[6] This states every graph G of tree-width k contains an $\Omega(k^{\varepsilon}) \times \Omega(k^{\varepsilon})$ grid minor for an absolute constant $\varepsilon > 0$.

5.4 Lower Bounds: AC^0 Formula Size

For the main result of this paper (Theorem 6), we require a lower bound on the AC^0 formula size of SUB_G (or in fact on the fan-in $O(n)$ depth of SUB_G). Since formulas are a subclass of circuits, Theorem 13 implies that the AC^0 formula size of SUB_G is at least $n^{\Omega(\mathbf{tw}(G)/\log \mathbf{tw}(G))}$. However, this does not match the $n^{\mathbf{td}(G)+O(1)}$ lower bound of Proposition 12, since $\mathbf{td}(G)$ may be larger than $\mathbf{tw}(G)$ (by up to a $\log|V(G)|$ factor). In particular, the path P_k has tree-width 1 and tree-depth $\lceil \log(k+1) \rceil$. Although Theorem 13 gives no non-trivial lower bound on the AC^0 formula size of SUB_{P_k}, a nearly optimal lower bound was proved in different work of the author [41]:

▶ **Theorem 14.** *The* AC^0 *formula size of* SUB_{P_k} *is* $n^{\Omega(\log k)}$. *More precisely, the depth-*d *formula size of* $\mathrm{SUB}_{P_k,n}$ *is* $n^{\Omega(\log k)}$ *for all* $k, d, n \in \mathbb{N}$ *with* $k \leq \log\log n$ *and* $d \leq \frac{\log n}{(\log\log n)^3}$.

Via the relationship between AC^0 formula size and fan-in $O(n)$ circuit depth, Theorem 14 implies:

▶ **Corollary 15.** *Circuits with fan-in* $O(n)$ *computing* SUB_{P_k} *have depth* $\Omega(\log k)$.

▶ **Remark 16.** We mention a few other lower bounds related to Corollary 15. A recent paper of Chen, Oliveira, Servedio and Tan [13] gives a nearly optimal size-depth trade-off for AC^0 circuits computing SUB_{P_k}. Namely, they prove that the depth-d circuit size of $\mathrm{SUB}_{P_k,n}$ is $n^{\Omega(d^{-1}k^{1/(d-1)})}$ for all $k \leq n^{1/5}$. (This result is incomparable to Theorem 14.) As a corollary, this shows that circuits with fan-in $O(n)$ computing SUB_{P_k} have depth $\Omega(\log k/\log\log k)$ (a slightly weaker bound than Corollary 15). Previous size-depth trade-offs due to Beame, Impagliazzo and Pitassi [9] and Ajtai [2] imply lower bounds of $\Omega(\log\log k)$ and $\Omega(\log^* k)$ respectively on the fan-in $O(n)$ depth of SUB_{P_k}.

In Section 7.1, we use Corollary 15 (together with Corollary 11) to prove a weak version of our main result, Theorem 6, with an exponential upper bound $\beta(k) \leq 2^{O(k)}$ on the quantifier-rank blow-up. We remark that the lower bound of Chen et al. implies a slightly weaker upper bound of $k^{O(k)}$, while the very first non-trivial lower bound of Ajtai implies a *non-elementary* upper bound on $\beta(k)$ (similar to the original proof of Theorem 4). For the polynomial upper bound $\beta(k) \leq k^{O(1)}$, we require a stronger $n^{\Omega(\mathbf{td}(G)^{\varepsilon})}$ lower bound on the AC^0 formula size of SUB_G for arbitrary graphs G, as we explain in Section 7.2.

6 Preliminaries, III

In this section, we state a few needed lemmas on the relationship between first-order logic and AC^0 formula size. As before, let σ be a fixed finite relational signature. However, we now stipulate that ***all structures in Sections 6 and 7 are finite***. That is, we drop the adjective "finite" everywhere since it is assumed. Asymptotic notation in these sections ($O(\cdot)$, etc.) implicitly depends on σ (although, essentially without loss of generality, it suffices to prove our results in the special case $\sigma = \{R^{(2)}\}$ of a single binary relation).

6.1 Descriptive Complexity: $\mathrm{FO} = \mathrm{AC}^0$

▶ **Definition 17** (Gaifman Graphs, Encodings, MODEL_Φ).

- For a structure $\mathcal{A}$, we denote by $\mathrm{Gaif}(\mathcal{A})$ the *Gaifman graph* of $\mathcal{A}$. This is the graph whose vertex set is the universe of $\mathcal{A}$ and whose edges are pairs $\{v, w\}$ such that $v \neq w$ and v, w appear together in a tuple of any relation of $\mathcal{A}$.

- If $\mathcal{A}$ has universe $[n]$, then we denote by $\mathrm{Enc}(\mathcal{A}) \in \{0,1\}^{\widehat{n}}$ the standard bit-string encoding of $\mathcal{A}$ where $\widehat{n} = \sum_{R^{(t)} \in \sigma} n^t$ $(= n^{O_\sigma(1)})$. That is, each bit of $\mathrm{Enc}(\mathcal{A})$ is the indicator for a tuple of some relation of $\mathcal{A}$. (Note that $\mathrm{Enc}(\cdot)$ is a bijection between structures with universe $[n]$ and strings in $\{0,1\}^{\widehat{n}}$.)
- For a first-order sentence Φ and $n \in \mathbb{N}$, let $\mathrm{MODEL}_{\Phi,n} : \{0,1\}^{\widehat{n}} \to \{0,1\}$ be the Boolean function defined, for structures $\mathcal{A}$ with universe $[n]$, by

$$\mathrm{MODEL}_{\Phi,n}(\mathrm{Enc}(\mathcal{A})) = 1 \overset{\text{def}}{\iff} \mathcal{A} \models \Phi.$$

We write MODEL_Φ for the sequence of Boolean functions $\{\mathrm{MODEL}_{\Phi,n}\}_{n\in\mathbb{N}}$.

The next lemma gives one-half of the descriptive complexity correspondence between first-order logic and AC^0:

▶ **Lemma 18** ("$\mathrm{FO} \subseteq \mathrm{AC}^0$"). *For all $1 \le w \le k$, if Φ is a first-order sentence of quantifier-rank k and variable-width w, then MODEL_Φ is computable by AC^0 circuits of depth k and fan-in $O(n)$ and size $O(n^w)$. These circuits are equivalent with AC^0 formulas of depth k and size $O(n^k)$.*

(To be completely precise, each of these $O(\cdot)$ terms is really $O_{\sigma,k}(\cdot)$, that is, with constants that depend on k as well as the signature σ.) We remark that Lemma 18 has a converse ("$\mathrm{AC}^0 \subseteq \mathrm{FO}$") with respect to both the uniform and non-uniform versions of AC^0. We omit the statement of these results, since the description of AC^0 circuits via first-order sentences is not needed in this paper (see [26] for details).

6.2 Retracts, Cores, Hom-Preserved Classes

The last bit of required background concerns homomorphism-preserved classes of structures. We begin by defining the key notions of homomorphic equivalence and cores.

▶ **Definition 19** (Homomorphic Equivalence, (Co-)Retracts, Cores).

- Recall notation $\mathcal{A} \to \mathcal{B}$ denoting the existence of a homomorphism from $\mathcal{A}$ to $\mathcal{B}$.
- Structures $\mathcal{A}$ and $\mathcal{B}$ are *homomorphically equivalent*, denoted $\mathcal{A} \rightleftarrows \mathcal{B}$, if $\mathcal{A} \to \mathcal{B}$ and $\mathcal{B} \to \mathcal{A}$.
- We write $\mathcal{A} \overset{\supseteq}{\to} \mathcal{B}$ and say that $\mathcal{B}$ is a *retract* of $\mathcal{A}$ and $\mathcal{A}$ is a *co-retract* of $\mathcal{B}$ if: (1) $\mathcal{B}$ is a substructure of $\mathcal{A}$ and (2) there exists a homomorphism $\mathcal{A} \to \mathcal{B}$ that fixes $\mathcal{B}$ pointwise (a.k.a. a retraction). (Note that $\mathcal{A} \overset{\supseteq}{\to} \mathcal{B}$ implies $\mathcal{A} \rightleftarrows \mathcal{B}$.)
- A structure $\mathcal{A}$ is a *core* if it has no proper retract (that is, $\mathcal{A} \overset{\supseteq}{\to} \mathcal{B} \implies \mathcal{A} = \mathcal{B}$).

The next lemma states a few basic properties of cores (see [22, 23]).

▶ **Lemma 20.**

(a) *Every $\rightleftarrows$-equivalence class contains a unique core up to isomorphism. (That is, every structure $\mathcal{A}$ is homomorphically equivalent to a unique core.)*

(b) *For every k, there are only finitely many non-isomorphic cores of tree-depth k. (This number depends on the signature σ.)*

(c) *(As an aside:) If a graph G is a core, then the colored and uncolored G-subgraph isomorphism problems are equivalent under linear-size monotone-projection reductions (see [19, 27]).*

▶ **Definition 21** (Hom-Preserved Classes, Minimal Cores).

- We say that a class of structures $\mathscr{C}$ (i.e. a class of finite structures) is *hom-preserved* if, whenever $\mathcal{A} \in \mathscr{C}$ and $\mathcal{A} \to \mathcal{B}$, we have $\mathcal{B} \in \mathscr{C}$.

- For a hom-preserved class $\mathscr{C}$, let MinCores($\mathscr{C}$) be the set of $\mathcal{M} \in \mathscr{C}$ with the property that for all structures $\mathcal{A}$, if $\mathcal{A} \in \mathscr{C}$ and $\mathcal{A} \to \mathcal{M}$, then $\mathcal{M}$ is isomorphic to a retract of $\mathcal{A}$.

The next lemma states the essential properties of MinCores($\mathscr{C}$) (see [39]).

▶ **Lemma 22.** *The following hold for any hom-preserved class $\mathscr{C}$:*

(a) *$\mathcal{A} \in \mathscr{C}$ if, and only if, there exists $\mathcal{M} \in$ MinCores($\mathscr{C}$) such that $\mathcal{M} \to \mathcal{A}$.*

(b) *Every structure in* MinCores($\mathscr{C}$) *is, indeed, a core.*

(c) *Every homomorphism between structures in* MinCores($\mathscr{C}$) *is an isomorphism.*

(d) *$\mathscr{C}$ is definable (i.e. within the class of all finite structures) by an existential-positive sentence of quantifier-rank k if, and only if, $\mathbf{td}(\text{Gaif}(\mathcal{M})) \leq k$ for all $\mathcal{M} \in$ MinCores($\mathscr{C}$).*

(e) *$\mathscr{C}$ is definable by an existential-positive sentence of variable-width w if, and only if,* MinCores($\mathscr{C}$) *contains finitely many non-isomorphic structures and $\mathbf{tw}(\text{Gaif}(\mathcal{M})) \leq w$ for every $\mathcal{M} \in$ MinCores($\mathscr{C}$).*

Since Lemma 22(d) in particular plays a key role in the next section, we briefly sketch the proof. In one direction: Suppose $\mathscr{C}$ is defined by an existential-positive sentence Φ of quantifier-rank k. It is easy to show (by a syntactic argument) that Φ is equivalent to a disjunction $\Psi_1 \vee \cdots \vee \Psi_t$ of *primitive-positive sentences* Ψ_i (i.e. existential-positive sentences that involve conjunctions $\wedge$ but no disjunctions $\vee$), each with quantifier-rank at most k. For each Ψ_i, there is a corresponding structure $\mathcal{A}_i$ with the property that $\mathcal{B} \models \Psi_i \Leftrightarrow \mathcal{A}_i \to \mathcal{B}$ and moreover the tree-depth of $\mathcal{A}_i$ is at most the quantifier-rank of Ψ_i (and hence at most k). Thus, $\mathscr{C}$ is generated by $\mathcal{A}_1, \ldots, \mathcal{A}_t$ and hence MinCores($\mathscr{C}$) consists of finitely many cores, each of tree-depth at most k (coming from the minimal elements among $\mathcal{A}_1, \ldots, \mathcal{A}_t$ in the homomorphism order).

For the reverse direction: Start with the assumption that all structures in MinCores($\mathscr{C}$) have tree-depth at most k. By Lemma 20(b), MinCores($\mathscr{C}$) contains finitely many non-isomorphic structures $\mathcal{M}_1, \ldots, \mathcal{M}_t$. For each $\mathcal{M}_i$, let Ψ_i be the corresponding primitive-positive sentence of quantifier-rank at most k. Then $\mathscr{C}$ is defined by the existential-positive sentence $\Psi_1 \vee \cdots \vee \Psi_t$.

7 Proof of Theorem 6

In this section, we finally prove our main result, the "Poly-rank" Homomorphism Preservation Theorem on Finite Structures (Theorem 6, stated in Section 3). We begin in Section 7.1 by proving a weaker version of the result with an exponential upper bound $\beta(k) \leq 2^{O(k)}$. In Section 7.2, we describe the improvement to $\beta(k) \leq k^{O(1)}$, which involves new results from circuit complexity and graph minor theory.

7.1 Preliminary Bound: $\beta(k) \leq 2^{O(k)}$

For simplicity sake, we will assume that σ consists of binary relations only. At the end of this subsection, we explain how to extend the argument to arbitrary σ.

Let Φ be a first-order sentence of quantifier-rank k, let $\mathscr{C}$ be the set of finite models of Φ, and assume that $\mathscr{C}$ is hom-preserved (that is, Φ is preserved under homomorphisms on finite structures). Our goal is to show that Φ is equivalent to an existential-positive sentence of quantifier-rank $2^{O(k)}$. By Lemma 22(d), it suffices to show that $\mathbf{td}(\text{Gaif}(\mathcal{M})) \leq 2^{O(k)}$ for all $\mathcal{M} \in$ MinCores($\mathscr{C}$).

Consider any $\mathcal{M} \in$ MinCores($\mathscr{C}$). Let G be the Gaifman graph of $\mathcal{M}$, and let m be the size of the universe of $\mathcal{M}$. (Note that $m = |V(G)|$.) The following claim is key to showing $\mathbf{td}(G) \leq 2^{O(k)}$.

▶ **Claim 23.** *For all $n \in \mathbb{N}$, there exists a monotone-projection reduction* $\mathrm{SUB}_{G,n} \leq_{\mathrm{mp}} \mathrm{MODEL}_{\Phi,mn}$.

In order to define this monotone-projection reduction, let us identify $[mn]$ with the set $V(G^{\uparrow n})$ $(= V(G) \times [n])$. Variables X_e of $\mathrm{SUB}_{G,n}$ are indexed by potential edges $e \in E(G^{\uparrow n})$ in a subgraph $X \subseteq G^{\uparrow n}$. Variables Y_i of $\mathrm{MODEL}_{\Phi,mn}$ are indexed by the set

$$I := \big\{(R,(v,a),(w,b)) : R^{(2)} \in \sigma,\ (v,a),(w,b) \in V(G^{\uparrow n})\big\}.$$

(That is, I is the set of potential 2-tuples of relations of structures with universe $V(G^{\uparrow n})$.) Define the monotone projection $\rho : \{Y_i\}_{i\in I} \to \{X_e\}_{e\in E(G^{\uparrow n})} \cup \{0,1\}$ by

$$\rho : Y_{(R,(v,a),(w,b))} \mapsto \begin{cases} X_{\{(v,a),(w,b)\}} & \text{if } (v,w) \in R^{\mathcal{M}} \text{ and } v \neq w, \\ 1 & \text{if } (v,w) \in R^{\mathcal{M}} \text{ and } v = w, \\ 0 & \text{otherwise.} \end{cases}$$

We must show that the corresponding map

$$\rho^* : \{\text{subgraphs of } G^{\uparrow n}\} \to \{\text{structures with universe } V(G^{\uparrow n})\}$$

is in fact a reduction from $\mathrm{SUB}_{G,n}$ to $\mathrm{MODEL}_{\Phi,mn}$. That is, we must show that for any $X \subseteq G^{\uparrow n}$,

$$\mathrm{SUB}_{G,n}(X) = 1 \iff \mathrm{MODEL}_{\Phi,mn}(\rho^*(X)) = 1. \tag{3}$$

For the $\Longrightarrow$ direction of (3): Assume $\mathrm{SUB}_{G,n}(X) = 1$. Then $G^{(\alpha)} \subseteq X$ for some $\alpha \in [n]^{V(G)}$. The definition of ρ ensures that the map $v \mapsto (v,\alpha_v)$ is a homomorphism from $\mathcal{M}$ to the structure $\rho^*(X)$.[7] Since $\mathscr{C}$ is hom-preserved, it follows that $\rho^*(X) \in \mathscr{C}$ and therefore $\mathrm{MODEL}_{\Phi,mn}(\rho^*(X)) = 1$.

For the $\Longleftarrow$ direction of (3): Assume $\mathrm{MODEL}_{\Phi,mn}(\rho^*(X)) = 1$, that is, $\rho^*(X) \in \mathscr{C}$. By Lemma 22(a) there exist $\mathcal{N} \in \mathrm{MinCores}(\mathscr{C})$ and a homomorphism $\gamma : \mathcal{N} \to \rho^*(X)$. The definition of ρ ensures that the map $\pi : (v,i) \mapsto v$ is a homomorphism from $\rho^*(X)$ to $\mathcal{M}$.[8] The composition $\pi \circ \gamma$ is a homomorphism from $\mathcal{N}$ to $\mathcal{M}$. By Lemma 22(c), it is an isomorphism. Therefore, without loss of generality, we may assume that $\mathcal{M} = \mathcal{N}$ and $\pi \circ \gamma$ is the identity map on the universe $V(G)$ of $\mathcal{M}$. This means that $\pi(v) \in \{(v,a) : a \in [n]\}$ for all $v \in V(G)$. We may now define $\alpha \in [n]^{V(G)}$ as the unique element such that $\gamma : v \mapsto (v,\alpha_v)$ for all $v \in V(G)$. From the definition of ρ and the fact that $G = \mathrm{Gaif}(\mathcal{M})$, we infer that $G^{(\alpha)} \subseteq X$.[9] We conclude that $\mathrm{SUB}_{G,n}(X) = 1$, finishing the proof of Claim 23.

---

[7] To see why, suppose we have $(v,w) \in R^{\mathcal{M}}$ for some $R^{(2)} \in \sigma$. We must show that $((v,\alpha_v),(w,\alpha_w)) \in R^{\rho^*(X)}$. First, consider the case that $v \neq w$. The assumption $G^{(\alpha)} \subseteq X$ implies that $\{(v,\alpha_v),(w,\alpha_w)\} \in E(X)$. Since ρ maps the variable $Y_{(R,(v,\alpha_v),(w,\alpha_w))}$ to the variable $X_{\{(v,\alpha_v),(w,\alpha_w)\}}$ (which has value 1 for X), it follows that $((v,\alpha_v),(w,\alpha_w)) \in R^{\rho^*(X)}$. Finally, consider the case that $v = w$. In this case, ρ maps the variable $Y_{(R,(v,\alpha_v),(w,\alpha_w))}$ to the constant 1. So again we have $((v,\alpha_v),(w,\alpha_w)) \in R^{\rho^*(X)}$.

[8] In fact, this holds for every $X \subseteq G^{\uparrow n}$ independent of the assumption that $\mathrm{MODEL}_{\Phi,mn}(\rho^*(X)) = 1$. This follows from the observation that π is (in particular) a homomorphism from $\rho^*(G^{\uparrow n})$ to $\mathcal{M}$. To see why, consider any $((v,a),(w,b)) \in R^{\rho^*(G^{\uparrow n})}$ (corresponding to $Y_{(R,(v,a),(w,b))} = 1$). It must be the case that $(v,w) \in R^{\mathcal{M}}$, since the contrary assumption $(v,w) \notin R^{\mathcal{M}}$ would mean that ρ maps the variable $Y_{(R,(v,a),(w,b))}$ to 0.

[9] Consider an edge $\{(v,\alpha_v),(w,\alpha_v)\} \in E(G^{(\alpha)})$. By definition of $G^{(\alpha)}$, we have $\{v,w\} \in E(G)$. Since $G = \mathrm{Gaif}(\mathcal{M})$, there exists a relation $R^{(2)} \in \sigma$ such that $(v,w) \in R^{\mathcal{M}}$ or $(w,v) \in R^{\mathcal{M}}$. Without loss of generality, assume $(v,w) \in R^{\mathcal{M}}$. Since $\gamma : \mathcal{M} \to \rho^*(X)$ is a homomorphism, we have $(\gamma(v),\gamma(w)) = ((v,\alpha_v),(w,\alpha_w)) \in R^{\rho^*(X)}$. Since $(v,w) \in R^{\mathcal{M}}$ and $v \neq w$, the monotone projection ρ maps $Y_{(R,(v,\alpha_v),(w,\alpha_w))}$ to $X_{\{(v,\alpha_v),(w,\alpha_w)\}}$. It follows that $\{(v,\alpha_v),(w,\alpha_w)\} \in E(X)$. Therefore, $G^{(\alpha)}$ is a subgraph of X.

We proceed to show that $\mathbf{td}(G) \leq 2^{O(k)}$. By Corollary 11, we have $\mathrm{SUB}_{P_{\mathbf{td}(G)},n} \leq_{\mathrm{mp}} \mathrm{SUB}_{G,n}$. By Claim 23 and transitivity of $\leq_{\mathrm{mp}}$, it follows that $\mathrm{SUB}_{P_{\mathbf{td}(G)},n} \leq_{\mathrm{mp}} \mathrm{MODEL}_{\Phi,kn}$. Therefore, $\mu(\mathrm{SUB}_{P_{\mathbf{td}(G)},n}) \leq \mu(\mathrm{MODEL}_{\Phi,kn})$ for every standard complexity measure $\mu : \{\text{Boolean functions}\} \to \mathbb{N}$ (in particular, depth-k formula size). By Lemma 18 (the simulation of first-order logic by AC^0), there exist depth-k formulas of size $O((mn)^k)$ which compute $\mathrm{MODEL}_{\Phi,mn}$. Therefore, there exist depth-k formulas of size $O((mn)^k)$ which compute $\mathrm{SUB}_{P_{\mathbf{td}(G)},n}$. On the other hand, by Theorem 14, the depth-k formula size of $\mathrm{SUB}_{P_{\mathbf{td}(G)},n}$ is $n^{\Omega(\log \mathbf{td}(G))}$ for all sufficiently large n such that $k < \log\log n$. Therefore, we have $n^{\Omega(\log \mathbf{td}(G))} \leq O((mn)^k)$ for all sufficiently large n. Since m $(= |V(G)|)$ is constant, it follows that $k \geq \Omega(\log \mathbf{td}(G))$, that is, $\mathbf{td}(G) \leq 2^{O(k)}$. This completes the proof that $\beta(k) \leq 2^{O(k)}$ for binary signatures σ.

▶ **Remark 24.** In this argument, as an alternative to *depth-k formula size*, we may instead consider *fan-in $O(n)$ depth* (i.e. *fan-in cn depth* for a sufficiently large constant c) and appeal to Corollary 15 instead of Theorem 14.

Finally, we explain how to adapt the above argument when σ is an arbitrary finite relational signature. Here the variables of $\mathrm{MODEL}_{\Phi,kn}$ are indexed by the set

$$\big\{(R,(v_1,a_1),\dots,(v_t,a_t)) : R^{(t)} \in \sigma,\ (v_1,a_1),\dots,(v_t,a_t) \in V(G)\times[n]\big\}$$

and the reduction $\{\text{subgraphs of } G^{\uparrow n}\} \to \{\text{structures with universe } V(G^{\uparrow n})\}$ is defined by

$$Y_{(R,(v_1,a_1),\dots,(v_t,a_t))} \mapsto \begin{cases} \bigwedge_{1\leq i<j\leq t\,:\,v_i\neq v_j} X_{\{(v_i,a_i),(v_j,a_j)\}} & \text{if } (v_1,\dots,v_t)\in R^{\mathcal{M}},\\ 0 & \text{otherwise.}\end{cases}$$

(By convention, $\bigwedge_{i\in\emptyset} X_i = 1$.) Note that this reduction is not a monotone projection, as we are mapping each Y-variable to a conjunction of X-variables. This reduction is, however, computed by a single layer of constant fan-in AND gates. Therefore, under this reduction, any Boolean formula computing $\mathrm{MODEL}_{\Phi,kn}$ is converted to a Boolean formula computing $\mathrm{SUB}_{G,n}$ with an increase of 1 in depth and a constant factor increase in size. Other than this change, the rest of the argument is identical to the case of binary signatures.

7.2 Improvement to $\beta(k) \leq k^{O(1)}$

The upper bound $\beta(k) \leq 2^{O(k)}$ in the previous section relies on the *exponential approximation* of tree-depth in terms of the longest path, that is, $\log(\mathbf{lp}(G)+1) \leq \mathbf{td}(G) \leq \mathbf{lp}(G)$ (inequality (2)). To achieve a polynomial upper bound on $\beta(k)$, we require a *polynomial approximation* of tree-depth in terms of a few manageable classes "excluded minors". This realization led to a conjecture of the author, which was soon proved in joint work with Ken-ichi Kawarabayashi [25].

▶ **Theorem 25.** *Every graph G of tree-depth k satisfies one (or more) of the following conditions for $\ell = \widetilde{\Omega}(k^{1/5})$:*

(i) $\mathbf{tw}(G) \geq \ell$,
(ii) *G contains a path of length 2^ℓ, or*
(iii) *G contains a B_ℓ-minor.*

This result is analogous to the Polynomial Grid-Minor Theorem [12], which can be used to replace condition (i) with the condition that G contains an $\Omega(k^\varepsilon)\times\Omega(k^\varepsilon)$ grid minor for an absolute constant $\varepsilon > 0$. In cases (i) and (ii), Theorems 13 and 14 respectively imply

that SUB_G has AC^0 formula size $n^{\widetilde{\Omega}(\mathbf{td}(G)^{1/5})}$. This leaves only case (iii), where forthcoming work of the author [42] shows the following (via a generalization of the "pathset complexity" framework of [41]).

▶ **Theorem 26.** *The* AC^0 *formula size of* SUB_{B_k} *is* $n^{\Omega(k^\varepsilon)}$ *for an absolute constant* $\varepsilon > 0$.

Together Theorems 25 and 26 imply:

▶ **Theorem 27.** *For all graphs* G*, the* AC^0 *formula complexity of* SUB_G *is* $n^{\Omega(\mathbf{td}(G)^\varepsilon)}$ *for an absolute constant* $\varepsilon > 0$.

Plugging Theorem 27 into the argument in the previous subsection directly yields the polynomial upper bound $\beta(k) \leq k^{O(1)}$ of Theorem 4. (In fact, we get $\beta(k) \leq k^{1/\varepsilon}$ for the constant $\varepsilon > 0$ of Theorem 27.)

8 Comparison with the Method in (R. 2008)

In this section, for the sake of comparison, we summarize the model-theoretic approach of the original proof of Theorem 4 in [39]. The starting point in [39] is a new compactness-free proof of the classical Homomorphism Preservation Theorem, which moreover yields the stronger "equi-rank" version (Theorem 5). The proof is based on an operation mapping each structure $\mathcal{A}$ to an infinite co-retract $\Gamma(\mathcal{A})$. (We drop the assumption of the last two sections that structures are finite by default.) In order to state the key property of this operation, we introduce notation $\mathcal{A} \equiv_{\mathrm{FO}(k)} \mathcal{B}$ (resp. $\mathcal{A} \equiv_{\exists^+\mathrm{FO}(k)} \mathcal{B}$) denoting the statement that $\mathcal{A}$ and $\mathcal{B}$ satisfy the same first-order sentences (resp. existential-positive sentences) of quantifier-rank k.

▶ **Theorem 28.** *There is an operation* $\Gamma : \{\textit{structures}\} \to \{\textit{structures}\}$ *associating every structure* $\mathcal{A}$ *with a co-retract* $\Gamma(\mathcal{A}) \overset{\supseteq}{\to} \mathcal{A}$ *such that, for all structures* $\mathcal{A}$ *and* $\mathcal{B}$ *and* $k \in \mathbb{N}$*,*

$$\mathcal{A} \equiv_{\exists^+\mathrm{FO}(k)} \mathcal{B} \implies \Gamma(\mathcal{A}) \equiv_{\mathrm{FO}(k)} \Gamma(\mathcal{B}).$$

There is a straightforward proof that Theorem 28 implies Theorem 5 (see [39]). The structure $\Gamma(\mathcal{A})$ is the Fraïsse limit of the class of co-finite co-retracts of $\mathcal{A}$ (that is, structures $\mathcal{A}'$ such that $\mathcal{A}' \overset{\supseteq}{\to} \mathcal{A}$ and $A' \setminus A$ is finite). We remark that $\Gamma(\mathcal{A})$ is infinite, even when $\mathcal{A}$ is finite. For this reason, Theorem 28 says nothing in the setting of finite structures.

The Homomorphism Preservation Theorem on Finite Structures (Theorem 4) is proved in [39] by considering a sequence of finitary "approximations" of $\Gamma(\mathcal{A})$. (This is somewhat analogous to sense in which large random graph $G(n, 1/2)$ "approximate" the infinite Rado graph.)

▶ **Theorem 29.** *There is a computable function* $\beta : \mathbb{N} \to \mathbb{N}$ *and a sequence* $\{\Gamma_k\}_{k\in\mathbb{N}}$ *of operations* $\Gamma_k : \{\textit{finite structures}\} \to \{\textit{finite structures}\}$ *associating every finite structure* $\mathcal{A}$ *with a sequence* $\{\Gamma_k(\mathcal{A})\}_{k\in\mathbb{N}}$ *of finite co-retracts* $\Gamma_k(\mathcal{A}) \overset{\supseteq}{\to} \mathcal{A}$ *such that, for all finite structures* $\mathcal{A}$ *and* $\mathcal{B}$ *and* $k \in \mathbb{N}$*,*

$$\mathcal{A} \equiv_{\exists^+\mathrm{FO}(\beta(k))} \mathcal{B} \implies \Gamma_k(\mathcal{A}) \equiv_{\mathrm{FO}(k)} \Gamma_k(\mathcal{B}).$$

Theorem 4 follows directly from Theorem 29, inheriting the same quantifier-rank blow-up $\beta(k)$. The proof of Theorem 29 in [39] implies a non-elementary upper bound on $\beta(k)$. While the present paper improves the upper bound $\beta(k) \leq k^{O(1)}$ in Theorem 4, we remark that this it does not imply any improvement to $\beta(k)$ in Theorem 29.

9 Syntax vs. Semantics in Circuit Complexity

We conclude this paper by stating some consequences of our results in circuit complexity. Let HomPreserved denote the class of all homomorphism-preserved graph properties (for example, $\{G : \text{girth}(G) \leq 20 \text{ or clique-number}(G) \geq 10\}$). This is a semantic class, akin to the class Monotone of all monotone languages. The new proof in this paper of the Homomorphism Preservation Theorem on Finite Structures using AC^0 lower bounds is easily to imply the following "Homomorphism Preservation Theorem for (non-uniform) AC^0":

$$\text{HomPreserved} \cap \text{AC}^0 = \exists^+\text{FO} \quad (\subseteq \{\text{poly-size monotone DNFs}\}).$$

In other words, every homomorphism-preserved graph property in AC^0 is definable (among finite graphs) by an existential-positive first-order sentence and, therefore, also by a polynomial-size monotone DNF (moreover, with constant bottom fan-in). As a consequence, for every integer $d \geq 2$, we get a collapse of the AC^0 depth hierarchy with respect to homomorphism-preserved properties:

$$\text{HomPreserved} \cap \text{AC}^0[\text{depth } d] = \text{HomPreserved} \cap \text{AC}^0[\text{depth } d+1].$$

In contrast, it is known that $\text{AC}^0[\text{depth } d] \neq \text{AC}^0[\text{depth } d+1]$ by the Depth Hierarchy Theorem [21].

These results have an opposite nature to the "syntactic monotonicity $\neq$ semantic monotonicity" counterexamples of Ajtai and Gurevich [1] and Razborov [35] (as well as Tardos [45]), which respectively show that

$$\text{Monotone} \cap \text{AC}^0 \neq \text{Monotone-AC}^0 \quad \text{and} \quad \text{Monotone} \cap \text{P} \neq \text{Monotone-P}.$$

In light of the results of this paper, I feel that questions of syntax vs. semantics in circuit complexity are worth re-examining. For instance, so far as I know, there is no known separation between the *uniform average-case* monotone vs. non-monotone complexity of any monotone function in any well-studied class of Boolean circuits (AC^0, NC^1, etc.) It is plausible that syntactic monotonicity = semantic monotonicity in the average-case. Evidence for this viewpoint comes from the considering the *slice distribution* (that is, the uniform distribution on inputs of Hamming weight exactly $\lfloor n/2 \rfloor$). With respect to the slice distribution, it is known that monotone and non-monotone complexity are equivalent within a $\text{poly}(n)$ factor by a classic result of Berkowitz [11].

As for an even stronger "Homomorphism Preservation Theorem" in circuit complexity, we can state the following: if for every k, SUB_{P_k} requires unbounded-depth formula size $n^{\Omega(\log k)}$ (which is widely conjectured to be true) or even $n^{\omega_k \to \infty(1)}$, then $\text{HomPreserved} \cap \text{NC}^1 = \exists^+\text{FO}$. Therefore, I strongly believe in a "Homomorphism Preservation Theorem for NC^1". On the other hand, the homomorphism-preserved property of being 2-colorable a.k.a. non-bipartite ($= \{G : C_k \to G \text{ for any odd } k\}$) is in Logspace (this follows from Reingold's theorem [36]), yet it is not $\exists^+\text{FO}$-definable. Therefore, we may assert that $\text{HomPreserved} \cap \text{Logspace} \neq \exists^+\text{FO}$.

Abstract

We provide new query complexity separations against sensitivity for total Boolean functions: a power 3 separation between deterministic (and even randomized or quantum) query complexity and sensitivity, and a power 2.22 separation between certificate complexity and sensitivity. We get these separations by using a new connection between sensitivity and a seemingly unrelated measure called one-sided unambiguous certificate complexity ($\mathrm{UC}_{\min}$). We also show that $\mathrm{UC}_{\min}$ is lower-bounded by fractional block sensitivity, which means we cannot use these techniques to get a super-quadratic separation between $\mathrm{bs}(f)$ and $\mathrm{s}(f)$.

Along the way, we give a power 1.22 separation between certificate complexity and one-sided unambiguous certificate complexity, improving the power 1.128 separation due to Göös [20]. As a consequence, we obtain an improved $\Omega(\log^{1.22} n)$ lower-bound on the co-nondeterministic communication complexity of the Clique vs. Independent Set problem.

1 Introduction

Sensitivity is one of the simplest complexity measures of a Boolean function. For $f : \{0,1\}^n \to \{0,1\}$ and $x \in \{0,1\}^n$, the sensitivity of x is the number of bits of x that, when flipped, change the value of $f(x)$. The sensitivity of f, denoted $\mathrm{s}(f)$, is the maximum sensitivity of any input x to f. Sensitivity lower bounds other important measures in query complexity, such as deterministic query complexity $\mathrm{D}(f)$, randomized query complexity $\mathrm{R}(f)$, certificate complexity $\mathrm{C}(f)$, and block sensitivity $\mathrm{bs}(f)$ (see Section 2 for definitions). $\sqrt{\mathrm{s}(f)}$ is a lower bound on quantum query complexity $\mathrm{Q}(f)$.

Despite its simplicity, sensitivity has remained mysterious. The other measures are polynomially related to each other: we have $\mathrm{bs}(f) \le \mathrm{C}(f) \le \mathrm{D}(f) \le \mathrm{bs}(f)^3$ and $\mathrm{Q}(f) \le$

$\mathrm{R}(f) \leq \mathrm{D}(f) \leq \mathrm{Q}(f)^6$. In contrast, no polynomial relationship connecting sensitivity to these measures is known, despite much interest (this problem was first posed by [31]. For a survey, see [26]. For recent progress, see [8, 13, 6, 4, 7, 9, 18, 39, 24, 25, 41]).

Until recently, the best known separation between sensitivity and any of these other measures was quadratic. Tal [41] showed a power 2.11 separation between $\mathrm{D}(f)$ and $\mathrm{s}(f)$. In this work, we improve this to a power 3 separation, and also show functions for which $\mathrm{Q}(f) = \tilde{\Omega}(\mathrm{s}(f)^3)$ and $\mathrm{C}(f) = \tilde{\Omega}(\mathrm{s}(f)^{2.22})$.

We do this by exploiting a new connection between sensitivity and a measure called one-sided unambiguous certificate complexity, which we denote by $\mathrm{UC}_{\min}(f)$. This measure, and particularly its two-sided version $\mathrm{UC}(f)$ (which is sometimes called subcube complexity), has received significant attention in previous work (e.g. [14, 17, 37, 11, 27, 23, 20, 21, 16, 5]), in part because it corresponds to partition number in communication complexity. Intuitively, $\mathrm{UC}_{\min}(f)$ is similar to (one-sided) certificate complexity, except that the certificates are required to be *unambiguous*: each input must be consistent with only one certificate. For a formal definition, see Section 2.5.

We prove the following theorem.

▶ **Theorem 1.** *For any $\alpha \in \mathbb{R}^+$, if there is a family of functions with $\mathrm{D}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^{1+\alpha})$, then there is a family of functions with $\mathrm{D}(f) = \tilde{\Omega}(\mathrm{s}(f)^{2+\alpha})$. The same is true if we replace $\mathrm{D}(f)$ by $\mathrm{bs}(f), \mathrm{C}(f), \mathrm{R}(f), \mathrm{Q}(f)$, and many other measures.*

Theorem 1 can be generalized from sensitivity $\mathrm{s}(f)$ to bounded-size block sensitivity $\mathrm{bs}_{(k)}(f)$ (block sensitivity where each block is restricted to have size at most k). However, there is a constant factor loss that depends on k.

We observe that cheat sheet functions (as defined in [2]) have low $\mathrm{UC}_{\min}$; in particular, one of the functions in [2] already has a quadratic separation between $\mathrm{Q}(f)$ and $\mathrm{UC}_{\min}(f)$, giving a cubic separation between $\mathrm{Q}(f)$ and $\mathrm{s}(f)$.

▶ **Corollary 2.** *There is a family of functions with $\mathrm{Q}(f) = \tilde{\Omega}(\mathrm{s}(f)^3)$.*

To separate $\mathrm{C}(f)$ from $\mathrm{s}(f)$, we will use a function f with a significant gap between $\mathrm{C}(f)$ and $\mathrm{UC}_{\min}(f)$. Göös [20], as part of the proof of his exciting $\omega(\log n)$ lower-bound for communication complexity of clique versus independent set problem, gave a construction of a function f such that $\mathrm{C}(f) \geq \mathrm{UC}_{\min}(f)^\alpha$ for $\alpha \approx 1.128$. Using Göös's function [20] would give a family of functions with $\mathrm{C}(f) = \Omega(\mathrm{s}(f)^{2.128})$. We show that it is possible to obtain an even better separation (Theorem 4 below), leading to the following separation between $\mathrm{C}(f)$ and $\mathrm{s}(f)$.

▶ **Corollary 3.** *There is a family of functions with $\mathrm{C}(f) = \Omega(\mathrm{s}(f)^{2.22})$.*

New separation between C and $\mathrm{UC}_{\min}$

It is known that $\mathrm{C}(f) \leq \mathrm{UC}_{\min}(f)^2$ (e.g., [20]), and analogously in the communication complexity world $\mathbf{coNP}^{cc}(f) \leq \mathbf{UP}^{cc}(f)^2$ ([43]). Next, we discuss a polynomial separation between C and $\mathrm{UC}_{\min}$ due to [20] that uses function composition.

Throughout the years, Boolean function composition was used extensively to separate different complexity measures; a non-exhaustive list includes [1, 3, 12, 19, 28, 32, 33, 34, 42, 36, 38, 40, 41]. The natural idea is to exhibit some constant separation between any two measures: $M(f)$ and $N(f)$ (i.e., $M(f) < N(f)$ for a constant size function f) and then to prove that $M(f^k) \leq M(f)^k$ and $N(f^k) \geq N(f)^k$, for any $k \in \mathbb{N}$. This yields an infinite family of functions with polynomial separation between M and N, as $N(f^k) \geq M(f^k)^{\log N(f)/\log M(f)}$.

However, this approach does not work straightforwardly in an attempt to separate $\mathrm{UC}_{\min}$ from C, since it is not necessarily true that $\mathrm{UC}_{\min}(f^k) \leq \mathrm{UC}_{\min}(f)^k$. [20] overcomes this barrier by considering gadgets over a larger alphabet where the letters of the alphabet are weighted. He constructs such a gadget using projective planes, and further shows how to compose gadgets over a weighted alphabet in a way that behaves multiplicatively for both $\mathrm{UC}_{\min}$ and C. Finally, he shows how to simulate the weights and the larger alphabet with a Boolean function. The gadget f_k constructed by Göös satisfies $\mathrm{C}(f_k) = k^2 - k + 1$ and $\mathrm{UC}_{\min}(f_k) = \frac{k(k+1)}{2}$, whenever $k-1$ is a prime power. The optimum separation is obtained when $k = 8$, giving a separation exponent of $\log(57)/\log(36) \geq 1.128$.

Since $\mathrm{C}(f_k) \approx k^2$ and $\mathrm{UC}_{\min}(f_k) \approx k^2/2$ and the separation exponent is

$$\log(\mathrm{C}(f_k))/\log(\mathrm{UC}_{\min}(f_k)) \approx \log(k^2)/\log(k^2/2),$$

it seems that one should try to take k as small as possible. However, the additive terms affect smaller k's more significantly, making the optimum attained at $k = 8$. This motivated us to try and reduce the weights in other ways, in order to improve the exponent. To do so, we introduce *fractional weights*. The argument of Göös as is does not allow fractional weights, and in particular when Booleanizing the function, it seems inherent to use integer weights. We overcome this difficulty by considering fractional weights in intermediate steps of the construction, and then round them up at the end to get integral weights. We obtain the following separation.

▶ **Theorem 4** ($\mathrm{UC}_{\min}(f)$ vs $\mathrm{C}(f)$ - Improved)**.** *There exists an infinite family of Boolean functions* $f_n : \{0,1\}^n \to \{0,1\}$ *such that* $\mathrm{C}(f_n) \geq \tilde{\Omega}\left(\mathrm{UC}_{\min}(f_n)^{\frac{\log(38/3)}{\log(8)}}\right) \geq \Omega(\mathrm{UC}_{\min}(f_n)^{1.22})$.

Using the lifting theorem of Göös et al. [22] (see also [20, Appendix A]), Theorem 4 implies the following

▶ **Theorem 5** ($\mathbf{UP}^{cc}(f)$ vs $\mathbf{coNP}^{cc}(f)$)**.** *There exists an infinite family of Boolean functions* $f_n : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ *such that* $\mathbf{coNP}^{cc}(f_n) \geq \Omega(\mathbf{UP}^{cc}(f_n)^{1.22})$.

Hence, the exponent between $\mathbf{coNP}^{cc}$ and $\mathbf{UP}^{cc}$ is somewhere between 1.22 and 2. We conjecture the latter to be tight. Moreover, we get as a corollary an improved lower-bound for the conondeterministic communication complexity of the Clique vs Independent Set problem.

▶ **Corollary 6.** *There is a family of graphs* G *such that*

$$\mathbf{coNP}^{cc}(\mathrm{CIS}_G) \geq \Omega(\log^{1.22} n).$$

We refer the reader to [20] for a discussion on the Clique vs Independent Set problem that shows how Theorem 5 implies Corollary 6.

Limitations of Theorem 1

We note that $\mathrm{UC}_{\min}(f)$ upper bounds $\deg(f)$, so this technique cannot be used to get super-quadratic separations between $\deg(f)$ and $\mathrm{s}(f)$. A natural question is whether we can use Theorem 1 to get a super-quadratic separation between $\mathrm{bs}(f)$ and $\mathrm{s}(f)$. To do so, it would suffice to separate $\mathrm{bs}(f)$ from $\mathrm{UC}_{\min}(f)$. It would even suffice to separate randomized certificate complexity $\mathrm{RC}(f)$ (a measure larger than $\mathrm{bs}(f)$) from $\mathrm{UC}_{\min}(f)$, because of the following theorem.

▶ **Theorem 7** ([28, Corollary 3.2])**.** *If there exists a family of functions with* $\mathrm{RC}(f) \geq \Omega(\mathrm{s}(f)^{2+\alpha})$*, then there exists a family of functions with* $\mathrm{bs}(g) \geq \Omega(\mathrm{s}(g)^{2+\alpha-o(1)})$.

Unfortunately, we show that separating $\mathrm{RC}(f)$ from $\mathrm{UC}_{\min}(f)$ is impossible. We conclude that Theorem 1 cannot be used to super-quadratically separate $\mathrm{bs}(f)$ from $\mathrm{s}(f)$.

▶ **Theorem 8.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. Then $\mathrm{RC}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$.*

We show that the factor of 2 in Theorem 8 is necessary. In Appendix A we strengthen this theorem to show that $\mathrm{RC}(f)$ also lower bounds one-sided conical junta degree.

Organization

In Section 2, we briefly define the many complexity measures mentioned here, and discuss the known relationships between them. In Section 3, we prove Theorem 1 and Corollary 2. In Section 4 we prove Theorem 4, from which Corollary 3 follows. In Section 5, we discuss a failed attempt to get a new separation between $\mathrm{bs}(f)$ and $\mathrm{s}(f)$, and in the process we prove Theorem 8.

2 Preliminaries

2.1 Query Complexity

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. Let A be a deterministic algorithm that computes $f(x)$ on input $x \in \{0,1\}^n$ by making queries to the bits of x. The worst-case number of queries A makes (over choices of x) is the query complexity of A. The minimum query complexity of any deterministic algorithm computing f is the deterministic query complexity of f, denoted by $\mathrm{D}(f)$.

We define the bounded-error randomized (respectively quantum) query complexity of f, denoted by $\mathrm{R}(f)$ (respectively $\mathrm{Q}(f)$), in an analogous way. We say an algorithm A computes f with bounded error if $\mathbf{Pr}[A(x) = f(x)] \geq 2/3$ for all $x \in \{0,1\}^n$, where the probability is over the internal randomness of A. Then $\mathrm{R}(f)$ (respectively $\mathrm{Q}(f)$) is the minimum number of queries required by any randomized (respectively quantum) algorithm that computes f with bounded error. It is clear that $\mathrm{Q}(f) \leq \mathrm{R}(f) \leq \mathrm{D}(f)$. For more details on these measures, see the survey by Buhrman and de Wolf [15].

2.2 Partial Assignments and Certificates

A partial assignment is a string $p \in \{0,1,*\}^n$ representing partial knowledge of a string $x \in \{0,1\}^n$. Two partial assignments are consistent if they agree on all entries where neither has a $*$. We will identify p with the set $\{(i, p_i) : p_i \neq *\}$. This allows us to write $p \subseteq x$ to denote that the string x is consistent with the partial assignment p. We observe that if p and q are consistent partial assignments, then $p \cup q$ is also a partial assignment. The size of a partial assignment p is $|p|$, the number of non-$*$ entries in p. The support of p is the set $\{i \in [n] : p_i \neq *\}$.

Fix a Boolean function $f : \{0,1\}^n \to \{0,1\}$. We say a partial assignment p is a certificate (with respect to f) if $f(x)$ is the same for all strings $x \supseteq p$. If $f(x) = 0$ for such strings, we say p is a 0-certificate; otherwise, we say p is a 1-certificate. We say p is a certificate for the string x if p is consistent with x. We use $\mathrm{C}_x(f)$ to denote the size of the smallest certificate for x. We then define the certificate complexity of f as $\mathrm{C}(f) := \max_{x \in \{0,1\}^n} \mathrm{C}_x(f)$. We also define the one-sided measures $\mathrm{C}_0(f) := \max_{x \in f^{-1}(0)} \mathrm{C}_x(f)$ and $\mathrm{C}_1(f) := \max_{x \in f^{-1}(1)} \mathrm{C}_x(f)$.

2.3 Sensitivity and Block Sensitivity

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function, and let $x \in \{0,1\}^n$ be a string. A block is a subset of $[n]$. If B is a block, we denote by x^B the string we get from x by flipping the bits in B; that is, $x_i^B = x_i$ if $i \notin B$, and $x^B = 1 - x_i$ if $i \in B$. For a bit i, we also use x^i to denote $x^{\{i\}}$.

We say that a block B is sensitive for x (with respect to f) if $f(x^B) \neq f(x)$. We say a bit i is sensitive for x if the block $\{i\}$ is sensitive for x. The maximum number of disjoint blocks that are all sensitive for x is called the block sensitivity of x (with respect to f), denoted by $\mathrm{bs}_x(f)$. The number of sensitive bits for x is called the sensitivity of x, denoted by $\mathrm{s}_x(f)$. Clearly, $\mathrm{bs}_x(f) \geq \mathrm{s}_x(f)$, since $\mathrm{s}_x(f)$ has the same definition as $\mathrm{bs}_x(f)$ except the size of the blocks is restricted to 1.

We now define the measures $\mathrm{s}(f)$, $\mathrm{s}_0(f)$, and $\mathrm{s}_1(f)$ analogously to $\mathrm{C}(f)$, $\mathrm{C}_0(f)$, and $\mathrm{C}_1(f)$. That is, $\mathrm{s}(f)$ is the maximum of $\mathrm{s}_x(f)$ over all x, $\mathrm{s}_0(f)$ is the maximum where x ranges over 0-inputs to f, and $\mathrm{s}_1(f)$ is the maximum over 1-inputs. We define $\mathrm{bs}(f)$, $\mathrm{bs}_0(f)$, and $\mathrm{bs}_1(f)$ similarly.

2.4 Fractional Block Sensitivity

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function, and let $x \in \{0,1\}^n$ be a string. Note that the support of any certificate p of x must have non-empty intersection with every sensitive block B of x; this is because otherwise, x^B would be consistent with p, which is a contradiction since $f(x^B) \neq f(x)$.

Note further that any subset S of $[n]$ that intersects with all sensitive blocks of x gives rise to a certificate x_S for x. This is because if x_S was not a certificate, there would be an input $y \supseteq x_S$ with $f(y) \neq f(x)$. If we write $y = x^B$, where B is the set of bits where x and y disagree, then B would be a sensitive block that is disjoint from S, which contradicts our assumption on S.

This means the certificate complexity $\mathrm{C}_x(f)$ of x is the hitting number for the set system of sensitive blocks of x (that is, the size of the minimum set that intersects all the sensitive blocks). Furthermore, the block sensitivity $\mathrm{bs}_x(f)$ of x is the packing number for the same set system (i.e. the maximum number of disjoint sets in the system). It is clear that the hitting number is always larger than the packing number, because if there are k disjoint sets we need at least k domain elements in order to have non-empty intersection with all the sets.

Moreover, we can define the fractional certificate complexity of x as the fractional hitting number of the set system; that is, the minimum amount of non-negative weight we can distribute among the domain elements $[n]$ so that every set in the system gets weight at least 1 (where the weight of a set is the sum of the weights of its elements). We can also define the fractional block sensitivity of x as the fractional packing number of the set system; that is, the maximum amount of non-negative weight we can distribute among the sets (blocks) so that every domain element gets weight at most 1 (where the weight of a domain element is the sum of the weights of the sets containing that element).

It is not hard to see that the fractional hitting and packing numbers are the solutions to dual linear programs, which means they are equal. We denote them by $\mathrm{RC}_x(f)$ for "randomized certificate complexity", following the original notation as introduced by Aaronson [1] (we warn that our definition differs by a constant factor from Aaronson's original definition). We define $\mathrm{RC}(f)$, $\mathrm{RC}_0(f)$, and $\mathrm{RC}_1(f)$ in the usual way. For more properties of $\mathrm{RC}(f)$, see [1] and [28].

2.5 Unambiguous Certificate Complexity

Fix $f : \{0,1\}^n \to \{0,1\}$. We call a set of partial assignments U an unambiguous collection of 0-certificates for f if

1. Each partial assignment in U is a 0-certificate (with respect to f)
2. For each $x \in f^{-1}(0)$, there is some $p \in U$ with $p \subseteq x$
3. No two partial assignments in U are consistent.

We then define $\mathrm{UC}_0(f)$ to be the minimum value of $\max_{p \in U} |p|$ over all choices of such collections U. We define $\mathrm{UC}_1(f)$ analogously, and set $\mathrm{UC}(f) := \max\{\mathrm{UC}_0(f), \mathrm{UC}_1(f)\}$. We also define the one-sided version, $\mathrm{UC}_{\min}(f) := \min\{\mathrm{UC}_0(f), \mathrm{UC}_1(f)\}$.

2.6 Degree Measures

A polynomial q in the variables $x_1, x_2, \ldots, x_n$ is said to represent the function $f : \{0,1\}^n \to \{0,1\}$ if $q(x) = f(x)$ for all $x \in \{0,1\}^n$. q is said to ϵ-approximate f if $q(x) \in [0, \epsilon]$ for all $x \in f^{-1}(0)$ and $q(x) \in [1-\epsilon, 1]$ for all $x \in f^{-1}(1)$. The degree of f, denoted by $\deg(f)$, is the minimum degree of a polynomial representing f. The ϵ-approximate degree, denoted by $\widetilde{\deg}^{\epsilon}(f)$, is the minimum degree of a polynomial ϵ-approximating f. We will omit ϵ when $\epsilon = 1/3$. [10] showed that $\mathrm{D}(f) \geq \deg(f)$, $\mathrm{R}(f) \geq \widetilde{\deg}(f)$, and $\mathrm{Q}(f) \geq \widetilde{\deg}(f)/2$.

We also define non-negative variants of degree. For each partial assignment p we identify a polynomial $p(x) := (\Pi_{i:\, p_i=1} x_i)\,(\Pi_{i:\, p_i=0}(1-x_i))$. We note that $p(x) = 1$ if $p \subseteq x$ and $p(x) = 0$ otherwise, and also that the degree of $p(x)$ is $|p|$. We say a polynomial is non-negative if it is of the form $\sum_p w_p p(x)$, where $w_p \in \mathbb{R}^+$ are non-negative weights. For such a sum, define its degree as $\max_{p:\, w_p > 0} |p|$. Define its average degree as the maximum over $x \in \{0,1\}^n$ of $\sum_{p:\, p \subseteq x} w_p |p|$. We note that if a non-negative polynomial q satisfies $|q(x)| \in [0,1]$ for all $x \in \{0,1\}^n$, then the average degree of q is at most its degree. Moreover, if all the monomials in q have the same size and $q(x) = 1$ for some $x \in \{0,1\}^n$, the degree and average degree of q are equal.

We define the non-negative degree of f as the minimum degree of a non-negative polynomial representing f. We note that this is a one-sided measure, since it may change when f is negated; we therefore denote it by $\deg_1^+(f)$, and use $\deg_0^+(f)$ for the degree of a non-negative polynomial representing the negation of f. We let $\deg^+(f)$ be the maximum of the two, and let $\deg^+_{\min}(f)$ be the minimum. We also define $\mathrm{avdeg}_1^+(f)$ as the minimum average degree of a non-negative polynomial representing f, with the other corresponding measures defined analogously. Finally, we define the approximate variants of these, denoted by (for example) $\widetilde{\deg}_1^{+,\epsilon}(f)$, in a similar way, except the polynomials need only to ϵ-approximate f.

2.7 Known Relationships

2.7.1 Two-Sided Measures

We describe some of the known relationships between these measures. To start with, we have

$$\mathrm{s}(f) \leq \mathrm{bs}(f) \leq \mathrm{RC}(f) \leq \mathrm{C}(f) \leq \mathrm{UC}(f) \leq \mathrm{D}(f),$$

where the last inequality holds because for each deterministic algorithm A, the partial assignments defined by the input bits A examines when run on some $x \in \{0,1\}^n$ form an unambiguous collection of certificates. We also have

$$\widetilde{\deg}(f) \leq 2\mathrm{Q}(f), \quad \widetilde{\deg}^{+}(f) \leq \mathrm{R}(f), \quad \deg^+(f) \leq \mathrm{D}(f),$$

with $\widetilde{\deg}(f) \leq \widetilde{\deg}^{+}(f) \leq \deg^{+}(f)$ and $\mathrm{Q}(f) \leq \mathrm{R}(f) \leq \mathrm{D}(f)$.

[10] showed $\mathrm{D}(f) \leq \mathrm{bs}(f)\,\mathrm{C}(f)$, and [31] showed $\mathrm{C}(f) \leq \mathrm{bs}(f)^2$. From this we conclude that $\mathrm{D}(f) \leq \mathrm{C}(f)^2$ and $\mathrm{D}(f) \leq \mathrm{bs}(f)^3$. [28] showed $\sqrt{\mathrm{RC}(f)} = O(\widetilde{\deg}(f))$; thus

$$\mathrm{D}(f) \leq \mathrm{bs}(f)^3 \leq \mathrm{RC}(f)^3 = O(\widetilde{\deg}(f)^6) = O(\mathrm{Q}(f)^6),$$

so the above measures are polynomially related (with the exception of sensitivity). Other known relationships are $\mathrm{RC}(f) = O(\mathrm{R}(f))$ (due to [1]), $\mathrm{D}(f) \leq \mathrm{bs}(f)\deg(f) \leq \deg(f)^3$ (due to [30]), and $\deg^{+}(f) \leq \mathrm{UC}(f)$ (since we can get a polynomial representing f by summing up the polynomials corresponding to unambiguous 1-certificates of f).

2.7.2 One-Sided Measures

One-sided measures such as $\mathrm{C}_1(f)$ are not polynomially related to the rest of the measures above, as can be seen from $\mathrm{C}_1(\mathrm{OR}_n) = 1$. This makes them less interesting to us. On the other hand, the one sided measures $\deg^{+}_{\min}(f)$, $\widetilde{\deg}^{+}_{\min}(f)$, and $\mathrm{UC}_{\min}(f)$ are polynomially related to the rest. An easy way to observe this is to note that $\widetilde{\deg}^{+}_{\min}(f) \geq \widetilde{\deg}(f)$, which follows from the fact that $\widetilde{\deg}(f) \leq \widetilde{\deg}^{+}_{1}(f)$ and that $\widetilde{\deg}(f)$ is invariant under negating f. Similarly, $\deg(f) \leq \deg^{+}_{\min}(f)$. We also have

$$\widetilde{\deg}^{+}_{\min}(f) \leq \deg^{+}_{\min}(f) \leq \mathrm{UC}_{\min}(f),$$

where the last inequality holds since we can form a non-negative polynomial representing f by summing up the polynomials corresponding to a set of unambiguous 1-certificates.

An additional useful inequality is $\mathrm{D}(f) \leq \mathrm{UC}_{\min}(f)^2$. The analogous statement in communication complexity was shown by [43]. The query complexity version of the proof can be found in [20].

3 Sensitivity and Unambiguous Certificates

We start by defining a transformation that takes a function f and modifies it so that $\mathrm{s}_0(f)$ decreases to 1. This transformation might cause $\mathrm{s}_1(f)$ to increase, but we will argue that it will remain upper bounded by $3\,\mathrm{UC}_1(f)$. We will also argue that other measures, such as $\mathrm{D}(f)$, do not decrease. This transformation is motivated by the construction of [41] that was used to give a power 2.115 separation between $\mathrm{D}(f)$ and $\mathrm{s}(f)$.

▶ **Definition 9** (Desensitizing Transformation). Let $f : \{0,1\}^n \to \{0,1\}$. Let U be an unambiguous collection of 1-certificates for f, each of size at most $\mathrm{UC}_1(f)$. For each $x \in f^{-1}(1)$, let $p_x \in U$ be the unique certificate in U consistent with x. The desensitized version of f is the function $f' : \{0,1\}^{3n} \to \{0,1\}$ defined by $f'(xyz) = 1$ if and only if $f(x) = f(y) = f(z) = 1$ and $p_x = p_y = p_z$.

The following lemma illustrates key properties of f'.

▶ **Lemma 10** (Desensitization). *Let f' be the desensitized version of $f : \{0,1\}^n \to \{0,1\}$. Then $\mathrm{s}_0(f') = 1$ and $\mathrm{UC}_1(f') \leq 3\,\mathrm{UC}_1(f)$. Also, for any complexity measure*

$$M \in \{\mathrm{D}, \mathrm{R}, \mathrm{Q}, \mathrm{C}, \mathrm{C}_0, \mathrm{C}_1, \mathrm{bs}, \mathrm{bs}_0, \mathrm{bs}_1, \mathrm{RC}, \mathrm{RC}_0, \mathrm{RC}_1, \mathrm{UC}, \mathrm{UC}_0, \mathrm{UC}_1, \mathrm{UC}_{\min}, \deg, \deg^{+}, \widetilde{\deg}, \widetilde{\deg}^{+}\},$$

we have $M(f') \geq M(f)$.

Proof. We start by upper bounding $\mathrm{s}_0(f')$. Consider any 0-input xyz to f' which has at least one sensitive bit. Pick a sensitive bit i of this input; without loss of generality, this bit is inside the x part of the input. Since flipping i changes xyz to a 1-input for f', we must have $f(x^i) = f(y) = f(z) = 1$ and $p_{x^i} = p_y = p_z$. In particular, it must hold that $f(y) = f(z) = 1$ and $p_y = p_z$. Let $p := p_y$, so $p = p_z$ and $p = p_{x^i}$. Since $f(xyz) = 0$, it must be the case that x is not consistent with p. Since p is consistent with x^i, it must be the case that p and x disagree exactly on the bit i.

Now, it's clear that xyz cannot have any sensitive bits inside the y part of the input, because then x would not be consistent with p_z. Similarly, xyz cannot have sensitive bits in the z part of the input. Any sensitive bits inside the x part of the input must make x consistent with p; but x disagrees with p on bit i, so this must be the only sensitive bit. It follows that the sensitivity of xyz is at most 1, as desired. We conclude that $\mathrm{s}_0(f') = 1$.

Next, we upper bound UC_1. Define $U' := \{ppp : p \in U\} \subseteq \{0,1,*\}^{3n}$. We show that this is an unambiguous collection of 1-certificates for f'. First, note that for $p \in U$, if $ppp \subseteq xyz$, then $f(x) = f(y) = f(z) = 1$ and $p_x = p_y = p_z = p$, so $f'(xyz) = 1$. Thus U' is a set of 1-certificates. Next, if xyz is a 1-input for f', then $f(x) = f(y) = f(z) = 1$ and $p_x = p_y = p_z$, which means $p_x p_x p_x \subseteq xyz$. Since $p_x \in U$, we have $p_x p_x p_x \in U'$. Finally, if $ppp, qqq \in U'$ with $ppp \neq qqq$, then $p \neq q$ and $p, q \in U$, which means p and q are inconsistent. This means ppp and qqq are inconsistent. This concludes the proof that U' is an unambiguous collection of 1-certificates for f'. We have $\max_{ppp \in U'} |ppp| = 3 \cdot \max_{p \in U} |p| = 3 \cdot \mathrm{UC}_1(f)$, so $\mathrm{UC}_1(f') \leq 3 \cdot \mathrm{UC}_1(f)$.

Finally, we show that almost all complexity measures do not decrease in the transition from f to f'. To see this, note that we can restrict f' to the promise that all inputs come from the set $\{xyz \in \{0,1\}^{3n} : x = y = z\}$. Under this promise, the function f' is simply the function f with each input bit occurring 3 times. But tripling input bits in this way does not affect the usual complexity measures (among the measures defined in Section 2, sensitivity is the only exception), and restricting to a promise can only cause them to decrease. This means that f' has higher complexity than f under almost any measure. ◀

We now prove Theorem 1, which we restate here for convenience.

▶ **Theorem 1.** *For any $\alpha \in \mathbb{R}^+$, if there is a family of functions with $\mathrm{D}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^{1+\alpha})$, then there is a family of functions with $\mathrm{D}(f) = \tilde{\Omega}(\mathrm{s}(f)^{2+\alpha})$. The same is true if we replace $\mathrm{D}(f)$ by $\mathrm{bs}(f), \mathrm{C}(f), \mathrm{R}(f), \mathrm{Q}(f)$, and many other measures.*

Proof. Fix $f : \{0,1\}^n \to \{0,1\}$ from the family for which $\mathrm{D}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^{1+\alpha})$. By negating f if necessary, assume $\mathrm{UC}_1(f) = \mathrm{UC}_{\min}(f)$. Apply the desensitizing transformation to get f'. By Lemma 10, we have $\mathrm{s}_0(f') \leq 1$ and $\mathrm{s}_1(f') \leq \mathrm{UC}_1(f') \leq 3\,\mathrm{UC}_{\min}(f)$, and also $\mathrm{D}(f') \geq \mathrm{D}(f)$. We now consider the function $\hat{f} := \mathrm{OR}_{3\,\mathrm{UC}_{\min}(f)} \circ f'$. It is not hard to see that $\mathrm{s}_0(\hat{f}) \leq 3\,\mathrm{UC}_{\min}(f)$ and $\mathrm{s}_1(\hat{f}) = \mathrm{s}_1(f') \leq 3\,\mathrm{UC}_{\min}(f)$, so $\mathrm{s}(\hat{f}) \leq 3\,\mathrm{UC}_{\min}(f)$.

We now analyze $\mathrm{D}(\hat{f})$. We have $\mathrm{D}(f') \geq \mathrm{D}(f)$; since deterministic query complexity satisfies a perfect composition theorem, we have

$$\mathrm{D}(\hat{f}) = \mathrm{D}(\mathrm{OR}_{3\,\mathrm{UC}_{\min}(f)})\,\mathrm{D}(f') \geq 3\,\mathrm{UC}_{\min}(f)\,\mathrm{D}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^{2+\alpha}) = \tilde{\Omega}(\mathrm{s}(\hat{f})^{2+\alpha}).$$

This concludes the proof for deterministic query complexity.

For other measures, we need the following properties: first, that the measure is invariant under negating the function (so that we can assume $\mathrm{UC}_{\min}(f) = \mathrm{UC}_1(f)$ without loss of generality); second, that the measure satisfies a composition theorem, at least in the case that the outer function is OR; and finally, that the measure is large for the OR function. We

note that the measures C, bs, RC, R, and Q all satisfy a composition theorem of the form $M(\mathrm{OR} \circ g) \geq \Omega(M(\mathrm{OR})M(g))$; for the first three measures, this can be found in [19], for R it can be found in [21], and for Q it follows from a general composition theorem [35, 29]. Moreover, $\mathrm{bs}(\mathrm{OR}_n) = \mathrm{C}(\mathrm{OR}_n) = \mathrm{RC}(\mathrm{OR}_n) = n$ and $\mathrm{R}(\mathrm{OR}_n) = \Omega(n)$. This completes the proof for these measures; for Q, we will have to work harder, since $\mathrm{Q}(\mathrm{OR}_n) = \Theta(\sqrt{n})$.

For quantum query complexity, the trick will be to use the function "Block k-sum" defined in [2]. It has the property that all inputs have certificates that use very few 0 bits. Actually, we'll swap the 0s and 1s so that all inputs have certificates that use very few 1 bits. When $k = \log n$ (where n the size of the input), we denote this function by BSUM_n. [2] showed that $\mathrm{Q}(\mathrm{BSUM}_n) = \tilde{\Omega}(n)$, and every input has a certificate with $O(\log^3 n)$ ones.

Consider the function $\hat{f} := \mathrm{BSUM}_{\mathrm{UC}_{\min}(f)} \circ f'$. We have $\mathrm{Q}(\hat{f}) = \mathrm{Q}(\mathrm{BSUM}_{\mathrm{UC}_{\min}(f)})\mathrm{Q}(f') = \tilde{\Omega}(\mathrm{UC}_{\min}(f)\mathrm{Q}(f))$. We now analyze the sensitivity of $\hat{f}$. Fix an input z to $\hat{f} = \mathrm{BSUM}_{\mathrm{UC}_{\min}(f)} \circ f'$. This input consists of $\mathrm{UC}_{\min}(f)$ inputs to f', which, when evaluated, form an input y to $\mathrm{BSUM}_{\mathrm{UC}_{\min}(f)}$. Note that some of the inputs to f' correspond to sensitive bits of y (with respect to $\mathrm{BSUM}_{\mathrm{UC}_{\min}(f)}$); the sensitive bits of z are then simply the sensitive bits of those inputs. Now, consider the certificate of y that uses only $O(\log^3 \mathrm{UC}_{\min}(f))$ bits that are 1. Since it is a certificate, it must contain all the sensitive bits of y; thus at most $O(\log^3 \mathrm{UC}_{\min}(f))$ of the 1 bits of y are sensitive. It follows that the number of sensitive bits of z is at most $\mathrm{UC}_{\min}(f)\,\mathrm{s}_0(f') + O(\log^3 \mathrm{UC}_{\min}(f))\,\mathrm{s}_1(f') = \tilde{O}(\mathrm{UC}_{\min}(f))$. This concludes the proof. ◀

It is not hard to see that the same approach can yield separations against bounded-size block sensitivity (where the blocks are restricted to have size at most k). To do this, we need the desensitizing construction to repeat the inputs $2k+1$ times instead of 3 times. Instead of increasing to $3\,\mathrm{UC}_{\min}(f)$, the bounded-size block sensitivity would increase to $(2k+1)\,\mathrm{UC}_{\min}(f)$, and the deterministic query complexity would increase to $(2k+1)\,\mathrm{D}(f)$. When k is constant, we get the same asymptotic separations as for sensitivity.

We now construct separations against $\mathrm{UC}_{\min}$. This proves Corollary 2 and Corollary 3.

▶ **Corollary 2.** *There is a family of functions with* $\mathrm{Q}(f) = \tilde{\Omega}(\mathrm{s}(f)^3)$.

Proof. By Theorem 1, it suffices to construct a family of functions with $\mathrm{Q}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^2)$. Our function will be a cheat sheet function $\mathrm{BKK}_{\mathrm{CS}}$ from [2] that quadratically separates quantum query complexity from exact degree. This function has quantum query complexity quadratically larger than $\mathrm{UC}_{\min}$, as shown in [5]. ◀

▶ **Corollary 3.** *There is a family of functions with* $\mathrm{C}(f) = \Omega(\mathrm{s}(f)^{2.22})$.

Proof. In Theorem 4, we construct a family of functions with $\mathrm{C}(f) = \tilde{\Omega}(\mathrm{UC}_{\min}(f)^{\frac{\log(38/3)}{\log(8)}})$. Thus, by Theorem 1, we can construct a family of functions with $\mathrm{C}(f) = \tilde{\Omega}(\mathrm{s}(f)^{1+\frac{\log(38/3)}{\log(8)}}) = \Omega(\mathrm{s}(f)^{2.22})$. ◀

4 Improved separation between UC_1 and C

In this section we prove Theorem 4, building on the proof by [20]. Our main contribution is to show how to adapt the argument in [20] to allow for fractional weights. We finally give a fractional weighting scheme that leads to our improved separation. We observe that in order to obtain our final result, one can just take Göös's construction and reweigh it in the end. Nonetheless, we include the full details here to show that any gadget with a separation between UC_1 and C implies an asymptotic separation (which was not explicit in [20]).

Throughout the section, Σ and Γ will denote finite sets that correspond to input and output alphabets of our functions. We shall assume that 0 is not in Σ, and will discuss functions $f : (\{0\} \cup \Sigma)^n \to \Gamma$ where 0 is a special symbol treated differently than others.

4.1 Certificates and Weighted-Certificates for Large-Alphabet Functions

We generalize the definition of certificates from Boolean functions to functions with arbitrary input and output alphabets.

▶ **Definition 11** (Multi-valued Certificates, Simple Certificates)**.** A certificate for a function $f : (\{0\} \cup \Sigma)^n \to \Gamma$ is a cartesian product of sets $S_1 \times S_2 \times \ldots S_n$ where each $S_i \subseteq \{0\} \cup \Sigma$ is a non-empty set and such that all $y \in S_1 \times S_2 \times \ldots S_n$ have the same f-value.

A simple certificate for f is a certificate where each S_i is either: (i) $\{0\} \cup \Sigma$, or (ii) S_i contains exactly one element, and this element is from Σ (i.e., not the 0 element).[1]

We define the size of a certificate as the number of i's such that $S_i \neq (\{0\} \cup \Sigma)$. For $x \in (\{0\} \cup \Sigma)^n$, we denote by $\mathrm{C}(f, x)$ the size of the smallest certificate for f which contains x.

For a set $T \subseteq \Gamma$ we say that $S_1 \times \ldots \times S_n$ certifies that "$f(\cdot) \in T$" if this is true for any $y \in S_1 \times \ldots \times S_n$. When $T = \Gamma \setminus \{i\}$ we write "$f(\cdot) \neq i$" for shorthand.

▶ **Definition 12** (Weight Schemes, Certificate Weights)**.** Let $w : \Sigma \to \mathbb{R}^+$ be a non-negative weight function. A weight scheme is a mapping, w, associating positive real numbers to non-empty subsets of $\{0\} \cup \Sigma$ such that:

1. If $S = \{i\}$, for some $i \in \Sigma$, then the weight of S is $w(i)$.
2. If $S = (\{0\} \cup \Sigma)$, then the weight of S is 0.
3. If $0 \in S$ an $S \neq (\{0\} \cup \Sigma)$, then the weight of S is $\max_{i \in \Sigma \setminus S}\{w(i)\}$. (In particular, if $S = \{0\}$ then the weight of S is $\max_{i \in \Sigma}\{w(i)\}$.)

(Note that we did not specify the weight of sets S of at least two elements which do not contain 0, as they will not be used in our analysis.)

The weight of a certificate $S_1 \times \ldots \times S_n$ is simply $\sum_{i=1}^{n} w(S_i)$. For a function $f : (\{0\} \cup \Sigma)^n \to \Gamma$ and an input $x \in (\{0\} \cup \Sigma)^n$ we define the certificate complexity $\mathrm{C}((f, w), x)$ to be the minimal weight of a certificate $S_1 \times \ldots \times S_n$ for f according to w, such that $x \in S_1 \times \ldots \times S_n$.

▶ **Definition 13** (Realization of Weight Schemes)**.** The weight-scheme defined by an integer-valued weight function $w : \Sigma \to \mathbb{N}$ is realized by $g_w : (\{0\} \cup \Sigma)^m \to (\{0\} \cup \Sigma)$ if:

- **(i)** For $i \in \Sigma$, there exists a collection of unambiguous certificates of size-$(w(i))$ for "$g_w(\cdot) = i$",
- **(ii)** $g_w(0^m) = 0$, and
- **(iii)** In order to prove "$g_w(0^m) \in S$" it is required to expose at least $w(S)$ coordinates of 0^m.

▶ **Lemma 14** (Weight-Scheme Implementation, [20])**.** *Let $w : \Sigma \to \mathbb{N}$ be an integer-valued weight function. Then, there exists a weight scheme associating natural numbers to non-empty subsets of $\{0\} \cup \Sigma$ that can be realized by a function $g_w : (\{0\} \cup \Sigma)^m \to (\{0\} \cup \Sigma)$ where $m = \max_i\{w_i\}$.*

[1] Note that a certificate for "$f(x) = 1$" for a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is always simple.

Proof. We define $g_w(x) = i$ iff the symbol i appears in the first $w(i)$ coordinates and i is the first non-zero symbol to appear in the string. We set $g_w(x) = 0$ if there is no such $i \in \Sigma$. (ii) holds trivially. For (i) note that the decision tree that queries the first $w(i)$ coordinates induces an unambiguous collection of certificates for "$g_w(\cdot) = i$". For (iii) we may assume without loss of generality that $S \neq (\{0\} \cup \Sigma)$ as otherwise the claim is trivial. Since we are proving that "$g_w(0^m) \in S$" and indeed $g_w(0^m) = 0$ it is required that $0 \in S$. It remains to show that it is required to expose the first $\max_{i \in \Sigma \setminus S} w(i)$ coordinates of the input to g_w. Let i be the element in $\Sigma \setminus S$ with maximal weight. Indeed, if one coordinate in the first $w(i)$ coordinates was not exposed, then it is still possible that $g_w(\cdot) = i$, as all coordinates that were exposed are equal to 0 and there is an unexposed position in the first $w(i)$ coordinates that might be marked with i. ◀

4.2 Composing Functions over Large Alphabet with Fractional Weights

Most of the results below are generalizations of arguments from [20]. However, since unlike [20] we deal with fractional weights, in addition to the total weight, we also need to take into account the number of coordinates in the intermediate certificates.

Let $f : (\{0\} \cup \Sigma)^N \to \{0, 1\}$, and let $w : \Sigma \to \mathbb{R}^+$. We treat the pair (f, w) as a "weighted function". Let $\mathcal{C}$ be an unambiguous collection of simple 1-certificates of size-s and weight at most W for (f, w). Let Σ_0 be a finite set that does not contain 0 and $w_0 : \Sigma_0 \to \mathbb{R}^+$. We define $(\tilde{f}, \tilde{w})$, where $\tilde{f} : (\{0\} \cup \Sigma \times \Sigma_0)^N \to (\{0\} \cup \Sigma_0)$ as follows. Denote by $\pi_1(x)$ and $\pi_2(x)$ the projection of $x \in (\{0\} \cup \Sigma \times \Sigma_0)^N$ to its $(\{0\} \cup \Sigma)^N$ coordinates and its $(\{0\} \cup \Sigma_0)^N$ coordinates respectively. The value of $\tilde{f}(x)$ is defined as follows.

> If $f(\pi_1(x)) = 0$, then set $\tilde{f}(x) := 0$. Otherwise, let $\mathcal{T} \in \mathcal{C}$ be the unique certificate for "$f(\cdot) = 1$" on $\pi_1(x)$. Read the corresponding coordinates of $\mathcal{T}$ from $\pi_2(x)$ and if all of them are equal to some $i \in \Sigma_0$, then set $\tilde{f}(x) := i$; otherwise set $\tilde{f}(x) := 0$.

Let $\tilde{w} : \Sigma \times \Sigma_0 \to \mathbb{R}^+$ be defined as $\tilde{w}(\sigma, i) = w(\sigma) \cdot w_0(i)$. The following lemma shows useful bounds on the certificates of the new function $\tilde{f}$ according to $\tilde{w}$.

▶ **Lemma 15** (From Boolean to Larger Output Alphabet). *Let $\tilde{f}$, f, $\tilde{w}$, w and w_0 be defined as above. Then,*

(B1) *There is an unambiguous collection of simple size-s certificates for "$\tilde{f}(\cdot) = i$" with weight at most $w_0(i) \cdot W$ according to $\tilde{w}$.*

(B2) *The certificate complexity of "$\tilde{f}(0^N) \neq i$" with respect to $\tilde{w}$ is at least $w_0(i) \cdot \mathrm{C}((f, w), 0^N)$.*

Proof.

(B1) The unambiguous collection of simple 1-certificates for f corresponds to unambiguous collection of simple i-certificates for $\tilde{f}$ by checking that each queried symbol has its Σ_0-part equals i. The weight of each certificate in the collection is at most $w_0(i) \cdot W$ as each coordinate weighs $w_0(i)$ times its "original" weight.

(B2) Fix $i \in \Sigma_0$. Assume we have a certificate for "$\tilde{f}(0^n) \neq i$". This is a cartesian product $S_1 \times \ldots \times S_N$ such that each S_i contains the 0 symbol and under which $\forall x \in S_1 \times \ldots \times S_N$ it holds that $\tilde{f}(x) \neq i$. Take $\hat{f}$ to be $\tilde{f}$ restricted only to input alphabet $\{0\} \cup (\Sigma \times \{i\})$. Then $S'_1 \times \ldots \times S'_n$ where $S'_j = S_j \cap (\{0\} \cup (\Sigma \times \{i\}))$ is a certificate for "$\hat{f}(0^N) \neq i$". Using property 3 in Definition 12, we show that $w(S'_j) \leq w(S_j)$. We consider two cases. If $S'_j = \{0\} \cup (\Sigma \times \{i\})$, then $w(S'_j) = 0 \leq w(S_j)$. Otherwise,

$$w(S'_j) = \max_{\sigma \in (\Sigma \times \{i\}) \setminus S'_j} w(\sigma) \leq \max_{\sigma \in (\Sigma \times \Sigma_0) \setminus S_j} w(\sigma) = w(S_j).$$

However, proving that "$\hat{f}(0^N) = 0$" is equivalent to proving that "$f(0^N) = 0$", except for the reweighing. Since each coordinate weighs according to $\tilde{w}$ at least $w_0(i)$ times its weight according to w, the weight of the certificate $S_1 \times \ldots \times S_n$ is at least $w_0(i) \cdot C((f,w),0^N)$. ◀

▶ **Lemma 16** (Composition Lemma). *Let $h : (\{0\} \cup [k])^n \to \{0,1\}$ with $h(0^n) = 0$, and let $w_0 : [k] \to \mathbb{R}^+$ such that (h, w_0) has an unambiguous collection of simple 1-certificates of size-k and (fractional) weight u, however any certificate for "$h(0^n) = 0$" is of (fractional) weight v.*

Let $\tilde{f}$ and $\tilde{w}$ be as defined above. Let $f' : (\{0\} \cup \Sigma \times [k])^{n \times N} \to \{0,1\}$ be defined by $f' = h \circ \tilde{f}$, and $w' : (\{0\} \cup \Sigma \times [k]) \to \mathbb{N}$ be equal to $\tilde{w}$. Then,

(A1) *(f', w') has an unambiguous collection of simple certificates 1-certificates with size at most sk and weight at most $u \cdot W$.*

(A2) $\mathrm{C}((f', w'), 0^{Nn}) \geq v \cdot \mathrm{C}((f,w), 0^N)$.

Proof.

(A1) Take the unambiguous collection $\mathcal{C}$ of simple 1-certificates for h of size-k and (fractional) weight u. For any certificate $\mathcal{T}$ from $\mathcal{C}$ replace the verification that some coordinate equals i with the simple certificate that the relevant N-length input of $\tilde{f}$ belongs to $\tilde{f}^{-1}(i)$. The cost of each such certificate to $\tilde{f}$ will be at most $W \cdot w_0(i)$ according to $\tilde{w} \equiv w'$. Thus, the overall cost will be $W \cdot u$, and the certificates will be of size at most sk. It is easy to verify that these certificates are unambiguous, since unambiguous collections of simple certificates are closed under composition.

(A2) Let $\mathcal{T}$ be a certificate for "$f'(0^{N \cdot n}) = 0$" of minimal weight (according to w'), and let $w_{\mathcal{T}}$ be its weight. Let $\mathcal{T}_1, \ldots, \mathcal{T}_n$ be the substrings of $\mathcal{T}$ of length N according to the composition of $h \circ \tilde{f}$. By Lemma 15[B1], if $\mathcal{T}_i$ certifies that "$\tilde{f}(0^N) \neq j$", then it costs at least $w_0(j) \cdot \mathrm{C}((f,w),0^N)$. We construct a certificate $\mathcal{H}$ for h from $\mathcal{T}$. If $\mathcal{T}_i$ certifies that $\tilde{f}(0^N) \neq j$ then $(\mathcal{H})_i \neq j$. More formally, let $\mathcal{H} = S_1 \times \ldots \times S_n$, where for $i \in [n]$ the set S_i consists of $\{0\}$ union with all j such that $\mathcal{T}_i$ *does not* certify that $\tilde{f}(0^N) \neq j$. Suppose by contradiction that $\mathcal{H}$ does not certify that "$h(0^n) = 0$". Then, there exists an input $y \in S_1 \times \ldots \times S_n$ (i.e., an input consistent with $\mathcal{H}$) such that $h(y) = 1$. Thus, there exist inputs $x^{(1)}, \ldots, x^{(n)}$ each of length N such that $\tilde{f}(x^{(i)}) = y_i$ and $\mathcal{T}_i$ is consistent with $x^{(i)}$, which shows that $\mathcal{T}$ is not a certificate for $h \circ \tilde{f}_{\tilde{w}}$. Thus, $\mathcal{H}$ is a certificate for $h(0^n) = 0$, and we get that

$$w_{\mathcal{T}} \geq w_0(\mathcal{H}) \cdot \mathrm{C}((f,w),0^N) = v \cdot \mathrm{C}((f,w),0^N).$$ ◀

Next, we show how to take any "gadget" h – a function over a constant number of symbols – with some gap between the $\mathrm{UC}_1(h)$ and $\mathrm{C}(h, 0^n)$, and convert it into an infinite family of functions with a polynomial separation between UC_1 and C.

▶ **Theorem 17** (From Gadgets to Boolean Unweighted Separations). *Let $u, v \in \mathbb{R}$, $k \in \mathbb{N}$ be constants such that $1 \leq k \leq u < v$. Let $h : (\{0\} \cup [k])^n \to \{0,1\}$ with $h(0^n) = 0$, and let $w_0 : [k] \to \mathbb{R}^+$ such that (h, w_0) has an unambiguous collection of simple 1-certificates of size-k and (fractional) weight u, however any certificate for "$h(0^n) = 0$" is of (fractional) weight v.*

Then, there exists an infinite family of Boolean functions $\{h'_m\}_{m \in \mathbb{N}}$ with

1. $\mathrm{UC}_1(h'_m) \leq \mathrm{poly}(m) \cdot u^m$
2. $\mathrm{C}(h'_m) \geq v^m$
3. *h'_m is defined over $\mathrm{poly}(m) \cdot \exp(O(m))$ many bits.*

Proof. We start by defining a sequence of weighted functions $\{(h_m, w_m)\}_{m\in\mathbb{N}}$ over large alphabet size with a polynomial gap between UC_1 and C. We then convert these functions into unweighted Boolean functions with the desired properties.

We take $h_1 := h$ and $w_1 := w_0$. For $m \geq 2$ we take (h_m, w_m) to be the composition of (h, w_0) with $(\tilde{h}_{m-1}, \tilde{w}_{m-1})$. Let $\Sigma_m = [k]^m$. Then, $h_m : (\{0\} \cup \Sigma_m)^{n^m} \to \{0,1\}$ and $w_m : (\{0\} \cup \Sigma_m) \to \mathbb{R}^+$. Using Lemma 16, we have that

(i) The maximal weight in w_m is at most $(w_{0,max})^m$, where $w_{0,max} := \max_i\{w_0(i)\}$.
(ii) There exists an unambiguous collection of simple 1-certificates of size k^m and weight at most u^m for (h_m, w_m).
(iii) $\mathrm{C}((h_m, w_m), \vec{0}) \geq v^m$.

Making Weights Integral

First, we modify the weights so that they will be integral. We take $w'_m(\cdot)$ to be $\lceil w_m(\cdot)\rceil$. Taking ceiling on the weights may only increase the certificate complexities. Thus, $\mathrm{C}((h_m, w'_m), \vec{0}) \geq v^m$. On the other hand, the weight of any certificate may only increase additively by its size, hence $\mathrm{UC}_1((h_m, w'_m)) \leq u^m + k^m \leq 2u^m$.

Eliminating Weights

Next, we convert the weighted function (h_m, w'_m) to an unweighted Boolean function h'_m with similar UC_1 and C complexities. First, we remove the weights by applying Lemma 14 (using the fact that w'_m is integer-valued). We define $h''_m = h_m \circ g_{w'_m}$. Lemma 14 implies that

$$\mathrm{C}(h''_m) \geq \mathrm{C}((h_m, w'_m)) \geq v^m$$

and

$$\mathrm{UC}_1(h''_m) \leq \mathrm{UC}_1((h_m, w'_m)) \leq 2 \cdot u^m.$$

Booleanizing

To make the inputs of the function h''_m Boolean we repeat the argument of Göös [20]. If f is a function $f : \Sigma^N \to \{0,1\}$, we may always convert it to a boolean function by composing it with some surjection $g_\Sigma : \{0,1\}^{\lceil \log|\Sigma|\rceil} \to \Sigma$. The following naive bounds will suffice for our purposes:

$$\mathcal{C}(f) \leq \mathcal{C}(f \circ g_\Sigma) \leq \mathcal{C}(f) \cdot \lceil \log|\Sigma|\rceil \quad \text{forall } \mathcal{C} \in \{\mathrm{UC}_1, \mathrm{C}\}. \tag{1}$$

In our final alphabet $\Sigma = \{0\} \cup [k]^m$, thus $h'_m = h''_m \circ g_\Sigma$ is a Boolean function with

$$\mathrm{C}(h'_m) \geq \mathrm{C}(h''_m) \geq v^m$$

and

$$\mathrm{UC}_1(h'_m) \leq \mathrm{UC}_1(h''_m) \cdot \lceil \log|\Sigma|\rceil \leq 2 \cdot u^m \cdot O(m \log k).$$

Input Length

The input length of h_m is n^m. By lemma 14, the input length of h''_m is at most $n^m \cdot (w^m_{0,max}+1)$. Thus the input length to h'_m is at most

$$O(\log(|\Sigma|) \cdot (n \cdot w_{0,max})^m) = O(m \cdot \log(k) \cdot (n \cdot w_{0,max})^m)$$ ◀

4.3 Gadgets Based on Projective Planes

We will use a reweighed version of the function constructed by Göös [20] based on projective planes as our gadget. Let us first recall the definition of a projective plane.

▶ **Definition 18** (Projective plane). A projective plane is a k-uniform hyper-graph with $n = k^2 - k + 1$ edges and n nodes with the following properties.

- Each node is incident on exactly k edges.
- For every two nodes, there exists a unique edge containing both.
- Every two edges intersect on exactly one node.

Given a projective plane, it follows from Hall's theorem that it is possible to assign an ordering to the edges incident to each vertex in a way that for each edge, its assigned order for each of its nodes is different. Namely, for each i, there are no two nodes for which their i-th incident edge is the same.

It is well-known that projective planes exist for every k such that $k-1$ is a prime power. Göös [20] introduced the following function $f : (\{0\} \cup \Sigma)^n \to \{0,1\}$ based on a projective plane, with $\Sigma = [k]$. We think of the inputs of f as a sequence of pointers, one for each node, where 0 is the Null pointer, and $i \in [k]$ is a pointer to the i-th edge on which the node is incident on. We set $f(x) = 1$ if there is an edge of the projective plane such that all its nodes point to it, and $f(x) = 0$ otherwise.

We will be interested in showing a gap between the certificate complexity of "$f(0^n) = 0$" and $\mathrm{UC}_1(f)$. However, the function as is, allows a certificate of size k for "$f(0^n) = 0$" matching its $\mathrm{UC}_1(f)$. One certificate for "$f(0^n) = 0$" is to pick an arbitrary edge of the projective plane, and certify that all its nodes have the Null pointer. This certifies "$f(0^n) = 0$" as every two edges in a projective plane intersect on a node. An unambiguous collection of size k certificates consists of picking for each edge all its nodes and ensuring that they point to that edge. This collection is unambiguous using the same property that every two edges intersect on one node.

In order to obtain a gadget with a gap between UC_1 and C, Göös introduced weights on the input alphabet of f. Each element $i \in \Sigma$ is assigned a weight $w(i)$, where the weights are intended to carry the following meaning: For every $i \in \Sigma$ it costs $w(i)$ for a certificate to assure that "$x_j = i$", and moreover 0 has the special property that it costs $\max_{i \in \Sigma} w(i)$ to assure that "$x_j = 0$" (as in Definition 12). In [20] each $i \in [k]$ is assigned a weight $w(i) = i$. Göös [20] implemented this weighting scheme specifically for the case when $w(i) := i$ via a weighting gadget $g_w : (\{0\} \cup \Sigma)^k \to (\{0\} \cup \Sigma)$ (as done in Lemma 14) and considering $f \circ g_w$. Our improvement comes from considering a different weighting scheme with fractional weights.

▶ **Claim 19** (Reweighing the Projective Plane). *Let f be defined as above, and let $w(i) := \frac{i}{(k+1)/2}$. Then, (f, w) has an unambiguous collection of simple 1-certificates of size k and weight k. Moreover, any certificate for $f(0^n) = 0$ is of weight at least $\frac{k^2-k+1}{(k+1)/2}$*

Proof. Göös [20, Claims 6 and 7] showed that with respect to the weight-function $w'(i) = i$, the function f has an unambiguous collection of simple 1-certificates of size-k and weight $(k \cdot (k+1))/2$. However, any certificate for "$f(0^n) = 0$" is of weight at least $k^2 - k + 1$.

From this, it is immediate that with respect to $w \equiv \frac{w'}{(k+1)/2}$, f has an unambiguous collection of simple 1-certificates of size-k and (fractional) weight $\frac{(k\cdot(k+1))/2}{(k+1)/2} = k$. However, any certificate for 0^n is of weight at least $\frac{k^2-k+1}{(k+1)/2}$. ◀

4.4 Putting Things Together

Given a gadget (h, w_0) such that h has unambiguous collection of simple 1-certificates of size-k and (fractional) weight u, however any certificate for 0^n is of (fractional) weight v, with $v > u > 1$ and $u \geq k$, Theorem 17 gives a polynomial separation between C and UC_1:

$$\mathrm{C}(h'_m) \geq v^m = (u^m)^{\log(v)/\log(u)} \geq \widetilde{\Omega}\left(\mathrm{UC}_1(h'_m)^{\log(v)/\log(u)}\right) . \tag{2}$$

We take h to be the projective plane function f described in Section 4.3 with $k = 8$, $n = k^2 - k + 1 = 57$ and weight function $w_0(i) = \frac{i}{(k+1)/2}$. By Claim 19, we have that with respect to w_0, h has an unambiguous collection of simple 1-certificates of size-k and weight $k = 8$. However, any certificate for 0^n is of weight $\frac{k^2-k+1}{(k+1)/2} = 38/3$. Plugging these values in Equation (2) we get a better separation:

$$\mathrm{C}(h'_m) \geq \widetilde{\Omega}\left(\mathrm{UC}_1(h'_m)^{\frac{\log(38/3)}{\log(8)}}\right) \geq \Omega(\mathrm{UC}_1(h'_m)^{1.22}) , \tag{3}$$

where the input length is $N \leq \mathrm{poly}(m) \cdot \exp(O(m))$. The lifting theorem of [22, 20] incurs a loss factor of $\log(N) = O(m)$ in the separation, however this is negligible compared to the $\mathrm{poly}(m) \cdot u^m$ versus v^m separation.

4.5 Further Improvements

Since our theorem is general in transforming a fractional weighted gadget into a polynomial separation, it is enough to only improve the gadget construction in order to improve the UC_1 vs C exponent. Indeed, even using the same gadget (the projective plane function of Göös) we can consider different weight function. Using computer search it seems that such reweighing is indeed better than our choice of w_0. However, the improvement is mild and currently we do not have a humanly verifiable proof for the lower bound on the certificate complexity of 0^n under the reweighing. Indeed, Göös relied on the fact that the weights were $w'(i) = i$ in order to present a simple proof of his lower bound on the certificate complexity of "$h(0^n) = 0$" according to w'. It seems though (we have verified this using computer-search for small values of k) that the best weights are attained by taking $w'(i) = i + 1$ and then reweighing by multiplying all weights by the constant $\alpha = \frac{1}{(k+3)/2}$, so that the unambiguous certificates for h will be of weights k. We leave proving a lower bound under this weight function as an open problem.

5 Attempting a Super-Quadratic Separation vs. Block Sensitivity

In this section, we describe why attempting to use Theorem 1 to get a super-quadratic separation between $\mathrm{bs}(f)$ and $\mathrm{s}(f)$ fails. In the process, we show some new lower bounds for $\mathrm{UC}_{\min}(f)$ and even for the one-sided non-negative degree measures.

One approach for the desired super-quadratic separation is to find a family of functions for which $\mathrm{bs}(f) \gg \mathrm{UC}_{\min}(f)$. In fact, by [28], it suffices to provide a family of functions for which $\mathrm{RC}(f) \gg \mathrm{UC}_{\min}(f)$ (as explained in Section 5.1). In Section 5.2, we show that even separating $\mathrm{RC}(f)$ from $\mathrm{UC}_{\min}(f)$ is impossible: we have $\mathrm{RC}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$. This means our techniques do not give anything new for this problem. This is perhaps surprising, since $\mathrm{RC}(f)$ is similar to $\mathrm{C}(f)$, yet [20] showed a separation between $\mathrm{C}(f)$ and $\mathrm{UC}_{\min}(f)$.

5.1 A Separation Against $\mathrm{RC}(f)$ is Sufficient

[28] showed that a separation between $\mathrm{s}(f)$ and $\mathrm{RC}(f)$ implies an equal separation between $\mathrm{s}(f)$ and $\mathrm{bs}(f)$ (see Theorem 7). The key insight is that $\mathrm{bs}(f)$ becomes $\mathrm{RC}(f)$ when the function is composed enough times; this was observed by [40] and by [19]. This means that if we start with a function separating $\mathrm{s}(f)$ and $\mathrm{RC}(f)$ and compose it enough times, we should get a function with the same separation between $\mathrm{s}(f)$ and $\mathrm{RC}(f)$, but with the additional property that $\mathrm{bs}(f) \approx \mathrm{RC}(f)$.

5.2 But $\mathrm{RC}(f)$ Lower Bounds $\mathrm{UC}_{\min}(f)$

We would get a super-quadratic separation between $\mathrm{bs}(f)$ and $\mathrm{s}(f)$ if we had a super-linear separation between $\mathrm{RC}(f)$ and $\mathrm{UC}_{\min}(f)$. Unfortunately, this is impossible using our paradigm, as we now show. Actually, we can prove an even stronger statement, namely that $\mathrm{RC}(f) \leq (2\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - 1)/(1-4\epsilon)$. We note that this implies Theorem 8, because when $\epsilon = 0$, we have

$$\mathrm{RC}(f) \;\leq\; 2\,\mathrm{avdeg}^{+}_{\min}(f) - 1 \;\leq\; 2\,\mathrm{deg}^{+}_{\min}(f) - 1 \;\leq\; 2\,\mathrm{UC}_{\min}(f) - 1.$$

This stronger statement says that one-sided conical junta degree is lower bounded by two-sided randomized certificate complexity, which helps clarify the hierarchy of lower bounds for randomized algorithms.

The proof of the relationship $\mathrm{RC}(f) \leq (2\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - 1)/(1-4\epsilon)$ is somewhat technical; we leave it for Appendix A, and provide a cleaner proof (of $\mathrm{RC}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$) below. One interesting thing to note about it is that it holds for partial functions as well, as long as the definition of $\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f)$ requires the approximating polynomial to evaluate to at most 1 on the entire Boolean hypercube.

Before providing the proof, we'll provide a warm up proof that $\mathrm{bs}(f) \leq 2\,\mathrm{UC}_{\min}(f)$.

▶ **Lemma 20.** *For all non-constant $f : \{0,1\}^n \to \{0,1\}$, we have $\mathrm{bs}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$.*

Proof. Without loss of generality, we have $\mathrm{UC}_{\min}(f) = \mathrm{UC}_1(f)$. We also have $\mathrm{bs}_1(f) \leq \mathrm{C}_1(f) \leq \mathrm{UC}_1(f)$, so it remains to show that $\mathrm{bs}_0(f) \leq 2\,\mathrm{UC}_1(f) - 1$. Also without loss of generality, we assume that the block sensitivity of 0^n is $\mathrm{bs}(f)$ and that $f(0^n) = 0$.

Let $B_1, B_2, \ldots, B_{\mathrm{bs}(f)}$ be disjoint sensitive blocks of 0^n. Let U be an unambiguous collection of 1-certificates for f, each of size at most $\mathrm{UC}_1(f)$. For each $i \in [\mathrm{bs}(f)]$, we have $f(\vec{0}^{B_i}) = 1$, so there is some 1-certificate $p_i \in U$ such that p_i is consistent with $\vec{0}^{B_i}$. Since p_i is a 1-certificate, it is not consistent with $\vec{0}$, so it has a 1 bit (which must have index in B_i). Now, if $i \neq j$, the certificate p_i has a 1 inside B_i and only 0 or $*$ symbols outside B_i, and the certificate B_j has a 1 inside B_j and only 0 or $*$ symbols outside B_j; thus p_i and p_j are different. Since U is an unambiguous collection, p_i and p_j must conflict on some bit (with one of them assigning 0 and the other assigning 1), or else there would be an input consistent with both.

We construct a directed graph on vertex set $[\mathrm{bs}(f)]$ as follows. For each $i, j \in [\mathrm{bs}(f)]$ with $i \neq j$, we draw an arc from i to j if p_i has a 0 bit in a location where p_j has a 1 bit. It follows that for each pair $i, j \in [\mathrm{bs}(f)]$ with $i \neq j$, we either have an arc from i to j or else we have an arc from j to i (or both). The number of arcs in this graph is at least $\mathrm{bs}(f)(\mathrm{bs}(f)-1)/2$, so the average out degree is at least $(\mathrm{bs}(f)-1)/2$. Hence there is some vertex i with out degree at least $(\mathrm{bs}(f)-1)/2$. But this means p_i conflicts with $(\mathrm{bs}(f)-1)/2$ other certificates $p_{j_1}, p_{j_2}, \ldots, p_{j_{(\mathrm{bs}(f)-1)/2}}$ with p_i having a bit 0 and p_{j_k} having a 1-bit; however, two different

certificates p_{j_x} and p_{j_y} cannot both agree on a 1 bit, since the 1 bits of p_{j_x} must come from block B_{j_x} and the blocks are disjoint. This means p_i has at least $(\mathrm{bs}(f)-1)/2$ zero bits. It must also have at least one 1 bit. Thus $|p_i| \geq \mathrm{bs}(f)/2 + 1/2$, so $\mathrm{bs}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$. ◀

We now generalize this lemma from bs to RC, proving Theorem 8. A further strengthening of the result can be found in Appendix A.

▶ **Theorem 8.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. Then* $\mathrm{RC}(f) \leq 2\,\mathrm{UC}_{\min}(f) - 1$.

Proof. Without loss of generality, we have $\mathrm{UC}_{\min}(f) = \mathrm{UC}_1(f)$. We also have $\mathrm{RC}_1(f) \leq \mathrm{C}_1(f) \leq \mathrm{UC}_1(f)$, so it remains to show that $\mathrm{RC}_0(f) \leq 2\,\mathrm{UC}_1(f) - 1$. Also without loss of generality, we assume that the randomized certificate of 0^n is $\mathrm{RC}(f)$ and that $f(0^n) = 0$.

We prove the theorem using the characterization of $\mathrm{RC}(f)$ as the fractional block sensitivity of f. Let $B_1, B_2, \ldots, B_m$ be minimal sensitive blocks of 0^n. Let $a_1, \ldots, a_m$ be weights assigned to blocks $B_1, \ldots, B_m$ such that

$$\sum_j a_j = \mathrm{RC}(f) \quad \text{, and} \quad \forall i \in [n] : \sum_{j : i \in B_j} a_j \leq 1 \,.$$

Let U be an unambiguous collection of 1-certificates for f, each of size at most $\mathrm{UC}_1(f)$. For each $i \in [m]$, we have $f(\vec{0}^{B_i}) = 1$, so there is some 1-certificate $p_i \in U$ such that p_i is consistent with $\vec{0}^{B_i}$. Since p_i is a 1-certificate, it is not consistent with $\vec{0}$, so it has a 1 bit (which must have index in B_i). Next, we show that if $i \neq j$, then p_i and p_j are different. Assume by contradiction that $p_i = p_j$, then p_i is a partial assignment that satisfy both $\vec{0}^{B_i}$ and $\vec{0}^{B_j}$, hence it must satisfy $\vec{0}^{B_i \cap B_j}$, but this means that $f(\vec{0}^{B_i \cap B_j}) = 1$ which contradicts the fact that both B_i and B_j are minimal sensitive blocks for $\vec{0}$.

We established that for any $i \neq j$, the partial assignments p_i and p_j are different. Since U is an unambiguous collection, p_i and p_j must conflict on some bit (with one of them assigning 0 and the other assigning 1), or else there would be an input consistent with both.

We construct a directed weighted graph on vertex set $[m]$ as follows. For each $i, j \in [m]$ with $i \neq j$, we draw an arc from i to j with weight $a_i \cdot a_j$, if p_i has a 0 bit in a location where p_j has a 1 bit. It follows that for each pair $i, j \in [m]$ with $i \neq j$, we either have an arc from i to j or else we have an arc from j to i (or both). The total weight of the arcs in this graph is

$$\begin{aligned}
\sum_{i<j} a_i \cdot a_j \cdot (|p_i^{-1}(1) \cap p_j^{-1}(0)| + |p_i^{-1}(0) \cap p_j^{-1}(1)|) &\geq \sum_{i<j} a_i \cdot a_j \\
&= \frac{1}{2} \cdot (\sum_i a_i)^2 - \frac{1}{2} \cdot \sum_i a_i^2 \\
&\geq \frac{1}{2} \cdot (\sum_i a_i)^2 - \frac{1}{2} \cdot \sum_i a_i \quad (a_i \leq 1) \\
&\geq \frac{1}{2} \cdot (\mathrm{RC}(f)^2 - \mathrm{RC}(f))
\end{aligned}$$

Note that by symmetry, the LHS equals

$$\sum_i a_i \cdot \sum_{j \neq i} a_j \cdot |p_i^{-1}(0) \cap p_j^{-1}(1)|.$$

Since $\sum_i a_i = \mathrm{RC}(f)$, by averaging,

$$\exists i : \ \frac{1}{2}(\mathrm{RC}(f) - 1) \leq \sum_{j \neq i} a_j \cdot |p_i^{-1}(0) \cap p_j^{-1}(1)|. \tag{4}$$

Next, we get a lower bound on $|p_i^{-1}(0)|$ from Eq. (4).

$$\begin{aligned}
\frac{1}{2}(\mathrm{RC}(f)-1) &\le \sum_{j\neq i} a_j \cdot |p_i^{-1}(0)\cap p_j^{-1}(1)| \\
&= \sum_{k:p_i(k)=0} \sum_{j:p_j(k)=1} a_j \\
&\le \sum_{k:p_i(k)=0} \sum_{j:k\in B_j} a_j && (p_j \text{ is consistent with } \vec{0}^{B_j}) \\
&\le |p_i^{-1}(0)|. && (\textstyle\sum_{j:k\in B_j} a_j \le 1 \text{ for all } k)
\end{aligned}$$

We showed that p_i has at least $(\mathrm{RC}(f)-1)/2$ zero bits. It must also have at least one 1 bit. Thus $|p_i| \ge \mathrm{RC}(f)/2 + 1/2$, so $\mathrm{RC}(f) \le 2\,\mathrm{UC}_{\min}(f) - 1$. ◀

We note that the relationships in Lemma 20 and Theorem 8 are tight.[2] Let k be any non-negative integer, we construct a function f on $n = 2k+1$ variables with $\mathrm{s}(f) = \mathrm{bs}(f) = \mathrm{RC}(f) = n$ and $\mathrm{UC}_{\min}(f) \le k+1$. This shows that the inequalities $\mathrm{bs}(f) \le 2\,\mathrm{UC}_{\min}(f) - 1$ and $\mathrm{RC}(f) \le 2\,\mathrm{UC}_{\min}(f) - 1$ are both tight for all values of $\mathrm{UC}_{\min}(f)$. We define the function f by describing a set of partial assignments $p_0, \ldots, p_{n-1}$ such that $f(x) = 1$ if and only if $\exists i : p_i \subseteq x$. Let $p = 0^k 1 *^k$. The assignments $p_0, \ldots, p_{n-1}$ are all possible cyclic-shifts of p, namely for $0 \le i \le k$, $p_i = 0^{k-i} 1 *^k 0^i$ and for $k+1 \le i \le 2k$ we have $p_i = *^{2k+1-i} 0^k 1 *^{i-1-k}$. It is easy to verify that any two different partial assignments p_i and p_j are not consistent with one another. Hence, $p_0, \ldots, p_{n-1}$ is an unambiguous collection of 1-certificates for f, each of size $k+1$, exhibiting that $\mathrm{UC}_{\min}(f) \le k+1$. On the other hand, $f(0) = 0$ and for all $i \in [n]$, we have $f(e_i) = 1$, showing that f has sensitivity n on the all-zeros input. Overall, we showed that $\mathrm{s}(f) = \mathrm{bs}(f) = \mathrm{RC}(f) = n = 2k+1$ while $\mathrm{UC}_{\min}(f) \le k$.

A Lower Bound for Approximate Non-Negative Degree

Here we show that the lower bound in Theorem 8 holds even for one-sided average approximate non-negative degree, the smallest version of conical junta degree. This is saying that conical juntas, in all their forms, give a more powerful lower bound technique for randomized algorithms than $\mathrm{RC}(f)$.

▶ **Theorem 21.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a non-constant function, and let $\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f)$ denote the minimum average degree of a non-negative polynomial that approximates either f or its negation with error at most ϵ (see Section 2.6 for definitions). If $\epsilon < 1/4$, we have $\mathrm{RC}(f) \leq \frac{2\,\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f)-1}{1-4\epsilon}$.*

Proof. Let q be the non-negative approximating polynomial with average degree $\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f)$. Without loss of generality, we assume q approximates f rather than its negation. We can write $q \equiv \sum_{p\in\{0,1,*\}} w_p p$, so for any $x \in \{0,1\}^n$, we have

$$q(x) = \sum_{p\in\{0,1,*\}} w_p p(x) = \sum_{p:\, p\subseteq x} w_p,$$

where recall that w_p are non-negative weights given to partial assignments. This means for all $x \in \{0,1\}^n$, we know that

$$\left| f(x) - \sum_{p:\, p\subseteq x} w_p \right| \leq \epsilon, \qquad \sum_{p:\, p\subseteq x} w_p \leq 1, \qquad \text{and} \qquad \sum_{p:\, p\subseteq x} w_p|p| \leq \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f).$$

Now, consider the input $y \in \{0,1\}^n$ for which $\mathrm{RC}_y(f) = \mathrm{RC}(f)$. There are two cases: either y is a 0-input, or else y is a 1-input. If y is a 1-input, we use the fractional certificate complexity interpretation of $\mathrm{RC}_y(f)$: the value $\mathrm{RC}_y(f)$ is the minimum amount of weight that can be distributed to the bits of y such that every sensitive block of y contains bits of total weight at least 1. We assign to bit $i \in [n]$ the weight

$$\frac{1}{1-2\epsilon} \sum_{p:\, p\subseteq y, p_i\neq *} w_p.$$

Then each sensitive block $B \subseteq [n]$ for y satisfies $f(y^B) = 0$, so the sum of w_p over all $p \subseteq y$ that have support disjoint from B must be at most ϵ. Since the sum of w_p over all $p \subseteq y$ is at least $1-\epsilon$, there must be weight at least $1-2\epsilon$ assigned to partial assignments consistent with p whose support overlaps B. It follows that the total weight given to the bits in B is at least 1, which means this weighting is feasible. This means the total weight upper bounds $\mathrm{RC}_y(f)$, so

$$\mathrm{RC}(f) = \mathrm{RC}_y(f) \leq \frac{1}{1-2\epsilon} \sum_{i\in[n]} \sum_{p:\, p\subseteq y,\, p_i\neq *} w_p = \frac{1}{1-2\epsilon} \sum_{p:\, p\subseteq y} w_p|p| \leq \frac{\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f)}{1-2\epsilon}.$$

It remains to deal with the case where y is a 0-input. In this case, we use the fractional block sensitivity interpretation of $\mathrm{RC}_y(f)$: the value of $\mathrm{RC}_y(f)$ is the maximum amount of weight that can be distributed to the sensitive blocks of y such that every bit of y lies inside blocks of total weight at most 1. Without loss of generality, we can assume only minimal sensitive blocks are assigned weight (minimal sensitive blocks are sensitive blocks such that all their proper subsets are not minimal).

Let $\mathcal{B} := \{B \subseteq [n] : f(y^B) \neq f(y)\}$ be the set of sensitive blocks of y, and let $\mathcal{M} := \{B \in \mathcal{B} : \forall B' \subset B, B' \notin \mathcal{B}\}$ be the set of minimal sensitive blocks of y. Let $\{a_B\}_{B\in\mathcal{M}}$ with $a_B \in \mathbb{R}^+$ be the optimal weighting of the minimal sensitive blocks. This means $\sum_{B\in\mathcal{M}} a_B = \mathrm{RC}_y(f)$ and $\sum_{B\ni i} a_B \leq 1$ for all $i \in [n]$.

We have $\sum_{p\subseteq y} w_p \leq \epsilon$ and $\sum_{p\subseteq y^B} w_p \geq 1-\epsilon$ for all $B \in \mathcal{B}$. Thus, for any $B_1, B_2 \in \mathcal{M}$ with $B_1 \neq B_2$, we can write

$$2-2\epsilon \leq \sum_{p\subseteq y^{B_1}} w_p + \sum_{p\subseteq y^{B_2}} w_p = \sum_{p\subseteq y^{B_1} : p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\subseteq y^{B_2} : p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\in G} w_p + \sum_{p\in H} w_p,$$

where $G := \{p : p \subseteq y^{B_1}, p \subseteq y^{B_1\cup B_2}\}$ and $H := \{p : p \subseteq y^{B_2}, p \subseteq y^{B_1\cup B_2}\}$. The last two sums are equal to $\sum_{p\in G\cup H} w_p + \sum_{p\in G\cap H} w_p$. We have $\sum_{p\in G\cup H} w_p \leq \sum_{p\subseteq y^{B_1\cup B_2}} w_p \leq 1$. Also, any $p \in G\cap H$ satisfies $p \subseteq y^{B_1\cap B_2}$. Since $B_1 \neq B_2$ and they are both minimal sensitive blocks, we have $f(y^{B_1\cap B_2}) = 0$, so $\sum_{G\cap H} w_p \leq \sum_{p\subseteq y^{B_1\cap B_2}} w_p \leq \epsilon$. It follows that

$$\sum_{p\subseteq y^{B_1} : p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\subseteq y^{B_2} : p\not\subseteq y^{B_1\cup B_2}} w_p \geq 1-3\epsilon.$$

Note that the above sums are over disjoint sets, since if $p \subseteq y^{B_1}$ and $p \not\subseteq y^{B_1\cup B_2}$, then p must disagree with y^{B_2} on some bit inside B_2. If we split out the parts of the sums for which $p \subseteq y$, we get

$$\sum_{p\subseteq y} w_p + \sum_{p\subseteq y^{B_1} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\subseteq y^{B_2} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p \geq 1-3\epsilon.$$

Since $f(y) = 0$, the first sum is at most ϵ, so

$$\sum_{p\subseteq y^{B_1} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\subseteq y^{B_2} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p \geq 1-4\epsilon.$$

We now write the following.

$$\begin{aligned}
\mathrm{RC}(f)^2 - \mathrm{RC}(f) &= \sum_{B_1\in\mathcal{M}} a_{B_1} \sum_{B_2\in\mathcal{M}} a_{B_2} - \sum_{B_1\in\mathcal{M}} a_{B_1} \\
&\leq \sum_{B_1\in\mathcal{M}} a_{B_1} \sum_{B_2\in\mathcal{M}} a_{B_2} - \sum_{B_1\in\mathcal{M}} a_{B_1}^2 \\
&= \sum_{B_1\in\mathcal{M}} a_{B_1} \sum_{B_2\neq B_1} a_{B_2} \\
&\leq \frac{1}{1-4\epsilon} \sum_{B_1\in\mathcal{M}} a_{B_1} \sum_{B_2\neq B_1} a_{B_2} \\
&\quad \left(\sum_{p\subseteq y^{B_1} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p + \sum_{p\subseteq y^{B_2} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p \right) \\
&= \frac{2}{1-4\epsilon} \sum_{B_1\in\mathcal{M}} a_{B_1} \sum_{B_2\neq B_1} a_{B_2} \sum_{p\subseteq y^{B_1} : p\not\subseteq y,\, p\not\subseteq y^{B_1\cup B_2}} w_p,
\end{aligned}$$

where the second line follows because $a_{B_1} \leq 1$ for all $B_1 \in \mathcal{M}$.

Note that $\sum_{B_1 \in \mathcal{M}} a_{B_1} = \mathrm{RC}(f)$, so if we divide both sides by $\mathrm{RC}(f)$, the last line becomes a weighted average. It follows that there exists some minimal block B_1 such that

$$\begin{aligned}\mathrm{RC}(f) - 1 &\leq \frac{2}{1-4\epsilon} \sum_{B_2 \neq B_1} a_{B_2} \sum_{p \subseteq y^{B_1} : p \not\subseteq y,\, p \not\subseteq y^{B_1 \cup B_2}} w_p \\ &= \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p \sum_{B_2 \neq B_1 : p \not\subseteq y^{B_1 \cup B_2}} a_{B_2}.\end{aligned}$$

Examine the inner summation above. Note that $y^{B_1 \cup B_2} = (y^{B_1})^{B_2 \setminus B_1}$. Since $p \subseteq y^{B_1}$, the condition $p \not\subseteq y^{B_1 \cup B_2}$ is equivalent to the support of p having non-empty intersection with $B_2 \setminus B_1$. Using $\mathrm{supp}(p)$ to denote the support of p, we have

$$\begin{aligned}\mathrm{RC}(f) - 1 &\leq \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p \sum_{i \in \mathrm{supp}(p) \setminus B_1} \sum_{B_2 \in \mathcal{M} : i \in B_2} a_{B_2} \\ &\leq \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p \sum_{i \in \mathrm{supp}(p) \setminus B_1} 1 \\ &= \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p |\mathrm{supp}(p) \setminus B_1| \\ &\leq \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p (|p| - 1) \\ &\leq \frac{2}{1-4\epsilon} \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - \frac{2}{1-4\epsilon} \sum_{p \subseteq y^{B_1} : p \not\subseteq y} w_p \\ &\leq \frac{2}{1-4\epsilon} \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - \frac{2}{1-4\epsilon} \left(\sum_{p \subseteq y^{B_1}} w_p - \sum_{p \subseteq y} w_p \right) \\ &\leq \frac{2}{1-4\epsilon} \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - \frac{2}{1-4\epsilon} (1 - \epsilon - \epsilon) \\ &\leq \frac{2}{1-4\epsilon} \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - \frac{2-4\epsilon}{1-4\epsilon},\end{aligned}$$

where the second line follows because the sum of a_B over all blocks $B \in \mathcal{M}$ containing a given element $i \in [n]$ is at most 1, and the fourth line follows because the conditions $p \subseteq y^{B_1}$ and $p \not\subseteq y$ imply that the support of p is not disjoint from B_1. Finally, we get

$$\mathrm{RC}(f) \leq \frac{2}{1-4\epsilon} \widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - \frac{1}{1-4\epsilon} = \frac{2\,\widetilde{\mathrm{avdeg}}^{+,\epsilon}_{\min}(f) - 1}{1-4\epsilon},$$

as desired. ◀

Testing k-Monotonicity

Abstract

A Boolean k-*monotone* function defined over a finite poset domain $\mathcal{D}$ alternates between the values 0 and 1 at most k times on any ascending chain in $\mathcal{D}$. Therefore, k-monotone functions are natural generalizations of the classical *monotone* functions, which are the 1-*monotone* functions.

Motivated by the recent interest in k-monotone functions in the context of circuit complexity and learning theory, and by the central role that monotonicity testing plays in the context of property testing, we initiate a systematic study of k-monotone functions, in the property testing model. In this model, the goal is to distinguish functions that are k-monotone (or are close to being k-monotone) from functions that are far from being k-monotone.

Our results include the following:

1. We demonstrate a separation between testing k-monotonicity and testing monotonicity, on the hypercube domain $\{0,1\}^d$, for $k \geq 3$;
2. We demonstrate a separation between testing and learning on $\{0,1\}^d$, for $k = \omega(\log d)$: testing k-monotonicity can be performed with $2^{O(\sqrt{d}\cdot\log d\cdot\log 1/\varepsilon)}$ queries, while learning k-monotone functions requires $2^{\Omega(k\cdot\sqrt{d}\cdot 1/\varepsilon)}$ queries (Blais et al. (RANDOM 2015)).
3. We present a tolerant test for functions $f\colon [n]^d \to \{0,1\}$ with complexity independent of n, which makes progress on a problem left open by Berman et al. (STOC 2014).

Our techniques exploit the testing-by-learning paradigm, use novel applications of Fourier analysis on the grid $[n]^d$, and draw connections to distribution testing techniques.

1 Introduction

A function $f\colon \mathcal{D} \to \{0,1\}$, defined over a finite partially ordered domain $(\mathcal{D}, \preceq)$ is said to be k-*monotone*, for some integer $k \geq 0$, if there does not exist $x_1 \preceq x_2 \preceq \ldots \preceq x_{k+1}$ in $\mathcal{D}$ such that $f(x_1) = 1$ and $f(x_i) \neq f(x_{i+1})$ for all $i \in [k]$. Note that 1-monotone functions are the classical *monotone* functions, satisfying $f(x_1) \leq f(x_2)$, whenever $x_1 \preceq x_2$.

Monotone functions have been well-studied on multiple fronts in computational complexity due to their natural structure. They have been celebrated for decades in the property

testing literature [25, 20, 24, 10, 15, 14, 16], where we have recently witnessed ultimate results [33, 18, 6], in the circuit complexity literature, where we now have strong lower bounds [43, 44], and in computational learning, where we now have learning algorithms in numerous learning models [11, 3, 32, 46, 40, 41].

The generalized notion of k-monotonicity has also been studied in the context of circuit lower bounds for more than 50 years. In particular, Markov [36] showed that any k-monotone function (even with multiple outputs) can be computed using circuits containing only $\log k$ negation gates. The presence of negation gates appears to be a challenge in proving circuit lower bounds: "the effect of such gates on circuit size remains to a large extent a mystery" [29]. The recent results of Blais *et al.* [9] on circuit lower bounds have prompted renewed interest in understanding k-monotone functions from multiple angles, including cryptography, circuit complexity, learning theory, and Fourier analysis ([45, 27, 26, 35]).

Motivated by the exponential lower bounds on PAC learning k-monotone functions due to [9], we initiate the study of k-monotonicity in the closely related *Property Testing* model. In this model, given query access to a function, one must decide if the function is k-monotone, or is far from being k-monotone, by querying the input only in a small number of places.

1.1 Our results

We focus on testing k-monotonicity of Boolean functions defined over the d-dimensional hypegrid $[n]^d$, and the hypercube $\{0,1\}^d$. We begin our presentation with the results for the hypercube, in order to build intuition into the difficulty of the problem, while comparing our results with the current literature on testing monotonicity. Our stronger results concern the hypegrid $[n]^d$.

1.1.1 Testing k-monotonicity on the hypercube $\{0,1\}^d$

In light of the recent results of [33] that provide a $O(\sqrt{d})$-query tester for monotonicity, we first show that testing k-monotonicity is strictly harder than testing monotonicity on $\{0,1\}^d$, for $k \geq 3$.

▶ **Theorem 1.** *For $1 \leq k \leq d^{1/4}/2$, any one-sided non-adaptive tester for k-monotonicity of functions $f\colon \{0,1\}^d \to \{0,1\}$ must make $\Omega\big(d/k^2\big)^{k/4}$ queries.*

Both Theorem 1 and its proof generalize the $\Omega(d^{1/2})$ lower bound for testing monotonicity, due to Fischer *et al.* [24].

On the upper bounds side, while the monotonicity testing problem is providing numerous potential techniques for approaching this new problem [25, 20, 14, 10, 19, 33], most common techniques appear to resist generalizations to k-monotonicity. However, our upper bounds demonstrate a separation between testing and PAC learning k-monotonicity, for large enough values of $k = \omega(\log d)$.

▶ **Theorem 2.** *There exists a one-sided non-adaptive tester for k-monotonicity of functions $f\colon \{0,1\}^d \to \{0,1\}$ with query complexity $q(d,\varepsilon,k) = 2^{O\left(\sqrt{d}\cdot\log d\cdot\log\frac{1}{\varepsilon}\right)}$.*

Indeed, in the related PAC learning model, [9] shows that learning k-monotone functions on the hypercube requires $2^{\Omega(k\cdot\sqrt{d}\cdot 1/\varepsilon)}$ many queries.

We further observe that the recent non-adaptive and adaptive 2-sided lower bounds of [18, 6], imply the same bounds for k-monotonicity, using black box reductions. We summarize the state of the art for testing k-monotonicity on the hypercube in Table 1.

Table 1 Testing k-monotonicity of a function $f\colon \{0,1\}^d \to \{0,1\}$

	upper bound	1.s.-n.a. lower bound	2.s.-n.a. lower bound	2.s.-a. lower bound
$k=1$	$O\left(\sqrt{d}\right)$ [33]	$\Omega\left(d^{1/2}\right)$ [24]	$\Omega\left(d^{1/2-o(1)}\right)$ [18]	$\tilde{\Omega}\left(d^{1/4}\right)$ [6]
$k \geq 2$	$d^{O(k\sqrt{d})}$ [9], $d^{O(\sqrt{d})}$ Thm 2	$\Omega\left(d/k^2\right)^{k/4}$ Thm 1 $(k = O(d^{1/4}))$	$\Omega\left(d^{1/2-o(1)}\right)$	$\tilde{\Omega}\left(d^{1/4}\right)$

Table 2 Summary of our results: testing k-monotonicity of a function $f\colon [n]^d \to \{0,1\}$ (first two columns). The last column contains known bounds on monotonicity testing and is provided for comparison.

1.1.2 Testing k-monotonicity on the hypergrid $[n]^d$

The remainder of the paper focuses on functions defined over the d-dimensional hypergrid domain $[n]^d$, where we denote by $(i_1, i_2, \ldots, i_d) \preceq (j_1, j_2, \ldots, j_d)$ the partial order in which $i_1 \leq j_1, i_2 \leq j_2, \ldots, i_d \leq j_d$. Testing monotonicity has received a lot of attention over the d-dimensional hypergrids [25, 21, 23, 5, 1, 28, 8, 15, 14, 16, 7], where the problem is well-understood, and we refer the reader the appendix of the full version for a detailed review on the state of the art in the area. We summarize our results on testing k-monotonicity over $[n]^d$ in Table 2.

1.1.2.1 Testing k-monotonicity on the line and the 2-dimensional grid

We begin with a study of functions $f\colon [n] \to \{0,1\}$. As before, note that 1-sided tests should always accept k-monotone functions, and so, they must accept unless they discover a violation to k-monotonicity in the form of a sequence $x_1 \preceq x_2 \preceq \ldots \preceq x_{k+1}$ in $[n]^d$, such that $f(x_1) = 1$ and $f(x_i) \neq f(x_{i+1})$. Therefore, lower bounds for 1-sided k-monotonicity testing must grow at least linearly with k. We show that this is indeed the case for both adaptive and non-adaptive tests, and moreover, we give a tight non-adaptive algorithm. Consequently, our results demonstrate that adaptivity does not help in testing k-monotonicity with one-sided error on the line domain.

▶ **Theorem 3.** *Any one-sided (possibly adaptive) tester for k-monotonicity of functions $f\colon [n] \to \{0,1\}$ must have query complexity $\Omega\left(\frac{k}{\varepsilon}\right)$.*

The upper bound generalizes the $O(1/\varepsilon)$ tester for monotonicity on the line.

▶ **Theorem 4.** *There exists a one-sided non-adaptive tester for k-monotonicity of functions $f\colon [n] \to \{0,1\}$ with query complexity $q(n, \varepsilon, k) = O\left(\frac{k}{\varepsilon}\right)$.*

Testing with 2-sided error, however, does not require a dependence on k. In fact the problem has been well-studied in the machine learning literature in the context of testing/learning "union of intervals" [31, 4], and in testing geometric properties, in the

context of testing surface area [34, 38],[1] resulting in an $O(1/\varepsilon^{7/2})$-query algorithm. Namely, the starting point of [4] (later improved by [34]) is a "Buffon Needle's"-type argument, where the crucial quantity to analyze is the noise sensitivity of the function, that is the probability that a randomly chosen pair of nearby points cross a "boundary" – i.e., have different values. (Moreover, the algorithm of [4] works in the *active testing* setting: it only requires a weaker access model that the standard query model).

We provide an alternate proof of a poly$(1/\varepsilon)$ bound (albeit with a worse exponent) that reveals a surprising connection with *distribution testing*, namely with the problem of estimating the support size of a distribution.

▶ **Theorem 5.** *There exists a two-sided non-adaptive tester for k-monotonicity of functions $f\colon [n] \to \{0,1\}$ with query complexity $q(n,\varepsilon,k) = \tilde{O}\big(1/\varepsilon^7\big)$,* independent of k.

An immediate implication of Theorem 5 is that one can test even $n^{1-\alpha}$-monotonicity of $f\colon [n] \to \{0,1\}$, for every $\alpha > 0$, with a constant number of queries. Hence, there is a separation between 1-sided and 2-sided testing, for $k = \omega(1)$.

Turning to the 2-dimensional grid, we show that 2-monotone functions can be tested with the minimum number of queries one could hope for:

▶ **Theorem 6.** *There exists a two-sided adaptive tester for 2-monotonicity of functions $f\colon [n]^2 \to \{0,1\}$ with query complexity $q(n,\varepsilon) = O\big(\frac{1}{\varepsilon}\big)$.*

We also discuss possible generalizations of Theorem 6 to general k or d in the full version.

1.1.2.2 Testing k-monotonicity on $[n]^d$, tolerant testing, and distance approximation

Moving to the general grid domain $[n]^d$, we show that k-monotonicity is testable with poly$(1/\varepsilon, k)$ queries in constant-dimension grids.

▶ **Theorem 7.** *There exists a non-adaptive tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon,k) = \min(\tilde{O}\Big(\frac{1}{\varepsilon^2}\left(\frac{5kd}{\varepsilon}\right)^d\Big), 2^{\tilde{O}\left(k\sqrt{d}/\varepsilon^2\right)})$.*

In fact, we obtain more general testing algorithms than in Theorem 7, namely our results hold for *tolerant* testers (as we define next).

The notion of tolerant testing was first introduced in [42] to account for the possibility of noisy data. In this notion, a test should accept inputs that are ε_1-close to the property, and reject inputs that are ε_2-far from the property, where ε_1 and ε_2 are given parameters. Tolerant testing is intimately connected to the notion of distance approximation: given tolerant testers for every $(\varepsilon_1, \varepsilon_2)$, there exists an algorithm that estimates the distance to the property within any (additive) ε, while incurring only a $\tilde{O}\big(\log\frac{1}{\varepsilon}\big)$ factor blow up in the number of queries. Furthermore, [42] shows that both tolerant testing and distance approximation are no harder than agnostic learning. We prove the following general result.

▶ **Theorem 8.** *There exist*

- *a non-adaptive (fully) tolerant tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon_1,\varepsilon_2,k) = \tilde{O}\left(\frac{1}{(\varepsilon_2-\varepsilon_1)^2}\left(\frac{5kd}{\varepsilon_2-\varepsilon_1}\right)^d\right)$;*
- *a non-adaptive tolerant tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon_1,\varepsilon_2,k) = 2^{\tilde{O}\left(k\sqrt{d}/(\varepsilon_2-3\varepsilon_1)^2\right)}$, under the restriction that $\varepsilon_2 > 3\varepsilon_1$.*

[1] We thank Eric Blais for mentioning the connection, and pointing us to these works.

To the best of our knowledge, the only previous results for tolerant testing for monotonicity on $[n]^d$ are due to Fattal and Ron [22]. They give both additive and multiplicative distance approximations algorithms, and obtain $O(d)$-multiplicative and ε-additive approximations with query complexity poly$(\frac{1}{\varepsilon})$. While very efficient, there results only give fully tolerant testers for dimensions $d = 1$ and $d = 2$. Our results generalize the work of [22] showing existence of tolerant testers for k-monotonicity (and hence for monotonicity) for any dimension $d \geq 1$, and any $k \geq 1$, but paying the price in the query complexity.

As a consequence to Theorem 8, we make progress on an open problem of Berman *et al.* [7], as explained next.

1.1.2.3 Testing k-monotonicity under L_p distance

The property of being a monotone Boolean function has a natural extension to real-valued functions. Indeed, a real-valued function defined over a finite domain D is monotone if $f(x) \leq f(y)$ whenever $x \preceq y$. For real-valued functions the more natural notion of distance is L_p distance, rather than Hamming distance. The study of monotonicity has been extended to real-valued functions in a recent work by Berman *et al.* [7]. They give tolerant testers for grids of dimension $d = 1$ and $d = 2$, and leave open the problem of extending the results to general d, as asked explicitly at the recent Sublinear Algorithms Workshop 2016 [47].

We make progress towards solving this open problem, by combining our Theorem 8 with a reduction from L_p testing to Hamming testing inspired by [7]. This reduction relates L_1-distance of a function $f\colon [n]^d \to [0,1]$ to monotonicity to *Hamming* distance to monotonicity of a "rounded" function $\tilde{f}\colon [n]^d \times [m] \to \{0,1\}$, essentially trading the range for an extra dimension (where m is a rounding parameter to be suitably chosen). Moreover, simulating query access to $\tilde{f}$ can be performed efficiently given query access to f.

▶ **Theorem 9.** *There exists a non-adaptive tolerant L_1-tester for monotonicity of functions $f\colon [n]^d \to [0,1]$ with query complexity*

- $\tilde{O}\left(\frac{1}{(\varepsilon_2-\varepsilon_1)^2}\left(\frac{5d}{\varepsilon_2-\varepsilon_1}\right)^d\right)$*, for any* $0 \leq \varepsilon_1 < \varepsilon_2 \leq 1$*;*
- $2^{\tilde{O}\left(\sqrt{d}/(\varepsilon_2-3\varepsilon_1)^2\right)}$*, for any* $0 \leq 3\varepsilon_1 < \varepsilon_2 \leq 1$*.*

1.2 Proofs overview and technical contribution

Structural properties and the separation between testing and learning on $\{0,1\}^d$

We first observe that basic structural properties, such as *extendability* (i.e. the feature that a function that is monotone on a sub-poset of $[n]^d$ can be extended into a monotone function on the entire poset domain), and properties of the *violation graph* (i.e., the graph whose edges encode the violations to monotonicity), extend easily to k-monotonicity (see the full version of the paper). These properties help us to argue the separation between testing and learning (Theorem 2). However, unlike the case of monotonicity testing, these properties do not seem to be enough for showing upper bounds that grow polynomially in d.

Grid coarsening and testing by implicit/explicit learning

One pervading technique, which underlies all the hypergrid upper bounds in this work, is that of *gridding*: i.e., partitioning the domain into "blocks" whose size no longer depends on the main parameter of the problem, n. This technique generalizes the approach of [22] who performed a similar gridding for dimension $d = 2$. By simulating query access to the "coarsened" version of the unknown function (with regard to these blocks), we are able to

leverage methods such as testing-by-learning (either fully or partially learning the function), or reduce our testing problem to a (related) question on these nicer "coarsenings." (The main challenge here lies in providing efficient and consistent oracle access to the said coarsenings.)

At a high-level, the key aspect of k-monotonicity which makes this general approach possible is reminiscent of the concept of *heredity* in property testing. Specifically, we rely upon the fact that "gridding preserves k-monotonicity:" if f *is* k-monotone, then so will be its coarsening g – but now g is much simpler to handle. This allows us to trade the domain $[n]^d$ for what is effectively $[m]^d$, with $m \ll n$. We point out that this differs from the usual paradigm of *dimension reduction*: indeed, the latter would reduce the study of a property of functions on $[n]^d$ to that of functions on $[n]^{d'}$ for $d' \ll d$ (usually even $d' = 1$) by projecting f on a lower-dimensional domain. In contrast, we do not take the dimension down, but instead reduce the size of the *alphabet*.Moreover, it is worth noting that this gridding technique is also orthogonal to that of *range reduction*, as used e.g. in [20]. Indeed, the latter is a reduction of the range of the function from $[R]$ to $\{0, 1\}$, while gridding is only concerned about the domain size.

Estimating the support of distributions

Our proof of the poly$(1/\varepsilon)$ upper bound for testing k-monotonicity on the line (Theorem 5) rests upon an unexpected connection to *distribution testing*, namely to the question of support size estimation of a probability distribution. In more detail, we describe how to reduce k-monotonicity testing to the support size estimation problem in (a slight modification of) the *Dual access model* introduced by Canonne and Rubinfeld [13], where the tester is granted samples from an unknown distribution as well as query access to its probability mass function.

For our reduction to go through, we first describe how any function $f\colon [n] \to \{0, 1\}$ determines a probability distribution D_f (on $[n]$), whose effective support size is directly related to the k-monotonicity of f. We then show how to implement dual access to this D_f from queries to f: in order to avoid any dependence on k and n in this step, we resort both to the gridding approach outlined above (allowing us to remove n from the picture) and to a careful argument to "cap" the values of D_f returned by our simulated oracle. Indeed, obtaining the exact value of $D_f(x)$ for arbitrary x may require $\Omega(k)$ queries to f, which we cannot afford; instead, we argue that only returning $D_f(x)$ whenever this value is "small enough" is sufficient. Finally, we show that implementing this "capped" dual access oracle is possible with no dependence on k whatsoever, and we can now invoke the support size estimation algorithm of [13] to conclude.

Fourier analysis on the hypergrid

We give an algorithm for fully tolerantly testing k-monotonicity whose query complexity in exponential in d. We also describe an alternate tester (with a slightly worse tolerance guarantee) whose query complexity is instead exponential in $\widetilde{O}(k\sqrt{d})$ for constant distance parameters. As mentioned above, we use our gridding approach combined with tools from learning theory. Specifically, we employ an agnostic learning algorithm of [30] using polynomial regression. Our coarsening methods allow us to treat the domain as if it were $[m]^d$ for some m that is independent of n. To prove that this agnostic learning algorithm will succeed, we turn to Fourier analysis over $[m]^d$. We extend the bound on average sensitivity of k-monotone functions over the Boolean hypercube from [9] to the hypergrid, and we show that this result implies that the Fourier coefficients are concentrated on "simple" functions.

1.3 Discussion and open problems

This is the first work to study k-monotonicity, a natural and well-motivated generalization of monotonicity. Hence this work opens up many intriguing questions in the area of property testing, with potential applications to learning theory, circuit complexity and cryptography.

As previously mentioned, the main open problem prompted by our work is the following:

Can k-monotonicity on the hypercube $\{0,1\}^d$ be tested with $\mathrm{poly}(d^k)$ queries?

A natural 1-sided tester for k-monotonicity is a *chain tester*: it queries points along a random chain, and rejects only if it finds a violation to k-monotonicity, in the form of a sequence $x_1 \preceq x_2 \preceq \ldots \preceq x_{k+1}$ in $\{0,1\}^d$, such that $f(x_1) = 1$ and $f(x_i) \neq f(x_{i+1})$. In particular, the testers in [25, 14, 19, 33] all directly imply a chain tester. We conjecture that there exists a chain tester for k-monotonicity that succeeds with probability $d^{-O(k)}$.

Another important open question concerns the hypergrid domain, and in particular it pushes for a significant strengthening of Theorem 7 and Theorem 9:

Can k-monotonicity on the hypergrid $[n]^d$ be (tolerantly) tested with $2^{o_k(\sqrt{d})}$ queries?

Answering this question would imply further progress on the L_1-testing question for monotonicity, left open in [7, 47].

There also remains the question of establishing two-sided lower bounds that would go beyond those of monotonicity. Specifically:

Is there an $d^{\Omega(k)}$-query two-sided *lower bound for k-monotonicity on the hypercube $\{0,1\}^d$?*

In this work we also show surprising connections to distribution testing (e.g. in the proof of Theorem 5), and to testing union of intervals and testing surface area. An intriguing direction is to generalize this connection to union of intervals and surface area in higher dimensions, to leverage or gain insight on k-monotonicity on the d-dimensional hypergrid.

Finally, while we only stated here a few directions, we emphasize that every question that is relevant to monotonicity is also relevant and interesting in the case of k-monotonicity.

1.4 Related work

As mentioned, k-monotonicity has deep connections with the notion of *negation complexity* of functions, which is the minimum number of negation gates needed in a circuit to compute a given function. The power of negation gates is intriguing and far from being understood in the context of circuit lower bounds. Quoting from Jukna's book [29], *the main difficulty in proving nontrivial lower bounds on the size of circuits using AND, OR, and NOT is the presence of NOT gates: we already know how to prove even exponential lower bounds for monotone functions if no NOT gates are allowed. The effect of such gates on circuit size remains to a large extent a mystery.*

This gap has motivated the study of circuits with *few* negations. Two notable works successfully extend lower bounds in the monotone setting to negation-limited setting: in [2], Amano and Maruoka show superpolynomial circuit lower bounds for $(1/6)\log\log n$ negations using the Clique function; and recently the breakthrough work of Rossman [45] establishes circuit lower bounds for NC^1 with roughly $\frac{1}{2}\log n$ negations by drawing upon his lower bound for monotone NC^1.

The divide between the understanding of monotone and non-monotone computation exists in general: while we usually have a fairly good understanding of the monotone case, many things get murky or fail to hold even when a single negation gate is allowed. In order to get a better grasp on negation-limited circuits, a body of recent work has been considering this model in various contexts: Blais *et al.* [9] study negation-limited circuits from a computational learning viewpoint, Guo *et al.* [27] study the possibility of implementing cryptographic primitives using few negations, and Lin and Zhang [35] are interested in verifying whether some classic Boolean function conjectures hold for the subset of functions computed by negation-limited circuits.

Many of these results implicitly or explicitly rely on a simple but powerful tool: the decomposition of negation-limited circuits into a composition of some "nice" function with monotone components. Doing so enables one to apply results on separate monotone components, and finally to carefully combine the outcomes (e.g., [26]). Though these techniques can yield results for as many as $O(\log n)$ negations, they also leave open surprisingly basic questions:

- [9] Can we have an efficient weak learning algorithm for functions computed by circuits with a *single* negation?
- [27] Can we obtain pseudorandom generators when allowing only a *single* negation?

In contexts where the circuit size is not the quantity of interest, the equivalent notion of 2-monotone functions is more natural than that of circuits allowing only one negation. Albeit seemingly simple, even the class of 2-monotone functions remains largely a mystery: as exemplified above, many basic yet non-trivial questions, ranging from the structure of their Fourier spectrum to their expressive power of k-monotone functions, remain open.

1.5 Organization of the paper

After recalling some notations and definitions in section 2, we consider the case of functions on the line in section 3, focusing on the proof of the two-sided upper bound of Theorem 3.

In section 4 we present our general algorithms for k-monotonicity on the hypergrid $[n]^d$, for arbitrary k and d. We prove Theorem 8 in two parts. We establish its first item (general tolerant testing algorithm with exponential dependence in d) in subsection 4.1 (Proposition 22). The second item (with query complexity exponential in $k\sqrt{d}$) is proven in subsection 4.2, where we analyze the Fourier-based tolerant tester of Proposition 31.

Our results on the Boolean hypercube, the two-dimensional grid, as well as some structural results and applications to tolerant L_1-testing of monotonicity have been left out of this short version, and are deferred to the full version of the paper [12].

2 Preliminaries

We denote by log the binary logarithm, and use $\tilde{O}(\cdot)$ to hide polylogarithmic factors in the argument (so that $\tilde{O}(f) = O(f \log^c f)$ for some $c \geq 0$).

Given two functions $f, g\colon \mathcal{X} \to \mathcal{Y}$ on a finite domain $\mathcal{X}$, we write $\mathrm{dist}(f,g)$ for the (normalized) Hamming distance between them, i.e.

$$\mathrm{dist}(f,g) = \frac{1}{|\mathcal{X}|}\sum_{x\in\mathcal{X}} \mathbb{1}_{\{f(x)\neq g(x)\}} = \Pr_{x\sim\mathcal{X}}[\,f(x)\neq g(x)\,]$$

where $x \sim \mathcal{X}$ refers to x being drawn from the uniform distribution on $\mathcal{X}$. A *property* of functions from $\mathcal{X}$ to $\mathcal{Y}$ is a subset $\mathcal{P} \subseteq \mathcal{X}^{\mathcal{Y}}$ of these functions; we define the distance of a function f to $\mathcal{P}$ as the minimum distance of f to any $g \in \mathcal{P}$:

$$\mathrm{dist}(f,\mathcal{P}) = \inf_{g\in\mathcal{P}} \mathrm{dist}(f,g)\,.$$

For some of our applications, we will also use another notion of distance specific to real-valued functions, the L_1 distance (as introduced in the context of property testing in [7]). For $f, g\colon \mathcal{X} \to [0,1]$, we write

$$L_1(f,g) = \frac{1}{|\mathcal{X}|}\sum_{x\in\mathcal{X}} |f(x)-g(x)| = \mathbb{E}_{x\sim\mathcal{X}}[|f(x)-g(x)|] \in [0,1]$$

and extend the definition to $L_1(f,\mathcal{P})$, for $\mathcal{P} \subseteq \mathcal{X}^{[0,1]}$, as before.

Property testing

We recall the standard definition of testing algorithms, as well as some terminology:

▶ **Definition 10.** Let $\mathcal{P}$ be a property of functions from $\mathcal{X}$ to $\mathcal{Y}$. A *q-query testing algorithm for $\mathcal{P}$* is a randomized algorithm $\mathcal{T}$ which takes as input $\varepsilon \in (0,1]$ as well as query access to a function $f\colon \mathcal{X} \to \mathcal{Y}$. After making at most $q(\varepsilon)$ queries to the function, $\mathcal{T}$ either outputs ACCEPT or REJECT, such that the following holds:

- if $f \in \mathcal{P}$, then $\mathcal{T}$ outputs ACCEPT with probability at least 2/3; (Completeness)
- if $\mathrm{dist}(f,\mathcal{P}) \geq \varepsilon$, then $\mathcal{T}$ outputs REJECT with probability at least 2/3; (Soundness)

where the probability is taken over the algorithm's randomness. If the algorithm only errs in the second case but accepts any function $f \in \mathcal{P}$ with probability 1, it is said to be a *one-sided* tester; otherwise, it is said to be *two-sided*. Moreover, if the queries made to the function can only depend on the internal randomness of the algorithm, but not on the values obtained during previous queries, it is said to be *non-adaptive*; otherwise, it is *adaptive*.

Additionally, we will also be interested in *tolerant* testers – roughly, algorithms robust to a relaxation of the first item above:

▶ **Definition 11.** Let $\mathcal{P}$, $\mathcal{X}$, and $\mathcal{Y}$ be as above. A *q-query tolerant testing algorithm for $\mathcal{P}$* is a randomized algorithm $\mathcal{T}$ which takes as input $0 \leq \varepsilon_1 < \varepsilon_2 \leq 1$, as well as query access to a function $f\colon \mathcal{X} \to \mathcal{Y}$. After making at most $q(\varepsilon_1,\varepsilon_2)$ calls to the oracle, $\mathcal{T}$ outputs either ACCEPT or REJECT, such that the following holds:

- if $\mathrm{dist}(f,\mathcal{P}) \leq \varepsilon_1$, then $\mathcal{T}$ outputs ACCEPT with probability at least 2/3; (Completeness)
- if $\mathrm{dist}(f,\mathcal{P}) \geq \varepsilon_2$, then $\mathcal{T}$ outputs REJECT with probability at least 2/3; (Soundness)

where the probability is taken over the algorithm's randomness. The notions of one-sidedness and adaptivity of Theorem 10 extend to tolerant testing algorithms as well.

Note that as stated, in both cases the algorithm "knows" $\mathcal{X}, \mathcal{Y}$, and $\mathcal{P}$; so that the query complexity q can be parameterized by these quantities. More specifically, when considering $\mathcal{X} = [n]^d$ and the property $\mathcal{P}$ of k-monotonicity, we will allow q to depend on n, d, and k. Finally, we shall sometimes require a probability of success $1-\delta$ instead of the (arbitrary) constant 2/3; by standard techniques, this can be obtained at the cost of a multiplicative $O(\log(1/\delta))$ in the query complexity.

PAC and agnostic learning [48]

A learning algorithm $\mathcal{A}$ for a *concept class* $\mathcal{C}$ of functions $f\colon \mathcal{X} \to \mathcal{Y}$ (under the uniform distribution) is given parameters $\varepsilon, \delta > 0$ and sample access to some target function $f \in \mathcal{C}$ *via* labeled samples $\langle x, f(x)\rangle$, where x is drawn uniformly at random from $\mathcal{X}$. The algorithm should output a hypothesis $h\colon \mathcal{X} \to \mathcal{Y}$ such that $\operatorname{dist}(h, f) \leq \varepsilon$ with probability at least $1-\delta$. The algorithm is *efficient* if it runs in time $\operatorname{poly}(n, 1/\varepsilon, 1/\delta)$. If $\mathcal{A}$ must output $h \in \mathcal{C}$ we say it is a *proper learning algorithm*, otherwise, we say it is an *improper learning* one.

Moreover, if $\mathcal{A}$ still succeeds when f does not actually belong to $\mathcal{C}$, we say it is an *agnostic learning algorithm*. Specifically, the hypothesis function h that it outputs must satisfy $\operatorname{dist}(f, g) \leq \textsc{opt}_f + \varepsilon$ with probability at least $1-\delta$, where $\textsc{opt}_f = \min_{g\in\mathcal{C}} \operatorname{dist}(f, g)$.

3 On the line

In this section we focus on testing k-monotonicity on the line, that is of functions $f\colon [n] \to \{0,1\}$. Our results include Theorem 4, which establishes that this can be done non-adaptively with one-sided error, with only $O(k/\varepsilon)$ queries; complemented by Theorem 3, which shows that this is the best one can hope for if we insist on one-sidedness. Due to space constraints, we only prove here Theorem 5 (restated below), which shows that – perhaps unexpectedly – *two-sided* algorithms, even non-adaptive, can break this barrier and test k-mononicity with *no* dependence on k. The proofs of Theorem 4 and Theorem 3 can be found in the full version.

▶ **Theorem 5.** *There exists a two-sided non-adaptive tester for k-monotonicity of functions $f\colon [n] \to \{0,1\}$ with query complexity $q(n, \varepsilon, k) = \tilde{O}\big(1/\varepsilon^7\big)$, independent of k.*

In what follows, we assume that $k > 20/\varepsilon$, as otherwise we can use for instance the $O(k/\varepsilon)$-query (non-adaptive, one-sided) tester of Theorem 4 to obtain an $O\big(1/\varepsilon^2\big)$ query complexity.

3.1 Testing k-monotonicity over $[Ck]$

In this section, we give a $\operatorname{poly}(C/\varepsilon)$-query tester for k-monotonicity over the domain $[Ck]$, where C is a parameter to be chosen (for our applications, we will eventually set $C = \operatorname{poly}(1/\varepsilon)$).

▶ **Lemma 12.** *There exists a two-sided non-adaptive tester for k-monotonicity of functions $f\colon [Ck] \to \{0,1\}$ with query complexity $O\Big(\frac{C^3}{\varepsilon^3}\Big)$.*

The tester proceeds by reducing to support size estimation and using (a slight variant of) an algorithm of Canonne and Rubinfeld [13]. Let $f\colon [Ck] \to \{0,1\}$, and suppose f is s-monotone but not $(s-1)$-monotone. Then there is a unique partition of $[Ck]$ into $s+1$ disjoint intervals $I_1, I_2, \ldots, I_{s+1}$ such that f is constant on each interval; note that this constant value alternates in consecutive intervals. We can then define a distribution D_f over $[s+1]$ such that $D_f(i) = |I_i|/(Ck)$.

Our next claims, Claim 13 and Claim 14, provide the basis for the reduction (from testing k-monotonicity of f to support size estimation of D_f).

▶ **Claim 13.** *If f is ε-far from k-monotone, then it is not $(1+\frac{\varepsilon}{4})k$-monotone, and in particular $|\operatorname{supp}(D_f)| > (1+\frac{\varepsilon}{4})k + 1$.*

▶ **Claim 14.** *To ε-test k-monotonicity of f, it suffices to estimate $|\operatorname{supp}(D_f)|$ to within $\frac{\varepsilon k}{10}$.*

The proofs of above claims are relatively straightforward. So we defer these proofs to the end of this section and now proceed to use algorithm of [13] to do support size estimation. The algorithm of [13] uses "dual access" to D; an oracle that provides a random sample from D, and an oracle that given an element of D, returns the probability mass assigned to this element by D.

▶ **Theorem 15** ([13, Theorem 14 (rephrased)]). *In the access model described above, there exists an algorithm that, on input a threshold $n \in \mathbb{N}^*$ and a parameter $\varepsilon > 0$, and given access to a distribution D (over an arbitrary set) satisfying $\min_{x \in \mathrm{supp}(D)} D(x) \geq \frac{1}{n}$ estimates the support size $|\mathrm{supp}(D)|$ up to an additive εn, with query complexity $O\left(\frac{1}{\varepsilon^2}\right)$.*

Note however that we only have access to D_f through query access to f, and thus have to manage to simulate (efficiently) access to the former. One difficulty is that, to access $D_f(i)$, we need to determine where I_i lies in f. For example, finding $D_f(k/2)$ requires finding $I_{k/2}$, which might require a large number of queries to f. We circumvent this by weakening the "dual access" model in two ways, arguing for each of these two relaxations that the algorithm of [13] can still be applied:

- we rewrite the support size as in [13], as $|\mathrm{supp}(D_f)| = \mathbb{E}_{x \sim D_f}[1/D_f(x)]$. We want to estimate it to within $\pm O(\varepsilon k)$ which we can do by random sampling;
- the quantity inside the expectation depends on $D_f(x)$ but not x itself, so "labels" are unnecessary for our random sampling. Thus, it will be sufficient to be able to compute $D_f(x)$ (and thus $1/D_f(x)$) for a random $x \sim D_f$, even if not actually knowing x itself;
- actually, even calculating $D_f(x)$ may possibly too expensive, so instead we will estimate $\mathbb{E}_{x \sim D_f}[1/\tilde{D}_f(x)]$ where $\tilde{D}_f(x) = \min(\frac{20}{\varepsilon k}, D_f(x))$. Note that $\tilde{D}_f$ might no longer define a probability distribution; but this expectation is only off by at most $\frac{\varepsilon k}{20}$, since $1/D'_f(x) = \max(\varepsilon k/20, 1/D_f(x))$ and $1/D_f(x)$ is positive.

More details follow.

First, we note as discussed above that the algorithm does not require knowing the "label" of any element in the support of the distribution: the only access required is being able to randomly sample elements according to D_f, and evaluate the probability mass on the sampled points. This, in turn, can be done, as the following two lemmas explain:

▶ **Lemma 16** (Sampling from D_f). *Let $i \in [n]$ be chosen uniformly at random, and let j be such that $i \in I_j$. Then, the distribution of j is exactly D_f.*

▶ **Lemma 17** (Evaluating $D_f(j)$). *Suppose $I_j = \{a, a+1, \ldots, b\}$. Given i such that $i \in I_j$, we can find I_j by querying $f(i+1) = f(i+2) = \cdots = f(b)$ and $f(b+1) \neq f(b)$, as well as $f(i-1) = f(i-2) = \ldots = f(a)$ and $f(a-1) \neq f(a)$. The number of queries to f is $b - a + 3 = |I_j| + 3$.*

Here comes the second difficulty: if we straightforwardly use these approaches to emulate the required oracles to estimate the support size of D_f, the number of queries is potentially very large. For instance, if we attempt to query $D_f(j)$ where $|I_j| = \Omega(k)$, we will need $\Omega(k)$ queries to f. This is where comes the second relaxation: specifically, we shall argue that it will be enough for us to "cap" the size of the interval (as per our next lemma).

▶ **Lemma 18** (Evaluating $D_f(j)$ with a cap). *Given i such that $i \in I_j$, we will query f on every point in $[i - 20C/\varepsilon, i + 20C/\varepsilon]$. If $|I_j| \leq 20C/\varepsilon$, then I_j will be determined by these queries. If these queries do not determine I_j, we know $|I_j| > 20C/\varepsilon$. Beyond querying i, this requires $40C/\varepsilon$ (nonadaptive) queries.*

We now can put all the above pieces together and give the proof for Lemma 12:

Proof of Theorem 12: As previously discussed, we use the algorithm of [13] for estimating support size. Inspecting their algorithm, we see that our cap of $20C/\varepsilon$ for interval length (and therefore $20/(\varepsilon k)$ for maximum probability reported) might result in further error of the estimate. The algorithm interacts with the unknown function by estimating the expected value of $1/D_f(j)$ over random choices of j with respect to D_f. Our cap can only decrease this expectation by at most $(\varepsilon k)/20$. Indeed, the algorithm works by estimating the quantity $\mathbb{E}_{x\sim D_f}[\frac{1}{D_f(x)}\mathbb{1}_{\{D_f(x)>\tau\}}]$, for some suitable parameter $\tau > 0$. By capping the value of $1/D_f(x)$ to $20/(\varepsilon k)$, we can therefore only decrease the estimate, and by at most $20/(\varepsilon k) \cdot D_f(\{\ x :\ D_f(x) > (\varepsilon k)/20\ \}) \le 20/(\varepsilon k)$.

The condition for their algorithm to estimate support size to within $\pm\varepsilon m$ is that all elements in the support have a probability mass of at least $1/m$. Since each nonempty interval has length at least 1, we have $\min_j D_f(j) \ge (1/Ck)$. In order for their algorithm to report an estimate within $\pm\varepsilon k/20$ of support size, we set $\varepsilon' = (\varepsilon/20C)$ in their algorithm.

The total error in support size is at most $\varepsilon k/20 + \varepsilon k/20 = \varepsilon k/10$. By Claim 14, this suffices to test ε-test k-monotonicity of f.

Using the algorithm of [13], we need $O(1/{\varepsilon'}^2) = O\big((C/\varepsilon)^2\big)$ queries to D_f. For every query to D_f, we need to make $O(C/\varepsilon)$ queries to f, so the overall query complexity is $O\big(C^3/\varepsilon^3\big)$. ◀

Proof of Claim 13. The last part of the statement is immediate from the first, so it suffices to prove the first implication. We show the contrapositive: assuming f is $(1+\frac{\varepsilon}{4})k$-monotone, we will "fix" it into a k-monotone function by changing at most εn points. In what follows, we assume $\frac{\varepsilon k}{4} \ge 1$, as otherwise the statement is trivial (any function that is ε-far from k-monotone is *a fortiori* not k-monotone).

Let as before ℓ^* be the minimum integer ℓ for which f is ℓ-monotone: we can assume $k < \ell^* \le (1+\frac{\varepsilon}{4})k$ (as if $\ell^* \le k$ we are done.) Consider as above the maximal consecutive monochromatic intervals $I_1, \ldots, I_{\ell^*}$, and let i be the index of the shortest one. In particular, it must be the case that $|I_i| \le \frac{n}{\ell^*+1}$. Flipping the value of f on I_i therefore has "cost" at most $\frac{n}{\ell^*+1}$, and the resulting function f' is now exactly (ℓ^*-2)-monotone if $1 < i < \ell^*$, and (ℓ^*-1)-monotone if $i \in \{1, \ell^*\}$. This means in particular that repeating the above $\frac{\varepsilon}{4}k$ times is enough to obtain a k-monotone function, and the total cost is upperbounded by

$$\sum_{j=0}^{\varepsilon k/4} \frac{n}{\ell^*+1-2j} \le \sum_{j=0}^{\varepsilon k/4} \frac{n}{k+1-2j} = \sum_{j=k(1-\frac{\varepsilon}{2})+1}^{k+1} \frac{n}{j} \le n\frac{\frac{\varepsilon}{2}k+1}{(1-\frac{\varepsilon}{4})k+1} \le n\frac{\frac{3\varepsilon}{4}k}{(1-\frac{\varepsilon}{4})k}$$

where for the last inequality (for the numerator) we used that $1 \le \frac{\varepsilon k}{4}$. But this last RHS is upperbounded by εn (as $\frac{3}{4}x \le x(1-\frac{1}{4}x)$ for $x \in [0,1]$), showing that therefore, f was ε-close to k-monotone to begin with, which is a contradiction. ◀

Proof of Claim 14. If f is ε-far from k-monotone, then $|\mathrm{supp}(D_f)| > (1+\frac{\varepsilon}{4})k = k + \frac{\varepsilon}{4}k$, and if f is k-monotone, then $|\mathrm{supp}(D_f)| \le k+1$. The fact that $k > 20/\varepsilon$ then allows us to conclude. ◀

3.2 Reducing $[n] \to \{0,1\}$ to $[Ck] \to \{0,1\}$.

Now we show how to reduce ε-testing k-monotonicity of $f\colon [n] \to \{0,1\}$ to ε'-testing k-monotonicity of a function $g\colon [Ck] \to \{0,1\}$ for $C = \mathrm{poly}(1/\varepsilon)$ and $\varepsilon' = \mathrm{poly}(\varepsilon)$, resulting in a $\mathrm{poly}(1/\varepsilon)$-query algorithm for ε-testing k-monotonicity.

The first step is (as before) to divide $[n]$ into blocks (disjoint intervals) of size $\frac{\varepsilon n}{4k}$ if $\varepsilon > \frac{8k}{n}$ (again assuming without loss of generality that $\frac{\varepsilon n}{4k}$ is an integer), and blocks of size 1 otherwise (in which case $n \leq \frac{8k}{\varepsilon}$ and we can directly apply the result of Theorem 12, with $C = n/k \leq 8/\varepsilon$). Let $m = 4k/\varepsilon$ be the number of resulting blocks, and define $f_m \colon [n] \to \{0,1\}$ as the *m-block-coarsening* of f: namely, for any $j \in B_i$, we set

$$f_m(j) = \text{argmax}_{b \in \{0,1\}} \Pr_{k \in B_i} [f_m(k) = b] \qquad \text{(majority vote)}$$

Ordering the blocks $B_1, B_2, \ldots, B_m$, we also define $g \colon [m] \to \{0,1\}$ such that $g(i) = \min_{a \in B_i} f_m(a)$.

It is easy to see that if f is k-monotone, then f has at most k non-constant blocks, and f_m is k-monotone. Because the function f only changes values k times; for a block to be non-constant, the block must contain a pair of points with a value change. We call a block *variable* if the minority points comprise at least an $\varepsilon/100$-fraction of the block; formally, B is variable if $\min_{b \in \{0,1\}} \Pr_{j \in B}[f(j) = b] \geq \varepsilon/100$.

We need following claims (their proofs are at the end of the section) to prove Theorem 5.

▶ **Claim 19.** *Suppose f has s variable blocks. Then* $\text{dist}(f, f_m) \leq s/m + \varepsilon/100$.

▶ **Claim 20.** *Suppose f is promised to be either (i) k-monotone or (ii) such that f_m has more than $\frac{5}{4}k$ variable blocks. Then we can determine which with $O\big(\frac{1}{\varepsilon^2} \log \frac{1}{\varepsilon}\big)$ queries, and probability* 9/10.

Proof of Theorem 5. We use the estimation/test from the previous claim as the first part of our tester. Assuming f passes, we can assume that f_m has less than $\frac{5}{4}k$ variable blocks. By Claim 19, $\text{dist}(f, f_m) \leq \frac{5k}{4}/m + \frac{\varepsilon}{100} = \frac{5\varepsilon}{32} + \frac{\varepsilon}{100} \leq \frac{\varepsilon}{3}$. This part takes $O\big(\frac{1}{\varepsilon^2} \log \frac{1}{\varepsilon}\big)$ queries.

Now, we apply the tester of Theorem 12 (with probability of success amplified to 9/10 by standard arguments) to $(\varepsilon/6)$-test k-monotonicity of $g \colon [m] \to \{0,1\}$, where $g(i)$ is the constant value of f_m on B_i, and $m = (4k)/\varepsilon$. Let q be the query complexity of the tester, and set $\delta = 1/(10q)$; to query $g(i)$, we randomly query f on $O\big(\frac{1}{\varepsilon} \log \frac{1}{\delta}\big)$ points in B_i and take the majority vote. With probability at least $1 - \delta$, we get the correct value of $g(i)$, and by a union bound all q simulated queries have the correct value with probability at least 9/10.

Therefore, to get a single query to g, we use $O((\log q)/\varepsilon)$ queries. In the context of our previous section, we have $C = 4/\varepsilon$, so $q = O(C^3/\varepsilon^3) = O\big(1/\varepsilon^6\big)$ and the overall query complexity of this part is $O((q \log q)/\varepsilon) = O\big(\frac{1}{\varepsilon^7} \log \frac{1}{\varepsilon}\big)$. This dominates the query complexity of the other part of the tester, from Claim 20, which is $O\big(\frac{1}{\varepsilon^2} \log \frac{1}{\varepsilon}\big)$. By a union bound over the part from Claim 20, the simulation of g, and the call to the tester of Theorem 12, the algorithm is correct with probability at least $1 - 3/10 > 2/3$. ◀

Proof of Claim 19. We will estimate the error of f_m in computing f on variable blocks and non-variable blocks separately. Each non-variable block B can contribute error on at most $\varepsilon |B| /100$ points. Each variable block B can contribute error on at most $|B| = n/m$ points. The total number of errors is at most $\varepsilon n/100 + s(n/m) = n(\varepsilon/100 + s/m)$, yielding the upper bound on $\text{dist}(f, f_m)$. ◀

Proof of Claim 20. We first note that given any fixed block B, it is easy to detect whether it is variable (with probability of failure at most δ) by making $O\big(\frac{1}{\varepsilon} \log \frac{1}{\delta}\big)$ uniformly distributed queries in B. Doing so, a variable block will be labelled as such with probability at least $1 - \delta$, while a constant block will never be marked as variable. (If a block is neither constant nor variable, then any answer will do.)

Letting s denote the number of variable blocks, we then want to non-adaptively distinguish between $s \geq \frac{5}{4}k = \frac{5\varepsilon}{16}m$ and $s \leq k = \frac{\varepsilon}{4}m$ (since if f were k-monotone, then f_m had at most k variable blocks). Doing so with probability at least 19/20 can be done by checking only $q = O\left(\frac{1}{\varepsilon}\right)$ blocks chosen uniformly at random: by the above, setting $\delta = \frac{1}{20q}$ all of the q checks will also yield the correct answer with probability no less than 9/10, so by a union bound we will distinguish (i) and (ii) with probability at least 9/10. We conclude by observing that all $O\left(q \cdot \frac{1}{\varepsilon}\log\frac{1}{q}\right) = O\left(\frac{1}{\varepsilon^2}\log\frac{1}{\varepsilon}\right)$ queries are indeed non-adaptive. ◀

4 On the high-dimensional grid

In this section, we give two algorithms for tolerant testing, that is testing whether a function $f\colon [n]^d \to \{0,1\}$ is ε_1-close to k-monotone vs. ε_2-far from k-monotone, establishing Theorem 8. The first has query complexity exponential in the dimension d and is *fully tolerant*, that is works for any setting of $0 \leq \varepsilon_1 < \varepsilon_2 \leq 1$. The second applies whenever $\varepsilon_2 > 3\varepsilon_1$, and has (incomparable) query complexity exponential in $\tilde{O}(k\sqrt{d}/(\varepsilon_2 - 3\varepsilon_1)^2)$. Both of these algorithms can be used for non-tolerant ("regular") testing by setting $\varepsilon_1 = 0$ and $\varepsilon_2 = \varepsilon$, which implies Theorem 7.

▶ **Theorem 8.** *There exist*

- *a non-adaptive (fully) tolerant tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon_1,\varepsilon_2,k) = \tilde{O}\left(\frac{1}{(\varepsilon_2-\varepsilon_1)^2}\left(\frac{5kd}{\varepsilon_2-\varepsilon_1}\right)^d\right)$;*
- *a non-adaptive tolerant tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon_1,\varepsilon_2,k) = 2^{\tilde{O}\left(k\sqrt{d}/(\varepsilon_2-3\varepsilon_1)^2\right)}$, under the restriction that $\varepsilon_2 > 3\varepsilon_1$.*

As a corollary, this implies Theorem 7, restated below:

▶ **Theorem 7.** *There exists a non-adaptive tester for k-monotonicity of functions $f\colon [n]^d \to \{0,1\}$ with query complexity $q(n,d,\varepsilon,k) = \min(\tilde{O}\left(\frac{1}{\varepsilon^2}\left(\frac{5kd}{\varepsilon}\right)^d\right), 2^{\tilde{O}\left(k\sqrt{d}/\varepsilon^2\right)})$.*

For convenience, we will view in this part of the paper the set $[n]$ as $[n] = \{0,1,\ldots,n-1\}$. Assuming that m divides n, we let $\mathcal{B}_{m,n}\colon [n]^d \to [m]^d$ be the mapping such that $\mathcal{B}_{m,n}(y)_i = \lfloor y_i/m \rfloor$ for $1 \leq i \leq m$. For $x \in [m]^d$, we define the set $\mathcal{B}^{-1}_{m,n}(x)$ to be the inverse image of x. Specifically, $\mathcal{B}^{-1}_{m,n}(x)$ is the set of points of the form $m \cdot x + [n/m]^d$, with standard definitions for scalar multiplication and coordinate-wise addition. That is, $\mathcal{B}^{-1}_{m,n}(x)$ is a "coset" of $[n/m]^d$ points in $[n]^d$. To keep on with the notations of the other sections, we will call these cosets *blocks*, and will say a function $h\colon [n]^d \to \{0,1\}$ is an *m-block function* if it is constant on each block. Moreover, for clarity of presentation, we will omit the subscripts on $\mathcal{B}$ and $\mathcal{B}^{-1}$ whenever they are not necessary.

We first establish a lemma that will be useful for the proofs of correctness of both algorithms.

▶ **Lemma 21.** *Suppose $f\colon [n]^d \to \{0,1\}$ is k-monotone. Then there is an m-block function $h\colon [n]^d \to \{0,1\}$ such that $\mathrm{dist}(f,h) < kd/m$.*

Proof. Fix any k-monotone function $f\colon [n]^d \to \{0,1\}$. We partition $[m]^d$ into chains of the form

$$C_x = \left\{ x + \ell \cdot 1^d \,:\, \ell \in \mathbb{N}, x \in [m]^d \text{ and } x_i = 0 \text{ for some } i \right\}.$$

There are $m^d - (m-1)^d \leq dm^{d-1}$ of these chains: we will show that f can only be nonconstant on at most k blocks of each chain.

Algorithm 1 Fully tolerant testing with $O(kd/(\varepsilon_2-\varepsilon_1)))^d$ queries.

Require: Query access to $f\colon [n]^d \to \{0,1\}$, $\varepsilon_2 > \varepsilon_1 \geq 0$, a positive integer k

$\alpha \leftarrow (\varepsilon_2 - \varepsilon_1), m \leftarrow \lceil 5kd/\alpha \rceil, t \leftarrow \lceil 25\ln(6m^d)/(2\alpha^2) \rceil$

▷ Define a distribution D over $[m]^d \times \{0,1\}$.

for $x \in [m]^d$ **do**

  Query f on t random points $T_x \subseteq \mathcal{B}^{-1}(x)$.

  $D(x,0) \leftarrow \Pr_{y\in T_x}[\,f(y)=0\,]/m^d$

  $D(x,1) \leftarrow \Pr_{y\in T_x}[\,f(y)=1\,]/m^d$

end for

▷ Define a distribution D' over $[n]^d \times \{0,1\}$ such that $D'(y,b) = D(\mathcal{B}(y),b)\cdot m^d/n^d$.

if there exists a k-monotone m-block function h such that $\Pr_{(y,b)\sim D'}[\,h(y)\neq b\,] \leq \varepsilon_1 + \frac{\alpha}{2}$ **then return** ACCEPT

end if

return REJECT

By contradiction, suppose there exists $x \in [m]^d$ such that f is nonconstant on $k+1$ different blocks $\mathcal{B}^{-1}(z^{(i)})$, where $z^{(1)} \prec z^{(2)} \prec \ldots \prec z^{(k)} \prec z^{(k+1)}$, and each $z^{(i)} \in C_x$. By construction, we have $\mathcal{B}^{-1}(z^{(i)}) \prec \mathcal{B}^{-1}(z^{(j)})$ for $i<j$. For each $1 \leq i \leq k+1$, there are two points $v_*^{(i)}, v_{**}^{(i)} \in \mathcal{B}^{-1}(z_i)$ such that $v_*^{(i)} \prec v_{**}^{(i)}$ and $f(v_*^{(i)}) \neq f(v_{**}^{(i)})$. By construction $v_*^{(1)} \prec v_{**}^{(1)} \prec v_*^{(2)} \prec v_{**}^{(2)} \prec v_*^{(3)} \prec v_{**}^{(3)} \prec \ldots \prec v_*^{(k+1)} \prec v_{**}^{(k+1)}$, and there must be at least $k+1$ pairs of consecutive points with differing function values. Out of these $2k+2$ many points, there is a chain of points $\bar{v}^{(1)} \prec \bar{v}^{(2)} \prec \ldots \prec \bar{v}^{(k+1)}$ where $f(\bar{v}^{(i)}) \neq f(\bar{v}^{(i+1)})$ for $1 \leq i \leq k$, which is a violation of the k-monotonicity of f.

Thus, in each of the dm^{d-1} many chains of blocks, there can only be k nonconstant blocks. It follows that there are at most kdm^{d-1} nonconstant blocks in total. We now define $h(y)$ to be equal to $f(y)$ if f is constant on $\mathcal{B}(y)$, and arbitrarily set $h(y)=0$ otherwise. Each set $\mathcal{B}^{-1}(y)$ contains $(n/m)^d = n^d \cdot m^{-d}$ many points, and f is not constant on at most kdm^{d-1} of these. It follows that $\mathrm{dist}(f,h) \leq kdm^{d-1}\cdot m^{-d} = kd/m$. ◀

4.1 Fully tolerant testing with $O(kd/(\varepsilon_2-\varepsilon_1)))^d$ queries

Our first algorithm (Algorithm 1) then proceeds by essentially brute-force learning an m-block function close to the unknown function, and establishes the first item of Theorem 8.

▶ **Proposition 22.** *Algorithm 1 accepts all functions ε_1-close to k-monotone functions, and rejects all functions ε_2-far from k-monotone (with probability at least $2/3$). Its query complexity is $O\left(\frac{d}{(\varepsilon_2-\varepsilon_1)^2}\left(\frac{5kd}{\varepsilon_2-\varepsilon_1}+1\right)^d \log\frac{kd}{\varepsilon_2-\varepsilon_1}\right)$.*

Proof. The algorithm first estimates $\Pr_{y\in\mathcal{B}^{-1}(x)}[\,f(y)=b\,]$ for every $x \in [m]^d$ and $b \in \{0,1\}$ to within $\pm\frac{\alpha}{5}$. We use $t = 25\ln(6m^d)/2\alpha^2$ points in each block to ensure (by an additive Chernoff bound) that each estimate is correct except with probability at most $m^{-d}/3$. By a union bound, the probability that all estimates are correct is at least $2/3$, and we hereafter condition on this. By construction, $\mathbb{E}_{(x,b)\sim D}[\Pr_{y\in\mathcal{B}^{-1}(x)}[\,f(y)\neq b\,]] = \Pr_{(y,b)\sim D'}[\,f(y)\neq b\,] \leq \frac{\alpha}{5}$. In this probability experiment, the marginal distribution of D' on y is uniform over $[n]^d$.

Let $f^*\colon [n]^d \to \{0,1\}$ be a k-monotone function minimizing $\Pr[\,f(y)\neq f^*(y)\,]$. Theorem 21 ensures that there is a k-monotone m-block function $h\colon [n]^d \to \{0,1\}$ such that $\mathrm{dist}(f^*,h) < kd/m \leq \alpha/5$. Let $h^*\colon [n]^d \to \{0,1\}$ be a k-monotone m-block function minimizing $\mathrm{dist}(f^*,h^*)$.

Completeness

Suppose $\mathrm{dist}(f, f^*) \le \varepsilon_1$. Then by the triangle inequality,

$$\begin{aligned}\Pr_{(y,b)\sim D'}[\,h^*(y) \neq b\,] &\le \Pr_{(y,b)\sim D'}[\,h^*(y) \neq f^*(y)\,] + \Pr_{(y,b)\sim D'}[\,f^*(y) \neq f(y)\,] \\ &\quad + \Pr_{(y,b)\sim D'}[\,f(y) \neq b\,] \\ &\le \varepsilon_1 + \frac{2\alpha}{5}.\end{aligned}$$

where to bound the first term $\Pr_{(y,b)\sim D'}[\,h^*(y) \neq f^*(y)\,]$ by $\mathrm{dist}(f^*, h^*) \le \alpha/5$ we used the fact that the marginal distribution of y is uniform when $(y, b) \sim D'$. Thus, the algorithm will find a k-monotone m-block function close to D (without using any queries to f) and accept.

Soundness

Suppose $\mathrm{dist}(f, f^*) \ge \varepsilon_2$. Then by the triangle inequality

$$\begin{aligned}\Pr_{(y,b)\sim D'}[h(y) \neq b] &\ge \Pr_{(y,b)\sim D'}[h(y) \neq f(y)] - \Pr_{(y,b)\sim D'}[f(y) \neq b] \\ &\ge \Pr_{(y,b)\sim D'}[f^*(y) \neq f(y)] - \Pr_{(y,b)\sim D'}[f(y) \neq b] \\ &\ge \varepsilon_2 - \frac{\alpha}{5}\end{aligned}$$

for every k-monotone m-block function h. Since $\varepsilon_2 - 2\alpha/5 \ge \varepsilon_1 + 3\alpha/5$, the algorithm never find a k-monotone m-block function h with low error with respect to D, and the algorithm will reject.

Query complexity

The algorithm only makes queries in constructing D; the number of queries required is $m^d \cdot t = O\Big(\frac{d}{\alpha^2}\left(\frac{5kd}{\alpha} + 1\right)^d \log\frac{kd}{\alpha}\Big)$. ◀

4.2 Tolerant testing *via* agnostic learning

We now present our second algorithm, Algorithm 2, proving the second item of Theorem 8. At its core is the use of an *agnostic learning algorithm* for k-monotone functions, which we first describe.[2]

▶ **Proposition 23.** *There exists an agnostic learning algorithm for k-monotone functions over $[r]^d \to \{0,1\}$ with excess error τ with sample complexity* $\exp(\widetilde{O}(k\sqrt{d}/\tau^2))$.

We will rely on tools from Fourier analysis to prove Proposition 23. For this reason, it will be convenient in this section to view the range as $\{-1, 1\}$ instead of $\{0, 1\}$.

[2] Recall that an *agnostic learner with excess error τ* for some class of functions $\mathcal{C}$ is an algorithm that, given an unknown distribution D, an unknown arbitrary function f, and access to random labelled samples $\langle x, f(x)\rangle$ where $x \sim D$, satisfies the following. It outputs a hypothesis function $\hat{h}$ such that $\Pr_{x\sim D}\left[\,f(x) \neq \hat{h}(x)\,\right] \le \mathrm{OPT}_D + \tau$ with probability at least $2/3$, where $\mathrm{OPT}_D = \min_{h\in\mathcal{C}} \Pr_{x\sim D}[\,f(x) \neq h(x)\,]$ (i.e., it performs "almost as well as the best function in $\mathcal{C}$").

Algorithm 2 Multiplicative approximation with $\exp(\widetilde{O}(k\sqrt{d}/((\varepsilon_2-3\varepsilon_1)^2))$ queries.

Require: Query access to $f\colon [n]^d \to \{0,1\}$, $\varepsilon_2 > 3\varepsilon_1 \geq 0$, a positive integer k

1: $\alpha \leftarrow (\varepsilon_2 - 3\varepsilon_1)$, $m \leftarrow \lceil 6kd/\varepsilon \rceil$, $t \leftarrow \lceil 3d(k+1)/\varepsilon \ln m + \ln 100 \rceil$
2: Define D to be the distribution over $[m]^d \times \{0,1\}$ such that $D(x,b) = \Pr_{y\in\mathcal{B}^{-1}(x)}[\, f(y) = b\,]$.
3: ▷ $\mathcal{A}_D(\tau, f)$ denotes the output of an agnostic learner of k-monotone functions with respect to D, with excess error τ and probability of failure $1/10$
4: $h\colon [m]^d \to \mathbb{R} \leftarrow \mathcal{A}_D(\alpha/12, f)$.
5: Estimate $\Pr_{(x,b)\sim D}[\, h(x) \neq b\,]$ to within $\pm\alpha/7$ with probability of failure $1/10$, using $O(1/\alpha^2)$ queries.
6: **if** the estimate is more than $\varepsilon_1 + \frac{5\alpha}{12}$ **then return** REJECT
7: **end if**
8: **if** $\mathrm{dist}(h,\ell) = \Pr_{x\in[m]^d}[\, h(x) \neq \ell(x)\,] \leq 2\varepsilon_1 + \frac{5\alpha}{12}$ for some k-monotone m-block function ℓ **then return** ACCEPT
9: **else return** REJECT
10: **end if**

▶ **Definition 24.** For a Boolean function $f\colon [r]^d \to \{-1,1\}$, we define

$$\mathbf{Inf}_i[f] = 2\Pr\Big[\, f(x) \neq f(x^{(i)})\,\Big]$$

where $x = (x_1, x_2, \ldots, x_d)$ is a uniformly random string over $[r]^d$, and

$$x^{(i)} = (x_1, x_2, \ldots, x_{i-1}, x_i', x_{i+1}, \ldots, x_d)$$

for x' drawn independently and uniformly from $[r]$. We also define $\mathbf{Inf}[f] = \sum_{i=1}^d \mathbf{Inf}_i[f]$.

We first generalize the following result, due to Blais *et al.*, for more general domains:

▶ **Proposition 25** ([9]). *Let $f\colon \{0,1\}^d \to \{-1,1\}$ be a k-monotone function. Then $\mathbf{Inf}[f] \leq k\sqrt{d}$.*

▶ **Lemma 26** (Generalization). *Let $f\colon [r]^d \to \{-1,1\}$ be a k-monotone function. Then $\mathbf{Inf}[f] \leq k\sqrt{d}$.*

Proof. For any two strings $y^0, y^1 \in [r]^d$, let $f_{y^0,y^1}\colon \{0,1\}^d \to \{-1,1\}$ be the function obtained by setting $f_{y^0,y^1}(x) = f(y^x)$, where $y^x \in [r]^d$ is defined as

$$y_i^x = \begin{cases} \min\{y_i^0, y_i^1\} & \text{if } x_i = 0 \\ \max\{y_i^0, y_i^1\} & \text{if } x_i = 1 \end{cases}$$

Since f was a k-monotone function, so is f_{y^0,y^1}. Thus $\mathbf{Inf}[f_{y^0,y^1}] \leq k\sqrt{d}$ for every choice of y^0 and y^1. It is not hard to see that for any fixed $i \in [d]$ the following two processes yield the same distribution over $[r]^d \times [r]^d$:

- Draw $z \in [r]^d$, $z_i' \in [r]$ independently and uniformly at random, set

$$z' \stackrel{\text{def}}{=} (z_1, \ldots, z_{i-1}, z_i', z_{i+1}, \ldots, z_d),$$

  and output (z, z');
- Draw $y^0, y^1 \in [r]^d, x \in \{0,1\}^d$ independently and uniformly at random, and output $(y^x, y^{x^{(i)}})$.

This implies that

$$\begin{aligned}
\mathbf{Inf}[f] &= \sum_{i=1}^{d} \mathbf{Inf}_i[f] = \sum_{i=1}^{d} 2 \Pr_{z\in[r]^d}[f(z) \neq f(z^{(i)})] \\
&= \sum_{i=1}^{d} 2\mathbb{E}_{y^0,y^1\in[r]^d}\left[\Pr_{x\in\{0,1\}^d}\left[f(y^x) \neq f(y^{x^{(i)}})\right]\right] \\
&= \mathbb{E}_{y^0,y^1\in[r]^d}\left[\sum_{i=1}^{d} 2 \Pr_{x\in\{0,1\}^d}\left[f(y^x) \neq f(y^{x^{(i)}})\right]\right] \\
&= \mathbb{E}_{y^0,y^1\in[r]^d}\left[\sum_{i=1}^{d} 2 \Pr_{x\in\{0,1\}^d}\left[f_{y_0,y_1}(x) \neq f_{y_0,y_1}(x^{(i)})\right]\right] \\
&= \mathbb{E}_{y^0,y^1}[\mathbf{Inf}[f_{y^0,y^1}]] \leq \mathbb{E}_{y^0,y^1}[k\sqrt{d}] = k\sqrt{d}.
\end{aligned}$$

◀

For two functions $f, g\colon [r]^d \to \mathbb{R}$, we define the inner product $\langle f, g\rangle = \mathbb{E}_x[f(x)g(x)]$, where the expectation is taken with respect to the uniform distribution. It is known that for functions $f\colon [r]^d \to \mathbb{R}$, there is a "Fourier basis" of orthonormal functions f. To construct such a basis, we can take any orthonormal basis $\{\phi_0 \equiv 1, \phi_1, \ldots, \phi_{|r|-1}\}$ for functions $f\colon [r] \to \mathbb{R}$. Given such a basis, a Fourier basis is the collection of functions ϕ_α, where $\alpha \in [r]^d$, and $\phi_\alpha(x) = \prod_{i=1}^{d} \phi_{\alpha_i}(x_i)$. Then every $f\colon [r]^d \to \mathbb{R}$ has a unique representation $f = \sum_{\alpha\in[r]^d} \widehat{f}(\alpha)\phi_\alpha$, where $\widehat{f}(\alpha) = \langle f, \phi_\alpha\rangle \in \mathbb{R}$.

Many Fourier formulæ hold in arbitrary Fourier bases, an important example being Parseval's Identity: $\sum_{\alpha\in[r]^d} \widehat{f}(\alpha)^2 = 1$. We will use the following property:

▶ **Lemma 27** ([39, Proposition 8.23]). *For $\alpha \in [r]^d$, let $|\alpha|$ denote the number of nonzero coordinates in α. Then we have*

$$\mathbf{Inf}[f] = \sum_{\alpha\in[r]^d} |\alpha|\, \hat{f}(\alpha)^2.$$

▶ **Lemma 28.** *If $\mathbf{Inf}[f] \leq k$, then $\sum_{\alpha:|\alpha|>k/\varepsilon} \widehat{f}(\alpha)^2 \leq \varepsilon$.*

Proof. If not, then $\mathbf{Inf}[f] = \sum_\alpha |\alpha|\, \widehat{f}(\alpha)^2 \geq \sum_{\alpha:|\alpha|>k/\varepsilon} |\alpha|\, \widehat{f}(\alpha)^2 \geq \frac{k}{\varepsilon} \sum_{\alpha:|\alpha|>k/\varepsilon} \widehat{f}(\alpha)^2 > \frac{k}{\varepsilon} \cdot \varepsilon = k$, a contradiction. ◀

▶ **Lemma 29.** *Let p be the function $\sum_{\alpha:|\alpha|\leq t} \widehat{f}(\alpha)\phi_\alpha$. Then*

- **(i)** $\|p - f\|_2^2 = \mathbb{E}_{x\in[r]^d}[(p(x) - f(x))^2] = \sum_{\alpha:|\alpha|>t} \widehat{f}(\alpha)^2$;
- **(ii)** *p is expressible as a linear combination of real-valued functions over $[r]^d$, each of which only depends on at most t coordinates;*
- **(iii)** *p is expressible as a degree-t polynomial over the rd indicator functions $\mathbb{1}_{\{x_i=j\}}$ for $1 \leq i \leq d$ and $j \in [r]$.*

▶ **Theorem 30** ([30, Theorem 5]). *Let $\mathcal{C}$ be a class of Boolean functions over $\mathcal{X}$ and $\mathcal{S}$ a collection of real-valued functions over $\mathcal{X}$ such that for every $f\colon \mathcal{X} \to \{-1, 1\}$ in $\mathcal{C}$, there exists a function $p\colon \mathcal{X} \to \mathbb{R}$ such that p is expressible as a linear combination of functions from $\mathcal{S}$ and $\|p - f\|_2^2 \leq \tau^2$. Then there is an agnostic learning algorithm for $\mathcal{C}$ achieving excess error τ which has sample complexity* $\mathrm{poly}(|\mathcal{S}|, 1/\tau)$.

Importantly, this algorithm is still successful with inconsistent labelled samples (examples), as long as they come from a distribution on $\mathcal{X} \times \{-1, 1\}$, where the marginal distribution on $\mathcal{X}$ is uniform.

Now we put all the pieces together. To agnostically learn a k-monotone function, we simply perform the agnostic learning algorithm of [30] on the distribution D over $[m]^d \times \{-1, 1\}$ defined by

$$D(x, b) = \Pr_{y \in \mathcal{B}^{-1}(x)} [\, f(y) = b \,] .$$

To generate a sample (x, b) from D, we draw a uniformly random string in $x \in [m]^d$, and b is the result of a query for the value of $f(y)$ for a uniformly random $y \in \mathcal{B}^{-1}(x)$. From Theorem 29, we can take $\mathcal{S}$ to be the set of $(k\sqrt{d}/\tau^2)$-way products of rd indicator functions. It follows that $|\mathcal{S}| = \binom{rd}{k\sqrt{d}/\tau^2} = \exp(\widetilde{O}(k\sqrt{d}/\tau^2))$.

▶ **Proposition 31.** *Algorithm 2 accepts all functions ε_1-close to k-monotone functions, and rejects all functions ε_2-far from k-monotone, when $\varepsilon_2 > 3\varepsilon_1$ (with probability at least $2/3$). Its query complexity is $\exp(\widetilde{O}(k\sqrt{d}/(\varepsilon_2 - 3\varepsilon_1)^2))$.*

Proof. By a union bound, we have that with probability at least $8/10$ both Step 5 and Step 4 succeed. We hereafter condition on this.

