which is equally constrained in the model as our problem, and this is what shed a light on the possibility of obtaining results in the same spirit for the universal stochastic optimization.

In two recent papers [48, 15] authors looked at universal optimization over scenarios, but compared against the average offline optimum, and not the optimum universal solution as we do. All the properties of submodular functions used in our work can be found here [50].

2 Preliminaries

Here we give some basic definitions and properties. Given a universe U, we call a function $f : 2^U \to \mathbb{R}$ submodular if $f(A)+f(B) \geq f(A\cap B)+f(A\cup B)$ for each pair of sets $A, B \subseteq U$. Function f is monotone if $f(B) \geq f(A)$ for $A \subseteq B$. When considering a submodular function, we assume that it is implicitly given in the form of an oracle that can be queried on a specific $A \subseteq U$ and returns the value $f(A)$ in constant time.

▶ **Theorem 1** (Iwata et al. [30]). *There is an algorithm to minimize a given submodular function $f : 2^U \to \mathbb{N}$ in polynomial time in $|U|$ and in the number of bits needed to encode the largest value of f.*

Let us introduce a function $g_\pi : 2^U \to \mathbb{R}^+$, $g_\pi(A) = \mathbb{P}[A \cap X \neq \emptyset]$ where X is drawn from the distribution π. Our framework exploits crucially the fact that g_π is a submodular function.

▶ **Lemma 2.** *Function g_π is submodular and monotone.*

Proof. Observe that $g_\pi(A) = \sum_{X \subseteq U} \pi(X) \cdot \mathbf{1}[A \cap X \neq \emptyset]$. Function $A \to \mathbf{1}[A \cap X \neq \emptyset]$ is submodular and a combination of such functions with positive coefficients is submodular. The monotonicity holds trivially by definition. ◀

3 Universal Set Cover

In this section we present our approximation algorithm for universal set cover. We start by considering the case that π is given in input, in the form of a set of N scenarios $X_1, \ldots, X_N$, where scenario $X_i \subseteq U$ is sampled with some given probability $p_i = \pi(X_i)$. Then we (partially) extend our approach to the oracle model. Recall that $n = |U|$ is the number of elements in the universe.

Consider the scenario case. Recall that, for $B \subseteq U$, $g_\pi(B) = \mathbb{P}[B \cap X \neq \emptyset]$, where the probability is taken over $X \subseteq U$ sampled from π (namely, one of the scenarios A_i in this case). As mentioned before, g_π is a submodular function over the universe U.

We start by expressing our problem as the following integer program (IP).

$$\begin{aligned} \min \quad & \sum_{S \in \mathcal{C}} c(S) \sum_{B \subseteq S} y_B^S \cdot g_\pi(B) && \text{(IP-SC)} \\ \text{s.t.} \quad & \sum_{B \ni u} \sum_{S \supseteq B} y_B^S \geq 1 && \forall_{u \in U} \\ & y_B^S \in \{0,1\} && \forall_{S \in \mathcal{C}} \forall_{B \subseteq S}. \end{aligned} \tag{1}$$

We obtain a linear relaxation (LP-SC) of (IP-SC) by replacing the integrality constraints (1) with $y_B^S \geq 0$.

▶ **Lemma 3.** *Integer program (IP-SC) is equivalent to Universal Stochastic Set Cover.*

Proof. It is easy to translate a mapping $\phi : U \to \mathcal{C}$ into some feasible solution to (LP-SC). All variables are zeros by default and for each $S \in \mathcal{C}$ such that $\phi^{-1}(S)$ is non-empty, we set $y^S_{\phi^{-1}(S)} = 1$. Note that always $\phi^{-1}(S) \subseteq S$. In that setting the objective value equals the expected cost of the covering.

Let us fix some feasible solution $\{y_B^S\}_{S \in \mathcal{C},\, B \subseteq S}$. We know that for each $u \in U$ there is some pair (B, S) so that $u \in B$ and $y_B^S = 1$ (we will call it a *covering pair*). As long as there are many covering pairs for some u, we replace one of them with $(B \setminus \{u\}, S)$. The new solution is still feasible and the objective value is no greater as function g_π is monotone. Therefore there exists an optimal solution so that each $u \in U$ admits exactly one covering pair (B_u, S_u). We can define $\phi(u) = S_u$ to obtain a covering with expected cost equal to the value of the objective function. ◀

(LP-SC) has an exponential number of variables: in order to solve it we consider its dual, and provide a separation oracle to solve it. Interestingly, our separation oracle uses submodular minimization.

▶ **Lemma 4.** *(LP-SC) can be solved in polynomial time.*

Proof. We show how to solve the dual of (LP-SC), which is as follows:

$$\begin{aligned} \max \quad & \sum_{u\in U} \alpha_u && \text{(DP-SC)} \\ \text{s.t.} \quad & \sum_{u\in B} \alpha_u \le c(S)\cdot g_\pi(B) && \forall_{S\in\mathcal{C}}\forall_{B\subseteq S} \\ & \alpha_u \ge 0 && \forall_{u\in U}. \end{aligned}$$

Observe that (DP-SC) has a polynomial number of variables and an exponential number of constraints. In order to solve (DP-SC), it is sufficient to provide a (polynomial-time) separation oracle, i.e. a procedure that, given a tentative solution $\{\alpha_u\}_{u\in U}$, either determines that it is feasible or provides a violated constraint.

This reduces to check, for each given $S \in \mathcal{C}$, whether there exists $B \subseteq S$ such that $\sum_{u\in B}\alpha_u > c(S)\cdot g_\pi(B)$. In other terms, we wish to determine whether the minimum of function $h_S(B) := c(S)\cdot g_\pi(B) - \sum_{u\in B}\alpha_u$ is negative. Observe that the value of $h_S(B)$ can be computed in polynomial time for a given B, since π is given in input as a set of scenarios. Note also that h_S is submodular: indeed g_π is submodular, costs $c(S)$ are non-negative by assumption, and $-\sum_{u\in B}\alpha_u$ is linear (hence submodular). Hence we can minimize h_S over $B \subseteq S$ in polynomial time via Theorem 1.[1] ◀

Given the optimal solution to (LP-SC), it is sufficient to round it with the usual randomized rounding algorithm for set cover.

▶ **Lemma 5.** *The optimal solution to (LP-SC) can be rounded to an integer feasible solution while increasing the cost by a factor $O(\log n)$ in expected polynomial time.*

Proof. In the optimal solution, for each $S \in \mathcal{C}$, variables $\{y_B^S\}_{B\subseteq S}$ define a probability distribution. We sample from this distribution (independently for each S) for $q = 2\ln n$ many times. Let $B_1^S, \dots, B_q^S$ be the sets sampled for S: we let $B^S := \cup_i B_i^S$ and tentatively map elements of B^S into S. In case the same element u belongs to $B^{S'}$ and $B^{S''}$ for $S' \neq S''$, we replace $B^{S'}$ with $B^{S'} \setminus \{u\}$ and iterate: this way each element is mapped into exactly one set. The final sets B^S induce our approximate mapping.

We can upper bound the expected cost of the solution by $\sum_{S\in\mathcal{C}} c(S)\sum_{i=1}^q g_\pi(B_i^S)$. Indeed, by the subadditivity of g_π (which is implied by submodularity and non-negativity), one has $g_\pi(B^S) \le \sum_{i=1}^q g_\pi(B_i^S)$. Furthermore, $g_\pi(B^{S'} \setminus \{u\}) \le g_\pi(B^{S'})$ since g_π is monotone. Trivially

$$\begin{aligned} \mathbb{E}\left[\sum_{S\in\mathcal{C}} c(S)\sum_{i=1}^q g_\pi(B_i^S)\right] &= 2\ln n\cdot \mathbb{E}\left[\sum_{S\in\mathcal{C}} c(S) g_\pi(B_1^S)\right] \\ &= 2\ln n\cdot \sum_{S\in\mathcal{C}} c(S)\sum_{B\subseteq S} y_B^S\cdot g_\pi(B^S) \le 2\ln n\cdot OPT. \end{aligned}$$

And from Markov's inequality

$$\mathbb{P}\left[\sum_{S\in\mathcal{C}} c(S)\sum_{i=1}^q g_\pi(B_i^S) > 4\ln n\cdot OPT\right] < \frac{1}{2}.$$

[1] In order to solve the configuration LP, there is an alternative to finding a separation oracle for the dual. We can transform the configuration LP into a optimization program where we need to minimize a sum of Lovasz's extensions [50], which are convex functions, over a convex region. This approach would be possibly more efficient, but we have chosen the one above for a simpler presentation.

The probability that an element $u \in U$ is not covered with a single sampling over y_B^S is

$$\prod_{B \ni u} \prod_{S \supseteq B} (1 - y_B^S) \leq \prod_{B \ni u} \prod_{S \supseteq B} e^{-y_B^S} = e^{-\sum_{B \ni u} \sum_{S \supseteq B} y_B^S} \leq \frac{1}{e}.$$

Therefore, by the independence of the sampling and the union bound, the probability that at least one element is not covered is at most $n \cdot \frac{1}{e^{2 \ln n}} = \frac{1}{n}$.

Altogether this gives a Monte-Carlo algorithm. As usual, this can be turned into a Las-Vegas algorithm with expected polynomial running time by repeating the procedure when some element is not covered or the cost of the solution is greater than $4 \ln n \cdot OPT$. ◀

The following theorem is a straight-forward consequence of Lemmas 4 and 5.

▶ **Theorem 6.** Universal Stochastic Set Cover *in the scenario model admits a polynomial-time $O(\log n)$ approximation algorithm w.r.t. the optimal universal mapping.*

It turns out that not only the randomized rounding technique can be adapted to the universal stochastic model but also the dual fitting technique. This allows us to improve the above result to a purely deterministic algorithm with the approximation ratio exactly equal to H_n. What is more, we are able to consider more general problems where each element u is required to be covered at least $r(u)$ times. Details will appear in the full version.

Our results can be also partially generalized to the oracle model, where the probability distribution is given only by a blackbox oracle. In the unweighted case we are able to give a polynomial time algorithm, while in the weighted case a pseudo-polynomial time one where the complexity depends also on $\max_S c(S)$. Again, details will appear in the full version.

Finally, since in the independent activation model we can compute function g_π in polynomial time, our approach works also in that case.

▶ **Theorem 7.** Universal Stochastic Set Cover *in the independent activation model admits a polynomial-time $O(\log n)$ approximation algorithm w.r.t. the optimal universal mapping.*

4 Metric facility location in the independent activation model

In the stochastic universal variant of the metric uncapacitated facility location (*UniStoch-FL*) problem, we have a set of clients C and a set of facilities F. For each client $c \in C$ and facility $f \in F$, there is a cost $d(c, f)$ paid if c is connected to f; furthermore, there is a cost o_f associated with opening facility $f \in F$. In the universal solution we need to assign every client $c \in C$ to a facility $\phi(c) \in F$. Once a set $X \subseteq U$ is realized we need to open all facilities $f \in \bigcup_{c \in X} \phi(c)$ and connect each $c \in X$ to $\phi(c)$. The goal is to minimize the expected total cost of opening the facilities and connecting clients to facilities:

$$\mathbb{E}_{X \sim \pi} \left[\sum_{f \in \bigcup_{c \in X} \phi(c)} o_f + \sum_{c \in X} d(c, \phi(c)) \right].$$

Just by direct modeling of the above formula with the configuration LP we can see that the following is a relaxation of an integer program that solves the problem:

$$\min \sum_{f \in F} o_f \sum_{B \subseteq C} y_B^f \cdot g_\pi(B) + \sum_{c \in C} \sum_{f \in F} g_\pi(c) \cdot d(c, f) \cdot \sum_{B \subseteq C : c \in B} y_B^f \qquad \text{(CONF-LP-FL)}$$

$$\text{s.t. } \forall_{c \in C} : \sum_{f \in F} \sum_{B \subseteq C : c \in B} y_B^f \geq 1 \qquad \text{and} \qquad \forall_{f \in F} \forall_{B \subseteq C} : y_B^f \geq 0.$$

Let $OPT_{CONF-LP-FL}$ be the optimal solution to the above LP. It holds that $OPT_{CONF-LP-FL}$ is a lower-bound on the expected outcome of an optimal universal solution.

What we are able to present in this section is a constant approximation in the case of independent activation where every client c is independently chosen into the scenario with probability p_c. This restriction is due to the fact that we do not know of a good rounding procedure in the general case, while we can solve the configuration LP even with the arbitrary scenario distribution.

▶ **Theorem 8.** *For* Universal Stochastic Facility Location *in the independent activation model there exists an algorithm with expected outcome cost at most* $6.33 \cdot OPT_{CONF\text{-}LP\text{-}FL}$.

4.1 Transforming the LP

We start off with the following two inequalities for any $S \subseteq C$ (see [33] for proof):

$$\min\left(1, \sum_{t\in S} p_t\right) \geq g_\pi(S) = 1 - \prod_{t\in S}(1-p_t) \geq \left(1-\frac{1}{e}\right)\min\left(1, \sum_{t\in S} p_t\right). \tag{2}$$

Now based on this inequality we shall transform and relax the (CONF-LP-FL) to get one that is a bit easier to tackle. The inequality implies that the solution of the following LP is at most $\frac{e}{e-1}$ bigger than the solution of (CONF-LP-FL):

$$\begin{aligned}
&\min \sum_{f\in F} o_f \sum_{B\subseteq C} y_B^f \cdot \min\left(1, \sum_{c\in B} p_c\right) + \sum_{c\in C}\sum_{f\in F} g_\pi(c)\cdot d(c,f)\cdot \sum_{B\subseteq C: c\in B} y_B^f && (3)\\
&\text{s.t.} \sum_{f\in F}\sum_{B\subseteq C: c\in B} y_B^f \geq 1 && \forall_{c\in C}\\
&\quad y_B^f \geq 0 && \forall_{f\in F}\forall_{B\subseteq C}.
\end{aligned}$$

Let Big be a collection of sets $B \subseteq C$ such that $\sum_{t\in B} p_t > 1$, and let Sml be a collection of sets $B \subseteq C$ such that $\sum_{t\in B} p_t \leq 1$. Define x_c^f to be the extent to which c was assigned to f via sets from Big, and $\bar{x}_c^f$ the extent to which c was assigned to f via sets from Sml, i.e., $x_c^f = \sum_{B\in Big: c\in B} y_B^f$ and $\bar{x}_c^f = \sum_{B\in Sml: c\in B} y_B^f$. Also, for every client c there is an obvious inequality $\sum_{B\in Big} y_B^f \geq \sum_{B\in Big: c\in B} y_B^f = x_c^f$. Now we can lower bound (3):

$$\begin{aligned}
&\sum_{f\in F} o_f \left(\sum_{B\in Big} y_B^f + \sum_{B\in Sml} y_B^f \cdot \left(\sum_{j\in B} p_j\right)\right) + \sum_{c\in C}\sum_{f\in F} p_c\cdot d(c,f)\cdot \sum_{B\subseteq C: c\in B} y_B^f\\
&= \sum_{f\in F} o_f \left(\sum_{B\in Big} y_B^f\right) + \sum_{f\in F}\sum_{c\in C} o_f\cdot p_c \left(\sum_{B\in Sml: c\in B} y_B^f\right) + \sum_{c\in C}\sum_{f\in F} p_c\cdot d(c,f)\cdot \sum_{B\subseteq C: c\in B} y_B^f\\
&\geq \sum_{f\in F} o_f \cdot \max_{c\in C}\left(x_c^f\right) + \sum_{f\in F}\sum_{c\in C} o_f\cdot p_c\cdot \bar{x}_c^f + \sum_{c\in C}\sum_{f\in F} p_c\cdot d(c,f)\cdot\left(x_c^f + \bar{x}_c^f\right).
\end{aligned}$$

▶ **Lemma 9.** *Let* OPT_{LP-FL} *be the optimum solution of the following LP:*

$$\begin{aligned}
&\min \sum_{f\in F} o_f \cdot \max_{c\in C}\left(x_c^f\right) + \sum_{f\in F} o_f \cdot \sum_{c\in C} p_c\cdot \bar{x}_c^f + \sum_{c\in C}\sum_{f\in F} p_c\cdot d(c,f)\cdot\left(x_c^f + \bar{x}_c^f\right) && \text{(LP-FL)}\\
&\text{s.t. } \forall_{c\in C}: \sum_{f\in F} x_c^f + \bar{x}_c^f \geq 1 \qquad \text{and} \qquad \forall_{f\in F}\forall_{c\in C}: x_c^f, \bar{x}_c^f \geq 0.
\end{aligned}$$

It holds that $OPT_{LP-FL} \leq \frac{e}{e-1}\cdot OPT_{CONF-LP-FL}$.

4.2 The rounding procedure

LP-FL has a polynomial number of variables and constraints, and so it can be solved in polynomial time; denote by $\left(x_c^f, \bar{x}_c^f\right)_{c\in C, f\in F}$ the optimal solution. Once we solve it we split the clients into two groups:

$$C_{\text{big}} := \left\{ c \in C \,\middle|\, \sum_{f\in F} x_c^f \geq \frac{3}{4} \right\} \text{ and } C_{\text{sml}} = \left\{ c \in C \,\middle|\, \sum_{f\in F} \bar{x}_c^f > \frac{1}{4} \right\}.$$

Dealing with clients from C_{big}

From the definition we get that $\left(\frac{4}{3}x_c^f\right)_{c\in C_{\text{big}}, f\in F}$ is a feasible solution to the following problem, which is a variant of the deterministic facility location problem where the price for the distance for client $c \in C$ is proportional to the factor p_c:

$$\begin{aligned} \min \; & \sum_{f\in F} o_f \cdot \max_{c\in C_{\text{big}}} \left(z_c^f\right) + \sum_{c\in C}\sum_{f\in F} p_c \cdot d\left(c,f\right) \cdot z_c^f \\ \text{s.t.} \; & \forall_{c\in C_{\text{big}}} : \sum_{f\in F} z_c^f \geq 1 \qquad \text{and} \qquad \forall_{f\in F}\forall_{c\in C_{\text{big}}} : z_c^f \geq 0. \end{aligned}$$

For this problem there exists a 3-approximation algorithm based on primal-dual method (the proof is a simple exercise and will appear in the full version of the paper); let $\left(z_c^f\right)_{c\in C, f\in F}$ be such an integral solution. Thus we have

$$\begin{aligned} & \sum_{f\in F} o_f \cdot \max_{c\in C_{\text{big}}} \left(z_c^f\right) + \sum_{c\in C_{\text{big}}}\sum_{f\in F} p_c \cdot d\left(c,f\right) \cdot z_c^f \\ \leq\; & 3 \cdot \sum_{f\in F} o_f \cdot \max_{c\in C_{\text{big}}} \left(\frac{4}{3}x_c^f\right) + 3 \cdot \sum_{c\in C_{\text{big}}}\sum_{f\in F} p_c \cdot d\left(c,f\right) \cdot \frac{4}{3}x_c^f \\ \leq\; & 4 \cdot \sum_{f\in F} o_f \cdot \max_{c\in C} \left(x_c^f\right) + 4 \cdot \sum_{c\in C}\sum_{f\in F} p_c \cdot d\left(c,f\right) \cdot x_c^f. \end{aligned} \tag{4}$$

Dealing with clients from C_{sml}

Now the $\left(4 \cdot \bar{x}_c^f\right)_{c\in C_{\text{sml}}, f\in F}$ vector is a feasible solution to the following LP:

$$\begin{aligned} \min \; & \sum_{c\in C_{\text{sml}}}\sum_{f\in F} p_c \left(o_f + d\left(c,f\right)\right) \cdot z_c^f \\ \text{s.t.} \; & \forall_{c\in C_{\text{sml}}} : \sum_{f\in F} z_c^f \geq 1 \qquad \text{and} \qquad \forall_{f\in F}\forall_{c\in C_{\text{sml}}} : z_c^f \geq 0. \end{aligned}$$

We can find an integral solution to this LP easily: just assign every client $c \in C_{\text{sml}}$ to the facility f that minimizes $o_f + d\left(c,f\right)$. If $\left(z_c^f\right)_{c\in C_{\text{sml}}, f\in F}$ is such an integral solution, then we have that

$$\sum_{c\in C_{\text{sml}}}\sum_{f\in F} p_c \left(o_f + d\left(c,f\right)\right) \cdot z_c^f \leq \sum_{c\in C_{\text{sml}}}\sum_{f\in F} p_c \left(o_f + d\left(c,f\right)\right) \cdot 4\bar{x}_c^f. \tag{5}$$

Combining the two solutions

In this way the solution composed from two integer vectors $\left(z_c^f\right)_{c\in C_{\text{big}},f\in F}$ and $\left(z_c^f\right)_{c\in C_{\text{sml}},f\in F}$ is a feasible solution to the (LP-FL), and by combining (4) and (5) its value is

$$\begin{aligned}
&\sum_{f\in F} o_f \cdot \max_{c\in C_{\text{big}}} \left(z_c^f\right) + \sum_{f\in F}\sum_{c\in C_{\text{sml}}} o_f \cdot p_c \cdot z_c^f + \sum_{c\in C}\sum_{f\in F} p_c \cdot d\left(c,f\right)\cdot z_c^f \\
\leq\ & 4\cdot \sum_{f\in F} o_f \cdot \max_{c\in C} \left(x_c^f\right) + \sum_{f\in F}\sum_{c\in C} o_f \cdot p_c \cdot 4\bar{x}_c^f + \sum_{c\in C}\sum_{f\in F} p_c \cdot d\left(c,f\right)\cdot \left(4x_c^f + 4\bar{x}_c^f\right) \\
\leq\ & 4\cdot \frac{e}{e-1} OPT_{CONF-LP-FL} < 6.33 \cdot OPT_{CONF-LP-FL}.
\end{aligned}$$

Thus we found a solution $\left(z_c^f\right)_{c\in C,f\in F}$ for the (LP-FL) whose value is at most $6.33 \cdot OPT_{CONF-LP-FL}$. However using the left-side inequality from (2) we can transform it into a solution of the (CONF-LP-FL) without losing its value. Hence we found a solution to the Universal Stochastic Facility Location which is a 6.33-approximation.

5 Multicut in the independent activation model

In the (classical version of the) Multicut problem we are given an undirected graph G with non-negative costs c_e for all $e \in E(G)$ and a set of pairs of vertices $(s_1,t_1),\ldots,(s_k,t_k)$. The goal is to erase a subset of edges F of small cost so that there is no path connecting s_c with t_c for any c. Multicut may be considered a covering problem in which the client c is covered if F contains some (s_c,t_c)-cut.

In the universal stochastic setting we are also given a probability distribution π over the subsets of $C=[1,k]$ and the solution is a mapping $\phi : C \to 2^E$ such that $\phi(c)$ forms a (s_c,t_c)-cut. The expected cost of the solution induced by a mapping ϕ equals $\mathbb{E}_{X\sim\pi}\left[\sum_{\substack{e\in\phi(c)\\ c\in X}} c_e\right]$.

We express the problem with a configuration integer program. Let $\mathcal{P}_c$ denote the family of all paths connecting s_c with t_c and let $y_B^e = 1$ mean that $B = \{c \in C : e \in \phi(c)\}$.

$$\begin{aligned}
&\min \sum_{e\in E} c_e \sum_{B\subseteq C} y_B^e \cdot g_\pi\left(B\right) && \text{(CONF-IP-MC)} && (6)\\
&\text{s.t.} \sum_{e\in P}\sum_{B\ni c} y_B^e \geq 1 && \forall_{c\in C}\,\forall_{P\in\mathcal{P}_c}. \\
&\quad y_B^e \in \{0,1\} && \forall_{e\in E}\,\forall_{B\subseteq C}.
\end{aligned}$$

We next use CONF-LP-MC to denote the linear relaxation of CONF-IP-MC. Likewise for Facility location, we will show that in the independent activation model we can reduce the universal stochastic setting to the buy-at-bulk setting, where each edge e can be either bought for price c_e to serve all the clients or be rented by client c for price $c_e \cdot p_c$. We define variables x^e to indicate that e has been bought and variables $\bar{x}_c^e$ to express the event of e being rented by c. This transition simplifies the linear program CONF-LP-MC to the following one by sacrificing an approximation factor of $\frac{e}{e-1}$.

$$\begin{aligned}
&\min \sum_{e\in E} c_e \cdot x^e + \sum_{e\in E} c_e \sum_{c\in C} p_c \cdot \bar{x}_c^e && \text{(LP-MC)} \\
&\text{s.t.} \sum_{e\in P} (x^e + \bar{x}_c^e) \geq 1 && \forall_{c\in C}\forall_{P\in\mathcal{P}_c} \\
&\quad x^e, \bar{x}_c^e \geq 0 && \forall_{e\in E}\forall_{c\in C}.
\end{aligned}$$

The proofs of the two following lemmas are similar to derivations in Sections 4.1 and 4.2 and so we omit them in this extended abstract.

▶ **Lemma 10.** *If π is an independent activation distribution, then the optimal value of LP-MP is at most $\frac{e}{e-1}$ times larger than the optimal value of CONF-LP-MP.*

▶ **Lemma 11.** *If G is a tree, then one can round a fractional solution to LP-MC to an integral one of cost at most 3 times larger. The procedure runs in polynomial time.*

In order to solve the problem on general graphs, we will embed the graph into a tree that approximately preserves the structure of cuts. The following construction has been introduced by Räcke [41]. We call a tree T decomposition tree of G if

1. the leaves of T correspond to vertices of G,
2. each edge e_t in T has weight $c^T_{e_t}$ equal to the weight of the cut it induces on $V(G)$ (we call this cut $m_T(e_t)$).

For an edge $e \in E(G)$ and a decomposition tree T we define the *relative load* of e as

$$rload_T(e) = \left(\sum_{\substack{e_t \in E(T) \\ e \in m_T(e_t)}} c^T_{e_t} \right) / c_e.$$

The main result in [41] concerns the relation between multicommodity flows in G and T_i. As our LP formulation is slightly more sophisticated we need to exploit this result in more detail. Section 2.1 in [41] describes how to find (in polynomial time) a convex combination of decomposition trees $\{\lambda_i T_i\}_{i=1}^q$ for a graph G, such that $\max_{e \in E(G)} [\sum_{i=1}^q \lambda_i rload_{T_i}(e)] = O(\log n)$.

▶ **Theorem 12.** Universal Stochastic Multicut *in the independent activation model admits a polynomial-time $O(\log n)$ approximation algorithm.*

Proof. Lemma 11 implies that a fractional solution to LP-MC over T_i can be rounded to an integer solution with ratio 3. Observe that each tree edge on a path between terminals corresponds to some cut between these terminals so any solution to Universal Stochastic Multicut on a decomposition tree induces a solution on the original graph of at most the same cost.

Let L_i denote the optimal value of LP-MC over T_i and L denote the same for G. We are going to show that $\sum_{i=1}^q \lambda_i L_i = O(L \log n)$. In particular this means that $\min_{i=1}^q L_i = O(L \log n)$. After rounding the fractional solution on T_i of the smallest value, we will obtain an integral solution for G of cost $O(L \log n)$, what entails an $O(\log n)$ approximation.

Let us consider the dual linear program of LP-MC.

$$\max \sum_{c \in C} \sum_{P \in \mathcal{P}_c} \alpha_P \qquad \text{(DP-MC)}$$

$$\text{s.t.} \sum_{c \in C} \sum_{\substack{P \in \mathcal{P}_c \\ e \in P}} \alpha_P \leq c_e \qquad \forall_{e \in E} \tag{7}$$

$$\sum_{\substack{P \in \mathcal{P}_c \\ e \in P}} \alpha_P \leq c_e \cdot p_c \qquad \forall_{c \in C} \forall_{e \in E} \tag{8}$$

$$\alpha_P \geq 0 \qquad \forall_{c \in C} \forall_{P \in \mathcal{P}_c}.$$

Feasible solutions to (DP-MC) are just multicommodity flows satisfying conditions (7)-(8). Let (β^{T_i}) be an optimal solution to (DP-MC) on a decomposition tree T_i (of value L_i) and let

(α^{T_i}) be a flow on G where a unit flow over e_t in (β^{T_i}) translates into a unit flow over $m_T(e_t)$. Note that the value of shipped commodities remains the same. Consider $(\alpha) = \sum_{i=1}^{q} \lambda_i(\alpha^{T_i})$. It is a (not necessarily feasible) solution of value $\sum_{i=1}^{q} \lambda_i L_i$.

As (β^{T_i}) routes at most $c_{e_t}^{T_i}$ flow through an edge e_t, then (α^{T_i}) routes at most $\sum_{\substack{e_t \in E(T_i) \\ e \in m_{T_i}(e_t)}} c_{e_t}^{T_i}$ flow through an edge e. Therefore constraint (7) is exceeded at most $rload_{T_i}(e)$ times in (α^{T_i}) and $\sum_{i=1}^{q} \lambda_i rload_{T_i}(e)$ times in (α). If we consider vectors $(\beta_c^{T_i})$ given by flow routed between terminals of client c, then we conclude the same for constraint (8).

After scaling (α) down times $M = \max_{e \in E(G)} [\sum_{i=1}^{q} \lambda_i rload_{T_i}(e)]$ we obtain a feasible solution to (DP-MC) for G. This means that L is no less than $\sum_{i=1}^{q} \lambda_i L_i$ divided by M. As we know that $M = O(\log n)$, the claim follows. ◀

Abstract

We provide a single-key functional encryption scheme for Deterministic Finite Automata (DFA). The secret key of our scheme is associated with a DFA M, and a ciphertext is associated with an input $\mathbf{x}$ of *arbitrary* length. The decryptor learns $M(\mathbf{x})$ and nothing else. The ciphertext and key sizes achieved by our scheme are optimal – the size of the public parameters is independent of the size of the machine or data being encrypted, the secret key size depends only on the machine size and the ciphertext size depends only on the input size.

Our scheme achieves full functional encryption in the "private index model", namely the entire input $\mathbf{x}$ is hidden (as against $\mathbf{x}$ being public and a single bit b being hidden). Our single key FE scheme can be compiled with symmetric key encryption as in [12] to yield reusable garbled DFAs for arbitrary size inputs, that achieves machine and input privacy along with reusability under a strong simulation based definition of security.

We generalize this to a functional encryption scheme for Turing machines TMFE which has short public parameters that are independent of the size of the machine or the data being encrypted, short function keys, and input-specific decryption time. However, the ciphertext of our construction is large and depends on the worst case running time of the Turing machine (but not its description size). These provide the first FE schemes that support unbounded length inputs, allow succinct public and function keys and rely on LWE.

Our construction relies on a new and arguably natural notion of *decomposable functional encryption* which may be of independent interest.

1 Introduction

Functional encryption permits *controlled disclosure* of encrypted data, enabling the evaluator to learn some authorised function of encrypted data in the clear. In functional encryption (FE), a secret key corresponds to a function f and ciphertexts correspond to strings from the domain of f. Given a function SK_f and a ciphertext $\mathsf{CT}_{\mathbf{x}}$, the decryptor learns $f(\mathbf{x})$ and nothing else. Functional encryption has found diverse applications, such as spam filtering on encrypted data [12], online dating [13], delegation of computation [16] and many others.

The function embedded within the secret key in FE is typically represented as a circuit. While circuits are a powerful model of computation, the circuit representation has significant drawbacks in practical scenarios. Consider the application of spam filtering on encrypted emails, where the email gateway may be given a key to test the incoming email for spam. Representing the computation as a circuit forces emails to be of a fixed length – a requirement which is ill-fitting and wasteful. Another significant drawback of the circuit model is that it incurs worst case running time on every input.

In practice, most spam filters as well as malware and intrusion detection systems are implemented using pattern matching operations represented as deterministic finite automata (DFA) [19, 14, 5, 10]. Note that in all these applications, the size of the input is highly variable and instance specific, and restricting it to be of fixed length is cumbersome. Therefore a functional encryption scheme for DFAs which supports dynamic data length would be the "right fit" in such situations. However, although functional encryption for circuits has been constructed based on the hardness of Learning With Errors (LWE) in the single key setting, it is unclear how to leverage these techniques to support the arbitrary data length required by DFAs.

1.1 Our Results

In this work, we provide a single-key functional encryption scheme for Deterministic Finite Automata (DFA). The secret key of our scheme is associated with a DFA M, and a ciphertext is associated with an input $\mathbf{x}$ of *arbitrary* length. The decryptor learns $M(\mathbf{x})$ and nothing else. The ciphertext and key sizes achieved by our scheme are optimal[1] – the public key size is independent of the machine and input size, the secret key size depends only on the machine size and the ciphertext size depends only on the input size.

Our scheme achieves full functional encryption in the "private index model", namely the entire input $\mathbf{x}$ is hidden (as against $\mathbf{x}$ being public and a single bit b being hidden). Our single key FE scheme can be compiled with symmetric key encryption as in [12] to yield reusable garbled DFAs for arbitrary size inputs, that achieves machine and input privacy along with reusability under a strong simulation based definition of security.

We generalize this to a functional encryption scheme for Turing machines TMFE which has short public parameters that are independent of the size of the machine or the data being encrypted, short function keys, and input-specific decryption time. However, the ciphertext of our construction is large and depends on the worst case running time of the Turing machine (but not its description size). These provide the first FE schemes that support unbounded length inputs, allow succinct public and function keys and rely on LWE.

Our construction relies on a new and arguably natural notion of *decomposable functional encryption* which may be of independent interest.

1.2 Related Work

Functional encryption for DFAs has received some attention already. Closest to our work is the "Attribute Based Encryption" scheme for DFAs constructed by Waters [20]. In [20], the encrypt algorithm takes as input a pair $(\mathbf{x}, b)$ where $\mathbf{x}$ may be of arbitrary size, and b is a bit. The key corresponds to a DFA machine M so that given a key for M and a ciphertext for $(\mathbf{x}, b)$, the decryptor learns the bit b if and only if M accepts $\mathbf{x}$. Note that in contrast to

[1] Up to logarithmic factors.

our work, the vector $\mathbf{x}$ is not hidden by the construction, neither is the machine M; only the bit b is hidden. On the other hand, the construction [20] can support polynomially many keys, whereas ours can only support a single key. Attrapadung [4] extended the work of Waters [20] to achieve adaptive rather than selective security. Another work that constructs Attribute Based Encryption for DFAs is by Boyen and Li [7]. However, in their construction, the input size to the DFA must be bounded in advance; avoiding this restriction is the main motivation for our work.

There are other known functional encryption systems that support unbounded size inputs, even supporting Turing machines, achieving input specific runtime and dynamic data length [11, 2, 6, 15, 8, 9]. However, the mildest assumption required by this line of work is the existence of indistinguishability obfuscation.

From standard assumptions, single key functional encryption has been constructed for all polynomial sized circuits [18, 12]. A natural approach to construct reusable garbled DFA/TM then, is to convert the machine to a circuit and leverage the constructions of [18, 12]. However, instantiating this compiler with the reusable garbled circuits construction [12] leads to a construction that cannot support dynamic data lengths, which is the main focus of this work. On the other hand, using the construction by Sahai and Seyalioglu [18] leads to a DFA/TM FE construction with large public key and ciphertext size, since the construction by [18] suffers from public key and ciphertext size that depend on the circuit size.

1.3 Our Techniques

To begin, we describe our single key FE scheme for DFA. Next, we describe how this construction may be generalized to Turing machines.

1.3.1 Single Key FE for DFA

We briefly recall how a DFA works. A DFA machine M is represented by the tuple $(Q, \Sigma, T, q_{st}, F)$ where Q is a finite set of states, Σ is a finite alphabet, $T : \Sigma \times Q \to Q$ is the transition function, q_{st} is the start state, $F \subseteq Q$ is the set of accepting states. Upon input $\mathbf{w} \in \Sigma^k$ for some arbitrary polynomial k, the machine M accepts $\mathbf{w}$ if and only if there exists a sequence of states $q_1, \ldots, q_k$ so that $q_1 = q_{st}$, $T(w_i, q_i) = q_{i+1}$ for $i \in [k-1]$, and $q_k \in F$.

To mimic the DFA computation, a natural starting point is to imagine a function key that stores the transition table of a DFA, receives as input the current (symbol, state) pair and produces as output an encryption of the next state of the computation. In more detail, say the encryptor provides encryptions of each input symbol x_i, for $i \in [|\mathbf{x}|]$, in addition to an encryption for the first (fixed) state q_{st}. Now, the function key could accept 2 inputs (x_1, q_{st}), lookup the transition table and produce an encryption of the next state q_2. Suppose this encryption can only be paired with the encryption of x_2 and none other, then we could provide (x_2, q_2) as input to the function in the next step, thus propagating the computation.

We tie together encryptions of symbol with encryptions of state via the notion of *decomposable functional encryption*. Intuitively, decomposability requires that the public key PK and the ciphertext $\mathsf{CT}_{\mathbf{y}}$ of a functional encryption scheme be decomposable into components PK_j and CT_j for $j \in [|\mathbf{y}|]$, where CT_j depends on a single deterministic bit y_j and the public key component PK_j. All components CT_j are tied together by *common randomness* used for their creation, although each CT_j may use additional independent randomness. Aside from the message dependent components, a ciphertext can contain components that are independent of the message and depend only on the common randomness. The main advantage

offered by decomposable functional encryption is that given the common randomness, each ciphertext component CT_j can be constructed independently of the rest. These components can then be joined together to create a complete ciphertext which can then be decrypted successfully. Additionally, only components that were constructed using the same randomness can be "joined", thereby preventing mix and match attacks where an adversary tries to treat mismatched symbol state pairs such (x_3, q_2) as a single legitimate input.

Now, suppose we have a decomposable functional encryption scheme for circuits. Then, we may proceed with the aforementioned strategy and divide the ciphertext into two components – the first encoding the current symbol, and the second encoding the current state. We may use the function key to generate the second component, *using the same common randomness that was used to generate the first component.*

To take this approach forward we must find a suitable decomposable functional encryption scheme for circuits – fortunately most functional encryption schemes in the literature are decomposable. In particular, we show that the the succinct single key FE by Goldwasser et al. [12] is decomposable. This scheme appears suitable for our purposes as the ciphertext and public key in this scheme are independent of circuit size.

However, note that the ciphertext of [12] suffers from *output-size dependence*, i.e. it grows linearly with the output length of the circuit. This implies that the function key may not produce an output that is proportional to the length of the ciphertext. To obtain a (single key) construction from LWE, we resolve this issue by repurposing a classic trick from Yao's garbled circuit construction, so that the output length of the circuit can be made independent of the ciphertext size, at the cost of blowing up the ciphertext size somewhat. More concretely, instead of having the circuit output a new ciphertext, the encryptor provides symmetric key encryptions of CktFE [12] ciphertext components, encrypting *all possible bit values* (nesting CktFE ciphertext inside SKE ciphertext), and the function key outputs the SKE keys to unlock the correct CktFE ciphertext components, corresponding to the bit values chosen by the key. This allows us to *select* the next state with a circuit output length independent of the ciphertext size. For more details, we refer the reader to Section 4. This provides input privacy and reusability but not machine privacy. We achieve machine privacy following ideas of [12] – please see the full version [1] for details.

1.3.2 Single key FE for Turing Machines

To extend the above construction to support Turing Machines, we must address two challenges: a) head movements should not reveal anything about the input and b) we need to write to the tape. Below we describe how to handle each challenge in turn.

To overcome the first challenge, a natural approach is to use oblivious TMs, which fix the head movement of a TM to be independent of the input. Moreover, there exist efficient transformations that convert any Turing machine M that takes time T to decide an input to an oblivious one that takes time $T \log T$ to decide the same input [17]. It remains to address the challenge of handling tape writes. Since the head movements of the TM are now fixed, the only thing that the transition function must specify is the next state, and the symbol that must be written to the current tape cell. We leverage decomposability and have the encryptor provide a ciphertext component encoding state, and another component encoding current work tape symbol *for every step in the computation.* Indeed, this forces our ciphertext to depend (linearly) on worst-case runtime of the Turing machine. All the ciphertext components for a given time step are tied together with common randomness as before. To ensure that the decryptor only learns the ciphertext components corresponding to the particular state and tape symbol that occur during computation, the encryptor encrypts

all CktFE ciphertexts with symmetric key encryption SKE. As in the case of DFA, the function key selects the appropriate SKE keys to reveal the CktFE ciphertext encoding next state and symbol to be read.

The careful reader may have noticed that the above description glosses over an important detail: the cell that is written into at step i may be next accessed at any step $j > i$, so the CktFE ciphertext at step i must encode SKE keys for some unknown future step j. Fortunately, the machinery of oblivious TMs comes to our aid again. Since in an oblivious TM, there exists a function t that computes the step that particular cell will be accessed next, in step i, in addition to selecting the state for step $i+1$ as we did in DFAs, the function key will also select the tape symbol to be read in step $t(i)$. At any step j, the appropriate SKE keys for the state were provided in step $j-1$ and for tape symbol were provided at step $i < j$ where $t(i) = j$. Hence, the decryptor at step j has the SKE keys to unlock the CktFE CT components for both state and tape symbol, which lets her proceed with the computation. For more details, please see the full version [1].

1.4 Organization of the paper

In Section 2, we define the preliminaries we require for our constructions. In Section 3, we define the notion of decomposable functional encryption. In Section 4, we provide our construction for single key FE for DFAs. In the full version [1], we provide our construction for single key functional encryption for Turing machines.

2 Definitions: FE for Deterministic Finite Automata

In this section we provide some notation and preliminaries that we require.

Functional encryption for deterministic finite automata (DFA) is defined analogously to functional encryption for circuits, except that the public parameters may not depend on the input length, which is unknown a priori. In this section, we will define single key functional encryption for DFAs.

A DFA machine M is represented by the tuple $(Q, \Sigma, T, q_{st}, F)$ where Q is a finite set of states, Σ is a finite alphabet, $T : \Sigma \times Q \to Q$ is the transition function (stored as a table), q_{st} is the start state, $F \subseteq Q$ is the set of accepting states. Upon input $\mathbf{w} \in \Sigma^k$ for some arbitrary polynomial k (not known to the setup algorithm), the machine M accepts the input if and only if there exists a sequence of states $q_1, \ldots, q_k$ so that $q_1 = q_{st}$, $T(w_i, q_i) = q_{i+1}$ for $i \in [k-1]$, and $q_k \in F$. We say $M(\mathbf{w}) = 1$ iff M accepts $\mathbf{w}$ and 0 otherwise.

2.1 Definition

Let $\mathcal{M}_\kappa : \mathcal{Q}_\kappa \times \Sigma_\kappa \to \mathcal{Q}_\kappa$ be a DFA family. A functional encryption scheme DfaFE for $\mathcal{M}$ consists of four algorithms DfaFE = (DfaFE.Setup, DfaFE.KeyGen, DfaFE.Enc, DfaFE.Dec) defined as follows.

- $\mathsf{DfaFE.Setup}(1^\kappa)$ is a p.p.t. algorithm takes as input the unary representation of the security parameter and outputs the master public and secret keys $(\mathsf{PK}, \mathsf{MSK})$.
- $\mathsf{DfaFE.KeyGen}(\mathsf{MSK}, \mathsf{M})$ is a p.p.t. algorithm that takes as input the master secret key MSK and a DFA machine M and outputs a corresponding secret key SK_M.
- $\mathsf{DfaFE.Enc}(\mathsf{PK}, \mathbf{w})$ is a p.p.t. algorithm that takes as input the master public key PK and an input message $\mathbf{w}$ and outputs a ciphertext $\mathsf{CT}_\mathbf{w}$.
- $\mathsf{DfaFE.Dec}(\mathsf{SK}_\mathsf{M}, \mathsf{CT}_\mathbf{w})$ is a deterministic algorithm that takes as input the secret key SK_M and a ciphertext $\mathsf{CT}_\mathbf{w}$ and outputs $M(\mathbf{w})$.