Completeness

Suppose f is ε_1-close to k-monotone. Theorem 21 and the triangle inequality imply that there is a k-monotone m-block function g^* such that $\mathrm{dist}(f, g^*) \leq \varepsilon_1 + \alpha/6$. The agnostic learning algorithm thus returns a hypothesis h such that $\mathrm{dist}(f, h) \leq \varepsilon_1 + \alpha/4$. The algorithm estimates this closeness to within $\alpha/7$, so the estimate obtained in Step 5 is at most $\varepsilon_1 + \varepsilon/4 + \varepsilon/7 < \varepsilon_1 + 5\alpha/12$ and the algorithm does not reject in this step. By the triangle inequality, h is $(2\varepsilon_1 + 5\alpha/12)$-close to k-monotone, and the algorithm will accept. There is no estimation error here, since no queries to f are required.

Soundness

Now suppose f is ε_2-far from k-monotone, where $\varepsilon_2 = 3\varepsilon_1 + \alpha$ for some $\alpha > 0$. Suppose the algorithm does not reject when estimating $\mathrm{dist}(f, h)$, where h is the hypothesis returned by the agnostic learning algorithm. Then $\mathrm{dist}(f, h) \leq \varepsilon_1 + 5\alpha/12 + \alpha/7 < \varepsilon_1 + 7\alpha/12$. By the triangle inequality, if t is a k-monotone function, $\mathrm{dist}(h, t) \geq \mathrm{dist}(f, t) - \mathrm{dist}(f, h) > \varepsilon_2 - (\varepsilon_1 + 7\alpha/12) = 2\varepsilon_1 + 5\alpha/12$. The algorithm will thus reject in the final step.

Query complexity

The query complexity of the algorithm is dominated by the query complexity of the agnostic learning algorithm, which is $\exp(\widetilde{O}(k\sqrt{d}/\alpha^2)) = \exp(\tilde{O}\Big(k\sqrt{d}/(\varepsilon_2 - 3\varepsilon_1)^2\Big))$. ◀

Acknowledgments. We would like to thank Eric Blais for helpful remarks on an earlier version of this paper, and an anonymous reviewer for very detailed and insightful comments.

Abstract

Despite decades of intensive research, efficient – or even sub-exponential time – distribution-free PAC learning algorithms are not known for many important Boolean function classes. In this work we suggest a new perspective on these learning problems, inspired by a surge of recent research in complexity theory, in which the goal is to determine whether and how much of a savings over a naive 2^n runtime can be achieved.

We establish a range of exploratory results towards this end. In more detail,

1. We first observe that a simple approach building on known uniform-distribution learning results gives non-trivial distribution-free learning algorithms for several well-studied classes including AC^0, arbitrary functions of a few linear threshold functions (LTFs), and AC^0 augmented with mod_p gates.
2. Next we present an approach, based on the method of random restrictions from circuit complexity, which can be used to obtain several distribution-free learning algorithms that do not appear to be achievable by approach (1) above. The results achieved in this way include learning algorithms with non-trivial savings for LTF-of-AC^0 circuits and improved savings for learning parity-of-AC^0 circuits.
3. Finally, our third contribution is a generic technique for converting lower bounds proved using Nečiporuk's method to learning algorithms with non-trivial savings. This technique, which is the most involved of our three approaches, yields distribution-free learning algorithms for a range of classes where previously even non-trivial uniform-distribution learning algorithms were not known; these classes include full-basis formulas, branching programs, span programs, etc. up to some fixed polynomial size.

1 Introduction

Simple concepts are easy to learn, while complicated ones are harder to learn. Some of the earliest and most fundamental work in computational learning theory aims at elucidating this truism from a theoretical computer science perspective: can we understand how the algorithmic complexity of learning Boolean functions (i.e. the running time required by

* The author is supported by NSF grants CCF-1420349 and CCF-1563155.
† The author is supported by NSF grant CCF-1563122; this research was done while visiting Columbia University.

learning algorithms) scales with the computational complexity of the functions being learned? Achieving such an understanding was first articulated as an explicit goal in (indeed, arguably *the* explicit goal of) Valiant's landmark paper "A theory of the learnable" [42]:

> "The results of learnability theory would then indicate the maximum granularity of the single concepts that can be acquired without programming. In summary, this paper attempts to explore the limits of what is learnable as allowed by algorithmic complexity. The identification of these limits is a major goal of the line of work proposed in this paper."

So, more than thirty years later, how has learning theory fared in achieving these goals? Perhaps disappointingly, the roster of concept classes (classes of Boolean functions over $\{0,1\}^n$) for which efficient learning algorithms have been developed in Valiant's original distribution-independent PAC learning model, or in other similarly general learning frameworks, is quite short. Classes that are known to be learnable in polynomial time include linear threshold functions (LTFs) and degree-k polynomial threshold functions for $k = O(1)$ [9] (subsuming the classes of k-CNF, k-DNF [42] and k-decision lists [38]); parity functions and $\mathbb{F}_2$ polynomials of constant degree [20, 13], and not much more. (If membership queries are allowed, then a few other classes are known to be distribution-independent PAC learnable in polynomial time, such as decision trees of polynomial size [10, 6] and regular languages computed by polynomial-size DFAs [1].) In fact, only a relatively small number of natural Boolean function classes are additionally known to be learnable even if we only require sub-exponential time for the learning. DNF formulas of $\mathrm{poly}(n)$ size can be learned in $2^{\tilde{O}(n^{1/3})}$ time [27], $\mathrm{poly}(n)$-sparse $\mathbb{F}_2$ polynomials can be learned in $2^{\tilde{O}(n^{1/2})}$ time [19], and de Morgan formulas of size s can be learned in time $n^{O(s^{1/2})}$ [37].

Even simple generalizations of the above-mentioned subexponential-time-learnable function classes have remained frustratingly out of reach for the distribution-independent PAC model. Prominent examples here include the class of $\mathrm{poly}(n)$-size depth-3 AC^0 circuits, and intersections of even just two LTFs over $\{0,1\}^n$: despite extensive research effort, no positive algorithmic results are known for these classes (hence, needless to say, for their generalizations as well). This is quite a disappointment, given the rich variety of natural Boolean function classes that have been intensively studied in concrete complexity over the past several decades: well-known examples include AC^0 (augmented in various ways with more exotic gates such as mod_p gates, majority gates, threshold gates, and the like), SYM^+ circuits, various classes of branching programs, functions of a few LTFs, and more. These functions play a starring role in concrete complexity theory, but learning theorists cannot even score an autograph.[1]

This work: A change of perspective

In this paper we propose a new point of view on the challenging learning problems discussed above. Since the quest for polynomial or even sub-exponential time distribution-independent learning algorithms has been unsuccessful, we suggest that a more fruitful perspective may be to *study the question of whether, and how much of, a savings over a naive* 2^n *running time can be achieved for these learning problems.* We thus are interested in obtaining learning

[1] We note that in the (significantly) easier *uniform-distribution* learning model, in which the learner need only succeed w.r.t. the uniform distribution over $\{0,1\}^n$, positive learning results are known for functions of a few LTFs [26, 16] and AC^0 [29] as well as some generalizations of these classes [15, 11]; we will have occasion to revisit these results later.

algorithms that run in time $2^{n-s(n)}$ for some *savings* function $s(n)$ which is as large as possible. (To use a hackneyed metaphor, instead of expecting a brim-full glass, we are now hoping for a mouthful of water at the bottom...)

While this appears to be a new lens through which to view learning problems, we stress that the point of view which we advocate here has been a mainstay in computational complexity for a long time. Well-known results give non-trivial upper bounds (mildly better than 2^n) on the running time of satisfiability or (exact) counting algorithms for k-CNFs, general CNFs, and a host of NP-hard or #P-hard problems (see e.g. [33, 39, 32, 40, 14, 21, 4, 7, 22]). Williams's breakthrough connection [43, 44] linking non-trivial savings of satisfiability algorithms to circuit lower bounds has intensified the interest in results of this sort for richer circuit classes, and even more recently there has been a surge of interest in questions of a similar flavor because of the connections that have been established between hypotheses like SETH and prominent questions in algorithm design (see e.g. the survey of [45]).

In this paper we explore some first questions in the study of what can be learned with non-trivial savings; happily, it turns out that this new perspective yields a rich bounty of positive results. As our main contribution, we present three techniques and show how each technique yields new learning algorithms of the sort we are interested in. Cumulatively, our results achieve the first non-trivial savings for many well-studied circuit classes; however, several natural questions about learning with non-trivial savings are left open by our work. We hope (and expect) that further results extending our knowledge of "non-trivially learnable" function classes will follow.

A quick and dirty proof of concept

Before describing our main results, for the sake of intuition we sketch a simple argument showing that AC^0 indeed admits a non-trivial distribution-free learning algorithm (more precisely, one whose running time is $2^{n-n^{\Omega(1/d)}}$ for poly(n)-size depth-d AC^0). The argument is based on Håstad's switching lemma [17] which, roughly speaking, states that any depth-d, poly(n)-size AC^0 circuit F collapses to a shallow decision tree with very high probability under a random restriction. This can be shown to imply that if $\{0,1\}^n$ is partitioned into translations of a random subcube (corresponding to all possible settings of the live variables of a random restriction), then with very high probability almost every such subcube has the property that if F is restricted to the subcube, then F collapses to a shallow decision tree. Since it is possible to learn such a shallow decision tree relatively efficiently (in time much less than the number of points in its domain, i.e. in the subcube), this means that by learning F separately on each subcube it is possible to achieve a significant savings over brute-force search on every "good" subcube, i.e. on almost every subcube. Trading off the fraction of bad subcubes (which corresponds to the failure probability of the switching lemma, and decreases with the dimension of the subcubes) against the number of subcubes (which provides a lower bound on the running time of this learning approach, and which increases as the dimension of the subcubes decreases) and working out the parameters, the running time of this simple-minded approach comes out to be $2^{n-n^{\Omega(1/d)}}$.

Two comments: First, we note that we will improve significantly on this running time in Section 3, using a more sophisticated instantiation of this idea, and will achieve this improved running time even for various augmentations of AC^0 circuits. Second, it may not be completely clear how to run a separate copy of a distribution-free learning algorithm on each subcube in the above sketch. This will become clear in Section 2 when we describe the formal model (based on online learning, or equivalently the model of exact learning from equivalence queries) that we will use for all of our positive results (and which is well-known to imply distribution-free PAC learnability).

Relation to previous work: compression of Boolean functions

We have already explained how our goal of achieving non-trivial savings for learning is directly inspired by work aiming towards this goal for the algorithmic problems of satisfiability and counting. Another line of research which is more closely related to our study of non-trivial learning is the recent work on "compression" of Boolean functions that was initiated by [12]. A compression algorithm for a class $\mathcal{C}$ (such as the class of AC^0 circuits) is a deterministic algorithm which is given as input the 2^n-bit truth table of a function in $\mathcal{C}$, must run in time polynomial in its input length (i.e. in $2^{O(n)}$ time), and must output any Boolean circuit C, computing f, such that the size of C is less than the trivial $2^n/n$ bound.

Deterministic learning is easily seen to be at least as hard as compression; we discuss the exact relation between the two tasks in more detail in Section 2, after we have given a precise definition of our learning model. Our learning algorithms, which are randomized, imply randomized variants of almost all of the compression results in [12], in several cases with new and simpler proofs. We also establish non-trivial learning results (and hence randomized compression results) for many classes for which compression results were not previously known. These classes include LTF-of-AC^0, arbitrary functions of $o(n/\log n)$ LTFs, $n^{1.99}$-size switching networks, $n^{1.49}$-size switching-and-rectifier networks, $n^{1.49}$-size non-deterministic branching programs, and $n^{1.49}$-size span programs; in fact, for the last four of these classes we obtain deterministic compression algorithms.

1.1 Our techniques and results

To begin, in Section 2.1 we make the simple observation that uniform-distribution PAC learning algorithms can be converted to exact learning algorithms with membership queries simply by "patching up" the $\varepsilon \cdot 2^n$ points where an ε-accurate hypothesis is in error. (This observation was already employed by [11] in the context of compression.) Using known uniform-distribution learning results, this straightforward approach gives non-trivial distribution-free learning algorithms for several well-studied classes including AC^0, arbitrary functions of a few LTFs, and AC^0 augmented with mod_p gates.

However, as we explain in Section 3, there are uniform-distribution learning algorithms (such as the algorithms of [15, 24] for LTF-of-AC^0 circuits) which for technical reasons do not yield exact learning algorithms with non-trivial savings. To address this, in Section 3 we show how the method of random restrictions from circuit complexity can be employed to obtain non-trivial learning algorithms in settings where the approach of Section 2.1 does not apply. Recall that, roughly speaking, the "method of random restrictions" refers to a body of results showing that certain types of Boolean functions "collapse" to simpler functions with high probability when they are hit with a random restriction fixing a random subset of input variables to randomly chosen constant values. Our approach is based on learning the simpler functions that result from random restriction and thereby obtaining an overall savings in learning the original unrestricted function. This is similar to the "quick and dirty" proof of concept sketched earlier, but by adapting a recent powerful "multi-switching" lemma of Håstad [18] to our learning context, we are able to achieve a significantly better savings than the "quick and dirty" argument which uses only the original [17] switching lemma. Via this approach we obtain exact learning algorithms for LTF-of-AC^0 and parity-of-AC^0 that match the savings of our learning algorithm for AC^0 from Section 2.1. As indicated above the uniform-distribution approach of Section 2.1 does not give a result for LTF-of-AC^0, while for parity-of-AC^0 circuits our random restriction approach yields significantly improved savings over the results achieved for this class in Section 2.1. Furthermore, for both these classes

our learning algorithms based on random restrictions do not require membership queries (in contrast to the uniform-distribution based approach, which does require membership queries).

Our third and most involved technique for non-trivial learning is based on Nečiporuk's celebrated lower bound method: in Section 4 we give a generic translation of lower bounds proved using Nečiporuk's method to non-trivial exact learning algorithms. Roughly speaking, Nečiporuk's lower bounds are established by showing that low complexity functions have few subfunctions (and exhibiting explicit functions that have many subfunctions, and hence must have high complexity). We give an exact learning algorithm that achieves non-trivial savings for classes of functions that have few subfunctions. A key technical component of our learning algorithm is a pre-processing-based technique for executing many copies of the classical halving algorithm in a highly efficient amortized manner. While simple, this technique appears to be new and may be of use elsewhere. We thus obtain a single unified learning algorithm that achieves non-trivial savings for a broad range of function classes, including full-basis binary formulas of size $n^{1.99}$, branching programs of size $n^{1.99}$, switching networks of size $n^{1.99}$, switching-and-rectifier network of size $n^{1.49}$, non-deterministic branching programs of size $n^{1.49}$, and span programs of size $n^{1.49}$. Our learning results recapture the [12] compression results for $n^{1.99}$-size formulas and branching programs with a new and simpler proof, and give the first compression results for the other classes of switching networks, switching-and-rectifier networks, non-deterministic branching programs, and span programs listed above.

2 Preliminaries

The learning model we consider

The distribution-independent PAC model has several parameters (a confidence parameter which is usually denoted δ, and an accuracy parameter usually denoted ε) which make precise statements of running times somewhat unwieldy. In this paper we will work in a elegant model of online mistake-bound learning [30] which is well known to be equivalent to the model of exact learning from equivalence queries only [2] and to be even more demanding than the distribution-independent PAC learning model [2, 8]. A brief description of this model is as follows: Let $\mathcal{C}$ be a class of functions from $\{0,1\}^n$ to $\{0,1\}$ that is to be learned and let $f \in \mathcal{C}$ be an unknown target function. The learning algorithm always maintains a hypothesis function $h : \{0,1\}^n \to \{0,1\}$ (more precisely, a representation of h in the form of a Boolean circuit computing h). The learning process unfolds in a sequence of *trials*: at the start of a given trial,

- If $h(x) = f(x)$ for all $x \in \{0,1\}^n$ then the learning algorithm has succeeded and the process stops.
- Otherwise a *counterexample* – an arbitrary x such that $h(x) \neq f(x)$ – is presented to the learning algorithm, and the learning algorithm may update its hypothesis h before the start of the next trial.

The running time of a learning algorithm in this framework is simply the worst-case running time until the algorithm succeeds (taken over all $f \in \mathcal{C}$ and all possible sequences of counterexamples). We will also sometimes have occasion to consider an extension of this model in which at each trial the learning algorithm may, instead of receiving a counterexample, at its discretion choose instead to make a *membership query* (i.e. to submit a string $x \in \{0,1\}^n$ of its choosing to the oracle, and receive the value $f(x)$ in response). This is the well-studied framework of "exact learning from membership and equivalence queries" [2].

We will also have occasion to consider randomized exact learning algorithms. We say that a randomized algorithm learns class $\mathcal{C}$ in time $T(n)$ if for any target function $f \in \mathcal{C}$, the algorithm succeeds with probability at least $1 - \delta$ (over its internal coin tosses) after at most $T(n) \cdot \log(1/\delta)$ time steps. While many of the learning results we present will be for randomized exact learning algorithms, in the rest of this section for simplicity we confine our discussion to deterministic learning algorithms.

Besides being a clean and attractive learning model, learnability in the exact learning model (optionally augmented with membership queries) is well known to imply learnability in the distribution-independent PAC model (correspondingly augmented with membership queries). More precisely, if a class $\mathcal{C}$ is learnable in time $T(n)$ using $Q(n)$ queries in the exact model, then by a standard argument[2] $\mathcal{C}$ is learnable to confidence $1 - \delta$ and accuracy $1 - \varepsilon$ in the PAC model in time $T_{\mathrm{PAC}} = O(\frac{T(n)}{\varepsilon} \ln(\frac{T(n)}{\delta}))$ using $O(\frac{Q(n)}{\varepsilon} \ln(\frac{Q(n)}{\delta}))$ queries.

Non-trivial savings

It is easy to see that any class $\mathcal{C}$ can be learned in time $\mathrm{poly}(n) \cdot 2^n$ in our model via a simple memorization-based approach; our goal in this work will be to come up with algorithms whose running time is $2^{n-s(n)}$ where the *savings* $s(n)$ is as large as possible. We say that any savings function $s(n) = \omega(\log n)$ is *non-trivial*. We observe that the conversion from exact learning to distribution-independent PAC learning described above preserves learnability with non-trivial savings: learnability with non-trivial savings in our exact model implies learnability to any $1/\mathrm{poly}(n)$ accuracy and confidence in the PAC model with non-trivial savings (since if $T(n) = 2^{n-\omega(\log n)}$ and $\varepsilon, \delta = 1/\mathrm{poly}(n)$ then $T_{\mathrm{PAC}} = 2^{n-\omega(\log n)}$).

Deterministic learning implies compression

As mentioned in the introduction, now that we have a precise definition of our learning model it is easy to verify that any class of functions that admits a non-trivial deterministic learning algorithm admits a compression algorithm. To see this, observe that our learning algorithms (i) are not given the full truth table of f as input, and (ii) must run in time strictly less than 2^n (as opposed to $2^{O(n)}$ for compression), while (iii) a learning algorithm in our framework must (like a compression algorithm) ultimately construct a circuit computing f that has size less than $2^n/n$. We may summarize this discussion in the following observation:

▶ **Observation 1.** *Let $\mathcal{C}$ be a class of n-variable Boolean functions that has a deterministic exact learning algorithm using membership and equivalence queries with savings $s(n) = \omega(\log n)$ (i.e. in time $2^{n-s(n)}$). Then there is a deterministic algorithm that compresses $\mathcal{C}$ to circuits of size $2^{n-s(n)}$.*

As an application of this observation, consider the class of size-S read-once branching programs (ROBPs) over $x_1, \ldots, x_n$. Since every such size-S ROBP is a deterministic finite automaton with S nodes over the binary alphabet $\{0, 1\}$ accepting only n-bit strings, Angluin's deterministic exact learning algorithm [1] (which uses membership and equivalence queries) can learn any such ROBP in time $O(S^2)$. By Observation 1, this implies an algorithm that compresses $2^{n/2-s(n)/2}$-size ROBPs to circuits of size $O(2^{n-s(n)})$. This recovers a compression result for this class that was previously obtained by Chen et al. in the paper [12] that initiated the study of compression algorithms (see their Theorem 3.8).

---

[2] See e.g. Section 2.4 of [2], replacing the expression "$i \ln 2$" by "$\ln(2i^2)$".

2.1 A first simple approach based on uniform-distribution learning

In contrast with the state of affairs for distribution-independent PAC learning, a more significant body of results is known for *uniform-distribution* PAC learning (as we will see later in this section). In this section we describe a simple approach by which some uniform-distribution PAC learning algorithms – roughly speaking, those which have a good dependence on the accuracy parameter ε – can easily be translated into non-trivial exact learning algorithms.

The simple approach, which was already suggested in [11] in the context of compression, is as follows. Using membership queries, we may simulate uniform random examples $(\boldsymbol{x}, f(\boldsymbol{x}))$ and run the uniform-distribution learning algorithm to obtain an ε-accurate hypothesis h in time $T(n, 1/\varepsilon, \log(1/\delta))$. Then we use at most $\varepsilon \cdot 2^n$ equivalence queries to identify and correct all of the (at most $\varepsilon \cdot 2^n$) many points on which h is incorrect. Since updating the hypothesis after each equivalence query can clearly be done in time $\mathrm{poly}(n)$ we thus obtain the following:

▶ **Claim 2.** *Let $\mathcal{C}$ be a class of n-variable Boolean circuits such that there is a uniform-distribution PAC learning algorithm (which may possibly use membership queries) running in time $T(n, 1/\varepsilon, \log(1/\delta))$, which with probability $1-\delta$ outputs an ε-accurate hypothesis. Then there is a randomized exact learning algorithm for $\mathcal{C}$ which uses membership and equivalence queries and runs in time*

$$\mathrm{poly}(n) \cdot \min_{\varepsilon > 0} \left\{ T(n, 1/\varepsilon, \log(1/\delta)) + \varepsilon \cdot 2^n \right\}. \tag{1}$$

First application of Claim 2: Learning AC^0 circuits

The seminal work of Linial, Mansour, and Nisan [29] established Fourier concentration bounds for size-M depth-d circuits, and showed how these bounds straightforwardly yield uniform-distribution learning algorithms. An essentially optimal strengthening of the Fourier concentration bound of [29] was recently obtained by Tal [41], who showed that there exists a universal constant $c > 0$ such that every size-M depth-d circuit C satisfies $\sum_{|S| \geq c \log^{d-1}(M) \log(1/\varepsilon)} \widehat{C}(S)^2 \leq \varepsilon$. Via the connection between Fourier concentration and uniform-distribution learning established by [29], this implies that the class of size-M depth-d circuits can be learned to accuracy ε by a randomized algorithm in time $\mathrm{poly}\left(\binom{n}{\leq c \log^{d-1}(M) \log(1/\varepsilon)}\right) \cdot \log(1/\delta)$. Consequently, by Claim 2, taking $\varepsilon = 2^{-\Theta(n/(\log M)^{d-1})}$ we get a randomized exact learning algorithm which uses membership and equivalence queries which runs in time $\mathrm{poly}(n) \cdot 2^{n - \Omega(n/(\log M)^{d-1})}$. We note that this matches the circuit size given by the compression theorem of [12] for such circuits.

Learning functions of k LTFs

Gopalan et al. [16] have given a randomized uniform-distribution membership-query algorithm that learns any function of k LTFs over $\{0,1\}^n$ in time $O((nk/\varepsilon)^{k+1})$. Choosing $\varepsilon = 2^{-\frac{n}{k+2}}$ in Claim 2, we get a randomized exact learning algorithm which uses membership and equivalence queries and runs in time $\mathrm{poly}(n) \cdot 2^{\frac{k+1}{k+2} n} = \mathrm{poly}(n) \cdot 2^{n - \frac{n}{k+2}}$, thus achieving a non-trivial savings for any $k = o(n/\log n)$, and a linear savings for any constant k.

Learning $\mathsf{AC}^0[p]$ circuits

A recent exciting result of [11] gives a randomized uniform-distribution membership-query algorithm for learning the class of n-variable size-M depth-d $\mathsf{AC}^0[p]$ circuits to accuracy ε

in time $2^{(\log(Mn/\varepsilon))^{O(d)}}$. By Claim 2, taking $\varepsilon = M \cdot 2^{-n^{\Theta(1/d)}}$, we get a randomized exact learning algorithm which uses membership and equivalence queries and runs in time $2^{n-n^{\Omega(1/d)}}$ for all circuits of size $M \leq 2^{n^{c/d}}$ for some absolute constant $c > 0$.

3 Beyond uniform-distribution learnability: Learning via random restrictions

As noted briefly in Section 2.1, in order for Claim 2 to give a non-trivial savings for exact learning the running time $T(n, 1/\varepsilon, \log(1/\delta))$ of the uniform-distribution learning algorithm must not depend too badly on $1/\varepsilon$. This requirement limits the applicability of Claim 2; to see a concrete example of this, let us consider the class of all poly(n)-size, depth $d = O(1)$ LTF-of-AC^0 circuits (so such a circuit has an arbitrary linear threshold function as the output gate with poly(n) many poly(n)-size depth-$(d-1)$ AC^0 circuits feeding into the threshold gate). Uniform-distribution learning results [15, 24] are known for this class, based on Fourier concentration which is established via known upper bounds on the average sensitivity of low-degree polynomial threshold functions. As discussed in [15], the best running time that can be achieved for learning via this approach is $n^{(\log n)^{O(d)}/\varepsilon^2}$, which would follow from a conjecture of Gotsman and Linial, known to be best possible, upper bounding the average sensitivity of low-degree polynomial threshold functions. (The current state of the art learning algorithms, based on Kane's upper bound [24] on the average sensitivity of low-degree polynomial threshold functions which nearly matches the Gotsman-Linial conjecture, have a slightly worse running time.) As a result of this poor dependence on ε, the value of (1) is $\Omega(2^n/\sqrt{n})$, so no non-trivial savings is achieved. We note that even for the $d = 1$ case of a single linear threshold gate as the function to be learned, the best possible running time of a learning algorithm based on Fourier concentration is $n^{\Omega(1/\varepsilon^2)}$ (see Theorem 23 of [26]).

An approach based on random restrictions

In this section we show that by taking a more direct approach than Claim 2, it is possible to achieve a non-trivial savings for LTF-of-AC^0 circuits, and to improve on the results achievable via Claim 2 for the class of Parity-of-AC^0 circuits, which is covered by the final learning result in Section 2.1. An additional advantage of this random restriction based approach is that (unlike the uniform distribution approach based on Claim 2) the resulting exact learning algorithms do not require membership queries, only equivalence queries.

This approach is based on the method of random restrictions; it is reminiscent of the simple "proof of concept" from the Introduction (though we will ultimately instantiate it with a more sophisticated switching lemma than Håstad's original switching lemma [17]). Roughly speaking the approach works as follows: Let $\mathcal{R}_p$ denote the distribution over n-variable random restrictions (i.e. over $\{0, 1, *\}^n$) that independently sets each coordinate to 0, 1, or $*$ with probabilities $\frac{1-p}{2}$, $\frac{1-p}{2}$ and p respectively. Let $\mathcal{C}$ be the class of functions that we would like to learn, and let $\mathcal{C}'$ be some other class of functions (which should be thought of as "simpler" than the functions in $\mathcal{C}$). If we have (i) a switching lemma type statement establishing that for $\boldsymbol{\rho} \leftarrow \mathcal{R}$, any $f \in \mathcal{C}$ with high probability collapses under $\boldsymbol{\rho}$ to a function in $\mathcal{C}'$, and (ii) an exact algorithm A that can learn functions in $\mathcal{C}'$ in time significantly faster than brute force, then we can achieve nontrivial savings by (a) drawing a random restriction $\boldsymbol{\rho} \leftarrow \mathcal{R}$, (b) partitioning $\{0,1\}^n$ into translates of the $|\boldsymbol{\rho}^{-1}(*)|$-dimensional subcube corresponding to the unfixed variables of $\boldsymbol{\rho}$, and (c) running the algorithm A on each of the $2^{n-|\boldsymbol{\rho}^{-1}(*)|}$ many such subcubes. By (i), for most subcubes we will achieve a significant savings over a brute-force $2^{|\boldsymbol{\rho}^{-1}(*)|}$ running time for that subcube; even "paying

full fare" for the (few) remaining bad subcubes, this results in an overall algorithm with non-trivial savings.

We make this discussion formal in the following lemma:

▶ **Lemma 3.** *Let $\mathcal{C}$ and $\mathcal{C}'$ be two classes of Boolean functions, where $\mathcal{C} = \bigcup_{n\geq 1} \mathcal{C}_n$ and functions in $\mathcal{C}_n$ are n-variable Boolean functions and likewise for $\mathcal{C}'$. Suppose that $\mathcal{C}$ and $\mathcal{C}'$ are such that for some value $\frac{8}{n} \leq p < 1$, we have*

1. *(switching lemma from $\mathcal{C}$ to $\mathcal{C}'$) For every function $f \in \mathcal{C}_n$,*

$$\mathop{\mathbf{Pr}}_{\boldsymbol{\rho}\leftarrow\mathcal{R}_p}\left[f \restriction \boldsymbol{\rho} \text{ does not belong to } \mathcal{C}'_{|\boldsymbol{\rho}^{-1}(*)|}\right] \leq \alpha(n); \tag{2}$$

2. *(efficient learnability of $\mathcal{C}'$) There is an exact learning algorithm A for $\mathcal{C}'$ that uses equivalence queries only and runs in time $T(\ell) = 2^{o(\ell)}$ when it is run on a function in $\mathcal{C}'_\ell$.*

Then there is a randomized exact learning algorithm for $\mathcal{C}_n$ which uses equivalence queries only, outputs a correct hypothesis with probability $1-\delta$, and runs in time

$$\mathrm{poly}(n) \cdot \left(2^{n-pn/2} \cdot T(pn/2) + \alpha(n) \cdot 2^n\right) \cdot \log(1/\delta). \tag{3}$$

Proof. The randomized exact learning algorithm executes a sequence of at most $O(\log(1/\delta))$ independent stages, halting the first time a stage succeeds. We will show below that each stage succeeds in producing an exactly correct hypothesis with probability at least 0.35, and runs in time $\mathrm{poly}(n) \cdot \left(2^{n-pn/2} \cdot T(pn/2) + \alpha(n) \cdot 2^n\right)$; the lemma follows easily from this.

Each stage consists of two substages and is structured as follows. In the first substage, the exact learning algorithm draws a random restriction $\boldsymbol{\rho} \leftarrow \mathcal{R}_p$. By a standard multiplicative Chernoff bound (using $p \geq \frac{8}{n}$) we have that $|\boldsymbol{\rho}^{-1}(*)| < pn/2$ with probability at most $\exp(-pn/8) < e^{-1}$; if $|\boldsymbol{\rho}^{-1}(*)| < pn/2$ then this stage ends in failure, otherwise the algorithm continues to the second substage (described in the next paragraph). Let $C_{\boldsymbol{\rho}}$ be the subcube of $\{0,1\}^n$ (of dimension $|\boldsymbol{\rho}^{-1}(*)|$ and containing $2^{|\boldsymbol{\rho}^{-1}(*)|}$ many points) corresponding to the live variables of $\boldsymbol{\rho}$, and let $C_{\boldsymbol{\rho},\text{translates}}$ be the set of all $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ many disjoint translates of $C_{\boldsymbol{\rho}}$ which together cover $\{0,1\}^n$. We say that a translate $C_{\boldsymbol{\rho}} + z \in C_{\boldsymbol{\rho},\text{translates}}$ (viewing addition as being over $\mathbb{F}_2$) of $C_{\boldsymbol{\rho}}$ is *bad* if the translated restriction $\boldsymbol{\rho} + z$ (whose $*$'s are in the exact same locations as those of $\boldsymbol{\rho}$) corresponding to $C_{\boldsymbol{\rho}} + z$ is such that $f \restriction (\boldsymbol{\rho} + z)$ does not belong to $\mathcal{C}'$, and we say that $\boldsymbol{\rho}$ is bad if more than a $4\alpha(n)$ fraction of the $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ translates of $C_{\boldsymbol{\rho}}$ are bad. By Markov's inequality applied to (2), we have that $\boldsymbol{\rho} \leftarrow \mathcal{R}_p$ is bad with probability at most $1/4$. We thus have that with overall probability at least $1 - 1/4 - e^{-1} > 0.35$ over the draw of $\boldsymbol{\rho} \leftarrow \mathcal{R}_p$, the stage proceeds to the second substage with a restriction $\boldsymbol{\rho}$ that is not bad (and that satisfies $|\boldsymbol{\rho}^{-1}(*)| \geq pn/2$).

In the second substage, the exact learning algorithm then runs $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ copies of algorithm A in parallel, each one to learn the $(\ell = |\boldsymbol{\rho}^{-1}(*)|)$-variable function which is $f \restriction (C_{\boldsymbol{\rho}} + z)$ for one of the translates of $C_{\boldsymbol{\rho}}$. This can be done using equivalence queries only: the overall hypothesis at each time step is obtained from the $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ many hypotheses (one for each subcube) in the obvious way. Each counterexample received allows one of the $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ copies of algorithm A (the one running over the subcube that received the counterexample) to update its hypothesis. Let $M(\ell) \leq T(\ell)$ be the maximum number of counterexamples that A can ever receive when it is run on a function in $\mathcal{C}'_\ell$. Within each subcube, if the copy of A running in that subcube receives more than $M(\ell)$ counterexamples, then since that subcube must be bad, the overall exact learning algorithm switches from running A on that subcube to running a naive equivalence-query learning algorithm that simply builds a truth table (and takes time at most $\mathrm{poly}(n) \cdot 2^{|\boldsymbol{\rho}^{-1}(*)|}$, the number of points in the subcube).

The second substage carries out this process until either

(i) no counterexample is provided (meaning that all $2^{|n-\boldsymbol{\rho}^{-1}(*)|}$ copies of the algorithm have obtained an exactly correct hypothesis, and thus the overall combined hypothesis is exactly correct and the stage succeeds), or

(ii) more than $4\alpha(n)2^{n-\ell}$ copies of the algorithm have each received more than $M(\ell)$ counterexamples; since this can only happen if $\boldsymbol{\rho}$ is bad, in this case the stage halts and ends in failure.

We observe that case (i) must occur if $\boldsymbol{\rho}$ is not bad, and hence case (i) occurs and the stage succeeds with overall probability at least 0.35. In either case the running time for the stage is at most

$$\begin{aligned}
&\mathrm{poly}(n) \cdot \left(2^{|n-\ell|} \cdot T(\ell) + 4\alpha(n)2^{n-\ell} \cdot (T(\ell) + 2^{\ell})\right) \\
&< \mathrm{poly}(n) \cdot \left(2^{|n-\ell|} \cdot T(\ell) + 4\alpha(n)2^{n-\ell} \cdot (2 \cdot 2^{\ell})\right) \\
&< \mathrm{poly}(n) \cdot \left(2^{n-pn/2} \cdot T(pn/2) + \alpha(n) \cdot 2^{n}\right)
\end{aligned}$$

time steps, where the first summand on the LHS upper bounds the total running time of all the learning algorithms that are running over non-bad subcubes, and the second summand bounds the total running time of all the learning algorithms that are running over the (at most $4\alpha(n)2^{n-\ell}$) many bad subcubes. As discussed at the beginning of the proof, this establishes the lemma. ◀

3.1 An application of Lemma 3: learning LTF-of-AC^0 and Parity-of-AC^0

In this subsection we use Lemma 3 to obtain non-trivial exact learning algorithms for LTF-of-AC^0 and Parity-of-AC^0 circuits. As discussed at the start of Section 3, it does not seem possible to obtain a non-trivial exact learning algorithm for LTF-of-AC^0 using known uniform-distribution learning results. The learning algorithm for Parity-of-AC^0 that we give in this subsection achieves significantly better savings than the algorithm from Section 2.1, and moreover does not require membership queries.

In order to apply Lemma 3 we need a suitable switching lemma from $\mathcal{C}$ to $\mathcal{C}'$ and a learning algorithm for $\mathcal{C}'$. Looking ahead, for LTF-of-AC^0 the class $\mathcal{C}'$ will be the class of low-degree polynomial threshold functions, and for Parity-of-AC^0 it will be the class of low-degree $\mathbb{F}_2$ polynomials. We can use the same switching lemma for both results; to describe the switching lemma we need, we recall some terminology from [18]. Let $\mathcal{G}$ be a family of Boolean functions. A decision tree T is said to be a *common ℓ-partial decision tree for $\mathcal{G}$* if every $g \in \mathcal{G}$ can be expressed as T with depth-ℓ decision trees hanging off its leaves. (Equivalently, for every $g \in \mathcal{G}$ and root-to-leaf path π in T, we have that $g \restriction \pi$ is computed by a depth-ℓ decision tree.)

If g is a Boolean function and $\mathcal{C}$ is a class of circuits, we say that g is *computed by a $(t, \mathcal{C})$-decision tree* if g is computed by a decision tree of depth t (with single Boolean variables x_i at internal nodes as usual) in which each leaf is labeled by a function from $\mathcal{C}$. We write DT_k to denote the class of depth-k decision trees.

We use a recent powerful switching lemma for multiple DNFs due to Håstad [18] (a similar switching lemma was independently obtained by [21]):[3]

[3] We note that this multi-switching lemma is the key technical ingredient in [41]'s sharpening of the [29] Fourier concentration result which gave our AC^0 learning result in Section 2.1.

▶ **Theorem 4** ([18] multi-switching lemma). *Let $\mathcal{F} = \{F_1, \ldots, F_S\}$ be a collection of depth-2 circuits with bottom fan-in w. Then for any $t \geq 1$,*

$$\mathop{\mathbf{Pr}}_{\boldsymbol{\rho} \leftarrow \mathcal{R}_p} \left[\mathcal{F} \restriction \boldsymbol{\rho} \text{ does not have a common } (\log S)\text{-partial DT of depth} \leq t \right] \leq S(24pw)^t.$$

We will use the following simple corollary for AC^0 circuits augmented with some gate G on top as our "switching lemma from $\mathcal{C}$ to $\mathcal{C}'$" in Lemma 3 (see Appendix A for the proof):

▶ **Corollary 5.** *Let G be any Boolean function, and let F be a size-S depth-$(d+1)$ $G \circ \mathsf{AC}^0$ circuit (where we view G as a single gate at the output of the circuit). Then for $p = \frac{1}{48}(48 \log S)^{-(d-1)}$ and any $t \geq 1$,*

$$\mathop{\mathbf{Pr}}_{\boldsymbol{\rho} \leftarrow \mathcal{R}_p} \left[F \restriction \boldsymbol{\rho} \text{ is not computed by a } (2^d t, G \circ \mathsf{DT}_{\log S})\text{-decision tree} \right] \leq d \cdot S \cdot 2^{-t}.$$

For the exact learning results we need, we recall the following well-known facts (the first follows easily from [31], see e.g. [19], and the second follows easily from Gaussian elimination):

▶ **Fact 6.**

1. *There is an exact learning algorithm (using equivalence queries only) that learns degree-d polynomial threshold functions (PTF) over ℓ Boolean variables in time* $\mathrm{poly}(\binom{\ell}{\leq d})$.
2. *The same running time holds for exact learning degree-d $\mathbb{F}_2$ polynomials (again using equivalence queries only).*

All the pieces are now place for our exact learning algorithms for LTF-of-AC^0 and parity-of-AC^0:

▶ **Theorem 7.**

1. *There is an exact learning algorithm (using equivalence queries only) that learns the class of size-S depth-$(d+1)$ LTF-of-AC^0 circuits over $\{0,1\}^n$ in time $S \cdot 2^{n - n/O(\log S)^{d-1}}$.*
2. *The same running time holds for exact learning size-S depth-$(d+1)$ Parity-of-AC^0 (again using equivalence queries only).*

Proof. We prove part (1) first (part (2) is almost identical). Let $\mathcal{C}'$ be the class of all PTFs of degree $2^d t + \log S$ (where t will be chosen later). We observe that any $\mathsf{LTF} \circ \mathsf{DT}_{\log S}$ circuit computes a PTF of degree $\log S$, and moreover that any $(2^d t, \mathsf{LTF} \circ \mathsf{DT}_{\log S})$-decision tree computes a PTF of degree $2^d t + \log S$. Applying part (1) of Fact 6, Corollary 5, and Lemma 3 with p as in Corollary 5 and choosing $t = 0.1pn/(2 \cdot 2^d)$, we get the desired learning algorithm. Part (2) follows similarly but now using the observation that any $(2^d t, \mathsf{PAR} \circ \mathsf{DT}_{\log S})$-decision tree computes an $\mathbb{F}_2$ polynomial of degree $2^d t + \log S$. ◀

4 Learning with non-trivial savings via Nečiporuk's method

In this section we present our third technique for learning with non-trivial savings. This technique is based on Nečiporuk's method, which gives a lower bound on the complexity of a function f (in various computational models such as formula size, branching program size, etc.) in terms of the number of subfunctions of f. In more detail, Nečiporuk's theorem essentially says that if the variables of f can be partitioned into disjoint subsets $S_1, S_2, \ldots$ such that the product, across all i, of (the number of distinct subfunctions than can arise when all variables in $[n] \setminus S_i$ are fixed to constants in all $2^{n-|S_i|}$ possible ways) is large, then f must have high complexity. Our technique is based on a contrapositive view: if f is a function of "not too high" complexity, then in any partition of the variables into

"large" equal-size subsets, $S_1, S_2, \ldots$ there must be some S_i over which f has "not too many" distinct subfunctions – in particular, far fewer than $2^{n-|S_i|}$, the number of distinct subcubes corresponding to the restrictions that fix all variables in $[n] \setminus S_i$. We show that this structure (having "few" subfunctions over a "large" subset of variables) can be exploited to learn f with non-trivial savings.

Warmup: Compression

In Section 4.1 we first develop this idea for the easier problem of compression rather than learning. We obtain a new and simpler algorithm and analysis recovering the deterministic compression results of [12] for $n^{1.99}$-size full-basis binary formulas and $n^{1.99}$-size branching programs. ([12] had to develop new high-probability analyses of shrinkage under random restrictions using novel martingale arguments and combine these analyses with a generalization of the greedy set-cover heuristic, whereas we only use the statement of Nečiporuk's theorem in a black-box way together with short and elementary arguments.) Thanks to the generality of Nečiporuk's method, our algorithm and analysis also yields new deterministic compression results for switching networks of size $n^{1.99}$, switching-and-rectifier networks of size $n^{1.49}$, non-deterministic branching programs of size $n^{1.49}$, and span programs of size $n^{1.49}$.

Learning

Progressing from compression to learning, next in Section 4.2 we describe how pre-processing can be used to create a data structure which enables a highly efficient implementation of the classic "halving algorithm" from learning theory. While a naive implementation of the halving algorithm to learn an unknown function from a class of N functions over an M-element domain takes time $O(NM)$, we show that by first carrying out a pre-processing step taking time $M^{O(\log N)}$ it is possible to run the halving algorithm in time only $\mathrm{poly}(\log N, \log M)$, an *exponential* savings. This means that if we need to run the halving algorithm many times, by first running the pre-processing step (which needs to be done only once) we can carry out these many runs of the halving algorithm in a highly efficient *amortized* way. Intuitively, running the halving algorithm many times is precisely what we need to do in our Nečiporuk-based learning approach: if S is the "large" subset of variables such that f has "not too many" subfunctions over S, then we will run the halving algorithm $2^{n-|S|}$ times, once for each possible subcube keeping the variables in S free, to learn the corresponding $2^{n-|S|}$ different restrictions of f.

Finally, in Section 4.3 we describe and analyze our general learning algorithm based on Nečiporuk's method. The algorithm has three stages: in the first stage, membership queries are used to randomly sample subcubes corresponding to S, which are exhaustively queried to learn the subfunctions they contain. In this way the first stage constructs a set A containing all "important" subfunctions (ones that occur in "many" subcubes); crucially, thanks to the Nečiporuk argument, the set is not too large (since there are "few" distinct subfunctions in total, important or otherwise). The second stage performs the above-described pre-processing on the set A of subfunctions, and the third stage runs the halving algorithm over all $2^{n-|S|}$ subcubes corresponding to S in the efficient amortized way described above. This results in a hypothesis which is exactly correct on every subcube containing an "important" subfunction; by definition there are only "few" subcubes that contain non-important subfunctions, and the hypothesis can be patched up on those subcubes at relatively small cost.

4.1 Compression based on having few subfunctions

Given $f : \{0,1\}^n \to \{0,1\}$ and $S \subseteq [n]$, let $\mathcal{R}_S$ denote the set of all $2^{n-|S|}$ restrictions that leave precisely the variables in S free and assign either 0 or 1 to each element of $[n] \setminus S$ in all possible ways. Let $\mathrm{Num}(f, S)$ denote the number of distinct functions from $\{0,1\}^S$ to $\{0,1\}$ that occur in $\{f \restriction \rho\}_{\rho \in \mathcal{R}_S}$ (i.e. that occur as subfunctions of f).

▶ **Lemma 8** (Compression based on few subfunctions). *Fix any partition $S_1, S_2, \ldots, S_{n^{1-\delta}}$ of $[n]$ into equal-size subsets S_i of size n^δ each, where $\delta > 0$. Let $\mathcal{C}$ be a class of n-variable functions such that for each $f \in \mathcal{C}$ there is a set S_i such that $\mathrm{Num}(f, S_i) \leq 2^{n^\beta}$, where $\beta < 1$. Then there is a compression algorithm for $\mathcal{C}$ running in time $2^{O(n)}$ with savings n^δ (i.e. given as input the truth table of any $f \in \mathcal{C}$, the algorithm outputs a circuit computing f of size $\mathrm{poly}(n) \cdot 2^{n-n^\delta}$).*

Proof. Fix $f \in \mathcal{C}$, and say that any $i \in [n^{1-\delta}]$ for which $\mathrm{Num}(f, S_i) \leq 2^{n^\beta}$ is *good*. The compression algorithm works as follows:

1. For $i = 1, 2, \ldots$ check whether i is good by building a sorted list of all the distinct subfunctions occuring in $\{f \restriction \rho\}_{\rho \in \mathcal{R}_{S_i}}$. This can be done in time $2^{O(n)}$. The hypothesis of the lemma ensures that some i is good; in the following steps for notational simplicity we suppose that $i = 1$ is good. So at this point the algorithm has a sorted list L containing at most 2^{n^β} truth tables (each being an 2^{n^δ}-bit string), and for every $\rho \in \mathcal{R}_{S_1}$ the truth table of $f \restriction \rho$ is in the list.
2. Iterate across all $\rho \in \mathcal{R}_{S_1}$ to construct a function $\Phi : \mathcal{R}_{S_1} \to [2^{n^\beta}]$ such that for each $\rho \in \mathcal{R}_{S_1}$ the value of $\Phi(\rho)$ is the index j such that the truth table of $f \restriction \rho$ is the j-th element of the list L. (Note that the description length of the function Φ is $|\mathcal{R}_{S_1}| \cdot \log(2^{n^\beta}) = \mathrm{poly}(n) \cdot 2^{n-n^\delta}$.) This can be done in time $2^{O(n)}$.
3. Finally, the compression algorithm outputs a circuit which works as follows: given input $x \in \{0,1\}^n$, let ρ_x be the element of $\mathcal{R}_{S_1}$ that is consistent with x (fixing the variables in $[n] \setminus S_1$ according to x). The circuit outputs the appropriate output bit (corresponding to the bit-string x restricted to the coordinates in S_1) from the $\Phi(\rho_x)$-th truth table of L. This circuit computes f and is of size $\mathrm{poly}(n) \cdot (|\mathcal{R}_{S_1}| + 2^{n^\delta} \cdot |L|) = \mathrm{poly}(n) \cdot (2^{n-n^\delta} + 2^{n^\delta} \cdot 2^{n^\beta}) \leq \mathrm{poly}(n) \cdot 2^{n-n^\delta}$, and this step can be done in time $2^{O(n)}$.

◀

Given Lemma 8, a direct invocation of the lower bounds provided by Nečiporuk's method for various computational models gives the following corollary, providing a wide range of deterministic compression results. We refer the reader to [23] for detailed definitions of all the computational models mentioned in Corollary 9.

▶ **Corollary 9.** *Boolean n-variable functions computable by computational model $\mathcal{A}$ of size S are compressible in time $2^{O(n)}$ to circuits of size at most 2^{n-n^ε} for a fixed $\varepsilon > 0$, where*

1. *$\mathcal{A}$ = full-basis binary formulas, $S = n^{1.99}$;*
2. *$\mathcal{A}$ = branching programs, $S = n^{1.99}$;*
3. *$\mathcal{A}$ = switching networks, $S = n^{1.99}$;*
4. *$\mathcal{A}$ = switching-and-rectifier networks, $S = n^{1.49}$;*
5. *$\mathcal{A}$ = non-deterministic branching programs, $S = n^{1.49}$;*
6. *$\mathcal{A}$ = span programs, $S = n^{1.49}$.*

Proof. We first give the argument for (1), full-basis binary formulas and $S = n^{1.99}$. We take $\delta = 0.004$ in Lemma 8, so $1 - \delta = 0.996$. Let f be any n-variable function with a full-basis

binary formula of size at most $n^{1.99}$. We recall that Nečiporuk's lower bound for full-basis formula size of f (denoted $L(f)$) implies that

$$\frac{1}{4}\sum_{i=1}^{n^{0.996}} \log(\mathrm{Num}(f, S_i)) \leq L(f) \leq n^{1.99},$$

so there is some $i \in [n^{0.996}]$ such that $\log(\mathrm{Num}(f, S_i)) \leq 4n^{0.994} < n^{0.995}$, so we have $\beta = 0.995$ and obtain the claimed compression result from Lemma 8.

The arguments for (2) and (3) follow similarly, using

$$\tau \cdot \sum_{i=1}^{n^{0.996}} \frac{\log(\mathrm{Num}(f, S_i))}{\log\log(\mathrm{Num}(f, S_i))} \leq S(f) \leq BP(f)$$

(see e.g. Theorem 15.1 of [23]) for some absolute constant τ, where $BP(f)$ denotes the branching program size of f and $S(f)$ denotes the switching network size of f.

(4) and (5) also follow similarly, recalling that Nečiporuk's method gives

$$\frac{1}{4} \cdot \sum_{i=1}^{n^{0.996}} \sqrt{\log(\mathrm{Num}(f, S_i))} \leq RS(f) \leq NBP(f)$$

(see [34]), where $RS(f)$ denotes the rectifier-and-switching network size of f and $NBP(f)$ denotes the non-deterministic branching program size of f. Finally, for (6) we recall that

$$\frac{1}{2} \cdot \sum_{i=1}^{n^{0.996}} \sqrt{\log(\mathrm{Num}(f, S_i))} \leq SPAN(f)$$

(see Theorem 1 of [25]), where $SPAN(f)$ denotes the span program size of f. ◀

4.2 More efficient implementation of the halving algorithm via pre-processing

We begin by recalling the halving algorithm [3, 2, 30] and its running time when it is executed over a domain X of M points to learn an unknown function that is promised to belong to a set $\mathcal{C}$ of at most N (known) functions, where each function in $\mathcal{C}$ may be viewed simply as a truth table of length M. (In the context of the previous subsection the domain size M corresponds to 2^{n^δ}, the number of points in each subcube, and N corresponds to 2^{n^β}, the number of subfunctions.) Recall that after a set A of labeled examples has been received, the *version space* of A is the subset of functions in $\mathcal{C}$ that are consistent with A. At each stage in the halving algorithm's execution, its current hypothesis is the majority vote over the version space of the labeled examples received thus far. Before any counterexamples have been received, initially the version space is all of $\mathcal{C}$; thus the first thing that the halving algorithm does is spend NM time to (a) read the entire bit-matrix corresponding to the current version space $\mathcal{C}$ (think of this matrix as having N columns, which are the truth tables of the functions in the class, and M rows corresponding to the points in the domain) and (b) for each row compute and record the majority vote over the elements in this row (which is the initial hypothesis). The halving algorithm gets a counterexample, and then updates its version space; since its hypothesis was the majority vote of all functions in the previous version space, at least half of the columns (the functions that are inconsistent with the counterexample) are erased, and the size of the version space goes down by at least 1/2.

To form the next hypothesis the halving algorithm spends at most $(N/2)M$ time to read the matrix corresponding to the current version space and for each row compute and record the majority vote over the surviving elements in this row. This proceeds for at most $\log N$ steps, after which the version space must be of size one, and this sole surviving function must be the unknown target function. In the i-th stage the time required is $(N/2^i)M$ so the overall runtime is $O(NM)$. (Note that if the halving algorithm were performed separately and independently Z times (corresponding in our setting to the $Z = 2^{n-|S|}$ many distinct subcubes), the overall runtime would be $ZNM > 2^n$, which is too expensive for learning with non-trivial savings.)

The following lemma shows that the halving algorithm can be implemented *exponentially* more efficiently after an initial pre-processing stage. (Crucially, the pre-processing can be done only once even if the halving algorithm will be run many times; this leads to a tremendous amortized savings.) While simple, we are not aware of previous work giving an efficient amortized implementation of the halving algorithm.

▶ **Lemma 10.** *Given a class $\mathcal{C}$ of N functions over an M-point domain X, there is a pre-processing procedure that (i) can be carried out in time $M^{O(\log N)}$ and (ii) creates a data structure* DS *such that given access to* DS*, the halving algorithm can be run to learn an unknown $f \in \mathcal{C}$ in time* $\mathrm{poly}(\log N, \log M)$*. (Consequently, given access to* DS*, the halving algorithm can be run Z times to learn a sequence $f_1, \ldots, f_Z$ of functions from $\mathcal{C}$ in total time $Z \cdot \mathrm{poly}(\log N, \log M)$.)*

Proof. We first describe the data structure DS and then establish (i) by explaining how it can be constructed in $M^{O(\log N)}$ time. We then establish (ii) by showing how DS can be used to run the halving algorithm efficiently.

The data structure DS

We say that a *size-i sample* is a set of precisely i labeled pairs $(x^1, y^1), \ldots, (x^i, y^i)$ where $x^1, \ldots, x^i$ may be any i distinct elements of X and $(y^1, \ldots, y^i)$ may be any bit-string in $\{0,1\}^i$. We write SAMP_i to denote the set of all size-i samples, so $|\mathsf{SAMP}_i| = \binom{M}{i} \cdot 2^i \leq (2M)^i$. Observe that some elements of SAMP_i may not be consistent with any function $f \in \mathcal{C}$, while others may be consistent with many elements of $\mathcal{C}$.

The data structure DS consists of $\log N$ different "structures" which we refer to as $\mathcal{S}_0, \ldots, \mathcal{S}_{1+\log N}$. The i-th structure $\mathcal{S}_i$ is a set of (at most) $(2M)^i$ many "i-substructures" $\{\mathcal{S}_{i,\mathsf{samp}}\}_{\mathsf{samp} \in \mathsf{SAMP}_i}$ which are indexed by elements of SAMP_i. Given an element $\mathsf{samp} = \{(x^1, y^1), \ldots, (x^i, y^i)\} \in \mathsf{SAMP}_i$, an i-substructure $\mathcal{S}_{i,\mathsf{samp}}$ has two parts: the "main part" $\mathsf{MAIN}(\mathcal{S}_{i,\mathsf{samp}})$ and one additional function (which we explain and give notation for below). The main part $\mathsf{MAIN}(\mathcal{S}_{i,\mathsf{samp}})$ is the subset of $\mathcal{C}$ that contains precisely those concepts in $\mathcal{C}$ that are consistent with samp, i.e. those functions $f \in \mathcal{C}$ that have $f(x^j) = y^j$ for all $j \in [i]$. The one additional function is $\mathsf{MAJ}(\mathsf{MAIN}(\mathcal{S}_{i,\mathsf{samp}}))$, the function that outputs, on any input $x \in X$, the majority vote over all the concepts in $\mathsf{MAIN}(\mathcal{S}_{i,\mathsf{samp}})$. This concludes the description of a generic i-substructure $\mathcal{S}_{i,\mathsf{samp}}$, and thus concludes the description of the i-th structure $\mathcal{S}_i$.

For example, the zeroth structure $\mathcal{S}_0$ consists of only one 0-substructure (since there is only one "empty sample" with no labeled pairs); call this 0-substructure $\mathcal{S}_{0,\mathsf{samp}_\emptyset}$. We have $\mathsf{MAIN}(\mathcal{S}_{0,\mathsf{samp}_\emptyset}) = \mathcal{C}$ (since every concept is consistent with the empty sample) and the one additional function is just the first hypothesis that the halving algorithm uses, the majority vote across $\mathcal{C}$.

Construction of DS

Suppose that $\mathcal{S}_{i-1}$, the $(i-1)$-st structure, has been constructed by the pre-processing procedure. The structure $\mathcal{S}_i$ is built from $\mathcal{S}_{i-1}$ as follows. $\mathcal{S}_i$ has exactly $2^i\binom{M}{i}$ substructures, one for each possible samp of size i. Consider such a $\mathsf{samp} = \{(x^1, y^1), \ldots, (x^i, y^i)\}$, and let samp' be $\{(x^1, y^1), \ldots, (x^{i-1}, y^{i-1})\}$, its length-$(i-1)$ prefix. Since $\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'})$ has been constructed already as part of $\mathcal{S}_{i-1}$, given x^i it is easy to enumerate over the functions in $\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'})$ and partition them into two groups; the functions f for which $f(x^i) = 0$ will go into $\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'\cup\{(x^i,0)\}})$ and the ones for which $f(x^i) = 1$ will go into $\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'\cup\{(x^i,1)\}})$. Finally once we have $\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'\cup\{(x^i,y^i)\}})$ it is straightforward to read the corresponding matrix and construct the one additional function $\mathsf{MAJ}(\mathsf{MAIN}(\mathcal{S}_{i-1,\mathsf{samp}'\cup\{(x^i,y^i)\}}))$. It is not hard to see that the total size of $\mathcal{S}_i$, and the total time required to build it from $\mathcal{S}_{i-1}$, is at most $(2M)^i \cdot O(NM)$. Even when $i = \log N$ this is at most $O(N \cdot M^{\log N} \cdot NM) = M^{O(\log N)}$.

Using DS to run the halving algorithm efficiently

Now we describe how to emulate the halving algorithm in total time $\mathrm{poly}(\log N, \log M)$ given access to the structures $\mathcal{S}_0, \ldots, \mathcal{S}_{\log N}$. The initial hypothesis of the halving algorithm is the additional function $\mathsf{MAJ}(\mathsf{MAIN}(\mathcal{S}_{0,\mathsf{samp}_\emptyset}))$, i.e. the majority vote over all functions in $\mathcal{C}$, so the emulator for the halving algorithm need only "point to" this portion of DS to construct its initial hypothesis. On receiving a first labeled counterexample (x^1, y^1), the hypothesis of the halving algorithm is then precisely $\mathsf{MAJ}(\mathsf{MAIN}(\mathcal{S}_{1,\{(x^1,y^1)\}}))$; conveniently, this has been pre-computed as part of $\mathcal{S}_1$, so the emulator again only needs to point to this portion of DS to construct its second hypothesis. On receiving a second labeled counterexample (x^2, y^2), the emulator updates its hypothesis by pointing to $\mathsf{MAJ}(\mathsf{MAIN}(\mathcal{S}_{2,\{(x^1,y^1),(x^2,y^2)\}}))$ as its hypothesis, and so on. This goes on for at most $\log N$ stages, and it is clear that each stage requires time at most $\mathrm{poly}(\log N, \log M)$, giving (ii) as claimed. ◀

4.3 The general learning result based on Nečiporuk's method

With Lemma 10 in hand, we are ready to state and prove our general learning result based on Nečiporuk's method. As suggested earlier, the approach is to first do random sampling to identify the "important" subfunctions (ones which occur in many subcubes), then run the pre-processing procedure using these important subfunctions and the halving algorithm to efficiently learn over all subcubes containing important subfunctions, patching up the hypothesis on any subcubes that do not contain important subfunctions.

▶ **Lemma 11** (Learning based on few subfunctions). *Fix any partition $S_1, S_2, \ldots, S_{n^{1-\delta}}$ of $[n]$ into equal-size subsets S_i of size n^δ each, where $\delta > 0$. Let $\mathcal{C}$ be a class of n-variable functions such that for each $f \in \mathcal{C}$ there is a set S_i such that $\mathrm{Num}(f, S_i) \leq 2^{n^\beta}$, where $\beta < 1$ and moreover $\beta + \delta < 1$. Then there is a randomized exact learning algorithm for $\mathcal{C}$ that uses membership and equivalence queries and achieves savings n^δ.*

Proof. We describe a randomized learning algorithm which works on S_1 and achieves the claimed runtime bound with high probability if $\mathrm{Num}(f, S_1) \leq 2^{n^\beta}$. If the algorithm runs for more than the claimed number of steps while working on S_1, it aborts and restarts, this time working on S_2, and so on. Hence in the following discussion we assume without loss of generality that $\mathrm{Num}(f, S_1) \leq 2^{n^\beta}$.

The learning algorithm works on S_1 in three stages as described below.

First stage: Identify important subfunctions

Recall that $\mathcal{R}_{S_1}$ is the set of all $2^{n-|S_1|} = 2^{n-n^\delta}$ restrictions that leave precisely the variables in S_1 free. Let $g_1, \ldots, g_{\mathrm{Num}(f,S_1)}$ be the subfunctions that occur in $\{f \restriction \rho\}_{\rho \in \mathcal{R}_{S_1}}$. For $i \in [\mathrm{Num}(f, S_1)]$ let p_i denote the fraction of the 2^{n-n^δ} subcubes in $\mathcal{R}_{S_1}$ that have g_i as the subcube there. We say that a subfunction g_i is *important* if $p_i \geq \varepsilon/(10 \cdot \mathrm{Num}(f, S_1))$ (we will specify the value of ε later). Let $F' \subseteq \{g_1, \ldots, g_{\mathrm{Num}(f,S_1)}\}$ be the set of all important subfunctions.

In the first stage we draw $A := 20n \cdot 2^{n^\beta}/\varepsilon$ independent uniform random elements of $\mathcal{R}_{S_1}$, and for each one we spend 2^{n^δ} many membership queries to exhaustively learn the associated truth table in time $\mathrm{poly}(n) \cdot 2^{n^\delta}$; let $F \subseteq \{g_1, \ldots, g_{\mathrm{Num}(f,S_1)}\}$ be the set of all the subfunctions that are discovered in this way. For any given fixed important subfunction, the probability that it is not included in F is at most $(1-\varepsilon/(10 \cdot \mathrm{Num}(f, S_1)))^A \leq (1-\varepsilon/(10 \cdot 2^{n^\beta}))^A < 1/2^{2n}$, so a union bound over all (at most 2^{n^β}) important subfunctions gives that with probability at least $1 - 1/2^n$ the set F contains the set F' of important subfunctions (for the rest of the algorithm's analysis and execution we suppose that indeed F contains F'). We observe that by the definition of F', at most an $\varepsilon/10$ fraction of all $\rho \in \mathcal{R}_{S_1}$ are such that $f \restriction \rho$ do not belong to F', and hence at most an $\varepsilon/10$ fraction of all $\rho \in \mathcal{R}_{S_1}$ are such that $f \restriction \rho$ do not belong to F.

Note that the total running time for the first stage of the algorithm is $2^{n^\delta} \cdot \mathrm{poly}(n) \cdot 2^{n^\beta}/\varepsilon$.

Second stage: Do the pre-processing on F

Next, the algorithm performs the pre-processing described in the previous subsection on the $N = |F|$ functions in F, each of which is defined over the $M = 2^{n^\delta}$-size domain $\{0,1\}^{S_1}$. Since $N \leq 2^{n^\delta}$ we have that this takes time at most $M^{O(\log N)} < 2^{O(n^\beta \cdot n^\delta)}$.

Third stage: Run the halving algorithm in parallel over all $Z := 2^{n-n^\delta}$ subcubes in $\mathcal{R}_{S_1}$ using the data structure DS from Lemma 10

In the amortized analysis of the halving algorithm with pre-processing given in the previous subsection, we assumed that every execution of the halving algorithm was performed on a target function that actually belonged to the class $\mathcal{C}$. In our current setting there may be up to $(\varepsilon/10) \cdot 2^{n-n^\delta}$ many subcubes that contain functions that are not in F. When the halving algorithm is run over a subcube that contains a subfunction in F, it will correctly converge to the target subfunction over that subcube after at most $\log N \leq n^\beta$ many counterexamples, and the efficient implementation of the halving algorithm via pre-processing will work correctly over that subcube. This will happen on at least $1 - \varepsilon/10$ fraction of all 2^{n-n^δ} subcubes. For the remaining (at most $(\varepsilon/10) \cdot 2^{n-n^\delta}$) subcubes that have a subfunction not on our list, the halving algorithm may not work correctly. If, in a given subcube, the version space ever vanishes (note that if this happens it must happen after at most $\log N$ counterexamples from that subcube), or it has size greater than one after $\log N$ counterexamples, then it must be the case that that subcube's subfunction does not belong to F. In this case the algorithm uses 2^{n^δ} membership queries to "patch up" the hypothesis over this subcube (which can be done in time $\mathrm{poly}(n) \cdot 2^{n^\delta}$). This happens for at most $(\varepsilon/10) \cdot 2^{n-n^\delta}$ subcubes. Thus, the total running time of this stage will be at most

$$
\begin{aligned}
&(\text{time on subcubes with subfunctions in } F) + (\text{time on other subcubes}) \\
&\leq Z \cdot \mathrm{poly}(\log N, \log M)) + (\varepsilon/10) \cdot 2^{n-n^\delta} \cdot \mathrm{poly}(n) \cdot 2^{n^\delta} \\
&\leq \mathrm{poly}(n) \cdot \left(2^{n-n^\delta} + (\varepsilon/10) \cdot 2^n\right).
\end{aligned}
$$

Hence the total running time for all stages can be upper bounded by

$$2^{n^\delta} \cdot \mathrm{poly}(n) \cdot 2^{n^\beta}/\varepsilon + 2^{O(n^\beta \cdot n^\delta)} + \mathrm{poly}(n) \cdot \left(2^{n-n^\delta} + (\varepsilon/10) \cdot 2^n\right).$$

Recalling that by assumption $\beta + \delta < 1$, we may take $\varepsilon = 2^{-n/2}$, and the overall running time is at most $\mathrm{poly}(n) \cdot 2^{n-n^\delta}$. ◀

4.4 Instantiating Lemma 11 using Nečiporuk's lower bounds

The proof of Corollary 9 extends unchanged to give our concrete learning results based on Nečiporuk's lower bounds:

▶ **Corollary 12.** *There is a randomized exact learning algorithm, using membership and equivalence queries, to learn Boolean n-variable functions computable by computational model $\mathcal{A}$ of size S in time 2^{n-n^ε} for a fixed $\varepsilon > 0$, where $\mathcal{A}$ and S can be instantiated as in items (1)–(6) of Corollary 9.*

5 Conclusion

We initiated the study of learning algorithms with non-trivial savings and gave a range of such learning algorithms for various natural circuit classes. There are many intriguing problems left open by our work, we list a few.

- Our learning algorithms of Sections 3 and 4 are based on influential lower bound techniques in circuit complexity, namely the method of random restrictions and Nečiporuk's lower bound method. Can other proof techniques from circuit complexity, such as Razborov's method of approximations for monotone circuit lower bounds [35, 36] or the "polynomial method" for various classes of constant-depth circuits [5], similarly be leveraged to obtain non-trivial learning algorithms?
- Related to the previous item, there are several prominent circuit classes for which lower bounds are known but we do not yet have non-trivial learning algorithms; examples include intersections of $\mathrm{poly}(n)$ many LTFs, de Morgan formulas of size $n^{2.99}$, monotone formulas of significantly sublinear depth, monotone circuits of polynomial size, etc. Can we develop learning algorithms with nontrivial savings for these classes?
- We strongly suspect that many of our learning results, specifically the ones for AC^0, LTF-of-AC^0, parity-of-AC^0, and all the classes covered by Corollary 12, are best possible given the state of the art of circuit lower bounds. If we had *deterministic* learning algorithms then this would follow from the work of [28] (see their Theorem 1). Is it possible to design deterministic algorithms for these classes (or alternatively, to extend Theorem 1 of [28] to cover randomized learning algorithms)?
- Finally, we close with an ambitious twist on the previous bullet: in the spirit of recent celebrated work [43, 44] wringing exciting new circuit lower bounds from non-trivial satisfiability algorithms, is it possible to leverage ideas from non-trivial learning algorithms to obtain new circuit lower bounds?

A Proof of Corollary 5

Proof. We shall assume that the depth-$(d+1)$ circuit F is *layered*, meaning that for any gate g it contains, every directed path from an input variable to g has the same length (converting an unlayered circuit to a layered one increases its size only by a factor of d). We prove the corollary with a failure probability of $S \cdot 2^{-t}$ for such layered circuits. Let S_i denote the number of gates in layer i (at distance i from the inputs), so $S = S_1 + \cdots + S_d$.

We begin by trimming the bottom fan-in of F: applying Theorem 4 with $\mathcal{F}$ being the S_1 many bottom layer gates of F (viewed as depth-2 circuits of bottom fan-in $w = 1$) and $p_0 := 1/48$, we get that

$$\begin{aligned}&\mathop{\mathbf{Pr}}_{\boldsymbol{\rho} \leftarrow \mathcal{R}_{p_0}} \left[F \restriction \boldsymbol{\rho} \text{ is not a } (t, G \circ \mathsf{AC}^0(\text{depth } d, \text{ bottom fan-in } \log S))\text{-decision tree} \right] \\ &\leq S_1 \cdot 2^{-t}.\end{aligned}$$

Let $F^{(0)}$ be any good outcome of the above, a $(t, G \circ \mathsf{AC}^0(\text{depth } d, \text{ bottom fan-in } \log S))$-decision tree. Note that there are at most 2^t many $\mathsf{AC}^0(\text{depth } d, \text{ fan-in } \log S)$ circuits at the leaves of the depth-t decision tree. Applying Theorem 4 to each of them with $p_1 := 1/(48 \log S)$ (and the 't' of Theorem 4 being $2t$) and taking a union bound over all 2^t many of them, we get that

$$\begin{aligned}&\mathop{\mathbf{Pr}}_{\boldsymbol{\rho} \leftarrow \mathcal{R}_{p_1}} \left[F^{(0)} \restriction \boldsymbol{\rho} \text{ is not a } (t + 2t, G \circ \mathsf{AC}^0(\text{depth } d - 1, \text{ fan-in } \log S))\text{-decision tree} \right] \\ &\leq S_2 \cdot 2^{-2t} \cdot 2^t = S_2 \cdot 2^{-t}.\end{aligned}$$

Repeat with $p_2 = \ldots = p_{d-1} := 1/(48 \log S)$, each time invoking Theorem 4 with its 't' being the one more than the current depth of the decision tree, so at the j-th invocation Theorem 4 is invoked with its 't' being 2^{j-1}. The claim then follows by summing the $S_1 2^{-t}$, $S_2 2^{-t}, \ldots, S_d 2^{-t}$ failure probabilities over all d stages and the fact that

$$\prod_{j=0}^{d-1} p_i = \frac{1}{48} \cdot \frac{1}{(48 \log S)^{d-1}}.$$ ◀

Expander Construction in VNC^1

Abstract

We give a combinatorial analysis (using edge expansion) of a variant of the iterative expander construction due to Reingold, Vadhan, and Wigderson [38], and show that this analysis can be formalized in the bounded arithmetic system VNC^1 (corresponding to the "NC^1 reasoning"). As a corollary, we prove the assumption made by Jeřábek [24] that a construction of certain bipartite expander graphs can be formalized in VNC^1. This in turn implies that every proof in Gentzen's sequent calculus LK of a monotone sequent can be simulated in the monotone version of LK (MLK) with only polynomial blowup in proof size, strengthening the quasipolynomial simulation result of Atserias, Galesi, and Pudlák [7].

1 Introduction

Expander graphs have become one of the most useful combinatorial objects in theoretical computer science, with many beautiful applications in computer science and mathematics [19], and responsible for several breakthroughs in computational complexity [37, 17]. These graphs have seemingly contradictory properties: sparseness and high connectivity. The high connectivity can be measured in a number of different, but essentially equivalent ways: vertex expansion (every small subset of vertices "expands", i.e., has a larger neighborhood), edge expansion (every small subset of vertices has many edges leaving the set), or fast mixing time (a random walk on a regular expander graph quickly converges to the uniform distribution on vertices).

The existence of expander graphs of constant degree can be argued nonconstructively using a simple probabilistic argument: for any constant $d \geq 3$, a random d-regular graph is almost surely an expander [33]. Constructing such graphs efficiently deterministically is much more difficult. The first explicit constructions were given by Margulis [27] and Gabber and Galil [18]. Lubotzky, Phillips, and Sarnak [25] gave a construction of expanders with particularly interesting properties, called Ramanujan graphs. All of these constructions are algebraic in nature: a graph is defined using a certain algebraic object (e.g., a group). Moreover, the analysis of correctness of the constructions is also algebraic. It relies on the algebraic notion of high connectivity called the *eigenvalue gap* and defined as follows. Consider the adjacency matrix of a given undirected d-regular graph, compute its eigenvalues, and order them according to the absolute value. It can be easily checked that d is the largest value. The difference between d and (the absolute value of) the second largest eigenvalue is the eigenvalue gap. The bigger this eigenvalue gap, the more connected the graph is. From this point of view, a d-regular expander is a graph with the eigenvalue gap at least $\Omega(d)$, i.e., the second largest eigenvalue should be at most some constant fraction of the degree.

A simpler, fully combinatorial construction of constant-degree expanders was given by Reingold, Vadhan, and Wigderson [38]. They started with constant-size expander graphs (which can found by brute-force search), and iteratively applied certain graph operations that increase the size of the graph while preserving its expansion property. This way, one can quickly construct an expander graph of any given size. While the construction of [38] is combinatorial, its analysis is still algebraic and is based on estimating the eigenvalue gap. Alon, Schwartz, and Shapira [4] gave a different construction of expanders, which combines algebraically constructed expanders of Alon and Roichman [3] with only two applications of a certain graph operation (replacement product), to obtain a constant-degree expander of arbitrary size. They also gave a fully combinatorial analysis of the replacement product operation they used in the second stage of the construction. Their full analysis, however, is still algebraic, as it relies on the algebraic construction and the eigenvalue gap analysis of [3]. In this respect, the situation in [4] is similar to that in [38] where the analysis of a related graph operation (zig-zag product) can be done in terms of min-entropy, while the analysis of the complete construction is still based on eigenvalues.

The focus of our paper is to give a construction of expanders with a simple (non-algebraic) analysis, where simplicity is measured in terms of the power of a system of bounded arithmetic needed to formalize the analysis. Informally, systems of bounded arithmetic are obtained by restricting the power of the standard first-order theory of Peano arithmetic. It is possible to devise systems of bounded arithmetic that correspond to systems of reasoning using only concepts from a given complexity class, e.g., P or NC^1. A natural question is: what is the weakest complexity class so that the existence of expander graphs can be proved using only the concepts of that complexity class?

The known expander constructions mentioned above can be formalized within a system of polytime reasoning, intuitively because eigenvalues and matrix determinants are known to be computable in polytime. Our main result is a construction of expanders that can be formalized within a system of NC^1 reasoning, VNC^1 (see below for a formal definition). As NC^1 algorithms are not known to compute the eigenvalues or determinant of a given matrix, any such formalization of an expander construction in VNC^1 must necessarily avoid the use of eigenvalues, and hence be "combinatorial" in that sense.

As expanders are used in a number of complexity-theoretic results, formalizing the expander construction within a weak system of bounded arithmetic is an important step in formalizing these complexity-theoretic results within the bounded arithmetic framework, which in turn may have other implications. For example, in proof complexity, we can use

our expander construction to argue that any Gentzen's sequent calculus LK proof (of a monotone sequent) can be simulated by a *monotone* LK (MLK) proof, with only polynomial blowup in proof size, improving upon the quasipolynomial simulation shown by Atserias, Galesi and Pudlák [7], and answering a question of Pudlák and Buss [36]. This simulation result follows by the work of Jeřábek [24] who proved the result under the assumption that a certain expander graph family can be proved to exist within a system of NC^1 reasoning. Our paper proves a strengthening of the assumption needed by Jeřábek.

1.1 Our results

Our main contribution is the analysis of one of the iterative expander constructions from [38], which we show to be formalizable in the bounded arithmetic system VNC^1 (of NC^1 reasoning). As in [38], the expander construction is *fully explicit* in the sense that that there is a deterministic polynomial-time algorithm that, given a vertex name v in binary and a number i, outputs the value of the rotation map $Rot(v,i) = (w,j)$, where w is the name of the ith neighbor of v in the graph, and j is the number such that v is the jth neighbor of w. Moreover, we show that there is an alternating linear-time algorithm that accepts exactly the triples of the form $\langle v, i, Rot(v,i)\rangle$; this kind of explicitness is what we will use to argue that the expander construction is formalizable in VNC^1.

▶ **Theorem 1** (Main result: Informal version). *The existence of an expander graph family can be proved using* NC^1 *reasoning only (within the system* VNC^1*).*

As our main application, building on Jeřábek [24] and Atserias, Galesi and Pudlák [7], we show that every proof in Gentzen's sequent calculus LK of a monotone sequent can be simulated by a monotone LK (MLK) proof (a sequent calculus proof in which all formulas are positive) with only polynomial blowup in size. This answers a question of Pudlák and Buss [36]. Previously, [7] showed such simulation with quasipolynomial blowup in proof size.

▶ **Theorem 2** (Main application). MLK *polynomially simulates* LK *on monotone sequents.*

It is easy to show that the intuitionistic propositional sequent calculus LJ polynomially simulates MLK (see Pudlák [34] and Bilková [8]); thus we get as an immediate corollary that propositional LJ polynomially simulates LK on monotone sequents, re-proving the result of Jeřábek [22, Theorem 3.9]. Many of the principles that have been considered in propositional proof complexity are expressed as monotone sequents, notably the pigeonhole principle and the clique-coloring tautologies. As these principles have polynomial size LK proofs [11], Theorem 2 implies that they also have polynomial size proofs in MLK as well as in propositional LJ. The prior best known results for the pigeonhole principle were the quasipolynomial size MLK proofs of Atserias, Galesi and Gavaldà [6].

It remains an open problem whether tree-like MLK can polynomially simulate MLK, equivalently whether tree-like MLK can polynomially simulate LK on monotone sequents. Note that [7] gives a quasipolynomial simulation.

Intuitively, to simulate an LK proof within MLK, one needs to construct (and prove correctness of) a monotone formula for the majority function. Such monotone formulas can be built using the classical AKS sorting networks [1]. Jeřábek [24] shows that the analysis of AKS sorting networks can be formalized within a certain system of NC^1 reasoning (slightly more powerful than VNC^1), under the assumption that the existence of expander graphs, with certain parameters, is also formalizable within the same system. Our Theorem 1 proves the assumption needed by Jeřábek (actually a slightly stronger version, as our proof of the existence of expanders is in the weaker system VNC^1), and so Theorem 2 immediately follows.

1.2 Relation to previous work

1.2.1 Expander constructions

The expander graph construction that we analyze is a variant of the iterative construction of expanders given in [38]. The idea is to start with a constant-size expander graph (found, say, by exhaustive search), and iteratively increase the size of the graph while keeping its expansion larger than some universal constant. The notion of expansion used by [38] is in terms of the eigenvalue gap. To analyze the expansion of the final graph, Reingold, Vadhan, and Wigderson [38] bound the effect of the graph operations they used (graph powering, graph tensoring, and zig-zag product) on the second largest eigenvalue of the adjacency matrix of the resulting graph. The analysis of graph powering (where an edge of the kth power of a graph G is a walk of length k in G) and graph tensoring (where an edge of the tensor product of G and H consists of a pair of edges, one from G and one from H) is immediate from the basic linear algebra. The analysis of the zig-zag product (a way to compose a graph G with a graph H so that the new graph has the degree of H) is technically the most difficult part of the algebraic analysis of the expander construction in [38].

In [4], a graph replacement product (closely related to the zig-zag product) is analyzed in terms of edge expansion, avoiding any mention of the eigenvalue gap. Since replacement product can be used instead of zig-zag product in an iterative expander construction along the lines of [38], this gives a combinatorial analysis of the part of the expander construction. In order to make the entire analysis combinatorial, it suffices to analyze graph powering and graph tensoring also in terms of edge expansion. This is exactly what we do in the present paper.

Our combinatorial analysis of graph tensoring, though subtle, is not very difficult. For the analysis to go through, it turns out necessary to work with graphs that have sufficiently many self-loops around every vertex (at least half the degree). On the other hand, graph powering is much more difficult to analyze combinatorially. Fortunately, here we were able to use the result of Mihail [28] who gave a combinatorial analysis of the mixing time of random walks on expanders in terms of edge expansion. (Interestingly, for her proof, she also had to work with graphs that have many self-loops around every vertex.) Finally, using Mihail's bounds, we are able to conclude the analysis of graph powering in terms of edge expansion, borrowing some ideas from [2].

1.2.2 Bounded arithmetic

There is a long history of formalizing complexity results in bounded arithmetic; indeed, this was one of the main motivations for the definitions of bounded arithmetic. First, bounded arithmetic theories can capture a range of complexity classes, from uniform AC^0 and uniform NC^1, to polynomial time, polynomial space and exponential time (see [10, 14]). Second, via the Paris-Wilkie or Cook translations, proofs in bounded arithmetic can be viewed as uniform families of propositional proofs. For this reason, a proof in bounded arithmetic can sometimes yield new propositional proofs.

There has been considerable progress in formalizing advanced results from computational complexity in weak theories of bounded arithmetic; these include approximate counting, randomized computations, and Arthur-Merlin games [20, 21], Toda's theorem [12], and the PCP theorem [32]. The present paper continues this tradition by formalizing the construction of expander graphs in the weak fragment VNC^1 which corresponds to NC^1 computation.

There are a number of prior works which use bounded arithmetic to obtain upper bounds in proof complexity. A big advantage of using bounded arithmetic is that the proofs can

be considerably simplified. A classic example is the work by Paris and Wilkie [29] who showed that the proofs of the weak pigeonhole principle in $I\Delta_0$ constructed by [30] yield constant-depth, polynomial-size Frege proofs of the propositional translations of the weak pigeonhole principle (via the "Paris-Wilkie translation"). Lower-depth, quasipolynomial-size Frege proofs were later given by [26] via a proof of the weak pigeonhole principle in a different fragment of bounded arithmetic. Similarly, [35] gave proofs of Ramsey's theorem in S_2, and these translate into quasipolynomial-size, constant-depth Frege proofs. Recently, [12] used formalization of Toda's theorem in bounded arithmetic with modular counting quantifiers to show that constant-depth $\mathsf{AC}^0(p)$-proofs, for p a prime, can be translated into quasipolynomial size, depth-three propositional proofs, with formulas being Boolean combinations of mod p gates of small conjunctions. Another classic example is Cook's theorem that extended Frege proofs have polynomial size proofs of their partial consistency statements, which was established via provability in PV [15].

The present paper establishes a new result of this type via a Cook-style translation: together with earlier work of Jeřábek [23], our formalization of expander graphs in VNC^1 implies that the monotone propositional proof system MLK polynomially simulates the proof system LK. We will use the system VNC^1 defined by Cook and Morioka [16]. We conservatively extend VNC^1 to facilitate reasoning about the compositions of NC^1 functions, which allows us to simplify the formalization of our recursive expander construction.

1.2.2.1 Remainder of the paper

Section 2 contains basic definitions. Our expander construction is defined in Section 3. In Section 4, we present a construction of bipartite expanders needed by Jeřábek [24]. In Section 5, we show that the existence of our expander graphs is provable in VNC^1, thereby proving a formal version of Theorem 1. We derive Theorem 2 in Section 6. Section 7 contains concluding remarks. For space considerations, some proofs are only sketched and other proofs are omitted from this conference version; for the full version (with all missing proofs), please see [9].

2 Preliminaries

2.1 Notation

We consider undirected graphs, possibly with parallel edges and self-loops. For an undirected graph $G = (V, E)$ on n nodes, we usually associate the vertex set V with the set $[n] = \{1, 2, \ldots, n\}$, and denote an edge $i \sim j$ between nodes i and j as $\{i, j\} \in E$. In this notation, we also allow self-loops $\{i, i\} \in E$.

The adjacencies of a d-regular graph G are given via its rotation map Rot_G so that, for vertex v of G and an index $i \in [d]$, we have $Rot_G(v, i) = (w, j)$ if w is the ith neighbor of v, and v is the jth neighbor of w; so, in particular, the rotation map induces some fixed numbering of neighbors of a given vertex.

For an n-vertex graph G, its *adjacency matrix* is an $n \times n$ matrix A' whose (i, j)th entry contains the number of edges between vertices i and j in G. For d-regular graphs G, it will be more convenient for us to consider the *normalized adjacency matrix* defined as $\frac{1}{d} \cdot A'$. Note that the normalized adjacency matrix A of G is the probability transition matrix for a random walk on G. That is, if π is a probability distribution on vertices of G, then $A\pi$ is the probability distribution induced by one step of a random walk on G starting from a vertex distributed according to π. It is also easy to see that A^k is the normalized adjacency matrix of the graph G^k.

2.2 Expanders

For a graph $G = (V, E)$ and a subset $U \subseteq V$ of vertices, we denote by $\overline{U}$ the set $V \setminus U$, and by $E(U, \overline{U})$ the set of edges between U and $\overline{U}$. The *edge expansion* of a d-regular graph $G = (V, E)$ on n vertices is defined as

$$\min_{\emptyset \neq U \subset V,\ |U| \leq n/2} \frac{|E(U,\overline{U})|}{d \cdot |U|} = \min_{\emptyset \neq U \subset V} \frac{|E(U,\overline{U})|}{d \cdot \min\{|U|, |\overline{U}|\}}. \tag{1}$$

For a graph $G = (V, E)$ and a subset $U \subseteq V$ of vertices, we denote by $\Gamma_G(U)$ the set of all neighbors of U in G, i.e.,

$$\Gamma_G(U) = \{v \in V \mid \exists u \in U, \{u, v\} \in E\}.$$

We drop the subscript G if the graph G is understood from the context. We denote by $\Gamma^+(U)$ the set $\Gamma(U) \setminus U$ of new neighbors of U. The *vertex expansion* of a graph $G = (V, E)$ on n vertices is defined as

$$\min_{\emptyset \neq U \subset V, |U| \leq n/2} \frac{|\Gamma^+(U)|}{|U|}.$$

2.3 Bounded arithmetic theory VNC^1

A number of bounded arithmetic theories have been proposed for uniform NC^1: these include the theory $\mathrm{A}^{\log}$ of Clote and Takeuti [13], the theory AID of Arai [5], the theory VNC^1 of Cook and Morioka [16], and a reformulated version of VNC^1 by Cook and Nguyen [14]. Jeřábek [23] describes a theory VNC^1_* for NC^1 under a relaxed notion of uniformity for logarithmic depth circuits.

Cook and Morioka [16] define VNC^1 using tree recursion (*TreeRec*). Cook and Nguyen [14] give an equivalent definition of VNC^1 using the Boolean formula value problem. It is easier to formalize the expander graph construction with tree recursion, so we work with the version of VNC^1 as defined by Cook and Morioka [16].

The bounded arithmetic theory VNC^1 is an extension of the theory V^0 of bounded arithmetic; V^0 corresponds in power to AC^0. V^0 is a second-order (two-sorted) system of arithmetic, with two sorts of numbers (first-order objects) and strings (second order objects). Strings are viewed as members of $\{0,1\}^*$. The notation $X(i)$, where X is a string and $i \geq 0$ is a natural number, means the Boolean value of the i^{th} entry in string X. Sometimes $i{\in}X$ is written instead of $X(i)$. The constants 0 and 1 are number terms, and addition and multiplication are number functions. Another term of type number is string length $|X|$, defined to be the value of the largest element in X when viewed as a set plus 1. Addition and multiplication are defined for numbers only, and equality is defined both for numbers and strings. The axioms of V^0 consist of a finite set of "BASIC" open axioms defining simple properties of the constants, relation symbols and function symbols, plus Σ^B_0-Comprehension axioms

$$\Sigma^B_0\text{-COMP:} \quad \exists X{\leq}y\, \forall z{<}y\, (X(z) \leftrightarrow \varphi(z))$$

for any formula φ in Δ^B_0 not containing X as a free variable, but possibly containing free variables other than z. A Δ^B_0 formula is one in which all quantifiers are bounded and which contains no second-order quantifiers. We write $(\exists X{\leq}y)\psi$ for $\exists X((|X|{\leq}y) \wedge \psi)$.

Let $\varphi(i, \vec{x}, \vec{X})[p, q]$ and $\psi(i, \vec{x}, \vec{X})$ be Σ^B_0-formulas. The notation "$[p, q]$" indicates that p and q are propositional variables that may occur as atomic subformulas in φ. The Σ^B_0-*TreeRec*

property [16] is defined by the formula $B^{\varphi,\psi}(a,\vec{x},\vec{X},Z)$:

$$(\forall i{<}a)[(Z(a{+}i) \leftrightarrow \psi(i)) \wedge (Z(i) \leftrightarrow \varphi(i,\vec{x},\vec{X})[Z(2i{+}1), Z(2i{+}2)])].$$

For $i < a$, this states that $Z(i)$ is a Boolean function of the two values $Z(2i+1)$ and $Z(2i+2)$. Thus $Z(i)$ is computed by a circuit which is a formed as a binary tree with gate types specified by φ and input values specified by ψ. We can always assume w.l.o.g. that $a = 2^{|a|}-1$; we call this the "depth condition" and it means the binary tree is exactly balanced and of depth $|a|$. This tree is of course a fanin two Boolean circuit. The type of the i-th gate is determined by $\varphi(i,\vec{x},\vec{X})$ and thus is a Σ^B_0-property of i and the inputs $\vec{x}$ and $\vec{X}$.

The theory VNC^1 is defined as V^0 plus the Σ^B_0-*TreeRec* axioms $(\exists Z{\leq}2a)B^{\varphi,\psi}(a,\vec{x},\vec{X},Z)$ for all φ and ψ in Σ^B_0. The language of VNC^1 can be extended by adding a new relation symbol $R^{\varphi,\psi}(i,a,\vec{x},\vec{X})$ for every formula $B^{\varphi,\psi}$. The defining axioms for $R^{\varphi,\psi}$ are

$$B^{\varphi,\psi}(a,\vec{x},\vec{X},R^{\varphi,\psi}) \qquad \text{and} \qquad i{\geq}2a \rightarrow \neg R^{\varphi,\psi}(i,a,\vec{x},\vec{X}).$$

Note that the defining axioms uniquely specify all the values of $R^{\varphi,\psi}$, provably in VNC^1. Adding the predicate symbols $R^{\varphi,\psi}$ and their defining axioms to VNC^1 yields the theory $\mathsf{VNC}^1(\mathit{TreeRec})$.[1] As an extension by definitions, this theory is conservative over VNC^1. This means that VNC^1 and $\mathsf{VNC}^1(\mathit{TreeRec})$ can be used interchangeably. Indeed, any $\forall\Sigma^B_1(\mathit{TreeRec})$-formula which is provable in $\mathsf{VNC}^1(\mathit{TreeRec})$ can be translated naturally to an equivalent $\forall\Sigma^B_1$-formula which is VNC^1-provable. Thus, in Section 5, we may work in VNC^1 but still use the full power of $\mathsf{VNC}^1(\mathit{TreeRec})$.

A key property of VNC^1 is that it can Σ^B_1-define precisely the (uniform) NC^1 functions; this is discussed in Section 5.1.

2.4 LK and MLK proof systems

The system MLK of monotone reasoning in [7] is a variant of Gentzen's sequent calculus LK in which all formulas are positive. An LK proof is a list of sequents of the form $\varphi_1,\ldots,\varphi_n \rightarrow \psi_1,\ldots\psi_m$, interpreted as $\bigwedge_{i=1}^n \varphi_i \rightarrow \bigvee_{j=1}^m \psi_j$. The axioms are $\varphi \rightarrow \varphi$, $\Gamma \rightarrow 1$, and $0 \rightarrow \Gamma$, for an arbitrary list of formulas Γ. Let φ,ψ denote formulas and Γ,Δ lists of formulas. The main derivation rules of LK are as follows.

- **Left derivation:** $\dfrac{\varphi,\psi,\Gamma\rightarrow\Delta}{(\varphi\wedge\psi),\Gamma\rightarrow\Delta}$ $\quad$ $\dfrac{\varphi,\Gamma\rightarrow\Delta \qquad \psi,\Gamma'\rightarrow\Delta'}{(\varphi\vee\psi),\Gamma,\Gamma'\rightarrow\Delta,\Delta'}$ $\quad$ $\dfrac{\Gamma\rightarrow\varphi,\Delta}{\neg\varphi,\Gamma\rightarrow\Delta}$
- **Right derivation:** $\dfrac{\Gamma\rightarrow\Delta,\varphi,\psi}{\Gamma\rightarrow\Delta,(\varphi\vee\psi)}$ $\quad$ $\dfrac{\Gamma\rightarrow\Delta,\varphi \qquad \Gamma'\rightarrow\Delta',\psi}{\Gamma,\Gamma'\rightarrow\Delta,\Delta',(\varphi\wedge\psi)}$ $\quad$ $\dfrac{\varphi,\Gamma\rightarrow\Delta}{\Gamma\rightarrow\Delta,\neg\varphi}$
- **Cut rule:** $\dfrac{\Gamma\rightarrow\Delta,\varphi \qquad \varphi,\Gamma'\rightarrow\Delta'}{\Gamma,\Gamma'\rightarrow\Delta,\Delta'}$

Additionally, LK includes structural rules on both sides of a sequent such as weakening, contraction of duplicate formulas, and changing order of formulas on the same side. LK is equivalent in power to Frege systems, and tree-like LK is equivalent to LK, thus VNC^1 proofs translate into polynomial-size LK proofs [5, 16, 14].

In Monotone LK (MLK), all formulas in the proof are over the $\wedge,\vee$ basis with no $\neg$.

[1] Cook and Morika [16] call this theory $\mathsf{VNC}^1(\mathcal{L}_{\mathit{TreeRec}})$.

3 Constructing edge expanders

Here we define an iterative construction of a constant-degree edge expander family, and argue its edge expansion properties using simple combinatorial tools. The simplicity of the analysis will allow us (in Section 5) to formalize it within the system VNC^1. The construction is a variant of the iterative construction given by Reingold, Vadhan, and Wigderson [38], using the graph operations described next.

3.1 Graph operations

We define the graph operations that we will use to construct expanders.

Powering For a graph $G = (V, E)$ and an integer $k \geq 1$, the kth power G^k is the graph on vertices V where for each walk of length k from a vertex u to a vertex v in G there is an edge $u \sim v$ in G^k.

If Rot_G is the rotation map of G, then the rotation map of G^k is

$$Rot_{G^k}(v, (i_1, \ldots, i_k)) = (w, (j_k, \ldots, j_1)),$$

where w is the vertex reached from v in G by edges $i_1, \ldots, i_k$ using the rotation map Rot_G, and $(j_k, \ldots, j_1)$ describes the same sequence of edges in reverse order from w's point of view. For instance, $Rot_G(v, i_1) = (v', j_1)$ for some $v' \in V$, then $Rot_G(v', i_2) = (v'', j_2)$ for some v'', etc.

Tensor product For graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, their tensor product $G_1 \otimes G_2$ is the graph on vertices $V_1 \times V_2$, where for every pair of edges $u \sim u'$ in G_1 and $v \sim v'$ in G_2 there is an edge $(u, v) \sim (u', v')$ in $G_1 \otimes G_2$.

If Rot_{G_1} and Rot_{G_2} are the rotation maps of G_1 and G_2, respectively, then the rotation map of $G_1 \otimes G_2$ is

$$Rot_{G_1 \otimes G_2}((v, w), (i, j)) = ((v', w'), (i', j')),$$

where $Rot_{G_1}(v, i) = (v', i')$ and $Rot_{G_2}(w, j) = (w', j')$.

Replacement product For a D-regular graph $G = (V, E)$ on n vertices and a d-regular graph $H = (V', E')$ on D vertices, the replacement product $G \circ H$ is a $2d$-regular graph on nD vertices $\{(v, i) \mid v \in V,\ 1 \leq i \leq D\}$. The graph $G \circ H$ has the edges $\{(v, i) \sim (v, j) \mid v \in V,\ i \sim j \in E'\}$ as well as, for every edge $v \sim w$ in G such that w is the ith neighbor of v, and v is the jth neighbor of w (i.e., $Rot_G(v, i) = (w, j)$), $G \circ H$ has d parallel edges between (v, i) and (w, j).

If Rot_G and Rot_H are the rotation maps of G and H, respectively, then the rotation map of the $G \circ H$ is

$$Rot_{G \circ H}((v, i), j) = \begin{cases} ((v, i'), j') \text{ for } Rot_H(i, j) = (i', j') & \text{if } j \leq d \\ ((w, i'), j) \text{ for } Rot_G(v, i) = (w, i') & \text{if } j > d. \end{cases}$$

Adding self-loops For a d-regular graph $G = (V, E)$, the graph $\bigcirc G$ is the $2d$-regular graph obtained from G by adding d parallel self-loops around every vertex of G; note that we count every self-loop around vertex v as one edge $v \sim v$.

If Rot_G is the rotation map of G, then the rotation map of $\bigcirc G$ is

$$Rot_{\bigcirc G}(v, i) = \begin{cases} Rot_G(v, i) & \text{if } i \leq d \\ (v, i) & \text{if } i > d. \end{cases}$$

3.2 Effect of graph operations on edge expansion

For the operation of adding self-loops, the following lemma is obvious.

▶ **Lemma 3** (Self-loops). *If G is a d-regular graph with edge expansion ϵ, then the graph $\bigcirc G$ is $2d$-regular with edge expansion $\epsilon/2$.*

▶ **Lemma 4** (Powering). *Let G be a d-regular graph with edge expansion ϵ. For every integer $k \geq 1$, the powered graph $(\bigcirc G)^k$ has edge expansion at least*

$$\frac{1}{2} \cdot \left(1 - \left(1 - \frac{\epsilon^2}{4}\right)^{k/2}\right).$$

Proof Sketch. Our analysis is done in two stages. First, we use the result of Mihail [28] showing that a random k-step walk on an edge expander $\bigcirc G$ quickly converges to the uniform distribution over the vertices of $\bigcirc G$. Then we show that such convergence to the uniform distribution implies good edge expansion of $(\bigcirc G)^k$, using some ideas from [2].

Mihail [28] gave a combinatorial proof of the following result showing the exponentially fast convergence of a random walk on a regular graph to the uniform distribution.

▶ **Claim 5** ([28]). *Let G be a d-regular graph with edge expansion ϵ. Let A be the normalized adjacency matrix of $G' = \bigcirc G$. Let π be any initial distribution on vertices of G', and let u be the uniform distribution on vertices of G'. Then*

$$\|A^k\pi - u\|^2 \leq (1 - (\epsilon^2/4))^k \cdot \|\pi - u\|^2.$$

Let $G' = \bigcirc G$, and let $G'' = (G')^k$. Next we relate the edge expansion of G'' to the mixing time of a k-step random walk on G'. Let u denote the uniform distribution on the vertices of G''. For a subset U of vertices of G'', we denote by u_U the probability distribution that is uniform over U, i.e., every vertex in U gets weight $1/|U|$, and every vertex outside of U gets weight 0. We denote by χ_U the characteristic vector of the set U (whose ith entry is 1 if $i \in U$, and is 0 otherwise). The following claim can be proved along the lines of [2].

▶ **Claim 6.** *Suppose $G'' = (V, E)$ is a regular graph on n vertices, with normalized adjacency matrix A such that for some $\delta > 0$ the following holds: for every subset $U \subset V$ of size at most $|V|/2$,*

$$\|Au_U - u\|^2 \leq \delta \cdot \|u_U - u\|^2.$$

Then G'' has edge expansion at least $(1 - \sqrt{\delta})/2$.

Now, by Claim 5, we get for the normalized adjacency matrix A of the graph $\bigcirc G$ and for every subset $U \subset V$ that

$$\|A^k u_U - u\|^2 \leq (1 - (\epsilon^2/4))^k \cdot \|u_U - u\|^2.$$

Applying Claim 6 concludes the proof of Lemma 4. ◀

▶ **Lemma 7** (Tensoring). *Let $G = (V_G, E_G)$ be a d_G-regular graph with $d_G/2$ self-loops at every vertex and $H = (V_H, E_H)$ be a d_H-regular graph with $d_H/2$ self-loops at every vertex. If G has edge expansion ϵ_G and H has edge expansion ϵ_H, then the tensor product graph $G \otimes H$ has edge expansion at least $\min\{\epsilon_G, \epsilon_H\}/50$.*

Proof Sketch. First, we give some intuition. Suppose G is a d_G-regular graph on n_G vertices, and H is d_H-regular graph on n_H vertices. As a "warm-up", consider the special case of a subset of vertices S of the tensor product $G \otimes H$ such that $S = A \times B$. Moreover, assume that $|B| < n_H/2$. Then at least $\epsilon_H d_H |B|$ edges are leaving the set B in graph H. Each of these edges paired up with an edge from A will be an edge leaving $A \times B$ in $G \otimes H$, yielding a total of at least $\epsilon_H d_H |B| d_G |A|$ edges leaving $A \times B$. After normalization (division by $d_G d_H |A||B|$), this yields edge expansion ϵ_H from the set S. In the case, B is larger than $n_H/2$, but A is smaller than $n_G/2$, we can use the edge expansion of A, to obtain the edge expansion at least ϵ_G from S.

For general sets S of vertices in $G \otimes H$, we consider the characteristic matrix of S, which is an $n_G \times n_H$ 0-1 matrix with (i,j)th entry being 1 iff $(i,j) \in S$. We then argue that it is possible to remove some rows or some columns of this matrix so that the resulting matrix has a constant fraction of 1's of the original matrix (i.e., we removed only a constant fraction of vertices from S), and either every row or every column has at most some constant fraction of 1's.

Suppose we have the former case (the other case is treated similarly). That is, we removed some rows of the characteristic matrix of S to obtain a new subset S' that has the form $\{a_1\} \times B_1 \cup \cdots \cup \{a_k\} \times B_k$, where $a_i \in V_G$ and $B_i \subset V_H$, and moreover, each $|B_i|$ is at most some constant fraction of n_H. Then for each B_i, we can use edge expansion of H to argue that ϵ_H fraction of edges from B_i are leaving B_i. Ideally, we would like then to argue that each such edge, when paired up with any edge from vertex a_i, will leave S'. This may not be true, however, as such an edge may go to some vertex in $\{a_j\} \times B_j$. To circumvent this problem, we use the assumption that both of our graphs G and H have many self-loops around every vertex (say, half of the degree). In that case, it is easy to argue that each edge leaving B_i in H, when paired up with any self-loop around a_i, yields an edge of $G \otimes H$ that leaves S. Since the number of self-loops around a_i is at least half the degree of G, this yields edge expansion at least $\epsilon_H/2$ from each set $\{a_i\} \times B_i$. Since S' is the union of the pairwise disjoint such sets, we get the edge expansion at least $\epsilon_H/2$ from S'. Finally, since S' contains a constant fraction of vertices from S, we conclude that the edge expansion from S is at least $\Omega(\epsilon_H)$. ◀

▶ **Lemma 8** (Replacement [4]). *Let $G = (V_G, E_G)$ be a D-regular graph on n vertices, and let $H = (V_H, E_H)$ be a d-regular graph on D vertices. If G has edge expansion ϵ_G and H has edge expansion ϵ_H, then $G \circ H$ has edge expansion at least $\epsilon_G^2 \epsilon_H/48$.*

Proof Sketch. The proof idea is to partition a given subset S of vertices of $G \circ H$ into n clusters $(\{a_1\} \times B_1) \cup \cdots \cup (\{a_n\} \times B_n)$, where each $a_i \in V_G$ and $B_i \subseteq V_H$. View the clusters where $|B_i|$ is at most some fraction of $|V_H|$ as light, and the remaining clusters as heavy. For every light cluster, one can use the expansion of H to lower-bound the expansion of B_i (within the copy of H associated with vertex a_i of G). If there are many vertices in light clusters, we get a good lower bound on the edge expansion of S. Otherwise, there are many vertices in heavy clusters. Using the expansion properties of G, one can argue in this case that there will be many edges between the set of vertices in heavy clusters and the vertices outside S. ◀

3.3 Construction

With the analysis of graph operations in hand, we can now present our iterative construction of edge expanders that will be shown formalizable in VNC[1]. Let G_0 be a $(2d)$-regular graph of constant size, where d is some constant. Let ϵ_0 be the edge expansion of G_0 such that

$\epsilon_0 \geq 1/1296$. Such a graph G_0 exists (by a counting argument) and can be found in constant time, using exhaustive search. Given G_0, we will define a bigger graph G_1 that is also $(2d)$-regular and has edge expansion at least $1/1296$. In general, given a $(2d)$-regular graph G_i with edge expansion at least $1/1296$, we define G_{i+1} as follows:

$$G_{i+1} \;=\; ((\bigcirc((\bigcirc G_i) \otimes (\bigcirc G_i)))^c) \circ H, \tag{2}$$

where c is some constant to be specified later, and H is a d-regular expander graph on $(2(4d)^2)^c$ vertices, with edge expansion at least $1/3$. Again, such a graph can be found using exhaustive search.

▶ **Theorem 9.** *There is a constant c such that the graph $G_{i+1} = (V_{i+1}, E_{i+1})$ defined from $G_i = (V_i, E_i)$ as above has the following parameters:*

- $|V_{i+1}| = |V_i|^2 \cdot D$, *where* $D = (2(4d)^2)^c$,
- *the degree of G_{i+1} is $2d$,*
- *the edge expansion of G_{i+1} is at least $1/1296$.*

Proof. The bounds on the size and the degree of G_{i+1} follow easily from the definitions of the graph operations used to define G_{i+1} from G_i. Let $\epsilon \geq 1/1296$ be the edge expansion of G_i. First, by Lemma 3, the edge expansion of $\bigcirc G_i$ is at least $\epsilon/2$. By Lemma 7, the edge expansion of $G' = (\bigcirc G_i) \otimes (\bigcirc G_i)$ is at least $\epsilon' = \epsilon/100$. By Lemma 4, the kth power of the graph $\bigcirc G'$ has edge expansion at least

$$\frac{1}{2} \cdot \left(1 - \left(1 - \frac{\epsilon^2}{40000}\right)^{k/2}\right).$$

Choose k to be a sufficiently large constant c so that the edge expansion of the cth power of our graph, as given by the formula above, is at least $1/3$. Finally, by Lemma 8, the edge expansion of the graph G_{i+1} is at least $(1/3)^3/48 = 1/1296$. This completes the proof. ◀

We give also a modified construction of expanders that allows explicit constructions of edge expanders $\tilde{G}_i = (\tilde{V}_i, \tilde{E}_i)$ with $|\tilde{V}_i| = 2^i$, and more generally of edge expanders on exactly M vertices for arbitrary $M \geq 1$.

Let c be a constant. Choose the constant d to be a sufficiently large power of two, $d = 2^\ell$, so that there is a d-regular graph H on $(2(4d)^2)^c$ vertices with edge expansion at least $1/3$ and so that for all $i \leq c\ell + 7$, there are $2d$-regular graphs $\tilde{G}_i$ on 2^i vertices with edge expansion at least $1/1296$. These graphs H and $\tilde{G}_i$ can be found by exhaustive search. We construct expander graphs $\tilde{G}_i$ with edge expansion $\geq 1/1296$. For $i > 2c\ell + 7$, let $i' = \lfloor (i - 2c\ell - 5)/2 \rfloor$ and $i'' = \lceil (i - 2c\ell - 5)/2 \rceil$, so $i = i' + i'' + 2c\ell + 5$. Define

$$\tilde{G}_i \;=\; ((\bigcirc((\bigcirc \tilde{G}_{i'}) \otimes (\bigcirc \tilde{G}_{i''})))^c) \circ H. \tag{3}$$

▶ **Theorem 10.** *There is a constant c such that the graph $\tilde{G}_i = (\tilde{V}_i, \tilde{E}_i)$ defined as above has the following parameters:*

- $|\tilde{V}_i| = 2^i$,
- *the degree of $\tilde{G}_i$ is $2d$,*
- *the edge expansion of $\tilde{G}_i$ is at least $1/1296$.*

Now that we have constructed edge expanders of sizes 2^i, it is easy to obtain an edge expander $\tilde{G}$ of a given *arbitrary size* M. For this, choose i so that $2^{i-1} < M \leq 2^i$. Partition the vertices of $\tilde{G}_i$ into M disjoint subsets each of size 1 or 2. Define the graph $\tilde{G}$ by collapsing each of these subsets of vertices of $\tilde{G}_i$ into a single vertex of $\tilde{G}$, and inheriting the edges from

the all of the nodes in the subset. It is easy to see the degree of $\tilde{G}$ is at most $4d$; by adding extra self-loops, we get a new graph that is $4d$-regular. It is also easy to show that this new graph has expansion at least $\epsilon/2$ where $\epsilon = 1/1296$.

We get the following.

▶ **Theorem 11.** *Fix constants c and d as above. There is a family of $4d$-regular expanders $\tilde{G}$ on M nodes, for any $M \geq 1$, with edge expansion at least $1/2592$.*

Moreover, there is a deterministic polynomial-time algorithm that, given the name of a vertex v (in binary) of $\tilde{G}$ and an index $i \in [2d]$, outputs the value $Rot_{\tilde{G}}(v, i)$. Furthermore, there is an alternating linear time algorithm which accepts the graph of $\tilde{G}$; namely, it accepts exactly the triples of the form $\langle v, i, Rot_{\tilde{G}}(v, i)\rangle$.

It may be unexpected that we discuss alternating linear time, but the point is that this is what we need for the formalization of our arguments in the bounded arithmetic theory VNC^1 in Section 5. For that, the important thing is the computational complexity of Rot_{G_k} as a function of the size $|V_k|$ of the graph, whereas Theorem 11 expresses runtimes in terms of the size of the name of the vertex. But, the alternating linear time algorithm of Theorem 11 will be viewed as an alternating logarithmic time algorithm for purposes of formalization in VNC^1. (In the same setting, the polynomial time algorithm would be a polylogarithmic time algorithm, and it is open whether such algorithms can in general be formalized in VNC^1.)

4 Constructing bipartite vertex expanders

Jeřábek [24] needs the existence of certain bipartite vertex expanders to formalize the AKS sorting networks in VNC^1_*. We define these graphs next. Recall that, for a set S of nodes in a graph G, $\Gamma(S)$ denotes the set of all neighbors of vertices in S.

Given constants $\alpha \in (0, 1)$ and $A > 1$, a *bipartite (α, A) vertex expander* is a bipartite graph $G = (L \cup R, E)$, where $|L| = |R| = m$, such that

1. the degree of G is at most A, and
2. for all $\ell \leq m$, every set $S \subseteq [m]$ of vertices in either partition with $|S| \geq \alpha\ell$ has $|\Gamma(S)| \geq (1 - \alpha)\ell$.

That is, for every set of vertices of size at least $\alpha\ell$ in one partition, there are at least $(1-\alpha)\ell$ neighbors in the other partition.

The assumption required by [24] is:

> For $\alpha = 1/600$, there exist a constant A and a parameter-free NC^1_* function $G(m)$ such that VNC^1_* proves "$\forall m \in \mathbb{N}$, $G(m)$ is an (α, A) bipartite vertex expander on $m + m$ vertices".

We will argue that such bipartite vertex expanders can be efficiently obtained from our edge expanders defined above.

▶ **Theorem 12.** *For any constant $0 < \alpha < 1$, there exist a constant $A \geq 1$ and an efficient (uniform NC^1) algorithm that, for every $m \in \mathbb{N}$, computes the rotation map of an (α, A) bipartite vertex expander on $m + m$ vertices.*

Proof. We use the edge expander $\tilde{G}$ constructed in Theorem 11 with $M = m$. The graph $\tilde{G} = (\tilde{V}, \tilde{E})$ has $|V| = m$, degree $4d$, and expansion at least $\epsilon/2$, where $\epsilon = 1/1296$. Starting with $\tilde{G}$, we will

1. Convert the edge expander $\tilde{G}$ into a vertex expander, and
2. Turn the latter vertex expander into a bipartite (α, A) vertex expander on $m+m$ vertices.

1. Getting a vertex expander from an edge expander: Let $G = (V, E)$ be the graph $\tilde{G}$ on m nodes constructed above, but with a self-loop added to every node. So G has constant degree $4d + 1$.

We have for every set $S \subseteq V$ of size $|S| \leq m/2$ that at least $\epsilon(2d)|S|$ edges are leaving S in $\tilde{G}$. As the degree of $\tilde{G}$ is $4d$, we conclude that the neighborhood $\Gamma(S)$ of S in G contains at least $\epsilon \cdot (2d) \cdot |S|/(4d) = \epsilon' \cdot |S|$ distinct nodes from $\overline{S}$, where $\epsilon' = \epsilon/2$. As G has self-loops around every node, we get

$$|\Gamma(S)| \geq (1 + \epsilon') \cdot |S|, \tag{4}$$

for every subset S of G with $|S| \leq m/2$.

Consider the power graph G^i, for any $i \geq 1$. Applying Eq. (4) inductively, we get for every subset S of G^i with $|S| \leq m/2$, and for every $i \geq 1$ that

$$|\Gamma_{G^i}(S)| \geq \min\{m/2, (1 + \epsilon')^i \cdot |S|\}. \tag{5}$$

Now let S be a subset of V of size $|S| \geq m/2$. We have $|\Gamma^+(S)| \geq \epsilon' \cdot |\overline{S}|$, where $\Gamma^+(S) = \Gamma(S) \cap \overline{S}$ is the set of new neighbors of S. It follows that

$$|\overline{\Gamma(S)}| \leq (1 - \epsilon') \cdot |\overline{S}|. \tag{6}$$

Applying Eq. (6) inductively, we get for every $i \geq 1$, and for every subset S of V of size $|S| \geq m/2$ that

$$|\overline{\Gamma_{G^i}(S)}| \leq (1 - \epsilon')^i \cdot |\overline{S}|. \tag{7}$$

▶ **Claim 13.** *There exists a constant $t' = t'(\alpha, \epsilon')$ such that, for every $\ell \leq m$ and every set S of $G^{t'}$ with $|S| \geq \alpha\ell$, we have $|\Gamma_{G^{t'}}(S)| \geq (1 - \alpha)\ell$.*

Proof of Claim 13. Consider two cases: $\ell \leq m/2$, and $\ell > m/2$. If $\ell \leq m/2$, then by Eq. (5) we get for $t_1 = \lceil \log_{1+\epsilon'}(1/\alpha) \rceil$ that

$$|\Gamma_{G^{t_1}}(S)| \;\geq\; \min\{m/2, (1 + \epsilon')^{t_1} \cdot \alpha\ell\} \;\geq\; \min\{m/2, \ell\} \;=\; \ell.$$

If $\ell > m/2$, then $|\overline{S}| \leq m - \alpha\ell < (1 - (\alpha/2)) \cdot m < m$. For $t_2 = \lceil (\log 1/\alpha)/(\log 1/(1 - \epsilon')) \rceil$, we get

$$|\overline{\Gamma_{G^{t_2}}(S)}| \;\leq\; (1 - \epsilon')^{t_2} \cdot m \;\leq\; \alpha \cdot m,$$

and hence, $|\Gamma_{G^{t_2}}(S)| \geq (1-\alpha)m \geq (1-\alpha)\ell$. Taking $t' = \max\{t_1, t_2\}$ concludes the proof. ◀

2. Getting a bipartite vertex expander: Let $G^{t'}$ be the vertex expander defined above. Observe that it has m nodes, and has constant degree $A = (4d + 1)^{t'}$. We turn this graph into a bipartite graph by taking two copies of the vertices of $G^{t'}$, denoted by L and R, connecting nodes $i \in L$ and $j \in R$ by an edge iff $\{i, j\}$ is an edge of $G^{t'}$. Claim 13 implies that the resulting graph is an (α, A) vertex expander.

Finally, the explicitness of this construction of (α, A) vertex expanders can be argued similarly to the case of the edge expanders of Theorem 11: we trace the construction of $G^{t'}$ to get an efficient (uniform NC^1) algorithm for computing the rotation map of the corresponding bipartite (α, A) expander on $m + m$ vertices. ◀

5 Formalizing the construction in bounded arithmetic

This section discusses the formalization of the expander graph construction in the theory VNC^1 of bounded arithmetic. A high-level description of how we formalize the expander graph construction in VNC^1 is as follows:

1. The first step is to establish (in Section 5.4) that VNC^1 can define the operations of graph powering, replacement product, and tensoring. From this it follows that VNC^1 can carry out the definition of G_{i+1} from G_i, for the graphs G_i defined in Section 3. Similarly, VNC^1 can carry out the construction of $\tilde{G}_i$ from $\tilde{G}_{i'}$ and $\tilde{G}_{i''}$ as in (3).
2. For the second step, we wish to use induction on t to prove the existence of the graph G_t for suitable t. However, since VNC^1 does not support induction on Σ^B_1-formulas, we cannot use the usual induction axioms for VNC^1. Instead, we exploit the fact that the graph G_{i+1} has size quadratic in the size of G_i, namely $|G_{i+1}| = \Theta(|G_i|^2)$. This large growth rate allows us to use Σ^B_1-induction to prove the existence of G_t for arbitrary (first-order) integers t. For this, Theorems 16 and 17 of Section 5.3 prove that the needed induction principle is provable in VNC^1. The intuition is that the computational content of the induction axioms corresponds to composing logarithmic depth circuits, and that since the G_i's are growing quadratically, arbitrary composition of logarithmic depth circuits for the G_i's yields a circuit which is still of only logarithmic depth.
   The same Σ^B_1-induction will also be used to prove the existence of the graphs $\tilde{G}_i$, exploiting the fact that the size of $\tilde{G}_i$ is quadratic in the sizes of $\tilde{G}_{i'}$ and $\tilde{G}_{i''}$.
3. Theorems 16 and 17 give the needed induction principle for handling compositions of circuits, but more work is needed for VNC^1 to formalize the iterated composition of circuits. What we mean by "iterated composition" of circuits is that there are multiple circuits (about $|(|t|)|$ many circuits) which are arranged with the outputs of one circuit feeding into the inputs of the next circuit. To formalize this circuit composition in VNC^1, we need to modify Cook and Morioka's definition [16] of *TreeRec* tree recursion in VNC^1. The problem with the *TreeRec* form of tree recursion is that the second order inputs to a circuit defined by tree recursion are not used at the input gates of the circuit, but rather are used throughout the circuit, indeed potentially at every gate in the circuit. To fix this, Section 5.2 introduces a modified version of tree recursion, called *TreeRec*$'$, which allows the use of second order inputs $X_0(i)$ only as input values. This allows composition of circuits using the inputs X_0 for the iteratively computed values. The *TreeRec*$'$ tree recursion and the new induction principle of Section 5.3 then suffice to define G_t by using recursively the definition of G_{i+1} from G_i.
4. The fourth step is to prove the expansion properties of G_{i+1} follow from those of G_i. Or, more precisely, proving that if G_{i+1} does not have the desired edge expansion then G_i also does not.
5. The fifth step is to use induction on t to prove the expansion properties for G_t. This is done in Theorem 21; its proof again utilizes the induction principle introduced in Section 5.3. This shows that VNC^1 can prove the existence of expander graphs.
6. The sixth, and final step, is to note that the proof of Theorem 12 can be carried out in VNC^1, so VNC^1 proves the existence of bipartite vertex expanders.

This proof is given below. We start by proving some useful properties of VNC^1 in Sections 5.1–5.3. We show in Section 5.4 that VNC^1 can express relevant graph properties. Section 5.5 shows that the edge expansion properties of our graph operations can be proved within VNC^1.

5.1 Defining NC^1 functions within VNC^1

Cook and Morioka [16, Lemma 13] show that $\mathsf{VNC}^1(\mathit{TreeRec})$ can prove the $\Sigma^B_0(\mathit{TreeRec})$-COMP axioms. They then define the FNC^1 functions F by using $\Sigma^B_0(\mathit{TreeRec})$-formulas $\varphi(i,\vec{x},\vec{X})$ and terms $t(\vec{x},\vec{X})$ and defining the string $F(\vec{x},\vec{X})$ by[2]

$$F(\vec{x},\vec{X})(j) \;\leftrightarrow\; j{<}t(\vec{x},\vec{X}) \wedge \varphi(j,\vec{x},\vec{X}). \tag{8}$$

They also show that the Σ^B_1-definable functions of VNC^1 are precisely the FNC^1 functions [16, Theorem 17]. Recall that a Σ^B_1-definition is given by VNC^1 proof of $(\exists!Y)\varphi(\vec{x},\vec{X},Y)$ where $\varphi \in \Sigma^B_1$; this serves as a definition of the string function $\vec{x},\vec{X} \mapsto Y$.

The definition of FNC^1 functions using (8) is equivalent to the usual definition of the FNC^1 functions as the functions whose bit graphs are computable in U_{E^*}-uniform NC^1, or equivalently are computable in $\mathsf{ALogTime}$. Those functions are computed by a family $\{C_n\}_n$ of fanin ≤ 2 Boolean circuits, taking inputs of length n and having depth $O(\log n)$. The U_{E^*}-uniformity condition was defined by Ruzzo [40] and means that the circuits C_n are described by two functions $g(i,n)$ and $p(i,w,n)$ which are computable in the linear time hierarchy (equivalently, they have Σ^B_0 graphs). The first function $g(i,n)$ returns the type of gate i in C_n. The second function $p(i,w,n)$ takes as input also a $w \in \{0,1\}^*$: the bits of w describe a path in the circuit starting at gate i and following successively the first or second input to gates according to the bits of w. The value of $p(i,w,n)$ is the index of the gate reached by following this path specified by w starting from gate i in C_n. The functions g and p are in the linear time hierarchy; however, since they have inputs of length $O(\log n)$, they run in time $O(\log n)$ using a constant number of alternations. For more details, see [40].

We will need to carefully analyze the effect of composing FNC^1 functions; for this reason it is important that the existence of U^*_E-uniform NC^1 circuits for FNC^1 functions can be proved by the theory VNC^1. This follows from Theorem 15 below.

5.2 A modified tree recursion

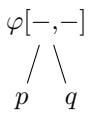
TreeRec acts like a fanin two, Boolean circuit where the internal gate types are given by $\varphi = \varphi(i,\vec{x},\vec{X})$. A disadvantage of this definition of *TreeRec* is that the side parameters $\vec{X}$ can be used unrestrictedly by the Σ^B_0-formulas φ and ψ. The formula $\varphi(i,\vec{x},\vec{X})$ defines the type of gate number i when the circuit has $\vec{x},\vec{X}$ as inputs. Likewise, $\psi(i,\vec{x},\vec{X})$ defines the True/False value of the i-th input. This differs from the usual conventions of having a circuit have fixed gate types, and having the inputs affect only the values of input gates. It also makes it difficult to define the notion of composing circuits, with the outputs of one family of circuits serving as the inputs to another circuit.

We define a new formulation of tree recursion called *TreeRec′* to address this problem. In a *TreeRec′* definition, one of the second order inputs, X_0, will serve as an "ordinary" input to the circuit, with the values $X_0(j)$ specifying the True/False values on inputs to the circuit. The other second order inputs, $\vec{X}'$, can be used to define gate types similarly as is done by *TreeRec*. This allows recursive computations on the value X_0 to be formalized with composition of circuits.

We assume X_0 is one of the side string parameters $\vec{X}$, so $\vec{X}$ is $X_0,\vec{X}'$. We modify the definition of *TreeRec* so that the values $X_0(i)$ are used only as inputs to the *TreeRec* circuit,

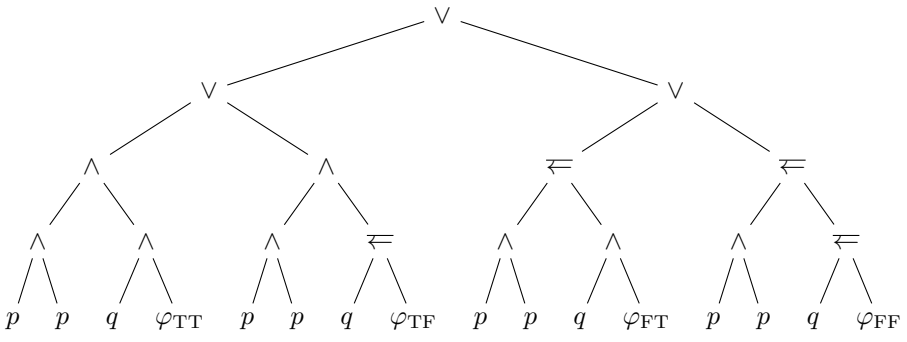
[2] This definition of FNC^1 is same as what Cook and Morioka [16] call "the function symbols in $\mathsf{VNC}^1(\mathsf{FNC}^1)$". We use just "$\mathsf{FNC}^1$" to keep the notation less cumbersome.

and are not used to determine the gate types; in particular, X_0 is not used by φ. The basic construction for the definition of *TreeRec*′ is that a single gate in a *TreeRec* circuit, of gate type $\varphi[-,-]$:



(9)

is replaced by a small tree of binary gates



(10)

Here the binary gate $r \Leftarrow s$ is $\neg r \wedge s$; and the values φ_{pq} are the truth values of $\varphi(i, a, \vec{x}, \vec{X})[p, q]$. By inspection, the circuit is depth four and fanin two: the top $\vee$ gate branches on the value of p; the next two $\vee$ gates branch on q. The last two levels select the correct value of φ_{pq}, for $p =$ T,F and $q =$ T,F based on the values of p and q. In other words, the circuit (10) implements a "lookup table", using the values p and q to select the appropriate value φ_{pq}. Assuming that the four values of φ_{pq} are correctly computed, the effect of replacing the binary gates (9) with the circuits (10) gives a circuit of depth $4|a|$ computing the same result as the original *TreeRec* circuit of depth $|a|$.

We wish to replace the four leaf nodes of (10) labelled φ_{pq} with Boolean circuits which have as inputs only the values $X_0(i)$. Since φ is Σ^B_0-formula, such circuits can easily be described by a polynomial time function of $i, \vec{x}, \vec{X}'$. These circuits are formed by applying the Paris-Wilkie transformation to φ, namely by replacing bounded quantifiers in φ with conjunctions and disjunctions, and hardcoding the values of $\vec{x}$ and $\vec{X}'$ (but not X_0) as constants. The result is that each leaf φ_{pq} of the circuit (10) can be replaced by a fanin two circuit which (a) has as inputs only $X_0(j)$'s and constants, (b) is size $\leq q(|a|, |\vec{x}|)$ and depth $\leq |q(|a|, |\vec{x}|)|$ for some polynomial q, and (c) there is a Σ^B_0-definable number function $f(p, q, i, a, \vec{x}, \vec{X})$ of VNC^1 which outputs a succinct description of the circuit. VNC^1 is able to straightforwardly define f and prove all these properties.

With this construction in hand, we define a modified version of tree recursion:

▶ **Definition 14.** Let $\varphi(i, a, \vec{x}, y_0, \vec{X}')[p, q]$ be a Σ^B_0-formula and let $k(i, a, \vec{x}, y_0, \vec{y}')$ be a Σ^B_0-definable number function. The Σ^B_0-*TreeRec*′ property for φ and k is given by:

$$B^{\varphi,k}(a, \vec{x}, X_0, \vec{X}', Z) = (\forall i{<}a)[\,(Z(i) \leftrightarrow \varphi(i, a, \vec{x}, |X_0|, \vec{X}')[Z(2i{+}1), Z(2i{+}2)]) \\ \wedge\ (Z(a+i) \leftrightarrow X_0(k(i, a, \vec{x}, |X_0|, |\vec{X}'|)))\,].$$

The *defining axioms for the predicate symbols* $R^{\varphi,k}(i, a, \vec{x}, X_0, \vec{X}')$ are the formulas

$$B^{\varphi,k}(a, \vec{x}, X_0, \vec{X}', R^{\varphi,k}) \qquad \text{and} \qquad i{\geq}2a \rightarrow \neg R^{\varphi,k}(i, a, \vec{x}, X_0, \vec{X}'). \tag{11}$$

Note that the gate type depends only on $|X_0|$, not on the values of $X_0(\cdot)$. VNC^1 proves that (11) uniquely specifies all values of $R^{\varphi,k}$. Furthermore, it is not hard to see that VNC^1 proves the existence of string objects satisfying the conditions of (11). Thus, we may conservatively extend $\mathsf{VNC}^1(\mathit{TreeRec})$ by adding all these predicate symbols along with their defining axioms. The resulting theory is called $\mathsf{VNC}^1(\mathit{TreeRec}, \mathit{TreeRec}')$.

The main advantage of $\mathit{TreeRec}'$ definitions is that they can explicitly give U_{E^*}-uniform log-depth circuits. For this, we assume that X_0 is the only second-order input (so $\vec{X}'$ is missing). We also assume that $a = s(\vec{x}, |X_0|)$ for some V^0-term s. It is usually convenient to assume in addition that each $x_i < |X_0|^{O(1)}$, so that we can think of $|X_0|$ as the size of the input (up to a polynomial); in fact, often $\vec{x}$ is missing, so the only first-order input is $|X_0|$. The other condition needed for U_{E^*}-uniformity is that there must be a linear time hierarchy algorithm (i.e., a Σ^B_0 formula) determining the extended connection language for the connectivity of gates in the circuit. Since the circuit is formed as a binary tree, with a natural numbering system for gates, the extended connection language of the circuit is trivial. Specifically, suppose $w \in \{0,1\}$ is a string of bits and i is a gate. Interpret bits "0" and "1" as selecting the first or second input to a gate, and let w specify a path starting at gate i, and traversing inputs according to the bits of w. The gate at the end of this path is gate i' where i' has binary representation obtained by concatenating the binary representation of i and the string w. The type of gate i can be defined with a Σ^B_0-formula using the Σ^B_0-formula φ and the Σ^B_0-defined function k. Thus, with the assumptions stated above, a $\mathit{TreeRec}'$ definition defines a U_{E^*}-uniform circuit.

The next theorem states that every $\Sigma^B_0(\mathit{TreeRec})$-property has log-depth, fanin two, Boolean circuits in the form used by $\mathit{TreeRec}'$.

▶ **Theorem 15.** *Let $\chi(\vec{x}, X_0, \vec{X}')$ be a $\Sigma^B_0(\mathit{TreeRec})$-formula. Then there are a Σ^B_0-formula $\varphi(i, a, \vec{x}, y_0, \vec{X}')$, a Σ^B_0-defined function $k(i, a, \vec{x}, y_0, |\vec{y}'|)$, and a V^0-term $s(\vec{x}, |X_0|, |\vec{X}'|)$ so that $\mathsf{VNC}^1(\mathit{TreeRec}, \mathit{TreeRec}')$ proves*

$$\chi(\vec{x}, X_0, \vec{X}') \;\leftrightarrow\; R^{\varphi,k}(0, s(\vec{x}, |X_0|, |\vec{X}'|), \vec{x}, X_0, \vec{X}').$$

$\Sigma^B_0(\mathit{TreeRec})$-properties may involve composing multiple *TreeRec* predicates with built-in function symbols, then combining them with Boolean operations and first-order quantifiers. Theorem 15 states that any such property χ may expressed as a $\mathit{TreeRec}'$: the advantage is that this gives an explicit NC^1 representation of χ; namely in terms of logarithmic depth Boolean circuits. "Logarithmic" means as a function of the values $\vec{x}$ and of the sizes $|X_0|, |\vec{X}'|$ of the second order inputs X_0, X'.

5.3 A conservation result

We prove the closure of VNC^1 under a rule of inference based on a "telescoping" iteration. This turns out to be exactly what is needed for the formalization of the expander graph construction inside VNC^1. We write $\sqrt{a}$ for the greatest integer at most $\sqrt{a}$.

▶ **Theorem 16.** *Suppose $\chi(X)$ is a Σ^B_0-formula containing only X free, and let $\psi(a)$ be $(\exists X{\leq}a)\chi(X)$. Also suppose VNC^1 proves*

$$(\forall a)(\psi(a) \to \psi(\sqrt{a})). \tag{12}$$

Then VNC^1 proves $\psi(a) \to \psi(1)$, and thus also proves $\chi(Y) \to (\exists X{\leq}\,1)\chi(X))$.

Theorem 16 used a descending induction; a similar theorem holds also for ascending induction:

▶ **Theorem 17.** *Suppose $\varphi(X)$ is a Σ_0^B-formula containing only X free. Also suppose* VNC^1 *proves*

$$\varphi(Y) \to (\exists X)(|X| \geq |Y|^2 \wedge \varphi(Y)).$$

Then VNC^1 *proves* $(\exists Y)\varphi(Y) \to (\forall x)(\exists X)(|X| > x \wedge \varphi(X))$.

5.4 Expressing expander graph properties in VNC^1

We now discuss how VNC^1 can express properties about graphs, adjacency matrices, expansion properties, and graph constructions such as powering, tensor product and replacement product. A graph G on n vertices will be encoded in VNC^1 as a string object (a second order object). Here n is a number (a first-order object), and the intent is to represent G in terms of its adjacency matrix. The (i,j)-th entry of the adjacency matrix is the number of edges between vertices i and j. It is represented by a three-place second order predicate $A(i,j,k)$ where $A(i,j,k)$ is true when there are exactly k edges between i and j. (Strictly speaking, we should write $A(\langle i,j,k\rangle)$, but we suppress this notation.) Each i,j,k is a number (a first order object); it will be important that we always have $k < p(n)$ for some fixed polynomial p, since then k is Σ_0^B-definable from A,i,j, and we can write $k = A(i,j)$ for the value of k.

Row vectors and column vectors (containing numbers) are likewise representable by strings, with $A(i,k)$ meaning that the i-th entry of the vector is equal to k.

With these conventions it is easy for VNC^1 to Σ_0^B- or Σ_1^B-define many properties of the graph G encoded as above. We illustrate this with several examples.

- For $u < n$, the set of edges containing vertex u can be defined as the set

  $$E(\{u\}) \;=\; \{\langle u,v,k\rangle : (\exists k' \leq p(n))(k < k' \wedge A(u,v,k'))\}.$$

  Note this allows for multiedges. The degree of v is $|E(\{v\})|$ and can be Σ_0^B-defined with the *Numones* function. G has degree d if each $u \in [n]$ has degree d. There will always be a polynomial upper bound $p(n)$ on the degree.
- For $U \subset [n]$, the set $E(U,\overline{U})$ is defined similarly as

  $$E(U,\overline{U}) \;=\; \{\langle i,j,k\rangle : i \in U \wedge j \notin U \wedge (\exists k' \leq p(n))(k < k' \wedge A(i,j,k'))\}.$$

- Rational numbers p/q are represented by pairs of integers (p,q) (not necessarily in reduced form). The usual ordering $p/q < p'/q'$ is of course definable by $pq' < p'q$, where $q, q' > 0$. Pairs of rational numbers may be added or multiplied or divided as usual.
  The proof of the Cauchy-Schwarz theorem, and more generally our proofs of expansion properties, argue about sums of vectors of rational numbers. VNC^1 can define summations of vectors of integers [14], but it is not clear whether it can define summations of vectors of arbitrary rational numbers. This will be handled in our VNC^1 proofs by clearing the denominators so that we can argue about summations of integers instead of about summations of rational numbers. In our applications, the least common multiple of the denominators will be easily computed, making it easy to clear the denominators.
- The edge expansion of a degree d graph G can thus be defined by as in equation (1) with $V = [n]$. This, however, is not a Σ_1^B-definition, since it requires minimizing over all subsets $U \subset [n]$. Instead we can define the property "G has edge expansion $> p/q$" as

  $$(\forall U{<}n)\Big(0 < |U| \leq \frac{n}{2} \to \frac{|E(U,\overline{U})|}{d \cdot |U|} > \frac{p}{q}\Big).$$

  This is a Π_1^B-condition. Recall that "$(\forall U{<}n)$" is quantifying over all subsets of $[n]$.

- A rotation map is encoded by a second order object $Rot(u, i, v, j)$ with the meaning that the i-th edge of u is the same as the j-th edge of v. We can relate the rotation map Rot and the adjacency matrix A by letting the i-th edge from u to v be the edge $\langle u, v, k\rangle$ such that

$$|\{\langle u, i', v, j\rangle : Rot(u, i', v, j) \wedge i' < i\}| \;=\; k$$

  Furthermore, the adjacency matrix A is Σ^B_1-definable in terms of Rot, since $A(u, v) = k$ holds exactly when there are exactly k values $\langle i, j\rangle$ such that $Rot(u, i, v, j)$. Since v, j are uniquely determined by u, i, we also use the notation $Rot(u, i) = (v, j)$.
  It is also possible to Σ^B_1-define a canonical rotation map as a function of the adjacency matrix.

Graph operations are also readily defined by VNC^1:

- To add self-loops to convert a d-regular G to a $2d$-regular G', define the adjacency matrix $A'(u, v, k)$ as

$$(u \neq v \wedge A(u, v, k)) \vee (u = v \wedge (\exists k' \leq d)(A(u, v, k') \wedge (k = k' + d))).$$

- (Graph Powering.) Let $k > 1$ be fixed. VNC^1 can Σ^B_1-define the graph power G^k from G as follows. We write $\langle i_1, \ldots, i_k\rangle$ for an efficient sequence coding so that each $\langle i_1, \ldots, i_k\rangle$ is represented by an integer $< d^k$. Then $Rot(u, \langle i_1, \ldots, i_k\rangle) = (v, \langle j_1, \ldots, j_k\rangle)$ holds iff

$$(\exists \langle u_0, \ldots, u_k\rangle)[u_0{=}u \wedge u_k{=}v \wedge \bigwedge\nolimits_{s=1}^{k} (Rot(u_{s-1}, i_s) = (u_s, j_{k-s+1}))].$$

  Since k is fixed and each $u_i < n$, the quantifier is a bounded number quantifier.
- Similar arguments give Σ^B_1-definitions of Tensor Product and Replacement Product. The constructions are straightforward and we leave the details to the reader.

These constructions, along with Theorem 17, allow VNC^1 to prove the existence of the graphs G_i as defined by (2). Fix constants d and c, and fix a $(2d)$-regular G_0 with edge expansion ϵ_0. Also, fix a rotation map $Rot_0 = Rot_{G_0}$ for G_0. Given G_i and Rot_i, for $i \geq 0$, VNC^1 can prove the existence of G_{i+1} satisfying (2) along with the existence of Rot_{i+1}. Furthermore, by Theorem 17, VNC^1 can prove the existence of a second-order object encoding a sequence of graphs and rotation maps

$$(G_0, Rot_0),\ (G_1, Rot_1),\ (G_2, Rot_2),\ \ldots,\ (G_{|a|}, Rot_{|a|}), \tag{13}$$

so each G_{i+1} and associated rotation map Rot_{i+1} is obtained from G_i and Rot_i by Equation (2). Letting the constant $D = 2(4d)^2)^c$ as before, each G_i has $(|V_0| \cdot 4D)^{2^i}/D$ many vertices, provably in VNC^1. (See Theorem 9.) The size of G_{i+1} is greater than the square of the size of G_i; indeed, $|V_{i+1}| = D \cdot |V_i|^2$. Therefore, Theorem 17 applies, to show that VNC^1 can Σ^B_1-define the sequence (13) as function of a, and hence can Σ^B_1-define $G_{|a|}$ and $Rot_{|a|}$ as functions of a.

Similar, only slightly more complicated, arguments allow VNC^1 to prove the existence of the graphs $\tilde{G}_i$ as defined by (3). Now i can be an arbitrary first-order (integer) value $i = a$, not just a length $|a|$. Fix appropriate constants $d = 2^\ell$ and c, and for $i \leq 2c\ell{+}8$, fix graphs $\tilde{G}_i$ with edge expansion $\geq 1/1296$ and their rotation maps Rot_i. Using induction on Σ^B_0-formulas, VNC^1 proves the existence of a sequence of values $k_0, \ldots, k_s$ such that $k_0 = a$ and each $k_{i+1} = \lfloor (k_i{-}2c\ell{-}5)/2 \rfloor$, and such that s is the first value where $k_s < 2c\ell{+}7$. Given both $\tilde{G}_{k_{i+1}}$ and $\tilde{G}_{k_{i+1}+1}$ and their rotation maps $Rot_{k_{i+1}}$ and $Rot_{k_{i+1}+1}$, and using

the definition (3), VNC^1 can prove the existence of both $\tilde{G}_{k_i}$ and $\tilde{G}_{k_i+1}$ and their rotation maps. Furthermore, the sizes of $\tilde{G}_{k_i}$ and $\tilde{G}_{k_i+1}$ are both greater than the square of the size of $\tilde{G}_{k_{i+1}+1}$. Therefore, by Theorem 17 again, VNC^1 can prove the existence of a second-order object encoding a sequence of pairs of graphs and rotation maps:

$$(\tilde{G}_{k_s}, Rot_{k_s}, \tilde{G}_{k_s+1}, Rot_{k_s+1}), (\tilde{G}_{k_{s-1}}, Rot_{k_{s-1}}, \tilde{G}_{k_{s-1}+1}, Rot_{k_{s-1}+1}), \ldots \\ (\tilde{G}_{k_0}, Rot_{k_0}, \tilde{G}_{k_0+1}, Rot_{k_0+1}), \tag{14}$$

with successive pairs of expander graphs obtained via (3). Since $k_0 = a$, this shows that VNC^1 can Σ^B_1-define $\tilde{G}_a$ and Rot_a as functions of a.

It is immediate from the definition of G_i, using induction on i, that VNC^1 proves that each G_i has degree $2d$ (for the appropriate value of d). Likewise VNC^1 proves that each $\tilde{G}_i$ has degree $2d$. It is more difficult to prove that VNC^1 proves G_i and $\tilde{G}_i$ have the edge expansion properties of Theorems 9 and 10. This is discussed in the next sections.

5.5 Formalizing edge expansion properties in VNC^1

We prove that the graph operations can be analyzed in VNC^1. For $\emptyset \neq U \subsetneq V$, we denote by $\textit{edge-exp}_G(U)$ the *edge expansion* ratio defined as follows:

$$\textit{edge-exp}_G(U) \;=\; \frac{|E(U, \overline{U})|}{d \cdot \min\{|U|, |\overline{U}|\}}.$$

▶ **Lemma 18.** *Let k be even.* VNC^1 *proves the following: Suppose G^k is the graph power of G as defined in Section 5.4, and V is the common vertex set of G and G^k. Then*

$$(\exists U)[U \subset V \wedge \textit{edge-exp}_{(\bigcirc G^k)}(U) < [\tfrac{1}{2}\big(1 - \big(1 - \tfrac{\epsilon^2}{4}\big)^{k/2}\big)] \rightarrow (\exists U)[U \subset V \wedge \textit{edge-exp}_G(U) < \epsilon].$$

▶ **Lemma 19.** VNC^1 *proves the following: Let $G = (V_G, E_G)$ be a d_G-regular graph with $d_G/2$ self-loops at every vertex and $H = (V_H, E_H)$ be a d_H-regular graph with $d_H/2$ self-loops at every vertex. Let $\epsilon = \min\{\epsilon_G, \epsilon_H\}$. Then,*

$$(\exists U)[U \subset (V_G \otimes V_H) \wedge \textit{edge-exp}_{G \otimes H}(U) < \epsilon/50] \\ \rightarrow\; (\exists U)[U \subset V_G \wedge \textit{edge-exp}_G(U) < \epsilon_G] \vee (\exists U)[U \subset V_H \wedge \textit{edge-exp}_H(U) < \epsilon_H].$$

▶ **Lemma 20.** VNC^1 *proves the following: Let $G = (V_G, E_G)$ be a D-regular graph on n vertices, and let $H = (V_H, E_H)$ be a d-regular graph on D vertices. Let $\epsilon = \epsilon_G^2 \epsilon_H/48$, and let $V_{G \circ H}$ denote the vertices of $G \circ H$. Then,*

$$(\exists U)[U \subset V_{G \circ H} \wedge \textit{edge-exp}_{G \circ H}(U) < \epsilon] \\ \rightarrow\; (\exists U)[U \subset V_G \wedge \textit{edge-exp}_G(U) < \epsilon_G] \vee (\exists U)[U \subset V_H \wedge \textit{edge-exp}_H(U) < \epsilon_H].$$

Finally, the arguments in Section 3.3 also formalize in VNC^1 to combine Lemmas 18-20 to prove the existence of expander graphs. For this, we need to formulate the arguments so as to apply Theorem 16. We first how how to prove the existence of the edge expanders G_i in VNC^1. To talk about the edge expansion of G_i, we encode a subset U of V_i using a string Y of length exactly $|V_i| + 1 = (|V_0| \cdot 4D)^{2^i}/D + 1$, by letting $Y = U \cup \{|V_i|\}$. It follows from the discussion at the end of Section 5.4 that VNC^1 can Σ^B_1-define G_i as a function of $|V_i|$, hence as a function of Y.

Let $A(Y)$ express the conditions that (a) $|Y| = |V_i| + 1$ for some i, and (b) Y encodes a subset U of V_i such that $\textit{edge-exp}_{G_i}(U) < 1/1296$. The (contrapositive of the) argument in Section 3.3, formalized in VNC^1, shows that the following is VNC^1 provable:

$$(\exists Y \leq a) A(Y) \rightarrow (\exists Y \leq \sqrt{a}) A(Y). \tag{15}$$

For $i = 0$, this uses the fact that G_0 has edge expansion $\geq 1/1296$, and since G_0 is a constant graph, this can be checked by a enumerating all of the finitely many subsets.

Applying Theorem 16 to (15) gives that VNC^1 proves

$$(\exists Y{\leq}a)A(Y) \to (\exists Y{\leq}1)A(Y).$$

There are only four possible Y's with $|Y| \leq 1$. The righthand side, $(\exists Y{\leq}1)A(Y)$, is a false Σ^B_0-formula asserting a finite property. Hence, VNC^1 can trivially disprove $(\exists Y{\leq}1)A(Y)$ by direct evaluation. Therefore, VNC^1 proves $\neg(\exists Y)A(Y)$, i.e., can prove that any V_i must be an expander. This completes the proof of the following.

▶ **Theorem 21.** *There is a constant d so that VNC^1 proves the existence of arbitrarily large, degree $2d$ graphs with edge expansion $\geq 1/1296$. Namely, VNC^1 proves*

$$(\forall a)(\exists V, E)[|V| \geq a \wedge (V, E) \text{ is a degree } 2d \text{ graph} \\ \wedge(\forall U)(U \subseteq V \to \textit{edge-exp}_{(V,E)}(U) \geq 1/1296)].$$

In fact, there is a Σ^B_1-definable function G of VNC^1 so that that VNC^1 proves

$$(\forall a)[G(a) \text{ is a degree } 2d \text{ graph } G(a) = (V, E) \text{ with } |V| \geq a \\ \wedge(\forall U)(U \subseteq V \to \textit{edge-exp}_{(V,E)}(U) \geq 1/1296)].$$

VNC^1 can also prove the existence of edge expander graphs of aribitrary size.

▶ **Theorem 22.** *There is a constant $d = 2^\ell$ and a Σ^B_1-definable function G of VNC^1 so that VNC^1 proves*

$$(\forall a)[G(a) \text{ is a 4d-regular graph } G(a) = (V(a), E(a)) \text{ with } |V| = a \\ \wedge(\forall U)(U \subseteq V \to \textit{edge-exp}_{(V,E)}(U) \geq 1/(2 \cdot 1296))].$$

Proof. Pick appropriate constant values for d and c. VNC^1 starts by proving the existence of $\tilde{G}_i$ for the least i such that $2^i \geq a$. VNC^1 can prove the existence of the sequence $k_0, \ldots, k_s$ with $k_0 = i$, and each $k_{i+1} = \lfloor (k_i - 2c\ell - 5) \rfloor$ and s the first value with $k_s < 2c\ell + 7$. In addition, by Section 5.4, VNC^1 can prove the existence of second-order objects encoding edge expanders $\tilde{G}_j = (\tilde{V}_j, \tilde{E}_j)$ for every value $j = k_i$ or $j = k_i + 1$ with $i \leq s$. Recall that $|\tilde{V}_j| = 2^j$. Let $A(Y)$ express the condition that for some $i \leq s$, either (a) $|Y| = 2^{k_i} + 1$ and Y encodes a subset U of $\tilde{V}_{k_i}$ such that $\textit{edge-exp}_{\tilde{G}_{k_i}}(U) < 1/1296$, or (b) $|Y| = 2^{k_i+1} + 1$ and Y encodes a subset U of $\tilde{V}_{k_i+1}$ such that $\textit{edge-exp}_{\tilde{G}_{k_i+1}}(U) < 1/1296$. The (contrapositive) of the argument in Section 3.3, now shows that

$$(\exists Y{\leq}a)A(Y) \to (\exists Y{\leq}\sqrt{a})A(Y).$$

is VNC^1-provable. Applying Theorem 16 gives that VNC^1 proves

$$(\exists Y{\leq}a)A(Y) \to (\exists Y{\leq}1)A(Y).$$

Therefore, VNC^1 proves $\neg(\exists Y{\leq}a)A(Y)$, i.e., it proves the edge expansion properties for arbitrary Y, and hence the edge expansion properties of $\tilde{G}_i$. ◀

Finally, VNC^1 can also formalize the argument given in Section 4 to construct bipartite vertex expanders. The only new proof ingredient is the use of logarithms to define t_1 and t_2 in the proof of Claim 13. VNC^1 can define rational approximations to logarithms; here we need only integers t_1 and t_2 such that $(1 + \epsilon')^{t_1} \geq 1/\alpha$ and $(1 - \epsilon')^{t_2} \leq \alpha$. Since ϵ' is

small, these values can be estimated as $|\lceil 1/\alpha \rceil|/\epsilon'$. Actually, in the argument for Section 4, we have $\alpha = 1/600$ and $\epsilon' = \epsilon/D'$ are fixed constants; hence t_1 and t_2 are constants as well. Finally, at the very end of the proof of Theorem 12, we have $A = (D'(2d)+1)^{\max\{t_1,t_2\}}$, where $t' = \max\{t_1, t_2\}$. Thus A is also a constant. Here it is important that t' is constant, or at least is not too large, so that t' can be used as an exponent.

Thus we have proved the following theorem.

▶ **Theorem 23.** VNC^1 *proves Theorem 12 for any constant* α*. Namely, for any fixed rational* $0 < \alpha < 1$*, there exists an* $A > 0$ *and a* Σ^B_1*-defined function* $F(m)$ *of* VNC^1 *so that the following holds:* VNC^1 *proves that for all* m*,* $F(m)$ *equals the rotation map* Rot_G *of an* (α, A) *bipartite vertex expander graph* G *on* $m+m$ *vertices.*

As VNC^1 is a subtheory of VNC^1_*, Theorem 23 is stronger than the assumption needed by Jeřábek [23].

6 Application to monotone sequent calculus

In [36], Pudlák and Buss introduced a proof system for reasoning with monotone formulas, motivated by strong lower bounds results for monotone circuits, and posed the question whether similar difference in complexity holds in the propositional proof system setting. More specifically, they formulated monotone sequent calculus and asked whether any non-monotone proof of a monotone sequent can be replaced by a monotone proof at most polynomially larger. In [34], Pudlák further investigated this question, focusing in particular on the pigeonhole principle. There, he discussed the need to formalize properties of monotone counting formulas such as AKS sorting networks of [1], and asked whether there are small proofs of basic properties of counting formulas.

The pigeonhole principle was shown to have polynomial-size monotone sequent calculus proofs by Atserias, Galesi and Gavaldá in [6]; this paper was the first to use the name MLK for this system. The same paper also gave quasipolynomial-size proofs of basic counting principles. Building upon the latter result, Atserias, Galesi and Pudlák [7] show that, in contrast to monotone circuit classes, monotone proof systems are nearly as powerful as non-monotone ones: polynomial-size non-monotone proofs can be simulated by monotone ones of quasipolynomial size. The quasipolynomial blowup is introduced in the [6] proofs of certain properties of threshold formulas.

To prove that every LK proof can be converted into an MLK proof of quasipolynomial size, [7] use monotone threshold formulas to eliminate negated variables. A *threshold formula* $TH^n_k(x_1, \ldots, x_n)$ asserts that at least k variables x_i are 1. The standard inductive definition builds TH^n_k as a disjunction of $TH^{n/2}_i(x_1, \ldots, x_{n/2}) \wedge TH^{n/2}_j(x_{n/2+1}, \ldots, x_n)$ for all pairs $i, j \leq n/2$ such that $i + j \geq k$. This definition yields quasipolynomial size formulas TH^n_k, and thus gives only quasipolynomial size LK proofs of properties of TH^n_k. If LK is polynomially bounded, then so is MLK (as in this case properties of threshold functions would have polynomial-size LK proofs). More generally, they use the following lemma based on results from [6]:

▶ **Lemma 24** ([7, Lemma 6])**.** *Let* TH^n_k *be a polynomial-size monotone threshold formula. Then* MLK *polynomially simulates* LK *on monotone sequents, provided there are polynomial-size* LK *proofs of the following sequents:*

1. $TH^n_k(x_1, \ldots, x_n) \to$ *and* $\to TH^n_0(x_1, \ldots, x_n)$ *for every* n *and* $k > n$.
2. $TH^n_k(x_1, \ldots, x_i/0, \ldots, x_n) \to TH^n_{k+1}(x_1, \ldots, x_i/1, \ldots, x_n)$ *for all* n*,* k *and* i *such that* $0 \leq k, i \leq n$.

Such polynomial-size monotone threshold formulas can be built using the classic construction of monotone log-depth sorting networks by Ajtai, Komlós and Szemerédi [1], known as AKS sorting networks. A sorting network can be thought of as a circuit with n outputs gates, which contain the values of the input gates in sorted order. That is, the k^{th} output of a sorting network is 0 iff there are at least k 0s among inputs to the network. The construction of AKS sorting networks is fairly involved; see [31, 41] for expositions. At the end of the paper, Atserias et al. note that replacing their threshold formulas with monotone NC^1 sorting networks of Ajtai, Komlós and Szemerédi would remove the blowup and allow for *polynomial-size* simulation, provided the relevant properties can be proven with NC^1 reasoning (not necessarily monotone).

Jeřábek [24] has shown just that, under the assumption that bipartite expanders graphs with appropriate parameters can be constructed, and their properties proven in NC^1 reasoning. More precisely, Jeřábek [24] has shown that AKS sorting networks (Paterson's [31] variant) are indeed formalizable in a theory VNC^1_* of NC^1 reasoning, under the assumption of the existence of a family of bipartite expanders provable in VNC^1_* (with parameters as in Claim 13). The theory VNC^1_* is somewhat stronger than VNC^1 that we use, in that it can evaluate and reason about less uniform families of log-depth circuits; however, proofs in VNC^1_* still translate into polynomial-size LK proofs [23]. Thus, Jeřábek obtains the following result:

▶ **Theorem 25** ([24, Theorem 5.5]). *Suppose that there exists a constant D and a parameter-free NC^1_* function $G(m)$ such that VNC^1_* proves that for all numbers m, $G(m)$ is a $\langle 1/600, D\rangle$ bipartite $m+m$ expander. Then* MLK *polynomially simulates* LK *on monotone sequents.*

The construction in Theorem 12 gives expanders with the appropriate parameters, and Theorem 23 shows that it can be done in VNC^1 (and thus VNC^1_*). As this proves the assumption of Theorem 25, we immediately get the following corollary.

▶ **Theorem 26** (Main application). MLK *polynomially simulates* LK *on monotone sequents.*

7 Conclusions and open problems

From the point of view of bounded reverse mathematics, the area that tries to pinpoint the minimal reasoning power needed to prove mathematical theorems, it is very interesting to understand what is the complexity of reasoning required to prove properties of expander graphs, and thus what is the complexity of reasoning in expander-based proofs such as the known proofs of $\mathsf{SL} = \mathsf{L}$ [37, 39]. This paper makes a step in this direction by showing that an expander construction can be formalized within the system VNC^1.

A number of open questions remain. Can we formalize expanders in a weaker theory than VNC^1, e.g., the system of TC^0 reasoning? Can Reingold's result that undirected graph connectivity is in deterministic logspace [37] be formalized in the system of logspace reasoning? The analysis of graph powering given in this paper and the analysis of replacement product given in [4] are not strong enough to achieve that goal.

Finally, as was already asked by [24], can the AKS construction of expanders be modified to yield U_{E^*}-uniform sorting networks?

Acknowledgements. We want to thank Denis Thérien and Pascal Tesson for inviting V.K., A.K., and M.K. to the 2007 McGill Complexity Workshop in Barbados, where this paper was initiated. V.K. and A.K. also wish to thank Josh Buresh-Oppenheim, Shlomo Hoory, and Rahul Santhanam for our many discussions on expander graphs. V.K. and A.K. are particularly thankful to Russell Impagliazzo for inviting them to spend a semester at UCSD in

the spring of 2016, where this work was finally completed. S.B. thanks Amir Akbar Tabatabai and Raheleh Jalali for useful discussions on VNC[1], and Rosalie Iemhoff and Anupam Das for discussions on intuitionistic logic. We also thank Anupam Das for his comments on our paper, and Albert Atserias for clarifying to us the history of the MLK proof system. We are especially grateful to Emil Jeřábek for carefully reading our manuscript and pointing out some errors in the early versions.

Abstract

We consider the problem of clearing a system of interconnected banks that have been exposed to a shock on their assets. Eisenberg and Noe [9] showed that when banks can only enter into simple debt contracts with each other, then a clearing vector of payments can be computed in polynomial time. In this paper, we show that the situation changes radically when banks can also enter into *credit default swaps* (*CDSs*), i.e., financial derivative contracts that depend on the default of another bank. We prove that computing an approximate solution to the clearing problem with sufficiently small constant error is PPAD-complete. To do this, we demonstrate how financial networks with debt and CDSs can encode arithmetic operations such as addition and multiplication. Our results have practical impact for network stress tests and reveal computational complexity as a new concern regarding the stability of the financial system.

1 Introduction

We consider systems of banks (or other financial institutions) that are connected by financial contracts. Due to a shock on their assets, some of the banks may not be able to meet their obligations towards other banks, thus forcing them into bankruptcy (or *default*). We study the *clearing problem* in this setting, i.e., the problem of computing a collection of payments between each pair of banks that are in accordance with standard bankruptcy law. Since banks' contractual relationships can be complex and are often cyclic, designing good clearing mechanisms is a nontrivial task.[1]

In their seminal paper, Eisenberg and Noe [9] devised an efficient clearing mechanism for financial systems. Their mechanism relies on the assumption that banks can only enter into simple *debt contracts*, i.e., loans from one bank to another. We argue, however, that the

growing importance of financial derivative contracts makes it necessary to reconsider the question if today's financial networks can still always be efficiently cleared. Specifically, *credit default swaps (CDSs)*, which are contracts that are only triggered when a reference entity goes into default, have received only little attention in a network context so far. Market participants use CDSs to insure themselves against a default of the reference entity or to place a speculative bet on this event. Because the reference entity can itself be a financial institution, CDSs create new dependencies that do not exist in pure debt networks.

In prior work [17], we have shown that if no money is lost in the bankruptcy process (i.e., banks do not incur *default costs*), then clearing payments always exist. However, our proof uses a non-constructive fixed point argument so that the question remained open if one could devise an efficient algorithm to actually *find* a clearing payment vector in this case.

In the present paper, we answer this question in the negative: we show that the problem FindClearing of finding an approximately clearing vector of payments in a financial network with debt and CDSs and without default costs is PPAD-complete even for a sufficiently small constant error bound. This implies that the problem does not have a polynomial-time approximation scheme (PTAS) unless P=PPAD and thus needs to be considered computationally intractable.

More in detail, we proceed as follows: we first describe a simplified variant of our model from [17] that only applies to the case without default costs (Section 3). We next argue that since solutions to the clearing problem can be irrational, FindClearing needs to be considered as an approximation problem. We define the notion of an *ε-approximately clearing vector* and we show that it makes the FindClearing problem well-posed and a member of PPAD (Section 4). Having done this, we describe our main contribution, namely a reduction from the problem of finding an approximate solution of a generalized circuit to FindClearing, establishing that FindClearing is PPAD-hard. We do this by composing *financial system gadgets*, i.e., fragments of financial networks that encode specific operations such as addition, subtraction, scaling, comparison, and Boolean operations like NOT and OR (Section 5).

Our results contribute to the literature on complexity in financial networks [3]. By studying financial networks from a computation perspective, we are able to accurately describe the effect of introducing a new class of financial products into the system in terms of computational complexity. Our hardness result has practical relevance for *stress tests*, in which regulators such as the European Central Bank evaluate the stability of the financial system under an array of adverse economic scenarios. We argue that, because of the complex interdependencies in real financial networks, future stress tests should take network effects into account, which would essentially require regulators to compute clearing payments. The approximation quality would be defined by the regulator and must thus be kept flexible. The fact that no PTAS for the clearing problem exists (unless P=PPAD) now implies that financial networks with CDSs cannot be reliably stress tested, which by itself poses a risk to the stability of the financial system.

2 Related Work

Prior work on financial networks has primarily focused on financial contagion, i.e., how small shocks may amplify to system-wide losses. Researchers have studied which network topologies are particularly susceptible to such effects [2, 10, 1] as well as developed measures for an individual bank's contribution to the risk of contagion [1, 4, 12].

The clearing problem was first studied by Eisenberg and Noe [9], who showed that in debt networks without default costs, clearing payments always exist and can be computed

in polynomial time. Rogers and Veraart [14] extended their result to debt networks *with* default costs.

Since all aforementioned pieces of work use a weighted graph as the underlying model of the financial network, they cannot accurately represent the *ternary* relationship introduced by a credit default swap between the holder, the writer, and the reference entity. We filled this gap in prior work [17] by devising a new model that *can* represent networks of debt and CDSs. We showed that the clearing problem in these networks is significantly more complex than in the debt-only case: if default costs are present, then clearing payments may not even exist and it is NP-hard to decide if they do. In the present paper, we study the case *without* default costs.

An extension of the clearing problem is to determine the maximum total loss an adversary could inflict on a financial system given a budget of shocks to banks. The problem is known [11] to be intractable in cross-ownership networks (which are similar to debt networks) despite the clearing problem being solvable in polynomial time.

The PPAD complexity class [13] is best known for the problem of computing a Nash equilibrium, the hardness of which was shown by reduction from generalized circuits [7, 5, 6, 15]. Our work builds on this technique, and in particular on Rubinstein's [15] PPAD-hardness result for constant accuracy. To the best of our knowledge, we are the first to implement generalized circuits using financial networks and, together with our prior work on the case with default costs, we are the first to present a computational complexity result for the clearing problem in financial networks.

3 Formal Model

Our model is based on the model by Eisenberg and Noe [9], which was restricted to debt contracts. We define an extension to credit default swaps. We adjust the notation where necessary. The model used in this paper is a simplified version of the one we previously introduced in [17], where default costs were also modeled. In this paper, we only consider financial systems without default costs.

We consider a two-period model:

- *Period 0:* Each bank receives an initial endowment called its *external assets*. Banks enter into bilateral contracts with each other. No bank is in default.
- *Period 1:* Banks' external assets change due to an exogenous shock. All banks must make payments according to their contractual commitments from period 0 and the new external assets.

We define the elements of the financial system in period 1.

Banks and External Assets

We denote by N a finite set of n *banks*. For any bank $i \in N$ let $e_i \geqslant 0$ denote the *external assets* of i as of period 1. Let $e = (e_i)_{i \in N}$ denote the vector of all external assets.

Contracts

There are two types of contracts: *debt contracts* and *credit default swap contracts (CDSs)*. Every contract gives rise to a conditional obligation to pay a certain amount, called a *liability*, from its *writer* to its *holder*. Banks that are unable to fulfill their obligations are said to be *in default*. The *recovery rate* r_i of a bank i is the share of its liabilities it is able to pay.

Thus, $r_i = 1$ if i is not in default and $r_i < 1$ if i is in default. Let $r = (r_i)_{i \in N}$ denote the vector of all recovery rates.

A *debt contract* obliges the writer i to unconditionally pay a certain amount to the holder j in period 1. This amount is called the *notional* of the contract and is denoted by $c^{\varnothing}_{i,j}$. A *credit default swap* obliges the writer i to make a conditional payment to the holder j in period 1. The amount of this payment depends on the default of a third bank k, called the *reference entity*. Specifically, the payment amount of the CDS contract from i to j with reference entity k and *notional* $c^k_{i,j}$ is $c^k_{i,j} \cdot (1 - r_k)$.

Note that when banks enter into contracts, there would typically be an initial payment. For example, debt contracts arise because the holder lends an amount of money to the writer, and holders of CDSs pay a premium to obtain them. In our model, any initial payments have been made in period 0 and are implicitly reflected by the external assets.

The contractual relationships between all banks are represented by a 3-dimensional matrix $c = (c^k_{i,j})_{i \in N,\, j \in N,\, k \in N \cup \{\varnothing\}}$. The entry $c^{\varnothing}_{i,j}$ is the total notional of the debt contracts from i to j and the entry $c^k_{i,j}$ for $k \in N$ is the total notional of CDS contracts from i to j with reference entity k. Zero entries indicate the absence of the respective contract. The set of contracts can alternatively be represented as an edge-weighted directed hypergraph.

We require that no bank enters a contract with itself (i.e., $c^k_{i,i} = 0$ for all $k \in N \cup \{\varnothing\}$ and $i \in N$). We further require that any bank that is a reference entity in a CDS must be a writer of some debt contract (i.e., for all $i \in N$, if $\sum_{k,l \in N} c^i_{k,l} > 0$, then $\sum_{j \in N} c^{\varnothing}_{i,j} > 0$). Both requirements are needed to rule out pathological cases. They are always assumed to hold in the following.

For any bank i, the *creditors of* i are the banks that are holders of contracts for which i is the writer, i.e., the banks to which i owes money. Conversely, the *debtors of* i are the writers of contracts of which i is the holder, i.e., the banks by which i is owed money. Note that the two sets can overlap: for example, a bank could hold a CDS on one reference entity while writing a CDS on another reference entity, both with the same counterparty.

Financial System Without Default Costs

A *financial system without default costs* (or, for the purpose of this paper just a *financial system*) is a tuple (N, e, c) where N is a set of banks, e is a vector of external assets, and c is a 3-dimensional matrix of contracts. The *length* of a financial system is the total number of bits needed to describe the tuple, including all numeric values.

Liabilities, Payments, and Assets

Given a recovery rate vector r, for any two banks i, j, the *liabilities of* i *to* j *at* r are the amount of money that i has to pay to j if recovery rates in the financial system are given by r, denoted by $l_{i,j}(r)$. They arise from the aggregate of all debt and CDS contracts from i to j:

$$l_{i,j}(r) := c^{\varnothing}_{i,j} + \sum_{k \in N} c^k_{i,j} \cdot (1 - r_k).$$

The *total liabilities of* i *at* r are the aggregate of all liabilities that i has towards other banks given the recovery rates r, denoted by $l_i(r)$:

$$l_i(r) := \sum_{j \in N} l_{i,j}(r).$$

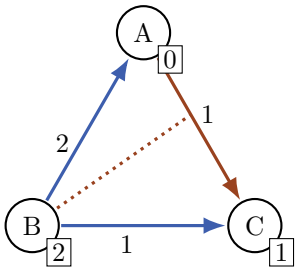

Figure 1 Example financial system.

The actual *payment* $p_{i,j}(r)$ from i to j at r can be lower than $l_{i,j}(r)$ if i is in default. By the *principle of proportionality*, a bank that is in default makes payments for its contracts in proportion to the respective liabilities:

$$p_{i,j}(r) := r_i \cdot l_{i,j}(r).$$

The *total assets* $a_i(r)$ of a bank i at r consist of its external assets e_i and the incoming payments to i:

$$a_i(r) := e_i + \sum_{j \in N} p_{j,i}(r).$$

Clearing Recovery Rate Vector

So far, r was just a candidate vector of recovery rates. We define what it means to be *clearing*:

▶ **Definition 3.1** (Clearing Recovery Rate Vector)**.** A recovery rate vector r is called *clearing* for a financial system without default costs $X = (N, e, c)$ if, for all banks $i \in N$, we have:

$$r_i = \min\left(1, \frac{a_i(r)}{l_i(r)}\right) \quad \text{if } l_i(r) > 0. \tag{1}$$

We also call a clearing recovery rate vector a *solution*.

Note that recovery rates of banks with zero liabilities are left unconstrained. While this might seem unintuitive at first, it corresponds exactly to our definition of the recovery rate: if there are no liabilities, then the "share of its liabilities bank i is able to pay" is not well-defined. Forcing the recovery rate to 1 in this case would introduce an artificial discontinuity because $\frac{a_i(r)}{l_i(r)}$ may converge to a value strictly below 1 while $l_i(r)$ converges to zero.[2,3]

[2] In the literature, (1) is often used directly as the definition of the recovery rate rather than "the share of its liabilities bank i is able to pay." Because we are always looking for a *clearing* recovery rate vector, the two definitions coincide.

[3] Eisenberg and Noe [9] define clearing *payments*, rather than recovery rates, by requiring that banks with sufficient assets pay their liabilities in full and banks without sufficient assets pay out all their assets proportionally to creditors. It is easy to show that this is equivalent to our definition.

Example and Visual Language

Figure 1 shows a visual representation of an example financial system. There are three banks $N = \{A, B, C\}$, drawn as circles, with external assets of $e_A = 0$, $e_B = 2$, and $e_C = 1$, drawn as rectangles on the banks. Debt contracts are drawn as blue arrows from the writer to the holder and they are annotated with the notionals $c^{\varnothing}_{B,A} = 2$ and $c^{\varnothing}_{B,C} = 1$. CDS contracts are drawn as orange arrows where a dashed line connects to the reference entity and are also annotated with notionals: $c^{B}_{A,C} = 1$. A clearing recovery rate vector for this example is given by $r_A = 1$, $r_B = \frac{2}{3}$, and $r_C = 1$. The liabilities arising from this recovery rate vector are $l_{B,A}(r) = 2$, $l_{B,C}(r) = 1$, and $l_{A,C}(r) = \frac{1}{3}$. The clearing payments are $p_{B,A}(r) = \frac{4}{3}$, $p_{B,C} = \frac{2}{3}$, and $p_{A,C}(r) = \frac{1}{3}$. This is the only solution for this system.

We stress that we are not concerned with the question whether or not it is "rational" for the banks to form a certain financial system: contracts might have been entered for reasons exogenous to the system or simply for cash transfers at time 0.

We are now ready to re-state an existence result which we have previously shown in [17].

▶ **Theorem 3.2** (Existence of Solutions [17]). *For every financial system without default costs, there exists a clearing recovery rate vector.*

Proof Outline. The proof rests on the fact that the right-hand side of equation (1) in Definition 3.1 is continuous as a function of r. Assume WLOG that $N = \{1, \ldots, n\}$. For $i \in N$ let

$$\rho_i : [0,1]^n \to 2^{[0,1]}$$
$$\rho_i(r) := \begin{cases} \{\min(1, \frac{a_i(r)}{l_i(r)})\} & \text{if } l_i(r) > 0 \\ [0,1] & \text{if } l_i(r) = 0 \end{cases}$$

and define $\rho : [0,1]^n \to 2^{[0,1]^n}$ by $\rho(r) := \times_{i=1}^{n} \rho_i(r)$.

Clearly, a recovery rate vector r is clearing iff it is a fixed point of the set-valued function ρ, i.e., iff $r \in \rho(r)$. To show that such a fixed point exists, one applies Kakutani's fixed point theorem for set-valued functions with a closed graph (a generalization of Brouwer's fixed point theorem for continuous functions). ◀

4 Defining the FindClearing Search Problem

We have just seen a non-constructive proof that a solution for a given financial system always exists. In this section, we define the corresponding total search problem. Since there are financial systems where all solutions contain irrational numbers (a simple example is provided in Appendix A), the best we can hope for is an algorithm that computes a recovery rate vector that is in some sense *approximately* clearing.

There are many ways to relax the definition of clearing recovery rate vectors to receive a concept of an approximate solution. The approach we will use in this paper is to relax the function ρ from the proof of Theorem 3.2. For $x \in \mathbb{R}$ let $[x] := \min(1, \max(0, x))$. For $\varepsilon \geqslant 0$ write $y = x \pm \varepsilon$ to mean that $|x - y| \leqslant \varepsilon$ if x and y are scalars and $\|x - y\| \leqslant \varepsilon$ if x and y are vectors, where $\|\cdot\|$ is the supremum norm. We also use the notation "$\pm\varepsilon$" in compound expressions such as $[x \pm \varepsilon]$ to indicate a range of possible values. This notation formally

corresponds to interval arithmetic. For $\varepsilon \geqslant 0$ and $i \in N = \{1, \ldots, n\}$ let

$$\rho_i^\varepsilon(r) : [0,1]^n \to 2^{[0,1]}$$
$$\rho_i^\varepsilon(r) := \begin{cases} [\frac{a_i(r)}{l_i(r)} \pm \varepsilon] & \text{if } l_i(r) > 0 \\ [0,1] & \text{if } l_i(r) = 0 \end{cases}$$

and let $\rho^\varepsilon : [0,1]^n \to [0,1]^n$ be defined accordingly.

▶ **Definition 4.1** (Approximately Clearing Recovery Rate Vector)**.** Fix a financial system without default costs and let $\varepsilon \geqslant 0$. A recovery rate vector r is called *ε-approximately clearing* or an *ε-solution* if it is a fixed point of the set-valued function ρ^ε, i.e., if $r \in \rho^\varepsilon(r)$. For clarity, we refer to solutions that are not approximate as *exact solutions*.

Our definition of an approximate solution has many desirable properties from an economic and technical point of view. We provide a discussion in Appendix B. Note in particular that if r is an ε-solution and $l_i(r) > 0$, then $r_i = [\frac{a_i(r)}{l_i(r)}] \pm \varepsilon$, though the converse does not necessarily hold.

It is easy to see that for any $\varepsilon > 0$, there always exists an ε-solution of finite length. To guarantee that there is also an ε-solution of *polynomial* length, we make an additional assumption that we call *non-degeneracy*.[4] We can then state our search problem.

▶ **Definition 4.2** (Non-degenerate Financial System)**.** A financial system without default costs $X = (N, e, c)$ is called *non-degenerate* if each bank that writes a CDS also writes a debt contract or has strictly positive external assets.

▶ **Definition 4.3** (ε-FindClearing Problem)**.** For any parameter $\varepsilon > 0$, ε-FindClearing is the following total search problem: given a non-degenerate financial system without default costs, find an ε-solution.

The following lemma establishes that under the assumption of non-degeneracy, sufficiently "short" approximate solutions always exist in the vicinity of exact solutions, thus making ε-FindClearing a well-posed search problem. The converse is not in general true: there can be additional approximate solutions that are not close to any exact solution. While this is unfortunate, it appears to be unavoidable for an approximate solution concept; for example, the well established concept of approximate Nash equilibrium also has this property.

▶ **Lemma 4.4** (ε-FindClearing is Well-posed and in PPAD)**.**

1. *If $X = (N, e, c)$ is a non-degenerate financial system without default costs and $\varepsilon > 0$, then there exists an ε-solution of length polynomial in the length of X and the length of ε.*
2. *For any $\varepsilon > 0$, the problem ε-FindClearing is in PPAD.*

Proof Outline (full proof in Appendix C). We define a function F such that any ε-approximate fixed point of F gives rise to an ε-solution of X. We prove that since X is non-degenerate, F has a polynomial Lipschitz constant. The lemma follows using standard techniques. ◀

5 FindClearing is PPAD-hard

Our main contribution in this paper is the proof that ε-FindClearing is PPAD-hard, and thus PPAD-complete, for a sufficiently small constant ε.

[4] It is an open question whether or not ε-solutions of polynomial length are also guaranteed to exist when this assumption is not made.

▶ **Theorem 5.1.** *There exists an $\varepsilon > 0$ such that the ε-FindClearing problem is PPAD-hard.*

The theorem immediately implies:

▶ **Corollary 5.2.** *There is no polynomial-time approximation scheme that computes an ε-solution for a given financial system without default costs and a given ε, unless $P = PPAD$.*

Towards a proof of the theorem, we proceed in two steps: we first introduce a variant of Rubinstein's [15] generalized circuit framework and we show that the problem of finding an approximate solution of a generalized circuit in this framework is still well-posed and PPAD-complete (Section 5.1). We then reduce this problem to ε-FindClearing (Section 5.2).

5.1 Generalized Circuits

A generalized circuit consists of a collection of interconnected arithmetic or Boolean gates. In contrast to regular arithmetic or Boolean circuits, generalized circuits may contain cycles, making the problem of finding a solution (or stable state) of the circuit a non-trivial fixed point problem. Rubinstein [15] introduced a framework for generalized circuits that is already well-suited for our purposes. To make our reduction to financial systems as simple as possible, we slightly adapt Rubinstein's definition by assuming a reduced set of gates.

▶ **Definition 5.3** (Generalized Circuit and Approximate Solution)**.** A *generalized circuit* is a collection of *nodes* and *gates*, where each node is labeled *input* of any number of gates (including zero) and *output* of at most one gate. Inputs to the same gate are distinguishable from each other. Each gate has one of the following types:

- For each $\zeta \in [0, 1]$ the *constant gate* C_ζ with no inputs and one output.
- Arithmetic gates: *addition* and *subtraction* gates, denoted C_+ and C_-, with two inputs and one output; for each $\zeta > 0$ the *scale by* ζ gate $C_{\times\zeta}$ with one input and one output.
- For each $\zeta \in (0, 1)$ the *compare to* ζ *gate* $C_{>\zeta}$ with one input and one output.
- Boolean gates: $C_\neg$ with one input and one output and $C_\vee$ with two inputs and one output.

The *length* of a generalized circuit is given by the number of nodes, the size of the mapping from nodes to inputs and outputs of gates, and the length of any ζ values involved.

If $\varepsilon \geqslant 0$ and C is a generalized circuit, then an *ε-approximate solution* (or *ε-solution*) to C is a mapping that assigns to each node v of C a value $x[v] \in [0, 1]$ such that at any gate of type g with inputs $a_1, \ldots, a_l$ and output v the respective condition from Figure 2 holds.

▶ **Definition 5.4** (ε-GCircuit Problem)**.** For any parameter $\varepsilon > 0$, ε-GCircuit is the following total search problem: given a generalized circuit, find an ε-solution.

Note how the comparison gadget $C_{>\zeta}$ is *brittle*: its value is arbitrary if $x[a_1]$ is close to ζ. This property is crucial for our second step of describing generalized circuits via financial systems because the function $\frac{a_i}{l_i}$ that ultimately defines an approximate solution is always continuous while a non-brittle comparison gadget, yielding low values for $x[a_1] < \zeta$ and high values for $x[a_1] \geqslant \zeta$, would correspond to a discontinuous function. We further use *approximate Boolean values* $0 \pm \varepsilon$ and $1 \pm \varepsilon$ instead of exact Boolean values 0 and 1 since the latter are not attainable if there can be ε errors at each bank. Note how chains of Boolean gadgets do not accumulate errors, but chains of arithmetic gadgets do.

It is well accepted in the literature that ε-GCircuit is well-posed and in PPAD. We provide a simple lemma for our variant of ε-GCircuit for completeness. PPAD-hardness, and thus PPAD-completeness, of the ε-GCircuit problem for constant ε follows by reduction from Rubinstein's variant. Both proofs can be found in Appendix D.

$$
\begin{aligned}
g = C_{\zeta} \quad &\Rightarrow \quad x[v] = \zeta \pm \varepsilon \\
g = C_{+} \quad &\Rightarrow \quad x[v] = [x[a_1] + x[a_2]] \pm \varepsilon \\
g = C_{-} \quad &\Rightarrow \quad x[v] = [x[a_1] - x[a_2]] \pm \varepsilon \\
g = C_{\times\zeta} \quad &\Rightarrow \quad x[v] = [\zeta \cdot x[a_1]] \pm (1+\zeta)\,\varepsilon \\
g = C_{>\zeta} \quad &\Rightarrow \quad x[a_1] \leqslant \zeta - \varepsilon \;\Rightarrow\; x[v] = 0 \pm \varepsilon \\
&\qquad\quad x[a_1] \geqslant \zeta + \varepsilon \;\Rightarrow\; x[v] = 1 \pm \varepsilon \\
g = C_{\neg} \quad &\Rightarrow \quad x[a_1] = 0 \pm \varepsilon \;\Rightarrow\; x[v] = 1 \pm \varepsilon \\
&\qquad\quad x[a_1] = 1 \pm \varepsilon \;\Rightarrow\; x[v] = 0 \pm \varepsilon \\
g = C_{\vee} \quad &\Rightarrow \quad x[a_1] = 0 \pm \varepsilon \text{ and } x[a_2] = 0 \pm \varepsilon \;\Rightarrow\; x[v] = 0 \pm \varepsilon \\
&\qquad\quad x[a_1] = 1 \pm \varepsilon \text{ or } \quad x[a_2] = 1 \pm \varepsilon \;\Rightarrow\; x[v] = 1 \pm \varepsilon
\end{aligned}
$$

Figure 2 Conditions to hold at the different gates in an ε-solution of a generalized circuit.

▶ **Lemma 5.5** (ε-GCircuit is Well-posed and in PPAD)**.**

1. *If C is a generalized circuit and $\varepsilon > 0$, then there exists an ε-solution for C of length polynomial in the length of C and the length of ε.*
2. *For any $\varepsilon > 0$, the ε-GCircuit problem is in PPAD.*

▶ **Lemma 5.6.** *There exists an $\varepsilon > 0$ such that the ε-GCircuit problem is PPAD-hard.*

5.2 Reduction from Generalized Circuits to Financial Systems

We now reduce the GCircuit problem to the FindClearing problem. To do so, we construct *financial system gadgets*, i.e., fragments of financial systems where the recovery rate of an *output bank* is given (approximately) by a function of certain *input banks*.

▶ **Definition 5.7** (Financial System Gadget)**.** A *financial system gadget* G is a polynomial-time computable function mapping a financial system without default costs $X = (N, e, c)$ to a new financial system $X' = (N', e', c')$ in the following way:

- Given are X, a set of *input banks* $a_1, \ldots, a_l \in N$ where l depends on the gadget, and an *output bank* $v \in N$ such that v has no assets or liabilities in X, i.e., $e_v = c^k_{v,j} = c^k_{j,v} = 0$ for all $j \in N$ and $k \in N \cup \{\varnothing\}$.
- X' consists of X together with some new banks and contracts.
- For any ε and any ε-solution r' of X', the restriction $r := r'|_N$ is an ε-solution for X.
- For any ε and any ε-solution r of X, there is an ε-solution r' of X' such that $r'_i = r_i$ for all $i \in N \backslash \{v\}$.

In addition to these properties, gadgets typically establish some relationship between the recovery rates of the input and output banks. We usually label input banks a and b instead of a_1 and a_2 for the sake of readability.

We will now describe our gadgets: addition gadgets, scaling and comparison gadgets, and Boolean gadgets. Some of the gadgets, shown in Figures 3–6, are *fundamental* while the others are defined as combinations of the fundamental ones. We use our graphical language for financial systems where we draw the (existing) input and output banks as dotted circles and the new banks as solid circles. Our gadgets add assets and liabilities to the output bank and CDS references to the input banks. This ensures that gadgets only restrict the recovery

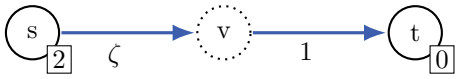

Figure 3 Constant Gadget: extension of an existing financial system with output bank v by new banks s, t and contracts such that $r_v = \zeta \pm \varepsilon$.

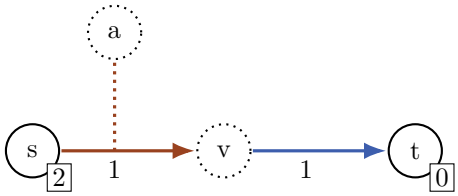

Figure 4 Inverter Gadget: extension of an existing financial system with input bank a and output bank v by new banks s, t and contracts such that $r_v = 1 - r_a \pm \varepsilon$.

rate of the output bank based on the recovery rates of the input banks, but not vice versa, and gadgets applied to different output banks do not conflict. In a final step, we iteratively apply our gadgets starting from a financial system with no contracts to receive a financial system that corresponds to a given generalized circuit. Our gadgets will be accurate up to an error of 3ε. We will later compensate for the factor 3 by choosing ε by factor 3 smaller. All gadgets lead to non-degenerate financial systems.

5.2.1 Addition Gadgets

The simplest gadget establishes a fixed recovery rate at the output bank:

▶ **Lemma 5.8** (Constant Gadget). *Let $\zeta \in [0, 1]$. There is a financial system gadget with no input banks and with output bank v such that if r is an ε-solution, then $r_v = \zeta \pm \varepsilon$.*

Proof. Consider the gadget in Figure 3. We have $\frac{a_s(r)}{l_s(r)} \geqslant 2 \geqslant 1 + \varepsilon$. It is easy to see that this implies that $r_s = 1$ in any ε-solution. Thus, s pays in full and $a_v(r) = \zeta$ and $l_v(r) = 1 \geqslant a_v(r)$, so in an ε-solution $r_v = \frac{a_v(r)}{l_v(r)} \pm \varepsilon = \zeta \pm \varepsilon$. ◀

An important building block for the following constructions is a gadget that "inverts" the recovery rate of a bank.

▶ **Lemma 5.9** (Inverter Gadget). *There is a financial system gadget with input bank a and output bank v such that if r is an ε-solution, then $r_v = 1 - r_a \pm \varepsilon$.*

Proof. Consider the gadget in Figure 4. Since $l_v(r) = 1$ we have in any ε-solution that $r_v = a_v(r) \pm \varepsilon$ and $a_v(r) = 1 - r_a$. ◀

We can now define the sum and difference gadgets:

▶ **Lemma 5.10** (Sum Gadget). *There is a financial system gadget with input banks a and b and output bank v such that if r is an ε-solution, then $r_v = [r_a + r_b] \pm 3\varepsilon$.*

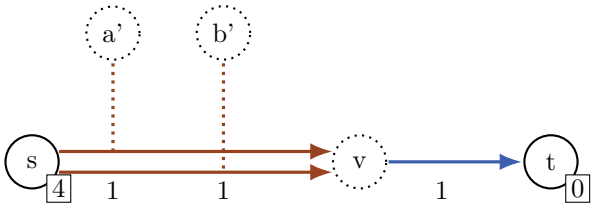

Figure 5 Sum Gadget: extension of an existing financial system with input banks a and b and output bank v by new banks s, t and contracts that translate $r_a + r_b$.

Proof. Apply inverter gadgets (Lemma 5.9) to both a and b and call the output banks a' and b', respectively. Now consider the gadget in Figure 5. We have

$$\begin{aligned} r_v &= [1 - r_{a'} + 1 - r_{b'}] \pm \varepsilon \\ &= [r_a + r_b \pm 2\varepsilon] \pm \varepsilon \\ &= [r_a + r_b] \pm 3\varepsilon. \end{aligned}$$

◀

▶ **Lemma 5.11** (Difference Gadget). *There is a financial system gadget with input banks a and b and output bank v such that if r is an ε-solution, then $r_v = [r_a - r_b] \pm 3\varepsilon$.*

Proof. Apply an inverter gadget (Lemma 5.9) to a and call the output bank a'. Apply the gadget in Figure 5 to a' and $b' := b$ and call the output bank u. From the proof of the previous lemma we know that

$$r_u = [1 - r_a + r_b] \pm 2\varepsilon$$

where the error is by one ε lower because we used one inverter gadget less. Now apply an inverter to u and call the output bank v. To show that r_v is as desired, we distinguish two cases:

- If $r_a \leqslant r_b$, then $1 - r_a + r_b \geqslant 1$, so $r_u = 1 \pm 2\varepsilon$ and thus $r_v = 1 - r_u \pm \varepsilon = 0 \pm 3\varepsilon = [r_a - r_b] \pm 3\varepsilon$ as required.
- If $r_a \geqslant r_b$, then $1 - r_a + r_b \leqslant 1$, so $r_u = 1 - r_a + r_b \pm 2\varepsilon$ and thus $r_v = 1 - r_u \pm \varepsilon = r_a - r_b \pm 3\varepsilon = [r_a - r_b] \pm 3\varepsilon$ as required.

◀

5.2.2 Scaling and Comparison

Towards the scaling and comparison gadgets, we introduce a versatile tool that can be used to re-scale and shift recovery rates.

▶ **Lemma 5.12** (Amplifier Gadget). *Let K and L be real numbers such that $K < L$, $K < 1$, and $L > 0$. Note that $K \leqslant 0$ and $L \geqslant 1$ are allowed. Let*

$$\begin{aligned} f &: [0,1] \to [0,1] \\ f(r_a) &:= \left[\frac{1}{L-K} r_a - \frac{K}{L-K} \right]. \end{aligned}$$

Note that f is monotonically increasing with $f(K) = 0$ and $f(L) = 1$.

There is a financial system gadget with input bank a and output bank v such that if r is an ε-solution, then $r_v = f(r_a) \pm (\delta + 1)\varepsilon$ where $\delta = \frac{1-K}{L-K}$. The construction can be performed in time polynomial in the lengths of L and K.