▶ **Definition 1** (Correctness)**.** A functional encryption scheme DfaFE is correct if for all $M \in \mathcal{M}$ and all $\mathbf{w} \in \Sigma^*$,

$$\Pr\left[\begin{array}{l}(\mathsf{PK},\mathsf{MSK}) \leftarrow \mathsf{DfaFE.Setup}(1^\kappa);\\ \mathsf{DfaFE.Dec}\Big(\mathsf{DfaFE.KeyGen}(\mathsf{MSK},\mathsf{M}),\mathsf{DfaFE.Enc}(\mathsf{PK},\mathbf{w})\Big) \neq \mathsf{M}(\mathbf{w})\end{array}\right] = \mathrm{negl}(\kappa)$$

where the probability is taken over the coins of DfaFE.Setup, DfaFE.KeyGen, and DfaFE.Enc.

2.2 Security

In this section, we define simulation based security for single key FE for DFAs.

▶ **Definition 2** (FULL-SIM- Security for DFA-FE)**.** Let $\mathcal{F}_{\mathcal{M}}$ be a functional encryption scheme for a DFA family $\mathcal{M}$. For every p.p.t. adversary $A = (A_1, A_2)$ and a p.p.t. simulator Sim, consider the following two experiments:

$\mathsf{Exp}^{\mathsf{real}}_{\mathsf{DfaFE},\mathsf{A}}(1^\kappa)$:	$\mathsf{Exp}^{\mathsf{ideal}}_{\mathsf{DfaFE},\mathrm{Sim}}(1^\kappa)$:
1: $(\mathsf{PK},\mathsf{MSK}) \leftarrow \mathsf{DfaFE.Setup}(1^\kappa)$	1: $(\mathsf{PK},\mathsf{MSK}) \leftarrow \mathsf{DfaFE.Setup}(1^\kappa)$
2: $(M, st_1) \leftarrow A_1(\mathsf{PK})$	2: $(M, st_1) \leftarrow A_1(\mathsf{PK})$
3: $\mathsf{sk}_M \leftarrow \mathsf{DfaFE.KeyGen}(\mathsf{MSK},\mathsf{M})$	3: $\mathsf{sk}_M \leftarrow \mathsf{DfaFE.KeyGen}(\mathsf{MSK},\mathsf{M})$
4: $(\mathbf{x}, st) \leftarrow A_2(st_1,\mathsf{PK},\mathsf{sk}_M)$	4: $(\mathbf{x}, st) \leftarrow A_2(st_1,\mathsf{PK},\mathsf{sk}_M)$
5: $\mathsf{CT} \leftarrow \mathsf{DfaFE.Enc}(\mathsf{PK},\mathbf{x})$	5: $\tilde{\mathsf{CT}} \leftarrow \mathrm{Sim}(\mathsf{PK},\mathsf{sk}_M, M, M(\mathbf{x}), 1^{\lvert\mathbf{x}\rvert})$
6: Output (st, CT)	6: Output $(st, \tilde{\mathsf{CT}})$

The DFA functional encryption scheme $\mathcal{F}_{\mathcal{M}}$ is then said to be single query FULL-SIM secure if there exists a p.p.t. simulator Sim such that for every p.p.t. adversary $A = (A_1, A_2)$, the following two distributions are computationally indistinguishable:

$$\left\{\mathsf{Exp}^{\mathsf{real}}_{\mathsf{DfaFE},\mathsf{A}}(1^\kappa)\right\}_{\kappa\in\mathbb{N}} \overset{c}{\approx} \left\{\mathsf{Exp}^{\mathsf{ideal}}_{\mathsf{DfaFE},\mathrm{Sim}}(1^\kappa)\right\}_{\kappa\in\mathbb{N}}.$$

3 Decomposable Functional Encryption for Circuits

In this section, we define the notion of *decomposable functional encryption* (DFE). Decomposable functional encryption is analogous to the notion of decomposable randomized encodings [3]. Intuitively, decomposability requires that the public key PK and the ciphertext $\mathsf{CT}_{\mathbf{x}}$ of a functional encryption scheme be decomposable into components PK_i and CT_i for $i \in [|\mathbf{x}|]$, where CT_i depends on a single deterministic bit x_i and the public key component PK_i. In addition, the ciphertext may contain components that are independent of the message and depend only on the randomness.

We assume that given the security parameter, the following spaces are fixed: $\mathcal{P}$ containing public key components, $\mathcal{R}_1$, $\mathcal{R}_2$ containing randomness used for encryption and $\mathcal{C}$ containing the encoding of a single message bit. The length of the message $|\mathbf{x}|$ can be any polynomial. Formally, let $\mathbf{x} \in \{0,1\}^k$. A functional encryption scheme is said to be decomposable if there exists a deterministic function $\mathcal{E} : \mathcal{P} \times \{0,1\} \times \mathcal{R}_1 \times \mathcal{R}_2 \to \mathcal{C}$ such that:

1. The public key may be interpreted as $\mathsf{PK} = (\mathsf{PK}_1, \ldots, \mathsf{PK}_k, \mathsf{PK}_{\mathsf{indpt}})$ where $\mathsf{PK}_i \in \mathcal{P}$ for $i \in [k]$. The component $\mathsf{PK}_{\mathsf{indpt}} \in \mathcal{P}^j$ for some $j \in \mathbb{N}$.

2. The ciphertext may be interpreted as $\mathsf{CT}_{\mathbf{x}} = (\mathsf{CT}_1, \ldots, \mathsf{CT}_k, \mathsf{CT}_{\mathsf{indpt}})$, where

$$\mathsf{CT}_i = \mathcal{E}\left(\mathsf{PK}_i, x_i, r, \hat{r}_i\right) \forall i \in [k] \quad \text{and} \quad \mathsf{CT}_{\mathsf{indpt}} = \mathcal{E}\left(\mathsf{PK}_{\mathsf{indpt}}, r, \hat{r}\right).$$

Here $r \in \mathcal{R}_1$ is common randomness used by all components of the encryption. Apart from the common randomness r, each CT_i may additionally make use of independent randomness $\hat{r}_i \in \mathcal{R}_2$.

We note that if a scheme is decomposable "bit by bit", i.e. into k components for inputs of size k, it is also decomposable into components corresponding to any partition of the interval $[k]$. Thus, we may decompose the public key and ciphertext into any $i \leq k$ components of length k_i each, such that $\sum k_i = k$. We will sometimes use $\bar{\mathcal{E}}(\mathbf{y})$ to denote the tuple of function values obtained by applying $\mathcal{E}$ to each component of a vector, i.e. $\bar{\mathcal{E}}(\mathsf{PK}, \mathbf{y}, r) \triangleq \left(\mathcal{E}(\mathsf{PK}_1, y_1, r, \hat{r}_1), \ldots, \mathcal{E}(\mathsf{PK}_k, y_k, r, \hat{r}_k)\right)$, where $|\mathbf{y}| = k$.

4 Single-Key Succinct FE for DFAs from LWE

In this section, we will construct a single key (public key) functional encryption scheme for deterministic finite automata (DFA). Our construction makes use a decomposable single key FE scheme for circuits, CktFE. In the full version [1], we show that:

▶ **Lemma 3.** *The single key, succinct functional encryption scheme for circuits by Goldwasser et al. [12], based on LWE is decomposable.*

Conceptually, we decompose the input into two components of size ℓ_1 and ℓ_2 each, where the second component is further decomposed bit by bit. We will use the first component to encrypt the current input symbol in the DFA computation and keys to select the next state in the computation, and the second component to encrypt the current state in the DFA computation. While the input symbol encoded in the first component can be treated as a unit of size ℓ_1, it will be helpful for us to represent the encoded input of size ℓ_2 bit by bit.

Thus, we have,

$$\mathsf{CktFE.PK} = (\mathsf{PK}_1, \mathsf{PK}_2, \mathsf{PK}_{\mathsf{indpt}}) \text{ and } \mathsf{CktFE.CT} = (\mathsf{CT}_1, \mathsf{CT}_2, \mathsf{CT}_{\mathsf{indpt}}).$$

Now let

$$\begin{aligned}\mathsf{CktFE.Enc}(\mathsf{PK}, \mathbf{x}\|\mathbf{y}) &= (\mathsf{CT}_1, \mathsf{CT}_2, \mathsf{CT}_{\mathsf{indpt}}) \\ &= \left(\bar{\mathcal{E}}(\mathsf{PK}_1, \mathbf{x}, r, \hat{\mathbf{r}}_1),\ \bar{\mathcal{E}}(\mathsf{PK}_2, \mathbf{y}, r, \hat{\mathbf{r}}_2),\ \bar{\mathcal{E}}(\mathsf{PK}_{\mathsf{indpt}}, r, \hat{\mathbf{r}}_3)\right).\end{aligned}$$

We decompose

$$\bar{\mathcal{E}}(\mathsf{PK}_2, \mathbf{y}, r, \hat{\mathbf{r}}_2) = \left(\mathcal{E}(\mathsf{PK}_{2,1}, y_1, r, \hat{r}_{2,1}), \ldots, \mathcal{E}(\mathsf{PK}_{2,\ell_2}, y_{\ell_2}, r, \hat{r}_{2,\ell_2})\right).$$

Recall that $\mathcal{E} : \mathcal{P} \times \{0,1\} \times \mathcal{R}_1 \times \mathcal{R}_2 \to \mathcal{C}$ and $\bar{\mathcal{E}}(\mathbf{x})$ denotes the tuple of function values obtained by applying $\mathcal{E}$ to each coordinate. Then,

$$\text{Let} \quad |\mathbf{x}| = \ell_1, \quad |\mathbf{y}| = \ell_2, \quad \mathsf{PK}_1 \in \mathcal{P}^{\ell_1}, \quad \mathsf{PK}_2 \in \mathcal{P}^{\ell_2},$$
$$j \in \mathbb{N}, \quad \mathsf{PK}_{\mathsf{indpt}} \in \mathcal{P}^j, \quad r \in \mathcal{R}_1, \quad \hat{\mathbf{r}}_1 \in \mathcal{R}_2^{\ell_1}, \quad \hat{\mathbf{r}}_2 \in \mathcal{R}_2^{\ell_2}, \quad \hat{\mathbf{r}}_3 \in \mathcal{R}_2^{j}.$$

In what follows, we abuse notation slightly and omit mention of the independent, fresh randomness from $\mathcal{R}_2$ needed for each invocation for $\mathcal{E}$. For convenience, we club the message independent component $\mathsf{CT}_{\mathsf{indpt}}$ with CT_1 and let

$$\mathbf{c} = (\mathsf{CT}_1, \mathsf{CT}_{\mathsf{indpt}}) \text{ and } \mathbf{d} = \mathsf{CT}_2 = (\mathsf{CT}_{2,1}, \ldots, \mathsf{CT}_{2,\ell_2}).$$

Let $\mathcal{M}_\kappa : \mathcal{Q}_\kappa \times \Sigma_\kappa \to \mathcal{Q}_\kappa$ be a DFA family. For notational convenience, we will drop the subscript κ here on. Let $Q = |\mathcal{Q}|$, the size of the state space of the DFA family. Then, the single key functional encryption scheme for DFAs is constructed as follows.

DfaFE.Setup(1^κ):

Upon input the security parameter 1^κ, do:

1. Choose a symmetric key encryption scheme SKE with key space $\mathcal{K}$.
2. Define a circuit family as follows. Let $\mathcal{F} : \mathcal{X} \to \mathcal{Y}$ where $\mathcal{X} = (\Sigma \times \mathcal{K}^{2\log Q} \times \{0,1\}) \times \mathcal{Q}$ and $\mathcal{Y} = \mathcal{K}^{\log Q}$. We set
$$\ell_1 = \lfloor \Sigma \rfloor + \lfloor \mathcal{K}^{2\log Q} \rfloor + 1, \quad \ell_2 = \lfloor \mathcal{Q} \rfloor = \log Q$$
where $\lfloor \cdot \rfloor$ denotes size in bits. Let $\ell = \ell_1 + \ell_2$.
3. Invoke $\mathsf{CktFE.Setup}(1^\kappa, 1^\ell)$ to obtain $\mathsf{PK} = \big(\mathsf{PK}_1, (\mathsf{PK}_{2,1}, \ldots, \mathsf{PK}_{2,\log Q}), \mathsf{PK}_{\mathsf{indpt}}\big)$ and MSK.
4. Output $(\mathsf{PK}, \mathsf{MSK})$.

DfaFE.Enc($\mathsf{PK}, \mathbf{w}$):

Let $|\mathbf{w}| = k$. Note that k is arbitrary, and unknown to $\mathsf{DfaFE.Setup}$. Do the following:

1. Sample randomness $r_i \leftarrow \mathcal{R}_1$ for $i \in [k]$.
2. Sample SKE keys as follows. We define
$$\mathbf{K}_{i+1} = \Big((K^0_{(i+1,1)}, K^1_{(i+1,1)}), \ldots, (K^0_{(i+1,\log Q)}, K^1_{(i+1,\log Q)}) \Big)$$
where $K^b_{i+1,j} \leftarrow \mathcal{K}$ for $i \in [k-1]$, $j \in [\log Q]$, $b \in \{0,1\}$.
3. Define message $\mathbf{y}_i = (w_i, \mathbf{K}_{i+1}, 0)$ for $i \in [k-1]$ and $\mathbf{y}_k = (w_k, \perp, 1)$.
4. For $i \in [k]$, we define:
$$\mathbf{c}_{i,1} = \bar{\mathcal{E}}(\mathsf{PK}_1, \mathbf{y}_i, r_i), \quad \mathbf{c}_{i,2} = \bar{\mathcal{E}}(\mathsf{PK}_{\mathsf{indpt}}, r_i), \quad \mathbf{c}_i = (\mathbf{c}_{i,1}, \mathbf{c}_{i,2})\,.$$
5. Let $\mathbf{d}_1 = \bar{\mathcal{E}}\,(\mathsf{PK}_2, q_{st}, r_1)$. Here q_{st} denotes the start state of the DFA. Further, let
$$\mathbf{d}^b_{i,j} = \mathcal{E}\,(\mathsf{PK}_{2,j}, b, r_i)\ \ \forall\, i \in [2,k],\ j\ \in [\log Q],\ b \in \{0,1\}.$$
$$\mathbf{d}_{i,q} \triangleq (\mathbf{d}^{q_j}_{i,j})\ \ \forall j \in [\log Q] \text{ where } q_j \text{ is the } j\text{th bit of } q.$$
6. For $i \in [2,k]$, $j \in [\log Q]$, $b \in \{0,1\}$ encrypt each $\mathbf{d}^b_{i,j}$ using the corresponding key $K^b_{i,j}$ as:
$$\hat{\mathbf{d}}^b_{i,j} = \mathsf{SKE.Enc}(K^b_{i,j}, \mathbf{d}^b_{i,j})\,.$$
7. Choose $b_{i,j} \leftarrow \{0,1\}$ randomly for $i \in [2,k]$, $j \in [\log Q]$ and define:
$$\hat{\mathbf{D}}_{i,j} = \big(\ \hat{\mathbf{d}}^{b_{i,j}}_{i,j}, \hat{\mathbf{d}}^{\bar{b}_{i,j}}_{i,j}\ \big), \quad \hat{\mathbf{D}}_i = (\hat{\mathbf{D}}_{i,j}), \quad \hat{\mathbf{D}}_1 = \mathbf{d}_1\,.$$
8. Output $\mathsf{CT}_{\mathbf{w}} = \{\mathbf{c}_i, \hat{\mathbf{D}}_i\}$ for $i \in [k]$.

DfaFE.KeyGen(MSK, M):

Let M denote a DFA machine and T denote its transition matrix. Let T_i denote the i^{th} row of T, with format $\big((\sigma, q) \to q'\big)$ indicating that the machine enters state q' upon input symbol σ and input state q. Let $\mathsf{SK}_M = \mathsf{CktFE.Keygen}(\mathsf{MSK}, f)$ where f is defined below in Figure 1.

Function $f\big((\sigma, \mathbf{K}, \mathsf{flag}), q\big)$

1. Lookup table T for (σ, q). Say that $(\sigma, q) \to q'$. If no entry is found, output $\perp$ and exit.
2. If $\mathsf{flag} = 1$, check if q' is an accepting state. If yes, output 1, else output 0 and exit.
3. If $\mathsf{flag} = 0$, parse $\mathbf{K}$ as $\{(K_j^0, K_j^1)\}$ for $j \in [\log Q]$, $b \in \{0,1\}$. Choose the $\log Q$ keys $K_j^{q'_j}$ (for $j \in [\log Q]$), corresponding to the bits of q' and output these.

Figure 1 Function to provide keys for next state in DFA computation.

$\mathsf{DfaFE.Dec}(\mathsf{SK}_f, \mathsf{CT}_{\mathbf{w}})$:

Interpret $\mathsf{CT}_{\mathbf{w}} = (\mathbf{c}_i, \hat{\mathbf{D}}_i)_{i\in[k]}$ and let $\mathbf{d}_{1,q_1} = \hat{\mathbf{D}}_1$.

Initialize $i = 1$. While $i \le k$, do the following:

- Let $\mathsf{CT}'_i = (\mathbf{c}_i, \mathbf{d}_{i,q_i})$. Recall that $\mathbf{d}_{i,q_i} = (\mathbf{d}_{i,j}^{q_{i,j}})$ for $j \in [\log Q]$. If $i = k$, let $b \leftarrow \mathsf{CktFE.Dec}(\mathsf{SK}_f, \mathsf{CT}'_k)$. Output b and exit.
- Else let $(K_{i+1,1}, \ldots, K_{i+1,\log Q}) = \mathsf{CktFE.Dec}(\mathsf{SK}_f, \mathsf{CT}'_i)$.
- For $j \in [\log Q]$, try to decrypt each value in $\hat{\mathbf{D}}_{i+1,j}$ using obtained key $K_{i+1,j}$. Exactly one of the two ciphertexts per bit position will be decrypted, say $\hat{\mathbf{d}}_{i+1,j}^{b_j}$. Set

$$\mathbf{d}_{i+1,q_{i+1}} = \Big(\mathsf{SKE.Dec}(K_{i+1,j}, \hat{\mathbf{d}}_{i+1,j}^{b_j}) \Big) \quad \forall j \in [\log Q]\,.$$

- Increment i.

4.1 Correctness

In this section, we establish correctness of the above construction. Before we proceed with the formal argument, we provide some intuition. Note that in the encryption, the first component $\mathbf{c}_i$ encrypts message $\mathbf{y}_i$, which contains the ith input symbol, along with the set of all $2\log Q$ symmetric keys used to construct SKE encryptions of the $(i+1)^{th}$ state. In the second component, the element $\mathbf{d}_{i,j}^b$ in tuple $(\ \mathbf{d}_{i,j}^b\ )$ for $j \in [\log Q]$ and $b \in \{0,1\}$, contains an encryption of bit b, corresponding to the event that the j^{th} bit of i^{th} state is b. The set $\hat{\mathbf{D}}_i$ contains $2\log Q$ SKE encryptions of $\mathbf{d}_{i,j}^b$ under keys $K_{i,j}^b$, shuffled for each position j. Decryption at step $i-1$ provides the level i symmetric keys $K_{i,j}^{b_j}$ to unlock the $\mathbf{d}_{i,j}^{b_j}$ for the correct next state of the computation q', i.e. $b_j = q'_{i,j}$. Thus, the decryptor recovers exactly the components $\mathbf{d}_{i,j}^{b_j}$ which may be combined to create the ciphertext $\mathbf{d}_{i,q_i}$. Put together with $\mathbf{c}_i$ we get an encryption of $(w_i, \mathbf{K}_{i+1}, q_i)$ which may again be decrypted with the function key to obtain the appropriate keys to decrypt the correct $\mathbf{d}_{i+1,q_{i+1}}$.

Formally, let k denote the length of input $\mathbf{w}$ and let $q_1, \ldots, q_k$ denote the states visited by the DFA during computation. We have by correctness of decomposable functional encryption that:

$$\forall i \in [k-1],\ \mathsf{CktFE.Enc}\big(\ \mathsf{PK}, (w_i, \mathbf{K}_{i+1}, 0, q_i)\ \big) = (\mathbf{c}_i, \mathbf{d}_{i,q_i}) \quad \text{where}$$
$$\mathbf{c}_k = \Big(\bar{\mathcal{E}}\big(\mathsf{PK}_1, (w_i, \mathbf{K}_{i+1}, 0), r_i,\big), \bar{\mathcal{E}}\big(\mathsf{PK}_{\mathsf{indpt}}, r_i\big)\Big), \quad \mathbf{d}_{i,q_i} = \big(\mathcal{E}(\mathsf{PK}_{2,j}, q_{i,j}, r_i)\big)_{j\in[\log Q]}$$
$$\text{s.t. } \mathsf{CktFE.Dec}\big(\mathsf{SK}_f, (\mathbf{c}_i, \mathbf{d}_{i,q_i})\big) = \mathbf{K}_{q_{i+1}} \triangleq (K_{i+1,1}^{b_1}, \ldots, K_{i+1,\log Q}^{b_{\log Q}}) \ \text{ where } \ b_j = q_{i+1,j}.$$

Now, both elements of $\hat{\mathbf{D}}_{i+1,j}$ are attempted for decryption by $K_{i+1,j}^{b_j}$, of which only the

element encoding the correct bit $q_{i+1,j}$ is recovered. Formally, we have:

$$\hat{\mathbf{D}}_{i+1,j} = \left(\hat{\mathbf{d}}^0_{i+1,j}, \hat{\mathbf{d}}^1_{i+1,j} \right) \quad \text{and}$$
$$\mathsf{SKE.Dec}\left(K^{b_j}_{i+1,j},\ \hat{\mathbf{d}}^b_{i+1,j} \right) = \perp \ \text{ if } \ b_j \neq b, \text{ and } \mathbf{d}^{q_{i+1,j}}_{i+1,j} \quad \text{otherwise.}$$

By putting together all the components, we get by decomposability:

$$\mathbf{d}_{i+1,q_{i+1}} = \left(\mathbf{d}^{q_{i+1,j}}_{i+1,j} \right) \ \forall\, j \in [\log Q]$$

Also, since each component of $\mathbf{d}_{i+1,q_{i+1}}$ uses the same common randomness r_{i+1} as is used by $\mathbf{c}_{i+1}$, we have that $\mathsf{CT}_{i+1} = (\mathbf{c}_{i+1}, \mathbf{d}_{i+1,q_{i+1}})$, hence we may repeat while $i < k$. Finally for $i = k$,

$$\mathsf{CktFE.Enc}\big(\ \mathsf{PK}, (w_k, \perp, 1, q_k)\ \big) = (\mathbf{c}_i, \mathbf{d}_{k,q_k})$$
so that $\mathsf{CktFE.Dec}\big(\mathsf{SK}_f, (\mathbf{c}_k, \mathbf{d}_{k,q_k})\big) = 1$ iff q_k is an accepting state, 0 otherwise.

Efficiency. We note that the public key size of our scheme is the public key size of CktFE [12] with message length $\ell = O(\log Q + \log|\Sigma| + \log Q \cdot \log|\mathcal{K}|$ which is polynomial in the security parameter κ. The ciphertext size is $O(|\mathbf{w}| \cdot \log Q)$ and the secret key size is $O(|M|)$ (ignoring polynomials in the security parameter).

4.2 Proof of Security

We proceed to show that our construction is secure. Formally:

▶ **Theorem 4.** *Assume that the underlying* CktFE *scheme satisfies* FULL-SIM *security according to definition (please see* [1]*). Then the construction for* DfaFE *achieves* FULL-SIM *security as defined in Definition 2.*

Proof. We proceed to construct a simulator DfaFE.Sim as required by Definition 2. The simulator receives $(\mathsf{PK}, \mathsf{SK}_M, M, M(\mathbf{w}), 1^{|\mathbf{w}|})$ and does the following:

1. Assign the bit $b = M(\mathbf{w})$, and construct the circuit f corresponding to M as defined in Figure 1 in the description of DfaFE.KeyGen.
2. Let $\mathsf{CktFE.SK_f} = \mathsf{SK_M}$ and invoke $\mathsf{CktFE.Sim}\big(\ \mathsf{PK}, f, \mathsf{CktFE.SK}_f, b\ \big)$ to receive $\tilde{\mathsf{CT}}_k$ where we may express $\tilde{\mathsf{CT}}_k = (\tilde{\mathbf{c}}_k, \tilde{\mathbf{d}}_{k,q_k})$ and $\tilde{\mathbf{d}}_{k,q_k} = (\tilde{\mathbf{d}}_{k,j})$ for $j \in [\log Q]$.
3. For $(i = k, i \geq 1, i--)$, do:
   a. If $i = 1$, set $\mathsf{Sim}.\hat{\mathbf{D}}_1 = \tilde{\mathbf{d}}_{1,q_1}$ and exit.
   b. Sample key $\mathbf{K}^*_i = (K^*_{i,1}, \ldots, K^*_{i,\log Q}) \leftarrow \mathcal{K}^{\log Q}$ and let
   $$\mathsf{Sim}.\hat{\mathbf{d}}_{i,j} = \mathsf{SKE.Enc}(K^*_{i,j}, \tilde{\mathbf{d}}_{i,j}) \ \ \forall j \in [\log Q]\,.$$
   c. Sample $\tilde{b}_{i,j} \leftarrow \{0,1\}$ and assign $\mathsf{Sim}.\hat{\mathbf{d}}^{\tilde{b}_{i,j}}_{i,j} = \mathsf{Sim}.\hat{\mathbf{d}}_{i,j}$.
   d. Choose another $\log Q$ keys $\tilde{K}_{i,1}, \ldots \tilde{K}_{i,\log Q} \leftarrow \mathcal{K}^{\log Q}$ and compute
   $$\mathsf{Sim}.\hat{\mathbf{d}}^{\bar{b}_{ij}}_{i,j} = \mathsf{SKE.Enc}(\tilde{K}_{i,j}, 0^{|\tilde{\mathbf{d}}_{i,j}|}) \ \ \forall\, j \in [\log Q]\,.$$
   e. Let $\mathsf{Sim}.\hat{\mathbf{D}}_{i,j} = \big(\mathsf{Sim}.\hat{\mathbf{d}}^{\tilde{b}_{i,j}}_{i,j},\ \mathsf{Sim}.\hat{\mathbf{d}}^{\bar{b}_{i,j}}_{i,j}\big)$ and $\mathsf{Sim}.\hat{\mathbf{D}}_i = \big(\ \mathsf{Sim}.\hat{\mathbf{D}}_{i,j}\ \big)$ for $j \in [\log Q]$.
   f. Let $(\tilde{\mathbf{c}}_{i-1}, \tilde{\mathbf{d}}_{i-1,q_{i-1}}) = \mathsf{CktFE.Sim}(\mathsf{PK}, f, \mathsf{SK}_f, \mathbf{K}^*_i)$.
4. Output the ciphertext as $\mathsf{CT_w} = (\tilde{\mathbf{c}}_1, \tilde{\mathbf{c}}_2, \ldots, \tilde{\mathbf{c}}_k, \mathsf{Sim}.\hat{\mathbf{D}}_1, \ldots, \mathsf{Sim}.\hat{\mathbf{D}}_k)$.

4.2.1 Analysis of Simulator

Correctness of the simulator DfaFE.Sim can be easily established using correctness of the simulator CktFE.Sim and the semantic security of SKE. Let us say that the DFA M visits states $q_1, \ldots, q_k$ while computing on input $\mathbf{w}$ where $|\mathbf{w}| = k$.

1. We have by correctness of CktFE.Sim that:

$$\left\{ \mathsf{CT}_k \leftarrow \mathsf{CktFE.Enc}\big(\mathsf{PK}, (w_k, \bot, 1, q_k)\big) \stackrel{c}{\approx} \tilde{\mathsf{CT}}_k \leftarrow \mathsf{CktFE.Sim}\big(\mathsf{PK}, f_M, \mathsf{SK}_f, b\big) \right\}.$$

   By decomposability, $\mathsf{CT}_k = (\mathbf{c}_k, \mathbf{d}_{k,q_k})$ where $\mathbf{d}_{k,q_k} = (\mathbf{d}_{k,j}^{b_j})$ for $j \in [\log Q]$ and $b_j = q_{k,j}$ defined as the j^{th} bit of state q_k. Similarly, $\tilde{\mathsf{CT}}_k = (\tilde{\mathbf{c}}_k, \tilde{\mathbf{d}}_{k,q_k})$ where $\tilde{\mathbf{d}}_{k,q_k}$ may be decomposed as $(\tilde{\mathbf{d}}_{k,j})$ for $j \in [\log Q]$. Let $i = k$.

2. We now establish that $(\hat{\mathbf{d}}_{i,j}^{b_j} \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{d}}_{i,j})$ where $b_j = q_{i,j}$ and $j \in [\log Q]$.
   - **a.** We have that in algorithm DfaFE.Enc,

$$\mathbf{K}_i = \Big((K^0_{(i,1)}, K^1_{(i,1)}), \ldots, (K^0_{(i,\log Q)}, K^1_{(i,\log Q)}) \Big)$$

     where $K^b_{i,j} \leftarrow \mathcal{K}$ for $j \in [\log Q]$. We also have, for $j \in [\log Q]$, $b \in \{0,1\}$:

$$\hat{\mathbf{d}}^b_{i,j} = \mathsf{SKE.Enc}(K^b_{i,j}, \mathbf{d}^b_{i,j}) \tag{4.1}$$

   - **b.** In simulator DfaFE.Sim:

$$\mathbf{K}^*_i = (K^*_{i,1}, \ldots, K^*_{i,\log Q}) \leftarrow \mathcal{K}^{\log Q} \quad \text{and}$$

$$\mathsf{Sim}.\hat{\mathbf{d}}_{i,j} = \mathsf{SKE.Enc}(K^*_{i,j}, \tilde{\mathbf{d}}_{i,j}) \;\; \forall j \in [\log Q]\,.$$

     Hence, since $\mathbf{d}^{b_j}_{i,j} \stackrel{c}{\approx} \tilde{\mathbf{d}}_{i,j}$ and the symmetric keys are picked using the same distribution in each case, we have that $(\hat{\mathbf{d}}^{b_j}_{i,j} \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{d}}_{i,j})$ where $b_j = q_{i,j}$ and $j \in [\log Q]$.

3. We now establish that $(\hat{\mathbf{d}}^{\bar{b}_j}_{i,j} \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{d}}^{\bar{b}_j}_{i,j})$ where $j \in [\log Q]$.
   - **a.** Construction of $\hat{\mathbf{d}}^{\bar{b}_j}_{i,j}$ is described in Equation 4.1.
   - **b.** For the latter, DfaFE.Sim samples $\tilde{b}_j$ and sets $\mathsf{Sim}.\hat{\mathbf{d}}^{\tilde{b}_j}_{i,j} = \mathsf{Sim}.\hat{\mathbf{d}}_{i,j}$. Next, it samples another $\log Q$ keys $\tilde{K}_{i,1}, \ldots \tilde{K}_{i,\log Q} \leftarrow \mathcal{K}^{\log Q}$ and computes

$$\mathsf{Sim}.\hat{\mathbf{d}}^{\bar{\tilde{b}}_j}_{i,j} = \mathsf{SKE.Enc}(\tilde{K}_{i,j}, 0^{|\tilde{\mathbf{d}}_{i,j}|}) \;\; \forall\, j \in [\log Q]\,.$$

     By semantic security of SKE, we have that $(\hat{\mathbf{d}}^{\bar{b}_j}_{i,j} \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{d}}^{\bar{b}_j}_{i,j})$.

4. Next, we show that $\hat{\mathbf{D}}_i \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{D}}_i$. For $i = 1$, we have by definitions of $\hat{\mathbf{D}}_1$ and $\mathsf{Sim}.\hat{\mathbf{D}}_1$, that the above holds. For $i > 1$, in DfaFE.Enc, we have $b_{i,j} \leftarrow \{0,1\}$ and

$$\hat{\mathbf{D}}_{i,j} = \big(\hat{\mathbf{d}}^{b_{i,j}}_{i,j}, \hat{\mathbf{d}}^{\bar{b}_{i,j}}_{i,j} \big)\,.$$

   In DfaFE.Sim, we have $\tilde{b}_{i,j} \leftarrow \{0,1\}$ and

$$\mathsf{Sim}.\hat{\mathbf{D}}_{i,j} = \big(\mathsf{Sim}.\hat{\mathbf{d}}^{\tilde{b}_{i,j}}_{i,j},\ \mathsf{Sim}.\hat{\mathbf{d}}^{\bar{\tilde{b}}_{i,j}}_{i,j}\big)\,.$$

   Since $\hat{\mathbf{D}}_i = (\hat{\mathbf{D}}_{i,j})$ and $\mathsf{Sim}.\hat{\mathbf{D}}_i = \big(\ \mathsf{Sim}.\hat{\mathbf{D}}_{i,j}\ \big)$ for $j \in [\log Q]$, we have that $\hat{\mathbf{D}}_i \stackrel{c}{\approx} \mathsf{Sim}.\hat{\mathbf{D}}_i$.

5. Let $i = i - 1$. Now, we have by correctness of $\mathsf{CktFE.Sim}$,

$$\left\{\mathsf{CT}_i \leftarrow \mathsf{CktFE.Enc}\big(\mathsf{PK}, (w_i, \mathbf{K}_{i+1}, 0, q_i)\big) \overset{c}{\approx} \tilde{\mathsf{CT}}_i \leftarrow \mathsf{CktFE.Sim}\big(\mathsf{PK}, f_M, \mathsf{SK}_f, \mathbf{K}^*_{i+1}\big)\right\}.$$

   By decomposability, $\mathsf{CT}_i = (\mathbf{c}_i, \mathbf{d}_{i,q_i})$ where $\mathbf{d}_{i,q_i} = (\mathbf{d}_{i,j}^{q_{i,j}})$ for $j \in [\log Q]$. Also, $\tilde{\mathsf{CT}}_i = (\tilde{\mathbf{c}}_i, \tilde{\mathbf{d}}_{i,q_i})$ where $\tilde{\mathbf{d}}_{i,q_i} = (\tilde{\mathbf{d}}_{i,j})$ for $j \in [\log Q]$. If $i > 1$, go to step 2. For $i = 1$, we have by definitions of $\hat{\mathbf{D}}_1$ and $\mathsf{Sim}.\hat{\mathbf{D}}_1$, that $(\mathbf{c}_1, \hat{\mathbf{D}}_1) \overset{c}{\approx} (\tilde{\mathbf{c}}_1, \mathsf{Sim}.\hat{\mathbf{D}}_1)$.
6. Now, a straightforward hybrid argument yield that:

$$\left\{(\mathbf{c}_1, \hat{\mathbf{D}}_1), (\mathbf{c}_2, \hat{\mathbf{D}}_2), \ldots, (\mathbf{c}_k, \hat{\mathbf{D}}_k)\right\} \overset{c}{\approx} \left\{(\tilde{\mathbf{c}}_1, \mathsf{Sim}.\hat{\mathbf{D}}_1), (\tilde{\mathbf{c}}_2, \mathsf{Sim}.\hat{\mathbf{D}}_2), \ldots, (\tilde{\mathbf{c}}_k, \mathsf{Sim}.\hat{\mathbf{D}}_k)\right\}$$

   as desired.

◀

Reusable Garbled DFA. In the full version [1] we show how to compile the above construction with symmetric key encryption to obtain the first construction of reusable garbled DFAs from standard assumptions.

5 Single Key Functional Encryption for Turing Machines

In the full version [1], we provide the construction of single key functional encryption for Turing machines. Our construction has short public parameters that are independent of the size of the machine or the data being encrypted, short function keys, and input-specific decryption time. However, the ciphertext of our construction is large and depends on the worst case running time of the Turing machine (but not its description size).

While the large ciphertext size of our TMFE construction restricts its utility for practical applications, we emphasize that the parameters obtained by our TMFE construction are not implied by previous work to the best of our knowledge (please see the full version [1] for a detailed discussion about previous work). To improve the ciphertext size of our construction, while allowing succinct keys, dynamic data length and input specific run time is an interesting open problem.

Abstract

An important benchmark for secure multi-party computation (MPC) protocols is their *round complexity*. For several important MPC tasks, (tight) lower bounds on the round complexity are known. However, for some of these tasks, such as broadcast, the lower bounds can be circumvented when the termination round of every party is not *a priori* known, and simultaneous termination is not guaranteed. Protocols with this property are called *probabilistic-termination (PT)* protocols.

Running PT protocols in parallel affects the round complexity of the resulting protocol in somewhat unexpected ways. For instance, an execution of m protocols with constant expected round complexity might take $O(\log m)$ rounds to complete. In a seminal work, Ben-Or and El-Yaniv (Distributed Computing '03) developed a technique for parallel execution of arbitrarily many broadcast protocols, while preserving expected round complexity. More recently, Cohen *et al.* (CRYPTO '16) devised a framework for universal composition of PT protocols, and provided the first composable parallel-broadcast protocol with a simulation-based proof. These constructions crucially rely on the fact that broadcast is "privacy free," and do not generalize to arbitrary protocols in a straightforward way. This raises the question of whether it is possible to execute *arbitrary* PT protocols in parallel, without increasing the round complexity.

In this paper we tackle this question and provide both feasibility and infeasibility results. We construct a round-preserving protocol compiler, secure against a minority of actively corrupted parties, that compiles arbitrary protocols into a protocol realizing their parallel composition, while having a black-box access to the underlying *protocols*. Furthermore, we prove that the same cannot be achieved, using known techniques, given only black-box access to the *functionalities* realized by the protocols, unless merely security against semi-honest corruptions is required, for which case we provide a protocol.

1 Introduction

Secure multi-party computation (MPC) [52, 30] allows a set of parties to jointly perform a computation on their inputs, in such a way that no coalition of cheating parties can learn any information beyond what is revealed by their outputs (privacy) or affect the outputs of the computation in any way other than by choosing their own inputs (correctness). Since the first seminal works on MPC [52, 30, 6, 12, 50], it has been studied in a variety of different settings and for numerous security notions: there exist protocols secure against passively corrupted (aka semi-honest) parties and against actively corrupted (aka malicious) parties; the underlying network can be synchronous or asynchronous; and the required security guarantees can be information-theoretic or computational – -to name but a few of the axes along which the MPC task can be evaluated.

The prevalent model for the design of MPC protocols is the synchronous model, where the protocol proceeds in rounds. In this setting, the round complexity, i.e., the number of rounds it takes for a protocol to deliver outputs, is arguably the most important efficiency metric. Tight lower bounds are known on the round complexity of several MPC tasks. For example, for the well-known problems of Byzantine agreement (BA) and broadcast [48, 44], it is known that any protocol against an active attacker corrupting a linear fraction of the parties has linear round complexity [25, 23]. This result has quite far-reaching consequences as, starting with the seminal MPC works mentioned above, a common assumption in the design of secure protocols has been that the parties have access to a broadcast channel, which they potentially invoke in every round. In reality, such a broadcast channel might not be available and would have to be implemented by a broadcast protocol designed for a point-to-point network. It follows that even though the round complexity of many MPC protocols is linear in the multiplicative depth of the circuit being computed, their actual running time depends on the number of parties, when executed over point-to-point channels.

The above lower bound on the number rounds for BA holds when all honest parties are required to complete the protocol together, at the same round [22]. Indeed, *randomized* BA protocols that circumvent this lower bound and run in *expected constant* number of rounds (cf. [4, 49, 24, 26, 41, 45]) do not provide simultaneous termination, i.e., once a party completes the protocol's execution it cannot know whether all honest parties have also terminated or if some honest parties are still running the protocol; in particular, the termination round of each party is not a priori known. A protocol with this property is said to have *probabilistic termination (PT)*.

As pointed out by Ben-Or and El-Yaniv [5], when several such PT protocols are executed in parallel, the expected round complexity of the combined execution might no longer be constant (specifically, might not be equal to the maximum of the expected running times of the individual protocols). Indeed, when m protocols, whose termination round is geometrically distributed (and so, have constant expected round complexity), are run in parallel, the expected number of rounds that elapse before all of them terminate is $\Theta(\log m)$ [14]. While an elegant mechanism was proposed in [5] for implementing parallel calls to broadcast such that the total expected number of rounds remains constant, it did not provide any guarantees to remain secure under composition, raising questions about its usability in a higher-level protocol (such as the MPC setting described above). Such a shortcoming was recently addressed by Cohen *et al.* [14] who provided a framework for universal composition of PT protocols (building upon the universal-composition framework of [8]). An application of their result was the first composable protocol for parallel broadcast (with a simulation-based proof) that can be used for securely replacing broadcast channels in arbitrary protocols, and whose round complexity is constant in expectation.

Indeed, an immediate application of the composable parallel-broadcast protocol from [14] is plugging it into broadcast-model MPC protocols in order to obtain point-to-point protocols with a round complexity that is independent of the number of parties. In the information-theoretic setting, this approach yields protocols whose round complexity depends on the depth of the circuit computing the function [6, 12, 50, 18], whereas in the computational setting, assuming standard cryptographic assumptions, this approach yields expected-constant-round protocols [43, 3, 20, 40, 1, 29, 31, 46]. However, the resulting point-to-point protocols have probabilistic-termination on their own. The techniques used for composing PT broadcast protocols in parallel crucially rely on the fact that broadcast is a privacy-free functionality, and a naïve generalization of this approach to arbitrary PT protocols fails to be secure. This raises the question of whether it is possible to execute *arbitrary* PT protocols in parallel, without increasing the round complexity.

We remark that circumventing lower bounds on round complexity is just one of the areas where such PT protocols have been successfully used. Indeed, randomizing the termination round has been proven to be a very useful technique in circumventing impossibilities and improving efficiency for many cryptographic protocols. Notable examples include *non-committing encryption* [21], cryptographic protocols designed for rational parties [34, 27, 47, 2, 32, 28], concurrent zero-knowledge protocols [9, 13] and parallel repetition of interactive arguments [33, 35]. The rich literature on such protocols motivates a thorough investigation of their security and composability. As mentioned above, in [14] the initial foundations were laid out for such an investigation, but what was proven for arbitrary PT protocols was a round-preserving *sequential* composition theorem, leaving parallel composition as an open question.

Our contributions. In this work, we investigate the issue of parallel composition for *arbitrary* protocols with probabilistic termination. In particular, we develop a compiler such that given functionalities $\mathcal{F}_1, \ldots, \mathcal{F}_{\mathtt{M}}$ and protocols $\pi_1, \ldots, \pi_{\mathtt{M}}$, where for every $i \in [\mathtt{M}]$, protocol π_i realizes $\mathcal{F}_i$ (possibly using correlated randomness as setup[1]), then the compiled protocol realizes the parallel composition of the functionalities, denoted $(\mathcal{F}_1 \| \cdots \| \mathcal{F}_{\mathtt{M}})$.

Our compiler uses the underlying protocols in a black-box manner,[2] is robust (i.e., secure without abort) and resilient against a computationally unbounded active adversary, adaptively corrupting up to $t < n/2$ parties (which is optimal [50]). Moreover, our compiler is round-preserving, meaning that if the maximal (expected) round complexity of each protocol is μ, then the expected round complexity of the compiled protocol is $O(\mu)$. For example, if each protocol π_i has constant expected round complexity, then so does the compiled protocol. Recall that this task is quite complicated even for the simple case of BA (cf. [5, 14]). For arbitrary functionalities it is even more involved, since as we show, the approach from [5] cannot be applied in a functionally black-box way in this case. Thus, effectively, our result is the first round-preserving parallel composition result for arbitrary multi-party protocols/tasks with probabilistic termination.

We now describe the ideas underlying our compiler. In [5] (see also [14]), a round-preserving parallel-broadcast protocol was constructed by iteratively running, for a constant number of rounds, *multiple* instances of BA protocols (each instance is executed multiple

[1] A trusted setup phase is needed for implementing broadcast in the honest-majority setting. As shown in [17, 16] some interesting functions can be computed without such a setup phase.

[2] Following [37], by a black-box access to a protocol we mean a black-box usage of a semi-honest MPC protocol computing its next-message function.

times in parallel, in a batch), hoping that at least one execution of every BA instance will complete. By choosing the multiplicity suitably, this would occur with constant probability, and the process need therefore be repeated a constant expected number of times only.