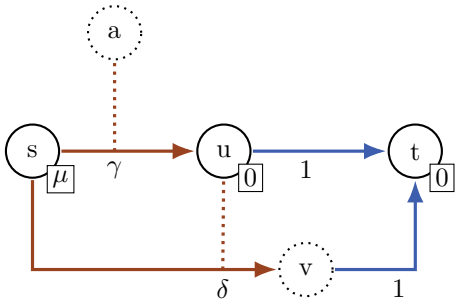

Figure 6 Amplifier Gadget: extension of an existing financial system with input bank a and output bank v by new banks s, t, u and contracts that translate the function f from Lemma 5.12. Let $\mu = 2(\gamma + \delta)$.

Proof. Consider the gadget in Figure 6 with

$$\gamma := \frac{1}{1-K}$$
$$\delta := \frac{1-K}{L-K}.$$

Let r be an ε-solution. We have

$$r_u = [\gamma(1 - r_a)] \pm \varepsilon$$
$$r_v = [\delta(1 - r_u)] \pm \varepsilon.$$

By replacing the first relation into the second one, we receive

$$\begin{aligned} r_v &\in [\delta\,(1 - ([\gamma(1 - r_a)] \pm \varepsilon))] \pm \varepsilon \\ &\subseteq [\delta\,(1 - [\gamma(1 - r_a)])] \pm (\delta + 1)\,\varepsilon \\ &= [\delta\,(1 - (\gamma(1 - r_a)))] \pm (\delta + 1)\,\varepsilon \\ &= [\delta - \delta\gamma + \delta\gamma r_a] \pm (\delta + 1)\,\varepsilon \;=\; \left[-\frac{K}{L-K} + \frac{1}{L-K} r_a\right] \pm (\delta + 1)\,\varepsilon \end{aligned}$$

where the third line is because $[\delta(1 - z)] = [\delta(1 - [z])]$ for any $z \geqslant 0$ and the last line is by simple algebra. Thus, r_v is as desired. ◀

We receive a scaling gadget by choosing $K = 0$:

▶ **Corollary 5.13** (Scale by Constant Gadget). *Let $\zeta > 0$. There is a financial system gadget with input bank a and output bank v such that if r is an ε-solution, then $r_v = [\zeta r_a] \pm (1 + \zeta)\varepsilon$. The construction can be performed in time polynomial in the length of ζ.*

Proof. Use an amplifier gadget (Lemma 5.12) with $K = 0$ and $L = \frac{1}{\zeta}$. Then $f(r_a) = [\zeta r_a]$ and $\delta = \zeta$. ◀

We receive a gadget that acts like the brittle comparison gate $C_{>\zeta}$ by choosing K and L closely together around a central point ζ. The gadget is less "brittle" the closer K and L are together, but this also increases the value δ and thus the output error of the gadget. To compensate for this, we first introduce a gadget that converts a wide range of values to approximate Boolean values with threshold 3ε.

▶ **Corollary 5.14** (Reset Gadget). *There is a financial system gadget with input bank a and output bank v such that if r is an ε-solution, then if $r_a \leqslant \frac{1}{4}$, then $r_v = 0 \pm 3\varepsilon$ and if $r_a \geqslant \frac{3}{4}$, then $r_v = 1 \pm 3\varepsilon$.*

Proof. Apply the amplifier gadget (Lemma 5.12) with $K = \frac{1}{4}$ and $L = \frac{3}{4}$. We have $\delta + 1 = \frac{5}{2} < 3$. If $r_a \leqslant \frac{1}{4}$, then $f(r_a) = 0$, so $r_v = f(r_a) \pm (1+\delta)\varepsilon = 1 \pm 3\varepsilon$. Likewise for $r_a \geqslant \frac{3}{4}$. ◀

▶ **Corollary 5.15** (Brittle Comparison to Constant Gadget). *Let $\zeta \in [0,1]$. There is a financial system gadget with input bank a and output bank v such that if $\varepsilon \leqslant 1/18$ and r is an ε-solution, then if $r_a \leqslant \zeta - 3\varepsilon$, then $r_v = 0 \pm 3\varepsilon$ and if $r_a \geqslant \zeta + 3\varepsilon$, then $r_v = 1 \pm 3\varepsilon$. The construction can be performed in time polynomial in the length of ζ.*

Proof. We apply two constructions involving the amplifier gadget (Lemma 5.12): first we apply an amplifier to a as an input bank with $K := \zeta - 3\varepsilon$ and $L := \zeta + 3\varepsilon$. Call the output bank u. We have $\delta = \frac{1-K}{L-K} = \frac{1-\zeta+3\varepsilon}{6\varepsilon} \leqslant \frac{1+3\varepsilon}{6\varepsilon} = \frac{1}{6\varepsilon} + \frac{1}{2}$. So this gadget has output error $(\delta+1)\varepsilon \leqslant \frac{1}{6} + \frac{1}{2}\varepsilon + \varepsilon \leqslant \frac{1}{4}$. Thus, if $r_a \leqslant K$, then $r_u \leqslant \frac{1}{4}$ and if $r_a \geqslant L$, then $r_u \geqslant \frac{3}{4}$. Now apply a reset gadget (Corollary 5.14) to u as the input bank to receive the desired lower output error of 3ε. ◀

5.2.3 Boolean Gadgets

We can re-use the addition gadgets from above to build Boolean gadgets, translating OR into "+" and NOT into "$1 - x$" (inversion). We use the reset gadget to prevent errors from propagating.

▶ **Lemma 5.16** (Boolean Gadgets). *There are financial system gadgets with input banks a and b and output bank v such that if $\varepsilon \leqslant 1/36$ and r is an ε-solution, then*

1. *(OR) If $r_a = 0 \pm 3\varepsilon$ and $r_b = 0 \pm 3\varepsilon$, then $r_v = 0 \pm 3\varepsilon$.*
   If $r_a = 1 \pm 3\varepsilon$ or $r_b = 1 \pm 3\varepsilon$, then $r_v = 1 \pm 3\varepsilon$.
2. *(NOT) If $r_a = 0 \pm 3\varepsilon$, then $r_v = 1 \pm 3\varepsilon$.*
   If $r_a = 1 \pm 3\varepsilon$, then $r_v = 0 \pm 3\varepsilon$.

Proof. 1. Apply a sum gadget (Lemma 5.10) to a and b and call the output bank u. Now apply a reset gadget (Corollary 5.14) to u and call the output bank v. We know that $r_u = [r_a + r_b] \pm 3\varepsilon$. If $r_a \geqslant 1 - 3\varepsilon$ or $r_b \geqslant 1 - 3\varepsilon$, then $r_u \geqslant 1 - 6\varepsilon \geqslant \frac{3}{4}$, so $r_v = 1 \pm 3\varepsilon$. If $r_a, r_b \leqslant 3\varepsilon$, then $r_u \leqslant 9\varepsilon \leqslant \frac{1}{4}$, so $r_v = 0 \pm 3\varepsilon$.

2. Apply similarly an inverter gadget (Lemma 5.9) and then a reset gadget. It is easy to show that the construction behaves as desired. ◀

5.2.4 Completing the PPAD-hardness Proof

We combine our gadgets to model generalized circuits, thus reducing ε-GCircuit to ε'-FindClearing (with $0 < \varepsilon' < \varepsilon$) and proving PPAD-hardness of ε-FindClearing:

Proof of Theorem 5.1. Let $\varepsilon > 0$ be arbitrary. We reduce ε-GCircuit to ε'-FindClearing where $\varepsilon' := \frac{\varepsilon}{3}$. Assume that we are given a generalized circuit C with n nodes and m gates. Construct a financial system via the following algorithm.

- Start with a system X^0 consisting of n banks, 0 external assets for each bank, and no contracts. Identify the n banks with the nodes of C.
- Consider the gates of C in any order. For each $t = 1, \ldots, m$ do the following:
  - Consider the t-th gate of C. Let g be the type, $a_1, \ldots, a_l$ the inputs, and v the output of this gate.

- Apply the gadget from above corresponding to g to X^{t-1} with input banks $a_1, \ldots, a_l$ and output bank v. Call the resulting financial system X^t.

- Let $X := X^m$.

For $t = 0, \ldots, m$ let C^t be C restricted to the first t gates. We show by induction on t that the ε'-solutions of X^t correspond to ε-solutions of C^t. For $t = 0$, the statement is clear. For $t > 0$, and assuming the statement for $t - 1$, it follows from the fact that the bank corresponding to the output of the t-th gate has no assets or liabilities in X^{t-1} and then from the definition of a financial system gadget and our above lemmas. By definition of the gadgets, each X^t, and thus X, is non-degenerate. ◀

▶ Remark. The intermediate systems X^t in the above construction may violate our assumption that any bank that is a reference entity in a CDS must be a writer of some debt contract (cf. Section 3). This happens when gadgets refer to a reference entity that is an output bank of another gadget that has not yet been executed. We can circumvent this problem by temporarily replacing such banks by a financial sub-system that fulfills all our assumptions and in which one of the banks can attain any recovery rate in some solution.[5] Alternatively, it is easy to show that not having the assumption does not lead to any problems in the proof.

6 Conclusion

In this paper, we have studied the problem of computing clearing payments in financial networks with debt and credit default swap (CDS) contracts and without default costs. We have shown that compared to debt-only networks, the addition of CDSs turns the clearing problem from being solvable exactly in polynomial time into an approximation problem that is PPAD-complete even when the desired approximation quality is kept constant. Consequently, no polynomial-time approximation scheme exists unless P=PPAD.

Further analysis shows that even very simple classes of financial systems can exhibit PPAD-hardness as long as banks are allowed to hold CDSs in a *naked* fashion, i.e., without also holding a corresponding debt contract from the reference entity.[6] Note that all our gadgets use naked CDSs, and they also seem to require them. Given this, future work should investigate whether financial networks in which naked CDSs are banned admit a polynomial-time algorithm for the clearing problem, similar to debt-only networks. We conjecture that this is the case. Another important task for future research is to find algorithms for general financial networks with CDSs that may not have polynomial worst-case running time, but are fast in practice. These algorithms could work by successively updating the set of defaulting banks in a systematic fashion. All algorithms for realistic financial systems must in addition be able to deal with non-linearities in the function $\frac{a_i}{l_i}$.

Acknowledgments. We would like to thank (in alphabetical order) Vitor Bosshard, Gianluca Brero, Yu Cheng, Marc Chesney, Constantinos Daskalakis, Marco d'Errico, Timo Mennle, Thomas Noe, and Joseph Stiglitz for helpful comments on this work. Furthermore, we are thankful for the feedback received from the anonymous reviewers at ITCS 2017. Any errors remain our own.

[5] Such a financial system is described in [17, Figure 3, $\delta = \gamma = 1$].

[6] We omit the analysis here due to space constraints. The interested reader is referred to our working paper [18]. For a discussion of naked CDSs, cf. Appendix B and [17].

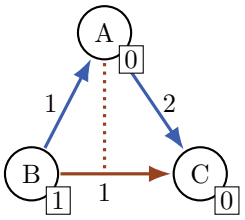

Figure 7 Financial System without default costs where the unique solution is irrational.

A Irrational Solutions

▶ **Example 1.1** (Irrational Solutions). Figure 7 shows a financial system the unique solution of which is irrational. To see this, note that by the contract structure r is clearing iff

$$r_A = \frac{1}{2} r_B, \qquad r_B = \frac{1}{2 - r_A},$$

and r_C is left unconstrained. One easily verifies that the unique solution in $[0,1]^2$ to this system of equations is given by

$$r_A = 2 - \sqrt{2}, \qquad r_B = 1 - \frac{1}{\sqrt{2}}.$$

B Properties of Approximate Solutions

Our definition of an approximate solution is well motivated from an economic point of view: assume that a bank A holds a debt contract of notional γ from bank B as well as a CDS on B from a highly capitalized bank C with the same notional. This contract pattern is called a *covered CDS* and it was the original use case CDSs were designed for: the CDS insures the debt contract. While nowadays, a large part of the CDSs are traded *naked* (i.e., they do not have this property), the covered case serves as a benchmark to which extent our solution concept is natural.

We describe the effect of ε errors in recovery rates on the three banks. If the insurer C is highly capitalized (its assets are greater than its liabilities by a factor $1 + \varepsilon$), then C never defaults ($r_C = 1$) and the assets of A are

$$\gamma r_B + \gamma(1 - r_B) r_C = \gamma.$$

That is, the covered CDS acts as a "full" insurance that eliminates A's dependence on B. This property is not affected by ε errors in the recovery rates of any bank. On the other hand, the writer C of the CDS might incur higher or lower liabilities due to errors in r_B, but this difference is bounded by $\varepsilon\gamma$. Finally, the recovery rate of B might be up to ε lower or higher than $\frac{a_B(r)}{l_B(r)}$. If it is lower, then B may keep up to $\varepsilon\gamma$ of its assets even though it is in default. If it is higher however, then B must make up to $\varepsilon\gamma$ in payments from money it does not have. This money would have to come from an external entity such as a government institution or the clearing mechanism itself. This is why clearing mechanisms should seek ε-solutions where ε is small compared to the inverse notionals in the system.

The following elementary properties serve as an indication that our definition of an approximate solution is also natural from a technical point of view. They are all easy to validate.

▶ **Proposition 2.1** (Natural Properties of Approximate Solutions). *Fix a financial system without default costs.*

1. *Any r is a 1-solution. r is a 0-solution iff it is an exact solution.*
2. *If $\varepsilon \leqslant \varepsilon'$, then any ε-solution is also an ε'-solution.*
3. *r is an ε-solution iff r is an ε'-solution for all $\varepsilon' > \varepsilon$.*
4. *Given r and ε, one can check in polynomial time if r is an ε-solution.*

C Proofs from Section 4

The following lemma lets us express ε-FindClearing as the problem of finding an approximate fixed point of a certain Lipschitz continuous function. Then the lemma follows using standard techniques.

▶ **Lemma C.1.** *Let $X = (N, e, c)$ be a non-degenerate financial system without default costs and let $\varepsilon > 0$. Assume WLOG that $N = \{1, \dots, n\}$. Define the function*

$$F : [0, 1+\varepsilon]^n \to [0, 1+\varepsilon]^n$$
$$F_i(s) := \begin{cases} \left[\frac{a_i([s])}{l_i([s])}\right]^{1+\varepsilon} & \text{if } l_i([s]) > 0 \\ 1+\varepsilon & \text{if } l_i([s]) = 0 \end{cases}$$

where $[x]^{1+\varepsilon} := \min(1+\varepsilon, \max(0, x))$ and $[s] := ([s_1], \dots, [s_n])$. Then the following hold:

1. *F is Lipschitz continuous with a Lipschitz constant polynomial-time computable from X and ε.*
2. *If s is an ε-approximate fixed point of F, then $[s]$ is an ε-solution of X.*

Proof. Part 1: It is sufficient to show that each F_i has an appropriate Lipschitz constant. So let $i \in N$. By non-degeneracy, bank i must fall into one of three cases: it either writes no contracts at all, or writes a debt contract, or has positive external assets. If i writes no contracts, then F_i is constant $1+\varepsilon$.

If i writes a debt contract, then $l_i([s]) > 0$ for all s, so

$$lF_i(s) = \left[\frac{a_i([s])}{l_i([s])}\right]^{1+\varepsilon} = \left([\,\cdot\,]^{1+\varepsilon} \circ \frac{a_i}{l_i} \circ [\,\cdot\,]\right)(s).$$

The functions $[\,\cdot\,]^{1+\varepsilon}$ and $[\,\cdot\,]$ are Lipschitz with constant 1. For $\frac{a_i}{l_i}$, we find a bound on the partial derivatives. We have

$$\begin{aligned} \frac{\partial \frac{a_i}{l_i}}{\partial r_k} &= \frac{\frac{\partial a_i}{\partial r_k} l_i - a_i \frac{\partial l_i}{\partial r_k}}{l_i^2} \\ &= \frac{(l_{k,i} - \sum_j r_j c^k_{j,i}) \cdot l_i + a_i \cdot \sum_j c^k_{i,j}}{l_i^2}. \end{aligned}$$

where the second line is easily seen by expanding a_i and l_i. The numerator is bounded from above in absolute value by

$$N^i_k := \left(c^{\varnothing}_{k,i} + \sum_j c^j_{k,i}\right) \cdot \left(\sum_j c^{\varnothing}_{i,j} + \sum_{j,l} c^l_{i,j}\right) + \left(e_i + \sum_j c^{\varnothing}_{j,i} + \sum_{j,l} c^l_{j,i}\right) \cdot \sum_j c^k_{j,i}$$

and the denominator is bounded from below by $D^i := (\sum_j c^{\varnothing}_{i,j})^2$. Thus, the partial derivative is bounded by $\frac{N^i_k}{D^i}$ and this bound is polynomial in X.

If i has positive external assets, then let $L_i := \{s \mid l_i([s]) > e_i\}$. For $s \notin L_i$, we have $F_i(s) = 1 + \varepsilon$ and further $F_i(s) \to 1 + \varepsilon$ as $l_i([s]) \to e_i$. On L_i, one receives a Lipschitz constant for the restriction of $\left[\frac{a_i([s])}{l_i([s])}\right]^{1+\varepsilon}$ to L_i by applying the same reasoning as above with $D_i := e_i^2$. Thus, F_i is the continuous union of two Lipschitz continuous functions and thus itself Lipschitz with the constant being the maximum of the two Lipschitz constants, namely $\max_k \frac{N_k^i}{D_i}$.

Part 2: Let s be an ε-approximate fixed point of F. Assume WLOG that $l_i([s]) > 0$. Let $i \in N$ and let $\tilde{s}_i := \frac{a_i([s])}{l_i([s])} \in [0, \infty)$. We have $F_i(s) = [\tilde{s}_i]^{1+\varepsilon}$ and $s_i = F_i(s) \pm \varepsilon$ and thus

$$\begin{aligned} & s_i = [\tilde{s}_i]^{1+\varepsilon} \pm \varepsilon \\ \Rightarrow\ & [s_i] \in \left[[\tilde{s}_i]^{1+\varepsilon} \pm \varepsilon\right] = [\tilde{s}_i \pm \varepsilon] \end{aligned}$$

where the last equality is easily seen by case distinction on $\tilde{s}_i \geqslant 1 + \varepsilon$ and $\tilde{s}_i < 1 + \varepsilon$. Thus, $[s]$ is an ε-solution at i. ◀

Proof of Lemma 4.4. Part 1: Let X and ε be given and consider the function F from Lemma C.1. Let K be the Lipschitz constant and recap that K is polynomial in X and ε. Since F is continuous on a compact domain, by Brouwer's fixed point theorem, it has an (exact) fixed point s. Let $\delta = \frac{\varepsilon}{K+1}$. Let s' be defined by $s'_i := \delta\lfloor\delta^{-1} s_i\rfloor$. That is, s'_i is s_i rounded to multiples of δ. s' has length $n \cdot L$ where L is the length of δ, and L is polynomial in the lengths of X and ε.[7] Further,

$$\begin{aligned} \left\|s' - F(s')\right\| &\leqslant \left\|s' - F(s)\right\| + \left\|F(s') - F(s)\right\| \\ &= \left\|s' - s\right\| + \left\|F(s') - F(s)\right\| \\ &\leqslant \delta + K\delta = (1 + K)\delta = \varepsilon. \end{aligned}$$

Hence, s' is an ε-approximate fixed point of F and thus an ε-solution.

Part 2: Proof by reduction to the PPAD-complete generic Brouwer problem [8]:

> Given an efficient algorithm for the evaluation of a function $F : [0,1]^n \to [0,1]^n$, a Lipschitz constant K for F, and an accuracy $\varepsilon > 0$, compute a point x such that $\|F(x) - x\| \leqslant \varepsilon$.

We apply the generic Brouwer problem to the function F from Lemma C.1. It is easy to see that one may replace the domain $[0,1]$ by $[0, 1+\varepsilon]$ without changing the problem in any significant way (e.g., by scaling inputs and outputs of F by a factor $1 + \varepsilon$ and replacing ε by $\frac{\varepsilon}{1+\varepsilon} \geqslant \frac{1}{2}\varepsilon$). Again by Lemma C.1, we know that the output of the Brouwer problem gives rise to an ε-solution for X. ◀

D Proofs from Section 5.1

Proof of Lemma 5.5. We show that the approximate solutions of a circuit correspond to the approximate fixed points of a certain Lipschitz continuous function. The statement of the lemma then follows like in the proof of Lemma 4.4.

[7] We assume here that numbers are encoded as fractions of binary integers. Alternatively, one could choose δ to be the largest power of two $\leqslant \frac{\varepsilon}{K+1}$.

For given C and ε define *gate functions* $f_g : [0,1]^l \to [0,1]$, where $l \in \{0,1,2\}$, as follows:

$$
\begin{aligned}
rLlf_{C_\zeta} &:= \zeta \\
f_{C_+}(a,b) &:= [a+b] \\
f_{C_-}(a,b) &:= [a-b] \\
f_{C_{\times\zeta}}(a) &:= [\zeta \cdot a] \\
f_{C_{>\zeta}}(a) &:= \left[\frac{1}{2\varepsilon}a + \frac{1}{2} - \frac{\zeta}{2\varepsilon}\right]
\end{aligned}
$$

Note that $f_{C_{>\zeta}}$ is monotonically increasing with $f_{C_{>\zeta}}(\zeta-\varepsilon) = 0$ and $f_{C_{>\zeta}}(\zeta+\varepsilon) = 1$. All gate functions are Lipschitz with constant $K := \max(2, \zeta_{\max}, \frac{1}{2\varepsilon})$ where $\zeta_{\max}$ is the maximum ζ such that C has a $C_{\times\zeta}$ gate.

Let $N = \{1, \dots, n\}$ be the set of nodes in the circuit. We define a function $F : [0,1]^n \to [0,1]^n$. For $x \in [0,1]^n$ and $i \in N$ let $F_i(x)$ be defined as follows:

- If i is an output of a gate g and the inputs of g are nodes $a_1, \dots, a_l$, then $F_i(x) := f_g(x_{a_1}, \dots, x_{a_l})$.
- If i is output of no gate, then $F_i(x) := x_i$.

Any ε-approximate fixed point of F is an ε-solution of C, though the converse does not hold. Since all gate functions are Lipschitz with constant K, so is F.

The first part of the lemma now follows just like in the proof of the first part of Lemma 4.4: if x is an exact fixed point of F and x' is x rounded to multiples of $\delta := \frac{\varepsilon}{K+1}$, then x' is an ε-approximate fixed point of F and thus an ε-solution of C and has polynomial length. It is not a problem that K depends on ε.

The second part of the lemma follows by reduction to the generic Brouwer problem just like in the proof of the second part of Lemma 4.4. This in fact proves that the weakly harder problem of computing an ε-solution where ε is not a parameter, but part of the input, is still in PPAD. It is again not a problem that K depends on ε because the generic Brouwer problem takes the Lipschitz constant as an input, just like ε. ◀

Proof of Lemma 5.6. Rubinstein [15] proved that the following variant of the ε-GCircuit problem is PPAD-hard for some ε:

1. Scaling is only allowed[8] by values $\zeta \leqslant 1$ and has error $\pm\varepsilon$ instead of $\pm(1+\zeta)\varepsilon$.
2. There are two additional, redundant gates: $C_=$ is a gate that (approximately) copies its input and $C_\wedge$ implements an approximate AND operator.
3. The comparison gate compares two inputs rather than compare one input to a constant.

For the first point, note that if $\zeta \leqslant 1$, then our $C_{\times\zeta}$ gate has error $(1+\zeta)\varepsilon \leqslant 2\varepsilon$ and thus we can achieve Rubinstein's error bound by considering an $\frac{\varepsilon}{2}$-solution instead. The second point does not make the problem any harder because we can express $C_=$ as $C_{\times 1}$ and $C_\wedge$ via the identity $x \wedge y = \neg(\neg x \vee \neg y)$.

Towards the third point, we show how to emulate the behavior of a binary comparison gate. Let a_1 and a_2 be the inputs and v the output of the would-be binary comparison gate. The expected behavior is that $x[v] = 0 \pm \varepsilon$ if $x[a_1] \leqslant x[a_2] - \varepsilon$ and $x[v] = 1 \pm \varepsilon$ if $x[a_1] \geqslant x[a_2] + \varepsilon$.

We rewrite the expression $x[a_1] < x[a_2]$ to use only comparison to a constant in a way that is robust against ε errors and cut-off at 0 and 1: construct, by combining the appropriate

[8] This assumption can be found in the full version of Rubinstein's paper [16].

gates, a sub-circuit corresponding to the expression $(\frac{1}{2} + (a_1 - a_2)) - (a_2 - a_1)$ and call the output node of that circuit u. If $\varepsilon' > 0$ and $x[\,\cdot\,]$ is an ε'-solution, then $x[u] = \tilde{u} \pm 4\varepsilon'$ where

$$\tilde{u} \;=\; \left[\left[\frac{1}{2} + [x[a_1] - x[a_2]]\right] - [x[a_2] - x[a_1]]\right] \;=\; \left[\frac{1}{2} + x[a_1] - x[a_2]\right].$$

Note that $x[a_1] < x[a_2] \Leftrightarrow \tilde{u} < \frac{1}{2}$. Add a $C_{>\frac{1}{2}}$ gate with input u and output v.

Now assume WLOG that $\varepsilon \leqslant \frac{1}{2}$, let $\varepsilon' = \frac{\varepsilon}{5}$, and let $x[\,\cdot\,]$ be an ε'-solution. Then

$$\begin{aligned} x[a_1] \leqslant x[a_2] - \varepsilon \Rightarrow \tilde{u} &\leqslant \frac{1}{2} - \varepsilon = \frac{1}{2} - 4\varepsilon' - \varepsilon' \\ &\Rightarrow x[u] \leqslant \frac{1}{2} - \varepsilon' \\ &\Rightarrow x[v] = 0 \pm \varepsilon' = 0 \pm \varepsilon. \end{aligned}$$

Analogously $x[a_1] \geqslant x[a_2] + \varepsilon \;\Rightarrow\; x[v] = 1 \pm \varepsilon$.

Altogether, we can construct from any circuit C in Rubinstein's [15] framework a circuit C' in our reduced framework such that the $\frac{\varepsilon}{5}$-solutions of C' are ε-solutions of C. This concludes the proof. ◀

Testing Submodularity and Other Properties of Valuation Functions

Abstract

We show that for any constant $\epsilon > 0$ and $p \geq 1$, it is possible to distinguish functions $f : \{0,1\}^n \to [0,1]$ that are submodular from those that are ϵ-far from every submodular function in ℓ_p distance with a *constant* number of queries.

More generally, we extend the testing-by-implicit-learning framework of Diakonikolas et al. (2007) to show that every property of real-valued functions that is well-approximated in ℓ_2 distance by a class of k-juntas for some $k = O(1)$ can be tested in the ℓ_p-testing model with a constant number of queries. This result, combined with a recent junta theorem of Feldman and Vondrák (2016), yields the constant-query testability of submodularity. It also yields constant-query testing algorithms for a variety of other natural properties of valuation functions, including fractionally additive (XOS) functions, OXS functions, unit demand functions, coverage functions, and self-bounding functions.

1 Introduction

Property testing is concerned with approximate decision problems of the following form: given oracle access to some function $f : \mathcal{X} \to \mathcal{Y}$ and some fixed property $\mathcal{P}$ of such functions, how many oracle calls (or queries) to f does a bounded-error randomized algorithm need to distinguish the cases where f has the property $\mathcal{P}$ from the case where f is ϵ-far—under some appropriately defined metric—from having the same property? Remarkably, many natural properties of functions can be tested with a number of queries that is *independent* of the size of the function's domain. For example, for any constant $\epsilon > 0$ and $t \geq 1$, a constant number of queries suffices to test whether a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is linear [7]; a polynomial of degree at most t [28]; a t-junta [5, 18]; a monomial [27]; computable by a Boolean circuit of size t [10]; or a linear threshold function [25].

In this work, we consider the problem of testing properties of bounded *real-valued* functions over the Boolean hypercube. In particular, are there natural examples of such properties that are testable with a constant number of queries? This question is best considered in the ℓ_p *testing* framework introduced by Berman, Raskhodnikova, and Yaroslavtsev [4]. In this

setting, the distance between a function $f : \{0,1\}^n \to [0,1]$ and some property $\mathcal{P}$ of these functions is $\text{dist}_p(f, \mathcal{P}) = \inf_{g \in \mathcal{P}} \|f - g\|_p$.

1.1 Testing properties of valuation functions

Natural properties of bounded real-valued Boolean functions have been studied extensively in the context of valuation functions in algorithmic game theory. For a sequence of n goods labeled with the indices $1, \ldots, n$, we can encode the value of each subset of these goods to some agent with a function $f : \{0,1\}^n \to [0,1]$ by setting $f(x)$ to be the (possibly normalized) value of the subset $\{i \in [n] : x_i = 1\}$ to the agent. Such a valuation function f is

Additive if there are weights $w_1, \ldots, w_n$ such that $f(x) = \sum_{i:x_i=1} w_i$;

a **Coverage function** if there exists a universe U, non-negative weights $\{w_u\}_{u \in U}$, and subsets $A_1, ..., A_n \subseteq U$ such that $f(x) = \sum_{u \in \bigcup_{i:x_i=1} A_i} w_u$.

Unit demand if there are weights $w_1, \ldots, w_n$ such that $f(x) = \max\{w_i : x_i = 1\}$;

OXS if there are $k \geq 1$ unit demand functions $g_1, \ldots, g_k$ such that $f(x) = \max\{g_1(x^{(1)}), \ldots, g_k(x^{(k)})\}$ where the maximum is taken over all $x^{(1)}, \ldots, x^{(k)}$ such that for every $i \in [n]$, $x_i = \sum_{j=1}^{k} x_i^{(j)}$;

Gross Substitutes if for any $p' \leq p \in \mathbb{R}^n$ and any x, x' that maximize $f(x) - \sum_{i:x_i=1} p_i$ and $f(x') - \sum_{i:x'_i=1} p'_i$, respectively, every $j \in [n]$ for which $x_j = 1$ and $p_j = p'_j$ also satisfies $x'_j = 1$;

Submodular if $f(x) + f(y) \geq f(x \wedge y) + f(x \vee y)$ for every $x, y \in \{0,1\}^n$, where $\wedge$ and $\vee$ are the bitwise AND and OR operations;

Fractionally subadditive (XOS) iff there are non-negative real valued weights $\{w_{ij}\}_{i,j \leq n}$ such that $f(x) = \max_i \sum_j w_{ij} \cdot x_j$;

Self-bounding if $f(x) \geq \sum_i (f(x) - \min_{x_i} f(x))$, where $\min_{x_i} f(x) = \min\{f(x), f(x \oplus e_i)\}$ and $\oplus$ is the bitwise XOR operator; and

Subadditive if $f(x \cup y) \leq f(x) + f(y)$ for every $x, y \in \{0,1\}^n$.

Each of these properties enforces some structure on valuation functions, and much work has been devoted to better understanding these structures (and their algorithmic implications) by studying the properties through the lenses of learning theory [2,3,15], optimization [13,14], approximation [16, 17], and sketching [1]. The problem of testing whether an unknown valuation function satisfies one of these properties offers another angle from which we can learn more about the structure imposed on the functions that satisfy these properties.

Indeed, there has already been some recent developments on the study of testing these properties. Notably, Seshadhri and Vondrák [30] initiated the study of testing submodularity for functions over the hypercube and showed that in the setting where we measure the distance to submodularity in terms of Hamming distance (rather than ℓ_p distance), submodularity can be tested with $\epsilon^{-\sqrt{n}\log n}$ queries and that it *cannot* be tested with a number of queries that is independent of n. Subsequently, Feldman and Vondrák [17] showed that in the ℓ_1 testing framework, we can do much better: testing submodularity in this model requires a number of queries that is only logarithmic in n. Our first result shows that, in fact, for any value of $p \geq 1$, it is possible to test submodularity in the ℓ_p setting with a number of queries that is completely *independent* of n.

▶ **Theorem 1.1.** *For any $\epsilon > 0$ and any $p \geq 1$, there is an ϵ-tester for submodularity in the ℓ_p testing model with query complexity $2^{\tilde{O}(1/\epsilon^{\max\{2,p\}})}$.*

Another property that has been considered in the (standard Hamming distance) testing model is that of being a coverage function. Chakrabarty and Huang [8] showed that for

constant values of $\epsilon > 0$, $O(nm)$ queries suffice to ϵ-test whether a function f is a coverage function on some universe U of size $|U| \leq m$. Note that, unlike in the learning and approximation settings, bounds on the number of queries required to test some property $\mathcal{P}$ do not imply anything about number of queries required to test properties $\mathcal{P}' \subset \mathcal{P}$, so even though coverage functions are submodular, results on testing submodularity do not imply any bounds on the query complexity for testing coverage functions. Nonetheless, our next result shows that this property—along with most of the other properties of valuation functions listed above—can also be tested with a number of queries that is independent of n.

▶ **Theorem 1.2.** *For any $\epsilon > 0$ and any $p \geq 1$, there are ϵ-testers in the ℓ_p testing model for additive functions, coverage functions, unit demand functions, OXS functions, and gross substitute functions that each have query complexity $2^{\tilde{O}(1/\epsilon^{\max\{2,p\}})}$, and there are ϵ-testers in the ℓ_p testing model for fractional subadditivity and self-bounded functions that have query complexity $2^{2^{\tilde{O}(1/\epsilon^{\max\{2,p\}})}}$.*

Theorems 1.1 and 1.2 are both special cases of a general testing result that we obtain by extending the technique of *testing by implicit learning* of Diakonikolas et al. [10]. We describe this general result in more details below.

1.2 Testing real-valued functions by implicit learning

There is a strong connection between property testing and learning theory that goes back to the seminal work of Goldreich, Goldwasser, and Ron [21]. As they first observed, any proper learning algorithm for the class of functions that have some property $\mathcal{P}$ can also be used to test $\mathcal{P}$: run the learning algorithm, and verify whether the resulting hypothesis function h is close to the tested function f or not. This approach yields good bounds on the number of queries required to test many properties of functions, but, as simple information theory arguments show, it cannot yield query complexity bounds that are smaller than $\log n$ for almost all natural properties of functions over $\{0,1\}^n$.

Diakonikolas et al. [10] bypassed this limitation for the special case when every function that has some property $\mathcal{P}$ is close to a junta. A function $f : \{0,1\}^n \to [0,1]$ is a *k-junta* if there is a set $J \subseteq [n]$ of cardinality $|J| \leq k$ such that the value of f on any input x is completely determined by the values x_i for each $i \in J$. Every k-junta f has corresponding "core" functions $f_{\text{core}} : \{0,1\}^k \to \{0,1\}$ that define its value based on the value of the k relevant coordinates of its input. Diakonikolas et al.'s key insight is that for testing properties whose functions are (very) close to juntas, it suffices to learn the core of the input function—without having to identify the identity of the relevant coordinates.

The wide applicability of the testing-by-implicit-learning methodology is due to the fact that for many natural properties of Boolean functions, the functions that have these properties must necessarily be close to juntas under the Hamming distance. The starting point for the current research is a recent breakthrough of Feldman and Vondrák, who showed that a similar junta theorem holds for many properties of real-valued functions when closeness is measured according to ℓ_2 distance.

▶ **Feldman–Vondrák junta theorem.** *Fix any $\epsilon \in (0, \frac{1}{2})$. For every submodular function $f : \{0,1\}^n \to [0,1]$, there exists a submodular function $g : \{0,1\}^n \to [0,1]$ that is a $O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$-junta such that $\|f - g\|_2 \leq \epsilon$. Furthermore, for every self-bounding function $f : \{0,1\}^n \to [0,1]$, there exists a self-bounding function $g : \{0,1\}^n \to [0,1]$ that is a $2^{O(\frac{1}{\epsilon^2})}$-junta such that $\|f - g\|_2 \leq \epsilon$.*

The logarithmic dependence on n for the problem of testing submodularity in the ℓ_1 testing model [17] follows directly from Feldman and Vondrák's junta theorem and the (standard) testing-by-proper-learning connection. This junta theorem also suggests a natural approach for obtaining a constant query complexity for the same problem by combining it with a testing-by-implicit-learning algorithm. In order to implement this approach, however, new testing-by-implicit-learning techniques are required to overcome two obstacles.

The first obstacle is that most existing testing-by-implicit-learning algorithms [9–11, 22] are designed for properties that contain functions which are close to juntas in Hamming distance, not ℓ_p distance. This is a stronger condition, and enables the analysis of these algorithms to assume that with large probability, when f is very close to a k-junta f', the queries x made by the algorithm all satisfy $f(x) = f'(x)$. In the ℓ_p distance model, however, we can have a function f that is extremely close to a k-junta but still has $f(x) \neq f'(x)$ for many (or even every!) input x.

The second (related) obstacle that we encounter when considering submodular functions is that current testing-by-implicit-learning algorithms only work in the regime where the functions in $\mathcal{P}$ are ϵ-close to k-juntas for some $k < \epsilon^{-1/2}$. (See for example the discussion in §2.5 of [29].) This condition is satisfied by the properties of Boolean functions that have been studied previously, but the bounds in the Feldman–Vondrák junta theorem, however, do not satisfy this requirement.

We give a new algorithm for testing-by-implicit-learning that overcomes both of these obstacles. As a result, we obtain the following general theorem.

▶ **Theorem 1.3.** *For any $0 < \epsilon < \frac{1}{2}$ and any property $\mathcal{P}$ of functions mapping $\{0,1\}^n \to [0,1]$, if $k \geq 1$ is such that for every function $f \in \mathcal{P}$, there is a k-junta h that satisfies $\|f - h\|_2 \leq \frac{\epsilon}{10^6}$, then there is an ϵ-tester for $\mathcal{P}$ in the ℓ_2 testing model with query complexity $\frac{2^{O(k \log k)}}{\epsilon^{10}}$.*

Theorems 1.1 and 1.2 are both obtained directly from Theorem 1.3, the Feldman–Vondrák junta theorem and Fact 2.1.

▶ Remark. Another testing-by-implicit-learning algorithm, the Implicit Sieve algorithm of Wimmer and Yoshida [31] based on the Kushilevitz–Mansour learning algorithm [23], was introduced to test properties in the Hamming model but has a natural analogue in the ℓ_2 testing model as well. It would be quite interesting to determine what properties can be tested efficiently in the ℓ_p models by this algorithm (or extensions of it).

1.3 Overview of the proofs

1.3.1 The algorithm

The current testing-by-implicit-learning algorithms proceed in two main stages. In the first stage, the coordinates in $[n]$ are randomly partitioned into poly(k) parts, and an influence test is used to identify the (at most k) parts that contain relevant variables of an unknown input function f that is very close to being a k-junta. In the second stage, inputs $x \in [n]$ are drawn at random according to some distribution, the value $f(x)$ is observed, and the value of the relevant coordinate in each of the parts identified in the second stage is determined using more calls to the influence test.

The Implicit Learning Tester algorithm that we introduce in this paper reverses the order of the two main stages. In the first stage, it draws a sequence of q queries $X = (x^{(1)}, \ldots, x^{(q)})$ at random and queries the value of f on each of these queries. It also uses X to partition the coordinates in $[n]$ into 2^q random parts according to the values of the coordinate on the q queries. In the second stage, the algorithm then uses an influence

estimator to identify the k parts that contain the relevant coordinates of a k-junta that is close to f and, since all the coordinates in a common part have the same value on each of the q queries, learn the value of the k relevant coordinates on each of these initial queries. The algorithm then checks whether the core function thus learned is consistent with those of functions in the property being tested.

The main advantage of the Implicit Learning Tester algorithm that its analysis does not require the assumption that our samples are exactly consistent with those of an actual k-junta (instead of those of a function that is only promised to be *close* to a k-junta). This feature enables us to overcome the obstacles listed in the previous section, at the cost of adding a few complications to the analysis, as described below.

1.3.2 The analysis

There are two main technical ingredients in the analysis of the algorithm. The first, established in Lemma 3, is used to show that when f is close to a k-junta in ℓ_2 distance, the search procedure identifies parts that contain the k relevant coordinates of some k-junta that is close to f. (Note that the search is not guaranteed to find the parts that contain the relevant coordinates of the k-junta that is *closest* to f, but it suffices to find those of any close k-junta.)

The second technical ingredient addresses the fact that by drawing the q samples $x^{(1)}, \ldots, x^{(q)}$ first and then using these samples to provide the initial partition of the coordinates in $[n]$, we no longer will obtain uniformly random samples of the core f_{core} of the input function f. Nonetheless, in Lemma 4, we show that when f is close to a k-junta, the distribution of these samples on the core function still enables us to accurately estimate the distance of f_{core} to the core functions of any other k-junta.

1.4 Discussion and open problems

Theorems 1.1–1.3 raise a number of intriguing questions. The most obvious question left open is whether we can also test subadditivity of real-valued functions with a constant number of queries: subadditive functions need not be close to juntas, so such a result would appear to require a different technique.

It is also useful to compare our bounds for submodularity testing with those for testing monotonicity: in the Hamming distance testing model, Seshadhri and Vondrák [30] showed that the query complexity for testing submodularity is at least as large as that for testing monotonicity. However, the best current bounds for testing monotonicity in the ℓ_p testing model have a linear dependence on n [4]. Is it also possible to test monotonicity with a constant number of queries? Or is it the case that testing submodularity is strictly easier than testing monotonicity in the ℓ_p testing setting?

2 Preliminaries

Let $\mathcal{F}_n$ denote the set of functions mapping $\{0,1\}^n$ to $[0,1]$. For any $f \in \mathcal{F}_n$ and $S \subseteq [n]$ with complement $\overline{S} = [n] \setminus S$, when $x \in \{0,1\}^S$ and $y \in \{0,1\}^{\overline{S}}$, we write $f(x,y)$ to denote the value $f(z)$ for the input z that satisfies $z_i = x_i$ for each $i \in S$ and $z_i = y_i$ otherwise.

We use the standard definitions and notation for the Fourier analysis of functions $f : \{0,1\}^n \to [0,1]$. For a complete introduction to the topic, see [26]. Throughout the paper, unless otherwise specified all probabilities and expectations are over the uniform distribution on the random variable's domain.

2.1 Property testing

A *property* $\mathcal{P}$ of functions in $\mathcal{F}_n$ is a subset of these functions that is invariant under relabeling of the n coordinates. The *Hamming distance* between $f, g \in \mathcal{F}_n$ is $\mathrm{dist}_{\mathrm{Ham}}(f,g) = \Pr_x[f(x) \neq g(x)]$ and the Hamming distance between f and a property $\mathcal{P}$ is $\mathrm{dist}_{\mathrm{Ham}}(f,\mathcal{P}) = \inf_{g\in\mathcal{P}} \mathrm{dist}_{\mathrm{Ham}}(f,g)$. For $p \geq 1$, the *ℓ_p distance* between f and g is $\mathrm{dist}_p(f,g) = \|f-g\|_p = (\mathrm{E}_x[|f(x)-g(x)|^p])^{1/p}$ and the ℓ_p distance between f and $\mathcal{P}$ is $\mathrm{dist}_p(f,\mathcal{P}) = \inf_{g\in\mathcal{P}} \mathrm{dist}_p(f,g)$.

Given $\epsilon > 0$, An *ϵ-tester* in the Hamming testing model (resp., ℓ_p testing model) for some property $\mathcal{P} \subseteq \mathcal{F}_n$ is a randomized algorithm that (i) accepts every function $f \in \mathcal{P}$ with probability at least $\frac{2}{3}$ and (ii) rejects every function f that satisfies $\mathrm{dist}_{\mathrm{Ham}}(f,\mathcal{P}) \geq \epsilon$ (resp., $\mathrm{dist}_p(f,\mathcal{P}) \geq \epsilon$) with probability at least $\frac{2}{3}$. An ϵ-tester for $\mathcal{P}$ is an *(ϵ',ϵ)-tolerant tester*, for some $\epsilon' < \epsilon$ if it additionally accepts every function f that satisfies $\mathrm{dist}_{\mathrm{Ham}}(f,\mathcal{P}) \leq \epsilon'$ (resp., $\mathrm{dist}_p(f,\mathcal{P}) \leq \epsilon$) with probability at least $\frac{2}{3}$.

Our proofs of Theorems 1.1–1.3 are established in the ℓ_2 testing model. The result for general ℓ_p testing models is obtained from the following elementary relation between the query complexities of testing any property in different ℓ_p testing models.

▶ **Fact 2.1** (c.f. Fact 5.2 in [4]). *For any $\mathcal{P} \subseteq \mathcal{F}_n$, any $\epsilon > 0$, and any $p \geq 1$, the number $Q_p(\mathcal{P},\epsilon)$ of queries required to ϵ-test $\mathcal{P}$ in the ℓ_p testing model satisfies $Q_2(\mathcal{P},\epsilon) \leq Q_p(\mathcal{P},\epsilon) \leq Q_2(\mathcal{P},\epsilon^{\frac{p}{2}})$.*

Theorem 1.2 also relies on the following hierarchy of properties. (See, e.g., [24].)

▶ **Lemma 1.** *The properties of $\mathcal{F}_n$ defined in the introduction satisfy the inclusion hierarchy*

$$\begin{aligned}&\textit{Additive} \subseteq \textit{Coverage} \subseteq \textit{Unit demand} \subseteq \textit{OXS} \subseteq \textit{Gross substitute}\\ &\qquad \subseteq \textit{Submodularity} \subseteq \textit{XOS} \subseteq \textit{Self-bounding}.\end{aligned}$$

2.2 Juntas

The function $f : \{0,1\}^n \to [0,1]$ is a *junta on the set $J \subseteq [n]$* if for every $x, y \in \{0,1\}^n$ that satisfy $x_i = y_i$ for every $i \in J$, we have $f(x) = f(y)$. The function f is a *k-junta* if it is a junta on some set $J \subseteq [n]$ of cardinality $|J| \leq k$. The function $f_{\mathrm{core}} : \{0,1\}^k \to [0,1]$ is a *core function* of the k-junta $f : \{0,1\}^n \to [0,1]$ if there is a projection $\psi : \{0,1\}^n \to \{0,1\}^k$ defined by setting $\psi(x) = (x_{i_1},\ldots,x_{i_k})$ for some distinct $i_1,\ldots,i_k \in [n]$ such that for every $x \in \{0,1\}^n$, $f(x) = f_{\mathrm{core}}\big(\psi(x)\big)$.

▶ **Definition 2.2.** For any function $f : \{0,1\}^n \to [0,1]$ and set $J \subseteq [n]$, the *J-junta projection* of f is the function $f_J : \{0,1\}^J \to [0,1]$ defined by setting $f_J(x) = \mathrm{E}_{y\in\{0,1\}^{\overline{J}}}[f(x,y)]$ for every $x \in \{0,1\}^J$.

A basic fact that we will require is that f_J is the J-junta that is closest to f under the ℓ_2 metric.

▶ **Proposition 2.3.** *For every $f : \{0,1\}^n \to [0,1]$ and $J \subseteq [n]$, if $g : \{0,1\}^n \to [0,1]$ is a J-junta, then $\mathrm{dist}_2(f,f_J) \leq \mathrm{dist}_2(f,g)$.*

Proof. By applying the identity $\|f-g\|_2^2 = \|f-f_J+f_J-g\|_2^2$ and by expanding the right-hand side, we obtain

$$\begin{aligned}\|f-g\|_2^2 &= \mathop{\mathrm{E}}_{x\in\{0,1\}^J}\left[\mathop{\mathrm{E}}_{y\in\{0,1\}^{\overline{J}}}\Big[\big(f(x,y)-f_J(x,y)+f_J(x,y)-g(x,y)\big)^2\Big]\right]\\ &= \|f-f_J\|_2^2 + \|f_J-g\|_2^2 + 2\mathop{\mathrm{E}}_x\Big[\mathop{\mathrm{E}}_y\Big[\big(f(x,y)-f_J(x,y)\big)\big(f_J(x,y)-g(x,y)\big)\Big]\Big].\end{aligned}$$

Since $f_J - g$ is a J-junta, it does not depend on y and, by the definition of f_J, the last term equals 0. Therefore, $\|f - g\|_2^2 = \|f - f_J\|_2^2 + \|f_J - g\|_2^2$ and the claim follows. ◀

The property $\mathcal{P} \subseteq \mathcal{F}_n$ is a *property of k-juntas* if every function $f \in \mathcal{P}$ is a k-junta. The *core property* of a property $\mathcal{P}$ of k-juntas is the property $\mathcal{P}_{\text{core}} \subseteq \mathcal{F}_k$ defined by $\mathcal{P}_{\text{core}} = \{f_{\text{core}} : f \in \mathcal{P}\}$. For any $\gamma > 0$, the *γ-discretized approximation* of a function $f \in \mathcal{F}_n$ is the function $f^{(\gamma)}$ obtained by rounding the value $f(x)$ for each $x \in \{0,1\}^n$ to the nearest multiple of γ. The γ-discretized approximation of a property $\mathcal{P}$ is the property $\mathcal{P}^{(\gamma)} = \{f^{(\gamma)} : f \in \mathcal{P}\}$.

2.3 Influence

The notion of influence of coordinates in functions over the Boolean hypercube plays a central role in both our algorithm and its analysis. Informally, the influence of a set of coordinate measures how much re-randomizing these coordinates affects the value of the function. This notion is made precise as follows.

▶ **Definition 2.4.** The *influence* of a set $S \subseteq [n]$ of coordinates in the function $f : \{0,1\}^n \to [0,1]$ is

$$\mathrm{Inf}_f(S) := \mathop{\mathrm{E}}_{x \in \{0,1\}^{\overline{S}}}\Big[\mathop{\mathrm{Var}}_{y \in \{0,1\}^S} f(x,y)\Big] = \tfrac{1}{2}\mathop{\mathrm{E}}_{x \in \{0,1\}^{\overline{S}}}\Big[\mathop{\mathrm{E}}_{y,y' \in \{0,1\}^S}\Big[\big(f(x,y) - f(x,y')\big)^2\Big]\Big].$$

Our proofs make use of a few standard facts regarding the influence of sets of coordinates in f.

▶ **Fact 2.5.** *The influence of $S \subseteq [n]$ in $f \in \mathcal{F}_n$ is $\mathrm{Inf}_f(S) = \sum_{T : T \cap S \neq \emptyset} \hat{f}^2(T)$.*

▶ **Fact 2.6.** *For every $f \in \mathcal{F}_n$ and $S, T \subseteq [n]$, we have $\mathrm{Inf}_f(S) \leq \mathrm{Inf}_f(S \cup T) \leq \mathrm{Inf}_f(S) + \mathrm{Inf}_f(T)$.*

▶ **Fact 2.7.** *For every $f \in \mathcal{F}_n$ and $J \subseteq [n]$, we have $\mathrm{Inf}_f(\overline{J}) = \mathrm{dist}_2(f, f_J)^2$.*

▶ **Proposition 2.8.** *Fix $\epsilon > 0$, and let $f, g : \{0,1\}^n \to [0,1]$ satisfy $\mathrm{dist}_2(f,g) \leq \epsilon$. Then for any set $S \subseteq [n]$, $|\mathrm{Inf}_f(S)^{\frac{1}{2}} - \mathrm{Inf}_g(S)^{\frac{1}{2}}| \leq \epsilon$.*

Proof. By Fact 2.7, we have $\mathrm{Inf}_f(S)^{\frac{1}{2}} = \|f - f_{\overline{S}}\|_2$ and $\mathrm{Inf}_g(S)^{\frac{1}{2}} = \|g - g_{\overline{S}}\|_2$. By Proposition 2.3, we also have that $\|f - f_{\overline{S}}\|_2 \leq \|f - g_{\overline{S}}\|_2$. Combining these observations with the triangle inequality, we obtain $\mathrm{Inf}_f(S)^{\frac{1}{2}} - \mathrm{Inf}_g(S)^{\frac{1}{2}} = \|f - f_{\overline{S}}\|_2 - \|g - g_{\overline{S}}\|_2 \leq \|f - g_{\overline{S}}\|_2 - \|g - g_{\overline{S}}\|_2 \leq \|f - g\|_2 \leq \epsilon$. Hence $\mathrm{Inf}_f(S)^{\frac{1}{2}} - \mathrm{Inf}_g(S)^{\frac{1}{2}} \leq \epsilon$ and, similarly, $\mathrm{Inf}_g(S)^{\frac{1}{2}} - \mathrm{Inf}_f(S)^{\frac{1}{2}} \leq \epsilon$ as well. ◀

▶ **Proposition 2.9.** *There is an algorithm* EstimateInf *such that for every $f : \{0,1\}^n \to [0,1]$, $S \subseteq [n]$, $m \geq 1$, and $t \geq 0$, it makes m queries to f and returns an estimate of the influence of S in f that satisfies*

$$\Pr\big[|\mathrm{Inf}_f(S) - \textsc{EstimateInf}(f, S, m)| \geq t\big] \leq 2e^{-2mt^2}.$$

We also use the following key lemma from [6].

▶ **Lemma 2** (Lemma 2.3 in [6]). *Let $f : \{0,1\}^n \to [0,1]$ be a function that is ϵ-far from k-juntas and P be a random partition of $[n]$ into $r > 20k^2$ parts. Then with probability at least $\frac{5}{6}$, $\mathrm{Inf}_f(\overline{J}) \geq \frac{\epsilon^2}{4}$ for any union J of k parts from P.*

For the reader's convenience, we include the proof of Lemma 2 in Appendix A; though the original lemma in [6] was only for Boolean-valued functions, the proof remains essentially unchanged.

Algorithm 1: IMPLICIT LEARNING TESTER$(\mathcal{F}, k, \epsilon)$

Data: $q = \frac{2^{O(k)}}{\epsilon^5}$, $m = O(\frac{k^6}{\epsilon^5})$, $r = \log \frac{2^k}{100k^4}$

1 Draw $x^{(1)}, \ldots, x^{(q)} \in \{0,1\}^n$ independently and uniformly at random;

2 For each $c \in \{0,1\}^q$, define $S_c \leftarrow \left\{i \in [n] : \left(x_i^{(1)}, \ldots, x_i^{(q)}\right) = c\right\}$;

3 Let $P_1, \ldots, P_{100k^4}$ be a random equi-partition of $\{0,1\}^q$;

4 **for** *each* $J \subseteq [100k^4]$ *of size* $|J| = k$ **do**

5 $\quad S_J \leftarrow \bigcup_{j \in J} \bigcup_{c \in P_j} S_c$;

6 $\quad \eta_J \leftarrow \text{ESTIMATEINF}(f, [n] \setminus S_J, m)$;

7 $\{j_1^*, \ldots, j_k^*\} \leftarrow \text{argmin}_J \, \eta_J$;

8 $(P_{0,1}, \ldots, P_{0,k}) \leftarrow (P_{j_1^*}, \ldots, P_{j_k^*})$;

9 **for** $\ell = 1, \ldots, r$ **do**

10 $\quad$ Let $P_{\ell,i,0}, P_{\ell,i,1}$ be a random equi-partition of $P_{\ell-1,i}$ for each $i \le k$;

11 $\quad$ **for** *every* $z \in \{0,1\}^k$ **do**

12 $\quad\quad S_z \leftarrow \bigcup_{i \le k} \bigcup_{c \in P_{\ell,i,z_i}} S_c$;

13 $\quad\quad \eta_z \leftarrow \text{ESTIMATEINF}(f, [n] \setminus S_z, m)$;

14 $\quad z_\ell^* \leftarrow \text{argmin}_z \, \eta_z$;

15 $\quad$ For each $i \le k$, update $P_{\ell,i} \leftarrow P_{\ell,i,z_\ell^*}$;

16 Let $B = \{b_1, ..., b_k\} \leftarrow \bigcup_{i \le k} P_{r,i}$;

17 If $\text{ESTIMATEINF}(f, [n] \setminus S_B, m) > \epsilon^2/1000$, reject;

18 Let $\phi : \{0,1\}^n \to \{0,1\}^k$ be any projection that satisfies $\phi(x)_i \in S_{b_i}$ for each $i \le k$;

19 **for** $h \in \mathcal{F}_{\text{core}}^{(\frac{\epsilon}{1000})}$ **do**

20 $\quad$ If $\frac{1}{q} \sum_{i=1}^q \left(f(x^{(i)}) - h(\phi(x^{(i)}))\right)^2 \le 0.35\epsilon$, accept and return h;

21 Reject;

3 Testing by implicit learning

The proof of Theorem 1.3 is established by analyzing the IMPLICIT LEARNING TESTER algorithm.

3.1 Proof of Theorem 1.3

The analysis of the IMPLICIT LEARNING TESTER relies on two technical lemmas. The first shows that when the input function f is close to a k-junta, then with reasonably large probability, the function f is close to a junta on the set B of k parts that is identified by the algorithm.

▶ **Lemma 3.** *For any $\varepsilon > 0$, if the function $f : \{0,1\}^n \to [0,1]$ is ε-close to a k-junta and every call to* ESTIMATEINF *returns an influence estimate with additive error at most $\frac{\varepsilon^2}{100k^2}$, then the set B obtained by the* JUNTA-PROPERTY TESTER *satisfies* $\Pr\left[\text{Inf}_f([n] \setminus S_B) > 100\varepsilon^2\right] \le \frac{1}{20}$.

The second lemma shows that the estimate in Step 20 provides a good estimate of the distance between f and the functions in $\mathcal{P}$.

▶ **Lemma 4.** *Fix $\varepsilon > 0$. Let $f : \{0,1\}^n \to [0,1]$ be a function that satisfies $\text{dist}_2(f, g) \le \varepsilon$ for some function g that is a junta on $J \subseteq [n]$, $|J| \le k$. Then for every $h_{\text{core}} \in \mathcal{F}_{\text{core}}^{(\frac{\varepsilon}{1000})}$, the*

mapping $\psi : \{0,1\}^n \to \{0,1\}^k$ *defined in the* Implicit Learning Tester *and the function* $h = h_{\text{core}} \circ \psi$ *satisfy*

$$\left| \left(\tfrac{1}{q} \sum_{i}^{q} \left(f(x^{(i)}) - h(x^{(i)}) \right)^2 \right)^{\frac{1}{2}} - \text{dist}_2(g,h) \right| \leq 3\varepsilon$$

except with probability at most $2e^{-16q\varepsilon^4} + \frac{5k^2}{2^q}$.

The proofs of these lemmas are presented in Sections 3.2 and 3.3. We now show how they are used to complete the proof of Theorem 1.3.

As a first observation, we note that by Hoeffding's inequality and the union bound, all of the calls to EstimateInf have additive error at most $\frac{\epsilon^2}{10^6 k^2}$ except with probability at most $\frac{1}{6}$. In the following, we assume that this condition holds and show how, when it does, the algorithm correctly accepts or rejects with probability with probability at least $\frac{5}{6}$.

▶ **Claim 3.1** (Completeness). *When* f *is* $\frac{\epsilon}{10^6}$*-close to the property* $\mathcal{F}$ *of* k*-juntas, the* Implicit Learning Tester *accepts with probability at least* $\frac{5}{6}$.

Proof. First, by Lemma 3, the probability that f is rejected on step 17 is at most $\frac{1}{18}$. In the rest of the proof, we will show that except with probability at most $\frac{1}{9}$, there is a function $h_{\text{core}} \in \mathcal{F}_{\text{core}}^{(\frac{\epsilon}{1000})}$ for which the algorithm accepts on line 20.

Let $g \in \mathcal{F}$ be a function that satisfies $\text{dist}_2(f,g) \leq \frac{\epsilon}{10^6}$. Without loss of generality, we can assume that g is a junta on $[k]$. Let $J = [k] \cap S_B$ be the set of the junta variables of g that are contained in the final parts selected by the algorithm. Again without loss of generality (by relabeling the input variables once again if necessary), we can assume that $J = [j]$ for some $j \leq k$, and $i \in S_{b_i}$, for $i \leq j$.

Define $\psi : \{0,1\}^n \to \{0,1\}^k$ to be the mapping defined by $\psi(x) = (x_1, \ldots, x_j, x_{i_1}, \ldots, x_{i_{k-j}})$ where $i_1, \ldots, i_{k-j} \in [n] \setminus [k]$ are representative coordinates from the remaining parts $b \in B$ for which $P_b \cap [k] = \emptyset$.

Let $g_{\text{core}} \in \mathcal{F}_{\text{core}}$ be the core of g corresponding to the projection $\psi(x) = (x_1, \ldots, x_k)$, and let $h_{\text{core}} \in \mathcal{F}_{\text{core}}^{(\frac{\epsilon}{10^6})}$ be the discretized approximation to g_{core}. Define $h = h_{\text{core}} \circ \psi$. By our choice of g, we have $\text{dist}_2(f,g) \leq \frac{\epsilon}{10^6}$. In order to invoke Lemma 4, we now want to bound $\text{dist}_2(g,h)$.

Let $h^* \in \mathcal{F}^{(\frac{\epsilon}{10^6})}$, be the discretized approximation of g. Then $\text{dist}_2(g,h^*) \leq \frac{\epsilon}{10^6}$ and the triangle inequality implies that

$$\text{dist}_2(f,h^*) \leq \text{dist}_2(f,g) + \text{dist}_2(g,h^*) \leq \tfrac{2\epsilon}{10^6}$$

and that

$$\text{dist}_2(g,h) \leq \text{dist}_2(g,h^*) + \text{dist}_2(h^*,h) \leq \text{dist}_2(h^*,h) + \tfrac{\epsilon}{10^6}.$$

Furthermore, since $h_{\text{core}} = h^*_{\text{core}}$,

$$\begin{aligned} \text{dist}_2(h^*,h) &= \mathop{\mathrm{E}}_{x} \left[\left(h^*_{\text{core}}(x_1, \ldots, x_k) - h^*_{\text{core}}(x_1, \ldots, x_j, x_{i_1}, \ldots, x_{i_{k-j}}) \right)^2 \right]^{\frac{1}{2}} \\ &= 2\,\text{Inf}_{h^*_{\text{core}}}([k] \setminus [j])^{\frac{1}{2}} = 2\,\text{Inf}_{h^*}([n] \setminus [j])^{\frac{1}{2}}. \end{aligned}$$

By Proposition 2.8 and Lemma 3, except with probability at most $\frac{1}{18}$,

$$\text{Inf}_{h^*}([n] \setminus [j])^{\frac{1}{2}} \leq \text{Inf}_f([n] \setminus [j])^{\frac{1}{2}} + \text{dist}_2(f,h^*) \leq \text{Inf}_f([n] \setminus S_B)^{\frac{1}{2}} + \tfrac{2\epsilon}{10^6} \leq \tfrac{12\epsilon}{10^6}$$

and the distance between g and h is bounded by $\text{dist}_2(g,h) \leq \frac{13}{10^6}\epsilon$. When this bound holds, by Lemma 4 with $\varepsilon = \frac{\epsilon}{100}$, the algorithm accepts f for this h except with probability at most $\frac{1}{18}$. ◀

▶ **Claim 3.2** (Soundness I). *If f is $\frac{\epsilon}{100}$-far from being a k-junta, then the* Implicit Learning Tester *rejects with probability at least $\frac{5}{6}$.*

Proof. The initial partition $S_{P_1}, \ldots, S_{P_{100k^4}}$ is a random partition of $[n]$ with more than $20k^2$ parts so, by Lemma 2, with probability at least $\frac{5}{6}$, for any union $J \subseteq [n]$ of at most k of these parts we have $\mathrm{Inf}_f([n] \setminus J) \geq \frac{\epsilon^2}{400}$. When this is the case, the inclusion $S_B \subseteq \overline{L_0}$ and the fact that L_0 is the complement of the union of some set of k parts in the random partition imply that

$$\mathrm{Inf}_f([n] \setminus S_B) \geq \mathrm{Inf}_f(L_0) \geq \frac{\epsilon^2}{400}$$

and, under the assumed accuracy of EstimateInf calls, the algorithm rejects f in Step 17. ◀

▶ **Claim 3.3** (Soundness II). *If f is $\frac{\epsilon}{100}$-close to a k-junta, but is $\frac{99\epsilon}{100}$-far from $\mathcal{F}$, then the* Implicit Learning Tester *rejects with probability at least $\frac{5}{6}$.*

Proof. Let g be any k-junta that satisfies $\mathrm{dist}_2(f, g) \leq \frac{\epsilon}{100}$. For any $h_{\mathrm{core}} \in \mathcal{F}_{\mathrm{core}}^{(\frac{\epsilon}{1000})}$ and any injective mapping $\psi : \{0,1\}^n \to \{0,1\}^k$, the function $h = h_{\mathrm{core}} \circ \psi$ is in $\mathcal{F}^{(\frac{\epsilon}{1000})}$ and so by the triangle inequality,

$$dist_2(f, \mathcal{F}^{(\frac{\epsilon}{1000})}) \geq dist_2(f, \mathcal{F}) - \tfrac{\epsilon}{1000}$$

and

$$\mathrm{dist}_2(g, h) \geq \mathrm{dist}_2(f, h) - \mathrm{dist}_2(f, g) \geq \tfrac{99}{100}\epsilon - \tfrac{\epsilon}{1000} - \tfrac{\epsilon}{100} \geq \tfrac{97}{100}\epsilon.$$

Then, by Proposition 2.8 and the union bound over all $|\mathcal{F}_{\mathrm{core}}^{(\frac{\epsilon}{1000})}| \leq (1000/\epsilon)^{2^k}$ functions in $\mathcal{F}_{\mathrm{core}}^{(\frac{\epsilon}{1000})}$, with probability at least $\frac{5}{6}$, the condition in Step 20 is never satisfied and the algorithm rejects. ◀

To complete the proof of Theorem 1.3 in the case where $p = 2$, consider now any property $\mathcal{P}$ that contains only functions which are $\frac{\epsilon}{10^6}$-close to some k-junta. Let $\mathcal{F}$ be the property that includes all k-juntas that are $\frac{\epsilon}{10^6}$-close to $\mathcal{P}$. Claim 3.1 shows that Implicit Learning Tester accepts every function in $\mathcal{P}$ with the desired probability, and Claims 3.2 and 3.3 shows that it rejects all functions that are ϵ-far from $\mathcal{P}$. Finally, we note that the query complexity of the algorithm is at most $q + 2m(2^{O(k\log(k))} + 2^k q) = \frac{2^{O(k\log k)}}{\epsilon^{10}}$, as claimed. Finally, the general result for ℓ_p testing when $p \neq 2$ follows from Fact 2.1.

3.2 Proof of Lemma 3

Let f be any function ε-close to a k-junta and assume without loss of generality (by relabeling the input variables if necessary) that f is close to a junta on $[k]$. The definition of $P_1, \ldots, P_{100k^4}$ in step 3, means that $S_{P_1}, \ldots, S_{P_{100k^4}}$ is a random partition of $[n]$. So by the union bound, the probability that any two of the coordinates in $[k]$ land in the same part is at most $\frac{1}{100k^2}$.

For each $\ell = 0, 1, 2, \ldots, r$, let $L_\ell = [n] \setminus \bigcup_{i=1}^{k} S_{P_{\ell,i}}$ denote the set of variables that have been "eliminated" after ℓ iterations of the loop. Then $[n] \setminus S_B = L_r$ and

$$\mathrm{Inf}_f([n] \setminus S_B) = \mathrm{Inf}_f(L_0) + \sum_{\ell=1}^{r} \Big(\mathrm{Inf}_f(L_\ell) - \mathrm{Inf}_f(L_{\ell-1})\Big). \tag{1}$$

We bound both terms on the right-hand side of the expression separately.

By Proposition 2.8, we have $\mathrm{Inf}_f([n] \setminus [k]) \leq \varepsilon^2$ and so by the monotonicity of influence there is a choice of $J \subseteq [k^2]$ of size $|J| \leq k$ for which $\mathrm{Inf}_f([n] \setminus S_J) \leq \varepsilon^2$. The guaranteed accuracy on EstimateInf then implies that

$$\mathrm{Inf}_f(L_0) \leq (1 + \tfrac{2}{100k^2})\varepsilon^2. \tag{2}$$

Define $\mathcal{E} = \{\ell \leq r : (L_\ell \setminus L_{\ell-1}) \cap [k] \neq \emptyset\}$ to be the set of rounds for which the algorithm eliminated at least one of the coordinates in $[k]$. By this definition, each $\ell \in [r] \setminus \mathcal{E}$ satisfies $(L_\ell \setminus L_{\ell-1}) \cap [k] = \emptyset$ and

$$\begin{aligned}\sum_{\ell \in [r]\setminus\mathcal{E}} \mathrm{Inf}_f(L_\ell) - \mathrm{Inf}_f(L_{\ell-1}) &= \sum_{\ell\in[r]\setminus\mathcal{E}} \sum_{T:\, T\cap L_\ell \neq \emptyset \wedge T \cap L_{\ell-1} = \emptyset} \hat{f}(T)^2 \\ &\leq \sum_{T \subseteq [n]\setminus[k]} \hat{f}(T)^2 \leq \mathrm{Inf}_f([n] \setminus [k]) \leq \varepsilon^2. \end{aligned} \tag{3}$$

For each $\ell \in \mathcal{E}$, define $X_\ell = \{\cup_{i=1}^k S_{P_{\ell,i,1-(z^*_\ell)_i}} : S_{P_{\ell,i,1-(z^*_\ell)_i}} \cap [k] \neq \emptyset\}$ to be the set of coordinates in the parts that contain a coordinate in $[k]$ that was eliminated in the ℓth iteration of the loop. Let also $Y_\ell = \{\cup_{i=1}^k S_{P_{\ell,i,(z^*_\ell)_i}} : S_{P_{\ell,i,1-(z^*_\ell)_i}} \cap [k] \neq \emptyset\}$ be the coordinates in the parts that were kept instead. Then the guaranteed accuracy of EstimateInf and the choice of z^*_ℓ implies that

$$\mathrm{Inf}_f(L_\ell) \leq \mathrm{Inf}_f\big((L_\ell \setminus X_\ell) \cup Y_\ell\big) + 2\,\tfrac{\varepsilon^2}{100k^2}$$

and, therefore,

$$\begin{aligned}\sum_{\ell\in\mathcal{E}} \mathrm{Inf}_f(L_\ell) - \mathrm{Inf}_f(L_{\ell-1}) &\leq \frac{2\varepsilon^2}{1000k} + \sum_{\ell\in\mathcal{E}} \mathrm{Inf}_f\big((L_\ell \setminus X_\ell) \cup Y_\ell\big) - \mathrm{Inf}_f(L_{\ell-1}) \\ &\leq \frac{2\varepsilon^2}{1000k} + \sum_{\ell\in\mathcal{E}} \sum_{T:\, T\cap(L_\ell\setminus X_\ell)\neq\emptyset\wedge T\cap L_{\ell-1}=\emptyset} \hat{f}(T)^2 \\ &\quad + \sum_{\ell\in\mathcal{E}} \sum_{T:\, T\cap Y_\ell\neq\emptyset\wedge T\cap L_{\ell-1}=\emptyset} \hat{f}(T)^2. \end{aligned} \tag{4}$$

As above, since $(L_\ell \setminus X_\ell) \cap [k] = \emptyset$,

$$\sum_{\ell\in\mathcal{E}} \sum_{T:\, T\cap(L_\ell\setminus X_\ell)\neq\emptyset\wedge T\cap L_{\ell-1}=\emptyset} \hat{f}(T)^2 \leq \sum_{T\subseteq[n]\setminus[k]} \hat{f}(T)^2 \leq \varepsilon^2. \tag{5}$$

It remains to bound the last sum on the right-hand side of (4). By splitting up the terms in this sum according to whether $|T| \leq k$ or not, we obtain

$$\sum_{T:T\cap Y_\ell\neq\emptyset\wedge T\cap L_{\ell-1}=\emptyset} \hat{f}(T)^2 \leq \sum_{|T|\leq k} \hat{f}(T)^2 \cdot \mathbf{1}[T \cap Y_\ell \neq \emptyset] + \sum_{|T|>k} \hat{f}(T)^2 \cdot \mathbf{1}[T \cap L_{\ell-1} = \emptyset].$$

Let $Z \subseteq [n] \setminus [k]$ denote the set of coordinates that occur in one of the the original parts $S_{P_1}, \ldots, S_{P_{100k^4}}$ that also contains one of the elements in $[k]$. Then $Y_\ell \subseteq Z$ and

$$\sum_{\ell\in\mathcal{E}} \sum_{|T|\leq k} \hat{f}(T)^2 \cdot \mathbf{1}[T\cap Y_\ell \neq \emptyset] \leq \sum_{\ell\in\mathcal{E}} \sum_{|T|\leq k} \hat{f}(T)^2 \cdot \mathbf{1}[T\cap Z \neq \emptyset] \leq k \cdot \sum_{|T|\leq k} \hat{f}(T)^2 \cdot \mathbf{1}[T\cap Z \neq \emptyset].$$

The probability, over the choice of $P_1, \ldots, P_{100k^4}$, that $T \cap Z \neq \emptyset$ is at most $|T|/100k^3$, so the expected value of the last expression (again over the choice of the initial partition) is bounded above by

$$\begin{aligned}\mathrm{E}\Big[\sum_{\ell\in\mathcal{E}}\sum_{|T|\le k}\hat{f}(T)^2\cdot\mathbf{1}[T\cap Y_\ell\neq\emptyset]\Big] &\le k\cdot\sum_{|T|\le k, T\setminus[k]\neq\emptyset}\hat{f}(T)^2\cdot\Big(\frac{k}{100k^3}\Big)\\ &\le \frac{1}{100k}\cdot\mathrm{Inf}_f([n]\setminus[k])\le\frac{\varepsilon^2}{100k}.\end{aligned}\tag{6}$$

Lastly, since $L_0 \subseteq L_{\ell-1}$ for each $\ell \geq 1$,

$$\sum_{|T|>k}\hat{f}(T)^2\cdot\mathbf{1}[T\cap L_{\ell-1}=\emptyset]\le\sum_{|T|>k}\hat{f}(T)^2\cdot\mathbf{1}[T\cap L_0=\emptyset].$$

A set T can be disjoint from L_0 only when its elements are contained in at most k of the parts of the initial random partition, which happens with probability at most $\frac{1}{100k^2}$ when $|T| > k$, so

$$\begin{aligned}\mathrm{E}\Big[\sum_{\ell\in\mathcal{E}}\sum_{|T|>k}\hat{f}(T)^2\cdot\mathbf{1}[T\cap L_{\ell-1}=\emptyset]\Big] &\le \mathrm{E}\Big[k\sum_{|T|>k}\hat{f}(T)^2\cdot\mathbf{1}[T\cap L_0=\emptyset]\Big]\\ &\le\frac{1}{100k}\sum_{|T|>k}\hat{f}(T)^2\le\frac{\varepsilon^2}{100k},\end{aligned}\tag{7}$$

where the last inequality uses the fact that $\sum_{|T|>k}\hat{f}(T)^2 \leq \mathrm{Inf}_f([n]\setminus[k])$.

Combining the inequalities (1)–(7), we obtain that the expected value of $\mathrm{Inf}_f([n]\setminus S_B)$ is bounded above by

$$\mathrm{E}\left[\mathrm{Inf}_f([n]\setminus S_B)\right]\le(1+\tfrac{2}{100k^2})\varepsilon^2+\tfrac{2\varepsilon^2}{100k}+(1+\tfrac{2}{100k})2\varepsilon^2\le 4\varepsilon^2.$$

Applying Markov's inequality and adding the probability that the junta variables are completely separated in the partition $P_1, \ldots, P_{100k^4}$ completes the proof of the lemma.

3.3 Proof of Lemma 4

For any $X = (x^{(1)}, \ldots, x^{(q)})$, let $\mathrm{dist}_X(f_1, f_2) = \left(\frac{1}{q}\sum_{i=1}^{q}\left(f_1(x^{(i)}) - f_2(x^{(i)})\right)^2\right)^{1/2}$ denote the empirical distance between f_1 and f_2 according to X. To prove the lemma, we want to show that $\mathrm{dist}_X(f, h)$ is within the specified bounds.

The function dist_X is a metric, so we can apply the triangle inequality to obtain

$$\mathrm{dist}_X(f,h)\le\mathrm{dist}_X(f,g)+\mathrm{dist}_X(g,h).$$

By Hoeffding's inequality, when $x^{(1)}, \ldots, x^{(q)}$ are drawn independently and uniformly at random, the upper bound

$$\mathrm{dist}_X(f,g)\le\mathrm{dist}_2(f,g)+\varepsilon\le 2\varepsilon$$

holds except with probability at most $e^{-16q\varepsilon^4}$.

We now want to show that $\mathrm{dist}_X(g, h)$ is also close to $\mathrm{dist}_2(g, h)$. This analysis is a bit more subtle, however, because the choice of samples $x^{(1)}, \ldots, x^{(q)}$ is *not* independent of h (as it affects what mapping ψ will be chosen by the algorithm). So before we can apply concentration inequalities, we must "decouple" X and h. To do so, we introduce a new

random process for generating X. Let $\lambda : [n] \to \{0,1\}^q$ be chosen uniformly at random. This function corresponds to a random partition of the set $[n]$ of coordinates into 2^q parts. Let $\pi : \{0,1\}^q \to \{0,1\}^q$ be a random permutation. Then the random variable X obtained by setting $x_j^{(i)} = \pi(\lambda(j))_i$ has the desired uniform distribution over sequences of q vectors in $\{0,1\}^n$.

This random process is designed so that the choice of ψ in the algorithm (and therefore also h) is *independent* of π; the only information about X used in determining it is the identity of the parts defined by λ, not what values the coordinates in each parts receive on the q queries. Then

$$\mathop{\mathrm{E}}_{X}[\mathrm{dist}_X(g,h)] = \mathop{\mathrm{E}}_{\lambda,r}[\mathop{\mathrm{E}}_{\pi}[\mathrm{dist}_X(g,h)]]$$

where r represents the internal randomness of the algorithm outside of that used to generate X. With probability at least $k^2/2^q$, the partition λ completely separates the indices in J. Fix such a partition λ. Define $J^* = J \cup \mathrm{supp}(\psi)$. Then $|J^*| \leq 2k$. Define $Y = (y^{(1)}, \ldots, y^{(q)})$ by setting $y^{(i)} = x^{(i)}_{J^*}$. Since $\mathrm{dist}_X(g,h)$ only depend on the coordinates in J^*, we can write it equivalently as $\mathrm{dist}_Y(g,h)$.

Let D denote the distribution on Y induced by π. The distribution D is close to but not equal to the uniform distribution U on $\{0,1\}^{q\times|J^*|}$, since D is equivalent to the distribution obtained by making drawing $(y_i^{(1)}, \ldots, y_i^{(q)})$ for each $i \in J^*$ without replacement from $\{0,1\}^q$. Then

$$\begin{aligned}
&\Pr_{Y\sim D}[|\mathrm{dist}_Y(g,h) - \mathop{\mathrm{E}}_{Y\sim U}\mathrm{dist}_Y(g,h)| \geq \varepsilon] \\
&\qquad\leq \mathrm{d_{TV}}(D,U) + \Pr_{Y\sim U}[|\mathrm{dist}_Y(g,h) - \mathop{\mathrm{E}}_{Y\sim U}\mathrm{dist}_Y(g,h)| \geq \varepsilon] \\
&\qquad\leq \tfrac{4k^2}{2^q} + e^{-16q\varepsilon^4}.
\end{aligned}$$

In the last inequality, the bound $\mathrm{d_{TV}}(D,U) \leq \frac{(2k)^2}{2^q}$ is by the standard total variation bound between sampling with and without replacement [19] and the other bound on the other term is by Hoeffding's inequality.

4 Applications

In this short section, we show how Theorems 1.1 and 1.2 both follow directly from Theorem 1.3 and the junta theorem of Feldman and Vondrák.

Proof of Theorem 1.1. By the first part of the Feldman–Vondrák junta theorem, every submodular function $f \in \mathcal{F}_n$ is $\frac{\epsilon}{10^6}$-close to a k-junta for some $k = O(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon})$. Therefore, by Theorem 1.3, submodularity can be tested with $2^{O(k\log k)}/\epsilon^{10} = 2^{\tilde{O}(1/\epsilon^2)}$ queries in the ℓ_2 testing model. By Fact 2.1, the number of queries for testing submodularity in the ℓ_p testing model for any $1 \leq p < 2$ is also $2^{\tilde{O}(1/\epsilon^2)}$ and for any $p > 2$ it is $2^{\tilde{O}(1/(\epsilon^{p/2})^2)} = 2^{\tilde{O}(1/\epsilon^p)}$. ◀

Proof of Theorem 1.2. By Lemma 1, additive functions, coverage functions, unit demand functions, OXS functions, and gross substitute functions are all also submodular. Therefore, the first part of the Feldman–Vondrák junta theorem also applies to these functions and the rest of the proof is identical to that of Theorem 1.1.

Lemma 1 also implies that fractionally subadditive functions are self-bounding, so the second part of the Feldman–Vondrák junta theorem shows that every function f that has either of these properties is $\frac{\epsilon}{10^6}$-close to a k-junta for some $k = 2^{O(\frac{1}{\epsilon^2})}$. Therefore,

by Theorem 1.3, fractional subadditivity and self-boundedness can both be tested with $2^{O(k \log k)}/\epsilon^{10} = 2^{2^{\tilde{O}(1/\epsilon^2)}}$ queries in the ℓ_2 testing model; the general result for the ℓ_p testing model again follows directly from Fact 2.1. ◀

A Missing proofs from Section 2

We begin with the proof of Lemma 2. We emphasize that the proof below is essentially as found in [6]; the reason we include it here is that the original statement of the proof only applied to Boolean-valued functions. As we see below, however, the same argument also holds for real-valued functions.

▶ **Theorem A.1.** *(Dinur and Safra [12]; Friedgut [20]) Let $\mathcal{G}$ be a t-intersecting family of subsets of $[n]$ for some $t \geq 1$. For any $p < \frac{1}{t+1}$, the p-biased measure of $\mathcal{G}$ is bounded by $\mu_p(\mathcal{G}) \leq p^t$.*

Proof of Lemma 2. For $0 \leq t \leq \frac{1}{2}$, let $\mathcal{G}_t = \{J \subseteq [n] : \mathrm{Inf}_f(\overline{J}) < t\varepsilon^2\}$ be the family of all the sets whose compliments have influence less than $t\varepsilon^2$. For any two sets $J, K \in \mathcal{G}_{\frac{1}{2}}$, the subadditivity of influence implies that

$$\mathrm{Inf}_f(\overline{J \cap K}) = \mathrm{Inf}_f(\overline{J} \cup \overline{K}) \leq \mathrm{Inf}_f(\overline{J}) + \mathrm{Inf}_f(\overline{K}) < \varepsilon^2.$$

But f is ε-far from every k-junta, so for any two sets $J, K \in \mathcal{G}_{\frac{1}{2}}$, $|J \cap K| > k$, from Proposition 2.8. Which means $\mathcal{G}_{\frac{1}{2}}$ is a $k+1$ intersecting family. There are two cases now, first one is, there is at least one set $J \in \mathcal{G}_{\frac{1}{2}}$ such that $|J| < 2k$, second one is all the sets $J \in \mathcal{G}_{\frac{1}{2}}$ will have $|J| \geq 2k$. We will show that in both the cases our lemma holds. In the first case let $J \in \mathcal{G}_{\frac{1}{2}}$ be a set which has fewer than $2k$ elements, with high probability the set J is completely separated by the partition $\mathcal{P}$, and we know that for any $K \in \mathcal{G}_{\frac{1}{2}}$, $|J \cap K| \geq k+1$, which means K is not covered by any union of k-parts in $\mathcal{P}$. Therefore, $\mathrm{Inf}_f(\overline{J}) \geq \frac{\varepsilon^2}{2} > \frac{\varepsilon^2}{4}$ as we wanted to show.

Consider the case where, all the sets in $\mathcal{G}_{\frac{1}{2}}$ have more than $2k$ elements. Then $G_{\frac{1}{4}}$ is a $2k$ intersecting family. Otherwise, if there are two sets $J, K \in \mathcal{G}_{\frac{1}{4}}$ such that $|J \cap K| < 2k$, then $\mathrm{Inf}_f(\overline{J \cap K}) \leq \mathrm{Inf}_f(\overline{J}) + \mathrm{Inf}_f(\overline{K}) < \frac{\varepsilon^2}{4} + \frac{\varepsilon^2}{4} < \frac{\varepsilon^2}{2}$, thus contradicting our assumption.

Let $J \subseteq [n]$ be the union of k parts in $\mathcal{P}$. Since $\mathcal{P}$ is a random partition, J is a random subset obtained by including each element of $[n]$ in J independently with probability $p = \frac{k}{r} < \frac{1}{2k+1}$. By Theorem A.1, $\Pr_{\mathcal{P}}[I_f(\overline{J}) < \frac{\varepsilon^2}{4}] = \Pr[J \in \mathcal{G}_{\frac{1}{4}}] = \mu_{\frac{k}{r}}(\mathcal{G}_{\frac{1}{4}}) \leq (\frac{k}{r})^{2k}$. By the union bound the probability that there exists a set $J \subseteq [n]$ that is the union of k parts in $\mathcal{P}$ for which $\mathrm{Inf}_f(\overline{J}) < \frac{\varepsilon^2}{4}$ is bounded above by $\binom{r}{k}(\frac{k}{r})^{2k} \leq (\frac{er}{k})^k(\frac{k}{r})^{2k} \leq (\frac{ek}{r})^k < \frac{1}{6}$. ◀

The proof of Proposition 2.9 is obtained by considering the EstimateInf algorithm below.

Algorithm 2: EstimateInf(f, S, m)

1 Draw $x_1, \ldots, x_m$ uniformly and independently at random from $\{0,1\}^{\overline{S}}$;
2 Draw $y_1, \ldots, y_m, y'_1, \ldots, y'_m$ uniformly and independently at random from $\{0,1\}^{S}$;
3 Return $\frac{1}{2m}\sum_{i=1}^{m}\left(f(x_i, y_i) - f(x_i, y'_i)\right)^2$;

The concentration of the estimated influence is obtained via the following (standard) version of Hoeffding's inequality.

▶ **Hoeffding's inequality.** *Let $X_1, ..., X_n$ be independent random variables bounded by $a_1 \leq X_i \leq b_i$. Let $X = X_1 + X_2 + \cdots X_n$ have expected value $E[X] = \mu$. Then for any $t > 0$,*

$$\Pr[|X - \mu| \geq t] \leq 2e^{-\frac{2t^2}{\sum_{i=1}^{n}(b_i - a_i)^2}}.$$

Algorithmic Aspects of Private Bayesian Persuasion*

Abstract

We consider a multi-receivers Bayesian persuasion model where an informed sender tries to persuade a group of receivers to take a certain action. The state of nature is known to the sender, but it is unknown to the receivers. The sender is allowed to commit to a signaling policy where she sends a private signal to every receiver. This work studies the computation aspects of finding a signaling policy that maximizes the sender's revenue.

We show that if the sender's utility is a submodular function of the set of receivers that take the desired action, then we can efficiently find a signaling policy whose revenue is at least $(1 - 1/e)$ times the optimal. We also prove that approximating the sender's optimal revenue by a factor better than $(1 - 1/e)$ is NP-hard and, hence, the developed approximation guarantee is essentially tight. When the sender's utility is a function of the number of receivers that take the desired action (i.e., the utility function is anonymous), we show that an optimal signaling policy can be computed in polynomial time. Our results are based on an interesting connection between the Bayesian persuasion problem and the evaluation of the concave closure of a set function.

1 Introduction

Sender-receiver models have been extensively studied in economics to understand the role of information in strategic settings; see, e.g., [5, 2, 12, 18]. Since these models study how information, or lack thereof, affects strategic decisions, they have found applications in various domains such as voting [2, 27], regulation policies [21, 28], marketing [8, 3], and auctions [7]. In these models, there is a sender who is more informed than the receiver, and the receiver has to take an action that affects both the sender's and the receiver's utility. An important objective behind studying these models is to quantify the *informational advantage* of the sender. In particular, the goal is to understand the optimal policy using which the sender can transmit (partial) information – or, equivalently send signals – to persuade the receiver into taking an action that is beneficial for the sender. Therefore, research work in

this field is aimed at characterizing signaling policies that yield the sender the maximum possible revenue.

A fundamental sender-receiver model considered in the literature is the *Bayesian persuasion* model, wherein the sender is allowed to *commit* to a signaling (information-revelation) policy *before* she receives the information.[1] In this model, the utilities of the sender and the receiver (obtained from different sender/receiver actions) depend on the state of nature, which is drawn from a prior distribution. This distribution is known to the receiver and the sender. But, only the sender knows the realized state of nature (i.e., the draw) and, hence, has an informational advantage. In this Bayesian model – building upon the classical work by Aumann and Maschler [5] – Kamenica and Gentzkow [18] study the case in which there is exactly one receiver and they obtain a clean characterization of the sender's optimal signaling policy and her optimal revenue. However, this clean characterization fails to hold when there are multiple receivers; this is true even if the receivers have no payoff externalities.

In fact, except for a few specific instances [29, 11], little is known about optimal signaling policies in settings wherein the sender has to transmit to multiple receivers. To address this limitation, in a recent work Arieli and Babichenko [4] examine the following multiple-receiver setting, which will also be the focus of the our work: there are two states of nature, a single sender, and n receivers with binary ($\{0,1\}$) actions. Like the standard Bayesian setting, in this model the state of nature is drawn from a prior distribution that is known to the receivers and the sender; but, only the sender has access to the realized state. Each receiver's utility depends on her action and the state of nature (which she does not know). Furthermore, in this model the sender is allowed to send *private* signals to the receivers, and her utility is a monotonic set function of the *profile* of actions of the receivers, i.e., the sender's utility is a function which depends upon the set of receivers that, say, play action one.

Our goal is to examine the algorithmic aspects of this model. In particular, we focus on the computation of an (approximately) optimal policy for the sender. When the sender's utility is a submodular function, we show that a signaling policy whose revenue is at least $(1-\frac{1}{e}-\epsilon)$ times the sender's optimal revenue can be found in polynomial time; here $\epsilon > 0$ is an arbitrarily small constant. In addition, we establish that there does not exist a polynomial-time algorithm which approximates the sender's optimal revenue by a factor better than $(1-\frac{1}{e}+\epsilon)$, unless P = NP. Hence, the obtained approximation ratio is almost tight. For the case in which the sender's utility is anonymous – i.e., depends only on the number of receivers that play action one and not on their identities – we develop a polynomial algorithm for finding the optimal policy.

Our results are based on an interesting connection between the sender's optimal policy and the *concave closure* of a set function. We observe that computation/approximation, of an optimal signaling policy is equivalent to computation/approximation of the concave closure. Our signaling results follow from the following analogous results for the concave closure: a tight $(1-\frac{1}{e})$ approximation bound for the concave closure of submodular functions and a polynomial-time algorithm for the concave closure of anonymous functions. Since concave closure is a fundamental object of study in discrete convex analysis (see, e.g., [26]) our results for the evaluation of the concave closure might be of independent interest.

Although our focus is on a basic setting (in particular, on a setting in which the receivers have no payoff externalities,[2] they have binary actions, and the state of nature is binary), the considered model does capture several interesting – albeit stylized – scenarios.

---

[1] The Bayesian persuasion model complements the classical *cheap talk* model [12] which assumes that sender decides which signal to send after she receives the information.

[2] That is, each receiver's utility depends on her action and the state of nature, and not on the action of other receivers.

For example, the model can be used to represent a marketer (a sender) who is trying to persuade consumers (the receivers) to buy a certain product. Here, it is natural to assume that the marketer has more information about the quality of the product than the consumers. Also, different potential consumers may have different utilities for adopting the product. Note that each consumer has two possible (binary) actions, either to buy the product or not. In addition, we can consider the product (state of nature) to be in one of two possible states: the product is either high-quality or low-quality. Furthermore, the marketer's production cost may not be linear. Since it is reasonable to assume that the marketer's utility depends on the number of consumers that buy the product, this example is exactly captured by our result on anonymous utilities. In particular, using the algorithm developed for anonymous utilities we can efficiently compute an optimal signaling policy for the marketer.

Along these lines, the considered model also captures a viral marketing scenario where the receivers are the "opinion leaders", say, in a social network. After persuading a subset of "opinion leaders" to adopt a product, the information about the product will be spread through the network according to some diffusion process. As demonstrated in the notable work for Kempe et al. [23], many diffusion processes satisfy the submodularity property. Hence, our result on submodular utilities can be applied in such settings.

Another example is that of a lobbyist who is trying to persuade politicians to support a certain proposal. The proposal will pass if the number of supporters is above a specified threshold. Under the assumption that politicians vote sincerely[3] (i.e., they vote in favor of the alternative that maximizes their utility, given the information they posses about the proposal), this example is captured by the anonymous supermajority utility case.

Techniques. As mentioned above, our proofs are based on an interesting connection between the Bayesian persuasion model and the *concave closure of a set function* [25, 13, 30]. Specifically, in Section 2 (Lemma 1) we show that computation (or approximation) of sender's optimal revenue with utility $V : 2^{[n]} \to \mathbb{R}_+$ is (computationally) equivalent to evaluation (or approximation) of the concave closure of the function V, here $[n]$ is the set of receivers. Concave closure has been studied in the context of submodular maximization, see, e.g., [10] and [30]. In particular, prior work has shown that even though the concave closure provides a tight relaxation for constrained maximization of submodular functions, it is NP-hard to compute. Hence, instead of focusing on the computation of the concave closure, approximation results for submodular maximization typically rely on finding the *multilinear relaxation*. It turns out that in the context of the Bayesian persuasion problem the concave closure is not just a technical tool, but a core object. Therefore, a key focus of the paper is on efficiently approximating concave closures.

Specifically, we develop a $(1 - \frac{1}{e})$-approximation algorithm for computing the concave closure of monotone submodular functions. Our tight approximation result rests on an approximation preserving reduction between computing the concave closure and the problem of maximizing a monotone submodular function subject to a matroid constraint. We obtain such a reduction by a careful rounding of the problem parameter to a discrete grid. Since submodular maximization under matroid constraints admits a $(1 - \frac{1}{e})$ approximation (see [10]) the desired result follows. For the hardness result, we use tools from [24] and [17] which were developed to establish the hardness of approximating the maximum social welfare in combinatorial auctions.

[3] Note that this simplifying assumption assumes that politicians adopt a simple behavioral rule rather than a sophisticated equilibrium behavior. In equilibrium, each politician should condition his vote on the event that his vote will be pivotal, which leads the politicians to a completely different behavior, see e.g., [6].

We establish the result for anonymous utility functions (which are not necessarily submodular/concave) by developing a polynomial-time algorithm for computing the concave closure of anonymous functions. This result builds upon a lemma from [4], which characterizes the maximum "mass" that can be assigned to subsets of size $k \leq n$ under given marginal constraints; see Lemma 3 below for details. In addition to Lemma 3, to obtain the result we show a non-trivial property that in this case the maximal assignment is "monotonous across all ks," see details in Lemma 4. This additional property allows us to formulate the original concave closure problem as an LP with a *polynomial* number of variables.

1.1 Additional Related Work

The current literature on Bayesian persuasion starts with the result of [18] who – building upon the classical work by [5] – analyze the case of a single sender and a single receiver. Several extensions of this model – including ones that consider multiple receivers – have been studied in recent years, see, e.g., [1, 19, 20]. The setting wherein the sender is only allowed to send a public signal to the receivers is considered in [2, 27]. Furthermore, the complementary setting in which the sender is allowed to send private signals to the receivers has been studied in [4, 29, 31]. Our result is most closely related to the work of [4] where the optimal policy and the optimal revenue are characterized for supermodular utilities, utilities that are both anonymous and submodular, and also for supermajority utilities. In particular, we build upon the work of [4] with a computation perspective. We show that for *every* anonymous utility the optimal revenue can be computed in polynomial time. This result generalizes the claim in [4] where the same result (along with a closed-form expression for the sender's revenue) was established for anonymous utilities that are also submodular. We provide a tight approximation result for submodular utilities. Our inapproximability result for submodular functions (Theorem 9) indicates that it is unlikely that there exists a closed-form expression for the sender's revenue when her utility function is submodular.

A number of recent results in the computer science community have examined algorithmic questions surrounding the above mentioned models and signaling in general [15, 14, 16, 22, 9]. In particular, an interesting paper by Dughmi and Xu [15] studies the complexity of Bayesian persuasion in the single-receiver model of Kamenica and Gentzkow [18]. They consider the case in which the receiver has n actions and there are $\exp(n)$ states of nature. Dughmi and Xu [15] show that when the payoff profiles are i.i.d. distributed (for all receiver's actions) the problem can be solved in polynomial time. The same is not true if the payoff profiles are independently, but not identically, distributed – in this case the problem becomes #P-hard. Finally, they also show that the general problem (with arbitrary payoff profiles) can be approximately solved efficiently in a query model, if we assume that the receiver follows the recommended action by the sender in all cases where no ε-better action (according to her belief) exists.[4]

2 Notations and Preliminaries

We consider a Bayesian persuasion model with a sender and n receivers, $[n] = \{1, 2, ..., n\}$. Write $\Omega = \{\omega_0, \omega_1\}$ to denote the two possible states of nature. Each receiver $i \in [n]$ has two actions, $\{0, 1\}$, and a utility function, u_i, that depends on the state of nature and its own action, $u_i : \Omega \times \{0, 1\} \to \mathbb{R}$. All receivers share a common prior distribution, where

[4] This notion is called ε-incentive compatibility.

$0 < \gamma < 1$ is the probability of state ω_1, and $1-\gamma$ of state ω_0. Note that even though the receivers' utilities are dependent on the realized state of nature they are a priori unaware of it. Throughout, we will use $\Delta(A)$ to denote the set of probability distributions over set A.

It is shown in [4] that, without loss of generality, we can assume that $u_i(\omega_0, 0) > u_i(\omega_0, 1)$ and $u_i(\omega_1, 1) > u_i(\omega_1, 0)$ for all receivers $i \in [n]$. In particular, it is shown in [4] that we can efficiently reduce an instance with arbitrary utility functions to an instance in which the receivers prefer to play 1 when the state of nature is ω_1 and prefer to play 0 when the state is ω_0. Hence, throughout the paper we will work with this assumption on receivers' utilities.

As mentioned earlier, the sender's utility, V, depends on the set of receivers that play action 1, $V : \{0,1\}^n \to \mathbb{R}$. With a slight abuse of notation, for a subset $S \subseteq [n]$, we will use $V(S)$ to denote $V(1_S)$, where 1_S is the characteristic vector of subset S. Throughout we will assume that the sender's utility monotonically increases with the set of receivers that play action 1: $V(S) \leq V(T)$ for every $S \subseteq T$.

Note that we have restricted our attention to the case wherein the sender's utility does not depend on Ω. More generally, the sender's utility can be defined to be a function of the state of nature as well, i.e., we can have $V : \Omega \times \{0,1\}^n \to \mathbb{R}$. It is shown in [4] that such a general case can always be efficiently reduced to a setting in which $V(\omega_0, S) = V(\omega_1, S)$ for each S. Hence, in this paper we will focus on utility functions, V, that are state independent.

Recall that the utility function V is said to be submodular if it satisfies the decreasing marginal property. That is, for every subset $S \subset T \subset [n]$ and each $i \in [n] \setminus T$, we have $V(S \cup \{i\}) - V(S) \geq V(T \cup \{i\}) - V(T)$.

As is typical is Bayesian persuasion models, we assume that only the sender knows the realized state. The receivers remain unaware of it. Furthermore, following the model of Kamenica and Gentzkow [18] we allow the sender to commit in advance to an information-revelation/signaling policy. In this work, however, we allow the sender to reveal the information to every receiver privately. This translates to a state dependent signaling distribution. Formally a policy of the informed sender consists of n finite sets $\{\Theta_i\}_{i=1,\ldots,n}$, where Θ_i is the private signal set of receiver i, and a mapping $F : \Omega \to \Delta(\Theta_1 \times \cdots \times \Theta_n)$. Write $\Theta := \Theta_1 \times \cdots \times \Theta_n$. The sender can commit to a policy F that is known to the receivers prior to stage in which the state ω is realized.

The sequence of the interaction between the sender and the receivers is as follows. First, the sender commits to a signaling policy F. Then, a state $\omega \in \Omega$ is realized in accordance with the prior $(\gamma, 1-\gamma)$. After that a profile of signals $\theta = (\theta_1, \ldots, \theta_n)$ is generated according to the distribution $F(\omega)$. Every receiver i observes her private signal realization $\theta_i \in \Theta_i$ and forms a posterior $\mathbb{P}_F(\omega_1|\theta_i) = p(\theta_i)$.

With the posterior in hand, receiver i selects an action that maximizes her expected utility. In other worlds, receiver i plays action 1 if and only if

$$p(\theta_i)u_i(\omega_1, 1) + (1 - p(\theta_i))u_i(\omega_0, 1) \geq p(\theta_i)u_i(\omega_1, 0) + (1 - p(\theta_i))u_i(\omega_0, 0).$$

We assume that in case of indifference, receivers plays action 1. Let $g_i(\theta_i) \in \{0,1\}$ denote receiver i's best-reply action when she observes the signal θ_i. Also, write $g(\theta)$ to be the action profile of the receivers when the realized vector of signals is θ. We will use $F_1 \in \Delta(\Theta)$ to denote the signal distribution conditional on state ω_1 and $F_0 \in \Delta(\Theta)$ to denote the signal distribution conditional on state ω_0.

Let $s(F)$ be the sender's utility from the policy (Θ, F):

$$s(F) := \gamma \mathbb{E}_{\theta \sim F_1}[V(g(\theta))] + (1-\gamma)\mathbb{E}_{\theta \sim F_0}[V(g(\theta))]. \tag{1}$$

A signaling policy (Θ, F) is said to be *optimal* if it maximizes sender's utility among all possible signal sets Θ and all possible signals $F : \Omega \to \Delta(\Theta)$.

We begin by stating a result from [4] (see Lemma 1 in [4]) that shows the existence of an optimal policy with the following useful properties:

- For every receiver i, the private signal set Θ_i is equal to $\{0,1\}$ and receiver i's best reply $g_i(\theta_i) = \theta_i$. In other words, when signal θ_i is recommended by the sender to receiver i it is profitable (after receiver i performs a Bayesian update of her belief on the state of the world) for her to follow the recommendation. In [18], such policies are called *straightforward*.
- In the optimal policy $F_1(1,1,\ldots,1) = 1$, i.e., when state ω_1 is realized the sender recommends everyone to adopt the product. Recall that F_1 is a distribution over the set Θ, which (by the previous property) is $\{0,1\}^n$ for the optimal policy under consideration.
- When the realized state is ω_0, the sender recommends to receiver i to adopt the product with probability of at most $a_i := \min\left\{\frac{\gamma}{1-\gamma}\frac{u_i(\omega_1,1)-u_i(\omega_1,0)}{u_i(\omega_0,0)-u_i(\omega_0,1)}, 1\right\}$. Write marginal $F_0(\theta_i = 1) := \sum_{\theta\in\{0,1\}^n:\ \theta_i=1} F_0(\theta)$. We succinctly express this condition as $F_0(\theta_i = 1) \le a_i$. The number a_i can be interpreted as the maximal probability that the sender can "lie" to the receiver, and will be called the *persuasion level of player i*.

Under such an optimal policy, the sender's utility is given by

$$s(F) = \gamma V([n]) + (1-\gamma)\mathbb{E}_{\theta\sim F_0} V(\theta) \tag{2}$$

Overall, in light of these properties the problem of determining an optimal policy (over general signal sets Θ and mappings $F : \Omega \to \Delta(\Theta)$) reduces to the following well-structured maximization problem:

$$\text{maximize} \quad \mathbb{E}_{\theta\sim F_0} V(\theta) \quad \text{subject to} \quad F_0(\theta_i = 1) \le a_i \quad \forall i \in [n]. \tag{3}$$

Note that the prior γ and the utility $V([n])$ are fixed parameters. Hence, an optimal solution of (3) gives us an optimal solution of (2).

For each subset $S \subset [n]$, with characteristic vector 1_S, write μ_S to be the probability that exactly the receivers is S will receive the recommendation to adopt the product, i.e., $\mu_S := F_0(1_S)$. For a given persuasion levels profile $a := (a_1, ..., a_n)$, the maximization problem (3) can be written as

$$\begin{aligned} V^+(a) := \max \ & \sum_{S\subseteq[n]} \mu_S V(S) \\ \text{s.t.} \ & \sum_{S\subset[n]} \mu_S 1_S \le a \\ & \sum_{S\subset[n]} \mu_S = 1 \\ & \mu_S \ge 0. \end{aligned} \tag{4}$$

This is exactly the definition of the concave closure of the set function V evaluated at a given vector a.

Throughout, we will use $V^+(a)$ to denote the concave closure of the sender's utility function V at $a \in [0,1]^n$. We will refer to solving (approximating) the optimization problem (4) as computing (approximating) the concave closure. Interestingly, the concave closure has been studied in the optimization literature. In particular, it is considered as a technical tool for submodular maximization; see, e.g., [10]. Note that computing the concave closure corresponds to solving a linear programming with polynomial number of constraints, but with an exponential number of variables (the variables are μ_S for every $S \subset [n]$).

In some cases we will be interested in approximating the optimal revenue of the sender and, hence, we introduce here the following lemma that states that computing (approximating) the concave closure is computationally equivalent to computing (approximating) the sender's optimal revenue. Note that, for a given parameter $\alpha \in (0,1]$, an α approximation of the concave closure corresponds to a distribution $\{\mu_S\}_{S\subseteq[n]}$ that satisfies the feasibility constraints of the optimization problem (4) and obtains an objective function value, $\sum_{S\subseteq[n]} \mu_S V(S)$, that is at least α times the optimal. The next lemma states that there exists an approximation-preserving, polynomial-time reduction between computing the concave closure and finding the optimal revenue of the sender. Specifically, the lemma establishes that computing the concave closure of the sender's utility function lies at the core of determining a revenue-maximizing policy for the sender.

▶ **Lemma 1.** *Given a persuasion profile $a \in [0,1]^n$ and utility function V along with an α approximation of the concave closure $V^+(a)$. We can find, in polynomial time, a policy for the sender (with utility function V and persuasion profile a) that obtains revenue at least α times the optimal.*

Furthermore, for every $\varepsilon > 0$, there exists a polynomial-time reduction from the problem of α approximating a sender's revenue (with utility function V and persuasion profile a) to the problem of computing an $(\alpha+\varepsilon)$ approximation of the concave closure $V^+(a)$.

Proof. The forward direction is direct: by equation (2), an α approximation of $\max \mathbb{E}_{\theta\sim F_0} V(\theta)$ is also an α approximation of $\gamma V(N) + (1-\gamma)\mathbb{E}_{\theta\sim F_0} V(\theta)$.

For the other direction, given function V and persuasion level profile $a = (a_i)_{i\in[n]}$, we can set the prior γ to be very small (e.g., $\gamma = \frac{\varepsilon(V(N))^2}{1-\alpha}$ suffices) and we set receiver i utilities to be

$$u_i(\omega_0, 0) = 1,\ u_i(\omega_0, 1) = u_i(\omega_1, 0) = 0,\ u_i(\omega_1, 1) = a_i \frac{1-\gamma}{\gamma}.$$

Such a choice guarantees that indeed $a_i = \min\left\{\frac{\gamma}{1-\gamma}\frac{u_i(\omega_1,1)-u_i(\omega_0,1)}{u_i(\omega_0,0)-u_i(\omega_0,1)}, 1\right\}$. It follows that for such instances an α approximation of the sender's revenue implies $(\alpha+\varepsilon)$ approximation of the concave closure of V. ◀

In subsequent sections we establish algorithmic and hardness results for the problem of finding the optimal policy (and revenue) of the sender. We do so by using the above mentioned lemma and, in particular, addressing the computation of the concave closure.

3 Anonymous Utility

This section considers the case wherein the sender's utility function is anonymous i.e., it satisfies $V(S) = f(|S|)$ for some monotonically increasing function $f : [n] \to \mathbb{R}$. Our main result for anonymous utilities is as follows.

▶ **Theorem 2.** *There exists a polynomial algorithm for computing the maximum revenue and an optimal signaling policy for a sender that has a monotone, anonymous utility function.*

3.1 Proof of Theorem 2

We show that the concave closure of anonymous function can be computed in polynomial time.

We use $\mathcal{S}_k$ to denote all the size-k subsets of $[n]$, $\mathcal{S}_k := \{S \subseteq [n] \mid |S| = k\}$. We denote by $\mathsf{marg}(\mu)_i := \sum_{S \subset [n]: i \in S} \mu(S)$ the marginal probability of the ith coordinate to be equal 1. Note that the constraints of the concave closure $V^+(a)$ can be written as $\mathsf{marg}(\mu)_i \leq a_i$ for every $i \in [n]$.

The following lemma from [4] characterizes the maximum probability mass that can be assigned to subsets of size k under the constraints imposed by the profile $b = (b_1, ..., b_n)$.

▶ **Lemma 3** ([4]). *Let $1 \geq b_1 \geq b_2 \geq \ldots \geq b_n \geq 0$ be a monotonic sequence. The optimal value of the following maximization problem*

$$\begin{aligned} \max \quad & \sum_{S \in \mathcal{S}_k} \nu(S) \\ s.t. \quad & \sum_{S:\ i \in S} \nu(S) \leq b_i \qquad \forall i \in [n] \\ & \nu_S \geq 0 \end{aligned} \tag{5}$$

where ν is a positive measure (not necessarily a probability measure), is equal to

$$\beta_k(b_1, ..., b_n) = \min_{0 \leq m < k} \frac{1}{k-m}(b_{m+1} + \ldots + b_n).$$

Moreover, a measure ν that maximizes (5) *can be computed in polynomial time.*

The key idea is to use this lemma to solve the LP corresponding to the concave closure – which has exponential (in n) number of variables – by another LP that has a polynomial number of variables. First, we assume, without loss of generality, that the point a (where we want to evaluate the concave closure) satisfies $a_1 \geq a_2 \geq ... \geq a_n$. We split the original problem into n problems of finding a measure μ_k over $\mathcal{S}_k$ for every $k = 1, ..., n$ (the final measure is defined by $\mu = \mu_1 + ... + \mu_n$). The new maximization problem has n^2 variables $(a_i^j)_{i,j \in [n]}$, where $(a_1^j, ..., a_n^j)$ represents the marginal constrain vector on subsets of size k. We denote by α_k the measure that is assigned to subsets of size k, then the original maximization problem can be translated to the following

$$\begin{aligned} \max \ & \alpha_1 f(1) + \alpha_2 f(2) + ... + \alpha_n f(n) \\ \text{s.t.} \ & \sum_{k \in [n]} \alpha_k = 1,\ 0 \leq \alpha_k \leq \beta_k(a_1^k, a_2^k, ..., a_n^k) \text{ for } k \in [n], \text{ and } \sum_{j \in [n]} a_i^j \leq a_i. \end{aligned} \tag{6}$$

where the first constraint corresponds to $\sum_{S \subset [n]} \mu_S = 1$, the second follows from Lemma 3, and the last constraint uses the fact that marginals preserve additivity, and thus correspond to $\sum_{S \subset [n]} \mu_S 1_S \leq a$.

Note that the only nonlinear constraints in (6) are $\alpha_k \leq \beta_k(a_1^k, a_2^k, ..., a_n^k)$. Interesting, these constraints are "almost linear" in the following sense: *If* $a_1^k \geq a_2^k \geq ... \geq a_n^k$ then the constraint $\alpha_k \leq \beta_k(a_1^k, a_2^k, ..., a_n^k)$ can be written as

$$\begin{cases} \alpha_k \leq \frac{1}{k}(a_1 + a_2 + ... + a_n) \\ \alpha_k \leq \frac{1}{k-1}(a_2 + a_3 ... + a_n) \\ \vdots \\ \alpha_k \leq \frac{1}{1}(a_k + a_{k+1} + ... + a_n) \end{cases}$$

So the only obstacle is that the marginal constraint vector, in principle, in not guaranteed to satisfy the monotonicity constraint $a_1^k \geq a_2^k \geq ... \geq a_n^k$ (for all $k \in [n]$). The following Lemma 4 proves that, in fact, there always exists an optimal solution that satisfies this monotonicity

constraint (for all $k \in [n]$). Therefore we can impose this constraint in the optimization problem (6), and then it becomes an LP maximization with $poly(n)$ variables (and $poly(n)$ constraints).

We also note that the proof of Lemma 3 in [4] is constructive, and computationally efficient. Thus, to compute an optimal policy (not only optimal revenue) after we have computed the values of $(a_i^j)_{i,j\in[n]}$ that maximize (6) we can use the constrictive algorithm of the proof of Lemma 3 for all $k \in [n]$. This completes the proof of Theorem 2.

▶ **Lemma 4.** *Assume that the point a satisfies $a_1 \geq a_2 \geq ... \geq a_n$. For $(\mu_S)_{S\subset[n]}$ we denote by $a_i^k = \sum_{S\in\mathcal{S}_k:\ i\in S} \mu(S)$. There exists μ that maximizes* (6) *and satisfies in addition $a_1^k \geq a_2^k \geq ... \geq a_n^k$ for all $k \in [n]$.*

Proof. The proof builds upon ideas that were used in the proof of Lemma 3 in [4].

Let ν be a distribution that satisfies the constraints $\mathsf{marg}(\nu)_i \leq a_i$, and let $\alpha_k = \nu(\mathcal{S}_k)$ be the weight of ν on subsets of size k. It is sufficient to construct another distribution μ that satisfies $\mu(\mathcal{S}_k) = \alpha_k$ (and thus μ has the same revenue as ν), and in addition $a_1^k \geq a_2^k \geq ... \geq a_n^k$.

The construction is done in n steps, where the steps $k = n, n-1, ..., 1$ are done in an decreasing order. At step k we assign a measure of α_k to subsets of size k, and we denote the assigned measure by μ_k. Each step k is done in finite number of stages. Here we describe the assignment of measure at stage $k.m$.

During the construction we "assign mass" and thus, we "spend marginal constraints." We take track of the remaining marginal constraints vector. At the beginning, we set the constraints vector $(a_1^{n.0}, ..., a_n^{n.0}) = (a_1, ..., a_n)$ to be the original constraints.

During the process we preserve the monotonicity of the marginal constraints vector and therefore we can denote the marginal constraints vector at stage $k.m$ by

$$(a_1^{k.m}, ..., a_n^{k.m}) = (b_1, ..., b_j, \underbrace{c, c, ..., c}_{l-j \text{ times}}, b_{l+1}, ..., b_n)$$

where $b_j > c > b_{l+1}$ and $j < k \leq l$. Note that if $a_k^{k.j} = a_{k+1}^{k.j} = ... = a_n^{k.j}$ then $l = n$ and for simplicity of notation we denote $b_{n+1} = 0$. Note that if $a_1^{k.j} = a_2^{k.j} = ... = a_k^{k.j}$ then $j = 0$, and for simplicity of notation we denote $b_0 > b_1$.

At stage $k.m$, the idea is to distribute mass equally over the subsets S of size k that satisfy $[j] \subseteq S \subseteq [l]$ (we have $\binom{l-j}{k-j}$ such sets). If we do so, after we have distributed x units of mass the remaining marginal constraints vector will be

$$b(x) = (b_1 - x, ..., b_j - x, c - \frac{k-j}{l-j}x, ..., c - \frac{k-j}{l-j}x, b_{l+1}, ..., b_n) \tag{7}$$

because every element $i = j+1, j+2, ..., l$ appears in exactly $\frac{k-j}{l-j}$ fraction of the above subsets. Step $k.m$ terminates at the moment when one of the following three happens:

(1) The total mass that has been assigned during step k reaches α_k. In such a case we proceed to step $k-1$.

(2) The jth coordinate becomes equal to the $(j+1)$th coordinate. In such a case we proceed to stage $k.(m+1)$.

(3) The lth coordinate becomes equal to the $(l+1)$th coordinate. In such a case we proceed to stage $k.(m+1)$.

We denote by $\alpha_{k.m}$ the amount of mass that has been assigned during step $k.m$. We denote by $b(\alpha_{k.m})$ the marginal constraints vector after step $k.m$, where $b(\cdot)$ is defined in

equation (7). This marginal constraints serves as the marginal constraint vector for the next step (in case (1) happens) or the next stage (in case (2) or (3) happens).

We argue the following two statements, which will complete the proof.

1. The described process succeeds to complete all the n steps.
2. The described process at each step k assigns mass in a way that $a_1^k \geq a_2^k \geq ... \geq a_n^k$.

Statement (2) follows from the fact that at each stage $k.m$ the marginals of the assigned mass is of the form $(\underbrace{x,...,x}_{j_m \text{ times}}, \underbrace{cx,...,cx}_{l_m - j_m \text{ times}}, 0, ..., 0)$ for $x = \alpha_{k.m}$ and $c < 1$. Moreover, during step k the coordinate j_m is monotonically decreasing, and the coordinate l_m is monotonically increasing. Therefore, the sum of those vectors, which is equal to the vector $(a_1^k, a_2^k, ..., a_n^k)$ is monotonically increasing.

Assume by way of contradiction that statement (1) is false. The above process cannot assign the required measure only if we are at step k and the marginal constraints vector becomes $(d_1, d_2, ..., d_m, 0, ..., 0)$ for $m < k$. In such a case indeed the process cannot proceed, because it will turn the $m+1$ coordinate of the marginal constraint vector negative. We denote by α'_k the measure at step k that has been assigned up to the moment of termination.

We argue that this is impossible from the fact that $\alpha_n, \alpha_{n-1}, ..., \alpha_k$ are feasible weights for some distribution ν. The idea is that the described above process has minimal marginals on the elements $m+1, ..., n$, thus if this process cannot proceed neither could some other distribution ν. Formally, we denote $\nu = \nu_1 + ... + \nu_n$, where ν_j is a measure over $\mathcal{S}_j$. Note that $|\nu_j| = \alpha_j$. We denote $(d_i^j)_{i \in [n]}$ the marginals of ν_j. We argue that $\sum_{i=m+1}^n d_i^j \geq (j-m)\alpha_j$, because every subset of size j contains at least $j-m$ elements from the set $\{m+1, ..., n\}$. Therefore we have

$$a_{m+1} + ... + a_n \geq \sum_{j=k}^{n} \sum_{i=m+1}^{n} d_i^j \geq \sum_{j=k}^{n} (j-m)\alpha_j \tag{8}$$

On the other hand, the constructed measure μ_n with marginals $(a_i^j)_{i \in [n]}$ satisfies $\sum_{i=m+1}^n a_i^j = (j-m)\alpha_j$, because this process assigns positive probability *only* to subsets that contain $\{1, ..., m\}$ (because $m < k \leq j$ and $a_m^j > a_{m+1}^j$). Since the process spent all the marginal constraints $a_{m+1}, ..., a_n$ we have

$$a_{m+1} + ... + a_n = \sum_{j=k}^{n} \sum_{i=m+1}^{n} a_i^j = (k-m)\alpha'_k + \sum_{j=k+1}^{n} (j-m)\alpha_j < \sum_{j=k}^{n} (j-m)\alpha_j \tag{9}$$

Inequalities (8) and (9) yield a contradiction. ◀

4 Submodular Utilities

This section considers private Bayesian persuasion settings in which the sender's utility function is submodular. In particular, we develop a tight $(1 - 1/e)$ approximation of the optimal signaling policy when the sender's utility is a monotone submodular function.

It is relevant to note that our algorithmic results require only query access to the submodular function, i.e., our results hold as long as we can access to $V(S)$, for any subset $S \subseteq [n]$. This, in particular, implies that we can address submodular functions that admit a *succinct* representation.

We begin by noting that finding the concave closure of a submodular function is NP-hard: Given a succinct, monotone, submodular function $f : 2^{[n]} \to \mathbb{R}$ and a vector $a \in [0,1]^n$, it is NP-hard to compute the concave closure $f^+(a)$; see, e.g. [30] and [13].

It is relevant to note that while the concave closure of submodular functions are known to be computationally hard, approximation algorithms and inapproximability results for them have not been directly addressed in prior work.

4.1 Approximation Algorithm for Submodular Utilities

This section provides a $(1-1/e)$-approximation algorithm for computing the concave closure of a monotone, submodular function V. We obtain the $\left(1-\frac{1}{e}\right)$ approximation by reducing the computation of the concave closure to the problem of maximizing a submodular function subject to a matroid constraint. The key implication of this approximation result is the following theorem.

▶ **Theorem 5.** *If in a private Bayesian persuasion problem the utility of the sender, V, is a monotone, submodular function. Then, in polynomial time, we can compute a signaling policy that achieves a revenue of at least $(1-1/e-\varepsilon)$ times the optimal; here, ε is an arbitrarily small constant.*

4.1.1 Proof of Theorem 5

We show that the concave closure of submodular function V at any given vector $a=(a_1,a_2,\ldots,a_n)\in[0,1]^n$ can be approximated to within a factor of $\left(1-\frac{1}{e}-\varepsilon\right)$, for an arbitrarily small $\varepsilon>0$, then Theorem 5 follows from Lemma 1.

We split the marginal values a_i into two sets: $\{a_i : a_i \geq \frac{1}{n^2}\}$ are the *high values* and $\{a_i : a_i < \frac{1}{n^2}\}$ are the *low values*. Without loss of generality we assume that $a_1,...,a_m$ are the high values and $a_{m+1},...,a_n$ are the low values, for $m\leq n$.

Every distribution μ over subsets of $[n]$ induces a distribution $\nu=\nu(\mu)$ over subsets of $[m]$ in the following natural way: the probability mass μ_S on $S\subset[n]$ is moved to the set $S\cap[m]$, formally for each subset $T\subseteq[m]$ define $\nu_T:=\sum_{S\subset[n]:S\cap[m]=T}\mu_S$. The following lemma holds for distribution ν.

▶ **Lemma 6.** *For every distribution μ that satisfies the marginal constraints (i.e., $\sum_{S\subseteq[n]:S\ni i}\mu_S\leq a_i$) we have*

$$\sum_{S\subset[n]}\mu_S V(S)\leq\sum_{T\subset[m]}\nu_T V(T)+\sum_{i=m+1}^{n}a_i V(\{i\}).$$

Here $a_1,\ldots,a_m\geq\frac{1}{n^2}$ and $a_m,a_{m+1},\ldots,a_n\leq\frac{1}{n^2}$.

Proof.

$$\begin{aligned}\sum_{S\subset[n]}\mu_S V(S)&\leq\sum_{S\subset[n]}\mu_S\left[V(S\cap[m])+\sum_{i\in S,i>m}V(\{i\})\right]\\&=\sum_{T\subset[m]}\nu_T V(T)+\sum_{S}\sum_{i\in S,i>m}\mu_S V(\{i\})\\&=\sum_{T\subset[m]}\nu_T V(T)+\sum_{i>m}\sum_{S:i\in S}\mu_S V(\{i\})\\&\leq\sum_{T\subset[m]}\nu_T V(T)+\sum_{i>m}a_i V(\{i\}).\end{aligned}$$

Here, the first inequality follows from subadditivity of V. The second equation follows from the definition of $\nu = \nu(\mu)$. The third equation is obtained by changing the order of summation and the last inequality follows from the fact that μ satisfies the marginal constraints. ◀

We can consider the optimization problem corresponding to the concave closure restricted to the set $[m]$:

$$\begin{aligned} V_m^+(a) := \max & \sum_{T\subset[m]} \nu_T V(T) \\ \text{s.t.} & \sum_{T\subseteq[m]:T\ni i} \nu_T \le a_i \qquad \forall i \in [m] \\ & \nu \text{ is a probability measure.} \end{aligned} \tag{10}$$

Given a distribution $\overline{\nu}$ that α-approximates problem (10), we define distribution $\overline{\mu}$ over $[n]$ as follows: For each subset $T \subseteq [m]$, set $\overline{\mu}_T := (1-\frac{1}{n})\overline{\nu}$. In addition, for every $i > m$ set $\overline{\mu}_{\{i\}} := a_i$. Finally, to ensure that $\overline{\mu}$ is a probability measure we assign a probability mass of $c = \frac{1}{n} - a_{m+1} - ... - a_n > 0$ to the empty set, i.e., $\mu_\phi := c$.

▶ **Lemma 7.** *If distribution $\overline{\nu}$ α-approximates problem* (10)*, then $\overline{\mu}$ provides a $(1-\frac{1}{n})\alpha$-approximation of the original concave closure problem* (4)*.*

Proof. Recall that $V^+(a)$ denotes the concave closure of function V evaluated at a and, similarly, $V_m^+(a)$ is optimal value of (10).

$$\begin{aligned} \sum_{S\subset[n]} \overline{\mu}_S V(S) &= (1-\frac{1}{n}) \sum_{T\subset[m]} \overline{\nu}_T V(T) + \sum_{i>m} a_i V(\{i\}) \\ &\ge (1-\frac{1}{n})\alpha V_m^+(a) + \sum_{i>m} a_i V(\{i\}) \\ &\ge (1-\frac{1}{n})\alpha [V_m^+(a) + \sum_{i>m} a_i V(\{i\})] \\ &\ge (1-\frac{1}{n})\alpha V^+(a). \end{aligned}$$

Here the first equation is implied by the definition of $\overline{\mu}$. The second inequality follows from the fact that $\overline{\nu}$ α-approximates the concave closure (on the set $[m]$). The third inequality is trivial and the last one follows from Lemma 6. ◀

Lemma 7 reduces the original concave closure problem to the problem of computing the concave closure over $[m]$ where (unlike the original problem) we know that $a_i \ge \frac{1}{n^2}$ for each $i \in [m]$. In the remainder of the proof, we consider the later problem. The idea is to translate this problem into a discrete one. A natural way do to so is by rounding the underlying terms to integer multiples of a parameter $\delta := \frac{1}{n^4(n+1)}$ and then working with the multiples, instead of the fractional terms.

Since (10) is a linear program (over variables $\{\nu_T\}_{T\subseteq[m]}$) with at most $n+1$ non-trivial constraints, without loss of generality we can restrict attention to solutions that have support size of at most $n+1$.

As mentioned previously, we set a grid of size $\delta := \frac{1}{n^4(n+1)}$, and we consider the maximization problem of V_m^+ where we restrict the probabilities $\{\nu_S\}$ to be integer multiples of δ.

$$\begin{aligned} \max \quad & \sum_{T\subset[m]} \nu_T V(T) \\ \text{s.t.} \quad & \sum_{T\subseteq[m]:T\ni i} \nu_T \le a_i \qquad \forall i\in[m] \\ & \nu \text{ is a probability measure.} \\ & \nu_T \in \{0,\delta,2\delta,\dots,1\}. \end{aligned} \tag{11}$$

▶ **Lemma 8.** *If distribution $\widehat{\nu}$ be an α-approximate solution of optimization problem* (11) *with support size at most $n+1$. Then, $\widehat{\nu}$ is a $(1-\frac{1}{n\alpha})\alpha$-approximate solution of the concave closure $V_m^+(a)$ as well.*

Proof. We prove that if we restrict our attention to probabilities in the set $\{0,\delta,2\delta,\dots,1\}$, then we incur at most a multiplicative loss of $(1-\frac{1}{n\alpha})$. Given a distribution ν with support size at most $n+1$ we round down the probabilities to integer multiples of δ (and put all the remaining probability mass on the empty set), we denote the resulting distribution by ν'. Formally $\nu'_T=\ell\delta$ where $k=\max\{j\in\mathbb{Z}: j\delta\le\nu_T\}$. Note that

$$\begin{aligned} &\sum_T \nu_T V(T) - \sum_T \nu'_T V(T) = \sum_T (\nu_T-\nu'_T)V(T) \le \sum_T \delta V(T) \\ &\le \sum_{T\in\mathsf{supp}(\nu)} \frac{1}{n^4(n+1)} V([m]) \le \frac{1}{n^4} V([m]) \\ &\le \frac{1}{n^4}\sum_{i\in[m]} V(\{i\}) \le \frac{1}{n^2}\sum_{i\in[m]} a_i V(\{i\}), \end{aligned} \tag{12}$$

where the first equality is trivial. The first and the second inequality is a consequence of the rounding and the value of δ. The third inequality follows from the fact that the support size is at most $n+1$. The subadditivity of V gives us the fourth inequality and the last inequality follows from the fact that $a_i\ge\frac{1}{n^2}$.

Note also that $V_m^+(a)\ge\frac{1}{n}\sum_{i\in[m]} a_i V(\{i\})$ because one feasible option is to put a mass of $\frac{a_i}{n}$ on the singleton $\{i\}$, and the remaining probability mass to put on the empty set. This is indeed feasible because $\sum_i \frac{a_i}{n}\le\sum_i\frac{1}{n}\le 1$.

Finally let $\overline{\nu}$ be an α approximation for $V_m^+(a)$, and let $\overline{\nu}'$ be the corresponding rounding. Then

$$\begin{aligned} \frac{\sum_T \overline{\nu}'_T V(T)}{\sum_T \overline{\nu}_T V(T)} &= 1 - \frac{\sum_T \overline{\nu}_T V(T) - \sum_T \overline{\nu}'_T V(T)}{\sum_T \overline{\nu}_T V(T)} \\ &\ge 1 - \frac{\frac{1}{n^2}\sum_{i\in[m]} a_i V(\{i\})}{\sum_T \overline{\nu}_T V(T)} \\ &\ge 1 - \frac{\frac{1}{n^2}\sum_{i\in[m]} a_i V(\{i\})}{\alpha\frac{1}{n}\sum_{i\in[m]} a_i V(\{i\})} = 1-\frac{1}{n\alpha} \end{aligned}$$

where the first inequality follows from (12), and the second one from the fact that $V_m^+(a)\ge\frac{1}{n}\sum_{i\in[m]} a_i V(\{i\})$. ◀

By Lemma 8 we can restrict attention to the discrete problem (11). Note that the the discrete problem (11) is equivalent to

$$\begin{aligned} \max_{S^1,\dots,S^k\subseteq[m]} \quad & \frac{1}{k}\sum_{j=1}^{k} V(S^j) \\ \text{subject to} \quad & |\{j\in[k]\mid i\in S^j\}| \le k_i \qquad \forall i\in[n] \end{aligned} \tag{13}$$

where $k = n^4(n+1)$ and $k_i = a_i n^4(n+1)$ for all $i \in [n]$.

We complete the proof of the theorem by showing that (13) admits a $(1-1/e)$ approximation. We do so by showing that (13) corresponds to the problem of maximizing a monotone submodular function subject to a matroid constraint.

Consider base set $U = [m] \times [k]$. We get that the size of U is polynomially bounded. For a subset $R = \{(i_1, j_1), (i_2, j_2), \ldots, (i_l, j_l)\}$ of U and $j \in [k]$, write R^j to denote the projected subset $\{i' \in [m] \mid (i', j) \in R\}$.

With this notation in hand, define function F for each subset $R = \{(i_1, j_1), (i_2, j_2), \ldots, (i_l, j_l)\} \subset U$ as follows

$$F(R) := \frac{1}{k} \sum_{j=1}^{k} V(R^j). \tag{14}$$

We claim that F is submodular: consider subsets $X \subset Y \subset U$ and element $(i,j) \in U$. Note that $F(X + (i,j)) - F(X) = \frac{1}{k} V(X^j + i) - \frac{1}{k} V(X^j)$ and $F(Y + (i,j)) - F(Y) = \frac{1}{k} V(Y^j + i) - \frac{1}{k} V(Y^j)$. Since $X^j \subset Y^j$, the submodulartiy (monotonicity) of V implies the submodularity (monotonicity) of F.

Next we consider a partition matroid $\mathcal{M}$ over U. Specifically, we say that a subset $R \subset U$ is independent (with respect to the matroid $\mathcal{M}$) iff $|\{(i', j') \in R \mid i' = i\}| \leq k_i$ for all $i \in [n]$. Note that this is a partition matroid where the disjoint partitions are $B_i := \{(i,1), (i,2), \ldots, (i,k)\}$ and the cardinality bounds are k_is. In other words, we obtain $\mathcal{M}$ by defining R to be an independent subset iff $|R \cap B_i| \leq k_i$ for all i.

Note that if a subset $R \subset U$ is independent then $R^1, R^2, \ldots R^k$ satisfy the constraints of the optimization problem (13), i.e., for an independent R we have $|\{j \in [k] \mid i \in S^j\}| \leq k_i$ for all i.

Overall, we get that optimization problem (13) is equivalent to the following problem:

$$\begin{aligned} \max_{R \subset U} \quad & F(R) \\ \text{subject to} \quad & R \in \mathcal{M} \end{aligned}$$

Since this is a submodular maximization problem subject to a matroid constraint, it admits a $(1 - \frac{1}{e})$ approximation; see [10]. This in turn implies that the original problem admits a $(1 - \frac{1}{n})(1 - \frac{1}{0.62n})(1 - \frac{1}{e}) = (1 - \frac{1}{e} - O(\frac{1}{n}))$ approximation. We can set parameters such that instead of a multiplicative factor of $(1 - \frac{1}{n})(1 - \frac{1}{0.62n})$ in the approximation we get a term that is arbitrarily close one. Hence, we get the desired result.

4.2 Hardness of Approximating the Concave Closure

This section shows that the $\left(1 - \frac{1}{e}\right)$ approximation guarantee obtained in Section 4.1.1 is tight. In particular, applying the machinery developed by [24] leads us to the following theorem. We note that [24] establish the hardness of approximating maximum social welfare in combinatorial auctions and similar tools were developed in [17] for studying the inapproximability of the domatic number.

▶ **Theorem 9.** *Given a monotone, submodular fucntion $V : 2^{[n]} \to \mathbb{R}_+$ and vector $a \in [0,1]^n$, for any $\varepsilon > 0$, it is* NP*-hard to approximate the concave closure, $V^+(a)$, by a factor better than $\left(1 - \frac{1}{e} - \varepsilon\right)$.*

Proof Sketch. [24] study the combinatorial auction problem where n goods have to be partitioned among m agents whose utilities are submodular functions of the goods assigned

to them. In this problem, the objective is to maximize social welfare, i.e., the sum of the utilities of the receivers. It is shown in [24] that for this problem and any $\varepsilon > 0$ there does not exist a polynomial time algorithm that obtains an approximation ratio better than $\left(1 - \frac{1}{e} - \varepsilon\right)$, unless P = NP.

Specifically, [24] start with a *label-cover* problem where it is NP-hard to distinguish whether the optimal value, $OPT(L)$, is one or less than a particular constant, $c < 1$. From the given label cover problem they construct a combinatorial auction instance, I, wherein the maximum social welfare, $OPT(I)$ is greater than a threshold, τ if the label cover problem admits a solution of value one. Furthermore, if the optimal value of the label cover problem is less than c – i.e., $OPT(L) \leq c$ – then it must be the case that $OPT(I) \leq \left(1 - \frac{1}{e} - \varepsilon\right)\tau$. This, overall, establishes a $\left(1 - \frac{1}{e} - \varepsilon\right)$ hardness-of-approximation bound for the combinatorial auction problem.

Interestingly, in the constructed instance I all of the m receivers have the same monotone, submodular utility function, say, $f : 2^{[n]} \to \mathbb{R}_+$. We claim that approximating the concave closure of constructed function f at marginal vector $a := (\frac{1}{m}, \frac{1}{m}, \ldots, \frac{1}{m})$ by a factor better than $\left(1 - \frac{1}{e} - \varepsilon\right)$ is NP-hard. In particular, if $OPT(L) = 1$ then $f^+(a) \geq \tau'$ and, moreover, if $OPT(L) \leq c$ then $f^+(a) \leq \left(1 - \frac{1}{e} - \varepsilon\right)\tau'$; here τ' is a fixed parameter.

The proof of this claim can be obtained by considering the subsets in the support of an optimal solution, μ^*, of problem (4) defined for function f. Note that the proof given in [24] proceeds by considering the subsets that constitute the partition of goods among receivers in I, instead we can focus on subsets in the support of μ^* to obtain the result for the concave closure. In particular, the arguments presented in [24] go through if, instead of cardinalities, we consider measure of sets and expected values of quantities with respected to μ^*.[5] This, overall, establishes the desired inapproximability result for the concave closure. ◀

[5] For example, in Lemma 5 in [24], we can redefine sets N_1^e (N_2^e) to be the collection of subsets – instead of collection of players – in the support of μ^* that cover (do not cover) an edge e in the label cover instance. Along these lines, instead of bounding the cardinalities of N_1^e and N_2^e (which are denoted by n_1^e and n_2^e in [24]), we can bound the measures $\sum_{S \in N_1^e} \mu_S^*$ and $\sum_{S \in N_2^e} \mu_S^*$. Among other things, these changes allow us to use Jensen's inequality and bound Δ_e as specified in Lemma 5 by [24].

Abstract

We consider the manipulability of tournament rules for round-robin tournaments of n competitors. Specifically, n competitors are competing for a prize, and a tournament rule r maps the result of all $\binom{n}{2}$ pairwise matches (called a *tournament*, T) to a distribution over winners. Rule r is *Condorcet-consistent* if whenever i wins all $n-1$ of her matches, r selects i with probability 1.

We consider strategic manipulation of tournaments where player j might throw their match to player i in order to increase the likelihood that one of them wins the tournament. Regardless of the reason why j chooses to do this, the potential for manipulation exists as long as $\Pr[r(T) = i]$ increases by more than $\Pr[r(T) = j]$ decreases. Unfortunately, it is known that every Condorcet-consistent rule is manipulable [1]. In this work, we address the question of *how manipulable* Condorcet-consistent rules must necessarily be - by trying to minimize the difference between the increase in $\Pr[r(T) = i]$ and decrease in $\Pr[r(T) = j]$ for any potential manipulating pair.

We show that every Condorcet-consistent rule is in fact 1/3-manipulable, and that selecting a winner according to a random single elimination bracket is not α-manipulable for any $\alpha > 1/3$. We also show that many previously studied tournament formats are all 1/2-manipulable, and the popular class of Copeland rules (any rule that selects a player with the most wins) are all in fact 1-manipulable, the worst possible. Finally, we consider extensions to match-fixing among sets of more than two players.

1 Introduction

In recent years, numerous scandals have unfolded surrounding match fixing and throwing at the highest levels of competitive sports (e.g. Olympic Badminton [11], Professional Tennis [6], European Football [22], and even eSports [24]). In some instances, the motivation behind these scandals was gambling profits, and no amount of clever tournament design can possibly mitigate this. In others, however, the surprising motivation was an improved performance *at that same tournament.* For instance, four Badminton teams (eight players) were disqualified from the London 2012 Olympics for throwing matches. Interestingly, the reason teams wanted to lose their matches was in order to *improve* their probability of winning an Olympic medal. Olympic Badminton (like many other sports) conducts a two-phase tournament. In the first stage, groups of four play a round-robin tournament, with the top two teams advancing. In

licensed under Creative Commons License CC-BY

the second stage, the advancing teams participate in a single elimination tournament, seeded according to their performance in the group stage. An upset in one group left one of the world's top teams with a low seed, so many teams actually preferred to receive a *lower* seed coming out of the group stage to face the tougher opponent as late as possible.

While much of the world blames the teams for their poor sportsmanship, researchers in voting theory have instead critiqued the poor tournament design that punished teams for trying to maximize their chances of winning a medal. Specifically, the two-phase tournament lacks the basic property of *monotonicity*, where no competitor can unilaterally improve their chances of winning by throwing a match that they otherwise could have won. Thus, recent work has addressed the question of whether tournament structures exist that are both fair, in that they select some notion of a qualified winner, and strategyproof, in that teams have no incentive to do anything but play their best in each match.

One minimal notion of fairness studied is *Condorcet-consistence*, which just guarantees that whenever one competitor wins *all* of their matches (and is what's called a *Condorcet winner*), they win the event with probability 1. Designing Condorcet-consistent, monotone rules is simple: any single elimination bracket suffices. Popular voting rules such as the Copeland Rule or the Random Condorcet Removal Rule are also Condorcet-consistent and monotone, but two-phase tournaments with an initial group play aren't [17].

Still, monotonicity only guarantees that no team wishes to unilaterally throw a match to improve their chances of winning, whereas one might also hope to guarantee that no two teams could fix the outcome of their match in order to improve the probability that one of them wins. While we have to go back further in history to find a clear instance of this kind of match-fixing, it did indeed result in a historical scandal. In the 1982 FIFA World Cup (again a two-stage tournament), Austria, West Germany, and Algeria were in the same group of four where two would advance. Algeria had already won two matches and lost one, Austria was 2-0, West Germany was 1-1, and the only remaining game was Austria vs. West Germany. Due to tie-breakers and the specific outcomes of previous matches, Austria would have been eliminated by a large West German victory, and West Germany would have been eliminated by a loss or draw. Once West Germany scored an early goal, *both* teams essentially threw the rest of the match, allowing both of them to advance at Algeria's expense [25]. While the incident was never formally investigated, many fans were confident the teams had colluded beforehand, and the event is remembered as the "disgrace of Gijón." Before being eliminated, Algeria had become the first African team to beat a European team at the World Cup, and also the first to win two games. West Germany went on to become the runners-up of the tournament.

Motivated by events like this, it is important also to design tournaments where no two teams can fix the outcome of their match and improve the probability that one of them wins. Altman and Kleinberg terms this property 2-Strongly Nonmanipulable (2-SNM), and showed that no tournament rule is both Condorcet-consistent and 2-SNM [1] (it was previously shown by Altman et. al. that no *deterministic* rule is both Condorcet-consistent and 2-SNM [2]).

In light of this, both works relax the notion of Condorcet-consistency and design tournament rules that are at least *non-imposing* (could possibly select each competitor as a winner) and 2-SNM [2], or α-Condorcet-consistent (if there is a Condorcet winner, she wins with probability at least α) and 2-SNM. While these relaxations are well-motivated for settings where pair-wise comparisons are only *implicitly* made, and not even necessarily learned in the end (e.g. elections), it is hard to imagine a successful sports competition format where a competitor could win all their matches and still leave empty handed. This happened during the 2008 NCAA Football Season. Utah went undefeated (#2, 13-0) in their region but

were not invited to the bowl game because critics deemed their schedule weak. They were eventually ranked second nation-wide and beat Alabama (#6, 12-2) in the Sugar Bowl, while Florida (#1, 13-1) beat Oklahoma (#5, 12-2) for the National Championship. This event prompted organizers to reconsider the process by which teams are invited to the National Championship game.

Motivated by match-based applications such as sporting events, where the outcome of pair-wise matches is *explicitly* learned and used to select a winner, we consider instead the design of tournament rules that are exactly Condorcet-consistent, but only approximately 2-SNM. Specifically, we say that a tournament rule is 2-SNM-α if it is *never* possible for two teams i and j to fix their match such that the probability that the winner is in $\{i, j\}$ improves by at least α. The idea behind this relaxation is that whatever motivates j to throw the match (perhaps j and i are teammates, perhaps i is paying j some monetary bribe, etc.), the potential gains scale with α. So it is easier to disincentivize manipulation (either through investigations and punishments, reputation, or just feeling morally lousy) in tournaments that are less manipulable.

1.1 Our Results

Our main result is a matching upper and lower bound of 1/3 on attainable values of α for Condorcet-consistent 2-SNM-α tournament rules. The optimal rule that attains this upper bound is actually quite simple: a random single elimination bracket. Specifically, each competitor is randomly placed into one of $2^{\lceil \log_2 n \rceil}$ seeds, along with $2^{\lceil \log_2 n \rceil} - n$ byes, and then a single elimination tournament is played.

Proving a lower bound of 1/3 is straight-forward: imagine a tournament with three players, A, B and C, where A beats B, B beats C, and C beats A. Then some pair must win with combined probability at most 2/3. Yet, any pair could create a Condorcet winner by colluding, who necessarily wins with probability 1 in any Condorcet-consistent rule. Embedding this within examples for arbitrary n is also easy: just have A, B, and C each beat all of the remaining $n - 3$ competitors[1].

On the other hand, proving that a random single elimination bracket is optimal is tricky, but our proof is still rather clean. For any i, j in any tournament, we directly show that i can improve her probability of winning by at most 1/3 when j throws their match using a coupling argument. For every deterministic single elimination bracket where i and j could potentially gain from manipulation (because i would be the champion if i beat j, but j would *not* be the champion even if j beat i), we construct *two* deterministic single elimination brackets where no potential exists (possibly because one of them will lose before facing each other, or because the winner would be in $\{i, j\}$ no matter the outcome of their match). For our coupling to be valid, we not only need each mapping to be invertible, but also for their images to be disjoint. Our coupling is necessarily somewhat involved in order to obtain this property, but otherwise we believe our proof is likely as simple as possible. Because the probability that j wins cannot possibly go up by throwing a match to i, this immediately proves that a random single elimination bracket is 2-SNM-1/3.

We also show that the Copeland rule, a popular rule that chooses the team with the most wins, is asymptotically 2-SNM-1, the *worst* possible. Essentially, the problem is that if all teams have the same number of wins, then any two can collude to guarantee that one of

[1] Interestingly, this lower-bound example is far from pathological and occurs at even the highest levels of professional sports (see [18], for instance).

them wins, no matter the tie-breaking rule. We further show that numerous other formats, (the Random Voting Caterpillar, the Iterative Condorcet Rule, and the Top Cycle Rule) are all at best 2-SNM-1/2. The same example is bad for all three formats: there is one superman who beats $n-2$ of the remaining players, and one kryptonite, who beats only the superman (but loses to the other $n-2$ players).

Our results extend to settings where the winner of each pairwise match is not deterministically known, but randomized (i.e. all partipants know that i will beat j with probability p_{ij}). Specifically, we show that any rule that is 2-SNM-α when all $p_{ij} \in \{0,1\}$ is also 2-SNM-α for arbitrary p_{ij}. Clearly, any lower bound using integral p_{ij} also provides a lower bound for arbitrary p_{ij}, so as far as upper/lower bounds are concerned the models are equivalent. Of course, the randomized model is much more realistic, so it is convenient that we can prove theorems in this setting by only studying the deterministic setting, which is mathematically much simpler.

Finally, we consider manipulations among coalitions of $k > 2$ participants. We say that a rule is k-SNM-α if no set S of size $\leq k$ can *ever* manipulate the outcomes of matches between players in S to improve the probability that the winner is in S by more than α. We prove a simple lower bound of $\alpha = \frac{k-1}{2k-1}$ on all Condorcet-consistent rules, and conjecture that this is tight.

1.2 Related Works

The mathematical study of tournament design has a rich literature, ranging from social choice theory to psychology. The overarching goal in these works is to design tournament rules that satisfy various properties a designer might find desirable. Examples of such properties might be that all players are treated equally, that a winner is chosen without a tiebreaking procedure, or that a "most qualified" winner is selected [8, 20, 7, 19, 28, 15, 23]. See [14] for a good review of this literature and its connections to other fields as well.

Most related to our work are properties involving *strategic manipulation*. In the more general field of Voting Theory, there is a rich literature on the design of strategyproof mechanisms dating back to Arrow's Impossibility Theorem [3] and the Gibbard-Satterthwaite Theorem [9, 21, 10]. While tournaments are a very special case (voters are indifferent among outcomes where they do not win, voters can only "lie" in specific ways, etc.), tournament design indeed seems to inherit much of the impossibility associated with strategyproof voting procedures [1], [2].

Specifically, Altman et. al. proved that no deterministic tournament rule is 2-SNM and Condorcet-consistent, and Altman and Kleinberg proved that no randomized tournament rule is 2-SNM and Condorcet-consistent either [2, 1]. More recently, Pauly studied the specific two-stage tournament rule used by the World Cup (and Olympic Badminton, etc.) [17]. There, it is shown essentially that the problem lies in the first round group stage: no changes to the second phase can possibly result in a strategyproof [2] tournament.

To cope with their impossibility results, Altman et. al. propose a relaxation of Condorcet-consistence called *non-imposing*. A rule r is non-imposing if for all i, there exists a T such that player i wins with probability 1. They design a clever recursive rule that is non-imposing and 2-SNM for all $n \neq 3$. Interestingly, they also show that for $n = 3$ no such rule exists. Altman and Kleinberg consider a different relaxation called α-*Condorcet-consistent*. A rule r is α-Condorcet-consistent if whenever i is a Condorcet winner in T, we have their probability of winning T is at least α. They design a rule that is $2/n$-Condorcet-consistent and 2-SNM (in fact it is also k-SNM for all k), but conjecture that much better is attainable.

[2] See [17] for the specific notion of strategyproofness studied.

The two works above are most similar to ours in spirit: motivated by the non-existence of Condorcet-consistent and 2-SNM tournament rules, we relax one of the notions. These previous works relax Condorcet-consistency while maintaining 2-SNM exactly, and are most appropriate in settings where pairwise comparisons of players are only learned *implicitly* (or perhaps not at all) through the outcome and not *explicitly* as the result of matches. Instead, we relax the notion of 2-SNM and maintain the notion of Condorcet-consistency exactly. In settings like sports competitions where pairwise comparisons of players are learned explicitly through matches played, Condorcet-consistency is a non-negotiable desideratum. Therefore, we believe our approach is more natural in such settings.

Another line of work introduced by [4] considers a different kind of strategyproofness: how much control does the designer of a single-elimination tournament have over the winner? Can the designer efficiently find a bracket in such a way to maximize the likelihood that a player of their choice wins the tournament? The models in this area assume that the designer is given the probabilities p_{ij} that team i beats team j and the problem is known in the literature as *agenda control* when p_{ij} are real numbers and Tournament Fixing Problem (TFP) when all probabilities are 0 or 1.

On the negative side, it is known that for n-player tournaments it is NP-hard to decide whether or not there exists a seeding such that the probability of team k winning is at least δ, given k, δ, even if $\mathsf{p}_{ij} \in \{0, 0.5, 1\}$ for all i, j [27]. [26] show that the hardness results persist even for the TFP when the given team k is a king (for every team j, either k beats j or k beats a team that beats j) with at least $n/4$ wins, or a 3−king (is at most 3 "wins" away from every team) that wins at least half of their games. Follow up work [13] shows that in the case of balanced single elimination brackets, it is still NP-hard to find a bracket that favors team k when the designer is allowed to bribe at most $(1 - \varepsilon) \log n$ of the teams to throw their respective matches.

On the positive side, there exist structural results that dictate when it is computationally efficient to find a tournament that favors a given team. [26] show conditions under which, for large enough tournaments, any sufficiently good team can be favored by the tournament seeding. Other results [13, 12] show conditions under which 3−kings can be made into winners of single-elimination tournaments.

A large body of literature exists regarding manipulation and bribery in the context of voting rules. For an introduction, we recommend the reader consult chapter 7 of the handbook [16].

1.3 Conclusions and Future Work

Our work contributes to a recent literature on incentive compatible tournament design. While most previous works insist on strong incentive properties and relaxed fairness properties, such rules are inadequate for sporting events. Instead, we insist at least that events maintain Condorcet-consistency, and aim to relax strategyproofness as minimally as possible.

At a high level, our work suggests (similar to previous works), that single elimination brackets are desirable whenever incentive issues come into play. However, previous desiderata (such as those considered in [1]) don't necessarily rule out other tournament formats, like the Copeland rule, which is ubiquitous in tournaments (both as a complete format and as subtournaments in a two-phase format). In comparison, our work identifies single elimination brackets (2-SNM-1/3) as having significantly better strategic properties versus the Copeland rule (2-SNM-1).

Our work also identifies two practical suggestions when match-fixing is a concern that aren't explained by prior benchmarks. First, when hosting a single elimination tournament,

it might be desirable to release the exact bracket as late as possible. The idea is that as soon as the exact bracket is known, competitors have greater incentive to fix matches (in our model, up to three times as much), which presumably takes some time and organization. Obviously, there are more tradeoffs at play: a later release inconveniences athletes and fans, and (perhaps more importantly to the designers) could negatively impact ticket sales. But our work does at least identify match-fixing as a part of this tradeoff. Note that some Olympic events (such as Taekwondo) contest the entire competition in a single day at a single venue, so a delayed release may indeed be practical. We also note that a similar "fix" was applied after the 1982 World Cup: the last two matches in each group are now played at the same time to minimize the amount of information teams have when making potentially strategic decisions.

Additionally, our work suggests that even in the optimal tournament, hefty punishments for cheaters might be necessary in order to discourage match-fixing (even without taking gambling into consideration). In many sports, winning an Olympic gold can make a career. Unfortunately, our work suggests that punishments roughly on this order might be necessary in order to properly deter match-fixing.

Finally, we propose two directions for future work. First, while we obtain tight results for Condorcet-consistent 2-SNM-α rules, we only prove a lower bound of k-SNM-$\frac{k-1}{2k-1}$ for Condorcet-consistent rules and $k > 2$. We conjecture that this is tight, but unfortunately simulations indicate that all of the formats studied in our work do *not* achieve this bound. So it is an interesting open question to design a rule that does. Even partial results (of the form identified below) would require a new tournament format than those considered in this work.

▶ **Open Question 1.** *Does there exist a tournament rule that is Condorcet-consistent and k-SNM-$\frac{k-1}{2k-1}$ for all k? What about a family of rules $\mathcal{F}$ such that for all k, F_k is k-SNM-$\frac{k-1}{2k-1}$? What about a rule that is k-SNM-$1/2$ for all k?*[3]

It is also important to study what bounds are attainable in restricted versions of our probabilistic model (e.g. if for all i, j, the probability that i beats j lies in $[\epsilon, 1-\epsilon]$). Realistic instances at least have *some* non-zero probability of an upset in every match, but our lower bounds don't hold in this model. So it is interesting to see if better formats are possible.

▶ **Open Question 2.** *Is a random single elimination bracket still optimal among Condorcet-consistent rules (w.r.t. 2-SNM-α) if for all i, j, the probability that i beats j lies in $[\epsilon, 1-\epsilon]$? How does the optimal attainable α for Condorcet-consistent, 2-SNM-α tournament formats change as a function of ϵ?*

2 Preliminaries and Notation

In this section, we present notation used throughout the remainder of the paper. Where possible, we adopt notation from [1].

▶ **Definition 1.** A (round-robin) *tournament* T on n players is the set of outcomes of the $\binom{n}{2}$ games played between all pairs of distinct players. We write $T_{ij} = 1$ if player i beats player j and $T_{ij} = -1$ otherwise. We also let $\mathcal{T}_n$ denote the set of tournaments on n players.

▶ **Definition 2.** For a subset $S \subseteq [n]$ of players, two tournaments T and T' are *S-adjacent* if they only differ on the outcomes of some subset of games played between members of S.

[3] Note that $\frac{k-1}{2k-1} \to 1/2$ as $k \to \infty$.

In particular, two tournaments T and T' are $\{i, j\}$ adjacent if they only differ in the result of the game played between player i and player j.

▶ **Definition 3.** A *tournament rule* (or *winner determination rule*) $r : \mathcal{T}_n \to \Delta([n])$ is a mapping from the set of tournaments on n players to probability distributions over these n players (representing the probability we choose a given player to be the winner). We will write $r_i(T) = \Pr[r(T) = i]$ to denote the probability that player i wins tournament T under rule r.

Many tournament rules, while valid by the above definition, would be ill-suited for running an actual tournament; for example, the tournament rule which always crowns player 1 the winner. In an attempt to restrict ourselves to 'reasonable' tournament rules, we consider tournaments that obey the following two criteria.

▶ **Definition 4.** Player i is a *Condorcet winner* in tournament T if player i wins their match against all the other $n - 1$ players. A tournament rule r is *Condorcet-consistent* if $r_i(T) = 1$ whenever i is a Condorcet winner in T.

▶ **Definition 5.** A tournament rule r is *monotone* if, for all i, $r_i(T)$ does not increase when i loses a game it wins in T. That is, if i beats j in T and T and T' are $\{i, j\}$ adjacent, then if r is monotone, $r_i(T) \geq r_i(T')$.

Intuitively, this first criterion requires us to award the prize to the winner in the case of a clear winner (hence making the tournament a contest of skill), and the second criterion makes it so that players have an incentive to win their games. There are various other criteria one might wish a tournament rule to satisfy; many can be found in [1].

In this paper, we consider the scenario where certain coalitions of players attempt to increase the overall chance of one of them winning by manipulating the outcomes of matches within players of the coalition. The simplest case of this is in the case of coalitions of size 2, where player j might throw their match to player i. If T is the original tournament and T' is the manipulated tournament where j loses to i, then player i gains $r_i(T') - r_i(T)$ from the manipulation, and player j loses $r_j(T) - r_j(T')$ (in terms of probability of winning). Therefore, as long as $r_i(T') - r_i(T) > r_j(T) - r_j(T')$, it will be in the players' interest to manipulate. Equivalently, if $r_i(T') + r_j(T') > r_i(T) + r_j(T)$ (i.e., the probability either player i or j wins increases upon throwing the match), there is incentive for i and j to manipulate.

Ideally, we would like to choose a tournament rule so that, regardless of the tournament, there will be no incentive to perform manipulations of the above sort. This is encapsulated in the following definition from [1].

▶ **Definition 6.** A tournament rule r is *2-strongly non-manipulable (2-SNM)* if, for all pairs of $\{i, j\}$-adjacent tournaments T and T', $r_i(T) + r_j(T) = r_i(T') + r_j(T')$.

Unfortunately, no tournament rules exist that are simultaneously Condorcet-consistent and 2-strongly non-manipulable (this is shown in [1] and also follows from our lower bound in Section 3.1). As tournament designers, one way around this obstacle is to discourage manipulation. This discouragement can take many forms, both explicit (if players are caught fixing matches, they are disqualified/fined) and implicit (it is logistically hard to fix matches, it is unsportsmanlike). So the focus of this paper is to quantify *how manipulable* certain tournament formats are (i.e. how much can teams possibly gain by fixing matches), the idea being that it is easier to discourage manipulation in tournaments that are less manipulable.

▶ **Definition 7.** A tournament rule r is *2-strongly non-manipulable at probability α (2-SNM-α)* if, for all i and j and pairs of $\{i, j\}$-adjacent tournaments T and T', $r_i(T') + r_j(T') - r_i(T) - r_j(T) \leq \alpha$.

It is straightforward to generalize this definition to larger coalitions of colluding players.

▶ **Definition 8.** A tournament rule r is *k-strongly non-manipulable at probability α (k-SNM-α)* if, for all subsets S of players of size at most k, for all pairs of S-adjacent tournaments T and T', $\sum_{i \in S} r_i(T') - \sum_{i \in S} r_i(T) \leq \alpha$.

2.1 The Random Single-Elimination Bracket Rule

Our main result concerns a specific tournament rule we call the *random single-elimination bracket rule*. This rule can be defined formally as follows.

▶ **Definition 9.** A *single-elimination bracket* (or *bracket*, for short) B on $n = 2^h$ players is a complete binary tree of height h whose leaves are labelled with some permutation of the n players. The outcome of a bracket B under a tournament T is the labelling of internal nodes of B where each node is labelled by the winner of its two children under T. The winner of B under T is the label of the root of B under this labelling.

▶ **Definition 10.** The *random single-elimination bracket rule* r is a tournament rule on $n = 2^h$ players where $r_i(T)$ is the probability player i is the winner of B under T when B is chosen uniformly at random from the set of $n!$ possible brackets.

If n is not a power of 2, we define the random single-elimination bracket rule on n players by introducing $2^{\lceil \log_2 n \rceil} - n$ dummy players who lose to all of the existing n players.

It is straightforward to check that the random single-elimination bracket rule is both Condorcet-consistent and monotone. Our main result (Theorem 13) shows that in addition to these properties, the random single-elimination bracket rule is 2-SNM-1/3 (which is the best possible, by Theorem 11).

We give some examples of other common tournament rules in Section 3.4. While many of these rules are both Condorcet-consistent and monotone, we do not know of any which are additionally 2-SNM-1/3.

3 Main Result

3.1 Lower bounds for k-SNM-α

We begin by showing that no tournament rule is 2-SNM-α for $\alpha < 1/3$. A similar theorem appears as Proposition 17 in [1] (which states that $\alpha = 0$ is impossible).

▶ **Theorem 11.** *There is no Condorcet-consistent tournament rule on n players (for $n \geq 3$) that is 2-SNM-α for $\alpha < \frac{1}{3}$.*

Proof. Consider the tournament T on three players A, B, and C where A beats B, B beats C, and C beats A (illustrated in Figure 1). . Note that, while this tournament has no Condorcet winner, changing the result of any of the three games results in a Condorcet winner. For example, if A bribes C to lose to A, then A becomes the Condorcet winner.

If we have a tournament rule r that is 2-SNM-α, then combining this with the above fact gives rise to the following three inequalities.

$$\begin{aligned} r_A(T) + r_B(T) &\geq 1 - \alpha \\ r_B(T) + r_C(T) &\geq 1 - \alpha \\ r_C(T) + r_A(T) &\geq 1 - \alpha \end{aligned}$$

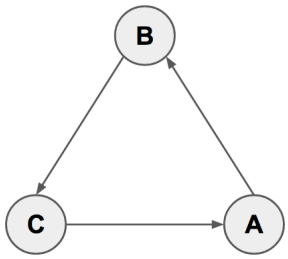

Figure 1 A tournament which attains the lower bound of $\alpha = 1/3$ for all tournament rules.

Together these imply $r_A(T)+r_B(T)+r_C(T) \geq \frac{3}{2}(1-\alpha)$. But $r_A(T)+r_B(T)+r_C(T) = 1$; it follows that $\alpha \geq \frac{1}{3}$, as desired.

We can extend this counterexample to $n > 3$ players by introducing $n-3$ dummy players who all lose to A, B, and C; the argument above continues to hold. ◀

We can use similar logic to prove lower bounds for the more general case of k-SNM-α.

▶ **Theorem 12.** *There is no Condorcet-consistent tournament rule on n players (for $n \geq 2k-1$) that is k-SNM-α for $\alpha < \frac{k-1}{2k-1}$.*

Proof. Consider the following tournament T on the $2k-1$ players labelled 1 through $2k-1$. Each player i wins their match versus the $k-1$ players $i+1, i+2, \ldots, i+(k-1)$, and loses their match versus the $k-1$ players $i-1, i-2, \ldots, i-(k-1)$ (indices taken modulo $2k-1$). Note that the coalition of players $S_i = \{i, i-1, \ldots, i-(k-1)\}$ of size k can cause i to become a Condorcet winner if all players in the coalition agree to lose their games with i. If we have a tournament rule r that is k-SNM-α, then this implies the following $2k-1$ inequalities (one for each $i \in [2k-1]$):

$$\sum_{j \in S_i} r_j(T) \geq 1 - \alpha \tag{1}$$

Summing these $2k-1$ inequalities, we obtain

$$k \sum_{j=1}^{2k-1} r_j(T) \geq (2k-1)(1-\alpha) \tag{2}$$

Since $\sum_{j=1}^{2k-1} r_j(T) \leq 1$, this implies that $\alpha \geq \frac{k-1}{2k-1}$, as desired. Again, it is possible to extend this example to any number of players $n \geq 2k-1$ by introducing dummy players who lose to all $2k-1$ of the above players. ◀

3.2 Random single elimination brackets are 2-SNM-1/3

We now show that the random single elimination bracket rule is optimal against coalitions of size 2. The proof idea is simple; for every bracket B that contributes to the incentive to manipulate $r_i(T') + r_j(T') - r_i(T) - r_j(T)$ we will show that there are two that do not (in other words, for every scenario where team i benefits from the manipulation, there exist two other scenarios where the maniuplation does not benefit either team).

▶ **Theorem 13.** *The random single elimination bracket rule is 2-SNM-1/3.*

Proof. Let $\mathcal{B}$ be the set of $n!$ different possible brackets amongst the n players. For a given tournament T and a given player i, write $\mathbb{1}(B, T, i)$ to represent the indicator variable which is 1 if i wins bracket B under the outcomes in T and 0 otherwise. Then we can write

$$r_i(T) = \frac{1}{|\mathcal{B}|} \sum_{B \in \mathcal{B}} \mathbb{1}(B, T, i).$$

Assume i loses to j in T. Then, if we let T' be the tournament that is $\{i, j\}$ adjacent to T, we can write the increase in utility resulting from j throwing to i

$$\frac{1}{|\mathcal{B}|} \sum_{B \in \mathcal{B}} \left(\mathbb{1}(B, T', i) + \mathbb{1}(B, T', j) - \mathbb{1}(B, T, i) - \mathbb{1}(B, T, j) \right). \tag{3}$$

Our goal is to show that this sum is at most 1/3. Now, note that if i does not end up playing j in bracket B under T, i also does not play j in B under T' (and vice versa). In these brackets, $\mathbb{1}(B, T', i) = \mathbb{1}(B, T, i)$ and $\mathbb{1}(B, T', j) = \mathbb{1}(B, T, j)$, so these brackets contribute nothing to the sum in Equation 3. On the other hand, in a bracket B where i does play j, we are guaranteed that $\mathbb{1}(B, T, i) = 0$ and $\mathbb{1}(B, T', j) = 0$ (since i loses to j in T and j loses to i in T'). Therefore, letting $\mathcal{B}_{ij}$ be the subset of $\mathcal{B}$ of brackets where i meets j, we can rewrite Equation 3 as

$$\frac{1}{|\mathcal{B}|} \sum_{B \in \mathcal{B}_{ij}} \left(\mathbb{1}(B, T', i) - \mathbb{1}(B, T, j) \right).$$

Since $\mathbb{1}(B, T', i) \leq 1$, this is at most

$$\frac{1}{|\mathcal{B}|} \sum_{B \in \mathcal{B}_{ij}} \left(1 - \mathbb{1}(B, T, j) \right).$$

This final sum counts exactly the number of brackets B where i and j meet (under T, so j beats i) but j does not win the tournament. Call such brackets *bad*, and call the remaining brackets *good*. We will exhibit two injective mappings σ_i and σ_j from bad brackets to good brackets such that the ranges of σ_i and σ_j are disjoint. This implies that there are at least twice as many good brackets as bad brackets, and thus that the sum above is at most 1/3, completing the proof.

For both mappings, we will need the following terminology. Consider a bad bracket B, and consider the path from j up to the root of this tree. The nodes of this path are labelled by players that j would face if they got that far. More specifically, j has some opponent in the first round. Should j win, j would face some opponent in the second round, then the third round, etc. all the way to the finals, and these opponents do not depend on the outcomes of any of j's matches. Then since B is a bad bracket, j does not win, and at least one of the players on this path can beat j. Choose the **latest** such player (i.e. the closest to the root) and call this player k. Note that k might *not* be the player that knocks j out of the tournament (that is the *first* player along this path who would beat j).

Suppose that i and j meet at height h of the bracket (i.e. in the h^{th} round). Let B_i, B_j, B_k be the subtrees of height h that contain i, j, and k respectively. An example is shown in Figure 2.

We first describe the simpler of the two maps, σ_i. Define $\sigma_i(B)$ by swapping the subtrees B_i and B_k as shown in Figure 3. In this bracket j will lose to k before ever meeting i, so $\sigma_i(B)$ is good. Moreover σ_i is injective since we can construct its inverse. In $\sigma_i(B)$, j certainly would lose to k at height h before reaching i. Furthermore, because we didn't

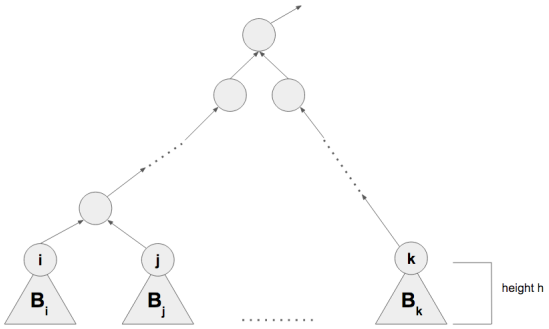

Figure 2 An example of a bad bracket B.

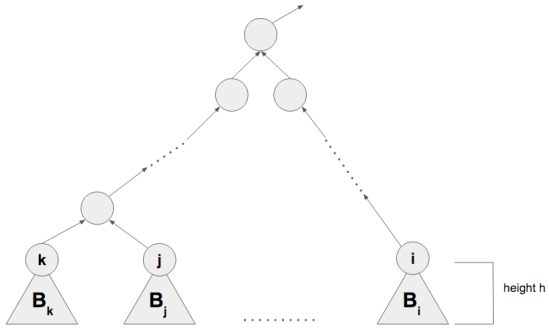

Figure 3 $\sigma_i(B)$.

change B_j at all, j still wins all of its first $h-1$ matches and makes it to k (because we started from a B where j makes it to i at height h). So we can identify k as the first player who beats j in $\sigma_i(B)$, learn the height h, and undo the swap of B_k and B_i.

We now describe the second map, σ_j. To construct $\sigma_j(B)$, begin by swapping the subtrees B_j and B_k (see Figure 4). Note that the bracket formed in this way is good; since we chose k to be the latest player on j's path to victory that can beat j, if j meets i, j will also beat all subsequent players and win the tournament (note that it is of course possible that j doesn't even make it to i, in which case $\sigma_j(B)$ is still good. But it is clear that *if* j meets i, then j will win the tournament, so $\sigma_j(B)$ is good in either case). Unfortunately, this map as stated is not injective; in particular, we cannot recover the height h to undo the swap as in the previous case.

The only reason we cannot uniquely identify k in the same way as when we invert σ_i is that i might meet some player k' at height $h' < h$ in B_i who also could beat j. So, intuitively, we would like to swap such players out with players who lose to j. Since j beats all of its opponents in B_j, B_j is an ample source of such players. We will therefore perform some additional 'subswap' operations, swapping subtrees of B_j and B_k so as to uniquely identify k as the first player i meets in $\sigma_j(B)$ who can beat j.

Specifically, for $0 \le h' < h$, let $a(h')$ be the opponent i plays at height h' in B_i, and let $B_i(h')$ be the subtree of B_i with root $a(h')$ (note that the player that i meets at height h' is the root of a subtree of height $h'-1$, and that all these subtrees are disjoint). Similarly, let $b(h')$ be the opponent j plays at height h' in B_j, and let $B_j(h')$ be the subtree of B_j with root $b(h')$. To construct $\sigma_j(B)$ from B, first swap B_j and B_k. Then for each $h' \in [0, h)$ such that $a(h')$ would beat j, swap the subtrees $B_i(h')$ and $B_j(h')$. See Figure 5 for an illustration of a subswap operation.

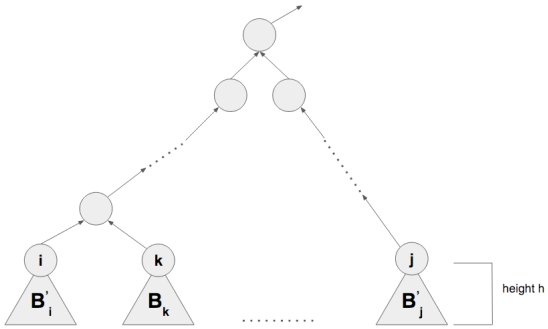

Figure 4 $\sigma_j(B)$.

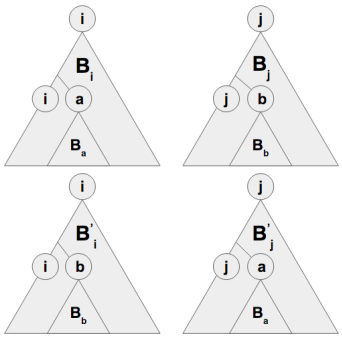

Figure 5 Subswap operation for σ_j.

Note that $\sigma_j(B)$ is still good; it is still the case that if j meets i, j will beat all subsequent players (all we have done in that part of the bracket is perhaps alter whether or not j will indeed meet i). On the other hand, since j makes it to height h in B_j, j can beat player $b(h')$ for all h', so k is now the first player i would encounter in $\sigma_j(B)$ who can beat j. From this, we can recover k and thus h, and undo the swap of B_i and B_j. To undo the subswaps, observe that because we started with a bad bracket B, that j must have beaten all opponents it faces in the first h rounds. Since all opponents on j's path who beat j at height less than h were necessarily put there by our subswap operations, we can just find all such opponents and swap them back out. This process inverts σ_j, thus proving that σ_j is injective.

Finally, note that in $\sigma_i(B)$, k must play j before either plays i, whereas in $\sigma_j(B)$, k must play i before either plays j. Therefore the ranges of σ_i and σ_j are disjoint, and this completes the proof.

For the reader aiming to understand our coupling argument better, Appendix A contains some specific examples. ◀

3.3 Extension to randomized outcomes

Thus far we have been assuming that all match results are deterministic and known to the players in advance. Of course, this is not true in general; in real life, the outcomes of games are inherently unpredictable. It is perhaps imaginable that this unpredictability could increase the incentive to manipulate. In this section we show that this is not the case; a simple application of linearity of expectation shows that results about deterministic tournaments still hold for their randomized counterparts. We begin by defining a randomized tournament as follows.

▶ **Definition 14.** A *randomized tournament* $\mathcal{T}$ is a random variable whose values range over (deterministic) tournaments T. As shorthand, we will write $\mathbb{P}_{\mathcal{T}}(T)$ to represent the probability that $\mathcal{T} = T$.

Note that this definition accounts for the most straightforward generalization of tournament outcomes from deterministic to randomized, where for each match between players i and j we assign a probability p_{ij} to the probability that i beats j. This definition further allows for the possibility of correlation between matches (e.g., with some probability player i has a good day and wins all his matches, and with some probability he has a bad day and loses all his matches).

Manipulations in this randomized model are similar to manipulations in the deterministic model in that they effectively force the result of a match to a win or a loss. Formally, let $\sigma_{ij}(T)$ for a (deterministic) tournament T be the tournament formed by T but where i beats j (if i beats j in T, then $\sigma_{ij}(T) = T$). A tournament rule r is 2-SNM-α if for all i and j,

$$\mathbb{E}_{\mathcal{T}}\left[r_i(\sigma_{ij}(\mathcal{T})) + r_j(\sigma_{ij}(\mathcal{T})) - r_i(\mathcal{T}) - r_j(\mathcal{T})\right] \leq \alpha \tag{4}$$

We then have the following theorem:

▶ **Theorem 15.** *If a rule r is 2-SNM-α in the deterministic tournament model, it is also 2-SNM-α in the randomized tournament model.*

Proof. Note that we can write the expectation in Equation 4 as

$$\sum_{T} \mathbb{P}_{\mathcal{T}}(T)\left(r_i(\sigma_{ij}(T)) + r_j(\sigma_{ij}(T)) - r_i(T) - r_j(T)\right)$$

If r is 2-SNM-α for deterministic tournaments, then each term in this sum is at most $\mathbb{P}_{\mathcal{T}}(T)\alpha$. It follows that this sum is at most α, and therefore r is also 2-SNM-α for randomized tournaments. ◀

It is straightforward to generalize the above definitions and result to the case of k-SNM-α.

3.4 Other tournament formats

Finally, there are many other tournament formats that are either used in practice or have been previously studied. In this section we show that many of these formats are more susceptible to manipulation than the random single elimination bracket rule; in particular, all of the following formats are at best 2-SNM-1/2.

By far the most common tournament rule for round robin tournaments is some variant of a 'scoring' rule, where the winner is the player who has won the most games (with ties broken in some fashion if multiple players have won the same maximum number of games). In voting theory, this rule is often called Copeland's rule, or Copeland's method [5].

▶ **Definition 16.** A tournament rule r is a *Copeland rule* if the winner is always selected from the set of players with the maximum number of wins.

We begin by showing that no Copeland rule can be 2-SNM-α for any $\alpha < 1$ (regardless of how the rule breaks ties).

▶ **Theorem 17.** *There is no Copeland rule on n players that is 2-SNM-α for $\alpha < 1 - \frac{2}{n-1}$.*

Proof. Assume to begin that $n = 2k + 1$ is odd, and let r be a Copeland rule on n players. Let T be the tournament where each player i beats the k players $\{i + 1, i + 2, \ldots, i + k\}$ but loses to the k players $\{i - 1, i - 2, \ldots, i - k\}$, with indices taken modulo n (similar to the tournament in the proof of Theorem 12).

Since $\sum_{i=1}^{n} r_i(T) = 1$, there must be some i such that $r_{i-1}(T) + r_i(T) \leq \frac{2}{n}$. On the other hand, if player $i - 1$ throws their match to player i, then player i becomes the unique Copeland winner (winning $k + 1$ games) and $r_i(T') = 1$. It follows that, for such a rule, if r is 2-SNM-α, then $\alpha \geq 1 - \frac{2}{n}$.

If n is even, then we can embed the above example for $n - 1$ by assigning one player to be a dummy player that loses to all teams. This immediately implies $\alpha \geq 1 - \frac{2}{n-1}$ in this case. ◀

In [1], Altman and Kleinberg provide three examples of tournament rules that are Condorcet-consistent and monotone: the top cycle rule, the iterative Condorcet rule, and the randomized voting caterpillar rule. We prove lower bounds on α for each of these in turn. Interestingly, the same tournament provides all three lower bounds.

▶ **Definition 18.** The *superman-kryptonite* tournament on n players has i beat j whenever $i < j$, except that player n beats player 1. That is, player 1 beats everyone except for player n, who loses to everyone except for player 1.

Now we show that the superman-kryptonite tournament provides lower bounds against the tournament rules considered in [1].

▶ **Definition 19.** The *top cycle* of a tournament T is the minimal set of players who never lose to any other player. The *top cycle rule* is a tournament rule which assigns the winner to be a uniformly random element of this set.

▶ **Theorem 20.** *The top cycle rule on n players is not 2-SNM-α for any $\alpha < 1 - \frac{2}{n}$.*

Proof. Let T be the superman-kryptonite tournament on n players. The top cycle in T contains all the players, so $r_1(T) + r_n(T) = \frac{2}{n}$. However, if player n throws their match to player 1, player 1 becomes a Condorcet winner and $r_1(T') = 1$. It follows that $\alpha \geq 1 - \frac{2}{n}$. ◀

▶ **Definition 21.** The *iterative Condorcet rule* is a tournament rule that uniformly removes players at random until there is a Condorcet winner, and then assigns that player to be the winner.

▶ **Theorem 22.** *The iterative Condorcet rule on n players is not 2-SNM-α for any $\alpha < \frac{1}{2} - \frac{1}{n(n-1)}$.*

Proof. Let T be the superman-kryptonite tournament on n players. Note that no Condorcet winner will appear until either player 1 is removed, player n is removed, or all other $n - 2$ players are removed. If all the other $n - 2$ players are removed before players 1 or n (which occurs with probability $\frac{2}{n(n-1)}$), then player n wins. If this does not happen and player n is removed before player 1 (which occurs with probability $\frac{1}{2}\left(1 - \frac{2}{n(n-1)}\right) = \frac{1}{2} - \frac{1}{n(n-1)}$), then player 1 becomes the Condorcet winner and wins. Otherwise, player 1 will be removed before player n, while some players in 2 through $n - 1$ remain, and one of them will become the Condorcet winner (the remaining player in $\{2, \ldots, n - 1\}$ with lowest index). It follows that $r_1(T) = \frac{1}{2} - \frac{1}{n(n-1)}$ and $r_n(T) = \frac{2}{n(n-1)}$, so $r_1(T) + r_n(T) = \frac{1}{2} + \frac{1}{n(n-1)}$.

On the other hand, if player n throws their match to player 1, then again player 1 becomes a Condorcet winner and $r_1(T') = 1$. It follows that $\alpha \geq \frac{1}{2} - \frac{1}{n(n-1)}$. ◀

▶ **Definition 23.** The *randomized voting caterpillar rule* is a tournament rule which chooses a winner as follows. Choose a random permutation π of $[n]$. Start by matching $\pi(1)$ and $\pi(2)$, and choose a winner according to T. Then for all $i \geq 3$ match $\pi(i)$ with the winner of the most recent match. The player that wins the last match (against $\pi(n)$) is declared the winner.

▶ **Theorem 24.** *The randomized voting caterpillar rule on n players is not 2-SNM-α for any $\alpha < \frac{1}{2} - \frac{n-3}{n(n-1)}$.*

Proof. Let T be the superman-kryptonite tournament on n players. The only way player 1 loses is if either player n occurs later in π than player 1 (which happens with probability $\frac{1}{2}$) or if $\pi(n) = 1$ and $\pi(1) = 2$ and they play in the first round (which happens with probability $\frac{1}{n(n-1)}$). The only way player n can win is if $\pi(n) = n$ (i.e., they only play the very last game), in which case they will play player 1 and win (this happens with probability $\frac{1}{n}$). It follows that $r_1(T) = \frac{1}{2} - \frac{1}{n(n-1)}$ and $r_n(T) = \frac{1}{n}$, so $r_1(T) + r_n(T) = \frac{1}{2} + \frac{n-2}{n(n-1)}$.

On the other hand, if player n throws their match to player 1, then again player 1 becomes a Condorcet winner and $r_1(T') = 1$. It follows that $\alpha \geq \frac{1}{2} - \frac{n-2}{n(n-1)}$. ◀

A More Details on our Coupling Argument

In this appendix we present examples of bracket transformations. Recall that our transformations took as input any "bad" bracket, where player i eventually meets player j, *and* player j will lose to some player k in the future if she advances past i (and k is the latest such player). The players benefit from manipulating these brackets. We transformed them into "good" brackets, where either player j is eliminated before even meeting player i, or where

player j would be the champion conditioned on getting past i. The players have no incentive to manipulate these brackets.

We designed two injective transformations with disjoint images, σ_i and σ_j. σ_i was more straight-forward, but we include an example below anyway. σ_j was more complex. We include below an example showing that the complexity is necessary, and then an example of σ_j. All figures are at the end.

A.1 Example of the transformation $\sigma_i(B)$

Recall that σ_i essentially swaps the sub-brackets rooted at i and k. See Section 3.2 for a formal description.

Consider the partial bracket B_1 shown in Figure 6. Then, applying the transformation $\sigma_i(B_1)$ as described in our paper will yield the bracket B_1' shown in Figure 7. Note that this mapping is injective: by examining $\sigma_i(B)$, we see exactly where j is eliminated, and conclude that this must be where i met j in the original B.

A.2 Counterexample to a naive $\sigma_j(B)$

We could try using the same ideas in σ_i for σ_j: simply swap the subtrees rooted at k and j. Unfortunately, this mapping is not injective.

Consider the two brackets B_3, B_4 shown in Figure 8. Then applying this naive transformation will map these brackets to the same bracket (see Figure 9), showing that the mapping may not be injective. This motivates the need for the more involved transformation σ_j from Section 3.2.

Specifically, observe that in B_3, i meets j in round 2, so the depth-2 subtree rooted at k would get swapped with the depth-2 subtree rooted at j. In B_4, i meets j in round 1, so the single node i_1 would get swapped with the single node j. It is easy, but tedious, to complete this into a full tournament/bracket.

A.3 Example of the transformation $\sigma_j(B)$

Essentially, the problem with the naive transformation is that it's hard to recover where i met j in the original B just from the naive $\sigma_j(B)$. This is because maybe on its path to j, i met many other competitors who also would have beaten j, in addition to the k we swap in from the mapping. Our more involved transformation fixes this by additionally swapping all such competitors out of the subtree below i, so we can again recover where i met j in the original B.

Consider the partial bracket B_2 shown in Figure 10 and assume that in the tournament in case i_2 would beat j. Then, applying the transformation $\sigma_j(B_2)$ as described in our paper will yield the bracket B_2' shown in 11.

Note that this mapping is injective! First, we can recover where i met j in the original B by looking at where i first encounters someone who would beat j in $\sigma_j(B)$. Once we learn this, we also know that in the original B, j actually advanced this far in the tournament to meet i, so we know exactly which subtrees we need to un-swap with subtrees of i.

Abstract

We study the problem of allocating m items to n agents subject to maximizing the Nash social welfare (NSW) objective. We write a novel convex programming relaxation for this problem, and we show that a simple randomized rounding algorithm gives a $1/e$ approximation factor of the objective, breaking the $1/2e^{1/e}$ approximation factor of Cole and Gkatzelis [8].

Our main technical contribution is an extension of Gurvits's lower bound on the coefficient of the square-free monomial of a degree m-homogeneous stable polynomial on m variables to all homogeneous polynomials. We use this extension to analyze the expected welfare of the allocation returned by our randomized rounding algorithm.

1 Introduction

We study the problem of allocating a set of indivisible items to agents subject to maximizing the Nash social welfare (NSW). We are given a set of m indivisible items and we want to assign them to n agents. An allocation vector is a vector $\mathbf{x} \in \{0,1\}^{n\times m}$ such that for each j, exactly one $x_{i,j}$ is 1. We assume that agents have additive valuations. That is, each agent i has nonnegative value $v_{i,j}$ for an item j and the value that i receives for an allocation $\mathbf{x}$ is

$$v_i(\mathbf{x}) = \sum_{j=1}^{m} x_{i,j} v_{i,j}.$$

The NSW objective is to compute an allocation $\mathbf{x}$ that maximizes the geometric mean of agents' values,

$$\left(\prod_{i=1}^{n} v_i(\mathbf{x})\right)^{\frac{1}{n}}.$$

The above objective naturally encapsulates both fairness and efficiency and has been extensively studied as a notion of fair division (see [14, 5] and references therein).

Recently, there have been a number of results that study the computational complexity of the Nash social welfare objective. For additive valuations it is known that it is NP-hard to approximate the NSW objective within $(1-c)$ [15, 13], for some constant $c > 0$. On the positive side, Nguyen and Rothe [16] designed a $\left(\frac{1}{m-n+1}\right)$ approximation algorithm and Cole and Gkatzelis [8] gave the first constant factor, $\left(\frac{1}{2e^{1/e}}\right)$-approximation. Recently, independent of our work, Cole et al. [7] gave a $\frac{1}{2}$-approximation.

A closely related problem, that captures only fairness, is the Santa-Clause problem where the goal is to find an allocation to maximize the minimum value among all agents, i.e., $\max_{\mathbf{x}} \min_i v_i(\mathbf{x})$ which has also been studied recently [1, 2, 3, 6].

1.1 Our Contributions

Our main contribution is to show an intricate connection between the Nash welfare maximization problem, the theory of real stable polynomials, and the problem of approximating the permanent. We establish this connection in the following manner. We first give a new mathematical programming relaxation for the problem; indeed the standard relaxation has arbitrarily large integrality gap as shown by Cole and Gkatzelis [8]. Our relaxation is a polynomial optimization problem[1] which, despite not being convex in the standard form, can be solved efficiently by a change of variables. We remark that a similar geometric program was used in the context of maximum sub-determinant problem [17].

More precisely, we study a real stable polynomial $p(y_1, \ldots, y_m)$. We give a simple randomized rounding algorithm such that the expected Nash welfare of the allocation returned by the algorithm exactly equals the sum of *square-free* coefficients of $p(\mathbf{y})$. Thus, our program needs to maximize the sum of square-free coefficients of $p(\mathbf{y})$. Unfortunately, such an optimization problem in not convex. Instead, we maximize the following proxy

$$\inf_{\substack{\mathbf{y}>0:\\ \prod_{i\in S} y_i \geq 1, \forall S \in \binom{[m]}{n}}} p(\mathbf{y}).$$

The main part of our analysis is to relate the sum of square-free coefficients of $p(\mathbf{y})$ to the above proxy. This desired inequality is a generalization of an elegant result of Gurvits [11] relating the problem of approximating the permanent of a matrix with the theory of real stable polynomials. We prove this generalization in theorem 1.2. The connection to permanents allows us to use algorithmic results for approximating the permanent due to Jerrum, Sinclair and Vigoda [12] and we obtain the following result.

▶ **Theorem 1.1.** *There is a randomized polynomial time algorithm for the Nash welfare maximization problem that, with high probability, returns a solution with objective at least $1/e$ fraction of the optimum.*

[1] It falls in the broad class of geometric programs, where the mathematical program is convex in logarithms of the variables and not the variables itself.

We emphasize that unlike the recent constant factor approximation algorithms by Cole and Gkatzelis [8] and [7], our algorithm and its analysis are purely algebraic and completely oblivious to the structure of the underlying market. In particular, unlike other approaches we are not taking advantage of the combinatorial structure of "spending restricted assignments" in our rounding algorithms (see [8] for more information). This generality makes our approach potentially applicable to a variety of resource allocation problems.

The crucial ingredient of our analysis is the following general inequality about real stable polynomials that generalizes the result of Gurvits [11] (see theorem 2.5) that provided an elegant proof of the Van-der-Waerden conjecture.

▶ **Theorem 1.2.** *Let p be a degree n-homogeneous real stable polynomial in $y_1, \ldots, y_m$ with nonnegative coefficients. For any set $S \subseteq [m]$, let c_S denote the coefficient of monomial $y^S := \prod_{i \in S} y_i$. If $\sum_{S \in \binom{[m]}{n}} c_S > 0$, then*

$$\begin{aligned} \sum_{S \in \binom{[m]}{n}} c_S &\geq \frac{m! \cdot (m-n)^{m-n}}{m^m \cdot (m-n)!} \inf_{\substack{\mathbf{y}>0: \\ y^S \geq 1, \forall S \in \binom{[m]}{n}}} p(\mathbf{y}) \qquad (1) \\ &\geq e^{-n} \inf_{\substack{\mathbf{y}>0: \\ y^S \geq 1, \forall S \in \binom{[m]}{n}}} p(\mathbf{y}). \end{aligned}$$

Note that second inequality follows by lemma 1.1, $\frac{m!}{m^m} \cdot \frac{(m-k)^{m-k}}{(m-k)!} \geq e^{-k}$. By setting $n = m$ in the above statement, we obtain the result of Gurvits as described in theorem 2.5.

It is not hard to see that the above inequality is (almost) tight. For the stable n-homogeneous polynomial $p(y_1, \ldots, y_m) = (y_1 + \cdots + y_n)^n$, the LHS is $n!$ and the RHS is $(n/e)^n$. This tight example was already studied by Friedland and Gurvits [9] to show tightness of a lower bound for the number of matchings in regular bipartite graphs.

2 Preliminaries

For a vector $\mathbf{y}$, we write $\mathbf{y} \leq 1$ to denote that all coordinates of $\mathbf{y}$ are at most 1. For an integer $n \geq 1$ we use $[n]$ to denote the set of numbers $\{1, 2, \ldots, n\}$. For any m, n, we let $\binom{[m]}{n}$ denote the collection of subsets of $[m]$ of size n.

2.1 Stable Polynomials

Stable polynomials are natural multivariate generalizations of real-rooted univariate polynomials. For a complex number z, let $\mathrm{Im}(z)$ denote the imaginary part of z. We say a polynomial $p(z_1, \ldots, z_m) \in \mathbb{C}[z_1, \ldots, z_m]$ is *stable* if whenever $\mathrm{Im}(z_i) > 0$ for all $1 \leq i \leq m$, $p(z_1, \ldots, z_m) \neq 0$. We say $p(.)$ is real stable, if it is stable and all of its coefficients are real. It is easy to see that any univariate polynomial is real stable if and only if it is real rooted.

We say a polynomial $p(z_1, \ldots, z_m)$ is degree n-homogeneous, or n-homogenous, if every monomial of p has degree exactly n. Equivalently, p is n-homogeneous if for all $a \in \mathbb{R}$, we have

$$p(a \cdot z_1, \ldots, a \cdot z_m) = a^n p(z_1, \ldots, z_m).$$

We say a monomial $z_1^{\alpha_1} \ldots z_m^{\alpha_m}$ is *square-free* if $\alpha_1, \ldots, \alpha_m \in \{0, 1\}$. For a set $S \subset 2^{[m]}$ we write

$$z^S = \prod_{i \in S} z_i.$$

Thus, we can represent a square-free monomial with the set of indices of variables in that monomial.

▶ **Fact 2.1.** *If $p(z_1, \ldots, z_m)$ and $q(z_1, \ldots, z_m)$ are stable then $p \cdot q$ is stable.*

▶ **Fact 2.2.** *The polynomial $\sum_i a_i z_i$ is stable if $a_i \geq 0$ for all i.*

Polynomial optimization problems involving real stable polynomials with nonnegative coefficients can often be turned into concave/convex programs. Such polynomials are log-concave in the positive orthant:

▶ **Theorem 2.3** ([10])**.** *For any n-homogeneous stable polynomial $p(x_1, \ldots, x_n)$ with nonnegative coefficients, $\log p(\mathbf{x})$ is concave in the positive orthant, $\mathbb{R}^n_{++}$.*

It is also an immediate corollary of Hölder's inequality that a polynomial with nonnegative coefficients is log-convex in terms of the log of its variables (for more details on log-convex functions see [4]).

▶ **Fact 2.4.** *For any polynomial $p(y_1, \ldots, y_m)$ with nonnegative coefficients, $\log p(\mathbf{y})$ is convex in terms of $\log \mathbf{y}$. In other words, $\log p(e^{z_1}, \ldots, e^{z_m})$ is convex in terms of $\mathbf{z}$.*

The following theorem is proved by Gurvits [11].

▶ **Theorem 2.5** ([11])**.** *For any degree m-homogeneous stable polynomial $p(z_1, \ldots, z_m)$ with nonnegative coefficients, let $c_{[m]}$ denote the coefficient of the multilinear monomial $z_1 \cdots z_m$. If $c_{[m]} > 0$, then*

$$c_{[m]} \geq \frac{m!}{m^m} \inf_{\mathbf{z}>0} \frac{p(z_1, \ldots, z_m)}{z_1 \ldots z_m}.$$

2.2 Counting Matchings in Bipartite Graphs

Given a bipartite graph $G = (X, Y, E)$ with weights $w : E \to \mathbb{R}$, the weight of a perfect matching M is defined as follows:

$$w(M) = \prod_{e \in M} w_e.$$

Jerrum, Sinclair, and Vigoda in their seminal work designed a FPRAS to count the sum of (weighted) perfect matchings of an arbitrary bipartite graph with nonnegative weights. This problem is also equivalent to the computation of the permanent of a nonnegative matrix.

▶ **Theorem 2.6** ([12])**.** *There exists a randomized polynomial time algorithm that for any arbitrary bipartite graph G with n vertices and nonnegative weights and $\epsilon > 0$ in time polynomial in the size of G and $1/\epsilon$ approximates the sum of weights of all perfect matchings of G within a $1 + \epsilon$ multiplicative error, with high probability.*

A k-matching of a bipartite graph $G = (X, Y, E)$ is a set $M \subseteq E$ of size $|M| = k$ such that no two edges share an endpoint. The following corollary follows immediately from the above theorem. For completeness, we prove it in the appendix.

▶ **Corollary 2.7.** *There is a randomized polynomial time algorithm that for any arbitrary bipartite graph G with nonnegative edge weights and for any given $\epsilon > 0$ and integer $k \leq n$ in time polynomial in the size of G and $1/\epsilon$ approximates the sum of the weights of all k-matchings of G within $1 + \epsilon$ multiplicative error, with high probability.*

3 Approximation Algorithm for NSW Maximization

In this section, we give an approximation algorithm for the NSW maximization problem. We begin by giving a mathematical programming relaxation that can be efficiently solved. For convenience, we will aim to optimize

$$\left(\prod_{i=1}^{n} v_i(\mathbf{x})\right),$$

which is the n^{th} power of the NSW objective. Thus, it is enough to give an e^{-n}-approximation to the above objective. With a slight abuse of notation, we will also refer to problem of maximizing the new objective as the Nash welfare problem. In section 3.2, we give a rounding algorithm that proves the guarantee claimed in Theorem 1.1.

3.1 Mathematical Programming Relaxation

We use the following mathematical program.

$$\begin{aligned} \max_{\mathbf{x}} \quad & \inf_{\mathbf{y}>0: y^S \geq 1, \forall S \in \binom{[m]}{n}} \quad \prod_{i=1}^{n}\left(\sum_{j=1}^{m} x_{i,j} v_{i,j} y_j\right), \\ \text{s.t.} \quad & \sum_{i=1}^{n} x_{i,j} \leq 1 \qquad \forall 1 \leq j \leq m, \\ & x_{i,j} \geq 0 \qquad \forall i,j. \end{aligned} \tag{2}$$

First, we show that (2) is a relaxation of the Nash welfare problem and can be optimized in polynomial time to an arbitrary accuracy.

▶ **Lemma 3.1.** *The mathematical program* (2) *is a relaxation of the Nash welfare problem and can be optimized in polynomial time.*

Proof. Let $x^* \in \{0,1\}^{n\times m}$ be an optimal solution of the Nash welfare problem and let $\sigma : [m] \to [n]$ denote the assignment, i.e., $\sigma(j) = i$ if and only if $x^*_{ij} = 1$. We show that x^* is a feasible solution (2) of objective $\prod_{i=1}^{n} v_i(x^*)$. Consider any $\mathbf{y} > 0$ such that $y^S \geq 1$ for each $S \subseteq \binom{[m]}{n}$. Moreover let $\mathcal{S} = \{S \in \binom{[m]}{n} : \forall i \in [n], \exists j \in S \text{ such that } x^*_{ij} = 1\}$. We have

$$\begin{aligned} \prod_{i=1}^{n}\left(\sum_{j=1}^{m} x^*_{i,j} v_{i,j} y_j\right) &= \textstyle\sum_{S\in\mathcal{S}} y^S \prod_{j\in S} v_{\sigma(j),j} \\ &\geq \textstyle\sum_{S\in\mathcal{S}} \prod_{j\in S} v_{\sigma(j),j} \\ &= \textstyle\prod_{i=1}^{n}\left(\sum_{j=1}^{m} x^*_{i,j} v_{i,j}\right) \end{aligned}$$

as required, where we use the fact that $y^S \geq 1$ for each $S \in \mathcal{S}$. To show that the objective of the mathematical program equals $\prod_{i=1}^{n} v_i(x^*)$, we consider the solution $y^*_j = 1$ for each $j \in [m]$.

To solve the mathematical program, we observe that the function $\log \prod_{i=1}^{n} \sum_{j=1}^{m} x_{i,j} v_{i,j} y_j$ is concave in x and convex in $\log \mathbf{y}$, where $\log \mathbf{y}$ is the vector defined by taking logarithms of the vector $\mathbf{y}$ coordinate-wise. These follow from theorem 2.3 and fact 2.4. Moreover, the constraints on $\mathbf{x}$ and $\log \mathbf{y}$ are linear. Thus the above program can be formulated as a convex program and solved to an arbitrary accuracy. ◀

Algorithm 1 An Algorithm for NSW Maximization.

Check whether the optimal solution has weight strictly more than zero using the bipartite matching algorithm. Return zero if answer is false.
Find an optimal solution $\mathbf{x}^*$ to the mathematical program (2).
Independently for each item $j \in [m]$, assign item j to one agent where agent $i \in [n]$ is chosen with probability x^*_{ij}.

3.2 Randomized Algorithm I

We now give a rounding algorithm that proves the required guarantee. Algorithm 1 will only satisfy the guarantee in expectation. Later, we show how to give a randomized algorithm that gives essentially the same guarantee with high probability.

The first step of the algorithm can be implemented by a bipartite matching problem. Indeed consider the bipartite graph with one side as agents and other as items. We have an edge (i, j) for agent i and item j if $v_{ij} > 0$. The optimal solution to the NSW maximization problem is strictly positive if and only if this bipartite graph has a matching that includes an edge at every agent. Thus, we can check in polynomial time whether the optimal solution has weight zero. For the remainder of the section, we assume that the optimal solution is strictly positive.

We say $\mathbf{x} \in \mathbb{R}_+^{n\times m}$ is a fractional allocation vector if for each $j \in [m]$, $\sum_{i=1}^n x_{i,j} = 1$. Given any fractional allocation $\mathbf{x}$, consider the following polynomial in variables $y_1, \ldots, y_n$,

$$p_{\mathbf{x}}(y_1, \ldots, y_n) = \prod_{i=1}^{n} \left(\sum_{j=1}^{m} x_{i,j} v_{i,j} y_j \right).$$

Observe that $p_{\mathbf{x}}(\mathbf{y})$ is a degree n-homogenous polynomial in m variables for any $\mathbf{x}$ or the identically 0 polynomial.

▶ **Lemma 3.2.** *We have the following.*

1. *For $S \subseteq [m]$ of size n, let c_S denote the coefficient of y^S in $p_{\mathbf{x}^*}(\mathbf{y})$. Then, the expected value of algorithm 1 equals*

$$\sum_{S \in \binom{[m]}{n}} c_S.$$

2. *The optimal value of the relaxation (2) is*

$$\inf_{\mathbf{y}: y^S \geq 1, \forall S \in \binom{[m]}{n}} p_{\mathbf{x}^*}(\mathbf{y}).$$

Proof. Let $X_{i,j}$ be the random variable indicating that j is assigned to i. Then, the value that i receives is $\sum_{j=1}^m X_{i,j} v_{i,j}$. So, the expected value of the algorithm is

$$\mathbb{E}\left[\prod_{i=1}^{n}\sum_{j=1}^{m} X_{i,j} v_{i,j}\right] = \sum_{\sigma:[n]\to[m]} \mathbb{E}\left[\prod_{i=1}^{n} X_{i,\sigma(i)} v_{i,\sigma(i)}\right] =$$

$$\sum_{\sigma:[n]\to[m]} \mathbb{P}\left[\forall i : X_{i,\sigma(i)} = 1\right] \prod_{i=1}^{n} v_{i,\sigma(i)}.$$

where σ is summed over all functions from $[n]$ to $[m]$. Observe that $\mathbb{P}\left[\forall i : X_{i,\sigma(i)=1}\right] \neq 0$ only if σ is a one-to-one function. In such a case, we have $\mathbb{P}\left[\forall i : X_{i,\sigma(i)} = 1\right] = \prod_{i=1}^{n} x_{i,\sigma(i)}$ where we use the fact that each item is assigned independently. Therefore,

$$\mathbb{E}\left[\prod_{i=1}^{n}\sum_{j=1}^{m} X_{i,j}v_{i,j}\right] = \sum_{\sigma:[n]\underset{\text{one-to-one}}{\to}[m]}\prod_{i=1}^{n} x_{i,\sigma(i)}v_{i,\sigma(i)}.$$

The lemma follows by the fact that for any one-to-one σ, the term $\prod_{i=1}^{n} x_{i,\sigma(i)}v_{i,\sigma(i)}$ on the RHS appears in the coefficient of the (square-free) monomial $\prod_{i=1}^{n} y_{\sigma(i)}$ of $p_{\mathbf{x}^*}(\mathbf{y})$. For any $S \in \binom{[m]}{n}$ the coefficient of y^S in $p_{\mathbf{x}^*}(\mathbf{y})$ is the sum of all such terms where $\sigma([n]) = S$.

The proof of the second claim is immediate by definition. ◀

We are now ready to apply theorem 1.2 and obtain the following immediate corollary.

▶ **Corollary 3.3.** *The expected objective of algorithm 1 is at least*

$$e^{-n} \cdot \mathrm{OPT}$$

where OPT *is the optimal NSW objective.*

Proof. From fact 2.1 and fact 2.2, it follows that $p_{\mathbf{x}^*}(\mathbf{y})$ as defined above is real stable with nonnegative coefficients. Moreover, it is an m-variate polynomial that is degree n-homogenous. Let c_S denote the coefficient of square-free monomial y^S for any $S \in \binom{[m]}{n}$. Since, we assume that there is at least one assignment that has strictly positive NSW objective, the sum of coefficients $\sum_{S\in\binom{[m]}{n}} c_S > 0$. Thus, from theorem 1.2, we have

$$\sum_{S\in\binom{[m]}{n}} c_S \quad \geq \quad e^{-n} \min_{\mathbf{y}:y^S\geq 1,\forall S\in\binom{[m]}{n}} p_{\mathbf{x}^*}(\mathbf{y}).$$

Now the proof is immediate using lemma 3.2. ◀

3.3 Randomized Algorithm II

From corollary 3.3, the expected NSW of the allocation returned by algorithm 1 is at least $1/e^n$ fraction of the optimum. Repeated applications of the algorithm to obtain a high probability bound is not possible since the output of algorithm 1 may have an exponentially large variance. In this section, we prove Theorem 1.1 by giving an algorithm that returns the same guarantee as algorithm 1 with high probability.

Proof of theorem 1.1. We use the method of conditional expectations to prove the theorem. We iteratively assign one item at a time, making sure that conditional expectation over the random assignment of the remaining items does not decrease (substantially). We now claim that for any assignment x, the expected value of the objective as given by randomized algorithm 1 equals the number of weighted n-matchings of a bipartite graph. Consider the weighted bipartite graph $G = ([n], [m], E)$ where for any $1 \leq i \leq n$ and $1 \leq j \leq m$, $w_{i,j} = x_{i,j}v_{i,j}$. Then, for one-to-one mapping $\sigma : [n] \to [m]$, the coefficient of the monomial $\prod_{i=1}^{n} x_{i,\sigma(i)}v_{i,\sigma(i)}$ is equal to the weight of the n-matching $\{(1,\sigma(1)),(2,\sigma(2)),\ldots,(n,\sigma(n))\}$. Therefore, the sum of square-free monomials of $p_{\mathbf{x}}(\mathbf{y})$ is equal to the sum of the weights of all n-matchings of G.

Now, pick any item $j \in [m]$ and any fractional assignment x. Consider the following n assignments, $x^1, \ldots, x^n$. Assignment x^i assigns item j to i and rest of the items identically

to the fractional assignment x. Thus $x^i_{ij} = 1$, $x^i_{i',j} = 0$ for all $i \neq i'$ and $x^i_{i'j'} = x_{i'j'}$ for any $j' \neq j$. Let ALG^i denote the objective value of the output of algorithm 1 on solution x^i and ALG on x. Since the objective value of the algorithm 1 is linear in $\{x_{ij} : i \in [n]\}$ for fixed j, we have

$$\mathrm{ALG} = \sum_{i=1}^{n} x_{ij}\, \mathrm{ALG}^i$$

Thus ALG is the expected value of the conditional expected value of the output of the algorithm 1 when we assign item j to one of the agents; it is assigned to agent i with probability x_{ij}.

By corollary 2.7, we can estimate ALG and ALG^i within a factor of $1 + 1/m^3$ factor in polynomial time. Therefore, using the method of conditional expectations, we obtain an allocation of NSW of value at least $\frac{\mathrm{OPT}}{e^n} \cdot (1 - 1/m^3)^m \geq \frac{\mathrm{OPT}}{\left((1+\frac{1}{n})e\right)^n}$ where OPT denotes the objective of the optimal allocation. ◀

4 A Generalization of Gurvits's Theorem

In this section we prove theorem 1.2. Let

$$q(y_1, \ldots, y_m) = (y_1 + \cdots + y_m)^{m-n}$$

be a degree $(m-n)$-homogenous polynomial. It is straightforward to see that it is real stable. Consider the polynomial $p(\mathbf{y})q(\mathbf{y})$. Observe that this is a degree m-homogeneous stable polynomial with nonnegative coefficients. Since from the assumption of theorem 1.2, at least one of the square-free monomials in $p(\mathbf{y})$ has a non-zero coefficient, the coefficient of the square-free monomial in $p(\mathbf{y})q(\mathbf{y})$ is non-zero. Let $\alpha_{[m]}$ be the coefficient of the square-free monomial $y_1 \cdots y_m$ in $p(\mathbf{y})q(\mathbf{y})$. Thus, from theorem 2.5, we have

$$\alpha_{[m]} \geq \frac{m!}{m^m} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})q(\mathbf{y})}{y_1 \ldots y_m}. \tag{3}$$

To prove theorem 1.2 it is enough to relate the LHS and the RHS of (3) to the two sides of (1). This is done in lemma 4.1 and proposition 4.2.

▶ **Lemma 4.1.** *We have*

$$(m-n)! \sum_{S \in \binom{[m]}{n}} c_S = \alpha_{[m]}.$$

Proof. The RHS is the coefficient of the square-free monomial $y_1 \ldots, y_m$ in $p(\mathbf{y})q(\mathbf{y})$. The square-free monomial of $p(\mathbf{y})q(\mathbf{y})$ is obtained whenever we multiply a square-free monomial y^S of $p(\mathbf{y})$ with the square-free monomial $y^{\overline{S}}$ of $q(\mathbf{y})$ for some $S \in \binom{[m]}{n}$. Lemma's statement follows by the fact that the coefficient of $y^{\overline{S}}$ in $q(\mathbf{y})$ is $(m-n)!$ for every $S \in \binom{[m]}{n}$ and the coefficient of y^S in $p(\mathbf{y})$ is c_S. ◀

The proof of theorem 1.2 is now immediate from the following proposition which relates the RHS of (3) and (1).

▶ **Proposition 4.2.**

$$\inf_{\mathbf{y}>0} \frac{p(\mathbf{y})q(\mathbf{y})}{y_1 \ldots y_m} \geq (m-n)^{m-n} \inf_{\mathbf{y}>0 : y^S \geq 1, \forall S \in \binom{[m]}{n}} p(\mathbf{y}).$$

In the rest of this section we prove the above proposition. We do the proof in two steps. First, we use convex duality to simplify the RHS, and then we prove the proposition.

▶ **Lemma 4.3.**

$$\inf_{\mathbf{y}>0: y^S \geq 1, \forall S \in \binom{[m]}{n}} p(\mathbf{y}) = \sup_{0\leq\theta\leq 1: \sum_{j=1}^m \theta_j = n} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1}\dots y_m^{\theta_m}}.$$

Proof. The proof follows by convex duality. By taking logarithm of $p(\mathbf{y})$ and the change of variable $z_j = e^{y_j}$, we obtain the following equivalent convex program to the LHS of the above inequality.

$$\begin{aligned} \inf \quad & \log p(e^{z_1}, \dots, e^{z_m}) \\ \text{s.t.} \quad & \sum_{i\in S} z_i \geq 0 \qquad\qquad \forall S \in \binom{[m]}{n}. \end{aligned} \tag{4}$$

Let λ_S be the Lagrange dual variable associated to the constraint corresponding to the set $S \in \binom{[m]}{n}$. The Lagrangian of the above convex program is defined as follows:

$$L(\mathbf{z}, \lambda) = \log p(e^{z_1}, \dots, e^{z_m}) - \sum_{S\in\binom{[m]}{n}} \lambda_S \sum_{i\in S} z_i.$$

The Lagrange dual to (4) is

$$\sup_{\lambda\geq 0} \inf_{\mathbf{z}} L(\mathbf{z}, \lambda).$$

Since $p(\mathbf{y})$ has a non-zero coefficient for at least one of the square-free monomials, the objective of the convex program (4) is finite for any $\mathbf{z}$ and it is easy to see that the Slater conditions are satisfied. Thus the optimum value of the Lagrange dual is exactly equal to the optimum of (4).

Let $\mathbf{z}^*, \lambda^*$ be an optimum of the above program. We claim that $\sum_S \lambda_S^* = 1$. This simply follows from first order optimality conditions. If $\sum_S \lambda_S^* < 1$, then

$$\begin{aligned} L(\mathbf{z}^* - \epsilon, \lambda^*) &= \log p(e^{z_1^*-\epsilon}, \dots, e^{z_m^*-\epsilon}) - \sum_{S\in\binom{[m]}{n}} \lambda_S^* \sum_{j\in S} (z_j^* - \epsilon) \\ &= L(\mathbf{z}^*, \lambda^*) - n\cdot\epsilon + \sum_{S\in\binom{[m]}{n}} n\lambda_S^*\epsilon < L(\mathbf{z}^*, \lambda^*). \end{aligned}$$

Similarly, if $\sum_{S\in\binom{[m]}{n}} \lambda_S > 1$, $L(\mathbf{z}^* + \epsilon, \lambda^*) < L(\mathbf{z}^*, \lambda^*)$. So, λ^* is a probability distribution on sets of size n. We let $L'(\mathbf{z}, \theta) = \log p(e^{\mathbf{z}}) - \sum_{j=1}^m z_j\theta_j$ Thus, we obtain that

$$\sup_{0\leq\theta\leq 1: \sum_{j=1}^m \theta_j = n} \inf_{\mathbf{z}} L'(\mathbf{z}, \theta) \geq \sup_{\lambda\geq 0} \inf_{\mathbf{z}} L(\mathbf{z}, \lambda).$$

by setting $\theta_j^* = \sum_{S\in\binom{[m]}{n}: j\in S} \lambda_S^*$ to be the marginal probability of the element j.

We now claim that equality must hold in the above. This follows since given any $\theta \in \{0 \leq \theta \leq 1 : \sum_{j=1}^m \theta_j = n\}$, there exists a probability distribution over sets of size n such that marginal of every element is exactly θ_j. Setting λ'_S to be the probability of set $S \in \binom{[m]}{n}$, we obtain that for any $\mathbf{z}$ and θ, we have $L'(\mathbf{z}, \theta) = L(\mathbf{z}, \lambda')$. Putting this together we have

$$\inf_{\sum_{j\in S} z_j \geq 0, \forall S\in\binom{[m]}{n}} \log p(e^{\mathbf{z}}) = \sup_{0\leq\theta\leq 1: \sum_{j=1}^m \theta_j = n} \inf_{\mathbf{z}} \left(\log p(e^{\mathbf{z}}) - \sum_{j=1}^m z_j\theta_j \right).$$

Substituting e^{z_j} with y_j and taking the exponential of the objective functions we have

$$\inf_{\mathbf{y}>0: y^S \geq 1, \forall S \in \binom{[m]}{n}} p(\mathbf{y}) = \sup_{0 \leq \theta \leq 1: \sum_{j=1}^m \theta_j = n} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1} \cdots y_m^{\theta_m}}$$

as desired. ◀

Now we give the proof of proposition 4.2.

Proof of proposition 4.2. By lemma 4.3, it is enough to show that

$$\inf_{\mathbf{y}>0} \frac{p(\mathbf{y})q(\mathbf{y})}{y_1 \dots y_m} \geq (m-n)^{m-n} \sup_{0 \leq \theta \leq 1: \sum_{j=1}^m \theta_j = n} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1} \cdots y_m^{\theta_m}}.$$

Let θ be any vector such that $0 \leq \theta \leq 1$ and $\sum_i \theta_i = n$. It is enough to show for any such θ,

$$\inf_{\mathbf{y}>0} \frac{p(\mathbf{y})q(\mathbf{y})}{y_1 \dots y_m} \geq (m-n)^{m-n} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1} \cdots y_m^{\theta_m}}.$$

We prove a stronger statement,

$$\inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1} \dots y_m^{\theta_m}} \cdot \inf_{\mathbf{y}>0} \frac{q(\mathbf{y})}{y_1^{1-\theta_1} \cdot y_m^{1-\theta_m}} \geq (m-n)^{m-n} \inf_{\mathbf{y}>0} \frac{p(\mathbf{y})}{y_1^{\theta_1} \dots y_m^{\theta_m}}.$$

Equivalently, we show that

$$\inf_{\mathbf{y}>0} \frac{q(\mathbf{y})}{y_1^{1-\theta_1} \dots y_m^{1-\theta_m}} \geq (m-n)^{m-n}$$

Taking $(m-n)$-th root of both sides it is enough to show that

$$\inf_{\mathbf{y}>0} \frac{y_1 + \dots + y_m}{y_1^{\alpha_1} \dots y_m^{\alpha_m}} \geq m-n, \tag{5}$$

where $\alpha_j = \frac{1-\theta_j}{m-n}$ for all $j \in [m]$. Note that by the definition of θ, we have $0 \leq \alpha_j \leq \frac{1}{m-n}$ and that

$$\sum_i \alpha_j = \frac{m - \sum_{j=1}^m \theta_j}{m-n} = 1.$$

Therefore, the ratio on the LHS of (5) is homogeneous in $\mathbf{y}$. Thus, to prove (5), it is enough to prove the following

$$\sup_{\mathbf{y}>0: \sum_{j=1}^m y_j = 1} y_1^{\alpha_1} \dots y_m^{\alpha_m} \leq \frac{1}{m-n}. \tag{6}$$

Next, we use the weighted AM-GM inequality. We let $\alpha_1, \dots, \alpha_m$ be the weights, and recall that α_j's sum to 1. Weighted AM-GM implies that

$$\sum_{j=1}^m \alpha_j \frac{y_j}{\alpha_j} \geq \prod_{j=1}^m \left(\frac{y_j}{\alpha_j}\right)^{\alpha_j} = \prod_{j=1}^m \alpha_j^{-\alpha_j} \prod_{j=1}^m y_j^{\alpha_j}$$

Therefore,

$$\sup_{\mathbf{y}>0: \sum_{j=1}^m y_j = 1} \prod_{j=1}^m y_j^{\alpha_j} \leq \prod_{j=1}^m \alpha_j^{\alpha_j}.$$

To prove (6), it is enough to show that

$$\prod_{j=1}^{m} \alpha_j^{\alpha_j} \leq \frac{1}{m-n}.$$

Or equivalently,

$$\sum_{j=1}^{m} -\alpha_j \log \alpha_j \geq \log(m-n).$$

Since $\alpha_j \leq \frac{1}{m-n}$ and that $\sum_{j=1}^{m} \alpha_j = 1$, we have

$$\sum_{j=1}^{m} -\alpha_j \log \alpha_j \quad \geq \quad \sum_{j=1}^{m} -\alpha_j \log \frac{1}{m-n} = \log(m-n) \sum_{j=1}^{m} \alpha_j = \log(m-n),$$

as required. ◀

A Miscellaneous Lemmas

▶ **Lemma 1.1.** *For any $k \leq m$, we have*

$$\frac{m!}{m^m} \cdot \frac{(m-k)^{m-k}}{(m-k)!} \geq e^{-k}.$$

Proof. We prove by induction on k. The claim obviously holds for $k = 0$. For the induction step, it is sufficient to show that

$$\frac{1}{e} \cdot \frac{m!}{m^m} \cdot \frac{(m-k)^{m-k}}{(m-k)!} \leq \frac{m!}{m^m} \cdot \frac{(m-(k+1))^{m-(k+1)}}{(m-(k+1))!}.$$

Equivalently, it is enough to show that

$$\left(\frac{m-k}{m-(k+1)}\right)^{m-(k+1)} \leq e.$$

The above can be written as $(1 + \frac{1}{m-k-1})^{m-k-1} \leq e$. The latter follows by the fact that $1 + x \leq e^x$. ◀

Proof of corollary 2.7. Suppose that we are given a bipartite graph $G = (X, Y, E)$ where $X = \{x_1, \ldots, x_m\}$ and $Y = \{y_1, \ldots, y_n\}$. Note that m is not necessarily equal to n. We construct another graph $G' = (X', Y', E')$ such there is a one-to-$(m-k)!(n-k)!$ and onto mapping between the k-matchings of G and the perfect matchings of G'. That is each k-matching of G is mapped to a unique set of $(m-k)!(n-k)!$ perfect matchings of G', and for each perfect matching M' of G' there is a k-matching of G that has M' in its image.

Let $X' = X \cup \{x_{m+1}, \ldots, x_{m+n-k}\}$ and $Y' = Y \cup \{y_{n+1}, \ldots, y_{m+n-k}\}$. The set of edges E' is the union of E and the following edges: Connect all vertices of $X' \setminus X$ to all vertices of Y with weight 1, and connect all vertices of $Y' \setminus Y$ to all vertices of X with weight 1. Observe that for any k-matching M of G there are exactly $(m-k)!(n-k)!$ perfect matchings in G' that contain M; for any such prefect matching M', we have $M' \setminus M \subseteq E' \setminus E$. So, this mapping is one-to-$(m-k)!(n-k)!$. Furthermore, any perfect matching M' of G' has exactly k edges in E, i.e., $|M' \cap E| = k$. So, this mapping is onto.

It follows that a $1+\epsilon$ approximation to the sum of the weights of all perfect matchings of G' is a $1+\epsilon$ approximation to the sum of the weights of all k-matchings of G. ◀

Multiplayer Parallel Repetition for Expanding Games

Abstract

We investigate the value of parallel repetition of one-round games with any number of players $k \geq 2$. It has been an open question whether an analogue of Raz's Parallel Repetition Theorem holds for games with more than two players, i.e., whether the value of the repeated game decays exponentially with the number of repetitions. Verbitsky has shown, via a reduction to the density Hales-Jewett theorem, that the value of the repeated game must approach zero, as the number of repetitions increases. However, the rate of decay obtained in this way is extremely slow, and it is an open question whether the true rate is exponential as is the case for all two-player games.

Exponential decay bounds are known for several special cases of multi-player games, e.g., free games and anchored games. In this work, we identify a certain expansion property of the base game and show all games with this property satisfy an exponential decay parallel repetition bound. Free games and anchored games satisfy this expansion property, and thus our parallel repetition theorem reproduces all earlier exponential-decay bounds for multiplayer games. More generally, our parallel repetition bound applies to all multiplayer games that are *connected* in a certain sense.

We also describe a very simple game, called the GHZ game, that does *not* satisfy this connectivity property, and for which we do not know an exponential decay bound. We suspect that progress on bounding the value of this the parallel repetition of the GHZ game will lead to further progress on the general question.

1 Introduction and Results

We consider multi-player one-round games, and their parallel repetition. In a k-player game G, a referee chooses a k-tuple of questions $(x^1, \ldots, x^k)$ from some question distribution μ, and sends x^t to player t. Each player t gives an answer a^t that only depends on their question (i.e., they cannot communicate with each other). The referee evaluates the players' questions

and answers according to some predicate $V((x^1, \ldots, x^k), (a^1, \ldots, a^k))$, and the players win if this predicate evaluates to 1. The *value* of a game G, denoted by $\mathrm{val}(G)$, is the players' maximum success probability over all possible strategies they may use.

Here is a very natural operation on games, called *parallel repetition*: starting with a k-player game G, we can construct a new k-player game $G^{\otimes n}$, called the n-fold parallel repetition of G. In $G^{\otimes n}$, the referee will select n independent question tuples $(x_i^1, \ldots, x_i^t)$ from μ for each *coordinate* $i = 1, \ldots, n$, and send $(x_1^t, \ldots, x_n^t)$ to each player t. Each player has to respond with n answers, and they win this repeated game if their answers and questions for each coordinate i satisfy the original game predicate V. We call G the *base game* of the parallel repeated game $G^{\otimes n}$.

The central question we consider is how $\mathrm{val}(G^{\otimes n})$ depends on the base game G and the number of repetitions n. When G is a two-player game, the behavior of $\mathrm{val}(G^{\otimes n})$ has been extensively studied, especially due to its applications to probabilistically checkable proofs and hardness of approximation. The central result in this area is Raz's Parallel Repetition Theorem [11] (coupled with subsequent improvements due to Holenstein [8]), which states the following:

▶ **Theorem 1** (Two-player parallel repetition)**.** *Let G be a one-round two-player game with $\mathrm{val}(G) \leq 1 - \varepsilon$ for some $\varepsilon \in (0, 1)$. Then for all $n \geq 0$,*

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\varepsilon^3 n}{\log |\mathcal{A}|}\right)$$

where $|\mathcal{A}|$ is the answer alphabet size of G and $c > 0$ is a universal constant.

In other words, for *nontrivial* two-player games G (i.e., games whose value is less than 1), $\mathrm{val}(G^{\otimes n})$ decays exponentially fast in n.

What about parallel repetition for games involving more than two players? It remains an intriguing open question whether Raz's Theorem can be extended to the multiplayer case. An early result of Verbitsky [13] shows that for multiplayer games G with $\mathrm{val}(G) < 1$, the value of the repeated game $G^{\otimes n}$ must decay to 0 as n goes to infinity. However, the bound on the rate of decay is extremely weak: his result only shows that $\mathrm{val}(G^{\otimes n})$ is bounded by a function that is inversely proportional to the inverse Ackermann function of n [10]! This poor rate of decay comes from its black-box usage of the density Hales-Jewett theorem from extremal combinatorics.

So far, Verbitsky's theorem is still the only result that gives a general parallel repetition bound for all multiplayer games. Exponential-decay parallel repetition bounds (à la Raz) for multiplayer games have been proven when there are additional assumptions on the game; for example, it has long been a folklore result that multiplayer *free* games satisfy an exponential-decay parallel repetition theorem [4].[1] Recently, Bavarian, Vidick and Yuen [1] studied a variant of parallel repetition (called "anchoring") where the base game G is first modified to an equivalent game $\widetilde{G}$ before being repeated in parallel, producing $\widetilde{G}^{\otimes n}$. They proved that the value of $\widetilde{G}^{\otimes n}$ is exponentially small in n when $\mathrm{val}(G) < 1$, and otherwise $\mathrm{val}(\widetilde{G}^{\otimes n}) = 1$.[2]

We observe that the class of multiplayer games for which we have exponential-decay parallel repetition bounds (or, for that matter, any rate of decay better than inverse Ackermann!) all share a particular feature in common: when viewed as hypergraphs, the games

[1] A free game is one where each players' question is independent of all the other players'.

[2] In fact, Bavarian, Vidick and Yuen were motivated by the question of parallel repetition for *quantum* players; they showed that so-called "anchored" games satisfy quantum parallel repetition theorems.

all possess a certain "well-connectedness" property. For example, consider any two question tuples $x, \widehat{x}$ in the support of the question distribution μ of a free game. The question tuple $x = (x^1, \ldots, x^k)$ can be "locally morphed" to $\widehat{x} = (\widehat{x}^1, \ldots, \widehat{x}^k)$ via a sequence of question tuples $(\widehat{x}^1, \ldots, \widehat{x}^j, x^{j+1}, \ldots, x^k)$ for $j = 1, \ldots, k$, each of which remain in the support of μ. Furthermore, the anchoring transformations of [1] can be understood as improving the connectivity properties of the base game before repetition. In this paper, we formalize this well-connectedness property as a type of *expansion* of the base game, and show that any connected multiplayer game has exponential-decay parallel repetition bounds. We associate with every base game G, a related graph H_G (see Definition 2) and show that if H_G is connected, then the value of the repeated game, $\mathrm{val}(G^{\otimes n})$, goes down exponentially in n, more precisely, for sufficiently large n,

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\varepsilon^5\lambda^2 n}{\log|\mathcal{A}|}\right),$$

where λ is the spectral gap of the Laplacian of the graph H_G and c is some universal constant (see Theorem 5 for an exact statement of the result). Thus, if the graph H_G is connected (i.e., $\lambda > 0$), we have an exponential decay in n. In the case of games G, wherein the associated graph H_G is not only connected but also expanding (i.e., λ is a constant), as is the case with free games, and anchored games, the rate of exponential decay is a function of alphabet size $|\mathcal{A}|$ of the base game G as in Raz's theorem.

Why care about games with more than two players?

The notion of a game is an extremely basic notion, and it's use is pervasive in communication complexity, probabilistically checkable proofs (PCPs), etc. Whereas two-player games are already quite powerful and give us a lot, many problems are inherently higher-dimensional, i.e., would more naturally be cast as games with more than two players. The reason this is not commonly done is because we don't know how to analyze these creatures. For example, constraint-satisfaction-problems with arity k are naturally cast as a k-player game. They can be reduced to a two-player game in the same way that a hypergraph can be converted to a graph, but this reduction in dimensionality might be lossy. Indeed, it is empirically true that PCPs with 3 or more queries are much more powerful than 2-query PCPs, but what is the reason for this?

Furthermore, this sudden jump in difficulty in going from two-player problems to three or more players is encountered also when studying multiparty communication complexity, and seemingly because of the same technique limitations. While direct sum and direct product theorems are known for two-party communication complexity, nothing is known for the multiparty setting (in the so-called *number-on-forehead* model), and in fact making progress on this is connected to hard problems in circuit complexity.

We feel that the study of games with three or more players is a very important component in understanding such questions.

1.1 Notation

We establish some notational conventions, before stating our results formally.

For a k-player game G, we will let $\mathcal{X}^t$ denote the question alphabet for player t, and $\mathcal{X} = \mathcal{X}^1 \times \mathcal{X}^2 \times \cdots \times \mathcal{X}^k$ is the question alphabet for all the players together, underlying the question distribution μ. We will let $\mathcal{A}^t$ denote the answer alphabet for player t, and $\mathcal{A} = \mathcal{A}^1 \times \cdots \times \mathcal{A}^k$ to denote the answer alphabet for all the players together.

We will use superscripts to denote the players, and subscripts to denote the coordinate in parallel repetition. For example, x_i^t denotes the question received by player t in coordinate i. A single variable x can denote questions to the players in some coordinate clear from context, or a single coordinate game. We use x^{-t} to denote the questions to all but the t-th player in a single coordinate. When talking about multiple coordinates, we will use subscripts: x_{-i} denotes the questions to players in all but the i'th coordinate, and x_{-i}^t denotes the all questions to player t in the repeated game except for the i'th coordinate. To denote the question to player t in all coordinates, we use $x_{[n]}^t$.

We largely adopt the notational conventions from [8] for probability distributions. We let capital letters denote random variables and lower case letters denote specific samples. We use P_X to denote the probability distribution of random variable X, and $\mathsf{P}_X(x)$ to denote the probability that $X = x$ for some value x. For multiple random variables, e.g., X, Y, Z, $\mathsf{P}_{XYZ}(x, y, z)$ denotes their joint distribution with respect to some probability space understood from context.

We use $\mathsf{P}_{Y|X=x}(y)$ to denote the conditional distribution $\mathsf{P}_{YX}(y, x)/\mathsf{P}_X(x)$, which is defined when $\mathsf{P}_X(x) > 0$. When conditioning on many variables, we usually use the shorthand $\mathsf{P}_{X|y,z}$ to denote the distribution $\mathsf{P}_{X|Y=y,Z=z}$. For an event W we let $\mathsf{P}_{XY|W}$ denote the distribution conditioned on W. We use the notation $\mathbb{E}_X f(x)$ and $\mathbb{E}_{\mathsf{P}_X} f(x)$ to denote the expectation $\sum_x \mathsf{P}_X(x) f(x)$.

Let P_{X_0} be a distribution over $\mathcal{X}$ and $\mathsf{P}_{X_1,Y}$ a joint distribution over $\mathcal{X} \times \mathcal{Y}$. Suppose for every x in the support of P_{X_0}, the conditional distribution $\mathsf{P}_{Y|X_1=x}$ defined over $\mathcal{Y}$ is well-defined. We then define the distribution $\mathsf{P}_{X_0}\mathsf{P}_{Y|X_1}$ over $\mathcal{X} \times \mathcal{Y}$ as

$$(\mathsf{P}_{X_0}\mathsf{P}_{Y|X_1})(x, y) := \mathsf{P}_{X_0}(x) \cdot \mathsf{P}_{Y|X_1=x}(y).$$

For two random variables X_0 and X_1 over the same set $\mathcal{X}$, we use

$$\|\mathsf{P}_{X_0} - \mathsf{P}_{X_1}\| := \frac{1}{2} \sum_{x \in \mathcal{X}} |\mathsf{P}_{X_0}(x) - \mathsf{P}_{X_1}(x)|,$$

to denote the total variation distance between P_{X_0} and P_{X_1}.

1.2 Our results

To define our class of connected and expanding games, we need the following notion of the $(k-1)$-*connection graph* of a game G. This graph, denoted H_G, has a vertex for every k-tuple of questions, and two k-tuples are connected by an edge if they agree on $(k-1)$ coordinates. A game is $(k-1)$-connected iff H_G is connected.

To further define our notion of expansion for a k-player game we need to take the weights of G into account when defining H_G. For this it is instructive to think of an intermediate bipartite graph $B_G = (\mathcal{X}', \mathcal{X}, E)$ as follows. The right hand vertices is simply $\mathcal{X}$, the set of all k-tuples of questions, and we endow these vertices with weights as given by G. The left hand vertices consists of all punctured k-tuples, which are k-tuples of questions where exactly one of the entries is replaced by a special $\star$ symbol. Connect each k-tuple of questions to all of the k ways to make it into a punctured k-tuple. Now, consider the distribution on punctured tuples obtained by selecting a random k-tuple from $\mathcal{X}$ according to the game distribution, and then puncturing it in a random location. The graph H_G is defined by selecting a random punctured tuple according to this distribution, and then selecting independently two k-tuples conditioned on this puncturing. Note that each completion is distributed exactly according to the original game distribution.

We now move to a completely explicit description consistent with the above. In what follows, $\mathsf{P}_X(x)$ denotes the probability of question tuple x under the question distribution μ, $\mathsf{P}_{X^t}(x^t)$ denotes the marginal probability of player t's question, and $P_{X^t|X^{-t}=x^{-t}}(x^t)$ denotes the same probability, conditioned on the other players having received x^{-t}.

▶ **Definition 2** ($(k-1)$-connection graph of G)**.** Let $G = (\mu, V)$ be a k-player game with question set $\mathcal{X} = \mathcal{X}^1 \times \cdots \mathcal{X}^k$. The **$(k-1)$-connection graph of G** is the weighted graph $H_G = (V_H, \rho)$ with vertex set $V_H = \mathcal{X}$ and weight function $\rho : \mathcal{X} \times \mathcal{X} \to [0,1]$, defined as follows: for every $x, x' \in \mathcal{X}$,

$$\rho(x,x') = \begin{cases} \frac{1}{k}\,\mathsf{P}_X(x)\left[\sum_{t\in[k]}\mathsf{P}_{X^t|x^{-t}}(x^t)\right] & \text{if } x = x', \\ \frac{1}{k}\,\mathsf{P}_{X^{-t}}(x^{-t})\cdot\mathsf{P}_{X^t|x^{-t}}(x^t)\cdot\mathsf{P}_{X^t|x^{-t}}(x'^t) & \text{if } \exists t \text{ s.t. } x^{-t} = x'^{-t},\ x^t \neq x'^t, \\ 0 & \text{otherwise.} \end{cases}$$

The weight function $\rho(x,x')$ can be viewed as the probability of generating the pair (x,x') according to the following random process: first, $x \in \mathcal{X}$ is sampled from the distribution P_X. Then, a coordinate $t \in [k]$ is chosen uniformly at random, and x' is sampled from the conditional distribution $\mathsf{P}_{X|x^{-t}}$ (that is, the distribution μ conditioned on x^{-t}).

Observe that ρ is symmetric, i.e., $\rho(x,x') = \rho(x',x)$. Furthermore, note that the weight on any given vertex is exactly:

$$\begin{aligned}\rho(x,\cdot) &= \sum_{x'}\rho(x,x') = \\ &= \mathsf{P}_X(x)\cdot\frac{1}{k}\sum_{t\in[k]}\mathsf{P}_{X^t|x^{-t}}(x^t) + \mathsf{P}_X(x)\cdot\frac{1}{k}\sum_{t\in[k]}\sum_{x'^t\neq x^t}\mathsf{P}_{X^t|x^{-t}}(x'^t) \\ &= \mathsf{P}_X(x).\end{aligned}$$

Therefore $\rho(\cdot,\cdot)$ is a probability distribution over $\mathcal{X}\times\mathcal{X}$.

▶ Remark. Henceforth, when we talk about graph properties such as diameter, connectedness or expansion of H_G, we will do so only with respect to the vertices having non-zero weight.

We now recall the definition of a graph with a weight function ρ being a spectral expander:

▶ **Definition 3** (Normalized Laplacian)**.** Let H be a weighted graph where $\rho(u,v) \le 1$ is the weight between vertices u and v. The normalized Laplacian $L_H \in \mathbb{R}^{|V|\times|V|}$ of H is defined to be

$$(L_H)_{u,v} = \begin{cases} 1 - \frac{\rho(u,v)}{\rho(v)} & \text{if } u = v \text{ and } \rho(v) \neq 0 \\ -\frac{\rho(u,v)}{\sqrt{\rho(u)\rho(v)}} & \text{if } \rho(u),\rho(v) \neq 0 \\ 0 & \text{otherwise} \end{cases}$$

where $\rho(u) = \sum_v \rho(u,v)$ and $\rho(v) = \sum_u \rho(u,v)$.

It is well-known that the second smallest eigenvalue of H is given by the following variational formula: for all $r \in \mathbb{N}$,

$$\lambda(H) = \inf_g \frac{\sum_{u,v}\rho(u,v)\|g(u)-g(v)\|^2}{\sum_u \rho(u)\|g(u)-\overline{g}\|^2} \tag{1}$$

where the infimum is over all vector-valued functions $g : V(H) \to \mathbb{R}^r$ defined on the vertices of H, and $\overline{g}$ is a vector in $\mathbb{R}^r$ where for each $i \in [r]$, $\overline{g}_i = \sum_u \rho(u) g(u)_i$.

▶ **Definition 4** (Expander graph). Let $\lambda \in (0,1)$. A graph H is a λ-expander if $\lambda(H) \geq \lambda$.

Our main result is an exponential-decay parallel repetition bound for multiplayer games whose $(k-1)$-connection graph is expanding:

▶ **Theorem 5** (Main theorem). *Let $\epsilon, \lambda \in (0,1)$. Let G be a k-player game with $\mathrm{val}(G) \leq 1-\varepsilon$. If the $(k-1)$-connection graph H_G is a λ-expander, then we have, for all $n \geq \frac{\log 4/\varepsilon}{\varepsilon^5 \lambda^2}$:*

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\varepsilon^5\lambda^2 n}{\log|\mathcal{A}|}\right)$$

where $\mathcal{A} = \mathcal{A}^1 \times \cdots \times \mathcal{A}^k$ is the answer alphabet in G, and c is a universal constant.

By applying our main theorem to free games and anchored games, we recover existing exponential-decay parallel repetition results for multiplayer games [4, 1]. We also get an exponential-decay lower bound for *connected games* – games whose $(k-1)$-connection graph is connected. We record these consequences in the following corollary:

▶ **Corollary 6.** *Let G be a k-player game with $\mathrm{val}(G) \leq 1-\varepsilon$, and let $n \geq \frac{\log 4/\varepsilon}{\varepsilon^5 \lambda^2}$. If G is:*

1. *Free, i.e., $\mu(x) = \mu^1(x^1) \times \cdots \times \mu^k(x^k)$, then*

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\,\varepsilon^5\,n}{k^2 \log|\mathcal{A}|}\right).$$

2. *α-Anchored (see Definition 12, and [1] for more details), then*

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\,\alpha^{2k}\,\varepsilon^5\,n}{64\ k^2 \log|\mathcal{A}|}\right).$$

3. *Connected, i.e., the $(k-1)$-connection graph is connected, then*

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\,\rho_{min}^2\,\varepsilon^5\,n}{\log|\mathcal{A}|}\right)$$

   where $\rho_{min} = \min_{u,v:\rho(u,v)>0} \rho(u,v)$. In particular, if the game G is such that μ is the uniform distribution over some set $S \subseteq \mathcal{X}$, then $\rho_{min} \geq (k|S|^2)^{-1}$.

where c is a universal constant.

The proof of Corollary 6 can be found in Appendix A.

Observe that our proof of exponential decay for games whose corresponding $(k-1)$-connection graph is connected proves a rate of exponential decay that is dependent on the size of the the base game G. It is conceivable that this rate of decay can be further improved to depend only on the alphabet size $|\mathcal{A}|$ of the base game and be independent of the size of the base game (as is the case in Raz's theorem for 2 player games). For games whose corresponding $(k-1)$-connection graph is expanding (as is the case with free games and anchoring games), we obtain a rate of exponential decay which is a function of only the base game's alphabet size.

▶ Remark. For simplicity, we state Theorem 5 assuming the base game has a connected $(k-1)$-connection graph. It is easy to check (from the proof of Theorem 5) that it also extends to games that are disjoint union of games each of which has a connected $(k-1)$-connection graph. By disjoint union we mean that each question occurs only in one of the components. For $k = 2$, this captures all possible games since every game is a union of

disjoint games whose ($k-1=2-1=1$)-connection graphs are connected). We note that for 2-player games, there are alternate proof techniques [11, 8] using correlated sampling which prove even better rate of exponential decay (our proof of Theorem 5 does not use correlated sampling). In contrast, for $k > 2$, there are many games that are not captured by our theorem. We will see below an example of such a $k = 3$-player game called the GHZ game.

A comment about fortified games

Bavarian, Vidick and Yuen also proved a parallel repetition bound for a special class of multiplayer games *fortified games* [2] (a class of games introduced by Moshkovitz [9]). However, we do not consider this a "true" exponential-decay parallel repetition bound, because it does not establish a decay bound of the form $\mathrm{val}(G^{\otimes n}) \leq \exp(-\beta n)$ for some constant β that depends on the game G, but is independent of n. Instead, it proves a decay bound that is exponential only for a small number of repetitions (depending on the base game). After this small number of repetitions, there are no guarantees about any further value decay (other than that promised by Verbitsky's theorem). Because we are interested in the asymptotic behavior of an n-repeated multiplayer game as n goes to infinity, we do not consider the parallel repetition of fortified games here.

A disconnected three-player game

It may seem that, given Corollary 6, we have established a general exponential-decay parallel repetition bound for *all* multiplayer games, albeit with some slightly annoying dependency on a quantity related to the minimum probability of any question from μ. Unfortunately, this is far from the case.

Here is a simple three-player game called the *GHZ game* whose parallel repetition resists analysis; the best decay bound we have comes from Verbitsky's theorem [13]. The GHZ game is a three-player game[3] where the referee samples a question triple (x, y, z) uniformly at random from $\{(1,0,0),(0,1,0),(0,0,1),(1,1,1)\}$, and sends each bit of the triple to the corresponding player. The players respond with bits a, b, c respectively, and they win iff $x \wedge y \wedge z = a \oplus b \oplus c$. It is easy to see that $\mathrm{val}(GHZ) = 3/4$ (achieved by the strategy where all players always output "0"). However, the best general bound we have on $\mathrm{val}(GHZ^{\otimes n})$ is the weak inverse-Ackermann decay given by Verbitsky's theorem.

Our main theorem does not apply because the $(k-1)$-connection graph H_{GHZ} of the GHZ game is actually *disconnected*; no two question triples are connected via a single coordinate change. One necessary criterion for the $(k-1)$-connection graph to be connected is that, after fixing any subset of $(k-1)$ players' questions, the remaining player's question is yet undetermined. On the other hand, the players' questions in the GHZ game satisfy a linear relation (i.e. $x \oplus y \oplus z = 1$), and thus fixing two players' questions also fixes the third.

We believe that the strong correlations present in the GHZ question distribution represent the "hardest instance" of the multiplayer parallel repetition problem. Existing techniques from the two-player case (which we leverage in this paper) appear to be incapable of analyzing games with question distributions with such strong correlations. Thus we explicitly

[3] The GHZ game comes from the study of non-locality in quantum physics; when the players use classical strategies, their maximum success probability is $\mathrm{val}(G) = 3/4$, but using quantum entanglement, the GHZ can be won with certainty [6].

raise the open question of proving an exponential-decay parallel repetition bound for the GHZ game:

▶ **Conjecture 7** (GHZ parallel repetition)**.** There exists a constant $\beta > 0$ such that for all n,

$$\mathrm{val}(GHZ^{\otimes n}) \leq \exp(-\beta n).$$

Finally, we remark that this challenge of handling strongly correlated question distributions is reminiscent of the challenge of proving *direct sum* theorems for multiparty communication complexity in the *Number-on-Forehead* (NOF) model. There, each player sees every players' inputs but their own, so fixing $(k-1)$ out of k players' inputs will fix the remaining player's inputs. Proving direct sum results in NOF communication complexity has resisted progress for reasons that appear to be related to the multiplayer parallel repetition problem.

2 Proof of Theorem 5

2.1 Proof outline

We first give a brief overview of the information-theoretic approach to proving two-player parallel repetition as in [11, 8], and explain the technical barrier to extending the proof to three or players. We then will describe how we circumvent this technical barrier.

Essentially all known proofs of parallel repetition proceed via reduction, showing how a "too good" strategy for the repeated game G^n can be "rounded" into a strategy for G with success probability strictly greater than $\mathrm{val}(G)$, yielding a contradiction.

Let $\mathcal{S}^n$ be a strategy for G^n that has a high success probability. Either by induction or via a probabilistic argument one can identify a set of coordinates S and an index i such that $\Pr(\text{Players win round } i | W_S) > \mathrm{val}(G) + \delta$, where W is the event that the players' answers satisfy the predicate V in all instances of G indexed by S. Given a pair of questions (x, y) in G the strategy $\mathcal{S}$ embeds them in the i-th coordinate of a n-tuple of questions

$$x_{[n]}y_{[n]} = \begin{pmatrix} x_1, x_2, \ldots, x_{i-1}, & x & , x_{i+1}, \ldots, x_n \\ y_1, y_2, \ldots, y_{i-1}, & y & , y_{i+1}, \ldots, y_n \end{pmatrix}$$

that is distributed according to $\mathsf{P}_{X_{[n]}Y_{[n]}|X_i=x,Y_i=y,W}$. The players then simulate $\mathcal{S}^n$ on $x_{[n]}$ and $y_{[n]}$ respectively to obtain answers $(a_1, \ldots, a_n)$ and $(b_1, \ldots, b_n)$, and return (a_i, b_i) as their answers in G. The single-shot strategy $\mathcal{S}$ succeeds with probability precisely $\Pr(\text{Win } i | W_S)$ in G, yielding the desired contradiction.

As $\mathcal{S}^n$ need not be a product strategy, conditioning on W_S may introduce correlations that make $\mathsf{P}_{X_{[n]}Y_{[n]}|X_i=x,Y_i=y,W_S}$ impossible to sample exactly. A key insight in Raz' proof of parallel repetition is that it is still possible for the players to *approximately* sample from this distribution. For this, we introduce a *dependency-breaking variable* R with the following properties:

(a) Given $r \sim \mathsf{P}_R$ the players can locally sample $x_{[n]}$ and $y_{[n]}$ according to $\mathsf{P}_{X_{[n]}Y_{[n]}|X_i=x,Y_i=y,W_S}$,

(b) The players can jointly sample from P_R using shared randomness.

In [8] R is defined so that a sample r fixes at least one of $\{x_{i'}, y_{i'}\}$ for each $i' \neq i$. It can then be shown that conditioned on x, R is nearly (though not exactly) independent of y, and vice-versa. In other words,

$$\mathsf{P}_{R|X_i=x,W_S} \approx \mathsf{P}_{R|X_i=x,Y_i=y,W_S} \approx \mathsf{P}_{R|Y_i=y,W_S} \tag{2}$$

where "≈" denotes closeness in statistical distance. Eq. (2) suffices to guarantee that the players can *approximately* sample the same r from $\mathsf{P}_{R|X_i=x,Y_i=y,W_S}$ with high probability, achieving point (b) above. This sampling is accomplished through a technique called *correlated sampling*.

This argument relies heavily on the assumption that there are only two players who employ a deterministic strategy. With more than two players, it is not known how to design an appropriate dependency-breaking variable R that satisfies *both* items (a) and (b) above: in order to be jointly sampleable, R needs to fix as few inputs as possible; in particular, no single player should require knowledge of the other player's questions to sample R. On the other hand, in order to allow players to locally sample their inputs conditioned on R, the variable needs to fix as many inputs as possible. These two requirements turn out to be in direct conflict as soon as there are more than two players, and a straightforward generalization of the two-player version of the dependency-breaking variable cannot be "correlatedly sampled" by all players, unless every player has knowledge of the question received by some other player.

We avoid this roadblock by proving in Section 2.4 that if the $(k-1)$-connected graph H_G is connected, then the players can avoid correlated sampling altogether. In fact, they can sample an appropriate dependency-breaking variable from a *global* distribution that does not depend on any player's question.

2.2 Following Raz-Holenstein

Fix a k-player game $G = (\mu, V)$, with answer alphabet $\mathcal{A} = \mathcal{A}_1 \times \cdots \times \mathcal{A}_k$ and $\mathrm{val}(G) = 1-\varepsilon$. Consider the n-fold parallel repetition $G^{\otimes n}$ and consider an optimal strategy $\{f^t : (\mathcal{X}^t)^{\otimes n} \to (\mathcal{A}^t)^{\otimes n}\}_{t\in[k]}$ for the k players.

For $i \in [n]$, let W_i denote the event that the players win coordinate i using this optimal strategy. Let $W = W_1 \wedge \cdots \wedge W_n$ denote the event that the players win all coordinates. For a set $S \subseteq [n]$, let $W_S = \wedge_{i\in S} W_i$. In the following, all probabilities are with respect to this optimal strategy.

▶ **Proposition 8.** *Let $\varepsilon > 0$. Suppose that $\log 1/\Pr(W) \le \varepsilon n/16 - \log 4/\varepsilon$. Then there exists a set $S \subseteq [n]$ of size at most $t = \frac{8}{\varepsilon}(\log 4/\varepsilon + \log 1/\mathsf{P}(W))$ such that*

$$\mathsf{P}_{i\notin S}(\neg W_i | W_S) \le \varepsilon/2$$

where i is chosen uniformly from $[n] - S$.

Proof. Set $\delta = \varepsilon/8$. Let $W_{>1-\delta}$ denote the event that the players won more than $(1-\delta)n$ rounds. To show existence of such a set S, we will show that $\mathbb{E}_S \mathsf{P}(\neg W_i | W_S) \le \varepsilon/2$, where S is a (multi)set of t independently chosen indices in $[n]$. This implies that there exists a particular set S such that $\mathsf{P}(\neg W_i | W_S) \le \varepsilon/2$, which concludes the claim.

First we write, for a fixed S,

$$\begin{aligned}\mathsf{P}(\neg W_i | W_S) = \Pr(\neg W_i | W_S, W_{>1-\delta})\mathsf{P}(W_{>1-\delta}|W_S) \\ + \mathsf{P}(\neg W_i | W_S, \neg W_{>1-\delta})\mathsf{P}(\neg W_{>1-\delta}|W_S).\end{aligned}$$

Observe that $\mathsf{P}(\neg W_i | W_S \wedge W_{>1-\delta})$ is the probability that, conditioned on winning all rounds in S, the randomly selected coordinate $i \in [n] - S$ happens to be one of the (at most) δn lost rounds. This is at most $\delta n/(n-t) \le \varepsilon/4$. Now observe that

$$\mathop{\mathbb{E}}_S \mathsf{P}(\neg W_{>1-\delta} | W_S) \le \mathop{\mathbb{E}}_S \frac{\mathsf{P}(W_S | \neg W_{>1-\delta})}{\mathsf{P}(W_S)} \le \frac{1}{\mathsf{P}(W)}(1-\delta)^t \le \varepsilon/4$$

where for the second inequality we used the fact that $\mathsf{P}(W_S) \ge \mathsf{P}(W)$. ◀

For the remainder of this proof we will fix a set S as given by Proposition 8. By renaming coordinates, we will assume without loss of generality that S is the last t coordinates of $[n]$. We will let $m = n - |S|$. We will refer to the games indexed by set S as the S-games.

2.3 Dependency-breaking variables

We define the k-player analogue of the dependency-breaking variable R that is used so crucially in information-theoretic proofs of parallel repetition [11, 8, 3]. R will consist of a variable Ω, which fixes the questions for the S-games, and at least $(k-1)$-of-k questions in every other coordinate, and a variable $Z = (A_S)$, which fixes the answers of S-games. More formally, $\Omega = (\Omega_1, \ldots, \Omega_m, X_S)$, where X_S are fixed questions for the S-games. Each $\Omega_i = (D_i, M_i)$, for $i \in \overline{S}$, where D_i is a uniformly random value in $[k]$, and

$$M_i = X_i^{-t} \quad \text{if } D_i = t$$

In other words, D_i specifies which player's question to omit; the other $(k-1)$ players are fixed.

For $i \notin S$, we let Ω_{-i} denote Ω with Ω_i omitted. We let $R_{-i} := (\Omega_{-i}, A_S)$. R_i will refer to Ω_i. We will use lowercase letters to denote instantiations of these random variables: e.g., r_{-i}, x_i^t refer to specific values of R_{-i}, X_i^t respectively.

▶ **Claim 9.** *Conditioned on R, $\{X_{[n]}^t\}_{t\in[k]}$ are independent.*

In the following, P_I denotes the distribution of a uniformly random $i \in [m]$, and "$\mathsf{P} \approx_\delta \mathsf{Q}$" indicates that the probability distributions P and Q are δ-close in statistical distance. We will fix

$$\delta = \frac{1}{m}\left(\log \frac{1}{\mathsf{P}(W_S)} + |S| \log |\mathcal{A}|\right).$$

The next lemma states that for an average i, if we sample questions $x_i, \widehat{x}_i$ from the joint probability distribution $\rho(x_i, \widehat{x}_i)$, the distributions of the corresponding dependency-breaking variables will be close.

▶ **Lemma 10.**

$$\frac{1}{m}\sum_i \sum_{x_i, \widehat{x_i} \in \mathcal{X}} \rho(x_i, \widehat{x}_i) \left\| \mathsf{P}_{R_{-i}|x_i, W_S} - \mathsf{P}_{R_{-i}|\widehat{x}_i, W_S} \right\|_1 \leq O(\sqrt{\delta})$$

where $\rho(\cdot,\cdot)$ is the weight function of the $(k-1)$-connection graph H_G.

Proof. First, we establish the following: for all $t \in [k]$, we have

$$\mathop{\mathbb{E}}_i \sum_{x_i^{-t}, x_i^t, \widehat{x}_i^t} \mathsf{P}_{X_i^{-t}}(x_i^{-t})\, \mathsf{P}_{X_i^t|x_i^{-t}}(x_i^t) \cdot \mathsf{P}_{\widehat{X}_i^t|x_i^{-t}}(\widehat{x}_i^t) \left\| \mathsf{P}_{R_{-i}|x_i, W_S} - \mathsf{P}_{R_{-i}|\widehat{x}_i, W_S} \right\|_1 \leq O(\sqrt{\delta}) \tag{3}$$

where we use the shorthand $x_i := x_i^{-t} x_i^t$ and $\widehat{x}_i := x_i^{-t} \widehat{x}_i^t$. This follows from the same arguments found in [8, 3]; for each player t, we can treat the other $(k-1)$ players as one "meta player", and apply the two-player analysis to obtain (3).

Observe that when $x_i^t \neq \widehat{x}_i^t$, we have

$$\mathsf{P}_{X_i^{-t}}(x_i^{-t}) \cdot \mathsf{P}_{X_i^t|x_i^{-t}}(x_i^t) \cdot \mathsf{P}_{\widehat{X}_i^t|x_i^{-t}}(\widehat{x}_i^t) = k\rho(x_i, \widehat{x}_i).$$

On the other hand, when $x_i^t = \widehat{x}_i^t$, $x_i = \widehat{x}_i$ so therefore $\left\|\mathsf{P}_{R_{-i}|x_i,W_S} - \mathsf{P}_{R_{-i}|\widehat{x}_i,W_S}\right\|_1 = 0$. Furthermore, for x_i and $\widehat{x}_i$ that differ in more than 1 coordinate, we have $\rho(x_i,\widehat{x}_i) = 0$, and for every $x_i, \widehat{x}_i$ such that $\rho(x_i,\widehat{x}_i) \neq 0$, there exists a unique $t \in [k]$ such that $x_i^t \neq \widehat{x}_i^t$. Thus we can bound for every i:

$$\sum_{x_i,\widehat{x}_i \in \mathcal{X}} \rho(x_i,\widehat{x}_i) \left\|\mathsf{P}_{R_{-i}|x_i,W_S} - \mathsf{P}_{R_{-i}|\widehat{x}_i,W_S}\right\|_1$$
$$= \frac{1}{k} \sum_{t\in[k]} \sum_{x_i^{-t},x_i^t,\widehat{x}_i^t} \mathsf{P}_{X_i^{-t}}(x_i^{-t}) \cdot \mathsf{P}_{X_i^t|x_i^{-t}}(x_i^t) \cdot \mathsf{P}_{\widehat{X}_i^t|x_i^{-t}}(\widehat{x}_i^t) \left\|\mathsf{P}_{R_{-i}|x_i,W_S} - \mathsf{P}_{R_{-i}|\widehat{x}_i,W_S}\right\|_1 .$$

Averaging over i and using (3), we obtain the statement of the lemma. ◀

2.4 Avoiding correlated sampling using expansion

At this point, ideally, every player would like to sample from $R_{-i}|x_i, W_S$. Lemma 10 establishes that $R_{-i}|x_i, W_S$ is close to $R_{-i}|x_i^{-t}, W_S$ for each $t \in [k]$. None of the players alone has knowledge of x_i^{-t}, however. We will show now that nevertheless, there is a *global* distribution known to all the players, from which the players can approximately sample $R_{-i}|x_i, W_S$.

▶ **Lemma 11.** *For all $i \in [m]$ there exists a distribution $\widetilde{\mathsf{P}}_{R_{-i}}$ over R_{-i} such that*

$$\frac{1}{m}\sum_i \sum_x \rho(x) \|\mathsf{P}_{R_{-i}|x,W_S} - \widetilde{\mathsf{P}}_{R_{-i}}\|_1 \leq O\left(\frac{\delta^{1/4}}{\sqrt{\lambda}}\right).$$

Proof. For each i, define the vector-valued function $g_i : \mathcal{X} \to \mathbb{R}^{R_{-i}}$ as follows: for all $x \in \mathcal{X}$,[4]

$$g_i(x) = \sqrt{\mathsf{P}_{R_{-i}|x,W_S}}$$

where $\sqrt{\mathsf{P}_{R_{-i}|x,W_S}}$ denotes the entry-wise square root of the probability distribution $\mathsf{P}_{R_{-i}|x,W_S}$, viewed as a vector. In other words, the entries of $g_i(x)$ are indexed by different values r_{-i} of the random variable R_{-i}. Thus, g_i is a unit vector in the ℓ_2 norm.

For any i and any $x, \widehat{x} \in \mathcal{X}$, the quantity $\|g_i(x) - g_i(\widehat{x})\|^2$ is simply the square of the *Hellinger distance* between $\mathsf{P}_{R_{-i}|x,W_S}$ and $\mathsf{P}_{R_{-i}|\widehat{x},W_S}$, which can be related to their statistical distance by

$$\|g_i(x) - g_i(\widehat{x})\|^2 \leq \|\mathsf{P}_{R_{-i}|x,W_S} - \mathsf{P}_{R_{-i}|\widehat{x},W_S}\|_1.$$

By Lemma 10, we can average the above inequality over all i and choosing $x, \widehat{x}$ according to the probability distribution $\rho(x,x')$, we get

$$\frac{1}{m}\sum_i \sum_{x,\widehat{x}} \rho(x,\widehat{x}) \|g_i(x) - g_i(\widehat{x})\|^2 \leq \mathop{\mathbb{E}}_i \sum_{x,\widehat{x}} \rho(x,\widehat{x}) \|\mathsf{P}_{R_{-i}|x,W_S} - \mathsf{P}_{R_{-i}|\widehat{x},W_S}\|_1 \leq O(\sqrt{\delta})$$

But now we can leverage Equation (1). For every i, define the vector $\overline{g}_i = \sum_x \mathsf{P}_X(x) g_i(x)$. This is not necessarily a unit vector, but we have the relation

$$\frac{1}{m}\sum_i \sum_x \rho(x) \|g_i(x) - \overline{g}_i\|^2 \leq \frac{1}{\lambda m} \sum_i \sum_{x,\widehat{x}} \rho(x,\widehat{x}) \ \|g_i(x) - g_i(\widehat{x})\|^2 \leq O\left(\frac{\sqrt{\delta}}{\lambda}\right).$$

[4] Here, when we write x, we are implicitly mean x_i; we drop the subscript i for notational convenience.

If $O(\sqrt{\delta}/\lambda)$ is small, then this implies that on average, the vectors $g_i(x)$ are all close to a fixed state $\overline{g}_i$. Since $g_i(x)$ are all unit vectors, this implies that $\overline{g}_i$ is close to a unit vector. By increasing the error by a constant factor, we can assume that $\overline{g}_i$ is in fact a unit vector. Thus we can construct the probability distribution

$$\widetilde{\mathsf{P}}_{R_{-i}}(r_{-i}) = \overline{g}_i(r_{-i})^2.$$

Using that the statistical distance is at most (up to constant factors) the square root of the Hellinger distance, we get that

$$\frac{1}{m}\sum_i \sum_x \rho(x) \|\mathsf{P}_{R_{-i}|x,W_S} - \widetilde{\mathsf{P}}_{R_{-i}}\|_1 \leq O(\delta^{1/4}\lambda^{-1/2}). \qquad \blacktriangleleft$$

2.5 Finishing the proof

Let $\{f^t\}$ be an optimal strategy for the game $G^{\otimes n}$. If $\mathsf{P}(W) \leq \frac{4}{\varepsilon}2^{-\varepsilon n/16}$, then we are done. Otherwise, suppose $\log 1/\mathsf{P}(W) \leq \varepsilon n/16 - \log 4/\varepsilon$. Let the subset S be as given by Proposition 8, and assume the coordinates are numbered so that S is the last $|S|$ coordinates of $[n]$. For all $i \in [m]$, let $\widetilde{\mathsf{P}}_{R_{-i}}$ be as given by Lemma 11. Consider the following single-shot strategy by the players, where x is drawn from μ and x^t is given to player t:

1. Using shared randomness, the players sample an $i \in [m]$ uniformly at random, and sample r_{-i} from $\widetilde{\mathsf{P}}_{R_{-i}}$. Each player t then sets x_i^t to be their "true" question x^t they received from the referee.
2. Using private randomness, each player t samples x_{-i}^t from $\mathsf{P}_{X^t_{-i}|x_i^t,r_{-i}}$. That is, each player samples questions for the n coordinates that come from the repeated game, conditioned on their own true input x_i^t and the dependency-breaking variable r_{-i}.
3. Player t outputs the i'th component of the answer vector $f^t(x^t_{[n]})$.

Lemma 11 implies that after the first step, the sample r_{-i} each player possesses will be, up to statistical error $O(\delta^{1/4}/\sqrt{\lambda})$, distributed according to $\mathsf{P}_{R_{-i}|x,W_S}$ (on average over i and x). Then, by Claim 9, the joint distribution of the random variables $\{X^t_{[n]}\}$ that the players have sampled is

$$\mathsf{P}_{X^1_{[n]}|x_i^t,r_{-i}} \times \cdots \times \mathsf{P}_{X^k_{[n]}|x_i^t,r_{-i}} = \mathsf{P}_{X_{[n]}|x_i,r_{-i}}.$$

Thus, conditioned on r_{-i} and x_i, the distribution of their answers a_i will be distributed according to $\mathsf{P}_{A_i|x_i,r_{-i}}$. Averaging over i, x_i, and r_{-i}, we get that their answers are $O(\delta^{1/4}/\sqrt{\lambda})$-close to being distributed according to

$$\mathsf{P}_I \cdot \mathsf{P}_{X_i} \cdot \mathsf{P}_{R_{-i}|X_i,W_S} \cdot \mathsf{P}_{A_i|X_i,R_{-i}}$$

where P_I stands for the uniform distribution over $i \in [m]$. We also have that, on average i, $\mathsf{P}_{X_i|W_S}$ is $O(\sqrt{\delta})$-close in statistical distance to P_{X_i}. Thus their answers are $O(\delta^{1/4}/\sqrt{\lambda}) + O(\sqrt{\delta})$ close to being distributed as

$$\mathsf{P}_I \cdot \mathsf{P}_{A_i|W_S}.$$

Thus by Proposition 8, the probability that the players win G is at least

$$1 - \varepsilon/2 - \left(O(\delta^{1/4}/\sqrt{\lambda}) + O(\sqrt{\delta})\right).$$

If $O(\delta^{1/4}/\sqrt{\lambda}) + O(\sqrt{\delta}) < \varepsilon/2$, then we would contradict the fact that $\mathrm{val}(G) = 1 - \varepsilon$. This implies that we must have $\delta = \Omega(\varepsilon^4\lambda^2)$. If we let $\mathsf{P}(W) = 2^{-\gamma n}$, then we can write

$$\delta \leq \frac{16}{\varepsilon}\left[\frac{1}{n}\log\frac{4}{\varepsilon} + 2\log|\mathcal{A}|\gamma\right]$$

where we plugged in the bound on $|S| \leq n/2$ from Proposition 8. This implies the lower bound

$$\gamma \geq \Omega\left(\frac{\varepsilon^5\lambda^2}{\log|\mathcal{A}|}\right) \tag{4}$$

when $n \geq \frac{\log 4/\varepsilon}{\varepsilon^5\lambda^2}$, proving the theorem.

A Proof of Corollary 6

For each type of game, we compute a lower bound on the second-smallest eigenvalue of the corresponding $(k-1)$-connection graph. Applying Theorem 5 then yields the statements of the corollary.

A.1 Free games

For simplicity, assume that $\mu(x)$ is the uniform distribution over $[d]^k$, where $d = |\mathcal{X}^1| = \cdots = |\mathcal{X}^k|$.[5] Then the $(k-1)$-connection graph is a weighted version of the d-ary, k-dimensional hypercube (with self loops). Indeed, the corresponding weight function ρ behaves as follows: for $x, x' \in [d]^k$, we have $\rho(x,x) = d^{-(k+1)}$, and $\rho(x,x') = d^{-(k+1)}/k$ when x and x' differ in exactly one coordinate, and is 0 otherwise. If we compute the normalized Laplacian L_H, we get that

$$(L_H)_{u,v} = \begin{cases} 1 - \frac{1}{d} & \text{if } u = v \text{ and } \rho(v) \neq 0 \\ -\frac{1}{kd} & \text{if } \rho(u), \rho(v) \neq 0 \\ 0 & \text{otherwise} \end{cases}$$

This is the normalized Laplacian corresponding to the Cayley graph over the Abelian group $(\mathbb{Z}/d\mathbb{Z})^k$ with (weighted) generators $\{g \in (\mathbb{Z}/d\mathbb{Z})^k : |g| \leq 1\}$ where $|g|$ is the number of non-zero components of g. If $g = (0, 0, \ldots, 0)$, then its weight is d^{-1}, and if $|g| = 1$, then its weight is $(kd)^{-1}$. The spectrum of Cayley graphs is well understood; we have that the smallest non-zero eigenvalue of L_H is therefore $\lambda(H) = \frac{1}{k}$. Thus H_G is a $1/k$-expander.

A.2 Anchored games

Here, we prove a lower bound on the second eigenvalue of the $(k-1)$-connection graph of an *anchored* game, and show that it is at least $8k/\alpha^k$. Plugging in this bound into Theorem 5 gives us

$$\mathrm{val}(G^{\otimes n}) \leq \exp\left(-\frac{c\,\alpha^{2k}\,\varepsilon^5\,n}{64\,k^2 \log|\mathcal{A}|}\right).$$

This asymptotically matches the bounds obtained in [1] in terms of the dependence on α and k.

Let us first recall the definition of an anchored game.

▶ **Definition 12** (α-anchored games [1]). Given a k-prover game G, and a parameter $\alpha < 1$ we define the α *anchored* game $G_\perp$ as follows: the referee chooses a question tuple $(x^1, \ldots, x^k)$, according to G, and independently, for every $t \in [k]$, replaces x^t by the anchoring symbol $\perp$ with probability α to get the tuple $(x'^1, \ldots x'^k)$. The new domain is thus $\mathcal{X}'^1 \times \mathcal{X}'^2 \ldots \mathcal{X}'^k$, where $X'^i = \mathcal{X} \cup \{\perp\}$. If any of the x''s are $\perp$, the verifier accepts trivially, otherwise the verifier accepts according to the predicate of the game G.

For convenience, we will denote the α-anchored game itself by G in this section, and its $(k-1)$-connection graph by H_G. We will show the following lemma.

[5] Indeed, by letting d be large enough, we can approximate μ arbitrarily well through discretization and identifying $[d]$ with $\mathcal{X}^t$ for $t = 1, \ldots, k$ in a many-to-one-fashion. Our bounds will not depend on d, so d can be taken to be arbitrarily large.

▶ **Lemma 13.** [6] *$\lambda(H_G) \geq \alpha^k/8k$, when $\alpha < 1/2$.*

In order to prove Lemma 13, we need to make a couple of observations. First, note that the 1-connection graph H_G's vertices can be partitioned into disjoint sets $V_0, V_1, \ldots, V_k$, where V_i has vertices of all question-tuples with exactly i bottom symbols. Thus, V_0 has vertices corresponding to the original question tuples, and $V_k = \{(\perp, \perp, \ldots, \perp)\}$. While V_0 has edges between its own vertices (corresponding to edges in the 1-connection graph of the un-anchored game), all other edges in H_G go between V_i and V_{i+1}.

We will lower bound $\lambda(H_G)$ using the notion of *congestion* in the graph. This technique was first introduced by Diaconis and Strook [5], and improved by Sinclair [12]. The below form can be found in the survey [7, Section 4].

Let us view H_G as an undirected graph[7], with weight function ρ on the edges. Since $\rho(x, y) = \rho(y, x)$ by our definition, this is well-defined. A set of canonical paths in H_G is a set $\mathcal{P}$ of simple paths, one between every ordered pair (x, y) in H_G. The *path congestion parameter* of this set of canonical paths is defined as follows:

$$\zeta(\mathcal{P}) \triangleq \max_{e \in E(H_G)} \frac{1}{\rho(e)} \sum_{p_{xy} \ni e} \rho(x)\rho(y)|p_{xy}|$$

Above, p_{xy} denotes the path from x to y in $\mathcal{P}$, and $|p_{xy}|$ is its length. Intuitively, the numerator in the above equation defines the 'load' on the edge (x, y), while $\rho(x, y)$ can be interpreted as its capacity. Thus, one would naturally expect that if we could find a set of canonical paths with low congestion parameter, the graph must be expanding in some sense. This is formalized in the following theorem:

▶ **Theorem 14** ([12], see also [7, Theorem 4.3]). *For any set of canonical paths $\mathcal{P}$,*

$$\lambda(H_G) \geq \frac{1}{\zeta(\mathcal{P})}$$

We will prove Lemma 13, by choosing a good set of canonical paths in H_G.

Proof of Lemma 13. Consider two vertices x, y in H_G. Let $\Delta(x, y) = \{i_1, \ldots, i_s\} \subseteq [k]$ be the set of (player) indices where the tuples differ, with $i_1 \leq i_2 \leq \ldots i_s$. We will define the canonical path from x to y to be the one obtained by flipping each of $x^{i_1}, \ldots x^{i_s}$ to $\perp$ in order, and then flip these to $y^{i_1}, \ldots y^{i_s}$, but in the reverse order $i_s \to \ldots \to i_1$. Each flip corresponds to moving along an edge in H_G. Call the set of these canonical paths $\mathcal{P}$. The path from x to y in $\mathcal{P}$ is exactly the reverse of the path from y to x.

We will upper bound the congestion through any edge $e = \{u, v\}$ caused by $\mathcal{P}$. If $u, v \in V_0$, then no path in $\mathcal{P}$ passes through this edge, and hence the congestion on e is 0. Suppose that $u \in V_l$, and $v \in V_{l+1}$ for some $l < k$.

We need to find which vertices x would use a canonical path that passes from u to v to reach another vertex. To identify this set, define $B_v \triangleq \{i \in [k] \ : \ v_i = \perp\}$, and similarly $B_u \triangleq \{i \in [k] \ : \ u_i = \perp\}$. Clearly $|B_v| = l + 1, |B_u| = l$, and $B_u \subseteq B_v$. Let us write u as $u = (\perp^l, z_u)$, where the indices are appropriately ordered (with z_u in $\overline{B}_u$).

[6] Although the proof of the lemma can be easily seen to show a bound dependent only on α and k for all $\alpha < 1$, the anchored game definition in [1] sets α to be a constant $< 1/2$. We only state this case, for clarity of exposition and comparison to their result.

[7] On the other hand, if viewed as a directed Markov chain, the transition probability $\Pr[y \mid x]$ for moving from x to y is exactly $\rho(x, y)/\rho(x)$. The stationary distribution on every vertex is $\rho(x)$.

For $0 \leq r \leq l$, a vertex $w \in V_r$ will be said to be in the r-th *shadow* of u (denoted by $S_r(u)$), if:

(a) $w|_{\overline{B}_u} = z_u$, and
(b) If $B_u = \{j_1, \ldots, j_l\}$, with $j_1 \leq \ldots \leq j_l$, then $w_{j_q} \neq \perp$ for every $q > l - r$.

The following Claim is easy to verify:

▶ **Claim 15.** $\rho(S_r(u)) = \Pr_{x\sim\rho}[x^{\overline{B}_u} = z_u] \times \alpha^r(1-\alpha)^{l-r}$

Proof. Any vertex in $S_r(u)$ can be seen to be generated by the verifier in the following way: pick a random question in the original (un-anchored) game conditioned on $x^{\overline{B}_u} = z_u$, then flip $j_1, \ldots j_r$ to $\perp$ (happens with probability α^r), and leave the others unflipped (happens with probability $(1-\alpha)^{k-r}$). The probability of not flipping $\overline{B}_u$ (i.e. $(1-\alpha)^{k-l}$) is accounted for in the distribution ρ of the anchored game. This yields the measure of the set $S_r(u)$ as being the expression given above. ◀

Any path in $\mathcal{P}$ that passes through u will necessarily either originate or end in one of its shadows. The length of any canonical path as defined above is at most $2k$. Hence, the load through the edge (u, v) can be upper bounded as follows (denoting $\Pr_{x\sim\rho}[x^{\overline{B}_u} = z_u]$ by $\Pr[z_u]$ for clarity):

$$\begin{aligned}
\sum_{p_{xy}\ni e} \rho(x)\rho(y)|p_{xy}| &\leq 2k \sum_{p_{xy}\ni e} \rho(x)\rho(y) \\
&\leq 4k \sum_{r=0}^{l} \rho(S_r(x)) \\
&= 4k \sum_{r=0}^{l} \Pr_{x\sim\rho}[x^{B_u} = z_u] \times \alpha^r(1-\alpha)^{l-r} \\
&= 4k(1-\alpha)^l \Pr[z_u] \sum_{r=0}^{l} \left(\frac{\alpha}{1-\alpha}\right)^r \\
&\leq 4k(l+1)(1-\alpha)^l \Pr[z_u] \qquad \ldots \text{ since } \alpha < 1/2 \\
&\leq 8k \Pr[z_u]
\end{aligned}$$

The capacity of edge (u, v) is $\rho(u, v) = \Pr[z_u] \times \alpha^l$. Thus, the congestion along the edge is bounded by

$$\zeta(e) \leq \frac{8k \Pr[z_u]}{\Pr[z_u] \times \alpha^l} = \frac{8k}{\alpha^l}.$$

Hence, the maximum congestion is bounded by $\zeta(\mathcal{P}) \leq \frac{8k}{\alpha^k}$, which yields the lower bound $\lambda(H_G) > \frac{\alpha^k}{8k}$, by invoking Theorem 14. ◀

A.3 Connected games

This follows from the observation that $\lambda(H) \geq \rho_{min}$ when the graph H is connected. The "in particular" statement follows from the definition of the weight function ρ of the $(k-1)$-connection graph: $\mathsf{P}_X(x)$ is simply $1/|S|$, and $\mathsf{P}_{X^t|x^{-t}}(x'^t)$ is also at least $1/|S|$.

Cumulative Space in Black-White Pebbling and Resolution*

Abstract

We study space complexity and time-space trade-offs with a focus not on peak memory usage but on overall memory consumption throughout the computation. Such a cumulative space measure was introduced for the computational model of parallel black pebbling by [Alwen and Serbinenko 2015] as a tool for obtaining results in cryptography. We consider instead the non-deterministic black-white pebble game and prove optimal cumulative space lower bounds and trade-offs, where in order to minimize pebbling time the space has to remain large during a significant fraction of the pebbling.

We also initiate the study of cumulative space in proof complexity, an area where other space complexity measures have been extensively studied during the last 10–15 years. Using and extending the connection between proof complexity and pebble games in [Ben-Sasson and Nordström 2008, 2011], we obtain several strong cumulative space results for (even parallel versions of) the resolution proof system, and outline some possible future directions of study of this, in our opinion, natural and interesting space measure.

1 Introduction

The time and space complexity measures are at the heart of understanding computation. Unfortunately, there is little we can say about general computation models such as Boolean circuits, let alone Turing machines. But if we allow ourselves to work with simpler models of computation, then we have a better chance at understanding these resources, and in fact there has been impressive progress in restricted models like bounded-depth circuits.

One of the first success stories in this direction are pebble games. The original *(black) pebble game* is played by a single player on a directed acyclic graph (DAG) with a single sink and all vertices having bounded indegree and consists of two simple rules:

1. we can add a pebble to a vertex if all its direct predecessors have pebbles, and
2. we can remove a pebble from a vertex at any time.

The goal of the game is to place a pebble on the sink of the graph. Time is measured as the number of moves to reach this goal, and the space is the maximum number of pebbles needed simultaneously at any point during the pebbling.

Quite surprisingly, this seemingly simple and innocent game can be used to obtain strong results even for general computation models, as it is at the core of the $\mathsf{DTIME}(t) \subseteq \mathsf{SPACE}(t/\log t)$ space upper bound for Turing machines in [33]. Pebbling was first used in [44] to study flowcharts and recursive schemata, and different variants of the game have later been applied to a rich selection of problems in computer science, including register allocation [50], algorithmic time and space trade-offs [17], parallel time [23], communication complexity [47], monotone space complexity [16, 28], cryptography [3, 22], and proof complexity [9, 11, 15] (where it should be emphasized that the above list of references is far from exhaustive). An excellent overview of pebbling up to ca 1980 is given in [46] and another in-depth treatment of some pebbling-related questions can be found in chapter 10 of [48]. Some more recent developments are discussed in the upcoming survey [42].

Let us briefly discuss what is known about space in proof complexity, since this is one of the two topics we are focusing on in this paper. The study of space in proof complexity was initiated in [25], which introduced the *clause space* measure for the well-known resolution proof system, a measure that has subsequently been thoroughly investigated. Informally, the clause space of a resolution proof can be defined as the maximal number of additional clauses – on top of the clauses in the original CNF formula – that a verifier needs to keep in memory at any time while checking the correctness of the proof.[1] While some formulas have proofs requiring only a small, sometimes even just constant, space overhead during verification, other formulas require a linear amount of extra space [1, 8, 25], and as shown in [25] no formulas require more than linear clause space in resolution.

Other papers have studied how space relates to other proof complexity measures. With respect to proof length, which can be viewed as a measure of (nondeterministic) running time, there is a wide range of trade-off results. It has been shown that there are formulas which have both short and space-efficient proofs, but as one of these measures is optimized the other one can blow up to almost worst-case behaviour [10]. Not only this, but there are even formulas where short proofs require more than the worst-case linear space [6, 7]. Yet other papers have studied other space measures such as *total space* [1, 12, 14], measuring the total number of symbols in a proof, and space complexity has also been considered for other proof systems than resolution. We refer the reader to the survey [41] for more details (although, for obvious reasons, it fails to cover the very latest results on total space).

All the space measures discussed above have in common the fact that they refer to the maximum space used at some point in the proof, but they are far from providing a complete picture of space usage during the whole proof. If we only know that a formula has high space complexity, it is not possible to distinguish between a formula that requires large space only at the beginning of the proof, say, and another that requires large space throughout the whole proof. This distinction might not be so important if we are considering the memory requirements of a verifier, since in this case we are chiefly interested in the

[1] Though slightly different from the definition in [25], this is equivalent up to a small additive constant.

maximum. However, it could be relevant for proof search: an algorithm that searches for a proof by producing clauses needs to discard many of them or risk exhausting its available memory. In this case, the difference between needing large space once versus at all times is the difference between making one lucky choice of which clauses to keep in memory versus being lucky all the time.

A similar issue occurs with so-called *memory-hard functions* in the context of cryptography. The idea behind memory-hard functions is that they should require a large amount of memory to evaluate, so that in order to compute such a function for many inputs as a part of a brute-force attack either an infeasible amount of memory is needed or the attack needs to be carried out sequentially. Yet, if the function only requires a large amount of memory during a limited time of the computation, then it is possible to reuse memory for different computations overlapping suitably in time as observed in [2]. Therefore, a more appropriate measure to analyse memory-hard functions is *cumulative space complexity* as introduced in [3], where one measures not the maximum memory consumption but the total memory usage aggregated over the time of the computation.

Although with hindsight this cumulative space complexity measure appears to be a very natural way of quantifying memory usage, it does not seem to have received too much attention in computational complexity theory, and to the best of our knowledge it has not been considered at all in the context of proof complexity. One of the main contributions of this paper is to transfer the concept of cumulative space to proof complexity and to initiate a study of this complexity measure for the resolution proof system.

Pebble games turn out to be a useful tool also for analysing cumulative space. For pebbling strategies cumulative space is straightforwardly defined as the sum over all steps of the pebbling of the number of pebbles on the DAG at each point in time. Thus, in the standard pebble game discussed above any DAG with n vertices can trivially be pebbled in time n and cumulative space $\mathrm{O}(n^2)$ by placing pebbles on all vertices in topological order. Since every vertex needs to be pebbled at some point, a trivial lower bound for the cumulative space is n. However, depending on the intended application one needs to consider other variations of this pebble game as discussed next.

In a proof complexity setting we need to study the *black-white pebble game*, which was introduced in [20] with the objective of modelling nondeterministic computations. Here white pebbles, corresponding to nondeterministic guesses, can be placed at any vertex at any time, but such a white pebble can only be removed from a vertex when all direct predecessors have (black or white) pebbles, corresponding to that the correctness of the nondeterministic guess can be verified.

To model parallel computation in a cryptographic setting, [3] introduced yet another pebble game, namely the *parallel (black) pebble game*. In this game, all the pebbling moves that are legal at some point in time can be performed simultaneously in one single step. This change of rules does not affect the maximal space required to pebble a DAG, but typically changes the pebbling time. Any connected DAG with a single sink requires linear time to pebble sequentially, but for a parallel pebbling it is easy to see that the time required is upper-bounded by the depth of the graph (i.e., the length of a longest path). We remark that an attractive feature of parallel pebbling is that it better captures the difference between maximal and cumulative space. Note that in any sequential pebbling game placing s pebbles requires s time steps, and during the last $s/2$ steps there will be at least $s/2$ pebbles on the DAG. Thus, any pebbling in maximal space s requires cumulative space $\Omega(s^2)$. In contrast, in a parallel pebbling the cumulative space can be small even when the maximal space is large.

1.1 Our Pebbling Contributions

In this paper, we study the cumulative space measure in the context of black-white pebbling. In order to do so, we also extend black-white pebbling to a parallel version. As pebble games go, this is a very powerful model, since it turns out that any DAG can be pebbled with a parallel black-white pebbling in constant time and linear cumulative space. Perhaps somewhat surprisingly, however, it is still possible to prove nontrivial time-space trade-offs. It can be shown that the parallel and sequential versions of black-white pebbling are closely connected (as discussed in more detail later in the paper), and therefore in this overview the exposition is focused on sequential black-white pebbling.

The first question we address is how the large cumulative space can be in the worst case for sequential black-white pebbling. As noted above, a trivial (black-only) pebbling in linear time and space has cumulative space $\mathrm{O}\big(n^2\big)$ for any graph over n vertices. In the other direction, the $\Omega(n/\log n)$ space lower bound in [30] already gives a $\Omega(n^2/\log^2 n)$ cumulative space lower bound for sequential black-white pebbling, as explained above. One cannot get a better cumulative space lower bound by this simple argument from maximal space lower bounds, however, since any DAG of constant indegree can be pebbled in maximal space $\mathrm{O}(n/\log n)$ [33].

We prove that the family of *grate graphs* in [49] require $\Omega(n^2)$ cumulative space for sequential black-white pebbling. This shows that for cumulative space it is not possible to improve on the trivial quadratic upper bound, in contrast to the maximal space measure where it is always possible to save a logarithmic factor from the trivial linear upper bound. This is also different from the parallel black pebble game, where there is a $\mathrm{o}(n^2)$ worst-case upper bound for cumulative space [2] and the best known cumulative space lower bound is $\Omega\big(n^2/\log n\big)$ [4]. In fact, it turns out that the difference between the sequential black-white and parallel black pebble games can be very large. We also prove that (a modified version of) the *butterfly graphs* in [51] require cumulative space $\Omega(n^2/\log n)$ in the sequential black-white pebble game but can be pebbled in linear cumulative space in the parallel black pebble game. Butterfly graphs also show that graphs that require large cumulative space do not necessarily require large maximal space, as they have logarithmic depth and thus can be pebbled in logarithmic space as observed in [33]. We obtain these results by studying the lower bounds on cumulative space in parallel black pebbling in [4] in terms of *depth-robustness* of graphs, and extending these lower bounds to other pebble games and other families of graphs.

Our next set of results concern trade-offs between time and space. Here our starting point is the family of *bit-reversal permutation graphs* studied in [37] which can be pebbled either with 3 pebbles or (as any graph) in linear time, but for which any pebbling in time t and space s must satisfy $t = \Omega(n^2/s^2)$, where as before n is the number of vertices in the graph.

We strengthen this trade-off to cumulative space, proving that pebblings of these graphs in space s require cumulative space $\Omega\big(n^2/s\big)$, which in particular implies that a pebbling in time $\mathrm{O}\big(n^2/s^2\big)$ must use space $\Omega(s)$ not only at some point but most of the time.[2] Furthermore, we establish an unconditional $\Omega\big(n^{3/2}\big)$ cumulative space lower bound, which provides another example of graphs that require (at least somewhat) large cumulative space but can be pebbled in very small (even constant) maximal space. Our proofs of these results work by adapting the *dispersion* technique from [4]. This technique has the advantage that it isolates an abstract combinatorial property of the graph that makes the lower bound argument go through, and this cleaner approach enables us to prove these results not only

[2] Note, importantly, that such a space lower bound is *not* implied by the simple "space s implies cumulative space $\Omega\big(s^2\big)$" argument discussed previously.

for bit-reversal graphs but also for *random permutation graphs* (by showing that these graphs possess the required combinatorial property with high probability). To the best of our knowledge no trade-offs (even non-cumulative ones) were known for such graphs before for any flavour of the pebble game.

Finally, we consider a very concrete, extremal question regarding pebbling time-space trade-offs. It is an easy observation that any sequential black-white pebbling in constant space s can be carried out in time $\mathrm{O}(n^s)$, since there are only $\sum_{k=0}^{s} 2^k \binom{n}{k}$ possible different configurations of s pebbles in the graph, and no configuration repeats in a pebbling (or else the intermediate moves can be removed). In fact, a bit more thought reveals that this time bound can be sharpened to $\mathrm{O}(n^{s-1})$, since every configuration in space s is immediately followed by a pebble removal, and so we only need to consider distinct configurations of $s-1$ pebbles. It is a natural question whether this simple counting argument is in fact tight, so that there are graphs that can be pebbled in space s but where any such pebbling requires time $\Omega(n^{s-1})$.

For pebbling space $s = 3$, the minimum space in which any nontrivial pebbling strategy is possible, the bit-reversal graphs in [37] discussed above show that the answer to this question is affirmative. It is not hard to see that by stacking $s-2$ bit-reversal DAGs on top of one another, identifying the top layer in one graph with the bottom layer in the graph above, one obtains graphs that are pebblable in space s but where the obvious pebbling strategy achieving this bound requires time $\mathrm{O}(n^{s-1})$. We prove that this trivial upper bound is indeed asymptotically tight for any constant s.

1.2 Our Proof Complexity Contributions

Turning now to proof complexity, we consider the main contribution of our paper to be that we initiate the study of the cumulative space measure. While the concept of cumulative space seems to be as natural as maximal space, we are not aware of it having been studied in the context of proof complexity before. As was the case for the first papers on (maximal) space complexity in resolution [25], in this first paper on cumulative space in proof complexity we focus on the resolution proof system.

An immediate observation is that proof length is always a lower bound on cumulative space, and so exponential lower bounds on proof length – as shown for resolution in [18, 32, 52] and many later papers – trivially imply exponential lower bounds on cumulative space. Therefore, it seems that the cumulative space measure will be of independent interest mostly for formulas which have reasonably short proofs. An obvious candidate family to study are pebbling formulas [11], which have proofs in linear length, but which exhibit a rich variety of properties with respect to space complexity depending on the underlying graphs in terms of which they are defined.

However, we also need to decide on an appropriate model of the resolution proof system in which to study cumulative space. In the context of pebbling we concluded that cumulative space makes most sense for parallel versions of the pebble games, and so it is natural to ask whether one should consider a parallel version of resolution when studying cumulative clause space. It is not hard to argue that such a parallel model of resolution could be interesting in its own right, since it might be useful as a tool to analyse attempts to parallelize state-of-the-art SAT solvers using so-called *conflict-driven clause learning (CDCL)* [5, 38].

We define and study several different versions of the resolution proof systems with varying degrees of parallelity. The running time of parallel CDCL solvers has previously been analysed using resolution depth and the related *conflict resolution depth* and *schedule makespan* measures introduced in [36], and our models of parallel resolution allow us to reason about space in addition to time.

Similarly to what is the case for pebble games, our most general model of parallel resolution, where clauses can be inferred not just by syntactic application of the resolution rule but by semantic inference, is extremely powerful, so much so that it can deal with any formula in a constant number of steps and linear space. Since we can establish a tight relation between space and parallel speedup also for resolution, however, we can still obtain lower bounds when the maximal space is limited.

Studying pebbling formulas in these different models of resolution, and revisiting the reductions between resolution and pebble games in [9, 10], we can translate the pebbling results in Section 1.1 to results for the resolution proof system. Summarizing very briefly, we exhibit different formulas that have

- proofs in linear length but require quadratic cumulative space,
- proofs in logarithmic space but require $\Omega(n^2/\log n)$ cumulative space, and
- trade-offs between proof length and cumulative space.

1.3 Paper Outline

The rest of this paper is organized as follows. In Section 2 we present a more detailed overview of our pebbling results, introducing formal definitions of the pebble games and measures discussed above, and we give an analogous overview for resolution in Section 3. The reader is referred to the upcoming full-length version for all missing proofs. We conclude in Section 4 with a discussion of possible directions for future research.

2 Pebbling Results Overview

Let us start our pebbling overview by giving formal definitions of the basic concepts.

2.1 Definition of Pebble Games and Basic Properties

We say that a directed acyclic graph (DAG) $G = (V, E)$ with $|V| = n$ has *size* n. A vertex $v \in V$ has *indegree* δ if it has δ incoming edges $\{(u_1, v), \ldots, (u_\delta, v)\} \subseteq E$, $u_i \neq u_j$ for $i \neq j$, and we say that G has indegree δ if the maximum indegree of any vertex of G is δ. A vertex with no incoming edges is called a *source* and a vertex with no outgoing edges is called a *sink*. We say that a vertex u is a *predecessor* of a vertex v if there exists a directed path from u to v; moreover, if this path consists of only one edge then u is a *direct predecessor* of v. We denote by $\mathsf{parents}(v)$ the set of all direct predecessors of v. For technical reasons, it will sometimes be convenient to allow paths of length 0 in the definition above, so that a vertex can be a predecessor of itself. We will sometimes consider graphs obtained from other graphs by removing subsets of vertices, and for $U \subseteq V$ we write $G - U = \big(V \setminus U, E \setminus ((U \times V) \cup (V \times U))\big)$ to denote the DAG obtained from G by removing the vertices in U and all edges incident to U.

To get a unified description of all flavours of the pebble game discussed in Section 1, it is convenient to define pebbling as follows.

▶ **Definition 1** (Pebble games)**.** Let $G = (V, E)$ be a DAG with a unique sink vertex z. The black-white pebble game on G is the following one-player game. At any time i, we have a *black-white pebbling configuration* $\mathbb{P}_i = (B_i, W_i)$ of black pebbles B_i and white pebbles W_i on the vertices of G, at most one pebble per vertex. The rules of how a pebble configuration $\mathbb{P}_{i-1} = (B_{i-1}, W_{i-1})$ can be changed to $\mathbb{P}_i = (B_i, W_i)$ are as follows:

1. A black pebble may be placed on a vertex v only if all immediate predecessors of v are covered by pebbles in both $\mathbb{P}_{i-1}$ and $\mathbb{P}_i$, i.e.,

   $$v \in (B_i \setminus B_{i-1}) \;\Rightarrow\; \mathsf{parents}(v) \subseteq \mathbb{P}_{i-1} \cap \mathbb{P}_i \;\;.$$

   Note that, in particular, a black pebble can always be placed on a source vertex.
2. A black pebble on any vertex v in $\mathbb{P}_{i-1}$ can be removed in $\mathbb{P}_i$.
3. A white pebble can be placed on any vertex v in $\mathbb{P}_i$.
4. A white pebble on a vertex v in $\mathbb{P}_{i-1}$ may be removed in $\mathbb{P}_i$ only if all immediate predecessors of v are covered by pebbles in both $\mathbb{P}_{i-1}$ and $\mathbb{P}_i$, i.e.,

   $$v \in (W_{i-1} \setminus W_i) \;\Rightarrow\; \mathsf{parents}(v) \subseteq \mathbb{P}_{i-1} \cap \mathbb{P}_i \;\;.$$

   In particular, a white pebble can always be removed from a source vertex.

A *legal pebbling* $\mathcal{P}$ of G is a sequence $\mathcal{P} = (\mathbb{P}_0, \ldots, \mathbb{P}_t)$ where every configuration $\mathbb{P}_i$ can be obtained from $\mathbb{P}_{i-1}$ using the rules 1–4. A *complete pebbling* $\mathcal{P} = (\mathbb{P}_0, \ldots, \mathbb{P}_t)$ is a legal pebbling where $\mathbb{P}_0 = \mathbb{P}_t = (\emptyset, \emptyset)$ and $z \in \bigcup_{i=0}^{t}(B_i \cup W_i)$ (i.e., the sink is pebbled at some point).

A *black pebbling* is a pebbling where $W_i = \emptyset$ for all $i \in [t]$. A pebbling is *sequential* if only a single application of a single rule 1–4 is used to get from from $\mathbb{P}_{i-1}$ to $\mathbb{P}_i$ for all $i \in [t]$. In a *(fully) parallel* pebbling an arbitrary number of applications of the rules 1–4 can be made to $\mathbb{P}_{i-1}$ to obtain $\mathbb{P}_i$ (but note that all pebble placements and removals have to be legal with respect to $\mathbb{P}_{i-1}$, and cannot make use of any pebble placements or removals made in parallel). Finally, we will also consider *parallel-black sequential-white* pebblings, which allows parallel applications of black pebble rules 1–2 to $\mathbb{P}_{i-1}$ to obtain $\mathbb{P}_i$, but only a single application of the white pebble rules 3–4. Note that, in the parallel setting, a simultaneous application of rules 1 and 4 on a same vertex replaces a white pebble by a black one.

The *time* of a pebbling $\mathcal{P} = (\mathbb{P}_0, \ldots, \mathbb{P}_t)$ is $t(\mathcal{P}) = t$; the (maximal) *space* is $s(\mathcal{P}) = s = \max_{i\in[t]}|B_i| + |W_i|$; and the *cumulative space* is $c(\mathcal{P}) = c = \sum_{i\in[t]}|B_i| + |W_i|$ (where we observe that $c \leq st$).

Parallel black pebbling was introduced in [3], where it was pointed out that for certain graphs parallel pebblings can be much more efficient than sequential, while for others they cannot do any better. For example, if we are considering time-space tradeoffs, any sequential black pebbling in space s and time t of the bit-reversal graph must satisfy $st = \Omega(n^2)$ [37], while in the parallel black game one can pebble such graphs in linear time and space $\mathrm{O}(\sqrt{n})$ [3]. In contrast, it was shown in [4] that there are graphs that can be pebbled sequentially in space s and time t satisfying $st = \mathrm{O}(n^2/\log n)$, but where these graphs even in the parallel model require not only $st = \Omega(n^2/\log n)$ but also cumulative space $\Omega(n^2/\log n)$.

Unlike the case of the black pebble game, we show that time and space in the black-white sequential and parallel games are closely related. Up to constant factors, it holds that if a parallel black-white pebbling $\mathcal{P}$ has maximal space s, then it is possible to save a factor s, but not more than a factor s, in time compared to a sequential black-white pebbling in the same space s.

▶ **Observation 2.** *Let $\mathcal{P}$ be a parallel black-white pebbling of a DAG G in time t, space s, and cumulative space c. Then there is a sequential black-white pebbling of G in time $2ts$, space $2s$, and cumulative space cs.*

Proof. Each parallel move places at most s pebbles and removes at most s pebbles, therefore we can simulate it by $2s$ sequential moves (making the pebble placements first, to make sure that these moves remain legal). ◀

▶ **Lemma 3.** *Let $\mathcal{P}$ be a sequential black-white pebbling of G in time t, space s, and cumulative space c, and let k be a positive integer. Then there is a parallel black-white pebbling of G in time $3\lceil t/k \rceil$, space $s + \lceil k/2 \rceil$, and cumulative space $3\lceil c/k \rceil + t$.*

Proof. We divide $\mathcal{P}$ into $\lceil t/k \rceil$ intervals of (at most) k moves. We reorder the pebbling moves within each of these intervals so that we do all placements first and removals afterwards. This is still essentially a valid pebbling, because each configuration is a superset of the corresponding configuration in $\mathcal{P}$, except that we can possibly have vertices temporarily covered by several pebbles. The space usage in any intermediate configuration increases to at most $s + \lceil k/2 \rceil$. We then collapse each subsequence into one parallel placement of white pebbles, one step replacing white pebbles with black pebbles as needed, and one parallel removal of black pebbles (this allows us to make all black pebble placements in parallel even though later black pebbles might be dependent on earlier pebble placements in the sequential pebbling). This decreases the time to $3\lceil t/k \rceil$.

To bound the cumulative space, note that if there is a configuration $\mathbb{P}_i$ in a sequential interval that has space s_i, then the corresponding three parallel configurations have aggregate space at most $3s_i + 2x_j$, where x_j is the number of placements in that interval. Now consider a partition of the sequential pebbling into k subsequences $\mathbb{P}_i, \mathbb{P}_{i+k}, \ldots, \mathbb{P}_{i+k(\lceil t/k \rceil - 1)}$ of t/k configurations, evenly spaced, starting at $i \in [1, k]$. By an averaging argument, at least one of these k subsequences has a cumulative space of at most $\lfloor c/k \rfloor$. Hence the total cumulative space is at most $\sum_{j \in [t/k-1]} (3s_{i+j} + 2x_{i+j}) = 3\sum_{j \in [t/k-1]} s_{i+j} + 2\sum_{j \in [t/k-1]} x_j \geq 3c/k + 2t/2$. ◀

Observe that when $k = \Theta(s)$ the cumulative space in Lemma 3 is dominated by the term t, so we only save a factor s in cumulative space when the sequential pebbling has cumulative space $c = \Theta(st)$. Since the graphs we will discuss in what follows have cumulative space lower bounds of this form, studying the sequential game already gives us all the information we want about the parallel game.

▶ **Corollary 4.** *Let $\mathcal{P}$ be a black-white pebbling of G in time t and space s. Then there is a parallel black-white pebbling of G in time $\lceil t/2s \rceil$, space $4s$, and cumulative space $2t$.*

2.2 Robustness and High Cumulative Space Complexity

We proceed to define the concept of *depth-robustness* of graphs, which is inspired by [24, 45] and which will be central to our work.

▶ **Definition 5** ($\mathcal{G}$ -robustness)**.** Let $\mathcal{G}$ be a family of DAGs and let $e, d \in \mathbb{N}^+$ be positive integers. We say that a DAG $G = (V, E)$ is (e, d)-*$\mathcal{G}$-robust* if for every subset of vertices $U \subseteq V$ of size at most e it holds that $G - U$ contains a subgraph $H \in \mathcal{G}$ of size at least d.

When $\mathcal{G}$ is the class of directed paths, then we say that G is *depth-robust*, and when $\mathcal{G}$ is the class of DAGs with one sink the DAG G is said to be *predecessor-robust*.[3]

For our pebbling lower bounds we are interested in graphs with very high robustness, i.e., for as large values of e and d as possible. Depth-robustness was first studied by Erdős, Graham and Szemerédi [24] who showed how to construct DAGs with indegree $\Theta(\log(n))$ possessing $(\Omega(n), \Omega(n))$-depth-robustness. However, in our applications it is important that

[3] This choice of terminology is inspired by [45], which discusses the dual notions of "depth-separators" and "predecessor-separators."

the graphs have *constant* indegree. Valiant [53] showed that for constant indegree and linear depth the best we can hope for is $(\mathrm{O}(n/\log n), \mathrm{O}(n))$-depth-robustness. Fortunately for us, it was shown in [4, 45] that such extremal $(\Theta(n/\log n), \Theta(n))$-depth-robust graphs do exist. Conversely, if we want constant indegree with the parameter e linear in the graph size, then $(\epsilon n, n^{1-\epsilon})$-depth-robustness is the best we can hope for [53]. In [49] a family of constant-indegree $(\Theta(n), \Theta(n^{1-\epsilon}))$-depth-robust graphs were presented.

The connection between depth-robustness and cumulative space was made in [4], where it was shown that an (e, d)-depth-robustness graph requires parallel black cumulative space at least ed. In this work, we give a more general theorem of this form for the case of $\mathcal{G}$-robustness. We then use this theorem to obtain the following lower bounds for depth-robust and predecessor-robust graphs.

▶ **Lemma 6.** *If G is an (e, d)-depth-robust DAG, then G requires sequential black-white cumulative space at least ed, and parallel-black sequential-white cumulative space at least $e\sqrt{d}$.*

▶ **Lemma 7.** *If G is an (e, d)-predecessor-robust DAG, then G requires black-white cumulative space at least ed.*

Focusing on the range of parameters discussed above, we can see that, it follows from Lemmas 6 and 7 that a $(\Theta(n/\log n), \Theta(n))$-depth-robust graph has sequential black-white cumulative space complexity $\Omega(n^2/\log n)$ and parallel-black sequential-white pebbling space complexity $\Omega(n^{3/2}/\log n)$.

A class of DAGs that are predecessor-robust are *grates* – graphs with n' sources and n' sinks such that after the removal of an arbitrary set of kn' vertices (for some constant k) there are still a linear number of sources and sinks that are all pairwise connected. *Butterfly graphs* [51] are grates with $n = n' \log n'$ vertices that are $(\Theta(n/\log n), \Theta(n/\log n))$-predecessor-robust. Moreover, it is not hard to show that if we append n' single-sink DAGs of size $\log n'$, one to each source of the butterfly graph, the resulting graph is $(\Theta(n/\log n), \Theta(n))$-predecessor-robust. This implies that these graphs require cumulative space $\Omega(n^2/\log n)$. Note that butterfly graphs (also in the modified version just described) can be pebbled with $\mathrm{O}(\log n)$ pebbles (since the graphs have depth $\mathrm{O}(\log n)$), and thus it is not the case that high cumulative space implies large maximal space.

It has been established that extremal depth-robustness is both a necessary [2] and sufficient [4] condition to have high cumulative space in the parallel black game. In particular, using the fact that no graph of size n with constant indegree is $(\omega(n/\log n), \Theta(n))$-depth-robust, it was shown in [2] that in the parallel black pebble game, for any constant $\epsilon > 0$, any such graph has cumulative space complexity $\mathrm{o}(n^2/\log^{1-\epsilon} n)$. A natural question is if this also holds for black-white pebbling. We show that this is not the case: there are graphs that have maximum cumulative space complexity $\Omega(n^2)$ in the black-white pebble game. This follows from Lemma 7 and the existence of grates of size linear in the number of sources and sinks [49].

2.3 Dispersion and Cumulative Space Trade-Offs

Another property of graphs that is important in the current paper is *dispersion*. This notion was used in [4] to obtain another condition ensuring high parallel black cumulative space complexity. We define two similar concepts and then use them to obtain cumulative space trade-offs. The results we get are for two classes of *permutation graphs* – graphs that consist two ordered paths of vertices $1, 2, \ldots, n$, where in addition an edge is added from each vertex i in the first path to its image under some specified permutation σ in the second path.

A family of permutations that will be of particular interest to us are the so-called *bit-reversal permutations*, which are defined for $n = 2^m$ and which simply reverse the binary representations of numbers. That is, if $j = (b_1 \cdots b_m)_{(2)}$, then the bit-reversal permutation σ sends j to $\sigma(j) = (b_m \cdots b_1)_{(2)}$. It was previously known [37] that any sequential black-white pebbling of a bit-reversal permutation graph on $2n$ vertices in time t and space s satisfies $st = \Omega\big(n^2/s\big)$. Moreover, it was shown in [37] that this is tight up to constant factors and that there is a black-white pebbling in time t and space s such that $st = \mathrm{O}\big(n^{3/2}\big)$.

We observe that while bit-reversal graphs are *not* $(2\sqrt{n}, 2\sqrt{n})$-depth-robust, they can be shown to be $(\sqrt{n}, n)$-predecessor-robust. Therefore, in constrast to [4], where it was not possible to establish a parallel black cumulative space lower bound of $n^{3/2}$ using depth-robustness, we are able to obtain a black-white cumulative space lower bound of $n^{3/2}$ using predecessor-robustness.

Our reason for studying dispersion properties of bit-reversal graphs is to characterize how cumulative space increases when space decreases. We show that the time-space trade-off in [37] can be strengthened to a cumulative space trade-off. Our result implies that if $\mathcal{P}$ is a sequential black-white pebbling of a bit-reversal graph in space s and time n^2/s^2, then it needs to use space s not only at some point of the pebbling, but during a large part of the time.

An advantage of our approach is that we identify a general property of graphs that imply cumulative space trade-offs, so that the task of establishing a trade-off reduces to proving that the graph has this desired property. As a consequence of this simplification, we are able to prove the same kind of trade-off results not only for bit-reversal graphs but also for random permutation graphs, a class of graphs for which it seems nothing was known before.

▶ **Theorem 8.** *If G is a random permutation graph, then it holds asymptotically almost surely that in the sequential black-white pebble game G requires cumulative space $\Omega(n^{3/2})$ and any pebbling $\mathcal{P}$ of G in maximal space s has cumulative space $\Omega(n^2/s)$.*

2.4 Pebblings in Small Space Can Require Maximum Length

Let us finally consider the question of how long a shortest sequential pebbling of a graph can be given constraints on the maximal pebbling space. Without loss of generality, a black pebbling in space s takes time at most $\binom{n}{\leq s} \leq n^s$, simply because there is no need to repeat any pebble configuration. A moment of thought reveals that in fact we get the upper bound $\binom{n}{s-1} + \binom{n}{\leq s-1} \leq n^{s-1}$, since every configuration in maximal space s is followed by an erasure yielding a space-$(s-1)$ configuration, and these configurations also do not repeat. For black-white pebbling the upper bound becomes $2^{s-1}\big(\binom{n}{s-1} + \binom{n}{\leq s-1}\big) \leq 2^{s-1}n^{s-1}$.

As discussed in the introduction, it can be read off from [37] that for space-3 pebblings the $\mathrm{O}\big(n^2\big)$ upper bound is tight up to constant factors – bit-reversal DAGs are examples of graphs for which pebblings in optimal space 3, or indeed any constant space, require quadratic time. We extend this result to any $s = \mathrm{O}(1)$ by exhibiting graphs that can be pebbled in space s but where any such pebbling requires time $\Omega\big(n^{s-1}\big)$. We do this by generalizing permutation graphs to multiple layers, where we have k directed path graphs of length n and $k-1$ layers of permutations between the vertices $1, 2, \ldots, n$ in consecutive paths (so that the permutation graphs considered in [37] are 2-layer bit-reversal graphs with paths of length n). We state two theorems below for the black and black-white sequential pebble games, and just as for the 2-layer graphs in [37] our bounds can be stated not just for minimal space but also an arbitrary space parameter s greater than this minimum.

▶ **Theorem 9.** *Let G be a k-layer bit-reversal graph with paths of length n. Then for any s such that $k+1 \leq s \leq \sqrt{n}$ there exists a sequential black pebbling of G in space s and time $\mathrm{O}(n^k/s^{2k-3})$. Furthermore, every sequential black pebbling of G in space s requires time $\Omega(n^k/s^{2k-3})$.*

▶ **Theorem 10.** *Let G be a k-layer bit-reversal graph with paths of length n. Then for any s such that $k+1 \leq s \leq \sqrt{n}$ there exists a sequential black-white pebbling of G in space s and time $\mathrm{O}(n^k/s^{2k-2})$. Furthermore, every sequential black-white pebbling of G in space s, requires time $\Omega(n^k/s^{2k-2})$.*

Our proofs of these results are inspired by the reasoning in [37] for 2-layer permutation graphs, but we also need to overcome some new challenges. The essence of the argument is that in order to place a pebble on the jth layer we need to do some work on the preceding layer. If we only have two layers the argument ends here, but when we want to apply the argument recursively we need to be more careful. Indeed, placing pebbles on the $(j-1)$st layer will now require placing more pebbles on the $(j-2)$nd layer, but if we choose the order in which we do the pebble placements wisely, we may be able to reuse part of the work in the $(j-2)$nd layer for several pebble placements in the $(j-1)$st layer. We are able to find a strategy to exploit this insight and obtain optimal upper bounds, but also to make the lower bound argument resilient enough to get asymptotically matching lower bounds.

3 Cumulative Space for the Resolution Proof System

We now proceed to describe in more detail the proof complexity results in our paper. We start this section by a brief review of some standard proof complexity preliminaries, after which we discuss how to refine the definition of the resolution proof system to be able to make meaningful and precise claims about maximal space and cumulative space. This then allows us to make the connection to the pebbling results in Section 2 and what proof complexity implications they have.

A *literal* over a Boolean variable x is either x itself (a *positive literal*) or its negation $\overline{x}$ (a *negative literal*). A *clause* $C = a_1 \vee \cdots \vee a_k$ is a disjunction of literals a_i over pairwise disjoint variables. A *k-clause* is a clause that contains at most k literals. A *CNF formula* $F = C_1 \wedge \cdots \wedge C_m$ is a conjunction of clauses and a *k-CNF formula* is a CNF formula consisting of k-clauses. We think of clauses and CNF formulas as sets: order is irrelevant and there are no repetitions.

The standard definition of a *resolution refutation* $\pi : F \vdash \bot$ of an unsatisfiable CNF formula F – or a *resolution proof* for (the unsatisfiability of) F – is as an ordered sequence of clauses $\pi = (D_1, \ldots, D_t)$ such that $D_t = \bot$ is the empty clause containing no literals, and each clause D_i, $i \in [t]$, is either an *axiom* $D_i \in F$ or is derived from clauses D_j and D_k, $j, k < i$, by the *resolution rule*

$$\frac{B \vee x \qquad C \vee \overline{x}}{B \vee C}\ , \tag{1}$$

where we refer to $B \vee C$ as the *resolvent over x* of $B \vee x$ and $C \vee \overline{x}$.

In order to study space in general, and cumulative space in particular, we refine the above definition into a family of proof systems as follows.

▶ **Definition 11** (Resolution)**.** A resolution refutation $\pi : F \vdash \bot$ of a CNF formula F is a sequence of *configurations*, or sets of clauses, $\pi = (\mathbb{C}_0, \ldots, \mathbb{C}_t)$ such that $\mathbb{C}_0 = \emptyset$, $\bot \in \mathbb{C}_t$, and for all $i \in [t]$ we obtain $\mathbb{C}_i$ from $\mathbb{C}_{i-1}$ by applying exactly one of the following type of rules:

Axiom download Add $A \in F$.
Inference Add D derived from clauses in $\mathbb{C}_{i-1}$.
Erasure Remove clauses from $\mathbb{C}_{i-1}$.
We say that a refutation is (a) *sequential* if at every time step we apply the chosen rule exactly once; (b) *inference-parallel* if only one clause can be downloaded but the inference rule can be applied an arbitrary number of times (but always deriving from $\mathbb{C}_{i-1}$); and (c) *fully parallel* (or just *parallel*) if both axiom download and inference rules can be applied an arbitrary number of times (but note that we cannot mix applications of different rules in the same step). Furthermore, a refutation is said to be (1) *syntactic* if inferences use the resolution rule (1) and (2) *semantic* if instead any clause D such that $\mathbb{C}_{i-1} \models D$ can be inferred immediately.

The *length* of a resolution refutation π is the number of derivation steps t and the *size* is the total number of clauses introduced in downloads and inference steps (counted with repetitions). The *maximal (clause) space*, or just *space*, of π is $\max\{|\mathbb{C}_i| : \mathbb{C}_i \in \pi\}$ and the *cumulative (clause) space* is $\sum_{\mathbb{C}_i \in \pi} |\mathbb{C}_i|$.

Note that Definition 11 yields a total of six different flavours of resolution 1(a)–2(c) depending on the amount of parallelism and on whether inferences are syntactic or semantic. In what follows, we will discuss our motivation for considering these different models and what we can say about them.

A first, general comment is that from a proof complexity point of view we are mainly interested in *syntactic* versions of the proof systems in Definition 11. Strictly speaking, the *semantic* versions are not even propositional proof system in the sense of Cook and Reckhow [19], since we do not know how to verify semantic implications in polynomial time. In any semantic system we can download all axioms in the formula and then derive contradiction in a single inference step, and efficiently verifying such an inference means solving Sat in polynomial time. However, most results on (clause) space in the proof complexity literature actually hold in the stronger semantic setting. For maximal space this is not so surprising, since the semantic and syntactic space measures are within a constant factor of each other [1], but even for trade-offs one tends to get results in the semantic setting for free (with the notable exceptions of [6, 7]).

Syntactic sequential resolution is the standard definition discussed at the beginning of this section (and note that for this version of resolution the length and size measures are essentially the same). A somewhat unsatisfactory feature of this model is that (analogously to what is the case for pebbling) a maximal space lower bound s immediately implies a cumulative space lower bound $\Omega(s^2)$. The reason is completely analogous: since we can only infer one new clause per time step, during the $s/2$ time steps before reaching space s we must have had at least $s/2$ clauses in memory. It turns out, however, that we can actually beat this lower bound in certain settings, and we also remark that cumulative length-space trade-offs do not necessarily follow from such trivial arguments and so make sense even for syntactic sequential resolution.

By allowing parallel application of inference steps we want to try to get away from cumulative space lower bounds that hold only for the trivial reason just discussed. In *syntactic inference-parallel resolution* we therefore allow clauses to be derived in parallel. As it turns out, anything we are currently able to prove for this model we can also establish for the stronger *semantic inference-parallel resolution* system.

We can also go in the other direction from the syntactic sequential model and introduce a parallelism of sorts by studying *semantic sequential resolution*. As already alluded to, this is a very powerful system since any formula can be refuted in linear size and space by

downloading all its axioms in a linear number of steps and then deriving contradiction in just one semantic inference step, but nevertheless the space lower bounds and length-space trade-offs in [9, 10] hold in this model, and can in fact be verified to hold even for semantic inference-parallel resolution.

The most challenging models in terms of lower bounds are the fully parallel ones. *Syntactic parallel resolution* could be viewed as a potentially interesting model for proving lower bounds on parallel SAT solvers using conflict-driven clause learning, where one could imagine an arbitrarily large number of solvers producing resolvents in parallel and having perfect access to shared memory. It is not hard to see that if a standard resolution proof is represented as a DAG in the natural way, then syntactic parallel length, which would be a proxy for execution time, is just the depth of this DAG.

In the semantic model, adding also parallel axiom downloads makes the proof system exceptionally powerful, since now any formula can be refuted in constant length 2, linear size, and linear cumulative space. This seems a bit too strong to be really interesting (and can be viewed as a reason for preferring the inference-parallel version described previously). However, we shall see that even for semantic fully parallel resolution it is still possible to obtain nontrivial trade-off results if the maximal (non-cumulative) space is bounded.

Moving on from this philosophical discourse to a more concrete discussion of results, we note that most of the proof complexity consequences we derive from the pebbling results in Section 2 are for semantic inference-parallel resolution, and thus hold for all models above except the fully parallel ones. We start by reporting a disappointing fact, however: even in semantic inference-parallel resolution we have the problem that cumulative space is at least maximal space squared.

▶ **Lemma 12.** *If F requires maximal space s in semantic inference-parallel resolution, then any semantic inference-parallel refutation of F has cumulative space $\Omega(s^2)$.*

Proof. For simplicity let us think of each step in a semantic inference-parallel resolution refutation as being either an inference-plus-erasure step or a download step. Clearly, this can only affect the clause space measure by a factor 2.

An inference-plus-erasure step can be seen as a compression operation. Since the proof system is semantic, we only care about the information contained in a configuration, and since an inference step cannot increase the information but only add explicitly clauses that are already implied by the configuration, there is no need to add any extra clauses on top of the minimum amount needed to encode the semantic information we want the proof to maintain at this point. Therefore, without loss of generality the number of clauses only increases at download steps, and since these are sequential we can conclude that the number of clauses increases by at most 1 at every step.

But this means that we can apply the same argument as for syntactic sequential resolution above: during the $s/2$ time steps preceding a space-s configuration we must have at least $s/2$ clauses in memory, and hence a cumulative lower bound $\Omega(s^2)$ follows. ◀

It is important to note, though, that Lemma 12 has no implications for cumulative space trade-offs for formulas where the maximal space complexity is at most $O(\sqrt{N})$ measured in the formula size N, since in this setting the max-space-squared argument only implies a trivial $\Omega(N)$ cumulative space lower bound, and we present such trade-off results below that do not follow from Lemma 12. We also report results that asymptotically beat the maximal-space-squared lower bound for cumulative space.

In order to obtain these results, we need to review how our cumulative pebbling results in Section 2 can be translated to claims about resolution refutations of so-called *XORified*

pebbling formulas. We will be very brief here, since all that needs to be done is to read the pebbling-to-resolution reductions in [10] and verify that the proofs work not only for semantic sequential resolution but also for semantic inference-parallel resolution. We just state the reduction that we need below, since we can use it in a completely black-box fashion without knowing any details about what these formulas are. The interested reader is referred to [10] for the missing details.[4]

▶ **Theorem 13** (by the proof of Theorem 2.1 in [10]). *Let π be a semantic inference-parallel resolution refutation of a XORified pebbling formula $Peb_G[\oplus]$ in length L, maximal space s, and cumulative clause space c. Then there is a sequential black-white pebbling of the underlying DAG G in time L, space s, and cumulative space c.*

Analogously to what is the case in [10], the generic reduction in Theorem 13 can now be applied to a multitude of different graph families with different pebbling properties to yield CNF formulas with the same properties in resolution. Below we just give a sample of such results that we find particularly interesting.

For maximal space it is known that formulas refutable in linear size $\mathrm{O}(N)$ never require space more than $\mathrm{O}(N/\log N)$. For cumulative space the lower bound can be truly quadratic, however, beating the max-space-squared bound in Lemma 12 by a factor $\log^2 N$.

▶ **Theorem 14.** *There is a family of 6-CNF formulas $\{F_N\}_{N\in\mathbb{N}^+}$ of size $\Theta(N)$ that have syntactic sequential resolution refutations in size $\mathrm{O}(N)$, and hence also in maximal clause space $\mathrm{O}(N/\log N)$, but for which any semantic inference-parallel refutations require cumulative clause space $\Omega(N^2)$.*

This theorem follows from studying pebbling formulas defined in terms of *grate graphs* as in [49] and using that the high predecessor-robustness of these graphs imply strong lower bounds on cumulative space as stated in Section 2.

A natural question is what cumulative space tells us about maximal space, and in particular whether high cumulative space complexity implies that the maximal space complexity must also be large. This might sound intuitively plausible, but turns out to be false in a very strong sense.

▶ **Theorem 15.** *There is a family of 6-CNF formulas $\{F_N\}_{N\in\mathbb{N}^+}$ of size $\Theta(N)$ that can be refuted in syntactic sequential resolution in size $\mathrm{O}(N)$ and also in maximal clause space $\mathrm{O}(\log N)$, but for which any semantic inference-parallel refutations require cumulative clause space $\Omega(N^2/\log N)$.*

Here the graphs we need are surprisingly simple, namely butterfly graphs. They again have high predecessor-robustness, but since they are shallow the pebbling formulas generated from them have refutations in small maximal space.

Finally, we turn to the question of length-space trade-offs. We remark that in a cumulative space setting formulas for which small-space proofs require superpolynomial length, as in the strongest results in [10, 7, 6], are not too interesting, since length is trivially a lower bound on cumulative space. Rather, we focus on formulas for which small-space proofs incur only a

[4] It might be worth noting, though, that just as in [10] our results hold not only for pebbling formulas substituted with exclusive or – substitution with any so-called *non-authoritarian* (or *robust*) function that can never be fixed by restricting any single variable to some value works fine. Binary exclusive or is just the simplest example of such a function, whereas standard or is a simple non-example since setting a single variable to true fixes the value of the function to true.

polynomial blow-up in proof length. Can we find such formulas for which it holds not only that short proofs must have large maximal space s, but where such short proofs must be memory-intensive in that this amount of space s must be used essentially throughout the whole proof? The answer to this question is yes, and one example are pebbling formulas over the bitreversal permutation graphs studied in [37]. The next theorem follows by combining the reduction in Theorem 13 with the fact that bitreversal graphs are dispersed as stated in Section 2.

▶ **Theorem 16.** *There is a family of 6-CNF formulas $\{F_N\}_{N\in\mathbb{N}^+}$ of size $\Theta(N)$ such that for any $s = \mathrm{O}(\sqrt{N})$ the formula F_N has a syntactic sequential resolution refutation in size $\mathrm{O}(N^2/s^2)$ and maximal clause space $\mathrm{O}(s)$, but any semantic inference-parallel refutation of F_N in maximal space s requires cumulative clause space $\Omega(N^2/s)$.*

In particular, a proof in maximal space s has length $\Omega(N^2/s^2)$, and if furthermore the proof has length $\mathrm{O}(N^2/s^2)$, then $\Omega(N^2/s^2)$ of the configurations have space $\Omega(s)$. Hence, these formulas have syntactic sequential resolution refutations in simultaneous length $\mathrm{O}(N)$ and space $\mathrm{O}(\sqrt{N})$, but any semantic inference-parallel refutation with the same parameters has $\Omega(N)$ configurations with space $\Omega(\sqrt{N})$. We remark that this result makes sense even in the weaker syntactic sequential model, since maximal space $\Omega(\sqrt{N})$ only implies a trivial $\Omega(N)$ cumulative space lower bound.

As already noted, semantic fully parallel resolution is an extremely powerful model, since we can refute any formula with just one (parallel) axiom download step followed by one (semantic) inference step, but if we limit the available space then the usefulness of parallelism is restricted. In fact, the speed-up from parallelism is proportional to the space.

▶ **Observation 17.** *Let π be a semantic parallel resolution refutation of a formula F in length L, maximal clause space s, and cumulative clause space c. Then there is a semantic sequential refutation of F in length Ls, maximal clause space s, and cumulative clause space cs.*

Proof. Each parallel axiom download or inference adds at most s new clauses, therefore we can simulate it by s sequential axiom downloads or inferences respectively. ◀

Using Observation 17 we can transfer the trade-offs above from inference-parallel to fully parallel semantic resolution by sacrificing a factor s.

▶ **Lemma 18.** *Let π be a syntactic sequential resolution refutation of a formula F in length L, maximal space s, and cumulative space c, and let $\ell \in \mathbb{N}^+$ be a positive integer. Then there is a semantic parallel resolution refutation of F in length $3\lceil L/\ell \rceil$, maximal space $s + \lceil \ell/2 \rceil$, and cumulative space $3\lceil c/\ell \rceil + L$.*

Proof sketch. Analogously to the proof of Lemma 3, we divide π into L/ℓ intervals of ℓ steps each. We reorder derivation steps within every interval so that we do all axiom downloads first, inferences next, and removals at the end of the interval. We then collapse each sequence into one axiom download, one inference, and one removal step. ◀

Let us finally just observe that although proving strong lower bounds for the fully parallel versions of resolution looks like a formidable challenge, which we leave as future work, we can obtain a simple separation between semantic and syntactic fully parallel resolution.

▶ **Proposition 19.** *Every syntactic, fully parallel resolution refutation of a minimally unsatisfiable CNF formula in space $s \leq N$ requires length $N/s + \log s - 2$.*

Proof Sketch. Since the inference rule is binary, the number of useful clauses in the second-to-last-last configuration, namely those used to infer contradiction, is at most 2. Analogously, the number of useful clauses in the ith last configuration is at most 2^i. Hence, in the last $\log s$ steps we see at most $2s$ useful clauses in total. Since we need to see each axiom at least once, we still need at least $N/s - 2$ more steps. ◀

In particular, any syntactic refutation requires length $\log N$, and a refutation in this length requires space $\Omega(N)$. This is in contrast to semantic refutations, which have proofs in length 2, and no space lower bound other than the trivial N/L.

By way of example, consider a (plain) pebbling formula on a path graph of length N. A syntactic refutation in length $\log N$ requires space $\Omega(N)$, while there exists semantic refutation in length $\log N$ and space $2N/\log N + \mathrm{O}(1)$: just download the axioms corresponding to $2N/\log N$ consecutive vertices at a time and infer one new clause.

While this is technically a separation, it is also very brittle. For any integer k, it is possible to find a syntactic proof in length $(1+1/k)\log N$ and space $2kN/\log N + \mathrm{O}(1)$. First, download the axioms corresponding to evenly spaced vertices at distance $\log N/k$. Then for $\frac{2}{k}\log N$ steps download the clauses corresponding to the previous and next vertex and do a parallel inference step. Another inference step leaves us with a path of length $N/k \log N$, which we can trivially refute in length $\log N - \log k - \log\log N$ and space $N/k \log N$.

4 Concluding Remarks

In this paper, we study space complexity with a focus not on peak memory usage but on aggregated memory consumption over the whole computation. We consider two computational models, namely pebble games on DAGs and the resolution proof system in proof complexity.

For black-white pebbling, which is a model of nondeterministic computation, we prove optimal cumulative space lower bounds and also time-space trade-offs where in order to achieve optimal time the space needs to be large not only at a single point in time but throughout essentially the whole computation. We do so by studying the concepts of *depth-robustness* and *dispersion* of graphs, drawing on and extending work in [2, 3, 4] and other papers, and proving that different graph families of interest possess these properties.

In the context of proof complexity we are not aware of the cumulative space measure having been studied before, and so our first contribution here is to give a suitable formal definition, and also to consider different, more or less parallel, versions of the resolution proof system in which it makes sense to study cumulative space. We then use, and slightly extend, the reductions between pebbling and resolution in [9, 10] to transfer our lower bounds and trade-off results for pebbling also to resolution.

Since, to the best of our knowledge, ours is the first paper to study cumulative space both for black-white pebbling and for proof complexity, it is perhaps not so surprising that there is a wealth of open problems that this paper does not resolve. Below, we briefly discuss some possible directions for future research.

One set of questions on which we make progress but which we do not answer completely concern the relation between maximal space and cumulative space. For sequential black-white pebblings of n-vertex DAGs we prove an optimal $\Omega\big(n^2\big)$ cumulative space lower bound for a particular family of DAGs, but for graphs that can be pebbled in maximal space $\mathrm{O}(\log n)$ we only obtain a $\Omega\big(n^2/\log n\big)$ cumulative space lower bound and for graphs pebblable in space $\mathrm{O}(1)$ the best cumulative bound we can get is $\Omega\big(n^{3/2}\big)$. Could it be the case that there are graphs that can be pebbled in maximal space $\mathrm{O}(1)$ but nevertheless require cumulative

space $\Omega(n^2)$? Or do strong enough cumulative space lower bounds by necessity imply also nontrivial maximal space lower bounds?

It has been shown for parallel black pebbling that extremal depth-robustness is both necessary and sufficient for a graph to have high cumulative space complexity. We prove that for black-white pebbling predecessor-robustness is sufficient to imply high cumulative space, but leave open whether this condition is necessary or not.

For standard time-space trade-offs in sequential pebbling, it was shown in [37] that bit-reversal DAGs have a black pebbling trade-off of the form $t = \Theta(n^2/s)$ whereas for black-white pebbling the trade-off is a slightly weaker $t = \Theta(n^2/s^2)$. It was conjectured in [37] that there are other permutation graphs for which the black-white pebbling trade-off could also be shown to be an optimal $t = \Theta(n^2/s)$. One natural candidate class of graphs to consider in this context are graphs obtained from random permutations, and this is the original reason why we were interested to study them in this paper. So far we were only able to obtain trade-offs with the same parameters as for bit-reversal DAGs, but it is an interesting question whether our tools could be sharpened to prove even stronger trade-offs results for random permutation graphs.

Turning to our proof complexity results, they can be seen to be yet another contribution to the sequence of papers [39, 43, 9, 40, 10] obtaining space bounds and time-space trade-offs in proof complexity by instead studying pebble games and reductions between pebblings of DAGs and resolution refutations of so-called pebbling formulas defined in terms of these DAGs. While these connections have turned out to be very fruitful, it would also be interesting to go beyond pebbling formulas and explore whether cumulative space results could be obtained for, e.g., Tseitin formulas on long and narrow rectangular grids as studied in [6, 7] or for other formulas.

One motivation behind our models of parallel resolution was the connection to parallel SAT solving, but our models do not take into account practical limitations such as the number of computing nodes or the communication between nodes. Could there be natural ways to incorporate such limitations, and could this also provide a better understanding of parallel resolution?

Another, somewhat related, question is whether formulas possessing strong cumulative space lower bounds are hard also in practice for (sequential or parallel) SAT solvers. Just maximal space lower bounds do not seem to be sufficient to imply practical hardness, as shown, e.g., in the fairly extensive empirical experiments on pebbling formulas in [35], but perhaps cumulative space could be a more relevant concept in this context.

Finally, it can be noted that our study of cumulative space in proof complexity as initiated in this paper is limited to the resolution proof system. This is mostly because resolution is the proof system where space complexity is best understood, and where the toolbox for studying these questions is most well developed. However, different concepts of maximal space and time-space trade-offs have been studied also for other proof systems such as polynomial calculus [1, 7, 13, 26, 27] and cutting planes [21, 29, 31, 34], and it would be interesting to extend the study of cumulative space to these proof systems.

Acknowledgements. The authors wish to thank Yuval Filmus for making us aware of each other's existence and thus providing the stimulus for the joint work that led up to this paper. Different subsets of the authors are grateful to Ilario Bonacina, with whom we had stimulating discussions during various stages of this project and who, in particular, provided valuable insights on dispersion, and to Adam Schill Collberg and Jan Elffers for helpful discussions on random permutation graphs.

A Hierarchy Theorem for Interactive Proofs of Proximity

Tom Gur[*1] **and Ron D. Rothblum**[†2]

Abstract

The number of rounds, or round complexity, used in an interactive protocol is a fundamental resource. In this work we consider the significance of round complexity in the context of *Interactive Proofs of Proximity* (IPPs). Roughly speaking, IPPs are interactive proofs in which the verifier runs in sublinear time and is only required to reject inputs that are far from the language.

Our main result is a round hierarchy theorem for IPPs, showing that the power of IPPs grows with the number of rounds. More specifically, we show that there exists a gap function $g(r) = \Theta(r^2)$ such that for every constant $r \geq 1$ there exists a language that (1) has a $g(r)$-round IPP with verification time $t = t(n, r)$ but (2) does not have an r-round IPP with verification time t (or even verification time $t' = \mathsf{poly}(t)$).

In fact, we prove a stronger result by exhibiting a *single* language $\mathcal{L}$ such that, for every constant $r \geq 1$, there is an $O(r^2)$-round IPP for $\mathcal{L}$ with $t = n^{O(1/r)}$ verification time, whereas the verifier in *any* r-round IPP for $\mathcal{L}$ must run in time at least t^{100}. Moreover, we show an IPP for $\mathcal{L}$ with a poly-logarithmic number of rounds and only poly-logarithmic verification time, yielding a sub-exponential separation between the power of constant-round IPPs versus general (unbounded round) IPPs.

From our hierarchy theorem we also derive implications to standard interactive proofs (in which the verifier can run in polynomial time). Specifically, we show that the round reduction technique of Babai and Moran (JCSS, 1988) is (almost) optimal among all blackbox transformations, and we show a connection to the algebrization framework of Aaronson and Wigderson (TOCT, 2009).

1 Introduction

Interactive Proofs, introduced by Goldwasser at el. [38] (and in their public-coin form, by Babai and Moran [8]), are protocols in which a computationally unbounded prover tries to convince a verifier that an input x belongs to a language $\mathcal{L}$. A recent line of work, initiated by Ergün, Kumar and Rubinfeld [19] and more recently by Rothblum, Vadhan and

Wigderson [58], considers a variant of interactive proofs in which the verifier is required to run in *sublinear* time. Since the verifier does not have enough time to even read its entire input, we cannot expect it to reject every false statement. Rather, following the property testing literature [59, 27] (see also [26]), we relax the soundness condition and only require that the verifier reject inputs that are *far* from the language (no matter what cheating strategy the prover uses). Since the verifier is only assured that the input is close to the language, such interactive proofs are called *interactive proofs of proximity* (IPPs). Indeed, IPPs may be thought of as the property testing analogue of interactive proofs.

From an information theoretic perspective, the key parameters of an IPP are its *query complexity*, *communication complexity* and *round complexity*. The *query complexity* is the number of bits of the input string that the verifier reads. The *communication complexity* is the number of bits exchanged between the prover and the verifier, and the *round complexity* is the number of rounds of interaction. We think of all of these parameters as being *sublinear* in the input length. Additional computational parameters that we aim to minimize are the verifier's running time (which should also be sublinear) and the prover's running time (which, ideally, should be proportional to the complexity of deciding the language).

In this work we focus on the round complexity of IPPs, and on the relation between the number of rounds and the other parameters. Specifically, we ask the following question:

Does the power of Interactive Proofs of Proximity grow with the number of rounds?

Understanding the round complexity of protocols is a central problem in the theory of computation (most notably in complexity theory and cryptography). Some of the main motivations for reducing round complexity are considerations such as network latency, the need to stay online or to synchronize messages between the parties, and the overhead involved in sending and receiving messages.

1.1 Our Results

Our main result answers the foregoing question by showing a hierarchy of IPPs: we show that for a gap function $g(r) = \Theta(r^2)$, and for every constant $r \geq 1$, it holds that r-round IPPs can be outperformed by $g(r)$-round IPPs, in the sense that the verifier in the latter system is significantly more efficient. We prove our hierarchy theorem by constructing a *single* explicit language for which the power of IPPs grows with the number of rounds.

▶ **Theorem 1** (Hierarchy theorem, informally stated (see Theorem 16)). *There exists an explicit language $\mathcal{L}$ such that for every constant $r \geq 1$ and for inputs of length n:*

1. *There is an $O(r^2)$-round* IPP *for $\mathcal{L}$ in which the verifier runs in time $t = n^{O(1/r)}$; and*
2. *The verifier in* any *r-round* IPP *for $\mathcal{L}$* must *run in time at least $t' = t^{100}$ (where the constant* 100 *is arbitrary). Furthermore, either the communication complexity or query complexity of the verifier must be at least t'.*

Thus, we obtain a characterization (which is exact, up to the specific polynomial of the gap function g) of the complexity of constant-round IPPs for the language $\mathcal{L}$.

For simplicity, the statement in Theorem 1 is restricted to constant-round protocols. However, the complexity of the IPP protocol in Theorem 1 actually reduces further as the round complexity grows to be super-constant. In particular, we obtain a poly-logarithmic round IPP for $\mathcal{L}$ with poly-logarithmic communication and query complexities, and an $\omega(1)$-round IPP with $n^{o(1)}$ communication and query complexities. Together with the lower bound in Theorem 1, these yield a separation between the power of constant-round IPPs and super-constant round IPPs, and a *sub-exponential* separation with respect to poly-logarithmic round IPPs.

▶ **Theorem 2** (Constant Round versus General IPPs). *There exists a language $\mathcal{L}$ that has a* polylog(n)*-round* IPP *with a* polylog(n) *time verifier and an $\omega(1)$-round* IPP *with $n^{o(1)}$ time verifier, but for every constant $r \geq 1$, the verifier in any r-round* IPP *for $\mathcal{L}$ must run in time at least $n^{\Omega(1/r)}$.*

Prior to this work, only a separation between the power of MAPs (which are *non-interactive* IPPs, i.e., the entire "interaction" consists of a *single* message) and IPPs was known [43].

We remark that Theorems 1 and 2, and their proofs, shed new light also on standard interactive proofs (in which the verifier is given direct access to the input and can run in polynomial time). We proceed to discuss such implications.

Optimality of the Babai-Moran Round Reduction. Following Vadhan [66], we consider *black-box transformations on interactive proofs*, which are transformations that take prover and verifier strategies $(\mathcal{P}, \mathcal{V})$, for an interactive-proof for some language $\mathcal{L}$, and output new strategies $(\mathcal{P}', \mathcal{V}')$, for the same language $\mathcal{L}$, such that new prover and verifier strategies can only make oracle calls to the original strategies $(\mathcal{P}, \mathcal{V})$. More specifically, the new verifier $\mathcal{V}'$ is only allowed to make oracle calls to $\mathcal{V}$ (and in particular does not have direct access to the input) and $\mathcal{P}'$ may make oracle calls to both $\mathcal{V}$ and $\mathcal{P}$.[1]

As pointed out by Vadhan, many (but not all) of the known transformations on interactive proofs from the literature are in fact black-box. We focus on such a transformation, due to Babai and Moran [8], for reducing the number of rounds of interaction in public-coin interactive proofs. Using our hierarchy theorem, we show that the overhead incurred by the round reduction transformation of [8] is close to optimal among all black-box transformations.

Algebrization of Interactive Proofs. As our second application, we show a connection between our hierarchy theorem and the *algebrization* framework of Aaronson and Wigderson [1]. This framework, which is an extension of the *relatization* framework of Baker, Gill, and Solovay [9], is viewed as a barrier to proving complexity-theoretic lower bounds using currently known proof techniques. Loosely speaking, [1] show that almost all known complexity theoretic results "algebrize" (i.e., fall within their framework), whereas making progress on some of our most fundamental questions (such as $\mathcal{P} \neq$ NP) requires non-algebrizing techniques.

Using our hierarchy theorem for IPPs, we show that any proof of the complexity class inclusion $\#\mathcal{P} \subseteq \mathcal{AM}$ (which is widely disbelieved, and in particular implies the collapse of the polynomial hierarchy) must make use of non-algebrizing techniques, and therefore *must* introduce a fundamentally different proof technique. A conceptual connection between our results and interactive proofs in the algebrization framework is further discussed in Section 1.3 and elaborated on in Section 5.

1.2 Technical Overview

Loosely speaking, the language for which we prove the round hierarchy theorem consists of error-correcting encodings of strings $x \in \{0,1\}^k$ whose Hamming weight $\mathsf{wt}(x) \stackrel{\text{def}}{=} \sum_{i \in [k]} x_i$, is divisible by 3 (i.e., $\mathsf{wt}(x) = 0 \pmod 3$).

[1] One could also restrict $\mathcal{P}'$ to make only oracle calls to $\mathcal{P}$ (and not to $\mathcal{V}$ as we do). However, giving $\mathcal{P}'$ more freedom only makes our results stronger (since we rule out the broader class of transformations).

The specific encoding that we use is the low degree extension code $\mathsf{LDE} : \mathbb{F}^k \to \mathbb{F}^n$, over a field $\mathbb{F}$ that is an extension field of $\mathsf{GF}(2)$.[2] Indeed, it is crucial that the characteristic of $\mathbb{F}$ is different than the modulus 3. The parameter k (which specifies the message length) is the same as in the preceding paragraph, where we view $\{0,1\}^k$ as a subset of the message space $\mathbb{F}^k$.

Before proceeding, we note that throughout this work we use the standard convention that codes map messages of length k to codewords of length $n = \mathsf{poly}(k)$. In particular, this will mean that inputs to IPPs, which will typically refer to (possibly corrupt) codewords, have length n, whereas inputs to other types of protocols and sub-routines, may refer to the underlying messages, which have length k.

Recall that the LDE code is parameterized by a finite field $\mathbb{F}$, a subset of the field $H \subseteq \mathbb{F}$ and a dimension m. To encode a message $x \in \{0,1\}^k$, where $k = |H|^m$, we view the message as a function $x : H^m \to \{0,1\}$ (by associating $[k]$ with H^m) and consider the unique individual degree $|H| - 1$ polynomial $P : \mathbb{F}^m \to \mathbb{F}$ that agrees with x on H^m. We denote this polynomial by $P = \mathsf{LDE}_{\mathbb{F},H,m}(x)$. For the time being, the sizes of $|\mathbb{F}|$, $|H|$ and m should all be thought of as at most poly-logarithmic in n. (See Section 2.3 for additional details about the LDE encoding.)

Thus, the language for which we prove our round hierarchy, which we denote by Enc-MOD3, consists of all polynomials $P : \mathbb{F}^m \to \mathbb{F}$ of individual degree $|H| - 1$ that obtain Boolean values in the subcube H^m, such that these Boolean values sum up to 0 (mod 3). That is, all polynomials P such that $P|_{H^m} : H^m \to \{0,1\}$ and $\sum_{z \in H^m} P(z) \equiv 0 \pmod 3$.

We prove our hierarchy theorem by showing that for every constant $r \geq 1$, the language Enc-MOD3 has an $O(r^2)$-round IPP in which the verifier runs in time roughly $n^{O(1/r)}$, and that the verifier in *any* r-round IPP for Enc-MOD3 must run in time at least $n^{\Omega(1/r)}$, where the constant in the Ω-notation can be made arbitrarily larger than the constant in the O-notation. In Section 1.2.1 we give an overview of the upper bound, which is technically more involved, and then, in Section 1.2.2 we give an overview of the lower bound.

1.2.1 Upper Bound

Our goal is to construct an IPP in which the verifier is given oracle access to a function $f : \mathbb{F}^m \to \mathbb{F}$ and needs to verify that f is close to a polynomial of individual degree $|H| - 1$ that obtains only Boolean values in H^m such that their sum modulo 3, over the subcube H^m, is 0. The verifier may interact with the prover for $O(r^2)$ rounds.

As its initial step, our verifier checks that the given input f is close to some low degree polynomial by invoking the low degree test. This test, introduced by Rubinfeld and Sudan [59], ensures that if f is far from every low degree polynomial, then the verifier will reject with high probability. Thus, we can assume that f is close to some low degree polynomial. Moreover, using the self-correction property of polynomials, this means that with a small overhead, we can treat f as though it were itself a low degree polynomial (rather than just being close).[3]

Given this initial step, we can now assume without loss of generality that the function $f : \mathbb{F}^m \to \mathbb{F}$ is in fact a low degree polynomial. However, the verifier still needs to check that $\sum_{z \in H^m} f(z) = 0 \pmod 3$ and that $f|_{H^m} : H^m \to \{0,1\}$. For now though, let us focus

[2] We remark that a similar result could be obtained if we replaced the modulus 3 and the field's characteristic by any two *distinct* and *constant-sized* primes.

[3] Loosely speaking, the self-correction property of polynomials says that if f is guaranteed to be close to a low degree polynomial P, then one can read values from P by only making few queries to f. See Lemma 30 for the precise statement.

on the former task, which is the main step in our proof: checking that $\sum_{z \in H^m} f(z) = 0 \pmod 3$ (and we just assume that $f|_{H^m} : H^m \to \{0,1\}$).

Viewing $f|_{H^m}$ as a string $x \in \{0,1\}^k$, we need to construct an interactive proof in which the verifier uses oracle access to $\mathsf{LDE}(x)$ to verify that $\mathsf{wt}(x) = 0 \pmod 3$ in sublinear time. We refer to this type of proof-system, in which the verifier is given oracle access to an *encoding* of the input and runs in sublinear time, as a *holographic*[4] *interactive proof* (HIP).

More precisely, we say that a language has an HIP, with respect to some error-correcting code C, if it has an interactive proof in which the verifier has oracle access to an encoding under C of the input and verifies membership in the language using few queries to this encoding. The redundant representation of the input often allows the verifier to run in *sub-linear time*. We remark that HIPs play a central role in this work and we discuss them more in Section 1.3.

Thus, our task is now to construct an HIP (with respect to the LDE code) for the language

$$\mathcal{L}_{\mathsf{MOD3}} \stackrel{\text{def}}{=} \left\{ x \in \{0,1\}^k \ : \ \mathsf{wt}(x) = 0 \pmod 3 \right\}.$$

Before describing the construction of an HIP for $\mathcal{L}_{\mathsf{MOD3}}$, it will be instructive to consider as a warm-up, the construction of an HIP for the related language $\mathcal{L}_{\mathsf{MOD2}} = \{x \in \{0,1\}^k : \mathsf{wt}(x) = 0 \pmod 2\}$, where the important distinction is that the modulus 2 is also the characteristic of the field $\mathbb{F}$ under which x is encoded.

In this warmup case, we assume that the verifier is given oracle access to a polynomial $f : \mathbb{F}^m \to \mathbb{F}$ that obtains Boolean values in H^m (i.e. $f|_{H^m} : H^m \to \{0,1\}$), and needs to check that $\sum_{z \in H^m} f(z) = 0$, where the sum is over $\mathsf{GF}(2)$. Importantly, since we assumed that $f|_{H^m}$ is Boolean valued, and that the field $\mathbb{F}$ has characteristic 2, we can instead take the sum over the field $\mathbb{F}$ (rather than taking the integer sum mod 2).

The latter problem, of checking whether the sum of a given input polynomial is 0 over a subcube of its domain (i.e., over H^m), has a well-known interactive proof due to Lund *et al.* [52], which is often referred to as the *sumcheck protocol*. In this protocol the verifier only needs to query the polynomial f at a single point and so it can be viewed as an HIP. Furthermore, there are known variants of the sumcheck protocol that offer a suitable tradeoff between the number of rounds and verifier's complexity, which suffice for our purposes (i.e., an r-round IPP with verification time roughly $n^{1/r}$).

The aforementioned variants of the sumcheck protocol suffice for an upper bound for the warmup case. However, we do not know how to prove a corresponding lower bound, which is the reason that we set the modulus in our construction to be different from the field's characteristic.[5] While the original language $\mathcal{L}_{\mathsf{MOD3}}$ allows us to prove the desired lower bound, unfortunately it makes obtaining an upper bound more challenging. We proceed to the actual problem at hand: constructing an HIP (with respect to the LDE code over a field of characteristic 2) for checking $\mathcal{L}_{\mathsf{MOD3}}$.

Since the modulus and characteristic are different, our task can no longer be expressed as a linear constraint (over $\mathbb{F}$) on the bits of x. Since we do not know how to solve this problem directly using the sumcheck protocol, we turn to more complex interactive proofs from the literature. Specifically, our starting point will be the interactive proof-system of Goldwasser, Kalai and Rothblum [37], which we shall refer to as the GKR protocol.[6]

[4] The terminology of "holographic" interactive proofs originates from the "holographic proofs" of Babai *et al.* [5], which refers to probabilistic proof systems for *encoded* inputs. The notion of HIP, and its relation to other notions, is further discussed in Section 1.3.

[5] We conjecture that for the warmup case (i.e., when the modulus is 2) a lower bound that (roughly) corresponds to the upper bound given by the sumcheck protocol does hold.

[6] In Section A.1 we discuss our reason for basing our protocol on the GKR proof-system, rather than

The GKR Protocol. Goldwasser *et al.* give an interactive proof for any language computable by a logspace-uniform circuit of size S and depth D such that the number of rounds in their protocol is $D \cdot \mathsf{polylog}(S)$, the communication is also $D \cdot \mathsf{polylog}(S)$, and the verifier runs in time $(n + D) \cdot \mathsf{polylog}(S)$. Their protocol is based on algebraic techniques and, in particular, uses ideas originating from the interactive proof and PCP literature (cf., [63]). Our HIP for MOD3 will be based on a variant of their proof system.

Observe that one can check whether a given string x's Hamming weight is divisible by 3 using a highly uniform logarithmic-depth formula.[7] Thus, applying the GKR result gives us an interactive proof for $\mathcal{L}_{\mathsf{MOD3}}$. Most importantly for our purposes, if the GKR verifier is given oracle access to the LDE encoding of the input, then it only needs to check a single (random) element from the encoding (and in particular runs in sublinear time). In other words, the GKR protocol can be thought of as an HIP with *sublinear* time verification.[8] While the GKR protocol does yield an HIP for $\mathcal{L}_{\mathsf{MOD3}}$, its round complexity is poly-logarithmic and therefore too large for our purposes (recall that we are aiming for constant round protocols). The large round complexity is due to the fact that the high-level strategy in the GKR protocol is to process the circuit layer by layer, where the transition between each two consecutive layers uses an interactive protocol, which itself is based on the sumcheck protocol.

Even if we were to use a constant-round variant of the sumcheck protocol for each transition, the GKR protocol still uses $\Omega(D)$ rounds, where D is the depth of the circuit, which in our case is logarithmic and therefore too large. To get around this, we rely on an unpublished observation, due to Kalai and Rothblum [45], which shows that for every constant $r \geq 1$, if the circuit satisfies an extreme (and somewhat unnatural) uniformity condition[9], then $\log(n)/r$ layers can be processed at once, using r rounds of interaction and roughly $n^{1/r}$ communication. Thus, overall, a logarithmic depth circuit can processed in $O(r^2)$ rounds. Using this observation, [45] obtain *constant-round* interactive-proofs for all languages in NC^1 that satisfy the aforementioned uniformity condition.[10]

In our actual construction we do not use the [45] protocol directly (even though the language $\mathcal{L}_{\mathsf{MOD3}}$ satisfies the desired uniformity), but rather give a special purpose protocol tailored for $\mathcal{L}_{\mathsf{MOD3}}$ (which is inspired by their techniques). Doing so allows us to avoid stating their somewhat cumbersome uniformity condition and to introduce other simplifications (due to the simple and regular structure of the formula for $\mathcal{L}_{\mathsf{MOD3}}$). We proceed to describe this HIP.

---

other general purpose interactive proof-systems from the literature.

[7] E.g., consider the $\log(k)$-depth full binary tree with the input bits at its leaves, in which each internal vertex computes the sum modulo 3 of its two children, where each such modulo 3 sum can be computed by a simple constant size gadget composed of AND, OR and NOT gates.

[8] Note that obtaining an interactive-proof for $\mathcal{L}_{\mathsf{MOD3}}$ with a *linear-time* verifier is trivial, since the verifier can decide membership by itself in linear-time. The key benefit that we get from using the GKR protocol is that it allows for *sublinear* time verification given access to an encoded input.

[9] Loosely speaking, the uniformity condition requires that it be possible to compute *low degree extensions* of gate indicator functions that refer to gates of fan-in $t = n^{O(1/r)}$. That is, we view the formula as a depth r circuit consisting of gates of fan-in $t = n^{O(1/r)}$ (by grouping together every $\log(n)/r$ consecutive layers). For each of these r layers, and every type of fan-in t gate $g : \{0,1\}^t \to \{0,1\}$ that appears in that layer, we consider a gate indicator function I_g that given as input indices of $t + 1$ wires, outputs 1 if the first wire is the result of an application of g to the other t wires. The [45] uniformity requirement is that it be possible to efficiently compute the *low degree extension* of I_g.

[10] Recall that the class NC^i consists of languages computable by polynomial-size $O\left((\log n)^i\right)$-depth circuits with fan-in 2. We emphasize that the [45] result gives *constant-round* protocols only for NC^1 circuits (that are sufficiently uniform), whereas the GKR result gives protocol with a *poly-logarithmic* round complexity for all (logspace uniform) languages in $\mathsf{NC} = \cup_{k \in \mathbb{N}} \mathsf{NC}^k$. (Furthermore, the GKR protocol for NC has poly-logarithmic communication complexity whereas the [45] protocol has $n^{1/O(1)}$ communication.)

A Holographic Interactive Proof for $\mathcal{L}_{\mathsf{MOD3}}$. Recall that we are given oracle access to a polynomial $X : \mathbb{F}^m \to \mathbb{F}$ promised to be the low-degree extension of a *Boolean* assignment $x \in \{0,1\}^k$, and our goal is to construct an $O(r^2)$-round HIP for verifying whether $x \in \mathcal{L}_{\mathsf{MOD3}}$. Also recall that we have fixed the parameters of the LDE code, including a field $\mathbb{F}$, a subset $H \subseteq \mathbb{F}$, and a dimension m such that $|H^m| = k$. However, for now we think of the sizes of these parameters as being $|H| = k^{1/r}$, $m = r$, and $|\mathbb{F}| = \mathsf{poly}(|H|, m)$, rather than $|H|$ being poly-logarithmic in k.[11]

For a given input polynomial $X : \mathbb{F}^m \to \mathbb{F}$ (of individual degree $|H| - 1$), we define a sequence of polynomials $V_0, \ldots, V_r$, where each $V_i : \mathbb{F}^i \to \mathbb{F}$ has individual degree $|H|-1$ (note that these polynomials have gradually increasing domains). The polynomial $V_r : \mathbb{F}^r \to \mathbb{F}$ is defined as $V_r \equiv X$. The polynomials $V_1, \ldots, V_{r-1}$ are each defined to be the (unique) individual degree $|H| - 1$ polynomial that satisfies the following recursive relation:

$$\forall i \in [r],\ \forall h \in H^{i-1}, \quad V_{i-1}(h) = \sum_{\alpha \in H} V_i(h, \alpha) \pmod 3, \tag{1}$$

where the arithmetic is over the integers (modulo 3). Indeed, $V_0 \in \mathbb{F}$ is defined as a single field element $V_0 = \sum_{\alpha \in H} V_1(\alpha) \pmod 3$. Note that we identify the integers $\{0,1,2\}$ with three distinct elements in $\mathbb{F}$. Indeed, each of the V_i polynomials takes values in the set $\{0,1,2\} \subseteq \mathbb{F}$ over the subcube H^i.

Taking the [37, 45] view, each polynomial $V_i : \mathbb{F}^i \to \mathbb{F}$ can be thought of as the low degree extension of the i^{th}-layer (counting from the output layer) in a depth r formula of fan-in $k^{1/r}$ for $\mathcal{L}_{\mathsf{MOD3}}$ such that each gate computes the sum modulo 3 of its $k^{1/r}$ children. In particular,

$$V_0 = \sum_{\alpha \in H} V_1(\alpha) = \cdots = \sum_{h \in H^i} V_i(h) = \cdots = \sum_{h \in H^r} V_r(h) = \mathsf{wt}(x) \pmod 3.$$

Our main step is an interactive protocol that reduces a claim about an (arbitrary) single point in the polynomial V_{i-1} to a claim about a single (random) point in V_i. By applying this interactive reduction r times, we can reduce the initial claim $V_0 = 0$ to a claim about a single point in V_r, which we can explicitly check (since we have oracle access to $V_r \equiv X$). Each interactive reduction will take $O(r)$ rounds so overall we get an HIP for $\mathcal{L}_{\mathsf{MOD3}}$ with $O(r^2)$ rounds.

Towards showing such an interactive reduction protocol, we would like to express Equation (1), which is a modular equation over the integers, as a low degree relation over the field $\mathbb{F}$. Let $t \stackrel{\text{def}}{=} |H| = k^{1/r}$, and let $\xi_1, \ldots, \xi_t$ be the enumeration of all elements in H. Define the polynomial $\widetilde{\mathsf{MOD3}} : \mathbb{F}^t \to \mathbb{F}$ as the (unique) individual degree two polynomial such that for every $z \in \{0,1,2\}^t$, it holds that $\widetilde{\mathsf{MOD3}}(z) = \sum_{j \in [t]} z_i \pmod 3$, where the tilde in the notation is meant to remind us that $\widetilde{\mathsf{MOD3}}$ is not the modulo 3 summation function but rather its low degree extension over $\mathbb{F}$. Equation (1) can now be re-stated as:

$$\forall i \in [r],\ \forall h \in H^{i-1}, \quad V_{i-1}(h) = \widetilde{\mathsf{MOD3}}\Big(V_i(h, \xi_1), \ldots, V_i(h, \xi_t)\Big) \tag{2}$$

(where we use the fact that the V_i polynomials take values in $\{0,1,2\}$ over H^i.)

[11] We remark that setting $|H| = k^{1/r}$ is actually problematic for us since it induces a dependence between the language $\mathsf{Enc\text{-}MOD3}$ and the desired round complexity r. Nevertheless, it does yield a weaker hierarchy theorem in which we use a different language for each value of r. At the end of Section 1.2.1 we discuss how we overcome this difficulty.

Observe that Equation (2) is a polynomial relation between V_{i-1} and V_i that holds for inputs in H^{i-1}. We would like to obtain a similar relation for general inputs (i.e., in $\mathbb{F}^{i-1}$). To do so, we observe that, for every $z \in \mathbb{F}^{i-1}$, we can express $V_{i-1}(z)$ as an $\mathbb{F}$-linear combination of the values $\{V_{i-1}(h)\}_{h\in H^{i-1}}$ (this follows directly from the fact that the low degree extension is a *linear* code). We denote the coefficients in this linear combination by $\{\beta_z(h)\}_{h\in H^{i-1}}$ (these coefficients arise from Lagrange interpolation, but we ignore the specifics for this overview). Combining this observation together with Equation (2) we obtain:

$$\begin{aligned}\forall i \in [r],\ \forall z \in \mathbb{F}^{i-1}, \quad V_{i-1}(z) &= \sum_{h\in H^{i-1}} \beta_z(h)\cdot V_{i-1}(h) \\ &= \sum_{h\in H^{i-1}} \beta_z(h)\cdot \widetilde{\mathsf{MOD3}}\Big(V_i(h,\xi_1),\ldots,V_i(h,\xi_t)\Big). \end{aligned} \tag{3}$$

Using Equation (3) we will describe an interactive reduction from a claim about V_{i-1} to a claim about V_i. Suppose that our interactive reduction starts with a claim that $V_{i-1}(z_{i-1}) = \nu_{i-1}$ for some $z_{i-1} \in \mathbb{F}^{i-1}$ and $\nu_{i-1} \in \mathbb{F}$. By Equation (3) this translates into the claim:

$$\nu_{i-1} = \sum_{h\in H^{i-1}} \beta_{z_{i-1}}(h)\cdot \widetilde{\mathsf{MOD3}}\Big(V_i(h,\xi_1),\ldots,V_i(h,\xi_t)\Big). \tag{4}$$

We now observe that $Q_i(w) \stackrel{\text{def}}{=} \beta_{z_{i-1}}(w)\cdot \widetilde{\mathsf{MOD3}}\Big(V_i(w,\xi_1),\ldots,V_i(w,\xi_t)\Big)$ is a low degree polynomial over $\mathbb{F}$ (since $\beta_{z_{i-1}}$, $\widetilde{\mathsf{MOD3}}$, and V_i have low degree). Thus, the claim in Equation (4) refers to the sum of a low degree polynomial over a subcube, which is precisely the problem that the sumcheck protocol solves.

It seems that we are done, except that a problem arises. In the sumcheck protocol the verifier is given oracle access to the polynomial whose sum over a subcube we wish to check. Although the polynomial Q_i on which we wish to run the sumcheck protocol is well-defined, our verifier does not have oracle access to it. Therefore it is not immediately clear how we can hope to run the sumcheck protocol with respect to Q_i.

We resolve this problem by noting that the sumcheck protocol can be used in an *input-oblivious* manner. In this variant, the verifier does not need to have oracle access to Q_i, but rather than accepting or rejecting, the verifier outputs a claim of the form $Q_i(w_{i-1}) = \gamma_{i-1}$, for some point $w_{i-1} \in \mathbb{F}^{i-1}$ and value $\gamma_{i-1} \in \mathbb{F}$. Completeness means that if the original claim is true (i.e., $\sum_{h\in H^{i-1}} Q_i(h) = \nu_{i-1}$), then the verifier always outputs (w_{i-1}, γ_{i-1}) such that $Q_i(w_{i-1}) = \gamma_{i-1}$, and soundness means that if the original claim is false (i.e., $\sum_{h\in H^{i-1}} Q_i(h) \neq \nu_{i-1}$), then for any cheating prover strategy, with high probability $Q_i(w_{i-1}) \neq \gamma_{i-1}$ (or the verifier rejects during the interaction). We stress that in this variant the verifier makes no queries to Q_i.[12] As for the number of rounds, recall that in the sumcheck protocol in each iteration one of the variables is "stripped" from the summation, which leads to a total of $i - 1 \leq r$ rounds.

Having run the input-oblivious variant of the sumcheck protocool, our verifier is now left with the claim $Q_i(w_{i-1}) = \gamma_{i-1}$. However, to obtain our interactive reduction, we still need to reduce the foregoing claim to a claim about a (single) point in the polynomial V_i. To do so, the first idea that comes to mind is to have the prover provide the values

[12] To see that this variant is possible, observe that in the classical sumcheck protocol [52], the verifier only queries the polynomial at a single point and (at the end of the interaction) checks that it is equal to a particular value.

$\mu_j = V_i(w_{i-1}, \xi_j)$, for every $j \in [t]$. Given these values, the verifier can explicitly check that indeed $\gamma_{i-1} = \beta_{z_{i-1}}(w_{i-1}) \cdot \widetilde{\mathsf{MOD3}}(\mu_1, \ldots, \mu_t)$.[13] If the prover indeed sent the correct values, then this last check assures us that indeed $Q_i(w_{i-1}) = \gamma_{i-1}$. However, since we cannot assume that the prover sent the correct values, we are left with t claim of the form $V_i(w_{i-1}, \xi_j) = \mu_j$, which the verifier needs to check.

Notice that we have actually reduced a single claim about V_{i-1} to t claims about V_i. This still falls short of our goal which was to reduce to only a *single* claim about V_i. (Indeed, we cannot afford to increase the number of claims by a t factor in each iteration, since this would yield a protocol with complexity $t^r = k$, which is trivial).

The final observation is that the points $\{(w_{i-1}, \alpha)\}_{\alpha \in H}$ lie on the (axis parallel) line $(w_{i-1}, *)$. Note that the restriction of a low degree polynomial to an axis parallel line is a low degree (univariate) polynomial. Thus, we will have the prover specify the entire polynomial $P_i : \mathbb{F} \to \mathbb{F}$ defined as $P_i(\alpha) = V_i(w_{i-1}, \alpha)$, for every $\alpha \in \mathbb{F}$. The verifier checks that $\gamma_{i-1} = \beta_{z_{i-1}}(w_{i-1}) \cdot \widetilde{\mathsf{MOD3}}(P_i(\xi_1), \ldots, P_i(\xi_t))$. The point is that now if the prover supplies an incorrect values for some $P_i(\alpha)$ (i.e., $P_i(\alpha) \neq V_i(w_{i-1}, \alpha)$), since both P_i and $V_i(w_{i-1}, *)$ are low degree polynomials, for most $\rho \in \mathbb{F}$ it holds that $P_i(\rho) \neq V_i(w, \rho)$. Thus, the verifier chooses at random $\rho_i \in \mathbb{F}$ and sets the claim for the next iteration to be $V_i(z_i) = \nu_i$, where $z_i = (w_{i-1}, \rho_i)$ and $\nu_i = P_i(\rho_i)$.[14]

To summarize, our HIP for $\mathcal{L}_{\mathsf{MOD3}}$ works in r phases. In the i^{th} phase we reduce a claim of the form $V_{i-1}(z_{i-1}) = \nu_{i-1}$, for some point $z_{i-1} \in \mathbb{F}^{i-1}$ and value $\nu_{i-1} \in \mathbb{F}$, into a claim $V_i(z_i) = \nu_i$, for $z_i \in \mathbb{F}^i$ and $\nu_i \in \mathbb{F}$ (which are generated during the interactive reduction). In particular, the first iteration begins with the claim $V_0 = 0$ (i.e., z_0 is the empty string and $\nu_0 = 0$), which corresponds to the claim that $x \in \mathcal{L}_{\mathsf{MOD3}}$ (i.e., $\mathsf{wt}(x) = 0 \pmod 3$). Thus, the i^{th} phase in our HIP begins with the claim $V_{i-1}(z_{i-1}) = \nu_{i-1}$. In the i^{th} phase, first the prover and verifier engage in the sumcheck protocol that arises from Equation (4). This yields the claim $Q_i(w_{i-1}) = \gamma_{i-1}$, for a point $w_{i-1} \in \mathbb{F}^{i-1}$ and value $\gamma_{i-1} \in \mathbb{F}$ (generated by the sumcheck protocol). Since the verifier has no access to Q_i, it asks the prover to send the polynomial $P_i : \mathbb{F} \to \mathbb{F}$ defined as $P_i(\alpha) = V_i(w_{i-1}, \alpha)$. The verifier checks that the values of this polynomial are consistent with the claim $Q_i(w_{i-1}) = \gamma_{i-1}$, and then selects a random point $\rho_i \in \mathbb{F}$. The claim for the following phase is that $V_i(z_i) = \nu_i$, where $z_i = (w_{i-1}, \rho_i)$ and $\nu_i = P_i(\rho_i)$. After r such phases we are left with the claim $V_r(z_r) = \nu_r$, for $z_r \in \mathbb{F}^r$ and $\nu_r \in \mathbb{F}$, which the verifier can explicitly check (since it has oracle access to $V_r \equiv X$).

The total number of rounds per interactive reduction is $O(r)$, and the communication complexity is roughly $\mathsf{poly}(t, r) = \mathsf{poly}(r, k^{1/r})$. Since we invoke r such reductions, overall we obtain an HIP for $\mathcal{L}_{\mathsf{MOD3}}$ with round complexity $O(r^2)$ and communication complexity $\mathsf{poly}(r, k^{1/r})$.

Obtaining an HIP over a Small Field. The approach outlined above yields an r^2-round HIP for $\mathcal{L}_{\mathsf{MOD3}}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, in which the field size $|\mathbb{F}|$ is quite large (i.e., $|\mathbb{F}| \geq k^{1/r}$) and in particular depends on the value of r. Unfortunately, when we transform this HIP into an IPP for the language Enc-$\mathsf{MOD3}$, the dependence of the field size on r in the HIP introduces a dependence of the language Enc-$\mathsf{MOD3} \stackrel{\text{def}}{=} \{C(x) \,:\, x \in \{0,1\}^k \text{ with } \mathsf{wt}(x) = 0 \pmod 3\}$ on r. This dependence results in a weaker hierarchy theorem, in which we use a

[13] Note that both $\beta_{z_{i-1}}$ and $\widetilde{\mathsf{MOD3}}$ are *explicit* functions that the verifier can compute. Moreover they can even be computed *efficiently* using standard techniques, see the technical sections for details.

[14] We remark that this final step is actually very reminiscent of an individual round of the sumcheck protocol.

different language for each value of r . Our goal however is to obtain a *single* language, for which we can show an r-round IPP for every value of r (with a corresponding lower bound, which will be discussed in Section 1.2.2).

To this end we show a general reduction that transforms any HIP over a large field $\mathbb{F}$ into an HIP over a much smaller field $\mathbb{F}'$, as long as $\mathbb{F}$ is an extension field of $\mathbb{F}'$. We do so by showing that any $\mathbb{F}$-linear claim regarding the input (e.g., a claim about a single point in the $\mathsf{LDE}_{\mathbb{F},H,m}$ encoding) can be broken down (coordinate-wise) into d claims that are $\mathbb{F}'$-linear, where $d = \log(|\mathbb{F}|/|\mathbb{F}'|)$ is the degree of the field extension (i.e., $(\mathbb{F}')^d$ is isomorphic to $\mathbb{F}$). We can then easily verify each one of these $\mathbb{F}'$-linear claims using the sumcheck protocol over the smaller field $\mathbb{F}'$.[15]

We remark that the ability to switch fields when using (holographic) interactive proofs seems like a useful tool, and we believe that it will be useful in other contexts as well.

Checking Booleanity. In the above analysis we assumed for simplicity that the input $x = f|_{H^m}$ is Boolean valued. In order to actually check this, we follow an idea of Kalai and Raz [46] (which was used in the context of constructing interactive PCPs). We observe that the polynomial $f : \mathbb{F}^m \to \mathbb{F}$ is Boolean valued in a subcube H^m if and only if the (slightly higher degree) polynomial $g : \mathbb{F}^m \to \mathbb{F}$, defined as $g(z) = f(z) \cdot (1 - f(z))$ is identically 0 in H^m. The latter problem (of checking whether a polynomial vanishes on a particular subcube) can be solved via a relatively simple reduction to the sumcheck protocol, that has been used in the construction of PCPs.[16] We note that we crucially use fact that the reduction from f to g is local (i.e., the value of g at a point depends on the value of f at $O(1)$ points), and therefore can be used in our setting.

1.2.2 Lower Bound

We need to show a lower bound on the complexity of r-round IPPs for our language $\mathsf{Enc\text{-}MOD3} = \{C(x) \ : \ x \in \{0,1\}^k \text{ with } \mathsf{wt}(x) = 0 \pmod 3\}$, where $C : \mathbb{F}^k \to \mathbb{F}^n$ is the low degree extension code. Our lower bound will strongly use the fact that any $\mathbb{F}$-linear code (and in particular the low degree extension code that we use), for a field $\mathbb{F}$ of characteristic 2, is also a GF(2)-linear code.

Our lower bound relies on a connection between IPPs and low-depth circuits, which was discovered by Rothblum, Vadhan and Wigderson [58]. Following their approach, in Section 4.3 we show that to prove an IPP lower bound for Enc-MOD3, it suffices to construct two distributions D_0 and D_1 over n-bit strings such that:

1. D_0 is distributed over the support of Enc-MOD3 (with high probability);
2. D_1 is far from Enc-MOD3 (with high probability); and
3. Every sufficiently small DNF formula cannot distinguish between inputs from D_0 and D_1 (with more than, say, 0.1 advantage).

[15] To obtain the desired *computational* efficiency for the latter task, we actually use the [45] protocol, which introduces an additional $O(r^2)$ rounds. We believe this use is an overkill, and we hope to replace it with a more elementary argument in a following revision.

[16] In a nutshell, to check whether $g|_{H^m} \equiv 0$ we consider the restriction of g to the domain H^m and take the low degree extension $\hat{g}$ of that partial function. We observe that g is identically 0 in H^m if and only if $\hat{g}$ is identically 0 in $\mathbb{F}^m$. Thus, it suffices to check whether for a random point $z \in \mathbb{F}^m$, which the verifier chooses, it holds that $\hat{g}(z) = 0$. The linearity of the LDE code now means that this check can be solved by invoking the sumcheck protocol. See Section 3.4 for details.

The two distributions that we consider are D_0 and D_1 such that D_b is uniform over the set $\{C(x) \ : \ x \in \{0,1\}^k \text{ and } \mathsf{wt}(x) = b \pmod 3\}$. Note that D_0 is the uniform distribution over Enc-MOD3, and so satisfies requirement (1), whereas the fact that D_1 satisfies requirement (2) follows from the distance of the code C. To show that the third requirement holds, consider a DNF ϕ that distinguishes between D_0 and D_1. We show that the size of ϕ must be large. Consider the distributions D'_0 and D'_1 over k-bit strings defined as

$$D'_b = \{x \in \{0,1\}^k \ : \ \mathsf{wt}(x) = b \pmod 3\}.$$

We can easily construct from ϕ a circuit ϕ' that distinguishes between D'_0 and D'_1: the circuit ϕ' first computes the encoding $C(x)$ of its input $x \in \{0,1\}^k$, and then applies the DNF ϕ to the result. Using the fact that C is linear over $\mathsf{GF}(2)$, it follows that ϕ' is a DNF of parities (i.e., a depth-3 formula with an OR gate at the top layer, AND gates at the middle layer, and XOR gates at the bottom layer). Now, we can apply the Razborov-Smolensky [59] lower bound, which shows that any small $\mathsf{AC}_0[2]$ circuit (i.e., circuits of constant-depth circuits with AND, OR, and PARITY gates of unbounded fan-in), and in particular a DNF of parities, cannot even approximate the summation modulo 3 function (i.e., distinguish between D'_0 and D'_1).

1.3 Holographic Interactive Proofs

The proof of our hierarchy theorem utilizes a special type of interactive proofs, which we call *holographic interactive proofs*. A holographic interactive proof (HIP) is an interactive proof in which, instead of getting its input x explicitly, the verifier is given *oracle* access to $C(x)$, an error-corrected encoding of the input x, for a bounded number of queries. Hence, HIPs may be thought of as interactive proofs for promise problems of the form $(\Pi_{\mathsf{YES}}, \Pi_{\mathsf{NO}})$ with $\Pi_{\mathsf{YES}} = \{C(x) : x \in \mathcal{L}\}$ and $\Pi_{\mathsf{NO}} = \{C(x) : x \notin \mathcal{L}\}$.

The notion of HIP was used, either implicitly or explicitly as a technical tool that underlies many probabilistic proof systems (e.g., [52, 6, 5, 46, 37, 47, 58, 43, 48, 56, 28]).[17] These works demonstrate that, by using the redundant encoding of the input, we can often achieve sublinear verification time. (As a matter of fact, in most of these works, it suffices for the verifier to read just a *single* point in the encoding.) We remark that throughout this work (as well as in most previous works[18]), the specific code that is used is the *low-degree extension code* (LDE).

Some of the techniques that were outlined in Section 1.2.1, can be viewed as generic transformations on HIPs (with respect to the LDE code), and we present them as such in the technical parts of this work. These techniques include the ability to switch fields, or check Booleanity, and the connection to IPPs. We wish to highlight the conceptual importance of HIPs, and advocate a continued systematic study of these proof systems.

We also remark that HIPs with respect to the LDE code are closely related to interactive proofs in the algebrization framework [1]. In both models the verifier is given oracle access to a low degree polynomial and may interact with the prover to decide on some property of the "message" or "oracle" encoded within the polynomial. See Section 5 for further discussion of this connection.

[17] The first explicit use is in [5].

[18] A notable exception is the work of Meir [53], which is based on general tensor codes. We remark that using Meir's techniques it may be possible to extend our results to other tensor codes. We leave exploring this possibility to future work.

1.4 Related Works

In this section, we discuss several lines of works that are related to our work.

Interactive Proofs of Proximity. The notion of interactive proofs of proximity (IPP) was first considered by Ergün, Kumar and Rubinfeld [19]. Its study was re-initiated by Rothblum, Vadhan and Wigderson [58], who showed that every language computable by a low-depth circuit has an IPP with a sublinear time verifier. IPPs were further studied by [31, 28] who showed more efficient IPPs for certain restricted complexity classes. Other works have focusing on variants such as non-interactive (MA) proofs of proximity [43, 20, 30] and interactive *arguments* of proximity [49]. Proofs of proximity have also found applications to property testing and related models [33, 34, 21].

Hierarchy Theorems for Standard Interactive Proofs. Aiello, Goldwasser and Håstad [2] showed a round hierarchy theorem in a relativized world (i.e., with respect to an oracle). However, the later results of [52, 60], which are based on non-relativizing techniques, demonstrate that relativization is not an actual barrier, especially in the context of interactive proofs.[19] We note that although they are technically quite different, both our lower bound and the lower bound of [2] are based on circuit lower bounds for low depth circuits.

Goldreich, Vadhan and Wigderson [36] showed a *conditional* round hierarchy result for standard interactive proofs, based on the assumption that co-SAT does not have a 1-round $\mathcal{AM}$ proof-system with complexity $2^{o(n)}$.[20] We emphasize that the result of [36] is based on an unproven and arguably strong (yet believable) assumption, whereas our result is unconditional.

We also note that for *computationally sound* proofs, also known as arguments, under reasonable cryptographic assumptions there are extremely efficient 2-round protocols [50] and even 1-round protocols [48]. In particular, these results show that the power of arguments does not scale with additional rounds (since a fixed constant number of rounds suffice). A similar statement holds for arguments of proximity that are the computationally sound variant of IPPs (see [58, 49]).

Interactive PCPs. Holographic interactive proofs (HIPs) are closely related to the notion of *interactive* PCPs, introduced by Kalai and Raz [46]. Roughly speaking, interactive-PCPs are encodings of NP-witnesses that, like PCPs can be verified using few queries, but here the verification procedure may use interaction with an unbounded (and untrusted) prover. Thus, using our terminology, an interactive PCP can be thought of as an HIP for checking the NP witness relation.

Arthur-Merlin Query Complexity. Every IPP for a language $\mathcal{L}$ can be viewed as a protocol, for a promise problem related to $\mathcal{L}$, in the Arthur Merlin query complexity model, previously studied by Raz *et al.* [54]. This model, similarly to IPPs, considers a sub-linear time verifier, that is given oracle access to an input and may interact with an (untrusted) prover. Indeed, one may view IPPs as Arthur Merlin query complexity protocols which focus on promise problems in which the goal of the verifier is to distinguish between inputs having a certain property from those that are *far* from having the property.

---

[19] Indeed, Fortnow and Sipser [22] show that the proof of IP = PSPACE cannot be relativized (in fact, IP does not even contain coNP relative to a random oracle [14]). In fact, the algebrization framework of Aaronson and Wigderson [1] was proposed precisely to address this issue. Connections between our results and algebrization are further discussed in Section 5.

[20] Related assumptions have recently been studied also by Carmosino *et al.* [10] and Williams [69].

Thus, our main result directly yields a round hierarchy theorem (for a promise problem) in the *Arthur-Merlin Query Complexity* model and a sub-exponential separation between the complexity of constant-round vs. general (i.e., unbounded round) Arthur-Merlin Query Complexity protocols.

Interactive Proofs in Other Models. Interactive proof systems were studied also in the communication complexity setting (e.g., [7, 51, 61, 41, 40]). Here Alice and Bob may interact with an untrusted Merlin, who sees both of their inputs. We remark that showing any non-trivial explicit lower bound in the $\mathcal{AM}$ variant of this model, much less a hierarchy of separations, is a notorious open problem.

A recent line of works has studied interactive proofs in the data streaming model (e.g., [12, 16, 17, 42, 11, 65, 18]). Most relevant is a result of Chakrabarti *et al.* [13], who show a hierarchy theorem for the first four levels in the model of *online interactive proofs* (with exponential separations between these four levels).

Universal Locally Verifiable Codes. In a recent work, Goldreich and Gur [29] introduced the notion of *universal locally verifiable codes* (universal-LVC), which is closely related to holographic interactive proofs. A universal-LVC $C : \{0,1\}^k \to \{0,1\}^n$ for a family of functions $\mathcal{F} = \{f_i : \{0,1\}^k \to \{0,1\}\}_{i\in[M]}$ is a code such that for every $i \in [M]$, membership in the subcode $\{C(x) : f_i(x) = 1\}$ can be verified locally given an explicit access to a short (sublinear length) proof; put differently, for every $i \in [M]$ there exists a 1-message IPP for the property $\{C(x) : f_i(x) = 1\}$, with sublinear communication and query complexity.

1.5 Organization

In Section 2 we define IPPs and introduce some notations and definitions that we use throughout this work. In Section 3 we define holographic interactive proofs (HIPs) and prove some general results on them. In Section 4, using some of the results of Section 3, we prove the hierarchy theorem. Lastly, in Section 5 we discuss the implications to classical complexity theory.

Some of the discussion and proofs are deferred to the appendix. In Appendix A.2 we discuss an alternative language for the round hierarchy theorem and our choice of basing our protocol on GKR rather than, say a recent protocol of Reingold *et al.* [56]. Appendices B to D contain some standard proofs that are included for completeness.