At first sight it might seem that this idea can be applied to arbitrary tasks, but this is not the case. Intuitively, the reason is that if the tasks that we want to compose in parallel have privacy requirements, then making the parties run them in (parallel) "batches" with the same input might compromise privacy, since the adversary will be able to use different inputs and learn multiple outputs of the function(s). This issue is not relevant for broadcast, because it is a "privacy-free" functionality; the adversary may learn the result of multiple computations using the same inputs for honest parties, without compromising security.

To cope with the above issue, our parallel-composition compiler generalizes the approach of [5] in a privacy-preserving manner. At a high level, it wraps the batching technique by an MPC protocol which restricts the parties to use the same input in all protocols for the same function. In particular, the compiler is defined in the *Setup-Commit-then-Prove* hybrid model [10, 39], which allows each party to commit to its input values and later execute multiple instances of every protocol, each time proving that the same input value is used in all executions.

The constructions in [10, 39] for realizing the Setup-Commit-then-Prove functionality are designed for the dishonest-majority setting and therefore allow for a premature abort. Since we assume an honest majority, we require security without abort. A possible way around would be, as is common in the MPC literature, to restart the protocol upon discovering some cheating or add for each abort a recovery round; this, however, would induce a linear overhead (in the number of parties) on the round complexity of the protocol.

Instead, in order to recover from a misbehavior by corrupted parties, we modify the Setup-Commit-then-Prove functionality and secret-share every committed random string between all the parties, using an error-correcting secret-sharing scheme (aka robust secret sharing [50, 19, 11]). In case a party is identified as cheating, every party broadcasts the share of the committed randomness corresponding to that party, reconstructs the correlated randomness for that party, and locally computes the messages corresponding to this party in every instance of every protocol. We also prove that the modified Setup-Commit-then-Prove functionality can be realized in a constant number of rounds, thus yielding no (asymptotic) overhead on the round complexity of the compiler.

Next, given that using only black-box access to the protocols π_i, it is possible to compile them into a protocol that implements the parallel composition $(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$ of the functionalities $\mathcal{F}_1, \ldots, \mathcal{F}_{\mathtt{M}}$ realized by protocols $\pi_1, \ldots, \pi_{\mathtt{M}}$, we investigate the question of whether there exists a protocol that securely realizes $(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$ given only black-box access to the *functionalities* $\mathcal{F}_1, \ldots, \mathcal{F}_{\mathtt{M}}$,[3] but not to protocols realizing them. This question is only sensible if asked for an entire *class* of functionalities (cf. [51]), since otherwise a protocol may always ignore the functionalities $\mathcal{F}_1, \ldots, \mathcal{F}_{\mathtt{M}}$ and implement $(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$ from scratch.

On the one hand, we prove that against semi-honest corruptions, there indeed exists a protocol for parallel composition of arbitrary functionalities $\mathcal{F}_i$ in a functionally black-box manner. On the other hand, in the case of active corruptions, we devise a class of functionalities for which, when using a generalization of the "batching" technique from [5],

[3] Loosely speaking, a functionally black-box protocol, as defined in [51], is a protocol that can compute a function f without knowing the code of f, i.e., given an oracle access to the function f. Note that in this model, each ideal functionality $\mathcal{F}_i$ has an oracle access to the function f_i it computes.

such a black-box transformation is not possible in the presence of a single active corrupted party. More precisely, (1) a naïve call to each of the ideal functionalities $\mathcal{F}_i$ until termination will not be round-preserving, (2) it is impossible to compute the parallel composition without calling every ideal functionality, and (3) using the same input value in more than one call to any of the ideal functionalities will break privacy.[4] This negative result validates our choice of a *protocol* compiler, and is evidence that such a task, if at all possible, would require entirely new techniques.

We phrase our results using the framework for composition of protocols with probabilistic termination [14], extending it (a side result of independent interest) to include parallel composition, reactive functionalities (to capture the Setup-Commit-then-Prove functionality), and the higher corruption threshold of $t < n/2$.

Organization of the paper. The rest of the paper is organized as follows. In Section 2 we describe the network model, the basics of the probabilistic-termination framework by Cohen *et al.* [14], and other tools that are used throughout the paper. We start Section 3 with the extensions to the PT framework, followed by the protocol that achieves round-preserving parallel composition for arbitrary functionalities in a functionally black-box manner against semi-honest adversaries. Section 4 is dedicated to active corruptions; first, the round-preserving protocol-black-box construction, followed by the negative result on round-preserving functionally black-box composition in the case of active corruptions. Due to space limitations, finer details of the model and PT framework, our extension of the PT framework to the honest-majority setting, and proofs, will only appear in the full version of the paper.

2 Model and Preliminaries

2.1 Synchronous Protocols in UC

We consider synchronous protocols in the model of Katz *et al.* [42], which is designed on top of the universal composability framework of Canetti [8]. More specifically, we consider n parties $P_1, \ldots, P_n$ and a computationally unbounded, adaptive *t-adversary* that can dynamically corrupt up to t parties during the protocol execution. Synchronous protocols in [42] are protocols that run in a hybrid model where parties have access to a simple "clock" functionality. This functionality keeps an indicator bit, which is switched once *all honest parties* request the functionality to do so, i.e., once all honest parties have completed their operations for the current round. In addition, all communication is done over bounded-delay secure channels, where each party requests the channel to fetch messages that are sent to him, such that the adversary is allowed to delay the message delivery by a bounded and a priori known number of fetch requests. Stated differently, once the sender has sent some message, it is guaranteed that the message will be delivered within a known number of activations of the receiver. For simplicity, we assume that every message is delivered within a single fetch request. A more detailed overview of [42] can be found in the full version.

[4] We note that our negative result does not contradict Ishai et al. [38, 36] who constructed two-round protocols with guaranteed output delivery for $n \geq 4$ and $t = 1$ without broadcast. Indeed, the protocols in [38, 36] are non-black-box with respect to the function to be computed.

2.2 The Probabilistic-Termination Framework

Cohen *et al.* [14] extended the UC framework to capture protocols with probabilistic termination, i.e., protocols without a fixed output round and without simultaneous termination. This section outlines their techniques; additional details can be found in the full version.

Canonical synchronous functionalities. The main idea behind modeling probabilistic termination is to separate the functionality to be computed from the round complexity that is required for the computation. The atomic building block in [14] is a functionality template called a *canonical synchronous functionality (CSF)*, which is a simple two-round functionality with explicit (one-round) input and (one-round) output phases. The functionality $\mathcal{F}_{\text{CSF}}$ has two parameters: (1) a (possibly) randomized function f that receives $n+1$ inputs (n inputs from the parties and one additional input from the adversary) and (2) a leakage function l that determines what information about the input values is leaked to the adversary.

$\mathcal{F}_{\text{CSF}}$ proceeds in two rounds: in the first (input) round, all the parties hand $\mathcal{F}_{\text{CSF}}$ their input values, and in the second (output) round, each party receives its output. Whenever some input is submitted to $\mathcal{F}_{\text{CSF}}$, the adversary is handed some leakage function of this input; the adversary can use this leakage when deciding the inputs of corrupted parties. Additionally, he is allowed to input an extra message, which – depending on the function f – might affect the output(s).

Wrappers and traces. Computation with probabilistic termination is captured by defining *output-round randomizing wrappers*. Such wrappers address the issue that while an ideal functionality abstractly describes a protocol's task, it does not describe its round complexity. Each wrapper is parametrized by a distribution (more precisely, an efficient probabilistic sampling algorithm) D that may depend on a specific protocol implementing the functionality. The wrapper samples a round $\rho_{\mathsf{term}} \leftarrow D$, by which all parties are guaranteed to receive their outputs. Two wrappers are considered: the first, denoted $\mathcal{W}_{\text{strict}}$, ensures in a strict manner that all (honest) parties terminate together in round ρ_{term}; the second, denoted $\mathcal{W}_{\text{flex}}$, is more flexible and allows the adversary to deliver outputs to individual parties at any time before round ρ_{term}.

As pointed out in [14], it is not sufficient to inform the simulator $\mathcal{S}$ about the round ρ_{term}. In many cases, the wrapper should explain to $\mathcal{S}$ *how* this round was sampled; concretely, the wrapper provides $\mathcal{S}$ with the random coins that are used to sample ρ_{term}. In particular, $\mathcal{S}$ learns the entire *trace* of calls to ideal functionalities that are made by the protocol in order to complete by round ρ_{term}. A trace basically records which hybrids were called by a protocol's execution, and in a recursive way, for each hybrid, which hybrids would have been called by a protocol realizing that hybrid.The recursion ends when the base case is reached, i.e., when the protocol is defined using the *atomic* functionalities that are "assumed" by the model.[5] Formally, a trace is defined as follows:

▶ **Definition 1** (Traces). A *trace* is a rooted tree of depth at least 1, in which all nodes are labeled by functionalities and where every node's children are *ordered*. The root and all internal nodes are labeled by wrapped CSFs (by either of the two wrappers), and the leaves are labeled by unwrapped CSFs. The *trace complexity* of a trace T, denoted $c_{\mathsf{tr}}(T)$, is the number of leaves in T. Moreover, denote by $\mathsf{flex}_{\mathsf{tr}}(T)$ the number nodes labeled by flexibly wrapped CSFs in T.

[5] The atomic functionalities considered in this work are the CSFs for the point-to-point communication functionality $\mathcal{F}_{\text{SMT}}$ and the correlated-randomness functionality for broadcast $\mathcal{F}_{\text{CORR-BC}}$.

Sequential composition of probabilistic-termination protocols. When a set of parties execute a probabilistic-termination protocol, or equivalently, invoke a flexibly wrapped CSF, they might get out-of-sync and start the next protocol in different rounds. The approach in [14] for dealing with sequential composition is to start by designing simpler protocols, that are in a so-called *synchronous normal form*, where the parties remain in-sync throughout the execution, and next, compile these protocols into slack-tolerant protocols.

▶ **Definition 2** (Synchronous normal form)**.** Let $\mathcal{F}_1, \ldots, \mathcal{F}_m$ be CSFs. A synchronous protocol π in the $(\mathcal{F}_1, \ldots, \mathcal{F}_m)$-hybrid model is in *synchronous normal form (SNF)* if in every round exactly one ideal functionality $\mathcal{F}_i$ is invoked by all honest parties, and in addition, no honest party hands inputs to other CSFs before this instance halts.

SNF protocols are designed as an intermediate step only, since the hybrid functionalities $\mathcal{F}_1, \ldots, \mathcal{F}_m$ are two-round CSFs, and, in general, cannot be realized by real-world protocols. In order to obtain protocols that can be realized in the real world, [14] introduced *slack-tolerant* variants of both the strict and the flexible wrappers, denoted $\mathcal{W}_{\text{sl-strict}}$ and $\mathcal{W}_{\text{sl-flex}}$. These wrappers are parametrized by a slack parameter $c \geq 0$ and can be used even if parties provide inputs within $c+1$ consecutive rounds (i.e., they tolerate input slack of c rounds); furthermore, the wrappers ensure that all honest parties obtain output within two consecutive rounds (i.e., they reduce the slack to $c = 1$). Next, [14] constructed compilers to convert any SNF protocol realizing a wrapped CSF $\mathcal{W}^{D}_{\text{strict}}(\mathcal{F})$ (resp., $\mathcal{W}^{D}_{\text{flex}}(\mathcal{F})$) into a (non SNF) protocol realizing $\mathcal{W}^{D',c}_{\text{sl-strict}}(\mathcal{F})$ (resp., $\mathcal{W}^{D',c}_{\text{sl-flex}}(\mathcal{F})$), using wrapped CSFs as hybrids. The compilers maintain the security and the asymptotic (expected) round complexity of the original SNF protocols. At the same time, the compilers take care of any potential slack that is introduced by the protocol and ensure that the resulting protocol can be safely executed even if the parties do not start the protocol simultaneously.

Finally, in [14], the authors also provided protocols for realizing wrapped variants of the atomic CSF functionality for secure point-to-point communication. This suggested the following design paradigm for realizing a wrapped functionality $\mathcal{W}_{\text{sl-strict}}(\mathcal{F})$ (resp., $\mathcal{W}_{\text{sl-flex}}(\mathcal{F})$): First, construct an SNF protocol for realizing $\mathcal{W}_{\text{strict}}(\mathcal{F})$ (resp., $\mathcal{W}_{\text{flex}}(\mathcal{F})$) using CSF hybrids $\mathcal{F}_1, \ldots, \mathcal{F}_m$. Next, for each of the non-atomic hybrids $\mathcal{F}_i$, show how to realize $\mathcal{W}_{\text{strict}}(\mathcal{F}_i)$ (resp., $\mathcal{W}_{\text{flex}}(\mathcal{F}_i)$) using CSF hybrids $\mathcal{F}'_1, \ldots, \mathcal{F}'_{m'}$. Proceed in this manner until all CSF hybrids are atomic functionalities. Finally, repeated applications of the composition theorems above yield a protocol for $\mathcal{W}_{\text{sl-strict}}(\mathcal{F})$ (resp., $\mathcal{W}_{\text{sl-flex}}(\mathcal{F})$) using only atomic functionalities as hybrids.

2.3 A Lemma on Termination Probabilities

The following lemma, which will be used in our positive results, provides a constant lower bound on the probability that when running simultaneously (i.e., in parallel) $\mathtt{N}$ copies of $\mathtt{M}$ probabilistic-termination protocols $\pi_1, \ldots, \pi_{\mathtt{M}}$, at least one copy of each π_i will complete after $\mathtt{R}$ rounds, for suitable choices of $\mathtt{N}$ and $\mathtt{R}$. The proof of the lemma appears in the full version.

▶ **Lemma 3.** *Let $M, N, R \in \mathbb{N}$. For $i \in [M]$ and $j \in [N]$, let X_{ij} be independent random variables over the natural numbers, such that $X_{i1}, \ldots, X_{iN}$ are identically distributed with expectation μ_i, for every $i \in [M]$. Denote $Y_i = \min\{X_{i1}, \ldots, X_{iN}\}$ and $\mu = \max\{\mu_1, \ldots, \mu_M\}$.*

Then, for any constant $0 < \epsilon < 1$, if $R > \mu$ and $N > \frac{\log(M/\epsilon)}{\log(R/\mu)}$, then $\Pr[\forall i : Y_i < R] \geq 1 - \epsilon$.

3 Round-Preserving Parallel Composition: Passive Security

In this section, we show that round-preserving parallel composition is feasible, in a functionally black-box manner, facing semi-honest adversaries. To that end we first extend, in Section 3.1, the probabilistic-termination framework [14] to capture the notions of functionally black-box protocols [51] and of parallel composition of canonical synchronous functionalities. The passively secure protocol is presented in Section 3.2.

3.1 Functionally Black-Box Protocols and Parallel Composition

Functionally black-box protocols. We formalize the notion of functionally black-box protocols of Rosulek [51] in the language of canonical synchronous functionalities. As in [51], we focus on secure function evaluation. The SFE functionality $\mathcal{F}_{\text{SFE}}^{g}$, parametrized by an n-party function g, is defined as the CSF $\mathcal{F}_{\text{CSF}}^{f_{\text{SFE}},l_{\text{SFE}}}$, where $f_{\text{SFE}}(x_1,\ldots,x_n,a) = g(x_1,\ldots,x_n)$ (i.e., computes the function g while ignoring the adversary's input a) and the leakage function is $l_{\text{SFE}}(x_1,\ldots,x_n) = (|x_1|,\ldots,|x_n|)$. The following definition explains what we mean by a protocol that realizes the secure function evaluation functionality in a black-box way with respect to the function g.

▶ **Definition 4.** Let $\mathcal{C} = \{g\colon (\{0,1\}^*)^n \to (\{0,1\}^*)^n\}$ be a class of n-party functions. Denote by $\mathcal{F}_{\text{SFE}}^{\mathcal{C}}$ the CSF, implemented as an (uninstantiated) oracle machine that in order to compute $f_{\text{SFE}}^{\mathcal{C}}(x_1,\ldots,x_n,a)$, queries the oracle with $(x_1,\ldots,x_n)$ and stores the response $(y_1,\ldots,y_n)$. The leakage function $l_{\text{SFE}}(x_1,\ldots,x_n) = (|x_1|,\ldots,|x_n|)$ is unchanged.

Then, a protocol $\pi = (\pi_1,\ldots,\pi_n)$ is a functionally black-box (FBB) protocol for (a wrapped version of) $\mathcal{F}_{\text{SFE}}^{\mathcal{C}}$, if for every $f \in \mathcal{C}$, the protocol $\pi^f = (\pi_1^f,\ldots,\pi_n^f)$ UC-realizes $\mathcal{F}_{\text{SFE}}^{f}$.

Parallel Composition of CSFs. The parallel composition of CSFs is defined in a natural way as the CSF that evaluates the corresponding functions in parallel.

▶ **Definition 5.** Let $f_1,\ldots,f_{\mathtt{M}}$ be n-input functions. We define the $(n\cdot\mathtt{M})$-input function $(f_1 \parallel \cdots \parallel f_{\mathtt{M}})$ as follows. Upon input $(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n)$, where each $\boldsymbol{x}_i$ is an $\mathtt{M}$-tuple $(x_i^1,\ldots,x_i^{\mathtt{M}})$, the output is the $\mathtt{M}$-tuple defined as

$$(f_1 \parallel \cdots \parallel f_{\mathtt{M}})(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) = \big((y_1^1,\ldots,y_1^{\mathtt{M}}),\ldots,(y_n^1,\ldots,y_n^{\mathtt{M}})\big)\,,$$

where $(y_1^j,\ldots,y_n^j) = f_j(x_1^j,\ldots,x_n^j)$.

Let $\mathcal{F}_{\text{CSF}}^{f_1,l_1},\ldots,\mathcal{F}_{\text{CSF}}^{f_{\mathtt{M}},l_{\mathtt{M}}}$ be CSFs, denote $\mathcal{F}_i = \mathcal{F}_{\text{CSF}}^{f_i,l_i}$. The parallel composition of $\mathcal{F}_1,\ldots,\mathcal{F}_{\mathtt{M}}$, denoted as $(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$, is the CSF defined by the function $(f_1 \parallel \cdots \parallel f_{\mathtt{M}})$ and the leakage function $(l_1 \parallel \cdots \parallel l_{\mathtt{M}})$.

3.2 Passively Secure FBB Parallel-Composition Protocol

The underlying idea of our protocol is based on a simplified form of the parallel-broadcast protocol of Ben-Or and El-Yaniv [5]. The protocol proceeds in iterations, where in each iteration, the parties invoke, in parallel and using the same input values, sufficiently many instances of each (oracle-aided) ideal functionality, but only for a constant number of rounds. If some party received an output in at least one invocation of every ideal functionality, it distributes all output values and the protocol completes; otherwise, the protocol resumes with another iteration. This protocol retains privacy for deterministic functions,[6] since the

[6] Although the result holds for deterministic functionalities, we note that using standard techniques every functionality can be transformed to an equivalent deterministic functionality in a black-box way.

adversary is semi-honest, and so corrupted parties will provide the same input values to all instances of each ideal functionality.

Intuitively, during the simulation of the protocol, the simulator should imitate every call for every ideal functionality towards the adversary. A subtle issue is that in order to do so, the simulator must know the exact trace that is sampled by each instance of each ideal functionality during the execution of the real protocol. Therefore, it is indeed essential for the simulator to receive the *random coins* used to sample the trace for the entire protocol, by the ideal functionality computing the parallel composition (cf. Section 2.2). By defining the trace-distribution sampler in a way that consists of all (potential) sub-traces for every instance of every ideal functionality, the simulator can induce the exact random coins used to sample the correct sub-trace for every ideal functionality that is invoked.

▶ **Theorem 6.** *Let $\mathcal{C}_1, \ldots, \mathcal{C}_M$ be (deterministic-)function classes, let $\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1}, \ldots, \mathcal{F}_{\text{SFE}}^{\mathcal{C}_M}$ be oracle-aided secure function evaluation functionalities, and let $t < n/2$. Let $D_1, \ldots, D_M$ be distributions, such that for every $j \in [M]$, the round complexity of $\mathcal{W}_{\text{flex}}^{D_j}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_j})$ has expectation μ_j. Denote $\mu = \max\{\mu_1, \ldots, \mu_M\}$.*

Then, $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1} \| \cdots \| \mathcal{F}_{\text{SFE}}^{\mathcal{C}_M})$, for some distribution D with expectation $\mu' = O(\mu)$, can be UC-realized by an FBB protocol in the $(\mathcal{F}_{\text{SMT}}, \mathcal{W}_{\text{flex}}^{D_1}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1}), \ldots, \mathcal{W}_{\text{flex}}^{D_M}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_M}))$-hybrid model, with information-theoretic security, in the presence of an adaptive, semi-honest t-adversary, assuming that all honest parties receive their inputs at the same round.

In particular, if for every $j \in [M]$, the expectation μ_j is constant, then μ' is constant.

The proof of Theorem 6 can be found in the full version.

4 Round-Preserving Parallel Composition: Active Security

In this section, we consider security against active adversaries. First, in Section 4.1, we show how to compute the parallel composition of probabilistic-termination functionalities, in a round-preserving manner, using a black-box access to *protocols* realizing the individual functionalities. In Section 4.2, we investigate the question of whether there exists a *functionally* black-box round-preserving malicious protocol for the parallel composition of probabilistic functionalities, and show that for a natural extension of protocols, following the techniques from [5], this is not the case – i.e., there exist functions such that no such protocol with black-box access to them can compute their parallel composition, in a round-preserving manner, tolerating even a single adversarial party.

4.1 Feasibility of Round-Preserving Parallel Composition

In this section, we show how to compile multiple protocols, realizing probabilistic-termination functionalities, into a single protocol that realizes the parallel composition of the functionalities, in a round-preserving manner, and while only using black-box access to the underlying protocols. We start by providing a high-level description of the compiler.

The compiler receives as input protocols $\pi_1, \ldots, \pi_M$, where each protocol π_j is defined in the point-to-point model, in which the parties are given correlated randomness in a secure setup phase, i.e., in the $(\mathcal{F}_{\text{SMT}}, \mathcal{F}_{\text{CORR}}^{D_j^{\text{corr}}})$-hybrid model.[7] It follows that the next-message function for each party in each protocol is a deterministic function that receives the input

[7] This captures, for example, broadcast-model protocols, where the broadcast channel is realized using an expected-constant-round protocol.

value, correlated randomness, private randomness and history of incoming messages, and outputs a vector of n messages to be sent in the following round (one message for each party). In particular, we note that the entire transcript of the protocol is fixed once the input value, correlated randomness and private randomness of each party are determined.

The underlying ideas of the compiler are inspired by the constructions in [5, 14], where a round-preserving parallel-broadcast protocol was constructed by iteratively running, for a constant number of rounds, multiple instances of BA protocols (each instance is executed multiple times in parallel), until at least one execution of every BA instance is completed. This approach is suitable for computing "privacy-free" functionalities, where the adversary may learn the results of multiple computations using the same inputs for honest parties, without compromising security. However, when considering the parallel composition of arbitrary functions, running two instances of a protocol *using the same inputs* will violate privacy, since the adversary can use different inputs to learn multiple outputs of the function.

The parallel-composition compiler generalizes the above approach in a privacy-preserving manner. The compiler follows the GMW paradigm [30] and is defined in the Setup-Commit-then-Prove hybrid model [10, 39], which generates committed correlated randomness for the parties and ensures that all parties follow the protocol specification. This mechanism allows each party to commit to its input values and later execute multiple instances of each protocol, while proving that the same input value is used in all executions. For simplicity and without loss of generality, we assume that each function is deterministic and has a public output. In this case it is ensured that if two parties receive output values in two executions of π_j, then they receive the same output value. The private random coins that are used in each execution only affect the termination round, but not the output value. Using this simplification, we can remove the leader-election phase from the output-agreement technique in [5, 14] and directly use the termination technique from Bracha [7].

Another obstacle is to recover from corruptions without increasing the round complexity. Indeed, in case some party misbehaves, e.g., by using different input values in different instances of the same protocol π_j, then the Setup-Commit-then-Prove functionality ensures that all honest parties will identify the cheating party. In this case, the parties cannot recover by, for example, backtracking and simulating the cheating party, as this will yield a round complexity that is linear in the number of parties. Furthermore, the protocol must resume in a way such that all instances of a specific protocol π_j will use the same input value that the identified corrupted party used throughout the protocol's execution until it misbehaved (since the cheating party might have learned an output value in one of the executed protocols).

To this end, we slightly adjust the Setup-Commit-then-Prove functionality and secret-share every committed random string r_i (the correlated randomness for party P_i) among all the parties, using an error-correcting secret-sharing scheme. Note that this can be done information theoretically as we assume an honest majority [50, 19, 11]. In case a cheating party is identified, every party broadcasts the share of the committed randomness corresponding to that party, reconstructs this party's correlated randomness and from that point onwards, locally computes the messages corresponding to this party in every instance of every protocol. Using this approach, every round in the original protocols $\pi_1, \ldots, \pi_{\mathtt{M}}$ is expanded by a constant number of rounds, and the overall round complexity is preserved.

▶ **Theorem 7.** *Let $\mathcal{F}_1, \ldots, \mathcal{F}_M$ be CSFs, let $t < n/2$, and let $c \geq 1$. Let $\pi_1, \ldots, \pi_M$ be SNF protocols such that for every $j \in [M]$, protocol π_j UC-realizes $\mathcal{W}_{\text{flex}}^{D_j}(\mathcal{F}_j)$ with expected round complexity μ_j and information-theoretic security, in the $(\mathcal{F}_{\text{SMT}}, \mathcal{F}_{\text{CORR}}^{D_j^{\mathsf{corr}}})$-hybrid model (for a distribution D_j and a distribution D_j^{corr} in NC^0), in the presence of an adaptive, malicious t-adversary, assuming that all honest parties receive their inputs at the same round. Denote $\mu = \max\{\mu_1, \ldots, \mu_M\}$.*

Then, $\mathcal{W}^{D,c}_{\text{sl-flex}}(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_M)$*, for some distribution* D *with expectation* $\mu' = O(\mu)$*, can be UC-realized with information-theoretic security by a protocol* π *in the* $(\mathcal{F}_{\text{SMT}}, \mathcal{F}_{\text{CORR-BC}})$*-hybrid model, in the same adversarial setting, assuming that all honest parties receive their inputs within* $c+1$ *consecutive rounds. In addition, protocol* π *requires only black-box access to the protocols* π_j*.*

In particular, if for every $j \in [M]$*,* μ_j *is constant, then* D *has constant expectation.*

The proof of Theorem 7 can be found in the full version.

4.2 An Impossibility of FBB Round-Preserving Parallel Composition

In this section, we prove that for a natural class of protocols, following and/or extending in various ways the techniques from Ben-Or and El-Yaniv [5],[8] there exist functions such that no protocol can compute their parallel composition in a round-preserving manner, while accessing the functions in a black-box way, tolerating even a single adversarial party. Although this is not a general impossibility result, it indicates that the batching approach of [5] is limited to semi-honest security (cf. Section 3) and/or functionally white-box transformations.

We observe that this impossibility serves as an additional justification for the optimality of our protocol-black-box parallel composition (cf. Section 4.1). Indeed, on the one hand, it formally confirms the generic observation that the natural parallel composition of a set of PT functionalities does not preserve their round complexity. On the other hand, and most importantly, it proves that all existing techniques for composing PT functionalities in parallel in the natural (FBB) manner fail in preserving the round complexity. Hence, the only known existing round-preserving composition for such functionalities are the protocol-black-box compiler presented in Section 4.1 or more inefficient non-black-box techniques. The wideness of the class of excluded protocols by our impossibility result justifies our conjecture that there exists no round-preserving FBB protocol for parallel composition of PT functionalities. Proving this conjecture is in our opinion a very interesting research direction.

We first argue informally why the approach of [5], cannot be directly extended to privacy-sensitive functions. The idea in [5] for allowing each of the n parties to broadcast its value is to have each of the n parties participate in $m = O(\log n)$ parallel invocations (hereafter called *batches*, to avoid confusion with the goal of parallel broadcast for different messages) of broadcast as sender with the same input. Each of those batches is executed in parallel for a fixed (constant) number of rounds (for the same broadcast message); this increases the probability that sufficiently many parties receive output from each batch. At the end of each batch execution, the parties check whether they jointly hold the output, and if not, they repeat the computation of the batches. It might seem that this idea can be applied to arbitrary tasks, but this is not the case. The reason is that this idea fails if the functionality has any privacy requirements, is that the adversary can input different values on different calls of the functionality within a batch and learn more information on the input.

Batched parallel composition. The above issue with privacy appears whenever a function is invoked twice in the same round on the same inputs from honest parties. Indeed, in this case the adversary can use different inputs to each invocation and learn information as sketched above. The same attack can be extended to composition-protocols which invoke the function in two different rounds ρ and ρ'; as long as the adversary knows these rounds

[8] To our knowledge, the only known techniques for round-preserving parallel composition are those of Ben-Or and El-Yaniv [5] and are only for the specific case of Byzantine agreement.

he can still launch the above attack on privacy. Generalizing the claim even further, for specific classes of functions, it suffices that there are two (possibly different) functions which are evaluated on the same inputs in rounds ρ and ρ'. This excludes protocols that might attempt to avoid using some functionality $\mathcal{W}_{\text{flex}}^{D_j}(\mathcal{F}_j)$ by invoking some other $\mathcal{W}_{\text{flex}}^{D_{j'}}(\mathcal{F}_{j'})$.

To capture the above generalization, we define the class of *batched-parallel composition* protocols: A protocol π implementing the PT parallel composition $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$ in the $(\mathcal{W}_{\text{flex}}^{D_1}(\mathcal{F}_1), \ldots, \mathcal{W}_{\text{flex}}^{D_{\mathtt{M}}}(\mathcal{F}_{\mathtt{M}}))$-hybrid model (for some distributions $D, D_1, \ldots, D_{\mathtt{M}}$) is a *batched-parallel composition* protocol if it has the following structure: It proceeds in rounds, where in each round the protocol might initiate (possibly multiple) calls to any number of the hybrid functionalities $\mathcal{W}_{\text{flex}}^{D_j}(\mathcal{F}_j)$ and/or continue calls that were initiated in previous rounds. Furthermore, there exist two publicly known protocol rounds ρ and ρ', and indices $j, j', \ell \in [\mathtt{M}]$, such that for the input vector $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ that π gives to $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_1 \parallel \cdots \parallel \mathcal{F}_{\mathtt{M}})$ (where $\boldsymbol{x}_i = (x_i^1, \ldots, x_i^{\mathtt{M}})$) the following properties are satisfied:

1. In round ρ the functionality $\mathcal{W}_{\text{flex}}^{D_j}(\mathcal{F}_j)$ is called on input $\boldsymbol{x}^\ell = (x_1^\ell, \ldots, x_n^\ell)$ and at least two of its rounds are executed.
2. In round ρ' the functionality $\mathcal{W}_{\text{flex}}^{D_{j'}}(\mathcal{F}_{j'})$ is also called on input $\boldsymbol{x}^\ell$ and at least two of its rounds are executed.

We next show that the there are classes of functions $\mathcal{C}_1, \ldots, \mathcal{C}_{\mathtt{M}}$ such and for any protocol π that securely computes the parallel composition $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1} \parallel \cdots \parallel \mathcal{F}_{\text{SFE}}^{\mathcal{C}_{\mathtt{M}}})$ while given hybrid access to PT functionalities $\mathcal{W}_{\text{flex}}^{D_i}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_i})$ the following properties hold *simultaneously*:

1. π has to call each of the hybrids $\mathcal{W}_{\text{flex}}^{D_i}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_i})$ (for at least 2 rounds each).[9]
2. The naïve solution of π calling each of the $\mathcal{W}_{\text{flex}}^{D_i}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_i})$'s in parallel until they terminate is not round-preserving (for an appropriate choice of D_i's.)
3. π cannot be a batched-parallel composition protocol.

The above shows that the classes $\mathcal{C}_1, \ldots, \mathcal{C}_{\mathtt{M}}$ not only exclude the existence of a batched-parallel composition protocol, but they also exclude all other known solutions. This implies that for this classes of functions, every known approach – and generalizations thereof – fail to compute the parallel composition of the corresponding functionality in an FBB and round-preserving manner. In the full version we prove the following theorem.

▶ **Theorem 8.** *Let $\mathtt{M} = O(\kappa)$. There exist n-party function classes $\mathcal{C}_1, \ldots, \mathcal{C}_{\mathtt{M}}$ and distributions $D_1, \ldots, D_{\mathtt{M}}$, such that the following properties hold in the presence of a malicious adversary corrupting any one of the parties:*

1. *The protocol that calls each $\mathcal{W}_{\text{flex}}^{D_i}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_i})$ in parallel (once) until termination is not round-preserving (its round complexity is asymptotically higher than of the distributions D_i).*
2. *Any $(\mathcal{F}_{\text{SMT}}, \mathcal{W}_{\text{flex}}^{D_1}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1}), \ldots, \mathcal{W}_{\text{flex}}^{D_{\mathtt{M}}}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_{\mathtt{M}}}))$-hybrid protocol for computing $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1} \parallel \cdots \parallel \mathcal{F}_{\text{SFE}}^{\mathcal{C}_{\mathtt{M}}})$ has to make a meaningful call (i.e., a call that executes at least two rounds) to each PT hybrid $\mathcal{W}_{\text{flex}}^{D_i}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_i})$.*
3. *There exists no functionally black-box batched-parallel composition protocol for computing $\mathcal{W}_{\text{flex}}^{D}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1} \parallel \cdots \parallel \mathcal{F}_{\text{SFE}}^{\mathcal{C}_{\mathtt{M}}})$ in the $(\mathcal{F}_{\text{SMT}}, \mathcal{W}_{\text{flex}}^{D_1}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_1}), \ldots, \mathcal{W}_{\text{flex}}^{D_{\mathtt{M}}}(\mathcal{F}_{\text{SFE}}^{\mathcal{C}_{\mathtt{M}}}))$-hybrid model, where D has (asymptotically) the same expectation as $D_1, \ldots, D_{\mathtt{M}}$.*

Abstract

Annihilation attacks, introduced in the work of Miles, Sahai, and Zhandry (CRYPTO 2016), are a class of polynomial-time attacks against several candidate indistinguishability obfuscation ($i\mathcal{O}$) schemes, built from Garg, Gentry, and Halevi (EUROCRYPT 2013) multilinear maps. In this work, we provide a *general* efficiently-testable property for two single-input branching programs, called *partial inequivalence,* which we show is sufficient for our variant of annihilation attacks on several obfuscation constructions based on GGH13 multilinear maps.

We give examples of pairs of natural NC^1 circuits, which – when processed via Barrington's Theorem – yield pairs of branching programs that are partially inequivalent. As a consequence we are also able to show examples of "bootstrapping circuits," (albeit somewhat artificially crafted) used to obtain obfuscations for all circuits (given an obfuscator for NC^1 circuits), in certain settings also yield partially inequivalent branching programs. Prior to our work, no attacks on any obfuscation constructions for these settings were known.

1 Introduction

An obfuscator is a program compiler which hides all partial implementation details of a program, intuitively. This is formalized via the notion of indistinguishability obfuscation [9]: we say an obfuscator $\mathcal{O}$ is an indistinguishability obfuscator if it holds for every pair C_0, C_1 of functionally equivalent circuits (i.e. computing the same function) that $\mathcal{O}(C_0)$ and $\mathcal{O}(C_1)$

are indistinguishable. A recent surge of results has highlighted the importance of this notion: virtually "any cryptographic task" can be achieved assuming indistinguishability obfuscation and one-way functions [34].

All known candidate constructions of indistinguishability obfuscation, e.g. [25, 8, 6], are based on multilinear-maps [24, 21, 27][1], which have been the subjects of various attacks [16, 18, 15, 29, 19]. Among them, the attacks (e.g. [24, 29]) on GGH13 [24] multilinear maps required explicit access to "low-level" encodings of zero, or differently represented low-level encodings of zero, e.g. [18]; such low-level zero-encodings do not appear naturally in obfuscation constructions. Recently Miles, Sahai, and Zhandry [32] introduced a new class of polynomial-time[2] attacks without requiring low-level zeros against several obfuscation constructions [12, 8, 3, 31, 33] and [7], when instantiated with the GGH13 multilinear maps.

More specifically, Miles et al. [32] exhibit two simple *branching programs* (and also programs padded with those) that are functionally equivalent, yet their BGKPS-obfuscations (put forward by Barak et al. in [8]) and similar constructions [12, 3, 31, 33, 7] are efficiently distinguishable.[3] However, the branching programs considered there, in particular the *all-identity* branching program, do not appear "in the wild". More specifically, obfuscation constructions for circuits first convert an NC^1 circuit into a branching program (e.g. via Barrington's transformation) that possibly results in programs with complex structures, even if one starts with simple circuits. This brings us to the following open question:

Is it possible to attack obfuscations of complex branching programs generated from NC^1 *circuits?*

1.1 Our Contributions

In this work, we are able to answer the above question affirmatively. In particular, our main contributions are:

- We first define a *general* and efficiently-testable property of two single-input[4] branching programs called *partial inequivalence* (discussed below) and demonstrate an annihilation attack against BGKPS-like obfuscations of any two (large enough) branching programs that satisfy this property.
- Next, using implementation in Sage [35] (see the full version for details on the implementation) we give explicit examples of pairs of (functionally equivalent) natural NC^1 circuits, which when processed via Barrington's Theorem yield pairs of branching programs that are partially inequivalent – and thus, attackable.
- As a consequence of the above result, we are also able to show that the "bootstrapping circuit(s)" technique used to boost $i\mathcal{O}$ for NC^1 to $i\mathcal{O}$ for $\mathsf{P/poly}$, for a certain choice of the universal circuit (albeit artificially crafted), yield partially inequivalent branching programs in a similar manner – and are, thus, also attackable.

---

[1] The work of [2] might be seen as an exception to this: Assuming the (non-explicit) existence of indistinguishability obfuscation, they provide an explicit construction of an indistinguishability obfuscator.

[2] Several subexponential-time or quantum-polynomial-time [22, 1, 17] attacks on GGH13 multilinear maps also have been considered. We do not consider these in this paper.

[3] To avoid repetitions, from now on we will refer to the obfuscation constructions of [8, 12, 3, 31, 33] by BGKPS-like constructions that use single-input branching programs.

[4] The branching programs, where any pair of matrices in the sequence depends on a single input location, are called single-input branching programs. Such branching programs naturally evolve from Barrington's transformation on circuits.

Figure 1 The Attack Landscape for GGH13-based Obfuscators. In all cases, the multilinear map is [24]. ○ means no attack is known. × means a prior attack is known, and we present more general attacks for this setting. ⊗ means we give the first known attack in this setting and ⊗ means a new attack is discovered concurrently to ours (namely [13]).

Our general partial inequivalence condition is broad and seems to capture a wide range of natural single-input branching programs. However, we require the program to be large enough.[5] Additionally, we need the program to output 0 on a large number of its inputs.

Finally, our new annihilation attacks are essentially based on linear system solvers and thus quite *systematic*. This is in contrast with the attacks of Miles et al. [32] which required an exhaustive search operation rendering it hard to extend their analysis for branching programs with natural structural complexity. Therefore, at a conceptual level, our work enhances the understanding of the powers and the (potential) limits of annihilation attacks.

One limitation of our technique is that they do *not* extend to so-called dual-input branching programs. We leave it as an interesting open question.

A Concurrent and Independent work

Concurrent and independent to our work,[6] Chen et al. [13] provides a polynomial time attack against the GGHRSW construction [25] based on GGH13 (and also GGH15 [27]) maps that works for so-called "input-partitioning" branching programs. Nonetheless, their attacks are not known to extend [14] for complex branching programs evolved from NC^1 circuits (e.g. via Barrington's Transformation). Hence, our work stands as the *only* work that breaks obfuscations of NC^1 circuits based on GGH13 till date.

Change in Obfuscation landscape

Given our work and the work of Chen et al. [13] the new *attack landscape against GGH13-based obfuscators* is depicted in Figure 1. We refer the reader to [2, Figure 13] for the state of the art on obfuscation constructions based on CLT13 and GGH15 multilinear maps.

[5] Note that, for our implementation we consider circuits that are quite small, only depth 3, and the resulting Barrington programs are of length 64. However, using the implementation we then "boost" the attack to a much larger NC^1 circuits that suffice for the real-world attack (discussed in the full version) to go through.

[6] The first draft of our full version [4] appeared online concurrently as their first draft [13]. At the same time another independent work [20] appeared that provided attacks against several CLT13 based obfuscators for a broader class of programs.

1.2 Technical Overview

Below, after providing some additional backgrounds on multilinear maps and known attacks, we provide an overview of our annihilation attacks.

Multilinear Maps: Abstractly

As a first approximation, one can say that a cryptographic multilinear map system encodes a value $a \in \mathbb{Z}_p$ (where p is a large prime) by using a *homomorphic* encryption scheme equipped with some additional structure. In other words, given encodings of a and b, one can perform homomorphic computations by computing encodings of $a + b$ and $a \cdot b$. Additionally, each multilinear map encoding is associated with some *level* described by a value $i \in \{1 \dots \kappa\}$ for a fixed universe parameter κ. Encodings can be added only if they are at the same level: $\mathsf{Enc}_i(a) \oplus \mathsf{Enc}_i(b) \to \mathsf{Enc}_i(a+b)$. Encodings can be multiplied: $\mathsf{Enc}_i(a) \odot \mathsf{Enc}_j(b) \to \mathsf{Enc}_{i+j}(a \cdot b)$ if $i + j \leq \kappa$ but is meaningless otherwise. We naturally extend the encoding procedure and the homomorphic operations to encode and to compute on matrices, respectively, by encoding each term of the matrix separately. Finally, the multilinear map system comes equipped with a *zero test*: an efficient procedure for testing whether the input is an encoding of 0 at level-κ. However, such zero-test procedure is not perfect as desired when instantiated with concrete candidate multilinear maps. In particular we are interested in the imperfection in GGH13 map.

An Imperfection of the GGH13 Multilinear Maps

Expanding a little on the abstraction above, a fresh multilinear map encoding of a value $a \in \mathbb{Z}_p$ at level i is obtained by first sampling a random value μ from $\mathbb{Z}_p$ and then encoding $\mathsf{Enc}_i(a + \mu \cdot p)$. Homomorphic operations can be performed just as before, except that the randomnesses from different encodings also get computed on. Specifically, $\mathsf{Enc}_i(a + \mu \cdot p) \oplus \mathsf{Enc}_i(b + \nu \cdot p)$ yields $\mathsf{Enc}_i(a + b + (\mu + \nu) \cdot p)$ and multiplication $\mathsf{Enc}_i(a + \mu \cdot p) \odot \mathsf{Enc}_j(b + \nu \cdot p)$ yields $\mathsf{Enc}_{i+j}(a \cdot b + (b \cdot \mu + a \cdot \nu + \mu \cdot \nu \cdot p) \cdot p)$ if $i + j \leq \kappa$ but is meaningless otherwise. An imperfection of the zero-test procedure is a feature characterized by two phenomena:

1. On input $\mathsf{Enc}_\kappa(0 + r \cdot p)$ the zero-test procedure additionally reveals r in a somewhat "scrambled" form.
2. For certain efficiently computable polynomials f and a collection of scrambled values $\{r_i\}$ it is efficient to check if $f(\{r_i\}) = 0 \mod p$ or not for any choice of r_i's.[7]

This imperfection has been exploited to perform attacks in prior works, such as the one by Miles et al. [32].[8]

Matrix Branching Programs

A matrix branching program of length ℓ for n-bit inputs is a sequence $BP = \left\{A_0, \left\{A_{i,0}, A_{i,1}\right\}_{i=1}^{\ell}, A_{\ell+1}\right\}$, where $A_0 \in \{0,1\}^{1\times 5}$, $A_{i,b}$'s for $i \in [\ell]$ are in $\{0,1\}^{5\times 5}$ and $A_{\ell+1} \in \{0,1\}^{5\times 1}$. Without providing details, we note that the choice of 5×5 matrices comes from Barrington's Theorem [10]. We use the notation $[n]$ to describe the set $\{1, \dots, n\}$.