2 Preliminaries

We begin with some standard notations:

- We denote the relative distance, over alphabet Σ, between two strings $x \in \Sigma^n$ and $y \in \Sigma^n$ by $\Delta(x,y) \stackrel{\text{def}}{=} \frac{|\{x_i \neq y_i \,:\, i\in[n]\}|}{n}$. If $\Delta(x,y) \leq \varepsilon$, we say that x is ε-close to y, and otherwise we say that x is ε-far from y. Similarly, we denote the relative distance of x from a non-empty set $S \subseteq \Sigma^n$ by $\Delta(x,S) \stackrel{\text{def}}{=} \min_{y\in S} \Delta(x,y)$. If $\Delta(x,S) \leq \varepsilon$, we say that x is ε-close to S, and otherwise we say that x is ε-far from S.
- We denote the projection of $x \in \Sigma^n$ to a subset of coordinates $I \subseteq [n]$ by $x|_I$ and, for $i \in [n]$, write $x_i = x|_{\{I\}}$ to denote the projection to a singleton.

An additional notation that we will use is that if $S = (S_k)_{k\in\mathbb{N}}$ and $T = (T_k)_{k\in\mathbb{N}}$ are ensembles of sets, we denote by $S \subseteq T$ the fact that $S_k \subseteq T_k$ for every $k \in \mathbb{N}$.

Integrality. Throughout this work, for simplicity of notation, we use the convention that all (relevant) integer parameters that are stated as real numbers are implicitly rounded to the closest integer.

2.1 Interactive Proofs of Proximity

A language is an ensemble $\mathcal{L} = (\mathcal{L}_n)_{n\in\mathbb{N}}$, where $\mathcal{L}_n \subseteq (\Sigma_n)^n$ for every $n \in \mathbb{N}$ and where $\Sigma = (\Sigma_n)_{n\in\mathbb{N}}$ is the alphabet.

▶ **Definition 3** (Interactive Proofs of Proximity (IPP))**.** Let $\Sigma = (\Sigma_n)_{n\in\mathbb{N}}$ be an alphabet ensemble. An r-round *interactive proof of proximity*, with respect to proximity parameter $\varepsilon > 0$, (in short, ε-IPP) for the language $\mathcal{L}$ is an interactive protocol between a prover $\mathcal{P}$, which gets *free* access to ε and to an input $x \in \Sigma^n$, and a verifier $\mathcal{V}$, which gets free access only to ε and n, as well as *oracle* access to x. At the end of the protocol, the following conditions are satisfied:

- **Completeness**: If $x \in \mathcal{L}$, then, when $\mathcal{V}$ interacts with $\mathcal{P}$, with probability 2/3 it accepts.
- **Soundness**: If x is ε-far from $\mathcal{L}$, then for every prover strategy $\mathcal{P}^*$, when $\mathcal{V}$ interacts with $\mathcal{P}^*$, with probability 2/3 it rejects.

If the completeness condition in Definition 3 holds with probability 1, then we say that the IPP has perfect completeness. A public-coin IPP is an IPP in which every message from the verifier to the prover consists only of fresh random coin tosses.

An IPP is said to have query complexity $q : \mathbb{N} \times [0,1] \to \mathbb{N}$ if for every $n \in \mathbb{N}$, $\varepsilon > 0$, $x \in \{0,1\}^n$, and any prover strategy $\mathcal{P}^*$, the verifier makes at most $q(n,\varepsilon)$ queries to x when interacting with $\mathcal{P}^*$. The IPP is said to have communication complexity $c : \mathbb{N} \times [0,1] \to \mathbb{N}$ if for every $n \in \mathbb{N}$, $\varepsilon > 0$, and $x \in \mathcal{L}_n$ the communication between $\mathcal{V}$ and $\mathcal{P}$ consists of at most $c(n,\varepsilon)$ bits.

2.2 Constructible Error Correcting Codes and Finite Fields

An error correcting code over an alphabet Σ is an injective function $C : \Sigma^k \to \Sigma^n$. The code C is said to have relative distance δ if for any $x \neq x' \in \Sigma^k$ it holds that $\Delta(x, x') \geq \delta$.

Throughout this work we deal with (uniform) polynomial-time algorithms, and so we will need (families of) codes that are efficiently computable. Formally, for a parameter $n = n(k) \geq 1$ that is called the blocklength, and ensemble of alphabets $\Sigma = (\Sigma_k)_{k\in\mathbb{N}}$, we define a constructible error correcting code over Σ as an ensemble $C = \left(C_k : \Sigma_k^k \to \Sigma_k^n\right)_{k\in\mathbb{N}}$ of error correcting codes, such that the function $f(x) = C_{|x|}(x)$ is computable by a polynomial-time Turing machine (in particular this implies that $n = \mathsf{poly}(k, \log(\Sigma))$). An ensemble of error correcting codes $C = (C_k)_{k\in\mathbb{N}}$ is said to have relative distance δ if for all sufficiently large k, each code C_k in the ensemble has relative distance δ.

Throughout this work, we mostly consider codes defined over finite fields (i.e., the alphabets Σ_k are all finite fields). Such codes are called linear if they are linear functions over the field.

Finite Fields and Polynomials. Many of our algorithms and interactive proofs deal with finite fields. We consider ensembles of finite fields $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$, where $|\mathbb{F}_k|$ and say that such ensembles are constructible if the field operations can be done in $\mathsf{poly}\log(|\mathbb{F}_k|)$ time. Namely, there exist a Turing machine that given as input k and an appropriate number of elements in $\mathbb{F}_k$ (represented as strings of length $O(\log(|\mathbb{F}_k|))$ bits) can compute the field operations (i.e., addition, subtraction, multiplication, inversion, and sampling random elements) in $\mathsf{polylog}(|\mathbb{F}_k|)$ time.

The following fact shows that there exist constructible finite fields of characteristic 2.

▶ **Fact 4.** *For every time-constructible function $f = f(k) \geq 1$, there exists a* constructible *field ensemble $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ such that $|\mathbb{F}| = O(f)$ and $\mathbb{F}_k$ has characteristic 2 (i.e., is an extension field of $\mathsf{GF}(2)$) for every $k \in \mathbb{N}$.*

For details see [24, Appendix G.3] and references therein. We will also use the well-known Schwartz-Zippel Lemma.

▶ **Lemma 5** (Schwartz-Zippel Lemma)**.** *Let $P : \mathbb{F}^m \to \mathbb{F}$ be a non-zero polynomial of total degree d over the field $\mathbb{F}$. Then,*

$$\Pr_{x\in_R\mathbb{F}^m}[P(x) = 0] \leq \frac{d}{|\mathbb{F}|}.$$

2.3 Low-Degree Extension

Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be an ensemble of fields, and let $H = (H_k)_{k\in\mathbb{N}} \subseteq \mathbb{F}$ (the notation $H \subseteq \mathbb{F}$ means that $H_k \subseteq \mathbb{F}_k$, for every $k \in \mathbb{N}$). Let $m = m(k) \geq 1$ be a parameter, which we often call the dimension.

A basic fact is that for every function $f : H^m \to \mathbb{F}$ there exists a *unique* function $\tilde{f} : \mathbb{F}^m \to \mathbb{F}$ such that $\tilde{f}$ is a polynomial with individual degree $|H| - 1$ that agrees with f on H^m. Moreover, there exists an individual degree $|H| - 1$ polynomial $\beta : \mathbb{F}^m \times \mathbb{F}^m \to \mathbb{F}$ such that for every function $f : H^m \to \mathbb{F}$ it holds that

$$\tilde{f}(z) = \sum_{x\in H^m} \beta(x, z) \cdot f(x).$$

The function $\tilde{f}$ is called the low degree extension of $\mathbb{F}$ (with respect to the field $\mathbb{F}$, subset H and dimension m).

The following two propositions show that the low degree extension encoding can be computed efficiently.

▶ **Proposition 6.** *Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be a constructible field ensemble, let $H = (H_k)_{k\in\mathbb{N}} \subseteq \mathbb{F}$ be an ensemble of subsets and let $m = m(k)$ be the dimension.*

There exists a Turing machine that on input k runs in time $\mathsf{poly}(|H|, m, \log|\mathbb{F}|)$ and space $O(\log(|\mathbb{F}|) + \log(m))$, and outputs the polynomial $\beta : \mathbb{F}^m \times \mathbb{F}^m \to \mathbb{F}$ defined above, represented as an arithmetic circuit over $\mathbb{F}$.

Moreover, the arithmetic circuit β can be evaluated in time $\mathsf{poly}(|H|, m, \log(|\mathbb{F}|))$ and space $O(\log(|\mathbb{F}|) + \log(m))$. Namely, there exists a Turing machine with the above time and space bounds that given an input pair $(x, z) \in \mathbb{F}^m \times \mathbb{F}^m$ outputs $\beta(x, z)$.

See, e.g., [57, Proposition 3.2.1] for a proof of Proposition 6.

▶ **Proposition 7.** *Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be a constructible field ensemble, let $H = (H_k)_{k\in\mathbb{N}} \subseteq \mathbb{F}$ be an ensemble of subsets and let $m = m(k)$ be the dimension.*

Let $\phi : H^m \to \mathbb{F}$ and suppose that ϕ can be evaluated by a Turing Machine in time t and space s. Then, there exists a Turing machine that, given as an input a point $z \in \mathbb{F}^m$, runs in time $|H|^m \cdot (\mathsf{poly}(|H|, m, \log(|\mathbb{F}|)) + O(t))$ and space $O(m \cdot \log(|H|) + s + \log(|\mathbb{F}|))$ and outputs the value $\hat{\phi}(z)$ where $\hat{\phi}$ is the unique low degree extension of ϕ (with respect to $H, \mathbb{F}, m$).

Proof. The Turing machine computes

$$\hat{\phi}(z) = \sum_{x\in H^m} \beta(x, z) \cdot \phi(x)$$

by generating and evaluating β as in Proposition 6. ◀

Low Degree Extension as an Error-Correcting Code. The low degree extension can also be viewed as an error-correcting code in the following way. Suppose that H and m are such that $|H|^m = k$. Then, we can associate a string $x \in \mathbb{F}^k$ with a function $x : H^m \to \mathbb{F}$ by identifying H^m with $[k]$ in some canonical way.

We define the low degree extension of a string x as $\mathsf{LDE}_{\mathbb{F},H,m}(x) = \tilde{x}$. That is, the function $\mathsf{LDE}_{\mathbb{F},H,m}$ is given as input the string $x \in \mathbb{F}^k$, views it as a function $x : H^m \to \mathbb{F}$ and outputs its low degree extension $\tilde{x}$. By Proposition 7 the code $\mathsf{LDE}_{\mathbb{F},H,m}$ is constructible, and by the Schwartz-Zippel Lemma (Lemma 5), the code $\mathsf{LDE}_{\mathbb{F},H,m}$ has relative distance $1 - \frac{m \cdot |H|}{|\mathbb{F}|}$.

3 Holographic Interactive Proofs

In this section we define *holographic interactive proofs* and show several transformations and generic results (which will be used in Section 4 for the proof of the hierarchy theorem). In Section 3.1 we give a formal definition and some basic facts. Having read Section 3.1, the reader may freely skip the rest of Section 3 and proceed directly to Section 4, which is the main technical section, and return to read the results of Sections 3.2 to 3.4 when they are used in Section 4.

Sections 3.2 to 3.4 focus on HIPs with respect to the low degree extension encoding. In Section 3.2 we show that such HIPs imply interactive proofs of *proximity* (for a related language). In Section 3.3 we show that one can switch the field under which the HIPs input is encoded (at a moderate cost) to any other field *that shares the same characteristic*. Finally, in Section 3.4 we show that HIPs can efficiently verify that the input (which can presumably be an arbitrary vector over the field) is actually Boolean valued (i.e., in $\{0,1\}^k$).

3.1 Definition and Basic Facts

A *holographic interactive proof* is similar to a standard interactive proof, except that rather than getting the input explicitly, the verifier gets oracle access to an encoding of the input (via an error correcting code). Using this redundant representation, we could potentially hope to have protocols in which the verifier runs in *sublinear* time and, in particular, does not even read its entire input. This hope is indeed materialized in several protocols from the literature (e.g., [52, 37, 56]).

As a matter of fact, it turns out that for some codes (specifically the low degree extension), reading just a single point p from the encoded input suffices for the verifier.[21] Thus, we restrict our attention to such protocols. Furthermore, in order to facilitate composition, rather than having the verifier actually read the (encoded) input at the point p, the verifier outputs a claim about the point (i.e., it outputs p together with a symbol that it would have expected to see, had it actually queried the (encoded) input at p).

Formally, holographic interactive proofs are parametrized by a (constructible) error correcting code C, under which the input is encoded, and are defined as follows.

▶ **Definition 8** (Holographic Interactive Proofs (HIP))**.** Let $\Sigma = (\Sigma_k)_{k\in\mathbb{N}}$ and $\Lambda = (\Lambda_k)_{k\in\mathbb{N}}$ be alphabet ensembles such that $\Lambda \subseteq \Sigma$. Let $\mathcal{L} \subseteq \Lambda$, and let $C : \Sigma^k \to \Sigma^n$ be a constructible error correcting code.

[21] For the low degree extension this can be shown to hold generically. The high level idea is to consider a low degree curve passing through all the points that the verifier wishes to read. The prover specifies the values for all the points on the curve and the verifier checks the provided answer on a random point on the curve. Soundness follows from the fact that composing a low-degree curve with a low-degree polynomial results in a low degree univariate polynomial. See, e.g., [46, Section 6] for details.

An r-round public-coin *holographic interactive proof (*HIP*)* for the language $\mathcal{L}$, with respect to the code C, is an interactive protocol between a prover $\mathcal{P}$, which gets as input $x \in \Sigma^k$, and a verifier $\mathcal{V}$, which gets as input only k. At the end of the protocol either the verifier rejects or it outputs a coordinate $i \in [n]$ and a symbol $\sigma \in \Sigma$ such that:

- **Completeness**: If $x \in \mathcal{L}$, then, when $\mathcal{V}$ interacts with $\mathcal{P}$, with probability 1 it outputs (i, σ) such that $C(x)|_i = \sigma$.
- **Soundness**: If $x \notin \mathcal{L}$, then for every prover strategy $\mathcal{P}^*$, when $\mathcal{V}$ interacts with $\mathcal{P}^*$, with probability $1 - \varepsilon$ either $\mathcal{V}$ rejects or it outputs (i, σ) such that $C(x)|_i \neq \sigma$, where $\varepsilon = \varepsilon(k) \in [0, 1]$ is called the *soundness error*.

In this work, all the holographic proofs that we consider are with respect to the low degree extension code (using a variety of different parameters), which was defined in Section 2.3 above.

▶ Remark (Different Alphabets for the Language and the Code). Typically, when using HIPs the alphabet Λ over which the language is defined will be the same as the alphabet Σ over which the code is defined. Still, in some cases it will be convenient for us to present HIPs that only work for particular sub-alphabets of the code (e.g., when the input is binary but the code is more naturally defined over some large alphabet) and so we give this more flexible definition.

Our definition of HIPs tries to capture many of the known interactive proof-systems in the literature, while being flexible and easy to compose. Indeed, the fact that HIPs can be transformed into standard interactive proofs which is immediate, is captured by the following proposition.

▶ **Proposition 9.** *Let $\Sigma = (\Sigma_k)_{k\in\mathbb{N}}$ and $\Lambda = (\Lambda_k)_{k\in\mathbb{N}}$ be alphabets such that $\Lambda \subseteq \Sigma$. Let $\mathcal{L}$ be a language over the alphabet Λ and let $C : \Sigma^k \to \Sigma^n$ be a constructible error correcting code.*

Any HIP *for $\mathcal{L}$ can be converted into a standard interactive proof with only a* poly(n) *additive overhead to the verifier's running time (and all other parameters remain unchanged). Moreover, the precise overhead is equal to the time that it takes to compute the i^{th} character of $C(x)$, given $x \in \Lambda^k$ and the index $i \in [n]$.*

Proof. The prover and verifier run the HIP. If the HIP verifier rejects, then we immediately reject. Otherwise, the HIP verifier outputs a pair $(i, \sigma) \in [n] \times \Sigma$ with the associated claim $C(x)|_i = \sigma$. We can now check this claim directly by computing $C(x)|_i$ and comparing with σ. ◀

The Sumcheck Protocol (as an HIP). We will make extensive use of the classical sumcheck protocol of Lund *et al.* [52]. Recall that the sumcheck protocol is an interactive proof for verifying that the sum, over a subcube, of a low degree polynomial is zero. Our protocol differs slightly from the "textbook" sumcheck protocol in two ways:

1. The verifier does not actually read any points from the input polynomial. Rather, at the end of the protocol it outputs a claim about a single point of the polynomial (i.e., the protocol is an HIP).
2. Following other works in the literature, our protocol allows a trade-off between the number of rounds and the communication complexity (rather than having the number of rounds correspond exactly to the dimension of the polynomial).

▶ **Lemma 10** (Sumcheck as an HIP). *Let $\mathbb{F}$ be a constructible field ensemble and let $H \subseteq \mathbb{F}$ be an ensemble of subsets of $\mathbb{F}$. Let $m = m(k)$ be an ensemble of integers such that $m = \log_{|H|}(k)$.*

Let $\mathcal{L} = \cup_{k\in\mathbb{N}}\mathcal{L}_k$, where $\mathcal{L}_k = \{x \in \mathbb{F}^k : \sum_{i\in[k]} x_i = 0\}$ and where the summation is over the field $\mathbb{F}$. Then, for every $r \in [m]$, there exists an r-round (public-coin) HIP for $\mathcal{L}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, with soundness error $\frac{m\cdot|H|}{|\mathbb{F}|}$ and communication complexity $|H|^{\lceil m/r\rceil}\cdot r\cdot\log|\mathbb{F}|$. The verifier runs in time $|H|^{\lceil m/r\rceil}\cdot r\cdot\mathsf{polylog}(|\mathbb{F}|)$ and the prover runs in time $\mathsf{poly}(|\mathbb{F}|^m, r)$.

The proof of Lemma 10, which is standard, is included for completeness in Appendix C.

3.2 From HIP to IPPs

Proposition 9 above, shows that an HIP can be easily transformed into a standard interactive proof. We now show that HIPs, with respect to the low degree extension encoding, can be easily transformed into highly efficient (and in particular sublinear) *interactive proof of proximity* (IPP) for a related language. More specifically, we transform an HIP for the language $\mathcal{L}$ with respect to the $\mathsf{LDE}_{\mathbb{F},H,m}$ code, into an IPP for the language $\mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L}) \stackrel{\text{def}}{=} \{\mathsf{LDE}_{\mathbb{F},H,m}(x) : x \in \mathcal{L}\}$.[22]

▶ **Lemma 11.** *Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be an ensemble of finite fields, let $H = (H_k)_{k\in\mathbb{N}}$ be an ensemble of subsets (i.e. $H \subseteq \mathbb{F}$) and let $m = m(k)$ be such that $|H|^m = k$.*

Suppose that the language $\mathcal{L}$ has an r-round HIP, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, with communication complexity c. Then, the language $\mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L})$ has an r-round ε-IPP with query complexity $O(|H|\cdot m\cdot 1/\varepsilon)$ and communication complexity c.

The key observations that we use to prove Proposition 11 are that (1) the IPP verifier can first check that its input is close to a low degree polynomial using low degree test. If the test passes, then, using the self-correctability of polynomials, the IPP verifier can emulate access to the encoded input of the HIP. Given these two observations the proof of Proposition 11 is standard and so we defer it to Appendix B.

3.3 Field Switching

In this subsection we show that HIPs can evaluate points in a LDE over an *extension* field of the base field under which the input is actually encoded. This fact is used in the proof Lemma 17 and allows us to first construct an HIP over a large field, and later convert it into an HIP over the smaller field.

The key observation for our field switching, is that verifying a linear claim involving the LDE over an extension field $\mathbb{K}/\mathbb{F}$ can be reduced to verifying several linear claims over the base field $\mathbb{F}$. Each of these linear claims can be verified via a sumcheck protocol (in fact, it suffices to verify a random linear combination of these claims), and so an HIP can emulate access to the LDE over the extension field $\mathbb{K}$ by making queries to the LDE over field $\mathbb{F}$. We proceed to the formal statement and proof.

Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ and $\mathbb{K} = (\mathbb{K}_k)_{k\in\mathbb{N}}$ be constructible field ensembles such that $\mathbb{K}$ is a degree $s = s(k) \le \log(k)$ field extension of $\mathbb{F}$ (i.e., $\mathbb{K}_k \cong \mathbb{F}_k^{s(k)}$, for every $k \in \mathbb{N}$). Let $H = (H_k)_{k\in\mathbb{N}} \subseteq \mathbb{F}$ and $G = (G_k)_{k\in\mathbb{N}} \subseteq \mathbb{K}$ be ensembles of subsets of $\mathbb{F}$ and $\mathbb{K}$, respectively. Let $m = m(k)$ and $\ell = \ell(k)$ be ensembles of integers such that $|H|^m = |G|^\ell = k$.

[22] More generally, for any code C that is locally testable and decodable (such as the LDE code), one can transform an HIP for the language $\mathcal{L}$ into an IPP for the language $C(\mathcal{L}) = \{C(x) : x \in \mathcal{L}\}$. Moreover, if the query location produced by the HIP verifier is uniformly distributed (which is typically the case), then local testability by itself suffices.

Recall that for a given string $x \in \{0,1\}^k$, we define $\mathsf{LDE}_{\mathbb{F},H,m}$ as the unique individual degree $|H|-1$ polynomial $P : \mathbb{F}^m \to \mathbb{F}$ such that $P(z) = x_z$, for every $z \in H^m$ (where we identify the sets H^m and $[k]$ in some, computationally efficient, canonical way). Similarly, we define $\mathsf{LDE}^{\mathbb{K}}_{G,\ell}$ as the unique individual degree $|G|-1$ polynomial $P : \mathbb{K}^\ell \to \mathbb{K}$ such that $P(z) = x_z$, for every $z \in G^\ell$ (where now we identify G^ℓ and $[k]$).

▶ **Lemma 12.** *Let Let Let $\mathbb{F}$ and $\mathbb{K}$ be finite field ensembles as defined above. Let $\mathcal{L} = \cup_{k\in\mathbb{N}}\mathcal{L}_k$ be a language such that $\mathcal{L}_k \subseteq \{0,1\}^k$ for every $k \in \mathbb{N}$. Suppose that $\mathcal{L}$ has a ρ-round* HIP*, with respect to the code $\mathsf{LDE}_{\mathbb{K},G,r}$, with soundness error $\delta = \delta(k) \in [0,1]$ and communication complexity $c = c(k)$. Then, for every parameter $r = r(k) \geq 1$, the language $\mathcal{L}$ also has a $(\rho + r + 1)$-round* HIP*, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, with soundness error $\left(\delta + O\left(\frac{|H|\cdot m}{|\mathbb{F}|}\right)\right)$ and communication $\left(c + \mathsf{poly}(k^{1/r}, |H|, r, \log|\mathbb{F}|)\right)$.*

Furthermore, the computational overhead for the verifier is $\mathsf{poly}(k^{1/r}, |H|, r, \log|\mathbb{F}|)$ and the computational overhead for the prover is $\mathsf{poly}(k)$.

We remark that for the furthermore part, we make use of the [45] constant-round variant of the GKR protocol.

Proof of Lemma 12. Before presenting the desired HIP, we start with some algebraic notation and basic facts. Throughout this proof we use $\langle\cdot,\cdot\rangle_{\mathbb{K}}$ and $\langle\cdot,\cdot\rangle_{\mathbb{F}}$ to denote inner products over the fields $\mathbb{K}$ and $\mathbb{F}$, respectively.

Recall that elements in $\mathbb{K}$ are represented as vectors in $\mathbb{F}^s$. Let $b_1,\ldots,b_s : \mathbb{K}^* \to \mathbb{F}^*$ be functions defined as follows. For every $\alpha \in \mathbb{K}^*$ it holds that $\alpha = (b_1(\alpha),\ldots,b_s(\alpha))$. That is, the functions $b_1,\ldots,b_s$ decompose a vector $w \in \mathbb{K}^t$ into its s components over $\mathbb{F}^t$.

▶ **Proposition 13.** *For every $w \in \mathbb{K}^k$ and $x \in \{0,1\}^k$ it holds that*

$$\langle w, x\rangle_{\mathbb{K}} = (\langle b_1(w), x\rangle_{\mathbb{F}}, \ldots, \langle b_s(w), x\rangle_{\mathbb{F}}).$$

Proof. We denote by $*$ multiplication in $\mathbb{K}$ and by $\cdot$ multiplication in $\mathbb{F}$. For $k = 1$ the proposition simply states that, for $w \in \mathbb{K}$ and $x \in \{0,1\}$ it holds that $w * x = (b_1(w)\cdot x,\ldots,b_s(w)\cdot x)$. The latter can be easily verified to hold for $x \in \{0,1\}$ by observing that, in both $\mathbb{K}$ and $\mathbb{F}$, multiplication by $x = 0$ always returns 0 and multiplication by $x = 1$ is identity. The proposition follows by induction on k. ◀

We proceed to describe the HIP $(\mathcal{P}',\mathcal{V}')$. Let $(\mathcal{P},\mathcal{V})$ be an HIP for $\mathcal{L}$, with respect to the code $\mathsf{LDE}_{\mathbb{K},G,r}$, with soundness error δ. To prove the lemma, we need to construct an HIP $(\mathcal{P}',\mathcal{V}')$ for $\mathcal{L}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$.

First, $\mathcal{P}'$ and $\mathcal{V}'$ emulate the HIP $(\mathcal{P},V)$. If $\mathcal{V}$ rejects, then $\mathcal{V}'$ immediately rejects. Otherwise, $\mathcal{V}$ outputs a pair $(z,\nu) \in \mathbb{K}^\ell \times \mathbb{K}$ with the associated claim that $\left(\mathsf{LDE}^{\mathbb{K}}_{G,\ell}(x)\right)|_z = \nu$. Since $\mathsf{LDE}^{\mathbb{K}}_{G,\ell}$ is a $\mathbb{K}$-linear code, there exists a vector $w \in \mathbb{K}^k$ (that depends only on the code $\mathsf{LDE}^{\mathbb{K}}_{G,\ell}$ and the point z) such that $\left(\mathsf{LDE}^{\mathbb{K}}_{G,\ell}(x)\right)|_z = \langle w, x\rangle$, for every $x \in \{0,1\}^k$. Thus, $\mathcal{V}'$ only needs to verify that $\langle w, x\rangle_{\mathbb{K}} = \nu$.

For every $i \in [s]$, let $w_i \stackrel{\text{def}}{=} b_i(w) \in \mathbb{F}^k$ and let $\nu_i \stackrel{\text{def}}{=} b_i(\nu) \in \mathbb{F}$. By Proposition 13 the $\mathbb{K}$-linear equation $\langle w, x\rangle = \nu$ is equivalent to the following s $\mathbb{F}$-linear equations:

$$\forall i \in [s], \quad \langle w_i, x\rangle_{\mathbb{F}} = \nu_i. \tag{5}$$

The verifier $\mathcal{V}'$ chooses at random an $\mathbb{F}$-linear combination of these s linear equations. Namely, it selects at random $\gamma_1,\ldots,\gamma_s \in \mathbb{F}$ and sends these coefficients to the prover. Let $w' \stackrel{\text{def}}{=} \sum_{i\in[s]} \gamma_i \cdot w_i$ and $\nu' \stackrel{\text{def}}{=} \sum_{i\in[s]} \gamma_i \cdot \nu_i$ (where the summations are over $\mathbb{F}$). Note that if

Equation (5) holds then (with probability 1) $\langle w', x\rangle_{\mathbb{F}} = \nu'$, whereas if Equation (5) does not hold then $\langle w', x\rangle_{\mathbb{F}} \neq \nu'$ with probability $1 - \frac{1}{|\mathbb{F}|}$ over the choice of $\gamma_1, \ldots, \gamma_s \in \mathbb{F}$. We next observe that the latter is an $\mathbb{F}$-linear claim about the input x and such claims can be directly solved using the sumcheck protocol.

Let $\tilde{x} : \mathbb{F}^m \to \mathbb{F}$ (resp., $\tilde{w'}$) be the low degree extension of the input x (resp., the vector $w' \in \mathbb{F}^k$) with respect to the field $\mathbb{F}$, set H and dimension m. That is, $\tilde{x}$ and $\tilde{w'}$ are the unique individual degree $|H| - 1$ polynomial that agree with x and w', respectively, on H^m. Let $P : \mathbb{F}^m \to \mathbb{F}$ be defined as the individual degree $2(|H|-1)$ polynomial $P(z) = \tilde{w'}(z) \cdot \tilde{x}(z)$. Note that $\sum_{z \in H^m} P(z) = \langle w', x\rangle_{\mathbb{F}}$. Thus, checking that $\langle w', x\rangle_{\mathbb{F}} = \nu'$ is equivalent to $\sum_{z \in H^m} P(z) = \nu'$ which we can solve by having the prover and verifier run the sumcheck protocol with respect to the polynomial P.[23]

In case the sumcheck verifier rejects then $\mathcal{V}'$ immediately rejects. Otherwise, the result is a pair $(z'', \nu'') \in \mathbb{F}^m \times \mathbb{F}$. The prover sends to the verifier the value $\mu = \tilde{x}(z'')$. The verifier $\mathcal{V}'$ checks that $\mu \cdot \tilde{w'}(z'') = \nu''$ and if so it outputs (z'', μ), otherwise it rejects. This completes the description of the protocol.

Actually, one point about this protocol remains unclear - how can the verifier efficiently compute $\tilde{w'}(z'')$. If we were to ignore the *computational* resources of the verifier, then we could do this by brute force (e.g., in time roughly $|H|^m$), since $\tilde{w'}$ is independent of the input x. Nevertheless, we do aim for efficient verification and so we need to be able to compute $\tilde{w'}(z'')$ efficiently. We will do so by using additional interaction with the prover, based on the [45] variant of the GKR protocol. We give a sketch in the following paragraph.

Computing $\tilde{w'}(z'')$. We start by taking a closer look at the vector w defined above. By the definition of the low degree extension (see Section 2.3), the vector $w \in \mathbb{K}^{G^\ell}$ is defined as $w_h = \beta(h, z)$, for every $h \in G^\ell$, where β is as defined in Section 2.3. Thus, we have that:

$$\tilde{w'}(z'') = \sum_{i \in [s]} \gamma_i \cdot b_i \left(\sum_{h \in H^m} \beta(h, z'') \cdot \beta(h, z) \right). \tag{6}$$

We observe that Equation (6) can be represented as a (highly uniform) depth $O(\log(s) + m \cdot \log(H) + \log(|G|) + \log(\ell)) = O(\log(k))$ Boolean circuit (on input z, z'') of size $s \cdot H^m \cdot \mathsf{poly}(|G|, \ell, \log(|\mathbb{K}|)) = \mathsf{poly}(k)$. Applying the [45] variant of the GKR protocol, we obtain an r-round interactive proof for verifying Equation (6) in which the verifier runs in time $k^{O(1/r)} \cdot \mathsf{polylog}(|\mathbb{F}|)$ and with similar communication complexity.

Completeness. Fix $x \in \mathcal{L}$. By the completeness of $(\mathcal{P}, \mathcal{V})$, the verifier outputs $(z, \nu) \in \mathbb{K}^\ell \times \mathbb{K}$ such that $\left(\mathsf{LDE}^{\mathbb{K}}_{G,\ell}(x)\right)\big|_z = \nu$, or equivalently, $\langle w, x\rangle_{\mathbb{K}} = \nu$. By Proposition 13 this implies that $\langle w_i, x\rangle_{\mathbb{F}} = \nu_i$, for every $i \in [s]$. Therefore, for every $\gamma_1, \ldots, \gamma_s \in \mathbb{F}$ it holds that:

$$\langle w', x\rangle_{\mathbb{F}} = \sum_{i \in [s]} \gamma_i \cdot \langle w_i, x\rangle_{\mathbb{F}} = \sum_{i \in [s]} \gamma_i \cdot \nu_i = \nu'.$$

By definition of P, this means that $\sum_{z \in H^m} P(z) = \langle w', x\rangle_{\mathbb{F}} - \nu' = 0$ and the completeness of the sumcheck protocol implies that $\nu'' = P(z'') = \tilde{x}(z'') \cdot \tilde{w}(z'')$. Thus the verifier accepts when checking that $\mu \cdot \tilde{w}(z'') = \nu''$.

[23] We remark that while we defined sumcheck as a protocol for the language $\mathcal{L} = \{x \in \mathbb{F}^k : \sum_{i \in [k]} x_i = 0\}$, a trivial, standard modification of the sumcheck protocol yields a protocol for $\mathcal{L}_\nu = \{x \in \mathbb{F}^k : \sum_{i \in [k]} x_i = \nu\}$, for every $\nu \in \mathbb{F}$.

Soundness. Fix $x \notin \mathcal{L}$ and a cheating prover strategy $\mathcal{P}^*$. By the soundness of (P, V), with probability $1 - \varepsilon$, the verifier either rejects (in which case $\mathcal{V}'$ also rejects) or outputs $(z, \nu) \in \mathbb{K}^\ell \times \mathbb{K}$ such that $\langle w, x \rangle_{\mathbb{K}} \neq \nu$. Assuming that the latter holds, by Proposition 13 there exists some $i^* \in [s]$ such that $\langle w_{i^*}, x \rangle_{\mathbb{F}} \neq \nu_{i^*}$. Therefore,

$$\begin{aligned}
\Pr\left[\langle w', x \rangle_{\mathbb{F}} = \nu'\right] &= \Pr\left[\sum_{i \in [s]} \gamma_i \cdot \langle w_i, x \rangle_{\mathbb{F}} = \sum_{i \in [s]} \gamma_i \cdot \nu_i\right] \\
&= \Pr\left[\gamma_{i^*} \cdot (\langle w_{i^*}, x \rangle_{\mathbb{F}} - \nu_{i^*}) = \sum_{i \neq i^*} \gamma_i \cdot (\nu_i - \langle w_i, x \rangle_{\mathbb{F}})\right] \\
&= 1/|\mathbb{F}|.
\end{aligned}$$

Thus, with probability $1 - \frac{1}{|\mathbb{F}|}$ it holds that $\langle w', x \rangle_{\mathbb{F}} \neq \nu'$, and in particular $\sum_{z \in H^m} P(z) \neq 0$ (where P is the polynomial as defined above).

Hence, by the soundness of the sumcheck protocol, with probability $\frac{|H| \cdot m}{|\mathbb{F}|}$ either the sumcheck verifier rejects (in which case we also reject) or it outputs a pair $(z'', \nu'') \in \mathbb{F}^m \times \mathbb{F}$ such that $P(z'') \neq \nu''$, or in other words $\tilde{x}(z'') \cdot \tilde{w}(z'') \neq \nu''$. Now, the prover sends over a value μ. If $\tilde{x}(z'') = \mu$ then, conditioned on the above event, the verifier rejects when checking that $\mu \cdot \tilde{w}(z'') = \nu'$. If $\tilde{x}(z'') \neq \mu$, then the verifier outputs a pair (z'', μ) such that $\left(\mathsf{LDE}_{\mathbb{F},H,m}(x)\right)_{z''} \neq \mu$ as desired. By a union bound, the overall soundness error is $\varepsilon + \frac{1}{|\mathbb{F}|} + \frac{|H| \cdot m}{|\mathbb{F}|}$.

Complexity. On top of the ρ rounds that $(\mathcal{P}, \mathcal{V})$ takes, the verifier also sends the message $(\gamma_1, \ldots, \gamma_s)$, but this message can be appended to the last message from $\mathcal{V}$ to $\mathcal{P}$. In addition, the two parties run an r-round sumcheck protocol and an r round variant of the GKR protocol. There is one additional message from the prover with the value μ, so the overall number of rounds is $\rho + O(r)$.

The communication in the first part of the protocol (i.e., the emulation of (P, V)) is c. In addition, the verifier sends the linear combination $(\gamma_1, \ldots, \gamma_s)$ which takes $s \cdot \log |\mathbb{F}|$ bits. Lastly, both the sumcheck and the GKR protocol add communication $\mathsf{poly}(k^{1/r}, |H|, r, \log |\mathbb{F}|)$ and the additional prover message is just $\log_2 |\mathbb{F}|$ bits.

As for the verifier's complexity, beyond running the original $(\mathcal{P}, \mathcal{V})$ protocol, it runs the sumcheck and GKR protocols which takes time $\mathsf{poly}(k^{1/r}, |H|, r, \log |\mathbb{F}|)$. The prover's additional time in running these two protocols is $\mathsf{poly}(|H|^m) = \mathsf{poly}(k)$. ◀

3.4 Booleanity Testing

In this subsection we show that HIPs can efficiently check that their input is the low-degree extension of a *Boolean* assignment. To do so, we follow an idea of Kalai and Raz [46], which was introduced in the context of constructing interactive PCPs.

We show a simple reduction from checking whether a polynomial $P : \mathbb{F}^m \to \mathbb{F}$ is Boolean valued in a subcube H^m (i.e., $P|_{H^m} H^m \to \{0, 1\}$) to checking whether a related (slightly higher degree) polynomial Q vanishes on H^m. Specifically, consider the polynomial $Q(x) = P(x) \cdot (1 - P(x))$, and observe that P is Boolean-valued in H^m if only if Q is identically zero in H^m. Checking whether a given polynomial is identically 0 (i.e., vanishes) on a subcube of its domain can be solved via a fairly well-known reduction to the sumcheck protocol. We also note that the reduction from P to Q is local (i.e., each query to Q can be computed by a single query to P) and therefore can be used in our setting.

We start by showing an HIP for inputs that vanish on a subcube. We first note that checking whether an individual degree $|H|-1$ polynomial vanishes on the subcube H^m is trivial, since such a polynomial vanishes on H^m if and only if it vanishes on $\mathbb{F}^m$. The actual challenge is checking whether a higher degree polynomial (e.g., with individual degree $|G|-1$ for some G such that $|G|>|H|$) vanishes on H^m.

Formally, for a given field ensemble $\mathbb{F}$, ensembles of subsets $H, G \subseteq \mathbb{F}$ and dimension m, let $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$ be the set of all functions $f : G^m \to \mathbb{F}$ that vanish on H^m (i.e., $f|_{H^m} \equiv 0$).

The following proposition, which gives an HIP for $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$, is implicit in many classical constructions of PCPs (e.g., [5]). We include a proof in Appendix D for completeness.

▶ **Proposition 14.** *Let $\mathbb{F}$ be a constructible field ensemble, let $H \subseteq G \subseteq \mathbb{F}$ be ensembles of subsets, and let $m = m(k)$. For every $r = r(k) \leq \frac{\log(k)}{\log\log(k)}$, there exists an $(r+2)$-round (public-coin) HIP for $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},G,m}$, with soundness error $O\left(\frac{m\cdot|G|}{|\mathbb{F}|}\right)$ and communication complexity $m\cdot\log(|\mathbb{F}|) + |G|^{\lceil m/r\rceil}\cdot r\cdot\log|\mathbb{F}|$. The verifier runs in time $|G|^{\lceil m/r\rceil}\cdot r\cdot\mathsf{polylog}(|\mathbb{F}|)$ and the prover runs in time $\mathsf{poly}(|\mathbb{F}|^m)$.*

Denote by $\mathsf{Bool}_{\mathbb{F}}$ the set of all Boolean strings, viewed as a subset of $\mathbb{F}^*$. We show an HIP for Bool, which given access to a polynomial $P = \mathsf{LDE}_{\mathbb{F},H,m}(x)$ for some $x \in \mathbb{F}^k$, checks that $x \in \{0,1\}^k$.

▶ **Proposition 15.** *Let $\mathbb{F}$ be a constructible field ensemble, let $H \subseteq \mathbb{F}$, and let $m \in \mathbb{N}$. For every $r \in [m]$, there exists an $(r+2)$-round (public-coin) HIP for $\mathsf{Bool}_{\mathbb{F},H,m}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, with communication complexity $O(r\cdot(2d+|H|-1)^{m/r}\cdot\log|\mathbb{F}| + m\cdot\log(|\mathbb{F}|))$ and soundness error $O\left(\frac{m\cdot|H|}{|\mathbb{F}|}\right)$.*

Proof. Given a degree d polynomial $P : \mathbb{F}^m \to \mathbb{F}$ such that $P = \mathsf{LDE}_{\mathbb{F},H,m}(x)$ for some $x \in \mathbb{F}^{|H|^m}$, define the degree $2d$ polynomial $Q : \mathbb{F}^m \to \mathbb{F}$ as $Q(x) \stackrel{\text{def}}{=} P(x)\cdot(1-P(x))$. Note that we can write $Q = \mathsf{LDE}_{\mathbb{F},G,m}(y)$ for $H \subseteq G \subseteq \mathbb{F}$ and $y \in \mathbb{F}^{|G|^m}$, where $|G| = O(|H|)$.

Observe that P is Boolean-valued in H^m if and only if Q is identically 0 in H^m (this follows from the fact that the univariate polynomial $z\cdot(1-z)$ has exactly two roots: 0 and 1). Thus, to verify that P is Boolean-valued in H^m, we run the HIP for $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$ in Proposition 14, with respect to the polynomial Q. Note that each query $Q(x)$ can be answered by a single query to P (specifically, by returning $P(x)\cdot(1-P(x))$). Correctness follows from the correctness of the HIP for $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$. Communication complexity and soundness error follow from Proposition 14. ◀

4 The Hierarchy Theorem

In this section we prove our main theorem: a round hierarchy for IPPs.

▶ **Theorem 16** (IPP Hierarchy Theorem)**.** *There exists a language $\mathcal{L}$ and a gap function $g(r) = \Theta(r^2)$ such that for every constant $r \geq 1$ it holds that:*

1. **Upper Bound:** *There exists a $g(r)$-round (public-coin) ε-IPP, for $\mathcal{L}$ with communication complexity $n^{O(1/r)}$ and query complexity $\mathsf{poly}(\log n, \varepsilon)$. The verifier runs in time $n^{O(1/r)} + \mathsf{poly}(\log(n), \varepsilon)$ and the prover runs in time $\mathsf{poly}(n)$.*
2. **Lower Bound:** *For every r-round IPP for $\mathcal{L}$, with respect to proximity parameter $\varepsilon = 1/10$, that has query complexity q and communication complexity c, it holds that $\max(c,q) = n^{\Omega(1/r)}$.*

Furthermore, $\mathcal{L}$ also has a $\mathsf{polylog}(n)$*-round (public-coin)* ε-IPP *with communication* $\mathsf{polylog}(n)$ *and query complexity* $\mathsf{poly}(\log n, 1/\varepsilon)$*, and with a* $\mathsf{poly}(\log n, \varepsilon)$*-verifier and* $\mathsf{poly}(n)$*-time prover.*

The O and Ω notation in the theorem statement hide universal constants that do not depend on r. Note that any constant gap between the exponents in the upper and lower bounds can be obtained by increasing g by a suitable constant factor.

The rest of this section is devoted to the proof of Theorem 16. In Section 4.1 we present the language for which we show the IPP round hierarchy, in Section 4.3 we prove the lower bound (see Lemma 23), and in Section 4.2 we prove the upper bound (see Lemma 17). Combining Lemma 23 and Lemma 17 yields Theorem 16.

4.1 The Language: Encoded MOD3

Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be a (constructible) field ensemble of characteristic 2 (i.e., each $\mathbb{F}_k$ is an extension field of $\mathsf{GF}(2)$). Let $H = (H_k)_{k\in\mathbb{N}}$ be an ensemble of subsets $H \subseteq \mathbb{F}$ and let $m = m(k)$ be the dimension such that $|H| = \log(k)$, $m = \frac{\log(k)}{\log\log(k)}$ and $|\mathbb{F}| = \Theta(|H|^2 m)$. Denote $n \stackrel{\text{def}}{=} |\mathbb{F}^m|$, and note that $|H|^m = k$ and that $k^2 \leq n \leq k^3$.

We first define an (auxiliary) language $\mathcal{L}_{\mathsf{MOD3}}$, where:

$$\mathcal{L}_{\mathsf{MOD3}} \stackrel{\text{def}}{=} \{x \in \{0,1\}^* \ : \ \mathsf{wt}(x) = 0 \pmod 3\}\,.$$

That is, $\mathcal{L}_{\mathsf{MOD3}}$ simply consists of strings whose Hamming weight is divisible by 3. The actual language for which we prove the IPP lower bound is $\mathsf{Enc\text{-}MOD3} = \mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L}_{\mathsf{MOD3}})$. That is,

$$\mathsf{Enc\text{-}MOD3} = \left\{\mathsf{LDE}_{\mathbb{F},H,m}(x) \ : \ x \in \mathcal{L}_{\mathsf{MOD3}}\right\}.$$

Or in words, $\mathsf{Enc\text{-}MOD3}$ consists of all m-variate polynomials over $\mathbb{F}$, of individual degree $|H| - 1$, that take Boolean values in H^m such that the integer sum over all elements in H^m is divisible by 3.

4.2 The Upper Bound

In this section, we construct an IPP for $\mathsf{Enc\text{-}MOD3}$. This IPP suffices both for the results in the constant-round regime and poly-logarithmic round regime of Theorem 16.

▶ **Lemma 17.** *For every $r = r(n) \leq \frac{\log(n)}{\log\log(n)}$, there exists an $O(r^2)$-round public-coin ε-IPP for $\mathsf{Enc\text{-}MOD3}$ with perfect completeness and soundness error $1/2$. The communication complexity is $n^{O(1/r)}$ and the query complexity is $\mathsf{poly}(\log(n), 1/\varepsilon)$. Furthermore, the verifier runs in time $\left(n^{O(1/r)} + \mathsf{poly}(\log(n), 1/\varepsilon)\right)$ and the prover runs in time $\mathsf{poly}(n)$.*

The main step in the proof of Lemma 17 is the construction of an HIP for the related language $\mathcal{L}_{\mathsf{MOD3}}$ (defined above), with respect to the LDE code (with the parameters that were specified in Section 4.1). Given this HIP, Lemma 17 follows by using a generic transformation from HIPs (with respect to the LDE encoding) into IPPs, which we establish in Proposition 11.

Before constructing this HIP, as an intermediate goal, we first construct an HIP for $\mathcal{L}_{\mathsf{MOD3}}$, with respect to the low-degree extension with different parameters than those that were set in Section 4.1. Specifically, we shall use a larger field $\mathbb{K}$, whose size is polynomially related to k (rather than poly-logarithmic). In particular, there will be a dependence between the size of $\mathbb{K}$ and the number of rounds in the HIP. Later we will use a generic transformation to

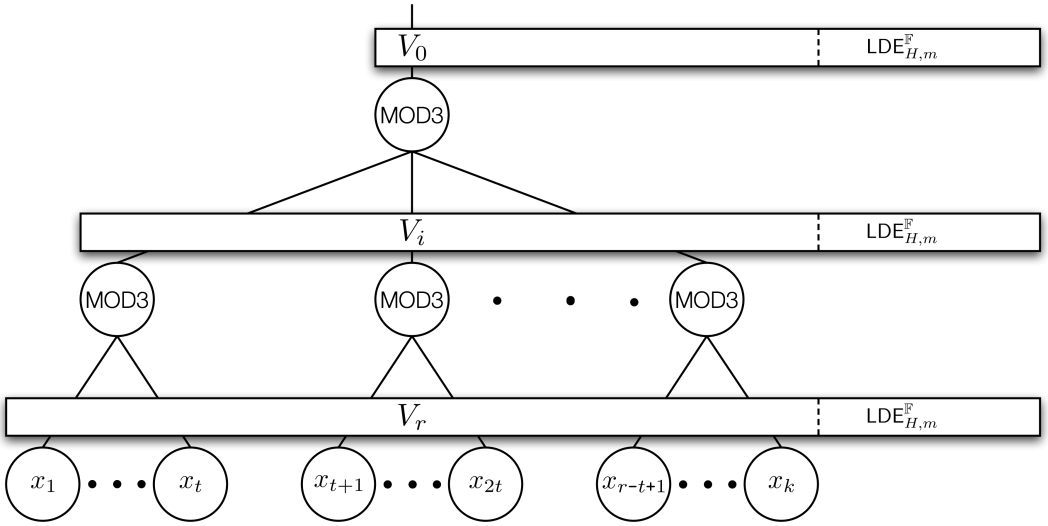

Figure 1 The recursive depth r formula of fan-in $k^{1/r}$ that computes the sum mod 3 of its input $x \in \{0,1\}^k$, and the low-degree extension of each one of the formula's layers when evaluated on x.

convert this HIP into one in which the low degree extension can be over a much smaller field (e.g., of poly-logarithmic size), which in particular does not depend on the number of rounds.

The following lemma, which is the main lemma proved in this section, gives an HIP for $\mathcal{L}_{\mathsf{MOD3}}$ over the relatively large field $\mathbb{K}$.

▶ **Lemma 18.** *Let $r = r(k) \geq 1$, let $\mathbb{K} = (\mathbb{K}_k)_{k\in\mathbb{N}}$ be a constructible field ensemble of size $|\mathbb{K}| = \Omega(r^2 \cdot k^{2/r})$, let $G = (G_k)_{k\in\mathbb{N}} \subseteq \mathbb{K}$ be an ensemble of subsets of $\mathbb{K}$ of size $|G| = k^{1/r}$.*

Then, there exists an r^2-round public-coin HIP *for $\mathcal{L}_{\mathsf{MOD3}}$, with perfect completeness and soundness error $O\left(\frac{r^2 \cdot k^{2/r}}{|\mathbb{K}|}\right)$. The communication complexity is $O(r^2 \cdot k^{2/r} \cdot \log|\mathbb{K}|)$. The verifier runs in time $k^{O(1/r)} \cdot \mathsf{poly}(r, \log(k))$ and the prover runs in time $\mathsf{poly}(|\mathbb{K}|^r)$.*

(See Section 1.2 for a high-level overview of the proof.)

Proof. Let $r = r(k) \geq 1$. Recall that $\mathbb{K} = (\mathbb{K}_k)_{k\in\mathbb{N}}$ is a constructible field ensemble field of size $|\mathbb{K}| = \Omega(r^2 \cdot k^{1/r})$ and that $G = (G_k)_{k\in\mathbb{N}}$ is an ensemble of subsets of size $|G| = k^{1/r}$. Since we only deal with a single input length k (which we think of as varying), in the following we omit the subscripts and use $\mathbb{K}$ (resp., G) when we actually mean $\mathbb{K}_k$ (resp., G_k).

Denote by $t \stackrel{\text{def}}{=} |G| = k^{1/r}$ and fix a canonical ordering $\alpha_1, \ldots, \alpha_t$ of the set of elements in G (i.e., $G = \{\alpha_1, \ldots, \alpha_t\}$). Let $\mathsf{MOD3}_t : \{0,1,2\}^t \to \{0,1,2\}$ be defined as $\mathsf{MOD3}_t(\sigma_1, \ldots, \sigma_t) \stackrel{\text{def}}{=} \sum_{j\in[t]} \sigma_j \pmod 3$.

Fix an input $x \in \{0,1\}^k$. As described in Section 1.2, we define polynomials $V_0, \ldots, V_r$ that contain sums, modulo 3, of certain intervals in x. Taking the [37] view, one can consider a depth r formula, with fan-in $t = k^{1/r}$, composed of $\mathsf{MOD3}_t$ gates, that computes the sum mod 3 of its input (see Figure 1). Viewed this way, each polynomial V_i corresponds to the low degree extension of the i^{th} layer of this formula (counting from output to input).

Since $|G^r| = k$, we can associate elements in G^r with the integers in the set $\{1, \ldots, k\}$ in the natural way. Thus, we can view the input $x \in \{0,1\}^k$ as a function, which we denote by $V_r : G^r \to \{0,1\}$, that is defined as $V_r(p) = x_p$, for every $p \in G^r$. We define functions $V_0, \ldots, V_{r-1}$ via backward recursion as follows. For every $i \in [r]$, let $V_{i-1} : G^{i-1} \to \{0,1,2\}$

be defined as:

$$\forall p \in G^{i-1}, \quad V_{i-1}(p) = \mathsf{MOD3}_t\big(V_i((p,\alpha_1)),\ldots,V_i((p,\alpha_t))\big), \tag{7}$$

where (p,α) denotes the element in G^i which is obtained by concatenating $p \in G^{i-1}$ with $\alpha \in G$. For the case $i = 0$, we define $G^0 = \{\perp\}$, where $\perp$ is defined as the empty string (in particular $(\perp,p) = (p,\perp) = p$), and note that, for $i = 1$, Equation (7) reduces to $V_0(\perp) = \mathsf{MOD3}_t\big(V_1(\alpha_1)\big),\ldots,V_1(\alpha_t)\big)$.

As noted above, intuitively, each V_i should be thought of as specifying a sum of certain intervals in the input, according to a partition (which depends on i). For example, V_r contains the value of each of the individual coordinate of x (i.e., the most fine grained partition) whereas V_0 contains the overall sum (i.e., the coarsest partition). More generally, we have the following immediate fact:

▶ **Fact 19.** *For every $i \in \{0,\ldots,r\}$ and $p \in G^i$ it holds that $V_i(p) = \sum_{q\in G^{r-i}} x_{(p,q)} \pmod 3$ (where (p,q) denotes the concatenation of the two vectors p and q).*

In particular, by setting $i = 0$, we have that $V_0(\perp) = \sum_{q\in G^r} x_q \pmod 3 = \sum_{i\in[k]} x_i \pmod 3$.

For the rest of the proof we use $\tilde{f}$ to denote the low degree extension of a function f (see Section 2.3 for details on the low degree extension encoding) and associate the integers 0, 1 and 2 with three distinct elements in $\mathbb{K}$ in some canonical way (so that we can view $\{0,1,2\} \subseteq \mathbb{K}$). Let $\widetilde{\mathsf{MOD3}}_t : \mathbb{K}^t \to \mathbb{K}$ be the unique individual degree 2 extension of the function $\mathsf{MOD3} : \{0,1,2\}^t \to \{0,1,2\}$ with respect to the field $\mathbb{K}$, the subset $\{0,1,2\} \subseteq \mathbb{K}$, and dimension t. For every $i \in [r]$, let $\tilde{V}_i : \mathbb{K}^i \to \mathbb{K}$ be the unique individual degree $|G| - 1$ extension of V_i with respect to the field $\mathbb{K}$, the set G and dimension i. Let $\tilde{V}_0 \equiv V_0$ (recall that $V_0 : \{\perp\} \to \{0,1,2\}$ is just a singleton value $V_0(\perp) \in \mathbb{K}$). Observe that the polynomial $\tilde{V}_r$ is the low degree extension of the input x with respect to the field $\mathbb{K}$, the set G and dimension r.

A crucial fact that we will use is that, for every $i \in [r]$, each point in $\tilde{V}_{i-1}$ can be expressed as a certain type of composition of the low degree polynomial $\tilde{V}_i$ with the low degree polynomial $\widetilde{\mathsf{MOD3}}$. More specifically, using the properties of the low degree extension (see Section 2.3), it holds that for every $i \in [r]$ and $z \in \mathbb{K}^{i-1}$:

$$\begin{aligned}
\tilde{V}_{i-1}(z) &= \sum_{p\in G^{i-1}} \beta(z,p)\cdot V_{i-1}(p) \\
&= \sum_{p\in G^{i-1}} \beta(z,p)\cdot \mathsf{MOD3}_t\big(V_i((p,\alpha_1)),\ldots,V_i((p,\alpha_t))\big) \\
&= \sum_{p\in G^{i-1}} \beta(z,p)\cdot \widetilde{\mathsf{MOD3}}_t\big(\tilde{V}_i((p,\alpha_1)),\ldots,\tilde{V}_i((p,\alpha_t))\big).
\end{aligned} \tag{8}$$

where the polynomial β is as defined in Section 2.3, and the last equality uses the fact that $\tilde{V}_i|_{G^i} \equiv V_i|_{G^i}$ and $\widetilde{\mathsf{MOD3}}_t|_{\{0,1,2\}^t} \equiv \mathsf{MOD3}_t|_{\{0,1,2\}^t}$.

Using the above definition, we proceed to describe our HIP for $\mathcal{L}_{\mathsf{MOD3}}$. The protocol is performed in r phases, each of which takes at most r rounds of interaction (for a total of at most r^2 rounds). We begin the protocol with a claim about the value of a single point (as a matter of fact, the only point) in $\tilde{V}_0$ (recall that, by Fact 19, the value of $\tilde{V}_0(\perp)$ corresponds to the desired output - the sum modulo 3 of the input bits). In the i^{th} phase, we reduce the task of verifying the value of a single (arbitrary) point in $\tilde{V}_{i-1}$ to verifying the value of a single point in $\tilde{V}_i$. Thus, after r phases, we have reduced the problem of

verifying $\tilde{V}_0(\perp) = \sum_{j\in[k]} x_j \pmod 3$ to verifying a single point in $\tilde{V}_r$, which is the low degree extension of the input x.

Define $z_0 = \perp$ and $\nu_0 = 0$. The original claim is that $\tilde{V}_r(z_0) = \nu_0$. We shall maintain the invariant that for every phase $i \in \{0,\ldots,r\}$, at the end of the i^{th} phase, the prover and verifier both know a vector $z_i \in \mathbb{K}^i$ and a scalar $\nu_i \in \mathbb{K}$ such that the current claim is that $\tilde{V}_i(z_i) = \nu_i$. Thus, the goal of the i^{th} phase is to (interactively) reduce the claim $\tilde{V}_{i-1}(z_{i-1}) = \nu_{i-1}$ to a claim of the form $\tilde{V}_i(z_i) = \nu_i$ (for some z_i and ν_i that are generated during the i^{th} phase):

Phase i.

1. **Reduce to Claim about t Points in $\tilde{V}_i$:** The phase begins with a claim that $\nu_{i-1} = \tilde{V}_{i-1}(z_{i-1})$. By Equation (8) this is equivalent to:

$$\nu_{i-1} = \sum_{p\in G^{i-1}} \beta(z_{i-1},p)\cdot \widetilde{\mathsf{MOD3}}_t\big(\tilde{V}_i((p,\alpha_1)),\ldots,\tilde{V}_i((p,\alpha_t))\big) \tag{9}$$

   We now observe that the right-hand side of Equation (9) corresponds to a sum, over an $(i-1)$-dimensional subcube, of the values of a low degree polynomial. Specifically, denote

$$f_{i-1}(w) = \beta(z_{i-1},w)\cdot \widetilde{\mathsf{MOD3}}_t\big(\tilde{V}_i((w,\alpha_1)),\ldots,\tilde{V}_i((w,\alpha_t))\big),$$

   and observe that f_{i-1} has *total* degree $(t-1)\cdot(i-1)+2t\cdot(t-1)\cdot i \le 3t^2 r$ polynomial. Equation (9) can be rewritten as $\nu_{i-1} = \sum_{p\in G^{i-1}} f_{i-1}(p)$. The prover and verifier run an i-round sumcheck protocol with respect to this equation.

   In case the sumcheck verifier rejects, our verifier immediately rejects. Otherwise, the output of the sumcheck protocol is a (random) point $w_{i-1} \in \mathbb{K}^{i-1}$ and value $\gamma_{i-1} \in \mathbb{K}$ with an associated alleged claim that $\gamma_{i-1} = f_{i-1}(w_{i-1})$.
2. **Query Reduction:** At this point the verifier has a claim regarding the values of t points of $\tilde{V}_i$ (specifically, the claim $\gamma_{i-1} = f_{i-1}(w_{i-1})$ refers to the points $(w_i,\alpha_1),\ldots,(w_i,\alpha_t)$). The goal of this step is to reduce this more elaborate claim to a claim about a *single* point in $\tilde{V}_i$:
   - **a.** The prover sends to the verifier the univariate degree $t-1$ polynomial $P_i : \mathbb{K}\to\mathbb{K}$ defined as $P_i(\eta) = \tilde{V}_i(w_i,\eta)$ (given by its t coefficients).
   - **b.** The verifier receives a degree $t-1$ polynomial Q_i (which is allegedly equal to P_i). The verifier checks that $\gamma_i = \beta(z_{i-1},w_{i-1})\cdot \widetilde{\mathsf{MOD3}}_t\big(Q_i(\alpha_1),\ldots,Q_i(\alpha_t)\big)$. If the check fails then the verifier immediately rejects and halts. Otherwise, the verifier chooses a random field element $\eta_i \in \mathbb{K}$ and sends η_i to the prover.
   - **c.** The claim for the next round is that $\tilde{V}_i(z_i) = \nu_i$, where $\nu_i = P_i(\eta_i)$ and $z_i = (w_i,\eta_i)$.

After all of the r phases are complete, the verifier outputs (z_r,ν_r) and the associated claim is that $\tilde{V}_r(z_r) = \nu_r$. Since $\tilde{V}_r$ is simply the low degree extension of the input x, the latter is a claim about a single point in the low degree extension of the input as required by the definition of an HIP verifier.

Complexity. Since the communication complexity of each sumcheck is $O(r\cdot k^{1/r}\cdot\log|\mathbb{K}|)$, the total communication complexity is $O(r^2\cdot k^{1/r}\cdot\log|\mathbb{K}|)$. As for the round complexity, the i^{th} phase uses a sumcheck of $i \le r$ rounds of interaction. Moreover, each sumcheck concludes with a message from the prover to the verifier so we can "piggyback"and attach the polynomial Q_i to that last message from the prover and send back the value η_i as our response (which is still part of the last round of the sumcheck protocol) so each phase just takes $\le r$ rounds and overall we have $\le r^2$ rounds.

As for computational complexity, in the first step of each phase, the parties invoke a sumcheck protocol in which, by Lemma 10, the verifier runs in time $k^{O(1/r)} \cdot r \cdot \mathsf{polylog}|\mathbb{K}|$, and the prover runs in time $\mathsf{poly}(|\mathbb{K}|^r)$. In the second step of each phase, the prover computes and sends P_i, which clearly can be done in time $\mathsf{poly}(|\mathbb{K}|^r)$, and the verifier computes γ_i, which boils down to evaluating the functions β and $\widetilde{\mathsf{MOD3}}_t$ at a single point, which can be done in time $\mathsf{poly}(t, \log k) = k^{O(1/r)} \cdot \mathsf{poly}(\log |\mathbb{K}|)$ (see Proposition 6 and Appendix E for the time complexity of computing β and $\widetilde{\mathsf{MOD3}}_t$, respectively). The obtain the total running times (for the entire r phases), we multiply the time per phase by r.

Completeness. Perfect completeness follows readily from the construction (and the prefect completeness of the sumcheck protocol).

Soundness. To conclude the proof of Lemma 18 we only need to show that soundness holds. Our analysis follows the soundness analysis in [37, Theorem 3.1].

Fix an input $x \in \{0,1\}^k$ such that $\sum_{i\in[k]} x_i \not\equiv 0 \pmod 3$ (i.e. $x \notin \mathcal{L}_{\mathsf{MOD3}}$) and a cheating strategy $\mathcal{P}^*$. Denote by A the event that the verifier does not reject in the interaction with the prover $\mathcal{P}^*$. For every $i \in \{0, 1, \ldots, r\}$, denote by T_i the event that $\tilde{V}_i(z_i) = \nu_i$. Note that since $\sum_{i\in[k]} x_i \neq 0 \pmod 3$ it holds that the event $\neg T_0$ occurs with probability 1. For every $i \in [r]$, let E_i denote the event that the polynomial Q_i that the prover sent is indeed identical to $P_i(\eta) = \tilde{V}_i(w_i, \eta)$.

Our analysis will be based on the following two claims.

▶ **Claim 20.**

$$\Pr\left[A \wedge E_i \mid \neg T_{i-1}\right] \leq \frac{3t^2 r}{|\mathbb{K}|}.$$

Proof. Assume that the event T_{i-1} occurs. Then, by the soundness of the sumcheck protocol, with probability $\frac{3t^2 r}{|\mathbb{K}|}$ (over the verifier's coins in the sumcheck protocol) it holds that $f_{i-1}(w_{i-1}) \neq \gamma_{i-1}$, or in other words $\beta(z_{i-1}, w_{i-1}) \cdot \widetilde{\mathsf{MOD3}}_t\big(\tilde{V}_i((w_{i-1}, \alpha_1)), \ldots, \tilde{V}_i((w_{i-1}, \alpha_t))\big) \neq \gamma_{i-1}$. If the latter happens and then the prover sends the correct polynomial P_i (i.e., the event E_i occurs) then the verifier immediately rejects in Item 2b. Thus, with probability $1 - \frac{3t^2 r}{|\mathbb{K}}$, either the event $\neg A$ or $\neg E_i$ must occur. ◀

On the other hand:

▶ **Claim 21.**

$$\Pr\left[T_i \mid \neg E_i\right] \leq \frac{t}{|\mathbb{K}|}.$$

Proof. The event $\neg E_i$ implies that the polynomial Q_i sent by the prover differs from the correct polynomial P_i. Since both Q_i and P_i are degree $t-1$ polynomials, they can agree on at most $t-1$ points, and so, with probability $1 - \frac{t-1}{|\mathbb{K}|}$ over the choice of η_i it holds that $\nu_i = Q(\eta_i) \neq P(\eta_i) = \tilde{V}_i((w_i, \eta_i)) = \tilde{V}_i(z_i)$. ◀

Finally, observe that the probability that the verifier errs is simply $\Pr[A \wedge \neg T_r]$, which

we can bound (using Claim 20, Claim 21 and elementary probability theory) as follows:

$$\begin{aligned}
\Pr[A \wedge T_r] &= \Pr[A \wedge \neg T_0 \wedge T_r] \\
&\leq \Pr\left[\exists i \in [r] \text{ such that } A \wedge \neg T_{i-1} \wedge T_i\right] \\
&\leq \sum_{i=1}^{r} \Pr\left[A \wedge \neg T_{i-1} \wedge T_i\right] \\
&= \sum_{i=1}^{r} \left(\Pr[A \wedge \neg T_{i-1} \wedge T_i \wedge E_i] + \Pr[A \wedge \neg T_{i-1} \wedge T_i \wedge \neg E_i]\right) \\
&\leq \sum_{i=1}^{r} \left(\Pr\left[A \wedge E_i \mid \neg T_{i-1}\right] + \Pr\left[T_i \mid \neg E_i\right]\right) \\
&\leq \sum_{i=1}^{r} \left(\frac{3t^2 r}{|\mathbb{K}|} + \frac{t}{|\mathbb{K}|}\right) \\
&\leq \frac{4t^2 r^2}{|\mathbb{K}|}.
\end{aligned}$$

This concludes the proof of Lemma 18. ◀

Lemma 18 provides an r^2-round HIP for $\mathcal{L}_{\mathsf{MOD3}}$, with respect to the code $\mathsf{LDE}_{\mathbb{K},G,r}$, where $\mathbb{K}$ is a field ensemble of size $\Theta\left(r^2 \cdot k^{2/r}\right)$. We now use a general result, which is stated and proved in Section 3, which transforms any such HIP, in which the field $\mathbb{K}$ has small characteristic, into an HIP over the code $\mathsf{LDE}_{\mathbb{F},H,m}$ where the size of the field $\mathbb{F}$ is now only *poly-logarithmic* in k. Specifically, by applying Lemma 12 to the protocol of Lemma 18, and using a field $\mathbb{K}$ which is an extension field of some field $\mathbb{F}$ of size $\mathsf{polylog}(k)$, we obtain the following corollary:

▶ **Corollary 22.** *Let $\mathbb{F} = (\mathbb{F}_k)_{k\in\mathbb{N}}$ be a constructible field ensemble, $H = (H_k)_{k\in\mathbb{N}} \subseteq \mathbb{F}$ be an ensembles of subsets of $\mathbb{F}$ and let $m = m(k)$ be a dimension such that $|H| = \log(k)$, $m = \frac{\log(k)}{\log\log(k)}$ and $|\mathbb{F}| = \Theta(|H| \cdot m)$.*

Then, for every parameter $r = r(k) \leq \frac{\log(k)}{\log\log(k)}$, the language $\mathcal{L}_{\mathsf{MOD3}}$ has an has an $O(r^2)$-round (public-coin) HIP with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$ with soundness error $1/2$ and communication complexity $k^{O(1/r)}$. The verifier runs in time $k^{O(1/r)}$ and the prover runs in time $\mathsf{poly}(k)$.

Lemma 17 follows from Corollary 22 by applying Proposition 11, which is a generic transformation from any HIP, over the low degree extension encoding, into an IPP.

4.3 The Lower Bound

▶ **Lemma 23.** *Let $r = r(k) \geq 1$ be a constant. For every r-round IPP for Enc-MOD3, with respect to proximity parameter $\varepsilon = 1/10$, with query complexity q and communication complexity $c \geq \Omega(\log n)$, it holds that $\max(c, q) = n^{\Omega(1/r)}$.*

We remark that our proof of Lemma 23 gives a similar result even for super constant values of r (as long as $r = O\left(\sqrt{\frac{\log(n)}{\log\log(n)}}\right)$) but for simplicity we restrict ourselves to constant r. We also remark that the constants in the lemma's statement can be improved but we avoid optimizing them for sake of readability.

Proof. Throughout the proof of Lemma 23 all proofs of proximity refer to proximity parameter $\varepsilon = 1/10$.

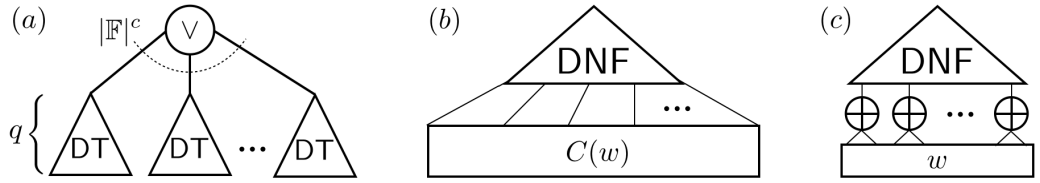

Figure 2 After fixing the randomness, an AMP for Π can be expressed as follows: (a) a disjunction over $O(2^c)$ decision trees of depth $q \cdot \log(|\mathbb{F}|)$, (b) a DNF formula with $O(2^{c+q\cdot\log(|\mathbb{F}|)})$ clauses of width $q \cdot \log|\mathbb{F}|$ over the linear code $C(w)$, and (c) a $\mathsf{DNF}_\oplus$ circuit of size $\tilde{O}(2^{c+q\cdot\log(|\mathbb{F}|)})$ over x.

The following proposition, due to [58] (building on [8, 39, 36]), shows that to prove Lemma 23, it suffices to prove a lower bound for AMPs, which are *public-coin* IPPs with only a *single* round of interaction between the verifier and prover. More precisely, in an AMP for a language $\mathcal{L}$, the verifier first sends a random string r to the prover, who responds with a proof π, which can depend on both the input x and the verifier's message r. Then, given π (and based on its original random coins r), the verifier needs to decide whether to accept or reject. (Note that the verifier is not allowed to toss additional coins after receiving the message from the prover.)

▶ **Proposition 24** (IPP to AMP). *If there exists an r-round (public or private coin)* IPP *for a language $\mathcal{L}$, with communication complexity $c \geq \log(n)$ and query complexity q, then there exists an* AMP *for $\mathcal{L}$ with communication complexity $c^{r+2} \cdot (\log(c) \cdot r)^{O(r)}$ and query complexity $c^{r+1} \cdot q \cdot (\log(c) \cdot r)^{O(r)}$.*

The proof of Proposition 24, which appears in [58, Section 4], proceeds by observing that the private-coin to public-coin transformation of [39] as well as the round reduction transformation of [8, 36], which are transformations on standard interactive proofs, can be applied to IPPs as well.

Thus, given Proposition 24, and using the fact that r is constant, to prove Lemma 23 it suffices to show that every AMP for Enc-MOD3 with query complexity q and communication complexity c satisfies $\max(c, q) = n^{\Omega(1)}$, or equivalently, since $n = O(k^3)$, that $\max(c, q) = k^{\Omega(1)}$. The following proposition, which is inspired by the [58] lower bound, shows that AMPs for properties of *linear codes* can be viewed as distributions over (relatively) small DNF*s of parities*. By DNF of parities, we refer to depth 3 circuits whose bottom layer consists of parity gates, middle layer consists of AND gates and top layer is a single OR gate. In the following we denote such circuits by $\mathsf{DNF}_\oplus$.

▶ **Proposition 25.** *Let $\mathbb{F}$ be an extension field of* GF(2)*, let $C : \mathbb{F}^k \to \mathbb{F}^n$ be an $\mathbb{F}$-linear code, and let $f : \{0,1\}^k \to \{0,1\}$. If there exists an* AMP *for $\Pi_f \stackrel{\text{def}}{=} \{C(x) : x \in \{0,1\}^k \wedge f(x) = 1\}$ with communication complexity $c \geq \log(n)$ and query complexity q, then there exists a distribution $\mathcal{D}$ over $\mathsf{DNF}_\oplus$ circuits of size $2^{O(c+q\cdot\log_2(|\mathbb{F}|))}$ such that $\Pr_{\varphi\sim\mathcal{D}}[\varphi(x) = f(x)] \geq 0.9$, for all $x \in \{0,1\}^k$.*

Proof. Let $\mathcal{V}$ be an AMP verifier for Π. We assume without loss of generality that $\mathcal{V}$ has soundness error at most 0.1 (e.g., by repeating the protocol in parallel $O(1)$ times). Recall that in an AMP protocol, for a given input $y \in \mathbb{F}^n$, the verifier first sends a random string r, then the prover replies with an alleged proof $\pi = \pi(r, y)$, and finally the verifier makes queries to y and decides whether to accept or reject. Denote by $\mathcal{V}^y_{r,\pi}$ the output of the verifier for a fixed string r, given oracle access to y and direct access to π.

For a fixed string r and alleged proof π, the verifier $\mathcal{V}^y_{r,\pi}$ can be represented as an $|\mathbb{F}|$-ary decision tree of depth q (on input y), which we denote by $D_{r,\pi} : \{0,1\}^k \to \{0,1\}$. The completeness and soundness requirements of an AMP guarantee that for a fixed string r, the verifier accepts an input $C(x)$ if and only if there exists a string π such that $\mathcal{V}^{C(x)}_{r,\pi} = 1$. Thus, $\mathcal{V}^{C(x)}_{r,\pi} = \bigvee_{\pi\in\{0,1\}^{O(c)}} D_{r,\pi}\big(C(x)\big)$ (see Figure 2(a)). Observe that by viewing elements of $\mathbb{F}$ in their bit-representation and assigning a clause for each accepting leaf in the decision tree, each $D_{r,\pi}$ can be represented as a *binary* DNF formula with $|\mathbb{F}|^{O(q)}$ clauses of width $O(q \cdot \log|\mathbb{F}|)$. Merging the two consecutive layers of disjunctions, we obtain a binary DNF formula that on input $y \in \mathbb{F}^n$ computes $\mathcal{V}^y_{r,\pi}$ with $2^{O(c+q\cdot\log_2(|\mathbb{F}|))}$ clauses of width $O(q \cdot \log_2(|\mathbb{F}|))$ each (see Figure 2(b) for an illustration).

We next observe that every linear combination over the field $\mathbb{F}$, which is an extension field of $\mathsf{GF}(2)$, can be represented by $\log_2(|\mathbb{F}|)$ linear combinations over $\mathsf{GF}(2)$.[24] Thus, we can view the function $C : \mathbb{F}^k \to \mathbb{F}^n$, which is an $\mathbb{F}$-linear function, as a $\mathsf{GF}(2)$-linear function $C : \mathsf{GF}(2)^{k\cdot\log_2(|\mathbb{F}|)} \to \mathsf{GF}(2)^{n\cdot\log_2(|\mathbb{F}|)}$. Hence, for every random string r, there exists a $\mathsf{DNF}_\oplus$ circuit of size:

$$2^{O(c+q\cdot\log_2(|\mathbb{F}|))} \cdot q \cdot \log_2(|\mathbb{F}|) + n \cdot \log_2(|\mathbb{F}|) = 2^{O(c+q\cdot\log(|\mathbb{F}|))}$$

(which is constructed by composing the code C with the DNF $\bigvee_{\pi\in\{0,1\}^{O(c)}} D_{r,\pi}$) that on input $x \in \{0,1\}^k$ outputs 1 if and only if there exists a proof π that $\mathcal{V}$ would accept, given input $C(x)$.

Therefore, there exists a distribution $\mathcal{D}$ over $\mathsf{DNF}_\oplus$s of size $2^{O(c+q\cdot\log(|\mathbb{F}|))}$ such that for every $x \in \{0,1\}^k$, it holds that $\Pr_{\varphi\in\mathcal{D}}[\varphi(x) = f(x)] \geq 0.9$. This concludes the proof of Proposition 25. ◀

Let $f_{\mathsf{MOD3}} : \{0,1\}^k \to \{0,1\}$ such that $f_{\mathsf{MOD3}} = 1$ if and only if $\sum_{i\in[k]} x_i \equiv 0 \pmod 3$. By Proposition 25, choosing $\Pi = \mathsf{Enc\text{-}MOD3}$, $C = \mathsf{LDE}^{\mathbb{F}}_{H,m}$, $f = f_{\mathsf{MOD3}}$, and using the (easy direction of) Yao's minimax principle, it suffices to show that there exists a distribution $\mathcal{X}$ over inputs in $\{0,1\}^k$ such that for every $\mathsf{DNF}_\oplus$ φ of size $\left(2^{O(c+q\cdot\log_2(|\mathbb{F}|))}\right)$ it holds that $\Pr_{x\in\mathcal{X}}[\varphi(x) = f_{\mathsf{MOD3}}(x)] < 0.9$ (where recall that $|\mathbb{F}| = \mathsf{polylog}(k)$). To that end, we shall use the celebrated result of Razborov [55] and Smolensky [62].

▶ **Theorem 26** (Razborov-Smolensky (see also [68, Theorem 2])). *Every* $\mathsf{AC}^0(\oplus)$ *circuit* φ *of size* s *and depth* d *satisfies*

$$\Pr_{x\in\{0,1\}^k}[\varphi(x) = f_{\mathsf{MOD3}}(x)] < \frac{2}{3} + O\left(\frac{\log(s)^d}{\sqrt{k}}\right).$$

This concludes the proof of Lemma 23. ◀

5 Implications for Classical Interactive Proofs

In this section, we derive from our hierarchy theorem implications to standard interactive proofs (in which the verifier can run in polynomial time). Loosely speaking, in Section 5.1 we show that the round reduction of public-coin interactive proofs, due to Babai and Moran [8], is (almost) optimal among all blackbox transformations, and in Section 5.2 we show that any proof that $\#\mathcal{P} \subseteq \mathcal{AM}$ will require using non-algebrizing techniques.

[24] Fix a linear combination $\alpha \in \mathbb{F}^t$ over $\mathbb{F}$ (the extension field). For every $i \in [\log_2(|\mathbb{F}|)]$, the function $\ell_{\alpha,i}(x) = \mathsf{bit}_i(\langle\alpha, x\rangle)$ that outputs the t^{th} bit of $\langle\alpha, x\rangle$ is a linear function over $\mathsf{GF}(2)$.

5.1 Blackbox Round Reduction Transformations

Babai and Moran [8] proved a "speedup" theorem, which loosely speaking, shows that very r-round public-coin interactive proof protocol can be transformed into an $(r-1)$-round protocol at the cost of increasing the communication complexity quadratically (some quantitative improvements were later obtained by Goldreich, Vadhan and Wigderson [36]). Combined with the private-coin to public-coin transformation of Goldwasser and Sipser [39], one can obtain a similar "speedup" theorem for private-coin interactive proofs.

Vadhan [66] considered the affect of certain transformations on interactive proofs. He introduced the notion of a "blackbox transformation" (defined below) and showed that the aforementioned private-coin to public-coin transformation, and a transformation from 2-sided error to 1-sided error of Goldreich, Mansour and Sipser [32], are (in a certain sense) optimal amongst all *black-box* transformation.

In this section, we use our hierarchy theorem to derive a similar result for the round reduction theorem of Babai and Moran. Following [66], we define a black-box transformation on interactive proofs as a procedure that takes as input an interactive proof $(\mathcal{P},\mathcal{V})$ for some language $\mathcal{L}$ and outputs a new interactive proof $(\mathcal{P}',\mathcal{V}')$, for the same language $\mathcal{L}$, such that:

- The strategy of the verifier $\mathcal{V}'$ can be implemented by an algorithm given oracle access to the strategy of $\mathcal{V}$.
- The strategy of the prover $\mathcal{P}'$ can be implemented by a algorithm given oracle access to the strategy of both $\mathcal{P}$ and $\mathcal{V}$.

Here, the strategy of a party (i.e., prover or verifier) is the function that takes the party's random coins and the history of messages exchanged and outputs its next message. We stress that the new strategies $(\mathcal{P}',\mathcal{V}')$ cannot even explicitly look at the input x; their only access to the input x is given by queries to the strategies $(\mathcal{P},\mathcal{V})$.

An r-to-r' blackbox round reduction transformation, for $r'<r$, is a black-box transformation that, given as input an r-round interactive proof, produces an r'-interactive proof (for the same language). We remark that the [8] round-reduction is a blackbox round reduction transformation, and we show that it is nearly optimal, out of all blackbox reductions.

▶ **Theorem 27.** *There exists a language $\mathcal{L}$ such that for every constant $r\geq 1$, there exists an r-round (public-coin) interactive proof $(\mathcal{P},V)$ for $\mathcal{L}$, with communication complexity $c=c(n)$, such that for every r-to-r' blackbox round reduction transformation T, in the resulting interactive proof $(\mathcal{P}',\mathcal{V}')=T(\mathcal{P},\mathcal{V})$ it holds that either the communication is at least $c^{\Omega(\sqrt{r}/r')}$ or $\mathcal{V}'$ invokes V at least $c^{\Omega(\sqrt{r}/r')}$ times.*

Proof. Let $r\in\mathbb{N}$ be a constant, and consider the language

$$\mathcal{L}_{\mathsf{MOD3}}=\left\{x\in\{0,1\}^k \;:\; \mathsf{wt}(x)=0 \pmod 3\right\}_{k\in\mathbb{N}}.$$

Fix input length $k\in\mathbb{N}$, field $\mathbb{F}$, subset $H\subset\mathbb{F}$, and dimension $m=\frac{\log(k)}{\log\log(k)}$ such that $|H|=\log(k)$ and $|\mathbb{F}|=\Theta(|H|^2 m)$.

By Corollary 22, there exists an r-round HIP for $\mathcal{L}_{\mathsf{MOD3}}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},H,m}$, with communication complexity $c\stackrel{\text{def}}{=}k^{O(1/\sqrt{r})}$. As noted in Proposition 9, this HIP implies an interactive proof $(\mathcal{P},\mathcal{V})$ for $\mathcal{L}_{\mathsf{MOD3}}$, with communication complexity c. Recall that on input $x\in\{0,1\}^k$, the parties $(\mathcal{P},\mathcal{V})$ invoke the HIP for $\mathcal{L}_{\mathsf{MOD3}}$, and the verifier checks the HIP's output claim by computing a single point of $\mathsf{LDE}_{\mathbb{F},H,m}(x)$.

Let T be an r-to-r' blackbox round reduction transformation on interactive proofs, and let $(\mathcal{P}',\mathcal{V}')=T(\mathcal{P},\mathcal{V})$ be the resulting r'-round interactive proof for $\mathcal{L}_{\mathsf{MOD3}}$. Using $(\mathcal{P}',\mathcal{V}')$,

we construct an r'-round ε-IPP for the language

$$\mathsf{Enc\text{-}MOD3} = \{\mathsf{LDE}_{\mathbb{F},H,m}(x) \ : \ x \in \mathcal{L}_{\mathsf{MOD3}}\}\,.$$

Recall that $\mathcal{V}$ only computes $\mathsf{LDE}_{\mathbb{F},H,m}(x)$ and queries it at a single point, and so each oracle call to $\mathcal{V}$ that $\mathcal{V}'$ makes can be emulated by making a single query to $\mathsf{LDE}_{\mathbb{F},H,m}(x)$. Therefore, we can view $(\mathcal{P}', \mathcal{V}')$ as an HIP, with respect to $\mathsf{LDE}_{\mathbb{F},H,m}$, for $\mathcal{L}_{\mathsf{MOD3}}$, with communication complexity c.

By applying Proposition 11 on $(\mathcal{P}', \mathcal{V}')$, we obtain an r'-round IPP for Enc-MOD3; denote its communication complexity by C and query complexity by Q. Finally, by Lemma 23 we have that:

$$\max(C, Q) = k^{\Omega(1/r')} = c^{\Omega(\sqrt{r}/r')}. \qquad \blacktriangleleft$$

5.2 The Algebrization Barrier

The *relatization* framework, introduced by Baker, Gill, and Solovay [9], tried to capture the intuition that we not understand how circuits operate and therefore we may as well treat them as black-boxes. Later on, the seminal result of [52, 60] showed that even without understanding how circuits operate, we can still do more than just evaluate them (i.e., treat them as oracles). Specifically, arithmetizing the circuit, allows us to evaluate points in a *low degree extension* of the function computed by the circuit. The latter cannot be done only via oracle access and has turned out to be incredibly useful.

The *algebrization* framework, introduced by Aaronson and Wigderson [1], tries to capture this additional power. Specifically, in this framework, rather than just giving oracle access to the given function, we give oracle access also to a low degree extension of the function. Results such as $\mathsf{IP} = \mathsf{PSPACE}$ can be showed to have "algebrizing" proofs. Despite the power that we obtain by having access to the low degree extension of the function, [1] also showed that some central questions in complexity theory cannot be proved within this framework (i.e., by "algebrizing") techniques.

Loosely speaking, for two complexity classes $\mathcal{C}_1$ and $\mathcal{C}_2$, the inclusion $\mathcal{C}_1 \subseteq \mathcal{C}_2$ is said to algebrize if $\mathcal{C}_1^A \subseteq \mathcal{C}_2^{\tilde{A}}$ for every oracle A and every low-degree extension $\tilde{A}$ of A. (See [1] for the precise definition, discussions and many more details.) We say that proving the inclusion $\mathcal{C}_1 \subseteq \mathcal{C}_2$ requires non-algebrizing techniques, or cannot be proved via algebrizing techniques, if the inclusion does *not* algebrize.

Before stating our results, we point out that there is an intimate connection (or a high level equivalence) between the class the algebrized class $\mathsf{IP}^{\tilde{A}}$ (where $\tilde{A}$ is the low degree extension of some oracle A) and the notion of HIPs (with respect to the low degree extension encoding). Indeed, in both cases the verifier needs to verify a property of some string, given oracle access to its low degree extension and interaction with the prover. For an $\mathsf{IP}^{\tilde{A}}$ the string is the truth table of A and for HIPs the string is simply the input.

Using this relation, we use our hierarchy theorem to show that the inclusion $\#\mathcal{P} \subseteq \mathcal{AM}$, which is widely believed *not* to hold[25], cannot be proved via algebrizing techniques. As a matter of fact, the proof of Theorem 28 can be easily extended to show that even the containment of $\#\mathcal{P}$ in a powerful variant of $\mathcal{AM}$ in which, for inputs of length N, the verifier is allowed to run in time $2^{o(N)}$ and with $2^{o(N)}$ communication, cannot be proved via algebrizing techniques.

[25] In particular it implies the collapse of the polynomial hierarchy to its second level.

▶ **Theorem 28.** *There exists an oracle A and a low-degree extension $\tilde{A}$ of A such that $\#\mathcal{P}^A \not\subseteq \mathcal{AM}^{\tilde{A}}$.*

Proof Sketch. Consider the problem #CSAT, which is the problem of counting the number of satisfying assignments of a given (Boolean) circuit C, and recall that #CSAT is $\#\mathcal{P}$-complete. Let $A : \{0,1\}^N \to \{0,1\}$ be an oracle and consider an input circuit C that, given as input $x \in \{0,1\}^N$, just outputs $A(x)$. We associate A with its truth table, which is a string of length 2^N. Let $\tilde{A} = \mathsf{LDE}_{\mathbb{F},H,m}(A)$, where $\mathbb{F}, H, m$ are defined as in Section 4.1, with respect to the parameter $k = 2^N$.

Observe that if $\#\mathcal{P}^A \subset \mathcal{AM}^{\tilde{A}}$, then there exists an $\mathcal{AM}$ proof system for computing the number of satisfying assignments of the circuit C, which is exactly the Hamming weight of A (viewed as an k-bit string), in which the communication complexity is $\mathsf{poly}(N)$ and in which the verifier only makes $\mathsf{poly}(N)$ oracle queries to $\tilde{A}$. Thus, following Proposition 11, we can obtain from this $\mathcal{AM}$ proof system a 1-round IPP for Enc-MOD3 with communication and query complexities $\mathsf{poly}(N) = \mathsf{polylog}(k)$, which violates the lower bound in Lemma 23. ◀

▶ Remark (Using Prime Order Fields). We remark that the proof of Theorem 28 is strongly based on the fact that we take a low degree extension over a field that has characteristic 2. Our result can extend to other constant size characteristics but we do not know how to extend it to arbitrary fields. In fact, it is consistent with our result (however unlikely) that there is a proof that $\#\mathcal{P} \subseteq \mathcal{AM}$ based (in a crucial way) on taking the low degree extension of the circuit with respect to a large prime order field.

We remark that we are unaware of any complexity class containments in the literature that are only known based on algebrization using *prime* order fields.[26]

Acknowledgements. We are grateful to Guy Rothblum for sharing [45] with us. We thank Oded Goldreich for his encouragement and support, for many technical and conceptual discussions on the contents of this work, and for valuable comments on its presentation. We thank Justin Holmgren for the proof of Proposition 33. Finally, we wish to thank Shafi Goldwasser, Guy Rothblum, and Rocco Servedio for insightful conversations.

A Talmudic Discussions

A.1 Why GKR and not other Interactive Proofs?

One may wonder whether we could base our upper bound on other interactive proofs from the literature. Other than the protocols of [37, 45], two other general purpose interactive proof-systems that come to mind are Shamir's[27] [60] protocol for IP = PSPACE and a recent protocol of Reingold, Rothblum and Rothblum [56] that gives constant-round interactive proofs for bounded-space computations.

[27] Indeed, here we specifically refer to Shamir's [60] protocol and not to the [52] protocol (on which [60] builds).

Shamir's protocol is not suitable for our needs both because it is not constant-round, and, perhaps more fundamentally, because the verifier in Shamir's protocol needs to access the low-degree extension of the input over a field that is only determined during the interaction (recall that the verifier in Shamir's protocol chooses a *random* prime p, and the players both work over the field of integers modulo p). For our purposes the field has to be fixed a priori (since we want the input for the IPP to be encoded under the LDE code corresponding to that field).

As for the protocol of [56], the latter does actually yield a constant-round HIP for $\mathcal{L}_{\mathsf{MOD3}}$ (which can be modified to yield an IPP for Enc-MOD3 as above) but the tradeoff that it offers between rounds and the verifier's complexity is exponentially worse than what we obtain. More specifically, for every constant $r \geq 1$, the [56] protocol yields a $2^{\tilde{O}(r)}$-round HIP for $\mathcal{L}_{\mathsf{MOD3}}$ with verification time roughly $2^{\tilde{O}(r)} \cdot k^{1/r}$. In contrast, we obtain an $O(r^2)$-round HIP with verification time roughly $\mathsf{poly}(r) \cdot k^{1/r}$.

A.2 An Alternative Candidate Language for the Round Hierarchy Theorem

The language for which we proved our round hierarchy consists of encodings of strings whose Hamming weight is divisible by 3. As described next, it seems as though a similar result can be obtained for a related language Enc-Maj that consists of encodings of strings $x \in \{0,1\}^k$ with $\mathsf{wt}(x) \geq k/2$, although there are some technical difficulties to overcome.

First note that the lower bound for Enc-Maj follows along the same lines as our lower bound for Enc-MOD3, where now we use the fact that $\mathsf{AC}_0[2]$ circuits cannot approximate the majority function [55, 62]. In contrast, showing an upper bound (i.e., an IPP or HIP) introduces some new difficulties. As explained in Section 1 (and formalized in Section 4), our upper bound for Enc-MOD3 is based on the observation that computing the sum, modulo 3, of the bits of an input string can be done by a (highly uniform) NC^1 circuit. Given this observation, we based our protocol on a variant of the GKR interactive proof for small-depth computations.

For Enc-Maj, we could similarly hope to base our protocol on an NC^1 circuit, but this time we need a circuit that computes the majority function. Obtaining such a circuit is less trivial and here we encounter some difficulties:

- Valiant [67] (see the presentation of Goldreich [25]) gave a *non-uniform* construction of an NC^1 circuit for majority. We could base our protocol on this result and obtain a *non-uniform* verifier (and in particular, its running time would be super-linear, although it would still have the desired query and communication complexities).
- The aforementioned construction of [67] can actually be shown to produce a (highly-uniform) *randomized* construction. That is, there exists a randomized logspace Turing machine that given as input 1^n, with all but exponentially vanishing probability, produces an NC^1 circuit, on n-bit strings, that computes the majority function correctly (on all inputs). We could have our verifier run this procedure to obtain the desired NC^1 circuit, but this would introduce an (exponentially small) completeness error, which we would like to avoid.
- Lastly, we mention that the celebrated [3] sorting network of Ajtai, Komlós and Szemerédi gives rise to a uniform (and deterministic) construction of an NC^1 circuit for majority (by sorting the input bits and outputting the median). This construction is quite complex and in particular we have not verifed whether it satisfies the uniformity condition that is required for the [45] result.[28]

[28] We note that other *partial*, but arguably simpler, de-randomization results of Valiant's formula have

B From HIPs to IPPs (Proof of Proposition 11)

The two main ingredients that we shall use to prove Proposition 11 are the well-known low (individual) degree test[29] for multivariate polynomials [59, 64, 4], and the self-correction procedure for polynomials [23, 64].

▶ **Lemma 29** (Individual Degree Test). *Let $d, m \in \mathbb{N}$ such that $dm < |\mathbb{F}|/10$ and $\varepsilon \in (0, 1/10)$. Denote by $\mathsf{Poly}_{d,m,\mathbb{F}}$ the set of all m-variate, individual degree d polynomials over $\mathbb{F}$. Then, there exists an ε-tester for $\mathsf{Poly}_{d,m,\mathbb{F}}$ with query complexity $dm \cdot \mathsf{poly}(1/\varepsilon)$.*

▶ **Lemma 30.** *Let $\varepsilon < 1/3$ and $d, m \in \mathbb{N}$ such that $d \leq |\mathbb{F}|$. There exists an algorithm (corrector) that, given $x \in \mathbb{F}^m$ and oracle access to an m-variate function $f : \mathbb{F}^m \to \mathbb{F}$ that is ε-close to a polynomial p of individual degree d, makes $O(d \cdot m)$ queries and outputs $p(x)$ with probability $9/10$. Furthermore, if f has total degree d, the algorithm outputs $p(x)$ with probability 1.*

Given Lemmas 29 to 30, we can now describe the IPP (with respect to some proximity parameter ε) for $\mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L})$. Recall that the verifier is given oracle access to a function $f : \mathbb{F}^m \to \mathbb{F}$ and the prover is given direct access to f. Assume, without loss of generality, that the HIP for $\mathcal{L}$ has soundness error $1/10$.[30]

First, the verifier and prover run the HIP protocol for $\mathcal{L}$ with respect to the input $f|_{H^m}$. (Recall that an HIP does not even query its input and therefore, so far, no queries have been made.) If the HIP verifier rejects then we immediately reject. Otherwise, the verifier outputs a pair $(z, \nu) \in \mathbb{F}^m \times \mathbb{F}$ (with the associated claim that $f(z) = \nu$). Then, the verifier runs the individual degree tester of Lemma 29 on f, with respect to proximity parameter ε, individual degree $|H| - 1$ (and soundness error $1/3$). If the low degree test rejects, the verifier immediately rejects. Lastly, the verifier decodes f at point z, using the self-correction procedure of Lemma 30, again with soundness error $1/10$. The procedure outputs a value ν'. The verifier accepts if $\nu = \nu'$ and otherwise it rejects.

Completeness follows from the perfect completeness of the HIP, the low degree test and the local self-correction. For soundness, let $f : \mathbb{F}^m \to \mathbb{F}$ be a function such that f is ε-far from $\mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L})$ and fix a cheating prover strategy $\mathcal{P}^*$. Consider first the case that f is ε-far from an individual degree $|H| - 1$ polynomial. In this case, by the low degree test, with probability at least $2/3$, the verifier rejects and we are done. Thus, we can assume that f is ε-close to some individual degree $|H| - 1$ polynomial $P : \mathbb{F}^m \to \mathbb{F}$. Observe that since f is ε-far from $\mathsf{LDE}_{\mathbb{F},H,m}(\mathcal{L})$ it must be the case that $P|_{H^m} \notin \mathcal{L}$.

We view the HIP as being applied to $P|_{H^m}$. By the soundness of the HIP, when the verifier interacts with any cheating prover (and in particular $\mathcal{P}^*$) with probability $9/10$ it either rejects (in which case we also reject) or it outputs a pair $(z, \nu) \in \mathbb{F}^m \times \mathbb{F}$ such that $P(z) \neq \nu$. The verifier reads the point z with self-correction and so, with probability at least $9/10$ it will obtain the actual value $\nu' = P(z)$ and reject when comparing ν' and ν. Thus, with probability $0.9^2 \geq 2/3$ our verifier rejects.

been obtained by [44] and [15]. However, these partial derandomizations do not seem to suffice for our purposes.

[29] Actually, the cited works provide a test for *total* degree. A test for *individual* degree (which is implicit in [35, Section 5.4.2]) can be obtained via a simple reduction (see, e.g., [43, Theorem A.8]).

[30] Indeed, parallel repetition of IPPs decreases their soundness error at an exponential rate (see [31, Appendix A] for details).

C The Sumcheck Protocol (Proof of Lemma 10)

In this appendix we prove Lemma 10.

We use a variant of the sumcheck protocol that takes r rounds, where for simplicity we assume that r divides m. We maintain the invariant that before the i^{th} rounds begins, both the verifier and the prover agree on values $w_1, \ldots, w_{i-1} \in \mathbb{F}^{m/r}$ and $\nu_{i-1} \in \mathbb{F}$, where $\nu_0 \stackrel{\text{def}}{=} 0$. For every $i \in [r]$, the i^{th} round of the sumcheck protocol is as follows.

1. The prover sends to the verifier the individual degree $|H| - 1$ polynomial $P_i : \mathbb{F}^{m/r} \to \mathbb{F}$ (by specifying its coefficients), defined as:

$$P_i(z) \stackrel{\text{def}}{=} \sum_{x_{i+1},\ldots,x_r \in H^{m/r}} P(w_1, \ldots, w_{i-1}, z, x_{i+1}, \ldots, x_r).$$

2. The verifier receives a polynomial $Q_i : \mathbb{F}^{m/r} \to \mathbb{F}$ (which is allegedly equal to P_i) and checks that $\sum_{z \in H^{m/r}} Q_i(z) = \nu_{i-1}$.
3. The verifier select uniformly at random $w_i \in \mathbb{F}^{m/r}$ and sends w_i to the prover.
4. Set $\nu_i \stackrel{\text{def}}{=} Q_i(w_i)$.

At the end of the protocol, the verifier outputs $((w_1, \ldots, w_r), \nu_r) \in \mathbb{F}^m \times \mathbb{F}$.

The running times and communication complexity of the protocol can be readily verified. We proceed to show that completeness and soundness hold.

C.1 Completeness

Let $P : \mathbb{F}^m \to \mathbb{F}$ be an individual degree $|H| - 1$ polynomial such that $\sum_{x \in H^m} P(x) = 0$. In this case, at every round $i \in [\rho]$, the prover sends the polynomial $Q_i \equiv P_i$. Hence, for every $i \in [r]$:

$$\begin{aligned}
\sum_{z \in H^{m/r}} Q_i(z) &= \sum_{z \in H^{m/r}} P_i(z) \\
&= \sum_{z \in H^{m/r}} \sum_{x_{i+1},\ldots,x_r \in H^{m/r}} P(w_1, \ldots, w_{i-1}, z, x_{i+1}, \ldots, x_r) \\
&= P_{i-1}(w_{i-1}) \\
&= Q_{i-1}(w_{i-1}) \\
&= \nu_{i-1}
\end{aligned}$$

and so all of the verifier's checks pass. At the end of the protocol the verifier outputs $((w_1, \ldots, w_r), \nu_r) \in \mathbb{F}^m \times \mathbb{F}$ and $\nu_r = P_r(w_r) = P(w_1, \ldots, w_r))$ as required.

C.2 Soundness

Let $P : \mathbb{F}^m \to \mathbb{F}$ be an individual degree $|H| - 1$ polynomial such that $\sum_{x \in H^m} P(x) \neq 0$ and fix a cheating prover strategy $\mathcal{P}^*$.

The next two claims relate the polynomials Q_i sent by the prover to the corresponding polynomials P_i (recall that P_i was defined as $P_i(z) = \sum_{x_{i+1},\ldots,x_r \in H^{m/r}} P(w_1, \ldots, w_{i-1}, z, x_{i+1}, \ldots, x_r)$). Recall that both polynomials depend only on $w_1, \ldots, w_{i-1}$.

▶ **Claim 31.** *If $Q_1 \equiv P_1$, then the verifier rejects with probability* 1.

Proof. Observe that $\sum_{x_1 \in H^{m/r}} P_1(x_1) = \sum_{z \in H^m} P(z) \neq 0$, and so, if $Q_1 \equiv P_1$, then the verifier rejects when testing that $\sum_{z \in H^{m/r}} Q_1(z) = \nu_0 = 0$. ◀

▶ **Claim 32.** *For every $i \in [r-1]$ and every $w_1, \ldots, w_{i-1} \in \mathbb{F}^{m/r}$, if $Q_i \not\equiv P_i$ then, with probability $1 - \frac{(m/r)\cdot|H|}{|\mathbb{F}|}$ over the choice of w_i, if $Q_{i+1} \equiv P_{i+1}$ then the verifier rejects.*

Proof. Since the (total degree $(m/r)\cdot(|H|-1)$) polynomials Q_i and P_i differ, by the Shwartz-Zippel lemma (Lemma 5), with probability $1 - \frac{(m/r)\cdot|H|}{|\mathbb{F}|}$ over the choice of $w_i \in_R \mathbb{F}^{m/r}$, it holds that $Q_i(w_i) \neq P_i(w_i)$. If the latter event occurs and the prover sends $Q_{i+1} \equiv P_{i+1}$, then the verifier rejects when testing whether $\sum_{z\in H^{m/r}} Q_{i+1}(z) = \nu_i$, since

$$\nu_i = Q_i(w_i) \neq P_i(w_i) = \sum_{z\in H^{m/r}} P_{i+1}(z) = \sum_{z\in H^{m/r}} Q_{i+1}(z). \qquad \blacktriangleleft$$

By Claims 31 and 32 and an application of the union bound, with probability $1-(r-1)\cdot\frac{(m/r)\cdot|H}{|\mathbb{F}|}$, if there exists an $i \in [r-1]$ such that $Q_i \not\equiv P_i$ but $Q_{i+1} \equiv P_{i+1}$ then the verifier rejects. However, by Claim 31, we can assume that $Q_1 \not\equiv P_1$ and so we get that with probability $1-(r-1)\cdot\frac{(m/r)\cdot|H}{|\mathbb{F}|}$ either the verifier rejects or $Q_r \not\equiv P_r$. Note that if $Q_r \not\equiv P_r$ then by the Shwartz Zippel Lemma with probability $1 - \frac{(m/r)\cdot|H|}{|\mathbb{F}|}$ it holds that $Q_r(w_r) \neq P_r(w_r)$ and therefore:

$$\nu_r = Q_r(w_r) \neq P_r(w_r) = P(w_1, \ldots, w_r)$$

and so the soundness condition holds, with soundness error $(r-1)\cdot\frac{(m/r)\cdot|H}{|\mathbb{F}|} + \frac{(m/r)\cdot|H}{|\mathbb{F}|} = \frac{m\cdot|H}{|\mathbb{F}|}$.

D Interactive Proof for Vanishing-Subcube (Proof of Proposition 14)

Let $\mathbb{F}$ be a constructible field ensemble, let $H \subseteq G \subseteq \mathbb{F}$ be ensembles of subsets, and let $m \in \mathbb{N}$. Recall that $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$ is the set of all functions $f : G^m \to \mathbb{F}$ that vanish on H^m (i.e., $f|_{H^m} \equiv 0$). We show that for every $r \in [m]$, there exists an $r+2$-round (public-coin) HIP for $\mathsf{Vanishing\text{-}Subcube}_{\mathbb{F},H,m,G}$, with respect to the code $\mathsf{LDE}_{\mathbb{F},G,m}$.

Recall that in an HIP with respect to the code $\mathsf{LDE}_{\mathbb{F},G,m}$, the input should be thought of as an m-variate polynomial P with individual degree $|G|-1$. The prover has direct access to P and the verifier needs to output a pair $(z,\nu) \in \mathbb{F}^m \times \mathbb{F}$, with the associated claim that $P(z) = \nu$.

For a given function $P : \mathbb{F}^m \to \mathbb{F}$, we define the polynomial $\tilde{P}(x) = \sum_{z\in H^m} \delta(z,x)\cdot P(z)$, where $\delta : \mathbb{F}^m \times \mathbb{F}^m \to \mathbb{F}$ is an individual degree $|H|-1$ polynomial such that for every $a, b \in H^m$, it holds that $\delta(a,b) = 1$ if $a = b$ and $\delta(a,b) = 0$ otherwise (and δ is arbitrary in $\mathbb{F}^{2m}\setminus H^{2m}$).[31]

To check that P is identically 0 in H^m, the verifier first chooses at random $r \in \mathbb{F}^m$ and sends r to the prover. Now, the prover and verifier run an interactive proof to check that $\tilde{P}(r) = 0$, by invoking the sumcheck protocol with respect to the summation $\sum_{z\in H^m} \delta(z,r)\cdot P(z) = 0$, where we observe that the polynomial $\delta(\cdot,r)\cdot P(\cdot)$ has individual degree $|H|+|G|-1$. If the sumcheck verifier rejects, then we immediately reject. Otherwise, the sumcheck verifier outputs a pair $(z,\nu) \in \mathbb{F}^m \times \mathbb{F}$, and the prover then sends the value $\nu' = P(z)$. Finally, the verifier checks that $\delta(z,r)\cdot\nu' = \nu$ and if so outputs (z,ν').

For completeness, note that if P is identically 0 in H^m, then $\tilde{P}$ is identically 0 in $\mathbb{F}^m$. In particular, with probability 1 over the choice of r it holds that $\tilde{P}(r) = \sum_{z\in H^m} \delta(z,r)\cdot P(h) = 0$. Thus, by the completeness of the sumcheck protocol, the sumcheck verifier outputs a pair

[31] We note that $\tilde{P}$ is in fact the low degree extension of the function P, when the latter is restricted to H^m.

(z, ν) such that $\delta(z, r) \cdot P(z) = 0$. The prover now sends the value $\nu' = P(z)$, and so the verifier's check that $\delta(z, r) \cdot \nu' = \nu$ passes, and it outputs the claim (z, ν'), which is correct since $P(z) = \nu'$.

As for soundness, if P is not identically 0 in H^m, then by definition, $\tilde{P}$ is not identically 0 in $\mathbb{F}^m$, and therefore by the Schwartz-Zippel lemma (see Lemma 5), with probability $1 - \frac{m \cdot (|H|-1)}{|\mathbb{F}|}$ over the choice of r, it holds that $\tilde{P}(r) \neq 0$. Thus, the sumcheck protocol is invoked on the sum $\sum_{z \in H^m} \delta(z, r) \cdot P(z) \neq 0$ and so, with probability $1 - \frac{m \cdot (|H|+|G|-2)}{|\mathbb{F}|}$ either the sumcheck verifier rejects, or it outputs a claim (z, ν) such that $\delta(z, r) \cdot P(z) \neq \nu$. Assuming the latter happens, if the prover now sends $\nu' = P(z)$, then the verifier rejects. Hence, it must send $\nu' \neq P(z)$, and so the verifier outputs the incorrect claim (z, ν').

E Efficiently Computing $\widetilde{\mathsf{MOD3}}_t$

Recall that $\widetilde{\mathsf{MOD3}}_t : \mathbb{K}^t \to \mathbb{K}$ was defined as the (unique) individual degree 2 polynomial such that for every $h \in \{0,1,2\}^t$ it holds that $\widetilde{\mathsf{MOD3}}_t(h) = \sum_{i \in [t]} h_i \pmod 3$. In this section we show that $\widetilde{\mathsf{MOD3}}$ is efficiently computable. Namely, that given a point $z \in \mathbb{K}^t$, one can compute $\widetilde{\mathsf{MOD3}}_t(z)$ in time $\mathsf{poly}(t, \log(|\mathbb{K}|))$.

▶ **Proposition 33.** *Let $\mathbb{K}$ be a constructible field ensemble. There exists a $\mathsf{poly}(t, \log(|\mathbb{K}|))$-time algorithm that given a point $z \in \mathbb{K}^t$ outputs the value $\widetilde{\mathsf{MOD3}}_t(z)$.*

Proof. To prove Proposition 33, we first show that for every $\sigma \in \{0,1,2\}$ and $i \in [t]$, we can construct a size $\mathsf{poly}(i)$ uniform arithmetic circuit over $\mathbb{K}$ that computes the function $F_i^{(\sigma)} : \mathbb{K}^i \to \mathbb{K}$, which is defined as the unique individual degree 2 polynomial such that:

$$\forall h \in \{0,1,2\}^i, \quad F_i^{(\sigma)}(h) = \begin{cases} 1 & \text{if } \sum_{i \in [t]} h_i = \sigma \pmod 3 \\ 0 & \text{otherwise} \end{cases}.$$

where the summation is over integers modulo 3. Despite their similarity, note that $\widetilde{\mathsf{MOD3}}_t$ is the low degree extension of a function that *computes* the sum modulo 3 of its input, whereas $F_t^{(\sigma)}$ is the low degree extension of a function that *indicates* whether the sum modulo 3 is congruent to σ.

Given arithmetic circuits that compute $\mathbb{F}_t^{(\sigma)}$, we can now compute $\widetilde{\mathsf{MOD3}}_t : \mathbb{K}^t \to \mathbb{K}$ as:

$$\widetilde{\mathsf{MOD3}}_t(z) = \sum_{\sigma \in \{0,1,2\}} \sigma \cdot F_i^{(\sigma)}(z), \tag{10}$$

where here the arithmetic is over the field $\mathbb{K}$, and the equality follows from the fact that both sides of the equation are polynomials of individual degree 2 that agree on $\{0,1,2\}^t$ and therefore must agree on $\mathbb{K}^t$. Thus, it remains to prove the following claim.

▶ **Claim 34.** *For every $\sigma \in \{0,1,2\}$ and $i \in \mathbb{N}$, there exists an arithmetic circuit of size $O\left(i^{\log_2(6)}\right)$ over $\mathbb{K}$ that computes $F_i^{(\sigma)}$.*

Proof. We prove the proposition for i's that are powers of two and note that the general case follows easily (e.g., by using a circuit of size that is the nearest power of two and fixing some of its inputs to 0).

The proof is by induction on i, where the base case $i = 1$, is trivial. Fix i (that is a power of two) and suppose that we have constructed arithmetic circuits for computing $F_i^{(\sigma)}$ for every $\sigma \in \{0,1,2\}$.

Fix $\tau \in \{0,1,2\}$. The main observation is that for every $z_1, z_2 \in \mathbb{K}^i$ it holds that

$$F_{2i}^{(\tau)}(z_1, z_2) = \sum_{\sigma \in \{0,1,2\}} F_i^{(\sigma)}(z_1) \cdot F_i^{(\tau - \sigma \bmod 3)}(z_2), \tag{11}$$

where the equality follows from the fact that that both sides of the equation are polynomials of individual degree 2 that agree on $\{0,1,2\}^i$ and therefore must agree on $\mathbb{K}^{2i}$.

Denoting by S_i the size of the arithmetic circuit that Equation (11) yields for $F_i^{(\sigma)}$, it holds that:

$$S_{2i} = 6 \cdot S_i + c = \cdots = 6^{\log(2i)} \cdot S_1 + c \cdot \sum_{j=0}^{i-1} 6^j = O\left((2i)^{\log_2(6)}\right),$$

where $c \leq 10$ is the constant overhead that arises from Equation (11). This concludes the proof of Claim 34. ◀

Proposition 33 now follows by combining Equation (10) and Claim 34. ◀

Cube vs. Cube Low Degree Test

Abstract

We revisit the Raz-Safra plane-vs.-plane test and study the closely related cube vs. cube test. In this test the tester has access to a "cubes table" which assigns to every cube a low degree polynomial. The tester randomly selects two cubes (affine sub-spaces of dimension 3) that intersect on a point $x \in \mathbb{F}^m$, and checks that the assignments to the cubes agree with each other on the point x. Our main result is a new combinatorial proof for a low degree test that comes closer to the soundness limit, as it works for all $\epsilon \geq \text{poly}(d)/|\mathbb{F}|^{1/2}$, where d is the degree. This should be compared to the previously best soundness value of $\epsilon \geq \text{poly}(m,d)/|\mathbb{F}|^{1/8}$. Our soundness limit improves upon the dependence on the field size and does not depend on the dimension of the ambient space.

Our proof is combinatorial and direct: unlike the Raz-Safra proof, it proceeds in one shot and does not require induction on the dimension of the ambient space. The ideas in our proof come from works on direct product testing which are even simpler in the current setting thanks to the low degree.

Along the way we also prove a somewhat surprising fact about connection between different agreement tests: it does not matter if the tester chooses the cubes to intersect on points or on lines: for every given table, its success probability in either test is nearly the same.

1 Introduction

Low degree tests are local tests for the property of being a low degree function. These were the first property testing results that were discovered, and are an important component in PCP constructions. Such tests were studied in the 1990's and their ballpark soundness behavior was more or less understood. In this work we revisit these tests and give a new and arguably simpler analysis for the cube vs. cube low degree test. Our proof method allows us to get a soundness guarantee that is much closer to the conjectured optimal value. Discovering the precise point in which soundness starts to hold is an intriguing open question that captures an interesting aspect of local-testing in the small soundness regime.

Let us begin with a short introduction to low degree tests. A low degree test can be described as a game between a prover and a verifier, in which the prover wants to convince the verifier that a function $f : \mathbb{F}^m \to \mathbb{F}$ is a low degree polynomial. The most straightforward

way for the prover to specify f would be to give its value on each point $x \in \mathbb{F}^m$. However, in this way, to check that f has degree at most d the verifier would have to read f on at least $d+2$ points. If we want a verifier that makes fewer queries while keeping the error small, it is useful to move to a more redundant representation of f. For example, the verifier can ask the prover to specify for every cube (affine subspace of dimension 3) $C \subset \mathbb{F}^m$, a function $f_C : C \to \mathbb{F}$ that is defined on the cube and is obtained by restricting f to that cube. This is called a "cubes-table", and similarly one can consider a lines table (with an entry for every line), or a planes table (with an entry for each plane).

Thus, in the cubes representation of a low degree function $f : \mathbb{F}^m \to \mathbb{F}$, we have a table entry $T(C)$ for every cube C and the value of that entry is supposed to be $T(C) = f|_C$. A general cubes table is a table $T(\cdot)$ indexed by all possible cubes and the C-th entry is a low degree function on the cube C. Each $T(C)$ is viewed as a local function. Indeed the number of bits needed to specify $T(C)$ is only $O(d^3 \log |\mathbb{F}|)$ which is much smaller than $\binom{m+d}{d} \log |\mathbb{F}|$ - the number of bits needed to represent a general degree d function f on $\mathbb{F}^m$.

The prover may cheat, as provers do, by giving a cubes table whose entries cannot be "glued together" into any one global low degree function. This is where the *agreement* test comes in. The verifier can check the table by reading two entries corresponding to two cubes that have a non-trivial intersection, and checking that the function $T(C_1)$ and the function $T(C_2)$ agree on points in the intersection of $C_1 \cap C_2$.

Test 1 Cube vs. Cube agreement test.

1. Select a point $x \in \mathbb{F}^m$.
2. Pick affine cubes C_1, C_2 randomly conditioned on $C_1, C_2 \ni x$.
3. Read $T(C_1), T(C_2)$ from the table and accept iff $T(C_1)(x) = T(C_2)(x)$.

Let $\alpha_{\mathcal{C}x\mathcal{C}}(T)$ be the *agreement* of the table T, i.e. the probability of acceptance of the test.

The test is local in that it accesses only two cubes. Different tests may differ in the distribution underlying the agreement test (for example, Raz and Safra look at two planes that intersect in a line, which clearly is a different distribution from choosing two planes that intersect in a point), but they all check agreement on the intersection, so we generally refer to all of these as agreement tests.

The interesting point, as proven by both Raz and Safra in [11], and by Arora and Sudan in [1], is that such tests have small soundness error. For example, the plane vs. plane theorem of Raz Safra is as follows,

▶ **Theorem 1** (Raz-Safra [11]). *There is some $\delta > 0$ such that for every d and prime power q and every $m \geq 3$ the following holds. Let $\mathbb{F}$ be a finite field $|\mathbb{F}| = q$, and let $T(\cdot)$ be a planes table, assigning to each plane $P \subset \mathbb{F}^m$ a bivariate degree d polynomial $T(P) : P \to \mathbb{F}$. Let $\alpha_{\mathcal{P}\ell\mathcal{P}}(T)$ be as defined in Test 2.*

For every $\epsilon \geq (md/q)^\delta$, if $\alpha_{P\ell P}(T) \geq \epsilon$ then there is a degree d function $g : \mathbb{F}^m \to \mathbb{F}$ such that $T(P) = g|_P$ on an $\Omega(\epsilon)$ fraction of the planes.

A similar theorem was proven by Arora and Sudan for T a lines table and for a natural test that checks if two intersecting lines agree on the point of intersection.

These results are called low degree tests although it makes sense to think of them as theorems relating local agreement to global agreement. We refer to them as low degree *agreement* test theorems.

Test 2 The Raz-Safra Plane vs. Plane agreement test.

1. Select an affine line $\ell \subset \mathbb{F}^m$.
2. Choose affine planes P_1, P_2 randomly conditioned on $P_1, P_2 \supset \ell$.
3. Read $T(P_1), T(P_2)$ from the table and accept iff $T(P_1)(x) = T(P_2)(x)$ for all $x \in \ell$.

Let $\alpha_{\mathcal{P}\ell\mathcal{P}}(T)$ be the *agreement* of the table T, i.e. the probability of acceptance of the test.

1.1 Towards the soundness threshold

The most important aspect of the low degree agreement theorems of [11, 1] is the fact that they have small soundness. Small soundness means that a cheating prover won't be able to fool the verifier into accepting with even a tiny $\epsilon > 0$ probability, unless the table has some non-trivial agreement with a global low degree function. Small soundness of low degree tests was used inside PCP constructions for getting PCPs with the smallest known soundness error. The fact that soundness holds for all values of $\epsilon \geq (d/q)^\delta$ was sufficient for the PCP constructions of [11, 1]. It is likely that finding the minimal threshold beyond which soundness is guaranteed to hold will be important for determining the best possible PCP gaps.

Regardless of the PCP application, this encoding of a function f by its restrictions to cubes (or to planes) is quite natural, and is a rare example of a property that has such strong testability. The low degree agreement test theorems guarantee that even the passing of the test with tiny ϵ probability has non-trivial structural consequences. Perhaps the best known comparable scenario is that of the long code, defined in [2], that has similar properties, and for which an extensive line of work has been able to determine the precise threshold of soundness. Another setting with a similarly strong soundness is related to the inverse theorems for the Gowers uniformity norms. In that setting the function is given as a points-table, and the Gowers norm measures success in a low degree test, so it is not altogether dissimilar from the situation here.

To summarize, one of our goals is to pinpoint the absolute minimal soundness value for which a theorem as above holds. Can this threshold be, as it is in the aforementioned cases, as small as the value of a random assignment? In other words, could it be true that for every table whose agreement parameter is an additive $\epsilon > 0$ above the value that we expect from a random table, already some structure exists?

The best known value for δ for the plane vs. plane test is due to Moshkovitz and Raz who proved in [10] that the plane vs. plane test has soundness for all $\epsilon \geq \text{poly}(d)/q^{1/8}$. But what is the correct exponent of q ?

We make progress on this question not for the plane vs. plane test but rather for the cube vs. cube test. For our test, since the intersection consists of one point, the soundness can not go below $1/q$ because the agreement of *every* table, even a random one, is always at least $1/q$.

Our main theorem is,

▶ **Theorem 2.** *There exist constants $\beta_1, \beta_2 > 0$ such that for every d, large enough prime power q and every $m \geq 3$ the following holds:*

Let $\mathbb{F}$ be a finite field, $|\mathbb{F}| = q$. Let T be a cubes table, assigning to each cube $C \subset \mathbb{F}^m$ a degree d polynomial $T(C) : C \to \mathbb{F}$. Let $\alpha_{\mathcal{C}x\mathcal{C}}(T)$ be as defined in Test 1. If $\alpha_{\mathcal{C}x\mathcal{C}}(T) \geq \epsilon$ for $\epsilon \geq \beta_1 d^4/q^{1/2}$, then there is a degree d function $g : \mathbb{F}^m \to \mathbb{F}$ such that $T(C) = g|_C$ on an $\beta_2\epsilon$ fraction of the cubes.

The improvement over previous theorems is that the dependence on q is $1/q^{1/2}$ compared to $1/q^{1/8}$. It is an intriguing question whether the dependence on q can be made inversely linear, i.e. $1/q$.

▶ Remark. We don't know the precise dependence of ϵ on the degree d. In this work we made no attempt to optimize this dependence. We would like to point out that our proof can be modified to change the dependence from d^4 to d^3. See Remark 3.3 for more details.

1.2 Simplified analysis

While the line vs. line test considered by Arora and Sudan [1] is the most natural to come up with, it is rather difficult to analyze. In contrast, one of the captivating aspects of the Raz-Safra proof is that it is combinatorial, and the low degree aspect of the table plays a role only in that it guarantees distance between distinct polynomials on a line. Our analysis continues this combinatorial approach, and further simplifies it. Unlike the Raz-Safra proof, we do not need to use induction on the dimension of the ambient space m but rather recover the global structure from T "in one shot". We rely on ideas from direct product testing, [5, 9, 7], and on some spectral properties of incidence graphs such as the cube-point graph.

1.3 Proof Outline

Given a table T, whose agreement is some small ϵ, the proof must somehow come up with the global low degree function $g : \mathbb{F}^m \to \mathbb{F}$ and then argue that on many of the cubes indeed $T(C) = g|_C$. Naively, we might try to define g at each point x according to the most common value among all cubes containing x. This is a viable approach when the agreement is close to 1, as is done, e.g. in the linearity testing theorem of [3]. However, when the agreement is a small $\epsilon > 0$, this will simply not work as we can see by considering the table half of whose entries are $T(C) \equiv 0$ and the other half $T(C) \equiv 1$. The agreement of this table is an impressive $\alpha_{\mathcal{C}x\mathcal{C}}(T) = 1/2$, and yet the suggested definition of g according to majority will yield a random function that might be quite far from any low degree function.

We get around this problem by taking a *conditional majority*. For every point $x \in \mathbb{F}^m$ and value $\sigma \in \mathbb{F}$ we consider only cubes containing x for which $T(C)(x) = \sigma$. These cubes already agree with each other on x and are thus likely to agree on any other point of their intersection. Since the cubes containing x cover every $y \in \mathbb{F}^m$, we can define a function $f_{x,\sigma} : \mathbb{F}^m \to \mathbb{F}$ on the entire space $\mathbb{F}^m$ by taking the most popular value among these cubes (i.e. the set of cubes whose value on x is σ). We choose a best σ for each x and are left with a global function f_x for each x.

The proof proceeds in three steps.

- Local structure: We show that this conditional majority definition is good, obtaining for each x and σ a function $f_x : \mathbb{F}^m \to \mathbb{F}$ that is "local" in that it comes from the cubes containing a point x. This is done in Section 3.1.
- Global Structure: We then show that there are many pairs x, y for which $f_x \approx f_y$ thus finding a global g that agrees with many of the cubes. This is done in Section 3.2.
- Low Degree: Finally, we show that g is very close to a true low degree function. This is done by reduction to the Rubinfeld-Sudan low degree test [12] that works in the high-soundness regime. This is done in Section 3.3.

1.4 Agreement tests: low degree tests and direct product tests

The proof outline above resembles works on direct product testing, and this is no coincidence. The low degree testing setting can be generalized to a more abstract "agreement testing"

in which a function $f : X \to \Sigma$ is represented not as a truth table but as a collection of restrictions $(f|_S)_{S\in\mathcal{S}}$ where $\mathcal{S} = \{S \subset X\}$ is a collection of subsets of X. A natural agreement test can be defined and studied. This type of question was first suggested in work of Goldreich and Safra [8] in an attempt to separate the algebraic aspect of the low degree test from the combinatorial. There has been a follow-up line of work on this, [6, 5, 9, 7], focusing especially on the case where X is a finite set, $X = [n]$, and $\mathcal{S}$ is the collection of all k-element subsets of X.

In the work here we bring some of the ideas from that line of work, most notably from [9], back to the low degree testing question. The fact that our table entries have low degree gives us extra power which makes our proof simpler than that in the abstract setting, yielding a particularly direct proof of a low degree agreement test.

Our proof makes an explicit use of the expansion properties of the relevant incidence graphs (cube vs. line, cube vs. point etc.). This allows us to prove that for every table T, different tests have similar agreement.

▶ **Lemma 3.** *Let T be a planes table, and let $\alpha_{\mathcal{P}x\mathcal{P}}(T)$ be the success probability of a test with two planes that intersects on a point. Let $\alpha_{\mathcal{P}\ell\mathcal{P}}(T)$ be the success probability of Test 2, then*

$$\alpha_{\mathcal{P}x\mathcal{P}}(T)\left(1-\frac{d}{q}\right) \leq \alpha_{\mathcal{P}\ell\mathcal{P}}(T) \leq \alpha_{\mathcal{P}x\mathcal{P}}(T) + \frac{1}{q}(1+o(1)).$$

In fact, we proved a more general equivalence between tests, the general statement appears on Section 4.

2 Preliminaries and Notations

2.1 Notations

All the graphs we discuss throughout the paper are bipartite bi-regular graphs. Given such graph G, whose sides are A, B we denote by $\mathbf{1}$ the all one vector, its size will be implied by the context. For a subset of vertices $A' \subset A$, we denote by $\mathbf{1}_{A'}$ the indicator vector for A'. For a vertex $a \in A$, we denote by $N(a) \subseteq B$ the neighbors of a in G.

We use normalized inner product, such that for $x, y \in \mathbb{R}^n$, $\langle x, y\rangle = \frac{1}{n}\sum_i x_i y_i$, which means that $\langle \mathbf{1}, \mathbf{1}\rangle = 1$. The norm is defined by $\|x\| = \sqrt{\langle x, x\rangle}$.

We use the notation $x \sim S$ to denote x being sampled uniformly at random (u.a.r) from the set S, in case this set S equals the entire space, we omit this symbol and simply write $\mathbf{Pr}_a$ or $\mathbf{E}_a$ to describe choosing a uniform vertex $a \in A$. We use the notation $\mathbb{I}(E)$ to denote the indicator random variable of the event E.

For two vectors u, v, we use the notation $u \overset{\gamma}{\approx} v$ if u and v are equal on at least $1-\gamma$ of the coordinates.

Fix a vector space $\mathbb{F}^m$. An affine space of S dimension k is defined by $k+1$ vectors $x_0, x_1, \ldots, x_k$ such that $x_1, \ldots, x_k$ are linearly independent,

$$S = x_0 + \mathtt{span}(x_1, \ldots, x_k) = \{x_0 + t_1 x_1 + \ldots t_k x_k \mid t_1, \ldots, t_k \in \mathbb{F}.\}$$

A *line* is a 1-dimensional affine space, a *plane* is a 2-dimensional affine space, and a *cube* is a 3-dimensional affine space. We will denote the set of all lines and cubes by $\mathcal{L}$ and $\mathcal{C}$ be respectively. For a point $x \in \mathbb{F}^m$ let

$$\mathcal{L}_x = \{\ell \in \mathcal{L} \mid \ell \ni x\} \qquad \mathcal{C}_x = \{C \in \mathcal{C} \mid C \ni x\}.$$

Similarly for a line $\ell \in \mathcal{L}$ let $\mathcal{C}_\ell$ be the set of all cubes that contains ℓ.

2.2 Spectral Expansion Properties

In this section, we prove two properties of bi-regular bipartite graphs with good spectral parameters. In an expander, the following is well known: if we sample a random neighbor of a small, but not too small, set of vertices, we get a nearly uniform distribution over the entire set of vertices. For our purposes, we will require something more. We need to consider not only the distribution over the vertices, but also the distribution over the edges. This is done in two lemmas below.

▶ **Definition 4.** Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, and let $M \in \mathbb{R}^{A \times B}$ be the adjacency matrix normalized such that $\|M\mathbf{1}\| = 1$, denote by $\lambda(G)$ the value

$$\lambda(G) = \max_{v \perp \mathbf{1}} \left\{ \frac{\|Mv\|}{\|v\|} \right\}.$$

This is really the second largest singular value of M, with a different normalization (such that the maximal singular value equals 1).

▶ **Definition 5.** Let $G = (A \cup B, E)$ be a bi-regular bipartite graph and let $B' \subseteq B$ be a subset of vertices. Define the following two distributions $D_i : A \times B \cup \perp \to [0, 1]$ for $i = 1, 2$.

- D_1 : Pick $b \in B'$ u.a.r. then pick $a \in N(b)$ u.a.r.
- D_2 : Pick $a \in A$ u.a.r. If $B' \cap N(a) = \emptyset$, return $\perp$. Else, pick $b \in N(a) \cap B'$ u.a.r.

Clearly if $B' = B$ then $D_1 = D_2$. Moreover, if G is sufficiently expanding, then even for smaller $B' \subsetneq B$, the distributions are similar. Indeed, for any event defined on the edges, i.e. a subset $E' \subset E$, the following lemma shows that the probability of E' is roughly the same under the two distributions.

▶ **Lemma 6.** *Let D_1, D_2 as defined in Definition 5. Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, then for every subset $B' \subset B$ of measure $\mu > 0$ and every $E' \subset E$*

$$\left| \Pr_{(a,b)\sim D_1}[(a, b) \in E'] - \Pr_{(a,b)\sim D_2}[(a, b) \in E'] \right| \leq \frac{\lambda(G)}{\sqrt{\mu}}.$$

Where it is understood that if D_2 output $\perp$, we treat it as if $(a, b) \notin E'$.

We now state a similar lemma, for sampling two adjacent edges instead of a single edge. We will need the graph to satisfy one more requirement.

▶ **Definition 7.** Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, such that every two distinct $b_1, b_2 \in B$ have exactly the same number of common neighbors (i.e for all distinct $b_1, b_2 \in B$, $|N(b_1) \cap N(b_2)|$ is the same), and this number is non-zero. Let $B' \subseteq B$ be a subset of vertices, we define the following distributions $D_i : (A \times B \times B) \cup \perp \to [0, 1]$, for $i = 3, 4$.

- D_3 : Pick $b_1, b_2 \in B'$ u.a.r. then pick $a \in N(b_1) \cap N(b_2)$ u.a.r.
- D_4 : Pick $a \in A$ u.a.r. If $B' \cap N(a) = \emptyset$, return $\perp$. Else, pick $b_1, b_2 \in N(a) \cap B'$ u.a.r.

▶ **Lemma 8.** *Let D_3, D_4 be as defined in Definition 7. Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, such that every two distinct $b_1, b_2 \in B$ have exactly the same number of common neighbors (i.e for all distinct $b_1, b_2 \in B$, $|N(b_1) \cap N(b_2)|$ is the same), and this number is non-zero. Then for every subset $B' \subset B$ of measure $\mu > 0$ and every $E' \subset E$*

$$\left| \Pr_{a,b_1,b_2\sim D_3}[(a, b_1)(a, b_2) \in E'] - \Pr_{a,b_1,b_2\sim D_4}[(a, b_1)(a, b_2) \in E'] \right| \leq \frac{2\lambda(G)}{\mu} + \frac{1}{\mu^2 d_A} + \frac{1}{\mu^2 |B|},$$

where d_A is the degree on A side, and it is understood that if D_4 output $\perp$, we treat it as if $(a, b) \notin E'$.

The proofs of these two lemmas appear in Appendix B.

2.3 Inclusion Graphs and Their Spectral Gap

We record here the expansion of several bi-partite *inclusion graphs* that will be relevant for our analysis. We prove the claims about these spectral gaps in Appendix A. Unless otherwise stated, $G(A, B)$ denotes a bipartite inclusion graph between A and B where $a \in A$ is connected to $b \in B$ if $a \subseteq b$. The relation of containment will be clear from the sets A and B.

For example, the in the graph $G_1(\mathcal{L} \setminus \mathcal{L}_x, \mathcal{C}_x)$, the left side vertices A are all the lines that do not contain $x \in \mathbb{F}^m$, and the right side vertices are all the cubes that contain x. There is an edge between a line ℓ and a cube C if $\ell \subset C$.

Recall Definition 4 of $\lambda(G)$ for a bipartite graph G.

▶ **Lemma 9.** *We have for every $m \geq 6$,*
(1) *For $G_1(\mathcal{L} \setminus \mathcal{L}_x, \mathcal{C}_x)$, $\lambda(G_1) \approx \frac{1}{\sqrt{q}}$.*
(2) *For $G_2(\mathcal{L}_x, \mathcal{C}_x))$, $\lambda(G_2) \approx \frac{1}{q}$.*
(3) *For $G_3(\mathbb{F}^m \setminus \ell, \mathcal{C}_\ell)$, $\lambda(G_3) \approx \frac{1}{\sqrt{q}}$.*
(4) *For $G_4(\mathbb{F}^m, \mathcal{C})$, $\lambda(G_4) \approx \frac{1}{q^{3/2}}$.*
(5) *For $G_5(\mathbb{F}^m \setminus \{x\}, \mathcal{C}_x)$, $\lambda(G_5) \approx \frac{1}{q}$.*
And for every $m \geq 3$
(6) *For $G_6(\mathbb{F}^m, \mathcal{L})$, $\lambda(G_6) \approx \frac{1}{\sqrt{q}}$.*
where $\approx$ denotes equality up to a multiplicative factor of $1 \pm o(1)$, and $o(1)$ denotes a function that approaches zero as $q \to \infty$.

In general one can see that $\lambda \approx \frac{1}{\sqrt{q^p}}$ where p is the number of degrees of freedom left after choosing a left hand vertex. We prove this lemma in Appendix A.

3 Proof of the Main Theorem

In this section we prove Theorem 2 in three steps - local structure, global structure and finally proving the agreement with a low degree polynomial. These parts are proved in the subsequent subsections.

Let T be a degree d cubes table, i.e. for every $C \in \mathcal{C}$, $T(C) : C \to \mathbb{F}$ is a degree d polynomial. Further assume that $\alpha_{\mathcal{C}x\mathcal{C}}(T) \geq \epsilon$, where $\epsilon = \Omega(d^4/\sqrt{q})$.

3.1 Local Structure

In this section we show that for many points $x \in \mathbb{F}^m$, there exists a function $f_x : \mathbb{F}^m \to \mathbb{F}$ for which $f_x|_C \overset{2\gamma}{\approx} T(C)$ for a good fraction of the cubes containing x, for $\gamma = \Omega(1/d^3)$. Recall that $\overset{2\gamma}{\approx}$ means that the two functions agree on $1 - 2\gamma$ fraction of the points in their domain.

For each $x \in \mathbb{F}^m$ and $\sigma \in \mathbb{F}$, we define

$$\mathcal{C}_{x,\sigma} = \{C \in \mathcal{C}_x | T(C)(x) = \sigma\}.$$

Following [9] we have the following important definition,

▶ **Definition 10** (Excellent pair)**.** (x, σ) is $(\frac{\epsilon}{2}, \gamma)$-excellent if:

1. $\mathbf{Pr}_{C \in \mathcal{C}_x}[C \in \mathcal{C}_{x,\sigma}] \geq \frac{\epsilon}{2}$.

2. Let C_1, ℓ, C_2 be chosen by the following probability distribution, $C_1 \in \mathcal{C}_{x,\sigma}$ u.a.r, $\ell \subset C_1$ a random line that contains x and $C_2 \in \mathcal{C}_{x,\sigma} \cap \mathcal{C}_\ell$ (a random cube in $\mathcal{C}_{x,\sigma}$ that contains ℓ).

$$\mathop{\mathbf{Pr}}_{C_1,\ell,C_2}[T(C_1)_{|\ell} \neq T(C_2)_{|\ell}] \leq \gamma.$$

A point $x \in \mathbb{F}^m$ is $(\frac{\epsilon}{2}, \gamma)$-excellent, if exists $\sigma \in \mathbb{F}$ such that (x, σ) is $(\frac{\epsilon}{2}, \gamma)$-excellent.

Note that in the definition of excellent, the marginal distribution of both C_1, C_2 is uniform in $\mathcal{C}_{x,\sigma}$.

In the sequel, we fix $\gamma = \Omega(1/d^3)$ and say that a point is excellent if it is $(\frac{\epsilon}{2}, \gamma)$-excellent. We now state the main lemma in this section.

▶ **Lemma 11** (Local Structure). *For $\gamma = \Omega(\frac{1}{d^3})$, let T be a cubes table that passes Test 1 with probability larger than $\epsilon = \Omega(\frac{d^4}{\sqrt{q}})$, then at least $\frac{\epsilon}{3}$ of the points $x \in \mathbb{F}^m$ are excellent, and for each excellent x there exist a function $f_x : \mathbb{F}^m \to \mathbb{F}$ such that*

$$\mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_x}[T(C) \overset{2\gamma}{\approx} f_{x|_C}] \geq \frac{\epsilon}{4}.$$

We will consider the distribution $\mathcal{D}$ on (x, ℓ, C_1, C_2) obtained by choosing x uniformly, choosing $\ell \in \mathcal{L}_x$ uniformly, and then choosing $C_1, C_2 \in \mathcal{C}_\ell$ uniformly.

This distribution induces a distribution $(x, T(C_1)(x))$ on pairs of point x and value $\sigma \in \mathbb{F}$.

▶ **Claim 12.** *For every $\gamma = \Omega(\frac{1}{d^3})$,*

$$\mathop{\mathbf{Pr}}_{(x,\sigma)}[(x, \sigma) \textit{ is } (\tfrac{\epsilon}{2}, \gamma) \textit{ - excellent}] \geq \frac{\epsilon}{3}.$$

Proof. We consider (x, ℓ, C_1, C_2) chosen according to $\mathcal{D}$, and we note that the marginal distribution over all elements is uniform. We also write $\sigma = T(C_1)(x)$. We define the following events on (x, ℓ, C_1, C_2):

1. E : "ℓ is confusing for x": $T(C_1)(x) = T(C_2)(x)$, $T(C_1)_{|\ell} \neq T(C_2)_{|\ell}$.
2. H : "x, C_1 is heavy": $\mathbf{Pr}_{C \sim \mathcal{C}_x}[T(C)(x) = T(C_1)(x)] \geq \frac{\epsilon}{2}$

Since $T(C_1)_{|\ell}, T(C_2)_{|\ell}$ are two degree d polynomials, and x is a random point in ℓ,

$$\mathop{\mathbf{Pr}}_{(x,\ell,C_1,C_2)}[E] \leq \frac{d}{q}.$$

Using the fact that $\alpha_{\mathcal{C}x\mathcal{C}}(T) \geq \epsilon$, and averaging, we get

$$\mathop{\mathbf{Pr}}_{(x,\ell,C_1,C_2)}[H] \geq \frac{\epsilon}{2}. \tag{1}$$

Instead of picking C_1 as a uniform cube containing x, we can choose it by the following process, pick σ proportional to its weight in $\mathcal{C}_x$, then pick $C_1 \sim \mathcal{C}_{x,\sigma}$. This process describes the same distribution.

Note that after deciding x, σ, the event H is already determined, so (1) becomes $\mathbf{Pr}_{x,\sigma}[H] \geq \epsilon/2$. Also, notice that conditioned on x, σ, the distribution $\mathcal{D}$ is choosing C_1 uniformly from $\mathcal{C}_{x,\sigma}$ and then $\ell \subset C_1$ a random line containing x and then C_2 a random cube containing ℓ (and we do not require that $T(C_2)(x) = \sigma$). The event H is already fixed by x, σ, but the event E will occur only if $C_2 \in \mathcal{C}_{x,\sigma}$ and also $T(C_1)|_\ell \neq T(C_2)|_\ell$.

We want to bound the probability of x, σ such that $H = 1$, but $\mathbf{E}_{C_1,\ell,C_2}[E|x,\sigma] \leq \gamma \cdot \frac{\epsilon}{2}$. We know that

$$\mathop{\mathbf{E}}_{x,\sigma}[\mathbf{Pr}[H \wedge E \mid x,\sigma]] = \mathbf{Pr}[H \wedge E] \leq \mathbf{Pr}[E] \leq \frac{d}{q}.$$

Therefore, by averaging, the probability over x, σ that we have $\mathbf{Pr}[H \wedge E|x,\sigma] > \epsilon\gamma/2$ is at most $\frac{d/q}{\epsilon\gamma/2}$. So for at least $\epsilon/2 - \frac{d/q}{\epsilon\gamma/2} \geq \epsilon/3$ of the pairs x, σ, we have that both H occurs, and that $\mathbf{E}_{C_1,\ell,C_2}[E|x,\sigma] \leq \epsilon\gamma/2$.

We end by showing that such x, σ are excellent. The first requirement follows by the fact that H occurs, for the second we need to show that for $C_1 \in \mathcal{C}_{x,\sigma}$, a uniform $\ell \in \mathcal{C}_1$ and a uniform $C_2 \in \mathcal{C}_{x,\sigma} \cap C_\ell$ the probability of $T(C_1)_{|\ell} \neq T(C_2)_{|\ell}$ is lower than γ.

We notice that after fixing (x, σ), the distribution $\mathcal{D}$ chooses $C_1 \in \mathcal{C}_{x,\sigma}$, a uniform $\ell \in \mathcal{C}_1$, but then a uniform $C_2 \in \mathcal{C}_\ell$.

The event E can be written as $E = E_1 \wedge E_2$ where E_1 is the event "$T(C_1)(x) = T(C_2)(x)$" and E_2 is the event "$T(C_1)_{|\ell} \neq T(C_2)_{|\ell}$". In this notation

$$\begin{aligned}
\mathop{\mathbf{E}}_{C_1,\ell,C_2}[E|x,\sigma] &= \mathop{\mathbf{E}}_{C_1,\ell,C_2}[E_1 \wedge E_2|x,\sigma] \\
&= \mathop{\mathbf{E}}_{C_1,\ell,C_2}[E_1|x,\sigma] \mathop{\mathbf{E}}_{C_1,\ell,C_2}[E_2|E_1,x,\sigma] \\
&\geq \frac{\epsilon}{2} \cdot \mathop{\mathbf{E}}_{C_1,\ell,C_2}[E_2|E_1,x,\sigma]. && \text{(since } H \text{ occurs)}
\end{aligned}$$

We notice that if E_1 occurs, then $C_2 \in \mathcal{C}_{x,\sigma}$, therefore

$$\mathop{\mathbf{E}}_{C_1,\ell,C_2}[T(C_1)_{|\ell} \neq T(C_2)_{|\ell}|C_2 \in \mathcal{C}_{x,\sigma},x,\sigma] \leq \frac{2}{\epsilon} \cdot \mathop{\mathbf{E}}_{C_1,\ell,C_2}[E|x,\sigma] \leq \frac{2}{\epsilon}\frac{\epsilon}{2}\gamma \leq \gamma,$$

which means that (x, σ) is $(\frac{\epsilon}{2}, \gamma)$ - excellent. ◀

For each (x, σ) we define $f_{x,\sigma}$ by plurality over all cubes $C \in \mathcal{C}_{x,\sigma}$.

▶ **Definition 13.** For a pair (x, σ) define a function $f_{x,\sigma} : \mathbb{F}^m \to \mathbb{F}$ as follows:

$$f_{x,\sigma}(y) = \mathop{\texttt{argmax}}_{C \sim \mathcal{C}_y \cap \mathcal{C}_{x,\sigma}} \{T(C)(y)\}.$$

If $\mathcal{C}_y \cap \mathcal{C}_{x,\sigma} = \emptyset$, define $f_{x,\sigma}(y)$ arbitrarily.

▶ **Claim 14.** *For an $(\frac{\epsilon}{2}, \gamma)$ excellent pair (x, σ),*

$$\mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_{x,\sigma}, y \sim C}[f_{x,\sigma}(y) = T(C)(y)] \geq 1 - \gamma.$$

Proof. Fix an $(\frac{\epsilon}{2}, \gamma)$ excellent pair (x, σ), and denote $f = f_{x,\sigma}$. If we pick a uniform $C_1 \in \mathcal{C}_{x,\sigma}$, then $y \in C_1$ such that $y \neq x$, and a uniform $C_2 \in \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y$, then

$$\mathop{\mathbf{Pr}}_{C_1,y,C_2}[T(C_1)(y) \neq T(C_2)(y)] \leq \mathop{\mathbf{Pr}}_{C_1,y,C_2}[T(C_1)_{|\ell(x,y)} \neq T(C_2)_{|\ell(x,y)}] \leq \gamma,$$

since (x, σ) is $(\frac{\epsilon}{2}, \gamma)$ excellent.

For each y, denote $\gamma_y = \mathbf{Pr}_{C_1,C_2 \sim \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y}[T(C_1)(y) \neq T(C_2)(y)]$. From the above we get that $\mathbb{E}_y[\gamma_y] \leq \gamma$, where y is distributed according to it's weight in $\mathcal{C}_{x,\sigma}$. For each y,

$$\begin{aligned}
1 - \gamma_y &= \sum_{\theta \in \mathbb{F}} \mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y}[T(C)(y) = \theta]^2 \\
&\leq \mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y}[T(C)(y) = f(y)] \sum_{\theta \in \mathbb{F}} \mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y}[T(C)(y) = \theta] \\
& && (f(y) \text{ is the most frequent value}) \\
&\leq \mathop{\mathbf{Pr}}_{C \sim \mathcal{C}_{x,\sigma} \cap \mathcal{C}_y}[T(C)(y) = f(y)].
\end{aligned}$$

Since it is true for each y, it is also true when taking expectation over y, for any distribution:

$$\mathop{\mathbf{Pr}}_{C\sim\mathcal{C}_{x,\sigma},y\sim C}[f(y)=T(C)(y)]=\mathop{\mathbf{E}}_{y}\left[\mathop{\mathbf{E}}_{C\sim\mathcal{C}_{x,\sigma}\cap\mathcal{C}_y}[\mathbb{I}(T(C)(y)=f(y))]\right]\geq\mathop{\mathbf{E}}_{y}[1-\gamma_y]\geq 1-\gamma.$$

In expectation, each y is chosen with probability proportional to it's weight in $\mathcal{C}_{x,\sigma}$, as before. ◀

Proof of Lemma 11. From Claim 12 we know that the probability of (x,σ) to be $(\frac{\epsilon}{2},\gamma)$-excellent is at least $\frac{\epsilon}{3}$. Since x is chosen uniformly, it means that for at least $\frac{\epsilon}{3}$ of the inputs $x\in\mathbb{F}^m$ there exists some $\sigma\in\mathbb{F}$ such that (x,σ) is excellent. If there is more than one such σ choose one arbitrarily.

Fixing an excellent x, let σ be the value such that (x,σ) is excellent. For this σ, $\mathbf{Pr}_{C\in\mathcal{C}_x}[C\in\mathcal{C}_{x,\sigma}]\geq\frac{\epsilon}{2}$. From Claim 14, $\mathbf{Pr}_{C\sim\mathcal{C}_{x,\sigma},y\sim C}[f_{x,\sigma}(y)=T(C)(y)]\geq 1-\gamma$. By averaging, at least half of the cubes $C\in\mathcal{C}_{x,\sigma}$ satisfy $\mathbf{Pr}_{y\sim C}[f_{x,\sigma}(y)=T(C)(y)]\geq 1-2\gamma$. For all these cubes $T(C)\overset{2\gamma}{\approx}f_{x,\sigma}$, and they are at least $\frac{\epsilon}{4}$ fraction of the cubes in $\mathcal{C}_x$. ◀

3.2 Global Structure

In this section, we prove the following lemma:

▶ **Lemma 15** (Global Structure). *Let T be a cubes table that passes Test 1 with probability at least $\epsilon=\Omega(\frac{d^4}{\sqrt{q}})$, then for every $\gamma=\Omega(\frac{1}{d^3})$, there exists an $(\frac{\epsilon}{2},\gamma)$-excellent x such that $f=f_x:\mathbb{F}^m\to\mathbb{F}$ satisfies*

$$\mathop{\mathbf{Pr}}_{C}[T(C)\overset{32\gamma}{\approx}f_{|C}]\geq\frac{\epsilon}{16}.$$

Let $X^\star\subseteq\mathbb{F}^m$ the set of $(\frac{\epsilon}{2},\gamma)$ excellent points.

The main idea in the proof of the global structure, is showing that there exist many pairs of excellent points $x,y\in X^\star$, such that for many cubes C, the $T(C)$ is similar both to f_x and to f_y (Claim 17). If this is the case, then the functions f_x,f_y must be very similar (Claim 18). Finally, the lemma is proven by averaging and finding a single x such that f_x agrees simultaneously with many of the f_y's and their supporting cubes.

▶ **Definition 16** (Supporting cubes). For any excellent $x\in X^\star$, we denote by F_x the set of cubes "supporting" f_x,

$$F_x=\left\{C\in\mathcal{C}_x\,\middle|\,T(C)\overset{2\gamma}{\approx}f_{x|_C}\right\}.$$

▶ **Claim 17.** *Let $\mathcal{D}$ be the following process: choose $x,y\in X^\star$ independently and uniformly at random, let C be a random cube containing both x and y. Then*

$$\mathop{\mathbf{Pr}}_{x,y,C\sim D}[C\in F_x\cap F_y]\geq\frac{\epsilon^2}{26}.$$

Proof. Since each $x\in X^\star$ is excellent, we know from the local structure lemma, Lemma 11, that $\mathbf{Pr}_{C\sim\mathcal{C}_x}[C\in F_x]\geq\frac{\epsilon}{4}$. This is of course also true when taking a uniform $x\in X^\star$, thus, $\mathbf{Pr}_{x\sim X^\star,C\sim\mathcal{C}_x}[C\in F_x]\geq\frac{\epsilon}{4}$.

From Lemma 9(4) , the inclusion graph $G=G(\mathbb{F}^m,\mathcal{C})$ has $\lambda(G)=\lambda\leq(1+o(1))\frac{1}{q^{3/2}}$. Denote the measure of $X^\star$ by μ, from Lemma 11, $\mu\geq\frac{\epsilon}{3}$. Hence, by the application of Lemma 6 on the graph G with $A=\mathcal{C},B=\mathbb{F}^m$ and $B'=X^\star$, we get

$$\left|\mathop{\mathbf{Pr}}_{x\sim X^\star,C\sim\mathcal{C}_x}[C\in F_x]-\mathop{\mathbf{Pr}}_{C\sim\mathcal{C},x\sim C\cap X^\star}[C\in F_x]\right|\leq\frac{\lambda}{\sqrt{\mu}}\leq\frac{2\lambda}{\sqrt{\epsilon}}.\tag{2}$$

For each $C \in \mathcal{C}$, let $p_C = \mathbf{Pr}_{x \sim C \cap X^\star}[C \in F_x]$, this measures for every cube C how many points $x \in C$ are such that $f_{x|_C} \overset{2\gamma}{\approx} T(C)$. In this notation, (2) implies $\mathbf{E}_C[p_C] \geq \frac{\epsilon}{4} - \frac{2\lambda}{\sqrt{\epsilon}} \geq \frac{\epsilon}{5}$. We can use this to bound the probability of the event $C \in F_x \cap F_y$ by first choosing C, then two independent points in $C \cap X^\star$,

$$\mathop{\mathbf{Pr}}_{\substack{C \sim \mathcal{C} \\ x,y \sim C \cap X^\star}}[C \in F_x \cap F_y] = \mathop{\mathbf{E}}_{C}[p_C^2] \geq \left(\mathop{\mathbf{E}}_{C}[p_C]\right)^2 \geq \frac{\epsilon^2}{25}.$$

We observe that this distribution is very similar to the required distribution D. The only difference is that here we first pick $C \in \mathcal{C}$ and then two excellent points in C, whereas in D we first pick two points in $X^\star$ and then a common neighbor C. The graph G satisfies that every two distinct points $x, y \in \mathbb{F}^m$ have exactly the same number of common neighbors. Therefore, we can use Lemma 8 on the graph G with $A = \mathcal{C}, B = \mathbb{F}^m$ and $B' = X^\star$ to get

$$\left| \mathop{\mathbf{Pr}}_{\substack{C \sim \mathcal{C} \\ x,y \sim C \cap X^\star}}[C \in F_x \cap F_y] - \mathop{\mathbf{Pr}}_{x,y,C \sim D}[C \in F_x \cap F_y] \right| \leq \frac{2\lambda}{\mu} + \frac{1}{\mu^2 d_A} + \frac{1}{\mu^2 |B|} \leq \frac{6\lambda}{\epsilon} + \frac{9}{q^m \epsilon^2} + \frac{9}{q^3 \epsilon^2}.$$

Recall that $\lambda \leq (1 + o(1))\frac{1}{q^{3/2}}$ and since $\epsilon = \Omega(\frac{d^4}{\sqrt{q}})$, we conclude that $\mathbf{Pr}_{x,y,C \sim D}[C \in F_x \cap F_y] \geq \frac{\epsilon^2}{25} - \frac{6\lambda}{\epsilon} - \frac{9}{q^m \epsilon^2} - \frac{9}{q^3 \epsilon^2} \geq \frac{\epsilon^2}{26}$. ◀

▶ **Claim 18.** *Let $x \neq y \in X^\star$, and let ℓ be the line containing x and y, if $\mathbf{Pr}_{C \sim \mathcal{C}_\ell}[C \in F_x \cap F_y] \geq \frac{\epsilon^2}{100}$ then $f_x \overset{5\gamma}{\approx} f_y$.*

Proof. Consider the graph $G = G(\mathbb{F}^m \setminus \ell, \mathcal{C}_\ell)$. This is a bi-regular bipartite graph, and by Lemma 9(3) it has $\lambda = \lambda(G) \leq (1 + o(1))\frac{1}{\sqrt{q}}$. Let $F = F_x \cap F_y$. By assumption, F has measure at least $\frac{\epsilon^2}{100}$ inside $\mathcal{C}_\ell$.

We denote by $E' \subset E$ the edges of G that indicate agreement with both f_x and f_y,

$$E' = \{(z, C) \mid T(C)(z) = f_x(z) = f_y(z)\}.$$

Every cube $C \in F$ has $1 - 2\gamma$ of the points $z \in C$ satisfying $T(C)(z) = f_x(z)$ and $1 - 2\gamma$ of the points satisfying $T(C)(z) = f_y(z)$. By a union bound we get $\mathbf{Pr}_{C \in F, z \in N(C)}[(z, C) \in E'] \geq 1 - 4\gamma$. By Lemma 6 on G when $A = \mathbb{F}^m \setminus \ell, B = \mathcal{C}_\ell, B' = F$,

$$\left| \mathop{\mathbf{Pr}}_{C \sim F, z \sim N(C)}[(z, C) \in E'] - \mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F}[(z, C) \in E'] \right| \leq \frac{20\lambda}{\epsilon},$$

which means that $\mathbf{Pr}_{z \sim \mathbb{F}^m, C \sim N(z) \cap F}[(z, C) \in E'] \geq 1 - 4\gamma - \frac{20\lambda}{\epsilon} \geq 1 - 5\gamma$. By the definition of E', for each point $z \in \mathbb{F}^m$ that has an adjacent edge in E', $f_x(z) = f_y(z)$. This means that

$$\mathop{\mathbf{Pr}}_{z}[f_x(z) = f_y(z)] \geq \mathop{\mathbf{Pr}}_{z}[\exists C \text{ s.t. } (z, C) \in E'] \geq \mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F}[(z, C) \in E'] \geq 1 - 5\gamma.$$ ◀

The above claim showed that if two functions have a large set of cubes on which they almost agree then these functions are similar. In order to prove the global structure, we also need to show that in this case, most of $C \in F_y$ will also be close to f_x.

▶ **Claim 19.** *Let $x, y \in X^\star$ such that $f_x \overset{5\gamma}{\approx} f_y$, then*

$$\mathop{\mathbf{Pr}}_{C \sim F_y}[T(C) \overset{32\gamma}{\approx} f_{x|_C}] \geq \frac{1}{2}.$$

Note that the function f_x may not be a low degree polynomial, so $T(C) \overset{32\gamma}{\approx} f_{x|_C}$ doesn't imply equality.

Proof. Let $G = G(\mathbb{F}^m \setminus \{y\}, \mathcal{C}_y)$, by Claim 9(5) it has $\lambda = \lambda(G) \approx \frac{1}{q}$. First, we denote by E'_y the following set of edges,

$$E'_y = \{(z, C) \mid T(C)(z) = f_y(z)\}.$$

For each $C \in F_y$, we know that $\mathbf{Pr}_{z \in N(C)}[(z, C) \in E'_y] \geq 1 - 2\gamma$. From Lemma 6 on G when $A = \mathbb{F}^m \setminus y, B = \mathcal{C}_y, B' = F_y$, we know that

$$\left| \mathop{\mathbf{Pr}}_{C \sim F_y, z \sim N(C)}[(z, C) \in E'_y] - \mathop{\mathbf{Pr}}_{z, C \in N(z) \cap F_y}[(z, C) \in E'_y] \right| \leq \frac{4\lambda}{\epsilon},$$

since the measure of F_y is at least $\frac{\epsilon}{4}$. This implies that $\mathbf{Pr}_{z, C \in N(z) \cap F_y}[(z, C) \in E'_y] \geq 1 - 3\gamma$.

We define a second set of edges, E'_x to be the same only for f_x,

$$E'_x = \{(z, C) \mid T(C)(z) = f_x(z)\}.$$

We notice that if z is a point such that $f_x(z) = f_y(z)$, then $(z, C) \in E'_y \Rightarrow (z, C) \in E'_x$.

$$\begin{aligned}
\mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F_y}[(z, C) \in E'_x] \geq & \mathop{\mathbf{Pr}}_{z}[f_x(z) = f_y(z)] \cdot \mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F_y}[(z, C) \in E'_y \mid f_x(z) = f_y(z)] \\
\geq & (1 - 5\gamma) \cdot \mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F_y}[(z, C) \in E'_y \mid f_x(z) = f_y(z)] \\
& \qquad \text{(since } f_x \overset{5\gamma}{\approx} f_y\text{)} \\
\geq & (1 - 5\gamma) \cdot \left(\mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F_y}[(z, C) \in E'_y] - 5\gamma \right) \\
\geq & 1 - 15\gamma.
\end{aligned}$$

Therefore, we can use Lemma 6 again on the same graph G and set F_y, now with the edge set E'_x, to conclude that

$$\mathop{\mathbf{Pr}}_{C \sim F_y, z \sim N(C)}[(z, C) \in E'_x] \geq \mathop{\mathbf{Pr}}_{z, C \sim N(z) \cap F_y}[(z, C) \in E'_x] - \frac{4\lambda}{\epsilon} \geq 1 - 16\gamma,$$

By averaging, at least half of $C \in F_y$ satisfies $T(C) \overset{32\gamma}{\approx} f_{x|_C}$. ◀

We are now ready to prove the global structure.

Proof of Lemma 15. Let T be the cubes table that passes Test 1 with probability at least $\epsilon = \Omega(\frac{d^4}{\sqrt{q}})$. From the local structure, Lemma 11, we know that there exists a set $X^\star$ of excellent points, such that each $x \in X^\star$ has a function f_x, and $|F_x| \geq \frac{\epsilon}{4} |\mathcal{C}_x|$.

From Claim 17, we know that $\mathbf{Pr}_{x,y,C \sim D}[C \in F_x \cap F_y] \geq \frac{\epsilon^2}{26}$, when x, y are chosen uniformly from $X^\star$ and C is a common neighbor. Therefore, there must be $x \in X^\star$ such that $\mathbf{Pr}_{y \sim X^\star, C \sim N(x) \cap N(y)}[C \in F_x \cap F_y] \geq \frac{\epsilon^2}{26}$.

Fix such $x \in X^\star$, and let X' be the set of $y \in X^\star$ such that $|F_x \cap F_y| \geq \frac{\epsilon^2}{100} |\mathcal{C}_\ell|$. By averaging, $|X'| \geq \frac{\epsilon^2}{100} |X^\star| \geq \frac{\epsilon^3}{400} |\mathbb{F}|^m$.

By Claim 18, for all $y \in X'$, $f_y \overset{5\gamma}{\approx} f_x$. For each $y \in X'$, let

$$F'_y = \{C \in F_y \mid T(C) \overset{32\gamma}{\approx} f_{x|_C}\}.$$

At this point we have a large collection of y's and for each one a large collection of cubes F'_y such that all of these support the same function f_x. It is immediate that f_x is supported by some poly(ϵ) fraction of all of the cubes. Since we are aiming for a better quantitative bound of $\Omega(\epsilon)$ fraction of $\mathcal{C}$, we will rely on the expansion once more.

In order to finish the proof, we need to show that $\left|\cup_{y\in X'} F'_y\right| \geq \frac{\epsilon}{16}|\mathcal{C}|$.

Let $G = G(\mathbb{F}^m, \mathcal{C})$, by Lemma 9(4) $\lambda(G) \leq q^{-\frac{3}{2}}$. We use X' as the set of vertices, and define

$$E' = \{(y, C) \mid T(C) \overset{32\gamma}{\approx} f_{x|_C}\}.$$

By Lemma 6 on G with $A = \mathcal{C}, B = \mathbb{F}^m, B' = X'$,

$$\left| \Pr_{y\sim X', C\sim N(y)}[(y, C) \in E'] - \Pr_{C\sim\mathcal{C}, y\sim N(C)\cap X'}[(y, C) \in E'] \right| \leq \frac{20\lambda}{\sqrt{\epsilon^3}} \leq \frac{20q^{-\frac{3}{2}}}{q^{-\frac{3}{4}}} \leq 20q^{-\frac{3}{4}} \leq \frac{\epsilon}{16},$$

where we used the fact that $\epsilon \geq \frac{1}{\sqrt{q}}$.

Claim 19 lets us bound the first term on the left, since for each $y \in X'$, $\mathbf{Pr}_{C\sim N(y)}[C \in F'_y] \geq \frac{1}{2}\mathbf{Pr}_{C\sim N(y)}[C \in F_y] \geq \frac{\epsilon}{8}$. Thus,

$$\Pr_{C\sim\mathcal{C}, y\sim N(C)\cap X'}[(y, C) \in E'] \geq \frac{\epsilon}{8} - \frac{\epsilon}{16} = \frac{\epsilon}{16}.$$

We notice that a cube with even a single adjacent edge in E' satisfies $T(C) \overset{32\gamma}{\approx} f_{x|_C}$, so we are done. ◀

3.3 Low Degree

The last step is to prove that the global function discovered in the previous section can be modified to make it a low degree function, while still maintaining large support for it among the cubes.

▶ **Theorem 20** (Theorem 2 restated). *For every d and large enough prime power q and every $m \geq 3$ the following holds. Let T be a cubes table that passes Test 1 with probability at least $\epsilon = \Omega(\frac{d^4}{\sqrt{q}})$, then there exist a degree d polynomial $g : \mathbb{F}^m \to \mathbb{F}$ such that $T(C) = g|_C$ on an $\Omega(\epsilon)$ fraction of the cubes.*

From Lemma 15, we get a function f such that $\Omega(\epsilon)$ of the cubes have $T(C) \approx f_{|_C}$. In this section, we will show that this function f is close to a degree d polynomial g. Afterwards, we also need to show that $\Omega(\epsilon)$ of the cubes satisfies $T(C) = g_{|_C}$

To show the first part, we will use a robust characterization of low degree polynomials given by Rubinfeld and Sudan.

▶ **Theorem 21** ([12, Theorem 4.1]). *Let $f : \mathbb{F}^m \to \mathbb{F}$ be a function, and let $N_{y,h} = \{y+i(h-y) \mid i \in \{0, \ldots, d+1\}\}$, if f satisfies*

$$\Pr_{y,h\in\mathbb{F}^m}[\exists \deg d \text{ polynomial } p \textbf{ s.t. } p_{|_{N_{y,h}}} = f_{|_{N_{y,h}}}] \geq 1 - \delta,$$

for $\delta \leq \frac{1}{2(d+2)^2}$, then there exists a degree d polynomial g such that $f \overset{2\delta}{\approx} g$.

For completeness, we present proof of the above theorem in Appendix C.

▶ **Claim 22.** *Fix any* $\gamma \leq \frac{1}{100(d+2)^3}$*, let* $f : \mathbb{F}^m \to \mathbb{F}$ *and* $x \in \mathbb{F}^m$ *such that*

$$\Pr_{C \in \mathcal{C}_x}[T(C) \overset{32\gamma}{\approx} f_{|C}] \geq \frac{\epsilon}{4},$$

then exists a degree d *polynomial* g *such that* $f \overset{84d\gamma}{\approx} g$*.*

Proof. Denote by $F \subseteq \mathcal{C}_x$ the following set

$$F = \{C \in \mathcal{C}_x \mid T(C) \overset{32\gamma}{\approx} f_{|C}\}.$$

Our first goal is to show that for nearly all lines, f agrees with a low degree function on almost all of the points of the line.

Fix $C \in F$, if we pick a uniform $\ell \subset C$ we expect that $T(C)_\ell \overset{O(\gamma)}{\approx} f_{|\ell}$. Using the spectral properties we show that almost all lines satisfy this property. Let $G_C = G(A \cup B, E)$ be the following bipartite inclusion graph where A is all the points in C, and B is all the affine lines in C. Let $A' \subset A$ be $A' = \{y \in A \mid T(C)(y) \neq f(y)\}$, and $B' \subset B$ be $B' = \{\ell \in B \mid |N(\ell) \cap A'| \geq 40\gamma\,|N(\ell)|\}$. From Lemma 9(6) with $m = 3$ (we apply the lemma where "$\mathbb{F}^m$" is the cube C), $\lambda_C = \lambda(G_C) \leq \frac{2}{\sqrt{q}}$. We apply Lemma 6 on G_C and the set B', where the set of edges is all the edges adjacent to A':

$$\left| \Pr_{y \in A, \ell \in N(y) \cap B'}[y \in A'] - \Pr_{\ell \in B', y \in N(\ell)}[y \in A'] \right| \leq \frac{\lambda_C}{\sqrt{\frac{|B'|}{|B|}}}.$$

We notice that $\mathbf{Pr}_{y \in A}[y \in A'] \leq 32\gamma$. By the definition of B', $\mathbf{Pr}_{\ell \in B', y \in N(\ell)}[y \in A'] \geq 40\gamma$. Therefore $|B'| \leq \left(\frac{\lambda_C}{8\gamma}\right)^2 |B| < \gamma\,|B|$.

We have shown that for every cube $C \in F$, almost all lines in it satisfy $T(C)_\ell \overset{40\gamma}{\approx} f_{|\ell}$. Now we need to show that the set F is large enough to cover $(1 - O(\gamma))$ of all the lines in $\mathcal{L}$. The inclusion graph $G = G(\mathcal{L} \setminus \mathcal{L}_x, \mathcal{C}_x)$ has $\lambda = \lambda(G) \leq \frac{1}{\sqrt{q}}$, by Lemma 9(1). We denote by E' the set of edges (ℓ, C) such that $T(C)_{|\ell} \overset{40\gamma}{\approx} f_{|\ell}$. As we've seen above, for every $C \in F$, $\mathbf{Pr}_{\ell \in N(C)}[(\ell, C) \in E'] \geq 1 - \gamma$.

By Lemma 6 on G, with $A = \mathcal{L} \setminus \mathcal{L}_x, B = \mathcal{C}_x, B' = F$,

$$\left| \Pr_{\ell, C \sim N(\ell) \cap F}[(\ell, C) \in E'] - \Pr_{C \sim F, \ell \sim C}[(\ell, C) \in E'] \right| \leq \frac{\lambda}{\sqrt{\epsilon}} \leq \gamma,$$

which means that

$$\Pr_{\ell}[\exists C \text{ s.t. } (\ell, C) \in E'] \geq \Pr_{\ell, C \sim N(\ell) \cap F}[(\ell, C) \in E'] \geq 1 - 2\gamma.$$

This means that for $1 - 2\gamma$ of the lines in $\mathcal{L}$, f agrees with a degree d function on $1 - 40\gamma$ fraction of the points of each line.

We are very close to being able to apply the low degree test of Rubinfeld and Sudan [12], that works in the high soundness regime. For this, we need to move to neighborhoods. For $y, h \in \mathbb{F}^m$, we define the neighborhood of y, h,

$$N_{y,h} = \{y + i(h - y) \mid 0 \leq i \leq d + 1\}.$$

Notice that $N_{y,h} \subset \ell(y, h)$. We show that on almost all of the neighborhoods $N_{y,h}$, the function $f_{|N_{y,h}}$ equals a degree d polynomial, by showing that for almost all $N_{y,h}$, there exists some cube C such that $f_{|N_{y,h}} = T(C)_{|N_{y,h}}$ ($T(C)$ is a degree d polynomial).

Picking a random neighborhood $N_{y,h}$ is equivalent to picking a random line $\ell \in \mathcal{L}$ and then uniform $y, h \in \ell$. We have already showed that almost all lines $\ell \in \mathcal{L}$, there exists a cube C such that $T(C)_\ell \overset{\Omega(\gamma)}{\approx} f_{|\ell}$.

Now we can bound the same probability over neighborhoods

$$\begin{aligned}
&\mathop{\mathbf{Pr}}_{y,h\sim\mathbb{F}^m}[\exists C \text{ s.t. } f(N_{y,h}) = T(C)(N_{y,h})] \\
&\quad \geq \mathop{\mathbf{Pr}}_{\ell}[\exists C \text{ s.t. } (\ell, C) \in E'] \cdot \mathop{\mathbf{Pr}}_{\ell,y,h\sim\ell}[f(N_{y,h}) = T(C)(N_{y,h}) \mid \exists C \text{ s.t. } (\ell, C) \in E'] \\
&\quad \geq (1-2\gamma) \mathop{\mathbf{Pr}}_{\ell,y,h\sim\ell}[f(N_{y,h}) = T(C)(N_{y,h}) \mid \exists C \text{ s.t. } (\ell, C) \in E'] \\
&\quad \geq (1-2\gamma)(1-(d+2)\cdot 40\gamma), \qquad (3) \\
&\quad \geq 1 - 42d\gamma,
\end{aligned}$$

where (3) is due to union bound on the neighborhoods inside ℓ. Therefore, the function f equals a degree d polynomial on $(1-42d\gamma)$ of the neighborhoods. Since $\gamma \leq 100(d+2)^{-3}$, by Theorem 21, we get that there exists a degree d polynomial g, such that $f \overset{84d\gamma}{\approx} g$. ◀

Proof of Theorem 20. Fix the cubes table T, and let $f : \mathbb{F}^m \to \mathbb{F}$ be the function promised from Lemma 15. This function satisfies the conditions of Claim 22, so there exists a degree d polynomial g such that $f \overset{84d\gamma}{\approx} g$.

Since g is a degree d polynomial, for every cube C either $T(C) = g_{|C}$, or else they are very different. Let G be the inclusion graph $G = G(\mathbb{F}^m, \mathcal{C})$, and let

$$F = \{C \in \mathcal{C} \mid T(C) \overset{32\gamma}{\approx} f_{|C}\}$$

From Lemma 15, the measure of F is at least $\frac{\epsilon}{16}$, let A' be the set of points on which $f \neq g$. By Lemma 9(4), $\lambda(G) \leq q^{-\frac{3}{2}}$. We use Lemma 6 on G with $A = \mathbb{F}^m, B = \mathcal{C}, B' = F$,

$$\left| \mathop{\mathbf{Pr}}_{C\in F, y\in N(C)}[y \in A'] - \mathop{\mathbf{Pr}}_{y, C\in N(y)\cap F}[y \in A'] \right| \leq \frac{q^{-\frac{3}{2}}}{\epsilon} \leq \gamma$$

We know that $\mathbf{Pr}_{y,C\in N(y)\cap F}[y \in A'] \leq \mathbf{Pr}_y[y \in A'] \leq 84d\gamma$, which implies that $\mathbf{Pr}_{C\in F, y\in N(C)}[y \in A'] \leq 85d\gamma$.

By averaging, for at least half of the cubes $C \in F$, $\mathbf{Pr}_{y\in C}[y \in A'] \leq 200d\gamma \leq \frac{1}{2}$. For all these cubes $T(C) = g_{|C}$, because $\mathbf{Pr}_{y\in C}[T(C)(y) = g(y)] \geq \mathbf{Pr}_{y\in C}[T(C)(y) = f(y), y \notin A'] \geq 1 - 32\gamma - \frac{1}{2} > d/q$, and since $g_{|C}, T(C)$ are both degree d polynomials, they must be equal. ◀

▶ Remark. Instead of Theorem 21, we can use another similar characterization from [12], where the neighborhood is defined as $N_{y,h} = \{y + i(h-y) \mid i \in \{0, \ldots, 10d\}\}$. The advantage of using this new neighborhood is that we can conclude $f \overset{(1+o(1))\delta}{\approx} g$ as long as $\delta = O(1/d)$. This will help in reducing the exponent of d by 1 in our main theorem. We chose to use Theorem 21 for a self contained proof.

4 Comparing between different tests and their agreement parameter

There are many variants for the low degree test, in this section we look into equivalences between similar low degree agreement tests. We first prove the equivalence in a more general setting and as a corollary we get some interesting results.

Throughout this section, we will work over $\mathbb{F}^m$ where $\mathbb{F}$ is a field of size q and let $s \leq m/2$ be fixed. Also, let T denotes a table which maps every s dimensional affine subspace in $\mathbb{F}^m$ to a degree d polynomial. Let $\mathcal{A}^s$ denote the set of all s dimensional affine subspaces in $\mathbb{F}^m$. For $r < s$ and for $R \in \mathcal{A}^r$ let $\mathcal{A}^s_R \subseteq \mathcal{A}^s$ denote all subspaces in $\mathcal{A}^s$ which contain a particular subspace R,

$$\mathcal{A}^s_R = \{S \subset \mathbb{F}^m \mid \dim(S) = s, R \subseteq S\}.$$

For parameters $s > k \geq r$ consider the following test:

Test 3 Subspace agreement test : $\alpha_{sks(r)}$

1. Select $K \in \mathcal{A}^k$ u.a.r.
2. Pick $S_1, S_2 \in \mathcal{A}^s_K$ u.a.r.
3. Pick a r dimensional subspace $R \subseteq K$ u.a.r.
4. Accept iff $T(S_1)_{|R} = T(S_2)_{|R}$.

Let $\alpha_{sks(r)}(T)$ be the *agreement* of the table $T = (f_S)_{S \in \mathcal{A}^s}$, i.e. the probability of acceptance of the test.

When $r = k$ we simply denote the agreement as $\alpha_{sks}(T)$. With these notations, the success probability of Test 1 is denoted by $\alpha_{3,0,3}(T)$, and of Test 2 by $\alpha_{2,1,2}(T)$.

In this section, we prove the following main lemma.

▶ **Lemma 23.** *Let $0 \leq r < k < s \leq \frac{m}{2}$, we have*

$$\alpha_{srs}(T)\left(1 - \left(\frac{d}{q}\right)^{r+1}\right) \leq \alpha_{sks}(T) \leq \alpha_{srs}(T) + (1 + o(1))q^{-(s-2k+r+1)},$$

From Lemma 23, we can deduce the following corollary,

▶ **Corollary 24.** *Let $\alpha_{\mathcal{C}\ell\mathcal{C}}(T) = \alpha_{3,1,3}(T)$ be the success probability of Test 3 with $s = 3, k = r = 1$, i.e checking consistency of two cubes that intersect on a line. Then for every cubes table T,*

$$\alpha_{\mathcal{C}x\mathcal{C}}(T)\left(1 - \frac{d}{q}\right) \leq \alpha_{\mathcal{C}\ell\mathcal{C}}(T) \leq \alpha_{\mathcal{C}x\mathcal{C}}(T) + \frac{1}{q^2}(1 + o(1)).$$

The corollary implies that Theorem 2 holds if we modify the test as selecting two cubes u.a.r from a pair of cubes intersecting in a line and checking consistency on the whole line.

Using Lemma 23, we can also compare the Raz-Safra Plane vs. Plane agreement tests where planes intersect at a point and on a line. Recall that $\alpha_{\mathcal{P}\ell\mathcal{P}}(T)$ is the acceptance probability of Test 2. Invoking Lemma 23 with $s = 2$, $k = 1$ and $r = 0$, we get the following corollary.

▶ **Corollary 25** (Lemma 3 restated)**.** *Let T be a planes table, and let $\alpha_{\mathcal{P}x\mathcal{P}}(T)$ be the success probability of Test 3 with $s = 2, k = r = 0$, i.e two planes that intersects on a point. Let $\alpha_{\mathcal{P}\ell\mathcal{P}}(T)$ be the success probability of Test 2 from the introduction (two planes that intersects on a line), then*

$$\alpha_{\mathcal{P}x\mathcal{P}}(T)\left(1 - \frac{d}{q}\right) \leq \alpha_{\mathcal{P}\ell\mathcal{P}}(T) \leq \alpha_{\mathcal{P}x\mathcal{P}}(T) + \frac{1}{q}(1 + o(1)).$$

4.1 Proof of Lemma 23

We prove a few claims that together with the observation $\alpha_{sks(r)}(T) \geq \alpha_{sks}(T)$, prove the lemma.

The following claim shows that two distinct low degree polynomials agree on a random subspace of fixed dimension with very small probability.

▶ **Claim 26.** *Let $P_1, P_2 : \mathbb{F}^t \to \mathbb{F}$ be two distinct degree d polynomials. For $r \leq t$*

$$\Pr_{R \in \mathcal{A}^r}\left[(P_1)_{|R} \equiv (P_2)_{|R}\right] \leq \left(\frac{d}{q}\right)^{r+1}.$$

Proof. Consider the following way of choosing an r dimensional *affine* subspace from $\mathcal{A}^r$ uniformly at random: Pick $x_0, x_1, x_2, \ldots, x_r$ from $\mathbb{F}_q^t$ independently and u.a.r. Then pick a r dimensional affine subspace R containing $\{x_0 + \mathtt{span}(x_1, x_2, \ldots, x_r)\}$ u.a.r (R is determined by $x_0, x_1, x_2, \ldots, x_r$, unless $\dim \mathtt{span}(x_1, x_2, \ldots, x_r) < r$). It is easy to see that R is distributed uniformly in $\mathcal{A}^r$. Now, P_1 and P_2 agreeing on the whole subspace R implies that they agree on the points $\{x_0, x_0 + x_1, x_0 + x_2, \ldots, x_0 + x_r\}$ as all these points are contained in R. Therefore,

$$\begin{aligned}\Pr_{R \in \mathcal{A}^r}[(P_1)_{|R} \equiv (P_2)_{|R}] &\leq \Pr_{x_0, x_1, \ldots, x_r \sim \mathbb{F}^t}[P_1(x_0) = P_2(x_0) \wedge_{i=1}^r P_1(x_0 + x_i) = P_2(x_0 + x_i)] \\ &= \left(\Pr_{x \in \mathbb{F}_q^t}[P_1(x) = P_2(x)]\right)^{r+1} \leq \left(\frac{d}{q}\right)^{r+1},\end{aligned}$$

where the last inequality is because two different degree d polynomial agree on at most $\frac{d}{q}$ fraction of the points (Schwartz-Zippel lemma). ◀

▶ **Claim 27.** *Let $M_{m \times n}$ be the adjacency matrix of a bi regular bipartite graph G, and let f be a n-dimensional $\{0,1\}$ vector such that $\mathbf{E}[f] = \mu$. Then*

$$\langle Mf, Mf \rangle \leq \mu^2 + \lambda(G)^2 \mu.$$

Proof. Let $\mathbf{1}$ be the unit vector. We write f as $f = f_1 + f_1^\perp$ where f_1 is in the direction of $\mathbf{1}$, the singular vector with the maximal singular value, and $f_1^\perp$ is its orthogonal component. We note that $f_1 = \mu \mathbf{1}$, and hence $\langle f_1, f_1 \rangle = \mu^2$. Also,

$$\mu = \langle f, f \rangle = \langle f_1 + f_1^\perp, f_1 + f_1^\perp \rangle = \langle f_1, f_1 \rangle + \langle f_1^\perp, f_1^\perp \rangle \geq \langle f_1^\perp, f_1^\perp \rangle.$$

Using this we can bound:

$$\begin{aligned}\langle Mf, Mf \rangle =& \langle Mf_1 + Mf_1^\perp, Mf_1 + Mf_1^\perp) \rangle \\ =& \langle f_1, f_1 \rangle + \langle Mf_1^\perp, Mf_1^\perp \rangle \\ \leq& \mu^2 + \lambda(G)^2 \langle f_1^\perp, f_1^\perp \rangle \\ \leq& \mu^2 + \lambda(G)^2 \mu.\end{aligned}$$ ◀

▶ **Claim 28.** $\alpha_{sks(r)}(T) \geq \alpha_{srs}(T)$.

Proof. We start by fixing $R \in \mathcal{A}^r, \sigma \in \mathbb{F}^{q^r}$. For each k dimensional subspace $K \in \mathcal{A}_R^k$, denote by p_K the following probability $p_K = \mathbf{Pr}_{S \sim \mathcal{A}_K^s}[T(S)_{|R} \equiv \sigma]$. In this notation

$$\begin{aligned}\Pr_{\substack{K \sim \mathcal{A}_R^k \\ S_1, S_2 \sim \mathcal{A}_K^s}}[T(S_1)_{|R} \equiv T(S_2)_{|R} \equiv \sigma] &= \mathop{\mathbf{E}}_K[p_K^2] \\ &\geq \left(\mathop{\mathbf{E}}_K[p_K]\right)^2 = \Pr_{S_1, S_2 \sim \mathcal{A}_R^s}[T(S_1)_{|R} \equiv T(S_2)_{|R} \equiv \sigma]. \quad (4)\end{aligned}$$

Now, we average over R, σ to get $\alpha_{srs}(T)$ and $\alpha_{sks(r)}(T)$:

$$\alpha_{srs}(T) = \mathop{\mathbf{Pr}}_{\substack{R\sim\mathcal{A}^r \\ S_1,S_2\sim\mathcal{A}^s_R}}[T(S_1)_{|R} \equiv T(S_2)_{|R}]$$
$$= \mathop{\mathbf{E}}_{R\sim\mathcal{A}^r}\left[\sum_{\sigma\in\mathbb{F}^{q^r}} \mathop{\mathbf{Pr}}_{S_1,S_2\sim\mathcal{A}^s_R}[T(S_1)_{|R} \equiv T(S_2)_{|R} \equiv \sigma]\right]. \tag{5}$$

Picking a uniform $R \in \mathcal{A}^r$ then $K \in \mathcal{A}^k_R$ is the same as picking $K \in \mathcal{A}^k$ and then a random r dimensional subspace R in K, so by definition

$$\alpha_{sks(r)}(T) = \mathop{\mathbf{Pr}}_{\substack{R\sim\mathcal{A}^r, K\sim\mathcal{A}^k_R \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \equiv T(S_2)_{|R}]$$
$$= \mathop{\mathbf{E}}_{R\sim\mathcal{A}^r}\left[\sum_{\sigma\in\mathbb{F}^{q^r}} \mathop{\mathbf{Pr}}_{\substack{K\sim\mathcal{A}^k_R \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \equiv T(S_2)_{|R} \equiv \sigma]\right]. \tag{6}$$

Using (4), (5) and (6), we get $\alpha_{sks(r)}(T) \geq \alpha_{srs}(T)$. ◀

▶ **Claim 29.** $\alpha_{sks}(T) \geq \alpha_{sks(r)}(T)\left(1 - \left(\frac{d}{q}\right)^{r+1}\right)$.

Proof. By the definition of the agreement,

$$\alpha_{sks}(T) = 1 - \mathop{\mathbf{E}}_{K\sim\mathcal{A}^k}\left[\mathop{\mathbf{Pr}}_{S_1,S_2\sim\mathcal{A}^s_K}[T(S_1)_{|K} \neq T(S_2)_{|K}]\right],$$

and

$$\alpha_{sks(r)}(T) = 1 - \mathop{\mathbf{E}}_{K\sim\mathcal{A}^k}\left[\mathop{\mathbf{Pr}}_{\substack{R\sim K, \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \neq T(S_2)_{|R}]\right],$$

where we use $R \sim K$ to denote a random r dimensional subspace in K. For every subspace $K \in \mathcal{A}^k$, $R \subseteq K$ is uniform and is independent of S_1, S_2.

$$\mathop{\mathbf{Pr}}_{\substack{R\sim K, \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \neq T(S_2)_{|R}] = \mathop{\mathbf{Pr}}_{\substack{R\sim K, \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|K} \neq T(S_2)_{|K}, T(S_1)_{|R} \neq T(S_2)_{|R}]$$
$$= \mathop{\mathbf{Pr}}_{S_1,S_2\sim\mathcal{A}^s_K}[T(S_1)_{|K} \neq T(S_2)_{|K}] \cdot \mathop{\mathbf{Pr}}_{\substack{R\sim K, \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \neq T(S_2)_{|R} \mid T(S_1)_{|K} \neq T(S_2)_{|K}]$$
$$\geq \mathop{\mathbf{Pr}}_{S_1,S_2\sim\mathcal{A}^s_K}[T(S_1)_{|K} \neq T(S_2)_{|K}] \cdot \left(1 - \left(\frac{d}{q}\right)^{r+1}\right).$$

The lower bound on the probability in the last inequality is as follows: the event $T(S_1)_{|K} \neq T(S_2)_{|K}$ implies that the degree d polynomials corresponding to $T(S_1)_{|K}$ and $T(S_2)_{|K}$ are distinct. Thus, using Claim 26 $\mathbf{Pr}_{R\sim K}[T(S_1)_{|R} \equiv T(S_2)_{|R}] \leq (d/q)^{r+1}$. Therefore, for a k dimensional subspace $K \in \mathcal{A}^k$,

$$\mathop{\mathbf{Pr}}_{\substack{R\sim K, \\ S_1,S_2\sim\mathcal{A}^s_K}}[T(S_1)_{|R} \neq T(S_2)_{|R}] \geq \mathop{\mathbf{Pr}}_{S_1,S_2\sim\mathcal{A}^s_K}[T(S_1)_{|K} \neq T(S_2)_{|K}]\left(1 - \left(\frac{d}{q}\right)^{r+1}\right).$$

Finally, taking the expectation of the inequality over K finishes the proof. ◀

We first state a lemma about an expansion of the kind of inclusion graphs which we will be dealing with in analyzing the Test 3, the proof of which appears in Appendix A.

▶ **Lemma 30.** *Let $r \leq k < s \leq \frac{m}{2}$ be integers, and let G be the inclusion graph $G = G(\mathcal{A}_R^k, \mathcal{A}_R^s)$ for a r dimensional subspace R, where $R \neq \emptyset$. Then,*

$$\lambda(G)^2 \leq (1 + o(1)) \cdot q^{-(s-2k+r+1)}.$$

▶ **Claim 31.** *$\alpha_{sks(r)}(T) \leq \alpha_{srs(r)}(T) + \lambda(G)^2$ where G is the inclusion graph $G = G(\mathcal{A}_R^k, \mathcal{A}_R^s)$ for an r dimensional subspace R.*

Proof. Fix an r dimensional affine subspace $R \in \mathcal{A}^r$. We prove the following inequality:

$$\mathop{\mathbf{Pr}}_{\substack{K \sim \mathcal{A}_R^k, \\ S_1, S_2 \sim \mathcal{A}_K^s}} [T(S_1)_{|R} \equiv T(S_2)_{|R}] \leq \mathop{\mathbf{Pr}}_{S_1, S_2 \sim \mathcal{A}_R^s} [T(S_1)_{|R} \equiv T(S_2)_{|R}] + \lambda(G)^2, \tag{7}$$

Note that this implies the claim if we take expectation over $R \in \mathcal{A}^r$. Towards proving (7), for each value $\sigma \in \mathbb{F}^{q^k}$, denote by $A_\sigma \subseteq \mathcal{A}_R^s$ the following set

$$A_\sigma = \{S \in \mathcal{A}_R^s \mid T(S)_{|R} \equiv \sigma\},$$

and $\mu_\sigma = \frac{|A_\sigma|}{|\mathcal{A}_R^s|}$. Let f_σ be the indicator function for A_σ, for $S \in A_\sigma$, $f_\sigma(S) = 1$. By definition

$$\mathop{\mathbf{Pr}}_{S_1, S_2 \sim \mathcal{A}_R^s} [T(S_1)_{|R} \equiv T(S_2)_{|R}] = \sum_\sigma \mu_\sigma^2. \tag{8}$$

Let $G = G(\mathcal{A}_R^k, \mathcal{A}_R^s)$ be the inclusion graph, and denote by $M \in \mathbb{R}^{|\mathcal{A}_R^k| \times |\mathcal{A}_R^s|}$ the normalized adjacency matrix, such that each entry is either 0 or $\frac{1}{\deg(K)}$ where $K \in \mathcal{A}_R^k$.