[7] One can alternatively consider the scrambled values as polynomials over $\{r_i\}$ and then check if $f(\{r_i\})$ is identically zero in $\mathbb{Z}_p$.

[8] Recent works such as [26, 23], have attempted to realize obfuscation schemes secure against such imperfection and are provably secure against our attacks. We refer to them as obfuscations from weak multilinear maps (see Figure 1).

Let inp be a fixed function such that $\mathsf{inp}(i) \in [n]$ is the input bit position examined in the i^{th} step of the branching program. The function computed by this matrix branching program is

$$f_{BP}(x) = \begin{cases} 0 & \text{if } A_0 \cdot \prod_{i=1}^{\ell} A_{i,x[\mathsf{inp}(i)]} \cdot A_{\ell+1} = 0 \\ 1 & \text{if } A_0 \cdot \prod_{i=1}^{\ell} A_{i,x[\mathsf{inp}(i)]} \cdot A_{\ell+1} \neq 0 \end{cases},$$

where $x[\mathsf{inp}(i)] \in \{0,1\}$ denotes the $\mathsf{inp}(i)^{th}$ bit of x.

The branching program described above inspects one bit of the input in each step. More generally, multi-arity branching programs inspect multiple bits in each step. For example, dual-input programs inspect two bits during each step. Our strategy only works against single-input branching programs, hence we restrict ourselves to that setting.

Exploiting the Imperfection/Weakness

At a high level, obfuscation of a branching program $BP = \{A_0, \{A_{i,0}, A_{i,1}\}_{i=1}^{\ell}, A_{\ell+1}\}$ yields a collection of encodings $\{M_0, \{M_{i,0}, M_{i,1}\}_{i=1}^{\ell}, M_{\ell+1}\}$, say all of which are obtained at level-1.[9] We let $\{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$ denote the randomnesses used in the generation of these encodings, where each Z corresponds to a matrix of random values (analogous to r above) in $\mathbb{Z}_p$. For every input x such that $BP(x) = 0$, we have that $M_0 \odot \bigodot_{i=1}^{\ell} M_{i,x[\mathsf{inp}(i)]} \odot M_{\ell+1}$ is an encoding of 0, say of the form $\mathsf{Enc}(0 + r_x \cdot p)$ from which r_x can be learned in a scrambled form. The crucial observations of Miles et al. [32] are: (1) for every known obfuscation construction, r_x is a *program dependent* function of $\{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$, and (2) for a large enough $m \in \mathbb{Z}$ the values $\{r_{x_k}\}_{k=1}^{m}$ must be correlated, which in turn implies that there exists a (program-dependent) efficiently computable function f^{BP} and input choices $\{x_k^{BP}\}_{k=1}^{m}$ such that for all $k \in [m]$, $BP(x_k^{BP}) = 0$ and $f^{BP}(\{r_{x_k^{BP}}\}_{k=1}^{m}) = 0 \mod p$.[10] Further, just like Miles et al. we are interested in constructing an attacker for the *indistinguishability* notion of obfuscation. In this case, given two arbitrarily distinct programs BP and BP' (such that $\forall x, BP(x) = BP'(x)$) an attacker needs to distinguish between the obfuscations of BP and BP'. Therefore, to complete the attack, it suffices to argue that for the sequence of $\{r'_{x_k^{BP'}}\}$ values obtained from execution of BP' it holds that, $f^{BP}(\{r'_{x_k^{BP'}}\}_{k=1}^{m}) \neq 0 \mod p$. Hence, the task of attacking any obfuscation scheme reduces to the task of finding such distinguishing function f^{BP}.

Miles et al. [32] accomplishes that by presenting specific examples of branching programs, both of which implement the constant zero function, and a corresponding distinguishing function. They then extend the attack to other related branching programs that are padded with those constant-zero programs. The details of their attack [32] is quite involved, hence we jump directly to the intuition behind our envisioned more general attacks.

Partial Inequivalence of Branching Programs and Our Attacks

We start with the following observation. For BGKPS-like-obfuscations for any branching program $BP = \{A_0, \{A_{i,0}, A_{i,1}\}_{i=1}^{\ell}, A_{\ell+1}\}$ the value $s_x = r_x \mod p$ looks something like: [11]

[9] Many obfuscation constructions use more sophisticate leveling structure, typically referred to as so-called "straddling sets". However we emphasize that, this structure does not affect our attacks. Therefore we will just ignore this in our setting.

[10] This follows from the existence of an annihilating polynomial for any over-determined non-linear systems of equations. We refer to [30] for more details.

[11] Obtaining this expression requires careful analysis that is deferred to the main body of the paper. Also, by abuse of notation let $A_{0,x_{\mathsf{inp}(0)}} = A_0$, $A_{\ell+1,x_{\mathsf{inp}(\ell+1)}} = A_{\ell+1}$, $Z_{0,x_{\mathsf{inp}(0)}} = Z_0$ and $Z_{\ell+1,x_{\mathsf{inp}(\ell+1)}} = Z_{\ell+1}$.

$$s_x \simeq \prod_{i=1}^{\ell} \alpha_{i,x[\mathsf{inp}(i)]} \underbrace{\left[\sum_{i=0}^{\ell+1} \left(\prod_{j=0}^{i-1} A_{j,x_{\mathsf{inp}(j)}} \cdot Z_{i,x[\mathsf{inp}(i)]} \cdot \prod_{j=i+1}^{\ell+1} A_{j,x_{\mathsf{inp}(j)}} \right)\right]}_{t_x},$$

where $\{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$ where $\{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$ are the randomnesses contributed by the corresponding encodings. Let $\overline{x}$ denote the value obtained by flipping every bit of x (a.k.a. the bitwise complement). Now observe that the product value $\Lambda = \prod_{i=1}^{\ell} \alpha_{i,x[\mathsf{inp}(i)]} \cdot \alpha_{i,\overline{x}[\mathsf{inp}(i)]}$ is independent of x. Therefore, $u_x = s_x \cdot s_{\overline{x}} = \Lambda \cdot t_x \cdot t_{\overline{x}}$. Absorbing Λ in the $\{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}$, we have that u_x is quadratic in the randomness values $\{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$, or linear in the random terms ZZ' obtained by multiplying every choice of $Z, Z' \in \{Z_0, \{Z_{i,0}, Z_{i,1}\}_{i=1}^{\ell}, Z_{\ell+1}\}$. In other words if BP evaluates to 0 both on inputs x and $\overline{x}$, the values revealed by two zero-test operations give one linear equation where the coefficients of the linear equations are program dependent. Now, if BP implements a "sufficiently non-evasive" circuit,(e.g. a PRF) such that there exist sufficiently many such inputs $x, \overline{x}$ for which $BP(x) = BP(\overline{x}) = 0$, then collecting sufficiently many values $\{x_k^{BP}, u_{x_k^{BP}}\}_{k=1}^{m}$, we get a dependent system of linear relations. Namely, there exist $\{\nu_k^{BP}\}_{k=1}^{m}$ such that $\sum_{k=1}^{m} \nu_k^{BP} \cdot u_{x_k^{BP}} = 0$. In other words, $\sum_{k=1}^{m} \nu_k^{BP} \cdot r_{x_k^{BP}} \cdot r_{\overline{x}_k^{BP}} = 0 \mod p$, where $\{\nu_k^{BP}\}_{k=1}^{m}$ depends only on the description of the branching program BP.

We remark that, in the process of linearization above we increased (by a quadratic factor) the number of random terms in the system. However, this can be always compensated by using more equations, because the number of random terms is $O(poly(n))$ (n is the input length) whereas the number of choices of input x is $2^{O(n)}$ which implies that there are exponentially many r_x available.

Note that for any branching program BP' that is "different enough" from BP, we could expect that $\sum_{k=1}^{m} \nu_k^{BP} \cdot r'_{x_k^{BP}} \cdot r'_{\overline{x}_k^{BP}} \neq 0 \mod p$ where $r'_{x_k^{BP}}$ are values revealed in executions of an obfuscation of BP'. This is because the values $\{\nu_k^{BP}\}_{k=1}^{m}$ depend on the specific implementation of BP through terms of the form $\prod_{j=0}^{i-1} A_{j,x[\mathsf{inp}(i)]}$ and $\prod_{j=i+1}^{\ell+1} A_{j,x[\mathsf{inp}(i)]}$ in s_x above. Two branching programs that differ from each other in this sense are referred to as *partially inequivalent*.[12]

What Programs are Partially Inequivalent? Attack on NC^1 circuits

The condition we put forth seems to be fairly generic and intuitively should work for large class of programs. In particular, we are interested in the programs generated from NC^1 circuits. However, due to complex structures of such programs the analysis becomes quite non-trivial.[13] Nonetheless, we manage to show via implementation in Sage [35] that the attack indeed works on a pair of branching programs obtained from a pair of simple NC^1 circuits, (say C_0, C_1) (see Sec. 6 for the circuit descriptions) by applying Barrington's Theorem. The circuits take 4 bits of inputs and on any input they evaluate to 0. In our attack we use

[12] Note that the only other constraint we need is that both BP and BP' evaluates to 0 for sufficiently many inputs, which we include in the definition (c.f. Def. 2) of partial inequivalence.

[13] Note that, the analysis of Miles et al. uses 2×2 matrices in addition to using simple branching programs. These simplifications allow them to base their analysis on many facts related to the structures of these programs. Our aim here is to see if the attack works for programs obtained from NC^1 circuits, in particular via Barrington's Theorem. So, unfortunately it is not clear if their approach can be applicable here as the structure of the programs yielded via Barrington's Theorem become much complex structurally (and also much larger in size) to analyze.

all possible 16 inputs. Furthermore, we can escalate the attack to any pair of NC^1 circuits (E_0, E_1) where $E_b = \neg C_b \wedge D_b$ $(b \in \{0,1\})$ for practically any two NC^1 circuits D_0, D_1 (we need only one input x for which $D(x) = D(\overline{x}) = 0$). We now take again a sequence of 16-inputs such that we vary the parts of all the inputs going into C_b and keep the part of inputs read by D_b fixed to x. Intuitively, since the input to D_b is always the same, each evaluation chooses the exactly same randomnesses (that is Z_i's) always. Hence in the resulting system all the random variables can be replaced by a single random variable and hence $\neg C_b \wedge D_b$ can be effectively "collapsed" to a much smaller circuit $\neg C_b \wedge 0$ (0 refers to the smallest trivial circuit consisting of only identities). Finally, again via our Sage-implementation we show that for circuits $\neg C_0 \wedge 0$ and $\neg C_1 \wedge 0$ the corresponding branching programs are partially inequivalent.

As a corollary we are also able to show examples of universal circuits U_b for which the same attack works. Since the circuit D can be almost any arbitrary NC^1 circuit, we can, in particular use any universal circuit U' and carefully combine that with C to obtain our attackable universal circuit U that results in partially inequivalent Barrington programs.

2 Notations and Preliminaries

2.1 Notations

We denote the set of natural numbers $\{1, 2, \ldots\}$ by $\mathbb{N}$, the set of all integers $\{\ldots, -1, 0, 1 \ldots\}$ by $\mathbb{Z}$ and the set of real numbers by $\mathbb{R}$. We use the notation $[n]$ to denote the set of first n natural numbers, namely $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$.

For any bit-string $x \in \{0,1\}^n$ we let $x[i]$ denotes the i-th bit. For a matrix A we denote its i-th row by $A[i, \star]$, its j-th column by $A[\star, j]$ and the element in the i-th row and j-th column by $A[i, j]$. The i-th element of a vector $\boldsymbol{v}$ is denoted by $\boldsymbol{v}[i]$.

For more notational conventions we refer to the full version [4].

3 Attack Model for Investigating Annihilation Attacks

Similar to Miles, Sahai, and Zhandry [32] we use an abstract attack model designed to encompass the main ideas of BGKPS-like-obfuscations [8, 12, 3, 33, 31, 7] as the starting point for our attacks. We formally describe the model in the full version [4].

4 Partially Inequivalent Branching Programs

In this section, we provide a formal condition on two single-input branching programs (naturally extends to multi-input settings), namely partial inequivalence, that is sufficient for launching a distinguishing attack in the abstract model. In Section 5 we prove that this condition is sufficient for the attack.[14]

▶ **Definition 1** (Partial Products)**.** Let $\mathbf{A} = (\mathsf{inp}, A_0, \{A_{i,b}\}_{i\in[\ell],b\in\{0,1\}}, A_{\ell+1})$ be a single-input branching program of matrix-dimension d and length ℓ over n-bit input.

[14] We note that this condition is not necessary. Looking ahead, we only consider first order partially inequivalent programs in paper and remark that higher order partially inequivalent programs could also be distinguished using our techniques.

1. For any input $x \in \{0,1\}^n$ and any index $i \in [\ell+1] \cup \{0\}$ we define the vectors $\phi^{(i)}_{\mathbf{A},x}$ as follows:

$$\phi^{(i)}_{\mathbf{A},x} \stackrel{\text{def}}{=} \begin{cases} \left(A_0 \cdot \prod_{j=1}^{i-1} A_{j,x[\mathsf{inp}(j)]}\right) \otimes \left(\prod_{j=i+1}^{\ell} A_{j,x[\mathsf{inp}(j)]} \cdot A_{\ell+1}\right)^T \in \{0,1\}^{1\times d^2} & \text{if } i \in [\ell]\,, \\ \left(\prod_{j=1}^{\ell} A_{j,x[\mathsf{inp}(j)]} \cdot A_{\ell+1}\right)^T \in \{0,1\}^{1\times d} & \text{if } i = 0\,, \\ A_0 \cdot \prod_{j=1}^{\ell} A_{j,x[\mathsf{inp}(j)]} \in \{0,1\}^{1\times d} & \text{if } i = \ell+1\,. \end{cases}$$

   Additionally, define $\widetilde{\phi}^{(i)}_{\mathbf{A},x}$ for any such branching program as:

$$\widetilde{\phi}^{(i)}_{\mathbf{A},x} \stackrel{\text{def}}{=} \begin{cases} [\phi^{(i)}_{\mathbf{A},x} \mid 0^{d^2}] & \text{if } i \in [\ell] \text{ and } x[\mathsf{inp}(i)] = 0\,, \\ [0^{d^2} \mid \phi^{(i)}_{\mathbf{A},x}] & \text{if } i \in [\ell] \text{ and } x[\mathsf{inp}(i)] = 1\,, \\ \phi^{(i)}_{\mathbf{A},x} & \text{if } i = 0 \text{ or } \ell+1\,, \end{cases}$$

   where inp is a function from $[\ell] \to [n]$ and that $x[\mathsf{inp}(i)]$ denotes the bit of x corresponding to location described by $\mathsf{inp}(x)$.
2. Then the **linear partial product vector** $\boldsymbol{\phi}_{\mathbf{A},x}$ and the **quadratic partial product vector** $\boldsymbol{\psi}_{\mathbf{A},x}$ of $\mathbf{A}$ with respect to x are defined as:

$$\boldsymbol{\phi}_{\mathbf{A},x} \stackrel{\text{def}}{=} [\widetilde{\phi}^{(0)}_{\mathbf{A},x} \mid \cdots \mid \widetilde{\phi}^{(\ell+1)}_{\mathbf{A},x}] \in \{0,1\}^{1\times(2d+2^\ell d^2)}\,,$$
$$\boldsymbol{\psi}_{\mathbf{A},x} \stackrel{\text{def}}{=} \boldsymbol{\phi}_{\mathbf{A},x} \otimes \boldsymbol{\phi}_{\mathbf{A},\overline{x}} \in \{0,1\}^{1\times(2d+2^\ell d^2)^2}\,,$$

   where $\overline{x} = x \oplus 1^n$ is the compliment of x.
3. For a set of inputs $X = \{x_1, x_2, \ldots, x_m\}$ the the **linear partial product matrix** $\Phi_{\mathbf{A},X}$ and the **quadratic partial product matrix** $\Psi_{\mathbf{A},X}$ of $\mathbf{A}$ with respect to X are defined as:

$$\Phi_{\mathbf{A},X} \stackrel{\text{def}}{=} \begin{bmatrix} \boldsymbol{\phi}_{\mathbf{A},x_1} \\ \boldsymbol{\phi}_{\mathbf{A},x_2} \\ \vdots \\ \boldsymbol{\phi}_{\mathbf{A},x_m} \end{bmatrix} \in \{0,1\}^{m\times(2d+2^\ell d^2)}\,,$$

$$\Psi_{\mathbf{A},X} \stackrel{\text{def}}{=} \Phi_{\mathbf{A},X} \boxtimes \Phi_{\mathbf{A},\overline{X}} + \Phi_{\mathbf{A},\overline{X}} \boxtimes \Phi_{\mathbf{A},X} = \begin{bmatrix} \boldsymbol{\psi}_{\mathbf{A},x_1} + \boldsymbol{\psi}_{\mathbf{A},\overline{x}_1} \\ \boldsymbol{\psi}_{\mathbf{A},x_2} + \boldsymbol{\psi}_{\mathbf{A},\overline{x}_2} \\ \vdots \\ \boldsymbol{\psi}_{\mathbf{A},x_m} + \boldsymbol{\psi}_{\mathbf{A},\overline{x}_m} \end{bmatrix} \in \{0,1\}^{m\times(2d+2^\ell d^2)^2},$$

   where $\overline{X} \stackrel{\text{def}}{=} \{\overline{x}_1, \overline{x}_2, \ldots\}$.

▶ **Definition 2** (Partial Inequivalence)**.** Let $\mathbf{A}_0$ and $\mathbf{A}_1$ be two single-input matrix branching programs of matrix-dimension d and length ℓ over n-bit input. Then they are called **partially inequivalent** if there exists a polynomial in security parameter sized set X of inputs such that:

- For every $x \in X$, we have that $\mathbf{A}_0(x) = \mathbf{A}_1(x) = 0$ and $\mathbf{A}_0(\overline{x}) = \mathbf{A}_1(\overline{x}) = 0$.
- $\mathsf{colsp}\left(\Psi_{\mathbf{A}_0,X}\right) \neq \mathsf{colsp}\left(\Psi_{\mathbf{A}_1,X}\right)$.

5 Annihilation Attacks for Partially Inequivalent Programs

In this section, we describe an abstract annihilation attack against any two branching programs that are partially inequivalent. We show an attack only in the abstract model and provide details on how it can be extended to the real GGH13 setting in the full version.

▶ **Theorem 3.** *Let $\mathcal{O}$ be the generic obfuscator described in Section 3.2 of the full version. Then for any two functionally equivalent same length single-input branching programs $\mathbf{A}_0, \mathbf{A}_1$ that are partially inequivalent there exists a probabilistic polynomial time attacker that distinguishes between between $\mathcal{O}(\mathbf{A}_0)$ and $\mathcal{O}(\mathbf{A}_1)$ with noticeable probability in the abstract attack model.*

Proof.

Setup for the attack

The given branching programs $\mathbf{A}_0$ and $\mathbf{A}_1$ are provided to be functionally equivalent and partially inequivalent. Therefore there exists a set X such that: (1) for all $x \in X, \mathbf{A}_0(x) = \mathbf{A}_0(\overline{x}) = \mathbf{A}_1(x) = \mathbf{A}_1(\overline{x}) = 0$, and (2) $\mathsf{colsp}\left(\Psi_{\mathbf{A}_0,X}\right) \neq \mathsf{colsp}\left(\Psi_{\mathbf{A}_1,X}\right)$. We will assume that the adversary has access to X as auxiliary information.

Challenge

$\mathcal{A}$ receives as a challenge the obfuscation of the branching program: $\mathbf{A} \in \{\mathbf{A}_0, \mathbf{A}_1\}$ by the challenger. Recall from the description of the abstract obfuscator that, the obfuscation of program $\mathbf{A} = (\mathsf{inp}, A_0, \{A_{i,b}\}_{i\in[\ell],b\in\{0,1\}}, A_{\ell+1})$, denoted by $\mathcal{O}(\mathbf{A})$ consists of the following public variables:

$$Y_0 := A_0 \cdot R_1^{adj} + gZ_0, \quad Y_{i,b} := \alpha_{i,b} R_i \cdot A_{i,b} \cdot R_{i+1}^{adj} + gZ_{i,b}, \quad Y_0 := R_{\ell+1} \cdot A_{\ell+1} + gZ_0,$$

where the arbitrary secret variables are:

$$\widetilde{A}_0 \stackrel{\text{def}}{=} A_0 \cdot R_1^{adj}, \quad \widetilde{A}_{i,b} \stackrel{\text{def}}{=} \alpha_{i,b}(R_{i,b} \cdot A_{i,b} \cdot R_{i,b}^{adj}), \quad \widetilde{A}_{\ell+1} \stackrel{\text{def}}{=} R_{\ell+1} \cdot A_{\ell+1};$$

for random variables (i.e. Killian randomizers) $R_1, \{R_i\}, R_{\ell+1}$ and the random secret variables are denoted by $Z_0, \{Z_{i,b}\}_{i\in[\ell],b\in\{0,1\}}, Z_{\ell+1}$ and the special secret variable is g. Via change of variables we can equivalently write:

$$Y_0 := (A_0 + gZ_0) \cdot R_1^{adj}; \quad Y_{i,b} := \alpha_{i,b} R_i \cdot (A_{i,b} + gZ_{i,b}) \cdot R_{i+1}^{adj}; \quad Y_{\ell+1} := R_{\ell+1} \cdot (A_{\ell+1} + gZ_{\ell+1}).$$

Pre-Zeroizing Computation (Type-1 queries)

On receiving the obfuscation of $\mathbf{A} \in \{\mathbf{A}_0, \mathbf{A}_1\}$, $\mathcal{O}(\mathbf{A}) = \{Y_0, \{Y_{i,b}\}, Y_{\ell+1}\}$ the attacker, in the pre-zeroizing step, performs a "valid" Type-1 queries on all the inputs $X, \overline{X}$ where $X = \{x_1, \ldots, x_m\}, \overline{X} = \{\overline{x}_1, \ldots, \overline{x}_m\}$. That is, for an $x \in \{0,1\}^n$, and the abstract obfuscation $\mathcal{O}(\mathbf{A})$, the attacker queries the polynomial:

$$P_{\mathbf{A},x} = Y_0 \cdot \prod_{i=1}^{\ell} Y_{i,x[\mathsf{inp}(i)]} \cdot Y_{\ell+1}.$$

Then, expressing $P_{\mathbf{A},x}$ stratified as powers of g we obtain:

$$P_{\mathbf{A},x} = P_{\mathbf{A},x}^{(0)}(\{Y_i\}_i) + g \cdot P_{\mathbf{A},x}^{(1)}(\{Y_i\}_i) + \ldots + g^{\ell+2} \cdot P_{\mathbf{A},x}^{(\ell+2)}(\{Y_i\}_i)$$

for some polynomials $P^{(j)}_{\mathbf{A},x}(\{Y_i\}_i)$ ($j \in \{0,...,\ell+1\}$). However, by Lemma 4 we have that:

$$P^{(0)}_{\mathbf{A},x} = \rho\widehat{\alpha}_x\mathbf{A}(x)$$

for $\rho \stackrel{\text{def}}{=} \prod_i \det(R_i)$ (or $\rho I = \prod_i R_i^{adj} R_i$) and $\widehat{\alpha}_x \stackrel{\text{def}}{=} \prod_{i=1}^{\ell} \alpha_{i,x_{\mathsf{inp}(i)}}$. Since for $x \in X$ we have that $\mathbf{A}(x) = 0$, the polynomial $P^{(0)}_{\mathbf{A},x}$ is identically 0. Consequently, for each such Type 1 query the attacker receives a new handle to a variable $W_{\mathbf{A},x}$ that can be expressed as follows:

$$W_{\mathbf{A},x} = P_{\mathbf{A},x}/g = P^{(1)}_{\mathbf{A},x} + g \cdot P^{(2)}_{\mathbf{A},x} + ... + g^{\ell+1} \cdot P^{(\ell+2)}_{\mathbf{A},x}.$$

Analogously, the attacker obtains handles $W_{\mathbf{A},\overline{x}}$. After obtaining handles

$$\{(W_{\mathbf{A},x_1}, W_{\mathbf{A},\overline{x}_1}), ...(W_{\mathbf{A},x_m}, W_{\mathbf{A},\overline{x}_m})\}$$

the attacker starts the post-zeroizing phase.

Post-Zeroizing Computation

The goal of post-zeroizing computation is to *find* a polynomial Q^{ann} of degree $poly(\lambda)$ such that following holds for some $b \in \{0,1\}$:

(i) $Q^{\mathsf{ann}}(P^{(1)}_{\mathbf{A}_b,x_1}, P^{(1)}_{\mathbf{A}_b,\overline{x}_1}..., P^{(1)}_{\mathbf{A}_b,x_m}, P^{(1)}_{\mathbf{A}_b,\overline{x}_m}) \equiv 0.$

(ii) $Q^{\mathsf{ann}}(P^{(1)}_{\mathbf{A}_{1-b},x_1}, P^{(1)}_{\mathbf{A}_{1-b},\overline{x}_1}..., P^{(1)}_{\mathbf{A}_{1-b},x_m}, P^{(1)}_{\mathbf{A}_{1-b},\overline{x}_m}) \not\equiv 0.$

Clearly, this leads to an attack on the obfuscation security as $\mathcal{A}$ would receive 0 from the challenger if and only if $Q^{\mathsf{ann}}(P^{(1)}_{\mathbf{A},x_1}, P^{(1)}_{\mathbf{A},\overline{x}_1}..., P^{(1)}_{\mathbf{A},x_m}, P^{(1)}_{\mathbf{A},\overline{x}_m})$ is identically zero, hence it would receive 0 if and only if $\mathbf{A}_b$ is chosen by the challenger in the challenge phase. To find such Q^{ann} the attacker continues as follows. Observe that by Lemma 4, for every $x \in X$ we have that:

$$P^{(1)}_{\mathbf{A},x} = \rho\widehat{\alpha}_x(\boldsymbol{\phi}_{\mathbf{A},x} \cdot \boldsymbol{z}^T)', \tag{1}$$

$$P^{(1)}_{\mathbf{A},\overline{x}} = \rho\widehat{\alpha}_{\overline{x}}(\boldsymbol{\phi}_{\mathbf{A},\overline{x}} \cdot \boldsymbol{z}^T). \tag{2}$$

Next, multiplying the polynomials $P^{(1)}_{\mathbf{A},x}$ and $P^{(1)}_{\mathbf{A},\overline{x}}$ (Eq. 1 and Eq. 2) we get:

$$\widetilde{P}^{(1)}_{\mathbf{A},x} \stackrel{\text{def}}{=} P^{(1)}_{\mathbf{A},x}P^{(1)}_{\mathbf{A},\overline{x}} = \rho^2\widehat{\alpha}\left((\boldsymbol{\phi}_{\mathbf{A},x} \cdot \boldsymbol{z}) \otimes (\boldsymbol{\phi}_{\mathbf{A},\overline{x}} \cdot \boldsymbol{z})\right) \tag{3}$$

$$= \rho^2\widehat{\alpha}\left((\boldsymbol{\phi}_{\mathbf{A},x} \otimes \boldsymbol{\phi}_{\mathbf{A},\overline{x}}) \cdot (\boldsymbol{z}^T \otimes \boldsymbol{z}^T)\right) \tag{4}$$

$$= \rho^2\widehat{\alpha}(\boldsymbol{\psi}_{\mathbf{A},x} \cdot \boldsymbol{z}^T \otimes \boldsymbol{z}^T).$$

where $\widehat{\alpha} \stackrel{\text{def}}{=} \widehat{\alpha}_x\widehat{\alpha}_{\overline{x}}$ is now independent of input x.[15] Similarly we can also have:

$$\widetilde{P}^{(1)}_{\mathbf{A},\overline{x}} \stackrel{\text{def}}{=} P^{(1)}_{\mathbf{A},\overline{x}}P^{(1)}_{\mathbf{A},x} = \rho^2\widehat{\alpha}\left((\boldsymbol{\phi}_{\mathbf{A},\overline{x}} \cdot \boldsymbol{z}) \otimes (\boldsymbol{\phi}_{\mathbf{A},x} \cdot \boldsymbol{z})\right)$$

$$= \rho^2\widehat{\alpha}\left((\boldsymbol{\phi}_{\mathbf{A},\overline{x}} \otimes \boldsymbol{\phi}_{\mathbf{A},x}) \cdot (\boldsymbol{z}^T \otimes \boldsymbol{z}^T)\right)$$

$$= \rho^2\widehat{\alpha}(\boldsymbol{\psi}_{\mathbf{A},\overline{x}} \cdot \boldsymbol{z}^T \otimes \boldsymbol{z}^T).$$

[15] Here, we use the fact that the branching programs are single-input. For multi-input programs we do *not* know how to make $\widehat{\alpha}$ independent of x. The rest of the analysis does not require the programs to be single-input.

However, since field multiplication is commutative, adding we get:

$$\begin{aligned}\widetilde{P}^{(1)}_{\mathbf{A},x} + \widetilde{P}^{(1)}_{\mathbf{A},\overline{x}} = 2P^{(1)}_{\mathbf{A},x}P^{(1)}_{\mathbf{A},\overline{x}} &= \rho^2\widehat{\alpha}(\boldsymbol{\psi}_{\mathbf{A},x}\cdot \boldsymbol{z}^T \otimes \boldsymbol{z}^T) + \rho^2\widehat{\alpha}(\boldsymbol{\psi}_{\mathbf{A},\overline{x}}\cdot \boldsymbol{z}^T \otimes \boldsymbol{z}^T)\\ &= \rho^2\widehat{\alpha}(\boldsymbol{\psi}_{\mathbf{A},x} + \boldsymbol{\psi}_{\mathbf{A},\overline{x}})\cdot(\boldsymbol{z}^T \otimes \boldsymbol{z}^T)\,.\end{aligned}$$

Using the given conditions that $\Psi_{\mathbf{A}_0,X}$ and $\Psi_{\mathbf{A}_1,X}$ have distinct column spaces (and hence distinct left-kernel) the attacker can efficiently compute (e.g. via Gaussian Elimination) a vector $\boldsymbol{v}_{\mathsf{ann}} \in \{0,1\}^{1\times m}$ that belongs to its left-kernel, call it the *annihilating vector*, such that for some $b \in \{0,1\}$ we have:

$$\boldsymbol{v}_{\mathsf{ann}}\cdot\Psi_{\mathbf{A}_b,X} = 0 \qquad \text{but} \qquad \boldsymbol{v}_{\mathsf{ann}}\cdot\Psi_{\mathbf{A}_{1-b},X} \neq 0.$$

The corresponding annihilation polynomial Q^{ann} can be written as:

$$Q^{\mathsf{ann}}_{\boldsymbol{v}_{\mathsf{ann}}}(W_{\mathbf{A},x_1}, W_{\mathbf{A},\overline{x}_1}, \ldots, W_{\mathbf{A},x_m}, W_{\mathbf{A},\overline{x}_m}) = \boldsymbol{v}_{\mathsf{ann}}\cdot\begin{bmatrix} W_{\mathbf{A},x_1}W_{\mathbf{A},\overline{x}_1}\\ \vdots \\ W_{\mathbf{A},x_m}W_{\mathbf{A},\overline{x}_m}\end{bmatrix}.$$

Observe that the coefficient of g^0 in the expression $Q^{\mathsf{ann}}_{\boldsymbol{v}_{\mathsf{ann}}}(W_{\mathbf{A},x_1}, W_{\mathbf{A},\overline{x}_1}, \ldots, W_{\mathbf{A},x_m}, W_{\mathbf{A},\overline{x}_m})$ from above is equal to $Q^{\mathsf{ann}}_{\boldsymbol{v}_{\mathsf{ann}}}(P^{(1)}_{\mathbf{A}_b,x_1}, P^{(1)}_{\mathbf{A}_b,\overline{x}_1}..., P^{(1)}_{\mathbf{A}_b,x_m}, P^{(1)}_{\mathbf{A}_b,\overline{x}_m})$. Moreover this value for $\mathbf{A} = \mathbf{A}_b$ is:

$$Q^{\mathsf{ann}}_{\boldsymbol{v}_{\mathsf{ann}}}(P^{(1)}_{\mathbf{A}_b,x_1}, P^{(1)}_{\mathbf{A}_b,\overline{x}_1}..., P^{(1)}_{\mathbf{A}_b,x_m}, P^{(1)}_{\mathbf{A}_b,\overline{x}_m}) = \boldsymbol{v}_{\mathsf{ann}}\cdot\frac{\Psi_{\mathbf{A}_b,X}}{2}\cdot(\boldsymbol{z}\otimes\boldsymbol{z})^T \equiv 0$$

but for $\mathbf{A}_{1-b}$:

$$Q^{\mathsf{ann}}_{\boldsymbol{v}_{\mathsf{ann}}}(P^{(1)}_{\mathbf{A}_{1-b},x_1}, P^{(1)}_{\mathbf{A}_{1-b},\overline{x}_1}..., P^{(1)}_{\mathbf{A}_{1-b},x_m}, P^{(1)}_{\mathbf{A}_{1-b},\overline{x}_m}) = \boldsymbol{v}_{\mathsf{ann}}\cdot\frac{\Psi_{\mathbf{A}_{1-b},X}}{2}\cdot(\boldsymbol{z}\otimes\boldsymbol{z})^T \not\equiv 0.$$

Hence, the response to Type 2 query is sufficient to distinguish between obfuscation of $\mathbf{A}_b$ and $\mathbf{A}_{1-b}$ in the abstract model. This concludes the proof. ◀

Evaluations of $P^{(0)}_{\mathbf{A},\boldsymbol{x}}$ and $P^{(1)}_{\mathbf{A},\boldsymbol{x}}$

Below we state a lemma without proof (that is deferred to the full version) that described what the terms $P^{(0)}_{\mathbf{A},x}$ and $P^{(1)}_{\mathbf{A},x}$ look like.

▶ **Lemma 4.** *For every $x \in \{0,1\}^n$, we have that:*

$$P^{(0)}_{\mathbf{A},x} = \rho\widehat{\alpha}_x\mathbf{A}(x)\,,$$
$$P^{(1)}_{\mathbf{A},x} = \rho\widehat{\alpha}_x(\boldsymbol{\phi}_{\mathbf{A},x}\cdot\boldsymbol{z}^T),$$

where $\rho \stackrel{\text{def}}{=} \prod_i \det(R_i)$ and $\widehat{\alpha}_x \stackrel{\text{def}}{=} \prod_{i=1}^{\ell}\alpha_{i,x_{\mathsf{inp}(i)}}$ and $\boldsymbol{z}$ is a vector consisting of the random terms $Z_0, Z_{i,b}$, and $Z_{\ell+1}$ used to generate the obfuscation terms $Y_0, Y_{i,b}$, and $Y_{\ell+1}$ in an appropriate sequence.

Extending the Abstract Attack to GGH13 Multilinear Maps

Based on the ideas from Miles et al. we can extend our abstract attacks to actual instantiations with GGH13, that we defer to the full version [4].

6 Example of Partially Inequivalent Circuits

In this section, we show examples of pairs of NC^1 circuits such that the corresponding Barrington-implemented[16] branching programs are partially inequivalent and therefore are subject to the abstract annihilation attacks shown in Section 5. Note that here we extend the notion of partial inequivalence from branching programs to circuits in a natural way. Unless otherwise mentioned, partial inequivalence of circuits specifically imply that the corresponding branching programs generated via applying Barrington's Theorem are partially inequivalent.

6.1 Simple Pairs of Circuits that are Partially Inequivalent

Consider the following pair of circuits (C_0, C_1) each of which implements a boolean function $\{0,1\}^4 \to \{0,1\}$:

$$C_0(x) \stackrel{\text{def}}{=} (x[1] \wedge 1) \bigwedge (x[2] \wedge 0) \bigwedge (x[3] \wedge 1) \bigwedge (x[4] \wedge 0),$$

$$C_1(x) \stackrel{\text{def}}{=} (x[1] \wedge 0) \bigwedge (x[2] \wedge 0) \bigwedge (x[3] \wedge 0) \bigwedge (x[4] \wedge 0).$$

Define the set $X \stackrel{\text{def}}{=} \{0,1\}^4$. Now, we provide an implementation (see the full version [4] for more details on the implementation) in Sage [35] that evaluates the column spaces of matrices produced via applying a Barrington-implementation to the above circuits. The outcome from the implementation led us to conclude the following claim:

▶ **Claim 5.** *Let $\mathbf{A}_{C_0}, \mathbf{A}_{C_1}$ be the Barrington-Implementation of the circuits C_0, C_1 respectively, then we have that:* $\mathsf{colsp}\left(\Psi_{\mathbf{A}_{C_0},X}\right) \neq \mathsf{colsp}\left(\Psi_{\mathbf{A}_{C_1},X}\right)$.

▶ Remark. We emphasize that we use branching programs generated with a particular Barrington-implementation that makes a set of specific choices. We refer the reader to the full version [4] for the details of our implementation. Throughout this section we refer to this particular Barrington-implementation.

The circuits presented above are of constant size. Looking ahead, though, they are partially inequivalent and hence (by Theorem 3) are susceptible to the abstract attack that does not translate to a real-world attack in GGH13 setting immediately. For that we need to consider larger (albeit NC^1) circuits which we construct next based on the above circuits.

6.2 Larger Pairs of Circuits that are Partially Inequivalent

Consider *any* pair of functionally equivalent NC^1 circuits (D_0, D_1) and an input $x^\star \in \{0,1\}^n$ such that $D_0(x^\star) = D_1(x^\star) = D_0(\overline{x^\star}) = D_1(\overline{x^\star}) = 0$. Now define the circuits E_0, E_1 each of which computes a boolean function $\{0,1\}^{n+4} \to \{0,1\}$ as follows:

$$E_0(y) \stackrel{\text{def}}{=} \neg C_0(x) \wedge D_0(x'),$$

$$E_1(y) \stackrel{\text{def}}{=} \neg C_1(x) \wedge D_1(x'),$$

($\neg C$ is the circuit C with output negated) such that for each $y \in \{0,1\}^{n+4}$ we have $y = x \circ x'$ ($\circ$ denotes concatenation) where $x \in \{0,1\}^4$ and $x' \in \{0,1\}^n$. Define the input-sequence $Y \stackrel{\text{def}}{=} \{x \circ x^\star \mid x \in \{0,1\}^4\}$ (consisting of 16 inputs). Then we show the following statement.

[16] Recall that by Barrington-implementation of a circuit we mean the single-input branching program produced as a result of Barrington Theorem on the circuit. Also we implicitly assume that the branching programs are input-oblivious.

▶ **Lemma 6.** *Let* $\mathbf{A}_{E_0}, \mathbf{A}_{E_1}$ *be the Barrington-implementations of* E_0, E_1 *respectively, then we have that:* $\mathsf{colsp}\left(\Psi_{\mathbf{A}_{E_0},Y}\right) \neq \mathsf{colsp}\left(\Psi_{\mathbf{A}_{E_1},Y}\right)$.

6.3 Partially Inequivalent Universal Circuits

In this section we present constructions of (NC^1) universal circuits that, when compiled with two arbitrary distinct (NC^1) but functionally equivalent circuits as inputs, then the obfuscations of the Barrington-implementation of the compiled circuits are distinguishable by the abstract attack.

▶ **Theorem 7.** *There exists a family of* NC^1 *universal circuits* $\mathcal{U} = \{U_1, U_2, \ldots, U_v\}$ *of size* $v = O(poly(\lambda))$ *such that: given two arbitrary functionally equivalent* NC^1 *circuits* G_0, G_1 *that computes arbitrary boolean function* $\{0,1\}^n \to \{0,1\}$ *satisfying (i)* $|G_0| = |G_1| = v$ *and (ii) there exists an input* $x^\star$ *such that* $G_0(x^\star) = G_1(x^\star) = G_0(\overline{x^\star}) = G_1(\overline{x^\star}) = 0$*; then for at least one* $i \in [v]$ *the Barrington-implementations of the circuits* $U_i[G_0]$ *and* $U_i[G_1]$ *are partially inequivalent.*

Abstract

De, Trevisan and Tulsiani [CRYPTO 2010] show that every distribution over n-bit strings which has constant statistical distance to uniform (e.g., the output of a pseudorandom generator mapping $n-1$ to n bit strings), can be distinguished from the uniform distribution with advantage ϵ by a circuit of size $O(2^n\epsilon^2)$.

We generalize this result, showing that a distribution which has less than k bits of min-entropy, can be distinguished from any distribution with k bits of δ-smooth min-entropy with advantage ϵ by a circuit of size $O(2^k\epsilon^2/\delta^2)$. As a special case, this implies that any distribution with support at most 2^k (e.g., the output of a pseudoentropy generator mapping k to n bit strings) can be distinguished from any given distribution with min-entropy $k+1$ with advantage ϵ by a circuit of size $O(2^k\epsilon^2)$.

Our result thus shows that pseudoentropy distributions face basically the same non-uniform attacks as pseudorandom distributions.

1 Introduction

De, Trevisan and Tulsiani [2] show a non-uniform attack against any pseudorandom generator (PRG) which maps $\{0,1\}^{n-1} \to \{0,1\}^n$. For any $\epsilon \geq 2^{-n/2}$, their attack achieves distinguishing advantage ϵ and can be realized by a circuit of size $O\left(2^n\epsilon^2\right)$. Their attack doesn't even need the PRG to be efficiently computable.

In this work we consider a more general question, where we ask for attacks distinguishing a distribution from any distribution with slightly higher min-entropy. We generalize [2], showing a non-uniform attack which, for any $\epsilon, \delta > 0$, distinguishes any distribution with $< k$ bits of min-entropy from any distribution with k bits of δ-smooth min-entropy with advantage ϵ, and where the distinguisher is of size $O(2^k\epsilon^2/\delta^2)$. As a corollary we recover the [2] result, showing that the output of any pseudoentropy generator $\{0,1\}^k \to \{0,1\}^n$ can be distinguished from any variable with min-entropy $k+1$ with advantage ϵ by circuits of size $O(2^k\epsilon^2)$.

- From a theoretical perspective, we prove where the separation between pseudoentropy and smooth min-entropy lies, by classifying how powerful computationally bounded adversaries can be so they can still be fooled to "see" more entropy than there really is.

- From a more practical perspective, our result shows that using pseudoentropy instead of pseudorandomness (which for many applications is sufficient and allows for saving in entropy *quantity* [3]), will not give improvements in terms of *quality* (i.e., the size and advantage of distinguishers considered), at least not against generic non-uniform attacks.

1.1 Notation and Basic Definitions

Two variables X and Y are (s,ϵ) indistinguishable, denoted $X \sim_{s,\epsilon} Y$, if for all boolean circuits D of size $|D| \leq s$ we have $|\Pr[D(X)=1] - \Pr[D(Y)=1]| \leq \epsilon$. The statistical distance of X and Y is $d_1(X;Y) \stackrel{\mathsf{def}}{=} \sum_x |P_X(x) - P_Y(x)|$ (where $P_X(x) \stackrel{\mathsf{def}}{=} \Pr[X=x]$), the Euclidean distance of X and Y is $d_2(P_X;P_Y) \stackrel{\mathsf{def}}{=} \sqrt{\sum_x (P_X(x)-P_Y(x))^2}$. A variable X has min-entropy k if it doesn't take any particular outcome with probability greater 2^{-k}, it has δ-smooth min-entropy k [6], if it's δ close to some distribution with min-entropy k. X has k bits of HILL pseudoentoentry of quality (s,ϵ) if there exists a Y with min-entropy k that is (s,ϵ) indistinguishable from X, we use the following standard notation for these notions:

min-entropy: $\mathsf{H}_\infty(X) \stackrel{\mathsf{def}}{=} -\log \max_x (\Pr[X=x])$.

smooth min-entropy: $\mathsf{H}^\delta_\infty(X) \stackrel{\mathsf{def}}{=} \max_{Y, d_1(X;Y)\leq\delta} \mathsf{H}_\infty(Y)$.