For each k dimensional subspace $K \in \mathcal{A}_R^k$, the value $(Mf_\sigma)_K$ is the fraction of K's neighbors in A_σ, $(Mf_\sigma)_K = \mathbf{Pr}_{S \sim \mathcal{A}_K^s}[S \in A_\sigma]$. Therefore, the inner product gives us the expected value:

$$\langle Mf_\sigma, Mf_\sigma \rangle = \mathop{\mathbf{E}}_{K \in \mathcal{A}_R^k} \left[\mathop{\mathbf{E}}_{S \in \mathcal{A}_K^s} [S \in A_\sigma]^2 \right] = \mathop{\mathbf{E}}_{K \in \mathcal{A}_R^k} \left[\mathop{\mathbf{E}}_{S_1, S_2 \in \mathcal{A}_K^s} [S_1, S_2 \in A_\sigma] \right].$$

Therefore

$$\begin{aligned}
\mathop{\mathbf{Pr}}_{\substack{K \sim \mathcal{A}_R^k, \\ S_1, S_2 \sim \mathcal{A}_K^s}} [T(S_1)_{|R} \equiv T(S_2)_{|R}] &= \sum_\sigma \langle Mf_\sigma, Mf_\sigma \rangle \\
&\leq \sum_\sigma \mu_\sigma^2 + \lambda(G)^2 \mu_\sigma && \text{(using Claim 27)} \\
&= \mathop{\mathbf{Pr}}_{S_1, S_2 \sim \mathcal{A}_R^s} [T(S_1)_{|R} \equiv T(S_2)_{|R}] + \lambda(G)^2. && \text{(from (8))}
\end{aligned}$$

which proves (7). ◀

Claim 31 together with Lemma 30 gives us $\alpha_{sks}(T) \leq \alpha_{srs}(T) + (1 + o(1))q^{-2(s-2k+r+1)}$. Claim 28 and Claim 29 prove the other inequality, $\alpha_{srs}(T)\left(1 - \left(\frac{d}{q}\right)^{r+1}\right) \leq \alpha_{sks}(T)$.

A Spectral properties of Certain Inclusion Graphs

Let $G_{s,k}$ be the intersection graph where the vertex set is all *linear subspaces* of dimension s in $\mathbb{F}_q^m$ and $U \sim U'$ iff $\dim(U \cap U') = k$. We will use the $T_{s,k}$ to denote the *Markov operator* associated with a random walk on this graph. We will need following fact about eigenvalues of $T_{k,k-1}$.

▶ **Definition 32.** k-th q-ary Gaussian binomial coefficient $\begin{bmatrix} m \\ k \end{bmatrix}_q$ is given by

$$\begin{bmatrix} m \\ k \end{bmatrix}_q := \prod_{i=0}^{k-1} \frac{q^m - q^i}{q^k - q^i}.$$

As q is fixed throughout the article, we will omit the subscript from now on.

▶ **Fact 33.** *([4, Theorem 9.3.3]) Suppose* $1 \leq k \leq \frac{m}{2}$,

1. *The number of k dimensional linear subspaces in $\mathbb{F}_q^m$ is exactly $\begin{bmatrix} m \\ k \end{bmatrix}$.*
2. *The degree of $G_{k,k-1}$ is $q\begin{bmatrix} k \\ 1 \end{bmatrix}\begin{bmatrix} m-k \\ 1 \end{bmatrix}$.*
3. *The eigen values of $T_{k,k-1}$ are*

$$\lambda_j(T_{k,k-1}) = \frac{q^{j+1}\begin{bmatrix} k-j \\ 1 \end{bmatrix}\begin{bmatrix} m-k-j \\ 1 \end{bmatrix} - \begin{bmatrix} j \\ 1 \end{bmatrix}}{q\begin{bmatrix} k \\ 1 \end{bmatrix}\begin{bmatrix} m-k \\ 1 \end{bmatrix}},$$

with multiplicities $\begin{bmatrix} m \\ j \end{bmatrix} - \begin{bmatrix} m \\ j-1 \end{bmatrix}$ for $j = 0, 1, \ldots, k$. Asymptotically, $\lambda_j(T_{k,k-1}) = \Theta(q^{-j})$.

▶ **Claim 34.** *For any $1 \leq k \leq \frac{m}{2}$ and , we have $\left|\lambda_1(T_{k,k-2}) - \lambda_1(T_{k,k-1})^2\right| = (1 + o(1))\frac{1}{q^k}$.*

Proof. Consider a two-step random walk on the graph $G_{k,k-1}$. We will show that with very high probability, a two-step random walk on $G_{k,k-1}$ corresponds to a single step random walk on $G_{k,k-2}$. Let U_1, U_2, U_3 be the vertices from a two-step random walk on $G_{k,k-1}$. Note that conditioned on the event $\dim(U_1 \cap U_3) = k-2$, the distribution of (U_1, U_3) is exactly same as a single step random walk on $G_{k,k-2}$. We will upper bound the probability of the event $\dim(U_1 \cap U_3) \neq k-2$.

Let $w_1 = U_1 \cap U_2$ and $w_2 = U_2 \cap U_3$, we can describe the distribution of the two-step random walk as follows:

1. Choose a uniform k dimensional subspace U_2.
2. Choose two random $k-1$ dimensional subspaces, $w_1, w_2 \subset U_2$.
3. Choose a point $x_1 \in \mathbb{F}^m \setminus U_2$, and set $U_1 = \mathrm{span}(w_1, x_1)$.
4. Choose a point $x_2 \in \mathbb{F}^m \setminus U_2$, and set $U_3 = \mathrm{span}(w_2, x_2)$.

By definition, U_2 has $\begin{bmatrix} k \\ k-1 \end{bmatrix}$ subspaces of size $k-1$, therefore $\mathbf{Pr}_{w_1,w_2}[w_1 = w_2] = \frac{1}{\begin{bmatrix} k \\ k-1 \end{bmatrix}}$. In order to satisfy $\dim(U_1 \cap U_3) \neq k-2$ given that $w_1 \neq w_2$, the point x_2 should be in U_1. There are $q^k - q^{k-1}$ points in $U_1 \setminus U_2$, and therefore this probability equals $\frac{|U_1 \setminus U_2|}{|\mathbb{F}^m \setminus U_2|} = \frac{q^k - q^{k-1}}{q^m - q^k}$.

$$\begin{aligned}
\mathbf{Pr}[\dim(U_1 \cap U_3) \neq k-2] &= \mathbf{Pr}[w_1 = w_2] + \mathbf{Pr}[\dim(U_1 \cap U_3) \neq k-2 \wedge w_1 \neq w_2] \\
&= \frac{1}{\begin{bmatrix} k \\ k-1 \end{bmatrix}} + \left(1 - \frac{1}{\begin{bmatrix} k \\ k-1 \end{bmatrix}}\right)\mathbf{Pr}[\dim(U_1 \cap U_3) \neq k-2 \mid w_1 \neq w_2] \\
&= \frac{1}{\begin{bmatrix} k \\ k-1 \end{bmatrix}} + \left(1 - \frac{1}{\begin{bmatrix} k \\ k-1 \end{bmatrix}}\right) \cdot \frac{q^k - q^{k-1}}{q^m - q^k} =: \beta.
\end{aligned}$$

Thus, we have

$$T_{k,k-1}^2 = \beta\mathcal{N} + (1-\beta)T_{k,k-2},$$

where $\mathcal{N}$ is a Markov operator corresponding to the two-step random walk on $G_{k,k-1}$, conditioning on $\dim(U_1 \cap U_3) \neq k-2$. The claim follows as $\beta = (1 + o(1))1/q^k$. ◀

Following fact follows from the definition of $\lambda(G)$.

▶ **Fact 35.** *For a bi-regular bipartite graph $G(A, B)$, if T is a Markov operator associated with a random walk of length two starting from A (or B) then $\lambda(G)^2 = \lambda(T)$.*

We now prove Lemma 9.

▶ **Lemma 36** (Restatement of Lemma 9). *We have for every $m \geq 6$,*
1. *For $G_1(\mathcal{L} \setminus \mathcal{L}_x, \mathcal{C}_x)$, $\lambda(G_1) \approx \frac{1}{\sqrt{q}}$.*

2. *For* $G_2(\mathcal{L}_x, \mathcal{C}_x)$, $\lambda(G_2) \approx \frac{1}{q}$.
3. *For* $G_3(\mathbb{F}^m \setminus \ell, \mathcal{C}_\ell)$, $\lambda(G_3) \approx \frac{1}{\sqrt{q}}$.
4. *For* $G_4(\mathbb{F}^m, \mathcal{C})$, $\lambda(G_4) \approx \frac{1}{q^{3/2}}$.
5. *For* $G_5(\mathbb{F}^m \setminus \{x\}, \mathcal{C}_x)$, $\lambda(G_5) \approx \frac{1}{q}$.

And for every $m \geq 3$

6. *For* $G_6(\mathbb{F}^m, \mathcal{L})$, $\lambda(G_6) \approx \frac{1}{\sqrt{q}}$.

where $\approx$ *denotes equality up to a multiplicative factor of* $1 \pm o(1)$.

Proof. Suppose T is an $n \times n$ Markov operator which is a convex combination of a bunch of other Markov operators: $T = \sum_{i=1}^{k} \alpha_i T_i$ where $\alpha_i \geq 0$ and $\sum_{i=1}^{k} \alpha_i = 1$, and that both T and T_i's are regular. As the row sum of each Markov operator is 1, the largest eigenvalue is 1, since both T and T_i's are regular, the eigenvector of the largest eigenvalue is the all 1 vector. The second largest eigenvalue of T can be upper bounded by

$$\begin{aligned}\lambda(T) &:= \max_{\substack{v\in\mathbb{R}^n, \|v\|=1, \\ v\perp\mathbf{1}}} \|Tv\| \\ &= \max_{\substack{v\in\mathbb{R}^n, \|v\|=1, \\ v\perp\mathbf{1}}} \left\| \sum_{i=1}^{k} \alpha_i T_i \right\| \\ &\leq \sum_{i=1}^{k} \max_{\substack{v\in\mathbb{R}^n, \|v\|=1, \\ v\perp\mathbf{1}}} \|\alpha_i T_i\| = \sum_{i=1}^{k} \alpha_i \lambda(T_i).\end{aligned}$$

In proving the lemma, we repeatedly use the above simple fact to upper bound the eigenvalue.

1. Without loss of generality, we can assume $x = \mathbf{0}$. Let d_L and d_R denote the left and right degree of G_1 respectively. Fix a line ℓ, d_L is the number of cubes containing ℓ and not passing through $\mathbf{0}$. Every point $x \notin \text{span}(\ell, \mathbf{0})$ defines a cube $C = \text{span}(x, \mathbf{0}, \ell)$. Thus, the number of linear cubes containing ℓ equals $d_L = \frac{q^m - q^2}{q^3 - q^2}$, where the denominator is the overcounting factor, the number of points that give the same cube.
   Fix a linear cube C. The right degree is the number of lines in C not passing through the origin which is $\frac{\binom{q^3}{2}}{\binom{q}{2}} - \frac{q^3-1}{q-1}$, where the first term counts all possible lines in C (each two different points define a line, we divide by the double counting) and the second term counts all the lines in C that pass through the origin.
   Let T_1 be the Markov operator associated with a two-step random walk in G_1 starting from $\mathcal{C}_x$. Using Fact 35, in order to bound $\lambda(G_1)$ it is enough to bound the second largest eigenvalue of T_1. Since G_1 is bi-regular, the first eigenvector of T_1 is the all ones vector. For every cube C, the number of two-step walks starting from C is $d_L \cdot d_R$.
   If $\dim\{C_1 \cap C_2\} = 1$, then the two cubes intersection is only on a line. Since both cubes are linear, it means that this line goes through the origin, therefore it doesn't correspond to a vertex on the left side, and there is no walk $C_1 \to \ell \to C_2$, so $(T_1)_{C_1,C_2} = 0$. Of course, the same holds if $\dim\{C_1 \cap C_2\} = 0$.
   If $\dim\{C_1 \cap C_2\} = 2$, there there is a plane going through the origin in both C_1, C_2. The number of walks $C_1 \to \ell \to C_2$ equals the number of lines in this plane that don't contain the origin, $\mathbf{0}$. Each pair of distinct points on the plane correspond to a line, and we divide by the double counting. Therefore the number of lines in a plane equals $\frac{\binom{q^2}{2}}{\binom{q}{2}}$. We subtract from it the number of lines in a plane that contains $\mathbf{0}$, resulting in $\frac{\binom{q^2}{2}}{\binom{q}{2}} - \frac{q^2-1}{q-1} =: \beta$.

If $C_1 = C_2$, then exists a path $C_1 \to \ell \to C_2$ for every line ℓ adjacent to C_1, and there are d_R such lines.
Since T_1 is a Markov operator, we need to normalize the number of paths between C_1, C_2 by dividing in the total number of outgoing paths from C_1, which equals $d_R \cdot d_L$. Therefore,

$$(T_1)_{C_i,C_j} = \begin{cases} \frac{d_R}{d_R \cdot d_L}, & \text{if } C_i = C_j \\ \frac{\beta}{d_R \cdot d_L}, & \text{if } \dim\{C_1 \cap C_2\} = 2 \\ 0, & \text{otherwise} \end{cases} \tag{9}$$

Thus, we can write T_1 as:

$$T_1 = \frac{1}{d_L} I + \frac{\beta}{d_R d_L} \cdot G_{3,2} = \frac{1}{d_L} I + \frac{\beta d'}{d_R d_L} \cdot T_{3,2},$$

where d' is the degree of a vertex in $G_{3,2}$. One can verify that T_1 is indeed a convex combination of two Markov operators I and $T_{3,2}$. Since $G_{3,2}$ is a regular graph, the second eigenvector of $T_{3,2}$ is also orthogonal to $\mathbf{1}$. Hence,

$$\begin{aligned} \lambda(G_1)^2 = \lambda(T_1) &= \max_{\substack{v \in \mathbb{R}^{|\mathcal{C}_x|}, v \perp \mathbf{1} \\ \|v\|=1}} \|T_1 v\| = \max_{\substack{v \in \mathbb{R}^{|\mathcal{C}_x|}, v \perp \mathbf{1} \\ \|v\|=1}} \left\| \left(\frac{1}{d_L} I + \frac{\beta d'}{d_R d_L} \cdot T_{3,2} \right) v \right\| \\ &= \frac{1}{d_L} + \frac{\beta d'}{d_R d_L} \cdot \lambda_1(T_{3,2}). \end{aligned} \tag{10}$$

We now just need to plug in the values of β, d' and $\lambda_1(T_{3,2})$. Using Fact 33, $\lambda_1(T_{3,2})$ is given by the following expression,

$$\lambda_1(T_{3,2}) = \frac{q^2 \begin{bmatrix} 2 \\ 1 \end{bmatrix} \begin{bmatrix} m-4 \\ 1 \end{bmatrix} - \begin{bmatrix} 1 \\ 1 \end{bmatrix}}{q \begin{bmatrix} 2 \\ 1 \end{bmatrix} \begin{bmatrix} m-3 \\ 1 \end{bmatrix}} = (1 + o(1)) \frac{1}{q}.$$

As we have seen before, $d_R = \frac{\binom{q^3}{2}}{\binom{q}{2}} - \frac{q^3-1}{q-1} = (1 + o(1))q^4$, $d_L = \frac{q^m - q^2}{q^3 - q^2} = (1 + o(1))q^{m-3}$ and $\beta = \frac{\binom{q^2}{2}}{\binom{q}{2}} - \frac{q^2-1}{q-1} = (1 + o(1))q^2$. From Fact 33, $d' = (1 + o(1))q^{m-1}$. Thus,

$$\frac{1}{d_L} = (1 + o(1)) \frac{1}{q^{m-3}}, \qquad \frac{\beta d'}{d_R d_L} \lambda_1(T_{3,2}) = (1 + o(1)) \frac{1}{q}$$

Plugging these values in (10) gives $\lambda(G_1) = (1 + o(1)) \frac{1}{\sqrt{q}}$ as required.

2. This bound is implied from a more general Lemma 30 we prove below with $s = 3, k = 1$ and $r = 0$.
3. In this case, it will be easier to bound the eigenvalue of the Markov operator associated with a random walk of length two starting from $\mathbb{F}^m \setminus \ell$. Let T_3 be the Markov operator. Now, the path of length two starting from x looks like $x \to C \to y$. Thus, the cube C contains all points from the affine plane spanned by x and ℓ. Let $p(x, \ell)$ be the affine plane spanned by x and ℓ. We have $\mathbf{Pr}[y \in p(x, \ell)] = \frac{q^2 - q}{q^3 - q} \approx \frac{1}{q}$. If $y \notin p(x, \ell)$ then the distribution of y is uniform in $\mathbb{F}^m \setminus p(x, \ell)$. Thus, we have

$$T_3 = (1 - o(1)) \left(1 - \frac{1}{q}\right) J + (1 + o(1)) \frac{1}{q} \mathcal{N},$$

where J is a Markov operator associated with a complete graph on $\mathbb{F}^m \setminus \ell$, with self loops and $\mathcal{N}$ is an appropriate Markov operator. Thus, we have bound $\lambda(T_3) = (1 + o(1)) \frac{1}{q}$. Since $\lambda(G_3)^2 = \lambda(T_3)$, the bound follows.

4. Proof of this is along the same lines as (3). The Markov operator here (starting a walk from the left side) can be written as

$$T_4 = (1 \pm o(1))\frac{1}{q^3}I + \left((1 \pm o(1))(1 - \frac{1}{q^3})\right) J,$$

where I is an identity matrix. Thus $\lambda(T_4) = (1 \pm o(1))\frac{1}{q^3} = \lambda(G_4)^2$.

5. The proof of this item is also similar to (3), we look on the path of length 2 starting from the left side, i.e $y \to C \to z$, and let T_5 be the Markov operator. Let $\ell(x,y)$ be the line spanned by x, y (where x is the fixed point, $G_5(\mathbb{F}^m \setminus \{x\}, \mathcal{C}_x)$), then $\mathbf{Pr}[z \in \ell(x,y)] = \frac{|\ell(x,y)\setminus\{x\}|}{|C\setminus\{x\}|} = \frac{q-1}{q^3-1} \approx \frac{1}{q^2}$, let $\mathcal{N}$ be the appropriate Markov operator of the event that x, y, z are colinear, then

$$T_5 = (1 - o(1))\left(1 - \frac{1}{q^2}\right) J + (1 + o(1))\frac{1}{q^2}\mathcal{N}.$$

Here J is the Markov operator of the complete graph on $\mathbb{F}^m \setminus \{x\}$. Thus $\lambda(G_5)^2 \approx \frac{1}{q^2}$.

6. Consider a two-step random walk in G_6, $x \to \ell \to y$. If we sample a random line through x then conditioned on $y \neq x$, y is uniformly distributed in $\mathbb{F}^m$. Thus, we can write the Markov operator T associated with this process as:

$$T = \frac{1}{q}I + \left(1 - \frac{1}{q}\right) T',$$

where T' is a Markov operator associated with a random walk on a complete graph on A, without self loops and I is an identity matrix. As $T' = \frac{1}{|A|-1}J - \frac{1}{|A|-1}I$, $\lambda(T') = \frac{1}{q^3-1}$. Thus, $\left|\lambda(T) - \frac{1}{q}\right| \leq \frac{1}{q^3-1}$. The claim follows as $\lambda(G_6)^2 = \lambda(T)$. ◀

Next, we prove Lemma 30. Recall that $\mathcal{A}^s$ denotes set of all s dimensional affine subspaces in $\mathbb{F}^m$. Also, for $r < s$ and for $R \in \mathcal{A}^r$, $\mathcal{A}^s_R \subseteq \mathcal{A}^s$ denotes all those subspaces in $\mathcal{A}^s$ which contains a particular subspace R.

▶ **Lemma 37** (Restatement of Lemma 30). *Let $r \leq k < s \leq \frac{m}{2}$ be integers, and let G be the inclusion graph $G = G(\mathcal{A}^k_R, \mathcal{A}^s_R)$ for an r dimensional subspace R, where $R \neq \emptyset$. Then,*

$$\lambda(G)^2 \leq (1 + o(1)) \cdot q^{-(s-2k+r+1)}.$$

Proof. Fix an r dimensional subspace $R \subseteq \mathbb{F}^m, R \neq \emptyset$ and recall that

$$\mathcal{A}^k_R = \{K \subset \mathbb{F}^m | \dim(K) = k, R \subset K\}.$$

Let $G = G(\mathcal{A}^k_R, \mathcal{A}^s_R)$ be the biregular bipartite inclusion graph and let d_k (resp. d_s) denote the degree of vertex in $\mathcal{A}^k_R$ (resp. $\mathcal{A}^s_R$).

For every $n, t, j \in \mathbb{N}$, let $h(n,t,j)$ be the number of t dimensional subspaces in $\mathbb{F}^n$ that contain a specific dimention j subspace,

$$h(n,t,j) = \frac{(q^n - q^j)\cdots(q^n - q^{t-1})}{(q^t - q^j)\cdots(q^t - q^{t-1})} \approx q^{(n-t)(t-j)}, \tag{11}$$

where $\approx$ denotes equality up to a multiplicative factor $(1 \pm o(1))$, as before. For any fixed j dimensional subspace X, the numerator equals the number of $t - j$ linearly independent points $y_1, y_2, \ldots, y_{t-j}$ in $\mathbb{F}^n$ such that $\dim(\mathtt{span}(X, y_1, y_2, \ldots, y_{t-j})) = t$, whereas for every t dimensional subspace Z, the denominator equals the double counting of Z, i.e the number

of $t-j$ linearly independent points $y_1, y_2, \ldots, y_{t-j}$ such that $\texttt{span}(X, y_1, y_2, \ldots, y_{t-j}) = Z$. We can now bound the number of vertices and the left and right degree in G.

$$\begin{aligned} \left|\mathcal{A}_R^k\right| &= h(m,k,r), & \left|\mathcal{A}_R^s\right| &= h(m,s,r), \\ d_k &= h(m,s,k), & d_s &= h(s,k,r). \end{aligned}$$

Let T be the two-step Markov operator on the bipartite graph G, starting from $\mathcal{A}_R^k$, we want to calculate the entries of T. Let $K_1, K_2 \in \mathcal{A}_R^k$, by definition $(T)_{K_1,K_2}$ is the probability that a two-step random walk will end at K_2, conditioned on it starting from K_1.

Let $r' = \dim(K_1 \cap K_2) \geq r$, in this notation $\dim(K_1 \cup K_2) = 2k - r'$. Any 2 step random walk from K_1 to K_2 looks like $K_1 \to S' \to K_2$ where S' is an s dimentional subspace containing both K_1 and K_2. The number of such S' is exactly $h(m, s, 2k - r')$. Thus, $(T)_{K_1,K_2}$ equals

$$\begin{aligned} (T)_{K_1,K_2} &= \mathbf{Pr}[\text{R.W ends at } K_2 | \text{ R.W starts at } K_1] \\ &= \frac{h(m,s,2k-r')}{d_k \cdot d_s} = \frac{h(m,s,2k-r')}{h(m,s,k) \cdot h(s,k,r)}. \end{aligned} \tag{12}$$

This probability is the same for every $K_1, K_2 \in \mathcal{A}_R^k$ such that $\dim(K_1 \cap K_2) = r'$, so we can denote this value by $p_{r'} = (T)_{K_1,K_2}$. Notice that $p_{r'} \geq p_r$ for every $r' \geq r$.

Let $G_{r'}$ be the graph with vertex set $\mathcal{A}_R^k$, where K_1, K_2 are connected by an edge if $\dim(K_1 \cap K_2) = r'$. We also denote the 0/1 adjacency matrix of graph $G_{r'}$ by $G_{r'}$. With these notations, the 2 step Markov operator T equals

$$T = \sum_{r'=r}^{k} p_{r'} G_{r'}.$$

Notice that this is not a convex combination, $\sum_{r'} p_{r'} \neq 1$, but rather $p_{r'}$ are the entries of T, and $G_{r'}$ are 0/1 matrices.

Let J be the all 1 matrix, we know that $J = \sum_{r'=r}^{k} G_{r'}$. The first matrix in the sum G_r is the only non sparse matrix, since for every subspace $K_1 \in \mathcal{A}_r^k$, almost all other subspaces intersects with K_1 only in R. Therefore we can write $G_r = J - \sum_{r'=r+1}^{k} G_{r'}$, and get

$$T = p_r J + \sum_{r'=r+1}^{k} (p_{r'} - p_r) G_{r'}.$$

Since T is a Markov operator of a regular graph, the all $\mathbf{1}$ vector is the vector with the maximal eigenvalue, which equals 1. Since $G_{r'}$ are also regular graphs, $\mathbf{1}$ is the vector with the maximal eigenvalue, which equals $\deg(G_{r'})$, which is the number of $K' \in \mathcal{A}_R^k$ such that $\dim(K \cap K') = r'$ (as the adjacency matrices are not normalized).

$$\begin{aligned} \deg(G_{r'}) =& h(k,r',r) \cdot \frac{(q^m - q^k) \cdots (q^m - q^{2k-r'-1})}{(q^k - q^{r'}) \cdots (q^k - q^{k-1})} \\ \approx& q^{(k-r')(r'-r)} \cdot q^{(m-k)(k-r')} = q^{(k-r')(m-k+r'-r)} \end{aligned}$$

For every $K \in \mathcal{A}_R^k$, the factor $h(k, r', r)$ is the number of r' dimensional subspace in K that contain R, the second factor is the number of k dimensional subspaces that intersect with K only in a specific r' dimensional subspace.

Let v be the normalized eigenvector of the second eigenvalue of T, this means that $v \perp \mathbf{1}$ and $\|v\| = 1$. Since J is the all 1 matrix, $Jv = 0$. We also know that for every $r' > r$,

$\|G_{r'}v\| \leq \deg(G_{r'})$, as it is true for every vector v.

$$\begin{aligned}\|Tv\| &= \left\| \sum_{r'=r+1}^{k} (p_{r'} - p_r) G_{r'} v \right\| \\ &\leq \sum_{r'=r+1}^{k} (p_{r'} - p_r) \|G_{r'}v\| && \text{(triangle inequality)} \\ &\leq \sum_{r'=r+1}^{k} p_{r'} \deg(G_{r'})\end{aligned}$$

For every r', by using the expression for $p_{r'}$ from (12) and bounds on h from (11) we get that

$$p_{r'} \deg(G_{r'}) \approx p_{r'} q^{(k-r')(m-s+r'-r)} \approx q^{-(r'-r)(s-2k+r')}.$$

Since $r' > r$, $(r'-r)(s-2k+r')$ is minimized when $r' = r+1$ and hence

$$\lambda(T) = \|Tv\| \leq (1+o(1)) \sum_{r'=r+1}^{k} \frac{1}{q^{s-2k+r'}} \leq (1+o(1)) \cdot \frac{1}{q^{s-2k+r+1}}.$$

The lemma statement now follows from the Fact 35. ◀

B Spectral Expansion Properties Proofs

▶ **Lemma 38** (Restatement of Lemma 6). *Let D_1, D_2 as defined in Definition 5. Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, then for every subset $B' \subset B$ of measure $\mu > 0$ and every $E' \subset E$*

$$\left| \mathop{\mathbf{Pr}}_{(a,b)\sim D_1}[(a,b) \in E'] - \mathop{\mathbf{Pr}}_{(a,b)\sim D_2}[(a,b) \in E'] \right| \leq \frac{\lambda(G)}{\sqrt{\mu}}.$$

Where is D_2 returned $\perp$, we treat is as it is not in E'.

Proof. In the proof we represent both probabilities as an inner product, and then use $\lambda(G)$ to bound the difference. Let $M \in \mathbb{R}^{A \times B}$ the adjacency matrix of the graph G, normalized such that $M\mathbf{1} = \mathbf{1}$ (where the first $\mathbf{1}$ is of dimension $|B|$ and the second of dimension $|A|$). We define the matrix M' representing the subset of edges E', $M'_{a,b} = M_{a,b} \cdot (\mathbf{1}_{E'})_{a,b}$.

Starting with the probability of $(a,b) \sim D_1$, the vector $M'\mathbf{1}_{B'}$ satisfies that for every $a \in A$, $(M'\mathbf{1}_{B'})_a = \mathbf{Pr}_{b\in N(a)}[(a,b) \in E', b \in B']$.

$$\begin{aligned}\langle \mathbf{1}, M'\mathbf{1}_{B'} \rangle &= \mathop{\mathbf{E}}_{a\sim A}\left[E_{b\sim N(a)}[\mathbb{I}((a,b) \in E', b \in B')]\right] \\ &= \mathop{\mathbf{Pr}}_{a\sim A, b\sim N(a)}[(a,b) \in E', b \in B'] && \text{(using bi-regularity of } G) \\ &= \mathop{\mathbf{Pr}}_{b\sim B, a\sim N(b)}[(a,b) \in E', b \in B'] \\ &= \mathop{\mathbf{Pr}}_{b\sim B}[b \in B'] \cdot \mathop{\mathbf{Pr}}_{b\sim B, a\sim N(b)}[(a,b) \in E' \mid b \in B'] \\ &= \mu \cdot \mathop{\mathbf{Pr}}_{(a,b)\sim D_1}[(a,b) \in E'].\end{aligned}$$

We now want to represent the second probability as an inner product. We define the vector $P \in [0,1]^A$ as follows, for each $a \in A$:

1. If $N(a) \cap B' = \emptyset$, then $P_a = 0$.
2. Else, $P_a = \mathbf{Pr}_{b \in N(a)}[(a,b) \in E' \mid b \in B']$.

In this notation $\mathbf{Pr}_{(a,b)\sim D_2}[(a,b) \in E'] = \langle \mathbf{1}, P \rangle$.

We now want to find a connection between the inner products. If $P_a \neq 0$, then it defined as the conditional probability, and

$$\mathop{\mathbf{Pr}}_{b\sim N(a)}[b \in B', (a,b) \in E'] = \mathop{\mathbf{Pr}}_{b\sim N(a)}[b \in B'] \mathop{\mathbf{Pr}}_{b\sim N(a)}[(a,b) \in E' \mid b \in B'] = \mathop{\mathbf{Pr}}_{b\sim N(a)}[b \in B'] P_a.$$

If $P_a = 0$ then also $\mathbf{Pr}_{b\sim N(a)}[b \in B', (a,b) \in E'] = 0$, and the above equality still holds. We notice that $(M'\mathbf{1}_{B'})_a = \mathbf{Pr}_{b\in N(a)}[(a,b) \in E', b \in B']$ and $(M\mathbf{1}_{B'})_a = \mathbf{Pr}_{b\in N(a)}[b \in B']$, which means that for every $a \in A$, $(M'\mathbf{1}_{B'})_a = (M\mathbf{1}_{B'})_a P_a$ and

$$\langle M\mathbf{1}_{B'}, P \rangle = \langle \mathbf{1}, M'\mathbf{1}_{B'} \rangle.$$

Therefore we can express the difference between the two probabilities as

$$\begin{aligned}
\left| \mathop{\mathbf{Pr}}_{(a,b)\sim D_1}[(a,b) \in E'] - \mathop{\mathbf{Pr}}_{(a,b)\sim D_2}[(a,b) \in E'] \right| &= \left| \frac{1}{\mu} \langle \mathbf{1}, M'\mathbf{1}_{B'} \rangle - \langle \mathbf{1}, P \rangle \right| \\
&= \left| \frac{1}{\mu} \langle M\mathbf{1}_{B'}, P \rangle - \langle \mathbf{1}, P \rangle \right| \\
&= \frac{1}{\mu} \left| \langle M\mathbf{1}_{B'} - \mu\mathbf{1}, P \rangle \right| \\
&\leq \frac{1}{\mu} \left\| M\mathbf{1}_{B'} - \mu\mathbf{1} \right\| \left\| P \right\| \quad \text{(By Cauchy Swartz)}
\end{aligned} \tag{13}$$

Since P is a vector in $[0,1]$ and the inner product we use is expectation, $\|P\| \leq 1$. In order to finish the proof we need to bound the size of the vector

$$M\mathbf{1}_{B'} - \mu\mathbf{1} = M\mathbf{1}_{B'} - \mu M\mathbf{1} = M(\mathbf{1}_{B'} - \mu\mathbf{1}).$$

We notice that $\mathbf{1}_{B'}$ is a $\{0,1\}$ vector of measure μ, so $\langle \mathbf{1}_{B'}, \mathbf{1} \rangle = \langle \mathbf{1}_{B'}, \mathbf{1}_{B'} \rangle = \mu$, and $(\mathbf{1}_{B'} - \mu\mathbf{1}) \perp \mathbf{1}_B$. By the definition of $\lambda(G)$, this means that

$$\|M(\mathbf{1}_{B'} - \mu\mathbf{1})\| \leq \lambda(G) \|\mathbf{1}_{B'} - \mu\mathbf{1}\| \leq \lambda\sqrt{\mu}.$$

We substitute the norm of the vector in equation (13) and we are done. ◀

▶ **Lemma 39** (Restatement of Lemma 8). *Let D_3, D_4 as defined in Definition 7. Let $G = (A \cup B, E)$ be a bi-regular bipartite graph, such that every two distinct $b_1, b_2 \in B$ have exactly the same number of common neighbors (i.e for all distinct $b_1, b_2 \in B$, $|N(b_1) \cap N(b_2)|$ is the same), and this number is non-zero. Then for every subset $B' \subset B$ of measure $\mu > 0$ and every $E' \subset E$*

$$\left| \mathop{\mathbf{Pr}}_{a,b_1,b_2\sim D_3}[(a,b_1)(a,b_2) \in E'] - \mathop{\mathbf{Pr}}_{a,b_1,b_2\sim D_4}[(a,b_1)(a,b_2) \in E'] \right| \leq \frac{2\lambda(G)}{\mu} + \frac{1}{\mu^2 d_A} + \frac{1}{\mu^2 |B|}$$

Where is D_4 returned $\perp$, we treat is as it is not in E' and d_A is the degree on A side.

Proof. This proof is similar in spirit to the proof of Lemma 6, with more complication since the event contains two edges instead of a single one.

Let $M \in \mathbb{R}^{A \times B}$ the adjacency matrix of the graph G, normalized such that $M\mathbf{1} = \mathbf{1}$. We denote by M' the matrix that represents the edges in E', i.e for each $a \in A, b \in B$, $M'_{a,b} = M_{a,b} \cdot (\mathbf{1}_{E'})_{a,b}$.

Starting from D_3, we first write the conditional probability

$$\begin{aligned}\Pr_{\substack{b_1,b_2\\ a\sim N(b_1)\cap N(b_2)}}&[b_1,b_2\in B',(a,b_1),(a,b_2)\in E']\\ &=\Pr_{b_1,b_2}[b_1,b_2\in B']\Pr_{a,b_1,b_2\sim D_3}[(a,b_1),(a,b_2)\in E']\\ &=\mu^2\Pr_{a,b_1,b_2\sim D_3}[(a,b_1),(a,b_2)\in E'].\end{aligned}\tag{14}$$

We want to express the left side as an inner product, we notice that for each $a\in A$:

$$(M'\mathbf{1}_{B'})_a=\mathop{\mathbf{E}}_{b\sim N(a)}[\mathbb{I}(b\in B',(a,b)\in E')].$$

Therefore the inner product satisfies

$$\begin{aligned}\langle M'\mathbf{1}_{B'},M'\mathbf{1}_{B'}\rangle&=\mathop{\mathbf{E}}_{a\sim A}\left[\mathop{\mathbf{E}}_{b_1,b_2\sim N(a)}[\mathbb{I}(b_1,b_2\in B',(a,b_1)(a,b_2)\in E')]\right]\\ &=\Pr_{a\sim A,b_1,b_2\sim N(a)}[b_1,b_2\in B',(a,b_1)(a,b_2)\in E']\end{aligned}\tag{15}$$

Since each two $b_1,b_2\in B$ has the same number of neighbors,

$$\Pr_{\substack{a\sim A\\ b_1\neq b_2\sim N(a)}}[b_1,b_2\in B',(a,b_1)(a,b_2)\in E']=\Pr_{\substack{b_1\neq b_2\sim B\\ a\sim N(b_1)\cap N(b_2)}}[b_1,b_2\in B',(a,b_1)(a,b_2)\in E'].$$

We want to switch the expression in (15) by the one is (14), we know that they are equal when $b_1\neq b_2$. But the probability of $b_1=b_2$ is different between the two cases, it is $\frac{1}{d_A}$ if we pick neighbors of a and $\frac{1}{|B|}$ if we pick two random vertices in B. If we add the probability of $b_1=b_2$ as an error, we get that

$$\left|\mu^2\Pr_{a,b_1,b_2\sim D_3}[(a,b_1)(a,b_2)\in E']-\langle M'\mathbf{1}_{B'},M'\mathbf{1}_{B'}\rangle\right|\leq\frac{1}{d_A}+\frac{1}{|B|}\tag{16}$$

Now we want to express the probability of $a,b_1,b_2\sim D_4$ as an inner product. In order to do that, we define the vector P, for every $a\in A$

1. If $N(a)\cap B'=\emptyset$, then $P_a=0$.
2. Else, $P_a=\mathbf{Pr}_{b_1,b_2\sim N(a)}[(a,b_1)(a,b_2)\in E'\mid b_1,b_2\in B']$.

The vector P is defined such that

$$\Pr_{a,b_1,b_2\sim D_4}[(a,b_1)(a,b_2)\in E']=\mathop{\mathbf{E}}_{a}[P_a]=\langle\mathbf{1},P\rangle.$$

We want to find a connection between this expression and the expression representing the probability $\mathbf{Pr}_{a,b_1,b_2\sim D_3}[(a,b_1)(a,b_2)\in E']$.

We use (16) and the triangle inequality to bound the difference between the two target probabilities

$$\begin{aligned}&\left|\Pr_{a,b_1,b_2\sim D_3}[(a,b_1)(a,b_2)\in E']-\Pr_{a,b_1,b_2\sim D_4}[(a,b_1)(a,b_2)\in E']\right|\\ &\quad\leq\left|\frac{1}{\mu^2}\langle M'\mathbf{1}_{B'},M'\mathbf{1}_{B'}\rangle-\langle\mathbf{1},P\rangle\right|+\frac{1}{\mu^2 d_A}+\frac{1}{\mu^2|B|}\end{aligned}\tag{17}$$

We now need to bound the expression in (17), in order to do that, we will first show that

$$\langle M'\mathbf{1}_{B'},M'\mathbf{1}_{B'}\rangle=\Pr_{a\sim A,b_1,b_2\sim N(a)}[(a_1,b)(a_2,b)\in E',b_1,b_2\in B']=\mathop{\mathbf{E}}_{a}[P_a(M\mathbf{1}_{B'})_a^2].\tag{18}$$

We notice that for a such that $P_a > 0$, it equals the conditional probability and

$$\mathop{\mathbf{Pr}}_{b_1,b_2\sim N(a)}[(a_1,b)(a_2,b)\in E', b_1,b_2\in B'] = \mathop{\mathbf{Pr}}_{b_1,b_2\sim N(a)}[b_1,b_2\in B']P_a.$$

If a is such that $P_a = 0$, then $\mathbf{Pr}_{b_1,b_2\sim N(a)}[(a_1,b)(a_2,b)\in E', b_1,b_2\in B'] = 0$ and the above equality still holds. We further notice that

$$(M\mathbf{1}_{B'})_a = \mathop{\mathbf{E}}_{b\sim N(a)}[\mathbb{I}(b\in B')].$$

If we substitute $\mathbf{Pr}_{b_1,b_2\sim N(a)}[b_1,b_2\in B']$ in $(M\mathbf{1}_{B'})_a^2$, we get (18).

In order to finish the proof, we upper bound

$$\left|\frac{1}{\mu^2}\langle M'\mathbf{1}_{B'}, M'\mathbf{1}_{B'}\rangle - \langle \mathbf{1}, P\rangle\right| = \left|\mathop{\mathbf{E}}_a\left[\frac{1}{\mu^2}P_a(M\mathbf{1}_{B'})_a^2 - P_a\right]\right| = \frac{1}{\mu^2}\left|\mathop{\mathbf{E}}_a[P_a((M\mathbf{1}_{B'})_a^2-\mu^2)]\right|.$$

We now upper bound the expectation as follows,

$$\begin{aligned}
\mathop{\mathbf{E}}_a[P_a((M\mathbf{1}_{B'})_a^2-\mu^2)] &= \mathop{\mathbf{E}}_a[P_a((M\mathbf{1}_{B'})_a-\mu)((M\mathbf{1}_{B'})_a+\mu)] \\
&\le \max_a\{|P_a|\}\mathop{\mathbf{E}}_a[|((M\mathbf{1}_{B'})_a-\mu)((M\mathbf{1}_{B'})_a+\mu)|] \\
&\le \|M\mathbf{1}_{B'}-\mu\mathbf{1}\|\,\|M\mathbf{1}_{B'}+\mu\mathbf{1}\| \qquad (19)\\
&\le \lambda\sqrt{\mu}\sqrt{4\mu}, \qquad (20)
\end{aligned}$$

where (19) is due to Cauchy-Schwarz inequality and using $|P_a|\le 1$. In (20), we bound $\|M\mathbf{1}_{B'}-\mu\mathbf{1}\|$ like in the previous proof,

$$\|M\mathbf{1}_{B'}-\mu\mathbf{1}\| = \|M\mathbf{1}_{B'}-\mu M\mathbf{1}\| = \|M(\mathbf{1}_{B'}-\mu\mathbf{1})\| \le \lambda\|\mathbf{1}_{B'}\| \le \lambda\sqrt{\mu}.$$

Finally, we bound $\|M\mathbf{1}_{B'}+\mu\mathbf{1}\|$:

$$\begin{aligned}
\|M\mathbf{1}_{B'}+\mu\mathbf{1}\|^2 &= \langle M\mathbf{1}_{B'}+\mu\mathbf{1}, M\mathbf{1}_{B'}+\mu\mathbf{1}\rangle \\
&= \langle M\mathbf{1}_{B'}, M\mathbf{1}_{B'}\rangle + 2\langle M\mathbf{1}_{B'},\mu\mathbf{1}\rangle + \langle\mu\mathbf{1},\mu\mathbf{1}\rangle \\
&\le \|\mathbf{1}_{B'}\|^2 + 2\mu + \mu^2\|\mathbf{1}\|^2 \\
&\le \mu + 2\mu + \mu^2 \le 4\mu.
\end{aligned}$$

◀

C Rubinfeld-Sudan Characterization

In this section, we present a proof of Theorem 21. The proof uses the following fact from [13]:

▶ **Fact 40.** *Let $f:\mathbb{F}^m\to\mathbb{F}$ be a function, and let $N_{y,h} = \{y+ih \mid i\in\{0,\dots,d+1\}\}$. f is degree d iff it satisfies the following identity for all y and h:*

$$\sum_{i=0}^{d+1}\alpha_i f(y+ih) = 0,$$

where $\alpha_i = \binom{d+1}{i}(-1)^{i+1}$.

Throughout this section we let $\alpha_i = \binom{d+1}{i}(-1)^{i+1}$ as in the above fact.

▶ **Theorem 41** (Restatement of Theorem 21). *Let $f : \mathbb{F}^m \to \mathbb{F}$ be a function, and let $N_{y,h} = \{y + ih \mid i \in \{0, \ldots, d+1\}\}$, if f satisfies*

$$\Pr_{y,h \in \mathbb{F}^m}[\exists \deg d \text{ polynomial } p \textbf{ s.t. } p_{|_{N_{y,h}}} = f_{|_{N_{y,h}}}] \geq 1 - \delta, \tag{21}$$

for $\delta \leq \frac{1}{2(d+2)^2}$, then there exists a degree d polynomial g such that $f \overset{2\delta}{\approx} g$.

Proof. Define a function $g : \mathbb{F}^m \to \mathbb{F}$ to be $g(y) = \mathtt{maj}_{h \in \mathbb{F}^m}\{\sum_{i=1}^{d+1} \alpha_i f(y + ih)\}$ breaking the ties arbitrarily. Next we argue that g is very close to f and g itself is a degree d function.

To see that g is $(1 - 2\delta)$ close to f, consider the set of all y for which $\mathbf{Pr}_h[f(y) = \sum_{i=1}^{d+1} \alpha_i f(y + ih)] > 1/2$. For all these y, $f(y) = g(y)$ as g was the majority vote. It is easy to see that fraction of y for which the probability is at most $1/2$ is at most 2δ as otherwise it will contradict the hypothesis (21). The rest of the proof will be proving the following two claims.

▶ **Claim 42.** *For all $y \in \mathbb{F}^m$, $\mathbf{Pr}_h[g(y) = \sum_{i=1}^{d+1} \alpha_i f(y + ih)] \geq 1 - 2(d+1)\delta$.*

▶ **Claim 43.** *For all y and h in $\mathbb{F}^m$, we have $\sum_{i=0}^{d+1} \alpha_i g(y + ih) = 0$.*

Claim 43 and Fact 40 imply that g is in fact a degree d function and hence the theorem follows. We now proceed with proving these two claims.

Proof of Claim 42: We will show that for all $y \in \mathbb{F}^m$,

$$\Pr_{h_1,h_2}\left[\sum_{i=1}^{d+1} \alpha_i f(y + ih_1) = \sum_{j=1}^{d+1} \alpha_j f(y + jh_2)\right] \geq 1 - 2(d+1)\delta. \tag{22}$$

Note that this is enough to prove the claim. To see this, let $p_a = \mathbf{Pr}_h[\sum_{i=1}^{d+1} \alpha_i f(y + ih) = a]$ for $a \in \mathbb{F}$. Then (22) becomes $\sum_{a \in \mathbb{F}} p_a^2 \geq 1 - 2(d+1)\delta$. Since $g(y)$ was the majority vote, we have $\mathbf{Pr}_h[g(y) = \sum_{i=1}^{d+1} \alpha_i f(y + ih)] = \max_{a \in \mathbb{F}} p_a \geq \sum_{a \in \mathbb{F}} p_a^2 \geq 1 - 2(d+1)\delta$.

To prove (22), consider the following $(d+2) \times (d+2)$ matrix Z with $(i,j)^{th}$ entry $Z_{i,j} = \alpha_i \alpha_j f(y + ih_1 + jh_2)$, for $i, j \in \{0, \ldots, d+1\}$.

$$Z = \begin{bmatrix} f(y) & \ldots & \alpha_0\alpha_j f(y + jh_2) & \ldots \\ \vdots & \ddots & \vdots & \ddots \\ \alpha_i\alpha_0 f(y + ih_1) & \ldots & \alpha_i\alpha_j f(y + ih_1 + jh_2) & \ldots \\ \vdots & \ddots & \vdots & \ddots \end{bmatrix}$$

If $h_1 \in \mathbb{F}^m$ u.a.r then for any $i \in \{1, 2, \ldots, d+1\}$, ih_1 is distributed uniformly in $\mathbb{F}^m$. Same is true for h_2 and jh_2. Consider the following events:

- For every $i \in \{1, 2, \ldots, d+1\}$, R_i be the event that the sum of the i'th row is *zero*, i.e $\sum_{j=0}^{d+1} Z_{i,j} = 0$.
- For every $j \in \{1, 2, \ldots, d+1\}$, C_j be the event that sum of the j'th column is *zero*, i.e $\sum_{i=0}^{d+1} Z_{i,j} = 0$.

Note that R_i, C_j are not defined for the first row and column ($i = 0$ and $j = 0$). Using the hypothesis (21) of the theorem and Fact 40, we have

$$\Pr_{h_1,h_2}[R_i] \geq 1 - \delta, \qquad \forall i \in \{1, 2, \ldots, d+1\}$$

$$\Pr_{h_1,h_2}[C_j] \geq 1 - \delta, \qquad \forall j \in \{1, 2, \ldots, d+1\}$$

The event in (22) is same as $\sum_{i=1}^{d+1} Z_{i,0} = \sum_{j=1}^{d+1} Z_{0,j}$ (note that the sums don't include the first element, $Z_{0,0}$). If all the above events R_i, C_j happen then $\sum_{i=1}^{d+1} Z_{i,0} = \sum_{j=1}^{d+1} Z_{0,j} = -\sum_{i,j=1}^{d+1} Z_{i,j}$. By using union bound we get $\mathbf{Pr}[\wedge_{i=1}^{d+1} R_i \wedge_{j=1}^{d+1} C_j] \geq 1 - 2(d+1)\delta$ which implies (22).

Proof of Claim 43: In this case, consider the following $(d+2) \times (d+2)$ matrix Y whose $(i,j)^{th}$ entry is $Y_{i,j} = \alpha_i \alpha_j f(y + ih + j(h_1 + ih_2))$ except when $j = 0$. When $j = 0$, $Y_{i,0} = \alpha_i \alpha_0 g(y + ih)$.

$$Y = \begin{bmatrix} \alpha_0\alpha_0 g(y) & \dots & \alpha_0\alpha_j f(y + jh_1) & \dots \\ \vdots & \ddots & \vdots & \ddots \\ \alpha_i\alpha_0 g(y + ih) & \dots & \alpha_i\alpha_j f(y + ih + j(h_1 + ih_2)) & \dots \\ \vdots & \ddots & \vdots & \ddots \end{bmatrix}$$

Define the following set of events:

- For $i \in \{0, 1, \dots, d+1\}$, R_i be the event that the sum of all elements from row i is *zero*, i.e $\sum_{i=0}^{d+1} Y_{i,j} = 0$.
- For $j \in \{0, 1, \dots, d+1\}$, C_j be the event that the sum of all elements from column j is *zero*, i.e $\sum_{j=0}^{d+1} Y_{i,j} = 0$.

Let h_1, h_2 are independent and distributed u.a.r in $\mathbb{F}^m$. As the event C_0 is independent of h_1 and h_2, in order to prove the claim it is enough to show that $\mathbf{Pr}_{h_1,h_2}[C_0] > 0$.

For each row $i \in \{0, 1, 2, \dots, d+1\}$ we apply Claim 42 with $y' = y + ih$ and $h' = h_1 + ih_2$, and get $\mathbf{Pr}_{h_1,h_2}[\neg R_i] \leq 2(d+1)\delta$ (note that $\alpha_0 = -1$). If h_1, h_2 are independent and distributed u.a.r in $\mathbb{F}^m$ then so are $(y + jh_1)$ and $(h + h_2)$. Therefore, using the hypothesis (21) of the theorem and Fact 40, we have for all columns except $j = 0$, $\mathbf{Pr}_{h_1,h_2}[\neg C_j] \leq \delta$. Using union bound, we get

$$\mathop{\mathbf{Pr}}_{h_1,h_2}\left[\bigwedge_{i=0}^{d+1} R_i \bigwedge_{j=1}^{d+1} C_j\right] \geq 1 - 2(d+1)(d+2)\delta + (d+1)\delta > 0.$$

The claim now follows using the observation that the event C_0 is implied by the event $\wedge_{i=0}^{d+1} R_i \wedge_{j=1}^{d+1} C_j$. To see this, the event $\wedge_{i=0}^{d+1} R_i$ implies that the sum of all entries in Y is *zero* whereas $\wedge_{j=1}^{d+1} C_j$ implies that the sum of all elements from the submatrix $(Y_{i,j})_{j=1}^{d+1}$ is *zero*. Hence, if both these events happen then the sum of all elements from column 0 must be *zero*. ◀

On the Power of Learning from k-Wise Queries

Vitaly Feldman[1] **and Badih Ghazi**[*2]

Abstract

Several well-studied models of access to data samples, including statistical queries, local differential privacy and low-communication algorithms rely on queries that provide information about a function of a single sample. (For example, a statistical query (SQ) gives an estimate of $\mathbb{E}_{x\sim D}[q(x)]$ for any choice of the query function $q : X \to \mathbb{R}$, where D is an unknown data distribution.) Yet some data analysis algorithms rely on properties of functions that depend on multiple samples. Such algorithms would be naturally implemented using k-wise queries each of which is specified by a function $q : X^k \to \mathbb{R}$. Hence it is natural to ask whether algorithms using k-wise queries can solve learning problems more efficiently and by how much.

Blum, Kalai, Wasserman [9] showed that for any weak PAC learning problem over a fixed distribution, the complexity of learning with k-wise SQs is smaller than the (unary) SQ complexity by a factor of at most 2^k. We show that for more general problems over distributions the picture is substantially richer. For every k, the complexity of distribution-independent PAC learning with k-wise queries can be exponentially larger than learning with $(k+1)$-wise queries. We then give two approaches for simulating a k-wise query using unary queries. The first approach exploits the structure of the problem that needs to be solved. It generalizes and strengthens (exponentially) the results of Blum et al. [9]. It allows us to derive strong lower bounds for learning DNF formulas and stochastic constraint satisfaction problems that hold against algorithms using k-wise queries. The second approach exploits the k-party communication complexity of the k-wise query function.

1 Introduction

In this paper, we consider several well-studied models of learning from i.i.d. samples that restrict the algorithm's access to samples to evaluation of functions of an individual sample. The primary model of interest is the statistical query model introduced by Kearns [31] as a restriction of Valiant's PAC learning model [39]. The SQ model allows the learning algorithm to access the data only via *statistical queries*, which are estimates of the expectation of any function of labeled examples with respect to the input distribution D. More precisely, if the domain of the functions is Z, then a statistical query is specified by a function

$\phi : Z \times \{\pm 1\} \to [-1, 1]$ and by a tolerance parameter τ. Given ϕ and τ, the statistical query oracle returns a value v which satisfies $|v - \mathbb{E}_{(z,b)\sim D}[\phi(z, b)]| \leq \tau$.

The SQ model is known to be closely-related to several other models and concepts: linear statistical functionals [41], learning with a distance oracle [5], approximate counting (or linear) queries extensively studied in differential privacy (e.g., [16, 7, 20, 34]), local differential privacy [30], evolvability [40, 23], and algorithms that extract a small amount of information from each sample [4, 26, 28, 36]. This allows to easily extend the discussion in the context of the SQ model to these related models and we will formally state several such corollaries.

Most standard algorithmic approaches used in learning theory are known to be implementable using SQs (e.g., [8, 17, 7, 11, 28, 3, 27]) leading to numerous theoretical (e.g., [2, 14, 19]) and practical (e.g., [11, 35, 38, 18]) applications. SQ algorithms have also been recently studied outside the context of learning theory [26, 28, 27]. In this case we denote the domain of data samples by X.

Another reason for the study of SQ algorithms is that it is possible to prove information-theoretic lower bounds on the complexity of any SQ algorithm that solves a given problem. Given that a large number of algorithmic approaches to problems defined over data sampled i.i.d. from some distribution can be implemented using statistical queries, this provides a strong and unconditional evidence of the problem's hardness. For a number of central problems in learning theory and complexity theory, unconditional lower bounds for SQ algorithms are known that closely match the known *computational* complexity upper bounds for those problems (*e.g.* [6, 26, 28, 12, 15]).

A natural strengthening of the SQ model (and other related models) is to allow function over k-tuples of samples instead of a single sample. That is, for a k-ary query function $\phi : X^k \to [-1, 1]$, the algorithm can obtain an estimate of $\mathbb{E}_{x_1,\ldots,x_k\sim D}[\phi(x_1, \ldots, x_k)]$. It can be seen as interpolating between the power of algorithms that can see all the samples at once and those that process a single sample at a time. While most algorithms can be implemented using standard unary queries, some algorithms are known to require such more powerful queries. The most well-known example is Gaussian elimination over $\mathbb{F}_2^n$ that is used for learning parity functions. Standard hardness amplification techniques rely on mapping examples of a function $f(z)$ to examples of a function $g(f(z_1), \ldots, f(z_k))$ (for example [10, 22]). Implementing such reduction requires k-wise queries and, consequently, to obtain a lower bound for solving an amplified problem with unary queries one needs a lower bound against solving the original problem with k-wise queries. A simple example of 2-wise statistical query is collision probability $\Pr_{x_1,x_2\sim D}[x_1 = x_2]$ that is used in several distribution property testing algorithms.

1.1 Previous work

Blum, Kalai and Wasserman [9] introduced and studied the power of k-wise SQs in the context of weak *distribution-specific* PAC learning: that is the learning algorithm observes pairs (z, b), where z is chosen randomly from some fixed and known distribution P over Z and $b = f(z)$ for some unknown function f from a class of functions $\mathcal{C}$. They showed that if a class of functions $\mathcal{C}$ can be learned with error $1/2 - \lambda$ relative to distribution P using q k-wise SQs of tolerance τ then it can be learned with error $\max\{1/2 - \lambda, 1/2 - \tau/2^k\}$ using $O(q \cdot 2^k)$ unary SQs of tolerance $\tau/2^k$.

More recently, Steinhardt et al. [36] considered k-wise queries in the b-bit sampling model in which for any query function $\phi : X^k \to \{0, 1\}^b$ an algorithm get the value $\phi(x_1, \ldots, x_k)$ for $x_1, \ldots, x_k$ drawn randomly and independently from D (it is referred to as one-way communication model in their work). They give a general technique for proving lower bounds on the number of such queries that are required to solve a given problem.

1.2 Our results

In this work, we study the relationship between the power of k-wise queries and unary queries for arbitrary problems in which the input is determined by some unknown input distribution D that belongs a (known) family of distributions $\mathcal{D}$ over domain X.

1.2.1 Separation for distribution-independent learning

We first demonstrate that for distribution-independent PAC learning $(k+1)$-wise queries are exponentially stronger than k-wise queries. We say that the k-wise SQ complexity of a certain problem is m if m is the smallest such that there exists an algorithm that solves the problem using m k-wise SQs of tolerance $1/m$.

▶ **Theorem 1.** *(Informal) For every positive integer k and any prime number p, there is a concept class $\mathcal{C}$ of Boolean functions defined over a domain of size p^{k+1} such that the $(k+1)$-wise SQ complexity of distribution-independent PAC learning $\mathcal{C}$ with is $O_k(\log p)$ whereas the k-wise SQ complexity of distribution-independent PAC learning of $\mathcal{C}$ is $\Omega_k(p^{1/4})$.*

The class of functions we use consists of all indicator functions of k-dimensional affine subspaces of $\mathbb{F}_p^{k+1}$. Our lower bound is a generalization of the lower bound for unary SQs in [25] (that corresponds to $k=1$ case of the lower bound). A simple but important observation that allows us to easily adapt the techniques from earlier works on SQs to the k-wise case is that a k-wise SQ for an input distribution $D \in \mathcal{D}$ are equivalent to unary SQ for a product distribution D^k.

The upper bound relies on the ability to find the affine subspace given $k+1$ positively labeled and linearly independent points in $\mathbb{F}_p^{k+1}$. Unfortunately, for general distributions the probability of observing such a set of points can be arbitrarily small. Nevertheless, we argue that there will exist a unique lower-dimensional affine subspace that contains enough probability mass of all the positive points in this case. This upper bound essentially implies that given k-wise queries one can solve problems that require Gaussian elimination over a system of k equations.

1.2.2 Reduction for flat $\mathcal{D}$

The separation in Theorem 1 relies on using an unrestricted class of distributions $\mathcal{D}$. We now prove that if $\mathcal{D}$ is "flat" relative to some "central" distribution $\bar{D}$ then one can upper bound the power of k-wise queries in terms of unary queries.

▶ **Definition 1.1** (Flat class of distributions)**.** *Let $\mathcal{D}$ be a set of distributions over X, and $\bar{D}$ a distribution over X. For $\gamma \geq 1$ we say that $\mathcal{D}$ is γ-flat if there exists some distribution $\bar{D}$ over X such that for all $D \in \mathcal{D}$ and all measurable subsets $E \subseteq X$, we have that $\Pr_{x\sim D}[x \in E] \leq \gamma \cdot \Pr_{x\sim \bar{D}}[x \in E]$.*

We now state our upper bound for flat classes of distributions, where we use $\mathsf{STAT}_D^{(k)}(\tau)$ to refer to the oracle that answers k-wise SQs for D with tolerance τ.

▶ **Theorem 2.** *Let $\gamma \geq 1$, $\tau > 0$ and k be any positive integer. Let X be a domain and $\mathcal{D}$ a γ-flat class of distributions over X. There exists a randomized algorithm that given any $\delta > 0$ and a k-ary function $\phi : X^k \to [-1,1]$ estimates $D^k[\phi]$ within τ for every (unknown) $D \in \mathcal{D}$ with success probability at least $1-\delta$ using*

$$\tilde{O}\left(\frac{\gamma^{k-1}\cdot k^3}{\tau^3}\cdot \log(1/\delta)\right)$$

queries to $\mathsf{STAT}_D^{(1)}(\tau/(6 \cdot k))$.

To prove this result, we use a recent general characterization of SQ complexity [25]. This characterization reduces the problem of estimating $D^k[\phi]$ to the problem of distinguishing between D^k and D_1^k for every $D \in \mathcal{D}$ and some fixed D_1. We show that when solving this problem, any k-wise query can be replaced by a randomly chosen set of unary queries. Finding these queries requires drawing samples from D^{k-1}. As we do not know D, we use $\bar{D}$ instead incurring the γ^{k-1} overhead in sampling. In Section 4 we show that weaker notions of "flatness" based on different notions of divergence between distributions can also be used in this reduction.

It is easy to see that, when PAC learning $\mathcal{C}$ with respect to a fixed distribution P over Z, the set of input distributions is 2-flat (relative to the distribution that is equal to P on Z and gives equal weight $1/2$ to each label). Therefore, our result generalizes the results in [9]. More importantly, the tolerance in our upper bound scales linearly with k rather than exponentially (namely, $\tau/2^k$).

This result can be used to obtain lower bounds against k-wise SQs algorithms from lower bounds against unary SQ algorithms. In particular, it can be used to rule out reductions that require looking at k points of the original problem instance to obtain each point of the new problem instance. As an application, we obtain exponential lower bounds for solving constraint stochastic satisfaction problems and DNF learning by k-wise SQ algorithm with $k = n^{1-\alpha}$ for any constant $\alpha > 0$ from lower bounds for CSPs given in [28]. We state the result for learning DNF here. Definitions and the lower bound for CSPs can be found in Section 4.3.

▶ **Theorem 3.** *For any constant $\alpha > 0$ (independent of n), there exists a constant $\beta > 0$ such that any algorithm that learns DNF formulas of size n with error $< 1/2 - n^{-\beta \log n}$ and success probability at least $2/3$ requires at least $2^{n^{1-\alpha}}$ calls to $\mathsf{STAT}_D^{(n^{1-\alpha})}(n^{-\beta \log n})$.*

This lower bound is based on a simple and direct reduction from solving the stochastic CSP that arises in Goldreich's proposed PRG [29] to learning DNF that is of independent interest (see Lemma 15). For comparison, the standard SQ lower bound for learning polynomial size DNF [6] relies on hardness of learning parities of size $\log n$ over the uniform distribution. Yet, parities of size $\log n$ can be easily learned from $(\log^2 n)$-wise statistical queries (since solving a system of $\log^2 n$ linear equations will uniquely identify a $\log n$-sparse parity function). Hence our lower bound holds against qualitatively stronger algorithms. Our lower bound is also exponential in the number of queries whereas the known argument implies only a quasipolynomial lower bound[1].

1.2.3 Reduction for low-communication queries

Finally, we point out that k-wise queries that require little information about each of the inputs can also be simulated using unary queries. This result is a simple corollary of the recent work of Steinhardt et al. [36] who show that any computation that extracts at most b bits from each of the samples (not necessarily at once) can be simulated using unary SQs.

▶ **Theorem 4.** *Let $\phi : X^k \to \{\pm 1\}$ be a function, and assume that ϕ has k-party public-coin randomized communication complexity of b bits per party with success probability $2/3$. Then,*

[1] We remark that an exponential lower bound on the number of queries has not been previously stated even for unary SQs. The unary version can be derived from known results as explained in Section 4.3.

there exists a randomized algorithm that, with probability at least $1-\delta$*, estimates* $\mathbb{E}_{x\sim D^k}[\phi(x)]$ *within* τ *using* $O(b\cdot k\cdot\log(1/\delta)/\tau^2)$ *queries to* $\mathsf{STAT}_D^{(1)}(\tau')$ *for some* $\tau'=\tau^{O(b)}/k$.

As a simple application of Theorem 4, we show a unary SQ algorithm that estimates the collision probability of an unknown distribution D within τ using $1/\tau^2$ queries $\mathsf{STAT}_D^{(1)}(\tau^{O(1)})$. The details appear in Section 5.

1.2.4 Corollaries for related models

Our separation result and reductions imply similar results for k-wise versions of two well-studied learning models: local differential privacy and the b-bit sampling model.

Local differentially private algorithms [30] (also referred to as randomized response) are differentially private algorithms in which each sample goes through a differentially private transformation chosen by the analyst. This model is the focus of recent privacy preserving industrial applications by Google [21] and Apple. We define a k-wise version of this model in which analyst's differentially private transformations are applied to k-tuples of samples. This model interpolates naturally between the usual (or global) differential privacy and the local model.

Kasiviswanathan et al. [30] showed that a concept class is learnable by a local differentially private algorithm if and only if it is learnable in the SQ model. Hence up to polynomial factors the models are equivalent (naturally, such polynomial factors are important for applications but here we focus only on the high-level relationships between the models). This result also implies that k-local differentially private algorithms (formally defined in Section 6.1) are equivalent to k-wise SQ algorithms (up to a polynomial blow-up in the complexity). Theorem 1 then implies an exponential separation between k-wise and $(k+1)$-wise local differentially private algorithms (see Corollary 21 for details). It can be seen as a substantial strengthening of a separation between the local model and the global one also given in [30]. The reductions in Theorem 2 and Theorem 4 imply two approaches for simulating k-local differentially private algorithms using 1-local algorithms.

The SQ model is also known to be equivalent (up to a factor polynomial in 2^b) to the b-bit sampling model introduced by Ben-David and Dichterman [4] and studied more recently in [26, 28, 43, 37, 36]. Lower bounds for the k-wise version of this model are given in [43, 36]. Our results can be easily translated to this model as well. We provide additional details in Section 6.

2 Preliminaries

For any distribution D over a domain X and any positive integer k, we denote by D^k the distribution over X^k obtained by drawing k i.i.d. samples from D. For a distribution D over a domain X and a function $\phi: X\to\mathbb{R}$, we denote $D[\phi]\doteq\mathbb{E}_{x\sim D}[\phi(x)]$.

Next, we formally define the k-wise SQ oracle.

▶ **Definition 2.1.** *Let* D *be a distribution over a domain* X *and* $\tau>0$*. A* k*-wise statistical query oracle* $\mathsf{STAT}_D^{(k)}(\tau)$ *is an oracle that given as input any function* $\phi: X^k\to[-1,+1]$*, returns some value* v *such that* $|v-\mathbb{E}_{x\sim D^k}[\phi(x)]|\le\tau$.

We say that a k-wise SQ algorithm is given access to $\mathsf{STAT}^{(k)}(\tau)$, if for every when the algorithm is given access to $\mathsf{STAT}_D^{(k)}(\tau)$, where D is the input distribution. We note that for $k=1$, Definition 2.1 reduces to the usual definition of an SQ oracle that was first introduced by Kearns [31]. The k-wise SQ complexity of solving a problem with access to $\mathsf{STAT}^{(k)}(\tau)$

is the minimum number of queries q for which exists a k-wise SQ algorithm with access to $\mathsf{STAT}^{(k)}(\tau)$ that solves the problem using at most q queries. Our discussion and results can also be easily extended to the stronger VSTAT oracle defined in [26] and to more general real-valued queries using the reductions in [24].

The PAC learning [39] is defined as follows.

▶ **Definition 2.2.** *For a class $\mathcal{C}$ of Boolean-valued functions over a domain Z, a PAC learning algorithm for $\mathcal{C}$ is an algorithm that for every P distribution over Z and $f \in \mathcal{C}$, given an error parameter $\epsilon > 0$, failure probability $\delta > 0$ and access to i.i.d. labeled examples of the form $(x, f(x))$ where $x \sim P$, outputs a hypothesis function h that, with probability at least $1 - \delta$, satisfies $\Pr_{x\sim P}[h(x) \neq f(x)] \leq \epsilon$.*

We next define one-vs-many decision problems, which will be used in the proofs in our Section 3 and Section 4.

▶ **Definition 2.3** (Decision problem $\mathcal{B}(\mathcal{D}, D_0)$)**.** *Let $\mathcal{D}$ be a set of distributions and D_0 a reference distribution over a set X. We denote by $\mathcal{B}(\mathcal{D}, D_0)$ the decision problem where we are given access to a distribution $D \in \mathcal{D} \cup \{D_0\}$ and wish to distinguish whether $D \in \mathcal{D}$ or $D = D_0$.*

3 Separation of $(k+1)$-wise from k-wise queries

We start by describing the concept class $\mathcal{C}$ that we use to prove Theorem 1. Let ℓ and k be positive integers with $\ell \geq k + 1$. The domain will be $\mathbb{F}_p^\ell$. For every $a = (a_1, \ldots, a_\ell) \in \mathbb{F}_p^\ell$, we consider the hyperplane

$$\mathsf{Hyp}_a \doteq \{z = (z_1, \ldots, z_\ell) \in \mathbb{F}_p^\ell : z_\ell = a_1 z_1 + \cdots + a_{\ell-1} z_{\ell-1} + a_\ell\}.$$

We then define the Boolean-valued function $f_a : \mathbb{F}_p^\ell \to \{\pm 1\}$ to be the indicator function of the subset $\mathsf{Hyp}_a \subseteq \mathbb{F}_p^\ell$, i.e., for every $z \in \mathbb{F}_p^\ell$,

$$f_a(z) = \begin{cases} +1 & \text{if } z \in \mathsf{Hyp}_a, \\ -1 & \text{otherwise.} \end{cases}$$

Then, we will consider the concept classes $\mathcal{C}_\ell \doteq \{f_a : a \in \mathbb{F}_p^\ell\}$. We denote $\mathcal{C} \doteq \mathcal{C}_{k+1}$. We start by stating our upper bound on the $(k+1)$-wise SQ complexity of the distribution-independent PAC learning of $\mathcal{C}_{k+1}$.

▶ **Lemma 3.1** ($(k+1)$-wise upper bound)**.** *Let p be a prime number and k be a positive integer. There exists a distribution-independent PAC learning algorithm for $\mathcal{C}_{k+1}$ that makes at most $t \cdot \log(1/\epsilon)$ queries to $\mathsf{STAT}^{(k+1)}(\epsilon/t)$, for some $t = O_k(\log p)$.*

We next state our lower bound on the k-wise SQ complexity of the same tasks considered in Lemma 3.1.

▶ **Lemma 3.2** (k-wise lower bound)**.** *Let p be a prime number and ℓ, k be positive integers with $\ell \geq k+1$ and $k = O(p)$. There exists $t = \Omega\left(p^{(\ell-k)/4}\right)$ such that any distribution-independent PAC learning alogrithm for $\mathcal{C}_\ell$ with error at most $1/2 - 2/t$ that is given access to $\mathsf{STAT}^{(k)}(1/t)$ needs at least t queries.*

Note that Lemma 3.1 and Lemma 3.2 imply Theorem 1.

3.1 Upper bound

3.1.1 Notation

We first introduce some notation that will be useful in the description of our algorithm. For any matrix M with entries in the finite field $\mathbb{F}_p$, we denote by $\mathsf{rk}(M)$ the rank of M over $\mathbb{F}_p$. Let $(a_1, \ldots, a_{k+1}) \in \mathbb{F}_p^{k+1}$ be the unknown vector that defines f_a and P be the unknown distribution over tuples $(z_1, \ldots, z_{k+1}) \in \mathbb{F}_p^{k+1}$.

Note that Hyp_a is an affine subspace of $\mathbb{F}_p^{k+1}$. To simplify our treatment of affine subspaces, we embed the points of $\mathbb{F}_p^{k+1}$ into $\mathbb{F}_p^{k+2}$ by mapping each $z \in \mathbb{F}_p^{k+1}$ to $(z, 1)$. This embedding maps every affine subspace V of $\mathbb{F}_p^{k+1}$ to a linear subspace W of $\mathbb{F}_p^{k+2}$, namely the span of the image of V under our embedding. Note that this mapping is one-to-one and allows us to easily recover V from W as $V = \{z \in \mathbb{F}_p^{k+1} \mid (z, 1) \in W\}$. Hence given $k+1$ examples

$$\big((z_{1,1}, \ldots, z_{1,k+1}), b_1\big), \big((z_{2,1}, \ldots, z_{2,k+1}), b_2\big), \ldots, \big((z_{k+1,1}, \ldots, z_{k+1,k+1}), b_{k+1}\big)$$

we define the matrix:

$$Z \doteq \begin{bmatrix} z_{1,1} & z_{1,2} & \cdot & z_{1,k+1} & 1 \\ z_{2,1} & z_{2,2} & \cdot & z_{2,k+1} & 1 \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ z_{k+1,1} & z_{k+1,2} & \cdot & z_{k+1,k+1} & 1 \end{bmatrix}. \tag{1}$$

For $\ell \in [k+1]$ we also denote by Z_ℓ the matrix that consists of the top ℓ rows of Z. Further, for a $(k+1)$-wise query function $\phi\big((z_1, b_1), \ldots, (z_{k+1}, b_{k+1})\big)$, we use Z to refer to the matrix obtained from the inputs to the function.

Let Q be the distribution defined by sampling a random example $\big((z_1, \ldots, z_{k+1}), b\big)$, conditioning on the event that $b = 1$ and outputting $(z_1, \ldots, z_{k+1}, 1)$. Note that if the examples from which Z is built are positively labeled i.i.d. examples then each row of Z is sampled i.i.d. from Q and hence Z_ℓ is distributed according to Q^ℓ. We denote by 1^{k+1} the all $+1$'s vector of length $k+1$.

3.1.2 Learning algorithm

We start by explaining the main ideas behind the algorithm. On a high level, in order to be able to use $(k+1)$-wise SQs to learn the unknown subspace, we need to make sure that there exists an affine subspace that contains most of the probability mass of the positively-labeled points and that is spanned by $k+1$ random positively-labeled points with noticeable probability. Here, the probability is with respect to the unknown distribution over labeled examples. Thus, for positively labeled tuples $(z_{1,1}, \ldots, z_{1,k+1})$, $(z_{2,1}, \ldots, z_{2,k+1})$, $\ldots$, $(z_{k+1,1}, \ldots, z_{k+1,k+1})$, we consider the $(k+1) \times (k+2)$ matrix Z defined in Equation (1). If W is the row-span of Z, then the desired (unknown) affine subspace is the set V of all points $(z_1, \ldots, z_{k+1})$ such that $(z_1, \ldots, z_{k+1}, 1) \in W$.

If the (unknown) distribution over labeled examples is such that with noticeable probability, $k+1$ random positively-labeled points form a full-rank linear system (i.e., the matrix Z has full-rank with noticeable probability conditioned on $(b_1, \ldots, b_{k+1}) = 1^{k+1}$), we can use $(k+1)$-wise SQs to find, one bit at a time, the $(k+1)$-dimensional row-span W of Z, and we can then output the set V of all points $(z_1, \ldots, z_{k+1})$ such that $(z_1, \ldots, z_{k+1}, 1) \in W$ as the desired affine subspace (below, we refer to this step as the Recovery Procedure).

We now turn to the (more challenging) case where the system is not full-rank with noticeable probability (i.e., the matrix Z is rank-deficient with high probability conditioned

Algorithm 1 $(k+1)$-wise SQ Algorithm.

Inputs. $k \in \mathbb{N}$, error probability $\epsilon > 0$.

Output. Function $f : \mathbb{F}_p^{k+1} \to \{\pm 1\}$.

Set tolerance of each SQ to $\tau = (\epsilon/2^{c\cdot(k+2)})^{(k+1)^{k+3}}$, where $c > 0$ is a large enough absolute constant.
Define the threshold $\tau_i = 2^{c\cdot(k+2-i)} \cdot k \cdot \tau^{1/(k+1)^{k+2-i}}$ for every $i \in [k+1]$.
Ask the SQ $\phi(z, b) \doteq \mathbb{1}(b = 1)$ and let w be the response.
if $w \leq \epsilon - \tau$ **then**
    Output the all -1's function.
end if
Let $\widetilde{\phi}\big((z_1, b_1), \ldots, (z_{k+1}, b_{k+1})\big) \doteq \mathbb{1}((b_1, \ldots, b_{k+1}) = 1^{k+1})$.
Ask the SQ $\widetilde{\phi}$ and let v be the response.
for $i = k+1$ down to 1 **do**
    Let $\phi_i\big((z_1, b_1), \ldots, (z_{k+1}, b_{k+1})\big) \doteq \mathbb{1}((b_1, \ldots, b_{k+1}) = 1^{k+1}$ and $\mathsf{rk}(Z) = i)$.
    Ask the SQ ϕ_i and let v_i be the response.
    if $v_i/v \geq \tau_i$ **then**
        Run Recovery Algorithm on input (i, v_i) and let $\widehat{V}$ be the subspace of $\mathbb{F}_p^{k+1}$ it outputs.
        Define function $f : \mathbb{F}_p^{k+1} \to \{-1, 1\}$ by:
        $f(z_1, \ldots, z_{k+1}) = +1$ if $(z_1, \ldots, z_{k+1}) \in \widehat{V}$.
        $f(z_1, \ldots, z_{k+1}) = -1$ otherwise.
        Return f.
    end if
end for

on $(b_1, \ldots, b_{k+1}) = 1^{k+1})$. Then, the system has rank at most i with high probability, for some $i < k+1$. There is a large number of possible i-dimensional subspaces and therefore it is no longer clear that there exists a single i-dimensional subspace that contains most of the mass of the positively-labeled points. However, we demonstrate that for every i, if the rank of Z is at most i with sufficiently high probability, then there exists a *fixed* subspace W of dimension at most i that contains a large fraction of the probability under the row-distribution of Z (it turns out that if this subspace has rank equal to i, then it should be *unique*). We can then use $(k+1)$-wise SQs to output the affine subspace V consisting of all points $(z_1, \ldots, z_{k+1})$ such that $(z_1, \ldots, z_{k+1}, 1) \in W$ (via the Recovery Procedure).

The general description of the algorithm is given in Algorithm 1, and the Recovery Procedure (allowing the reconstruction of the affine subspace V) is separately described in Algorithm 2. We denote the indicator function of event E by $\mathbb{1}(E)$. Note that the statistical query corresponding to the event $\mathbb{1}(E)$ gives an estimate of the probability of E.

3.1.3 Analysis

We now turn to the analysis of Algorithm 1 and the proof of Lemma 3.1. We will need the following lemma, which shows that if the rank of Z is at most i with high probability, then there is a *fixed* subspace of dimension at most i containing most of the probability mass under the row-distribution of Z.

▶ **Lemma 3.3.** *Let $i \in [k+1]$. If $\Pr_{Q^{k+1}}[\mathsf{rk}(Z) \leq i] \geq 1 - \xi$, then there exists a subspace W of $\mathbb{F}_p^{k+2}$ of dimension at most i such that $\Pr_{z\sim Q}[z \notin W] \leq \xi^{1/k}$.*

Algorithm 2 Recovery Procedure

Input. Integer $i \in [k+1]$.

Output. Subspace $\widehat{V}$ of $\mathbb{F}_p^{k+1}$ of dimension i.

Let $m_i = (k+2) \cdot i \cdot \lceil \log p \rceil$
for each bit $j \leq m_i$ **do**
  Define event $E_j(Z) = \mathbb{1}(\text{bit } j \text{ of row span of } Z \text{ is } 1)$.
  Let $\phi_{i,j}\big((z_1, b_1), \ldots, (z_{k+1}, b_{k+1})\big) \doteq \mathbb{1}(E_j(Z) \text{ and } (b_1, \ldots, b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i)$.
  Ask the SQ $\phi_{i,j}$ and let $u_{i,j}$ be the response.
  if $u_{i,j}/v_i \geq (9/10)$ **then**
    Set bit j in binary representation of $\widehat{W}$ to 1.
  else
    Set bit j in binary representation of $\widehat{W}$ to 0.
  end if
end for
Let $\widehat{V}$ be the set all points $(z_1, \ldots, z_{k+1})$ such that $(z_1, \ldots, z_{k+1}, 1) \in \widehat{W}$.

▶ Remark. We point out that the exponential dependence on $1/k$ in the probability upper bound in Lemma 3.3 is tight. To see this, let $p = 2$, and $\{e_1, \ldots, e_k\}$ be the standard basis in $\mathbb{F}_2^k$. Consider the base distribution P on $\mathbb{F}_2^k$ that puts probability mass $1 - \alpha$ on e_1, and probability mass $\alpha/(k-1)$ on each of e_2, e_3, …, e_k. Then, a Chernoff bound implies that if we draw k i.i.d. samples from P, then the dimension of their span is at most $2 \cdot \alpha \cdot k$ with probability at least $1 - \exp(-k)$. On the other hand, for any subspace W of $\mathbb{F}_2^k$ of dimension $2 \cdot \alpha \cdot k$, the probability that a random sample from P lies inside W is only $1 - \Theta(\alpha)$.

To prove Lemma 3.3, we will use the following proposition.

▶ **Proposition 3.4.** *Let $\ell \in [k+1]$, $i \in [\ell - 1]$ and $\eta > 0$. If $\Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq i] \geq 1 - \eta$, then for every $\nu \in (0, 1]$, either there exists a subspace W of $\mathbb{F}_p^{k+2}$ of dimension i such that $\Pr_{z \sim Q}[z \notin W] \leq \nu$ or $\Pr_{Q^i}[\mathsf{rk}(Z_i) \leq i - 1] \geq 1 - \eta/\nu$.*

Proof. Let $p \doteq \Pr_{Q^i}[\mathsf{rk}(Z_i) \leq i - 1]$. For every (fixed) matrix $A_i \in \mathbb{F}_p^{i \times (k+2)}$, define

$$\mu(A_i) \doteq \Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq i \mid Z_i = A_i].$$

Then,

$$\begin{aligned}\Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq i] &= p + (1-p) \cdot \Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq i \mid \mathsf{rk}(Z_i) = i] \\ &= p + (1-p) \cdot \mathbb{E}_{Q^i}\Big[\mu(Z_i) \Big| \mathsf{rk}(Z_i) = i\Big].\end{aligned}$$

Since $\Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq i] \geq 1 - \eta$, we have that

$$\mathbb{E}_{Q^i}\Big[\mu(Z_i) \Big| \mathsf{rk}(Z_i) = i\Big] \geq 1 - \eta/(1-p).$$

Hence, there exists a setting $A_i \in \mathbb{F}_p^{i \times (k+2)}$ of Z_i such that $\mathsf{rk}(A_i) = i$ and

$$\Pr[\mathsf{rk}(Z_\ell) \leq i \mid Z_i = A_i] \geq 1 - \eta/(1-p).$$

We let W be the $\mathbb{F}_p$-span of the rows of A_i. Note that the dimension of W is equal to i and that $\Pr_{z \sim Q}[z \notin W] \leq \eta/(1-p)$. Thus, we conclude that for every $\nu \in (0, 1]$, either $p \geq 1 - \eta/\nu$ or $\Pr_{z \sim Q}[z \notin W] \leq \nu$, as desired. ◀

We now complete the proof of Lemma 3.3.

Proof of Lemma 3.3. Starting with $\ell = k+1$ and $\eta = \xi$, we inductively apply Proposition 3.4 with $\nu = \xi^{1/k}$ until we either get the desired subspace W or we get to the case where $i = 1$. In this case, we have that $\Pr_{Q^\ell}[\mathsf{rk}(Z_\ell) \leq 1] \geq 1 - \xi^{1/k}$ for $\ell \geq 2$. Since the last column of Z_ℓ is the all 1's vector, we conclude that there exists $z^* \in \mathbb{F}_p^{k+1}$ such that $\Pr_{z\sim Q}[z \neq (z^*, 1)] \leq \xi^{1/k}$. We can then set our subspace W to be the $\mathbb{F}_p$-span of the vector $(z^*, 1)$. ◀

For the proof of Lemma 3.1 we will also need the following lemma, which states sufficient conditions under which the Recovery Procedure (Algorithm 2) succeeds.

▶ **Lemma 3.5.** *Let $i \in [k+1]$. Assume that in Algorithm 1, $v > \epsilon^{k+1}/2$ and $v_i/v \geq \tau_i$. If there exists a subspace W of $\mathbb{F}_p^{k+2}$ of dimension equal to i such that*

$$\Pr_{z\sim Q}[z \notin W] < \frac{\tau_i}{4 \cdot (k+1)}, \tag{2}$$

then the affine subspace $\widehat{V}$ output by Algorithm 2 (i.e., the Recovery Procedure) consists of all points $(z_1, \ldots, z_{k+1})$ such that $(z_1, \ldots, z_{k+1}, 1) \in W$.

We note that Lemma 3.5 would still hold under quantitatively weaker assumptions on v, v_i/v and $\Pr_{z\sim Q}[z \notin W]$ in Equation (2). In order to keep the expressions simple, we however choose to state the above version which will be sufficient to prove Lemma 3.1. The proof of Lemma 3.5 appears in Section A.1. We are now ready to complete the proof of Lemma 3.1.

Proof of Lemma 3.1. If Algorithm 1 terminates at Step 5, then the error of the output hypothesis is at most ϵ, as desired. Henceforth, we assume that Algorithm 1 does not terminate at Step 5. Then, we have that $\Pr[b = 1] > \epsilon$, and hence $\Pr[(b_1, \ldots, b_{k+1}) = 1^{k+1}] > \epsilon^{k+1}$. Thus, the value v obtained in Step 8 of Algorithm 1 satisfies $v > \epsilon^{k+1} - \tau \geq \epsilon^{k+1}/2$, where the last inequality follows from the setting of τ. Let i^* be the first (i.e., largest) value of $i \in [k+1]$ for which $v_i/v \geq \tau_i$. To prove that such an i^* exists, we proceed by contradiction, and assume that for all $i \in [k+1]$, it is the case that $v_i/v < \tau_i$. Note that Z has an all 1's column, so it has rank at least 1. Moreover, it has rank at most $k+1$. Therefore, we have that

$$\begin{aligned}
1 &= \Pr[1 \leq \mathsf{rk}(Z) \leq k+1 \mid (b_1, \ldots, b_{k+1}) = 1^{k+1}] \\
&= \sum_{i=1}^{k+1} \Pr[\mathsf{rk}(Z) = i \mid (b_1, \ldots, b_{k+1}) = 1^{k+1}] \\
&\leq \sum_{i=1}^{k+1} \frac{v_i + \tau}{v - \tau} \\
&\leq 2 \cdot \sum_{i=1}^{k+1} \frac{v_i + \tau}{v} \\
&\leq 2 \cdot \sum_{i=1}^{k+1} \left(\frac{v_i}{v} + \frac{2\tau}{\epsilon^{k+1}}\right) \\
&< 2 \cdot \sum_{i=1}^{k+1} \tau_i + 4 \cdot (k+1) \cdot \frac{\tau}{\epsilon^{k+1}}.
\end{aligned}$$

Using the fact that τ_i is monotonically non-increasing in i and the settings of τ_1 and τ, the last inequality gives

$$1 \leq 2 \cdot (k+1) \cdot \tau_1 + 4 \cdot (k+1) \cdot \frac{\tau}{\epsilon^{k+1}} < 1,$$

a contradiction.

We now fix i^* as above. We have that

$$\begin{aligned}
\Pr[\mathsf{rk}(Z) \le i^* \mid (b_1,\dots,b_{k+1}) = 1^{k+1}] &= 1 - \sum_{i=i^*+1}^{k+1} \Pr[\mathsf{rk}(Z) = i \mid (b_1,\dots,b_{k+1}) = 1^{k+1}] \\
&\ge 1 - \sum_{i=i^*+1}^{k+1} \frac{v_i + \tau}{v - \tau} \\
&\ge 1 - 2 \cdot \sum_{i=i^*+1}^{k+1} (\frac{v_i}{v} + \frac{2\tau}{\epsilon^{k+1}}) \\
&> 1 - 2 \cdot \sum_{i=i^*+1}^{k+1} (\tau_i + 2 \cdot \frac{\tau}{\epsilon^{k+1}}) \\
&\ge 1 - 4 \cdot \sum_{i=i^*+1}^{k+1} \tau_i \\
&\ge 1 - 4 \cdot k \cdot \tau_{i^*+1}.
\end{aligned}$$

By Lemma 3.3, there exists a subspace W of $\mathbb{F}_p^{k+2}$ of dimension at most i^* such that

$$\Pr_{z \sim Q}[z \notin W] \le (4 \cdot k)^{1/k} \cdot \tau_{i^*+1}^{1/k}. \tag{3}$$

▶ **Proposition 3.6.** *For every $i \in [k]$, we have that $(k+1) \cdot (4 \cdot k)^{1/k} \cdot \tau_{i+1}^{1/k} \le \tau_i/4$.*

We note that Proposition 3.6 follows immediately from the definitions of τ_i and τ (and by letting c by a sufficiently large positive absolute constant). Moreover, Proposition 3.6 (applied with $i = i^*$) along with Equation (3) imply that $\Pr_{z \sim Q}[z \notin W]$ is at most $\tau_{i*}/(4(k+1))$.

By a union bound, we get that with probability at least

$$1 - (k+1) \cdot \Pr_{z \sim Q}[z \notin W] \ge 1 - \frac{\tau_{i^*}}{4}, \tag{4}$$

all the rows of Z belong to W.

Since $v_{i*}/v \ge \tau_{i*}$, we also have that:

$$\begin{aligned}
\Pr[\mathsf{rk}(Z) = i^* \mid (b_1,\dots,b_{k+1}) = 1^{k+1}] &\ge \frac{v_{i*} - \tau}{v + \tau} \\
&\ge \frac{1}{2} \cdot \frac{(v_{i*} - \tau)}{v} \\
&\ge \frac{1}{2} \cdot (\tau_{i^*} - \frac{2 \cdot \tau}{\epsilon^{k+1}}) \\
&\ge \frac{\tau_{i^*}}{3}
\end{aligned} \tag{5}$$

Combining Equation (4) and Equation (5), we get that the rank of W is *equal to* i^*.

Let V be the affine subspace consisting of all points $(z_1,\dots,z_{k+1})$ such that $(z_1,\dots,z_{k+1},1) \in W$. By Lemma 3.5, we get that Algorithm 2 (and hence Algorithm 1) correctly recovers the affine subspace V.

We note that the function f output by Algorithm 1 is the ± 1 indicator of a subspace of the true hyperplane Hyp_a. To see this, note that f is the ± 1 indicator function of the subspace V, and by Equations (3) and (5), we have that with probability at least $\tau_{i*}/12$ over $Z \sim Q^{k+1}$, all the columns of Z belong to W and $\mathsf{rk}(Z) = i^*$. Since the dimension of W

is equal to i^* and since we are conditioning on $(b_1, \ldots, b_{k+1}) = 1^{k+1}$, this implies that the correct label of all the points in V is $+1$. Hence, f only possibly errs on positively-labeled points (by wrongly giving them the label -1). Moreover, Algorithm 1 ensures that the output function f gives the label $+1$ to every $(z_1, \ldots, z_{k+1}) \in \mathbb{F}_p^{k+1}$ for which $(z_1, \ldots, z_{k+1}, 1) \in W$. Therefore, the function f that is output by Algorithm 1 (when it does not terminate at Step 5) has error at most the right hand side of (3). So to upper-bound the error probability, it suffices for us to verify that the right-hand side of (3) is at most ϵ. This is obtained by applying the next proposition with $i = i^* + 1$.

▶ **Proposition 3.7.** *For every $i \in [k+1]$, we have that $(4 \cdot k)^{1/k} \cdot \tau_i^{1/k} \leq \epsilon^k$.*

The proof of Proposition 3.7 follows immediately from the definitions of τ_i and τ and by letting c be a sufficiently large positive absolute constant.

The number of queries performed by the $(k+1)$-wise algorithm is at most $O(k^2 \cdot \log p)$, and their tolerance is $\tau \geq (\epsilon / 2^{c \cdot (k+2)})^{(k+1)^{k+3}}$, where c is a positive absolute constant. Finally, we remark that the dependence of the SQ complexity of the above algorithm on the error parameter ϵ is $\epsilon^{-k^{O(k)}}$. It can be improved to a linear dependence on $1/\epsilon$ by learning with error $1/3$ and then using boosting in the standard way (boosting in the SQ model works essentially as in the regular PAC model [1]). ◀

3.2 Lower bound

Our proof of lower bound is a generalization of the lower bound in [25] (for $\ell = 2$ and $k = 1$). It relies on a notion of *combined randomized statistical dimension* ("combined" refers to the fact that it examines a single parameter that lower bounds both the number of queries and the inverse of the tolerance). In order to apply this approach we need to extend it to k-wise queries. This extension follows immediately from a simple observation. If we define the domain to be $X' \doteq X^k$ and the input distribution to be $D' \doteq D^k$ then asking a k-wise query $\phi : X^k \to [-1, 1]$ to $\mathsf{STAT}_D^{(k)}(\tau)$ is equivalent to asking a unary query $\phi : X' \to [-1, 1]$ to $\mathsf{STAT}_{D'}^{(k)}(\tau)$. Using this observation we define the k-wise versions of the notions from [25] and give their properties that are needed for the proof of Lemma 3.2.

3.2.1 Preliminaries

Combined randomized statistical dimension is based on the following notion of average discrimination.

▶ **Definition 3.8** (k-wise average κ_1-discrimination)**.** *Let k be any positive integer. Let μ be a probability measure over distributions over X and D_0 be a reference distribution over X. Then,*

$$\bar{\kappa}_1^{(k)}(\mu, D_0) \doteq \sup_{\phi : X^k \to [-1,+1]} \left\{ \mathbb{E}_{D \sim \mu}[|D^k[\phi] - D_0^k[\phi]|] \right\}.$$

We denote the problem of PAC learning a concept class $\mathcal{C}$ of Boolean functions up to error ϵ by $\mathcal{L}_{PAC}(\mathcal{C}, \epsilon)$. Let Z be the domain of the Boolean functions in $\mathcal{C}$. For any distribution D_0 over labeled examples (i.e., over $Z \times \{\pm 1\}$), we define the Bayes error rate of D_0 to be

$$\mathsf{err}(D_0) = \sum_{z \in Z} \min\{D_0(z, 1), D_0(z, -1)\} = \min_{h : Z \to \{\pm 1\}} \Pr_{(z,b) \sim D_0}[h(z) \neq b].$$

▶ **Definition 3.9** (k-wise combined randomized statistical dimension)**.** *Let k be any positive integer. Let $\mathcal{D}$ be a set of distributions and D_0 a reference distribution over X. The k-wise combined randomized statistical dimension of the decision problem $\mathcal{B}(\mathcal{D}, D_0)$ is then defined as*

$$\mathsf{cRSD}^{(k)}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}, D_0)) \doteq \sup_{\mu \in S^{\mathcal{D}}} (\bar{\kappa}^{(k)}_1(\mu, D_0))^{-1},$$

where $S^{\mathcal{D}}$ denotes the set of all probability distributions over $\mathcal{D}$.

Further, for any concept class $\mathcal{C}$ of Boolean functions over a domain Z, and for any $\epsilon > 0$, the k-wise combined randomized statistical dimension of $\mathcal{L}_{PAC}(\mathcal{C}, \epsilon)$ is defined as

$$\mathsf{cRSD}^{(k)}_{\bar{\kappa}_1}(\mathcal{L}_{PAC}(\mathcal{C}, \epsilon)) \doteq \sup_{D_0 \in S^{Z \times \{\pm 1\}} : \mathsf{err}(D_0) > \epsilon} \mathsf{cRSD}^{(k)}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}_{\mathcal{C}}, D_0)),$$

where $\mathcal{D}_{\mathcal{C}} \doteq \{P^f : P \in S^Z, f \in \mathcal{C}\}$ with P^f denoting the distribution on labeled examples $(x, f(x))$ with $x \sim P$.

The next theorem lower bounds the randomized k-wise SQ complexity of PAC learning a concept class in terms of its k-wise combined randomized statistical dimension.

▶ **Theorem 5** ([25])**.** *Let $\mathcal{C}$ be a concept class of Boolean functions over a domain Z, k be a positive integer and $\epsilon, \delta > 0$. Let $d \doteq \mathsf{cRSD}^{(k)}_{\bar{\kappa}_1}(\mathcal{L}_{PAC}(\mathcal{C}, \epsilon))$. Then, the randomized k-wise SQ complexity of solving $\mathcal{L}_{PAC}(\mathcal{C}, \epsilon - 1/\sqrt{d})$ with access to $\mathsf{STAT}^{(k)}(1/\sqrt{d})$ and success probability $1 - \delta$ is at least $(1 - \delta) \cdot \sqrt{d} - 1$.*

To lower bound the statistical dimension we will use the following "average correlation" parameter introduced in [26].

▶ **Definition 3.10** (k-wise average correlation)**.** *Let k be any positive integer. Let $\mathcal{D}$ be a set of distributions and D_0 a reference distribution over X. Assume that the support of every distribution $D \in \mathcal{D}$ is a subset of the support of D_0. Then, for every $x \in X^k$, define $\hat{D}(x) \doteq \frac{D^k(x)}{D_0^k(x)} - 1$. Then, the k-wise average correlation is defined as*

$$\rho^{(k)}(\mathcal{D}, D_0) \doteq \frac{1}{|\mathcal{D}|^2} \cdot \sum_{D, D' \in \mathcal{D}} |D_0^k[\hat{D} \cdot \hat{D}']|.$$

Lemma 3.11 relates the average correlation to the average discrimination (from Definition 3.8).

▶ **Lemma 3.11** ([25])**.** *Let k be any positive integer. Let $\mathcal{D}$ be a set of distributions and D_0 a reference distribution over X. Let μ be the uniform distribution over $\mathcal{D}$. Then,*

$$\bar{\kappa}^{(k)}_1(\mu, D_0) \leq 4 \cdot \sqrt{\rho^{(k)}(\mathcal{D}, D_0)}.$$

3.2.2 Proof of Lemma 3.2

Denote $X \doteq \mathbb{F}_p^\ell \times \{\pm 1\}$. Let $\mathcal{D}$ be the set of all distributions over X^k that are obtained by sampling from any given distribution over $(\mathbb{F}_p^\ell)^k$ and labeling the k samples according to any given hyperplane indicator function f_a. Let D_0 be the uniform distribution over X^k. We now show that $\mathsf{cRSD}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}, D_0)) = \Omega\big(p^{(\ell-k)/2}\big)$. By definition,

$$\mathsf{cRSD}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}, D_0)) \doteq \sup_{\mu \in S^{\mathcal{D}}} (\bar{\kappa}_1(\mu, D_0))^{-1}.$$

We now choose the distribution μ. For $a \in \mathbb{F}_p^\ell$, we define P_a to be the distribution over $\mathbb{F}_p^\ell$ that has density $\alpha = 1/(2(p^\ell - p^{\ell-1}))$ on each of the $p^\ell - p^{\ell-1}$ points outside Hyp_a, and density $\beta = 1/p^{\ell-1} - \alpha p + \alpha = 1/(2p^{\ell-1})$ on each of the $p^{\ell-1}$ points inside Hyp_a. We then define D_a to be the distribution obtained by sampling k i.i.d. random examples of Hyp_a, the marginal of each over $\mathbb{F}_p^\ell$ being P_a. Let $\mathcal{D}' \doteq \{D_a \mid a \in \mathbb{F}_p^\ell\}$, and let μ be the uniform distribution over $\mathcal{D}'$. By Lemma 3.11, we have that $\bar{\kappa}_1(\mu, D_0) \leq 4 \cdot \sqrt{\rho(\mathcal{D}, D_0)}$, so it is enough to upper bound $\rho(\mathcal{D}, D_0)$.

We first note that for $a, a' \in \mathbb{F}_p^\ell$, we have

$$\begin{aligned}
D_0[\hat{D}_a \cdot \hat{D}_{a'}] &= \mathbb{E}_{(z,b)\sim D_0}[\hat{D}_a(z,b) \cdot \hat{D}_{a'}(z,b)] \\
&= \mathbb{E}_{(z,b)\sim D_0}\left[\left(\frac{D_a(z,b)}{D_0(z,b)} - 1\right) \cdot \left(\frac{D_{a'}(z,b)}{D_0(z,b)} - 1\right)\right] \\
&= \mathbb{E}_{(z,b)\sim D_0}\left[\frac{D_a(z,b) \cdot D_{a'}(z,b)}{D_0^2(z,b)} - \frac{D_a(z,b)}{D_0(z,b)} - \frac{D_{a'}(z,b)}{D_0(z,b)} + 1\right] \\
&= \mathbb{E}_{(z,b)\sim D_0}\left[\frac{D_a(z,b) \cdot D_{a'}(z,b)}{D_0^2(z,b)}\right] - 2 \cdot \mathbb{E}_{(z,b)\sim D_0}\left[\frac{D_a(z,b)}{D_0(z,b)}\right] + 1 \\
&= 2^{2k} \cdot p^{2k\ell} \cdot \mathbb{E}_{(z,b)\sim D_0}[D_a(z,b) \cdot D_{a'}(z,b)] \\
&\quad - 2^{k+1} \cdot p^{k\ell} \cdot \mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)] + 1
\end{aligned}$$

We now compute each of the two expectations that appear in the last equation above.

▶ **Proposition 3.12.** *For every $a \in \mathbb{F}_p^\ell$,*

$$\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)] = \frac{1}{2^k} \cdot \left(\frac{1}{p} \cdot \beta + \left(1 - \frac{1}{p}\right) \cdot \alpha\right)^k = \frac{1}{2^k \cdot p^{k\cdot\ell}}.$$

The proof of Proposition 3.12 appears in the appendix.

▶ **Proposition 3.13.** *For every $a, a' \in \mathbb{F}_p^\ell$,*

$$\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b) \cdot D_{a'}(z,b)] = \begin{cases} \frac{1}{2^k} \cdot (\frac{1}{p} \cdot \beta^2 + (1 - \frac{1}{p}) \cdot \alpha^2)^k & \text{if } \mathsf{Hyp}_a = \mathsf{Hyp}_{a'}, \\ \frac{1}{2^k} \cdot (\alpha^2 \cdot (1 - \frac{2}{p}))^k & \text{if } \mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} = \emptyset, \\ \frac{1}{2^k} \cdot (\frac{\beta^2}{p^2} + \alpha^2 \cdot (1 - \frac{2}{p} + \frac{1}{p^2}))^k & \text{otherwise.} \end{cases}$$

The proof of Proposition 3.13 appears in the appendix. Using Proposition 3.12 and Proposition 3.13, we now compute $D_0[\hat{D}_a \cdot \hat{D}_{a'}]$.

▶ **Proposition 3.14.** *For every $a, a' \in \mathbb{F}_p^\ell$,*

$$D_0[\hat{D}_a \cdot \hat{D}_{a'}] = \begin{cases} (p + 1 - \frac{1}{p-1})^k - 1 & \text{if } \mathsf{Hyp}_a = \mathsf{Hyp}_{a'}, \\ \frac{1}{2^k} \cdot \frac{(1-\frac{2}{p})^k}{(1-\frac{1}{p})^{2k}} - 1 & \text{if } \mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} = \emptyset, \\ 0 & \text{otherwise.} \end{cases}$$

The proof of Proposition 3.14 appears in the appendix. When computing $\rho(\mathcal{D}, D_0)$, we will also use the following simple proposition.

▶ **Proposition 3.15.**

1. *The number of pairs $(a, a') \in (\mathbb{F}_p^\ell)^2$ such that $\mathsf{Hyp}_a = \mathsf{Hyp}_{a'}$ is equal to p^ℓ.*
2. *The number of pairs $(a, a') \in (\mathbb{F}_p^\ell)^2$ such that Hyp_a and $\mathsf{Hyp}_{a'}$ are distinct and parallel is equal to $p^\ell \cdot (p-1)$.*

3. *The number of pairs* $(a, a') \in (\mathbb{F}_p^\ell)^2$ *such that* Hyp_a *and* $\mathsf{Hyp}_{a'}$ *are distinct and intersecting is equal to* $p^{2\cdot\ell} - p^{\ell+1}$.

Using Proposition 3.14 and Proposition 3.15, we are now ready to compute $\rho(\mathcal{D}, D_0)$ as follows

$$\begin{aligned}\rho(\mathcal{D}, D_0) &\leq \frac{1}{p^{2\cdot\ell}} \cdot \left[p^\ell \cdot (p + 1 - \frac{1}{p-1})^k + p^\ell \cdot (p-1) + p^{2\cdot\ell} \cdot 0\right] \\ &\leq O\left(\frac{1}{p^{\ell-k}}\right) + \frac{1}{p^{\ell-1}} \\ &= O\left(\frac{1}{p^{\ell-k}}\right),\end{aligned}$$

where we used above the assumption that $k = O(p)$. We deduce that $\bar{\kappa}_1(\mu, D_0) = O\left(1/p^{(\ell-k)/2}\right)$, and hence $\mathsf{cRSD}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}, D_0)) = \Omega\left(p^{(\ell-k)/2}\right)$. This lower bound on $\mathsf{cRSD}_{\bar{\kappa}_1}(\mathcal{B}(\mathcal{D}, D_0))$, along with Definition 3.9, Theorem 5 and the fact that D_0 has Bayes error rate equal to $1/2$, imply Lemma 3.2.

4 Reduction for flat distributions

To prove Theorem 2 we use the characterization of the SQ complexity of the problem of estimating $D^k[\phi]$ for $D \in \mathcal{D}$ using a notion of statistical dimension from [25]. Specifically, we use the characterization of the complexity of solving this problem using unary SQs and also the generalization of this characterization that characterizes the complexity of solving a problem using k-wise SQs. The latter is equal to 1 (since a single k-wise SQ suffices to estimate $D^k[\phi]$). Hence the k-wise statistical dimension is also equal to 1. We then upper bound the unary statistical dimension by the k-wise statistical dimension. The characterization then implies that an upper bound on the unary statistical dimension gives an upper bound on the SQ complexity of estimating $D^k[\phi]$.

We also give a slightly different way to define flatness that makes it easier to extend our results to other notions of divergence.

▶ **Definition 4.1.** *Let* $\mathcal{D}$ *be a set of distributions over* X. *Define*

$$R_\infty(\mathcal{D}) \doteq \inf_{\bar{D} \in S^X} \sup_{D \in \mathcal{D}} \mathrm{D}_\infty(D \| \bar{D}),$$

where S^X *denotes the set of all probability distributions over* X *and*

$$\mathrm{D}_\infty(D \| \bar{D}) \doteq \sup_{y \in X} \ln \frac{\Pr_{x \sim D}[x = y]}{\Pr_{x \sim \bar{D}}[x = y]}$$

denotes the max-divergence. We say that $\mathcal{D}$ *is* γ*-flat if* $R_\infty(\mathcal{D}) \leq \ln \gamma$.

For simplicity, we will start by relating the k-wise SQ complexity to unary SQ complexity for decision problems. The statistical dimension for this type of problems is substantially simpler than for the general problems but is sufficient to demonstrate the reduction. We then build on the results for decision problems to obtain the proof of Theorem 2.

4.1 Decision problems

The k-wise generalization of the statistical dimension for decision problems from [25] is defined as follows.

▶ **Definition 4.2.** *Let k be any positive integer. Consider a set of distributions $\mathcal{D}$ and a reference distribution D_0 over X. Let μ be a probability measure over $\mathcal{D}$ and let $\tau > 0$. The k-wise maximum covered μ-fraction is defined as*

$$\kappa_1\text{-}\mathsf{frac}^{(k)}(\mu, D_0, \tau) \doteq \sup_{\phi: X^k \to [-1,+1]} \left\{ \Pr_{D\sim\mu}[|D^k[\phi] - D_0^k[\phi]| > \tau] \right\}.$$

▶ **Definition 4.3** (k-wise randomized statistical dimension of decision problems)**.** *Let k be any positive integer. For any set of distributions $\mathcal{D}$, a reference distribution D_0 over X and $\tau > 0$, we define*

$$\mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau) \doteq \sup_{\mu \in S^{\mathcal{D}}} (\kappa_1\text{-}\mathsf{frac}^{(k)}(\mu, D_0, \tau))^{-1},$$

where $S^{\mathcal{D}}$ denotes the set of all probability distributions over $\mathcal{D}$.

As shown in [25], RSD tightly characterizes the randomized statistical query complexity of solving the problem using k-wise queries. As observed before, the k-wise versions below are implied by the unary version in [25] simply by defining the domain to be $X' \doteq X^k$ and the set of input distributions to be $\mathcal{D}' \doteq \{D^k \mid D \in \mathcal{D}\}$.

▶ **Theorem 6** ([25])**.** *Let $\mathcal{B}(\mathcal{D}, D_0)$ be a decision problem, $\tau > 0, \delta \in (0, 1/2)$, $k \in \mathbb{N}$ and $d = \mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau)$. Then there exists a randomized algorithm that solves $\mathcal{B}(\mathcal{D}, D_0)$ with success probability $\geq 1 - \delta$ using $d \cdot \ln(1/\delta)$ queries to $\mathsf{STAT}^{(k)}_D(\tau/2)$. Conversely, any algorithm that solves $\mathcal{B}(\mathcal{D}, D_0)$ with success probability $\geq 1 - \delta$ requires at least $d \cdot (1 - 2\delta)$ queries to $\mathsf{STAT}^{(k)}_D(\tau)$.*

We will also need the following dual formulation of the statistical dimension given in Theorem 4.3.

▶ **Lemma 4.4** ([25])**.** *Let k be any positive integer. For any set of distributions $\mathcal{D}$, a reference distribution D_0 over X and $\tau > 0$, the statistical dimension $\mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau)$ is equal to the smallest d for which there exists a distribution $\mathcal{P}$ over functions from X^k to $[-1, +1]$ such that for every $D \in \mathcal{D}$,*

$$\Pr_{\phi\sim\mathcal{P}}[|D^k[\phi] - D_0^k[\phi]| > \tau] \geq \frac{1}{d}.$$

We can now state the relationship between $\mathsf{RSD}^{(k)}_{\kappa_1}$ and $\mathsf{RSD}^{(1)}_{\kappa_1}$ for any γ-flat $\mathcal{D}$.

▶ **Lemma 4.5.** *Let $\gamma \geq 1$, $\tau > 0$ and $k \in \mathbb{N}$. Let X be a domain, $\mathcal{D}$ be a γ-flat class of distributions over X and D_0 be any distribution over X. Then*

$$\mathsf{RSD}^{(1)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau/(2k)) \leq \frac{4k \cdot \gamma^{k-1}}{\tau} \cdot \mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau).$$

Proof. Let $d \doteq \mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}, D_0), \tau)$. Fact 4.4 implies the existence of a distribution $\mathcal{P}$ over k-wise functions such that for every $D \in \mathcal{D}$,

$$\Pr_{\phi\sim\mathcal{P}}[|D^k[\phi] - D_0^k[\phi]| > \tau] \geq \frac{1}{d}.$$

We now fix D and let ϕ be such that $|D^k[\phi] - D_0^k[\phi]| > \tau$.

By the standard hybrid argument,

$$\mathbb{E}_{j\sim[k]}\left[\left|D^j D_0^{k-j}[\phi] - D^{j-1} D_0^{k-j+1}[\phi]\right|\right] > \frac{\tau}{k}, \tag{6}$$

where $j \sim [k]$ denotes a random and uniform choice of j from $[k]$. This implies that

$$\mathbb{E}_{j\sim[k]}\mathbb{E}_{x_{<j}\sim D^{j-1}}\mathbb{E}_{x_{>j}\sim D_0^{k-j}}\left[\left|D[\phi(x_{<j},\cdot,x_{>j})] - D_0[\phi(x_{<j},\cdot,x_{>j})]\right|\right] > \frac{\tau}{k}.$$

By an averaging argument (and using the fact that ϕ takes values between -1 and $+1$), we get that with probability at least $\tau/(4\cdot k)$ over the choice of $j \sim [k]$, $x_{<j} \sim D^{j-1}$ and $x_{>j} \sim D_0^{k-j}$, we have that

$$\left|D[\phi(x_{<j},\cdot,x_{>j})] - D_0[\phi(x_{<j},\cdot,x_{>j})]\right| > \frac{\tau}{2\cdot k}.$$

Since $\mathcal{D}$ is a γ-flat class of distributions, there exists a (fixed) distribution $\bar{D}$ over X such that for every measurable event $E \subset X$, $\Pr_{x\sim D}[x \in E] \leq \gamma \cdot \Pr_{x\sim\bar{D}}[x \in E]$. Thus, we can replace the unknown input distribution D by the distribution $\bar{D}$ and get that, with probability at least $\tau/(4\cdot k\cdot\gamma^{k-1})$ over the choice of $j \sim [k]$, $x_{<j} \sim \bar{D}^{j-1}$ and $x_{>j} \sim D_0^{k-j}$, we have

$$\left|D[\phi(x_{<j},\cdot,x_{>j})] - D_0[\phi(x_{<j},\cdot,x_{>j})]\right| > \frac{\tau}{2\cdot k}. \tag{7}$$

We now consider the following distribution $\mathcal{P}'$ over unary SQ functions (i.e., over $[-1,+1]^X$): Independently sample ϕ from $\mathcal{P}$, j uniformly from $[k]$, $x_{<j} \sim \bar{D}^{j-1}$ and $x_{>j} \sim D_0^{k-j}$, and output the (unary) function $\phi'(x) = \phi(x_{<j}, x, x_{>j})$. Then, for every $D \in \mathcal{D}$, we have that with probability at least $\frac{1}{d}\cdot\frac{\tau}{4k}\cdot\frac{1}{\gamma^{k-1}}$ over the choice of ϕ' from $\mathcal{P}'$, we have that $|D[\phi'] - D_0[\phi']| > \tau/(2\cdot k)$. Thus, by Fact 4.4

$$\mathsf{RSD}^{(1)}_{\kappa_1}\left(\mathcal{B}(\mathcal{D},D_0),\frac{\tau}{2\cdot k}\right) \leq \frac{4d\cdot\gamma^{k-1}\cdot k}{\tau}.$$ ◀

Lemma 4.5 together with the characterization in Theorem 6 imply the following upper bound on the SQ complexity of a decision problem in terms of its k-wise SQ complexity.

▶ **Theorem 7.** *Let $\gamma \geq 1$, $\tau > 0$ and $k \in \mathbb{N}$. Let X be a domain, $\mathcal{D}$ be a γ-flat class of distributions over X and D_0 be any distribution over X. If there exists an algorithm that, with probability at least $2/3$ solves $\mathcal{B}(\mathcal{D},D_0)$ using t queries to $\mathsf{STAT}^{(k)}_D(\tau)$, then for every $\delta > 0$, there exists an algorithm that, with probability at least $1-\delta$ solves $\mathcal{B}(\mathcal{D},D_0)$ using $t\cdot 12k\cdot\gamma^{k-1}\cdot\ln(1/\delta)/\tau$ queries to $\mathsf{STAT}^{(1)}_D(\tau/(4k))$.*

4.2 General problems

We now define the general class of problems over sets of distributions and a notion of statistical dimension for these types of problems.

▶ **Definition 4.6** (Search problems). *A search problem $\mathcal{Z}$ over a class $\mathcal{D}$ of distributions and a set $\mathcal{F}$ of solutions is a mapping $\mathcal{Z}: \mathcal{D} \to 2^{\mathcal{F}} \setminus \{\emptyset\}$, where $2^{\mathcal{F}}$ denotes the set of all subsets of $\mathcal{F}$. Specifically, for every distribution $D \in \mathcal{D}$, $\mathcal{Z}(D) \subseteq \mathcal{F}$ is the (non-empty) set of valid solutions for D. For a solution $f \in \mathcal{F}$, we denote by $\mathcal{Z}_f$ the set of all distributions for which f is a valid solution.*

▶ **Definition 4.7** (Statistical dimension for search problems [25]). *For $\tau > 0$, $k \in \mathbb{N}$, a domain X and a search problem $\mathcal{Z}$ over a class of distributions $\mathcal{D}$ over X and a set of solutions $\mathcal{F}$, we define the k-*wise statistical dimension *with κ_1-discrimination τ of $\mathcal{Z}$ as*

$$\mathsf{SD}^{(k)}_{\kappa_1}(\mathcal{Z},\tau) \doteq \sup_{D_0\in S^X}\inf_{f\in\mathcal{F}}\mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D}\setminus\mathcal{Z}_f,D_0),\tau),$$

where S^X denotes the set of all probability distributions over X.

Lemma 8 lower-bounds the deterministic k-wise SQ complexity of a search problem in terms of its (k-wise) statistical dimension.

▶ **Theorem 8** ([25]). *Let $\mathcal{Z}$ be a search problem, $\tau > 0$ and $k \in \mathbb{N}$. The deterministic k-wise SQ complexity of solving $\mathcal{Z}$ with access to $\mathsf{STAT}^{(k)}(\tau)$ is at least $\mathsf{SD}^{(k)}_{\kappa_1}(\mathcal{Z}, \tau)$.*

The following theorem from [25] gives an upper bound on the SQ complexity of a search problem in terms of its statistical dimension. It relies on the multiplicative weights update method to reconstruct the unknown distribution sufficiently well for solving the problem. The use of this algorithm introduces dependence on KL-radius of $\mathcal{D}$. Namely, we define

$$R_{\mathrm{KL}}(\mathcal{D}) \doteq \inf_{\bar{D} \in S^X} \sup_{D \in \mathcal{D}} \mathrm{KL}(D \| \bar{D}),$$

where $\mathrm{KL}(\cdot\|\cdot)$ denotes the KL-divergence.

▶ **Theorem 9** ([25]). *Let $\mathcal{Z}$ be a search problem, $\tau, \delta > 0$ and $k \in \mathbb{N}$. There is a randomized k-wise SQ algorithm that solves $\mathcal{Z}$ with success probability $1 - \delta$ using*

$$O\left(\mathsf{SD}^{(k)}_{\kappa_1}(\mathcal{Z}, \tau) \cdot \frac{R_{\mathrm{KL}}(\mathcal{D})}{\tau^2} \cdot \log\left(\frac{R_{\mathrm{KL}}(\mathcal{D})}{\tau \cdot \delta}\right)\right)$$

queries to $\mathsf{STAT}^{(k)}(\tau/3)$.

Note that KL-divergence between two distributions is upper-bounded (and is usually much smaller) than the max-divergence we used in the definition of γ-flatness. Specifically, if $\mathcal{D}$ is γ-flat then $R_{\mathrm{KL}}(\mathcal{D}) \leq \ln \gamma$. We are now ready to prove Theorem 2 which we restate here for convenience.

▶ **Theorem 2** (restated). *Let $\gamma \geq 1$, $\tau > 0$ and k be any positive integer. Let X be a domain and $\mathcal{D}$ be a γ-flat class of distributions over X. There exists a randomized algorithm that given any $\delta > 0$ and a k-ary function $\phi : X^k \to [-1, 1]$, estimates $D^k[\phi]$ within τ for every (unknown) $D \in \mathcal{D}$ with success probability at least $1 - \delta$ using*

$$\tilde{O}\left(\frac{\gamma^{k-1} \cdot k^3}{\tau^3} \cdot \log(1/\delta)\right)$$

queries to $\mathsf{STAT}^{(1)}_D(\tau/(6 \cdot k))$.

Proof. We first observe that the task of estimating $D^k[\phi]$ up to additive τ can be viewed as a search problem $\mathcal{Z}$ over the set $\mathcal{D}$ of distributions and over the class $\mathcal{F}$ of solutions that corresponds to the interval $[-1, +1]$. Next, observe that one can easily estimate $D^k[\phi]$ up to additive τ using a single query to $\mathsf{STAT}^{(k)}_D(\tau)$. Lemma 8 implies that $\mathsf{SD}^{(k)}_{\kappa_1}(\mathcal{Z}, \tau) = 1$. By Definition 4.7, for every $D_1 \in S^X$, there exists $f \in \mathcal{F}$, such that $\mathsf{RSD}^{(k)}_{\kappa_1}(\mathcal{B}(\mathcal{D} \setminus \mathcal{Z}_f, D_1), \tau) = 1$. By Lemma 4.5,

$$\mathsf{RSD}^{(1)}_{\kappa_1}\left(\mathcal{B}(\mathcal{D} \setminus \mathcal{Z}_f, D_1), \frac{\tau}{2 \cdot k}\right) \leq \frac{4 \cdot \gamma^{k-1} \cdot k}{\tau}.$$

Thus, Fact 4.4 and Definition 4.7 imply that

$$\mathsf{SD}^{(1)}_{\kappa_1}(\mathcal{Z}, \frac{\tau}{2 \cdot k}) \leq \frac{4 \cdot \gamma^{k-1} \cdot k}{\tau}.$$

Applying Lemma 9, we conclude that there exists a randomized unary SQ algorithm that solves $\mathcal{Z}$ with probability at least $1 - \delta$ using at most

$$O\left(\gamma^{k-1} \cdot k^3 \cdot \frac{R_{\mathrm{KL}}(\mathcal{D})}{\tau^3} \cdot \log\left(\frac{k \cdot R_{\mathrm{KL}}(\mathcal{D})}{\tau \cdot \delta}\right)\right)$$

queries to $\mathsf{STAT}^{(1)}(\tau/(6\cdot k))$. This – along with the fact that $R_{\mathrm{KL}}(\mathcal{D}) \leq \ln(\gamma)$ whenever $\mathcal{D}$ is a γ-flat set of distributions – concludes the proof of Theorem 2. ◀

4.2.1 Other divergences

While the max-divergence that we used for measuring flatness suffices for the applications we give in this paper (and is relatively simple), it might be too conservative in other problems. For example, such divergence is infinite even for two Gaussian distributions with the same standard deviation but different means. A simple way to obtain a more robust version of our reduction is to use approximate max-divergence. For $\delta \in [0,1)$ it is defined as:

$$\mathrm{D}^{\delta}_{\infty}(D\|\bar{D}) \doteq \ln \sup_{E\subseteq X} \frac{\Pr_{x\sim D}[x\in E]-\delta}{\Pr_{x\sim \bar{D}}[x\in E]}.$$

Note that $\mathrm{D}^{0}_{\infty}(D\|\bar{D}) = \mathrm{D}_{\infty}(D\|\bar{D})$. Similarly, we can define a radius of $\mathcal{D}$ in this divergence

$$R^{\delta}_{\infty}(\mathcal{D}) \doteq \inf_{\bar{D}\in S^X} \sup_{D\in\mathcal{D}} \mathrm{D}^{\delta}_{\infty}(D\|\bar{D}).$$

Now, it is easy to see that, if $\mathrm{D}^{\delta}_{\infty}(D\|\bar{D}) \leq r$ then $\mathrm{D}^{k\delta}_{\infty}(D^k\|\bar{D}^k) \leq kr$. This means that if in the proof of Lemma 4.5 we use the condition $R^{\tau/(8k^2)}_{\infty}(\mathcal{D}) \leq \ln\gamma$ instead of γ-flatness then we will obtain that the event in Equation (7) holds with probability at least

$$\left(\frac{\tau}{4k} - (k-1)\cdot\frac{\tau}{8k^2}\right)/\gamma^{k-1} \geq \frac{\tau}{\gamma^{k-1}\cdot 8k}$$

over the same random choices.

This implies the following generalization of Theorem 2.

▶ **Theorem 10.** *Let $\tau > 0$ and k be any positive integer. Let $\mathcal{D}$ be a class of distributions over a domain X and $\gamma = \exp(R^{\tau/(8k^2)}_{\infty}(\mathcal{D}))$. There exists a randomized algorithm that given any $\delta > 0$ and a k-ary function $\phi : X^k \to [-1,1]$, estimates $D^k[\phi]$ within τ for every (unknown) $D \in \mathcal{D}$ with success probability at least $1-\delta$ using*

$$\tilde{O}\left(\frac{\gamma^{k-1}\cdot k^3\cdot R_{\mathrm{KL}}(\mathcal{D})}{\tau^3}\cdot\log(1/\delta)\right)$$

queries to $\mathsf{STAT}^{(1)}_{D}(\tau/(6\cdot k))$.

An alternative approach is to use Renyi divergence of order $\alpha > 1$ defined as follows:

$$\mathrm{D}_{\alpha}(D\|\bar{D}) \doteq \frac{1}{1-\alpha}\cdot\ln\left(\mathbb{E}_{y\sim D}\left[\left(\frac{\Pr_{x\sim D}[x=y]}{\Pr_{x\sim\bar{D}}[x=y]}\right)^{\alpha-1}\right]\right).$$

The corresponding radius is defined as

$$R_{\alpha}(\mathcal{D}) \doteq \inf_{\bar{D}\in S^X} \sup_{D\in\mathcal{D}} \mathrm{D}_{\alpha}(D\|\bar{D}).$$

To use it in our application we need the standard property of the Renyi divergence for product distributions $\mathrm{D}_{\alpha}(D^k\|\bar{D}^k) = k\cdot\mathrm{D}_{\alpha}(D\|\bar{D})$ and also the following simple lemma from [33, Lemma 1]:

▶ **Lemma 4.8.** *For $\alpha > 1$, any two distributions $D, \bar{D}$ over X and an event $E \subseteq X$:*

$$\Pr_{x\sim D}[x\in E] \leq \left(\exp(\mathrm{D}_{\alpha}(D\|\bar{D}))\cdot\Pr_{x\sim\bar{D}}[x\in E]\right)^{\frac{\alpha-1}{\alpha}}.$$

We will need the inverted version of this lemma:

$$\Pr_{x\sim\bar{D}}[x \in E] \geq \frac{(\Pr_{x\sim D}[x \in E])^{\frac{\alpha}{\alpha-1}}}{\exp(\mathrm{D}_\alpha(D\|\bar{D}))}.$$

Applying this in the proof of Lemma 4.5 for $\gamma = \exp(R_\alpha(\mathcal{D}))$, we obtain that the event in Equation (7) holds with probability at least

$$\left(\frac{\tau}{4k}\right)^{\frac{\alpha}{\alpha-1}} / \gamma^{k-1}.$$

This gives the following generalization of Theorem 2.

▶ **Theorem 11.** *Let $\tau > 0, \alpha > 1$ and k be any positive integer. Let $\mathcal{D}$ be a class of distributions over a domain X and $\gamma = \exp(R_\alpha(\mathcal{D}))$. There exists a randomized algorithm that given any $\delta > 0$ and a k-ary function $\phi : X^k \to [-1, 1]$, estimates $D^k[\phi]$ within τ for every (unknown) $D \in \mathcal{D}$ with success probability at least $1 - \delta$ using*

$$\tilde{O}\left(\gamma^{k-1} \cdot \left(\frac{k}{\tau}\right)^{2+\frac{\alpha}{\alpha-1}} \cdot \log(1/\delta)\right)$$

queries to $\mathsf{STAT}_D^{(1)}(\tau/(6 \cdot k))$.

4.3 Applications to solving CSPs and learning DNF

We now give some examples of the application of our reduction to obtain lower bounds against k-wise SQ algorithms. Our applications for stochastic constraint satisfaction problems (CSPs) and DNF learning. We start with the definition of a stochastic CSP with a *planted solution* which is a pseudo-random generator based on Goldreich's proposed one-way function [29].

▶ **Definition 12.** Let $t \in \mathbb{N}$ and $P : \{\pm 1\}^t \to \{\pm 1\}$ be a fixed predicate. We are given access to samples from a distribution P_σ, corresponding to a ("planted") assignment $\sigma \in \{\pm 1\}^n$. A sample from this distribution is a uniform-random t-tuple $(i_1, \ldots, i_t)$ of distinct variable indices along with the value $P(\sigma_{i_1}, \ldots, \sigma_{i_t})$. The goal is to recover the assignment σ when given m independent samples from P_σ. A (potentially) easier problem is to distinguish any such planted distribution from the distribution U_t in which the value is an independent uniform-random coin flip (instead of $P(\sigma_{i_1}, \ldots, \sigma_{i_t})$).

We say that a predicate $P : \{\pm 1\}^t \to \{\pm 1\}$ has complexity r if r is the degree of the lowest-degree non-zero Fourier coefficient of P. It can be as large as t (for the parity function). A lower bound on the (unary) SQ complexity of solving such CSPs was shown by [28] (their result is for the stronger VSTAT oracle but here we state the version for the STAT oracle).

▶ **Theorem 13** ([28]). *Let $t, q \in \mathbb{N}$ and $P : \{\pm 1\}^t \to \{\pm 1\}$ be a fixed predicate of complexity r. Then for any $q > 0$, any algorithm that, given access to a distribution $D \in \{P_\sigma \mid \sigma \in \{\pm 1\}^n\} \cup \{U_t\}$ decides correctly whether $D = P_\sigma$ or $D = U_t$ with probability at least $2/3$ needs $q/2^{O(t)}$ queries to $\mathsf{STAT}_D^{(1)}\left(\left(\frac{\log q}{n}\right)^{r/2}\right)$.*

The set of input distributions in this problem is 2-flat relative to U_t and it is one-to-many decision problem. Hence Theorem 7 implies[2] the following lower bound for k-wise SQ algorithms.

[2] We can also get essentially the same result by applying the simulation of a k-wise SQ using unary SQs from Theorem 2.

▶ **Theorem 14.** *Let $t \in \mathbb{N}$ and $P : \{\pm 1\}^t \to \{\pm 1\}$ be a fixed predicate of complexity r. Then for any $\alpha > 0$, any algorithm that, given access to a distribution $D \in \{P_\sigma \mid \sigma \in \{\pm 1\}^n\} \cup \{U_t\}$ decides correctly whether $D = P_\sigma$ or $D = U_t$ with probability at least $2/3$ needs $2^{n^{1-\alpha}-O(t)}$ queries to $\mathsf{STAT}_D^{(n^{1-\alpha})}\left((2/n^\alpha)^{r/2} \cdot n^{1-\alpha}/4\right)$.*

Proof. Let $\mathcal{A}$ be a k-wise SQ algorithm using q' queries to $\mathsf{STAT}_D^{(n^{1-\alpha})}\left((2/n^\alpha)^{r/2} \cdot n^{1-\alpha}/6\right)$ which solves the problem with success probability $2/3$. We let $k = n^{1-\alpha}$ and apply Theorem 7 to obtain an algorithm that uses unary SQs and solves the problem with success probability $2/3$. This algorithm uses $q_0 = q' \cdot 2^{n^{1-\alpha}} \cdot n^{O(r)}$ queries to $\mathsf{STAT}_D^{(1)}\left((2/n^\alpha)^{r/2}\right)$. Now choosing $q = 2^{2n^{1-\alpha}}$ we get that $\left(\frac{\log q}{n}\right)^{r/2} \leq (2/n^\alpha)^{r/2}$. This means that $q_0 \geq q/2^{O(t)} = 2^{2n^{1-\alpha}-O(t)}$. Hence $q' = 2^{2n^{1-\alpha}-O(t)-n^{1-\alpha}-O(r)} = 2^{n^{1-\alpha}-O(t)}$. ◀

Similar lower bounds can be obtained for other problems considered in [28], namely, planted satisfiability and t-SAT refutation.

To obtain a lower bound for learning DNF formulas we can use a simple reduction from the Goldreich's PRG defined above to learning DNF formulas of polynomial size. It is based on ideas implicit in the reduction from t-SAT refutation to DNF learning from [13].

▶ **Lemma 15.** *$P : \{\pm 1\}^t \to \{\pm 1\}$ be a fixed predicate. There exists a mapping M from t-tuples of indices in $[n]$ to $\{0,1\}^{tn}$ such that for every $\sigma \in \{\pm 1\}^n$ there exists a DNF formula f_σ of size 2^t satisfying $P(\sigma_{i_1}, \ldots, \sigma_{i_t}) = f_\sigma(M(i_1, \ldots, i_t))$.*

Proof. The mapping M maps $(i_1, \ldots, i_t)$ to the concatenation of the indicator vectors of each of the indices. Namely, for $j \in [t]$ and $\ell \in [n]$, $M(i_1, \ldots, i_t)_{j,\ell} = 1$ if and only if $i_j = \ell$, where we use the double index j, ℓ to refer to element $n(j-1)+\ell$ of the vector. Let $v_{j,\ell}$ denote the variable with the index j, ℓ. Let σ be any assignment and we denote by z_j^σ the j-th variable of our predicate P when the assignment is equal to σ. We first observe that $z_j^\sigma \equiv \bigwedge_{\ell \in [n], \sigma_\ell = 0} \bar{v}_{j,\ell}$. This is true since, by definition, the value of the j-th variable of our predicate is σ_{i_j}. This value is 1 if and only if $i_j \notin \{\ell \in [n] \mid \sigma_\ell = 0\}$. This is equivalent to $v_{j,\ell}$ being equal to 0 for all $\ell \in [n]$ such that $\sigma_\ell = 0$. Analogously, $\bar{z}_j^\sigma \equiv \bigwedge_{\ell \in [n], \sigma_\ell = 1} \bar{v}_{j,\ell}$. This implies that any conjunction of variables $z_1^\sigma, \bar{z}_1^\sigma, \ldots, z_t^\sigma, \bar{z}_t^\sigma$ can be expressed as a conjunction over variables $\bar{v}_{j,\ell}$. Any predicate P can be expressed as a disjunction of at most 2^t conjunctions and hence there exists a DNF formula f_σ of size at most 2^t whose value on $M(i_1, \ldots, i_t)$ is equal to $P(\sigma_{i_1}, \ldots, \sigma_{i_t})$. ◀

This reduction implies that by converting a sample $((i_1, \ldots, i_t), b)$ to a sample $(M(i_1, \ldots, i_t), b)$ we can transform the Goldreich's PRG problem into a problem in which our goal is to distinguish examples of some DNF formula f_σ from randomly labeled examples. Naturally, an algorithm that can learn DNF formulas can output a hypothesis which predicts the label (with some non-trivial accuracy), whereas such hypothesis cannot exist for predicting random labels. Hence known SQ lower bounds on planted CSPs [28] immediately imply lower bounds for learning DNF. Further, by applying Lemma 15 together with Thm. 14 for $t = r = \log n$ we obtain the first lower bounds for learning DNF against $n^{1-\alpha}$-wise SQ algorithms.

▶ **Theorem 16.** *For any constant (independent of n) $\alpha > 0$, there exists a constant $\beta > 0$ such that any algorithm that PAC learns DNF formulas of size n with error $< 1/2 - n^{-\beta \log n}$ and success probability at least $2/3$ needs at least $2^{n^{1-\alpha}}$ queries to $\mathsf{STAT}_D^{(n^{1-\alpha})}(n^{-\beta \log n})$.*

We remark that this is a lower bound for PAC learning polynomial size DNF formulas with respect to some fixed (albeit non-uniform) distribution over $\{0,1\}^n$. The approach for relating k-wise SQ complexity to unary SQ complexity given in [9] applies to this setting. Yet, in their proof the tolerance needed for the unary SQ algorithm is $\tau/2^k$ and therefore it would not give a non-trivial lower bounds beyond $k = O(\log n)$.

5 Reduction for low-communication queries

In this section, we prove Theorem 4 using a recent result of Steinhardt, Valiant and Wager [36]. Their result can be seen giving a SQ algorithm that simulates a communication protocol between n parties. Each party is holding a sample drawn i.i.d. from distribution D and broadcasts at most b bits about its sample (to all the other parties). The bits can be sent over multiple rounds. This is essentially the standard model of multi-party communication complexity (*e.g.* [32]) but with the goal of solving some problem about the unknown distribution D rather than computing a specific function of the inputs. Alternatively, one can also see this model as a single algorithm that extracts at most b-bits of information about each random sample from D and is allowed to extract the bits in an arbitrary order (generalizing the b-bit sampling model that we discuss in Section 6.2 and in which b-bits are extracted from each sample at once). We refer to this model simply as algorithms that extract at most b bits per sample.

▶ **Theorem 17** ([36]). *Let $\mathcal{A}$ be an algorithm that uses n samples drawn i.i.d. from a distribution D and extracts at most b bits per sample. Then, for every $\beta > 0$, there is an algorithm $\mathcal{B}$ that makes at most $2 \cdot b \cdot n$ queries to $\mathsf{STAT}_D^{(1)}(\beta/(2^{b+1} \cdot k))$ and the output distributions of $\mathcal{A}$ and $\mathcal{B}$ are within total variation distance β.*

We will use this simulation to estimate the expectation of k-wise functions that have low communication complexity. Specifically, we recall the following standard model of public-coin randomized k-party communication complexity.

▶ **Definition 5.1.** *For a function $\phi : X^k \to \{\pm 1\}$ we say that ϕ has a k-party public-coin randomized communication complexity of at most b bits per party with success probability $1 - \delta$ if there exist a protocol satisfying the following conditions. Each of the parties is given $x_i \in X$ and access to shared random bits. In each round one of the parties can compute one or more bits using its input, random bits and all the previous communication and then broadcast it to all the other parties. In the last round one of the parties computes a bit that is the output of the protocol. Each of the parties communicates at most b bits in total. For every $x_1, \ldots, x_k \in X$, with probability at least $1 - \delta$ over the choice of the random bits the output of the protocol is equal to $\phi(x_1, \ldots, x_k)$.*

We are now ready to prove Theorem 4 which we restate here for convenience.

▶ **Theorem 4** (restated). *Let $\phi : X^k \to \{\pm 1\}$ be a function, and assume that ϕ has k-party public-coin randomized communication complexity of b bits per party with success probability $2/3$. Then, there exists a randomized algorithm that, with probability at least $1 - \delta$, estimates $\mathbb{E}_{x \sim D^k}[\phi(x)]$ within τ using $O(b \cdot k \cdot \log(1/\delta)/\tau^2)$ queries to $\mathsf{STAT}_D^{(1)}(\tau')$ for some $\tau' = \tau^{O(b)}/k$.*

Proof. We first amplify the success probability of the protocol for computing ϕ to $\delta' \doteq \tau/8$ using the majority vote of $O(\log(1/\delta'))$ repetitions. By Yao's minimax theorem [42] there exists a deterministic protocol Π' that succeeds with probability at least $1 - \delta'$ for $(x_1, \ldots, x_k) \sim D^k$. Applying Theorem 17, we obtain a unary SQ algorithm $\mathcal{A}$ whose output

is within total variation distance at most $\beta \doteq \tau/8$ from $\Pi'(x_1, \ldots, x_k)$ (and we can assume that the output of $\mathcal{A}$ is in $\{\pm 1\}$). Therefore:

$$|\mathbb{E}[\mathcal{A}] - D^k[\phi]| \leq |\mathbb{E}[\mathcal{A}] - \mathbb{E}_{D^k}[\Pi'(x_1, \ldots, x_k)]| + |\mathbb{E}_{D^k}[\Pi'(x_1, \ldots, x_k)] - D^k[\phi]| \leq \frac{2\tau}{8} + \frac{2\tau}{8} = \frac{\tau}{2}.$$

Repeating $\mathcal{A}$ $O(\log(1/\delta)/\tau^2)$ times and taking the mean, we get an estimate of $D^k[\phi]$ within τ with probability at least $1-\delta$. This algorithm uses $O(b \cdot k \cdot \log(1/\delta)/\tau^2)$ queries to $\mathsf{STAT}_D^{(1)}(\tau')$ for $\tau' = \frac{\tau}{8}/(2^{O(\log(8/\tau)\cdot b)} \cdot k) = \tau^{O(b)}/k$. ◀

The collision probability for a distribution D is defined as $\Pr_{(x_1,x_2)\sim D^2}[x_1 = x_2]$. This corresponds to $\phi(x_1, x_2)$ being the Equality function which, as is well-known, has randomized 2-party communication complexity of $O(1)$ bits per party with success probability $2/3$ (see, e.g., [32]). Applying Theorem 4 with $k = 2$ we get the following corollary.

▶ **Corollary 18.** *For any $\tau, \delta > 0$, there is a SQ algorithm that estimates the collision probability of an unknown distribution D within τ with success probability $1 - \delta$ using $O(\log(1/\delta)/\tau^2)$ queries to $\mathsf{STAT}_D^{(1)}(\tau^{O(1)})$.*

6 Corollaries for other models

6.1 k-local differential privacy

We start by formally defining the k-wise version of the *local differentially privacy* model from [30].

▶ **Definition 6.1** (k-local randomizer)**.** *A k-local ϵ-differentially private (DP) randomizer is a randomized map $R : X^k \to W$ such that for all $u, u' \in X^k$ and all $w \in W$, we have that $\Pr[R(u) = w] \leq e^\epsilon \cdot \Pr[R(u') = w]$ where the probabilities are taken over the coins of R.*

The following definition gives a k-wise generalization of the local randomizer (LR) oracle which was used in [30].

▶ **Definition 6.2** (k-local Randomizer Oracle)**.** *Let $z = (z_1, \ldots, z_n) \in X^n$ be a database. A k-LR oracle $\mathsf{LR}_z(\cdot, \cdot)$ gets a k-tuple of indices $\bar{i} \in [n]^k$ and a k-local ϵ-DP randomizer as inputs, and outputs an element $w \in W$ which is sampled from the distribution $R(z_{i_1}, \ldots, z_{i_k})$.*

We are now ready to give the definition of k-local differential privacy.

▶ **Definition 6.3** (k-local differentially private algorithm)**.** *A k-local ϵ-differentially private algorithm is an algorithm that accesses a database $z \in X^n$ via a k-LR oracle LR_z with the restriction that for all $i \in [n]$, if $\mathsf{LR}_z(\bar{i}_1, R_1), \ldots, \mathsf{LR}_z(\bar{i}_t, R_t)$ are the algorithm's invocations of LR_z on k-tuples of indices that include index i, where for each $j \in [t]$ R_j is a k-local ϵ_j-DP randomizer, then $\epsilon_1 + \cdots + \epsilon_t \leq \epsilon$.*

The following two theorems – which follow from Theorem 5.7 and Lemma 5.8 of [30] – show that k-local differentially private algorithms are equivalent (up to polynomial factors) to k-wise statistical query algorithms.

▶ **Theorem 19.** *Let $\mathcal{A}_{SQ}$ be a k-wise SQ algorithm that makes at most t queries to $\mathsf{STAT}_D^{(k)}(\tau)$. Then, for every $\beta > 0$, there exists a k-local ϵ-DP algorithm $\mathcal{A}_{DP}$ such that if the database z has $n \geq n_0 = O(k \cdot t \cdot \log(t/\beta)/(\epsilon^2 \cdot \tau^2))$ entries sampled i.i.d. from the distribution D, then $\mathcal{A}_{DP}$ makes n_0/k queries and the total variation between $\mathcal{A}_{DP}$'s and $\mathcal{A}_{SQ}$'s output distributions is at most β.*

▶ **Theorem 20.** *Let $z \in X^n$ be a database with entries drawn i.i.d. from a distribution D. For every k-local ϵ-DP algorithm $\mathcal{A}_{DP}$ making t queries to LR_z and $\beta > 0$, there exists a k-wise statistical query algorithm $\mathcal{A}_{SQ}$ that in expectation makes $O(t \cdot e^{\epsilon})$ queries to $\mathsf{STAT}_D^{(k)}(\tau)$ for $\tau = \Theta(\beta/(e^{2\epsilon} \cdot t))$ such that the total variation between $\mathcal{A}_{SQ}$'s and $\mathcal{A}_{DP}$'s output distributions is at most β.*

By combining Theorem 1, Theorem 19 and Theorem 20 we then obtain the following corollary.

▶ **Corollary 21.** *For every positive integer k and any prime number p, there is a concept class $\mathcal{C}$ of Boolean functions defined over a domain of size p^{k+1} for which there exists a $(k+1)$-local 1-DP distribution-independent PAC learning algorithm using a database consisting of $\widetilde{O}_k(\log p)$ i.i.d. samples, whereas any k-local 1-DP distribution-independent PAC learning algorithm requires $\Omega_k(p^{1/4})$ samples.*

The reduction in Theorem 2 then implies that for γ-flat classes of distributions a k-local DP algorithm can be simulated by a 1-local DP algorithm with an overhead that is linear in γ^{k-1} and polynomial in other parameters.

▶ **Theorem 22.** *Let $\gamma \geq 1$, k be any positive integer. Let X be a domain and $\mathcal{D}$ a γ-flat class of distributions over X. Let $z \in X^n$ be a database with entries drawn i.i.d. from a distribution $D \in \mathcal{D}$. For every k-local ϵ-DP algorithm $\mathcal{A}$ making t queries to a k-LR oracle LR_z and $\beta > 0$, there exists a 1-local ϵ-DP algorithm $\mathcal{B}$ such that if $n \geq n_0 = \tilde{O}\left(\frac{\gamma^{k-1} \cdot t^6 \cdot k^6 \cdot e^{11\epsilon}}{\beta^3 \epsilon^2}\right)$ then for every $D \in \mathcal{D}$, $\mathcal{B}$ makes n_0/k queries to 1-LR oracle LR'_z and the total variation distance between $\mathcal{B}$'s and $\mathcal{A}$'s output distributions is at most β.*

The reduction from Theorem 4 can be translated to this model analogously.

6.2 k-wise b-bit sampling model

For an integer $b > 0$, a b-bit sampling oracle $\mathrm{BS}_D(b)$ is defined as follows: Given any function $\phi : X \to \{0,1\}^b$, $\mathrm{BS}_D(b)$ returns $\phi(x)$ for x drawn randomly and independently from D, where D is the unknown input distribution. This oracle was first studied by Ben-David and Dichterman [4] as a *weak Restricted Focus of Attention* model. They showed that algorithms in this model can be simulated efficiently using statistical queries and vice versa. Lower bounds against algorithms that use such an oracle have been studied in [26, 28]. More recently, motivated by communication constraints in distributed systems, the sample complexity of several basic problems in statistical estimation has been studied in this and related models [43, 37, 36]. These works also study the natural k-wise generalization of this model. Specifically, $\mathrm{BS}_D^{(k)}(b)$ is the oracle that given any function $\phi : X^k \to \{0,1\}^b$, returns $\phi(x)$ for x drawn randomly and independently from D^k.

The following two theorems – which follow from Theorem 5.2 in [4] and Proposition 3 in [36] (that strengthens a similar result in [4]) – show that k-wise algorithms in the b-bit sampling model are equivalent (up to polynomial and 2^b factors) to k-wise statistical query algorithms.

▶ **Theorem 23.** *Let $\mathcal{A}_{SQ}$ be a k-wise SQ algorithm that makes at most t Boolean queries to $\mathsf{STAT}_D^{(k)}(\tau)$. Then, for every $\beta > 0$, there exists a k-wise 1-bit sampling algorithm $\mathcal{A}_{1\text{-}bit}$ that uses $O(\frac{t}{\tau^2} \cdot \log(t/\beta))$ queries to $BS_D^{(k)}(b)$ and the total variation distance between $\mathcal{A}_{SQ}$'s and $\mathcal{A}_{1\text{-}bit}$'s output distributions is at most β.*

▶ **Theorem 24.** *Let $\mathcal{A}_{b\text{-}bit}$ be a k-wise b-bit sampling algorithm that makes at most t queries to $BS_D^{(k)}(b)$. Then, for every $\beta > 0$, there exists a k-wise SQ algorithm $\mathcal{A}_{SQ}$ that makes $2bt$ queries to $\mathsf{STAT}_D^{(k)}(\beta/(2^{b+1}t))$ and the total variation distance between $\mathcal{A}_{SQ}$'s and $\mathcal{A}_{b\text{-}bit}$'s output distributions is at most β.*

Feldman et al. [26] give a tighter correspondence between the BS oracle and the slightly stronger VSTAT oracle. Their simulations can be extended to the k-wise case in a similar way.

The following corollary now follows by combining Theorem 1, Theorem 23 and Theorem 24.

▶ **Corollary 25.** *Let $b = O(1)$. For every positive integer k and any prime number p, there is a concept class $\mathcal{C}$ of Boolean functions defined over a domain of size p^{k+1} for which there exists a $(k+1)$-wise b-bit sampling distribution-independent PAC learning algorithm making $\widetilde{O}_k(\log p)$ queries, whereas any k-wise b-bit sampling distribution-independent PAC learning algorithm requires $\widetilde{\Omega}_k(p^{1/12})$ queries.*

The reduction in Theorem 2 then implies that for γ-flat classes of distributions a k-wise 1-bit sampling algorithm can be simulated by a 1-wise 1-bit sampling algorithm.

▶ **Theorem 26.** *Let $\gamma \geq 1$, k be any positive integer. Let X be a domain and $\mathcal{D}$ a γ-flat class of distributions over X. For every algorithm $\mathcal{A}$ making t queries to $BS_D^{(k)}(1)$ and every $\beta > 0$, there exists a 1-bit sampling algorithm $\mathcal{B}$ that for every $D \in \mathcal{D}$, uses $\tilde{O}\left(\frac{\gamma^{k-1} \cdot t^6 \cdot k^5}{\beta^3}\right)$ queries to $BS_D(1)$ and the total variation distance between $\mathcal{B}$'s and $\mathcal{A}$'s output distributions is at most β.*

A Omitted proofs

A.1 Proof of Lemma 3.5

In the following, we denote by $o_c(\cdot)$ and $\omega_c(\cdot)$ asymptotic functions obtained by taking the limit as the parameter c goes to infinity. In particular, $o_c(1)$ can be made arbitrarily close to 0 by letting c be large enough.

Let W be as in the statement of Lemma 3.5. To prove the lemma, it suffices to show that each bit j in the binary representation of the subspace $\widehat{W}$ constructed by Algorithm 2 is equal to the corresponding bit of W. Henceforth, we fix j. We consider the two cases where bit j of W is equal to 1, and where it is equal to 0.

First, we assume that bit j of W is equal to 1, and prove that in the execution of Algorithm 2, it will be the case that $u_{i,j}/v_i \geq 1 - o_c(1)$. We can then set c to be sufficiently large to ensure that $u_{i,j}/v_i \geq (9/10)$. Note that for any positive real numbers N, D and τ such that $\tau = o(N)$ and $\tau = o(D)$, we have that

$$\frac{N-\tau}{D+\tau} \geq \frac{N}{D} \cdot (1 - o(1)).$$

Thus, it is enough to show that the next three statements hold:

(i) $\tau = o_c(\overline{v}_i)$,
(ii) if bit j of W is 1, then $(\overline{u}_{i,j}/\overline{v}_i) \geq 1 - o_c(1)$,
(iii) if bit j of W is 1, then $\tau = o_c(\overline{u}_{i,j})$,

where $\overline{u}_{i,j} \triangleq \mathbb{E}[\phi_{i,j}]$ and $\overline{v}_i \triangleq \mathbb{E}[\phi_i]$.

To show (i) above, note that

$$\begin{aligned}
\overline{v}_i &= \Pr\left[(b_1, \ldots, b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i\right] \\
&\geq v_i - \tau \\
&\geq v \cdot \tau_i - \tau \\
&\geq \omega_c(\tau),
\end{aligned}$$

where the first inequality follows from the definition of v_i and the SQ guarantee, the second inequality follows from the given assumption (in the statement of Lemma 3.5) that $(v_i/v) \geq \tau_i$, and the last inequality follows from the fact that since $v > \epsilon^{k+1}/2$, for every $i \in [k+1]$, we have that

$$\tau = o_c\Big((v \cdot \tau_i - \tau) \cdot (1 - \tau_i/4)\Big).$$

.

Recall the definition of the event $E_j(Z)$ from the description of Algorithm 2. To show (ii) above, note that

$$\begin{aligned}
\frac{\overline{u}_{i,j}}{\overline{v}_i} &= \Pr\left[E_j(Z) \mid (b_1,\ldots,b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i\right] \\
&\geq \Pr\left[\text{all rows of } Z \text{ belong to } W \mid (b_1,\ldots,b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i\right] \\
&= 1 - \Pr\left[\exists \text{ a row of } Z \text{ that } \notin W \mid (b_1,\ldots,b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i\right] \\
&\geq 1 - (k+1) \cdot \Pr_{z\sim Q}[z \notin W] \\
&\geq 1 - \frac{\tau_i}{4} \\
&\geq 1 - o_c(1),
\end{aligned}$$

where the first inequality uses the assumption that bit j in the binary representation of W is 1 and the facts that the dimension of W is equal to i and that we are conditioning on $\mathsf{rk}[Z] = i$. The second inequality follows from the union bound, the third inequality follows from the assumption given in Lemma 2, and the last inequality follows from the fact that for every $i \in [k+1]$, we have that $\tau_i = o_c(1)$.

To show (iii) above, note that

$$\begin{aligned}
\overline{u}_{i,j} &= \overline{v}_i \cdot \frac{\overline{u}_{i,j}}{\overline{v}_i} \\
&\geq \omega_c(\tau) \cdot (1 - o_c(1)) \\
&\geq \omega_c(\tau),
\end{aligned}$$

where the first inequality follows from (i) and (ii) above.

We now turn to the (slightly different) case where bit j of W is equal to 0, and prove that in the execution of Algorithm 2, we will have that $u_{i,j}/v_i = o_c(1)$. Note that for any positive real numbers N, D and τ such that $\tau = o(D)$, we have that

$$\frac{N+\tau}{D-\tau} \leq \frac{N}{D} \cdot (1 + o(1)) + o(1).$$

Thus, it is enough to use the fact that $\tau = o_c(\overline{v}_i)$ (proven in (i) above) and to show the next statement:

(iv) if bit j of W is 0, then $(\overline{u}_{i,j}/\overline{v}_i) = o_c(1)$.

To prove (iv), note that since bit j of W is 0, we have that

$$\begin{aligned}
\frac{\overline{u}_{i,j}}{\overline{v}_i} &\leq \Pr\left[\exists \text{ a row of } Z \text{ that } \notin W \mid (b_1,\ldots,b_{k+1}) = 1^{k+1} \text{ and } \mathsf{rk}(Z) = i\right] \\
&\leq \frac{\tau_i}{4} \\
&\leq o_c(1),
\end{aligned}$$

where the first inequality above follows from the assumption that bit j in the binary representation of W is 0 and the facts that the dimension of W is equal to i and that we are conditioning on $\mathsf{rk}[Z] = i$. The second inequality above follows from the union bound and the assumption given in Lemma 2, and the last inequality follows from the fact that for every $i \in [k+1]$, we have that $\tau_i = o_c(1)$. As before, we choose c to be sufficiently large to ensure that this last probability is smaller than $(1/10)$.

A.2 Proof of Proposition 3.12

Let $a \in \mathbb{F}_p^\ell$. We have that:

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)] &= \mathbb{E}_{(z,b)\sim D_0}\left[\prod_{i=1}^{k}\mathbb{E}_{(z_i,b_i)\sim D_0}[D_a(z_i,b_i)\right] \\
&= \prod_{i=1}^{k}\mathbb{E}_{(z_i,b_i)\sim D_0}\left[D_a(z_i,b_i)\right] \\
&= \prod_{i=1}^{k}\mathbb{E}_{(z_i,b_i)\sim D_0}\left[D_a(z_i)\cdot\mathbb{1}(b_i = f_a(z_i))\right] \\
&= \prod_{i=1}^{k}\mathbb{E}_{z_i\sim D_0}\left[D_a(z_i)\cdot\mathbb{E}_{b_i\in_R\{\pm 1\}}[\mathbb{1}(b_i = f_a(z_i))]\right] \\
&= \frac{1}{2^k}\cdot\prod_{i=1}^{k}\mathbb{E}_{z_i\sim D_0}\left[D_a(z_i)\right] \\
&= \frac{1}{2^k}\cdot\left(\frac{1}{p}\cdot\beta + \left(1-\frac{1}{p}\right)\cdot\alpha\right)^k.
\end{aligned}$$

A.3 Proof of Proposition 3.13

Let $a, a' \in \mathbb{F}_p^\ell$. First, assume that $\mathsf{Hyp}_a = \mathsf{Hyp}_{a'}$, i.e., that $a = a'$. Then,

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)^2] \\
&= \mathbb{E}_{(z,b)\sim D_0}\left[\prod_{i=1}^{k}D_a(z_i,b_i)^2\right] \\
&= \prod_{i=1}^{k}\mathbb{E}_{(z_i,b_i)\sim D_0}[D_a(z_i,b_i)^2] \\
&= \prod_{i=1}^{k}\mathbb{E}_{(z_i,b_i)\sim D_0}[D_a(z_i)^2\cdot\mathbb{1}(b_i = f_a(z_i))] \\
&= \prod_{i=1}^{k}\mathbb{E}_{z_i}\left[D_a(z_i)^2\cdot\mathbb{E}_{b_i}[\mathbb{1}(b_i = f_a(z_i))]\right]
\end{aligned}$$

Thus,

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \frac{1}{2^k}\cdot\prod_{i=1}^{k}\mathbb{E}_{z_i}[D_a(z_i)^2] \\
&= \frac{1}{2^k}\cdot\prod_{i=1}^{k}\left(\frac{1}{p}\cdot\beta^2 + \left(1-\frac{1}{p}\right)\cdot\alpha^2\right) \\
&= \frac{1}{2^k}\cdot\left(\frac{1}{p}\cdot\beta^2 + \left(1-\frac{1}{p}\right)\cdot\alpha^2\right)^k.
\end{aligned}$$

Now we assume that $\mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} = \emptyset$. Then,

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \mathbb{E}_{(z,b)\sim D_0}\left[\prod_{i=1}^{k} D_a(z_i,b_i)\cdot D_{a'}(z_i,b_i)\right] \\
&= \prod_{i=1}^{k} \mathbb{E}_{(z_i,b_i)\sim D_0}[D_a(z_i,b_i)\cdot D_{a'}(z_i,b_i)] \\
&= \prod_{i=1}^{k} \mathbb{E}_{(z_i,b_i)\sim D_0}[D_a(z_i)\cdot \mathbb{1}(b_i = f_a(z_i)) \\
&\quad \cdot D_{a'}(z_i)\cdot \mathbb{1}(b_i = f_{a'}(z_i))] \\
&= \prod_{i=1}^{k} \mathbb{E}_{z_i}\Big[D_a(z_i)\cdot D_{a'}(z_i)\cdot \mathbb{1}(f_a(z_i) = f_{a'}(z_i)) \\
&\quad \cdot \mathbb{E}_{b_i}[\mathbb{1}(b_i = f_a(z_i))]\Big] \\
&= \frac{1}{2^k}\cdot \prod_{i=1}^{k} \mathbb{E}_{z_i}\Big[D_a(z_i)\cdot D_{a'}(z_i)\cdot \mathbb{1}(f_a(z_i) = f_{a'}(z_i))\Big] \\
&= \frac{1}{2^k}\cdot \prod_{i=1}^{k} \left(\alpha^2\cdot\left(1-\frac{2}{p}\right)\right) \\
&= \frac{1}{2^k}\cdot \left(\alpha^2\cdot\left(1-\frac{2}{p}\right)\right)^k.
\end{aligned}$$

Finally, we assume that $\mathsf{Hyp}_a \neq \mathsf{Hyp}_{a'}$ and $\mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} \neq \emptyset$. Then,

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \frac{1}{2^k}\cdot \prod_{i=1}^{k} \mathbb{E}_{z_i}\Big[D_a(z_i)\cdot D_{a'}(z_i)\cdot \mathbb{1}(f_a(z_i) = f_{a'}(z_i))\Big] \\
&= \frac{1}{2^k}\cdot \prod_{i=1}^{k} \left(\frac{\beta^2}{p^2} + \alpha^2\cdot\left(1-\frac{2}{p}+\frac{1}{p^2}\right)\right) \\
&= \frac{1}{2^k}\cdot \left(\frac{\beta^2}{p^2} + \alpha^2\cdot\left(1-\frac{2}{p}+\frac{1}{p^2}\right)\right)^k.
\end{aligned}$$

A.4 Proof of Proposition 3.14

First, we assume that $a, a' \in \mathbb{F}_p^\ell$ are such that $\mathsf{Hyp}_a = \mathsf{Hyp}_{a'}$, i.e., $a = a'$. Then, by Proposition 3.13 and by our settings of α and β, we have that

$$\begin{aligned}
\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \frac{1}{2^k}\cdot \left(\frac{1}{p}\cdot\beta^2 + \left(1-\frac{1}{p}\right)\cdot\alpha^2\right)^k \\
&= \frac{1}{2^{2k}\cdot p^{(2\ell-1)\cdot k}}\cdot\left(1+\frac{1}{p-1}\right)^k.
\end{aligned}$$

Hence, $D_0[\hat{D}_a\cdot\hat{D}_{a'}] = \left(p+1-\frac{1}{p-1}\right)^k - 1$, as desired.

Next, we assume that $a, a' \in \mathbb{F}_p^\ell$ are such that $\mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} = \emptyset$. Then, by Proposition 3.13

and by our setting of α, we have that

$$\begin{aligned}\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \frac{1}{2^k}\cdot(\alpha^2\cdot(1-\frac{2}{p}))^k \\ &= \frac{1}{2^{3k}\cdot p^{2k\ell}}\cdot\frac{(1-\frac{2}{p})^k}{(1-\frac{1}{p})^{2k}}.\end{aligned}$$

Hence, $D_0[\hat{D}_a\cdot\hat{D}_{a'}] = \frac{1}{2^k}\cdot\frac{(1-\frac{2}{p})^k}{(1-\frac{1}{p})^{2k}} - 1$, as desired.

Finally, we assume that $a, a' \in \mathbb{F}_p^\ell$ are such that $\mathsf{Hyp}_a \neq \mathsf{Hyp}_{a'}$ and $\mathsf{Hyp}_a \cap \mathsf{Hyp}_{a'} \neq \emptyset$. Then, by Proposition 3.13 and by our settings of α and β, we have that

$$\begin{aligned}\mathbb{E}_{(z,b)\sim D_0}[D_a(z,b)\cdot D_{a'}(z,b)] &= \frac{1}{2^k}\cdot(\frac{\beta^2}{p^2}+\alpha^2\cdot(1-\frac{2}{p}+\frac{1}{p^2}))^k \\ &= \frac{1}{2^{2k}\cdot p^{2k\ell}}.\end{aligned}$$

Hence, $D_0[\hat{D}_a\cdot\hat{D}_{a'}] = 0$, as desired.

Detecting Communities Is Hard (And Counting Them Is Even Harder)*

Abstract

We consider the algorithmic problem of community detection in networks. Given an undirected friendship graph $G = (V, E)$, a subset $S \subseteq V$ is an (α, β)-community if:

- Every member of the community is friends with an α-fraction of the community;
- Every non-member is friends with at most a β-fraction of the community.

Arora et al [3] gave a quasi-polynomial time algorithm for enumerating all the (α, β)-communities for any constants $\alpha > \beta$.

Here, we prove that, assuming the Exponential Time Hypothesis (ETH), quasi-polynomial time is in fact necessary - and even for a much weaker approximation desideratum. Namely, distinguishing between:

- G contains an $(1, o(1))$-community; and
- G does not contain a $(\beta + o(1), \beta)$-community for any $\beta \in [0, 1]$.

We also prove that counting the number of $(1, o(1))$-communities requires quasi-polynomial time assuming the weaker #ETH.

1 Introduction

Identifying communities is a central graph-theoretic problem with important applications to sociology and marketing (when applied to social networks), biology and bioinformatics (when applied to protein interaction networks), and more (see e.g. Fortunato's classic survey [21]). Defining what exactly is a *community* remains an interesting problem on its own (see Arora et al [3] and Borgs et al [11] for excellent treatment from a theoretical perspective). Ultimately, there is no single "right" definition, and the precise meaning of community should be different for social networks and protein interaction networks.

In this paper we focus on the algorithmic questions arising from one of the simplest and most canonical definitions, which has been considered by several theoretical computer scientists [30, 3, 5, 12] (see Subsection 1.1 for further discussion):

▶ **Definition 1** ((α, β)-Community)**.** Given an undirected graph $G = (V, E)$ an (α, β)-community is a subset $S \subseteq V$ that satisfies:

Strong ties inside the community For every $v \in S$, $|\{v\} \times S| \cap E \geq \alpha \cdot |S|$; and

Weak ties to nodes outside the community For every $u \notin S$, $|\{u\} \times S| \cap E \leq \beta \cdot |S|$.

Arora et al [3, Theorem 3.1] gave a simple quasi-polynomial ($n^{O(\log n)}$) time for detecting (α, β)-communities whenever $\alpha - \beta$ is at least some positive constant. The algorithm enumerates over $O(\log n)$-tuples of vertices. For each tuple, consider the set of vertices that are neighbors of an $(\alpha + \beta)/2$-fraction of the tuple; test whether this candidate set is indeed a community.

Arora et al's algorithm and analysis are very similar to related algorithms for approximate Nash equilibrium [27], Densest k-Subgraph [8] and Dughmi's Zero-Sum Signaling problem [17]. Recently, matching quasi-polynomial hardness results have been proved for approximate Nash equilibrium [13, 4, 35, 18], Densest k-Subgraph [12, 29], and Zero-Sum Signaling [34, 10] using or inspired by the technique of "birthday repetition" [1]. A natural question, made explicit in [12], is whether similar techniques can be shown to prove quasi-polynomial time hardness, assuming the Exponential Time Hypothesis (ETH)[1], for (α, β)-community detection, for any constants $\alpha > \beta \in [0, 1]$.

Here we show that, for *every* constants $\alpha > \beta \in (0, 1]$, community detection requires quasi-polynomial time (assuming ETH). For example, when $\alpha = 1$ and $\beta = 0.01$, this means that we can hide a clique C, such that every single vertex not in C is connected to at most 1% of C. Our main result is actually a much stronger inapproximability: even in the presence of a $(1, o(1))$-community, finding any $(\beta + o(1), \beta)$-community is hard.

▶ **Theorem 2.** *For every n there exists an $\epsilon = \epsilon(n) = o(1)$ such that, assuming ETH, distinguishing between the following requires time $n^{\tilde{\Omega}(\log n)}$:*
Completeness *G contains an $(1, \epsilon)$-community; and*
Soundness *G does not contain an $(\beta + \epsilon, \beta)$-community for any $\beta \in [0, 1]$.*

Unlike all quasi-polynomial approximation schemes mentioned above, Arora et al's algorithm has the unique property that it can also *exactly count* all the (α, β)-communities. Our second result is that counting even the number of $(1, o(1))$-communities requires quasi-polynomial time. A nice feature of this result is that we can base it on the much weaker #ETH assumption, which asserts that counting the satisfying assignment for a 3SAT instance requires time $2^{\Omega(n)}$. (Note, for example, that #ETH is likely to be true even if $\mathsf{P} = \mathsf{NP}$.)

▶ **Theorem 3.** *For every n there exists an $\epsilon = \epsilon(n) = o(1)$ such that, assuming #ETH, counting $(1, \epsilon)$-communities requires time $n^{\log^{1-o(1)} n}$.*

1.1 Related works

The most closely related work is a reduction by Balcan, Borgs, Braverman, Chayes, and Teng [5, Theorem 5.3] from Planted Clique to finding $(1, 1 - \gamma)$-communities, for some small (unspecified) constant $\gamma > 0$. Note that our inapproximability in Theorem 2 is much stronger in all parameters; furthermore, although formally incomparable, our ETH assumption is preferable over the average-case hardness assumption of Planted Clique.

Algorithms for special cases

Mishra, Schreiber, Stanton, and Tarjan [30] gave a polynomial-time algorithm for finding (α, β)-communities that contain a vertex with very few neighbors outside the community.

[1] The Exponential Time Hypothesis (ETH) [25] asserts that solving 3SAT requires time $2^{\Omega(n)}$. Note that (given our current understanding of complexity) this assumption is essentially necessary - an NP-hardness result is very unlikely given [3]'s quasi-polynomial algorithm. Recall also that ETH is a significantly weaker assumption than the related SETH [24, 14] and NSETH [15],

Balcan et al [5] give a polynomial-time algorithm for enumerating (α, β)-communities in the special case where the degree of every node is $\Omega(n)$.

Arora, Ge, Sachdeva, and Schoenebeck [3] consider several semi-random models where the edges inside the community are generated at random, according to the expected degree model. (In fact, their quasi-polynomial time algorithm is also stated in this setting, but only their "Gap Assumption", which is equivalent to $\alpha - \beta = \Omega(1)$, is used in the analysis.)

Stochastic Block Model

Variants of the community detection problem on graphs generated by different stochastic models are extremely popular (see e.g. [6, 7, 16, 20, 22, 28, 31, 33, 37] for papers in conference proceedings from June 2016). Perhaps the most influential is the *Stochastic Block Model* [23]: The graph is partitioned into two disjoint communities; the edges within each community are present with probability α, independently, whereas edges between communities are present with probability β. Hence this model can also be seen as a special case of the (α, β)-Community Detection problem.

Stochastic models are extremely helpful in physics, for example, because atoms' interactions obey simple mathematical formulas with high precision. Unfortunately, for applications such as social networks, existing models do not describe human behavior with atomic precision, hence casting a shadow over the applicability of algorithms that work on ideal stochastic models. Recent works [31, 28] attempted to bridge the gap from ideal model to practice by showing that certain SDP-based algorithms continue to work in a particular semi-random model where a restricted adversary is allowed to modify the random input graph. These success stories beg the question of how strong can one make the adversary? The current paper illuminates some of the computational barriers.

Alternative approaches to modeling communities

As we mentioned above, there are many different definitions of "communities" in networks. For in-depth discussion of different definitions see Arora et al [3] or Borgs et al [11]. As pointed out by the latter, for some definitions even verifying that a candidate subset is a community is intractable.

There is also an important literature on axiomatic approaches to the related problem of clustering (e.g. [26, 9, 38]); note that while clustering typically aims to partition a set of nodes, our main focus is on detecting just a single community; in particular, different communities may intersect.

1.2 Overview of proofs

A good starting point for the technical discussion is a recent subexponential reduction from 3SAT to the related problem of Densest-k-Subgraph [12]. In Densest-k-Subgraph, we seek a subgraph of size k of maximal density. The two ingredients in [12]'s reduction are "birthday repetition" [1] and the "FGLSS graph" [19]:

"Birthday repetition" Starting with an instance of Label Cover (see definition in Section 2), the reduction considers a mega-variable for every ρ-tuple of variables, for $\rho \approx \sqrt{n}$. By the birthday paradox, almost every pair of ρ-tuples of variables intersect, inducing a consistency constraint on the two mega-assignments. Similarly, we expect to see some Label Cover edges in the union of the two ρ-tuples, inducing an additional Label Cover constraint between the two mega assignments. Notice that we have $\binom{n}{\rho} \approx 2^{\sqrt{n}}$

mega variables, and the alphabet size is also approximately $N = 2^{\sqrt{n}}$. Therefore, assuming ETH, finding an approximately satisfying assignment for the mega-variables requires time $2^{\Omega(n)} \approx N^{\log N}$.

FGLSS Similarly to the classic reduction by Feige et al. [19] for the Clique problem, [12] construct a vertex for each mega assignment to each mega variable, and draw an edge between two vertices if the induced assignments do not violate any consistency or Label Cover constraints. Notice that if the Label Cover instance has a satisfying assignment, then the graph contains a clique of size $\binom{n}{\rho}$ where each mega variable receives the mega assignment induced by the globally satisfying assignment. On the other hand, any subgraph that corresponds to a consistent assignment which violates many constraints must be missing most of its edges.

Now this simple reduction is still far from working for the Community Detection problem, and indeed the latter was listed as an open problem in [13]. Below we describe some of the obstacles and outline how we overcome them.

Completeness

Surprisingly, the main problem with using the same reduction for Community Detection is the completeness: even if the Label Cover instance has a satisfying assignment, the resulting graph has no (α, β)-communities, for any constants $\alpha > \beta$! Observe, in particular, that the clique that corresponds to the satisfying assignment does not satisfy the weak ties condition. For any vertex v in that clique, consider any vertex v' that corresponds to changing the assignment to just one variable x_i in v's assignment. If v agrees with the assignments of all other vertices in the clique, v' agrees with almost all of them - except for the negligible fraction that cover x_i or its neighbors in the Label Cover graph.

To overcome this problem of vertices that are "just outside the community", we use error correcting codes. Namely, we encode each assignment as a low-degree bivariate polynomial over finite field $\mathcal{G}$ of size $|\mathcal{G}| \approx \sqrt{n}$. Now vertices correspond to low-degree assignments to rows/columns of the polynomial. This guarantees that the assignments induced by every two vertices are far. If v agrees with all other vertices in the community, then almost all of those vertices disagree with v'.

Soundness

The main challenge for soundness is ruling out communities that do not correspond to a single, globally consistent assignment to the Label Cover instance. The key idea is to introduce auxiliary vertices that punish such communities by violating the weak ties desideratum.

Let us begin with the reduction to the counting variant (Theorem 3), which is easier, mostly because we are not concerned with approximation (i.e. we only have to show that subsets that are exactly $(1, \epsilon)$-communities correspond to satisfying assignments). Here we further simplify matters by sketching a construction with weighted edges. The full reduction (Section 3) uses unweighted edges and is only slightly more involved. Consider, for every $g \in \mathcal{G}$, an auxiliary vertex that is ϵ-connected to all proper vertices that do not correspond to assignments to the g-th row/column. Now if a $(1, \epsilon)$-community C does not contain a vertex with assignment to the g-th row/column, the auxiliary vertex must simultaneously: (i) belong to C so as not to violate the weak ties desideratum; yet (ii) it cannot belong to C because all its edges have weight ϵ (this would violate the strong ties desideratum). Therefore every $(1, \epsilon)$-community assigns values to every row/column in $\mathcal{G}^2$.

The reduction we described above suffices to show that (assuming ETH) deciding whether the graph contains a $(1, \epsilon)$-community also requires quasi-polynomial time. To get the stronger statement of Theorem 2 we must rule out even $(\beta, \beta + \epsilon)$-communities in case the Label Cover instance is far from satisfiable. In particular, we need to show that subsets that do not correspond to unique, consistent assignments are never $(\beta, \beta + \epsilon)$-communities. Instead of a single column/row, we let each proper vertex correspond to a subset of $t \approx \log n$ columns/rows. Instead of a single $g \in \mathcal{G}$, each auxiliary vertex corresponds to subset $H \subset \mathcal{G}$ of size $|H| = |\mathcal{G}|/2$. We draw an edge between an auxiliary vertex and a proper vertex if the indices of all t columns/rows are contained in H; if they are picked randomly this only happens with polynomially small probability. If, however, a β-fraction of the community is restricted to a small subset $R \subset \mathcal{G}$, then there are auxiliary vertices for $H \supseteq R$ that connect to all those nodes and violate the weak ties desideratum. Roughly, we show that at least a $(1 - \beta)$-fraction of the vertices have assignments that are "well spread" over $\mathcal{G}^2$, and among those assignments there are many violations of the Label Cover constraints.

2 Preliminaries

2.1 Label Cover

▶ **Definition 4** (Label Cover)**.** Label Cover is a maximization problem. The input is a bipartite graph $G = (A, B, E)$, alphabets Σ_A, Σ_B, and a projection $\pi_e : \Sigma_A \to \Sigma_B$ for every $e \in E$.

The output is a labeling $\varphi_A : A \to \Sigma_A$, $\varphi_B : B \to \Sigma_B$. Given a labeling, we say that a constraint (or edge) $(a, b) \in E$ is *satisfied* if $\pi_{(a,b)}(\varphi_A(a)) = \varphi_B(b)$. The *value of a labeling* is the fraction of $e \in E$ that are satisfied by the labeling. The value of the instance is the maximum fraction of constraints satisfied by any assignment.

▶ **Theorem 5** (Moshkovitz-Raz PCP [32, Theorem 11])**.** *For every n and every $\epsilon > 0$ (in particular, ϵ may be a function of n), solving* 3SAT *on inputs of size n can be reduced to distinguishing between the case that a (d_A, d_B)-bi-regular instance of* Label Cover*, with parameters $|A| + |B| = n^{1+o(1)} \cdot \mathsf{poly}(1/\epsilon)$, $|\Sigma_A| = 2^{\mathsf{poly}(1/\epsilon)}$, and $d_A, d_B, |\Sigma_B| = \mathsf{poly}(1/\epsilon)$, is completely satisfiable, versus the case that it has value at most ϵ.*

Counting the number of satisfying assignments is even harder. The following hardness is well-known, and we sketch its proof only for completeness:

▶ **Fact 1.** *There is a linear-time reduction from #3SAT to counting the number of satisfying assignments of a* Label Cover *instance.*

Proof. Construct a vertex in A for each variable and a vertex in B for each clause. Set $\Sigma_A \triangleq \{0, 1\}$ and let $\Sigma_B \triangleq \{0, 1\}^3 \setminus (000)$ (i.e. Σ_B is the set of satisfying assignments for a 3SAT clause, after applying negations). Now if variable x appears in clause C, add a constraint that the assignments to x and C are consistent (taking into account the sign of x in C). Notice that any assignment to A: (i) corresponds to a unique assignment to the 3SAT formula; and (ii) if the 3SAT formula is satisfied, this assignment uniquely defines a satisfying assignment to B. Therefore there is a one-to-one correspondence between satisfying assignments to the 3SAT formula and to the instance of Label Cover. ◀

2.2 Finding a good partition

▶ **Theorem 6** (k-wise independence Chernoff bound [36, Theorem 5.I]). *Let $x_1 \dots x_n \in [0,1]$ be k-wise independent random variables, and let $\mu \triangleq \mathsf{E}\left[\sum_{i=1}^{n} x_i\right]$ and $\delta \leq 1$. Then*

$$\Pr\left[\left|\sum_{i=1}^{n} x_i - \mu\right| > \delta\mu\right] \leq \mathrm{e}^{-\Omega\left(\min\left\{k,\delta^2\mu\right\}\right)}.$$

We use Chernoff bound with $\Theta(\log n)$-wise independent variables to deterministically partition variables into subsets of cardinality $\approx \sqrt{n}$. Our (somewhat naive) deterministic algorithm for finding a good partition takes quasi-polynomial time ($n^{O(\log n)}$), which is negligible with respect to the sub-exponential size ($N = 2^{\tilde{O}(\sqrt{n})}$) of our reduction[2].

▶ **Lemma 7.** *Let $G = (A, B, E)$ be a bipartite (d_A, d_B)-bi-regular graph, and let $n_A \triangleq |A|$, $n_B \triangleq |B|$; set also $n \triangleq n_B + n_A$ and $\rho \triangleq \sqrt{n}\log n$. Let $T_1, \dots, T_{n_B/\rho}$ be an arbitrary partition of B into disjoint subsets of size ρ. There is a quasi-polynomial deterministic algorithm (alternatively, linear-time randomized algorithm) that finds a partition of A into $S_1, \dots, S_{n_A/\rho}$, such that:*

$$\forall i \quad \left||S_i| - \rho\right| < \rho/2, \tag{1}$$

and

$$\forall i,j \quad \left|\left|(S_i \times T_j) \cap E\right| - \frac{d_A\rho^2}{n_B}\right| < \frac{d_A\rho^2}{2n_B}. \tag{2}$$

Proof. Suppose that we place each $a \in A$ into a uniformly random S_i. By Chernoff bound and union bound, (1) and (2) hold with high probability. Now, by Chernoff Bound for k-wise independent variables (Theorem 6), it suffices to partition A using a $\Theta(\log n)$-wise independent distribution. Such distribution can be generated with a sample space of $n^{O(\log n)}$ (e.g. [2]). Therefore, we can enumerate over all possibilities in quasi-polynomial time. By the probabilistic argument, we will find at least one partition that satisfies (1) and (2). ◀

3 Hardness of Counting Communities

▶ **Theorem 8.** *There exists an $\epsilon(n) = o(1)$ such that, assuming #ETH, counting $(1,\epsilon)$-communities requires time $n^{\log^{1-o(1)} n}$.*

Construction

Begin with an instance (A, B, E, π) of Label Cover of size $n = n_A + n_B$ where $n_A \triangleq |A|$ and $n_B \triangleq |B|$. Let $\mathcal{G}$ be a finite field of size $\sqrt{n}/\epsilon^3$, and let $\mathcal{F} \subset \mathcal{G}$ be an arbitrary subset of size $|\mathcal{F}| = \sqrt{n}$. We identify between $A \cup B$ and points in $\mathcal{F}^2$; we also identify between a subset of $\mathcal{G}$ and $\Sigma_A \cup \Sigma_B$. Thus there is a one-to-one correspondence between a subset of assignments to $P_{\mathcal{F}} \colon \mathcal{F}^2 \to \mathcal{G}$ and assignments to the Label Cover instance. We can extend any such $P_{\mathcal{F}}$ to an individual-degree-$(|\mathcal{F}|-1)$ polynomial $P : \mathcal{G}^2 \to \mathcal{G}$. In the other

[2] Do not confuse this with the quasi-polynomial lower bound ($N^{\tilde{O}(\log N)}$) we obtain for the running time of the community detection problem.

direction, we think of each low individual degrees polynomial $P : \mathcal{G}^2 \to \mathcal{G}$ as a (possibly invalid) assignment to the Label Cover instance.

For every $g \in \mathcal{G}$, and degree-$(|\mathcal{F}|-1)$ polynomials $p_1, p_2 : \mathcal{G} \to \mathcal{G}$ such that $p_1(g) = p_2(g)$, we construct $1/\epsilon$ vertices $\{v_{g,p_1,p_2,i}\}_{i=1}^{1/\epsilon} \subset V$ in the communities graph. Each vertex naturally induces an assignment (p_1, p_2) on $(\mathcal{G} \times \{g\}) \cup (\{g\} \times \mathcal{G})$. We draw an edge between two vertices in V if they agree on the intersection of their lines, and if their induced assignments satisfy all the Label Cover constraints.

For every $g \in \mathcal{G}$ and $i \in [1/\epsilon]$, we also add two identical auxiliary vertices $u_{g,i}$ which are connected to every $v_{g',p_1,p_2,i}$ for $g' \neq g$ (but not to each other).

Completeness

For each assignment to the Label Cover instance, we construct a $(1,\epsilon)$-community by taking the induced assignment $P_{\mathcal{F}} \colon \mathcal{F}^2 \to \mathcal{G}$ and extending it to an individual-degree-$(|\mathcal{F}|-1)$ polynomial $P : \mathcal{G}^2 \to \mathcal{G}$. Let C be all the vertices $v_{g,p_1,p_2,i}$ such that p_1, p_2 are the restrictions of P to $(\mathcal{G} \times \{g\}), (\{g\} \times \mathcal{G})$. This correspondence is one-to-one and we need to show that the resulting C is actually a $(1,\epsilon)$-community.

Because all the vertices correspond to a consistent satisfying assignment, C is a clique. Let $v_{g,q_1,q_2,i} \notin C$; wlog q_1 disagrees with the restriction of P to $(\mathcal{G} \times \{g\})$. Since both q_1 and the restriction of P are degree-$(|\mathcal{F}|-1)$ polynomials, they must disagree on all but at most $(|\mathcal{F}|-1)$ elements of $\mathcal{G}$. For all other $h \in \mathcal{G}$, the vertex $v_{g,q_1,q_2,i}$ does not share edges with any $v_{h,p_1,p_2,j} \in C$. Therefore, $v_{g,q_1,q_2,i}$ has edges to less than an $(|\mathcal{F}| / |\mathcal{G}|)$-fraction of vertices in C. Finally, every auxiliary vertex $u_{g,i}$ has edges to a $\frac{|\mathcal{G}|-1}{|\mathcal{G}|} \cdot \epsilon < \epsilon$-fraction of the vertices in ϵ. Therefore, C is a $(1,\epsilon)$-community.

3.1 Soundness

Structure of $(1,\epsilon)$-communities

▶ **Claim 1.** *Every $(1,\epsilon)$-community C contains exactly $1/\epsilon$ vertices $\{v_{g,p_1,p_2,i}\}_{i=1}^{1/\epsilon}$ for each g.*

Proof. First, observe that C cannot contain any auxiliary vertices: if C contains one copy of $u_{g,i}$, it must also contain the other; but they don't have an edge between them, so they cannot both belong to a $(1,\epsilon)$-community.

Now, assume by contradiction that for some $g \in \mathcal{G}$, C does not contain any vertices with assignments for $(\mathcal{G} \times \{g\}) \cup (\{g\} \times \mathcal{G})$. Then every vertex in C is connected to (both copies of) $u_{g,i}$, for some $i \in [1/\epsilon]$. Therefore there is at least one $i \in [1/\epsilon]$ such that $u_{g,i}$ is connected to an ϵ-fraction of the vertices in C. But this is a contradiction since $u_{g,i} \notin C$.

If we ignore the auxiliary vertices (which, as we argued, C does not contain), the different vertices $v_{g,p_1,p_2,i}$ that correspond to the same assignment to the same lines (i.e. if we only change i) are indistinguishable. Therefore if C contains one of them, it must contain all of them (hence, at least $1/\epsilon$ vertices for each g).

Finally, since C is a clique, it cannot contain vertices that disagree on any assignments. (In particular, it cannot contain more than $1/\epsilon$ vertices for each g.) ◀

Completing the proof

Proof of Soundness. By Claim 1, every $(1,\epsilon)$-community C contains exactly $1/\epsilon$ vertices $\{v_{g,p_1,p_2,i}\}_{i=1}^{1/\epsilon}$ for each g. Furthermore, since C is a clique, all the induced assignments agree on all the intersections. So every $(1,\epsilon)$-community corresponds to a unique consistent

assignment to the Label Cover instance. Finally, appealing again to the fact that C is a clique, this assignment must also satisfy all the Label Cover constraints. ◀

4 Hardness of Detecting Communities

▶ **Theorem 9.** *There exists an $\epsilon(n) = o(1)$ such that, assuming ETH, distinguishing between the following requires time $n^{\tilde{\Omega}(\log n)}$:*

Completeness *G contains an $(1, \epsilon)$-community; and*

Soundness *G does not contain an $(\beta + \epsilon, \beta)$-community for any $\beta \in [0, 1]$.*

The rest of this section is devoted to the proof of Theorem 9. Our starting point is the Label Cover of Moshkovitz-Raz (Theorem 5). We compose the birthday repetition technique of [1] with a bi-variate low-degree encoding. We then encode this as a graph a-la FGLSS [19]. We add auxiliary vertices to ensure that any $(\beta + \epsilon, \beta)$-community corresponds, approximately, to a uniform distribution over the variables.

Construction

Begin with a (d_A, d_B)-bi-regular instance (A, B, E, π) of Label Cover of size $n = n_A + n_B$ where $n_A \triangleq |A|$ and $n_B \triangleq |B|$. Let $\rho \triangleq \sqrt{n} \log n$; let $\mathcal{G}$ be a finite field of size $\rho/\epsilon^3 = \tilde{O}(\rho)$, and let $\mathcal{F} \subset \mathcal{G}$ be an arbitrary subset of size $|\mathcal{F}| = 2\rho$. Let $\mathcal{F}_A, \mathcal{F}_B \subset \mathcal{F}$ be disjoint subsets of size n_A/ρ, n_B/ρ, respectively. By Lemma 7, we can partition A and B into subsets $X_1, \ldots, X_{|\mathcal{F}_A|}$ and $Y_1, \ldots, Y_{|\mathcal{F}_B|}$ of size at most $|\mathcal{F}|$ such that between every two subsets there are approximately $\frac{d_A \rho^2}{n_B} = \frac{d_B \rho^2}{n_A}$ constraints. For $i \in \mathcal{F}_A$, we think of the points $\{i\} \times \mathcal{F} \subset \mathcal{G}^2$ as representing assignments to variables in X_i; for $j \in \mathcal{F}_B$, we think of $\mathcal{F} \times \{j\} \subset \mathcal{G}^2$ as representing assignments to variables in Y_j. Notice that each point in $\mathcal{F}^2$ may represent an assignment to both a vertex from A and a vertex from B, to one of them, or to neither. In particular, any assignment $P \colon \mathcal{G}^2 \to \mathcal{G}$ induces an assignment for the Label Cover instance; note that since $|\mathcal{G}| > |\Sigma_A| \, |\Sigma_B|$, one value $P(f_1, f_2) \in \mathcal{G}$ suffices to describe assignments to both $a \in A$ and $b \in B$.

Let $t \triangleq \log n \cdot \left(\frac{|\mathcal{G}|}{|\mathcal{F}_A|} + \frac{|\mathcal{G}|}{|\mathcal{F}_B|} \right) = \mathsf{polylog}(n)$. We say that a subset $S \in \binom{\mathcal{G}}{t}$ is *balanced* if: $|S \cap \mathcal{F}_A| = \frac{|\mathcal{F}_A|}{|\mathcal{G}|} \cdot t$ and $|S \cap \mathcal{F}_B| = \frac{|\mathcal{F}_B|}{|\mathcal{G}|} \cdot t$. For every balanced subset S, consider $2t$ polynomials $q_\ell \colon \mathcal{G} \to \mathcal{G}$ of degree at most $|\mathcal{F}| - 1$, representing an assignment[3] $Q \colon (S \times \mathcal{G}) \cup (\mathcal{G} \times S) \to \mathcal{G}$. For balanced S and $2t$-tuple of polynomials (q_ℓ), we construct a corresponding vertex $v_{S,(q_\ell)}$ in the communities graph. Let V denote the set of vertices defined so far. For $g \in \mathcal{G}$ we abuse notation and say that $g \in v_{S,(q_\ell)}$ if $g \in S$. We construct an edge in the communities graph between two vertices in V if their assignments agree on the variables in their intersection, and their induced assignments to $A \cup B$ satisfy all the Label Cover constraints.