HILL pseudoentropy: $\mathsf{H}^{\mathsf{HILL}}_{s,\epsilon}(X) \stackrel{\mathsf{def}}{=} \max_{Y, Y\sim_{(s,\epsilon)}X} \mathsf{H}_\infty(Y)$.

1.2 Our Contribution

In this work give generic non-uniform attacks on pseudoentropy distributions. A seemingly natural goal is to consider a distribution X with $\mathsf{H}_\infty(X) \leq k$ bits of min-entropy, strictly larger $\mathsf{H}^{\mathsf{HILL}}_{s,\epsilon}(X) \geq k+1$ bits of HILL entropy, and then give an upper bound on s in terms of ϵ. This does not work as there are X where $\mathsf{H}_\infty(X) \ll \mathsf{H}^\delta_\infty(X)$,[1] and as by definition $\mathsf{H}^\delta_\infty(X) = \mathsf{H}^{\mathsf{HILL}}_{\infty,\delta}(X)$, we can have a large entropy gap $\mathsf{H}^{\mathsf{HILL}}_{\infty,\delta}(X) - \mathsf{H}_\infty(X)$ even when considering unbounded adversaries against HILL entropy. For this reason, in our main technical result 1 below, we must consider distributions with bounded *smooth* min-entropy. This makes the statement of the lemma somewhat technical. In practice, the distributions considered often have bounded support, for example because they were generated from a short seed by a deterministic process (like a pseudorandom generator). In this case we can drop the smoothness requirement as stated in Theorem 2 below.

▶ **Lemma 1** (Nonuniform attacks against pseudoentropy). *Suppose that $X \in \{0,1\}^n$ does not have k bits of δ-smooth min-entropy, i.e., $\mathsf{H}^\delta_\infty(X) < k$, then for any ϵ we have*

$$\mathsf{H}^{\mathsf{HILL}}_{\tilde{O}(2^k\epsilon^2\delta^{-2}),\epsilon}(X) < k$$

where $\tilde{O}(\cdot)$ hides a factor linear in n.

▶ **Theorem 2.** *Let $f : \{0,1\}^k \to \{0,1\}^n$ be a deterministic (not necessarily efficient) function. Then we have*

$$\mathsf{H}^{\mathsf{HILL}}_{\tilde{O}(2^k\epsilon^2),\epsilon}(f(U_k)) \leq k+1.$$

more generally, for any X over $\{0,1\}^n$ with support of size $\leq 2^k$

$$\mathsf{H}^{\mathsf{HILL}}_{\tilde{O}(2^k\epsilon^2),\epsilon}(X) \leq k+1.$$

[1] Consider an X which is basically uniform over $\{0,1\}^n$, but has mass δ on one particular point, then $\log \delta^{-1} = \mathsf{H}_\infty(X) \ll \mathsf{H}^\delta_\infty(X) = n$.

▶ Remark (Concluding best attacks against PRGs). For the special case $n = k + 1$ we recover the bound for pseudo*random* generators from [2].

Proof of Theorem 2. The theorem follows from Lemma 1 when $\delta = 1/2$; consider any X with support of size $\leq 2^k$, then $\mathsf{H}^{\delta}_{\infty}(X) \leq k + 1$, as no matter how we cut probability mass of $1 - \delta = 1/2$ over 2^k elements, one element will have the weight at least 2^{-k-1}. ◀

1.3 Proof Outline

1.3.1 A Weaker Result as a Ball-Bins Problem

We outline the proof of a somewhat weakened version of Theorem 2 in the language of balls and bins. For every Y of min-entropy $k' = k + \Omega(1)$ we want to distinguish Y from $X = f(U_k)$. Suppose for simplicity that Y is flat and f is injective, so that X is also flat. Our strategy will be to hash the points randomly into two bins and take advantage of the fact that the *average maximum load* is closer to $\frac{1}{2}$ when we sample from Y than when drawing from X. The reason is that Y has more balls, so by the law of large numbers, we expect the load to be "more concentrated" around the mean.

Think of throwing balls (inputs x) into two bins (labeled by -1 and 1). If the balls come from the support of X, the expected maximum load (over two bins) equals $\approx 2^{k-1} + \sqrt{2/\pi} \cdot 2^{k/2}$. Similarly, if the balls come from the support of Y, then maximum load is $2^{k'-1} + \sqrt{2/\pi} \cdot 2^{k'/2}$. In terms of the average load (the load normalized by the total number of balls):

$$\mathsf{AverageMaxLoad}(X) \approx 0.5 + \sqrt{2/\pi} \cdot 2^{-k/2} \quad \text{w.h.p. when drawing from } X\,,$$
$$\mathsf{AverageMaxLoad}(Y) \approx 0.5 + \sqrt{2/\pi} \cdot 2^{-k'/2} \quad \text{w.h.p. when drawing from } Y\,.$$

As $k' = k + \Omega(1)$ we obtain (with good probability):

$$\mathsf{AverageMaxLoad}(X) - \mathsf{AverageMaxLoad}(Y) = \Omega(2^{-k/2}).$$

Letting D be one of these bins assignments we obtain a distinguisher with advantage $\epsilon = \Omega(2^{-k/2})$. To generate the assignments efficiently we relax the assumption about choosing bins and assume only that the choices of bins are independent for any group of $\ell = 4$ balls. The fourth moment method allows us to keep sufficiently good probabilistic guarantees on the maximum load.

1.3.2 The General Case by Random Walk Techniques

1.3.2.1 A high-level outline and comparison to [2]

Below in Figure 1 we sketch the flow of our argument.

Our starting point is the proof from [2]. They use the fact that a random mapping $\mathsf{D} : \{0,1\}^n \to \{-1,1\}$ likely distinguishes any two distributions X and Y over $\{0,1\}^n$ with advantage being the Euclidean distance $d_2(X;Y) \stackrel{\mathsf{def}}{=} \sqrt{\sum_x (P_X(x) - P_Y(x))^2}$.

For any X and Y with constant statistical distance $\sum_x |P_X(x) - P_Y(x)| = \Theta(1)$ (which is the case for the PRG setting where $Y = U_n$ and $X = PRG(U_{n-1})$) this yields a bound $\Omega\left(2^{-\frac{n}{2}}\right)$. This bound can be then amplified, at the cost of extra advice, by partitioning the domain $\{0,1\}^n$ and combining corresponding advantages (advice basically encodes if there is a need for flipping the output). Finally one can show that 4-wise independence provides enough randomness for this argument, which makes sampling D efficient. Our argument deviates from this approach in two important aspects.

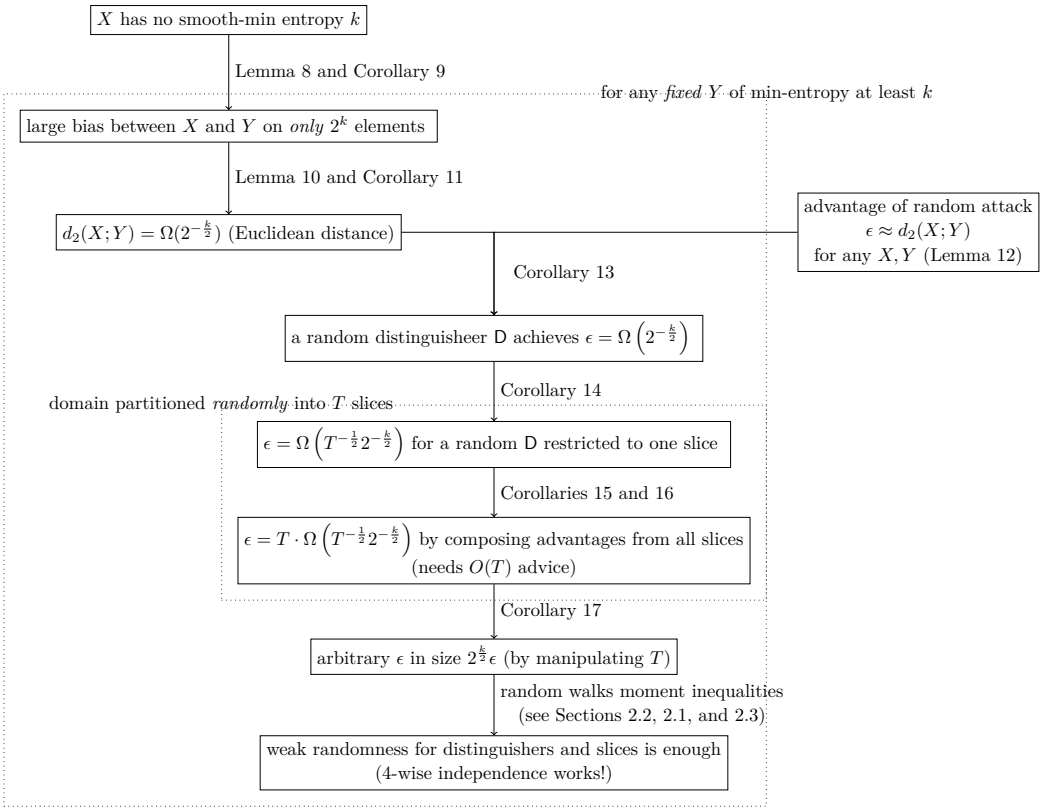

Figure 1 The map of our proof.

The first difference is that in the pseudoentropy case we can improve the advantage from $\Omega\left(2^{-\frac{n}{2}}\right)$, where n is the logarithm of the support of the variables considered, to $\Omega\left(2^{-\frac{k}{2}}\right)$, where k is the min-entropy of the variable we want to distinguish from. The reason is that being statistically far from any k-bit min-entropy distributions implies a *large bias on already* 2^k *elements*. This fact (see Lemma 8 and Corollary 9, and also Figure 3) is a new characterization of smooth min-entropy of independent interest.

The second subtlety arises when it comes to amplify the advantage over the partition slices. For the pseudorandomness case it is enough to split the domain in a deterministic way, for example by fixing prefixes of n-bit strings, in our case this is not sufficient. For us a "good" partition must shatter the 2^k-element high-biased set, which can be arbitrary. Our solution is to use *random partitions*, in fact, we show that using 4-universal hashing is sufficient. Generating base distinguishers and partitions at the same time makes probability calculations more involved.

Technical calculations are based on the fourth moment method, similarly as in [2]. The basic idea is that for settings where the second and fourth moment are easy to compute (e.g. sums of independent symmetric random variables) we can obtain good upper and lower bounds on the first moment. In the context of algorithmic applications these techniques are usually credited to [1]. Interestingly, exploiting natural relations to *random walks*, we show that calculations immediately follow by adopting classical (almost one century old) tools and results [5, 4]. Our technical novelty is an application of moment inequalities due to Marcinkiewicz-Zygmund and Paley-Zygmund, which allow us to prove slightly more than just the existence of an attack. Namely we generate it with constant success probability.

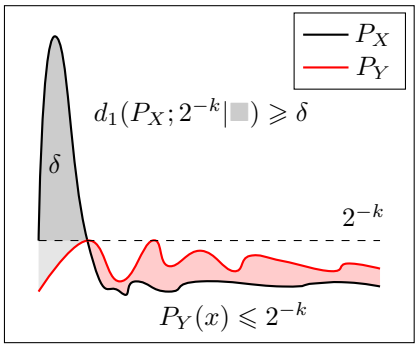

Figure 2 An intuition behind the attack. Random ± 1-weights make the bias equal to the ℓ_2-distance of P_X and P_Y. This distance can be bounded in terms of the ℓ_1 distance, which concentrates mass difference δ on less than 2^k elements (the region in gray).

1.3.2.2 Advantage $\Omega(2^{-k/2})$

Consider any X with δ-smooth min-entropy smaller than k. This requirement can be seen as a statement about the "shape" of the distribution. Namely, the mass of X that is above the threshold 2^{-k} equals at least δ, that is

$$\sum_x \max(P_X(x) - 2^{-k}, 0) \geqslant \delta.$$

For an illustration see Figure 2.

We construct our attack based on this observation. Define the advantage of a function D for distributions X and Y as

$$\mathsf{Adv}^{\mathsf{D}}(X;Y) = \left| \sum_x \mathsf{D}(x)(P_X(x) - P_Y(x)) \right|$$

(writing also $\mathsf{Adv}^{\mathsf{D}}_S$ when the summation is restricted to a subset S). Consider a random distinguisher $\mathsf{D} : \{0,1\}^n \to \{-1,1\}$. Random variables $\mathsf{D}(x)$ for different x are independent, have zero-mean and second moment equal to 1. Therefore the expected square of of the advantage, over the choice of D, equals

$$\mathbb{E}\left[\left(\mathsf{Adv}^{\mathsf{D}}(X;Y)\right)^2\right] = \mathbb{E}\left|\sum_x \mathsf{D}(x)(P_X(x) - P_Y(x))\right|^2 = \sum_x (P_X(x) - P_Y(x))^2 .$$

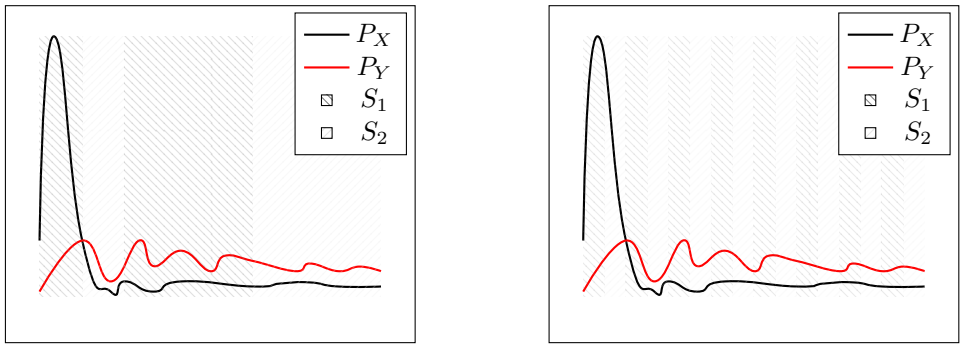
Let S be the set of x such that $P_X(x) > 2^{-k}$. For any Y of min-entropy at least k we obtain

$$\sum_{x\in S}(P_X(x) - P_Y(x))^2 \geqslant \sum_{x\in S}(P_X(x) - 2^{-k})^2 \geqslant |S|^{-1}\left(\sum_{x\in S}\left(P_X(x) - 2^{-k}\right)\right)^2 \geqslant 2^{-k}\delta^2$$

where the first inequality follows because $P_Y(x) \leqslant 2^{-k} < P_X(x)$ for $x \in S$, the second inequality is by the standard inequality between the first and second norm, and the third inequality follows because we showed that $\Pr[X \in S] \geqslant |S| \cdot 2^{-k} + \delta$ (illustrated in Figure 2) which also implies $|S|^{-1} \geqslant 2^{-k}$.

By the previous formula on the expected squared advantage this means that

$$\mathbb{E}\left[\left(\mathsf{Adv}^{\mathsf{D}}(X;Y)\right)^2\right] \geqslant 2^{-k}\delta^2$$



(a) An example of a "bad" partition. Almost all advantage is captured by one partition slice S_1.

(b) An example of a "good" partition. The advantage is evenly distributed among slices S_1, S_2.

Figure 3 Illustration of good and bad partitions.

for at least one choice of D. This implies

$$\mathsf{Adv}^{\mathsf{D}}(X;Y) \geqslant 2^{-\frac{k}{2}}\delta.$$

A random D as defined would be of size exponential in n, but since we used only the second moment in calculations, it suffices to generate $\mathsf{D}(x)$ as pairwise independent random variables. By assuming 4-wise independence – which can be computed by $O(n^2)$ size circuits – we can prove slightly more, namely that a constant fraction of generated D's are good distinguishers. This property will be important for the next step, where we amplify the advantage assuming larger distinguishers.

1.3.2.3 Leveraging the advantage by slicing the domain

Consider a random and equitable partition $\{S_i\}_{i=1}^{T}$ of the set $\{0,1\}^n$. From the previous analysis we know that a random distinguisher achieves advantage $\epsilon = d_2(P_X;P_Y)$ over the whole domain. Note that (for any, not necessarily random partition $\{S_i\}_i$) we have

$$\left(d_2(P_X;P_Y)\right)^2 = \sum_{i=1}^{T} \left(d_2(P_X;P_Y|S_i)\right)^2$$

where $d_2(P_X;P_Y|S_i)$ is the restriction of the distance to the set S_i (by restricting the summation to S_i). From a random partition we expect the mass difference between P_X and P_Y to be *distributed evenly* among the partition slices (see Figure 3(b)). Based on the last equation, we expect

$$d_2(P_X;P_Y|S_i) \approx \frac{d_2(P_X;P_Y)}{\sqrt{T}}$$

to hold with high probability over $\{S_i\}_i$.

In fact, if the mass difference is not well balanced amongst the slices (in the extreme case, concentrated on one slice) our argument will not offer any gain over the previous construction (see Figure 3(a)).

By applying the previous argument to individual slices, for every i we can obtain an advantage $\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \Omega\left((T^{-\frac{1}{2}}2^{-\frac{k}{2}})\delta\right)$ when restricted to the set S_i (with high probability

over the choice of D and $\{S_i\}_i$). Now if the sets S_i are *efficiently recognizable*, we can combine them into a better distinguisher. Namely for every i we chose a value $\beta_i \in \{-1,1\}$ such that D's advantage (before taking the absolute value) restricted to S_i has sign β_i, and set

$$\hat{\mathsf{D}}(x) = \beta_i \mathsf{D}(x), \text{ where } i \text{ is such that } x \in S_i,$$

then the advantage equals (with high probability over D and the S_i's)

$$\mathsf{Adv}^{\hat{\mathsf{D}}}(X;Y) = \sum_{i=1}^{T} \mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \Omega\left(T^{\frac{1}{2}} 2^{-\frac{k}{2}} \delta\right).$$

We need to specify a 4-wise independent hash for D, another 4-wise independent hash for deciding in which of the T slices an element lies, and T bits to encode the β_i's. Thus for a given T the size of $\hat{\mathsf{D}}$ will be $T + \tilde{O}(n)$. Using the above equation, we then get a smooth tradeoff $s = O(2^k \epsilon^2 \delta^{-2})$ between the advantage ϵ and the circuit size s. This discussion shows that to complete the argument we need the following two properties of the partition (a) the mass difference between P_X and P_Y is (roughly) equidistributed among slices and (b) the membership in partition slices can be efficiently decided.

1.3.2.4 Slicing using 4-wise independence

To complete the argument, we assume that T is a power of 2, and generate the slicing by using a 4-universal hash function $h : \{0,1\}^n \to \{0,1\}^{\log T}$. The i-th slice S_i is defined as $\{x \in \{0,1\}^n : h(x) = i\}$. These assumptions are enough to prove that

$$\mathbb{E}\, \mathsf{Adv}^{\hat{\mathsf{D}}}_{S_i}(X;Y) = \Omega\left(T^{-\frac{1}{2}} d_2(P_X;P_Y)\right) = \Omega\left(T^{-\frac{1}{2}} 2^{-\frac{k}{2}} \delta\right).$$

Interestingly, the expected advantage (left-hand side) cannot be computed directly. The trick here is to bound it in terms of the second and fourth moment. The above inequality, coupled with bounds on second moments of the advantage $\mathsf{Adv}^{\hat{\mathsf{D}}}_{S_i}$ (obtained directly), allows us to prove that

$$\Pr\left[\sum_{i=1}^{T} \mathsf{Adv}^{\hat{\mathsf{D}}}_{S_i} \geqslant \Omega(1) \cdot T^{\frac{1}{2}} 2^{-\frac{k}{2}} \delta\right] > \Omega(1).$$

This shows that there exists the claimed distinguisher $\hat{\mathsf{D}}$. In fact, a *constant fraction* of generated (over the choice of D and $\{\S_i\}_i$) distinguishers $\hat{\mathsf{D}}$'s works.

1.3.2.5 Random walks

From a technical point of view, our method involves computing higher moments of the advantages to obtain concentration and anti-concentration results. The key observation is that the advantage written down as

$$\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \left|\sum_x (P_X(x) - P_Y(x)) \mathbf{1}_{S_i}(x) \mathsf{D}(x)\right|$$

which can be then studied as a *random walk*

$$\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \left|\sum_x \xi_{i,x}\right|$$

with zero-mean increments $\xi_{i,x} = (P_X(x) - P_Y(x)) \mathbf{1}_{S_i}(x) \mathsf{D}(x)$. The difference with respect to classical model is that the increments are only ℓ-wise independent (for $\ell = 4$). However, that classical moment bounds still apply (see Sections 2.2 and 2.3 for more details).

2 Preliminaries

2.1 Interpolation Inequalities

Interpolation inequalities show how to bound the p-th moment of a random variable if we know bounds on one smaller and one higher moment. The following result is known also as *log-convexity of L_p norms*, and can be proved by the Hölder Inequality.

▶ **Lemma 3** (Moments interpolation). *For any $p_1 < p < p_2$ and any bounded random variable Z we have*

$$\|Z\|_p \leqslant (\|Z\|_{p_1})^{\theta} (\|Z\|_{p_2})^{1-\theta}$$

where θ is such that $\frac{\theta}{p_1} + \frac{1-\theta}{p_2} = \frac{1}{p}$, and for any r we define $\|Z\|_r = (\mathbb{E}\,|Z|^r)^{\frac{1}{r}}$.

Alternatively, we can *lower bound* a moment given *two higher moments*. This is very useful when higher moments are easier to compute. In this work will bound first moments from below when we know the second and the fourth moment (which are easier to compute as they are even-order moments)

▶ **Corollary 4.** *For any bounded Z we have $\mathbb{E}\,|Z| \geqslant \frac{(\mathbb{E}\,|Z|^2)^{\frac{3}{2}}}{(\mathbb{E}\,|Z|^4)^{\frac{1}{2}}}$.*

2.2 Moments of random walks

For a random walk $\sum_x \xi(x)$, where $\xi(x)$ are independent with zero-mean, we have good control over the moments, namely $\mathbb{E}\,|\sum_x \xi(x)|^p = \Theta(1) \cdot (\sum_x \mathrm{Var}(\xi(x)))^{\frac{p}{2}}$ where constants depend on p. This result is due to Marcinkiewicz and Zygmund [5] who extended the former result of Khintchine [4]. Below we notice that for *small moments* p it suffices to assume only p-wise independence (most often used versions assume fully independence)

▶ **Lemma 5** (Strengthening of Marcinkiewicz-Zygmund's Inequality for $p = 4$). *Suppose that $\{\xi(x)\}_{x\in\mathcal{X}}$ are 4-wise independent, with zero mean. Then we have*

$$\frac{1}{\sqrt{3}} \left(\sum_{x\in\mathcal{X}} \mathrm{Var}(\xi(x))\right)^{\frac{1}{2}} \leqslant \mathbb{E}\left|\sum_{x\in\mathcal{X}} \xi(x)\right| \leqslant \left(\sum_{x\in\mathcal{X}} \mathrm{Var}(\xi(x))\right)^{\frac{1}{2}},$$

$$\mathbb{E}\left|\sum_{x\in\mathcal{X}} \xi(x)\right|^2 = \sum_{x\in\mathcal{X}} \mathrm{Var}(\xi(x)),$$

$$\left(\sum_{x\in\mathcal{X}} \mathrm{Var}(\xi(x))\right)^2 \leqslant \mathbb{E}\left|\sum_{x\in\mathcal{X}} \xi(x)\right|^4 \leqslant 3\left(\sum_{x\in\mathcal{X}} \mathrm{Var}(\xi(x))\right)^2.$$

The proof appears in Section 4.1.

2.3 Anticontentration bounds

▶ **Lemma 6** (Paley-Zygmund Inequality). *For any positive random variable Z and a parameter $\theta \in (0,1)$ we have*

$$\Pr\left[Z > \theta\,\mathbb{E}\,Z\right] \geqslant (1-\theta)^2 \frac{(\mathbb{E}\,Z)^2}{\mathbb{E}\,Z^2}.$$

By applying Lemma 6 to the setting of Lemma 5, and choosing $\theta = \frac{1}{\sqrt{3}}$ we obtain:

▶ **Corollary 7** (Anticoncentration for walks with 4-wise independent increments). *Suppose that* $\{\xi(x)\}_{x\in\mathcal{X}}$ *are* 4*-wise independent with zero-mean, then we have*

$$\Pr\left[\left|\sum \xi(x)\right| > \frac{1}{3}\left(\sum \mathrm{Var}(\xi(x))\right)^{\frac{1}{2}}\right] > \frac{1}{17}.$$

where the summation is over $x \in \mathcal{X}$.

3 Proof of Lemma 1

▶ **Lemma 8** (Characterizing smooth min-entropy). *For any random variable* X *with values in a finite set* $\mathcal{X}$*, any* δ *and* k *we have the following equivalence*

$$H_\infty^\delta(X) \geqslant k \iff \sum_{x\in\mathcal{X}} \max\left(P_X(x) - 2^{-k}, 0\right) \leqslant \delta.$$

The proof appears in Section 4.2. We will work with the following equivalent statement

▶ **Corollary 9** (No smooth min-entropy k implies bias w.r.t. distributions of min-entropy k over at most 2^k elements). *We have* $\mathsf{H}_\infty^\delta(X) < k$ *if and only if there exists a set* S *of at most* 2^k *elements such that*

$$\sum_{x\in S} |P_X(x) - P_Y(x)| > \delta$$

for all Y *of min-entropy at least* k.

Proof of Corollary 9. The direction $\Longleftarrow$ trivially follows by the definition of smooth min-entropy. Now assume $\mathsf{H}_\infty^\delta(X) < k$. Let S be the set of all x such that $P_X(x) > 2^{-k}$, then $|S| < 2^k$, and moreover by Lemma 8 we have $\sum_{x\in S}\left(P_X(x) - 2^{-k}\right) > \delta$. In particular for any Y of min-entropy k (i.e., $P_Y(x) \leqslant 2^{-k}$ for all x)

$$\sum_{x\in S} (P_X(x) - P_Y(x)) > \delta\,. \qquad \blacktriangleleft$$

▶ **Lemma 10** (Bias implies Euclidean distance). *For any distributions* P_X, P_Y *on* $\mathcal{X}$ *and any subset* S *of* $\mathcal{X}$ *we have*

$$\left(\sum_{x\in S} (P_X(x) - P_Y(x))^2\right)^{\frac{1}{2}} > |S|^{-1/2} \sum_{x\in S} |P_X(x) - P_Y(x)|\,.$$

Proof. By the Jensen Inequality we have

$$|S|^{-1}\left(\sum_{x\in S} (P_X(x) - P_Y(x))^2\right) > \left(|S|^{-1}\sum_{x\in S} |P_X(x) - P_Y(x)|\right)^2$$

which is equivalent to the statement. ◀

▶ **Corollary 11** (No smooth min-entropy implies Euclidean distance to min-entropy distributions). *Suppose that* $\mathsf{H}_\infty^\delta(X) < k$*. Then for any* Y *of min-entropy at least* k *we have* $\left(\sum_x |P_X(x) - P_Y(x)|^2\right)^{\frac{1}{2}} > 2^{-\frac{k}{2}}\delta$.

Proof of Corollary 11. It suffices to combine Lemma 10 and Corollary 9. ◀

By Corollary 7 we conclude that the advantage of a random distinguisher for any two measures (in our case P_X and P_Y) equals the Euclidean distance.

▶ **Lemma 12** (The advantage of a random distinguisher equals the Euclidean distance). *Let $\{\mathsf{D}(x)\}_{x\in\{0,1\}^n}$ be 4-wise independent as indexed by x and such that $\mathsf{D}(x)$ outputs a random element from $\{-1,1\}$. Then for any set S we have*

$$\left|\sum_{x\in S}\mathsf{D}(x)(P_X(x)-P_Y(x))\right| > \frac{1}{3}\cdot d_2(P_X;P_Y)$$

with probability $\frac{1}{17}$ over the choice of D (the result actually holds for any measures in place of P_X, P_Y).

For our case, that is the setting in Lemma 10, we obtain

▶ **Corollary 13** (A random attack achieves $\Omega\left(2^{-k}\delta\right)$ with significant probability). *For X,Y as in Corollary 11, and D as in Lemma 12 we have $\mathsf{Adv}^{\mathsf{D}}(X;Y) \geq \frac{1}{3}\cdot 2^{-\frac{k}{2}}\delta$ w.p. $\frac{1}{17}$ over D.*

3.1 Partitioning the domain into T slices

Let $h : \{0,1\}^n \to [1\ldots 2^t]$, where $t = \lceil \log T \rceil$, be a 4-universal hash function. Define $S_i = \{x : h(x) = i\}$, $\Delta(x) = P_X(x) - P_Y(x)$ and consider advantages on slices S_i

$$\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \left|\sum_x \Delta(x)\mathsf{D}(x)\mathbf{1}_{S_i}(x)\right| .$$

The following corollary shows that on each of our T slices, we get the advantage $T^{-\frac{1}{2}}2^{-\frac{k}{2}}\delta$. The proof appears in Section 4.3.

▶ **Corollary 14** ((Mixed) moments of slice advantages). *For D, $\{S_u\}_u$ as above and every i,j*

$$\mathbb{E}_{\mathsf{D},\{S_u\}_u}\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) \geqslant 3^{-\frac{1}{2}}T^{-\frac{1}{2}}\cdot d_2\left(P_X;P_Y\right),$$
$$\mathbb{E}_{\mathsf{D},\{S_u\}_u}\left(\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y)\,\mathsf{Adv}^{\mathsf{D}}_{S_j}(X;Y)\right) \leqslant T^{-1}\cdot d_2(P_X;P_Y)^2,$$

(the statement is valid for arbitrary measures in place of P_X, P_Y).

Denote $Z = \sum_i \mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y)$. Using Lemma 6 with $\theta = \frac{1}{\sqrt{3}}$ where we compute $\mathbb{E}\,Z^2$ and $\mathbb{E}\,Z$ according to Corollary 14 we obtain $\Pr\left[|Z| > \frac{1}{\sqrt{3}}\cdot\mathbb{E}\,|Z|\right] \geqslant \frac{1}{17}$. Bounding once again $\mathbb{E}\,|Z|$ as in Corollary 14 we get

▶ **Corollary 15** (Total advantage on all partition slices). *For X,Y as in Corollary 11, D and S_i defined above we have*

$$\Pr_{\mathsf{D},\{S_u\}_u}\left[\sum_{i=1}^{T}\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) \geqslant \frac{1}{3}\cdot T^{\frac{1}{2}}2^{-\frac{k}{2}}\delta\right] \geqslant \frac{1}{17}$$

(for general X,Y the lower bound is $\Omega(1)\cdot T^{\frac{1}{2}}\cdot d_2(P_X;P_Y)$).

The corollary shows that the *total absolute advantage* over all partition slices, is as expected. Since $\{S_i\}_i$ is a partition we have

$$\sum_{i=1}^{T}\mathsf{Adv}^{\mathsf{D}}_{S_i}(X;Y) = \sum_{i=1}^{T}\left|\sum_{x\in S_i}\left(P_X(x)-P_Y(x)\right)\mathsf{D}(x)\right| = \sum_x\left(P_X(x)-P_Y(x)\right)\mathsf{D}(x)\beta(x)$$

where for $\beta_i \stackrel{def}{=} \text{sgn}\left(\sum_{x\in S_i}(P_X(x')-P_Y(x))\,\mathsf{D}(x)\right)$ (the sign of the advantage on the i-th slice) we define $\beta(x)=\beta_i$ where S_i contains x. This shows that by "flipping" the distinguisher output on the slices we achieve the sum of individual advantages. Since the bit $\beta(x)$ can be computed with $O(T)+\tilde{O}(n)$ advice (the complexity of the function $i\to\beta_i$ plus the complexity of finding i for a given x) we obtain

▶ **Corollary 16** (Computing total advantage by one distinguisher). *For X,Y as in Corollary 11, D and $\{S_i\}_i$ defined above there exists a modification to D which in time $\tilde{O}(n)$ and advice $O(T)$ achieves advantage $\frac{1}{3}\cdot T^{\frac{1}{2}}2^{-\frac{k}{2}}\delta$ with probability $\frac{1}{17}$.*

Finally by setting $\epsilon = T^{\frac{1}{2}}2^{-\frac{k}{2}}\delta$ and manipulating T we arrive at

▶ **Corollary 17** (Continue tradeoff). *For any ϵ there exists T such that the distinguisher in Corollary 16 has advantage ϵ and circuit complexity $s=O\left(2^k\epsilon^2\delta^{-2}\right)$.*

4 Omitted Proofs

4.1 Proof of Lemma 5 (Strengthening of Marcinkiewicz-Zygmund's Inequality for $p=4$)

Let $Z=\sum_x \xi(x)$. Since $\xi(x)$ are (in particular) 2-wise independent with zero mean, we get

$$\mathbb{E}\left(\sum_x \xi(x)\right)^2 = \sum_{x,y}\mathbb{E}\left(\xi(x)\xi(y)\right) = \sum_{x=y}\mathbb{E}\left(\xi(x)\xi(y)\right) = \sum_x \text{Var}(\xi(x))\,,$$

(the summation taken over $x,y\in\mathcal{X}$). The fourth moment is somewhat more complicated

$$\begin{aligned}
\mathbb{E}\left(\sum_x \xi(x)\right)^4 &= \sum_{x_1,x_2,x_3,x_4}\mathbb{E}\left(\xi(x_1)\xi(x_2)\xi(x_3)\xi(x_4)\right)\\
&= \sum_{x_1=x_2=x_3=x_4}\mathbb{E}\left(\xi(x_1)\xi(x_2)\xi(x_3)\xi(x_4)\right)+\\
&\quad +3\sum_{x_1=x_2\neq x_3=x_4}\mathbb{E}\left(\xi(x_1)\xi(x_2)\xi(x_3)\xi(x_4)\right)\\
&= \sum_x \mathbb{E}\,\xi(x)^4 + 3\sum_{x\neq y}\mathbb{E}\,\xi(x)^2\,\mathbb{E}\,\xi(y)^2\\
&= 3\left(\sum_x \mathbb{E}\,\xi(x)^2\right)^2 - 2\sum_x \mathbb{E}\,\xi(x)^4\,.
\end{aligned}$$

The second equality follows because whenever $\xi(x)$ occurs in an odd power, for example $x=x_1\neq x_2=x_3=x_4$, the expectation is zero (this way one can simplify and bound also higher moments, see [7]). It remains to estimate the first moment. By Corollary 4 and bounds on the second and fourth moment we have just computed we obtain

$$\frac{1}{\sqrt{3}}\cdot\left(\sum_{x\in\mathcal{X}}\text{Var}(\xi(x))\right)^{\frac{1}{2}} \leqslant \mathbb{E}\left|\sum_{x\in\mathcal{X}}\xi(x)\right|$$

and the upper bound follows by Jensen's Inequality (with constant 1).

4.2 Proof of Lemma 8 (Characterizing smooth min-entropy)

Suppose that $\mathsf{H}_\infty^\delta(X) \geqslant k$. then, by definition, there is Y such that $\mathsf{H}_\infty(Y) \geqslant k$ and $\sum_{x:P_X(x)>P_Y(x)} P_X(x) - P_Y(x) \leqslant \delta$. Since all the summands are positive and since $P_Y(x) \leqslant 2^{-k}$, ignoring those x for which $P_Y(x) < 2^{-k}$ yields

$$\sum_{x:P_X(x)>2^{-k}} P_X(x) - P_Y(x) \leqslant \delta.$$

Again, since $P_Y(x) \leqslant 2^{-k}$ we obtain

$$\sum_{x:P_X(x)>2^{-k}} P_X(x) - 2^{-k} \leqslant \delta,$$

which finishes the proof of the "$\Longrightarrow$" part.

Assume now that $\delta' = \sum_{x\in\mathcal{X}} \max\left(P_X(x) - 2^{-k}, 0\right) \leqslant \delta$. Note that

$$\sum_{x\in\mathcal{X}} \max\left(P_X(x) - \frac{1}{2^k}, 0\right) + \sum_{x\in\mathcal{X}} \max\left(\frac{1}{2^k} - P_X(x), 0\right) = \\ = 2\sum_{x\in\mathcal{X}} \left|P_X(x) - \frac{1}{2^k}\right| \geqslant 2\sum_{x\in\mathcal{X}} \max\left(P_X(x) - \frac{1}{2^k}, 0\right)$$

and therefore we have $\sum_{x\in\mathcal{X}} \max\left(2^{-k} - P_X(x), 0\right) \geqslant \delta'$. By this observation we can construct a distribution Y by shifting δ' of the mass of P_X from the set $S^- = \{x : P_X(x) > 2^{-k}\}$ to the set $\{x : 2^{-k} \geqslant P_X(x)\}$ in such a way that we have $P_Y(x) \leqslant 2^{-k}$ for all x. Thus $\mathsf{H}_\infty(Y) \geqslant k$ and since a δ' fraction of the mass is shifted and redistributed we have $d_1(X;Y) \leqslant \delta'$. This finishes the proof of the "$\Longleftarrow$" part.

4.3 Proof of Corollary 14 ((Mixed) moments of slice advantages)

For shortness denote $\Delta(x) = P_X(x) - P_Y(x)$ and $\mathsf{Adv}_{S_i}^{\mathsf{D}} = \mathsf{Adv}_{S_i}^{\mathsf{D}}(X;Y)$.

Note that by Lemma 5, applied to the family $f_x = \Delta(x)\mathsf{D}(x)\mathbf{1}_{S_i}(x)$ (which is 4-wise independent) we have

$$\mathbb{E}\,\mathsf{Adv}_{S_i}^{\mathsf{D}} \geqslant 3^{-\frac{1}{2}} \left(\sum_x \Delta(x)^2\right)^{\frac{1}{2}}$$

which is the first inequality claimed in the corollary. In turn, again by Lemma 5, we have

$$\mathbb{E}\left(\mathsf{Adv}_{S_i}^{\mathsf{D}}\right)^2 = T^{-1} \cdot \sum_x \Delta(x)^2.$$

Since this holds for any i, by Cauchy-Schwarz we get for any i, j

$$\mathbb{E}\,\mathsf{Adv}_{S_i}^{\mathsf{D}}\mathsf{Adv}_{S_j}^{\mathsf{D}} \leqslant \sqrt{\mathbb{E}\left(\mathsf{Adv}_{S_i}^{\mathsf{D}}\right)^2 \cdot \mathbb{E}\left(\mathsf{Adv}_{S_j}^{\mathsf{D}}\right)^2} \leqslant T^{-1} \cdot \sum_x \Delta(x)^2$$

which proves the second inequality in the corollary.

Abstract

We study *interactive oracle proofs* (IOPs) [7, 43], which combine aspects of probabilistically checkable proofs (PCPs) and interactive proofs (IPs). We present IOP constructions and techniques that let us achieve tradeoffs in proof length versus query complexity that are not known to be achievable via PCPs or IPs alone. Our main results are:

1. *Circuit satisfiability has* 3*-round IOPs with linear proof length (counted in bits) and constant query complexity.*
2. *Reed–Solomon codes have 2-round IOPs of proximity with linear proof length and constant query complexity.*
3. *Tensor product codes have 1-round IOPs of proximity with sublinear proof length and constant query complexity.* (A familiar example of a tensor product code is the Reed–Muller code with a bound on individual degrees.)

For all the above, known PCP constructions give *quasilinear* proof length and constant query complexity [12, 16]. Also, for circuit satisfiability, [10] obtain PCPs with linear proof length but *sublinear* (and super-constant) query complexity. As in [10], we rely on algebraic-geometry codes to obtain our first result; but, unlike that work, our use of such codes is much "lighter" because we do not rely on any automorphisms of the code.

We obtain our results by building "IOP-analogues" of tools underlying numerous IPs and PCPs:

- **Interactive proof composition.** Proof composition [3] is used to reduce the query complexity of PCP verifiers, at the cost of increasing proof length by an additive factor that is exponential in the verifier's randomness complexity. We prove a composition theorem for IOPs where this additive factor is linear.
- **Sublinear sumcheck.** The sumcheck protocol [34, 46] is an IP that enables the verifier to check the sum of values of a low-degree multi-variate polynomial on an exponentially-large hypercube, but the verifier's running time depends linearly on the bound on individual degrees. We prove a sumcheck protocol for IOPs where this dependence is sublinear (e.g., polylogarithmic).

1 Introduction

We study *Interactive Oracle Proofs* (also known as *Probabilistically Checkable Interactive Proofs*) [7, 43], which combine aspects of probabilistically checkable proofs (PCPs) and interactive proofs (IPs). We present IOP constructions and general techniques that enable us to obtain tradeoffs in proof length versus query complexity that are not known to be achievable by either PCPs or IPs alone. For some applications (e.g., constructing non-interactive arguments in the random oracle model [7]) considering such general types of proof systems suffices (as opposed to focusing only on PCPs or IPs) and thus these applications inherit the efficiency improvements over PCPs.

1.1 Motivation

Probabilistically checkable proofs (PCPs) were introduced by [22, 5, 20, 3, 2]: in a PCP, a probabilistic polynomial-time verifier has oracle access to the proof string. The complexity class $\mathbf{PCP}[\mathsf{r}, \mathsf{q}]$ denotes those languages for which the verifier uses at most r random bits and queries at most q proof locations; the proof length is then at most 2^{r}. The PCP Theorem [3, 2] states that $\mathbf{NP} = \mathbf{PCP}[O(\log n), O(1)]$: every NP statement has a proof of polynomial length that can be verified via a constant number of queries (say, with soundness error $1/2$).

A fundamental question is how long a PCP needs to be, compared to the corresponding "standard" NP proof. Given $T\colon \mathbb{N} \to \mathbb{N}$, the PCP Theorem states that every language $\mathcal{L}$ in $\mathbf{NTIME}(T)$ has a proof of length $\mathrm{poly}(T(n))$ that can be verified with $O(1)$ queries. A sequence of works [42, 30, 24, 13, 9, 12, 16] gradually reduced the proof length to quasilinear, i.e., $T(n) \cdot \mathrm{polylog}(T(n))$; much of this progress was accompanied by progress on efficient reductions from **NTIME** to "PCP-friendly" problems, as well as efficient constructions of PCPs of proximity (PCPPs) for key classes of linear codes. Despite much progress, the following question remains open: *are there PCPs with linear proof length and constant query complexity?*

Ben-Sasson et al. [10] make progress in this direction by proving that there is $a > 0$ such that for every $\epsilon > 0$ there is a PCP for circuit satisfiability with proof length $2^{a/\epsilon} n$ and query complexity n^{ϵ}. Beyond the sublinear query complexity, [10]'s result comes with other caveats not affecting most prior constructions: the verifier is *non-uniform*, namely it requires a polynomial-size advice string for every circuit size; and the verifier is not succinct, namely it cannot run in time that is sublinear in the circuit size even if the circuit comes from a uniform circuit family. (Recent constructions of high-rate locally testable codes with sub-polynomial query complexity [32] are not yet known to be convertible to PCPs with similar parameters.)

In this paper, we continue the study of the tradeoff between proof length and query complexity, but we do so for a natural extension of the PCP model (sufficient for some useful

applications, e.g., [7]) that can be thought of as a "multi-round PCP", described below. Also, from this point onwards, we switch to using relations instead of languages. We denote by $\mathcal{R}$ a relation consisting of pairs $(\mathtt{x}, \mathtt{w})$, where $\mathtt{x}$ is the *instance* and $\mathtt{w}$ is the *witness*; we think of $\mathcal{R}$ naturally induced by a non-deterministic language $\mathcal{L}$. We denote by $\mathcal{R}|_{\mathtt{x}}$ the (possibly empty) set of witnesses for a given instance $\mathtt{x}$, and by n the size of $\mathtt{x}$.

1.2 A more general model: interactive oracle proofs

Interactive Oracle Proofs (IOPs) are a type of proof system introduced in [7, 43] that combines aspects of IPs [4, 26] and PCPs [5, 3, 2], and generalizes interactive PCPs [31]. IOPs naturally extend the notion of a PCP to multiple rounds or, viewed from an another angle, they naturally extend the notion of an IP by allowing probabilistic checking. Prior work shows that IOPs can be used to construct non-interactive proofs in the random oracle model [7], that IOPs efficiently achieve unconditional zero knowledge [6], and that IOPs can be used to obtain doubly-efficient constant-round IPs for polynomial-time bounded-space computations [43].

Informally, an IOP extends an IP as follows: whenever the prover sends to the verifier a message, the verifier does not have to read the message in full but may probabilistically query it. In more detail, a k-round IOP comprises k rounds of interaction. In the i-th round of interaction: the verifier sends a message m_i to the prover; then the prover replies with a message f_i to the verifier, which the verifier can query in this and all later rounds (by having oracle access to it). After the k rounds of interaction, the verifier either accepts or rejects.

An *IOP system* for a relation $\mathcal{R}$ with round complexity k and soundness ε is a pair (P, V), where P, V are probabilistic algorithms, that satisfies natural notions of completeness and soundness: for every instance-witness pair $(\mathtt{x}, \mathtt{w})$ in $\mathcal{R}$, $V(\mathtt{x})$ always accepts after $\mathsf{k}(n)$ rounds of interaction with $P(\mathtt{x}, \mathtt{w})$; and, for every instance $\mathtt{x}$ with $\mathcal{R}|_{\mathtt{x}} = \emptyset$ and unbounded prover $\tilde{P}$, $V(\mathtt{x})$ accepts with probability at most $\varepsilon(n)$ after $\mathsf{k}(n)$ rounds of interaction with $\tilde{P}$.

Like the IP model, one efficiency measure is the round complexity k. Like the PCP model, two additional efficiency measures are the *proof length* l, which is the total number of alphabet symbols in all of the prover's messages, and the *query complexity* q, which is the total number of locations queried by the verifier across all of the prover's messages. Considering all of these parameters, we say that a relation $\mathcal{R}$ belongs to the complexity class $\mathbf{IOP}[\mathsf{k}, \mathsf{a}, \mathsf{l}, \mathsf{r}, \mathsf{q}, \varepsilon]$ if there is an IOP system for $\mathcal{R}$ in which on instances of size n:

1. the number of rounds is $\mathsf{k}(n)$;
2. the prover messages are over the alphabet $\mathsf{a}(n)$;
3. the proof length over this alphabet is $\mathsf{l}(n)$;
4. the verifier uses $\mathsf{r}(n)$ random bits;
5. the verifier queries the prover messages in $\mathsf{q}(n)$ locations;
6. the soundness error is $\varepsilon(n)$.

Many other definitions for IPs and PCPs carry over naturally. An IOP is *public coin* if m_i is a random string and the verifier postpones any oracle queries until after receiving all the oracles from the prover (i.e., after the k-th round of interaction). An IOP is *non-adaptive* if the query locations do not depend on answers to any previous queries.

Prior work on IOPs. In prior work, [7] prove that public-coin IOPs can be compiled into non-interactive proofs in the random oracle model; their compiler is as a generalization of the Fiat–Shamir paradigm for public-coin IPs [21, 41], and of the "CS proof" constructions of Micali [37] and Valiant [49] for PCPs. Also, [6] construct 2-round IOPs (called "duplex

PCPs" there) with unconditional zero knowledge and quasilinear proof length; in comparison, short PCPs with unconditional zero knowledge are not known. Also, [43] use IOPs to obtain doubly-efficient constant-round IPs for polynomial-time bounded-space computations. In this paper, we do not study compilers for cryptographic proofs, nor zero knowledge, nor applications to interactive proofs; instead, we focus on tradeoffs of proof length versus query complexity for IOPs.

Prior work on interactive PCPs. An interactive PCP [31] is a PCP followed by a standard IP; in particular, it is an IOP where the verifier sends an empty first message and may query only the first prover message (but must read any other prover messages in full). Prior work on interactive PCPs obtains proof length that depends on the witness size rather than computation size [31, 25], as well as unconditional zero knowledge [28]. In this paper we also study proof length but our results to not seem to extend to the more restricted setting of interactive PCPs.

1.3 Proximity and robustness

To facilitate upcoming technical discussions we briefly introduce two notions that strengthen a PCP.

- *PCPs of proximity* (PCPPs) [17, 9]. On the one hand, a PCP verifier has oracle access to a candidate proof π and only decides if $\mathcal{R}|_{\mathtt{x}} \neq \emptyset$ ($\mathtt{x} \in \mathcal{L}$) or $\mathcal{R}|_{\mathtt{x}} = \emptyset$ ($\mathtt{x} \notin \mathcal{L}$). On the other hand, a PCPP verifier has oracle access to a candidate witness $\mathtt{w}$ and proof π and decides if $\mathtt{w} \in \mathcal{R}|_{\mathtt{x}}$ or $\mathtt{w}$ is far from $\mathcal{R}|_{\mathtt{x}}$ (in particular, if $\mathcal{R}|_{\mathtt{x}} = \emptyset$, then $\mathtt{w}$ is far from $\mathcal{R}|_{\mathtt{x}}$). A quantity δ known as the *proximity parameter* specifies what "far" means: if $\mathtt{w}$ is δ-far from $\mathcal{R}|_{\mathtt{x}}$ then the PCPP verifier accepts with probability at most ε, where ε is the soundness error.
- *Robust PCPs* [9]. When $\mathcal{R}|_{\mathtt{x}} = \emptyset$, the answers to the verifier's queries are, with high probability, far from any answers that make the verifier accept. A quantity ρ known as the *robustness parameter* specifies what "far" means: if $\mathcal{R}|_{\mathtt{x}} = \emptyset$ then, with probability at least $1 - \varepsilon$, the answers are ρ-far from accepting ones.

The two above notions can also be combined, yielding the definition of a *robust PCP of proximity*.

Extension to IOPs. The notions of proximity and robustness naturally extend to IOPs; see the full version for details. For example, we say that an IOP has *proximity parameter* δ if the analogous property for PCPs of proximity holds; we can then correspondingly define the complexity class $\mathbf{IOPP}[\mathsf{k}, \mathsf{a}, \mathsf{l}, \mathsf{r}, \mathsf{q}, \varepsilon, \delta]$.

2 Results

We obtain several IOP constructions with proof length and query complexity that are not known to be achievable either via PCPs or IPs alone (or even via interactive PCPs [31]). First, we show that for circuit satisfiability we can obtain IOPs with linear proof length and constant query complexity; constant round complexity and public coins suffice.

▶ **Theorem 1** (informal). *Let $\mathcal{R}$ be the relation consisting of instance-witness pairs (ϕ, w) where ϕ is a boolean circuit (of two-input NAND gates) and w is a binary input that satisfies ϕ; we use n to denote the number of gates in ϕ. There exists $a > 0$ and a public-coin IOP*

system that puts $\mathcal{R}$ in the complexity class

$$\mathbf{IOP}\left[\begin{array}{llcl} \text{rounds} & \mathsf{k}(n) & = & 3 \\ \text{answer alphabet} & \mathsf{a}(n) & = & \mathbb{F}_2 \\ \text{proof length} & \mathsf{l}(n) & = & a \cdot n \\ \text{query complexity} & \mathsf{q}(n) & = & a \\ \text{soundness error} & \varepsilon(n) & = & 1/2 \end{array}\right].$$

In particular, via [40]'s reduction from Turing machines to circuits, we deduce that

$$\mathbf{NTIME}(T) \subseteq \mathbf{IOP}\left[\begin{array}{llcl} \text{rounds} & \mathsf{k}(T) & = & 3 \\ \text{answer alphabet} & \mathsf{a}(T) & = & \mathbb{F}_2 \\ \text{proof length} & \mathsf{l}(T) & = & a \cdot T \log T \\ \text{query complexity} & \mathsf{q}(T) & = & a \\ \text{soundness error} & \varepsilon(T) & = & 1/2 \end{array}\right].$$

The main points of comparison of the above theorem with prior work are the following.

- For PCPs with constant query complexity, prior work achieved only quasilinear proof length [12, 16], with the "quasilinear" hiding several logarithmic factors. In comparison, we achieve linear proof length for circuit satisfiability, and $O(T \log T)$ proof length for nondeterministic T-time relations.
- Ben-Sasson et al. [10] show that there is $a > 0$ such that for every $\epsilon > 0$ there is a non-uniform PCP for circuit satisfiability with proof length $2^{a/\epsilon}n$ and query complexity n^{ϵ}; the non-uniformity comes from the use of algebraic-geometry (AG) codes with transitive automorphism groups, for which uniform families are not known. In comparison, we simultaneously achieve linear proof length and constant query complexity; moreover, we make a much "lighter" use of AG codes, which also allows us to avoid non-uniformity. Namely, we rely only on the multiplication properties of AG codes [14, 36], and do not rely on any code automorphisms. Looking ahead, this is because we do not route circuits on Cayley graphs induced by the automorphisms of the underlying code, unlike [10].

Second, we show that Reed–Solomon codes over binary fields (fields of characteristic 2) have 2-round IOPs of proximity with linear proof length and constant query complexity. Such codes are a key ingredient for constructing PCPs with quasilinear proof length [12]. Recall that a word $w\colon D \to \mathbb{F}$ is represented via $|w| = |D| \cdot \log|\mathbb{F}|$ bits.

▶ **Theorem 2** (informal). *Given a "fractional degree" $\varrho \in (0,1)$, define $\mathcal{R}$ to be the relation consisting of instance-witness pairs $((\mathbb{F}_{2^\lambda}, d), w)$ where $d \leq \varrho 2^\lambda$ and $w\colon \mathbb{F}_{2^\lambda} \to \mathbb{F}_{2^\lambda}$ is the evaluation of a polynomial of degree less than d; we define the instance size to be λ, and note that w has $|w| = 2^\lambda \cdot \lambda$ bits. For every $\delta \in (0, \frac{1}{2}(1-\varrho))$ there exist $a > 0$ and a public-coin IOP of proximity (P, V) that puts $\mathcal{R}$ in the complexity class*

$$\mathbf{IOPP}\left[\begin{array}{llcl} \text{rounds} & \mathsf{k}(\lambda) & = & 2 \\ \text{answer alphabet} & \mathsf{a}(\lambda) & = & \mathbb{F}_2 \\ \text{proof length} & \mathsf{l}(\lambda) & = & a \cdot 2^\lambda \cdot \lambda \\ \text{query complexity} & \mathsf{q}(\lambda) & = & a \\ \text{soundness error} & \varepsilon(\lambda) & = & 1/2 \\ \text{proximity parameter} & \delta(\lambda) & = & \delta \end{array}\right].$$

More generally, our result concerns *additive Reed–Solomon codes*, where the domain of a codeword is a λ-dimensional affine subspace S of a potentially larger binary field $\mathbb{F}$; in such cases the above statement involves more parameters but achieves the same asymptotics. The

main point of comparison of the above theorem with prior work is [12, 16], who achieve PCPs of proximity with the same parameters but superlinear proof length: $a \cdot 2^{\lambda} \cdot \lambda \cdot \mathrm{poly}(\lambda)$.

Third, we show that tensor product codes have 1-round IOPs of proximity with sublinear proof length and constant query complexity. Given a positive integer m and linear code C with domain D and alphabet $\mathbb{F}$, the tensor product code $C^{\otimes m}$ is the linear code that comprises all functions $w\colon D^m \to \mathbb{F}$ whose restriction to any axis-parallel line is in C; the message length, block length, and distance of $C^{\otimes m}$ are each the m-th power of the corresponding parameters of C. Tensor product codes are a large family, and they include Reed–Muller codes (at least when considering the definition that bounds the variables' individual degrees, which we do, as opposed to the one that bounds their sum).

▶ **Theorem 3** (informal). *Let $m \geq 3$ and C be a linear code with domain D, alphabet $\mathbb{F}$, and relative distance τ; let $\ell := |D|$ be the block length. Define $\mathcal{R}$ to be the relation of instance-witness pairs $\big((C, m), w\big)$ such that $w \in C^{\otimes m}$; note that w has $|w| = \ell^m \cdot \log|\mathbb{F}|$ bits. For every $\delta \in (0, \frac{1}{2}\tau^m)$ there exist $a > 0$ and a public-coin IOPP system (P, V) that puts $\mathcal{R}$ in the complexity class*

$$\mathbf{IOPP}\left[\begin{array}{lccl} \text{rounds} & \mathsf{k}(\ell^m) & = & 1 \\ \text{answer alphabet} & \mathsf{a}(\ell^m) & = & \mathbb{F}_2 \\ \text{proof length} & \mathsf{l}(\ell^m) & = & o(\ell^m \cdot \log|\mathbb{F}|) \\ \text{query complexity} & \mathsf{q}(\ell^m) & = & a \\ \text{soundness error} & \varepsilon(\ell^m) & = & 1/2 \\ \text{proximity parameter} & \delta(\ell^m) & = & \delta \end{array}\right].$$

The main points of comparison of the above theorem with prior work are the following.

- Ben-Sasson and Sudan [11] and Viderman [51] give local testers for all tensor product codes with query complexity $\mathsf{q}(\ell^m) = \ell^2$; Dinur et al. [18] give local testers with $\mathsf{q}(\ell^m) = \ell$ for certain tensor product codes. In contrast, we achieve constant query complexity, with only sublinear proof length, for all tensor product codes. Moreover, given additional mild conditions, we obtain constant soundness error *even for non-constant m*.
- The work of [12, 16] implies PCPs of proximity for tensor product codes with superlinear proof length and constant query complexity. In contrast, we obtain sublinear proof length, with a single round of interaction.

Analogously to [51], we can invoke Theorem 3 on different choices of linear codes so to derive different code families that have good properties and an IOP tester (instead of a local tester as in [51]). For example, we can choose a family of linear codes with arbitrarily high rate, constant relative distance, linear-time encoding, and linear-time decoding from a constant fraction of errors [48, 29, 44]; our theorem implies a code with the same properties that *also* has a 1-round IOP of proximity with sublinear proof length and constant query complexity (cf. [51, Section 3.1]).

Similar statements hold for list-decodable codes with good parameters [27] (cf. [51, Section 3.2]); and also for locally correctable and, more generally, locally decodable codes with good parameters [52, 50, 19, 33, 32] (cf. [51, Section 3.3]). In each of these cases, the tensor product operation preserves the "key" properties of the choice of underlying code C, while endowing the resulting code with an IOP of proximity.

We obtain the above results via techniques of independent interest: we prove that, in the IOP model, there are more efficient analogues of tools that are fundamental to constructing PCPs and IPs. We now discuss these techniques.

3 Techniques

Recall that IOPs generalize both IPs, by treating the prover's messages as oracle strings, and PCPs, by allowing for multiple rounds of interaction; they also generalize interactive PCPs [31]. We prove that IOPs can express two fundamental techniques in a more efficient way than in these prior models:

(i) in *interactive proof composition*, the prover is more efficient than in PCP proof composition; and

(ii) in *sublinear sumchecks*, the verifier is more efficient than in IP sumcheck protocols.

We now discuss both of our new tools, and then how we use them.

3.1 Interactive proof composition

Proof composition [3] is used to reduce PCP query complexity, cf. [2, 30, 9]; it involves two PCPs: an outer one and an inner one. One should think of the outer proof system as having short proofs but large query complexity, while the inner proof system has long proofs but small query complexity.

The composed prover uses the outer prover to send a PCP to the composed verifier, who does not run the outer verifier but, instead, uses the inner verifier to check that the outer verifier would have accepted had it made its queries to the PCP. The composed verifier also needs an auxiliary sub-PCP for the claim that the outer verifier would have accepted; in fact, he needs one sub-PCP for each possible random string of the outer verifier. Hence, the composed prover also sends all of these sub-PCPs along with the first PCP. The benefit is that the query complexity of the composed verifier equals that of the inner verifier, which is typically verifying a much smaller statement than the outer verifier.

Beyond query complexity, most other parameters of the composed proof system are simply the sum of corresponding parameters of the outer and inner proof systems. An exception is the proof length l: it does not simply equal the sum $\mathsf{l}_{\mathsf{out}} + \mathsf{l}_{\mathsf{in}}$, but instead equals $\mathsf{l}_{\mathsf{out}} + 2^{\mathsf{r}_{\mathsf{out}}} \cdot \mathsf{l}_{\mathsf{in}}$, because the composed prover uses the inner proof system to generate a proof *for each choice of randomness of the outer proof system*. (The same is true for prover running time.)

We prove an **Interactive Proof Composition Theorem** that avoids the above limitations. The outer proof system is a robust PCP $(P_{\mathsf{out}}, V_{\mathsf{out}})$ for a relation $\mathcal{R}$, while the inner one is a k-round IOP $(P_{\mathsf{in}}, V_{\mathsf{in}})$ for V_{out}'s relation; the composed proof system is a $(\mathsf{k}+1)$-round IOP (P, V) for $\mathcal{R}$. The parameters of the composed proof system are exactly as before, except that now the new proof length is *much smaller*: $\mathsf{l}_{\mathsf{out}} + \mathsf{l}_{\mathsf{in}}$. (Ditto for the prover running time.) The crucial observation is that, after the prover sends the outer proof to the verifier, *soundness is not harmed if the verifier tells the prover his choice of outer randomness*; hence, the prover does not have to invest work for all randomness choices but can simply invest work only for the outer randomness that was chosen, which he now knows.

▶ **Theorem 4** (Interactive Proof Composition – informal). *Suppose that the relation $\mathcal{R}$ satisfies the following:*

(1) there exists a robust PCPP system $(P_{\mathsf{out}}, V_{\mathsf{out}})$ that puts $\mathcal{R}$ in the complexity class

$$\textbf{PCPP}\left[\begin{array}{ll} \text{proof length} & \mathsf{l}_{\mathsf{out}} \\ \text{randomness} & \mathsf{r}_{\mathsf{out}} \\ \text{query complexity} & \mathsf{q}_{\mathsf{out}} \\ \text{soundness error} & \varepsilon_{\mathsf{out}} \\ \text{proximity parameter} & \delta_{\mathsf{out}} \\ \text{robustness parameter} & \rho_{\mathsf{out}} \end{array}\right]$$

and

(2) for every $\mathtt{x}$ there exists an IOPP system $(P_{\mathsf{in}}, V_{\mathsf{in}})$ that puts V_{out}'s relation in the complexity class

$$\textbf{IOPP}\left[\begin{array}{ll} \text{rounds} & \mathsf{k}_{\mathsf{in}} \\ \text{proof length} & \mathsf{l}_{\mathsf{in}} \\ \text{randomness} & \mathsf{r}_{\mathsf{in}} \\ \text{query complexity} & \mathsf{q}_{\mathsf{in}} \\ \text{soundness error} & \varepsilon_{\mathsf{in}} \\ \text{proximity parameter} & \delta_{\mathsf{in}} \end{array}\right]$$

If $\delta_{\mathsf{in}} \leq \rho_{\mathsf{out}}$ then there exists an IOPP system (P, V) that puts $\mathcal{R}$ in the complexity class

$$\textbf{IOPP}\left[\begin{array}{lcl} \text{rounds} & \mathsf{k} & = 1 + \mathsf{k}_{\mathsf{in}} \\ \text{proof length} & \mathsf{l} & = \mathsf{l}_{\mathsf{out}} + \mathsf{l}_{\mathsf{in}} \\ \text{randomness} & \mathsf{r} & = \mathsf{r}_{\mathsf{out}} + \mathsf{r}_{\mathsf{in}} \\ \text{query complexity} & \mathsf{q} & = \mathsf{q}_{\mathsf{in}} \\ \text{soundness error} & \varepsilon & = \varepsilon_{\mathsf{out}} + \varepsilon_{\mathsf{in}} \\ \text{proximity parameter} & \delta & = \delta_{\mathsf{out}} \end{array}\right].$$

The above discussion and informal theorem statement omit many technical details that already arise in non-interactive proof composition (e.g., see lengthy discussions in [9, 8]), and we also need to deal with. For instance, one has to clarify the size of the sub-claim on which the the inner proof system is invoked; also, one has to carefully define the notion of a verifier to allow for the composed verifier's running time to be *smaller* than the outer verifier's query complexity. For more details, see the full version.

3.2 Sublinear sumcheck

The *sumcheck protocol* [34, 46] is an interactive proof for the claim "$\sum_{\vec{\alpha} \in H^m} w(\vec{\alpha}) = 0$", where w is the evaluation on $\mathbb{F}^m$ of an m-variate polynomial of individual degree d and H is a subset of $\mathbb{F}$. More generally, w may be a codeword in the tensor product code $C^{\otimes m}$, for a given linear code C with domain D and alphabet $\mathbb{F}$, and H is a subset of D [36]. The prover receives H and w as input, while the verifier receives H as input and w as an oracle. The protocol has m rounds and, if C has relative distance τ, the protocol has soundness error $1 - \tau^m$; also, the prover runs in time $\text{poly}(\ell^m)$, and the verifier in time $\text{poly}(\ell + m)$, where $\ell := |D|$ is C's block length.

In each round, the verifier receives a codeword w_i in C and checks that $\sum_{\alpha \in H} w_i(\alpha)$ equals a certain value γ_{i-1} determined in the previous round; in particular, the verifier reads $\Omega(\ell)$ bits. We show that the verifier complexity can be *sublinear* in ℓ, if the prover and verifier engage in an IOP instead of an IP. The intuition to "go sublinear" is simple: instead of doing these checks explicitly, the verifier uses proximity testers for doing so. Thus, in each round, the prover sends to the verifier two oracles: the codeword in w_i, and a proximity proof attesting that $w_i \in C$ and that $\sum_{\alpha \in H} w_i(\alpha) = \gamma_{i-1}$. The use of proximity proofs complicates the soundness analysis because the verifier only sees noisy codewords, but the backbone of the proof follows that of the standard sumcheck protocol. Overall, we obtain a sumcheck IOP protocol that enables a verifier to efficiently check sumchecks for codes of much larger blocklength than what he can afford in the standard sumcheck protocol.

We state our **Sublinear Sumcheck Theorem** below as a reduction: given a PCP of proximity $(P_{\text{SC}}, V_{\text{SC}})$ for subcodes of the form $C|_{H,\gamma} := \{w \in C \text{ s.t. } \sum_{\alpha \in H} w(\alpha) = \gamma\}$, we

construct an IOP of proximity (P, V) for sumchecks over H^m for $C^{\otimes m}$. The complexity of the PCPP verifier V_{SC} determines the complexity of the resulting IOPP verifier V; e.g., if the former is sublinear in C's block length ℓ, so is the latter.

▶ **Theorem 5** (Sublinear Sumcheck – informal). *Let m be a positive integer, and C a linear code with relative distance τ and block length ℓ. Suppose that there is a PCP of proximity for subcodes of the form $C|_{H,\gamma} := \{w \in C \text{ s.t. } \sum_{\alpha \in H} w(\alpha) = \gamma\}$ with proof length l_{SC}, query complexity q_{SC}, soundness error $\varepsilon_{\mathrm{SC}}$, proximity parameter δ_{SC}, prover running time $\mathsf{tp}_{\mathrm{SC}}$, and verifier running time $\mathsf{tv}_{\mathrm{SC}}$. Then there is a public-coin IOP for sumchecks over H^m for $C^{\otimes m}$ with the following parameters:*

$$\mathbf{IOP}\left[\begin{array}{llll} \text{rounds} & \mathsf{k} & = & m \\ \text{proof length} & \mathsf{l} & = & m \cdot \mathsf{l}_{\mathrm{SC}} + m \cdot \ell \\ \text{query complexity} & \mathsf{q} & = & m \cdot \mathsf{q}_{\mathrm{SC}} + m + 1 \\ \text{soundness error} & \varepsilon & = & 1 - \tau^m + \left(\varepsilon_{\mathrm{SC}} + m \cdot \delta_{\mathrm{SC}}\right) \\ \text{prover time} & \mathsf{tp} & = & m \cdot \mathsf{tp}_{\mathrm{SC}} + m \cdot \ell^m \\ \text{verifier time} & \mathsf{tv} & = & m \cdot \mathsf{tv}_{\mathrm{SC}} + O(m) \end{array}\right].$$

In later sections, it is more natural to state the theorem without assuming that w is a codeword in $C^{\otimes m}$, so the reduction also takes as input a PCP of proximity $(P_{\otimes}, V_{\otimes})$ for $C^{\otimes m}$ that is invoked on w; this introduces additional terms in the parameters. More generally, both of the PCPs of proximity $(P_{\mathrm{SC}}, V_{\mathrm{SC}})$ and $(P_{\otimes}, V_{\otimes})$ can in fact be IOPs of proximity, and we state our theorem for this more general case, which we need. For more details, see the full version.

3.3 Applying the new tools

We now sketch how we use the above new tools to derive the results of Section 2. We begin by discussing our results on proximity testing to codes (stated later); we then turn to circuit satisfiability (stated earlier) because its proof requires one of these results on proximity testing.

Intuition behind Theorem 2. The construction of linear-size IOPs of proximity for Reed–Solomon codes over binary fields follows from one invocation of our Interactive Proof Composition Theorem with [12]'s robust PCPs of proximity for Reed–Solomon codes as the outer proof system, and [38]'s PCPs of proximity for nondeterministic languages as the inner proof system. Informally, in the first round, the prover sends to the verifier a [12] PCP of proximity, which reduces proximity testing of codewords over $\mathbb{F}_{2^\lambda}$ to proximity testing of sub-codewords over $\mathbb{F}_{2^{\lambda/2}+O(1)}$ with only constant overheads; in the second round, the verifier sends his choice of outer randomness, and the prover replies with a [38] PCP of proximity for the sub-codeword. The proof length of this latter component is quasilinear, but is applied to a claim of "square-root size" only, so we obtain linear proof length.

Intuition behind Theorem 3. The construction of sublinear-size IOPs of proximity for tensor product codes follows from one invocation of our Interactive Proof Composition Theorem with [11, 51]'s robust local tester for tensor product codes as the outer proof system, and [38]'s PCPs of proximity for nondeterministic languages as the inner proof system. Unlike before, we now use one round, because the outer proof system only relies on a local tester rather than a PCP of proximity. The verifier thus simply sends his choice of outer randomness, and the prover replies with a [38] PCP of proximity for a suitable sublinear-size

sub-codeword. Since the proof length of this latter component is quasilinear but is applied to a sublinear-size claim, we obtain sublinear proof length.

A summary: overall, we can summarize the above sketches via the following diagram of implications.

Theorem 2 linear-size IOPP for Reed–Solomon codes	⟵	Theorem 4 interactive proof composition	+	[12] robust PCPs of proximity for Reed–Solomon codes	+	[38] PCP of proximity for **NTIME**
Theorem 3 sublinear-size IOPP for tensor product codes	⟵	Theorem 4 interactive proof composition	+	[11, 51] robust local testing for tensor product codes	+	[38] PCP of proximity for **NTIME**

Intuition behind Theorem 1. We now turn to how to construct 3-round IOPs for circuit satisfiability with linear proof length and constant query complexity.

The first step of many PCP constructions is to arithmetize the NP statement at hand (in our case, the satisfiability of a boolean circuit) by reducing it to a "PCP-friendly" problem that looks like a constraint satisfaction problem over a well-chosen graph and whose assignments involve codewords in a well-chosen linear code C. Meir observes in [35, 36] that key features of C are good relative distance and, moreover, a *multiplication property*: coordinate-wise multiplication of codewords yields codewords in a code whose relative distance is still good [14, 36]. Moreover, to obtain short PCPs, the aforementioned graph is typically chosen so to behave like a routing network [42]; for example, [12] use De Bruijn graphs, while [10] use hypercubes. To support such graphs, the automorphism group of C has to be rich enough. This typically holds for Reed–Solomon codes [12] which have a doubly-transitive automorphism group, but is a significantly harder condition to fulfill for AG codes [10], for which obtaining a transitive automorphism group is quite involved and, currently, can only be achieved non-uniformly.

The aforementioned first step would be problematic in our setting, because known routing techniques introduce either logarithmic overheads (as in [12]) or large query complexity (as in [10]), so it is not clear how we could use them. Departing from these prior works, we do not rely on any routing, and instead immediately leverage one round of interaction to directly reduce circuit satisfiability to a sumcheck instance over a given linear code C. Also, we only assume that C has good relative distance and a multiplication property [14], *but we do not rely on any automorphisms.*

Informally, the prover first sends three codewords w_1, w_2, w_3 over a field $\mathbb{F}$; the first codeword encodes values of the left wires of all gates, the second encodes values for the right wires of all gates, and the third encodes values for the output wires of all gates. (When a gate has fan-out greater than 1 we still consider 1 output wire.) The verifier now must check several things. First, that wire values are boolean and the output gate wire equals 0. Second, that the wire values are "locally consistent" with each gate: for every $i \in [n]$, $w_3(i)$ is the NAND of $w_1(i)$ and $w_2(i)$. Third, that the three encodings of wire values are consistent with the circuit topology: namely, if $\ell(i)$ represents the left wire used to compute i, and $r(i)$ represents the right wire used to compute i, the topology requires that $w_3(\ell(i)) = w_1(i)$ and $w_3(r(i)) = w_2(i)$ for every i. The verifier cannot directly conduct these checks (as doing so would incur linear query complexity); instead, the verifier sends some randomness to the prover so to "bundle" the checks into one sumcheck.

But how should the verifier sample randomness to achieve this bundling? One option is to sample a random element in $\mathbb{F}$ per check so to construct a random subset sum, which can be viewed as an n-variate polynomial of total degree 1, whose coefficients are the checks,

evaluated at a random point. If not all checks are satisfied, the polynomial is non-zero, and its random evaluation cannot attain any value with too large probability. However, constructing a random subset sum is inefficient because the verifier samples and sends to the prover $\Omega(n)$ random bits, in order to describe the random point. Nevertheless, the verifier may hope to do better by using a *different* low-degree polynomial for the bundling. In general, if the polynomial has m variables each of degree at most d, the verifier must sample and send m field elements; this preserves soundness provided that $|\mathbb{F}| = \Omega(md)$ (for a constant probability of avoiding any particular output value by the Schwartz–Zippel Lemma [45, 53, 15]) and $d^m = \Omega(n)$ (to bundle all checks). For example, the univariate case of $m = 1$ was considered in [5] when reducing to a sumcheck problem; the multivariate case of $m = \log n$ or $m = \frac{\log n}{\log \log n}$ was considered in later works. Unfortunately, either setting does not work for *constant-size* fields, which we ultimately use to obtain linear proof length.

Taking a step back from polynomials, we see that all we need is an *evading set* S for $\mathbb{F}^n$, which is a small set such that for any non-zero $v \in \mathbb{F}^n$ the inner product $\langle r, v \rangle$, for random $r \in S$, does not attain any particular value $a \in \mathbb{F}$ with too high probability. Good constructions of evading sets are known: they relax a well-studied notion called ϵ-biased sets [39]. In particular, results of [1] imply that, for any ϵ, $\mathbb{F}^n$ has an evading set S of size $\text{poly}(\frac{n}{\epsilon})$ and the aforementioned probability is $\gamma := \epsilon + \frac{1}{|\mathbb{F}|}$; in particular, such a construction is suitable for constant-size fields.

Below we informally state the reduction (see the full version for details), using the following notion: we say that a linear code C' is a *degree d-closure* of C if, for every $w_1, \ldots, w_m \in C$ and m-variate polynomial P of total degree at most d, it holds that $w' \in C'$ where the i-th entry of w' is the evaluation of P on the i-th coordinates of $w_1, \ldots, w_m$.

▶ **Lemma 6** (Circuit SAT to Sumcheck – informal). *Let n be a positive integer, $C \subseteq \mathbb{F}^D$ an n-systematic linear code, ϕ an n-gate boolean circuit (of two-input NAND gates), and S an evading set for $\mathbb{F}^n$. There is a 1-round IOP that reduces satisfiability of ϕ to proximity testing to C and a sumcheck over any degree-3 closure of C. Moreover, the IOP introduces only constant overheads in all relevant parameters, including proof length and query complexity.*

After reducing circuit satisfiability to sumcheck over the given code C, we are left to choose C so to ensure that the sumcheck can be carried out with 2 additional rounds, linear proof length, and constant query complexity.

For this, our starting point is [23, 47]'s efficient construction of a code family with constant rate, relative distance, and alphabet size. Note that since these codes are AG codes, they have a naturally-defined degree-3 closure. Also, their construction is uniform, and thus represents a much "lighter" use of AG codes as compared to in [10].

If we simply choose C to be a code from this AG code family, then it is not clear how to efficiently conduct the sumcheck. However, what does work is to take C to be the tensor product of $O(1)$ copies of this AG code. Informally, in this way, we can invoke our Sublinear Sumcheck Theorem (Theorem 5) on the tensor product code C and we can test proximity to it by Theorem 3. See the full version for details.

Overall, we can summarize the above sketch via the following diagram of implications.

$$\underset{\substack{\text{linear-size IOP}\\ \text{for circuit SAT}}}{\textbf{Theorem 1}} \longleftarrow \underset{\substack{\text{from circuit SAT}\\ \text{to sumcheck}}}{\text{Lemma 6}} + \underset{\substack{\text{sublinear}\\ \text{sumcheck}}}{\text{Theorem 5}} + \underset{\substack{\text{sublinear-size IOP}\\ \text{for tensor product codes}}}{\text{Theorem 3}} + \underset{\substack{\text{efficient construction}\\ \text{of AG codes}}}{[23, 47]}$$

4 Open questions

The question of whether there exist PCPs with linear proof length and constant query complexity remains open. Nevertheless, our work suggests additional questions that may be stepping stones in this and other intriguing directions:

1. Is there a *one*-round IOP for circuit satisfiability with linear proof length and query complexity? (Our IOP for circuit satisfiability requires 3 rounds.)
2. Is there an IOP for $\mathbf{NTIME}(T)$ with linear proof length and query complexity, for *some* number of rounds? (Our results, like [10], only imply proof length $O(T \log T)$.)
3. Is there an IOP for *succinct* circuit satisfiability with linear proof length and query complexity? (Our results, like [10], "stop" at **NP** but do not extend to **NEXP**.)

Finally, while "positive" applications of IOPs are known (e.g., non-interactive proofs in the random oracle model [7]), "negative" ones are not: do IOP constructions with good parameters imply inapproximability results that are not known to be implied by known PCP constructions?

Abstract

Fixed-parameter algorithms and kernelization are two powerful methods to solve NP-hard problems. Yet, so far those algorithms have been largely restricted to *static* inputs.

In this paper we provide fixed-parameter algorithms and kernelizations for fundamental NP-hard problems with *dynamic* inputs. We consider a variety of parameterized graph and hitting set problems which are known to have $f(k)n^{1+o(1)}$ time algorithms on inputs of size n, and we consider the question of whether there is a data structure that supports small updates (such as edge/vertex/set/element insertions and deletions) with an update time of $g(k)n^{o(1)}$; such an update time would be essentially optimal. Update and query times independent of n are particularly desirable. Among many other results, we show that Feedback Vertex Set and k-Path admit dynamic algorithms with $f(k)\log^{O(1)} n$ update and query times for some function f depending on the solution size k only.

We complement our positive results by several conditional and unconditional lower bounds. For example, we show that unlike their undirected counterparts, Directed Feedback Vertex Set and Directed k-Path do not admit dynamic algorithms with $n^{o(1)}$ update and query times even for constant solution sizes $k \leq 3$, assuming popular hardness hypotheses. We also show that unconditionally, in the cell probe model, Directed Feedback Vertex Set cannot be solved with update time that is purely a function of k.

1 Introduction

The area of dynamic algorithms studies data structures that store a dynamically changing instance of a problem, can answer queries about the current instance and can perform small changes on it. The major question in this area is, how fast can updates and queries be?

The most studied dynamic problems are dynamic graph problems such as connectivity (e.g., [45, 47, 48, 67]), reachability [41], shortest paths (e.g., [7, 26, 42]), and maximum matching [8, 39, 66]. For a dynamic graph algorithm, the updates are usually edge or vertex insertions and deletions. Any dynamic graph algorithm that can perform edge insertions can be used for a static algorithm by starting with an empty graph, and using m insertions to insert the m-edge input graph. That is, if the update time of the dynamic algorithm is $u(m)$ then the static problem can be solved in $O(m \cdot u(m))$ time, plus the time to query for the output. Hence, if a problem requires $\Omega(f(m))$ time to be solved statically, then any dynamic algorithm that can insert edges, and can be queried for the problem solution in $o(f(m))$ time, must need $\Omega(f(m)/m)$ (amortized) time to perform updates. This is not limited to edge updates; similar statements are true for vertex insertions and other update types. A fundamental question is which problems can be fully dynamized, i.e., have dynamic algorithms supporting updates in $O(f(m)/m)$ time where $f(m)$ is the static runtime?

This question is particularly interesting for static problems that can be solved in near-linear time. For them, we are interested in near-constant time updates—the holy grail of dynamic algorithms. The field of dynamic algorithms has achieved such full dynamization for many problems. A prime example of the successes of this vibrant research area is the *dynamic connectivity* problem: maintaining the connected components of a graph under edge updates, to answer queries about whether a pair of vertices is connected. This problem can be solved with amortized expected update time $O(\log n \log\log^2 n)$ [48, 67] and query time $O(\log n/\log\log\log n)$; polylogarithmic deterministic amortized bounds are also known, the current best by Wulff-Nielsen [71]. After much intense research on the topic [44, 46, 47], the first polylogarithmic *worst case expected* update times were obtained by Kapron et al. [53], who were the first to break through what seemed like an $\Omega(\sqrt{n})$ barrier; the bounds of Kapron et al. [53] were recently improved by Gibb et al. [37]. Similar $\tilde{O}(1)$ update and query time bounds[1] are known for many problems solvable in linear time such as dynamic minimum spanning tree, biconnectivity and 2-edge connectivity [45, 47], and maximal matching [5, 66].

Barriers for dynamization have also been studied extensively. Many unconditional, cell probe lower bounds are known. For instance, for connectivity and related problems it is known [64, 65] that either the query time or the update time needs to be $\Omega(\log n)$. However, current cell probe lower bound techniques seem to be limited to proving polylogarithmic lower bounds. In contrast, conditional lower bounds based on popular hardness hypotheses have been successful at giving tight bounds for problems such as dynamic reachability, dynamic strongly connected components and many more [1, 43, 54, 62].

While the field of dynamic algorithms is very developed, practically all the problems which have been studied are polynomial-time solvable problems. What about NP-hard problems? Do they have fast dynamic algorithms? By the discussion above, it seems clear that (unless $\mathsf{P} = \mathsf{NP}$), superpolynomial query/update times are necessary, and surely this is not as interesting as achieving near-constant time updates. If the problem is relaxed, and instead of exact solutions, approximation algorithms are sufficient, then efficient dynamic algorithms have been obtained for some polynomial time approximable problems such as dynamic approximate vertex cover [5, 8, 61]. What if we insist on exact solutions?

The efficient dynamization question does make sense for *parameterized* NP-hard problems. For such problems, each instance is measured by its size n as well as a *parameter* k that measures the optimal solution size, the treewidth or genus of the input graph, or any similar structural property. If $\mathsf{P} \neq \mathsf{NP}$, then the runtime of any algorithm for such a problem needs

[1] Throughout this paper, we write $\tilde{O}(f(n,k))$ to hide polylog(n) factors.

to be superpolynomial, but it is desirable that the superpolynomiality is only in terms of k. That is, one searches for so-called *fixed-parameter algorithms* with runtime $f(k) \cdot n^c$ for some computable function f and some fixed constant c independent of k and n. The *holy grail* here is an algorithm with runtime $f(k) \cdot n$ where f is a modestly growing function. Such linear-time fixed-parameter algorithms can be very practical for small k. The very active area of fixed-parameter algorithms has produced a plethora of such algorithms for many different parameterized problems. Some examples include (1) many branching tree algorithms such as those for Vertex Cover and d-Hitting Set, (2) many algorithms based on color-coding [4] such as for k-Path, (3) all algorithms that follow from Courcelle's theorem[2] [18], and (4) many more [11, 28, 32, 52, 58, 68, 70].

We study whether NP-hard problems with (near-)linear time fixed-parameter algorithms can be made efficiently dynamic. The main questions we address are:

- Which problems solvable in $f(k) \cdot n^{1+o(1)}$ time have dynamic algorithms with update and query times at most $f(k) \cdot n^{o(1)}$?
- Which problems solvable in $f(k) \cdot n$ time have dynamic algorithms with update and query times that depend solely on k and not on n?
- Can one show that (under plausible conjectures) a problem requires $\Omega(f(k) \cdot n^{\delta})$ (for constant $\delta > 0$) update time to maintain dynamically even though statically it can be solved in $f(k) \cdot n^{1+o(1)}$ time?

1.1 Prior Work

We are aware of only a handful papers related to the question that we study. Bodlaender [9] showed how to maintain a tree decomposition of constant treewidth under edge and vertex insertions and deletions with $O(\log n)$ update time, as long as the underlying graph always has treewidth at most 2. Dvořák et al. [29] obtained a dynamic algorithm maintaining a tree-depth decomposition of a graph under the promise that the tree-depth never exceeds D; edge and vertex insertions and deletions are supported in $f(D)$ time for some function f. Dvořák and Tůma [30] obtained a dynamic data structure that can count the number of induced copies of a given h-vertex graph, under edge insertions and deletions, and if the maintained graph has bounded expansion, the update time is bounded by $O(\log^{h^2} n)$.

A more recent paper by Iwata and Oka [51] gives several dynamic algorithms for the following problems, under the promise that the solution size never grows above k: (1) an algorithm that maintains a Vertex Cover in a graph under $O(k^2)$ time edge insertions and deletions and $f(k)$ time queries[3], (2) an algorithm for Cluster Vertex Deletion under $O(k^8 + k^4 \log n)$ time edge updates and $f(k)$ time queries[4], and (3) an algorithm for Feedback Vertex Set in graphs with maximum degree Δ where edge insertions and deletions are supported in amortized time $2^{O(k)}\Delta^3 \log n$. Notably, when discussing Feedback Vertex Set, the paper concludes: "It seems an interesting open question whether it is possible to construct an efficient dynamic graph without the degree restriction."

The final related papers are by Abu-Khzam et al. [2, 3]. Although these papers talk about parameterized problems and dynamic problems, the setting is very different. Their

[2] Courcelle's theorem states that every problem definable in monadic second-order logic of graphs can be decided in linear time on graphs of bounded treewidth.

[3] Here $f(k)$ denotes the runtime of the fastest fixed-parameter algorithm for Vertex Cover when run on k-vertex graphs.

[4] Here $f(k)$ denotes the runtime of the fastest fixed-parameter algorithm for Cluster Vertex Deletion when run on k^5-vertex graphs.

problem is, given two instances I_1 and I_2 of a problem that only differ in k "edits", and a solution S_1 of I_1, to find a feasible solution S_2 of I_2 that is at Hamming distance at most d from S_1. The question of study is whether such problems admit fixed-parameter algorithms for parameters k and ℓ. That question though is not about data structures but about a single update. Moreover, their algorithm is given S_1 as input, which—unlike a dynamic data structure—cannot force the initial solution to have any useful properties. Thus, the hardness results in their setting do not translate to our data structure setting. Furthermore, the runtimes in their setting, unlike ours, must have at least a linear dependence on the size of the input, as one has to at least read the entire input.

Besides the work on parameterized dynamic algorithms, there has been some work on parameterized streaming algorithms by Chitnis et al. [17]. This work focused on Maximal Matching and Vertex Cover. The difference between streaming and dynamic algorithms is that (a) the space usage of the algorithm is the most important aspect for streaming, and (b) in streaming, a solution is only required at the end of the stream, whereas a dynamic algorithm can be queried at any point and needs to be efficient throughout, but can use a lot of space. For Vertex Cover instances whose solution size never exceeds k, Chitnis et al. [17] give a one-pass randomized streaming algorithm that uses $O(k^2)$ space and answers the final query in $2^{O(k)}$ time; when the vertex cover size can exceed k at any point, there is a one-pass randomized streaming algorithm using $O(\min\{m, nk\})$ space and answering the query in $O(\min\{m, nk\}) + 2^{O(k)}$ time.