Additionally, for every $H \subset \mathcal{G}$ of size $|H| = |\mathcal{G}|/2$, define $|V|^2$ identical auxiliary vertices u_H in the communities graph. We draw an edge between auxiliary vertex u_H and vertex $v_{S,(q_\ell)}$ if $S \subset H$. Similarly, for every $H_A \subset \mathcal{F}_A$ of size $|H_A| = |\mathcal{F}_A|/2$, we define $|V|^2$ identical auxiliary vertices u_{H_A} with edges to every vertex $v_{S,(q_\ell)}$ such that $(S \cap \mathcal{F}_A) \subset H_A$. For $H_B \subset \mathcal{F}_B$ of size $|H_B| = |\mathcal{F}_B|/2$, we draw edges between u_{H_B} and $v_{S,(q_\ell)}$ such that $(S \cap \mathcal{F}_B) \subset H_B$.

[3] We will only consider polynomials that correspond to a consistent assignment Q; i.e. for each point in $S \times S$ we expect the two corresponding polynomials to agree with each other.

Completeness

Suppose that the Label Cover instance has a satisfying assignment. Let $\mathcal{Z} \subseteq \mathcal{G}^2$ denote the subset of points that correspond to at least one variable in A or B. Let $P_{\mathcal{Z}} : \mathcal{Z} \to \mathcal{G}$ be the induced function on $\mathcal{Z}$ that corresponds to the satisfying assignment, and let $P : \mathcal{G}^2 \to \mathcal{G}$ be the extension of $P_{\mathcal{Z}}$ by setting $P(f_1, f_2) = 0$ for $(f_1, f_2) \in \mathcal{F}^2 \setminus \mathcal{Z}$ (this choice is arbitrary), and then extending to an $(|\mathcal{F}| - 1)$-individual-degree polynomial over all of $\mathcal{G}^2$.

Let C be the set of vertices that correspond to restrictions of P to balanced sets, i.e.

$$C = \left\{ v_{S,(P|_S)} : S \text{ is balanced} \right\},$$

where $P\ |_S$ denotes the restriction of P to $(S \times \mathcal{G}) \cup (\mathcal{G} \times S)$. Since all those vertices correspond to a consistent satisfying assignment, C is a clique.

For any vertex $v_{S,(q_\ell)} \notin C$, at least one of the polynomials, q_{ℓ^*} disagrees with the restriction of P to the corresponding line. Since both q_{ℓ^*} and the restriction of P to that line are degree-$(|\mathcal{F}| - 1)$ polynomials, they must disagree on at least $\left(1 - \frac{|\mathcal{F}|}{|\mathcal{G}|}\right)$-fraction of the coordinates. The probability that a random balanced set S' is contained in the $O\left(\epsilon^3\right)$-fraction of coordinates where they do agree is smaller than ϵ (and in fact polynomially small in n). Therefore $v_{S,(q_\ell)}$ has inconsistency violations with all but (less than) an ϵ-fraction of the vertices in C.

For any auxiliary vertex u_{H_A}, the probability that a random vertex $v_{S,(P|_S)} \in C$ is connected to u_{H_A} is $2^{-|S \cap \mathcal{F}_A|} < 1/n$, and similarly for u_{H_B} and u_H. Therefore, every auxiliary vertex is connected to less than a $(1/n)$-fraction of the vertices in C.

4.1 Soundness

▶ **Lemma 10.** *If the* Label Cover *instance has value at most ϵ^3, then there are no $(\beta + \epsilon, \beta)$-communities.*

4.1.0.1 Auxiliary vertices

▶ **Claim 2.** *Every $(\beta + \epsilon, \beta)$-community does not contain any auxiliary vertices.*

Proof. There are $|V|^2$ identical copies of each auxiliary vertex. Since they are identical, any community must either contain all of them, or none of them. If the community contains all $|V|^2$ copies, then it has a vast majority of auxiliary vertices, so none of them can have edges to an ϵ-fraction of the community. ◀

4.1.0.2 List decoding

▶ **Claim 3.** *The vertices in any $(\beta + \epsilon, \beta)$-community C induce at most $4/\epsilon$ different assignments for each variable.*

Proof. Suppose by contradiction that this is not the case. Then, wlog, there is a line $\{g_1\} \times \mathcal{G}$ that receives at least $2/\epsilon$ different assignments from vertices in C. Every two assignments agree on at most $|\mathcal{F}|$ points (g_1, g') on the line, so in total there are at most $2|\mathcal{F}|/\epsilon^2$ points where at least two assignments agree. Let $R \subseteq \mathcal{G}$ denote the set of g' such that no two assignments agree on (g_1, g'); we have that $|R| \geq |\mathcal{G}| - 2|\mathcal{F}|/\epsilon^2 \geq |\mathcal{G}|/2$. Therefore, by the weak ties property, for at most a β-fraction of the vertices $v_{S,(q_\ell)} \in C$, $S \cap R = \emptyset$.

Consider the remaining $(1 - \beta)$-fraction of vertices in C. Suppose that v assigns a value to some (g_1, g') for $g' \in R$: this value can only agree with one of the $2/\epsilon$ different assignments

to (g_1, g'). Therefore, in expectation, each of the $2/\epsilon$ vertices that assign different values for (g_1, g') is connected to at most a $(\beta + \epsilon/2)$-fraction of the vertices in C. This is a contradiction to C being a $(\beta + \epsilon, \beta)$-community. ◀

4.1.0.3 Completing the proof

Proof of Lemma 10. Suppose that at most a ϵ^3-fraction of the Label Cover constraints can be satisfied by any single assignment, and assume by contradiction that C is a $(\beta + \epsilon, \beta)$-community. By Claim 3, C induces at most $4/\epsilon$ assignments on each variable, so at most $O(\epsilon)$-fraction of the constraints are satisfied by any pair of assignments.

By Markov's inequality, for at least half of the subsets $X_i \subset A$, only an $O(\epsilon)$-fraction of the constraints that depend on X_i are satisfied. By Claim 2 at least $(1 - \beta)$-fraction of the vertices in C assign values to at least one such X_i. Consider any such vertex $v_{S,(q_\ell)}$ where $S \ni i$. By construction of the partitions (Lemma 7), each X_i shares approximately the same number of constraints with each Y_j. Therefore, for all but an $O(\epsilon)$-fraction of Y_j's, X_i and Y_j observe a violation - for all the assignments given by vertices in C to the variables in Y_j. In other words, $v_{S,(q_\ell)}$ cannot have edges to any vertex $v_{T,(r_\ell)}$ such that $T \ni j$, for a $(1 - O(\epsilon))$-fraction of $j \in [n_B/k_B]$. Finally, applying Claim 2 again, at most a β fraction of vertices in C do not contain any of those j's. This is a contradiction to $v_{S,(q_\ell)}$ having edges to $(\beta + \epsilon)$-fraction of the vertices in C. ◀

Inherent Trade-Offs in the Fair Determination of Risk Scores

Abstract

Recent discussion in the public sphere about algorithmic classification has involved tension between competing notions of what it means for a probabilistic classification to be fair to different groups. We formalize three fairness conditions that lie at the heart of these debates, and we prove that except in highly constrained special cases, there is no method that can satisfy these three conditions simultaneously. Moreover, even satisfying all three conditions approximately requires that the data lie in an approximate version of one of the constrained special cases identified by our theorem. These results suggest some of the ways in which key notions of fairness are incompatible with each other, and hence provide a framework for thinking about the trade-offs between them.

1 Introduction

There are many settings in which a sequence of people comes before a decision-maker, who must make a judgment about each based on some observable set of features. Across a range of applications, these judgments are being carried out by an increasingly wide spectrum of approaches ranging from human expertise to algorithmic and statistical frameworks, as well as various combinations of these approaches.

Along with these developments, a growing line of work has asked how we should reason about issues of bias and discrimination in settings where these algorithmic and statistical techniques, trained on large datasets of past instances, play a significant role in the outcome. Let us consider three examples where such issues arise, both to illustrate the range of relevant contexts, and to surface some of the challenges.

A set of example domains

First, at various points in the criminal justice system, including decisions about bail, sentencing, or parole, an officer of the court may use quantitative *risk tools* to assess a defendant's probability of recidivism — future arrest — based on their past history and other attributes. Several recent analyses have asked whether such tools are mitigating or exacerbating the sources of bias in the criminal justice system; in one widely-publicized report, Angwin et al.

© Jon Kleinberg, Sendhil Mullainathan, and Manish Raghavan;

analyzed a commonly used statistical method for assigning risk scores in the criminal justice system — the COMPAS risk tool — and argued that it was biased against African-American defendants [1, 15]. One of their main contentions was that the tool's errors were asymmetric: African-American defendants were more likely to be incorrectly labeled as higher-risk than they actually were, while white defendants were more likely to be incorrectly labeled as lower-risk than they actually were. Subsequent analyses raised methodological objections to this report, and also observed that despite the COMPAS risk tool's errors, its estimates of the probability of recidivism are equally well calibrated to the true outcomes for both African-American and white defendants [17, 6, 9, 12].

Second, in a very different domain, researchers have begun to analyze the ways in which different genders and racial groups experience advertising and commercial content on the Internet differently [5, 18]. We could ask, for example: if a male user and female user are equally interested in a particular product, does it follow that they're equally likely to be shown an ad for it? Sometimes this concern may have broader implications, for example if women in aggregate are shown ads for lower-paying jobs. Other times, it may represent a clash with a user's leisure interests: if a female user interacting with an advertising platform is interested in an activity that tends to have a male-dominated viewership, like professional football, is the platform as likely to show her an ad for football as it is to show such an ad to an interested male user?

A third domain, again quite different from the previous two, is medical testing and diagnosis. Doctors making decisions about a patient's treatment may rely on tests providing probability estimates for different diseases and conditions. Here too we can ask whether such decision-making is being applied uniformly across different groups of patients [11, 19], and in particular how medical tests may play a differential role for conditions that vary widely in frequency between these groups.

Providing guarantees for decision procedures

One can raise analogous questions in many other domains of fundamental importance, including decisions about hiring, lending, or school admissions [16], but we will focus on the three examples above for the purposes of this discussion. In these three example domains, a few structural commonalities stand out. First, the algorithmic estimates are often being used as "input" to a larger framework that makes the overall decision — a risk score provided to a human expert in the legal and medical instances, and the output of a machine-learning algorithm provided to a larger advertising platform in the case of Internet ads. Second, the underlying task is generally about classifying whether people possess some relevant property: recidivism, a medical condition, or interest in a product. We will refer to people as being *positive instances* if they truly possess the property, and *negative instances* if they do not. Finally, the algorithmic estimates being provided for these questions are generally not pure yes-no decisions, but instead probability estimates about whether people constitute positive or negative instances.

Let us suppose that we are concerned about how our decision procedure might operate differentially between two groups of interest (such as African-American and white defendants, or male and female users of an advertising system). What sorts of guarantees should we ask for as protection against potential bias?

A first basic goal in this literature is that the probability estimates provided by the algorithm should be *well-calibrated*: if the algorithm identifies a set of people as having a probability x of constituting positive instances, then approximately an x fraction of this set should indeed be positive instances [4, 10]. Moreover, this condition should hold when

applied separately in each group as well [9]. For example, if we are thinking in terms of potential differences between outcomes for men and women, this means requiring that an x fraction of men and an x fraction of women assigned a probability x should possess the property in question.

A second goal focuses on the people who constitute positive instances (even if the algorithm can only imperfectly recognize them): the average score received by people constituting positive instances should be the same in each group. We could think of this as *balance for the positive class*, since a violation of it would mean that people constituting positive instances in one group receive consistently lower probability estimates than people constituting positive instances in another group. In our initial criminal justice example, for instance, one of the concerns raised was that white defendants who went on to commit future crimes were assigned risk scores corresponding to lower probability estimates in aggregate; this is a violation of the condition here. There is a completely analogous property with respect to negative instances, which we could call *balance for the negative class*. These balance conditions can be viewed as generalizations of the notions that both groups should have equal false negative and false positive rates.

It is important to note that balance for the positive and negative classes, as defined here, is distinct in crucial ways from the requirement that the average probability estimate globally over *all* members of the two groups be equal. This latter global requirement is a version of *statistical parity* [8, 3, 13, 14]. In some cases statistical parity is a central goal (and in some it is legally mandated), but the examples considered so far suggest that classification and risk assessment are much broader activities where statistical parity is often neither feasible nor desirable. Balance for the positive and negative classes, however, is a goal that can be discussed independently of statistical parity, since these two balance conditions simply ask that once we condition on the "correct" answer for a person, the chance of making a mistake on them should not depend on which group they belong to.

The present work: Trade-offs among the guarantees

Despite their different formulations, the calibration condition and the balance conditions for the positive and negative classes intuitively all seem to be asking for variants of the same general goal — that our probability estimates should have the same effectiveness regardless of group membership. One might therefore hope that it would be feasible to achieve all of them simultaneously.

Our main result, however, is that these conditions are in general incompatible with each other; they can only be simultaneously satisfied in certain highly constrained cases. Moreover, this incompatibility applies to *approximate* versions of the conditions as well.

In the remainder of this section we formulate this main result precisely, as a theorem building on a model that makes the discussion thus far more concrete.

1.1 Formulating the Goal

Let's start with some basic definitions. As above, we have a collection of people each of whom constitutes either a positive instance or a negative instance of the classification problem. We'll say that the *positive class* consists of the people who constitute positive instances, and the negative class consists of the people who constitute negative instances. For example, for criminal defendants, the positive class could consist of those defendants who will be arrested again within some fixed time window, and the negative class could consist of those who will not. The positive and negative classes thus represent the "correct" answer to the

classification problem; our decision procedure does not know them, but is trying to estimate them.

Feature vectors

Each person has an associated *feature vector* σ, representing the data that we know about them. Let p_σ denote the fraction of people with feature vector σ who belong to the positive class. Conceptually, we will picture that while there is variation within the set of people who have feature vector σ, this variation is invisible to whatever decision procedure we apply; all people with feature vector σ are indistinguishable to the procedure. Our model will assume that the value p_σ for each σ is known to the procedure.[1]

Groups

Each person also belongs to one of two *groups*, labeled 1 or 2, and we would like our decisions to be unbiased with respect to the members of these two groups.[2] In our examples, the two groups could correspond to different races or genders, or other cases where we want to look for the possibility of bias between them. The two groups have different distributions over feature vectors: a person of group t has a probability $a_{t\sigma}$ of exhibiting the feature vector σ. However, people of each group have the same probability p_σ of belonging to the positive class provided their feature vector is σ. In this respect, σ contains all the relevant information available to us about the person's future behavior; once we know σ, we do not get any additional information from knowing their group as well.[3]

Risk Assignments

We say that an *instance* of our problem is specified by the parameters above: a feature vector and a group for each person, with a value p_σ for each feature vector, and distributions $\{a_{t\sigma}\}$ giving the frequency of the feature vectors in each group.

Informally, risk assessments are ways of dividing people up into sets based on their feature vectors σ (potentially using randomization), and then assigning each set a probability estimate that the people in this set belong to the positive class. Thus, we define a *risk assignment* to consist of a set of "bins" (the sets), where each bin is labeled with a *score* v_b that we intend to use as the probability for everyone assigned to bin b. We then create a rule for assigning people to bins based on their feature vector σ; we allow the rule to divide people with a fixed feature vector σ across multiple bins (reflecting the possible use of randomization). Thus, the rule is specified by values $X_{\sigma b}$: a fraction $X_{\sigma b}$ of all people with feature vector σ are assigned to bin b. Note that the rule does not have access to the group t of the person being considered, only their feature vector σ. (As we will see, this does not mean that the rule is incapable of exhibiting bias between the two groups.) In summary, a

---

[1] Clearly the case in which the value of p_σ is unknown is an important version of the problem as well; however, since our main results establish strong limitations on what is achievable, these limitations are only stronger because they apply even to the case of known p_σ.

[2] We focus on the case of two groups for simplicity of exposition, but it is straightforward to extend all of our definitions to the case of more than two groups.

[3] As we will discuss in more detail below, the assumption that the group provides no additional information beyond σ does not restrict the generality of the model, since we can always consider instances in which people of different groups never have the same feature vector σ, and hence σ implicitly conveys perfect information about a person's group.

risk assignment is specified by a set of bins, a score for each bin, and values $X_{\sigma b}$ that define a mapping from people with feature vectors to bins.

Fairness Properties for Risk Assignments

Within the model, we now express the three conditions discussed at the outset, each reflecting a potentially different notion of what it means for the risk assignment to be "fair."

(A) *Calibration within groups* requires that for each group t, and each bin b with associated score v_b, the expected number of people from group t in b who belong to the positive class should be a v_b fraction of the expected number of people from group t assigned to b.

(B) *Balance for the negative class* requires that the average score assigned to people of group 1 who belong to the negative class should be the same as the average score assigned to people of group 2 who belong to the negative class. In other words, the assignment of scores shouldn't be systematically more inaccurate for negative instances in one group than the other.

(C) *Balance for the positive class* symmetrically requires that the average score assigned to people of group 1 who belong to the positive class should be the same as the average score assigned to people of group 2 who belong to the positive class.

Why Do These Conditions Correspond to Notions of Fairness?

All of these are natural conditions to impose on a risk assignment; and as indicated by the discussion above, all of them have been proposed as versions of fairness. The first one essentially asks that the scores mean what they claim to mean, even when considered separately in each group. The second and third ask that if two individuals in different groups exhibit comparable future behavior (negative or positive), they should be treated comparably by the procedure. In other words, a violation of, say, the second condition would correspond to the members of the negative class in one group receiving consistently higher scores than the members of the negative class in the other group, despite the fact that the members of the negative class in the higher-scoring group have done nothing to warrant these higher scores.

We can also interpret some of the prior work around our earlier examples through the lens of these conditions. For example, in the analysis of the COMPAS risk tool for criminal defendants, the critique by Angwin et al. focused on the risk tool's violation of conditions (B) and (C); the counter-arguments established that it satisfies condition (A). While it is clearly crucial for a risk tool to satisfy (A), it may still be important to know that it violates (B) and (C). Similarly, to think in terms of the example of Internet advertising, with male and female users as the two groups, condition (A) as before requires that our estimates of ad-click probability mean the same thing in aggregate for men and women. Conditions (B) and (C) are distinct; condition (C), for example, says that a female user who genuinely wants to see a given ad should be assigned the same probability as a male user who wants to see the ad.

1.2 Determining What is Achievable: A Characterization Theorem

When can conditions (A), (B), and (C) be simultaneously achieved? We begin with two simple cases where it's possible.

- *Perfect prediction.* Suppose that for each feature vector σ, we have either $p_\sigma = 0$ or $p_\sigma = 1$. This means that we can achieve perfect prediction, since we know each person's class label (positive or negative) for certain. In this case, we can assign all feature vectors σ with $p_\sigma = 0$ to a bin b with score $v_b = 0$, and all σ with $p_\sigma = 1$ to a bin b' with score $v_{b'} = 1$. It is easy to check that all three of the conditions (A), (B), and (C) are satisfied by this risk assignment.
- *Equal base rates.* Suppose, alternately, that the two groups have the same fraction of members in the positive class; that is, the average value of p_σ is the same for the members of group 1 and group 2. (We can refer to this as the *base rate* of the group with respect to the classification problem.) In this case, we can create a single bin b with score equal to this average value of p_σ, and we can assign everyone to bin b. While this is not a particularly informative risk assignment, it is again easy to check that it satisfies fairness conditions (A), (B), and (C).

Our first main result establishes that these are in fact the only two cases in which a risk assignment can achieve all three fairness guarantees simultaneously.

▶ **Theorem 1.** *Consider an instance of the problem in which there is a risk assignment satisfying fairness conditions (A), (B), and (C). Then the instance must either allow for perfect prediction (with p_σ equal to 0 or 1 for all σ) or have equal base rates.*

Thus, in every instance that is more complex than the two cases noted above, there will be some natural fairness condition that is violated by any risk assignment. Moreover, note that this result applies regardless of how the risk assignment is computed; since our framework considers risk assignments to be arbitrary functions from feature vectors to bins labeled with probability estimates, it applies independently of the method — algorithmic or otherwise — that is used to construct the risk assignment.

The conclusions of the first theorem can be relaxed in a continuous fashion when the fairness conditions are only approximate. In particular, for any $\varepsilon > 0$ we can define ε-approximate versions of each of conditions (A), (B), and (C) (specified precisely in the next section), each of which requires that the corresponding equalities between groups hold only to within an error of ε. For any $\delta > 0$, we can also define a δ-approximate version of the equal base rates condition (requiring that the base rates of the two groups be within an additive δ of each other) and a δ-approximate version of the perfect prediction condition (requiring that in each group, the average of the expected scores assigned to members of the positive class is at least $1 - \delta$; by the calibration condition, this can be shown to imply a complementary bound on the average of the expected scores assigned to members of the negative class).

In these terms, our approximate version of Theorem 1 is the following.

▶ **Theorem 2.** *There is a continuous function f, with $f(x)$ going to 0 as x goes to 0, so that the following holds. For all $\varepsilon > 0$, and any instance of the problem with a risk assignment satisfying the ε-approximate versions of fairness conditions (A), (B), and (C), the instance must satisfy either the $f(\varepsilon)$-approximate version of perfect prediction or the $f(\varepsilon)$-approximate version of equal base rates.*

Thus, anything that approximately satisfies the fairness constraints must approximately look like one of the two simple cases identified above.

Finally, in connection to Theorem 1, we note that when the two groups have equal base rates, then one can ask for the most accurate risk assignment that satisfies all three fairness conditions (A), (B), and (C) simultaneously. Since the risk assignment that gives the same

score to everyone satisfies the three conditions, we know that at least one such risk assignment exists; hence, it is natural to seek to optimize over the set of all such assignments. We consider this algorithmic question in the final technical section of the paper.

To reflect a bit further on our main theorems and what they suggest, we note that our intention in the present work isn't to make a recommendation on how conflicts between different definitions of fairness should be handled. Nor is our intention to analyze which definitions of fairness are violated in particular applications or datasets. Rather, our point is to establish certain unavoidable trade-offs between the definitions, regardless of the specific context and regardless of the method used to compute risk scores. Since each of the definitions reflect (and have been proposed as) natural notions of what it should mean for a risk score to be fair, these trade-offs suggest a striking implication: that outside of narrowly delineated cases, any assignment of risk scores can in principle be subject to natural criticisms on the grounds of bias. This is equally true whether the risk score is determined by an algorithm or by a system of human decision-makers.

Special Cases of the Model

Our main results, which place strong restrictions on when the three fairness conditions can be simultaneously satisfied, have more power when the underlying model of the input is more general, since it means that the restrictions implied by the theorems apply in greater generality. However, it is also useful to note certain special cases of our model, obtained by limiting the flexibility of certain parameters in intuitive ways. The point is that our results apply *a fortiori* to these more limited special cases.

First, we have already observed one natural special case of our model: cases in which, for each feature vector σ, only members of one group (but not the other) can exhibit σ. This means that σ contains perfect information about group membership, and so it corresponds to instances in which risk assignments would have the potential to use knowledge of an individual's group membership. Note that we can convert any instance of our problem into a new instance that belongs to this special case as follows. For each feature vector σ, we create two new feature vectors $\sigma^{(1)}$ and $\sigma^{(2)}$; then, for each member of group 1 who had feature vector σ, we assign them $\sigma^{(1)}$, and for each member of group 2 who had feature vector σ, we assign them $\sigma^{(2)}$. The resulting instance has the property that each feature vector is associated with members of only one group, but it preserves the essential aspects of the original instance in other respects.

Second, we allow risk assignments in our model to split people with a given feature vector σ over several bins. Our results also therefore apply to the natural special case of the model with *integral* risk assignments, in which all people with a given feature σ must go to the same bin.

Third, our model is a generalization of binary classification, which only allows for 2 bins. Note that although binary classification does not explicitly assign scores, we can consider the probability that an individual belongs to the positive class given that they were assigned to a specific bin to be the score for that bin. Thus, our results hold in the traditional binary classification setting as well.

Data-Generating Processes

Finally, there is the question of where the data in an instance of our problem comes from. Our results do not assume any particular process for generating the positive/negative class labels, feature vectors, and group memberships; we simply assume that we are given such a

collection of values (regardless of where they came from), and then our results address the existence or non-existence of certain risk assignments for these values.

This increases the generality of our results, since it means that they apply to any process that produces data of the form described by our model. To give an example of a natural generative model that would produce instances with the structure that we need, one could assume that each individual starts with a "hidden" class label (positive or negative), and a feature vector σ is then probabilistically generated for this individual from a distribution that can depend on their class label and their group membership. (If feature vectors produced for the two groups are disjoint from one another, then the requirement that the value of p_σ is independent of group membership given σ necessarily holds.) Since a process with this structure produces instances from our model, our results apply to data that arises from such a generative process.

1.3 Further Related Work

Mounting concern over discrimination in machine learning has led to a large body of new work seeking to better understand and prevent it. Barocas and Selbst survey a range of ways in which data-analysis algorithms can lead to discriminatory outcomes [2]. Kamiran and Calders, among others, seek to modify datasets to remove any information that might permit discrimination [13, 8]. Similarly, Zemel et al. look to learn fair intermediate representations of data while preserving information needed for classification [20].

One common notion of fairness, adopted by Feldman et al., Kamishima et al., and others, is "statistical parity" – equal fractions of each group should be treated as belonging to the positive class [8, 3, 13, 14]. Work in this direction has developed learning algorithms that penalize violations of statistical parity [3, 14]. As noted above, we consider definitions other than statistical parity that take into account the class membership (positive or negative) of the people being classified.

Dwork et al. propose a framework based on a task-specific externally defined similarity metric between individuals, seeking to achieve fairness through the goal that "similar people [be] treated similarly" [7]. They strive towards individual fairness, which is a stronger notion of fairness than the definitions we use; however, our approach shares some of the underlying motivation (though not the specifics) in that our balance conditions for the positive and negative classes also reflect the notion that similar people should be treated similarly.

Much of the applied work on risk scores, as noted above, focuses on calibration as a central goal [4, 6, 9]. In particular, responding to the criticism of their risk scores as displaying asymmetric errors for different groups, Dietrich et al. note that empirically, both in their domain and in similar settings, it is typically difficult to achieve symmetry in the error rates across groups when base rates differ significantly. Our formulation of the balance conditions for the positive and negative classes, and our result showing the incompability of these conditions with calibration, provides a theoretical basis for such observations.

2 The Characterization Theorems

Starting with the notation and definitions from the previous section, we now give a proof of Theorem 1.

First, let N_t be the number of people in group t. Since an $a_{t\sigma}$ fraction of the people in group t have feature vector σ, we write $n_{t\sigma} = a_{t\sigma} N_t$ for the number of people in group t with feature vector σ. Many of the components of the risk assignment and its evaluation

can be written in terms of operations on a set of underlying matrices and vectors, which we begin by specifying.

- First, let $|\sigma|$ denote the number of feature vectors in the instance, and let $p \in \mathbb{R}^{|\sigma|}$ be a vector indexed by the possible feature vectors, with the coordinate in position σ equal to p_σ. For group t, let $n_t \in \mathbb{R}^{|\sigma|}$ also be a vector indexed by the possible feature vectors, with the coordinate in position σ equal to $n_{t\sigma}$. Finally, it will be useful to have a representation of p as a diagonal matrix; thus, let P be a $|\sigma| \times |\sigma|$ diagonal matrix with $P_{\sigma\sigma} = p_\sigma$.
- We now specify a risk assignment as follows. The risk assignment involves a set of B bins with associated scores; let $v \in \mathbb{R}^B$ be a vector indexed by the bins, with the coordinate in position b equal to the score v_b of bin b. Let V be a diagonal matrix version of v: it is a $B \times B$ matrix with $V_{bb} = v_b$. Finally, let X be the $|\sigma| \times B$ matrix of $X_{\sigma b}$ values, specifying the fraction of people with feature vector σ who get mapped to bin b under the assignment procedure.

There is an important point to note about the $X_{\sigma b}$ values. If all of them are equal to 0 or 1, this corresponds to a procedure in which all people with the same feature vector σ get assigned to the same bin. When some of the $X_{\sigma b}$ values are not equal to 0 or 1, the people with vector σ are being divided among multiple bins. In this case, there is an implicit randomization taking place with respect to the positive and negative classes, and with respect to the two groups, which we can think of as follows. Since the procedure cannot distinguish among people with vector σ, in the case that it distributes these people across multiple bins, the subset of people with vector σ who belong to the positive and negative classes, and to the two groups, are divided up randomly across these bins in proportions corresponding to $X_{\sigma b}$. In particular, if there are $n_{t\sigma}$ group-t people with vector σ, the expected number of these people who belong to the positive class and are assigned to bin b is $n_{t\sigma} p_\sigma X_{\sigma b}$.

Let us now proceed with the proof of Theorem 1, starting with the assumption that our risk assignment satisfies conditions (A), (B), and (C).

Calibration within groups

We begin by working out some useful expressions in terms of the matrices and vectors defined above. We observe that $n_t^\top P$ is a vector in $\mathbb{R}^{|\sigma|}$ whose coordinate corresponding to feature vector σ equals the number of people in group t who have feature vector σ and belong to the positive class. $n_t^\top X$ is a vector in $\mathbb{R}^B$ whose coordinate corresponding to bin b equals the expected number of people in group t assigned to bin b.

By further multiplying these vectors on the right, we get additional useful quantities. Here are two in particular:

- $n_t^\top XV$ is a vector in $\mathbb{R}^B$ whose coordinate corresponding to bin b equals the expected sum of the scores assigned to all group-t people in bin b. That is, using the subscript b to denote the coordinate corresponding to bin b, we can write $(n_t^\top XV)_b = v_b(n_t^\top X)_b$ by the definition of the diagonal matrix V.
- $n_t^\top PX$ is a vector in $\mathbb{R}^B$ whose coordinate corresponding to bin b equals the expected number of group-t people in the positive class who are placed in bin b.

Now, condition (A), that the risk assignment is calibrated within groups, implies that the two vectors above are equal coordinate-wise, and so we have the following equation for all t:

$$n_t^\top PX = n_t^\top XV \tag{1}$$

Calibration condition (A) also has an implication for the total score received by all people in group t. Suppose we multiply the two sides of (1) on the right by the vector $\mathbf{e} \in \mathbb{R}^B$ whose coordinates are all 1, obtaining

$$n_t^\top PX\mathbf{e} = n_t^\top XV\mathbf{e}. \tag{2}$$

The left-hand-side is the number of group-t people in the positive class. The right-hand-side, which we can also write as $n_t^\top Xv$, is equal to the sum of the expected scores received by all group-t people. These two quantities are thus the same, and we write their common value as μ_t.

Fairness to the positive and negative classes

We now want to write down vector equations corresponding to the fairness conditions (B) and (C) for the negative and positive classes. First, recall that for the B-dimensional vector $n_t^\top PX$, the coordinate corresponding to bin b equals the expected number of group-t people in the positive class who are placed in bin b. Thus, to compute the sum of the expected scores received by all group-t people in the positive class, we simply need to take the inner product with the vector v, yielding $n_t^\top PXv$. Since μ_t is the total number of group-t people in the positive class, the average of the expected scores received by a group-t person in the positive class is the ratio $\frac{1}{\mu_t} n_t^\top PXv$. Thus, condition (C), that members of the positive class should receive the same average score in each group, can be written

$$\frac{1}{\mu_1} n_1^\top PXv = \frac{1}{\mu_2} n_2^\top PXv \tag{3}$$

Applying strictly analogous reasoning but to the fractions $1 - p_\sigma$ of people in the negative class, we we can write condition (B), that members of the negative class should receive the same average score in each group, as

$$\frac{1}{N_1 - \mu_1} n_1^\top (I - P)Xv = \frac{1}{N_2 - \mu_2} n_2^\top (I - P)Xv \tag{4}$$

Using (1), we can rewrite (3) to get

$$\frac{1}{\mu_1} n_1^\top XVv = \frac{1}{\mu_2} n_2^\top XVv \tag{5}$$

Similarly, we can rewrite (4) as

$$\frac{1}{N_1 - \mu_1} (\mu_1 - n_1^\top XVv) = \frac{1}{N_2 - \mu_2} (\mu_2 - n_2^\top XVv) \tag{6}$$

The portion of the score received by the positive class

We think of the ratios on the two sides of (3), and equivalently (5), as the average of the expected scores received by a member of the positive class in group t: the numerator is the sum of the expected scores received by the members of the positive class, and the denominator is the size of the positive class. Let us denote this fraction by γ_t. By (2), we can alternately think of the denominator as the sum of the expected scores received by all group-t people. Hence, the two sides of (3) and (5) can be viewed as representing the ratio of the sum of the expected scores in the positive class of group t to the sum of the expected scores in group t as a whole. (3) requires that $\gamma_1 = \gamma_2$; let us denote this common value by γ.

Now, we observe that $\gamma = 1$ corresponds to a case in which the sum of the expected scores in just the positive class of group t is equal to the sum of the expected scores in all of group t. In this case, it must be that all members of the negative class are assigned to bins of score 0. If any members of the positive class were assigned to a bin of score 0, this would violate the calibration condition (A); hence all members of the positive class are assigned to bins of positive score. Moreover, these bins of positive score contain no members of the negative class (since they've all been assigned to bins of score 0), and so again by the calibration condition (A), the members of the positive class are all assigned to bins of score 1. Finally, applying the calibration condition once more, it follows that the members of the negative class all have feature vectors σ with $p_\sigma = 0$ and the members of the positive class all have feature vectors σ with $p_\sigma = 1$. Hence, when $\gamma = 1$ we have perfect prediction.

Finally, we use our definition of γ_t as $\frac{1}{\mu_t} n_t^\top XVv$, and the fact that $\gamma_1 = \gamma_2 = \gamma$ to write (6) as

$$\begin{aligned}
\frac{1}{N_1 - \mu_1}(\mu_1 - \gamma\mu_1) &= \frac{1}{N_2 - \mu_2}(\mu_2 - \gamma\mu_2) \\
\frac{1}{N_1 - \mu_1}\mu_1(1-\gamma) &= \frac{1}{N_2 - \mu_2}\mu_2(1-\gamma) \\
\frac{\mu_1/N_1}{1 - \mu_1/N_1}(1-\gamma) &= \frac{\mu_2/N_2}{1 - \mu_2/N_2}(1-\gamma)
\end{aligned}$$

Now, this last equality implies that one of two things must be the case. Either $1 - \gamma = 0$, in which case $\gamma = 1$ and we have perfect prediction; or

$$\frac{\mu_1/N_1}{1 - \mu_1/N_1} = \frac{\mu_2/N_2}{1 - \mu_2/N_2},$$

in which case $\mu_1/N_1 = \mu_2/N_2$ and we have equal base rates. This completes the proof of Theorem 1.

Some Comments on the Connection to Statistical Parity

Earlier we noted that conditions (B) and (C) — the balance conditions for the positive and negative classes — are quite different from the requirement of *statistical parity*, which asserts that the average of the scores over *all* members of each group be the same.

When the two groups have equal base rates, then the risk assignment that gives the same score to everyone in the population achieves statistical parity along with conditions (A), (B), and (C). But when the two groups do not have equal base rates, it is immediate to show that statistical parity is inconsistent with both the calibration condition (A) and with the conjunction of the two balance conditions (B) and (C). To see the inconsistency of statistical parity with the calibration condition, we take Equation (1) from the proof above, sum the coordinates of the vectors on both sides, and divide by N_t, the number of people in group t. Statistical parity requires that the right-hand sides of the resulting equation be the same for $t = 1, 2$, while the assumption that the two groups have unequal base rates implies that the left-hand sides of the equation must be different for $t = 1, 2$. To see the inconsistency of statistical parity with the two balance conditions (B) and (C), we simply observe that if the average score assigned to the positive class and to the negative class are the same in the two groups, then the average of the scores over all members of the two groups cannot be the same provided they do not contain the same proportion of positive-class and negative-class members.

3 The Approximate Theorem

In this section we prove Theorem 2. First, we must first give a precise specification of the approximate fairness conditions:

$$(1-\varepsilon)[n_t^\top XV]_b \le [n_t^\top PX]_b \le (1-\varepsilon)[n_t^\top XV]_b \tag{A'}$$

$$\begin{aligned}(1-\varepsilon)\left(\frac{1}{N_2-\mu_2}\right) n_2^\top (I-P)Xv &\le \left(\frac{1}{N_1-\mu_1}\right) n_1^\top (I-P)Xv \\ &\le (1+\varepsilon)\left(\frac{1}{N_2-\mu_2}\right) n_2^\top (I-P)Xv \end{aligned} \tag{B'}$$

$$(1-\varepsilon)\left(\frac{1}{\mu_2}\right) n_2^\top PXv \le \left(\frac{1}{\mu_1}\right) n_1^\top PXv \le (1+\varepsilon)\left(\frac{1}{\mu_2}\right) n_2^\top PXv \tag{C'}$$

For (B') and (C'), we also require that these hold when μ_1 and μ_2 are interchanged.

We also specify the approximate versions of perfect prediction and equal base rates in terms of $f(\varepsilon)$, which is a function that goes to 0 as ε goes to 0.

- *Approximate perfect prediction.* $\gamma_1 \ge 1 - f(\varepsilon)$ and $\gamma_2 \ge 1 - f(\varepsilon)$
- *Approximately equal base rates.* $|\mu_1/N_1 - \mu_2/N_2| \le f(\varepsilon)$

A brief overview of the proof of Theorem 2 is as follows. It proceeds by first establishing an approximate form of Equation (1) above, which implies that the total expected score assigned in each group is approximately equal to the total size of the positive class. This in turn makes it possible to formulate approximate forms of Equations (3) and (4). When the base rates are close together, the approximation is too loose to derive bounds on the predictive power; but this is okay since in this case we have approximately equal base rates. Otherwise, when the base rates differ significantly, we show that most of the expected score must be assigned to the positive class, giving us approximately perfect prediction.

The remainder of this section provides the full details of the proof.

Total scores and the number of people in the positive class

First, we will show that the total score for each group is approximately μ_t, the number of people in the positive class. Define $\hat{\mu}_t = n_t^\top Xv$. Using (A'), we have

$$\begin{aligned}\hat{\mu}_t &= n_t^\top Xv \\ &= n_t^\top XVe \\ &= \sum_{b=1}^{B} [n_t^\top PX]_b \\ &\le (1+\varepsilon)\sum_{b=1}^{B} [n_t^\top PX]_b \\ &= (1+\varepsilon) n_t^\top PXe \\ &= (1+\varepsilon)\mu_t\end{aligned}$$

Similarly, we can lower bound $\hat{\mu}_t$ as

$$\begin{aligned}\hat{\mu}_t &= \sum_{b=1}^{B} [n_t^\top PX]_b \\ &\geq (1-\varepsilon) \sum_{b=1}^{B} [n_t^\top PX]_b \\ &= (1-\varepsilon)\mu_t\end{aligned}$$

Combining these, we have

$$(1-\varepsilon)\mu_t \leq \hat{\mu}_t \leq (1+\varepsilon)\mu_t. \tag{7}$$

The portion of the score received by the positive class

We can use (C') to show that $\gamma_1 \approx \gamma_2$. Recall that γ_t, the average of the expected scores assigned to members of the positive class in group t, is defined as $\gamma_t = \frac{1}{\mu_t} n_t PXv$. Then, it follows trivially from (C') that

$$(1-\varepsilon)\gamma_2 \leq \gamma_1 \leq (1+\varepsilon)\gamma_2. \tag{8}$$

The relationship between the base rates

We can apply this to (B') to relate μ_1 and μ_2, using the observation that the score not received by people of the positive class must fall instead to people of the negative class. Examining the left inequality of (B'), we have

$$\begin{aligned}(1-\varepsilon)\left(\frac{1}{N_2-\mu_2}\right) n_t^\top (I-P)Xv &= (1-\varepsilon)\left(\frac{1}{N_2-\mu_2}\right)(n_t^\top Xv - n_t^\top PXv) \\ &= (1-\varepsilon)\left(\frac{1}{N_2-\mu_2}\right)(\hat{\mu}_2 - \gamma_2\mu_2) \\ &\geq (1-\varepsilon)\left(\frac{1}{N_2-\mu_2}\right)((1-\varepsilon)\mu_2 - \gamma_2\mu_t) \\ &= (1-\varepsilon)\left(\frac{\mu_2}{N_2-\mu_2}\right)(1-\varepsilon-\gamma_2) \\ &\geq (1-\varepsilon)\left(\frac{\mu_2}{N_2-\mu_2}\right)\left(1-\varepsilon-\frac{\gamma_1}{1-\varepsilon}\right) \\ &= (1-2\varepsilon+\varepsilon^2-\gamma_1)\left(\frac{\mu_2}{N_2-\mu_2}\right)\end{aligned}$$

Thus, the left inequality of (B') becomes

$$(1-2\varepsilon+\varepsilon^2-\gamma_1)\left(\frac{\mu_2}{N_2-\mu_2}\right) \leq \left(\frac{1}{N_1-\mu_1}\right) n_t^\top (I-P)Xv \tag{9}$$

By definition, $\hat{\mu}_1 = n_t^\top Xv$ and $\gamma_t\mu_t = n_t^\top PXv$, so this becomes

$$(1-2\varepsilon+\varepsilon^2-\gamma_1)\left(\frac{\mu_2}{N_2-\mu_2}\right) \leq \left(\frac{1}{N_1-\mu_1}\right)(\hat{\mu}_1 - \gamma_1\mu_1) \tag{10}$$

If the base rates differ

Let ρ_1 and ρ_2 be the respective base rates, i.e. $\rho_1 = \mu_1/N_1$ and $\rho_2 = \mu_2/N_2$. Assume that $\rho_1 \leq \rho_2$ (otherwise we can switch μ_1 and μ_2 in the above analysis), and assume towards contradiction that the base rates differ by at least $\sqrt{\varepsilon}$, meaning $\rho_1 + \sqrt{\varepsilon} < \rho_2$. Using (10),

$$\frac{\rho_1 + \sqrt{\varepsilon}}{1 - \rho_1 - \sqrt{\varepsilon}} \leq \frac{\rho_2}{1 - \rho_2} \leq \left(\frac{1 + \varepsilon - \gamma_1}{1 - 2\varepsilon + \varepsilon^2 - \gamma_1}\right)\left(\frac{\rho_1}{1 - \rho_1}\right)$$

Simplifiying,

$$\begin{aligned}
(\rho_1 + \sqrt{\varepsilon})(1 - \rho_1)(1 - 2\varepsilon + \varepsilon^2 - \gamma_1) &\leq \rho_1(1 - \rho_1 - \sqrt{\varepsilon})(1 + \varepsilon - \gamma_1) \\
(\rho_1 + \sqrt{\varepsilon})(1 - \rho_1)(1 - 2\varepsilon) - \rho_1(1 - \rho_1 - \sqrt{\varepsilon})(1 + \varepsilon) &\leq \gamma_1[(\rho_1 + \sqrt{\varepsilon})(1 - \rho_1) \\
&\quad - \rho_1(1 - \rho_1 - \sqrt{\varepsilon})] \\
(\rho_1 + \sqrt{\varepsilon})(1 - \rho_1)(1 - 2\varepsilon) - \rho_1(1 - \rho_1 - \sqrt{\varepsilon})(1 + \varepsilon) &\leq \gamma_1[\sqrt{\varepsilon}(1 - \rho_1) + \sqrt{\varepsilon}\rho_1]
\end{aligned}$$

$$\begin{aligned}
\rho_1[(1 - \rho_1)(1 - 2\varepsilon) - (1 - \rho_1 - \sqrt{\varepsilon})(1 + \varepsilon)] + \sqrt{\varepsilon}(1 - \rho_1)(1 - 2\varepsilon) &\leq \gamma_1\sqrt{\varepsilon} \\
\rho_1(-2\varepsilon + 2\varepsilon\rho_1 - \varepsilon + \varepsilon\rho_1 + \sqrt{\varepsilon} + \varepsilon\sqrt{\varepsilon}) + \sqrt{\varepsilon}(1 - 2\varepsilon - \rho_1 + 2\varepsilon\rho_1) &\leq \gamma_1\sqrt{\varepsilon} \\
\rho_1(-3\varepsilon + 3\varepsilon\rho_1 + \sqrt{\varepsilon} + \varepsilon\sqrt{\varepsilon} - \sqrt{\varepsilon} + 2\varepsilon\sqrt{\varepsilon}) + \sqrt{\varepsilon}(1 - 2\varepsilon) &\leq \gamma_1\sqrt{\varepsilon} \\
\varepsilon\rho_1(-3 + 3\rho_1 + 3\sqrt{\varepsilon}) + \sqrt{\varepsilon}(1 - 2\varepsilon) &\leq \gamma_1\sqrt{\varepsilon} \\
3\varepsilon\rho_1(-1 + \rho_1) + \sqrt{\varepsilon}(1 - 2\varepsilon) &\leq \gamma_1\sqrt{\varepsilon} \\
1 - 2\varepsilon - 3\sqrt{\varepsilon}\rho_1(1 - \rho_1) &\leq \gamma_1 \\
1 - \sqrt{\varepsilon}\left(2\sqrt{\varepsilon} + \frac{3}{4}\right) &\leq \gamma_1
\end{aligned}$$

Recall that $\gamma_2 \geq \gamma_1(1 - \varepsilon)$, so

$$\begin{aligned}
\gamma_2 &\geq (1 - \varepsilon)\gamma_1 \\
&\geq (1 - \varepsilon)\left(1 - \sqrt{\varepsilon}\left(2\sqrt{\varepsilon} + \frac{3}{4}\right)\right) \\
&\geq 1 - \varepsilon - \sqrt{\varepsilon}\left(2\sqrt{\varepsilon} + \frac{3}{4}\right) \\
&= 1 - \sqrt{\varepsilon}\left(3\sqrt{\varepsilon} + \frac{3}{4}\right)
\end{aligned}$$

Let $f(\varepsilon) = \sqrt{\varepsilon}\max(1, 3\sqrt{\varepsilon} + 3/4)$. Note that we assumed that ρ_1 and ρ_2 differ by an additive $\sqrt{\varepsilon} \leq f(\varepsilon)$. Therefore if the ε-fairness conditions are met and the base rates are not within an additive $f(\varepsilon)$, then $\gamma_1 \geq 1 - f(\varepsilon)$ and $\gamma_2 \geq 1 - f(\varepsilon)$. This completes the proof of Theorem 2.

4 Reducing Loss with Equal Base Rates

In a risk assigment, we would like as much of the score as possible to be assigned to members of the positive class. With this in mind, if an individual receives a score of v, we define their *individual loss* to be v if they belong to the negative class, and $1 - v$ if they belong to the positive class. The loss of the risk assignment in group t is then the sum of the expected individual losses to each member of group t. In terms of the matrix-vector products used in

the proof of Theorem 1, one can show that the loss for group t may be written as

$$\begin{aligned}\ell_t(X) &= n_t^\top (I - P)Xv + (\mu_t - n_t^\top PXv) \\ &= 2(\mu_t - n_t^\top PXv),\end{aligned}$$

and the total loss is just the weighted sum of the losses for each group.

Now, let us say that a *fair assignment* is one that satisfies our three conditions (A), (B), and (C). As noted above, when the base rates in the two groups are equal, the set of fair assignments is non-empty, since the calibrated risk assignment that places everyone in a single bin is fair. We can therefore ask, in the case of equal base rates, whether there exists a fair assignment whose loss is strictly less than that of the trivial one-bin assignment. It is not hard to show that this is possible if and only if there is any assignment using more than one bin; we will call such an assignment a *non-trivial assignment*.

Note that the assignment that minimizes loss is simply the one that assigns each σ to a separate bin with a score of p_σ, meaning X is the identity matrix. While this assignment, which we refer to as the identity assignment I, is well-calibrated, it may violate fairness conditions (B) and (C). It is not hard to show that the loss for any other assignment is strictly greater than the loss for I. As a result, unless the identity assignment happens to be fair, every fair assignment must have larger loss than that of I, forcing a tradeoff between performance and fairness.

4.1 Characterization of Well-Calibrated Solutions

To better understand the space of feasible solutions, suppose we drop the fairness conditions (B) and (C) for now and study risk assignments that are simply well-calibrated, satisfying (A). As in the proof of Theorem 1, we write γ_t for the average of the expected scores assigned to members of the positive class in group t, and we define the *fairness difference* to be $\gamma_1 - \gamma_2$. If this is nonnegative, we say the risk assignment *weakly favors* group 1; if it is nonpositive, it weakly favors group 2. Since a risk assignment is fair if and only if $\gamma_1 = \gamma_2$, it is fair if and only if the fairness difference is 0.

We wish to characterize when non-trivial fair risk assignments are possible. First, we observe that without the fairness requirements, the set of possible fairness differences under well-calibrated assignments is an interval.

▶ **Lemma 3.** *If group 1 and group 2 have equal base rates, then for any two non-trivial well-calibrated risk assignments with fairness differences d_1 and d_2 and for any $d_3 \in [d_1, d_2]$, there exists a non-trivial well-calibrated risk assignment with fairness difference d_3.*

Proof. The basically idea is that we can effectively take convex combinations of well-calibrated assignments to produce any well-calibrated assignment "in between" them. We carry this out as follows.

Let $X^{(1)}$ and $X^{(2)}$ be the allocation matrices for assignments with fairness differences d_1 and d_2 respectively, where $d_1 < d_2$. Choose λ such that $\lambda d_1 + (1 - \lambda)d_2 = d_3$, meaning $\lambda = (d_2 - d_3)/(d_2 - d_1)$. Then, $X^{(3)} = [\lambda X^{(1)} \quad (1 - \lambda)X^{(2)}]$ is a nontrivial well-calibrated assignment with fairness difference d_3.

First, we observe that $X^{(3)}$ is a valid assignment because each row sums to 1 (meaning everyone from every σ gets assigned to a bin), since each row of $\lambda X^{(1)}$ sums to λ and each row of $(1 - \lambda)X^{(2)}$ sums to $(1 - \lambda)$. Moreover, it is nontrivial because every nonempty bin created by $X^{(1)}$ and $X^{(2)}$ is a nonempty bin under $X^{(3)}$.

Let $v^{(1)}$ and $v^{(2)}$ be the respective bin labels for assignments $X^{(1)}$ and $X^{(2)}$. Define $v^{(3)} = \begin{bmatrix} v^{(1)} \\ v^{(2)} \end{bmatrix}$.

Finally, let $V^{(3)} = \text{diag}(v^{(3)})$. Define $V^{(1)}$ and $V^{(2)}$ analogously. Note that

$$V^{(3)} = \begin{bmatrix} V^{(1)} & 0 \\ 0 & V^{(2)} \end{bmatrix}.$$

We observe that $X^{(3)}$ is calibrated because

$$\begin{aligned} n_t^\top P X^{(3)} &= n_t^\top P[\lambda X^{(1)} \quad (1-\lambda)X^{(2)}] \\ &= [\lambda n_t^\top P X^{(1)} \quad (1-\lambda) n_t^\top P X^{(2)}] \\ &= [\lambda n_t^\top X^{(1)} V^{(1)} \quad (1-\lambda) n_t^\top X^{(2)} V^{(2)}] \\ &= n_t^\top [\lambda X^{(1)} \quad (1-\lambda)X^{(2)}] V^{(3)} \\ &= n_t^\top X^{(3)} V^{(3)} \end{aligned}$$

Finally, we show that the fairness difference is d_3. Let $\gamma_1^{(1)}$ and $\gamma_2^{(1)}$ be the portions of the total expected score receieved by the positive class from each group respectively. Define $\gamma_1^{(2)}, \gamma_2^{(2)}, \gamma_1^{(3)}, \gamma_2^{(3)}$ similarly.

$$\begin{aligned} \gamma_1^{(3)} - \gamma_2^{(3)} &= \frac{1}{\mu} n_1^\top P X^{(3)} v^{(3)} - \frac{1}{\mu} n_2^\top P X^{(3)} v^{(3)} \\ &= \frac{1}{\mu}(n_1^\top - n_2^\top) P X^{(3)} v^{(3)} \\ &= \frac{1}{\mu}(n_1^\top - n_2^\top) P[\lambda X^{(1)} v^{(1)} \quad (1-\lambda) X^{(2)} v^{(2)}] \\ &= \frac{1}{\mu}(\lambda(n_1^\top - n_2^\top) P X^{(1)} v^{(1)} + (1-\lambda)(n_1^\top - n_2^\top) X^{(2)} v^{(2)}]) \\ &= \lambda(\gamma_1^{(1)} - \gamma_2^{(1)}) + (1-\lambda)(\gamma_1^{(2)} - \gamma_2^{(2)}) \\ &= \lambda d_1 + (1-\lambda) d_2 \\ &= d_3 \end{aligned}$$

◀

▶ **Corollary 4.** *There exists a non-trivial fair assignment if and only if there exist non-trivial well-calibrated assignments $X^{(1)}$ and $X^{(2)}$ such that $X^{(1)}$ weakly favors group 1 and $X^{(2)}$ weakly favors group 2.*

Proof. If there is a non-trivial fair assignment, then it weakly favors both group 1 and group 2, proving one direction.

To prove the other direction, observe that the fairness differences d_1 and d_2 of $X^{(1)}$ and $X^{(2)}$ are nonnegative and nonpositive respectively. Since the set of fairness differences achievable by non-trivial well-calibrated assignments is an interval by Lemma 3, there exists a non-trivial well-calibrated assignment with fairness difference 0, meaning there exists a non-trivial fair assignment. ◀

It is an open question whether there is a polynomial-time algorithm to find a fair assignment of minimum loss, or even to determine whether a non-trivial fair solution exists.

4.2 NP-Completeness of Non-Trivial Integral Fair Risk Assignments

As discussed in the introduction, risk assignments in our model are allowed to split people with a given feature vector σ over several bins; however, it is also of interest to consider the special case of *integral* risk assignments, in which all people with a given feature σ must go to the same bin. For the case of equal base rates, we can show that determining whether there is a non-trivial integral fair assignment is NP-complete. The proof uses a reduction from the Subset Sum problem and is given in the Appendix.

The basic idea of the reduction is as follows. We have an instance of Subset Sum with numbers $x_1, \ldots, x_n$ and a target number T; the question is whether there is a subset of the x_i's that sums to T. As before, γ_t denotes the average of the expected scores received by members of the positive class in group t. We first ensure that there is exactly one non-trivial way to allocate the people of group 1, allowing us to control γ_1. The fairness conditions then require that $\gamma_2 = \gamma_1$, which we can use to encode the target value in the instance of Subset Sum. For every input number x_i in the Subset Sum instance, we create $p_{\sigma_{2i-1}}$ and $p_{\sigma_{2i}}$, close to each other in value and far from all other p_σ values, such that grouping σ_{2i-1} and σ_{2i} together into a bin corresponds to choosing x_i for the subset, while not grouping them corresponds to not taking x_i. This ensures that group 2 can be assigned with the correct value of γ_2 if and only if there is a solution to the Subset Sum instance.

5 Conclusion

In this work we have formalized three fundamental conditions for risk assignments to individuals, each of which has been proposed as a basic measure of what it means for the risk assignment to be fair. Our main results show that except in highly constrained special cases, it is not possible to satisfy these three constraints simultaneously; and moreover, a version of this fact holds in an approximate sense as well.

Since these results hold regardless of the method used to compute the risk assignment, it can be phrased in fairly clean terms in a number of domains where the trade-offs among these conditions do not appear to be well-understood. To take one simple example, suppose we want to determine the risk that a person is a carrier for a disease X, and suppose that a higher fraction of women than men are carriers. Then our results imply that in any test designed to estimate the probability that someone is a carrier of X, at least one of the following undesirable properties must hold: (a) the test's probability estimates are systematically skewed upward or downward for at least one gender; or (b) the test assigns a higher average risk estimate to healthy people (non-carriers) in one gender than the other; or (c) the test assigns a higher average risk estimate to carriers of the disease in one gender than the other. The point is that this trade-off among (a), (b), and (c) is not a fact about medicine; it is simply a fact about risk estimates when the base rates differ between two groups.

It is also interesting to note that the basic set-up of our model, with the population divided across a set of feature vectors that convey no information about race, is in fact a very close match to the information one gets from the output of a well-calibrated risk tool. In this sense, one setting for our model would be the problem of applying post-processing to the output of such a risk tool to ensure additional fairness guarantees. Indeed, since much of the recent controversy about fair risk scores has involved risk tools that are well-calibrated but lack the other fairness conditions we consider, such an interpretation of the model could be a useful way to think about how one might work with these tools in the context of a broader system.

Finally, we note that our results suggest a number of interesting directions for further work. First, when the base rates between the two underlying groups are equal, our results

do not resolve the computational tractability of finding the most accurate risk assignment, subject to our three fairness conditions, when the people with a given feature vector can be split across multiple bins. (Our NP-completeness result applies only to the case in which everyone with a given feature vector must be assigned to the same bin.) Second, there may be a number of settings in which the cost (social or otherwise) of false positives may differ greatly from the cost of false negatives. In such cases, we could imagine searching for risk assignments that satisfy the calibration condition together with only one of the two balance conditions, corresponding to the class for whom errors are more costly. Determining when two of our three conditions can be simultaneously satisfied in this way is an interesting open question. More broadly, determining how the trade-offs discussed here can be incorporated into broader families of proposed fairness conditions suggests interesting avenues for future research.

A Appendix: NP-Completeness of Non-Trivial Integral Fair Risk Assignments

We can reduce to the integral assignment problem, parameterized by $a_{1\sigma}, a_{2\sigma}$, and p_σ, from subset sum as follows.

Given n numbers $x_1, \ldots, x_n$ and a target T, we create an instance of the integral assignment problem with $\sigma_1, \ldots, \sigma_{2n+2}$. $a_{1,\sigma_i} = 1/2$ if $i \in \{2n+1, 2n+2\}$ and 0 otherwise. $a_{2,\sigma_i} = 1/(2n)$ if $i \leq 2n$ and 0 otherwise. We make the following definitions:

$$\begin{aligned}
\hat{x}_i &= x_i/(Tn^4) \\
\varepsilon_i &= \sqrt{\hat{x}_i/2} \\
p_{\sigma_{2i-1}} &= i/(n+1) - \varepsilon_i && (1 \leq i \leq n) \\
p_{\sigma_{2i}} &= i/(n+1) + \varepsilon_i && (1 \leq i \leq n) \\
\gamma &= 1/n \sum_{i=1}^{2n} p_{\sigma_i}^2 - 1/n^5 \\
p_{\sigma_{2n+1}} &= (1 - \sqrt{2\gamma - 1})/2 \\
p_{\sigma_{2n+2}} &= (1 + \sqrt{2\gamma - 1})/2
\end{aligned}$$

With this definition, the subset sum instance has a solution if and only if the integral assignment instance given by $a_{1,\sigma}, a_{2,\sigma}, p_{\sigma_1}, \ldots, p_{\sigma_{2n+2}}$ has a solution.

Before we prove this, we need the following lemma.

▶ **Lemma 5.** *For any* $y_1, \ldots, y_k \in \mathbb{R}$,

$$\sum_{i=1}^{k} y_i^2 - \frac{1}{k}\left(\sum_{i=1}^{n} y_i\right)^2 = \frac{1}{k}\sum_{i<j}^{k}(y_i - y_j)^2$$

Proof.

$$\begin{aligned}
\sum_{i=1}^{k} y_i^2 - \frac{1}{k}\left(\sum_{i=1}^{n} y_i\right)^2 &= \sum_{i=1}^{k} y_i^2 - \frac{1}{k}\left(\sum_{i=1}^{k} y_i^2 + 2\sum_{i<j}^{k} y_i y_j\right) \\
&= \frac{k-1}{k}\sum_{i=1}^{k} y_i^2 - \frac{2}{k}\sum_{i<j}^{k} y_i y_j \\
&= \frac{1}{k}\sum_{i<j}^{k}(y_i^2 + y_j^2) - \frac{2}{k}\sum_{i<j}^{k} y_i y_j \\
&= \frac{1}{k}\sum_{i<j}^{k} y_i^2 - 2y_i y_j + y_j^2 \\
&= \frac{1}{k}\sum_{i<j}^{k}(y_i - y_j)^2
\end{aligned}$$

◀

Now, we can prove that the integral assignment problem is NP-hard.

Proof. First, we observe that for any nontrivial solution to the integral assignment instance, there must be two bins $b \neq b'$ such that $X_{\sigma_{2n+1},b} = 1$ and $X_{\sigma_{2n+2},b'} = 1$. In other words, the people with σ_{2n+1} and σ_{2n+2} must be split up. If not, then all the people of group 1 would be in the same bin, meaning that bin must be labeled with the base rate $\rho_1 = 1/2$. In order to maintain fairness, the same would have to be done for all the people of group 2, resulting in the trivial solution. Moreover, b and b' must be labeled $(1 \pm \sqrt{2\gamma - 1})/2$ respectively because those are the fraction of people of group 1 in those bins who belong to the positive class.

This means that $\gamma_1 = 1/\rho \cdot (a_{1,\sigma_{2n+1}} p_{\sigma_{2n+1}}^2 + a_{1,\sigma_{2n+2}} p_{\sigma_{2n+2}}^2) = p_{\sigma_{2n+1}}^2 + p_{\sigma_{2n+2}}^2 = \gamma$ as defined above. We know that a well-calibrated assignment is fair if and only if $\gamma_1 = \gamma_2$, so we know $\gamma_2 = \gamma$.

Next, we observe that $\rho_2 = \rho_1 = 1/2$ because all of the positive $a_{2,\sigma}$'s are $1/2n$, so ρ_2 is just the average of $\{p_{\sigma_1}, \ldots, p_{\sigma_{2n}}\}$, which is $1/2$ by symmetry.

Let Q be the partition of $[2n]$ corresponding to the assignment, meaning that for a given $q \in Q$, there is a bin b_q containing all people with σ_i such that $i \in q$. The label on that bin is

$$\begin{aligned}
v_q &= \frac{\sum_{i \in q} a_{2,\sigma_i} p_{\sigma_i}}{\sum_{i \in q} a_{2,\sigma_i}} \\
&= \frac{1/2n \sum_{i \in q} p_{\sigma_i}}{|q|/2n} \\
&= \frac{1}{|q|}\sum_{i \in q} p_{\sigma_i}
\end{aligned}$$

Furthermore, bin b_q contains $\sum_{i \in q} a_{2,\sigma_i} p_{\sigma_i} = 1/2n \sum_{i \in q} p_{\sigma_i}$ positive fraction. Using this, we can come up with an expression for γ_2.

$$\begin{aligned}\gamma_2 &= \frac{1}{\rho} \sum_{q \in Q} \left(v_b \cdot \frac{1}{2n} \sum_{i \in q} p_{\sigma_i} \right) \\ &= \frac{1}{n} \sum_{q \in Q} \frac{1}{|q|} \left(\sum_{i \in q} p_{\sigma_i} \right)^2\end{aligned}$$

Setting this equal to γ, we have

$$\begin{aligned}\frac{1}{n} \sum_{q \in Q} \frac{1}{|q|} \left(\sum_{i \in q} p_{\sigma_i} \right)^2 &= \frac{1}{n} \sum_{i=1}^{2n} p_{\sigma_i}^2 - \frac{1}{n^5} \\ \sum_{q \in Q} \frac{1}{|q|} \left(\sum_{i \in q} p_{\sigma_i} \right)^2 &= \sum_{i=1}^{2n} p_{\sigma_i}^2 - \frac{1}{n^4}\end{aligned}$$

Subtracting both sides from $\sum_{i=1}^{2n} p_{\sigma_i}^2$ and using Lemma 5, we have

$$\sum_{q \in Q} \frac{1}{|q|} \sum_{i<j \in q} (p_{\sigma_i} - p_{\sigma_j})^2 = \frac{1}{n^4} \tag{11}$$

Thus, Q is a fair nontrivial assignment if and only if (11) holds.

Next, we show that there exists Q that satisfies (11) if and only if there there exists some $S \subseteq [n]$ such that $\sum_{i \in S} \hat{a}_i = 1/n^4$.

Assume Q satisfies (11). Then, we first observe that any $q \in Q$ must either contain a single i, meaning it does not contribute to the left hand side of (11), or $q = \{2i-1, 2i\}$ for some i. To show this, observe that the closest two elements of $\{p_{\sigma_1}, \ldots, p_{\sigma_{2n}}\}$ not of the form $\{p_{\sigma_{2i-1}}, p_{\sigma_{2i}}\}$ must be some $\{p_{\sigma_{2i}}, p_{\sigma_{2i+1}}\}$. However, we find that

$$
\begin{aligned}
(p_{\sigma_{2i+1}} - p_{\sigma_{2i}})^2 &= \left(\frac{i+1}{n+1} - \varepsilon_{i+1} - \left(\frac{i}{n+1} + \varepsilon_i\right)\right)^2 \\
&= \left(\frac{1}{n+1} - \varepsilon_{i+1} - \varepsilon_i\right)^2 \\
&= \left(\frac{1}{n+1} - \sqrt{\frac{\hat{x}_{i+1}}{2}} - \sqrt{\frac{\hat{x}_i}{2}}\right)^2 \\
&\geq \left(\frac{1}{n+1} - \sqrt{\frac{2}{n^4}}\right)^2 && (\hat{x}_i \leq 1/n^4) \\
&= \left(\frac{1}{n+1} - \frac{\sqrt{2}}{n^2}\right)^2 \\
&\geq \left(\frac{1}{2n} - \frac{\sqrt{2}}{n^2}\right)^2 \\
&= \left(\frac{n - 2\sqrt{2}}{2n^2}\right)^2 \\
&\geq \left(\frac{n}{4n^2}\right)^2 \\
&= \left(\frac{1}{4n}\right)^2 \\
&= \frac{1}{16n^2}
\end{aligned}
$$

If any q contains any j, k not of the form $2i-1, 2i$, then (11) will have a term on the left hand side at least $1/n \cdot 1/(16n^2) = 1/(16n^3) > 1/n^4$ for large enough n, and since there can be no negative terms on the left hand side, this immediately makes it impossible for Q to satisify (11).

Consider every $2i-1, 2i \in [2n]$. Let $q_i = \{2i-1, 2i\}$. As shown above, either $q_i \in Q$ or $\{2i-1\} \in Q$ and $\{2i\} \in Q$. In the latter case, neither $p_{\sigma_{2i-1}}$ nor $p_{\sigma_{2i}}$ contributes to (11). If $q_i \in Q$, then q_i contributes $1/2(p_{\sigma_{2i} - p_{\sigma_{2i-1}}})^2 = 1/2(2\varepsilon_i)^2 = \hat{x}_i$ to the overall sum on the left hand side. Therefore, we can write the left hand side of (11) as

$$\sum_{q \in Q} \frac{1}{|q|} \sum_{i<j \in q} (p_{\sigma_i} - p_{\sigma_j})^2 = \sum_{q_i \in Q} \frac{1}{2} (p_{\sigma_{2i} - p_{\sigma_{2i-1}}})^2 = \sum_{q_i \in Q} \hat{x}_i = \frac{1}{n^4}$$

Then, we can build a solution to the original subset sum instance as $S = \{i : q_i \in Q\}$, giving us $\sum_{i \in S} \hat{x}_i = \frac{1}{n^4}$. Multiplying both sides by Tn^4, we get $\sum_{i \in S} x_i = T$, meaning S is a solution for the subset sum instance.

To prove the other direction, assume we have a solution $S \subseteq [n]$ such that $\sum_{i \in S} x_i = T$. Dividing both sides by Tn^4, we get $\sum_{i \in S} \hat{x}_i = 1/n^4$. We build a partition Q of $2n$ by starting with the empty set and adding $q_i = \{2i-1, 2i\}$ to Q if $i \in S$ and $\{2i-1\}$ and $\{2i\}$ to Q otherwise. Clearly, each element of $[2n]$ appears in Q at most once, making this a valid partition. Moreover, when checking to see if (11) is satisfied (which is true if and only if Q is a fair assignment), we can ignore all $q \in Q$ such that $|q| = 1$ because they don't contribute to the left hand side. Since, we again have

$$\sum_{q \in Q} \frac{1}{|q|} \sum_{i<j \in q} (p_{\sigma_i} - p_{\sigma_j})^2 = \sum_{q_i \in Q} \frac{1}{2} (p_{\sigma_{2i} - p_{\sigma_{2i-1}}})^2 = \sum_{q_i \in Q} \hat{x}_i = \frac{1}{n^4}$$

meaning Q is a fair assignment. This completes the reduction. ◀

We have shown that the integral assignment problem is NP-hard, and it is clearly in NP because given an integral assignment, we can verify in polynomial time whether such an assignment satisfies the conditions (A), (B), and (C). Thus, the integral assignment problem is NP-complete.

Non-Backtracking Spectrum of Degree-Corrected Stochastic Block Models

Abstract

Motivated by community detection, we characterise the spectrum of the non-backtracking matrix B in the Degree-Corrected Stochastic Block Model.

Specifically, we consider a random graph on n vertices partitioned into two asymptotically equal-sized clusters. The vertices have i.i.d. weights $\{\phi_u\}_{u=1}^n$ with second moment $\Phi^{(2)}$. The intra-cluster connection probability for vertices u and v is $\frac{\phi_u\phi_v}{n}a$ and the inter-cluster connection probability is $\frac{\phi_u\phi_v}{n}b$.

We show that with high probability, the following holds: The leading eigenvalue of the non-backtracking matrix B is asymptotic to $\rho = \frac{a+b}{2}\Phi^{(2)}$. The second eigenvalue is asymptotic to $\mu_2 = \frac{a-b}{2}\Phi^{(2)}$ when $\mu_2^2 > \rho$, but asymptotically bounded by $\sqrt{\rho}$ when $\mu_2^2 \leq \rho$. All the remaining eigenvalues are asymptotically bounded by $\sqrt{\rho}$. As a result, a clustering positively-correlated with the true communities can be obtained based on the second eigenvector of B in the regime where $\mu_2^2 > \rho$.

In a previous work we obtained that detection is impossible when $\mu_2^2 < \rho$, meaning that there occurs a phase-transition in the sparse regime of the Degree-Corrected Stochastic Block Model.

As a corollary, we obtain that Degree-Corrected Erdős-Rényi graphs asymptotically satisfy the graph Riemann hypothesis, a quasi-Ramanujan property.

A by-product of our proof is a weak law of large numbers for local-functionals on Degree-Corrected Stochastic Block Models, which could be of independent interest.

1 Introduction

The non-backtracking matrix B of a graph $G = (V, E)$ is indexed by the set of its oriented edges $\vec{E} = \{(u, v) : \{u, v\} \in E\}$. For $e = (e_1, e_2), f = (f_1, f_2) \in \vec{E}$, B is defined as

$$B_{ef} = 1_{e_2=f_1} 1_{e_1 \neq f_2}.$$

This matrix was introduced by Hashimoto [10] in 1989.

We study the spectrum of B when G is a random graph generated according to the Degree-Corrected Stochastic Block Model (DC-SBM) [11]. We characterise its leading eigenvalues

and corresponding eigenvectors when the number of vertices in G tends to infinity. Our motivation stems from community detection problems: experiments in [14] show that the spectral method based on the non-backtracking matrix seems to work well on real datasets. We test the robustness of this method and show in particular that, above a certain threshold, the second eigenvector of B is correlated with the underlying communities.

The DC-SBM [11] is an extension of the *ordinary* Stochastic Block Model (SBM) [8]. The latter model has as a drawback that vertices in the same community are stochastically indistinguishable and it therefore fails to accurately describe networks with high heterogeneity. Compare this to fitting a straight line on intrinsically curved data, which is doomed to miss important information. The DC-SBM is a more realistic model: it allows for very general degree-sequences.

The special case of the DC-SBM under consideration here is defined as follows: It is a random graph on n vertices partitioned into two asymptotically equal-sized clusters. The vertices have bounded i.i.d. weights $\{\phi_u\}_{u=1}^n$ with second moment $\Phi^{(2)}$. The intra-cluster connection probability for vertices u and v is $\frac{\phi_u\phi_v}{n}a$ and the inter-cluster connection probability is $\frac{\phi_u\phi_v}{n}b$, for two constants $a, b > 0$.

Note that those graphs are thus sparse, which is a challenging regime for community detection. Indeed, in the *ordinary* SBM (obtained by putting $\phi_1 = \ldots = \phi_n = 1$), an instance of the graph might not contain enough information to distinguish between the two clusters if the difference between a and b is small. More precisely, reconstruction is impossible when $(a-b)^2 \leq 2(a+b)$ [18]. Interestingly, positively-correlated reconstruction can be obtained by thresholding the second-eigenvector of B [2] immediately above the threshold (i.e., $(a-b)^2 > 2(a+b)$). The SBM thus has a phase-transition in its sparse regime.

Does the DC-SBM exhibit a similar behaviour? We showed in an earlier work [6] that detection is impossible when $(a-b)^2\Phi^{(2)} \leq 2(a+b)$. In our current work we analyse the regime where $(a-b)^2\Phi^{(2)} > 2(a+b)$. We answer the following questions: is detection possible in this regime and if so, can we use again the non-backtracking matrix or do we need to modify it? *A priori this is unclear, because an algorithm solely based on B cannot use any information on the weights as input.* Our main result shows that the spectral method based on the non-backtracking matrix (thus the same method as in [2]) successfully detects communities in the regime $(a-b)^2\Phi^{(2)} > 2(a+b)$. Surprisingly, no modification of the matrix, nor information about the weights is needed (compare this to the adjacency matrix, which needs to be adapted to the degree-corrected setting [7]), which shows the robustness of the method. Moreover as in the standard SBM, the algorithm is optimal in the sense that it works all the way down to the detectability-threshold.

Informally, we have the following results: With high probability, the leading eigenvalue of the non-backtracking matrix B is asymptotic to $\rho = \frac{a+b}{2}\Phi^{(2)}$. The second eigenvalue is asymptotic to $\mu_2 = \frac{a-b}{2}\Phi^{(2)}$ when $\mu_2^2 > \rho$, but asymptotically bounded by $\sqrt{\rho}$ when $\mu_2^2 \leq \rho$. All the remaining eigenvalues are asymptotically bounded by $\sqrt{\rho}$. Further, a clustering positively-correlated with the true communities can be obtained based on the second eigenvector of B in the regime where $\mu_2^2 > \rho$ (i.e., precisely when $(a-b)^2\Phi^{(2)} > 2(a+b)$).

A side-result is that Degree-Corrected Erdős-Rényi graphs asymptotically satisfy the graph Riemann hypothesis, a quasi-Ramanujan property.

In our proof we derive and use a weak law of large numbers for local-functionals on Degree-Corrected Stochastic Block Models, which could be of independent interest.

1.1 Community detection background

In this paper we are interested in community detection: The problem of clustering vertices in a graph into groups of "similar" nodes. In particular, the graphs here are generated according to the DC-SBM and the goal is to retrieve the spin (or group-membership) of the nodes based on a single observation of the DC-SBM.

When the average degree of a vertex grows sufficiently fast with the size of the network (i.e., the average degree is $\Omega(\log(n))$), we speak about dense networks. Community-detection is then well understood and we consider instead sparse graphs where the average degree is bounded by a constant. This setting is more realistic as most real networks are sparse, but is at the same time more challenging. Indeed, traditional methods based on the Adjacency or Laplacian matrix working well in the dense case break down when employed in the sparse case.

In the sparse regime, with high probability, at least a positive fraction of the nodes is isolated. Consequently, one cannot hope to find the community-membership of *all* vertices. We therefore address here the problem of finding a clustering that is positively correlated with the true community-structure.

In [3] it was first conjectured that a detectability phase transition exists in the *ordinary* SBM: When $(a-b)^2 > 2(a+b)$, the belief propagation algorithm would succeed in finding such a positively correlated clustering. Conversely, due to a lack of information, detection would be impossible when $(a-b)^2 \leq 2(a+b)$.

In [18], impossibility of reconstruction when $(a-b)^2 \leq 2(a+b)$ is shown for the SBM. This paper builds further on a tree-reconstruction problem in [4].

The authors of [14] conjectured that detection using the second eigenvector of B would succeed all the way down to the conjectured detectability threshold. Two variants of this so-called spectral redemption conjecture were proven before the work in [2] appeared:

In [16] it is shown that detection based on the second eigenvector of a matrix counting self-avoiding paths in the graph leads to consistent recovery when $\left(\frac{a-b}{2}\right)^2 > \frac{a+b}{2}$.

Independently, in [17], the authors prove the positive side of the conjecture by using a constructing based on counting non-backtracking paths in graphs generated according to the SBM.

More recently, in [2] the spectral redemption conjecture is proved. This work moreover determines the limits of community detection based on the non-backtracking spectrum in the presence of an arbitrary number of communities.

Here we extend the work in [2] to the more general setting of the DC-SBM.

1.2 Quasi Ramanujan property

Following the definition introduced in [15], a k-regular graph is Ramanujan if its second largest absolute eigenvalue is no larger than $2\sqrt{k-1}$. In [9], a graph is said to satisfy the graph Riemann hypothesis if B has no eigenvalues λ such that $|\lambda| \in (\sqrt{\rho_B}, \rho_B)$, where ρ_B is the Perron-Frobenius eigenvalue of B. The graph Riemann hypothesis can be seen as a generalization of the Ramanujan property, because a regular graph satisfies the graph Riemann hypothesis if and only if it has the Ramanujan property [9, 19].

Now, put $a = b = 1$ to obtain a Degree-Corrected Erdős-Rényi graph where vertices u and v are connected by an edge with probability $\frac{\phi_u \phi_v}{n}$. Our results imply that, with high probability, $\rho_B = \Phi^{(2)} + o(1)$, while all other eigenvalues are in absolute value smaller than $\sqrt{\Phi^{(2)}} + o(1)$. Consequently, these Degree-Corrected Erdős-Rényi graphs asymptotically satisfy the graph Riemann hypothesis.

1.3 Outline and main differences with ordinary SBM

We follow the same general approach as in [2]. We focus primarily on the differences and complications here: we often omit or shorten the proof of a statement if it may be proven in a very similar way.

In Section 2 we define the DC-SBM and state the assumptions we make. This is then followed by Theorem 1 on the spectrum of B and its consequences for community detection, Theorem 2.

In Section 3, we give the necessary background on non-backtracking matrices. Further, we give an extension of the Bauer-Fike Theorem, that first appeared in [2].

In Section 4 we give the proof of Theorem 1. It builds on Propositions 4 and 5. Their proofs are deferred to later sections.

In Section 5 we consider two-type branching process where the offspring distribution is governed by a Poisson mixture to capture the weights of the vertices. We associate two martingales to this process and extend limiting results by Kesten and Stigum [12, 13]. Hoeffding's inequality plays an important role here to prove concentrations results for the weights. Further, we define a cross-generational functional on these branching processes that is correlated with the spin of the root.

In Section 6 we state a coupling between local neighbourhoods and the branching process with weights in Section 5. We established this coupling in an earlier work [6], it is technically more involved than the ordinary coupling on graphs with unit weight. It is crucial that the weights in the graph and the branching process are perfectly coupled. We further establish a growth condition on the local neighbourhoods, using a stochastic domination argument that is more involved than its analogue in unweighed graphs.

In Section 7 we define local functionals that map graphs, together with their spins *and* weights to the real numbers. We establish, using Efron-Stein's inequality, a weak law of large numbers for those functionals, which could be of independent interest. Part of the work here is again hidden in the coupling from [6].

In Section 8 we apply those local functionals to establish Proposition 4.

In Section 9 we decompose powers of the matrix B as a sum of products. This technique appeared first in [16] for matrices counting self-avoiding paths and was elaborated in [2]. To bound the norm of the individual matrices occurring in the decomposition, we use the trace method initiated in [5]. In doing so, we need to bound the expectation of products of higher moments of the weights over certain paths. This is a significant complication with respect to the ordinary SBM, see Section 9.2 for a comparison.

In Section 10 we prove that positively correlated clustering is possible based on the second eigenvector of B, i.e., Theorem 2. We use the symmetry present in the two-communities setting here, which gets in general broken in models with more than two communities.

Detailed proofs of the statements in Sections 5, 6, 7, 9 and 10 can be found in Appendices A–E in the detailed version of the underlying article: arXiv:1609.02487.

In each section we give a detailed comparison with the ordinary SBM.

2 Main Results

We define our model more precisely and state the two main theorems.

We consider random graphs on n nodes $V = \{1, \dots, n\}$ drawn according to the Degree-Corrected Stochastic Block Model [11]. The vertices are partitioned into two clusters of sizes n_+ and n_- by giving each vertex v a spin $\sigma(v)$ from $\{+, -\}$. The vertices have i.i.d. weights

$\{\phi_u\}_{u=1}^n$ governed by some law ν with support in $[\phi_{\min}, \phi_{\max}]$, where $0 < \phi_{\min} \leq \phi_{\max} < \infty$ are constants. We denote the second moment of the weights by $\Phi^{(2)}$. An edge is drawn between nodes u and v with probability $\frac{\phi_u\phi_v}{n}a$ when u and v have the same spin and with probability $\frac{\phi_u\phi_v}{n}b$ otherwise. The model parameters a and b are constant. We assume that for some constant $\gamma \in (0, 1]$,

$$n_\pm = \frac{n}{2} + \mathcal{O}(n^{1-\gamma}), \tag{1}$$

i.e., the communities have nearly equal size.

The ordinary SBM on two or more communities was first introduced in [8], which is a generalization of Erdős-Rényi graphs. The Degree-Corrected SBM appeared first in [11]. General inhomogeneous random graphs are considered in [1].

Note that we retrieve the two-communities ordinary SBM by giving all nodes *unit* weight.

Local neighbourhoods in the sparse graphs under consideration are tree-like with high probability. In [6] we showed that these trees are distributed according to a Poisson-mixture two-type branching process, detailed in Section 5 below. We denote the mean progeny matrix of the branching process by

$$M = \frac{\Phi^{(2)}}{2}\begin{pmatrix} a & b \\ b & a \end{pmatrix}. \tag{2}$$

We introduce the orthonormal vectors

$$g_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ 1 \end{pmatrix}, \text{ and } g_2 = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ -1 \end{pmatrix}, \tag{3}$$

together with the scalars

$$\rho = \mu_1 = \frac{a+b}{2}\Phi^{(2)}, \text{ and } \mu_2 = \frac{a-b}{2}\Phi^{(2)}. \tag{4}$$

Then, g_k $(k = 1, 2)$ are the left-eigenvectors of M associated to eigenvalues μ_k:

$$g_k^* M = \mu_k g_k^*, \quad k = 1, 2. \tag{5}$$

Note that ρ and μ_2 are also asymptotically eigenvalues of the expected adjacency matrix conditioned on the weights.

Indeed, if A denotes the adjacency matrix, and if ψ_1 and ψ_2 are the vectors defined for $u \in V$ by $\psi_1(u) = \frac{1}{\sqrt{2}}\phi_u$ and $\psi_2(u) = \frac{1}{\sqrt{2}}\sigma_u\phi_u$, then

$$\mathbb{E}\left[A|\phi_1, \ldots, \phi_n\right] = \frac{a+b}{n}\psi_1\psi_1^* + \frac{a-b}{n}\psi_2\psi_2^* - a\frac{1}{n}\mathrm{diag}\{\phi_u^2\}.$$

Put $\widehat{\psi}_i = \frac{\psi_i}{\|\psi_i\|_2}$. Then, by the law of large numbers, for $i = 1, 2$,

$$\left\|\mathbb{E}\left[A|\phi_i, \ldots, \phi_n\right]\widehat{\psi}_i - \mu_i\widehat{\psi}_i\right\|_2 \to 0,$$

in probability, as n tends to ∞.

Finally, we define for $k \in \{1, 2\}$,

$$\chi_k(e) = g_k(\sigma(e_2))\phi_{e_2}, \quad \text{for } e \in \vec{E}. \tag{6}$$

We show that the *candidate eigenvectors*

$$\zeta_k = \frac{B^\ell B^{*\ell}\check{\chi}_k}{\|B^\ell B^{*\ell}\check{\chi}_k\|} \tag{7}$$

are then, for $\ell \sim \log(n)$, asymptotically aligned with the first two eigenvectors of B. Note the weight in (6), which is *not* present in the ordinary SBM.

▶ **Theorem 1** (Degree-Corrected Extension of Theorem 4 in [2]). *Let G be drawn according to the DC-SBM such that assumption (1) holds. Assume that $\ell = C_{min}\log(n)$, with $C_{min} > 0$ a small constant defined in (9).*

If $\mu_2^2 > \rho$, then, with high probability, the eigenvalues λ_i of B satisfy

$$|\lambda_1 - \rho| = o(1), |\lambda_2 - \mu_2| = o(1), \quad \text{and, for } i \geq 3, \quad |\lambda_i| \leq \sqrt{\rho} + o(1).$$

Further, if, for $k \in \{1,2\}$, ξ_k is a normalized eigenvector associated to λ_k, then ξ_k is asymptotically aligned with ζ_k. The vectors ξ_1 and ξ_2 are asymptotically orthogonal.

If $\rho > 1$, and $\mu_2^2 \leq \rho$, then, with high probability, the eigenvalues λ_i of B satisfy

$$|\lambda_1 - \rho| = o(1), \quad \text{and, for } i \geq 2, \quad |\lambda_i| \leq \sqrt{\rho} + o(1).$$

Further, ξ_1 is asymptotically aligned with ζ_1.

Note that $\mu_2^2 > \rho$ implies $\rho > 1$, so that we consider the DC-SBM precisely in the regime where a giant component emerges, see [1].

In Theorem 2 we show that positively correlated clustering is possible based on the second eigenvector of B when above the feasibility threshold. More precisely, let $\widehat{\sigma} = \{\widehat{\sigma}(v)\}_{v\in V}$ be estimators for the spins of the vertices. Following [3], we say that $\widehat{\sigma}$ has positive overlap with the true spin configuration $\sigma = \{\sigma(v)\}_{v\in V}$ if for some $\delta > 0$, with high probability,

$$\min_p \frac{1}{n}\sum_{v=1}^{n} 1_{\widehat{\sigma}(v)=p\circ\sigma(v)} > \frac{1}{2} + \delta,$$

where p runs over the identity mapping on $\{+,-\}$ and the permutation that swaps $+$ and $-$.

▶ **Theorem 2** (Degree-Corrected Extension of Theorem 5 in [2]). *Let G be drawn according to the DC-SBM such that assumption (1) holds and such that $\mu_2^2 > \rho$. Let ξ_2 be the second normalized eigenvector of B.*

Then, there exists a deterministic threshold $\tau \in \mathbb{R}$, such that the following procedure yields asymptotically positive overlap: Put for vertex $v \in V$ its estimator $\widehat{\sigma}(v) = +$ if $\sum_{e:e_2=v} \xi_2(e) > \frac{\tau}{\sqrt{n}}$ and put $\widehat{\sigma}(v) = -$ otherwise.

2.1 Notation

We say that a sequence $(E_n)_n$ of events happens with high probability (w.h.p.) if $\lim_{n\to\infty} \mathbb{P}(E_n) = 1$.

We denote by $\|\cdot\|$ both the euclidean norm for vectors and the operator norm of matrices. I.e., for vectors $x = (x_1, \ldots, x_m)$, and a matrix A, $\|x\| = \sqrt{\sum_{u=1}^m x_u^2}$, and $\|A\| = \sup_{x,\|x\|=1} \|Ax\|$.

Below we use that the neighbourhoods with a radius no larger than $C_{\text{coupling}}\log_\rho(n)$ can be coupled w.h.p. to certain branching processes, where

$$C_{\text{coupling}} := \frac{\left(\frac{1}{3} - \frac{1}{9}\log(4/e)\right) \wedge \left(\frac{1}{80} \wedge \frac{\gamma}{4}\right)}{\log_\rho(2(a+b)\phi_{\max}^2)}. \tag{8}$$

We put,

$$C_{\min} = \frac{1}{10} C_{\text{coupling}} \tag{9}$$

and consider often neighbourhoods of radius $C_{\min}\log_\rho(n)$.

We denote the k-th moment of the weight distribution ν by $\Phi^{(k)}$. I.e., $\mathbb{E}\left[\phi_1^k\right] = \Phi^{(k)}$.

The non-backtracking property for oriented edges $e, f \in \vec{E}$ is denoted by $e \to f$, i.e., $e_2 = f_1$ and $f_2 \neq e_1$.

In proofs, we often use the symbols $c_1, c_2, \ldots$ for suitably chosen constants.

3 Preliminaries

3.1 Background on non-backtracking matrix

We repeat here the most important observations made in [2].

Firstly, for any $k \geq 1$, B^k_{ef} counts the number of non-backtracking paths between oriented edges e and f. A non-backtracking path is defined as an oriented path between two oriented edges such that no edge is the inverse of its preceding edge, i.e., the path makes no backtrack.

Another import observation is that $(B^*)_{ef} = B_{fe} = B_{e^{-1}f^{-1}}$, where for oriented edge $e = (e_1, e_2)$, we set $e^{-1} = (e_2, e_1)$. If we introduce the swap notation, for $x \in \mathbb{R}^{\vec{E}}$,

$$\check{x}_e = x_{e^{-1}}, \quad e \in \vec{E},$$

then for any $x, y \in \mathbb{R}^{\vec{E}}$, and integer $k \geq 0$,

$$\langle y, B^k x \rangle = \langle B^k \check{y}, \check{x} \rangle.$$

Denote by P the matrix on $\mathbb{R}^{\vec{E} \times \vec{E}}$, defined on oriented edges e, f as

$$P_{ef} = 1_{f=e^{-1}}.$$

Then, $Px = \check{x}$, $P^* = P$ and $P^{-1} = P$. Further,

$$(B^k P)^* = P(B^*)^k = B^k P,$$

so that we can write the symmetric matrix $B^k P$ in diagonal form: Let $(\sigma_{k,j})_j$ be eigenvalues of $B^k P$ ordered in decreasing order of absolute value, and let $(x_{k,j})_j$ be the corresponding orthonormal eigenvectors. Then,

$$B^k = (B^k P)P = \sum_j \sigma_{k,j} x_{k,j} x^*_{k,j} P = \sum_j \sigma_{k,j} x_{k,j} \check{x}^*_{k,j} = \sum_j s_{k,j} x_{k,j} y^*_{k,j}, \tag{10}$$

where $s_{k,j} = |\sigma_{k,j}|$ and $y_{k,j} = \mathrm{sign}(\sigma_{k,j}) \check{x}_{k,j}$. Since P is an orthogonal matrix, $(\check{x}_{k,j})_j$ form an orthonormal base for $\mathbb{R}^{\vec{E}}$ and the term furthest on the right of (10) is thus the spectral value decomposition of B^k. Now, if B is irreducible and if ξ denotes the normalized Perron eigenvector of B with eigenvalue $\lambda_1(B) > 0$, we have $\lambda_1(B) = \lim_{k\to\infty} (\sigma_{k,1})^{1/k}$, and $\lim_{k\to\infty} \|x_{k,1} - \xi\| = 0$.

In [2], the Bauer-Fike Theorem is extended to prove the spectral claims we make here.

3.2 Extension of Bauer-Fike Theorem

Tailored to our needs, we use the following proposition from [2]:

▶ **Proposition 3** (Special case of Proposition 8 in [2]). *Let $\ell = C \log_\rho n$, with $C > 0$. Let $A \in M_n(\mathbb{R})$, such that for some vectors $x_1 = x_{\ell,1}, y_1 = y_{\ell,1}, x_2 = x_{\ell,2}, y_2 = y_{\ell,2} \in \mathbb{R}$, some matrix $R_\ell \in M_n(\mathbb{R})$, and some non-zero constants $\rho > \mu_2$ with $\mu_2^2 > \rho$,*

$$A^\ell = \rho^\ell x_1 y_1^* + \mu_2^\ell x_2 y_2^* + R_\ell. \tag{11}$$

Assume there exist $c_0, c_1 > 0$ such that for all $i \in \{1, 2\}$, $\langle y_i, x_i \rangle \geq c_0$, $\|x_i\| \|y_i\| \leq c_1$. Assume further that $\langle x_1, y_2 \rangle = \langle x_2, y_1 \rangle = \langle x_1, x_2 \rangle = \langle y_1, y_2 \rangle = 0$ and for some $c > 0$

$$\|R_\ell\| < \rho^{\ell/2} \log^c(n).$$

Let $(\lambda_i)_{1\le i\le n}$, be the eigenvalues of A with $|\lambda_n|\le\ldots\le|\lambda_1|$. Then,

$$|\lambda_1-\rho|=o(1),|\lambda_2-\mu_2|=o(1),\quad \text{and, for } i\ge 3,\quad |\lambda_i|\le\sqrt{\rho}+o(1).$$

Further, there exist unit eigenvectors ψ_1,ψ_2 of A with eigenvalues λ_1, respectively λ_2 such that

$$||\psi_i-\frac{x_i}{\|x_i\|}||=o(1).$$

Proof. This is a special case of Proposition 8 in [2]. In the notation of the latter, we have $\ell'=\ell-2$, $\theta_1=\rho$, $\theta_2=\mu_2$, $\theta=\mu_2$, $\gamma\ge\frac{a+b}{|a-b|}>1$. Further $\frac{c_0(c_0\gamma^k-c_1)_+}{4c_1}\wedge\frac{c_0^2}{2(\ell\vee\ell')c_1}\sim\frac{1}{\log_\rho n}$, and thus

$$\|R_\ell\|\le\log^c(n)\left(\frac{\sqrt{\rho}}{|\mu_2|}\right)^\ell|\mu_2|^\ell=o(1)\frac{1}{\log_\rho n}|\theta|^\ell.$$ ◀

To prove the case $\mu_2^2>\rho$ of Theorem 1, we thus need to find candidate vectors x_1,x_2,y_1 and y_2 that meet the conditions in Proposition 3 and further verify that the remainder R_ℓ has small norm. Note that the last condition is true whenever $\|B^\ell x\|\le\rho^{\ell/2}\log^c(n)$ for all normalized x in $\mathrm{span}\{y_1,y_2\}^\perp$.

To address the case $\mu_2^2\le\rho$ of Theorem 1, we appeal to Proposition 7 in [2], which is very similar in spirit to Proposition 3.

4 Proof of Theorem 1

4.1 The case $\mu_2^2>\rho$

We start with the case $\mu_2^2>\rho$. We decompose, for some vectors x_1,y_1,x_2 and y_2 and matrix R_ℓ,

$$B^\ell=\rho^\ell x_1y_1^*+\mu_2^\ell x_2y_2^*+R_\ell,$$

and we show that the assumptions of Proposition 3 are met.

Let ℓ be as in Theorem 1 and recall χ_k and ζ_k from (6) and (7). For ease of notation, we introduce for $k\in\{1,2\}$,

$$\varphi_k=\frac{B^\ell\chi_k}{\|B^\ell\chi_k\|},\quad \text{and } \theta_k=\|B^\ell\check{\varphi}_k\|. \tag{12}$$

Then, $\zeta_k=\frac{B^\ell\check{\varphi}_k}{\theta_k}$.

To prove the main theorem, we need the following two propositions. The proofs are deferred to Section 8 and 9.1. The material in Section 8 builds on ingredients from Sections 6 - 7, where we assume that $\mu_2^2>\rho$, unless stated otherwise.

▶ **Proposition 4** (Degree-Corrected Extension of Proposition 19 in [2]). *Assume that $\mu_2^2>\rho$. Let $\ell=C\log_\rho n$ with $0<C<C_{min}$. For some $b,c>0$, with high probability,*

(i) $b|\mu_k^\ell|\le\theta_k\le c|\mu_k^\ell|$ *if* $k\in\{1,2\}$,
(ii) $sign(\mu_k^\ell)\langle\zeta_k,\check{\varphi}_k\rangle\ge b$ *if* $k\in\{1,2\}$,
(iii) $|\langle\varphi_1,\varphi_2\rangle|\le(\log n)^3n^{C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$,
(iv) $|\langle\zeta_j,\check{\varphi}_k\rangle|\le(\log n)^3n^{\frac{3}{2}C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$ *if* $k\ne j\in\{1,2\}$.
(v) $|\langle\zeta_1,\zeta_2\rangle|\le(\log n)^8n^{2C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$.

Put $H = \text{span}\{\check{\varphi}_1, \check{\varphi}_2\}$, then

▶ **Proposition 5** (Degree-Corrected Extension of Proposition 20 in [2]). *Let $\ell = C \log_\rho n$ with $0 < C < C_{min}$. For some $c > 0$, with high probability,*

$$\sup_{x \in H^\perp, \|x\|=1} \|B^\ell x\| \leq (\log n)^c \rho^{\ell/2}. \tag{13}$$

Put $\bar{\varphi}_1 = \check{\varphi}_1$, and $\bar{\varphi}_2 = \frac{\check{\varphi}_2 - \langle \check{\varphi}_1, \check{\varphi}_2 \rangle \check{\varphi}_1}{||\check{\varphi}_2 - \langle \check{\varphi}_1, \check{\varphi}_2 \rangle \check{\varphi}_1||}$, then $\bar{\varphi}_1$ and $\bar{\varphi}_2$ are orthonormal and $||\bar{\varphi}_2 - \check{\varphi}_2|| = o(\rho^{-\ell/2})$, due to Proposition 4 (iii).

Let $\bar{\zeta}_1$ be the normalized orthogonal projection of ζ_1 on $\text{span}\{\bar{\varphi}_2\}^\perp$. Similarly, let $\bar{\zeta}_2$ be the normalized orthogonal projection of ζ_2 on $\text{span}\{\bar{\zeta}_1, \bar{\varphi}_1\}^\perp$.

Then $\langle \bar{\zeta}_1, \bar{\zeta}_2 \rangle = 0$ and for $i = 1, 2$, $||\bar{\zeta}_i - \zeta_i|| = o(\rho^{-\ell/2})$, as follows from Proposition 4 (iv) and (v).

We set

$$D = \theta_1 \bar{\zeta}_1 \bar{\varphi}_1^* + \theta_2 \bar{\zeta}_2 \bar{\varphi}_2^* = \rho^\ell \left(\frac{\theta_1}{\rho^\ell} \bar{\zeta}_1 \right) \bar{\varphi}_1^* + \mu_2^\ell \left(\frac{\theta_2}{\mu_2^\ell} \bar{\zeta}_2 \right) \bar{\varphi}_2^*.$$

Note that,

$$\|B^\ell \bar{\varphi}_1\| = \theta_1 = O(\rho^\ell),$$

and

$$\|B^\ell \bar{\varphi}_2\| = \|B^\ell \left((1 + o(1)) \check{\varphi}_2 + o(1) \bar{\varphi}_1 \right) \| = O(\rho^\ell).$$

As a consequence, from Proposition 5,

$$\|B^\ell\| = O(\rho^\ell).$$

Since $D\bar{\varphi}_i = B^\ell \check{\varphi}_i + \theta_i (\bar{\zeta}_i - \zeta_i)$,

$$\|B^\ell \bar{\varphi}_i - D\bar{\varphi}_i\| \leq \|B^\ell\| \|\bar{\varphi}_i - \check{\varphi}_i\| + \theta_i \|\bar{\zeta}_i - \zeta_i\| = \mathcal{O}\left(\rho^{\ell/2}\right).$$

Let P be the orthogonal projection on $H = \text{span}\{\bar{\varphi}_1, \bar{\varphi}_2\} = \text{span}\{\check{\varphi}_1, \check{\varphi}_2\}$, then $\|B^\ell P - D\| = \mathcal{O}\left(\rho^{\ell/2}\right)$.

Put $R_\ell = B^\ell - D$. Write for $y \in \mathbb{R}^{\vec{E}}$ with unit norm, $y = h + h^\perp$, with $h \in H$ and $h^\perp \in H^\perp$, then

$$\begin{aligned} \|R_\ell y\| &= \|B^\ell h^\perp + (B^\ell - D)h\| \\ &\leq \sup_{x \in H^\perp, \|x\|=1} \|B^\ell x\| + \|B^\ell P - D\| \\ &= \mathcal{O}\left(\log^c(n) \rho^{\ell/2}\right), \end{aligned} \tag{14}$$

as follows from Proposition 5.

We finish by applying Proposition 3 with $x_1 = \frac{\theta_1}{\rho^\ell} \bar{\zeta}_1, y_1 = \bar{\varphi}_1, x_2 = \frac{\theta_2}{\mu_2^\ell} \bar{\zeta}_2$, and, $y_2 = \bar{\varphi}_2$.

4.2 The case $\mu_2^2 \leq \rho$

In case $\mu_2^2 \leq \rho$, Proposition 4 (i) and (ii) continue to hold for $k = 1$. Further, Proposition 4 (iii) as well as Proposition 5 continue to hold. We need however the following bound for $k = 2$:

▶ **Proposition 6.** *Assume that* $\mu_2^2 \le \rho$. *Let* $\ell = C \log_\rho n$ *with* $0 < C < C_{min}$. *For some* $c > 0$, *with high probability,*

$$\theta_2 \le (\log n)^c \rho^{\ell/2}.$$

Using this proposition and $||\bar{\varphi}_2 - \check{\varphi}_2|| = o(\rho^{-\ell/2})$, we get

$$\|B^\ell \bar{\varphi}_2\| \le (\log n)^{c+1} \rho^{\ell/2}.$$

It remains to apply Proposition 7 from [2].

5 Poisson-mixture two-type branching processes

The proofs of the statements in this section can be found in Appendix A in the detailed version of the underlying article (Arxiv:1609.02487).

5.1 A theorem of Kesten and Stigum

We consider the following branching process starting with a single particle, the root o, having spin $\sigma_o \in \{+,-\}$ and weight $\phi_o \in [\phi_{\min}, \phi_{\max}]$ (which we often take random). The root is replaced in generation 1 by Poi $\left(\frac{a}{2}\Phi^{(1)}\phi_o\right)$ particles of spin σ_o and Poi $\left(\frac{b}{2}\Phi^{(1)}\phi_o\right)$ particles of spin $-\sigma_o$. Further, the weights of those particles are i.i.d. distributed following law ν^*, the size-biased version of ν, defined for $x \in [\phi_{\min}, \phi_{\max}]$ by

$$\nu^*([0,x]) = \frac{1}{\Phi^{(1)}} \int_{\phi_{\min}}^{x} y \mathrm{d}\nu(y). \tag{15}$$

For generation $t \ge 1$, a particle with spin σ and weight ϕ^* is replaced in the next generation by Poi $\left(\frac{a}{2}\Phi^{(1)}\phi^*\right)$ particles with the same spin and Poi $\left(\frac{b}{2}\Phi^{(1)}\phi^*\right)$ particles of the opposite sign. Again, the weights of the particles in generation $t+1$ follow in an i.i.d. fashion the law ν^*. The offspring-size of an individual is thus a **Poisson-mixture**.

We use the notation $Z_t = \begin{pmatrix} Z_t(+) \\ Z_t(-) \end{pmatrix}$ for the population at generation $t \ge 1$, where $Z_t(\pm)$ is the number of type $\pm$ particles in generation t. We let $(\mathcal{F}_t)_{t\ge1}$ denote the natural filtration associated to $(Z_t)_{t\ge1}$.

We associate two matrices to the branching process, namely M defined in (2), and, for a root with weight ϕ_o,

$$M_{\phi_o} = \frac{\Phi^{(1)}\phi_o}{\Phi^{(2)}} M. \tag{16}$$

Then, M is the *transition* matrix for generations $t \ge 1$ and later:

$$\mathbb{E}\left[Z_{t+1} | Z_t\right] = M Z_t, \quad \text{for all } t \ge 1, \tag{17}$$

and M_{ϕ_o} describes the transition from the root to the first generation:

$$\mathbb{E}\left[Z_1 | Z_0, \phi_o\right] = M_{\phi_o} Z_0, \tag{18}$$

where, by assumption $Z_0 = \begin{pmatrix} 1_{\sigma_o=+} \\ 1_{\sigma_o=-} \end{pmatrix}$. Note that the difference between the root and later generations stems from the fact that the root's weight is deterministic in the conditional expectation, whereas the weight of a particle in any later generation has expectation $\frac{\Phi^{(2)}}{\Phi^{(1)}}$.

Recall from (5) that g_k $(k = 1, 2)$ are the left-eigenvectors of M associated to eigenvalues μ_k:

$$g_k^* M = \mu_k g_k^*, \quad k = 1, 2. \tag{19}$$

Note that M_{ϕ_o} has the same left-eigenvectors as M, while the corresponding eigenvalues are given by

$$\mu_{k,\phi_o} = \frac{\Phi^{(1)}\phi_o}{\Phi^{(2)}}\mu_k, \quad k = 1, 2. \tag{20}$$

Theorem 7 shows that a Kesten-Stigum theorem applies to the "classical" branching process obtained after restricting the above process to generations 1 and later. Corollary 8, then, joins this classical branching process to the transition from the root to generation 1.

We further consider the vector $\Psi_t = (\Psi_t(+), \Psi_t(-))$, containing sums of the weights,

$$\Psi_t(\pm) = \sum_{u \in Y_t} 1_{\sigma_u = \pm}\phi_u, \tag{21}$$

where Y_t is the set of particles at distance t from the root, and where ϕ_u and σ_u denote the weight respectively spin of a particle u. Note that $\Psi_t = Z_t$ in case of unit weights.

The martingale Theorem 9 is not present in [2]. We need it to bound the variance of the cross-generational functional defined in Section 5.3.

▶ **Theorem 7** (Degree-Corrected Extension of Theorem 21 in [2]). *Assume that $\mu_2^2 > \rho$. Put $\mathcal{F}_t = \{Z_s\}_{s \le t}$. For any $k = 1, 2$,*

$$\left(X_k(t) := \frac{\langle g_k, Z_t \rangle}{\mu_k^{t-1}} - \langle g_k, Z_1 \rangle \right)_{t \ge 1},$$

is an $\mathcal{F}_t$-martingale converging a.s. and in L^2 such that for some $C > 0$ and all $t \ge 1$, $\mathbb{E}[X_k(t)] = 0$ and $\mathbb{E}\left[X_k^2(t)|Z_1\right] \le C\|Z_1\|_1$.

▶ **Corollary 8.** *Assume that $\mu_2^2 > \rho$. For $k = 1, 2$, with the weight $\phi_o = \psi_o$ of the root fixed, the sequence of random variables $(Y_{k,\psi_o}(t))_{t \ge 1} = \left(\frac{\langle g_k, Z_t \rangle}{\mu_k^{t-1}\mu_{k,\psi_o}}\right)_{t \ge 1}$ converges* almost surely *and in L^2 to a random variable $Y_{k,\psi_o}(\infty)$ with $\mathbb{E}[Y_{k,\psi_o}(\infty)|\sigma_o] = g_k(\sigma_o)$. Further, the L^2-convergence takes place uniformly over all ψ_o.*

▶ **Theorem 9.** *Assume that $\mu_2^2 > \rho$. Put $\mathcal{G}_t = \{\Psi_s\}_{s \le t}$. For any $k = 1, 2$,*

$$\left(X_k(t) := \frac{\langle g_k, \Psi_t \rangle}{\mu_k^{t-1}} - \langle g_k, \Psi_1 \rangle \right)_{t \ge 1},$$

is an $\mathcal{G}_t$-martingale converging a.s. and in L^2 such that for some $C > 0$ and all $t \ge 1$, $\mathbb{E}[X_k(t)] = 0$ and $\mathbb{E}\left[X_k^2(t)|Z_1\right] \le C\|Z_1\|_1$.

5.2 Quantitative version of the Kesten-Stigum theorem

We now quantify the growth of the population size. The latter is defined as

$$S_t = \|Z_t\|_1, \quad t \ge 0,$$

i.e., the number of individuals in generation $t \ge 0$. Given S_t, for $t \ge 1$ we have

$$S_{t+1} = \mathrm{Poi}\left(\sum_{l=1}^{S_t} X_t^{(l)} \right), \tag{22}$$

where $\left(X_t^{(l)}\right)_l$ are i.i.d. copies of $\frac{a+b}{2}\Phi^{(1)}\phi^*$, where ϕ^* follows law ν^*.

Note that in the *ordinary* Stochastic Block Model (i.e., when all vertices have unit weight), the argument of the Poisson random variables in (22) is deterministic, contrary to the general case under consideration here. Using (17) recursively in conjunction with (18), it follows that

$$\mathbb{E}\left[S_t|\phi_o\right] = \frac{\Phi^{(1)}\phi_o}{\Phi^{(2)}}\rho^t, \quad \forall t \geq 1.$$

In the following lemma we show that deviations from this average are small. In fact, there exists a constant C such that for each $t \geq 0$, S_t is asymptotically stochastically dominated by an Exponential random variable with mean $C\rho^t$. An important ingredient in the proof below is Hoeffding's inequality, which we use to derive a concentration result for the parameter of the Poisson variable in (22).

▶ **Lemma 10** (Degree-Corrected Extension of Lemma 23 in [2]). *Assume $S_0 = 1$. There exist $c, c' > 0$ such that for all $s \geq 0$,*

$$\mathbb{P}\left(\forall k \geq 1, S_k \leq s\rho^k\right) \geq 1 - c'e^{-cs}.$$

From Theorem 7 and Corollary 8, we know that the different components (expressed in the basis of eigenvectors of M) grow exponentially with rate ρ, respectively μ_2. We now quantify the error. Recall Ψ_t from (21).

5.2.1 The case $\mu_2^2 > \rho$

▶ **Theorem 11** (Degree-Corrected Extension of Theorem 24 in [2]). *Assume that $\mu_2^2 > \rho$. Let $\beta > 0$, $Z_0 = \delta_x$ and $\phi_o = \psi_o$ be fixed. There exists $C = C(x, \beta) > 0$ such that with probability at least $1 - n^{-\beta}$, for all $k \in \{1, 2\}$, all $0 \leq s < t \leq C_{min}\log(n)$, with $0 \leq s < t$,*

$$|\langle g_k, Z_s\rangle - \mu_k^{s-t}\langle g_k, Z_t\rangle| \leq C(s+1)\rho^{s/2}(\log n)^{3/2},$$

and,

$$|\langle g_k, \Psi_s\rangle - \mu_k^{s-t}\langle g_k, \Psi_t\rangle| \leq C\rho^{s/2}(\log n)^{5/2}.$$

5.2.2 The case $\mu_2^2 \leq \rho$

▶ **Theorem 12.** *Assume that $\mu_2^2 \leq \rho$. Let $\beta > 0$, $Z_0 = \delta_x$ and $\phi_o = \psi_o$ be fixed. There exists $C = C(x, \beta) > 0$ such that with probability at least $1 - n^{-\beta}$, for all $t \geq 1$,*

$$|\langle g_2, \Psi_t\rangle| \leq Ct^2\rho^{t/2}(\log n)^2,$$

and,

$$\mathbb{E}\left[|\langle g_2, \Psi_t\rangle|^2\right] \leq Ct^3\rho^t.$$

5.3 $B^\ell B^{*\ell}\check{\chi}_k$ on trees: a cross generation functional

Recall our claim that $B^\ell B^{*\ell}\check{\chi}_k$ are asymptotically aligned with the eigenvectors of B. In the DC-SBM, the local-neighbourhood of a vertex has with high probability a tree-like structure described by the branching process above. In this section we analyse $B^\ell B^{*\ell}\check{\chi}_k$ on trees.

To this end we define a cross-generational functional slightly different from its analogue in [2] due to the presence of weights:

$$Q_{k,\ell} = \sum_{(u_0,\dots,u_{2\ell+1})\in\mathcal{P}_{2\ell+1}} g_k(\sigma(u_{2\ell+1}))\phi_{u_{2\ell+1}}, \tag{23}$$

where $\mathcal{P}_{2\ell+1}$ is the set of paths $(u_0,\dots,u_{2\ell+1})$ (of length $2\ell+1$) in the tree starting from $u_0 = o$ with both $(u_0,\dots,u_\ell)$ and $(u_\ell,\dots,u_{2\ell+1})$ non-backtracking and $u_{\ell-1} = u_{\ell+1}$. Note that these paths thus make a back-track exactly once at step $\ell+1$.

Explicitly, we have

$$Q_{1,\ell} = \sum_{(u_0,\dots,u_{2\ell+1})\in\mathcal{P}_{2\ell+1}} \frac{1}{\sqrt{2}}\phi_{u_{2\ell+1}}, \tag{24}$$

and,

$$Q_{2,\ell} = \sum_{(u_0,\dots,u_{2\ell+1})\in\mathcal{P}_{2\ell+1}} \frac{1}{\sqrt{2}}\sigma(u_{2\ell+1})\phi_{u_{2\ell+1}}. \tag{25}$$

Consider a tree $\mathcal{T}'$ and a leaf e_1 on it that has unique neighbour, say, o. Then, if e is the oriented edges from e_1 to o and if $B_{\mathcal{T}'}$ denotes the non-backtracking matrix defined on $\mathcal{T}'$,

$$\left(B^{\ell}_{\mathcal{T}'}B^{*\ell}_{\mathcal{T}'}\check{\chi}_k\right)(e) = Q_{k,\ell} + g_k(\sigma(e_1))\phi_{e_1}\|Z_\ell\|_1, \tag{26}$$

where $Q_{k,\ell}$ and Z_ℓ are defined on the tree $\mathcal{T}$ with root o obtained after removing vertex e_1 from $\mathcal{T}'$.

In the sequel we analyse $Q_{k,\ell}$ on the branching process defined above, starting with a single particle, the root o. Let V indicate the particles of the random tree. Denote the spin of a particle $v\in V$ by $\sigma_v\in\{+,-\}$ and its weight by $\phi_v\in S$.

For $t\geq 0$, let Y_t^v denote the set of particles, *including* their spins and weights, of generation t from v in the subtree of particles with common ancestor $v\in V$. Let $Z_t^v = (Z_t^{v,+}, Z_t^{v,-})$ denote the number of $\pm$ vertices in generation t; i.e., $Z_t^{v,\pm} = \sum_{u\in Y_t^v} 1_{\sigma(u)=\pm}$. Finally, let $\Psi_t^v = (\Psi_t^{v,+}, \Psi_t^{v,-})$, with $\Psi_t^{v,\pm} = \sum_{u\in Y_t^v} 1_{\sigma(u)=\pm}\phi_u$.

We rewrite $Q_{k,\ell}$ into a more manageable form: First observe that every path in $\mathcal{P}_{2\ell+1}$, after reaching $u_{\ell+1}$, climbs back to a depth t from which it then again moves down the tree (that is, in the direction away from the root). Let us call the vertex at level t (to which the path climbs back before descending again) u. Then, (if $t\neq 0$) there are two children of u, say v and w such that w lies on the path between u and $u_{\ell+1}$ and v is in between u and $u_{2\ell+1}$. For such fixed v and w in Y_1^u, only the children $u_{2\ell+1}\in Y_t^v$ determine the contribution of a path to (23), regardless of the choice of $u_{\ell+1}\in Y_{\ell-t-1}^w$. Hence, for such fixed u and $v,w\in Y_1^u$ and $u_{2\ell+1}$, there are $|Y_{\ell-t-1}^w| = S_{\ell-t-1}^w$ paths giving the same contribution to (23):

$$Q_{k,\ell} = \sum_{t=0}^{\ell-1}\sum_{u\in Y_t^o} L_{k,\ell}^u, \tag{27}$$

where, for $|u| = t\geq 0$,

$$L_{k,\ell}^u = \sum_{w\in Y_1^u} S_{\ell-t-1}^w \left(\sum_{v\in Y_1^u\setminus\{w\}} \langle g_k, \Psi_t^v\rangle\right). \tag{28}$$

The following theorem is an extension of Theorem 25 in [2]. The important observation is that, again, for $Z_0 = \delta_\tau$ fixed, $\left(Q_{2,\ell}/\mu_2^{2\ell}\right)_\ell$ converges to a random variable with mean a

constant times τ, that is, the spin of the root. Its proof uses both martingale theorems stated above. We use the second martingale statement, which is not present in the ordinary SBM, to bound the variance of $Q_{k,\ell}$:

▶ **Theorem 13** (Degree-Corrected Extension of Theorem 25 in [2]). *Assume that $\mu_2^2 > \rho$. Let $Z_0 = \delta_x$ and $\phi_o = \psi_o$ be fixed. For $k \in \{1,2\}$, $\left(Q_{k,\ell}/\mu_k^{2\ell}\right)_\ell$ converges in L^2 as ℓ tends to infinity to a random variable with mean $\frac{\Phi^{(3)}}{\Phi^{(2)}} \frac{\rho}{\mu_k^2 - \rho} \mu_{k,\psi_o} g_k(x)$. Further, the L^2-convergence takes place uniformly for all ψ_o.*

5.3.1 The case $\mu_2^2 \leq \rho$

▶ **Theorem 14.** *Assume that $\mu_2^2 \leq \rho$. Let $Z_0 = \delta_x$ and $\phi_o = \psi_o$ be fixed. There exists a constant C such that $\mathbb{E}\left[Q_{2,\ell}^2\right] \leq C\rho^{2\ell}\ell^5$.*

5.4 Orthogonality: Decorrelation in branching process

Again, as in [2], $Q_{1,\ell}$ and $Q_{2,\ell}$ are uncorrelated when defined on the branching process above. The proof presented here is simpler than the corresponding one in [2] and uses that for the two communities-case, $Q_{1,\ell}$ and $Q_{2,\ell}$ are *explicitly* known.

The orthogonality of the candidate eigenvectors (i.e., $(iii) - (v)$ in Proposition 4) follows from this fact, see Proposition 24 $(ii), (iii)$ and Proposition 25 (ii) below.

▶ **Theorem 15** (Degree-Corrected Extension of 28 in [2]). *Assume that the spin σ_o of the root is drawn uniformly from $\{+,-\}$. Then for any $\ell \geq 0$,*

$$\mathbb{E}\left[Q_{1,\ell} Q_{2,\ell} | \mathcal{T}\right] = 0.$$

6 Coupling of local neighbourhood

The proofs of the statements in this section can be found in Appendix B in the detailed version of the underlying article (Arxiv:1609.02487).

6.1 Coupling

Here we establish the connection between neighbourhoods in the DC-SBM and the branching process in Section 5. We established this coupling in an earlier paper [6] using an exploration process that we repeat below. Compared to the ordinary SBM, vertices are now weighted, so that two facts need to be verified: At each step of the exploration process, unexplored vertices have a weight drawn from a distribution close in total variation distance to ν. Detected vertices on their turn follow a law close to ν^*.

We distinguish between two different concepts of neighbourhood: the classical neighbourhood that is rooted at a vertex and another neighbourhood that starts with an edge. For the latter, we need the following concept of *oriented* distance $\vec{d}$, which for $e, f \in \vec{E}(V)$ is defined as

$$\vec{d}(e,f) = \min_\gamma \ell(\gamma)$$

where the minimum is taken over all self-avoiding paths $\gamma = (\gamma_0, \gamma_1, \cdots, \gamma_{\ell+1})$ in G such that $(\gamma_0, \gamma_1) = e$, $(\gamma_\ell, \gamma_{\ell+1}) = f$ and for all $1 \leq k \leq \ell + 1$, $\{\gamma_k, \gamma_{k+1}\} \in E$. and where for such a path γ, $\ell(\gamma) = \ell$. Note that $\vec{d}(e,f) = \vec{d}(f^{-1}, e^{-1})$, i.e., $\vec{d}$ is not symmetric.

We introduce the vector $Y_t(e) = (Y_t(e)(i))_{i\in\{+,-\}}$ where, for $i \in \{+,-\}$,

$$Y_t(e)(i) = \left|\left\{f \in \vec{E} : \vec{d}(e,f) = t, \sigma(f_2) = i\right\}\right|, \tag{29}$$

we denote the number of vertices at oriented distance t from e by

$$S_t(e) = \|Y_t(e)\|_1 = \left|\left\{f \in \vec{E} : \vec{d}(e,f) = t\right\}\right|,$$

and we define vector $\Psi_t(e) = (\Psi_t(e)(i))_{i\in\{+,-\}}$ where, for $i \in \{+,-\}$,

$$\Psi_t(e)(i) = \sum_{f\in\vec{E}:\vec{d}(e,f)=t} 1_{\sigma(f_2)=i}\phi_{f_2}. \tag{30}$$

We denote the classical neighbourhood of radius r rooted at vertex v by $(G,v)_r$ and the neighbourhood around oriented edge $e = (e_1,e_2)$ by $(G,e)_r$. With the definitions above, we then have, $(G,e)_r = (G',e_2)_r$, where G' is the graph G with edge $\{e_1,e_2\}$ removed. In particular,

$$S_t(e) = S'_t(e_2),$$

where S'_t is S_t defined on G'.

The two branching processes that describe the neighbourhoods are almost identical, the only difference lies in the weight of the root: In the classical branching processes, the weight is drawn according to distribution ν. In the branching process starting at an edge oriented towards, say, o, the root o has weight governed by ν^*. See Proposition 16 below.

As a corollary we obtain an analogue of Theorem 11 for local neighbourhoods: the components of $\Psi_t(e)$ grow exponentially, see Corollary 17.

We bound the growth of S_t in Lemma 18. We use a coupling argument to show that the weights of the unexplored vertices and selected vertices are stochastically dominated by variables following law ν, respectively ν^*. This argument is not needed in the ordinary SBM.

Following [17], we need to verify that certain problematic structures, namely *tangles*, are excluded with high probability. We say that a graph H is tangle-free if all its $\ell-$ neighbourhoods contain at most one cycle. If there is at least one $\ell-$ neighbourhood in H that contains more than one cycle, we call H tangled. Note that in the sequel we shall often suppress the dependence on ℓ and simply call a graph tangle-free or tangled; the ℓ dependence is then tacitly assumed.

Following standard arguments we establish in Lemma 19 that the graph is with high probability $\log(n)$-tangle free.

We prepare by recalling the exploration process in [6] starting at a vertex:

At time $m = 0$, choose a vertex ρ in $V(G)$, where G is an instant of the DC-SBM. Initially, it is the only active vertex: $\mathcal{A}(0) = \{\rho\}$. All other vertices are neutral at start: $\mathcal{U}(0) = V(G) \setminus \{\rho\}$. No vertex has been explored yet: $\mathcal{E}(0) = \emptyset$.

At each time $m \geq 0$ we arbitrarily pick an active vertex u in $\mathcal{A}(m)$ that has shortest distance to ρ, and explore all its edges in $\{uv : v \in \mathcal{U}(m)\}$: if $uv \in E(G)$ for $v \in \mathcal{U}(m)$, then we set v active in step $m+1$, otherwise it remains neutral.

At the end of step m, we designate u to be explorated.

Thus,

$$\mathcal{E}(m+1) = \mathcal{E}(m) \cup \{u\},$$

$$\mathcal{A}(m+1) = (\mathcal{A}(m) \setminus \{u\}) \cup (\mathcal{N}(u) \cap \mathcal{U}(m)),$$

and,

$$\mathcal{U}(m+1) = \mathcal{U}(m) \setminus \mathcal{N}(u).$$

▶ **Proposition 16** (Degree-Corrected Extension of Proposition 31 in [2]). *Let $\ell = C\log_\rho(n)$, with $C < C_{coupling}$. Let $\rho \in V$ and $e = (e_1, e_2) \in \vec{E}$. Let (T, o) be the branching process with root o defined in Section 5, where the root has spin $\sigma(v)$ and weight governed by ν. Similarly, Let (T', o) be that same branching process, when the root has spin $\sigma(e_2)$ and weight governed by ν^*. Then, the total variation distance between the law of $(G, v)_\ell$ and $(T, o)_\ell$ goes to zero as $1 - n^{-\left(\frac{\gamma}{2} \wedge \frac{1}{40}\right)}$. The same is true for the difference between the law of $(G, e)_\ell$ and (T', o).*

▶ Remark. Note that with the event $(G, v)_\ell = (T, o)_\ell$, we mean that the graph and tree are equal, **including** their **spins and weights**. See [6] for more details.

▶ **Corollary 17** (Degree-Corrected Extension of Corollary 32 in [2]). *Assume $\mu_2^2 > \rho$. Let $\ell = C\log_\rho n$ with $0 < C < C_{coupling}$. For $e \in \vec{E}(V)$, we define the event $\mathcal{E}(e)$ that for all $0 \le t < \ell$ and $k \in \{1, 2\}$: $|\langle g_k, \Psi_t(e)\rangle - \mu_k^{t-\ell}\langle g_k, \Psi_\ell(e)\rangle| \le (\log n)^3 \rho^{t/2}$. Then, with high probability, the number of edges $e \in \vec{E}$ such that $\mathcal{E}(e)$ does not hold is at most $\log(n)\ n^{1-(\frac{\gamma}{2} \wedge \frac{1}{40})}$.*

▶ **Lemma 18** (Degree-Corrected Extension of Lemma 29 in [2]). *There exist $c, c' > 0$ such that for all $s \ge 0$ and for any $w \in [n] \cup \vec{E}(V)$,*

$$\mathbb{P}\left(\forall t \ge 0 : S_t(w) \le s\vec{\rho}_n^t\right) \ge 1 - ce^{-c's}.$$

Consequently, for any $p \ge 1$, there exists $c'' > 0$ such that

$$\mathbb{E}\left[\max_{v \in [n], t \ge 0} \left(\frac{S_t(v)}{\vec{\rho}_n^t}\right)^p\right] \le c''(\log n)^p.$$

▶ **Lemma 19** (Degree-Corrected Extension of Lemma 30 in [2]). *Let $\ell = C\log_\rho(n)$, with $0 < C < C_{coupling}$. Then, w.h.p., at most $\rho^{2\ell}\log(n)$ vertices have a cycle in their ℓ - neighbourhood. Further, w.h.p., the graph is ℓ - tangle-free.*

6.2 Geometric growth

Here we show that for $k \in \{1, 2\}$, $\langle B^\ell \chi_k, \delta_e\rangle$ grows nearly geometrically in t with rate μ_k. Corollary 21 then establishes a bound for $r \le \ell$ on $\sup_{\langle B^\ell\chi_k, x\rangle = 0, \|x\|=1} \|\langle B^r\chi_k, x\rangle\|$ crucial for the norm bounds in Section 9.

▶ **Proposition 20** (Degree-Corrected Extension of Proposition 33 in [2]). *Assume $\mu_2^2 > \rho$. Let $\ell = C\log_\rho(n)$, with $0 < C < C_{coupling} \wedge \left(\frac{1}{2} - \left(\frac{\gamma}{4} \wedge \frac{1}{80}\right)\right) = C_{coupling}$. For $e \in \vec{E}(V)$, let $\vec{E}_\ell$ be the set of oriented edges such that either $(G, e_2)_\ell$ is not a tree or the event $\mathcal{E}(e)$ (defined in Corollary 17) does not hold. Then, w.h.p. for $k \in \{1, 2\}$:*

(i) $|\vec{E}_\ell| \ll (\log n)^2 n^{1-\frac{\gamma}{2} \wedge \frac{1}{40}}$,

(ii) *for all $e \in \vec{E} \setminus \vec{E}_\ell$, $0 \le r \le \ell$,*

$$|\langle B^r\chi_k, \delta_e\rangle - \mu_k^{r-\ell}\langle B^\ell\chi_k, \delta_e\rangle| \le (\log n)^4 \rho^{r/2},$$

(iii) *for all $e \in \vec{E}_\ell$, $0 \le r \le \ell$,*

$$|\langle B^r\chi_k, \delta_e\rangle| \le (\log n)^2 \rho^r.$$

▶ **Corollary 21** (Degree-Corrected Extension of Corollary 34 in [2]). *Let $\ell = C\log_\rho(n)$, with $0 < C < C_{coupling} \wedge \left(1 - \frac{\gamma}{2} \wedge \frac{1}{40}\right) \wedge \left(\frac{\gamma}{4} \wedge \frac{1}{80}\right) = C_{coupling}$. W.h.p. for any $0 \le r \le \ell - 1$ and $k \in \{1, 2\}$:*

$$\sup_{\langle B^\ell\chi_k, x\rangle = 0, \|x\|=1} \|\langle B^r\chi_k, x\rangle\| \le (\log n)^5 n^{1/2} \rho^{r/2}.$$

7 A weak law of large numbers for local functionals on the DC-SBM

The proofs of the statements in this section can be found in Appendix C in the detailed version of the underlying article (Arxiv:1609.02487).

Here we show that a weak law of large numbers applies for local functionals defined on *weighted coloured* random graphs generated according to the DC-SBM.

By a *weighted coloured* graph we mean a graph $G = (V, E)$ together with maps $\sigma : V \to \{+, -\}$ and $\phi : V \to [\phi_{\min}, \phi_{\max}]$. For $v \in V$, we identify $\sigma(v)$ as the spin of v and $\phi(v)$ as its weight. We denote by $\mathcal{G}^*$ the set of *rooted weighted coloured* graphs. We denote an element of $\mathcal{G}^*$ by (G, o): $G = (V, E)$ is then a weighted coloured graph and $o \in V$ is some distinguished vertex. A function $\tau : \mathcal{G}^* \to \mathbb{R}$ is said to be $\ell-$ local if $\tau(G, o)$ depends only on $(G, o)_\ell$.

To derive the claimed weak law when G is drawn according to the DC-SBM, we prepare with a variance bound for $\sum_{v=1}^n \tau(G, v)$, see Proposition 22. The bound follows from the law of total variance,

$$\begin{aligned}\operatorname{Var}\left(\sum_{v=1}^n \tau(G,v)\right) &= \mathbb{E}\left[\operatorname{Var}\left(\sum_{v=1}^n \tau(G,v)\middle|\, \phi_1,\dots,\phi_n\right)\right] \\ &\quad + \operatorname{Var}\left(\mathbb{E}\left[\sum_{v=1}^n \tau(G,v)\middle|\, \phi_1,\dots,\phi_n\right]\right),\end{aligned}$$

together with an application of Efron-Stein's inequality to both terms on the right. Note that $\mathbb{E}\left[\sum_{v=1}^n \tau(G, v)|\, \phi_1, \dots, \phi_n\right]$ is a constant in the *ordinary* SBM, whereas here it needs a careful analysis.

The sample average $\frac{1}{n}\sum_{v=1}^n \tau(G, v)$ concentrates then around $\mathbb{E}[\tau(T, o)]$, where (T, o) is the branching process from Section 5, with root o having spin drawn uniformly from $\{+, -\}$ and weight governed by ν, see Proposition 23. The coupling, and in particular the matching of the weights, plays an important role in its proof.

In the next section we apply the latter proposition to some specific functionals.

▶ **Proposition 22** (Degree-Corrected Extension of Proposition 35 in [2]). *Let G be drawn according to the DC-SBM. There exists $c > 0$ such that if $\tau, \varphi : \mathcal{G}^* \to \mathbb{R}$ are ℓ-local, $|\tau(G, o)| \le \varphi(G, o)$ and φ is non-decreasing by the addition of edges, then*

$$\operatorname{Var}\left(\sum_{v=1}^n \tau(G,v)\right) \le cn\rho^{2\ell}\left(\mathbb{E}\left[\max_{v\in[n]} \varphi^4(G,v)\right]\right)^{1/2}.$$

▶ **Proposition 23** (Degree-Corrected Extension of Proposition 36 in [2]). *Let G be drawn according to the DC-SBM. Let (T, o) be the branching process from Section 5, with root o having spin drawn uniformly from $\{+, -\}$ and weight governed by ν. Let $\ell = C\log_\rho(n)$, with $C < C_{coupling}$. There exists $c > 0$ such that if $\tau, \varphi : \mathcal{G}^* \to \mathbb{R}$ are ℓ-local, $|\tau(G, o)| \le \varphi(G, o)$ and φ is non-decreasing by the addition of edges, then*

$$\begin{aligned}&\mathbb{E}\left[\left|\frac{1}{n}\sum_{v=1}^n \tau(G,v) - \mathbb{E}[\tau(T,o)]\right|\right] \\ &\le c_2 n^{-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}\left(\mathbb{E}\left[\max_{v\in[n]}\varphi^4(G,v)\right]^{1/4} \vee \mathbb{E}\left[\varphi^2(T,o)\right]^{1/2}\right) + \mathcal{O}(n^{-\gamma})\end{aligned} \tag{31}$$

7.1 Application with some specific local functionals

Here we consider $\langle B^\ell\chi_1, B^\ell\chi_2\rangle$, $\langle B^{2\ell}\chi_k, B^\ell\chi_j\rangle$, and $\langle B^\ell B^{*\ell}\chi_1, B^\ell B^{*\ell}\chi_2\rangle$, quantities occurring in Proposition 4.

Explicitly, $B^\ell \chi_k(e) = \sum_f B^\ell_{ef} g_k(\sigma(f_2))\phi_{f_2}$, where we recall that B^ℓ_{ef} is the number of non-backtracking walks from e to f. Now, if the oriented $\ell-$ neighbourhood of e is a *tree*, then $B^\ell \chi_k(e) = \langle g_k, \Psi_\ell(e)\rangle$. With this intuition in mind, we analyse likewise expressions in Proposition 24 below.

Inspired by (26), which expresses $B^\ell B^{*\ell}\chi_k$ on *trees* in terms of the operator $Q_{k,\ell}$, we extend the latter to an operator defined on general graphs. First, for $e \in \vec{E}(V)$ and $t \geq 0$, set $\mathcal{Y}_t(e) = \{f \in \vec{E} : \vec{d}(e,f) = t\}$. Then, for $k \in \{1,2\}$, we set

$$P_{k,\ell}(e) = \sum_{t=0}^{\ell-1} \sum_{f \in \mathcal{Y}_t(e)} L_k(f), \tag{32}$$

with

$$L_k(f) = \sum_{(g,h)\in \mathcal{Y}_1(f)\setminus \mathcal{Y}_t(e); g\neq h} \langle g_k, \tilde{\Psi}_t(g)\rangle \tilde{S}_{\ell-t-1}(h),$$

where $\tilde{\Psi}_t(g)$, $\tilde{S}_{\ell-t-1}(h) = \|\tilde{Y}_{\ell-t-1}(h)\|_1$ are the variables $\Psi_t(g)$, respectively $S_{\ell-t-1}(h)$, defined on the graph G where all edges in $(G,e_2)_t$ have been removed. Note that, if $(G,e)_{2\ell}$ is a tree, then $\tilde{\Psi}_s(g) = \Psi_s(g)$ for $s \leq 2\ell - t$. Compare $P_{k,\ell}$ to $Q_{k,\ell}$ in (23) and $L_k(f)$ to $L^u_{k,\ell}$ in (28).

Finally, define

$$S_{k,\ell}(e) = S_\ell(e) g_k(\sigma(e_1))\phi_{e_1}. \tag{33}$$

We then have an extension of (26), when $(G,e_2)_{2\ell}$ is a tree:

$$B^\ell B^{*\ell}\check{\chi}_k(e) = P_{k,\ell}(e) + S_{k,\ell}(e). \tag{34}$$

We analyse (34) in Proposition 25 below.

7.1.1 The case $\mu_2^2 > \rho$

▶ **Proposition 24** (Degree-Corrected Extension of Proposition 37 in [2]). *Assume that $\mu_2^2 > \rho$. Let $\ell = C\log_\rho n$ with $0 < C < C_{coupling}$.*

(i) *For any $k \in \{1,2\}$, there exists $c'_k > 0$ such that, in probability,*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{\langle g_k, \Psi_\ell(e)\rangle^2}{\mu_k^{2\ell}} \to c'_k.$$

(ii) *For any $k \in \{1,2\}$, there exists $c''_k > 0$ such that, in probability,*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{\langle g_k, Y_\ell(e)\rangle^2}{\mu_k^{2\ell}} \to c''_k.$$

(iii)

$$\mathbb{E}\left[\left|\frac{1}{n}\sum_{e\in\vec{E}} \langle g_1, \Psi_\ell(e)\rangle\langle g_2, \Psi_\ell(e)\rangle\right|\right] \leq (\log n)^3 n^{2C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)} + n^{-\gamma}.$$

(iv) *For any $k \neq j \in \{1,2\}$,*

$$\mathbb{E}\left[\left|\frac{1}{n}\sum_{e\in\vec{E}} \langle g_k, \Psi_{2\ell}(e)\rangle\langle g_j, \Psi_\ell(e)\rangle\right|\right] \leq (\log n)^3 n^{3C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)} + n^{-\gamma}.$$

(v) *For any $k \in \{1,2\}$, in probability*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{\langle g_k, \Psi_{2\ell}(e)\rangle\langle g_k, \Psi_\ell(e)\rangle}{\mu_k^{3\ell}} \to c_k'''.$$

▶ **Proposition 25** (Degree-Corrected Extension of Proposition 38 in [2]). *Assume that $\mu_2^2 > \rho$. Let $\ell = C\log_\rho n$ with $C < C_{coupling}$.*

(i) *For any $k \in \{1,2\}$, there exists $c_k'''' > 0$ such that in probability*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{P_{k,\ell}^2(e)}{\mu_k^{4\ell}} \to c_k''''.$$

(ii)

$$\mathbb{E}\left[\left|\frac{1}{n}\sum_{e\in\vec{E}}(P_{1,\ell}(e)+S_{1,\ell}(e))(P_{2,\ell}(e)+S_{2,\ell}(e))\right|\right] \le (\log n)^8 n^{4C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$$

7.1.2 The case $\mu_2^2 \le \rho$

Most of the above claims continue to hold if $\mu_2^2 \le \rho$. We treat the exceptions here.

▶ **Proposition 26.** *Assume that $\mu_2^2 \le \rho$. Let $\ell = C\log_\rho n$ with $0 < C < C_{coupling}$. There exists some $c > 0$, such that w.h.p.,*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{\langle g_2, \Psi_\ell(e)\rangle^2}{\rho^\ell} \ge c.$$

▶ **Proposition 27.** *Assume that $\mu_2^2 \le \rho$. Let $\ell = C\log_\rho n$ with $C < C_{coupling}$. There exists $c > 0$ such that w.h.p.,*

$$\frac{1}{n}\sum_{e\in\vec{E}} \frac{P_{2,\ell}^2(e)}{\rho^{2\ell}\log^5(n)} \le c.$$

8 Proof op Propositions 4 and 6

We introduce for $k \in \{1,2\}$ the vector $N_{k,\ell}$, defined on $e \in \vec{E}$ as

$$N_{k,\ell}(e) = \langle g_k, \Psi_\ell(e)\rangle.$$

If $(G, e_2)_\ell$ is a tree, then

$$N_{k,\ell}(e) = \langle B^\ell \chi_k, \delta_e\rangle,$$

and we have a similar expression for $B^\ell B^{*\ell}\check{\chi}_k$ in (34). Now, at most $\rho^{2\ell}\log(n)$ vertices have a cycle in their ℓ-neighbourhood (see Lemma 19). Therefore:

▶ **Lemma 28** (Degree-Corrected Extension of Lemma 39 in [2]). *Let $\ell = C\log_\rho n$ with $0 < C < C_{min}$. Then, w.h.p. $\|B^\ell\chi_k - N_{k,\ell}\| = O\left((\log n)^{5/2}\rho^{2\ell}\right) = o\left(\rho^{\ell/2}\sqrt{n}\right)$, $\|B^\ell B^{*\ell}\check{\chi}_k - P_{k,\ell} - S_{k,\ell}\| = O((\log n)^4\rho^{4\ell})$ and $\|B^\ell B^{*\ell}\check{\chi}_k - P_{k,\ell}\| = O(\rho^\ell\sqrt{n})$.*

Proof. The proof of Lemma 39 in [2] can be easily adapted to the current setting. The key idea is pointed out above. It thus remains to bound $|(B^\ell \chi_k - N_{k,\ell})(e)|$ and $|(B^\ell B^{*\ell}\check{\chi}_k - P_{k,\ell})(e)|$ on edges e for which $(G, e_2)_\ell$ is not a tree. For this, use that with high probability the graph is 2ℓ-tangle free so that there are at most two non-backtracking paths between e and any edge at distance ℓ. ◀

We can thus in our calculations replace $B^\ell \chi_k$ by $N_{k,\ell}$ and $B^\ell B^{*\ell}\check{\chi}_k$ by $P_{k,\ell}$. From Propositions 24 and 25, Proposition 4 then follows:

Proof of Proposition 4. This proof follows the corresponding proof in [2]. We give the key observations: (i) From Proposition 24 (i), $\|N_{k,\ell}\| \sim \sqrt{n}\mu_k^\ell$ and from Proposition 25 (i), $\|P_{k,\ell}\| \sim \sqrt{n}\mu_k^{2\ell}$.

(ii) From Proposition 24 (v), $|\langle N_{k,\ell}, N_{k,2\ell}\rangle| \sim n\mu_k^{3\ell}$.

(iii) From Proposition 24 (iii), $|\langle N_{1,\ell}, N_{2,\ell}\rangle| \sim (\log n)^3 n^{3C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$.

(iv) From Proposition 24 (iv), $|\langle N_{k,2\ell}, N_{j,\ell}\rangle| \sim (\log n)^3 n^{4C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$.

(v) From Proposition 25 (ii), $|\langle P_{1,\ell} + S_{1,\ell}, P_{2,\ell} + S_{2,\ell}\rangle| \sim (\log n)^8 n^{5C-\left(\frac{\gamma}{2}\wedge\frac{1}{40}\right)}$. ◀

Proposition 6 follows similarly from the case $\mu_2^2 \le \rho$ treated in Section 7.1:

Proof of Proposition 6. This follows from Propositions 26 and 27 in conjunction with Lemma 28. ◀

9 Norm of non-backtracking matrices

The proofs of the statements in this section can be found in Appendix D in the detailed version of the underlying article (Arxiv:1609.02487).

In this section the product over an empty set is defined to be one.

It is convenient to extend matrix B and vector χ_k to the set of directed edges on the *complete* graph, $\vec{E}_K(V) = \{(u,v) : u \neq v \in V\}$: For $e, f \in \vec{E}_K(V)$, B_{ef} is then extended to

$$B_{ef} = A_e A_f 1_{e_2=f_1} 1_{e_1 \neq f_2}, \tag{35}$$

where A is the adjacency matrix. For each $e \in \vec{E}_K(V)$ we set $\chi_k(e) = g_k(\sigma(e_2))\phi_{e_2}$.

For integer $k \ge 1$, $e, f \in \vec{E}_K(V)$, we let Γ_{ef}^k be the set of non-backtracking walks $\gamma = (\gamma_0, \dots, \gamma_k)$ of length k from $(\gamma_0, \gamma_1) = e$ to $(\gamma_{k-1}, \gamma_k) = f$ on the *complete* graph with vertex set V.

By induction it follows that

$$(B^k)_{ef} = \sum_{\gamma \in \Gamma_{ef}^{k+1}} \prod_{s=0}^{k} A_{\gamma_s \gamma_{s+1}}. \tag{36}$$

Indeed, note that $\prod_{s=0}^k A_{\gamma_s\gamma_{s+1}}$ is one when γ is a path in G and zero otherwise.

To each walk $\gamma = (\gamma_0, \dots, \gamma_k)$, we associate the graph $G(\gamma) = (V(\gamma), E(\gamma))$, with the set of vertices $V(\gamma) = \{\gamma_i, 0 \le i \le k\}$ and the set of edges $E(\gamma) = \{\{\gamma_i, \gamma_{i+1}\}, 0 \le i \le k-1\}$.

From Lemma 19, the graphs following the DC-SBM are tangle-free with high probability. Hence, it makes sense to consider the subset $F_{ef}^{k+1} \subset \Gamma_{ef}^{k+1}$ of tangle-free non-backtracking walks on the *complete* graph. Indeed, if G is tangle-free, we need only consider the tangle-free paths in the summation (36):

$$(B^{(k)})_{ef} = \sum_{\gamma \in F_{ef}^{k+1}} \prod_{s=0}^{k} A_{\gamma_s \gamma_{s+1}}, \tag{37}$$

and $B^k = B^{(k)}$ for $1 \leq k \leq \ell$.

Define for $u \neq v$ the *centred* random variable

$$\underline{A}_{uv} = A_{uv} - \frac{\phi_u \phi_v}{n} W_{\sigma_u \sigma_v}, \tag{38}$$

where

$$W = \begin{pmatrix} a & b \\ b & a \end{pmatrix}.$$

Compare this to the SBM *without* degree-corrections in Section 10.1 **of [2]:** $\phi_u = 1$ **for all** u **in the latter model.**

Using $\underline{A}$ we shall attempt to center B^k when the underlying graph G is tangle-free through considering

$$\Delta_{ef}^{(k)} = \sum_{\gamma \in F_{ef}^{k+1}} \prod_{s=0}^{k} \underline{A}_{\gamma_s \gamma_{s+1}}. \tag{39}$$

Further, we set

$$\Delta_{ef}^{(0)} = 1_{e=f} \underline{A}_e \quad \text{and} \quad B_{ef}^{(0)} = 1_{e=f} A_e. \tag{40}$$

To decompose (37), following a decomposition that appeared first in [16], we use

$$\prod_{s=0}^{\ell} x_s = \prod_{s=0}^{\ell} y_s + \sum_{t=0}^{\ell} \prod_{s=0}^{t-1} y_s (x_t - y_t) \prod_{s=t+1}^{\ell} x_s,$$

with $x_s = A_{\gamma_s \gamma_{s+1}}$ and $y_s = \underline{A}_{\gamma_s \gamma_{s+1}}$ on a path $\gamma \in F_{ef}^{k+1}$:

$$\prod_{s=0}^{\ell} A_{\gamma_s \gamma_{s+1}} = \prod_{s=0}^{\ell} \underline{A}_{\gamma_s \gamma_{s+1}} + \sum_{t=0}^{\ell} \prod_{s=0}^{t-1} \underline{A}_{\gamma_s \gamma_{s+1}} \left(\frac{\phi_{\gamma_t} \phi_{\gamma_{t+1}}}{n} W_{\sigma_{\gamma_t} \sigma_{\gamma_{t+1}}} \right) \prod_{s=t+1}^{\ell} A_{\gamma_s \gamma_{s+1}}.$$

Summing over all $\gamma \in F_{ef}^{\ell+1}$ then gives

$$\begin{aligned} B_{ef}^{(\ell)} &= \sum_{\gamma \in F_{ef}^{\ell+1}} \prod_{s=0}^{\ell} \underline{A}_{\gamma_s \gamma_{s+1}} \\ &\quad + \sum_{t=0}^{\ell} \sum_{\gamma \in F_{ef}^{\ell+1}} \prod_{s=0}^{t-1} \underline{A}_{\gamma_s \gamma_{s+1}} \left(\frac{\phi_{\gamma_t} \phi_{\gamma_{t+1}}}{n} W_{\sigma_{\gamma_t} \sigma_{\gamma_{t+1}}} \right) \prod_{s=t+1}^{\ell} A_{\gamma_s \gamma_{s+1}} \\ &= \Delta_{ef}^{(\ell)} + \sum_{t=0}^{\ell} \sum_{\gamma \in F_{ef}^{\ell+1}} \prod_{s=0}^{t-1} \underline{A}_{\gamma_s \gamma_{s+1}} \left(\frac{\phi_{\gamma_t} \phi_{\gamma_{t+1}}}{n} W_{\sigma_{\gamma_t} \sigma_{\gamma_{t+1}}} \right) \prod_{s=t+1}^{\ell} A_{\gamma_s \gamma_{s+1}}. \end{aligned} \tag{41}$$

Consider the two products in the summation over $F_{ef}^{\ell+1}$ on the right of (41): We can, for $1 \leq t \leq \ell - 1$, replace the summation over $F_{ef}^{\ell+1}$ by summing over all pairs $\gamma' = (\gamma_0, \ldots, \gamma_t) \in F_{eg}^{t}$ and $\gamma'' = (\gamma_{t+1}, \ldots, \gamma_{\ell+1}) \in F_{g'f}^{\ell-t}$ for some $g, g' \in \vec{E}(V)$ such that there exists a non-backtracking path with one intermediate edge, on the *complete* graph, between oriented edges g and g' (we denote this property by $g \xrightarrow{2} g'$). However caution is needed, as this summation also includes *tangled* paths, namely those in the sets $\{F_{t,ef}^{\ell+1}\}_{t=0}^{\ell}$. Where, for $1 \leq t \leq \ell - 1$,

$F^{\ell+1}_{t,ef}$ is defined as the collection of all *tangled* paths $\gamma = (\gamma_0, \dots, \gamma_{\ell+1}) = (\gamma', \gamma'') \in \Gamma^{\ell+1}_{ef}$ with γ' and γ'' as above. For $t = 0$, $F^{\ell+1}_{0,ef}$ consists of all non-backtracking *tangled* paths (γ', γ'') with $\gamma' = (e_1)$ and $\gamma'' \in F^{\ell}_{g'f}$ for any g' such that $g'_1 = e_2$. For $t = \ell$, $F^{\ell+1}_{\ell,ef}$ is the set of non-backtracking *tangled* paths (γ', γ'') such that $\gamma'' = (f_2)$ and $\gamma' \in F^{\ell}_{eg}$ for some $g \in \vec{E}(V)$ with $g_2 = f_1$. We rewrite (41) as

$$B^{(\ell)} = \Delta^{(\ell)} + \frac{1}{n} K B^{(\ell-1)} + \frac{1}{n} \sum_{t=1}^{\ell-1} \Delta^{(t-1)} K^{(2)} B^{(\ell-t-1)} + \frac{1}{n} \Delta^{(\ell-1)} \widehat{K} - \frac{1}{n} \sum_{t=0}^{\ell} R^{(\ell)}_t, \tag{42}$$

where for $e, f \in E_K$,

$$K_{ef} = 1_{e \to f} \phi_{e_1} \phi_{e_2} W_{\sigma(e_1)\sigma(e_2)}, \tag{43}$$

the *weighted* non-backtracking matrix on the *complete* graph (recall that $e \to f$ represents the non-backtracking property),

$$\widehat{K}_{ef} = 1_{e \to f} \phi_{f_1} \phi_{f_2} W_{\sigma(f_1)\sigma(f_2)}, \tag{44}$$

$$K^{(2)}_{ef} = 1_{e \overset{2}{\to} f} \phi_{e_2} \phi_{f_1} W_{\sigma(e_2)\sigma(f_1)}, \tag{45}$$

and where

$$(R^{(\ell)}_t)_{ef} = \sum_{\gamma \in F^{\ell+1}_{t,ef}} \prod_{s=0}^{t-1} \underline{A}_{\gamma_s \gamma_{s+1}} \phi_{\gamma_t} \phi_{\gamma_{t+1}} W_{\sigma(\gamma_t)\sigma(\gamma_{t+1})} \prod_{s=t+1}^{\ell} A_{\gamma_s \gamma_{s+1}}. \tag{46}$$

Indeed,

$$\begin{aligned} \left(\sum_{t=1}^{\ell-1} \Delta^{(t-1)} K^{(2)} B^{(\ell-t-1)} \right)_{ef} &= \sum_{t=1}^{\ell-1} \sum_{g,g'} \Delta^{(t-1)}_{eg} K^{(2)}_{gg'} B^{(\ell-t-1)}_{g'f} \\ &= \sum_{t=1}^{\ell-1} \sum_{g,g'} \sum_{\gamma' \in F^{t}_{eg}} \sum_{\gamma'' \in F^{\ell-t}_{g'f}} \prod_{s=0}^{t-1} \underline{A}_{\gamma'_s \gamma'_{s+1}} 1_{g \overset{2}{\to} g'} \phi_{\gamma'_t} \phi_{\gamma''_0} \\ &\quad \cdot W_{\sigma(\gamma'_t)\sigma(\gamma''_0)} \prod_{s=0}^{\ell-t-1} A_{\gamma''_s \gamma''_{s+1}}, \end{aligned} \tag{47}$$

$$\left(K B^{(\ell-1)} \right)_{ef} = \sum_{g} \sum_{\gamma'' \in F^{\ell}_{gf}} 1_{e \to g} \phi_{e_1} \phi_{e_2} W_{\sigma(e_1)\sigma(e_2)} A_{e_2, g_2} \prod_{s=1}^{\ell-2} A_{\gamma''_s \gamma''_{s+1}} A_{f_1 f_2}, \tag{48}$$

and,

$$\left(\Delta^{(\ell-1)} \widehat{K} \right)_{ef} = \sum_{g} \sum_{\gamma' \in F^{\ell}_{eg}} \underline{A}_{e_1 e_2} \prod_{s=1}^{\ell-2} \underline{A}_{\gamma'_s \gamma'_{s+1}} \underline{A}_{g_1 f_1} 1_{g \to f} \phi_{f_1} \phi_{f_2} W_{\sigma(f_1)\sigma(f_2)} \tag{49}$$

that is exactly the splitting described just below (41), where we also pointed out the need to compensate for *tangled* paths occuring in (47), which is precisely the role of $R^{(\ell)}_t$ in (42).

To bound (42), we introduce

$$\overline{W} = \frac{2}{\Phi^{(2)}} \left(\rho \chi_1 \check{\chi}_1^* + \mu_2 \chi_2 \check{\chi}_2^*\right) = \left(\phi_{e_2} \phi_{f_1} W_{\sigma(e_2)\sigma(f_1)}\right)_{ef}, \tag{50}$$

and,

$$L = K^{(2)} - \overline{W}. \tag{51}$$

Note the presence of weights in (50), hence our choice for the candidate eigenvectors.

Further, we set for $1 \leq t \leq \ell - 1$,

$$S_t^{(\ell)} = \Delta^{(t-1)} L B^{(\ell-t-1)}. \tag{52}$$

We then have:

▶ **Proposition 29** (Degree-Corrected Extension of Proposition 13 in [2]). *If G is tangle-free and $x \in \mathbb{C}^{\vec{E}(V)}$ with norm smaller than one, we have*

$$\|B^\ell x\| \leq \|\Delta^{(\ell)}\| + \frac{1}{n}\|KB^{(\ell-1)}\| + \frac{1}{n}\sum_{j=1,2}\frac{2\mu_j}{\Phi^{(2)}}\sum_{t=1}^{\ell-1}\|\Delta^{(t-1)}\chi_j\|\|\langle \check{\chi}_j, B^{\ell-t-1}x\rangle\|$$
$$+ \frac{1}{n}\sum_{t=1}^{\ell-1}\|S_t^{(\ell)}\| + \phi_{max}^2(a\vee b)\|\Delta^{(\ell-1)}\| + \frac{1}{n}\sum_{t=0}^{\ell}\|R_t^{(\ell)}\|.$$

Proof. Due to the tangle-freeness, $B^\ell = B^{(\ell)}$. Further $K^{(2)} = L + \overline{W}$ and $||K|| \leq \phi_{\max}^2(a \vee b)n$. ◀

In Appendix D in the detailed version of the underlying article (Arxiv:1609.02487) we prove the following bounds on the matrices in Proposition 29:

▶ **Proposition 30** (Degree-Corrected Extension of Proposition 14 in [2]). *Let $\ell = C\log_\rho n$ with $C < 1$. With high probability, the following norm bounds hold for all k, $0 \leq k \leq \ell$, and $i = 1, 2$:*

$$\|\Delta^{(k)}\| \leq (\log n)^{10}\rho^{k/2}, \tag{53}$$
$$\|\Delta^{(k)}\chi_i\| \leq (\log n)^5\rho^{k/2}\sqrt{n}, \tag{54}$$
$$\|R_k^{(\ell)}\| \leq (\log n)^{25}\rho^{\ell-k/2}, \tag{55}$$
$$\|KB^{(k)}\| \leq \sqrt{n}(\log n)^{10}\rho^k, \tag{56}$$

and the following bound holds for all k, $1 \leq k \leq \ell - 1$:

$$\|S_k^{(\ell)}\| \leq \sqrt{n}(\log n)^{20}\rho^{\ell-k/2}. \tag{57}$$

9.1 Proof of Proposition 5

From Propositions 29 and 30, the geometric growth in Corollary 21 together with the tangle-freeness due to Lemma 19, the proof of Proposition 5 follows:

Let $j \in \{1, 2\}$. If, for some vector x, $\langle \check{\varphi}_j, x\rangle = 0$, then $\langle B^\ell \chi_j, \check{x}\rangle = 0$. Therefore, using Corollary 21,

$$\begin{aligned}\sup_{\|x\|=1, \langle \check{\varphi}_j, x\rangle = 0} \langle \check{\chi}_j, B^{\ell-t-1}x\rangle &= \sup_{\|x\|=1, \langle B^\ell\chi_j, \check{x}\rangle = 0} \langle B^{\ell-t-1}\chi_j, \check{x}\rangle \\ &= \sup_{\|\check{x}\|=1, \langle B^\ell\chi_j, \check{x}\rangle = 0} \langle B^{\ell-t-1}\chi_j, \check{x}\rangle \\ &\leq \log^2(n) n^{1/2}\rho^{\frac{\ell-t-1}{2}}.\end{aligned} \tag{58}$$

With high probability, the graph is $\ell-$ tangle free (Lemma 19). Thus, invoking Propositions 29 and 30, with high probability,

$$\begin{aligned}\sup_{x\in H^{\perp},\|x\|=1}\|B^{\ell}x\| &\leq \log^{10}(n)\rho^{\frac{\ell}{2}}+n^{-1/2}\log^{10}(n)\rho^{\ell-1}\\ &\quad+c_1\log^{8}(n)\rho^{\frac{\ell}{2}}+n^{-1/2}\log^{21}(n)\rho^{\ell}\\ &\quad+c_2\log^{10}(n)\rho^{\frac{\ell}{2}}+n^{-1}\log^{26}(n)\rho^{\ell}\\ &\leq \log^{c}(n)\rho^{\frac{\ell}{2}},\end{aligned} \tag{59}$$

since $C<1$.

9.2 Comparison with the Stochastic Block Model in [2]

Putting $\phi_u=1$ for all u, we retrieve exactly **the same bounds as in the Stochastic Block Model**, that is equations $(30)-(34)$ in [2].

Below we use the trace method and therefore path counting combinatorial arguments to establish Proposition 30. In particular, we bound the expectation of expressions of the form

$$\mathbb{E}\left[\prod_{i=1}^{2m}\prod_{s=1}^{k}\underline{A}_{\gamma_{i,s-1}\gamma_{i,s}}\right], \tag{60}$$

for certain paths $\gamma=(\gamma_1,\ldots,\gamma_{2m})$ with $\gamma_i=(\gamma_{i,0},\cdots,\gamma_{i,k})\in V^{k+1}$, where $\underline{A}$ is defined in (38).

In bounding (60) the following term occurs:

$$\prod_{u\in V(\gamma)}\Phi^{(d_u)},$$

where $(d_u)_u$ are the degrees of the vertices in a specific tree (or forest) spanning the path γ. See, for instance, (D.4) and (D.17) in the detailed version of the underlying article (Arxiv:1609.02487). Here lies a major complication with respect to the Stochastic Block Model: those terms are not present in the latter model. In (D.8) and (D.19) in the detailed version of the underlying article, we find

$$\prod_{u=1}^{|V(\gamma)|}\Phi^{(d_u)}\leq C_2^{\sum_{u:d_u>2}(d_u-2)}\left(\Phi^{(2)}\right)^{|V(\gamma)|-n_{\mathcal{C}}},$$

where $C_2>1$ is some constant and where $n_{\mathcal{C}}\geq 1$ is the number of components on the path γ. To compare this term with powers of $\Phi^{(2)}$ (which are present in powers of $\rho=\frac{a+b}{2}\Phi^{(2)}$), we bound $\sum_{u:d_u>2}(d_u-2)$, see in particular Lemma (D.2) and (D.5) in the detailed version of the underlying article.

10 Detection: Proof of Theorem 2

The proofs of the statements in this section are deferred to Appendix E in the detailed version of the underlying article (Arxiv:1609.02487).

We need the following special case of a lemma in [2]:

▶ **Lemma 31** (Special case of Lemma 40 in [2]). *Assume that there exists a function $F : V \to \{0,1\}$ such that in probability, for any $i \in \{+,-\}$,*

$$\lim_{n\to\infty} \frac{1}{n} \sum_{v=1}^{n} 1_{\sigma(v)=i} F(v) = \frac{f(i)}{2},$$

where $f : \{+,-\} \to [0,1]$ is such that $f(+) > f(-)$. Then, assigning to each vertex a label $\widehat{\sigma}(v) = +$ if $F(v) = 1$ and $\widehat{\sigma}(v) = -$ if $F(v) = 0$, yields asymptotically positive overlap with the true spins.

Recall the eigenvector ξ_2 from Theorem 1. Below we use the function $F : v \mapsto 1_{\sum_{e:e_2=v} \xi_2(e) > \frac{\tau}{\sqrt{n}}}$ or $F : v \mapsto 1_{\sum_{e:e_2=v} \xi_2(e) \leq \frac{\tau}{\sqrt{n}}}$ for some fixed parameter τ. We verify also that ξ_2 is aligned with $P_{2,\ell}$. It is therefore useful to introduce the vector I_ℓ, defined element-wise by

$$I_\ell(v) = \sum_{e \in \vec{E} : e_2 = v} P_{2,\ell}(e), \tag{61}$$

for $v \in V$.

Further, put

$$\widehat{c} = \frac{a+b}{2} \frac{(\Phi^{(1)})^2 \Phi^{(3)}}{\Phi^{(2)}} \frac{\rho}{\mu_2^2 - \rho} \mu_2$$

The following lemma shows that I_ℓ is correlated with the spins:

▶ **Lemma 32** (Degree-Corrected Extension of Lemma 41 in [2]). *Let $\ell = C \log_\rho n$ with $C < C_{coupling}$ and $i \in \{+,-\}$. There exists a random variable Y_i such that $\mathbb{E}[Y_i] = 0$, $\mathbb{E}[|Y_i|] < \infty$ and for any continuity point t of the distribution of Y_i, in L^2,*

$$\frac{1}{n} \sum_{v=1}^{n} 1_{\sigma(v)=i} 1_{I_\ell(v)\mu_2^{-2\ell} - \widehat{c} g_2(i) \geq t} \to \frac{1}{2} \mathbb{P}(Y_i \geq t).$$

Recall from Theorem 1 that the eigenvector ξ_2 is asymptotically *aligned* with

$$\frac{B^\ell B^{*\ell} \check{\chi}_2}{\|B^\ell B^{*\ell} \check{\chi}_2\|}, \tag{62}$$

where $\ell \sim \log_\rho(n)$. Hence, for some unknown sign ω, the vector $\xi_2' = \omega \xi_2$ is asymptotically *close* to (62). From Lemma 28 we know that $B^\ell B^{*\ell} \check{\chi}_2$ and $P_{2,\ell}$ are asymptotically close. Consequently, properly renormalizing ξ_2' will make it asymptotically close to $P_{2,\ell}$, so that we can replace $P_{2,\ell}$ in (61) by ξ_2'. That is, we set for $v \in V$,

$$I(v) = \sum_{e:e_2=v} s\sqrt{n} \xi_2'(e),$$

with $s = \sqrt{c_2'''}$ the limit in Proposition 25. Then, I and $I_\ell/\mu_2^{2\ell}$ are close, which leads to the following lemma:

▶ **Lemma 33** (Degree-Corrected Extension of Lemma 42 in [2]). *Let $i \in \{+,-\}$ and $\widehat{Y}_i$ be as in Lemma 32. For any continuity point t of the distribution of $\widehat{Y}_i$, in L^2,*

$$\frac{1}{n} \sum_{v=1}^{n} 1_{\sigma(v)=i} 1_{I(v) - \widehat{c} g_2(i) \geq t} \to \frac{1}{2} \mathbb{P}\left(\widehat{Y}_i \geq t\right).$$

Put for $i \in \{+,-\}$, $X_i = \widehat{Y}_i + \widehat{c} g_2(i) = \widehat{Y}_i + \frac{1}{\sqrt{2}}\widehat{c} i$. Then, for all $t \in \mathbb{R}$ that are continuity points of the distribution of X_i, the following convergence holds in probability

$$\frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=i} 1_{I(v)>t} \to \frac{1}{2}\mathbb{P}\left(X_i > t\right).$$

Since $\mathbb{E}\left[X_+\right] > 0$, the argument below (90) in [2] establishes the existence of a continuity point $t_0 \in \mathbb{R}$ such that $\mathbb{P}\left(X_+ > t_0\right) > \mathbb{P}\left(X_- > t_0\right)$.

Further, we note that X_+ is in distribution equal to $-X_-$, a fact that we use below.

We are now in a position to apply Lemma 31 and thereby finishing the proof of Theorem 2:

If $\omega = 1$, then we define F, for $v \in V$, by

$$F(v) = 1_{\sum_{e:e_2=v} \xi_2(e) > \frac{t_0}{s\sqrt{n}}} = 1_{I(v)>t_0}.$$

Then,

$$\lim_{n\to\infty} \frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=+} F(v) = \frac{1}{2}\mathbb{P}\left(X_+ > t_0\right) =: \frac{f(+)}{2},$$

and,

$$\lim_{n\to\infty} \frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=-} F(v) = \frac{1}{2}\mathbb{P}\left(X_- > t_0\right) =: \frac{f(-)}{2},$$

so that $f(+) > f(-)$ and Lemma 31 applies.

If, however, $\omega = -1$, then we define F, for $v \in V$, by

$$F(v) = 1_{\sum_{e:e_2=v} \xi_2(e) \le \frac{t_0}{s\sqrt{n}}} = 1_{-I(v)\le t_0}.$$

Then, this time,

$$\lim_{n\to\infty} \frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=+} F(v) = \lim_{n\to\infty} \frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=+} 1_{I(v)>-t_0} = \frac{1}{2}\mathbb{P}\left(X_+ > -t_0\right) =: \frac{f(+)}{2},$$

since $-t_0$ is a continuity point of X_+, which follows from the fact that X_+ is in distribution equal to $-X_-$ and t_0 is a continuity point of X_-.

Similarly,

$$\lim_{n\to\infty} \frac{1}{n}\sum_{v=1}^{n} 1_{\sigma(v)=-} F(v) = \frac{1}{2}\mathbb{P}\left(X_- > -t_0\right) =: \frac{f(-)}{2}.$$

Now,

$$f(+) = \mathbb{P}\left(X_+ > -t_0\right) = 1 - \mathbb{P}\left(X_- > t_0\right) > 1 - \mathbb{P}\left(X_+ > t_0\right) = \mathbb{P}\left(X_- > -t_0\right) = f(-),$$

exactly the setting of Lemma 31.

Conditional Sparse Linear Regression

Brendan Juba*

Washington University, St. Louis, USA
bjuba@wustl.edu

Abstract

Machine learning and statistics typically focus on building models that capture the vast majority of the data, possibly ignoring a small subset of data as "noise" or "outliers." By contrast, here we consider the problem of *jointly* identifying a significant (but perhaps small) segment of a population in which there is a highly sparse linear regression fit, together with the coefficients for the linear fit. We contend that such tasks are of interest both because the models themselves may be able to achieve better predictions in such special cases, but also because they may aid our understanding of the data. We give algorithms for such problems under the sup norm, when this unknown segment of the population is described by a k-DNF condition and the regression fit is s-sparse for constant k and s. For the variants of this problem when the regression fit is *not* so sparse or using expected error, we also give a preliminary algorithm and highlight the question as a challenge for future work.

1 Introduction

Linear regression, the fitting of linear relationships among variables in a data set, is a standard tool in data analysis. In particular, for the sake of interpretability and utility in further analysis, we desire to find *highly sparse* linear relationships, i.e., involving only a few variables. Of course, such simple linear relationships often will not hold across an entire population. But, more frequently there will exist conditions – perhaps a range of parameters or a segment of a larger population – under which such sparse models fit the data quite well. For example, Rosenfeld et al. [22] used data mining heuristics to identify small segments of a population in which a few additional risk factors were highly predictive of certain kinds of cancer, whereas these same risk factors were not significant in the overall population. Simple rules for special cases may also hint at the more complex general rules. More generally, we need to develop new techniques to reason about populations in which most members are atypical in some way, which are colloquially (and somewhat abusively) referred to as *long-tailed* distributions. We are seeking computationally efficient, principled alternatives to ad-hoc approaches such as trying a variety of methods for clustering the data and hoping that the identified clusters can be modeled well.

1.1 Our results

In this work we consider the design and analysis of efficient algorithms for the *joint* task of identifying significant segments of a population in which a sparse model provides a good fit. We are able to identify such segments when they are described by a k-DNF and there is a s-sparse regression fit for constant k and s. More specifically, we give algorithms when there is a linear relationship with respect to which the error is bounded by ϵ with probability 1 (i.e., ϵ sup norm). In this case, we find a condition in which the error is bounded by ϵ for a $1-\gamma$ fraction of the population (with probability $1-\delta$ over the sample of data).

▶ **Theorem 1** (Conditional sparse linear regression). *Suppose that D is a joint probability distribution over $\vec{x} \in \{0,1\}^n$, $\vec{y} \in \mathbb{R}^d$, and $z \in \mathbb{R}$ such that there is a k-DNF c for which for some s-sparse $\vec{a} \in \mathbb{R}^d$*

$$\Pr_{(x,y,z)\in D}\left[|\langle \vec{a}, \vec{y}\rangle - z| \le \epsilon \middle| c(\vec{x}) = 1\right] = 1 \qquad \text{and} \qquad \Pr_{(x,y,z)\in D}[c(\vec{x}) = 1] \ge \mu.$$

Then given ϵ, μ, and δ in $(0,1)$, $\gamma \in (0, 1/2]$, and access to examples from D, for any constants s and k, there is an algorithm that runs in polynomial time in n, d, $1/\mu$, $1/\gamma$, and $\log 1/\delta$, and finds an s-sparse $\vec{a}'$ and k-DNF c' such that with probability $1-\delta$,

$$\Pr_{(x,y,z)\in D}\left[|\langle \vec{a}', \vec{y}\rangle - z| \le \epsilon \middle| c'(\vec{x}) = 1\right] \ge 1-\gamma \qquad \text{and} \qquad \Pr_{(x,y,z)\in D}[c'(\vec{x}) = 1] \ge (1-\gamma)\mu.$$

Our algorithms make crucial use of the sought solution's sparsity. The key observation is that since the linear rule has constant sparsity, with respect to the relevant dimensions there are a constant number of "extremal examples" such that we can obtain low error on the unknown event by fitting these extremal examples. We can then use the linear rule we obtain from fitting such a set of examples to label the data according to whether or not that point has low error under the linear rule. Finally, this enables us to find an event on which the linear rule has low error. Thus, it suffices to simply perform a search over candidates for the extremal examples and return one for which the corresponding event captures enough of the data.

We also note a trivial (weak) approximation algorithm for an expected-error variant of the problem that does not rely on sparsity: when there is a k-DNF c and a linear rule a giving conditional expected error ϵ (and c is true with probability μ), we find a condition c' and a linear rule a' with conditional expected error $O(n^k\epsilon)$ and probability $\Omega(\mu/n^k)$. We pose the design of better algorithms for the dense regression and expected-error tasks as challenges for future work.

1.2 Related work

We are building on recent work by Juba [15] on identifying potentially rare events of interest in a distribution, which captures a family of data mining tasks similar to, e.g., association rule discovery [1] or "bump hunting" [10]. This work is closely related to theoretical work on *positive-reliable learning* [16, 17], which is in turn very closely related to the "heuristic learning" model introduced by Pitt and Valiant [21] and studied in depth by Bshouty and Burroughs [5]: these are models of classification in which one type of error is minimized subject to a hard bound on the other type of error. The key difference between heuristic or positive-reliable learning on the one hand, and the work by Juba or the work in data mining on the other, is that the latter works focus on bounding the error *conditioned on the identified event* (i.e., the *precision* rather than the raw *false-positive rate*). In the present

work, we develop this perspective further, and seek to perform *supervised learning* in such a conditional distribution. In this context, these earlier works can be viewed as identifying a conditional distribution in which the class consisting solely of the constant 1 function fits the selected points with low error. We are generalizing this to the problem of fitting a (sparse) linear rule in the identified conditional distribution.

Our work also has some relationship to the enormous body of work on *robust statistics* [13, 23], in which *outliers* are identified and ignored or otherwise mitigated. The difference in what we consider here is two-fold. First, we are specifically interested in the case where *we may decline to fit the vast majority of the data,* thus treating most of the data as "outliers" in the model of robust statistics. Second, we are also interested in *finding a (simple) rule that identifies which subset of the data we are fitting* (and which subset we are ignoring). By contrast, in robust statistics, an arbitrary subset of the data may be considered "corrupted" and ignored. Note that without this extra structure, Hardt and Moitra [12] found that the problem of finding subspaces described by a single linear constraint is intractable (precisely, SSE-hard) when the subspace does not contain nearly all $(1 - 1/d$ fraction) of the data.

Similarly, our problem differs from linear mixed models [18, 14] in that linear mixed models seek several linear rules to try to explain (almost) all of the data. Again, in such models, the only description of the "clusters" are the linear models themselves (so points are taken to lie in the cluster of the linear fit with which they have the smallest residual).

Our problem is also very closely related to the problem solved by RANSAC [9] and its variants, that use sampling to find nontrivial linear relationships in data even when these are only of moderate density. The difference is principally that RANSAC is designed to find linear relationships in very low dimension (e.g., in $\mathbb{R}^2$), and does not scale to high dimensions since we need d points to determine a linear fit in $\mathbb{R}^d$, i.e., we need to hit the subspace d times when sampling. In the present work, by contrast, although the linear fit we are seeking is of constant sparsity, we wish to find linear relationships in asymptotically growing dimension d. Also, RANSAC-like algorithms, as in robust statistics (or linear mixed models), do not aim to provide a description of the data for which they find a linear relationship.

Finally, we note that our work has a connection to the list-learning model introduced independently (subsequent to the original posting of this work on arXiv) by Charikar et al. [6]. The connection is more technical, and we postpone discussing it to Section 5.

2 Problem definition and background

In this work, we primarily focus on the following task:

▶ **Definition 2** (Conditional linear regression)**.** The *conditional (realizable) linear regression* task is the following. We are given access to examples from an arbitrary distribution D over $\{0,1\}^n \times \mathbb{R}^d \times \mathbb{R}$ for which there exists a k-DNF c^* and $\vec{a}^* \in \mathbb{R}^d$ such that

1. $\Pr_{(x,y,z)\in D}[|\langle \vec{a}^*, \vec{y}\rangle - z| \leq \epsilon | c^*(\vec{x}) = 1] = 1$ and
2. $\Pr_{(x,y,z)\in D}[c^*(\vec{x}) = 1] \geq \mu$,

for some $\epsilon, \mu \in (0,1]$. Then with probability $1 - \delta$, given ϵ, μ, δ, and γ as input, we are to find some $\vec{a}' \in \mathbb{R}^d$ and k-DNF c' such that

1. $\Pr_{(x,y,z)\in D}[|\langle \vec{a}', \vec{y}\rangle - z| \leq \epsilon | c'(\vec{x}) = 1] \geq 1 - \gamma$ and
2. $\Pr_{(x,y,z)\in D}[c'(\vec{x}) = 1] \geq \Omega\left(\left((1-\gamma)\frac{\mu}{nd}\right)^k\right)$ for some k

in time polynomial in $n, d, 1/\mu, 1/\epsilon, 1/\gamma$, and $1/\delta$. If $\vec{a}^*$ is assumed to have at most s nonzero entries and $\vec{a}'$ is likewise required to have at most s nonzero entries, then this is the *conditional sparse linear regression* task with *sparsity* s.

We will also briefly consider the following variant that in some contexts may be more natural.

▶ **Definition 3** (Conditional ℓ_2-linear regression)**.** The *conditional ℓ_2-linear regression* task is the following. We are given access to examples from an arbitrary distribution D over $\{0,1\}^n \times \{\vec{y} \in \mathbb{R}^d : \|\vec{y}\|_2 \leq B\} \times [-B, B]$ for which there exists a k-DNF c^* and $\vec{a}^* \in \mathbb{R}^d$ with $\|\vec{a}^*\|_2 \leq B$ such that

1. $\mathbb{E}_{(x,y,z)\in D}\left[(\langle \vec{a}^*, \vec{y}\rangle - z)^2 | c^*(\vec{x}) = 1\right] \leq \epsilon$ and
2. $\Pr_{(x,y,z)\in D}[c^*(\vec{x}) = 1] \geq \mu$,

for some $B \in \mathbb{R}^+$, $\epsilon, \mu \in (0, 1]$. Then with probability $1 - \delta$, given B, ϵ, μ, δ, and γ as input, we are to find some $\vec{a}' \in \mathbb{R}^d$ and k-DNF c' such that

1. $\mathbb{E}_{(x,y,z)\in D}\left[(\langle \vec{a}', \vec{y}\rangle - z)^2 | c'(\vec{x}) = 1\right] \leq \mathrm{poly}(B, d, n)\epsilon$ and
2. $\Pr_{(x,y,z)\in D}[c'(\vec{x}) = 1] \geq \Omega\left(\left((1-\gamma)\frac{\mu}{Bdn}\right)^k\right)$ for some k

in time polynomial in $n, d, B, 1/\mu, 1/\epsilon, 1/\gamma$, and $1/\delta$.

One could further consider, for example, regression under the other ℓ_p norms, but we will not pursue this here.

In both variants of the problem, we have sought to only recover a condition c' that only comprises a polynomial fraction of the probability of the optimal condition μ. A controllable $1 - \gamma$ factor loss is generally necessary when we are choosing among various candidate "clusters" based on sampling. Although in the earlier work on conditional distribution search [15] (see Definition 4, next), it was possible to find an event c' that actually captured the same probability mass as the target c (since there we are uniquely seeking a "cluster" that selects positive points), even in that setting, the reductions between related models generally incurred a controllable $1-\gamma$ loss. Nevertheless, the value of such a formal definition is usually in enabling us to formulate negative results, and in that case we seek the most liberal definition possible. Hence, here, we allow c' to only contain a polynomial fraction of μ depending on the main parameters, B, d, and n, that we might expect to encounter in an approximation guarantee, such as the one we show for Algorithm 2.

The restriction of c to be a k-DNF is not arbitrary. Although we could consider other classes of representations for c, it seems that essentially any of the other standard hypothesis classes that we might naturally consider here will lead to an intractable problem, even under the relatively liberal version of the problems defined above. This will follow since we can reduce the simpler problem of finding such conditions to our problem:

▶ **Definition 4** (Conditional distribution search)**.** For a *representation class* $\mathcal{C}$ of $c : \{0,1\}^n \to \{0,1\}$, the *conditional distribution search problem* is as follows. Given access to i.i.d. examples $(\vec{x}^{(1)}, b^{(1)}), \ldots, (\vec{x}^{(m)}, b^{(m)})$ from an arbitrary distribution D over $\{0,1\}^n \times \{0,1\}$ for which there exists $c^* \in \mathcal{C}$ such that $\Pr_{(x,b)\in D}[b = 1 | c^*(\vec{x}) = 1] = 1$ and $\Pr_{(x,b)\in D}[c^*(\vec{x}) = 1] \geq \mu$, with probability $1 - \delta$, find some circuit c' such that

1. $\Pr_{(x,b)\in D}[b = 1 | c'(\vec{x}) = 1] \geq 1 - \gamma$ and
2. $\Pr_{(x,b)\in D}[c'(\vec{x}) = 1] \geq \Omega(((1-\gamma)\mu/n)^k)$ for some k

in time polynomial in $n, 1/\mu, 1/\gamma$, and $1/\delta$.

▶ **Theorem 5** (Conditional distribution search reduces to conditional linear regression)**.** *Suppose there is an algorithm that given access to examples from an arbitrary distribution D' over $\{0,1\}^n \times \{0,1\} \times \{0,1\}$ for which there exists $c^* \in \mathcal{C}$ and $a^* \in \mathbb{R}$ such that*

$$\Pr_{(x,y,z)\in D'}\left[|a^* y - z| \leq \epsilon \middle| c^*(\vec{x}) = 1\right] = 1 \text{ and } \Pr_{(x,y,z)\in D'}[c^*(\vec{x}) = 1] \geq \mu,$$

with probability $1-\delta$*, finds some* $a' \in \mathbb{R}$ *and circuit* c' *such that*

$$\Pr_{(x,y,z)\in D'}\left[|a'y - z| \leq \epsilon \middle| c'(\vec{x}) = 1\right] \geq 1-\gamma \qquad \textit{and}$$

$$\Pr_{(x,y,z)\in D'}[c'(\vec{x}) = 1] \geq \Omega\left(\left(\frac{(1-\gamma)\mu}{n}\right)^k\right) \qquad \textit{for some } k$$

in time polynomial in $n, 1/\mu, 1/\gamma, 1/\epsilon$ *and* $1/\delta$*. Then there is a randomized polynomial-time algorithm for conditional distribution search for* $\mathcal{C}$*.*

Proof. Let D be a distribution satisfying the hypotheses of the conditional distribution search task for $\mathcal{C}$, that is, for some $c^* \in \mathcal{C}$,

1. $\Pr_{(x,b)\in D}[b = 1 | c^*(\vec{x}) = 1] = 1$ and
2. $\Pr_{(x,b)\in D}[c^*(\vec{x}) = 1] \geq \mu$.

Let D' be the distribution over $\{0,1\}^n \times \{0,1\} \times \{0,1\}$ sampled as follows: given an example $(\vec{x}, b)$ from D, if $b = 1$ we produce $(\vec{x}, 1, 0)$ and otherwise we produce $(\vec{x}, 1, b')$ for b' uniformly distributed over $\{0,1\}$. Notice that for c^* and $a^* = 0$, then whenever $c^*(\vec{x}) = 1$, $|a^*y - z| = 0 \leq 1/3$ over the entire support of the distribution; and, by assumption, $\Pr_{(x,y,z)\in D'}[c^*(\vec{x}) = 1] = \Pr_{(x,b)\in D}[c^*(\vec{x}) = 1] \geq \mu$. So, the pair $a^* = 0$ and c^* certainly satisfy the conditions for our task for $\epsilon = 1/3$. Therefore, by hypothesis, an algorithm for our task given access to D' with $\epsilon = 1/3$ and $\gamma' = \gamma/2$ must return a' and a circuit c' such that

1. $\Pr_{(x,y,z)\in D'}\left[|a'y - z| \leq 1/3 | c'(\vec{x}) = 1\right] \geq 1 - \gamma'$ and
2. $\Pr_{(x,y,z)\in D'}[c'(\vec{x}) = 1] \geq \Omega(((1-\gamma')\mu/n)^k)$ for some k.

But now, since the distribution we used is uniform over examples with $z = 0$ and $z = 1$ whenever $b = 0$ (and $y \equiv 1$), it must be that whatever a' is returned, $|a' - z| > 1/3$ with probability $1/2$ conditioned on $b = 0$ in the underlying draw from D. We must therefore actually have that

$$\frac{1}{2}\Pr_{(x,b)\in D}[b = 0 | c'(\vec{x}) = 1] \leq \Pr_{(x,y,z)\in D'}\left[|a'y - z| > 1/3 \middle| c'(\vec{x}) = 1\right] \leq \frac{\gamma}{2}$$

so indeed, also $\Pr_{(x,b)\in D}[b = 1 | c'(\vec{x}) = 1] \geq 1 - \gamma$. Thus c' is as needed for a solution to the conditional distribution search problem. Since it is trivial to implement the sampling oracle for D' given a sampling oracle for D, we obtain the desired algorithm. ◀

In turn now, algorithms for finding such conditions would yield algorithms for PAC-learning DNF [15], which is currently suspected to be intractable (c.f. in particular work by Daniely and Shalev-Shwartz [8] for some strong consequences of learning DNF).

▶ **Theorem 6** (Theorem 5 of [15])**.** *If there exists an algorithm for the conditional distribution search problem for conjunctions, then DNF is PAC-learnable in polynomial time.*

Informally, therefore, an algorithm for conditional realizable linear regression for conjunctions, or any class that can *express* conjunctions (instead of k-DNF), even under the relatively lax version of the problem formulated here, would yield a randomized polynomial time algorithm for PAC-learning DNF. This seems to rule out, in particular, the possibility of developing algorithms to perform regression under conditions described by halfspaces, decision trees, and so on.

For conditional ℓ_2-linear regression, a stronger conclusion holds: such algorithms would solve the *agnostic* variant of the conditional distribution search task, with a similar error bound:

▶ **Theorem 7** (Agnostic condition search reduces to conditional ℓ_2-linear regression)**.** *Suppose there is an algorithm that given access to examples from an arbitrary distribution D' over $\{0,1\}^n \times \{0,1\} \times \{0,1\}$ for which there exists $c^* \in \mathcal{C}$ and $a^* \in [0,1]$ such that $\mathbb{E}_{(x,y,z)\in D'}\left[(a^*y - z)^2 | c^*(\vec{x}) = 1\right] \leq \epsilon$ and $\Pr_{(x,y,z)\in D'}[c^*(\vec{x}) = 1] \geq \mu$, with probability $1-\delta$, finds some a' and circuit c' such that*
1. $\mathbb{E}_{(x,y,z)\in D'}\left[(a'y - z)^2 | c'(\vec{x}) = 1\right] \leq p(n)\epsilon$ *for some polynomial p and*
2. $\Pr_{(x,y,z)\in D'}[c'(\vec{x}) = 1] \geq \Omega(((1-\gamma)\mu/n)^k)$ *for some k*
in time polynomial in $n, 1/\mu, 1/\gamma, 1/\epsilon$ and $1/\delta$. Then there is a randomized polynomial-time algorithm for agnostic conditional distribution search for $\mathcal{C}$: that is, if there exists $c \in \mathcal{C}$ achieving
1. $\Pr_{(x,b)\in D}[b = 1 | c(\vec{x}) = 1] \geq 1 - \epsilon$ *and*
2. $\Pr_{(x,b)\in D}[c(\vec{x}) = 1] \geq \mu$
then the algorithm finds a circuit c'' achieving
1. $\Pr_{(x,b)\in D}[b = 1 | c''(\vec{x}) = 1] \geq 1 - 2p(n)\epsilon$ *and*
2. $\Pr_{(x,b)\in D}[c''(\vec{x}) = 1] \geq \Omega(((1-\gamma)\mu/n)^k)$ *for some k*
in time polynomial in $n, 1/\mu, 1/\gamma, 1/\epsilon$ and $1/\delta$.

Proof. For a given distribution D over (x, b) satisfying the promise for conditional distribution search, we use the same construction of D' and reduction as in the proof of Theorem 5. Here, we note that for $a^* = 0$, given that $\Pr_{(x,b)\in D}[b = 1 | c(\vec{x}) = 1] \geq 1 - \epsilon$ for the c assumed to exist for conditional distribution search

$$\mathop{\mathbb{E}}_{(x,y,z)\in D'}\left[(0 \cdot 1 - z)^2 \middle| c(\vec{x}) = 1\right] \leq \frac{1}{2}\epsilon.$$

Therefore, an algorithm for conditional ℓ_2-linear regression must find some a' and circuit c' such that $\Pr_{(x,y,z)\in D'}[c'(\vec{x}) = 1] \geq \Omega(((1-\gamma)\mu/n)^k)$ for some k and

$$\mathop{\mathbb{E}}_{(x,y,z)\in D'}\left[((a' - z)^2 \middle| c'(\vec{x}) = 1\right] \leq \frac{1}{2}p(n)\epsilon.$$

Now, again, since D' gives $z = 0$ and $z = 1$ equal probability whenever $b = 0$, we note that for such examples the expected value of $(a' - z)^2$ is minimized by $a' = 1/2$, where it achieves expected value $1/4$. Thus as $(a' - z)^2$ is surely nonnegative,

$$\frac{1}{4}\Pr_{(x,b)\in D}[b = 0 | c'(\vec{x}) = 1] \leq \mathop{\mathbb{E}}_{(x,y,z)\in D'}\left[(a' - z)^2 \middle| c'(\vec{x}) = 1\right] \leq \frac{1}{2}p(n)\epsilon$$

so c' indeed also achieves $\Pr_{(x,b)\in D}[b = 1 | c'(\vec{x}) = 1] \geq 1 - 2p(n)\epsilon$. ◀

The restriction to constant sparsity is also key, as our problem contains as a special case (when $\mu = 1$, that is, when the trivial condition that takes the entire population can be used) the standard sparse linear regression problem. Sparse linear regression for *constant* sparsity is easy, but when the sparsity is allowed to be large, the problem quickly becomes intractable: In general, finding sparse solutions to linear equations is known to be NP-hard [20], and Zhang, Wainwright, and Jordan [30] extend this to bounds on the quality of sparse linear regression that is achievable by polynomial-time algorithms, given that NP does not have polynomial-size circuits.

3 Algorithms for conditional sparse linear regression

We now turn to stating and proving our main theorem. In what follows, we use the following (standard) notation: $\Pi_{d_1,\ldots,d_s}$ denotes the projection (of $\mathbb{R}^d$) to the s coordinates $d_1, d_2, \ldots, d_s$

Algorithm 1: Find-and-eliminate.

input : Examples $(\vec{x}^{(1)}, \vec{y}^{(1)}, z^{(1)}), \ldots, (\vec{x}^{(m)}, \vec{y}^{(m)}, z^{(m)})$, target fit ϵ and fraction $(1-\gamma/2)\mu$.

output : A k-DNF over $x_1, \ldots, x_n$ and linear predictor over $y_1, \ldots, y_d$, or INFEASIBLE if none exist.

begin

  forall $(d_1, \ldots, d_s) \in \binom{[d]}{s}$, $(\sigma_1, \ldots, \sigma_{s+1}) \in \{\pm 1\}^{s+1}$ *and* $(j_1, \ldots, j_{s+1}) \in \binom{[m]}{s+1}$ **do**

    Initialize c to be the (trivial) k-DNF over all $\binom{2n}{k}$ terms of size k.