The relevant prior work on (static) fixed-parameter algorithms [4, 6, 10, 12, 13, 14, 15, 16, 19, 20, 22, 23, 24, 27, 31, 34, 38, 40, 49, 50, 56, 57, 59, 68] is described in the appendix.

1.2 Our Contributions

Algorithmic Results. We first define the notion of a fixed parameter dynamic problem as a parameterized problem with parameter k that has a data structure supporting updates and queries to an instance of size n in time $f(k)n^{o(1)}$. The class FPD contains all such parameterized problems. By a formalization of our earlier discussion, FPD is contained in the class of parameterized problems admitting algorithms running in time $f(k)n^{1+o(1)}$. After this, we introduce two techniques for making fixed-parameter algorithms dynamic, and then use them to develop dynamic fixed-parameter algorithms for a multitude of fundamental optimization problems. Our algorithmic contributions are stated in Theorem 1 below. In the runtimes, $DC(n)$ refers to the time per update to a dynamic connectivity data structure on n vertices, which from prior work can be:

- *expected amortized* update time $O(\log n(\log\log n)^2)$, or
- *expected worst case* time $O(\log^4 n)$, or
- *deterministic amortized* time $O(\log^2 n/\log\log n)$.

Which of these bounds we pick determines the type of guarantees (expected vs. deterministic, worst case vs. amortized) that the algorithm gives.

▶ **Theorem 1.** *The following problems admit dynamic fixed-parameter algorithms:*

- Vertex Cover *parameterized by solution size under edge insertions and deletions, with* $O(1)$ *amortized or* $O(k)$ *worst case update time and* $O(1.2738^k)$ *query time,*
- Connected Vertex Cover *parameterized by solution size under edge insertions and deletions, with* $O(k2^k)$ *update time and* $O(4^k)$ *query time,*
- d-Hitting Set *for all values of* d *parameterized by solution size under set insertions and deletions, either with* $O(kd^k)$ expected *update time and* $O(k)$ *query time, or with*

$O(f(k,d))$ *(worst-case, deterministic) update time and* $O(d^k d!(k+1)^d)$ *query time, for some function* f *loosely bounded by* $(d!)^d k^{O(d^2)}$.

- Edge Dominating Set *parameterized by solution size under edge insertions and deletions, with* $O(1)$ *update time and* $O(2.2351^k)$ *query time,*
- Feedback Vertex Set *parameterized by solution size under edge insertions and deletions, with* $2^{O(k \log k)} \log^{O(1)} n$ *amortized update time and* $O(k)$ *query time,*
- Max Leaf Spanning Tree *parameterized by solution size under edge insertions and deletions, with* $O(3.72^k + k^5 \log n + DC(n))$ *amortized update time, and maintains the current max leaf spanning tree explicitly in memory,*
- Dense Subgraph in Graphs with Degree Bounded by Δ *parameterized by the number of vertices in the subgraph under edge insertions and deletions, with* $2^{O(k\Delta)} \cdot DC(n)$ *update time and* $2^{O(k\Delta)} \log n$ *query time.*
- Undirected k-Path *parameterized by the number of vertices on the path, with* $k!2^{O(k)} \cdot DC(n)$ *update time and* $k!2^{O(k)} \log n$ *query time.*
- Edge Clique Cover *parameterized by the number of cliques and under the promise that the solution never grows bigger than* $g(k)$*, with* $O(4^{g(k)})$ *update time and* $2^{2^{O(k)}} + O(2^{4g(k)})$ *query time.*
- Point Line Cover *and* Line Point Cover *parameterized by the size of the solution and under point and line insertions and deletions, respectively, with* $O(g(k)^3)$ *update time and* $O(g(k)^{2g(k)+2})$ *query time, under the promise that the solution never grows to more than* $g(k)$.

Discussion of the Algorithmic Results. Our dynamic algorithm for Vertex Cover and that of Iwata and Oka [51] both have query time $O(1.2738^k)$, by using the best known fixed parameter algorithm for Vertex Cover on the maintained kernel. However, our algorithm improves upon theirs in two ways. First, our update time is amortized *constant* or $O(k)$ worst case, whereas the Iwata-Oka algorithm has update time $O(k^2)$. Second, their update time bound of $O(k^2)$ only holds if the vertex cover is guaranteed to never grow larger than k throughout the sequence of updates. Namely, their update time depends on the size of their maintained kernel, which may become unbounded in terms of k. Our algorithm does not need any such promise—it will always have fast (amortized $O(1)$ or $O(k)$ worst case) update time and return a vertex cover of size k if it exists, or determine that one does not. This is a much stronger guarantee.

Our dynamic algorithm and Chitnis et al.'s streaming algorithm for Vertex Cover are both based on Buss' kernel, but our algorithm is markedly different from theirs. In particular, we actually work with a modified kernel that allows us to achieve constant amortized update time. Because our algorithm is completely deterministic, it necessarily needs $\Omega(m)$ space, and our algorithm does indeed take linear space.

We give two algorithms for d-Hitting Set. The first is based on a randomized branching tree method, while the second is deterministic and maintains a small kernel for the problem. For every constant d, any d-Hitting Set instance on m sets and n elements has a kernel constructible in time $O(dn+2^d m)$ that has $O(d^{d+1}d!(k+1)^d)$ sets, due to van Bevern [68], and a kernel constructible in time $O(m)$ that has $O((k+1)^d)$ sets, due to Fafianie and Kratsch [33]. Unfortunately, it seems difficult to efficiently dynamize these kernel constructions. Because of this, we present a *novel kernel* for the problem. Our kernel can be constructed in $O(dn+3^d m)$ time and has size $O((d-1)!(k+1)^d)$. It also has nice properties that make it possible to maintain it dynamically with update time that is a function of only k and d. In fact, for any fixed d, the update time is polynomial in k.

Our algorithm for Feedback Vertex Set is a nice combination of kernelization and a branching tree. Aside from our dynamic kernel for d-Hitting Set, this is probably the most involved of our algorithms. Iwata and Oka [51] had also presented a dynamic fixed-parameter algorithm for Feedback Vertex Set. However, their update time depends linearly on the maximum degree of the graph, and is hence efficient only for bounded degree graphs. Their paper asks whether one can remove this costly dependence on the degree. Our algorithm answers their question in the affirmative—it has fast updates regardless of the graph density.

All of our algorithms, except for the last two in the theorem, meet their update and query time guarantees regardless of whether the currently stored instance has a solution of size k or not. The two exceptions, Edge Clique Cover and Point Line Cover, only work under the promise that the solution never grows bigger than a function of k. In this sense they are similar to most of the algorithms from prior work [29, 51]. There does seem to be an inherent difficulty to removing the promise requirement, however. In fact, in the parameterized complexity literature, these two problems are also exceptional, in the sense that their fastest fixed parameter algorithms run by computing a kernel and then running a brute force algorithm on it [23, 55], rather than anything more clever.

Hardness Results. In addition to the above algorithms, we also prove conditional lower bounds for several parameterized problems, showing that they are likely not in FPD. To our knowledge, ours are the first lower bounds for any dynamic parameterized problems.

The hardness hypothesis we assume concerns Reachability Oracles (ROs) for DAGs: an RO is a data structure that stores a directed acyclic graph and for any queried pair of vertices s, t, can efficiently answer whether s can reach t. (An RO does not perform updates.) Our main hypothesis is as follows:

▶ **Hypothesis 2** (RO Hypothesis). *On a word-RAM with $O(\log m)$ bit words, any Reachability Oracle for directed acyclic graphs on m edges must either use $m^{1+\varepsilon}$ preprocessing time for some $\varepsilon > 0$, or must use $\Omega(m^{\delta})$ time to answer reachability queries for some constant $\delta > 0$.*

The only known ROs either work by computing the transitive closure of the DAG during preprocessing, thus spending $\Theta(\min\{mn, n^{\omega}\})$ time (where n is the number of vertices and $2 \leq \omega < 2.373$ [36, 69]), or by running a BFS/DFS procedure after each query, thus spending $O(m)$ time. Both of these runtimes are much larger than our assumed hardness; hence the RO Hypothesis is very conservative.

We also use a slightly weaker version of the RO Hypothesis, asserting that its statement holds true even restricted to DAGs that consist of ℓ layers of vertices (for some fixed constant ℓ), so that the edges go only between adjacent layers in a fixed direction, from layer i to layer $i + 1$. While this new *LRO Hypothesis* is certainly weaker, we show that it is implied by either of two popular hardness hypotheses: the 3SUM Conjecture and the Triangle Conjecture. The former asserts that when given n integers within $\{-n^c, \ldots, n^c\}$ for some constant c, deciding whether three of them sum to 0 requires $n^{2-o(1)}$ time on a word-RAM with $O(\log n)$ bit words. The latter asserts that detecting a triangle in an m-edge graph requires $\Omega(m^{1+\varepsilon})$ time for some $\varepsilon > 0$. These two conjectures have been used for many conditional lower bounds [1, 35, 54].

Pătraşcu studied the RO Hypothesis, and while he was not able to prove it, the following strong cell probe lower bound follows from his work [63]: there are directed acyclic graphs on m edges for which any RO that uses $m^{1+o(1)}$ preprocessing time (and hence space) in the word-RAM with $O(\log n)$ bit words, must have $\omega(1)$ query time. Using this statement, unconditional, albeit weaker lower bounds can be proven as well. This is what we prove:

▶ **Theorem 3.** *Fix the word-RAM model of computation with w-bit words for $w = O(\log n)$ for inputs of size n. Assuming the LRO Hypothesis, there is some $\delta > 0$ for which the following dynamic parameterized graph problems on m-edge graphs require either $\Omega(m^{1+\delta})$ preprocessing or $\Omega(m^{\delta})$ update or query time:*

- Directed k-Path *under edge insertions and deletions,*
- Steiner Tree *under terminal activation and deactivation, and*
- Vertex Cover Above LP *under edge insertions and deletions.*

Under the RO Hypothesis (and hence also under the LRO Hypothesis), there is a $\delta > 0$ so that Directed Feedback Vertex Set *under edge insertions and deletions requires $\Omega(m^{\delta})$ update time or query time.*

Unconditionally, there is no computable function f for which a dynamic data structure for Directed Feedback Vertex Set *performs updates and answers queries in $O(f(k))$ time.*

Our lower bounds show that, although k-Path and Feedback Vertex Set have fixed parameter dynamic algorithms for undirected graphs, they probably do not for directed graphs. Interestingly, the fixed-parameter algorithms for k-Path in the static setting work similarly on both undirected and directed graphs, so there only seems to be a gap in the dynamic setting.

All problems for which we prove lower bounds have $f(k)n^{1+o(1)}$ time static algorithms, except for Vertex Cover above LP. However, it seems that the reason why the current algorithms are slower is largely due to the fact that near-linear time algorithms for maximum matching are not known. Recent impressive progress on the matching problem [60] gives hope that an $f(k)n^{1+o(1)}$ time algorithm for Vertex Cover above LP might be possible.

A common feature of most of the problems above is that they are either not known to have a polynomial kernel (like Directed Feedback Vertex Set), or do not have one unless $\mathsf{NP} \subseteq \mathsf{coNP}/poly$ (like k-Path [10] and Steiner Tree parameterized by the number of terminal pairs [27]). One might therefore conjecture that problems which cannot be made fixed parameter dynamic do not have polynomial kernels, or vice versa. Tempting as it is, this intuition turns out to be false. Vertex Cover Above LP does not have a dynamic fixed-parameter algorithm, yet it is known to admit a polynomial kernel [56]. On the other hand, the k-Path problem on undirected graphs also does not admit a polynomial kernel unless $\mathsf{NP} \subseteq \mathsf{coNP}/poly$ [10], yet we give a dynamic fixed-parameter algorithm for it. Hence, the existence of a polynomial kernel for a parameterized problem is not related to the existence of a dynamic fixed-parameter algorithm for it.

Preliminaries. We assume familiarity with basic combinatorial algorithms, especially graph algorithms and hitting set algorithms. When referring to a graph G, we will write $V(G)$ to denote its vertex set and $E(G)$ to denote its edge set. Unless otherwise specified, n and m will refer to the number of nodes and edges in G, respectively. We use the terms nodes and vertices interchangeably. By $\tilde{O}(f(n))$ we denote $f(n)\log^{O(1)} n$. We also assume familiarity with dynamic problems and parameterized problems.

2 Overview of the Algorithmic Techniques

Promise model and Full model. There are two different models of dynamic parameterized problems in which we design algorithms: the *promise model* and the *full model*. When solving a problem with parameter k in the promise model, there is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that one is promised that throughout the sequence of updates, there always

exists a solution with parameter at most $g(k)$. Hence, one only needs to maintain a solution under updates with good guarantees on both query and update times as long as the promise continues to hold. If at any point during the execution no solution to the parameterized problem with parameter $g(k)$ exists, then the algorithm is not required to provide any guarantees.

In the full model, there is no such promise. One needs to efficiently maintain a solution with parameter at most k, or the fact that no such solution exists, under any sequence of updates. When possible, it is desirable to have an algorithm with guarantees in the full model instead of only the promise model, and all but two of our algorithms (Point Line Cover and Edge Clique Cover) do work in the full model.

2.1 Techniques for designing dynamic fixed-parameter algorithms

We present two main techniques for obtaining dynamic fixed-parameter algorithms: dynamic kernels and dynamic branching trees.

Dynamization via kernelization. Using the notation of Cygan et al. [21], a *kernelization algorithm* for a parameterized problem Π is an algorithm $\mathcal{A}$ that, given an instance (I, k) of Π, runs in polynomial time and returns an instance (I', k') of Π such that the size of the new instance is bounded by a computable function of k and so that (I', k') is a 'yes' instance of Π if and only if (I, k) is. Frequently, when the problem asks us to output more than just a Boolean answer, then an answer for (I', k') must be valid for (I, k) as well. We will refer to the output of $\mathcal{A}$ as a *kernel*. For example, a kernelization algorithm for Vertex Cover might take as input a graph G, and return a subgraph G' such that any vertex cover of G' is also a vertex cover of G.

In the first approach, we compute a kernel for the problem, and maintain that this is a valid kernel as we receive updates. In other words, as we receive updates, we will maintain what the output of a kernelization algorithm $\mathcal{A}$ would be, without actually rerunning $\mathcal{A}$ each time. Similar to kernelizations for static fixed-parameter algorithms, if we can prove that the size of our kernel is only a function of k whenever a solution with parameter k exists, then we can answer queries in time independent of n by running the fastest known static algorithms on the kernel.

The difficult part, then, is to efficiently dynamically maintain the kernel. The details of how efficiently we can handle updates to the kernel also determines which model of dynamic fixed-parameter algorithm our algorithm works for. If the kernel is defined by sufficiently simple or local rules such that updates can take place in time independent of the current kernel size, then the algorithm should work in the full model. If updates might take time linear in the kernel size, then the algorithm only works in the promise model.

As we will see, there are many problems for which we can efficiently maintain a kernel. In some instances we will be able to maintain the classical kernels known for the corresponding static problem, while in others, we will design new kernels which are easier to maintain.

Dynamization via branching tree. In the second approach, we consider so-called *set selection problems*. In these problems, the instance consists of a set of objects U (e.g., vertices of a graph), the parameter is k, and one needs to select a subset $S \subseteq U$ of size k (at least k/at most k) so that a certain predicate $P(S)$ is satisfied. Many parameterized problems are of this nature, such as k-Path, Vertex Cover, and (Directed) Feedback Vertex Set.

Consider a (static) set selection problem which admits a branching solution. By this we mean, for every instance U of the problem, there is an 'easy to find' subset $T \subseteq U$ of size

$|T| \leq f(k)$ (for some function f) so that any solution S of size at most k must intersect T. Furthermore, for any choice of $t \in T$ to be placed in the solution, one can efficiently obtain a reduced instance of the problem with parameter $k-1$, which corresponds to picking t to be in the solution. For instance, for Vertex Cover, every edge $\{u, v\}$ can be viewed as such a subset T since at least one of u and v is in any vertex cover, and if we pick u, then we can remove it and all its incident edges from the graph to get a reduced instance.

For such problems, there is a simple fixed-parameter algorithm called the branching tree algorithm: The algorithm can be represented as a tree $\mathcal{T}$ rooted at a node r. Each node v of the tree corresponds to a reduced instance of the original one, and in this instance, v has a subset T of size $f(k)$, and a child v_i for every $i \in T$, where v_i corresponds to selecting i to be placed in the solution, and v_i carries the reduced instance where i is selected. The height of the tree X is bounded by k since at most k elements need to be selected, and the branching factor is $f(k)$. Each leaf ℓ of the tree $\mathcal{T}$ is either a "yes"-leaf (when the predicate is satisfied on the set of elements selected on the path from r to ℓ) or a "no"-leaf (when the predicate is not satisfied). The runtime of the algorithm bounded by $f(k)^k \cdot t(N)$, where $t(N)$ is the time to find a subset T that must contain an element of the solution in instances of size N, together with the time to find a reduced instance, once an element is selected.

What we have described so far is a static algorithmic technique, but we investigate when this algorithmic technique can be made dynamic. In other words, given an update, we would like to quickly update $\mathcal{T}$ so that it becomes a valid branching tree for the updated instance. Since the number of nodes in the branching tree is only a function of k, one can afford to look at every tree node. Ideally, one would like the time spent per node to only depend on k. However, for most problems that we consider, the branching tree needs to be rebuilt every so often, since the subset T to branch on may become invalid after an update, and the time to rebuild can have a dependence on the instance size. We use two methods to avoid this. The first is to randomize the decisions made in the branching tree (e.g., which set T to pick) so that, assuming an oblivious adversary that must provide the update sequence in advance, it is relatively unlikely that we need to rebuild the tree $\mathcal{T}$ (or its subtrees) after each update, and in particular, so that the expected cost of an update is only a function of k. The second is to make 'robust' choices of T, so that many updates are requires before the choice of T becomes incalid, and then amortize the cost of rebuilding the tree over all the updates required to force such a rebuilding.

2.2 Algorithm Examples

We give overviews of the techniques used in some of our algorithms, to demonstrate the dynamic kernel and dynamic branching tree approaches, and different ways in which they can be used. We emphasize that these descriptions are substantial simplifications which hide many non-trivial details and ideas.

Vertex Cover. We give both a dynamic kernel algorithm and a dynamic branching tree algorithm for Vertex Cover.

Our first algorithm maintains a kernel obtained as follows: Every node of degree $\geq k+1$ 'selects' $k+1$ incident edges arbitrarily and adds them to the edge set E' of the kernel, independently of other nodes. Next, every edge incident to two nodes of degree $\leq k$ is also added to E'. Finally, the node set of the kernel consists of all nodes that are not isolated in E'. This is a valid kernel, since any vertex cover of size at most k needs to include every vertex of degree strictly greater than k. Every edge in E' either has both its end points of degree $\leq k$, or is selected by one of its end points of degree at least $k+1$. Any node of a

vertex cover of the kernel either has degree $\leq k$ or selects $k+1$ edges. Thus the kernel must have size $O(k^2)$ when a k-vertex cover exists. To insert an edge we simply add the edge to the kernel unless one of its incident vertices has degree greater than k. If one of the end points x used to be of degree $\leq k$ and is now of degree $k+1$, we have x select all its incident edges and add them to the kernel. To delete an edge, we simply remove it from the kernel. If it was incident to a vertex v of degree higher than $k+2$, then we need to find another edge incident to v which is in the graph but not selected by v to put into the kernel. If one of the end points now has degree k, we need to go through the incident edges and remove them from the kernel if their other end point has high degree and did not select them. All these operations can be performed by storing appropriate pointers so that the updates run in $O(k)$ time. With a little bit more work one can make them run in $O(1)$ amortized time. To answer queries, we answer "no" in constant time if the kernel has more than $2k(k+1)$ edges, and otherwise we run the fastest static k-Vertex Cover fixed-parameter algorithm on the kernel of size $O(k^2)$. This results in a $O(1.2738^k)$ update time.

Our second algorithm maintains a branching tree of depth at most k, which corresponds to using following randomized branching strategy: pick a uniformly random edge, and branch on adding each of its endpoints into the vertex cover. For a static branching algorithm, there is no need to pick a uniformly random edge to branch on, since at least one endpoint of every single edge must be in the vertex cover. However, a deterministic branching strategy like this in a dynamic algorithm would be susceptible to an adversarial edge update sequence, in which the adversary frequently removes edges which have been chosen to branch on. By ensuring that each edge we branch on is a uniformly random edge, we make the probability that we need to recompute any subtree of the branching tree $\mathcal{T}$ low. We compute the expected update time to be only $O(k2^k)$. Queries can be answered in only $O(k)$ time by following a path in the branching tree to an accepting leaf, if one exists.

These algorithms demonstrate some subtleties of the two techniques. In the branching tree algorithm, we use a randomized branching rule to deal with adversarial updates. In some of our other branching tree algorithms, like for Feedback Vertex Set, we are able to find a deterministic branching rule to yield a deterministic algorithm instead. In the kernelization algorithm, we manage to find a kernel which can be updated quickly even when the answer becomes larger than k and the kernel size becomes large. In other problems, it will be harder to do this, and we may need to restrict ourselves to the promise model where we are guaranteed that the kernel will not grow too big in order to have efficient update times. Dynamic kernelization techniques typically lead to faster update times and query times, like in this case, because we can apply the fastest known static algorithm for the problem to the kernel to answer queries. In a branching tree algorithm, we may be using a branching rule which does not lead to the fastest algorithm because it is easier to dynamically maintain.

Interestingly, we are able to generalize both of these algorithms to the d-Hitting Set problem. The d-Hitting Set branching tree algorithm is similar to that of Vertex Cover, but the d-Hitting Set dynamic kernelization algorithm is much more complicated, and involves a tricky recursive rule for determining which sets to put in the kernel. We include an overview of the static kernel construction in Sect. 3.

Max Leaf Spanning Tree. Our algorithm for Max Leaf Spanning Tree uses the dynamic kernel approach. The kernel we maintain is simply the given graph, where we contract vertices of degree two whose neighbors both also have degree two. We can maintain this kernel by storing paths of contracted vertices in lists corresponding to edges they have been contracted into. As long as this kernel has $\Omega(k^2)$ nodes, it must always have a spanning tree with at least k leaves.

Unlike in other dynamic kernel algorithms, where we maintain that the kernel does not get too large, this kernel may grow to have $\Omega(n^2)$ edges. We can nonetheless find a tree with at least k leaves in time independent of n, by breadth-first searching from an arbitrary node in the kernel until we have $\Omega(k^2)$ kernel vertices, and just finding a tree within those vertices.

This method finds a subtree T_S with at least k leaves, but we need to find a tree which spans the whole graph. In the static problem, this could be accomplished by a linear-time breadth-first search away from T_S, but in the dynamic problem, this is too slow. To overcome this, we also maintain a spanning tree T of the entire graph, which does not necessarily have k leaves, using a known dynamic tree data structure. When queried for a spanning tree, we find T_S, and then perform a 'merge' operation to combine T and T_S into a spanning tree with at least k leaves. This merge operation makes only $O(k^4)$ changes to T, so we are able to maintain a desired spanning tree in time independent of n.

We are able to maintain a linear size answer in only logarithmic time per update because the output is not very 'sensitive' to updates: we can always output an answer very close to T, which itself only changes in one edge per update. In other problems where the output can be more sensitive to updates, like Edge Clique Cover, we need to maintain a small intermediate representation of the answer instead of the answer itself.

Feedback Vertex Set in undirected graphs. Our algorithm for Feedback Vertex Set combines the dynamic kernel approach with the dynamic branching tree approach. We will maintain a branching tree, where we branch off of which node to include in our feedback vertex set. Then, at each node in the branching tree, we will maintain a kernel to help decide what nodes to branch on. Similar to the situation with Max Leaf Spanning Tree, our kernel can possibly have $\Omega(n^2)$ edges. Here we will deal with this by branching off of only $O(k)$ nodes in the kernel to add to our feedback vertex set, so that we can answer queries in sublinear time in the kernel size.

The kernel we maintain at each node of the branching tree is the given graph, in which vertices of degree one are deleted, and vertices of degree two are contracted. This involves many details for maintaining contracted trees, and dealing with resulting self-loops. Since the resulting graph has average degree at least three, whereas forests have much lower average degree, we show that a feedback vertex set of size at most k must contain a vertex of high degree, whose degree is at least $1/(3k)$ of the total number of edges in the kernel. Since there are at most $6k$ such vertices, we can branch on which to include in our feedback vertex set.

This branching strategy works well for the static problem, but it is hard to maintain dynamically. Each edge update might change the set of vertices with high enough degree to branch on, and changing which vertex we branch on, and recomputing an entire subtree of the branching tree, can be expensive. We alleviate this issue using amortization. Instead of branching only on the $6k$ highest degree vertices, we instead branch on the $12k$ highest degree vertices. If our kernel has m edges, then we prove that $\Omega(m)$ edge updates need to happen before there might be a small feedback vertex set containing none of the vertices we branched on. After these updates we need to recompute the branching tree, but this is inexpensive when amortized over the required $\Omega(m)$ updates.

3 A dynamic kernel for d-Hitting Set

In this section we present our dynamic kernel for the d-Hitting Set problem; we describe how to efficiently compute and maintain it in the full version of the paper. The d-Hitting Set problem asks to find a set $X \subseteq U$ of at most k elements of a given a universe U which

intersects all sets from a family $\mathcal{F}$ of subsets of U, each of cardinality exactly d. Here we present a kernel for d-Hitting Set, with $(d-1)!k(k+1)^{d-1}$ sets and $d!k(k+1)^{d-1}$ elements. It is known [25] that a kernel of size $O(k^{d-\varepsilon})$ for any constant $\varepsilon > 0$ would imply that $\mathsf{NP} \subseteq \mathsf{coNP}/poly$; thus, the k^d dependence on the number of sets in the kernel is optimal.

Let us describe the kernel. We will recursively define the notion of a *good* set.

▶ **Definition 4** (good set)**.** Let $r \in \mathbb{N}$ and $\nu_r = r!(k+1)^r$. Let $d \in \mathbb{N}$ and let $(U, \mathcal{F})$ be an instance of d-Hitting Set. We define the notion of an "(ℓ, r)-good" set inductively, in decreasing order of ℓ from d to 1, and for fixed ℓ, for increasing r from 1 to $d - \ell$.

- Any set $S \in \mathcal{F}$ is (d, r)-*good* for all r.
- A set $S \subseteq U$ is ℓ-*good* if S is (ℓ, r)-good for some r.
- A set $S \subseteq U$ is (ℓ', r)-*strong* if S is ℓ'-good and does not contain any $(\ell' - j, j)$-good subsets for any $j \in \{1, \ldots, r-1\}$.
- A set $S \subseteq U$ is (ℓ, r)-*good* if $|S| = \ell$ and S is a subset of at least ν_r $(\ell + r, r)$-strong sets.
- A set $S \subseteq U$ is *good* if S is ℓ-good for $\ell = |S|$.

Notice that if a set is (ℓ', r)-strong, then it is also (ℓ', r')-strong for all $r' < r$. Also, any ℓ-good set is $(\ell, 1)$-strong. Further, note that since the notion of $(\ell + r, r)$-strong only depends on $(\ell + a, r - a)$-good sets for $a \geq 1$, the definition of (ℓ, r)-good is sound.

Let $\mathcal{F}'$ consist of those $S \subseteq U$ that are good and none of their subsets are good. Let U' consist of all $u \in U$ that are contained in some set of $\mathcal{F}'$. Let $K = (U', \mathcal{F}')$. In the full version we prove the following lemma that shows that (K, k) is a kernel for the instance $(U, \mathcal{F})$.

▶ **Lemma 5.** *Let $(U, \mathcal{F})$ be an instance of d-Hitting Set. If $(U, \mathcal{F})$ admits a hitting set X of size at most k, then any good set $S \subseteq U$ intersects X non-trivially.*

The lemma implies that (K, k) is a kernel: first, if X' is a hitting set of K, it is a hitting set for $\mathcal{F}$ as well since for every $F \in \mathcal{F}$, either $F \in \mathcal{F}'$ or some subset of F is in $\mathcal{F}'$. Now let X be a hitting set of $\mathcal{F}$ with size at most k. By the lemma, if some S is in $\mathcal{F}'$, then it intersects X non-trivially and so X is a hitting set of $\mathcal{F}'$ as well. Now we argue about the size of K.

▶ **Lemma 6.** *If $(U, \mathcal{F})$ (and hence also $(U', \mathcal{F}')$) admits a hitting set of size at most k, then $|U'| \leq d|\mathcal{F}'|$ and $|\mathcal{F}'| \leq \left(1 + \frac{2}{(k+1)(d-1)}\right) \cdot d!(k+1)^d$.*

Proof. If $\{u\} \in \mathcal{F}'$, then no other set containing u can be in $\mathcal{F}'$. Otherwise, consider some u such that $\{u\} \notin \mathcal{F}'$. Consider all sets of size $r+1$ in $\mathcal{F}'$ that contain u, for any choice of $r \in \{1, \ldots, d-1\}$.

Since $\{u\} \notin \mathcal{F}'$, we know that u cannot be $(1, r)$-good, and thus u is contained in fewer than ν_r $(r+1)$-good sets that do not contain any $(j+1, r-j)$-good subsets for any $j \in \{2, \ldots, r-1\}$. Now since for every $F \in \mathcal{F}'$ we have that it contains no good subsets, this means that u is contained in fewer than ν_r sets in $\mathcal{F}'$ of size $r+1$.

Thus, the number of sets of $\mathcal{F}'$ containing u is at most

$$\sum_{r=1}^{d-1} \nu_r = \sum_{r=1}^{d-1} r!(k+1)^r \leq \left(1 + \frac{2}{(k+1)(d-1)}\right)(d-1)!(k+1)^{d-1},$$

where the last inequality can be proven inductively. Thus, if there is a hitting set of size at most k for $\mathcal{F}'$, then the size of $\mathcal{F}'$ is at most $(1 + \frac{2}{(k+1)(d-1)})d!(k+1)^d$. ◀

In the full version we additionally show that the kernel can be computed in $O(3^d n + m)$ time and can be dynamically maintained with very fast updates.

Abstract

We introduce a new dynamic data structure for maintaining the strongly connected components (SCCs) of a directed graph (digraph) under edge deletions, so as to answer a rich repertoire of connectivity queries. Our main technical contribution is a decremental data structure that supports sensitivity queries of the form "are u and v strongly connected in the graph $G \setminus w$?", for any triple of vertices u, v, w, while G undergoes deletions of edges. Our data structure processes a sequence of edge deletions in a digraph with n vertices in $O(mn \log n)$ total time and $O(n^2 \log n)$ space, where m is the number of edges before any deletion, and answers the above queries in constant time. We can leverage our data structure to obtain decremental data structures for many more types of queries within the same time and space complexity. For instance for edge-related queries, such as testing whether two query vertices u and v are strongly connected in $G \setminus e$, for some query edge e.

As another important application of our decremental data structure, we provide the first nontrivial algorithm for maintaining the dominator tree of a flow graph under edge deletions. We present an algorithm that processes a sequence of edge deletions in a flow graph in $O(mn \log n)$ total time and $O(n^2 \log n)$ space. For reducible flow graphs we provide an $O(mn)$-time and $O(m + n)$-space algorithm. We give a conditional lower bound that provides evidence that these running times may be tight up to subpolynomial factors.

1 Introduction

Dynamic graph algorithms have been extensively studied for several decades, and many important results have been achieved for dynamic versions of fundamental problems, including connectivity, 2-edge and 2-vertex connectivity, minimum spanning tree, transitive closure, and shortest paths (see, e.g., the survey in [14]). We recall that a dynamic graph problem is said to be *fully dynamic* if it involves both insertions and deletions of edges, *incremental* if it only involves edge insertions, and *decremental* if it only involves edge deletions.

The decremental strongly connected components (SCCs) problem asks us to maintain, under edge deletions in a directed graph G, a data structure that given two vertices u and v answers whether u and v are strongly connected in G. We extend this problem to sensitvity queries of the form "are u and v strongly connected in the graph $G \setminus w$?", for any triple of vertices u, v, w, i.e., we additionally allow the query to temporarily remove a third vertex w. We show that this extended decremental SCC problem can be used to answer fast a rich repertoire of connectivity queries, and we present a new and efficient data structure for the problem. In particular, our data structure for the extended decremental SCC problem can be used to support edge-related queries, such as maintaining the strong bridges of a digraph, testing whether two query vertices u and v are strongly connected in $G \setminus e$, reporting the SCCs of $G \setminus e$, or the largest and smallest SCCs in $G \setminus e$, for any query edge e. Furthermore, using our framework, it is possible to maintain the 2-vertex-and 2-edge-connected components of a digraph under edge deletions. All of these extensions can be handled with the same time and space bounds as for the extended decremental SCC problem. (Most of these reductions have been deferred to the full version of the paper.)

A naive approach to solving the extended decremental SCC problem is to maintain separately the SCCs in every subgraph $G \setminus w$ of G, for all vertices w. After an edge deletion we then update the SCCs of all these n subgraphs, where n is the number of vertices in G. If we simply perform a static recompution after each deletion, then we, for example, obtain decremental algorithms with $O(m^2 n)$ total time and $O(n^2)$ space by recomputing the SCCs in each $G \setminus w$ [37] or $O(m^2 + mn)$ total time and $O(m + n)$ space by constructing a more suitable static connectivity data structure [22], respectively. Here m denotes the initial number of edges. The current fastest (randomized) decremental SCC algorithm by Chechik et al. [10] trivially gives $O(mn^{3/2} \log n)$ total update time and $O(mn)$ space for our extended decremental SCC problem.

The main technical contribution of this paper is a data structure for the extended decremental SCC problem with $O(mn \log n)$ total update time that uses $O(n^2 \log n)$ space, and that answers queries in constant time. We obtain this data structure by extending Łącki's decremental SCC algorithm [30]. His algorithm maintains the SCCs of a graph under edge deletions by recursively decomposing the SCCs into smaller and smaller subgraphs. We therefore refer to his data structure as an SCC-decomposition. His total update time is $O(mn)$ and the space used is $O(m + n)$. We observe that the naive algorithm based on SCC-decompositions can be implemented in such a way that most of the work performed is redundant. We obtain our data structure by merging n SCC-decompositions into one joint data structure, which we refer to as a joint SCC-decomposition. Our data structure, like that of Łącki, is deterministic. Using completely different techniques, Georgiadis et al. [21] showed how to answer the same sensitivity queries in $O(mn)$ total time in the incremental setting, i.e., when the input digraph undergoes edge insertions only.

The extended SCC problem is related to the so-called *fault-tolerant model*. Here, one wishes to preprocess a graph G into a data structure that is able to answer fast certain

sensitivity queries, i.e., given a failed vertex w (resp., failed edge e), compute a specific property of the subgraph $G \setminus w$ (resp., $G \setminus e$) of G. Our data structure supports sensitivity queries when a digraph G undergoes edge deletions, which gives an aspect of *decremental fault-tolerance*. This may be useful in scenarios where we wish to find the best edge whose deletion optimizes certain properties (fault-tolerant aspect) and then actually perform this deletion (decremental aspect). This is, e.g., done in the computational biology applications considered by Mihalák et al. [32]. Their recursive deletion-contraction algorithm repeatedly finds the edge of a strongly connected digraph whose deletion maximizes quantities such as the number of resulting SCCs or minimizes their maximum size.

As another important application of our joint SCCs data structure, we provide the first nontrivial algorithm for maintaining the dominator tree of a flow graph under edge deletions. A flow graph $G = (V, E, s)$ is a directed graph with a distinguished start vertex $s \in V$, w.l.o.g. containing only vertices reachable from s. A vertex w *dominates* a vertex v (w is a *dominator* of v) if every path from s to v includes w. The *immediate dominator* of a vertex v, denoted by $d(v)$, is the unique vertex that dominates v and is dominated by all dominators of v. The *dominator tree* D is a tree with root s in which each vertex v has $d(v)$ as its parent. Dominator trees can be computed in linear time [2, 7, 8, 23]. The problem of finding dominators has been extensively studied, as it occurs in several applications, including program optimization and code generation [12], constraint programming [34], circuit testing [4], theoretical biology [1], memory profiling [31], fault-tolerant computing [5, 6], connectivity and path-determination problems [16, 17, 19, 18, 25, 27, 28, 29], and the analysis of diffusion networks [24].

In particular, the dynamic dominator problem arises in various applications, such as data flow analysis and compilation [11, 15]. Moreover, the results of Italiano et al. [27] imply that dynamic dominators can be used for dynamically testing 2-vertex connectivity, and for maintaining the strong bridges and strong articulation points of digraphs. The decremental dominator problem appears in the computation of maximal 2-connected subgraphs in digraphs [25, 29, 13]. The problem of updating the dominator relation has been studied for a few decades (see, e.g., [3, 9, 11, 20, 33, 35, 36]). For the incremental dominator problem, there are algorithms that achieve total $O(mn)$ running time for processing a sequence of edge insertion in a flow graph with n vertices, where m is the number of edges after all insertions [3, 11, 20]. Moreover, they can answer dominance queries, i.e., whether a query vertex w dominates another query vertex v, in constant time. Prior to our work, to the best of our knowledge, no decremental algorithm with total running time better than $O(m^2)$ was known for general flow graphs. In the special case of *reducible* flow graphs (a class that includes acyclic flow graphs), Cicerone et al. [11] achieved an $O(mn)$ update bound for the decremental dominator problem. Both the incremental and the decremental algorithms of [11] require $O(n^2)$ space, as they maintain the transitive closure of the digraph.

Our algorithm is the first to improve the trivial $O(m^2)$ bound for the decremental dominator problem in *general* flow graphs. Specifically, our algorithm can process a sequence of edge deletions in a flow graph with n vertices and initially m edges in $O(mn \log n)$ time and $O(n^2 \log n)$ space, and after processing each deletion can answer dominance queries in constant time. For the special case of *reducible* flow graphs, we give an algorithm that matches the $O(mn)$ running time of Cicerone et al. while improving the space usage to $O(m+n)$. We remark that the reducible case is interesting for applications in program optimization since one notion of a "structured" program is that its flow graph is reducible. (The details about this result appear in the full paper.) Finally, we complement our results with a conditional lower bound, which suggests that it will be hard to substantially improve our update bounds. In particular, we prove that there is no incremental nor decremental algorithm for maintaining

the dominator tree (or more generally, a dominance data structure) that has total update time $O((mn)^{1-\epsilon})$ (for some constant $\epsilon > 0$) unless the OMv Conjecture [26] fails. The same lower bound applies to the extended decremental SCC problem. Unlike the update time, it is not clear that the $O(n^2 \log n)$ space used by our joint SCC-decomposition is near-optimal. We leave it as an open problem to improve this bound.

Further Notation and Terminology. For a given digraph $G = (V, E)$, we denote the set of vertices by $V(G) = V$ and the set of edges by $E(G) = E$. We let $|E| = m$ and $|V| = n$. Two vertices u and v are *strongly connected* in G if there is a path from u to v and a path from v to u. G is *strongly connected* if every vertex is reachable from every other vertex. The *strongly connected components* (SCCs) of G are its maximal strongly connected subgraphs. We denote by $G \setminus S$ (resp., $G \setminus e$)) the graph obtained after deleting a set S of vertices (resp., an edge e) from G. For a strongly connected graph H, we say that deleting an edge e *breaks* H, if $H \setminus e$ is not strongly connected.

An edge (resp., a vertex) of G is a *strong bridge* (resp., a *strong articulation point*) if its removal increases the number of SCCs. An edge e (resp., a vertex v) is a *separating edge* (resp., a *separating vertex*) for two vertices u and v if u and v are not strongly connected in $G \setminus e$ (resp., in $G \setminus v$). Two vertices u and v are 2-*edge connected* (2-*vertex connected*) if there are two edge-disjoint paths (internally vertex-disjoint paths) between u and v. We denote by G^{R} the *reverse graph* of G, i.e., the graph which has the same vertices as G and contains an edge $e^{\mathrm{R}} = (v, u)$ for every edge $e = (u, v)$ of G.

2 A Data Structure for Maintaining Joint SCC-Decompositions

For a given initial graph G, the *decremental SCC problem* asks us to maintain a data structure that allows edge deletions and can answer whether (arbitrary) pairs (u, v) of vertices are in the same SCC. The goal is to update the data structure as quickly as possible while answering queries in constant time. In this paper we present a data structure for the *extended decremental SCC problem* in which a query provides an additional vertex w and asks whether u and v are in the same SCC when w is deleted from G. We maintain this information under edge deletions, and our data structure relies on Łącki's *SCC-decomposition* [30] for doing so.

2.1 Review of Łącki's SCC Decomposition

An SCC-decomposition recursively partitions the graph G into smaller strongly connected subgraphs. This generates a rooted tree T, whose root r represents the entire graph, and where the subtree rooted at each node ϕ represents some vertex-induced strongly connected subgraph G_ϕ (we refer to vertices of T as nodes to distinguish T from G). Every non-leaf node ϕ is a vertex of G_ϕ, and the children of ϕ correspond to SCCs of $G_\phi \setminus \phi$. The concept was introduced by Łącki [30] and slightly extended by Chechik et al. [10]. We adopt the notation from [10].

▶ **Definition 1** (SCC-decomposition)**.** Let $G = (V, E)$ be a strongly connected graph. An *SCC-decomposition* of G is a rooted tree T, whose nodes form a partition of V. For a node ϕ of T we define G_ϕ to be the subgraph of G induced by the union of all descendants of ϕ (including ϕ). Then, the following properties hold:

- Each internal node ϕ of T is a single-element set. (In this case, we sometimes abuse notation and assume that ϕ is the vertex itself.)

- Let ϕ be any internal node of T, and let $H_1, \ldots, H_t$ be the SCCs of $G_\phi \setminus \phi$. Then the node ϕ has t children $\phi_1, \ldots, \phi_t$, where $G_{\phi_i} = H_i$ for all $i \in \{1, \ldots, t\}$.

An SCC-decomposition of a graph G that is not strongly connected is a collection of SCC-decompositions of the SCCs of G. We say that T is a *partial* SCC-decomposition when the leaves of T are not required to be singletons.

Observe that for each node ϕ, the graph G_ϕ is strongly connected. Moreover, the subtree of T rooted at ϕ is an SCC-decomposition of G_ϕ. Also, for a leaf ϕ we have that $\phi = V(G_\phi)$. To build an SCC-decomposition T of a strongly connected graph G we pick an arbitrary vertex v, put it in the root of T, then recursively build SCC-decompositions of SCCs of $G \setminus \{v\}$ and make them the children of v in T. Note that since the choice of v is arbitrary, there are many ways to build an SCC-decomposition of the same graph. Łącki [30] (and Chechik et al. [10]) introduced a procedure Build-SCC-Decomposition(G, S) that takes as input a set of vertices S and returns a partial SCC-decomposition whose internal nodes are the vertices of S, i.e., these vertices are picked first and therefore appear at the top of the constructed tree. We refer to the vertices in S as internal nodes and the remaining nodes as external nodes. Note that all external nodes appear in the leaves of T, while internal nodes can be both leaves and non-leaves. This distinction is helpful when describing our algorithm.

Łącki [30] showed that the total initialization and update time under edge deletions of an SCC-decomposition is $O(m\gamma)$, where γ is the depth of the decomposition.

2.2 Towards a Joint SCC-Decomposition

Recall that the extended decremental SCC problem asks us to maintain under edge deletions a data structure for a graph G such that we can answer whether u and v are strongly connected in $G \setminus \{w\}$ when given $u, v, w \in V(G)$. A naive algorithm does this by maintaining n SCC-decompositions, each with a distinct vertex w as its root. The children of w in an SCC-decomposition that has w as its root are then exactly the SCCs of $G \setminus \{w\}$. Hence, u and v are in the same SCC if and only if they appear in the same subtree below w. The total update time of this data structure is however $O(mn^2)$, which is undesirable. With a more refined approach, we improve the time bound to $O(mn \log n)$.

Observe that the external nodes of a partial SCC-decomposition T produced by the procedure Build-SCC-Decomposition(G, S) exactly correspond to the SCCs of $G \setminus S$. This is true regardless of the order in which vertices from S are picked by the procedure. If two SCC-decompositions are built using the same set S, but with vertices being picked in a different order, then the nodes below S represent the same SCCs, which means that they can be shared by the two SCC-decompositions. Our algorithm is based on this observation. We essentially construct the n SCC-decompositions of the naive algorithm described above such that large parts of their subtrees are shared, and such that we do not need to maintain multiple copies of these subtrees. The idea is to partition the set S into two subsets S_1 and S_2 of equal size (we assume for simplicity that n is a power of 2), and then construct half of the SCC-decompositions with S_1 at the top and the other half with S_2 at the top. The procedure is repeated recursively on the top part of both halves. We refer to the bottom part, i.e., nodes that are not from S_1 and S_2, respectively, as the *extension* of the top part. Note that we eventually get a distinct vertex as the root of each of the n SCC-decompositions. The following definition formalizes the idea.

▶ **Definition 2** (Joint SCC-decomposition). A *joint SCC-decomposition* J is a recursive structure. It is either a regular SCC-decomposition T (the base case), or a pair of joint SCC-decompositions J_1, J_2 with the same set of internal nodes S and a shared set of external nodes

Input: A graph G and a set of vertices $S \subseteq V(G)$
Output: A balanced joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$ of G on S.

if $|S| = 1$ **then**
  return $T =$ Build-SCC-Decomposition(G, S).
end
Let S_1 and S_2 be the first and second half of S, respectively, and let Φ be an empty list.
foreach $i \in \{1, 2\}$ **do**
  Compute $J_i =$ Build-Joint-SCC-Decomposition(G, S_i).
  foreach *external node* ϕ *of* J_i **do**
    Compute $T_\phi =$ Build-SCC-Decomposition$(G_\phi, \phi \cap S)$.
    Add each external node of T_ϕ to Φ, if it is not already there.
  end
end
return $J = (J_1, J_2, S, \Phi)$

Figure 1 Build-Joint-SCC-Decomposition(G,S).

Φ. In the second case we refer to J as the tuple (J_1, J_2, S, Φ). A joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$ is *balanced* on S if it has one of the following two properties:

1. S is a singleton and J is a regular (partial) SCC-decomposition T with the vertex from S as root and no other internal nodes (the base case).
2. S can be partitioned into two equally sized halves S_1 and S_2, and J consists of two joint SCC-decompositions $J_1 = (J_{1,1}, J_{1,2}, S_1, \Phi_1)$ and $J_2 = (J_{2,1}, J_{2,2}, S_2, \Phi_2)$ that are balanced on S_1 and S_2, respectively. Also, each external node ϕ in Φ_1 and Φ_2 is extended with an associated SCC-decomposition T_ϕ for G_ϕ whose internal nodes are those of $\phi \cap S$. The combined set of external nodes of T_ϕ for all $\phi \in \Phi_1$ is equal to the combined set of external nodes of $T_{\phi'}$ for all $\phi' \in \Phi_2$, and these nodes are the external nodes Φ of J.

The procedure Build-Joint-SCC-Decomposition(G, S) describes how we build a balanced joint SCC-decomposition. G is the graph that we wish to decompose, and S is the set of vertices that we wish to place at the top. Initially S is the set of all vertices. The following lemma bounds the number of SCC-decompositions that make up a joint balanced SCC-decomposition. The lemma is proved by observing that the number of SCC-decompositions constructed by Build-Joint-SCC-Decomposition(G, S) is given by the recurrence $g(s) = 2g(s/2) + 2$ when $s > 1$ and $g(s) = 1$ otherwise, where $s = |S|$.

▶ **Lemma 3.** *A balanced joint SCC-decomposition for a graph G with n vertices consists of $O(n)$ SCC-decompositions.*

▶ **Lemma 4.** *Let $J = (J_1, J_2, S, \Phi)$ be a balanced joint SCC-decomposition of a graph G such that $S = V(G)$. Then the total number of nodes of J is $O(n \log n)$, where $n = |V(G)|$.*

Proof. The proof is by induction. Our induction hypothesis says that the total number of internal nodes of a balanced joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$, counting not only S but also recursively the number of internal nodes of J_1 and J_2, is $|S| \cdot (1 + \log |S|)$.

In the base case, J is an SCC-decomposition with a single internal node, and the induction hypothesis is clearly satisfied. For the induction step we count separately the total number of internal nodes of $J_1 = (J_{1,1}, J_{1,2}, S_1, \Phi_1)$ and $J_2 = (J_{2,1}, J_{2,2}, S_2, \Phi_2)$, and add the number of internal nodes of the SCC-decompositions T_ϕ for $\phi \in \Phi_1$ and $\phi \in \Phi_2$, i.e., the extensions

of J_1 and J_2 to S. Since $|S_1| = |S_2| = |S|/2$, it follows from the induction hypothesis that both J_1 and J_2 have $\frac{|S|}{2} \cdot \log |S|$ internal nodes in total. The internal nodes of T_ϕ for $\phi \in \Phi_1$ are exactly S_2, and the internal nodes of T_ϕ for $\phi \in \Phi_2$ are exactly S_1. Hence the number of internal nodes in the extensions are $|S_1| + |S_2| = |S|$. It follows that the total number of internal nodes of J is $|S| \cdot (1 + \log |S|)$ as desired.

It remains to count the external nodes of J. Note that external nodes of J_1 and J_2 correspond to internal nodes of J, i.e., they are roots of the SCC-decompositions that extend J_1 and J_2. Therefore there are at most as many external nodes inside the recursion as there are internal nodes in total. There are $O(n)$ external nodes in the extensions of J_1 and J_2 to S, and we conclude that the total number of nodes when $S = V(G)$ is at most $O(n \log n)$. ◀

Recall that an SCC-decomposition of depth γ can be initialized in time $O(m\gamma)$ [30]. Since the depth of an SCC-decomposition is at most the number of internal nodes plus one, and since Lemma 4 shows that the total number of nodes in a joint SCC-decomposition is $O(n \log n)$, it follows that the combined depth of all the SCC-decompositions that make up a joint SCC-decomposition is at most $O(n \log n)$, which proves the following lemma.

▶ **Lemma 5.** *The procedure* Build-Joint-SCC-Decomposition(G, S) *constructs a joint SCC-decomposition in time* $O(mn \log n)$.

To answer queries for the extended decremental SCC problem in constant time, we also construct and maintain an $n \times n$ matrix A such that $A[u, w]$ is the index of the SCC of $G \setminus \{w\}$ that contains u. Two vertices u and v are in the same SCC of $G \setminus \{w\}$ if and only if $A[u, w] = A[v, w]$. To avoid cluttering the pseudo-code we describe separately how A is maintained. In Build-Joint-SCC-Decomposition(G, S) we initialize A in the base case when we compute an SCC-decomposition T for a singleton $S = \{w\}$. Indeed, in this case w is the root of T, and the external nodes are exactly the SCCs of $G \setminus \{w\}$. Hence, for every vertex $u \in V(G) \setminus \{w\}$ we set $A[u, w]$ to the index of the SCC it is part of in $G \setminus \{w\}$.

Note that storing the matrix A takes space $O(n^2)$. The time spent initializing A is however dominated by the other work performed by the algorithm.

2.3 Deleting Edges from a Joint SCC-Decomposition

We next show how to maintain a joint SCC-decomposition under edge deletions. It is again instructive to consider the work performed by the naive algorithm that maintains n SCC-decompositions with distinct roots. If these are constructed as described in Section 2.2, then the SCC-decompositions will share many identical subtrees, and the work performed on these subtrees will be the same. In the joint SCC-decomposition such subtrees are shared, but otherwise the work performed is the same as the work performed for individual SCC-decompositions. We therefore use Łącki's algorithm [30] to delete edges from the individual SCC-decompositions, and we introduce a new procedure for handling the interface between the SCC-decompositions. We next briefly sketch Łącki's algorithm (see also [10, 30]).

Recall that each node ϕ of an SCC-decomposition T represents a strongly connected subgraph G_ϕ induced by the vertices in the subtree rooted at ϕ. If ϕ is an internal node of T, then the children of ϕ are the SCCs of $G_\phi \setminus \phi$. Łącki uses the following two operations to compactly represent edges among ϕ and its children.

▶ **Definition 6.** Let G be a graph. The *condensation* of G, denoted by Condense(G), is the graph obtained from G by contracting all its SCCs into single vertices. Let $v \in V(G)$. By Split(G, v) we denote the graph obtained from G by splitting v into two vertices: v_{in} and v_{out}. The in-edges of v are connected to v_{in} and the out-edges to v_{out}.

The two operations are often used together, and to simplify notation we use the shorthand $G_v^{\text{con}} = \textsc{Condense}(\textsc{Split}(G, v))$. The graph G_ϕ^{con} is stored with every internal node ϕ of the SCC-decomposition T. This introduces at most three copies of every vertex v of G: The two vertices v_{in} and v_{out} in G_v^{con}, and possibly a third vertex in the condensed graph of the parent of v in T. Moreover, every edge (u, v) appears in exactly one condensed graph, namely that of the lowest common ancestor of u and v in T, which we denote by $\text{LCA}(u, v)$. The combined space used for storing all the condensed graphs is thus $O(m + n)$.

To delete an edge (u, v), Łącki [30] locates $\phi = \text{LCA}(u, v)$, and deletes (u', v') from G_ϕ^{con}, where u' and v' are the vertices whose subtrees contain u and v. (He uses $O(m)$ space to store a pointer from every edge (u, v) to $\text{LCA}(u, v)$, enabling him to find the lowest common ancestor in constant time.) To preserve connectivity, he then checks whether u' and v' have non-zero out- and in-degrees, respectively, in G_ϕ^{con}. If this is not the case, then he repeatedly removes vertices with out- or in-degree zero and their adjacent edges from G_ϕ^{con}. All such vertices can be located, starting from u' and v', in time that is linear in the number of edges adjacent to the removed vertices. The corresponding children of ϕ are then moved up one level in T and are made siblings of ϕ. They are also inserted into $G_{par(\phi)}^{\text{con}}$, where $par(\phi)$ is the parent of ϕ, and their edges and the edges of ϕ in $G_{par(\phi)}^{\text{con}}$ are updated correspondingly. This can again be done in time linear in the number of edges in the original graph that are adjacent to vertices in the subtrees that are moved. The procedure is then repeated in $G_{par(\phi)}^{\text{con}}$. Since every vertex increases its level at most γ times, where γ is the initial depth of T, it follows that the total update time of the algorithm is at most $O(m\gamma)$.

We let $\textsc{Delete-Edge-from-SCC-decomposition}(T, u, v)$ be the procedure for deleting an edge (u, v) from an SCC-decomposition T. We also denote the recursive procedure for moving nodes $\phi_1, \ldots, \phi_k$ from being children of ϕ to being siblings of ϕ in T after an edge (u, v) is deleted by $\textsc{Fix-SCC-decomposition}(T, u, v, \phi, \{\phi_1, \ldots, \phi_k\})$. Both procedures return the resulting SCC-decomposition, or a collection of SCC-decompositions in case the graph is not strongly connected. (The pseudo-code appears in the full version of the paper.)

In a joint SCC-decomposition, vertices and edges may appear in multiple nodes as part of smaller SCC-decompositions. We therefore need to find every occurence of the edge that we wish to delete. We introduce a procedure $\textsc{Delete-Edge}(J, u, v)$ that does that by recursively searching through the nested joint SCC-decompositions and deleting (u, v) from the relevant SCC-decompositions. The procedure also handles the interface between SCC-decompositions. Note that deleting (u, v) from an SCC-decomposition T may cause the SCC corresponding to the root ϕ of T to break. The procedure $\textsc{Delete-Edge-from-SCC-decomposition}(T, u, v)$ will in this case return a collection of SCC-decompositions $\{T_1, \ldots, T_k\}$, one for each new SCC. Suppose $J = (J_1, J_2, S, \Phi)$. If T extends J_1 (resp. J_2), then it is an SCC-decomposition of the subgraph G_ϕ associated with some external node ϕ of J_1 (resp. J_2). ϕ is then itself a leaf of an SCC-decomposition T' in J_1 (resp. J_2). Moreover, when the SCC corresponding to ϕ breaks, then this leaf must be split into multiple leaves of T', one for each new SCC. Note however that the levels in T' of the involved vertices do not change after the split. We therefore cannot charge the work performed when splitting ϕ to the analysis by Łącki [30].

Let $\phi_1, \ldots, \phi_k$ be the roots of the SCC-decompositions $T_1, \ldots, T_k$ that are created when the deletion of (u, v) breaks the SCC G_ϕ. As mentioned above, we need to replace ϕ in T' by $\phi_1, \ldots, \phi_k$, which means that $\phi_1, \ldots, \phi_k$ should replace ϕ in $G_{par(\phi)}^{\text{con}}$, where $par(\phi)$ is the parent of ϕ in T'. To efficiently reconnect $\phi_1, \ldots, \phi_k$ in $G_{par(\phi)}^{\text{con}}$ we identify the vertex ϕ_i whose associated graph G_{ϕ_i} has the most vertices, and we then scan through all the vertices in the other graphs $G_{\phi_1}, \ldots, G_{\phi_{i-1}}, G_{\phi_{i+1}}, \ldots, G_{\phi_k}$ and reconnect their adjacent edges in $G_{par(\phi)}^{\text{con}}$ when relevant. The work performed is exactly the same as when Łącki

fixes an SCC-decomposition after an edge is removed. We can therefore call Fix-SCC-decomposition(T',u,v,ϕ,$\{\phi_1, \ldots, \phi_{i-1}, \phi_{i+1}, \ldots, \phi_k\}$). Note that this makes ϕ_i take over the role of ϕ. Also note that we provide the procedure with the end-points u and v of the edge that was deleted, since u and v are used as starting points for the search for disconnected vertices when propagating the update further up the tree.

Finally, observe that splitting the leaf ϕ of the SCC-decomposition T' may propagate all the way to the root of T' and break the SCC corresponding to T'. We therefore use a recursive procedure, Split-Leaf(J,u,v,ϕ,$\{\phi_1, \ldots, \phi_k\}$), to perform the split. Here u and v are again the end-points of the edge that was deleted.

▶ **Theorem 7.** *The total update time spent by* Delete-Edge(J, u, v) *in order to maintain a balanced joint SCC-decomposition under edge deletions is* $O(mn \log n)$.

Proof. We only sketch the proof, and refer to the full paper for additional details.

The time spent by Delete-Edge(J, u, v) consists of three parts: checking whether $\{u, v\} \subseteq V(G_\phi)$ for some $\phi \in \Phi$, the work performed while deleting edges from SCC-decompositions, and the work performed by Split-Leaf$(J_i, u, v, \phi, \{\phi_1, \ldots, \phi_k\})$, for $i \in \{1, 2\}$. To check in constant time whether $\{u, v\} \subseteq V(G_\phi)$, we maintain for each SCC-decomposition T an array on the vertices of the original graph G, such that $T\langle v\rangle =$ True if v appears in T, and $T\langle v\rangle =$ False otherwise. Storing these arrays takes up $O(n^2)$ space, and they are updated when the SCC of the root of an SCC-decomposition breaks.

Recall that Łącki [30] showed that the total initialization and update time of an SCC-decomposition is $O(m\gamma)$, where γ is the depth of the decomposition. By Lemma 4, the total number of nodes of the SCC-decompositions in J is $O(n \log n)$, and therefore the combined depth of the SCC-decompositions is also $O(n \log n)$. It follows that the time spent on Delete-Edge-from-SCC-decomposition(T_ϕ, u, v) is bounded by $O(mn \log n)$.

It remains to analyze the time spent on Split-Leaf$(J_i, u, v, \phi, \{\phi_1, \ldots, \phi_k\})$. Recall that Split-Leaf identifies the node ϕ_i that contains the most vertices from G, and then breaks off $\phi_1, \ldots, \phi_{i-1}, \phi_i, \ldots, \phi_k$ from ϕ. This means that ϕ is turned into ϕ_i, and that we do not scan through edges adjacent to vertices in ϕ_i. Since a split therefore moves vertices to new nodes of at most half the size, each vertex v can only be moved $O(\log n)$ times in one particular SCC-decomposition T by Split-Leaf. Each move takes time proportional to the number of edges adjacent to v, so the total time spent splitting leaves of T is at most $O(m \log n)$. Since, by Lemma 3, there are only $O(n)$ SCC-decompositions in J, it follows that the total time spent splitting leaves is $O(mn \log n)$. Furthermore, the time spent by Split-Leaf on fixing SCC-decompositions can be charged to the depth reduction of the vertices that are moved, and this part of the analysis is therefore the same as for Delete-Edge-from-SCC-decomposition(T_ϕ, u, v). ◀

Recall that we also maintain a matrix A for answering queries, where $A[u, w]$ is the index of the SCC of $G \setminus \{w\}$ that contains u. We again update A when we make changes to the topmost SCC-decompositions that each only contain a single internal node, i.e., when such a root ϕ gets a new child, or when G_ϕ breaks into multiple SCCs. The time spent updating A is dominated by the rest of the work that is performed by our algorithm, where we scan through all edges adjacent to vertices whose SCC is changed.

As described briefly in Section 2.3, Łącki's SCC-decomposition can be implemented such that is uses $O(m + n)$ space [30]. Since a balanced joint SCC-decomposition consists of $O(n)$ SCC-decompositions (Lemma 3), it follows that a naive implementation of our data structure uses $O(mn)$ space. In the full version of the paper we show how to obtain an alternative bound of $O(n^2 \log n)$. Doing so requires two observations:

- After an edge (u', v') is deleted from a condensed graph G_ϕ^{con}, the vertex u' has a path to ϕ_{in} if and only if u' has non-zero out-degree, and there is a path from ϕ_{out} to v' if and only if v' has non-zero in-degree. Instead of storing the edges of the condensed graphs we therefore store the in- and out-degrees of the vertices. To visit all neighbors of a vertex u' in G_ϕ^{con}, we then collect from the original graph G all edges adjacent to vertices in the subgraph of u', and we check for each edge whether the other end-point is part of G_ϕ^{con} and which vertex of G_ϕ^{con} it goes to. To do so we store pointers between the vertices of G and the vertices of the condensed graphs that they are part of. Since a joint SCC-decomposition contains $O(n \log n)$ nodes this takes $O(n^2 \log n)$ space.
- Since a joint SCC-decomposition contains $O(n \log n)$ nodes in total, we have time to visit all the nodes of an SCC-decomposition T when searching for the lowest common ancestor of two vertices u and v. This is done in a bottom-up fashion. We therefore do not need to store a pointer from every edge (u, v) to $\text{LCA}(u, v)$.

3 Applications

In this section we exploit the decremental joint SCC-decomposition to design decremental algorithms for various connectivity notions defined with respect to vertex or edge failures.

Maintaining Decrementally the Dominator Tree. We show how to maintain a dominator tree D of a flow graph G, rooted at a starting vertex s. We denote by $d(v)$ the parent of v in D. We first produce a flow graph G_s from G by adding an edge from each vertex $v \in V \setminus s$ to s. The addition of those edges has the following property. If a vertex u is not strongly connected to s in G_s then there is no path from s to u in G. Conversely, if a vertex u is not strongly connected to s in $G_s \setminus v$, while s and u are strongly connected in G_s, then all paths from s to u in G contain v. That is, v is a dominator of u in G.

We maintain decrementally a joint SCC-decomposition of G_s in a total of $O(mn \log n)$ time and $O(n^2 \log n)$ space. Therefore, for each vertex v we maintain the SCCs in $G \setminus v$. Let $v \neq s$: after the SCC containing s in $G \setminus v$ breaks, all the vertices that are not in the new SCC that contains s are dominated from v in G. We can report the newly dominated vertices from v in G in time proportional to their number. Therefore, after each edge deletion we need to process a batch $\mathcal{N}$ of incoming new dominance relations $N(v) = \{u_1, \ldots, u_k\}$, where $u_1, \ldots, u_k$ are dominated by v in G. We can process a batch of updates $\mathcal{N}$ in two phases as follows. For each vertex $u \neq s$ we keep a counter $\mathit{depth}(u)$ of the number of vertices that dominate u. For each dominance relation $N(v) \in \mathcal{N}$, we increase $\mathit{depth}(u)$ for each $u \in N(v)$. After this first phase ends, all vertices have updated counters. Then the new parent of each vertex u in D is the vertex with the largest counter among $d(u)$ (i.e., the parent of u in D before the edge insertion) and all vertices v such that $u \in N(v)$ and $N(v) \in \mathcal{N}$.

Now we bound the total time required to maintain the dominator tree. The running time of the above procedure, during the whole sequence of deletions, is bounded by the total size of all the sets $N(v)$. Note that any vertex can appear in a specific $N(v)$ set at most once during the deletion sequence. Hence, the total size of all the sets $N(v)$ is $O(n^2)$.

▶ **Lemma 8.** *The dominator tree of a directed graph G with start vertex s can be maintained decrementally in $O(mn \log n)$ total update time and $O(n^2 \log n)$ space, where m is the number of edges in the initial graph and n is the number of vertices.*

Maintaining Decrementally the Strong Bridges of the Graph. Let G be strongly connected: its strong bridges can be computed efficiently from a dominator tree D of G and a

dominator tree D^R of G^R, both rooted at the same start vertex s. We present a randomized algorithm that maintains such a pair of dominator trees in each SCC of a digraph in $O(mn \log n)$ total expected time, and $O(n^2 \log n)$ space. This allows us to maintain the set of strong bridges of a digraph in the same (expected) running time and space.

Maintaining Decrementally the 2-Edge-Connected Components. In this section we show how to maintain the 2-edge-connected components of directed graph. Two vertices w and z are 2-edge-connected if and only if there is no edge e such that w and z are not strongly connected in $G \setminus e$. A 2-edge-connected component is a maximal subset $B \subseteq V$, such that w and z are 2-edge-connected, for all $z, w \in B$. Therefore, a simple-minded algorithm for computing the 2-edge-connected components is the following. We start with the trivial partition $\mathcal{P}$ of the vertices that is equal to the set of SCCs of the graph. For every strong bridge e, we compute the SCCs $C_1, \ldots, C_k$ of $G \setminus e$ and we refine the maintained partition $\mathcal{P}$ according to the partition induced by the SCCs $C_1, \ldots, C_k$. After performing all refinements on $\mathcal{P}$ two vertices are in the same set if and only if we did not find an edge that separates them, which is exactly the definition of 2-edge-connected components.

Our algorithm is a dynamic version of the aforementioned simple-minded algorithm. That is, we maintain the SCCs of $G \setminus e$, for each strong bridge e, and refine the maintained partition $\mathcal{P}$ whenever we identify that $\mathcal{P}$ no longer contains the 2-vertex-connected components of G. We do this as follows. Assume that a component $C \in \mathcal{P}$ contains vertices in different SCCs of $G \setminus e$, for some e. Let $C_1, C_2, \ldots, C_k$ be the SCCs in $G \setminus e$. We replace C by $\{C \cap C_1\}, \ldots, \{C \cap C_k\}$. These refinements can be easily performed in $O(n)$ time, and therefore we spend total time $O(n^2)$ for all refinements throughout the algorithm.

In order to make our algorithm efficient we need to specify how to detect whether two 2-edge-connected vertices appear in different SCCs in $G \setminus e$, for some edge e. Whenever an SCC C in $G \setminus e$, breaks into k SCCs $C_1, \ldots, C_k$, for all SCCs C_i except the largest one we examine whether the components $C \in \mathcal{P}$ containing subsets of vertices of C_i are entirely contained in C_i. We develop machinery that allows us to list all vertices in the resulting SCCs $C_1, \ldots, C_k$ except the largest one, in time proportional to their number. The details can be found in the full paper. Each vertex can appear at most $\log n$ times in an SCC of $G \setminus e$, for some strong bridge e, that is not the largest after a big SCC breaks. This implies that we spend $O(n \log n)$ time for each graph $G \setminus e$ on testing whether an edge deletion leaves two (previously) 2-edge-connected vertices in different SCCs in $G \setminus e$, for some edge e. We show that at most $O(n)$ strong bridges can appear throughout any sequence of edge deletions. Thus we spend $O(n^2 \log n)$ time in total.

▶ **Lemma 9.** *The 2-edge-connected components of a digraph G can be maintained decrementally in $O(mn \log n)$ total expected time against an oblivious adversary, using $O(n^2 \log n)$ space, where m is the number of edges in the initial graph and n is the number of vertices.*

4 Conditional Lower Bound

In the following we give a conditional lower bound for the partially dynamic dominator tree problem. We show that there is no incremental nor decremental algorithm for maintaining the dominator tree that has total update time $O((mn)^{1-\epsilon})$ (for some constant $\epsilon > 0$) unless the OMv Conjecture [26] fails. This also holds for algorithms that do not explicitly maintain the tree, but are able to answer parent-queries. Formally, we prove the following statement.

▶ **Theorem 10.** *For any constant $\delta \in (0, 1/2]$ and any n and $m = \Theta(n^{1/(1-\delta)})$, there is no algorithm for maintaining a dominator tree under edge deletions/insertions allowing queries*

of the form "is x the parent of y in the dominator tree" that uses polynomial preprocessing time, total update time $u(m,n) = (mn)^{1-\epsilon}$ and query time $q(m) = m^{\delta-\epsilon}$ for some constant $\epsilon > 0$, unless the OMv conjecture fails.

Under this conditional lower bound, the running time of our algorithm is optimal up to sub-polynomial factors. We give the reduction for the decremental version of the problem. Hardness of the incremental version follows analogously.

In the online Boolean matrix-vector problem we are first given a Boolean $n \times n$ matrix M to preprocess. After the preprocessing, we are given a sequence of n-dimensional Boolean vectors $v^{(1)}, \ldots, v^{(n)}$ one by one. For each $1 \leq t \leq n$, we have to return the result of the matrix-vector multiplication $Mv^{(t)}$ before we are allowed to see the next vector $v^{(t+1)}$. The OMv Conjecture states that there is no algorithm that computes each matrix-vector product correctly (with high probability) and in total spends time $O(n^{3-\epsilon})$ for some constant $\epsilon > 0$.

We will not use the OMv problem directly as the starting point of our reduction. Instead we consider the following γ-OuMv problem (for a fixed $\gamma > 0$) and parameters n_1, n_2, and n_3 such that $n_1 = \lfloor n_2^\gamma \rfloor$: We are first given a Boolean $n_1 \times n_2$ matrix M to preprocess. After the preprocessing, we are given a sequence of pairs of n_1-dimensional Boolean vectors $(u^{(1)}, v^{(1)}), \ldots, (u^{(n_3)}, v^{(n_3)})$ one by one. For each $1 \leq t \leq n_3$, we have to return the result of the Boolean vector-matrix-vector multiplication $(u^{(t)})^\intercal M v^{(t)}$ before we see the next pair of vectors $(u^{(t+1)}, v^{(t+1)})$. It has been shown [26] that under the OMv Conjecture, there is no algorithm for this problem with polynomial preprocessing time and total processing time $O(n_1^{1-\epsilon_1} n_2^{1-\epsilon_2} n_3^{1-\epsilon_3})$ such that all ϵ_i are ≥ 0 and at least one ϵ_i is a constant > 0.

We now give the reduction from the γ-OuMv problem with $\gamma = \delta/(1-\delta)$ to the decremental dominator tree problem. In the following we denote by v_i the i-th entry of a vector i and by $M_{i,j}$ the entry at row i and column j of a matrix M.

Consider an instance of the γ-OuMv problem with parameters $n_1 = m^{1-\delta}$, $n_2 = m^\delta$, and $n_3 = m^{1-\delta}$. We preprocess the matrix M by constructing a graph $G^{(0)}$ with the set of vertices $V = \{s, x_1, \ldots, x_{n_3}, x_{n_3+1}, y_1, \ldots, y_{n_1}, z_1, \ldots, z_{n_2}\}$ and the following edges: (1) an edge (s, x_1), and, for every $1 \leq t \leq n_3$, an edge (x_t, x_{t+1}), (2) for every $1 \leq j \leq n_2$, an edge (t, z_j), (3) for every $1 \leq t \leq n_3$ and every $1 \leq i \leq n_1$, an edge (x_t, y_i), and (4) for every $1 \leq i \leq n_1$ and every $1 \leq j \leq n_2$, an edge (y_i, z_j) if and only if $M_{i,j} = 1$.

Whenever the algorithm is given the next pair of vectors $(u^{(t)}, v^{(t)})$, we first create a graph $G^{(t)}$ by performing the following edge deletions in $G^{(t-1)}$: If $t \geq 2$, we first delete all outgoing edges of x_{t-1}, except the one to x_t. Then (for any value of t), for every i such that $u_i^{(t)} = 0$ we delete the edge from x_t to y_i. Thus, for every $1 \leq i \leq n_1$, there will be an edge from x_t to y_i in $G^{(t)}$ if and only if $u_i^{(t)} = 1$. Having created $G^{(t)}$, we now, for every j such that $v_j^{(t)} = 1$, check whether x_t is the parent of z_j in the dominator tree. If this is the case for at least one j we return that $(u^{(t)})^\intercal M v^{(t)}$ is 1, otherwise we return 0.

The correctness of our reduction follows from the following lemma.

▶ **Lemma 11.** *For every $1 \leq t \leq n$, the j-th entry of $(u^{(t)})^\intercal M$ is 1 if and only if x_t is the immediate dominator of z_j in $G^{(t)}$*

Note that $(u^{(t)})^\intercal M v^{(t)}$ is 1 if and only if there is a j such that both the j-th entry of $u^{(t)}M$ as well as the j-th entry of $v^{(t)}$ are 1. Furthermore, x_t is the parent of z_j in the dominator tree if and only if x_t is an immediate dominator of z_j in the current graph. Therefore the lemma establishes the correctness of the reduction.

The initial graph $G^{(0)}$ has $n := \Theta(n_1 + n_2 + n_3) = \Theta(m^\delta + m^{1-\delta}) = \Theta(m^{1-\delta})$ vertices and $\Theta(n_1 n_2 + n_2 n_3) = \Theta(m)$ edges. The total number of parent-queries is $O(n_1 n_3) = m^{2(1-\delta)}$. Suppose the total update time of the decremental dominator tree algorithm is $O(u(m,n)) =$

$(mn)^{1-\epsilon}$ and its query time is $O(q(m)) = m^{\delta-\epsilon}$. Using the reduction above, we can thus solve the γ-OuMv problem for the parameters n_1, n_2, n_3 with polynomial preprocessing time and total update time $O(u(m,n) + m^{2(1-\delta)}q(m)) = O(u(m, m^{1-\delta}) + m^{2(1-\delta)}q(m)) = O(m^{2-\delta-\epsilon})$. Since $n_1 n_2 n_3 = m^{2-\delta}$, this means we would get an algorithm for the γ-OuMv problem with polynomial preprocessing time and total update time $O(n_1^{1-\epsilon_1} n_2^{1-\epsilon_2} n_3^{1-\epsilon_3})$ where at least one ϵ_i is a constant > 0. This contradicts the OMv Conjecture.

Abstract

We propose a theoretical framework to capture incremental solutions to cardinality constrained maximization problems. The defining characteristic of our framework is that the cardinality/support of the solution is bounded by a value $k \in \mathbb{N}$ that grows over time, and we allow the solution to be extended one element at a time. We investigate the best-possible competitive ratio of such an incremental solution, i.e., the worst ratio over all k between the incremental solution after k steps and an optimum solution of cardinality k. We define a large class of problems that contains many important cardinality constrained maximization problems like maximum matching, knapsack, and packing/covering problems. We provide a general 2.618-competitive incremental algorithm for this class of problems, and show that no algorithm can have competitive ratio below 2.18 in general.

In the second part of the paper, we focus on the inherently incremental greedy algorithm that increases the objective value as much as possible in each step. This algorithm is known to be 1.58-competitive for submodular objective functions, but it has unbounded competitive ratio for the class of incremental problems mentioned above. We define a relaxed submodularity condition for the objective function, capturing problems like maximum (weighted) (b-)matching and a variant of the maximum flow problem. We show that the greedy algorithm has competitive ratio (exactly) 2.313 for the class of problems that satisfy this relaxed submodularity condition.

Note that our upper bounds on the competitive ratios translate to approximation ratios for the underlying cardinality constrained problems.

1 Introduction

Practical solutions to optimization problems are often inherently *incremental* in the sense that they evolve historically instead of being established in a one-shot fashion. This is especially true when solutions are expensive and need time and repeated investments to be implemented, for example when optimizing the layout of logistics and other infrastructures.

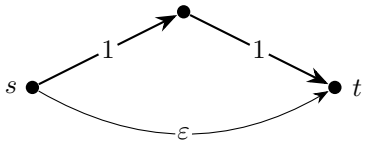

Figure 1 Example showing that the s-t-flow problem does not always admit good incremental solutions, where $\varepsilon > 0$ is arbitrarily small.

In this paper, we propose a theoretical framework to capture *incremental maximization* problems in some generality.

We describe an incremental problem by a set U containing the possible elements of a solution, and an objective function $f\colon 2^U \to \mathbb{R}^+$ that assigns to each solution $S \subseteq U$ some non-negative value $f(S)$. We consider problems of the form

$$\begin{aligned} &\max\ f(S) \\ &\text{s.t. } |S| \leq k \\ &\quad S \subseteq U, \end{aligned} \tag{1}$$

where $k \in \mathbb{N}$ grows over time.

An incremental solution $\vec{S}$ is given by an order $\{s_1, s_2, \dots\} := U$ in which the elements of U are to be added to the solution over time. A good incremental solution needs to provide a good solution after k steps, for every k, compared to an optimum solution $S_k^\star$ with k elements, where we let $S_k^\star \in \arg\max_{S\subseteq U, |S|=k} f(S)$ and $f_k^\star := f(S_k^\star)$. Formally, we measure the quality of an incremental solution by its *competitive ratio*. For $\vec{S}_k := \{s_1, \dots, s_k\} \subseteq U$ being the first k elements of $\vec{S}$, we say that $\vec{S}$ is (strictly) ρ-competitive if

$$\max_{k\in\{1,\dots,|U|\}} \frac{f_k^\star}{f(\vec{S}_k)} \leq \rho.$$

An algorithm is called ρ-competitive if it always produces a ρ-competitive solution, and its *competitive ratio* is the infimum over all $\rho \geq 1$ such that it is ρ-competitive. Notice that we do not require the algorithm to run in polynomial time.

While all cardinality constrained optimization problems can be viewed in an incremental setting, clearly not all such problems admit good incremental solutions. For example, consider a cardinality constrained formulation of the classical maximum s-t-flow problem: For a given graph $G = (V, E)$, two vertices $s, t \in V$ and capacities $u\colon E \to \mathbb{R}^+$, we ask for a subset $E' \subseteq E$ of cardinality $k \in \mathbb{N}$ such that the maximum flow in the subgraph (V, E') is maximized. The example in Figure 1 shows that we cannot hope for an incremental solution that is simultaneously close to optimal for cardinalities 1 and 2.

In order to derive general bounds on the competitive ratio of incremental problems, we need to restrict the class of objective functions f that we consider. Intuitively, the unbounded competitive ratio in the flow example comes from the fact that we have to invest in the s-t-path of capacity 1 as soon as possible, but this path only yields its payoff once it is completed after two steps.

In order to prevent this and similar behaviors, we require f to be monotone (i.e., $f(S) \leq f(T)$ if $S \subseteq T$) and sub-additive (i.e., $f(S) + f(T) \geq f(S \cup T)$). Many important optimization problems satisfy these weak conditions, and we give a short list of examples below. We will see that all these (and many more) problems admit incremental solutions with a bounded competitive ratio. More specifically, we develop a general 2.618-competitive

incremental algorithm that can be applied to a broad class of problems, including all problems mentioned below. We illustrate in detail how to apply our model to obtain an incremental variant of the matching problem, and then list incremental versions of other important problems that are obtained analogously.

- Maximum Weighted Matching: Consider a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_{\geq 0}$. If we think of edges as *potential* connections and edge weights as *potential* payoffs, then it is not enough to find the final matching because we cannot construct the edges all at once: the goal is to find a sequence of edges that achieves a high pay-off in the short, the medium, and the long term. In terms of our formal framework, we add edges to a set S one at a time with $U = E$ and $f(S)$ is the maximum weight of a matching $M \subseteq S$. In order to be ρ-competitive, we need that, after k steps for every k, our solution S of cardinality k is no worse than a factor of ρ away from the optimum solution of cardinality k, i.e., $f(S) \geq f(S^\star_k)/\rho$.
  This model captures the setting where the infrastructure (e.g. the matching, the knapsack, the covering, or the flow) must be built up over time. The online model would be too restrictive in this setting because here we know our options in advance. Note that, as we add more edges, the set of edges S only needs to contain a large matching M, but does not have to be a matching itself; The matching M can change to an arbitrary subset of S from one cardinality to the next and does not have to stay consistent. This ensures that $f(S)$ is monotonically increasing, and is in keeping with the infrastructures setting where the potential regret present in the online model does not apply: building more infrastructure can only help, since once it is built, we can change how it is used. Accordingly, in all the problems below the set S does not have to be a valid solution to the cardinality constrained problem at hand, but rather needs to *contain* a good solution as a subset. The objective $f(S)$ is consistently defined to be the value of the best solution that is a subset of S. Notice that this approach can easily be generalized to Maximum b-Matching.
- Set Packing: Given a set of weighted sets $\mathcal{X}$ we ask for an incremental subset $S \subseteq \mathcal{X}$ where $f(S)$ is the maximum weight of mutually disjoint subsets in S. This problem captures many well-known problems such as Maximum Hypergraph Matching and Maximum Independent Set.
- Maximum Coverage: Given a set of weighted sets $\mathcal{X} \subseteq 2^U$ over an universe of elements U, we ask for an incremental subset $S \subseteq \mathcal{X}$, where $f(S)$ is the weight of elements in $\bigcup_{X \in S} X$. This problem captures maximization versions of clustering and location problems. We can include opening costs $c \colon \mathcal{X} \to \mathbb{R}_{\geq 0}$ by letting $f(S)$ be the maximum over all subsets $S' \subseteq S$ of the number (or weight) of the sets in S' minus their opening costs.
- Knapsack: Given a set X of items, associated sizes $s \colon X \to \mathbb{R}_{\geq 0}$ and values $v \colon X \to \mathbb{R}_{\geq 0}$, and a knapsack of capacity 1, we ask for an incremental subset $S \subseteq X$, where $f(S)$ is the largest value $\sum_{x \in S'} v(x)$ of any subset $S' \subseteq S$ with $\sum_{x \in S'} s(x) \leq 1$. This problem can be generalized to Multi-Dimensional Knapsack by letting item sizes be vectors and letting the knapsack have a capacity in every dimension.
- Disjoint Paths: Given a graph $G = (V, E)$, a set of pairs $\mathcal{X} \subseteq V^2$ with weights $w \colon \mathcal{X} \to \mathbb{R}_{\geq 0}$, we ask for an incremental subset $S \subseteq \mathcal{X}$, where $f(S)$ is the maximum weight of a subset $S' \subseteq S$, such that G contains mutually disjoint paths between every pair in S'.
- Maximum Bridge-Flow: We argued above that the maximum s-t-flow problem is not amenable to the incremental setting because it does not pay off to build paths partially.

To overcome this, we consider a natural restriction of the flow problem where most edges are freely available to be used, and only the edges of a directed s-t-cut need to be built incrementally. If the directed cut has no backward edges, every s-t-path contains exactly one edge that needs to be built, and we never have to invest multiple steps to establish a single path. This problem captures logistical problems where links need to be established between two clusters, like when bridges need to be built across a river, cables across an ocean, or when warehouses need to be opened in a supplier-warehouse-consumer network. Formally, given a directed graph $G = (V, E)$ with capacities $u\colon E \to \mathbb{R}$, vertices $s, t \in V$, and a directed s-t-cut $C \subseteq E$ induced by the partition (U, W) of V such that the directed cut induced by (W, U) is empty, we ask for an incremental subset $S \subseteq C$ where $f(S)$ is the value of a maximum flow in the subgraph $(V, E \setminus (C \setminus S))$.

It is easy to verify that all the problems mentioned above (and many more) indeed have a monotone and sub-additive objective function. In addition, each one of these problems satisfies the following property: For every $S \subseteq U$, there exists $s \in S$ with $f(S \setminus \{s\}) \geq f(S) - f(S)/|S|$. We call this property the *accountability* property – to our knowledge, it has not been named before. Intuitively, this property ensures that the value of a set $S \subseteq U$ is the sum of individual contributions of its elements, and there cannot be additional value that emerges only when certain elements of U combine. While it is easy to formulate artificial problems that have monotonicity and sub-additivity but no accountability, we were not able to identify any natural problems of this kind. This justifies to add accountability to the list of properties that we require of incremental problems.

▶ **Definition 1.** Given a set of elements U, and a function $f\colon 2^U \to \mathbb{R}$, we say that the function f is *incremental* if it satisfies the following properties for every $S, T \subseteq U$:

1. (monotonicity): $S \subseteq T \Rightarrow f(S) \leq f(T)$,
2. (sub-additivity): $f(S) + f(T) \geq f(S \cup T)$,
3. (accountability): $\exists s \in S\colon f(S \setminus \{s\}) \geq f(S) - f(S)/|S|$.

We say that a cardinality constrained problem with increasing cardinality (eq. (1)) is *incremental* if its objective function is incremental.

Observe that a ρ-competitive incremental algorithm immediately yields a ρ-approximation algorithm for the underlying cardinality constrained problem, with the caveat that the resulting approximation algorithm might not be efficient since we make no demands on the runtime of the incremental algorithm. The converse is rarely the case since approximation algorithms usually do not construct their solution in incremental fashion. A prominent exception are *greedy* algorithms that are inherently incremental in the sense that they pick elements one-by-one such that each pick increases the objective by the maximum amount possible. This type of a greedy algorithm has been studied as an approximation algorithm for many cardinality constrained problems, and approximation ratios translate immediately to competitive ratios for the incremental version of the corresponding problem. In particular, the greedy algorithm is known to have competitive ratio (exactly) $\frac{e}{e-1} \approx 1.58$ if the objective function f is monotone and submodular [27]. Note, however, that of all the incremental problems listed above, only Maximum Coverage (without opening costs) has a submodular objective function. It is also known that if we relax the submodularity requirement and allow f to be the minimum of two monotone (sub-)modular functions, the greedy algorithm can be arbitrarily bad [21]. We provide a different relaxation of submodularity that captures Maximum (Weighted) (b-)Matching and Maximum Bridge-Flow, and where the greedy algorithm has a bounded competitive/approximation ratio.

Our Results. As our first result, we show that every incremental problem admits a bounded competitive ratio.

▶ **Theorem 2.** *Every incremental problem admits a $(1+\varphi)$-competitive algorithm, where φ is the golden ratio and $(1+\varphi) \approx 2.618$. No general deterministic algorithm for this class of problems has a competitive ratio of 2.18 or better.*

Again, note that we make no guarantees regarding the running time of our incremental algorithm. In fact, our algorithm relies on the ability to compute the optimum of the underlying cardinality constrained problem for increasing cardinalities. If we can provide an efficient approximation of this optimum, we get an efficient incremental algorithm in the following sense.

▶ **Corollary 3.** *If there is a polynomial time α-approximation algorithm for a cardinality constrained problem with incremental objective function, then we can design a polynomial time $\alpha(1+\varphi)$-competitive incremental algorithm.*