    Let $(\vec{a}, \epsilon')$ be a solution to the following linear system:

$$\langle \vec{a}, \Pi_{d_1,\ldots,d_s} \vec{y}^{(j_\ell)} \rangle - z^{(j_\ell)} = \sigma_\ell \epsilon' \text{ for } \ell = 1, \ldots, s+1$$

    if $\epsilon' > \epsilon$ **then** continue to the next iteration.

    for $j = 1, \ldots, m$ **do** **if** $|\langle \vec{a}, \Pi_{d_1,\ldots,d_s} \vec{y}^{(j)} \rangle - z^{(j)}| > \epsilon$ **then**

      forall $T \in c$ **do** **if** $T(\vec{x}^{(j)}) = 1$ **then** Remove T from c.

    end

    if $\#\{j : c(\vec{x}^{(j)}) = 1\} > (1-\gamma/2)\mu m$ **then** **return** $\vec{a}$ *and* c.

  end

  return *INFEASIBLE.*

end

from $[d]$ (which denotes the integers $1, \ldots d$). For a set S, we let $\binom{S}{k}$ denote the subsets of S of size exactly k.

At a high level, the algorithm (Algorithm 1, below) generates a *list* of possible coefficient vectors for the regression fit. For each such candidate, it generates labels for the points indicating whether or not the candidate linear fit achieves small error under that fit or not. It then solves the conditional distribution search problem given by these labels (by using the Elimination algorithm [15]), and estimates the fraction of the data captured this way. It returns the first linear fit that captures a sufficiently large fraction (or "INFEASIBLE" if none do).

▶ **Theorem 8** (Realizable sparse regression – full statement of Theorem 1). *Suppose that D is a joint probability distribution over $\vec{x} \in \{0,1\}^n$, $\vec{y} \in \mathbb{R}^d$, and $z \in \mathbb{R}$ such that there is a k-DNF c for which for some s-sparse $\vec{a} \in \mathbb{R}^d$*

$$\Pr_{(x,y,z)\in D}\left[|\langle \vec{a}, \vec{y}\rangle - z| \le \epsilon \middle| c(\vec{x}) = 1\right] = 1 \qquad \text{and} \qquad \Pr_{(x,y,z)\in D}[c(\vec{x}) = 1] \ge \mu.$$

Then given ϵ, μ, and δ in $(0,1)$ and $\gamma \in (0, 1/2]$ and

$$m = O\left(\frac{1}{\mu\gamma}\left(s\log s + s\log d + n^k + \log\frac{1}{\delta}\right)\right)$$

examples from D, for any constants s and k, Algorithm 1 runs in polynomial time in n, d, and m $(= \mathrm{poly}(n, d, 1/\mu, 1/\gamma, \log 1/\delta))$ and finds an s-sparse $\vec{a}'$ and k-DNF c' such that with probability $1-\delta$,

$$\Pr_{(x,y,z)\in D}\left[|\langle \vec{a}', \vec{y}\rangle - z| \le \epsilon \middle| c'(\vec{x}) = 1\right] \ge 1-\gamma \qquad \text{and} \qquad \Pr_{(x,y,z)\in D}[c'(\vec{x}) = 1] \ge (1-\gamma)\mu.$$

Proof. It is clear that the algorithm runs for $O(d^s m^{s+1})$ iterations, where each iteration (for constant s) runs in time polynomial in the bit length of our examples and $O(mn^k)$. Thus, for constant s and k, the algorithm runs in polynomial time overall, and it only remains to argue correctness.

We will first argue that the algorithm succeeds at returning some solution with probability $1 - \delta/3$ over the examples. We will then argue that any solution returned by the algorithm is satisfactory with probability $1 - 2\delta/3$ over the examples, thus leading to a correct solution with probability $1 - \delta$ overall.

Completeness part 1: Generating the linear rule

We first note that for $m \geq \frac{6}{\mu\gamma} \ln \frac{3}{\delta}$ examples, a Chernoff bound guarantees that with probability $1-\delta/3$, there are at least $(1-\gamma/2)\mu m$ examples satisfying the unknown condition c in the sample. Let S be the set of examples satisfying c. Given the set of s dimensions that are used in the sparse linear rule, we set up a linear program in $s+1$ dimensions to minimize ϵ' subject to the constraints

$$-\epsilon' \leq \langle \vec{a}, \vec{y}^{(j)} \rangle - z^{(j)} \leq \epsilon' \text{ for } j \in S.$$

It is well known (see, for example, Schrijver [24, Chapter 8]) that the optimum value for any feasible linear program may be obtained at a *basic feasible solution,* i.e., a vertex of the polytope, given by satisfying $s+1$ of the constraints with equality. Since each constraint corresponds to an example and sign (for the lower or upper inequality), this means that we can obtain $\vec{a}$ by solving for $\vec{a}$ and ϵ' in the following linear system

$$\langle \vec{a}, \vec{y}^{(j_\ell)} \rangle - z^{(j_\ell)} = \sigma_\ell \epsilon' \text{ for } \ell = 1, \ldots, s+1$$

for some set of $s+1$ examples, $j_1, \ldots, j_{s+1}$ and $s+1$ signs $\sigma_1, \ldots, \sigma_{s+1}$ corresponding to the tight constraints. Thus, when the algorithm uses the appropriate set of s dimensions, the appropriate $s+1$ examples, and the appropriate $s+1$ signs, we will recover an $\vec{a}^*$ and ϵ^* such that for all $j \in S$, $|\langle \vec{a}^*, \vec{y}^{(j)} \rangle - z^{(j)}| \leq \epsilon^* \leq \epsilon$.

Completeness part 2: Recovering a suitable condition given a rule

Now, given $\vec{a}^*$ such that for all $j \in S$, $|\langle \vec{a}^*, \vec{y}^{(j)} \rangle - z^{(j)}| \leq \epsilon$, we observe that the algorithm identifies a k-DNF h^* such that $h^*(\vec{x}^{(j)}) = 1$ for all $j \in S$. Indeed, the algorithm only eliminates a k-term T for examples j such that $|\langle \vec{a}^*, \vec{y}^{(j)} \rangle - z^{(j)}| > \epsilon$. Thus, it never eliminates any term appearing in c, and so in particular, $\Pr_{(x,y,z)\in D}[h^*(\vec{x}) = 1] \geq \Pr_{(x,y,z)\in D}[c(\vec{x}) = 1] \geq \mu$. Moreover, since (as noted above, with probability $1 - \delta/3$) there are at least $(1-\gamma/2)\mu m$ examples satisfying c in the sample, there are at least $(1-\gamma/2)\mu m$ examples satisfying h^*. Thus, with probability $1 - \delta/2$, when the algorithm considers the relevant s dimensions in the support of $\vec{a}$ and considers an appropriate choice of $s+1$ examples to obtain a suitable $\vec{a}^*$, it will furthermore obtain an h^* that will lead the algorithm to terminate and return $\vec{a}^*$ and h^*.

Soundness: Generalization bounds

Next, we argue that any $\vec{a}'$ and h' returned by the algorithm will suffice with probability $1 - 2\delta/3$ over the examples.

We will use the facts that

1. a union of k hypothesis classes of VC-dimension d has VC-dimension at most $O(d \log d + \log k)$ (for example, see [25, Exercise 6.11]),
2. linear threshold functions in $\mathbb{R}^s$ have VC-dimension $s+1$ (e.g., [25, Section 9.1.3]), and
3. the composition of classes of VC-dimension d_1 and d_2 has VC-dimension at most $d_1 + d_2$ (follows from [25, Exercise 20.4]).

We now consider the class of disjunctions of a k-CNF over $\{0,1\}^n$ and (intersections of) linear threshold functions $[|\langle(\vec{a},-1),(\vec{y},z)\rangle| \leq \varepsilon]$ for an s-sparse $\vec{a}$ over $\mathbb{R}^d$. By writing this latter class as a union over the $2^{\binom{n}{k}}$ k-CNFs and $\binom{d}{s}$ coordinate subsets of size s, we find that it has VC-dimension $O(s \log s + s \log(d/s) + n^k) = O(\log d + n^k)$ for constant s.[1]

An optimal bound for sample complexity in terms of VC-dimension was recently obtained by Hanneke [11] (superseding the earlier bounds, e.g., by Vapnik [28] and Blumer et al. [4], although these would suffice for us, too): in this case, given

$$m = O\left(\frac{1}{\mu\gamma}\left(s \log s + s \log d + n^k + \log \frac{1}{\delta}\right)\right)$$

examples, if $[|\langle(\vec{a}',-1),(\vec{y},z)\rangle| \leq \varepsilon] \vee \neg h'(\vec{x})$ is consistent with all of the examples, then with probability $1 - \delta/3$ over the examples,

$$\Pr_{(x,y,z)\in D}[(|\langle(\vec{a}',-1),(\vec{y},z)\rangle| \leq \varepsilon) \vee \neg h'(\vec{x})] \geq 1 - \mu\gamma/2$$

or, equivalently,

$$\Pr_{(x,y,z)\in D}[(|\langle(\vec{a}',-1),(\vec{y},z)\rangle| > \varepsilon) \wedge h'(\vec{x})] \leq \mu\gamma/2.$$

Now, since for $m \geq \frac{4}{\mu\gamma} \ln \frac{3}{\delta}$, with probability $1 - \delta/3$,

$$\Pr_{(x,y,z)\in D}[h'(\vec{x})] \geq \frac{1-\gamma/2}{1+\gamma/2}\mu \geq (1-\gamma)\mu,$$

we find that for our choice of $\vec{a}'$ and h',

$$\Pr_{(x,y,z)\in D}\left[|\langle\vec{a}',\vec{y}\rangle - z| > \varepsilon \middle| h'(\vec{x})\right] \leq \frac{\gamma}{2}\frac{1+\gamma/2}{1-\gamma/2}$$

and so, $\Pr_{(x,y,z)\in D}\left[|\langle\vec{a}',\vec{y}\rangle - z| \leq \varepsilon \middle| h'(\vec{x})\right] \geq 1 - \gamma$ since $\gamma \leq 1/2$

as needed. ◀

Although it was not a focus of the analysis, we remark that the multiplicative Chernoff bound also guarantees that if *no* k-DNF event of probability greater than $(1-\gamma)\mu$ has a linear rule that is γ-close to having ϵ sup norm, then the algorithm is guaranteed to output INFEASIBLE with probability $1 - \delta$: the k-DNFs of probability less than $(1-\gamma)\mu$ fail the final test, and for the rest, the standard VC-dimension sample complexity analysis guarantees that we catch a point with error greater than the sup norm bound of ϵ in the sample (and so rule out the k-DNF during the Elimination algorithm). It follows that the algorithm is easily modified to solve a few natural variants of our problem. Suppose we return the list of all

[1] Exercises in Anthony and Biggs [2, Chapter 8, Exercise 6] and Mohri et al. [19, Exercise 3.15] on the growth function for ANDs/ORs of two distinct concept classes also yield this easily.

Algorithm 2: Dense Expected-error Regression Pigeonhole (DERP)

input : Examples $(\vec{x}^{(1)}, \vec{y}^{(1)}, z^{(1)}), \ldots, (\vec{x}^{(m)}, \vec{y}^{(m)}, z^{(m)})$, target fit ϵ.
output : A k-DNF over $x_1, \ldots, x_n$ and linear predictor over $y_1, \ldots, y_d$.
begin
  Initialize $c = \perp$, $\mu^* = 0$.
  forall *Terms T of size k over $x_1, \ldots, x_n$* **do**
    Put $S(T) = \{j : T(\vec{x}^{(j)}) = 1\}$.
    Let $\vec{a}$ minimize the squared-error on $(\vec{y}^{(j)}, z^{(j)})$ over $j \in S(T)$ subject to $\|\vec{a}\|_2 \leq B$.
    if $\frac{1}{m}\sum_{j \in S(T)}(\langle \vec{a}, \vec{y}^{(j)} \rangle - z^{(j)})^2 \leq 4\mu\epsilon$ *and* $|S(T)| \geq \mu^* m$ **then**
      Put $c = T$ and $\mu^* = |S(T)|/m$.
    end
  end
  return *c and $\vec{a}$*
end

coefficient vectors and k-DNFs that would pass our termination condition. We then obtain a list that contains all events that have probability μ (and only those that have probability at least $(1-\gamma)\mu$) for which the conditional distribution is γ-close to one where the linear rule has ϵ sup norm. Or, suppose we return the pair for which the k-DNF empirically satisfies the most examples. We then return a k-DNF that is within a $1-\gamma$ factor of having the largest probability (provided that this is at least μ) among those with a suitable linear rule.

4 Towards conditional dense, expected-error linear regression

While sparsity is a highly desirable feature to have of a linear regression fit, it may be the case that solutions are often not so sparse that Algorithm 1 is truly efficient. Moreover, we may also wish for an algorithm that handles an *expected error* variant of the regression task; the sup norm is particularly sensitive to noise or outliers, and thus is usually not a particularly desirable norm to use on real data. Our technique certainly does not address either of these concerns. The simple Algorithm 2 illustrates the best technique we currently have for either dense regression or expected error regression.

▶ **Theorem 9.** *Algorithm 2 solves the conditional ℓ_2-linear regression task: given access to a joint distribution D over $\vec{x} \in \{0,1\}^n$, $\vec{y} \in \mathbb{R}^d$ with $\|\vec{y}\|_2 \leq B$, and $z \in [-B, B]$ such that there is a k-DNF c and $\vec{a} \in \mathbb{R}^d$ with $\|\vec{a}\|_2 \leq B$ such that*

$$\mathop{\mathbb{E}}_{(x,y,z)\in D}\left[(\langle \vec{a}, \vec{y}\rangle - z)^2 \middle| c(\vec{x}) = 1\right] \leq \epsilon \qquad \text{and} \qquad 2\mu \geq \Pr_{(x,y,z)\in D}[c(\vec{x}) = 1] \geq \mu$$

and given B, k, ϵ, μ, and $\delta \in (0,1)$, using

$$m = O\left(\frac{B^8 n^k}{\mu\epsilon}\left(k\log n + \log\frac{1}{\delta}\right)\right)$$

examples from D, for any constant k, Algorithm 2 runs in polynomial time and finds a $\vec{a}'$ and k-DNF c' such that with probability $1-\delta$,

$$\mathop{\mathbb{E}}_{(x,y,z)\in D}\left[(\langle \vec{a}', \vec{y}\rangle - z)^2 \middle| c'(\vec{x}) = 1\right] \leq O(n^k\epsilon) \qquad \text{and} \qquad \Pr_{(x,y,z)\in D}[c'(\vec{x}) = 1] \geq \Omega(\mu/n^k).$$

Note that we can find such an estimate for μ by binary search.

Proof. We first observe that in particular, since for any T the objective function

$$\sum_{j \in S(T)} (\langle \vec{a}, \vec{y}^{(j)} \rangle - z^{(j)})^2$$

is convex, as is the set of $\vec{a}$ of ℓ_2-norm at most B, the main step of the algorithm is a convex optimization problem that can be solved in polynomial time, for example by gradient descent (see, e.g., [25, Chapter 14]). Thus, the algorithm can be implemented in polynomial time as claimed.

We next turn to correctness. Let c^* be the k-DNF promised by the theorem statement. By the pigeonhole principle, there must be some term T^* of c^* such that $\Pr[T^*(\vec{x}) = 1] \geq \mu / \binom{2n}{k}$. Observe that for the rule $\vec{a}^*$ promised to exist,

$$\begin{aligned}\mathop{\mathbb{E}}_{D}\left[(\langle \vec{a}^*, \vec{y} \rangle - z)^2 \middle| T^*(\vec{x}) = 1\right] \Pr_D[T^*(\vec{x}) = 1] &\leq \mathop{\mathbb{E}}_{D}\left[(\langle \vec{a}^*, \vec{y} \rangle - z)^2 \middle| c^*(\vec{x}) = 1\right] \Pr_D[c^*(\vec{x}) = 1] \\ &\leq \epsilon \cdot 2\mu.\end{aligned}$$

For a suitable choice of leading constant in the number of examples, a (multiplicative) Chernoff bound yields that with probability $1 - \delta/4$, at least $m \Pr[T^*(\vec{x}) = 1]/2$ examples satisfy T^* and noting that $(\langle \vec{a}^*, \vec{y} \rangle - z)^2 \in [0, 2B^4]$, with probability $1 - \delta/4$,

$$\frac{1}{m} \sum_{j=1}^{m} (\langle \vec{a}^*, \vec{y} \rangle - z)^2 T^*(\vec{x}) \leq 4\mu\epsilon$$

Thus, the $\vec{a}'$ minimizing the squared error on the set of examples also achieves

$$\frac{1}{m} \sum_{j : T^*(\vec{x}^{(j)}) = 1} (\langle \vec{a}', \vec{y}^{(j)} \rangle - z^{(j)})^2 \leq 4\mu\epsilon$$

as needed, so with probability $1 - \delta/2$, at least T^* is considered for c and the algorithm produces some c and $\vec{a}$ as output.

To see that any such T and $\vec{a}$ is satisfactory, we first note that any T we produce as output must satisfy at least as many examples as T^* by construction, so T must satisfy at least

$$\Pr_D[T^*(\vec{x}) = 1] m/2 \geq \Omega\left(\frac{B^8}{\epsilon}\left(k \log n + \log \frac{1}{\delta}\right)\right)$$

examples. In particular, this is at least $\mu m / 2\binom{2n}{k}$ examples, and a Chernoff bound guarantees that for suitable constants, with probability $1 - \delta/4\binom{2n}{k}$, no T with $\Pr_D[T(x) = 1] < \mu/4\binom{2n}{k}$ satisfies so many examples. Next, simply note that if for the best a for T with $\|\vec{a}\|_2 \leq B$, $\mathbb{E}_D\left[(\langle \vec{a}, \vec{y} \rangle - z)^2 | T(\vec{x}) = 1\right] \Pr[T(x) = 1] > 8\mu\epsilon$, then since $\|\vec{y}\|_2 \leq B$, $z^2 \leq B^2$, and the loss function is B-Lipschitz on this domain, a Rademacher bound (see, for example, [25, Theorem 26.12]) guarantees that with probability $1 - \delta/4\binom{2n}{k}$, for any such $\vec{a}$,

$$\frac{1}{m} \sum_{j : T(\vec{x}^{(j)}) = 1} (\langle \vec{a}, \vec{y}^{(j)} \rangle - z^{(j)})^2 > 4\mu\epsilon$$

and T will not be considered. A union bound over both events for all such T establishes that any T that is returned has, with probability $1 - \delta/2$, both

$$\Pr_D[T(\vec{x}) = 1] \geq \frac{\mu}{4\binom{2n}{k}} \text{ and } \mathop{\mathbb{E}}_{D}\left[(\langle \vec{a}, \vec{y} \rangle - z)^2 \middle| T(\vec{x}) = 1\right] \Pr_D[T(\vec{x}) = 1] \leq 8\mu\epsilon$$

and thus is as needed. Therefore, overall, with probability $1 - \delta$, the algorithm considers at least T^* as a candidate to output, and outputs a suitable term T and vector $\vec{a}$. ◀

5 Discussion and future directions

The main defect of Algorithm 2 is that in general it only recovers a condition with a $\Omega(1/n^k)$-fraction of the possible probability mass of the best k-DNF condition. This is in stark contrast to both Algorithm 1 and all of the earlier positive results for condition identification [15], in which we find a condition with probability at least a $(1-\gamma)$-fraction of that of the best condition, for any γ we choose. Indeed, we are most interested in the case where the probability of this event is relatively small and thus a $1/n^k$-fraction is extremely small. The main challenge here is to develop an algorithm for the dense and/or expected-error regression problem that similarly identifies a condition with probability that is a $(1-\gamma)$-fraction of that of the best condition.

Of course, the $O(n^k)$ blow-up in the expected error is also undesirable, but as indicated by Theorem 7, this is the same difficulty encountered in *agnostic learning*. Naturally, minimizing the amount by which constraints are violated is generally a harder problem than finding a solution to a system of constraints, and this is reflected in the quality of results that have been obtained. The results for such agnostic condition identification of k-DNFs in the previous work by Juba [15] suffers a similar blow-up in the error, which was recently improved to $\tilde{O}(\sqrt{n^k})$ by Zhang et al. [29]. The state-of-the-art algorithms for agnostic supervised learning for disjunctive classifiers by Awasthi et al. [3] suffer a similar blow-up of a $n^{k/3+o(1)}$-factor, and yet even for the harder problem of agnostic learning of linear threshold functions, only a sub-polynomial approximation factor is known to be necessary [7]. The question of what approximation factor is necessary is similarly wide open for our problem. We note briefly that a variant of Algorithm 2 in which we seek $\vec{a}$ satisfying $|\langle \vec{a}, \vec{y}^{(j)} \rangle - z^{(j)}| \leq \epsilon$ for all j satisfying a candidate term T solves the sup norm variant of Definition 2 for dense regression, and *does not* suffer this increase of the error. Of course, as mentioned earlier, one typically wishes to solve ℓ_1 or ℓ_2-norm regression, as these are much better behaved.

It is also natural to ask if instead of constant sparsity (as used here), we could simply bound the ℓ_1-norm of the coefficient vector, as in LASSO [27]. It's well known that this tends to produce sparse solutions (with ℓ_2-regression), without necessarily demanding an a priori fixed constant bound on the sparsity. Again, our technique does not achieve this.

Looking towards developing a better algorithm and solving further, related tasks, we note that a common strategy seems to be emerging. Our first algorithm, for the sup norm (Algorithm 1) operated by first generating a list of possible coefficient vectors for the regression fit, and then learning a condition that captures the various candidates in the list. This strategy is similar to the list-learning model independently introduced by Charikar et al. [6] for solving a variety of statistical problems when seeking to capture only a minority fraction of the data. Of course, in our work we ultimately sought to find a condition to single out one member of the list, rather than producing the entire list as output. Also, at a technical level, while their work applies to a much, much broader variety of problems, their technique also suffers an increase in the losses that grows with $1/\sqrt{\mu}$. (The relatively trivial Algorithm 2, as discussed above, suffers a n^k-factor increase, but has no dependence on μ, which naturally may be more or less desirable depending on the setting.) These technical differences aside, we believe that both of these works suggest that a relatively broad family of problems involving statistics of minority sub-populations may be tackled by variants of the list-learning approach. Indeed, we observe that the problem is essentially similar to that tacked by list-decoding in coding theory (e.g., see Sudan [26] for an overview): although the amount of agreement with the data may be too small to uniquely determine a "best" hypothesis, it may be possible to output a small list containing all possible hypotheses. Although most of the work in coding

theory is focused on finite characteristic (in contrast to most problems we would seek to solve in data analysis), it may be informative.

One immediate family of questions to be addressed is, which *conditional* variants of the standard supervised learning tasks can be solved efficiently? In particular, when can such tasks solved without suffering an increase in the loss that depends polynomially on $1/\mu$? For example, for which families of Boolean classification tasks do such algorithms exist? We know that the conditions (essentially) must be described by k-DNFs, but this seems to tell us nothing about which rules we can fit on such conditional distributions.

Acknowledgements. I thank Madhu Sudan for originally suggesting the joint problem of learning under conditional distributions. I also thank Ben Moseley for many helpful discussions about these problems. Finally, I thank the reviewers for their comments and suggestions.

Abstract

One of the central challenges in the study of quantum many-body systems is the complexity of simulating them on a classical computer. A recent advance [8] gave a polynomial time algorithm to compute a succinct classical description for unique ground states of gapped 1D quantum systems. Despite this progress many questions remained unresolved, including whether there exist rigorous efficient algorithms when the ground space is degenerate (and poly(n) dimensional), or for the poly(n) lowest energy states for 1D systems, or even whether such states admit succinct classical descriptions or area laws.

In this paper we give a new algorithm for finding low energy states for 1D systems, based on a rigorously justified renormalization group (RG)-type transformation. In the process we resolve some of the aforementioned open questions, including giving a polynomial time algorithm for poly(n) degenerate ground spaces and an $n^{O(\log n)}$ algorithm for the poly(n) lowest energy states for 1D systems (under a mild density condition). We note that for these classes of systems the existence of a succinct classical description and area laws were not rigorously proved before this work. The algorithms are natural and efficient, and for the case of finding unique ground states for frustration-free Hamiltonians the running time is $\tilde{O}(nM(n))$, where $M(n)$ is the time required to multiply two $n \times n$ matrices.

1 Introduction

One of the central challenges in the study of quantum many-body systems is the classical complexity of finding low energy states of local Hamiltonians. This problem is the quantum analog of constraint satisfaction problems, and is known to be QMA-complete, even for one-dimensional Hamiltonians [1]. This means that we do not even expect that there is a sub-exponential size classical description of the ground state that allows efficient computation of local observables such as the energy. In sharp contrast, the widely used heuristic density matrix renormalization group (DMRG) algorithm invented two decades ago [14] has been remarkably successful in practice on one-dimensional (1D) problems. A recent advance [8] resolved this seeming contradiction by giving a polynomial time algorithm to actually compute a succinct classical description for unique ground states of quantum systems coming from *gapped* 1D Hamiltonians.

In this paper we give a fundamentally different algorithm that applies to a significantly larger class of 1D Hamiltonians, namely:

1. *Hamiltonians with a degenerate gapped ground space:* H has smallest eigenvalue ε_0 with associated eigenspace of dimension $r = \text{poly}(n)$, and second smallest eigenvalue ε_1 such that $\varepsilon_1 - \varepsilon_0 \geq \gamma$.
2. *Gapless Hamiltonians with a low density of low-energy states:* The dimension of the space of all eigenvectors of H with eigenvalue in the range $[\varepsilon_0, \varepsilon_0 + \eta]$, for some constant $\eta > 0$, is $r = \text{poly}(n)$.

For both classes of Hamiltonians, our results show the existence of succinct representations in the form of matrix product states (MPS) for a basis for (a good approximation to) the ground space (resp. low energy subspace) of the Hamiltonian. The bond dimension of the MPS is polynomial in r and n and exponential in μ^{-1} (respectively η^{-1} in case 2). Furthermore the algorithms return these MPS descriptions in polynomial time for the first case and quasi-polynomial time in the second. For the special case of finding unique ground states for frustration-free Hamiltonians the algorithm is particularly efficient, with a running time of $\tilde{O}(nM(n))$, where $M(n)$ is the time required to multiply two $n \times n$ matrices.

Our results should be understood in the context of a substantial body of prior work studying ground state entanglement in 1D systems. Central to this work is the so-called *area law for entanglement entropy* — a conjecture which states that in ground states of gapped local Hamiltonians the entanglement entropy of a region scales as its surface area, rather than its volume. A landmark result by Hastings [5] proved this conjecture for gapped 1D systems with unique ground state, and a sequence of follow up results substantially strengthened the bounds (see, for example, the review article Ref. [4]). However, the techniques for these results break down for low energy and degenerate ground states, and few results were known for these questions: Chubb and Flammia [3] extended the approach from Ref. [8] and subsequent improvements from Ref. [6] to establish an efficient algorithm (and area law) for gapped Hamiltonians with a constant degeneracy in the ground space. Masanes [9] proves an area law with logarithmic correction under a strong assumption on the density of states, together with an additional assumption on the exponential decay of correlations in the ground state.

Our algorithm hinges on novel ideas that can be viewed as giving a rigorous underpinning to the well known Renormalization Group (RG) formalism within condensed matter physics [15]. This formalism occupies a central place in many-body physics and provides a sweeping computational approach to the "physically relevant corner of Hilbert space" by suggesting that such states can be coarse-grained at different levels of granularity, or length scales,

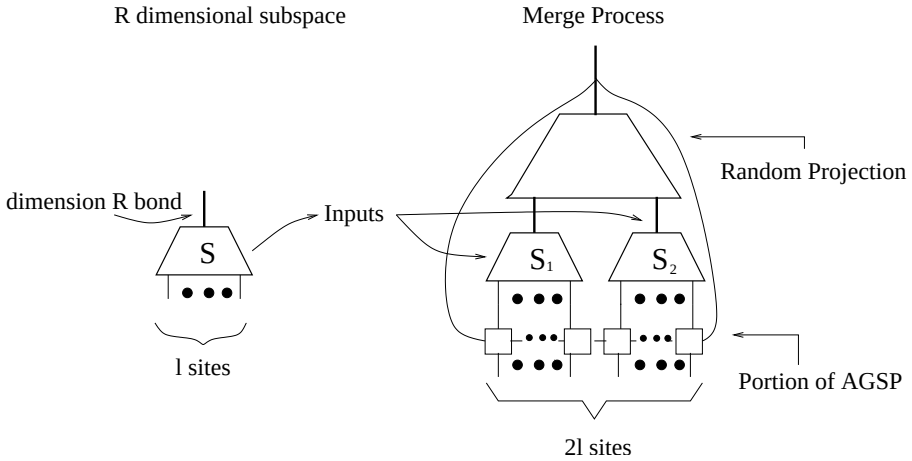
thereby iteratively eliminating the irrelevant degrees of freedom. There are recent suggestions that RG may be intimately related to feature extraction and the success of deep nets [10].

The new algorithm relies on three innovations. The first innovation starts with the idea that if our goal is to approximate a subspace T (of low energy states, say) on n qubits, the algorithm can make progress by locally maintaining a small dimensional subspace S on k particles, with the property that T is close to $S \otimes X$ where X is the entire Hilbert space on the remaining $n-k$ particles. A major challenge here is measuring the quality of this partial solution. This is accomplished by a suitable generalization of the definition of a viable set introduced in [8] to the setting of a target subspace T, and is one of the conceptual contributions of this paper.

As the number of qubits k on which the partial solution lies is increased, the fundamental challenge is to keep the dimension of the subspace S, which will otherwise naturally grow exponentially, polynomial, while maintaining the quality of the solution which will otherwise decay. To address this, we design a two step process: we deal with the dimension problem by projecting onto a small random subspace. Of course this degrades the quality i.e. blows up the error. So in turn, we control the error by the application of an AGSP, an operator with small entanglement rank which preserves low-energy states while reducing the norm of high energy states. The success of this two-step process depends upon the construction of a suitable class of AGSPs — uniform AGSPs — that ensures a favorable tradeoff between dimension and error between random projection and AGSP. The two-step process may be visualized as a (two stroke) pump: the first step (random projection) reduces the dimension, but leaves the dimension-error tradeoff essentially unchanged. The second step (AGSP) improves the dimension-error tradeoff sufficiently, so that the two steps together restore both dimension and error to their values at the start of the iteration.

The third innovation is to design an algorithm whose analysis does not rely on an area law: instead of processing one particle per iteration, it acts in parallel on all sites at each iteration, merging the results along a binary tree. Consequently, the algorithm uses only $O(\log(n))$ iterations. This is important because besides the number of quantum states stored (the dimension of the subspace S), the running time of the algorithm is also governed by the description complexity (bond dimension) of these states. The bond dimension grows exponentially with the number of iterations, yielding an $n^{O(\log n)}$ algorithm.

A tensor network picture of the resulting process, called Merge, is provided in the figure below.[1] Beginning with inputs representing subspaces of ℓ qubits shown on the left, the Merge process (shown on the right) outputs a representation of a small subspace on 2ℓ qubits.



[1] We are grateful to Christopher T. Chubb for originally suggesting these pictures to us.

The algorithm iteratively applies the Merge process. The overall construction results in a partial isometry that is reminiscent of a MERA [12, 13], and it should be fruitful to compare and contrast them as well as to standard RG. In particular, both our construction and RG build subspaces in a binary tree fashion. However, whereas RG can be realized as a tensor network on a binary tree (where each node represents the partial isometry associated with selecting only a small portion of the previous space), the use of the AGSP in our construction allows for selection of the small subspace outside the tensor product of the previous two spaces.

This hierarchical merge process establishes a new operational description of the entanglement structure of the low energy states of local Hamiltonians in 1D. It allows us to prove an area law for poly(n) degenerate ground spaces and (up to log correction) for low energy states, and is the basis of the rigorously justified RG transformation.

Our new algorithms could potentially be made very efficient. The main bottlenecks are the complexity of the AGSP and the MPS bond dimension that must be maintained. In the case of a frustration-free Hamiltonian with unique ground state we obtain a running time of $O(2^{O(1/\gamma^2)}n^{1+o(1)}\mathrm{M}(n))$, where $\mathrm{M}(n)$ is matrix multiplication time. This has an exponentially better scaling in terms of the spectral gap γ (due to avoidance of the ε-net argument) and saves a factor of $n/\log n$ (due to the logarithmic, instead of linear, number of iterations) as compared to an algorithm for the same problem considered in [6]. We speculate that it might further be possible to limit the bond dimension of all MPS considered to $n^{o(1)}$ (instead of $n^{1+o(1)}$ currently), which, if true, would imply a nearly-linear time $O(n^{1+o(1)})$ algorithm.

Organization of the paper

We start with some preliminaries and notation in Section 2. Section 3 introduces our main tool, the Merge process, and employs it to derive an area law for 1D gapped Hamiltonian with polynomial degeneracy in the ground space. In Section 4 we build on the approach to develop an efficient algorithm for the same systems. The constructions of AGSP that underlie our results, as well as the algorithm for the case of gapless Hamiltonians with a low density of low-energy states, are described in the full version of this paper [2].

2 Preliminaries and Notation

We begin by describing the basic setup for our results.

▶ **Definition 1.** Let $H = \sum_{i=1}^{n} h_i$ be a local Hamiltonian acting on the Hilbert space

$$\mathcal{H} = \mathbb{C}^d \otimes \mathbb{C}^d \otimes \cdots \otimes \mathbb{C}^d \simeq (\mathbb{C}^d)^{\otimes n}$$

associated with a 1D chain of n qudits, each of local dimension d. Each h_i is assumed to be a non-negative operator with norm at most 1 acting on the i-th and $(i+1)$-st qudits. We denote by $\varepsilon_0 \geq 0$ the smallest eigenvalue (ground energy) of H, and consider the following assumptions:

(FF) Frustration-Free: H is frustration-free ($\varepsilon_0 = 0$) with a unique ground state $|\Gamma\rangle$ and a spectral gap $\gamma > 0$ above the ground state. In this case we let $T = \mathrm{Span}\{|\Gamma\rangle\}$ denote the one-dimensional ground space of H.

(DG) Degenerate Gapped: H has a degenerate ground space T of dimension $r = \mathrm{poly}(n)$, along with a spectral gap $\gamma > 0$ above the ground space.

For $A \subseteq \{1, \cdots, n\}$ we denote the Hilbert associated with the qudits in A by $\mathcal{H}_A$, e.g. $\mathcal{H}_{[1,3]} = \mathbb{C}^d \otimes \mathbb{C}^d \otimes \mathbb{C}^d$ corresponds to the first three qudits. Separately, for any operator (Hamiltonian) H, $H_{[a,b]}$ will denote the subspace spanned by the eigenvectors of H with eigenvalues in the interval $[a, b]$. For a set S of vectors we denote by P_S the orthogonal projection onto the span of S and refer to $\dim(\mathrm{Span}(S))$ as the *size* of S, denoted $|S|$. We often identify sets of vectors with the vector space they span.

We use standard $O(\cdot), o(\cdot), \Omega(\cdot), \omega(\cdot)$ and $\Theta(\cdot)$ notation. The use of a tilde, such as $\tilde{O}(\cdot)$, will indicate a polylogarithmic overhead, i.e. $\tilde{O}(f) = O(f \operatorname{poly} \log f)$. We use $f = \mathrm{poly}(n)$ to mean that there is a fixed polynomial p such that $f(n) \leq p(n)$ for all n.

3 Viable sets, the merge process, and area laws

Recall that our goal is to formalize and analyze an RG-like transformation in the spirit of the following claim, which for ease of explanation we state for the gapped degenerate case:

▶ **Proposition 2.** *Let H be a local Hamiltonian satisfying Assumption (DG) (q.v. Definition 1).*

1. *For every length scale ℓ and contiguous block A of ℓ qudits, there is a subspace $S \subseteq \mathcal{H}_A$ of dimension $q = r^{1+o(1)} e^{\tilde{O}\left(\frac{1}{\gamma} \log^3 d\right)}$ such that S* approximates *the ground space T of H, in the following sense: every state in T has large overlap with a state whose reduced density matrix on $\mathcal{H}_A$ is supported on S.*
2. *Suppose given two subspaces $S_1 \subseteq \mathcal{H}_1$ and $S_2 \subseteq \mathcal{H}_2$ on adjacent blocks of ℓ qudits each, such that each of S_1, S_2 has dimension at most q and approximates T. Then it is possible to generate a subspace $S \subseteq \mathcal{H}_1 \otimes \mathcal{H}_2$ of the composite system that has the* same *dimension q and approximates T to the* same *extent as S_1, S_2.*

The key feature of the second item in the proposition is that the dimension of the merged set S has not increased: the set has the same size as S_1, S_2 separately, and yet it combines all the information each of these sets holds about the restriction of the ground space T to $\mathcal{H}_1$ and $\mathcal{H}_2$ respectively.

As we will see, the first item in the proposition leads naturally to an area law and succinct MPS representations for good approximations to states in T. The proof of the first item will be obtained by iteratively performing the merging procedure described in the second item. With additional work the merging procedure can be made efficient, leading to an efficient algorithm for computing these succinct representations.

3.1 Viable sets

We formalize the notion of a subspace *approximating* another as follows.

▶ **Definition 3.** A subspace T is *δ-close* to a subspace T' if

$$P_{T'} P_T P_{T'} \geq (1 - \delta) P_{T'}.$$

We say that T and T' are *mutually δ-close* if each is δ-close to the other, and denote by $\angle_m(T, T')$ the smallest δ such that T, T' are mutually δ-close.

Geometrically,

$$\angle_m(T, T') = 1 - \min_{\substack{x \in T \\ \|x\|=1}} \max_{\substack{x' \in T' \\ \|x'\|=1}} |x \cdot x'|^2$$

is the squared sine of the largest principal angle between the subspaces T and T' (where the cosines of the principal angles are given by the singular values of $P_T P'_T$); in particular the statement that T is δ-close to T' is equivalent to the fact that for every $|\psi\rangle \in T'$ there exists $|\phi\rangle \in T$ such that $|\langle\psi|\phi\rangle|^2 \geq 1-\delta$. Note that mutually close subspaces always have the same dimension.

With a view towards working with subsystems, we extend the notion of closeness to capture approximation by subspaces defined only on one half of a factored Hilbert space $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$.

▶ **Definition 4.** Given a subspace $T \subseteq \mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$, a subspace $S \subseteq \mathcal{H}_A$ is *δ-viable* for T if

$$P_T P_{S_{ext}} P_T \geq (1-\delta) P_T, \tag{1}$$

where $S_{ext} := S \otimes \mathcal{H}_B$.

This definition generalizes the definition of a viable set from Ref. [8], which was specialized to the case where T is a one-dimensional subspace containing a unique ground state. Informally it captures the notion that a reasonable approximation of T can be made using the subspace $S \otimes \mathcal{H}_B$. With the definition in place, we can make the statement of item 1 of Proposition 2 precise. For ease of exposition we relax the dependence of q on r to $\tilde{O}(r^2)$.

▶ **Theorem 5.** *Let H be a local Hamiltonian satisfying Assumption (DG). Then for any block $A \subseteq \{1,\ldots,n\}$ of $\ell \leq n$ qudits there exists a .015-viable set $S \subset \mathcal{H}_A$ for the ground space T of H of dimension at most $q = \tilde{O}(r^2) e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)}$.*

We further note that the dependence of q on the dimension r can be improved to $\tilde{O}(r)$, using a direct "bootstrapping" argument that is slightly different from the more "algorithmic" argument that we give in Section 3.3. This improved bound and bootstrapping argument are presented in the full version [2].

While the notion of viable set is quite intuitive for small δ, our arguments will also involve viable sets with parameter δ close to 1, a regime where there is less intuition. A helpful interpretation of the definition is that it formalizes the fact that for a viable set S, the image of the unit ball of S_{ext} when projected to T contains the ball of radius $(1-\delta)$.

▶ **Lemma 6.** *If S is δ-viable for T then for every $|t\rangle \in T$ of unit norm, there exists an $|s\rangle \in S_{ext}$ such that $P_T|s\rangle = |t\rangle$ and $\||s\rangle\| \leq \frac{1}{1-\delta}$.*

The proof of this and the following two useful lemmas appear in the full version [2]. The first summarizes the effect of tensoring two viable sets supported on disjoint spaces.

▶ **Lemma 7.** *Suppose S_1, S_2 are δ_1-viable and δ_2-viable for T respectively, defined on disjoint sets of qudits. Then the set $S := S_1 \otimes S_2$ is $(\delta_1+\delta_2)$-viable for T.*

The second lemma shows that our notion of closeness can be chained together and is compatible with the notion of viable set:

▶ **Lemma 8.** *If T is δ-close to T' and T' is δ'-close to T'' then T is $2(\delta+\delta')$-close to T''. Consequently if S is δ-viable for T and T is δ'-close to T' then S is $2(\delta+\delta')$-viable for T'.*

3.2 The Merge Process

We are ready to outline the merging procedure referred to in item 2 of Proposition 2, which lies at the heart of our RG transformation. Assume we are given a decomposition $\mathcal{H} = \mathcal{H}_L \otimes (\mathcal{H}_1 \otimes \mathcal{H}_2) \otimes \mathcal{H}_R$ of the global Hilbert space. The merge process **Merge** takes as input two subsets $V_1 \subseteq \mathcal{H}_1$ and $V_2 \subseteq \mathcal{H}_2$ and returns a subset $V \subseteq \mathcal{H}_1 \otimes \mathcal{H}_2$. To do so, it requires two additional inputs: a finite set of operators $\{A_i\}_{i=1}^{D^2}$ each acting on $\mathcal{H}_1 \otimes \mathcal{H}_2$, along with a positive integer s. The procedure consists of the following three simple steps.

Merge$(V_1, V_2, \{A_i\}, s)$**:**
Step 1: Tensoring. Set $W = V_1 \otimes V_2$.
Step 2: Random Sampling. Let $W' \subseteq W$ be a random s-dimensional subspace of W.
Step 3: Error Reduction. Set $V = \mathrm{Span}(\cup_i A_i W')$.
Return V.

The effectiveness of **Merge** relies on the properties of the operators $\{A_i\}$, with a sufficiently good choice of these operators leading to a formalization of item 2. of Proposition 2. Suitable operators can be obtained from the decomposition of an *approximate ground state projection* (AGSP). The detailed construction is given in the full paper [2]; the following theorem summarizes the essential properties of the resulting $\{A_i\}$.

▶ **Theorem 9** (Existence of AGSP, (DG))**.** *Let H be a local Hamiltonian satisfying Assumption (DG), and $\mathcal{H} = \mathcal{H}_L \otimes \mathcal{H}_M \otimes \mathcal{H}_R$ a decomposition of the n-qudit space in three contiguous blocks. There exists a collection of D^2 operators $\{A_i\}_{i=1}^{D^2}$ acting on $\mathcal{H}_M$ along with a subspace $\tilde{T} \subseteq \mathcal{H}$ such that:*

- $\angle_m(T, \tilde{T}) \leq .005$,
- $D = e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)}$,
- *There is $\Delta > 0$ such that $D^{12}\Delta \leq \frac{1}{2000}$ and whenever $S \subseteq \mathcal{H}_M$ is δ-viable for $\tilde{T}$ then $S' = \mathrm{Span}\{\cup_i A_i S\}$ is δ'-viable for $\tilde{T}$, with $\delta' = \frac{\Delta}{(1-\delta)^2}$.*

Given a finite collection of operators $\{A_i\}$ we denote by $\{A_i\}^k$ the set of all products of k of the A_i. The following theorem states the guarantees offered by the **Merge** process when initialized with operators $\{A_i\}$ satisfying the guarantees of Theorem 9.

▶ **Theorem 10.** *Let H be a local Hamiltonian satisfying Assumption (DG), and $\mathcal{H} = \mathcal{H}_L \otimes (\mathcal{H}_1 \otimes \mathcal{H}_2) \otimes \mathcal{H}_R$ a decomposition of the n-qudit space into contiguous blocks. Let $\{A_i\}$ and D be as in Theorem 9,*

$$s \geq 1600r(\log r + 1) \qquad \text{and} \qquad k = \frac{1}{2}\lceil \log_D(s) \rceil.$$

Let $V_1 \subseteq \mathcal{H}_1$ and $V_2 \subseteq \mathcal{H}_2$ be .015-viable subspaces for T of size $q = s^2$ each. Then with probability $1 - e^{-\Omega(s)}$ the space $V = \mathbf{Merge}(V_1, V_2, \{A_i\}^k, s)$ is .015-viable for T with $|V| \leq q$.

The proof below analyzes the effect of each of the three steps of the **Merge** process. The first creates the trivial subspace $V_1 \otimes V_2$, whose dimension $q^2 = \dim(V_1)\dim(V_2)$ is too large, and whose overlap with T is worse than desired by a factor of 2. The random sampling step roughly evenly trades off size for overlap: it picks a random s dimensional subspace for $s \ll q$, at the expense of making the overlap roughly $\frac{s}{q^2}$. Finally, the application of the AGSP (via the operators $\{A_i\}$) blows up the size from s to at most q, while increasing overlap to at least the original overlap of V_1 and V_2. This relies on the highly favorable D, Δ-tradeoff of the AGSP.

Proof. We analyze each of the three steps of the **Merge** process:

1. Tensoring. Applying Lemma 7 yields that the result of step 1, $W = V_1 \otimes V_2 \subseteq \mathcal{H}_1 \otimes \mathcal{H}_2$, is a .03 viable set for T of size q^2. Using the first condition from Theorem 9 and applying Lemma 8, W is .07-viable for $\tilde{T}$.

2. Random Sampling. We show that at the end of this step, with high probability W' is $(1-\alpha)$-viable for $\tilde{T}$ with $\alpha = (.8)s/q^2$. We accomplish this by establishing that with high probability $\|P_{W'_{ext}}|v\rangle\|^2 \geq \alpha$ for all states $|v\rangle \in \tilde{T}$, where $W'_{ext} = \mathcal{H}_L \otimes W' \otimes \mathcal{H}_R$ and $W_{ext} = \mathcal{H}_L \otimes W \otimes \mathcal{H}_R$.

Let $|v\rangle \in \tilde{T}$ have norm 1, and $|w\rangle = P_{W_{ext}}|v\rangle \in W_{ext}$. Using that W is .07-viable for $\tilde{T}$ it follows that $\||w\rangle\|^2 \geq .995$. Since $W'_{ext} \subseteq W_{ext}$, $P_{W'_{ext}}|v\rangle = P_{W'_{ext}}|w\rangle$. Applying a standard concentration argument it holds that $\|P_{W'_{ext}}|v\rangle\|^2 \geq (.9)(.995)\frac{s}{q^2}$ with probability at least $1 - q^2 e^{-s/400}$.

By a simple volume argument (see e.g. [11, Lemma 5.2]) there exists a ν-net for the Euclidean unit ball of $\tilde{T}$ consisting of at most $(1+\frac{2}{\nu})^r$ elements of $\tilde{T}$, where $\nu = \sqrt{(.1)(.9)(.995)\frac{s}{q^2}}$. Applying the preceding argument to each $|v\rangle$ in the net, a choice of s such that

$$\eta = \left(1 + \frac{2}{\nu}\right)^r q^2 e^{-s/400} < 1 \tag{2}$$

will guarantee that with probability at least $1-\eta$, $\|P_{W'_{ext}}|v\rangle\|^2 \geq (.9)(.995)\frac{s}{q^2}$ for all $|v\rangle$ in the net; hence $\|P_{W'_{ext}}|v\rangle\|^2 \geq (.99)(.9)(.995)\frac{s}{q^2} \geq .8\frac{s}{q^2}$ for all $|v\rangle \in \tilde{T}$ of unit norm. The equation (2) is satisfied with

$$s > 400\Big(2\log q + \frac{r}{2}\log\Big(1 + \sqrt{47\frac{q^2}{s}}\Big)\Big),$$

a condition verified by the choices of s and q made in the theorem.

Step 3: Error Reduction. Applying Theorem 9 k times in sequence, $V = \mathrm{Span}\{\{A_i\}^k \cdot W'\}$ is $\frac{\Delta^k}{(1-\delta)^2} = \frac{\Delta^k}{\alpha^2}$-viable for T' of size at most $D^{2k}s$. Our choice of k ensures $D^{2k}s = q$, and the relation between D and Δ implies that

$$\frac{\Delta^k}{\alpha^2} = \frac{s^6\Delta^k}{.64} = \frac{D^{12k}\Delta^k}{.64} \leq \frac{1}{(.64)}\frac{1}{2000} \leq .001.$$

Thus V is .001-viable for $\tilde{T}$, and by Lemma 8 it is $.012 < .015$-viable for T. ◀

3.3 Area law for degenerate Hamiltonians

In this section we first prove Theorem 5 establishing the claim made in the first item of Proposition 2. From the theorem we then deduce an area law for local Hamiltonians satisfying Assumption (DG) (degenerate ground space with a spectral gap; q.v. Definition 1).

Proof of Theorem 5. Consider a system A of $\ell \leq n$ consecutive qudits; for ease of notation we'll assume that ℓ is a power of 2 and A consists of the first ℓ qudits of the n-qudit chain on which H acts. The proof of the theorem is based on the following iterative procedure for constructing the .015-viable set claimed in the theorem. The procedure depends on a set of operators $\{A_i\}$ obtained from Theorem 9 for various decompositions of $\mathcal{H}$, and we let s and k be as in the theorem.

The proof of Theorem 5 follows by showing that with positive probability Procedure 1 returns a subspace $V_1^{\log \ell}$ that is .015-viable for T and such that $|V_1^{\log \ell}| = \tilde{O}(r^2)e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)}$.

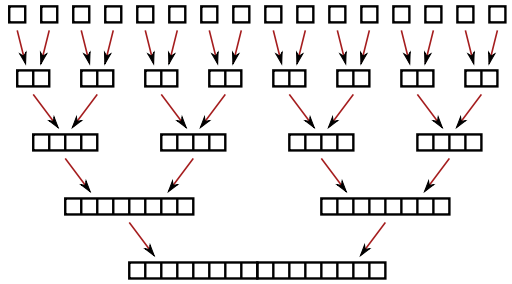


Figure 1 The parallel structure of Procedure 1. Each square represents a qudit, and successive viable sets are supported on neighboring groups of squares.

Procedure 1: Given a local Hamiltonian H satisfying(DG), returns a viable set for T supported on the first ℓ qudits.

Initialization: Set $V_j^0 = \mathcal{H}_j$ for $j = 1, 2, \ldots \ell$.

Iteration:

For $i = 1, \ldots, \log(\ell)$ do:

For all $j \in \{1, 2, \ldots \frac{\ell}{2^i}\}$, set

$$V_j^i = \textbf{Merge}(V_{2j-1}^{i-1}, V_{2j}^{i-1}, \{A_i\}^k, s) \subseteq \mathcal{H}_{[(j-1)2^i+1, j2^i]},$$

where $\{A_i\}$ are as in Theorem 9 for the decomposition

$$\mathcal{H} = \mathcal{H}_{[1,(j-1)2^i]} \otimes (\mathcal{H}_{[(j-1)2^i+1,(2j-1)2^{i-1}]} \otimes \mathcal{H}_{[(2j-1)2^{i-1}+1, j2^i]}) \otimes \mathcal{H}_{[j2^i+1,\ell]},$$

and s and k are as in Theorem 10.

Let $q = D^{2k}s$ be the size of the space output by **Merge**, and observe that by Theorem 9 it holds that $q = \tilde{O}(r^2)e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)}$. We prove the result by induction, showing that V_j^i is .015-viable for T with $|V_j^i| \leq q$ for each i, j. The initialization step establishes this for $i = 0$ since each V_j^0 is 0-viable for T with $|V_j^0| = d$. The induction step is a direct consequence of Theorem 10, which establishes that at each iteration with probability $1 - e^{-\Omega(s)}$ the set $V_j^i = \textbf{Merge}(V_{2j-1}^{i-1}, V_{2j}^{i-1}, s, \{A_i\}^k)$ is .015-viable for T with $|V_j^i| \leq q$. Each merging operation succeeds with independent probability, therefore there is a positive probability that the procedure terminates with a .015-viable set $V_1^{\log \ell}$ for T. ◀

An area law for gapped Hamiltonians with a degenerate ground space follows readily from Theorem 5. Indeed, for any desired cut Theorem 5 establishes the existence of 0.015-viable sets of size at most q for the block of qudits on either side of the cut. As a consequence each element of the ground space T has a constant approximation by a state of Schmidt rank at most q. Applying a suitable AGSP to the tensor product of two such viable sets one can obtain a δ-viable set, for any desired δ, at a modest (depending on δ) increase in size. This kind of trade-off leads to a standard proof bounding both the Schmidt rank and the von Neumann entropy across the cut for any state in the ground space. We state the result here, referring to the full version [2] for the proof.

▶ **Corollary 11** (Area law for degenerate gapped Hamiltonians). *Let H be a local Hamiltonian satisfying Assumption (DG). For any cut and any $\delta = \text{poly}^{-1}(n)$ there is subspace $S \subseteq \mathcal{H}$*

that is δ-close to T and such that every element of S has Schmidt Rank no larger than

$$s(\delta) = \tilde{O}(r^2)e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)} \cdot e^{\tilde{O}\left(\gamma^{-1/4}\log^{3/4}(\frac{1}{\delta})\log d\right)}.$$

Moreover, every state $|\psi\rangle \in T$ has entanglement entropy

$$S(|\psi\rangle\langle\psi|) \leq 4\log r + \tilde{O}\Big(\frac{1}{\gamma}\log^3 d\Big)$$

and can be approximated by a state $|\psi'\rangle$ such that $|\langle\psi|\psi'\rangle| > 1-\delta$ and $|\psi'\rangle$ has an MPS representation with bond dimension bounded by

$$\tilde{O}(r^2)e^{\tilde{O}\left(\frac{1}{\gamma}\log^3 d\right)}e^{\tilde{O}\left(\gamma^{-1/4}\log^{3/4}(\frac{n}{\delta})\log d\right)}.$$

We note that the dependence on r in the bounds for the Schmidt rank and the bond dimension of the MPS approximation can be improved from $\tilde{O}(r^2)$ to $r^{1+o(1)}$. In fact there is a simpler way of getting these bounds through a clean "bootstrapping" argument, for which we refer to the full version [2].

4 Moving to algorithms

There are two main obstacles to turning Procedure 1 into an efficient algorithm. The first consists in showing that operators $\{A_i\}$ satisfying the conditions of Theorem 9 can be generated efficiently from a description of the Hamiltonian, and that it is possible to apply these operators efficiently, as required to complete the error reduction step of the **Merge** process. The following theorem states that this can be achieved.

▶ **Theorem 12** (Efficient AGSP, (DG)). *There exists a procedure* **Generate**(H, M, ε'_M) *which takes as input*

- *A local Hamiltonian H satisfying Assumption (DG),*
- *A decomposition $\mathcal{H} = \mathcal{H}_L \otimes \mathcal{H}_M \otimes \mathcal{H}_R$ of the n-qudit space into contiguous blocks,*
- *An estimate ε'_M for the minimal energy ε_M of the restriction of H to $\mathcal{H}_M$ such that $|\varepsilon_M - \varepsilon'_M| \leq 10$,*

and returns

- *MPO representations for a collection of D^2 operators $\{A_i\}_{i=1}^{D^2}$ acting on $\mathcal{H}_M$ and of bond dimension at most $n^{\tilde{O}(\gamma^{-2})}$ satisfying the conditions of Theorem 9 for some subspace $\tilde{T}$,*
- *An MPO for an operator $\tilde{H}_M$ such that $\|\tilde{H}_M\| = O(\gamma^{-1}\log\gamma^{-1})$ and the minimal energy $\tilde{\varepsilon}_M$ of $\tilde{H}_M$ restricted to $\tilde{T}$ satisfies $|\varepsilon_M - \tilde{\varepsilon}_M| < 1/2$.*

Moreover, **Generate**(H, M, ε'_M) *runs in time $n^{\tilde{O}(\gamma^{-2})}$.*[2]

The proof of Theorem 12 relies on new constructions of approximate ground state projections (AGSP), details of which are given in the full version [2]. The theorem guarantees that the $\{A_i\}$ can be constructed efficiently *provided* it is possible to provide a good approximation to the ground state energy of the restriction of H to $\mathcal{H}_M$. This is the reason for including $\tilde{H}_M$ as parts of the output of **Generate** , which is then used by an additional step of *energy estimation* incorporated in Algorithm 2.

[2] Here and in all our estimates on running times we suppress dependence on the local dimension d, which is treated as a constant.

Algorithm 2: Given a local Hamiltonian H satisfying Assumption (GS), returns a set $V_1^{\log n}$ that is 0.015-close to the ground space T of H.

Initialization: Set $V_j^0 = \mathcal{H}_j$ and $\varepsilon'_{0,j} = 0$ for $j \in \{1, 2, \dots n\}$.

Iteration:

For $i = 1, \dots, \log(n)$ and $j \in \{1 \dots \frac{n}{2^i}\}$ do:

Generate. Let $M = \{(j-1)2^i, (j-1)2^i + 1, \dots, j2^i - 1\}$, $\varepsilon'_M = \varepsilon'_{i-1,2j-1} + \varepsilon'_{i-1,2j}$. Set $(\{A_i\}, \tilde{H}_M) = \mathbf{Generate}(H, M, \varepsilon'_M)$.

Merge. Set $V_j^i = \mathbf{Merge'}(V_{2j-1}^{i-1}, V_{2j}^{i-1}, \{A_i\}, s, k, \xi) \subseteq \mathcal{H}_{[(j-1)2^i+1, j2^i]}$, where s and k are specified in Theorem 10 and $\xi = \text{poly}^{-1}(n, r)$ is chosen small enough (see proof of Theorem 13).

New Energy Estimation. Form the subspace $V = \{A_i\}^t \cdot (V_{2j-1}^{i-1} \otimes V_{2j}^{i-1})$ for $t = \Theta(\log \gamma^{-1})$. Compute the smallest eigenvalue $\varepsilon'_{i,j}$ of the restriction of $\tilde{H}_M$ to V.

Final step: Return $V_1^{\log n}$.

The second difficulty encountered in turning Procedure 1 into an algorithm is that, even if the $\{A_i\}$ can be applied efficiently, due to the logarithmic number of iterations it may be that the bond dimension of MPS representations for the elements of the viable sets we work with increase to super-polynomial. This difficulty can be overcome by introducing a *bond trimming* component Trim_ξ to the **Merge** procedure, resulting in the following modified procedure **Merge**' taking an additional trimming parameter ξ as input (ξ will usually be of order $\text{poly}^{-1}(n)$):

Merge'$(V_1, V_2, \{A_i\}, s, k, \xi)$:

Step 1: Tensoring. Set $W = V_1 \otimes V_2$.

Step 2: Random Sampling. Let $W' \subseteq W$ be a random s-dimensional subspace of W.

Step 3: Error Reduction. Set $V = W'$. Repeat k times:

Set $V = \text{Trim}_\xi(\text{Span}(\cup_i A_i V))$.

Return V.

Correctness of **Merge**' (for an appropriate choice of ξ) is based on the area law proven in Corollary 11. The details of the trimming[3] procedure Trim_ξ, together with the analysis of **Merge**', are given in the full paper [2].

The following theorem proves the correctness of Algorithm 2.

▶ **Theorem 13.** *Let H be a local Hamiltonian satisfying Assumption (DG). Then with probability at least $1 - \frac{1}{n}$ the set $V_1^{\log n}$ returned by Algorithm 2 is 0.015-viable for T.*[4] *The running time of the algorithm is $n^{\tilde{O}(\gamma^{-2})}$.*

Proof. The proof mirrors the analysis of Procedure 1 given in the proof of Theorem 5 in Section 3.3; the two main differences are that we must show that at every step, with high enough probability the call to **Merge**' yields a good viable set and the **New Energy Estimation** step yields a sufficiently accurate energy estimate for the next iteration.

[3] We note that the trimming procedure differs from that of [8]

[4] The probability of success can be improved to $1 - \text{poly}^{-1}(n)$ by scaling the parameter s used in the algorithm by an appropriate constant.

Both conditions are satisfied at initialization since each V_j^0 is 0-viable for T with $|V_j^0| = d$ and the energy estimates are accurate since there are no terms of the Hamiltonian when restricting to single particles.

Assume V_{2j-1}^{i-1} and V_{2j}^{i-1} are both .015-viable for T with $|V_{2j-1}^{i-1}|, |V_{2j}^{i-1}| \leq q$, and $\varepsilon'_{i-1,2j-1}$, $\varepsilon'_{i-1,2j}$ both within an additive ± 3 of their respective true values (the ground state energy of the restriction of H to the corresponding spaces). As a result ε'_M is within 7 of the correct value ε_M, and by Theorem 12 **Generate** yields a set $\{A_i\}$ with the properties stated in Theorem 9. Thus by Theorem 10 V_j^i is .015-viable for T with probability $1 - e^{-\Omega(s)} \geq 1 - \frac{1}{n^2}$ (provided $r \geq \log n$, which we may always assume without loss of generality). For this we need to check Theorem 10 still applies when **Merge** is replaced by **Merge**' . The analysis of the trimming procedure given in [2] shows that this is the case provided the error reduction parameter Δ associated with the $\{A_i\}$ is replaced by $(\Delta + 2\sqrt{krs}\xi)$; choosing $\xi = \text{poly}^{-1}(n, r)$ we may ensure that $2\sqrt{krs}\xi < .0001D^{-12}$. With this choice, the remaining calculation of 10 applies to still yields that V_j^i is .015-viable for T.

Once this has been established, an application of the third item from Theorem 9 shows that provided the constant implicit in the definition of t is chosen large enough the subpace V obtained after the **New Energy Estimation** step is $O(\gamma^2)$-viable for $\tilde{T}$. Using that $\|\tilde{H}_M\| = O(\gamma^{-1} \log \gamma^{-1})$ it follows that $\varepsilon'_{i,j}$ is within an arbitrarily small constant of the minimal energy of $\tilde{H}_M$ restricted to $\tilde{T}$. Using the last guarantee from Theorem 12, $\varepsilon'_{i,j}$ is within $\frac{3}{2}$ of the minimal energy ε_M of the restriction of H to $\mathcal{H}_M$. This completes the inductive step.

We have shown that the iterative step succeeds with probability at least $1 - 1/n^2$; since there are a total of n such merging steps, applying a union bound the final set $V_1^{\log n}$ is .015-viable with probability at least $1 - \frac{1}{n}$.

In total the complete algorithm requires only a polynomial number of operations on MPS representations of vectors. Due to trimming, all these vectors have polynomial bond dimension and thus each operation can be implemented in polynomial time. The complexity is dominated by the complexity of the procedure **Generate** and the application of the operators A_i, which is $n^{\tilde{O}(\gamma^{-2})}$. ◀

We end this section by noting that in case one desires a better than constant approximation to T the final step of Algorithm 2 can be replaced by the following:

Final step. Set $K = (\mathbb{1} - H/\|H\|)$ and $\tau = 10\|H\|\gamma^{-1} \log(1/\delta)$. Choose an orthonormal basis $\{|y_i^{(0)}\rangle\}$ for $V_1^{\log n}$. Repeat for $t = 1, \ldots, \tau$:

Set $\{|y_i^{(t)}\rangle\} = \text{Trim}_\xi(\text{Span}\{K|y_i^{(t-1)}\rangle\})$.

Return $\{|z_i\rangle\}$, the smallest r eigenvectors of H restricted to $W = \text{Span}\{|y_i^{(\tau)}\rangle\}$.

The result of this step is a basis $\{|z_i\rangle\}$ for a subspace S such that $\angle_m(S, T) \leq \delta$.

Frustration-free Hamiltonians with a unique ground state

The computation-intensive step of the AGSP-based RG transformation introduced in Section 3 is the construction and subsequent application of the set of operators $\{A_i\}$. In the special case where the Hamiltonian H satisfies Assumption (FF), i.e. H is frustration-free and has a spectral gap, the operators $\{A_i\}$ can be constructed very efficiently, yielding strong bounds on the running time. We state a specialized theorem for this setting. The proof is given in the full version [2].

Algorithm 3: Given a local Hamiltonian H satisfying Assumption (FF), returns a δ-approximation to its ground state $|\Gamma\rangle$.

Initialization: Set $V_j^0 = \mathcal{H}_j$ for $j \in \{1, 2, \dots n\}$.

Iteration:

For $i = 1, \dots, \log(n)$ and all $j \in \{1, \dots, \frac{n}{2^i}\}$,

Generate. Let $M = \{(j-1)2^i, (j-1)2^i + 1, \dots, j2^i - 1\}$.

Set $\{A_i\} =$ **Generate 2**(H, M).

Merge. Set $V_j^i =$ **Merge'**$(V_{2j-1}^{i-1}, V_{2j}^{i-1}, \{A_i\}, s, k, \xi) \subseteq \mathcal{H}_{[(j-1)2^i+1, j2^i]}$, where k, s are as in Theorem 10 (with $r = 1$) and $\xi = \tilde{\Theta}(n^{-1/2})$.

Final step:

Let K be the unique operator A computed at the last iteration, and $\tau = 10\|H\|\gamma^{-1}\log(1/\delta)$. Choose an orthonormal basis $\{|y_i^{(0)}\rangle\}$ for $V_1^{\log n}$. Repeat for $t = 1, \dots, \tau$:

Set $\{|y_i^{(t)}\rangle\} = \mathrm{Trim}_\xi(\mathrm{Span}\{|Ky_i^{(t-1)}\rangle\})$, for $\xi = \tilde{\Theta}(n^{-1/2})$.

Return the smallest eigenvector $|z\rangle$ of H restricted to $W = \mathrm{Span}\{|y_i^{(\tau)}\rangle\}$.

▶ **Theorem 14** (Efficient AGSP, (FF))**.** *Let H be a local Hamiltonian satisfying Assumption (FF), and $\mathcal{H} = \mathcal{H}_L \otimes \mathcal{H}_M \otimes \mathcal{H}_R$ a decomposition of the n-qudit space into contiguous regions. There exists a procedure* **Generate 2**(H, M) *which takes as input*

- *A local Hamiltonian H satisfying Assumption (DG),*
- *A decomposition $\mathcal{H} = \mathcal{H}_L \otimes \mathcal{H}_M \otimes \mathcal{H}_R$ of the n-qudit space into contiguous blocks,*

and returns MPO representations for a collection of D^2 operators $\{A_i\}_{i=1}^{D^2}$ acting on $\mathcal{H}_M$ such that the following hold:

- $D = 2^{\tilde{O}(\gamma^{-1}\log^3 d)}$
- *There is $\Delta > 0$ such that $D^{12}\Delta < \frac{1}{2000}$ and for any $S \subseteq \mathcal{H}_M$ that is δ-viable for $\{|\Gamma\rangle\}$ it holds that $S' = \mathrm{Span}\{\cup_i A_i S\}$ is δ'-viable for T with $\delta' = \frac{\Delta}{(1-\delta)^2}$.*
- *Each A_i has bond dimension at most $2^{\tilde{O}(\gamma^{-2}\log^5 d)}$.*

Moreover, for constant d and $\gamma > 0$ the procedure **Generate 2**(H, M, ε'_M) *runs in time $n^{(1+o(1))}$.*

We note that in the case where M consists of all n qudits the procedure returns a single operator A acting on the whole space. Algorithm 3 is an adaptation of Algorithm 2 to the case of frustration-free Hamiltonians.

▶ **Theorem 15.** *Let H be a local Hamiltonian satisfying Assumption (FF) and $\delta = n^{-\omega(1)}$. With probability at least $1 - \frac{1}{n}$ the vector $|z\rangle$ returned by Algorithm 3 is such that $|\langle z|\Gamma\rangle| \geq 1 - \delta$. Moreover the algorithm runs in time $O(n^{1+o(1)}\mathrm{M}(n))$, where $\mathrm{M}(n) = O(n^{2.38})$ denotes matrix multiplication time.*

The proof follows the same outline as that of Theorem 13 analyzing Algorithm 2, and we refer to the full version [2] for details. We note that in [7], Huang gives a very simple, though less efficient, algorithm for this frustration free case, by adding one particle at a time and within each step randomly projecting onto a one dimensional space followed by application of an AGSP.

Abstract

In two-party interactive quantum communication protocols, we study a recently defined notion of quantum information cost (QIC), which has most of the important properties of its classical analogue (IC). Notably, its link with amortized quantum communication complexity has been used to prove an (almost) tight lower bound on the bounded round quantum complexity of Disjointness. However, QIC was defined through a purification of the input state. This is valid for fully quantum inputs and tasks but difficult to interpret even for classical tasks. Also, its link with other notions of information cost that had appeared in the literature was not clear.

We settle both these issues: for quantum communication with classical inputs, we characterize QIC in terms of information about the input registers, avoiding any reference to the notion of a purification of the classical input state. We provide an operational interpretation of this new characterization as the sum of the costs of revealing and of forgetting information about the inputs. To obtain this result, we prove a general Information Flow Lemma assessing the transfer of information in general interactive quantum processes. Specializing this lemma to interactive quantum protocols accomplishing classical tasks, we are able to demistify the link between QIC and other previous notions of information cost in quantum protocols. Furthermore, we clarify the link between QIC and IC by simulating quantumly classical protocols.

Finally, we apply these concepts to argue that any quantum protocol that does not forget information solves Disjointness on n-bits in $\Omega(n)$ communication, completely losing the quadratic quantum speedup. Hence forgetting information is here a necessary feature in order to obtain any significant improvement over classical protocols. We also prove that QIC at 0-error is exactly n for Inner Product, and $n(1 - o(1))$ for a random Boolean function on $n + n$ bits.

Abstract

An ideal system of n qubits has 2^n dimensions. This exponential grants power, but also hinders characterizing the system's state and dynamics. We study a new problem: the qubits in a physical system might not be independent. They can "overlap," in the sense that an operation on one qubit slightly affects the others.

We show that allowing for slight overlaps, n qubits can fit in just polynomially many dimensions. (Defined in a natural way, all pairwise overlaps can be $\leq \epsilon$ in $n^{O(1/\epsilon^2)}$ dimensions.) Thus, even before considering issues like noise, a real system of n qubits might inherently lack any potential for exponential power.

On the other hand, we also provide an efficient test to certify exponential dimensionality. Unfortunately, the test is sensitive to noise. It is important to devise more robust tests on the arrangements of qubits in quantum devices.

1 Introduction

Quantum computers start with the qubit, a two-level quantum system. They achieve their power by combining many qubits. A system of n independent qubits is associated to a 2^n-dimensional tensor-product space, $(\mathbf{C}^2)^{\otimes n}$, and quantum algorithms exploit this exponential dimensionality. However, with great power also comes great guile. In experiments, it is exceedingly difficult to characterize the states and dynamics of large quantum systems. An efficient test, running in polynomial time, can only probe a limited portion of an exponentially complex system.

Before getting to state or process tomography, however, there is the problem of characterizing the system's Hilbert space, and the arrangement of the qubits within it. In particular, what if the qubits are not in tensor product, but "overlap," so an operation on one qubit

can slightly affect the others? Given a system that supposedly has n independent qubits, how can we efficiently test that there really are 2^n dimensions? Unfortunately, we show that very small systems, with only polynomially many dimensions, can contain n qubits that are nearly pairwise independent, i.e., an operation on qubit i can have only a small effect on qubit j for all $i \neq j$. In fact, there are particular states in n^2-dimensional systems for which n qubits look to be exactly pairwise independent, in tensor product. (We will give more technical statements of these results in a moment.)

The issue of overlapping qubits is a new concern for the characterization of quantum devices. A common complaint about today's quantum devices, especially those targeted at adiabatic quantum optimization or quantum annealing, is that it is difficult even to verify their quantum-ness [1]. High noise rates can decohere systems, making them classical. Our examples raise a different problem: a system might indeed be quantum mechanical and even look like it has many qubits, but still quantum power is lacking because the system is low-dimensional.

On the other hand, we show that low-dimensional systems cannot totally fool us. First, if all pairs among n qubits are sufficiently close to being independent, then in fact there are nearby qubits that are exactly independent (in tensor product); and hence the dimension must be at least 2^n. Second, we provide a test for independence, one that efficiently checks not just pairwise interactions but n-wise interactions, and thereby can verify that the system dimension is almost 2^n. The test only involves measuring the qubits one at a time, so it is conceivably practical—except it is still sensitive to noise.

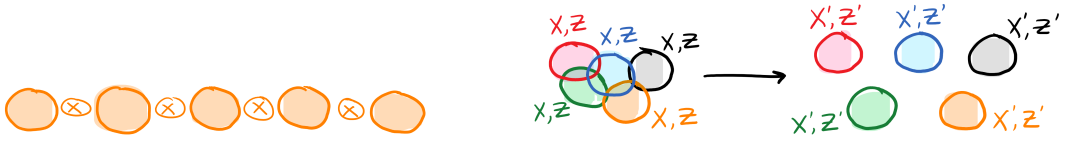
Overlapping qubits

The concept of overlapping, dependent qubits is not standard in quantum information theory. In general, multiple qubits are always assumed to be in tensor product; in common usage n qubits directly means $(\mathbf{C}^2)^{\otimes n}$. However, though it may be invisibly built into our notation and habits of thought, this is in fact an independence assumption, which needs to be justified. Precisely, then, what is a qubit, and what does it mean for two qubits to overlap?

1. What is a qubit? A qubit in a space $\mathcal{H}$ is a two-dimensional register in tensor product with the rest of the space. That is, from an isomorphism between $\mathcal{H}$ and $\mathbf{C}^2 \otimes \mathcal{H}'$, the $\mathbf{C}^2$ register defines a qubit. Since the basis for $\mathcal{H}'$ does not matter, instead of specifying the isomorphism it is more convenient to work in the dual Heisenberg picture, in which a qubit is defined through the observables that act on it, an algebra generated by the four Pauli matrices. In fact, a pair of norm-one observables X and Z that anti-commute suffice to define a qubit; it is then possible to choose a basis in which $X = \sigma^x \otimes \mathbf{1}_{\mathcal{H}'}$ and $Z = \sigma^z \otimes \mathbf{1}_{\mathcal{H}'}$, where σ^x and σ^z are the standard Pauli operators (see Lemma 2.2).
2. Two qubits are independent, or in tensor product, when all operators on the qubits commute. Thus n qubits, defined by anti-commuting X_j, Z_j for $j = 1, \ldots, n$, are pairwise independent if $[X_i, X_j] = [X_i, Z_j] = [Z_i, Z_j] = 0$ for all $i \neq j$. It follows that there is a change of basis under which $\mathcal{H} = (\mathbf{C}^2)^{\otimes n} \otimes \mathcal{H}'$ and $X_j = \sigma_j^x \otimes \mathbf{1}_{\mathcal{H}'}$, $Z_j = \sigma_j^z \otimes \mathbf{1}_{\mathcal{H}'}$ (Theorem 2.3).

When are two qubits "almost" independent? For qubits specified by reflections X_1, Z_1 and X_2, Z_2, how close they are to lying in tensor product can be measured by the largest commutator norm, $\max_{S,T \in \{X,Z\}} \|[S_1, T_2]\|$.

Almost independence is a useful concept because in reality one can never probe for the existence of n independent qubits. The exact tensor-product structure of a Hilbert space cannot be experimentally tested. Due to inevitable measurement imprecision, one



(a) (b)

Figure 1 (a) A qubit is a two-dimensional system in tensor product with the rest of the space. Qubits "overlap" if the corresponding Pauli operators do not commute. When their Pauli operators do commute, the qubits are in tensor product with each other (Theorem 2.3). (b) We ask how many qubits can be packed into a 2^n dimensional space with small pairwise overlap. For a lower bound, we give a randomized construction, based on the Johnson-Lindenstrauss Lemma and fermion algebra (Theorem 3.1). For an upper bound, we separate qubits with small pairwise overlap, finding nearby qubits with zero overlap (Theorem 3.6).

could at best hope to show approximate relations, like $\|[S_i, T_j]\| \leq \epsilon$. This concept is also mathematically well-motivated. It amounts to studying approximate representations of the n-qubit Pauli group.[1] It can alternatively be tied to questions on the stability of relations defining the Pauli algebra [10].

Our results

We begin by asking: how many overlapping qubits can be packed into 2^n dimensions? We prove both lower and upper bounds. Of course, only n independent qubits fit.

For the lower bound, we give a randomized construction, based on the Johnson-Lindenstrauss lemma, for packing many nearly orthogonal unit vectors, and on the exterior algebra. We show that exponential in n many qubits can be packed with pairwise overlaps $\|[S_i, T_j]\|$ of order $\sqrt{(\log n)/n}$. In general, for overlaps $\|[S_i, T_j]\| \leq \epsilon$, $e^{O(n\epsilon^2)}$ qubits can be packed into 2^n dimensions; see Theorem 3.1. Parameterized differently, the construction places n ϵ-overlapping qubits in only $n^{O(1/\epsilon^2)}$ dimensions.

Note that this construction does not allow for compressing information. Even though exponentially many nearly independent qubits can be packed into $(\mathbf{C}^2)^{\otimes n}$, this does not allow for reliably storing more than n bits, and thus does not violate Nayak's private information retrieval bound [14]. If one tried to store $\gg n$ bits into $(\mathbf{C}^2)^{\otimes n}$ by putting a bit into each of the embedded qubits, one at a time, by the end the early bits would be unrecoverable because of accumulated errors.

For the upper bound, we show that even allowing pairwise overlaps $\|[S_i, T_j]\|$ as large as c/n, for a certain constant c, there is still room only for n qubits in 2^n dimensions. The precise statement is in Theorem 3.6. The proof constructively extracts n independent qubits from n overlapping qubits. The key difficulty is to ensure that errors do not explode; naively separating, say, the second qubit from the first could double its overlap with each of the remaining qubits, yielding an unmanageable exponential blow-up in the total displacement needed to separate the qubits. See Figure 1.

The construction in the upper bound loses a factor of n, and we give an example to show that this is necessary (Lemma 3.9). Yet there is still a gap between our lower and upper bounds. For the range of overlaps $1/n \lesssim \epsilon \lesssim \sqrt{(\log n)/n}$, we do not know whether strictly more than n qubits can be packed into 2^n dimensions.

[1] We caution that there does not seem to be a standard definition for an approximate group representation in the mathematical literature; see, e.g., [3, 13] for work in this direction.

Given access to an experimental system, it is difficult to imagine tests for determining $\|[S_i, T_j]\|$. The problem is that the quantum system can be in an unknown state $|\psi\rangle$, and we can only learn about operators' effects on $|\psi\rangle$. If S_i and T_j are far from commuting, but only on a portion of the Hilbert space in which $|\psi\rangle$ has no support, this is undetectable. In Section 4, we therefore consider a *state-dependent* overlap measure. This is the same measure that is used in results on self-testing such as [11, 12], and it is the relevant measure for applications to device-independent cryptography [8]. Note however that our setting differs from the usual one in self-testing, as we do not assume any a priori bipartite structure on the Hilbert space.

We first give a practical protocol for testing if $\|[S_i, T_j]|\psi\rangle\| \approx 0$: measure S_i, measure T_j, then measure S_i again and check that it gives the same result. However, this test is not enough; we give a construction of a state and n qubit operators in $< n^2$ dimensions, such that for $i \neq j$, $[S_i, T_j]|\psi\rangle = 0$ exactly. Finally we give a more advanced test that efficiently checks not just pairwise commutation relationships, like $[S_i, T_j]|\psi\rangle \approx 0$, but also higher-order relationships like $S_i T_j U_k|\psi\rangle \approx U_k T_j S_i|\psi\rangle$. This test can verify that the system dimension is almost 2^n.

2 What is a qubit? When are qubits in tensor product?

As explained in the introduction, we take a basis-independent, operator-centric view of what it means to have a qubit, or multiple independent qubits, in an a priori unstructured Hilbert space $\mathcal{H}$. The following definition formalizes these notions. Notation: Let $[n] = \{1, 2, \ldots, n\}$, and $I = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$, $\sigma^x = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma^y = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$ and $\sigma^z = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ be the Pauli matrices. The commutator is $[S, T] = ST - TS$, and the anticommutator is $\{S, T\} = ST + TS$. When we write, e.g., "S_j for $S \in \{X, Z\}$" we mean the set $\{X_j, Z_j\}$, i.e., the letter S is meant to be directly replaced by X or Z.

▶ **Definition 2.1.** A *qubit* in a Hilbert space $\mathcal{H}$ is a pair of anti-commuting reflections (X, Z) on $\mathcal{H}$. The *overlap* between two qubits (X_1, Z_1) and (X_2, Z_2) is given by $\max_{S,T \in \{X,Z\}} \|[S_1, T_2]\|$. The qubits are in *tensor product* if they have overlap 0; in this case we also say that the qubits are *independent*.

The following simple lemma ties this definition to the more usual one of a qubit as defined by a factorization $\mathcal{H} \simeq \mathbf{C}^2 \otimes \mathcal{H}'$. The lemma is a special case of Theorem 2.3 below.

▶ **Lemma 2.2.** *Let X and Z be reflections (Hermitian operators that square to the identity) on a separable Hilbert space $\mathcal{H}$ such that X and Z anti-commute: $\{X, Z\} = 0$. Then there exists a separable space $\mathcal{H}'$ such that $\mathcal{H}$ is isomorphic to $\mathbf{C}^2 \otimes \mathcal{H}'$, and up to a unitary change of basis the reflections X, Z are the standard Pauli operators:*

$$X = \sigma^x \otimes \mathbf{1}_{\mathcal{H}'}, \qquad Z = \sigma^z \otimes \mathbf{1}_{\mathcal{H}'} \ .$$

The following theorem justifies our definition of two qubits being in "tensor product" when their overlap is 0, or equivalently when the associated reflections pairwise commute.

▶ **Theorem 2.3.** *Suppose that $X_1, Z_1, \ldots, X_n, Z_n$ are reflections on $\mathcal{H}$ such that for all j, $\{X_j, Z_j\} = 0$ and furthermore for all $i \neq j$ and $S, T \in \{X, Z\}$, S_i and T_j pairwise commute, $[S_i, T_j] = 0$. Then there exists a separable space $\mathcal{H}''$ such that $\mathcal{H}$ is isomorphic to $(\mathbf{C}^2)^{\otimes n} \otimes \mathcal{H}''$, and up to a unitary change of basis the reflections X_j, Z_j are the standard Pauli operators on n qubits:*

$$X_1 = \sigma^x \otimes I^{\otimes(n-1)} \otimes \mathbf{1}_{\mathcal{H}''} \qquad \cdots \qquad X_n = I^{\otimes(n-1)} \otimes \sigma^x \otimes \mathbf{1}_{\mathcal{H}''}$$
$$Z_1 = \sigma^z \otimes I^{\otimes(n-1)} \otimes \mathbf{1}_{\mathcal{H}''} \qquad \cdots \qquad Z_n = I^{\otimes(n-1)} \otimes \sigma^z \otimes \mathbf{1}_{\mathcal{H}''} \ .$$

Proof. Let $X = X_1$, $Z = Z_1$. As $Z^2 = \mathbf{1}$, $\Pi_\pm = \frac{1}{2}(\mathbf{1} \pm Z)$ are projections, with $\Pi_+ + \Pi_- = \mathbf{1}$, $\Pi_+ - \Pi_- = Z$ and $\Pi_+\Pi_- = \Pi_-\Pi_+ = 0$. Multiplying both sides of $\{X, Z\} = 0$ by $\Pi_\pm$ yields $\Pi_\pm X \Pi_\pm = 0$, i.e., $X = \Pi_+ X \Pi_- + \Pi_- X \Pi_+$. Then $X^2 = \mathbf{1}$ implies that $\Pi_\pm X \Pi_\mp X \Pi_\pm = \Pi_\pm$; and comparing the ranks of both sides gives $\mathrm{Rank}(\Pi_\mp) \geq \mathrm{Rank}(\Pi_\pm)$, i.e., $\mathrm{Rank}(\Pi_+) = \mathrm{Rank}(\Pi_-)$.

Let $|u_1^\pm\rangle, |u_2^\pm\rangle, \ldots$ be an orthonormal basis for $\mathrm{Range}(\Pi_\pm)$. Let $S = \sum_j (|u_j^+\rangle\langle u_j^-| + |u_j^-\rangle\langle u_j^+|)$. Then $S = S^\dagger$, $S^2 = \mathbf{1}$ and $S\Pi_\pm = \Pi_\mp S$. Let $U = \Pi_+ X \Pi_- S + \Pi_-$. U is unitary: $UU^\dagger = U^\dagger U = \mathbf{1}$. Furthermore, $U^\dagger Z U = Z$, and $U^\dagger X U = S$. Relabeling the basis elements $|0, j\rangle = |u_j^+\rangle$, $|1, j\rangle = |u_j^-\rangle$, we obtain $U^\dagger Z U = \sigma^z \otimes \mathbf{1}$ and $U^\dagger X U = \sigma^x \otimes \mathbf{1}$, as desired.

Now consider X_2. In the above basis, it can be expanded as $I \otimes A + \sum_{\beta \in \{x,y,z\}} \sigma^\beta \otimes B_\beta$, but the commutation relationships $[X_2, X_1] = [X_2, Z_1] = 0$ imply that each $B_\beta = 0$. Similarly, all the reflections $Z_2, \ldots, X_n, Z_n$ act trivially on the first $\mathbf{C}^2$ register. Inductively repeating the above argument for X_1 and Z_1 gives the theorem. ◀

Registers that are in tensor product are independent of each other, in the sense that for a quantum state $|\psi\rangle \in \mathcal{H}' \otimes \mathcal{H}''$, a quantum operation on $\mathcal{H}'$ cannot affect the reduced density matrix $\mathrm{Tr}_{\mathcal{H}'} |\psi\rangle\langle\psi|$ in the other register. It should be noted, though, that a qubit can simultaneously have maximal overlap with many other mutually independent qubits. For example, for n odd, $X = (\sigma^x)^{\otimes n}$ and $Z = (\sigma^z)^{\otimes n}$ are anti-commuting reflections, defining a qubit, such that for every $j \in [n]$, $\|[X, \sigma_j^z]\| = \|[Z, \sigma_j^x]\| = 2$. (Similarly, in $(\mathbf{C}^2)^{\otimes n}$, for a Haar random unitary U, $\|[U\sigma_1^\alpha U^\dagger, \sigma_j^\beta]\|$ will be concentrated around the maximal value of 2.) Thus the norm of the reflections' commutator is not a "monogamous" measure of qubit overlap.

3 Packing qubits

How many pairwise ϵ-overlapping qubits can be packed into 2^n dimensions? Formally, in 2^n dimensions, we wish to place $2m$ reflections $(X_1, Z_1), \ldots, (X_m, Z_m)$ such that each pair (X_j, Z_j) defines a qubit, so that $\{X_j, Z_j\} = 0$, and operators with different indices nearly commute: $\|[S_i, T_j]\| \leq \epsilon$ for $i \neq j$ and $S, T \in \{X, Z\}$. How large can m be?

One's intuition might be pulled in either of two directions. From the perspective of information theory, Nayak's private information retrieval bound $m \leq n/(1 - H(p))$ [14] suggests that packing $\omega(n)$ qubits into 2^n dimensions is unlikely to be possible. However, a formal connection between our problem and private information retrieval is not obvious: the existence of m pairs of approximately commuting qubit operators does not imply that there exists a family of 2^m states that could be used to encode m bits with a good probability of recovery.

From a geometric perspective the problem can be viewed as one of packing subspaces. Each reflection R_j is about a certain subspace, projected to by $\frac{1}{2}(I + R_j)$. As explained in the previous section, the anticommutation condition implies that X_j and Z_j correspond to subspaces with all principal angles $\pi/4$, while the approximate commutation condition $\|[S_i, T_j]\| \leq \epsilon$ translates into the corresponding subspaces making principal angles close to 0 or $\pi/2$. By analogy to the problem of packing nearly orthogonal unit vectors[2] one might guess that as long as ϵ is not required to go to 0 too fast with n, m can be exponential in n.

The results in this section demonstrate that the geometric intuition is more accurate. Theorem 3.2 shows that for sufficiently small ϵ (inverse linear in n), no more than $m \leq n$

[2] For vector packing upper bounds on m, see, e.g., [7], [2, Lemma 9.1], [15].

ϵ-overlapping qubits can fit in 2^n dimensions. In contrast, Theorem 3.1 shows that as long as $\epsilon = \Omega(1)$, m can be exponential in n; more generally $m = \omega(n)$ for any $\epsilon = \omega(\sqrt{(\log n)/n})$. For the range of overlaps $1/n \lesssim \epsilon \lesssim \sqrt{(\log n)/n}$, we do not know whether strictly more than n qubits can be packed into 2^n dimensions.

3.1 Lower bound: packing exponentially many qubits in 2^n dimensions

We give a randomized construction that packs $m = e^{\Theta(n\epsilon^2)}$ qubits into 2^n dimensions. This beats the trivial $m = n$ for $\epsilon = \Omega(\sqrt{(\log n)/n})$, and is exponential in n for constant $\epsilon > 0$.

▶ **Theorem 3.1.** *There exist 2^n-dimensional reflections $X_1, Z_1, \ldots, X_m, Z_m$, for $m = e^{\Omega(n\epsilon^2)}$, such that $\{X_j, Z_j\} = 0$ and $\|[S_i, T_j]\| = O(\epsilon)$ for all $i \neq j$ and $S, T \in \{X, Z\}$.*

Proof. By the Johnson-Lindenstrauss Lemma [6, 5], $e^{n\epsilon^2/4}$ unit vectors can be chosen in $\mathbf{R}^{2n}$ so that for any pair $|u\rangle, |v\rangle$, $|\langle u|v\rangle| \leq \epsilon$. Collecting these vectors in triples, we obtain $m = \frac{1}{3}e^{n\epsilon^2/4}$ three-dimensional subspaces with the angles between any two in the range $[\frac{\pi}{2} - O(\epsilon), \frac{\pi}{2}]$. Let $\{|e_j\rangle, |f_j\rangle, |g_j\rangle\}$, for $j \in [m]$, be orthonormal bases for the subspaces.

Let $C_1, \ldots, C_{2n}$ denote a 2^n-dimensional representation of the Clifford algebra, i.e., Hermitian matrices that satisfy $\{C_i, C_j\} = 2\delta_{ij}\mathbf{1}$. For each $j \in [m]$, let

$$E_j = \sum_k \langle k|e_j\rangle\, C_k \qquad F_j = \sum_k \langle k|f_j\rangle\, C_k \qquad G_j = \sum_k \langle k|g_j\rangle\, C_k \ .$$

Then it is easy to check that for distinct $S, T \in \{E, F, G\}$, $\{S_j, T_j\} = 0$ and $\|\{S_i, T_j\}\| = O(\epsilon)$ for $i \neq j$. Let $X_j = iE_jF_j$ and $Z_j = iE_jG_j$; these matrices are Hermitian, square to $\mathbf{1}$, and anti-commute. Moreover, for $i \neq j$ and $S, T \in \{X, Z\}$, we have $\|[S_i, T_j]\| = O(\epsilon)$. ◀

Appendix A gives an alternative proof of Theorem 3.1 using the exterior algebra.

3.2 Upper bound: Separating overlapping qubit operators

We provide two different methods for creating independent qubits from partially overlapping qubits. The first argument, given in Section 3.2.1, performs a careful analysis of a sequential block-diagonalization procedure. The second argument, in Section 3.2.3, is simpler but requires the introduction of a larger Hilbert space in which to define the approximating operators.

3.2.1 Separating nearly commuting projections

We first consider the case of separating projections that nearly commute pairwise.

▶ **Theorem 3.2.** *Let $P_1, \ldots, P_n$ be projections on a finite-dimensional Hilbert space such that for some $\epsilon \leq \frac{1}{32n}$,*

$$\|[P_i, P_j]\| \leq \epsilon \qquad \text{for all } i, j.$$

Then there exist projections $Q_1, \ldots, Q_n$ with, for all i, j,

$$[Q_i, Q_j] = 0$$
$$\|P_i - Q_i\| \leq 8n\epsilon \ .$$

The bound in Theorem 3.2 is nearly tight; see Lemma 3.9 below.

The proof of the theorem is constructive. It uses two basic operations, that we analyze with two lemmas. First we block-diagonalize operators with respect to a projection Q so that they commute with Q. The first lemma bounds how block-diagonalizing two operators affects their commutator.

▶ **Lemma 3.3.** *Let Q be a projection, and for operators P_i, $i = 1, 2$, let $P_i' = QP_iQ + (\mathbf{1} - Q)P_i(\mathbf{1} - Q)$. Then $[Q, P_i'] = 0$, $\|P_i' - P_i\| = \|[Q, P_i]\|$, and*

$$\|[P_1', P_2']\| \leq \|[P_1, P_2]\| + 2\|[Q, P_1]\| \cdot \|[Q, P_2]\| \ .$$

Proof. Work in a basis in which Q is diagonal: $Q = \left(\begin{smallmatrix} \mathbf{1} & 0 \\ 0 & 0 \end{smallmatrix}\right)$. Then $P_i = \left(\begin{smallmatrix} A_i & B_i \\ C_i & D_i \end{smallmatrix}\right)$ and $P_i' = \left(\begin{smallmatrix} A_i & 0 \\ 0 & D_i \end{smallmatrix}\right)$. As $[Q, P_i] = \left(\begin{smallmatrix} 0 & B_i \\ -C_i & 0 \end{smallmatrix}\right)$, $\|P_i' - P_i\| = \max\{\|B_i\|, \|C_i\|\} = \|[Q, P_i]\|$. We also compute

$$[P_1, P_2] = \begin{pmatrix} [A_1, A_2] + B_1C_2 - B_2C_1 & A_1B_2 + B_1D_2 - A_2B_1 - B_2D_1 \\ C_1A_2 + D_1C_2 - C_2A_1 - D_2C_1 & [D_1, D_2] + C_1B_2 - C_2B_1 \end{pmatrix} \ .$$

Each diagonal block in $[P_1, P_2]$ above, $Q[P_1, P_2]Q$ and $(\mathbf{1} - Q)[P_1, P_2](\mathbf{1} - Q)$, must have norm at most $\|[P_1, P_2]\|$. The claimed bound for $\|[P_1', P_2']\| = \max\{\|[A_1, A_2]\|, \|[D_1, D_2]\|\}$ follows. ◀

When one block-diagonalizes a projection, the result might not be a projection. The second basic operation consists in rounding the eigenvalues to the closest integer, 0 or 1. The second lemma bounds how this affects the commutator with another operator.

▶ **Lemma 3.4.** *Let Q be a projection and Q' Hermitian with $[Q, Q'] = 0$ and $\|Q - Q'\| < 1/2$. Then for any Hermitian P,*

$$\|[Q, P]\| \leq \frac{\|[Q', P]\|}{1 - 2\|Q - Q'\|} \ .$$

This bound can be much stronger than the trivial $\|[Q, P]\| \leq \|[Q', P]\| + 2\|P\|\|Q - Q'\|$.[3] It follows by substituting $A = \left(\begin{smallmatrix} 0 & P(2Q-\mathbf{1}) \\ (2Q-\mathbf{1})P & 0 \end{smallmatrix}\right)$, $B = \left(\begin{smallmatrix} 0 & (2Q-\mathbf{1})P \\ P(2Q-\mathbf{1}) & 0 \end{smallmatrix}\right)$ and $\Gamma = |2Q' - \mathbf{1}| \oplus |2Q' - \mathbf{1}|$ into the following theorem, and using $|2Q' - \mathbf{1}|(2Q - \mathbf{1}) = (2Q - \mathbf{1})|2Q' - \mathbf{1}| = 2Q' - \mathbf{1}$.

▶ **Theorem 3.5** ([4, Theorem 1])**.** *If A and B are Hermitian, and $\Gamma \succ 0$, then*

$$\|A - B\| \leq \|\Gamma^{-1}\| \cdot \|A\Gamma - \Gamma B\| \ .$$

Proof of Theorem 3.2. We proceed inductively. The induction hypothesis is that we have defined $Q_1, \ldots, Q_k, P_{k+1}^{(k)}, \ldots, P_n^{(k)}$ such that

- $0 \preceq P_j^{(k)} \preceq \mathbf{1}$, $\|P_j^{(k)} - P_j\| \leq \delta_k$, $\|[P_i^{(k)}, P_j^{(k)}]\| \leq \epsilon_k$.
- $Q_1, \ldots, Q_k$ are projections, commuting with each other and all $P_j^{(k)}$, with $\|P_k - Q_k\| \leq 2\delta_{k-1}$.

[3] For $P \succeq 0$, trivially $\|[Q, P]\| \leq \|[Q', P]\| + \|[Q - Q', P - \frac{\|P\|}{2}\mathbf{1}]\| \leq \|[Q', P]\| + \|P\|\|Q - Q'\|$, but Lemma 3.4 is still stronger.

For the base case, $\delta_0 = 0$ and $\epsilon_0 = \epsilon$.

In the induction step, we let Q_{k+1} be the projection formed by rounding $P_{k+1}^{(k)}$'s eigenvalues to 0 or 1, and define $P_{k+2}^{(k+1)}, \ldots, P_n^{(k+1)}$ by block-diagonalizing the $P_j^{(k)}$ operators with respect to Q_{k+1}:

$$P_j^{(k+1)} = Q_{k+1} P_j^{(k)} Q_{k+1} + (\mathbf{1} - Q_{k+1}) P_j^{(k)} (\mathbf{1} - Q_{k+1}) \ .$$

Indeed, then $\|Q_{k+1} - P_{k+1}\| \leq \|P_{k+1}^{(k)} - P_{k+1}\| + \|Q_{k+1} - P_{k+1}^{(k)}\| \leq 2\delta_k$. Also, $0 \preceq P_j^{(k+1)} \preceq \mathbf{1}$. Using Lemma 3.3, we compute

$$\begin{aligned} \|P_j^{(k+1)} - P_j\| &\leq \|P_j^{(k)} - P_j\| + \|P_j^{(k+1)} - P_j^{(k)}\| \\ &\leq \delta_k + \|[Q_{k+1}, P_j^{(k)}]\| \\ \|[P_i^{(k+1)}, P_j^{(k+1)}]\| &\leq \|[P_i^{(k)}, P_j^{(k)}]\| + 2\|[Q_{k+1}, P_i^{(k)}]\| \cdot \|[Q_{k+1}, P_j^{(k)}]\| \ . \end{aligned}$$

Thus we may take $\delta_{k+1} = \delta_k + \max_j \|[Q_{k+1}, P_j^{(k)}]\|$ and $\epsilon_{k+1} = \epsilon_k + 2\max_j \|[Q_{k+1}, P_j^{(k)}]\|^2$. It remains to bound $\max_j \|[Q_{k+1}, P_j^{(k)}]\|$.

The naive bound $\|[Q_{k+1}, P_j^{(k)}]\| \leq \|[P_{k+1}^{(k)}, P_j^{(k)}]\| + 2\|Q_{k+1} - P_{k+1}^{(k)}\| \leq \epsilon_k + 2\delta_k$ is no good, as it allows the errors to grow exponentially with k. Instead, applying Lemma 3.4 gives

$$\left\|[Q_{k+1}, P_j^{(k)}]\right\| \leq \frac{\epsilon_k}{1 - 2\delta_k} \ .$$

Provided that all $\epsilon_k \leq 2\epsilon$ and $\delta_k \leq 1/4$, $(1 - 2\delta_k)^{-1} \leq 2$, and we obtain the recursions

$$\begin{aligned} \delta_{k+1} &\leq \delta_k + 2\epsilon_k \leq \delta_k + 4\epsilon \\ \epsilon_{k+1} &\leq \epsilon_k + 8\epsilon_k^2 \leq \epsilon_k + 32\epsilon^2 \ . \end{aligned}$$

Thus $\delta_{k+1} \leq 4(k+1)\epsilon$ and $\epsilon_{k+1} \leq \epsilon + 32k\epsilon^2$. Given $\epsilon \leq \frac{1}{32n}$, indeed $\epsilon_k \leq 2\epsilon$ and $\delta_k \leq 1/4$. ◀

3.2.2 Separating partially overlapping qubits

The following theorem is an extension of Theorem 3.2 which allows us to separate ϵ-overlapping qubits.

▶ **Theorem 3.6.** *Let $X_1, Z_1, \ldots, X_n, Z_n$ be Hermitian matrices each having eigenvalues in the range $[-1, -1+\epsilon] \cup [1-\epsilon, 1]$, and satisfying $\|\{X_j, Z_j\}\| \leq \epsilon$ and $\|[S_i, T_j]\| \leq \epsilon$ for all $i \neq j$ and $S, T \in \{X, Z\}$. Assume $\epsilon/(1-\epsilon)^2 \leq \frac{1}{64n}$. Then there exist reflections $X_1', Z_1', \ldots, X_n', Z_n'$ with $\{X_j', Z_j'\} = 0$, and $[S_i', T_j'] = 0$ and $\|S_j' - S_j\| \leq 4n\epsilon/(1-\epsilon)^2 + \epsilon$ for all $i \neq j$ and $S, T \in \{X, Z\}$.*

Proof. Let $\mathcal{H}$ be the finite-dimensional Hilbert space on which the matrices act. Introduce n additional qubits, and on $(\mathbf{C}^2)^{\otimes n} \otimes \mathcal{H}$, define

$$\begin{aligned} R_{2j-1}' &= \sigma_j^x \otimes X_j \\ R_{2j}' &= \sigma_j^z \otimes Z_j \ , \end{aligned}$$

for $j = 1, \ldots, n$, where σ_j^x and σ_j^z are the standard Pauli operators acting on the jth added qubit.

For Pauli operators σ and τ,

$$[\sigma \otimes A, \tau \otimes B] = \begin{cases} (\sigma\tau) \otimes [A, B] & \text{if } [\sigma, \tau] = 0 \\ (\sigma\tau) \otimes \{A, B\} & \text{if } \{\sigma, \tau\} = 0 \end{cases} \ .$$

Thus for all i, j,

$$\|[R'_i, R'_j]\| \leq \epsilon \ .$$

Define reflections $R_1, \ldots, R_{2n}$ by rounding to ± 1 the eigenvalues of each of $R'_1, \ldots, R'_{2n}$. The operators R_j still have the form (Pauli) $\otimes$ (Reflection). By Theorem 3.5,

$$\|[R_i, R_j]\| \leq \frac{1}{(1-\epsilon)^2}\epsilon \ .$$

Define projections $P_1, \ldots, P_{2n}$ by $P_j = \frac{1}{2}(\mathbf{1} + R_j)$. Then

$$\begin{aligned}\|[P_i, P_j]\| &= \tfrac{1}{4}\|[R_i, R_j]\| \\ &\leq \frac{1}{4}\frac{1}{(1-\epsilon)^2}\epsilon \ .\end{aligned}$$

Applying Theorem 3.2 for separating projections yields projections $Q_1, \ldots, Q_{2n}$ satisfying $[Q_i, Q_j] = 0$ and

$$\|Q_j - P_j\| \leq 8 \cdot (2n) \cdot \frac{1}{4}\frac{1}{(1-\epsilon)^2}\epsilon = \frac{4n\epsilon}{(1-\epsilon)^2} \ ,$$

provided that $\epsilon/(1-\epsilon)^2 \leq 1/(64n)$.

We claim that the reflections $2Q_{2j-1} - \mathbf{1}$ and $2Q_{2j} - \mathbf{1}$ still have the form $\sigma_j^x \otimes X'_j$ and $\sigma_j^z \otimes Z'_j$, resepectively, for reflections X'_j and Z'_j on $\mathcal{H}$. Indeed, the proof of the projections separation theorem, Theorem 3.2, involved two basic operations:

1. Block-diagonalizing an operator A with respect to a reflection R:

$$\begin{aligned}A &\to \tfrac{1}{2}(\mathbf{1} + R)A\tfrac{1}{2}(\mathbf{1} + R) + \tfrac{1}{2}(\mathbf{1} - R)A\tfrac{1}{2}(\mathbf{1} - R) \\ &= \frac{1}{2}(A + RAR) \ .\end{aligned}$$

2. Rounding the eigenvalues of a Hermitian operator A to ± 1.

Observe that if $A = \sigma \otimes A'$ for a Pauli σ, and $R = \tau \otimes R'$ for a Pauli τ, then both of these basic operations result in an operator $\sigma \otimes A''$, for the same Pauli σ.

Thus indeed $\{X'_j, Z'_j\} = 0$ and $[S'_i, T'_j] = 0$ for $i \neq j$ and $S, T \in \{X, Z\}$. Also $\|Q_j - P_j\| \leq 4n\epsilon/(1-\epsilon)^2$ implies

$$\begin{aligned}\|S'_j - S_j\| &\leq 2\|Q_j - P_j\| + \|R'_j - R_j\| \\ &\leq \frac{8n\epsilon}{(1-\epsilon)^2} + \epsilon \ .\end{aligned}$$

◀

Since Theorem 3.6 yields n qubits in tensor product, the dimension of the ambient space $\mathcal{H}$ must be at least 2^n. Rephrasing this, we obtain:

▶ **Corollary 3.7.** *In 2^n dimensions, at most n qubits can be placed with pairwise "overlaps" $\|[S_i, T_j]\| \leq \epsilon$, if $\epsilon/(1-\epsilon)^2 \leq 1/(64n)$.*

3.2.3 SWAP-based argument

If we are willing to work in a larger space, then there is a simpler argument for moving overlapping qubits into tensor product. Instead of repeatedly block-diagonalizing operators and rounding their eigenvalues to ± 1, as in Theorem 3.6, we can swap in fresh qubits to enforce a tensor-product structure. We will show:

▶ **Theorem 3.8.** *Let $X_1, Z_1, \ldots, X_n, Z_n$ be reflections on $\mathcal{H}$, satisfying $\{X_j, Z_j\} = 0$ and $\|[S_i, T_j]\| \leq \epsilon$ for all $i \neq j$ and $S, T \in \{X, Z\}$. Extend these operators by the identity to act on $\mathcal{H} \otimes (\mathbf{C}^2)^{\otimes n}$.*

Then there exist reflections $X'_1, Z'_1, \ldots, X'_n, Z'_n$ on $\mathcal{H} \otimes (\mathbf{C}^2)^{\otimes n}$, with $\{X'_j, Z'_j\} = 0$, $[S'_i, T'_j] = 0$ and $\|S'_j - S_j\| \leq 2n\epsilon$.

Proof. For $j \in [n]$, let $\mathcal{S}_j = \frac{1}{2}\big(\mathbf{1} \otimes \mathbf{1} + X_j \otimes \sigma_j^x + Z_j \otimes \sigma_j^z + i(X_j Z_j) \otimes \sigma_j^y\big)$. Acting on $\mathcal{H} \otimes (\mathbf{C}^2)^{\otimes n}$, $\mathcal{S}_j$ swaps the jth added $\mathbf{C}^2$ register with the qubit defined by X_j, Z_j.

For $T \in \{X, Z\}$ and $i \in \{1, \ldots, j\}$ define

$$T_j^{(i)} = (\mathcal{S}_1 \cdots \mathcal{S}_{i-1})\, T_j\, (\mathcal{S}_{i-1} \cdots \mathcal{S}_1) \ .$$

Let $T'_j = T_j^{(j)} = (\mathcal{S}_1 \cdots \mathcal{S}_{j-1}) T_j (\mathcal{S}_{j-1} \cdots \mathcal{S}_1)$.

Then for $i < j$, $\|[S'_i, T'_j]\| = \|[S_i, \mathcal{S}_i \cdots \mathcal{S}_{j-1} T_j \mathcal{S}_{j-1} \cdots \mathcal{S}_i]\|$. This is 0, since for any operator A that is the identity on the ith added $\mathbf{C}^2$ register, $[S_i, \mathcal{S}_i A \mathcal{S}_i] = 0$.

Furthermore,

$$\begin{aligned}
\|T'_j - T_j\| &\leq \sum_{i=1}^{j-1} \|T_j^{(i+1)} - T_j^{(i)}\| \\
&= \sum_{i=1}^{j-1} \|\mathcal{S}_i T_j \mathcal{S}_i - T_j\| \\
&= \sum_{i=1}^{j-1} \|[\mathcal{S}_i, T_j]\| \\
&\leq \frac{1}{2} \sum_{i=1}^{j-1} \big(\|[X_i, T_j]\| + \|[Z_i, T_j]\| + \|[X_i Z_i, T_j]\|\big) \\
&\leq 2\epsilon(j-1) \ .
\end{aligned}$$

◀

Since Theorem 3.8 works in the larger space $\mathcal{H} \otimes (\mathbf{C}^2)^{\otimes n}$, unlike Theorem 3.6 it does not give an upper bound on the number of nearly independent qubits that can be packed into $\mathcal{H}$.

3.2.4 Lower bound: Sometimes $\Omega(n\epsilon)$ movement is necessary

Theorem 3.6 shows that n qubits with pairwise "overlaps" at most ϵ can be separated into tensor product by moving each qubit $O(n\epsilon)$ in operator norm. Is the loss of a factor of n necessary? The following example shows that our bound is essentially tight.

▶ **Lemma 3.9.** *For any integer n, and any $\epsilon \in [0, \pi/n^2]$, there exist $2n$ qubits $X_1, Z_1, \ldots, X_{2n}, Z_{2n}$ in $(\mathbf{C}^2)^{\otimes(2n)}$ such that $\|[S_i, T_j]\| \leq \epsilon$ for all $i \neq j$ and $S, T \in \{X, Z\}$ but such that for any* independent *qubits $X'_1, Z'_1, \ldots, X'_{2n}, Z'_{2n}$ (with $[S'_i, T'_j] = 0$ for $i \neq j$),*

$$\max_{\substack{1 \leq j \leq 2n \\ S \in \{X,Z\}}} \big\|S_j - S'_j\big\| \geq \frac{n\epsilon}{2\pi} \ .$$

Proof. Construct qubits X_j, Z_j as the standard qubits, except with the second n qubit operators perturbed by the Hamiltonian

$$H = \tfrac{1}{4}(\sigma_1^z + \cdots + \sigma_n^z)(\sigma_{n+1}^z + \cdots + \sigma_{2n}^z) \ .$$

That is, $X_j = \sigma_j^x$, $Z_j = \sigma_j^z$ for $j \leq n$, and $X_j = e^{i\epsilon H} \sigma_j^x e^{-i\epsilon H}$, $Z_j = e^{i\epsilon H} \sigma_j^z e^{-i\epsilon H} = \sigma_j^z$ for $j > n$. Then if $j, k \leq n$ or $j, k > n$, the operators for qubits j and k commute. If $j \leq n < k$,

then the operators for qubits j and k commute, except for X_j and X_k. We compute $\|[X_j, X_k]\| = \|X_j X_k X_j - X_k\| = \|e^{-i\epsilon H}\sigma_j^x e^{i\epsilon H}\sigma_k^x e^{-i\epsilon H}\sigma_j^x e^{i\epsilon H} - \sigma_k^x\| = \|e^{i\epsilon\sigma_j^z\sigma_k^z} - \mathbf{1}\| = |e^{i\epsilon} - 1| \leq \epsilon$.

Let $X'_1, \ldots, X'_{2n}$ be any pairwise commuting reflections. Let $J = \{1, \ldots, n\}$, $K = \{n+1, \ldots, 2n\}$. Let $X_J = \prod_{j\in J} X_j$, $X_K = \prod_{k\in K} X_k$. Similarly define X'_J, X'_K and σ_J^x, σ_K^x. Thus $X_J = \sigma_J^x$, $X_K = e^{i\epsilon H}\sigma_K^x e^{-i\epsilon H}$. In order to lower-bound $\max_j \|X_j - X'_j\|$, we study $\|[X_J, X_K]\| = \|(X_J X_K)^2 - \mathbf{1}\|$.

On one hand, since the X'_j operators commute, $(X'_J X'_K)^2 = \mathbf{1}$. By triangle inequalities, and using $\|X_j\| = \|X'_j\| = 1$ for all j, $\|X_J X_K - X'_J X'_K\| \leq \sum_j \|X_j - X'_j\|$, and hence

$$\|(X_J X_K)^2 - \mathbf{1}\| \leq 2\sum_j \|X'_j - X_j\| \leq 4n \cdot \max_j \|X'_j - X_j\| \ . \tag{1}$$

On the other hand,

$$\begin{aligned}(X_J X_K)^2 &= \sigma_J^x\big(e^{i\epsilon H}\sigma_K^x\, e^{-i\epsilon H}\big)\sigma_J^x\big(e^{i\epsilon H}\sigma_K^x\, e^{-i\epsilon H}\big)\\ &= e^{-i\epsilon H}\sigma_K^x\, e^{2i\epsilon H}\sigma_K^x\, e^{-i\epsilon H}\\ &= e^{-4i\epsilon H}\ .\end{aligned}$$

Since $\|H\| = n^2/4$, provided that $n^2\epsilon \leq \pi$ it holds that

$$\big\|(X_J X_K)^2 - \mathbf{1}\big\| = |e^{in^2\epsilon} - 1| \geq \frac{2}{\pi}\cdot n^2\epsilon\ . \tag{2}$$

Combining the bounds (1) and (2) gives $\frac{2}{\pi}n^2\epsilon \leq \|(X_J X_K)^2 - \mathbf{1}\| \leq 4n \cdot \max_j \|X'_j - X_j\|$, or $\max_j \|X'_j - X_j\| \geq n\epsilon/(2\pi)$. ◀

4 State-dependent qubit separation

A problem with both Theorem 3.6 and Theorem 3.8 is that they might be difficult to apply to real experimental systems. This is because it is difficult to establish the assumption of qubits nearly in tensor product, $\|[S_i, T_j]\| \leq \epsilon$ for $i \neq j$ and $S, T \in \{X, Z\}$. In addition to the operators, a physical system involves an underlying state $|\psi\rangle$. The operators can be understood only in terms of their effects on $|\psi\rangle$. Consider for example a Hilbert space that splits as $\mathcal{H} \oplus \mathcal{H}'$, where $|\psi\rangle$ is supported only on $\mathcal{H}$ and available operators leave $\mathcal{H}$ invariant. Then there is no experimental way to fathom the operators' behavior, e.g., their commutation relationships, on $\mathcal{H}'$. Theorems 3.6 and 3.8 cannot be applied. This example might not seem so troubling, because we can simply restrict everything to $\mathcal{H}$; but it becomes more problematic if $|\psi\rangle$, say, has nonzero but very small support on $\mathcal{H}'$.

We would like qubit-separation theorems that have experimentally accessible assumptions. In particular, the theorems' assumptions should be stated relative to the system's state $|\psi\rangle$. For example, in Theorems 3.6 and 3.8 we might loosen the assumption $\|[S_i, T_j]\| \leq \epsilon$ for $i \neq j$ to be only $\|[S_i, T_j]|\psi\rangle\| \leq \epsilon$. Naturally, the conclusions will have to be correspondingly weakened. In the above example with $\mathcal{H} \oplus \mathcal{H}'$, if the reflections are far from commuting on $\mathcal{H}'$ then we cannot hope to find nearby commuting operators, $\|S'_j - S_j\| \approx 0$; but perhaps we can get $\|(S'_j - S_j)|\psi\rangle\| \approx 0$.

In order to extend our results to experimental systems we proceed in three steps.

1. First, in Section 4.1 below, we give a protocol that can be used to test if two reflections, S and T, are close to commuting on a state $|\psi\rangle$: $[S, T]|\psi\rangle \approx 0$. The protocol is very simple:

measure S, measure T, then measure S again. If S and T commute on $|\psi\rangle$, then the two S measurements will give the same result; and, intuitively, when they do not commute measuring T will disturb the state and make it less likely to get the same S result.

2. However, in Section 4.2, we show that the condition $[S_i, T_j]|\psi\rangle \approx 0$ for operators on different qubits is not sufficient to establish that there are nearby independent qubits $X'_1, Z'_1, \ldots, X'_n, Z'_n$. In fact, we give an explicit construction of a state $|\psi\rangle$ and n qubit operators $X_1, Z_1, \ldots, X_n, Z_n$ in $< n^2$ dimensions such that for $i \neq j$, $[S_i, T_j]|\psi\rangle = 0$ precisely. Since $n^2 \leq 2^n$ for $n \geq 4$, the dimension of the space is not sufficient to fit n independent qubits.

   (We also show why the basic induction argument used to prove Theorem 3.6 fails when errors are measured relative to a state $|\psi\rangle$. The errors accumulate too rapidly, leading to an exponential dependence on n, instead of polynomial.)

3. We remedy this problem in Section 4.3 with a more advanced testing protocol. Intuitively, the improved protocol tests not just pairwise commutation relationships, such as $S_i T_j |\psi\rangle \approx T_j S_i |\psi\rangle$, but also higher-order relationships such as $S_i T_j U_k |\psi\rangle \approx U_k T_j S_i |\psi\rangle$. The protocol is still quite simple, though. Basically, measure all the qubit operators in order (either $X_1, Z_1, X_2, Z_2, \ldots$ or $Z_1, X_1, Z_2, X_2, \ldots$), then go back and measure a random qubit operator (Z_j or X_j, respectively), and verify that the measurement result is unchanged. We show that if the protocol accepts with probability $1 - \epsilon$, then the qubit operators "simulate" n independent qubit operators in a certain sense. In particular, as a corollary, the system's dimension must be at least $(1 - O(n^2\epsilon))2^n$.

   The dimension bound is not fully satisfactory. A 2^n lower bound would be preferable. However, speculatively, the simulation statement might be strong enough to form the foundation for an analysis that the system can be used as an n-qubit quantum computer. Such an extension is nontrivial, though, and we leave it to future work.

4.1 Protocol for testing state-dependent commutation

We present a protocol that can be used to test whether two reflections approximately commute on a given state.

▶ **Theorem 4.1.** *Let S and T be reflections, acting on a state $|\psi\rangle$. Consider the following protocol:*

1. *Measure S.*
2. *Measure T, but ignore the result.*
3. *Measure S again. Accept if the result is unchanged.*

Then the probability of accepting is given by

$$\Pr[\text{accept}] = 1 - \tfrac{1}{8}\big\|[S,T]|\psi\rangle\big\|^2 \ .$$

Proof. For $a, b \in \{0,1\}$, let $S_a = \frac{1}{2}(\mathbf{1} + (-1)^a S)$ and $T_b = \frac{1}{2}(\mathbf{1} + (-1)^b T)$. Then since $[S, T_0] = -[S, T_1] = \frac{1}{2}[S, T]$,

$$\begin{aligned}\|[S,T]|\Psi\rangle\|^2 &= 2\big(\|[S,T_0]|\psi\rangle\|^2 + \|[S,T_1]|\psi\rangle\|^2\big) \\ &= \sum_{a,b} \big\|S_a[S,T_b]|\psi\rangle\big\|^2 \ ,\end{aligned}$$

where we have used $\||\phi\rangle\|^2 = \|S_0|\phi\rangle\|^2 + \|S_1|\phi\rangle\|^2$ for any $|\phi\rangle$. Then from $S_a S = S S_a = (-1)^a S_a$, we find $S_a[S, T_b] = S_a[S, T_b](S_0 + S_1) = 2(-1)^a S_a T S_{\bar{a}}$, so

$$\begin{aligned}\|[S,T]|\psi\rangle\|^2 &= 8\sum_{a,b}\left\|S_a T_b S_{\bar{a}}|\psi\rangle\right\|^2 \\ &= 8\left(1 - \Pr[\text{accept}]\right) \ .\end{aligned}$$

◀

4.2 Qubits that commute on a state need not be close to independent qubits

In the projection separating argument of Theorem 3.2, the key observation was that for projections P, Q, R with $\|[P,Q]\|, \|[P,R]\| \leq \delta$ and $\|[Q,R]\| \leq \epsilon$, if Q and R are both block-diagonalized with respect to P then the results still nearly commute:

$$\left\|\left[PQP + (\mathbf{1}-P)Q(\mathbf{1}-P), PRP + (\mathbf{1}-P)R(\mathbf{1}-P)\right]\right\| \leq \epsilon + 2\delta^2 \ .$$

The quadratic dependence on δ meant that errors did not accumulate badly through the induction.

Here is a counterexample showing that errors *can* accumulate badly in block diagonalization if we measure errors relative to a state $|\psi\rangle$, using $\|[P,Q]|\psi\rangle\|$. Define P, Q, R and $|\psi\rangle$ as

$$P = \begin{pmatrix} 1 & 0 & 0 & \delta \\ 0 & 1/2 & 1/2 & 0 \\ 0 & 1/2 & 1/2 & 0 \\ \delta & 0 & 0 & 0 \end{pmatrix} \qquad Q = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \qquad R = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1/2 & 1/2 \\ 0 & 0 & 1/2 & 1/2 \end{pmatrix} \qquad |\psi\rangle = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} \ . \tag{3}$$

Then P, Q and R are projections (up to second order in δ for P), with $\|[P,Q]|\psi\rangle\|, \|[P,R]|\psi\rangle\| = O(\delta)$, $[Q,R]|\psi\rangle = 0$, and yet

$$\left\|\left[PQP + (\mathbf{1}-P)Q(\mathbf{1}-P), PRP + (\mathbf{1}-P)R(\mathbf{1}-P)\right]|\psi\rangle\right\| = \Omega(\delta) \ .$$

The idea is that Q and R commute on the first two dimensions, and are far from commuting on the last two dimensions; but this property is broken by the block diagonalization.

This example suggests that in a simple induction argument, starting with projections $P_1, \ldots, P_n$ having pairwise commutators $\|[P_i, P_j]|\psi\rangle\| \sim \epsilon$, after block-diagonalizing with respect to P_1, the errors can grow to $\sim 2\epsilon$, then to $\sim 4\epsilon$ after block-diagonalizing with respect to the new P_2, and so on; the errors potentially grow exponentially.

In fact, it is not only our *proof* of Theorems 3.2 and 3.6 that fails when errors are measured relative to a state $|\psi\rangle$. The theorems themselves fail, as shown by the following construction.

▶ **Lemma 4.2.** *For any n and $k \in [n]$, there exists a space $\mathcal{H}$ of dimension at most $1 + \sum_{j=0}^{k}\binom{n}{j}$, a vector $|\psi\rangle \in \mathcal{H}$ and n qubits X_j, Z_j such that*

$$S_{j_1}^{(1)} \cdots S_{j_k}^{(k)}|\psi\rangle = S_{j_{\sigma(1)}}^{\sigma(1)} \cdots S_{j_{\sigma(k)}}^{\sigma(k)}|\psi\rangle$$

for all distinct indices $j_1, \ldots, j_k \in [n]$, $S^{(1)}, \ldots, S^{(k)} \in \{X, Z\}$, and permutations σ of $[k]$.

In particular, for $k = 2$, the lemma places n qubits in $O(n^2)$ dimensions—for example, four qubits in 12 dimensions—such that $[S_i, T_j]|\psi\rangle = 0$ for all $i \neq j$ and $S, T \in \{X, Z\}$.

Protocol to test for n independent qubits

Let $|\psi\rangle \in \mathcal{H}$ be a state. Let $X_1, Z_1, \ldots, X_n, Z_n$ be qubit operators on $\mathcal{H}$, i.e., reflections satisfying $\{X_j, Z_j\} = 0$ for all j.

1. With equal probabilities 1/2, measure the reflections in order, either $X_1, Z_1, X_2, Z_2, \ldots$, or $Z_1, X_1, Z_2, X_2, \ldots$.
2. Pick a uniformly random index $j \in [n]$. If Z went second in step (1), then measure Z_j; and if X went second, then measure X_j. Accept if the result is unchanged from the operator's previous measurement. Otherwise reject.

Figure 2 Protocol to test for n independent qubits.

Proof. Let us begin by explaining the $n = 4$, $k = 2$ special case of the construction. Define $\mathcal{H}$ to have orthonormal basis $|0000\rangle, |1000\rangle, \ldots, |0001\rangle, |1100\rangle, \ldots, |0011\rangle, |d\rangle$, i.e., all n-bit strings of Hamming weight at most k, together with an additional vector $|d\rangle$. Let $|\psi\rangle = |0000\rangle$, and consider the following operators for the first qubit:

$$X_1 = \begin{array}{c} \\ 0000 \\ 1000 \\ 0100 \\ 0010 \\ 0001 \\ 1100 \\ 1010 \\ 1001 \\ 0110 \\ 0101 \\ 0011 \\ d \end{array} \begin{array}{c} \begin{array}{cccccccccccc} 0000 & 1000 & 0100 & 0010 & 0001 & 1100 & 1010 & 1001 & 0110 & 0101 & 0011 & d \end{array} \\ \begin{pmatrix} 0 & 1 & & & & & & & & & & \\ 1 & 0 & & & & & & & & & & \\ & & 0 & & 1 & & & & & & & \\ & & & 0 & & 1 & & & & & & \\ & & & & 0 & & 1 & & & & & \\ & & 1 & & & 0 & & & & & & \\ & & & 1 & & & 0 & & & & & \\ & & & & 1 & & & 0 & & & & \\ & & & & & & & & 0 & 1 & & \\ & & & & & & & & 1 & 0 & & \\ & & & & & 0 & & & & & 0 & 1 \\ & & & & & & & & & & 1 & 0 \end{pmatrix} \end{array} \qquad Z_1 = \begin{array}{c} \\ 0000 \\ 1000 \\ 0100 \\ 0010 \\ 0001 \\ 1100 \\ 1010 \\ 1001 \\ 0110 \\ 0101 \\ 0011 \\ d \end{array} \begin{array}{c} \begin{array}{cccccccccccc} 0000 & 1000 & 0100 & 0010 & 0001 & 1100 & 1010 & 1001 & 0110 & 0101 & 0011 & d \end{array} \\ \begin{pmatrix} 1 & & & & & & & & & & & \\ & -1 & & & & & & & & & & \\ & & 1 & & & & & & & & & \\ & & & 1 & & & & & & & & \\ & & & & 1 & & & & & & & \\ & & & & & -1 & & & & & & \\ & & & & & & -1 & & & & & \\ & & & & & & & -1 & & & & \\ & & & & & & & & 1 & & & \\ & & & & & & & & & -1 & & \\ & & & & & 0 & & & & & 1 & \\ & & & & & & & & & & & -1 \end{pmatrix} \end{array} .$$

Unspecified matrix entries are 0. X_2 and Z_2 can be obtained from X_1 and Z_1 by switching the first and second bits in each basis element, leaving $|d\rangle$ alone; and similarly for X_3, Z_3 and X_4, Z_4. Then $P_i^2 = \mathbf{1}$, $\{X_i, Z_i\} = 0$ and $[P_i, Q_j]|\psi\rangle = 0$, for $i \neq j$ and $P, Q \in \{X, Z\}$.

The idea behind this construction is that X_j, Z_j act largely as the Pauli operators σ_j^x, σ_j^z. However, we have truncated the standard basis $|0000\rangle, \ldots, |1111\rangle$ for $(\mathbf{C}^2)^{\otimes 4}$ to include only strings of Hamming weight ≤ 2. Since applying σ_1^x to $|0110\rangle, |0101\rangle$ and $|0011\rangle$ would give strings of Hamming weight 3, we instead pair these dimensions up arbitrarily for X_1, and define Z_1 on them to make it anti-commute with X_1. The extra dimension $|d\rangle$ is needed to make the total dimension even.

It is straightforward to generalize the example: by truncating strings at Hamming weight k the same construction places n qubits in $\sum_{j=0}^{k} \binom{n}{j}$ dimensions (or one more if this dimension is odd), such that any combination of up to k qubit operators commute on $|\psi\rangle = |0^n\rangle$, e.g., if $k \geq 3$, $X_1 X_2 X_3 |\psi\rangle = X_3 X_2 X_1 |\psi\rangle = |1110^{n-3}\rangle$. ◀

4.3 Protocol to test for n independent qubits

The problem with the protocol in Theorem 4.1 is that it only tests commutation between pairs of operators on the state $|\psi\rangle$: $[S, T]|\psi\rangle \approx 0$. Lemma 4.2 shows that n qubits in only $O(n^2)$ dimensions can pass this test on every pair. The lemma furthermore suggests that any test involving qubit operator sequences of length $o(n)$ can be satisfied in dimension $2^{o(n)}$. Therefore, we need a protocol that has at least n steps.

Figure 2 gives our testing protocol. We argue that if the protocol accepts with high probability, then the n overlapping qubits X_j, Z_j are nearly equivalent to n independent qubits $\hat{X}_j, \hat{Z}_j$ in an enlarged space $\mathcal{H}' = \mathcal{H} \otimes (\mathbf{C}^2)^{\otimes 2n}$.

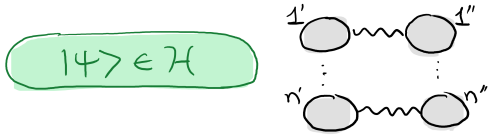


Figure 3 The state $|\Psi_0\rangle$ is given by $|\psi\rangle \otimes |\mathrm{EPR}\rangle^{\otimes n}$, where the EPR states are on qubits $1'$ and $1''$, $2'$ and $2''$, and so on. To get $|\Psi\rangle$, swap qubit j' with the qubit in $\mathcal{H}$ defined by X_j, Z_j, for $j = 1, \ldots, n$. Observe that starting from $|\psi\rangle$ and depolarizing the X_j, Z_j qubits, for $j = 1, \ldots, n$, is equivalent to tracing out all j' and j'' qubits from $|\Psi\rangle\langle\Psi|$.

▶ **Theorem 4.3.** *Consider the protocol of Figure 2. Assume the probability it accepts is at least* $1 - \epsilon$.

Let $|\mathrm{EPR}\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$. *Let* $|\Psi_0\rangle = |\psi\rangle \otimes |\mathrm{EPR}\rangle^{\otimes n} \in \mathcal{H}' = \mathcal{H} \otimes (\mathbf{C}^2)^{\otimes 2n}$, *and let* $|\Psi\rangle$ *be obtained from* $|\Psi_0\rangle$ *by swapping each qubit* X_j, Z_j *with the first half of one of the EPR states, in order* $j = 1, \ldots, n$. *(See Figure 3.) Then there exist* n *independent qubits, given by* $\hat{X}_1, \hat{Z}_1, \ldots, \hat{X}_n, \hat{Z}_n$, *on* $\mathcal{H}'$ *such that for any sequence of qubit operators* $U_{j_1}, \ldots, U_{j_k}$, *where* U_j *acts on the* X_j, Z_j *qubit and* $\|U_j\| \leq 1$,

$$\left\| U_{j_1} \cdots U_{j_k} |\Psi\rangle - \hat{U}_{j_1} \cdots \hat{U}_{j_k} |\Psi\rangle \right\| = O(kn\sqrt{\epsilon}) \ . \tag{4}$$

Here $\hat{U}_j$ *is the same operator as* U_j, *except acting on the* $\hat{X}_j, \hat{Z}_j$ *qubit. That is, if* U_j *has Pauli expansion* $U_j = \alpha_j \mathbf{1} + \beta_j X_j + \gamma_j Z_j + \delta_j (i X_j Z_j)$ *for scalars* $\alpha_j, \beta_j, \gamma_j, \delta_j$, *then* $\hat{U}_j = \alpha_j \mathbf{1} + \beta_j \hat{X}_j + \gamma_j \hat{Z}_j + \delta_j (i \hat{X}_j \hat{Z}_j)$.

Observe that if the X_j, Z_j qubits are independent of each other, then the measurements on different qubits commute, and so the protocol accepts with probability one. In that case, there is nothing to show. In general, however, measuring qubits $j+1, \ldots, n$ can disturb the last measurement on qubit j.

The EPR state appears in the conclusion of Theorem 4.3 even though it is not used in the testing protocol. Essentially this is because of the following two properties of $|\mathrm{EPR}\rangle$:

1. Depolarizing a qubit, i.e., replacing it with the maximally mixed state, is equivalent to swapping it with the first qubit of a fresh EPR state then tracing out the EPR state's registers.
2. For any 2×2 matrix M, $(I \otimes M)|\mathrm{EPR}\rangle = (M^T \otimes I)|\mathrm{EPR}\rangle$.

The second property is key in our analysis for algebraically manipulating operators to show approximate commutation. To see how, consider for example a state $|\phi\rangle$ that involves four qubits, labeled $1, 2, 1', 2'$, where the j' qubits do not overlap with any others. If $|\phi\rangle$ is close to an EPR state on qubits $(1, 1')$ and $(2, 2')$, then operators on qubits 1 and 2 necessarily nearly commute on $|\phi\rangle$:

$$\begin{aligned} U_1 V_2 |\phi\rangle &\approx U_1 V_{2'}^T |\phi\rangle = V_{2'}^T U_1 |\phi\rangle \\ &\approx V_{2'}^T U_{1'}^T |\phi\rangle = U_{1'}^T V_{2'}^T |\phi\rangle \\ &\approx U_{1'}^T V_2 |\phi\rangle = V_2 U_{1'}^T |\phi\rangle \\ &\approx V_2 U_1 |\phi\rangle \ . \end{aligned}$$

The trick is to pull operators from one side of an approximate EPR state to the other, commute them there, then pull them back.

Proof of Theorem 4.3. To analyze the protocol, we relate it to a separate protocol that is based on swapping qubits with halves of EPR states. Observe that measuring either X_i

then Z_i, or Z_i then X_i, and discarding the second measurement result, is equivalent to depolarizing the qubit. Depolarizing a qubit is equivalent to swapping it with one half of $|\mathrm{EPR}\rangle$ and tracing out the original EPR state's registers. Therefore, the protocol of Figure 2 accepts with the same probability as the following protocol:

1. Append to the system n EPR states, on qubits labeled $1', 1'', \ldots, n', n''$. Thus the system is in the state $|\Psi_0\rangle = |\psi\rangle \otimes |\mathrm{EPR}\rangle^{\otimes n} \in \mathcal{H} \otimes (\mathbf{C}^2_{1'} \otimes \mathbf{C}^2_{1''}) \otimes \cdots \otimes (\mathbf{C}^2_{n'} \otimes \mathbf{C}^2_{n''})$; see Figure 3.
2. For i from 1 up to n, swap the qubit defined by X_i, Z_i with the new qubit i'.
3. Pick a uniformly random index $j \in [n]$. With equal probabilities 1/2, measure either X_j and $\sigma^x_{j''}$, or Z_j and $\sigma^z_{j''}$. Accept if the measurement results are the same, both $+1$ or both -1.

Indeed, for $\alpha \in \{x, z\}$, measuring $\sigma^\alpha_{j''}$ at the end of the protocol is equivalent to measuring $\sigma^\alpha_{j'}$ at the start, which is also equivalent to measuring just after swapping with the X_j, Z_j qubit.

If the protocol accepts with probability $1-\epsilon$, then for probabilities ϵ_j satisfying $\epsilon = \frac{1}{n}\sum_j \epsilon_j$, we have $\min\{\|\frac{1}{2}(\mathbf{1} + X_j \otimes \sigma^x_{j''})|\Psi\rangle\|^2, \|\frac{1}{2}(\mathbf{1} + Z_j \otimes \sigma^z_{j''})|\Psi\rangle\|^2\} \geq 1 - 2\epsilon_j$, where $|\Psi\rangle$ is the state after the swap gates in step (2). In particular,

$$\max\left\{\left\|X_j \otimes \sigma^x_{j''}|\Psi\rangle - |\Psi\rangle\right\|, \left\|Z_j \otimes \sigma^z_{j''}|\Psi\rangle - |\Psi\rangle\right\|\right\} \leq 2\sqrt{2\epsilon_j} \ .$$

This implies that for any one-qubit operator U_j acting on the X_j, Z_j qubit, $U_j|\Psi\rangle \approx U^T_{j''}|\Psi\rangle$, where $U_{j''}$ is the same operator, but acting on the j'' qubit. More precisely, if $U_j = \alpha_j \mathbf{1} + \beta_j X_j + \gamma_j Z_j + \delta_j(iX_jZ_j)$ for complex scalars $\alpha_j, \beta_j, \gamma_j, \delta_j$, then $U^T_{j''} = \alpha_j \mathbf{1} + \beta_j \sigma^x_{j''} + \gamma_j \sigma^z_{j''} - \delta_j \sigma^y_{j''}$; and, since $\max\{|\alpha_j|, |\beta_j|, |\gamma_j|, |\delta_j|\} \leq \|U_j\|$,

$$\begin{aligned}\left\|(U_j - U^T_{j''})|\Psi\rangle\right\| &\leq (|\beta_j| + |\gamma_j| + 2|\delta_j|) \cdot 2\sqrt{2\epsilon_j} \\ &\leq 4\|U_j\| \cdot 2\sqrt{2\epsilon_j} \ .\end{aligned}$$

For each i, let $\mathcal{S}_i$ be the operator on that swaps the X_i, Z_i qubit with the new qubit i': $\mathcal{S}_i = \frac{1}{2}\big(\mathbf{1} + X_i \otimes \sigma^x_{i'} + Z_i \otimes \sigma^z_{i'} + i(X_iZ_i) \otimes \sigma^y_{i'}\big)$. For $i \leq j$, let $\mathcal{S}_{i,j} = \mathcal{S}_i\mathcal{S}_{i+1}\ldots\mathcal{S}_j$ and $\mathcal{S}_{j,i} = \mathcal{S}_j\mathcal{S}_{j-1}\ldots\mathcal{S}_i$. Thus $|\Psi\rangle = \mathcal{S}_{n,1}|\Psi_0\rangle$.

Let $\hat{P}_i = \mathcal{S}_{n,i+1}P_i\mathcal{S}_{i+1,n} = \mathcal{S}_{n,i}\sigma^P_{i'}\mathcal{S}_{i,n} = \mathcal{S}_{n,1}\sigma^P_{i'}\mathcal{S}_{1,n}$. As $[\sigma^P_{i'}, \sigma^Q_{j'}] = 0$ for $i \neq j$ and $P, Q \in \{X, Z\}$, so too $[\hat{P}_i, \hat{Q}_j] = 0$. Observe that

$$\hat{U}_j|\Psi\rangle = U^T_{j''}|\Psi\rangle \ , \tag{5}$$

since

$$\begin{aligned}\hat{U}_j\mathcal{S}_{n,1}|\Psi_0\rangle &= (\mathcal{S}_{n,1}U_{j'}\mathcal{S}_{1,n})\mathcal{S}_{n,1}|\Psi_0\rangle \\ &= \mathcal{S}_{n,1}U_{j'}|\Psi_0\rangle \\ &= \mathcal{S}_{n,1}U^T_{j''}|\Psi_0\rangle \ ,\end{aligned}$$

where the last equality is because $|\Psi_0\rangle$ includes an EPR state between qubits j' and j''. It follows that for any unitary U acting only on the X_j, Z_j qubit,

$$\left\|(U_j - \hat{U}_j)|\Psi\rangle\right\| \leq 8\sqrt{2\epsilon_j} \ . \tag{6}$$

Now consider a sequence of operators $U_{j_1}, \ldots, U_{j_k}$, where U_j acts on the X_j, Z_j qubit and

$\|U_j\| \le 1$. Then iterating $\hat{U}_j|\Psi\rangle = U_{j''}^T|\Psi\rangle$ gives

$$\begin{aligned}\hat{U}_{j_1}\cdots\hat{U}_{j_k}|\Psi\rangle &= \hat{U}_{j_1}\cdots\hat{U}_{j_{k-1}}U_{j_k''}^T|\Psi\rangle \\ &= U_{j_k''}^T\hat{U}_{j_1}\cdots\hat{U}_{j_{k-1}}|\Psi\rangle \\ &= \cdots \\ &= U_{j_k''}^T\cdots U_{j_1''}^T|\Psi\rangle \ .\end{aligned}$$

To continue, iterate on $U_j|\Psi\rangle \approx U_{j''}^T|\Psi\rangle$:

$$\begin{aligned}&\approx U_{j_1}U_{j_k''}^T\cdots U_{j_2''}^T|\Psi\rangle \\ &\approx \cdots \\ &\approx U_{j_1}\cdots U_{j_k}|\Psi\rangle \ .\end{aligned}$$

The overall error satisfies

$$\big\|U_{j_1}\cdots U_{j_k}|\Psi\rangle - \hat{U}_{j_1}\cdots\hat{U}_{j_k}|\Psi\rangle\big\| \le k\cdot 4\max\|U_{j_\ell}\|\cdot 2\sqrt{2\epsilon_{j_\ell}} = O(k\sqrt{n\epsilon}) \ . \qquad \blacktriangleleft$$

In Theorem 4.3, the definition of $|\Psi\rangle$ requires adding to $\mathcal{H}$ an additional ancilla register $(\mathbf{C}^2)^{\otimes 2n}$. It is therefore not clear that the theorem should imply an exponential lower bound on the dimension of $\mathcal{H}$. In fact, though, it does lower-bound $\dim\mathcal{H}$:

▶ **Corollary 4.4.** *If the protocol in Figure 2 accepts with probability at least $1-\epsilon$, then*

$$\dim\mathcal{H} \ge \big(1-O(n^2\epsilon)\big)\,2^n \ .$$

Proof. For $(a,b)\in\{0,1\}^n\times\{0,1\}^n$ let

$$|\Psi_{a,b}\rangle = \big(X_n^{a_n}Z_n^{b_n}\big)\cdots\big(X_1^{a_1}Z_1^{b_1}\big)|\Psi\rangle \ .$$

▶ Claim 4.5. The $|\Psi_{a,b}\rangle$ satisfy $\dim\mathrm{Span}\{|\Psi_{a,b}\rangle\} \ge \big(1-O(n^2\epsilon)\big)4^n$.

Proof. Let $B = \sum_{a,b}|\Psi_{a,b}\rangle\langle a,b|$. Adopt the notation from the proof of Theorem 4.3. For $k\in\{0,\ldots,n\}$ define $|\hat{\Psi}_{a,b}^{(k)}\rangle$ similarly to $|\Psi_{a,b}\rangle$, except using the operators $\hat{X}_j$ and $\hat{Z}_j$ in place of X_j and Z_j for $j\le k$. Thus $|\hat{\Psi}_{a,b}^{(0)}\rangle = |\Psi_{a,b}\rangle$. Let $|\hat{\Psi}_{a,b}\rangle = |\hat{\Psi}_{a,b}^{(n)}\rangle$ and define $\hat{B}$ as B using the $|\hat{\Psi}_{a,b}\rangle$ instead of $|\Psi_{a,b}\rangle$. Using the triangle inequality and $\|X_j\|, \|Z_j\| \le 1$,

$$\begin{aligned}\big\||\hat{\Psi}_{a,b}\rangle - |\Psi_{a,b}\rangle\big\| &\le \sum_{k=1}^n \big\||\hat{\Psi}_{a,b}^{(k)}\rangle - |\hat{\Psi}_{a,b}^{(k-1)}\rangle\big\| \\ &\le \sum_{k=1}^n \Big\|\big(\hat{X}_k^{a_k}\hat{Z}_k^{b_k} - X_k^{a_k}Z_k^{b_k}\big)\Big(\prod_{j<k}\hat{X}_j^{a_j}\hat{Z}_j^{b_j}\Big)|\Psi\rangle\Big\| \ . \qquad (7)\end{aligned}$$

By Eq. (5) from the proof of Theorem 4.3, $\hat{P}_j|\Psi\rangle = P_{j''}^T|\Psi\rangle$, where $P_{j''}$ acts only on the j'' ancilla qubit and therefore commutes with all Q_k and $\hat{Q}_k$. Thus for any $k\in[n]$,

$$\big(\hat{X}_k^{a_k}\hat{Z}_k^{b_k} - X_k^{a_k}Z_k^{b_k}\big)\Big(\prod_{j<k}\hat{X}_j^{a_j}\hat{Z}_j^{b_j}\Big)|\Psi\rangle = \Big(\prod_{j<k}\big(X_{j''}^{a_j}Z_{j''}^{b_j}\big)^T\Big)\big(\hat{X}_k^{a_k}\hat{Z}_k^{b_k} - X_k^{a_k}Z_k^{b_k}\big)|\Psi\rangle \ .$$

Thus starting from Eq. (7) and applying (6), we obtain the bound

$$\big\||\hat{\Psi}_{a,b}\rangle - |\Psi_{a,b}\rangle\big\| \le \sum_{k=1}^n 8\sqrt{2\epsilon_k} \ . \qquad (8)$$

Moreover, the $|\hat{\Psi}_{a,b}\rangle$ vectors are orthonormal:

$$\begin{aligned}\langle\hat{\Psi}_{a,b}|\hat{\Psi}_{c,d}\rangle &= \langle\Psi_0|\mathcal{S}_{1,n}\prod_{j=1}^{n}\big(\hat{Z}_j^{b_j}\hat{X}_j^{a_j+c_j}\hat{Z}_j^{d_j}\big)\mathcal{S}_{n,1}|\Psi_0\rangle \\ &= (-1)^{(a+c)\cdot b}\langle\mathrm{EPR}|^{\otimes n}\prod_{j=1}^{n}\big((\sigma_{j'}^x)^{a_j+c_j}(\sigma_{j'}^z)^{b_j+d_j}\big)|\mathrm{EPR}\rangle^{\otimes n} \\ &= \delta_{a,c}\delta_{b,d}\ .\end{aligned}$$

Therefore $\hat{B}$ is an isometry. Its singular values are 1 with multiplicity 4^n. Let $\lambda_1 \geq \cdots \geq \lambda_{4^n} \geq 0$ be the singular values of B. (Some λ_i may be zero.) Then, relating the singular values of B and $\hat{B}$ to the Frobenius norm of their difference,

$$\begin{aligned}\sum_i |\lambda_i - 1|^2 &\leq \|B - \hat{B}\|_F^2 \\ &= \sum_{a,b}\big\||\Psi_{a,b}\rangle - |\hat{\Psi}_{a,b}\rangle\big\|^2 \\ &\leq 4^n \cdot 128 \cdot n^2\epsilon\ ,\end{aligned}$$

where the last bound is by Eq. (8) and $\sum_k \epsilon_k = n\epsilon$. Since the left-hand side is at least $4^n - \mathrm{rank}(B)$, we obtain $\mathrm{rank}(B) \geq \big(1 - O(n^2\epsilon)\big)4^n$. ◀

Let $|\Psi\rangle$ have Schmidt decomposition $|\Psi\rangle = \sum_{i=1}^{d}\sqrt{p_i}|u_i\rangle \otimes |v_i\rangle$ across the partition $\mathcal{H}$, $(\mathbf{C}^2)^{\otimes 2n}$. Extend the set $\{|u_1\rangle, \ldots, |u_d\rangle\}$, if necessary, to form an orthonormal basis for $\mathcal{H}$. The vectors $|\Psi_{a,b}\rangle$ are obtained from $|\Psi\rangle$ by applying operators X_j, Z_j supported only on $\mathcal{H}$. Therefore, they lie in the span of $\{|u_i\rangle \otimes |v_j\rangle : i \in [\dim\mathcal{H}], j \in [d]\}$. In particular, $\dim \mathrm{Span}\{|\Psi_{a,b}\rangle\} \leq d\dim\mathcal{H} \leq (\dim\mathcal{H})^2$, as desired. ◀

▶ Remark. In Theorem 3.6, different qubits overlapping by $\epsilon = O(1/n)$ already implies $\dim\mathcal{H} \geq 2^n$. In contrast, in Corollary 4.4, ϵ must be exponentially small before $\dim\mathcal{H} \geq 2^n$ is required. Is this polynomial versus exponential separation a consequence of loose analysis, an inherent drawback of the protocol in Figure 2, or an inherent property of any efficient state-dependent qubit testing protocol?

The following example suggests at least that our analysis is not too loose. Let $\mathcal{H} = \mathrm{Span}\{|x\rangle : x \neq 0^n, 1^n\} \subset (\mathbf{C}^2)^{\otimes n}$. Define n qubits by $Z_j = \sigma_j^z|_{\mathcal{H}}$ and $X_j = \sigma_j^x|_{\mathcal{H}} + \sigma_j^x(|1^n\rangle\langle 0^n| + |0^n\rangle\langle 1^n|)\sigma_j^x$. That is, while σ_j^x maps the basis states $\sigma_j^x|0^n\rangle$ and $\sigma_j^x|1^n\rangle$ outside of $\mathcal{H}$, X_j instead maps them to each other. Even though $\dim\mathcal{H} = 2^n - 2 < 2^n$, it seems that these n qubits can pass our testing protocol with probability $1 - 1/\exp(n)$.[4]

Acknowledgements. We would like to thank Greg Kuperberg for helpful comments, particularly regarding the proof of Theorem 3.1.

A Qubit packing using the exterior algebra

An alternative proof of Theorem 3.1 was suggested to the authors by Greg Kuperberg [9]. The rough idea is to begin by packing nearly orthogonal unit vectors in $\mathbf{R}^n$, then define qubits using fermion creation and annihilation operators on the 2^n-dimensional exterior algebra.

Proof of Theorem 3.1. By the Johnson-Lindenstrauss Lemma [6, 5], $e^{n\epsilon^2/8}$ unit vectors can be chosen in $\mathbf{R}^n$ so that for any pair $|u\rangle, |v\rangle$, $|\langle u|v\rangle| \leq \epsilon$. Pairing these vectors up arbitrarily, we obtain $m = \frac{1}{2}e^{n\epsilon^2/8}$ two-dimensional planes the angles between any two of which are in the range $(\frac{\pi}{2} - \epsilon, \frac{\pi}{2}]$.

If $|1\rangle, \ldots, |n\rangle$ is a basis for $\mathbf{R}^n$, let $\Lambda(\mathbf{R}^n)$ be the 2^n-dimensional exterior algebra, with basis $|i_1\rangle \wedge |i_2\rangle \wedge \ldots \wedge |i_k\rangle$ for $i_1, \ldots, i_k \in [n]$ and $k = 0, 1, \ldots, n$. For a unit vector $|v\rangle \in \mathbf{R}^n$ and $|w\rangle \in \Lambda(\mathbf{R}^n)$, define the fermion creation and annihilation operators

$$a_v^\dagger |w\rangle = |v\rangle \wedge |w\rangle$$
$$a_v |w\rangle = (\langle v| \otimes \mathbf{1})|w\rangle \ .$$

Observe that this definition is basis independent, in the sense that for any unitary R on $\mathbf{R}^n$,

$$a_{Rv}^\dagger \hat{R}|w\rangle = \hat{R} a_v^\dagger |w\rangle$$
$$a_{Rv} \hat{R}|w\rangle = \hat{R} a_v |w\rangle \ ,$$

where $\hat{R}(|v_1\rangle \wedge \cdots \wedge |v_k\rangle) = (R|v_1\rangle) \wedge \cdots \wedge (R|v_k\rangle)$.

If we choose a basis for $\mathbf{R}^n$ beginning with $|v\rangle$, then $a_v^\dagger a_v$ projects onto those basis terms in $\Lambda(\mathbf{R}^n)$ that include $|v\rangle$, while $a_v a_v^\dagger$ projects onto the complementary set of basis terms. Thus $a_v^\dagger a_v + a_v a_v^\dagger = \mathbf{1}$, while also $a_v^2 = (a_v^\dagger)^2 = 0$. Furthermore, if $|u\rangle$ is a unit vector perpendicular to $|v\rangle$, then the anticommutators satisfy $\{a_v, a_u\} = \{a_v^\dagger, a_u^\dagger\} = 0$, as $|u\rangle \wedge |v\rangle = -|v\rangle \wedge |u\rangle$, while if $|w\rangle$ has k terms,

$$\begin{aligned} a_u a_v^\dagger |w\rangle &= (\langle u| \otimes \mathbf{1})(|v\rangle \wedge |w\rangle) \\ &= (-1)^k (\langle u| \otimes \mathbf{1}|w\rangle \wedge |v\rangle \\ &= -a_v^\dagger a_u |w\rangle \ . \end{aligned}$$

Thus $\{a_u, a_v^\dagger\} = 0$.

Now for each of the m pairwise nearly orthogonal planes, let $\{|u_j\rangle, |v_j\rangle\}$ constitute an orthonormal basis. Define

$$X_j = (-a_{u_j} + a_{u_j}^\dagger)(a_{v_j} + a_{v_j}^\dagger)$$
$$Z_j = 2a_{v_j} a_{v_j}^\dagger - \mathbf{1} = a_{v_j} a_{v_j}^\dagger - a_{v_j}^\dagger a_{v_j} \ . \tag{9}$$

To understand this construction, observe that for orthonormal vectors $|u\rangle, |v\rangle \in \mathbf{R}^n$, and any $|w\rangle \in \Lambda(\mathbf{R}^n)$ with $a_u|w\rangle = a_v|w\rangle = 0$, the operators $a_u, a_u^\dagger, a_v, a_v^\dagger$ fix the subspace spanned by $|w\rangle, |v\rangle \wedge |w\rangle, |u\rangle \wedge |w\rangle, |u\rangle \wedge |v\rangle \wedge |w\rangle$. In this basis,

$$a_u = \begin{pmatrix} 0&0&1&0 \\ 0&0&0&1 \\ 0&0&0&0 \\ 0&0&0&0 \end{pmatrix} \qquad a_v = \begin{pmatrix} 0&1&0&0 \\ 0&0&0&0 \\ 0&0&0&-1 \\ 0&0&0&0 \end{pmatrix} \ .$$

Hence,

$$(-a_u + a_u^\dagger)(a_v + a_v^\dagger) = \begin{pmatrix} 0&0&0&1 \\ 0&0&1&0 \\ 0&1&0&0 \\ 1&0&0&0 \end{pmatrix} \qquad 2a_v a_v^\dagger - \mathbf{1} = \begin{pmatrix} 1&0&0&0 \\ 0&-1&0&0 \\ 0&0&1&0 \\ 0&0&0&-1 \end{pmatrix} \ .$$

The former matrix is $\sigma_X \otimes \sigma_X$, and the latter matrix is $I \otimes \sigma_Z$, where σ_X, σ_Z are the standard Pauli operators. In particular, observe that $X_j^2 = Z_j^2 = \mathbf{1}$, $X_j Z_j = -Z_j X_j$.

The above construction satisfies that if $|u_1\rangle, |v_1\rangle, |u_2\rangle, |v_2\rangle$ are pairwise orthogonal, then $[X_1, X_2] = [X_1, Z_2] = [Z_1, X_2] = [Z_1, Z_2] = 0$. The reason we use two vectors to define each X_j, Z_j (instead of just taking $X = a_u + a_u^\dagger$, $Z = 2a_u a_u^\dagger - \mathbf{1}$) is to obtain the above commutation relationships. Since X_1, Z_1 are each quadratic in $a_{u_1}, a_{u_1}^\dagger, a_{v_1}, a_{v_1}^\dagger$, terms involving only $a_{u_2}, a_{u_2}^\dagger, a_{v_2}, a_{v_2}^\dagger$ commute past them.

Next, for *nearly* orthogonal planes we will show that the commutator norm $\|[S_i, T_j]\| = O(\epsilon)$, for $i \neq j$ and $S, T \in \{X, Z\}$.

If $|u\rangle, |v\rangle$ are orthonormal, and $|t\rangle = \epsilon|u\rangle + \sqrt{1-\epsilon^2}|v\rangle$, then

$$a_t = \epsilon a_u + \sqrt{1-\epsilon^2} a_v = \begin{pmatrix} 0 & \sqrt{1-\epsilon^2} & \epsilon & 0 \\ 0 & 0 & 0 & \epsilon \\ 0 & 0 & 0 & -\sqrt{1-\epsilon^2} \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

satisfies $\{a_t, a_u\} = 0$, $\{a_t, a_u^\dagger\} = \epsilon \mathbf{1}$. In general,

$$\begin{aligned} \{a_t, a_u\} &= 0 \\ \{a_t, a_u^\dagger\} &= \langle u|t\rangle \mathbf{1} \ . \end{aligned}$$

It follows that if $|\langle u_1|u_2\rangle|, |\langle u_1|v_2\rangle|, |\langle v_1|u_2\rangle|, |\langle v_1|v_2\rangle| \leq \epsilon$, then $\|[S_1, T_2]\| = O(\epsilon)$ for $S, T \in \{X, Z\}$. Indeed,

$$\begin{aligned} X_1 a_{u_2} &= (-a_{u_1} + a_{u_1}^\dagger)(a_{v_1} + a_{v_1}^\dagger) a_{u_2} \\ &= -(-a_{u_1} + a_{u_1}^\dagger)\big[a_{u_2}(a_{v_1} + a_{v_1}^\dagger) - \langle u_2|v_1\rangle \mathbf{1}\big] \\ &= \big[a_{u_2}(-a_{u_1} + a_{u_1}^\dagger) - \langle u_2|u_1\rangle \mathbf{1}\big](a_{v_1} + a_{v_1}^\dagger) + \langle u_2|v_1\rangle(-a_{u_1} + a_{u_1}^\dagger) \\ &= a_{u_2} X_1 - \langle u_2|u_1\rangle(a_{v_1} + a_{v_1}^\dagger) + \langle u_2|v_1\rangle(-a_{u_1} + a_{u_1}^\dagger) \ , \end{aligned}$$

implying $\|[X_1, a_{u_2}]\| \leq |\langle u_2|u_1\rangle| + |\langle u_2|v_1\rangle| \leq 2\epsilon$. Similarly,

$$\begin{aligned} Z_1 a_{u_2} &= (2 a_{u_1} a_{u_1}^\dagger - \mathbf{1}) a_{u_2} \\ &= 2 a_{u_1}(\langle u_1|u_2\rangle \mathbf{1} - a_{u_2} a_{u_1}^\dagger) - a_{u_2} \\ &= a_{u_2} Z_1 + 2|\langle u_1|u_2\rangle| a_{u_1} \ , \end{aligned}$$

implying $\|[Z_1, a_{u_2}]\| \leq 2|\langle u_1|u_2\rangle| \leq 2\epsilon$. Thus $\|[S_1, T_2]\| \leq c\,\epsilon$ for a fairly small constant c. ◀

Quantum Recommendation System

Abstract

A recommendation system uses the past purchases or ratings of n products by a group of m users, in order to provide personalized recommendations to individual users. The information is modeled as an $m \times n$ preference matrix which is assumed to have a good rank-k approximation, for a small constant k.

In this work, we present a quantum algorithm for recommendation systems that has running time $O(\text{poly}(k)\text{polylog}(mn))$. All known classical algorithms for recommendation systems that work through reconstructing an approximation of the preference matrix run in time polynomial in the matrix dimension. Our algorithm provides good recommendations by sampling efficiently from an approximation of the preference matrix, without reconstructing the entire matrix. For this, we design an efficient quantum procedure to project a given vector onto the row space of a given matrix. This is the first algorithm for recommendation systems that runs in time polylogarithmic in the dimensions of the matrix and provides an example of a quantum machine learning algorithm for a real world application.

1 Introduction

A recommendation system uses information about past purchases or ratings of products by a group of users in order to provide personalized recommendations to individual users. More precisely, we assume there are m users, for example clients of an online platform like Amazon or Netflix, each of whom have some inherent preference or utility about n products, for example books, movies etc. The user preferences are modeled by an $m \times n$ matrix P, where the element P_{ij} denotes how much the user i values product j. If the preference matrix P had been known in advance, it would have been easy to make good recommendations to the users by selecting elements of this matrix with high value. However, this matrix is not known a priori. Information about P arrives in an online manner each time a user buys a product, writes a review, or fills out a survey. A recommendation system tries to utilize the

already known information about all users in order to suggest products to individual users that have high utility for them and can eventually lead to a purchase.

There has been an extensive body of work on recommendation systems, since it is a very interesting theoretical problem and also of great importance to the industry. We cite the works of [5, 18, 8, 4] who studied the problem in a combinatorial or linear algebraic fashion. There has also been a series of works in the machine learning community many of them inspired by a practical challenge by Netflix on real world data [14, 6, 13].

We next discuss the low rank assumption on the preference matrix underlying recommendation systems and the way this assumption is used to perform matrix reconstruction in classical recommendation systems. We then describe the computational model for our quantum recommendation algorithm that is based on matrix sampling and compare it to classical recommendation algorithms based on matrix reconstruction. We provide a high level overview of our algorithm in section 1.1 and then, we compare it with previous work on quantum machine learning in section 1.2.

The low-rank assumption

The underlying assumption in recommendation systems is that one can infer information about a specific user from the information about all other users because, in some sense, the majority of users belong to some well-defined “types". In other words, most people's likes are not unique but fall into one of a small number of categories. Hence, we can aggregate the information of “similar" users to predict which products have high utility for an individual user.

More formally, the assumption in recommendation systems is that the preference matrix P can be well approximated (according to some distance measure) by a low-rank matrix. There are different reasons why this assumption is indeed justified. First, from a philosophical and cognitive science perspective, it is believed that there are few inherent reasons why people buy or not a product: the price, the quality, the popularity, the brand recognition, etc. (see for example [5, 21]). Each user can be thought of as weighing these small number of properties differently but still, his preference for a product can be computed by checking how the product scores in these properties. Such a model produces a matrix P which has a good rank-k approximation, for a small k, which can be thought of as a constant independent of the number of users m or the number of products n. Moreover, a number of theoretical models of users have been proposed in the literature which give rise to a matrix with good low-rank approximation. For example, if one assumes that the users belong to a small number of “types", where a type can be thought of as an archetypical user, and then each individual user belonging to this type is some noisy version of this archetypical user, then the matrix has a good low-rank approximation [8, 18]. In addition, preference matrices that come from real data have been found to have rank asymptotically much smaller than the size of the matrix.

For these reasons, the assumption that the matrix P has a good low-rank approximation has been widely used in the literature. In fact, if we examine this assumption more carefully, we find that in order to justify that the recommendation system provides high-value recommendations, we assume that users “belong" to a small number of user types and also that they agree with these types on the high-value elements. For contradiction, imagine that there are k types of users, where each type has very few high-value elements and many small value elements. Then, the users who belong to each type can agree on all the small value elements and have completely different high-value elements. In other words, even though the matrix is low-rank, the recommendations would be of no quality. Hence, the assumption

that has been implicitly made, either by philosophical reasons or by modeling the users, is that there are k types of users and the users of each type "agree" on the high-value elements.

Recommendations by Matrix Reconstruction

One of the most powerful and common ways to provide competitive recommendation systems is through a procedure called matrix reconstruction. In this framework, we assume that there exists a hidden matrix A, in our case the preference matrix, which can be well approximated by a low-rank matrix. The reconstruction algorithm gets as input a number of samples from A, in our case the previous data about the users' preferences, and outputs a rank-k matrix with the guarantee that it is "close" to A according to some measure (for example, the 2- or the Frobenius norm). For example, the reconstruction algorithm can perform a Singular Value Decomposition on the subsample matrix $\widehat{A}$, where $\widehat{A}$ agrees with A on known samples and is 0 on the remaining entries, and output the projection of $\widehat{A}$ onto the space spanned by its top-k singular vectors. The "closeness" property guarantees that the recommendation system will select an element that with high probability corresponds to a high-value element in the matrix A and hence it is a good recommendation ([8, 5]). Another commonly used algorithm for matrix reconstruction is a variant of alternating minimization, this has been successful in practice [14] and has been recently analyzed theoretically [11]. Note that all known algorithms for matrix reconstruction require time polynomial in the matrix dimensions.

An important remark is that matrix reconstruction is a harder task than recommendation systems, in the sense that a good recommendation system only needs to output a high value element of the matrix and not the entire matrix [20, 3]. Nevertheless, classical algorithms perform a reconstruction of the entire matrix as the resources required for finding high value elements are the same as the resources needed for full reconstruction.

Computational resources and performance

In order to make a precise comparison between classical recommendation systems and our proposed system, we discuss more explicitly the computational resources in recommendation systems. We are interested in systems that arise in the real world, for example on Amazon or Netflix, where the number of users can be about 100 million and the products around one million. For such large systems, storing the entire preference matrix or doing heavy computations every time a user comes into the system is prohibitive.

The memory model for an online recommendation system is the following. A data structure is maintained that contains the information that arrives into the system in the form of elements P_{ij} of the preference matrix. We require that the time needed to write the tuple (i, j, P_{ij}) into the memory data structure and to read it out is polylogarithmic in the matrix dimensions. In addition, we require that the total memory required is linear (up to polylogarithmic terms) in the number of entries of the preference matrix that have arrived into the system. For example, one could store the elements (i, j, P_{ij}) in an ordered list.

Most classical recommendation systems use a two stage approach. The first stage involves preprocessing the data stored in memory. For example, a matrix reconstruction algorithm can be performed during the preprocessing stage to produce and store a low-rank approximation of the preference matrix. This computation takes time polynomial in the matrix dimensions, poly(mn), and the stored output is the top-k row singular vectors that need space $O(nk)$. The second stage is an online computation that is performed when a user comes into the system. For example, one can project the row of the subsample matrix that corresponds to

this user onto the already stored top-k row singular vectors of the matrix and output a high value element in time $O(nk)$.

The goal is to minimize the time needed to provide an online recommendation while at the same time keeping the time and the extra memory needed for the preprocessing reasonable. In general, the preprocessing time is polynomial in the dimensions of the preference matrix, i.e. poly(mn), the extra memory is $O(nk)$, while the time for the online recommendation is $O(nk)$. Note that in real world applications, it is prohibitive to have a system where the preprocessing uses memory $O(mn)$, even though with such large memory the online recommendation problem becomes trivial as all the answers can be pre-computed and stored.

A recommendation system performs well, when with high probability and for most users it outputs a recommendation that is good for a user. The performance of our recommendation system is similar to previous classical recommendation systems based on matrix reconstruction and depends on how good the low-rank approximation of the matrix is. Our algorithm works for any matrix, but as in the classical case, it guarantees good recommendations only when the matrix has a good low-rank approximation.

1.1 Our results

In this section, we provide a high level overview of our quantum recommendation algorithm which requires time polylogarithmic in the matrix dimensions and polynomial only in the rank of the matrix, which as we have argued is assumed to be much smaller than the dimension of the matrix. This is the first algorithm for recommendation systems with complexity polylogarithmic in the matrix dimensions.

Our model

First, we describe a simple and general model for online recommendation systems. We start with a hidden preference matrix T, where the element T_{ij} takes values 0 or 1 and indicates whether product j is "good" for user i. Such boolean matrices arise naturally in a "thumbs up / thumbs down" system, where users can declare whether they like or not a certain product. We can also easily construct such matrices from non-boolean preference matrices. For each user, we split the products into two categories, the “good" and the “bad" recommendations, based on the matrix entries. This categorization can be done in different ways and we do not have to impose any constraints. For example, good recommendations can be every product with value higher than a threshold or the 100 products with the highest values etc.

Our assumption is that the matrix T has a good low-rank approximation. The reasons that justify this assumption are the ones used already in the literature. As before, we believe that there is a small number of user types, and within each type the users “agree" on the high-value elements. This modelling of the users gives rise to a matrix T with a good low-rank approximation. Once we have defined the matrix T, then any algorithm that reconstructs a matrix close to T, will provide a good recommendation, since T is the indicator matrix of good recommendations.

Recommendations by Matrix Sampling

The low-rank approximation of the matrix T can be computed as follows: first, define the matrix $\widehat{T}$, where with some probability each element of $\widehat{T}$ is equal to the corresponding element in T normalized and otherwise it is zero. This matrix, that we call a subsample matrix, corresponds to the information the recommendation system has already gathered about the matrix T. Then, by performing a Singular Value Decomposition and computing

the projection of this matrix to its top-k row singular vectors, we compute a matrix $\widehat{T}_k$ which can be proven to be close to the matrix T, as long as T had a good rank-k approximation.

As we remarked, in principle, we do not need to explicitly compute the entire matrix $\widehat{T}_k$. It is sufficient to be able to sample from the matrix $\widehat{T}_k$ which is close to T. Since T is a 0-1 matrix, sampling from $\widehat{T}_k$ means finding with high probability a 1-element in T. By the fact that T indicates the good recommendations, our algorithm will output a good recommendation with high probability. Hence, we reduce the question of providing good recommendations to being able to sample from the matrix $\widehat{T}_k$. In fact, since we want to be able to recommend products to any specific user i, we need to be able, given an index i, to sample from the i-th row of the matrix $\widehat{T}_k$, denoted by $(\widehat{T}_k)_i$, i.e. output an element $(\widehat{T}_k)_{ij}$ with probability $|(\widehat{T}_k)_{ij}|^2/\|(\widehat{T}_k)_i\|^2$. Note that the row $(\widehat{T}_k)_i$ is the projection of the row $\widehat{T}_i$ onto the top-k row singular vectors of $\widehat{T}$.

An efficient quantum algorithm for Matrix Sampling

Here is where quantum computing becomes useful: we design a quantum procedure that samples from the row $(\widehat{T}_k)_i$ in time polylog(mn). Note that the quantum algorithm does not output the row $(\widehat{T}_k)_i$, which by itself would take time linear in the dimension n, but only samples from this row. But this is exactly what is needed for recommendation systems: Sample a high-value element of the row, rather than explicitly output the entire row. More precisely, we describe an efficient quantum procedure that takes as input a vector, a matrix, and a threshold parameter and generates the quantum state corresponding to the projection of the vector onto the space spanned by the row singular vectors of the matrix whose corresponding singular value is greater than the threshold. From the outcome of this procedure it is clear how to sample a product by just measuring the quantum state in the computational basis.

1.2 Comparisons with related work

The development of quantum algorithms for linear algebra was initiated by the breakthrough algorithm of Harrow, Hassidim, Lloyd [10]. The HHL algorithm takes as input a sparse (the number of non zero entries in each row of the matrix is polylogarithmic) and well-conditioned system of linear equations and in time polylogarithmic in the dimension of the system outputs a quantum state which corresponds to the classical solution of the system. Note that this algorithm does not explicitly output the classical solution, nevertheless, the quantum state enables one to sample from the solution vector. This is a very powerful algorithm and has been very influential in recent times, where several works [16, 15, 17] obtained quantum algorithms for machine learning problems based on similar assumptions. However, when looking at these applications, one needs to be extremely careful about two things: first, the assumptions that one needs to make on the input in order to achieve efficient running time, since, for example, the running time of the HHL algorithm is polylogarithmic only when the matrix is well conditioned (i.e. the minimum singular value is at least inverse polynomially big) and sparse; and second, whether the quantum algorithm solves the original classical problem or a weaker variant to account for the fact that the classical solution is not given explicitly but is encoded in a quantum state [1, 17]. In addition, we mention a recent but orthogonal proposal to use techniques inspired by the structure of quantum theory for classical recommender systems [22].

Let us be more explicit about our algorithm's assumptions. We assume the data is stored in a classical data structure which enables the quantum algorithm to efficiently create

superpositions of rows of the subsample matrix. The HHL algorithm also needs to be able to efficiently construct quantum states from classical vectors given as inputs. In the Appendix, we describe a classical data structure for storing the matrix $\widehat{T}$. The data structure maintains some extra information about the matrix entries, so that, the total memory needed is linear (up to polylogarithmic terms) in the number of entries in the subsample matrix, the data entry time remains polylogarithmic in the matrix dimensions, and an algorithm with quantum access to the data structure can create the necessary superpositions in polylogarithmic time. Note also, that even in the case the data has been stored as a normal array or list, we can preprocess it in linear time to construct our needed data structure. Thus, our quantum algorithm works under the same memory model as any other quantum query algorithm (e.g. Grover's algorithm): it assumes that there exists a classical data structure to which we can make quantum queries. Overall, our system retains the necessary properties for the data entry and retrieval stage. Moreover, the classical complexity of matrix reconstruction does not change given the new data structure.

Importantly, in our system, we do not perform any preprocessing nor do we need any extra memory. Our recommendation algorithm just performs an online computation that requires time $\text{poly}(k)\text{polylog}(mn)$. This can be viewed as exponentially smaller than the classical time if the rank k is a small constant and the matrix dimensions are of the same order. Unlike the HHL algorithm, our running time does not depend on the sparsity of the input matrix nor on its condition number, i.e. its smallest singular value. In other words, we do not make any additional assumptions about the classical data beyond the low rank approximation assumptions made by classical recommendation systems.

It is also crucial to note that we have not changed what one needs to output, as was the case for the HHL algorithm and its applications, where instead of explicitly outputting a classical solution, they construct a quantum state that corresponds to this solution. We have instead described a real world application, where the ability to sample from the solution is precisely what is needed. Our work also suggests a new avenue for classical recommendation systems, which we state below as an open problem.

▶ **Open Problem 1.** *Find a classical recommendation algorithm using matrix sampling that requires time $O(poly(k)polylog(mn))$ or prove a lower bound that rules out the existence of such an algorithm.*

The rest of this paper is organized as follows. We introduce some preliminaries in section 2. In sections 3 and 4 we show that sampling from an approximate reconstruction of the matrix T suffices to provide good recommendations and that if the sub-samples $\widehat{T}$ are uniformly distributed then projecting onto the top k singular vectors of $\widehat{T}$ is an approximate reconstruction for T. In section 5 we describe an efficient quantum algorithm for projecting a vector onto the space of singular vectors of $\widehat{T}$ whose corresponding singular values are greater than a threshold. In section 6 we combine these components to obtain a quantum recommendation algorithm and analyze its performance and running time.

2 Preliminaries

2.1 Linear algebra

The set $\{1, 2, \cdots, n\}$ is denoted by $[n]$, the standard basis vectors in $\mathbb{R}^n$ are denoted by $e_i, i \in [n]$. For any matrix $A \in \mathbb{R}^{m\times n}$, the Frobenius norm is defined as $\|A\|_F^2 = \sum_{ij} A_{ij}^2 = \sum_i \sigma_i^2$, where σ_i are the singular values. We also say that we sample from the matrix A

when we pick an element (i,j) with probability $|A_{ij}|^2/\|A\|_F^2$, and write $(i,j) \sim A$. For a vector $x \in \mathbb{R}^n$ we denote the norm $\|x\|^2 = \sum_i x_i^2$.

The matrix A is unitary if $AA^* = A^*A = I$, the eigenvalues of a unitary matrix have unit norm. A matrix $P \in \mathbb{R}^{n\times n}$ is a projector if $P^2 = P$. If A is a matrix with orthonormal columns, then AA^t is the projector onto the column space of A.

Singular value decomposition The singular value decomposition of $A \in \mathbb{R}^{m\times n}$ is a decomposition of the form $A = U\Sigma V^t$ where $U \in \mathbb{R}^{m\times m}, V \in \mathbb{R}^{n\times n}$ are unitary and $\Sigma \in \mathbb{R}m \times n$ is a diagonal matrix with positive entries. The SVD can be written as $A = \sum_{i\in[r]} \sigma_i u_i v_i^t$ where r is the rank of A. The column and the row singular vectors u_i and v_i are the columns of U and V respectively. The Moore Penrose pseudo-inverse is defined as $A^+ = V\Sigma^+U^t$, where $A^+ = \sum_{i\in[r]} \frac{1}{\sigma_i} v_i u_i^t$. It follows that AA^+ is the projection onto the column space $Col(A)$ while A^+A is the projection onto the row space $Row(A)$. The truncation of A to the space of the singular vectors that correspond to the k largest singular values is denoted by A_k, that is $A_k = \sum_{i\in[k]} \sigma_i u_i v_i^t$. We denote by $A_{\geq\sigma}$ the projection of the matrix A onto the space spanned by the singular vectors whose corresponding singular value is bigger than σ, that is $A_{\geq\sigma} = \sum_{i:\sigma_i\geq\sigma} \sigma_i u_i v_i^t$.

2.2 Quantum information

We use the standard bra-ket notation to denote quantum states. We use the following encoding for representing n dimensional vectors by quantum states,

▶ **Definition 2.** *The vector state $|x\rangle$ for $x \in \mathbb{R}^n$ is defined as $\frac{1}{\|x\|}\sum_{i\in[n]} x_i |i\rangle$.*

In case $x \in \mathbb{R}^{mn}$, we can either see it as a vector in this space or as a matrix with dimensions $m \times n$ and then we can equivalently write $\frac{1}{\|x\|}\sum_{i\in[m],j\in[n]} x_{ij} |i,j\rangle$.

A quantum measurement ($POVM$) is a collection of positive operators $M_a \succeq 0$ such that $\sum_a M_a = I_n$. The probability of obtaining outcome a when state $|\phi\rangle$ is measured is $Tr(\langle\phi|M_a\phi\rangle)$. If $|x\rangle$ is measured in the standard basis, then outcome i is observed with probability $x_i^2/\|x\|^2$.

We also use a well-known quantum algorithm called phase estimation. The phase estimation algorithm estimates the eigenvalues of a unitary operator U with additive error ϵ in time $O(T(U)\log n/\epsilon)$ if $T(U)$ is the time required to implement the unitary U.

▶ **Theorem 3.** Phase estimation [12]*: Let U be a unitary operator, with eigenvectors $|v_j\rangle$ and eigenvalues $e^{\iota\theta_j}$ for $\theta_j \in [-\pi,\pi]$, i.e. we have $U|v_j\rangle = e^{\iota\theta_j}|v_j\rangle$ for $j \in [n]$. For a precision parameter $\epsilon > 0$, there exists a quantum algorithm that runs in time $O(T(U)\log n/\epsilon)$ and with probability $1-1/\mathrm{poly}(n)$ maps a state $|\phi\rangle = \sum_{j\in[n]} \alpha_j |v_j\rangle$ to the state $\sum_{j\in[n]} \alpha_j |v_j\rangle|\overline{\theta_j}\rangle$ such that $\overline{\theta_j} \in \theta_j \pm \epsilon$ for all $j \in [n]$.*

Note that we use ι to denote the imaginary unit i to avoid confusion with summation indices. The analysis of phase estimation shows that the algorithm outputs a discrete valued estimate for each eigenvalue that is within additive error ϵ with probability at least 0.8, the probability is boosted to $1 - 1/\mathrm{poly}(n)$ by repeating $O(\log n)$ times and choosing the most frequent estimate.

3 A model for recommendation systems

3.1 The preference matrix

We define a simple and general model for recommendation systems. We define a *preference matrix* T of size $m \times n$, where every row corresponds to a user, every column to a product, and the element T_{ij} is 0 or 1 and denotes whether product j is a good recommendation for user i or not.

▶ **Definition 4.** *A product j is a good recommendation for user i iff $T_{ij} = 1$, otherwise it is bad. We also write it as the pair (i, j) is a good or bad recommendation.*

Such matrices arise in systems where the information the users enter is binary, for example in a "thumbs up / thumbs down" system. We can also construct such matrices from more general preference matrices where the users use a star system to grade the products. One can imagine, for example, that the good recommendations could be the products for which the user has a preference higher than a threshold, or the hundred products with highest preference etc.

3.2 Sampling an approximation of the preference matrix

Note that sampling from the preference matrix T would always yield a good recommendation, since the products that correspond to bad recommendations have probability 0. This remains true even when we want to sample from a specific row of the matrix in order to provide a recommendation to a specific user. Our goal now is to show that sampling from a matrix that is close to the matrix T under the Frobenius norm yields good recommendations with high probability for most users.

▶ **Lemma 5.** *Let $\widetilde{T}$ be an approximation of the matrix T such that $\|T - \widetilde{T}\|_F \leq \epsilon \|T\|_F$. Then, the probability a sample according to $\widetilde{T}$ is a bad recommendation is*

$$\Pr_{(i,j)\sim\widetilde{T}}[(i,j) \text{ bad}] \leq \left(\frac{\epsilon}{1-\epsilon}\right)^2$$

Proof. By the theorem's assumption and triangle inequality, we have

$$(1+\epsilon)\|T\|_F \geq \|\widetilde{T}\|_F \geq (1-\epsilon)\|T\|_F.$$

We can rewrite the approximation guarantee as

$$\epsilon^2 \|T\|_F^2 \geq \|T - \widetilde{T}\|_F^2 = \sum_{(i,j):good} (1 - \widetilde{T}_{ij})^2 + \sum_{(i,j):bad} \widetilde{T}_{ij}^2 \geq \sum_{(i,j):bad} \widetilde{T}_{ij}^2 \tag{1}$$

The probability that sampling from $\widetilde{T}$ provides a bad recommendation is

$$\Pr[(i,j) \text{ bad}] = \frac{\sum_{(i,j):bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}\|_F^2} \leq \frac{\sum_{(i,j):bad} \widetilde{T}_{ij}^2}{(1-\epsilon)^2 \|T\|_F^2} \leq \left(\frac{\epsilon}{1-\epsilon}\right)^2. \tag{2}$$

◀

The above can be rewritten as follows denoting the i-th row of T by T_i,

$$\Pr[(i,j) \text{ bad}] = \frac{\sum_{(i,j):bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}\|_F^2} = \sum_{i\in[m]} \frac{\|\widetilde{T}_i\|_F^2}{\|\widetilde{T}\|_F^2} \cdot \frac{\sum_{j:(i,j)bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}_i\|_F^2} \leq \left(\frac{\epsilon}{1-\epsilon}\right)^2. \tag{3}$$

We can see that the above lemma provides the guarantee that the probability of a bad recommendation for an average user is small, where the average is weighted according to the weight of each row. In other words, if we care more about users that have many products they like and less for users that like almost nothing, then the sampling already guarantees good performance.

While this might be sufficient in some scenarios, it would be nice to also have a guarantee that the recommendation is good for most users, where now every user has the same importance. Note that only with the closeness guarantee in the Frobenius norm, this may not be true, since imagine the case where almost all rows of the matrix T have extremely few 1s and a few rows have almost all 1s. In this case, it might be that the approximation matrix is close to the preference matrix according to the Frobenius norm, nevertheless the recommendation system provides good recommendations only for the very heavy users and bad ones for almost everyone else.

Hence, if we would like to show that the recommendation system provides good recommendations for most users, then we need to assume that most users are "typical", meaning that the number of products that are good recommendations for them is close to the average. We cannot expect to provide good recommendations for example to users that like almost nothing. One way to enforce this property is, for example, to define good recommendations for each user as the 100 top products, irrespective of how high their utilities are or whether there are even more good products for some users. In what follows we prove our results in most generality, where we introduce parameters for how many users are typical and how far from the average the number of good recommendations of a typical user can be.

▶ **Theorem 6.** *Let T be an $m \times n$ matrix. Let S be a subset of rows of size $|S| \geq (1-\zeta)m$ (for $\zeta > 0$) such that for all $i \in S$,*

$$\frac{1}{1+\gamma}\frac{\|T\|_F^2}{m} \leq \|T_i\|^2 \leq (1+\gamma)\frac{\|T\|_F^2}{m} \tag{4}$$

for some $\gamma > 0$. Let $\widetilde{T}$ be an approximation of the matrix T such that $\|T-\widetilde{T}\|_F \leq \epsilon\|T\|_F$. Then, there exists a subset $S' \subseteq S$ of size at least $(1-\delta-\zeta)m$ (for $\delta > 0$), such that on average over the users in S', the probability that a sample from the row $\widetilde{T}_i$ is a bad recommendation is

$$\Pr_{i\sim\mathcal{U}_{S'}, j\sim\widetilde{T}_i}[(i,j) \text{ bad}] \leq \frac{\left(\frac{\epsilon(1+\epsilon)}{1-\epsilon}\right)^2}{\left(1/\sqrt{1+\gamma} - \epsilon/\sqrt{\delta}\right)^2 (1-\delta-\zeta)}.$$

Proof. We first use the guarantee that the matrices T and $\widetilde{T}$ are close in the Frobenius norm to conclude that there exist at least $(1-\delta)m$ users for which

$$\|T_i - \widetilde{T}_i\|^2 \leq \frac{\epsilon^2\|T\|_F^2}{\delta m}. \tag{5}$$

If not, summing the error of the strictly more than δm users for which equation 5 is false we get the following contradiction,

$$\|T-\widetilde{T}\|_F^2 > \delta m \frac{\epsilon^2\|T\|_F^2}{\delta m} > \epsilon^2\|T\|_F^2.$$

Then, at least $(1-\delta-\zeta)m$ users both satisfy equation 5 and belong to the set S. Denote this set by S'. Using equations (4) and (5) and the triangle inequality $\|\widetilde{T}_i\| \geq \|T_i\| - \|T_i - \widetilde{T}_i\|$, we have that for all users in S'

$$\|\widetilde{T}_i\|_F^2 \geq \frac{\|T\|_F^2}{m}\left(\frac{1}{\sqrt{1+\gamma}} - \frac{\epsilon}{\sqrt{\delta}}\right)^2 \geq \frac{\|\widetilde{T}\|_F^2}{(1+\epsilon)^2 m}\left(\frac{1}{\sqrt{1+\gamma}} - \frac{\epsilon}{\sqrt{\delta}}\right)^2. \tag{6}$$

We now use equations (3) and (6) and have

$$\left(\frac{\epsilon}{1-\epsilon}\right)^2 \geq \sum_{i\in[m]} \frac{\|\widetilde{T}_i\|_F^2}{\|\widetilde{T}\|_F^2} \cdot \frac{\sum_{j:(i,j)bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}_i\|_F^2} \geq \frac{\left(1/\sqrt{1+\gamma} - \epsilon/\sqrt{\delta}\right)^2}{(1+\epsilon)^2 m} \sum_{i\in S'} \frac{\sum_{j:(i,j)bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}_i\|_F^2}. \quad (7)$$

We are now ready to conclude that,

$$\Pr_{i\sim\mathcal{U}_{S'}, j\sim\widetilde{T}_i}[(i,j) \text{ bad}] = \frac{1}{|S'|} \sum_{i\in S'} \frac{\sum_{j:(i,j)bad} \widetilde{T}_{ij}^2}{\|\widetilde{T}_i\|_F^2} \leq \frac{\left(\frac{\epsilon(1+\epsilon)}{1-\epsilon}\right)^2}{\left(1/\sqrt{1+\gamma} - \epsilon/\sqrt{\delta}\right)^2 (1-\delta-\zeta)}.$$

◀

We note that by taking reasonable values for the parameters, the error does not increase much from the original error. For example, if we assume that 90% of the users have preferences between 1/1.1 and 1.1 times the average, then the error over the typical users has increased by at most a factor of 1.5. Note also that we can easily make the quality of the recommendation system even better if we are willing to recommend a small number of products, instead of just one, and are satisfied if at least one of them is a good recommendation. This is in fact what happens in practical systems.

4 Matrix Sampling

We showed in the previous section that providing good recommendations reduces to being able to sample from a matrix $\widetilde{T}$ which is a good approximation to the recommendation matrix T in the Frobenius norm. We will now define the approximation matrix $\widetilde{T}$, by extending known matrix reconstruction techniques. The reconstruction algorithms provides good guarantees under the assumption that the recommendation matrix T has a good k-rank approximation for a small k, i.e. $\|T - T_k\|_F \leq \epsilon\|T\|_F$ (for some small constant $\epsilon \geq 0$).

Let us now briefly describe the matrix reconstruction algorithms. In general, the input to the reconstruction algorithm is a subsample of some matrix A. There are quite a few different ways of subsampling a matrix, for example, sampling each element of the matrix with some probability or sampling rows and/or columns of the matrix according to some distribution. We present here in more detail the first case as is described in the work of Achlioptas and McSherry [2]. Each element of the matrix A that has size $m \times n$ is sampled with probability p and rescaled so as to obtain the random matrix $\widehat{A}$ where each element is equal to $\widehat{A}_{ij} = A_{ij}/p$ with probability p and 0 otherwise. Note that $E[\widehat{A}] = A$ and that it is assumed that k and $\|A\|_F$ are known.

The reconstruction algorithm computes the projection of the input matrix $\widehat{A}$ onto its k-top singular vectors; we denote the projection by $\widehat{A}_k$. The analysis of the algorithm shows that the approximation error $\|A - \widehat{A}_k\|$ is not much bigger than $\|A - A_k\|$. Projecting onto the top k singular vectors of the subsampled matrix $\widehat{A}$ thus suffices to reconstruct a matrix approximating A.

The intuition for the analysis is that $\widehat{A}$ is a matrix whose entries are independent random variables, thus with high probability the top k spectrum of $\widehat{A}$ will be close to the one of its expectation matrix $E[\widehat{A}] = A$. This intuition was proven in [2].

▶ **Theorem 7.** *[2] Let $A \in \mathbb{R}^{m\times n}$ be a matrix and $b = \max_{ij} A_{ij}$. Define the matrix $\widehat{A}$ to be a random matrix obtained by subsampling with probability $p = 16nb^2/(\eta\|A\|_F)^2$ (for $\eta > 0$)*

and rescaling, that is $\widehat{A}_{ij} = A_{ij}/p$ *with probability* p *and* 0 *otherwise. With probability at least* $1 - exp(-19(\log n)^4)$ *we have for any* k

$$\|A - \widehat{A}_k\|_F \leq \|A - A_k\|_F + 3\sqrt{\eta}k^{1/4}\|A\|_F. \tag{8}$$

Here, we will need to extend this result in order to be able to use it together with our quantum procedure. First, we will consider the matrix which is not the projection on the k-top singular vectors, but the projection on the singular vectors whose corresponding singular values are larger than a threshold. For any matrix A and any $\sigma \geq 0$, we denote by $A_{\geq\sigma}$ the projection of the matrix A onto the space spanned by the singular vectors whose corresponding singular value is bigger than σ. Intuitively, since the spectrum of the matrix is highly concentrated on the top k singular vectors, then the corresponding singular values should be of order $O(\frac{\|A\|_F}{\sqrt{k}})$.

Note that we do not use anything about how the matrix $\widehat{A}$ was generated, only that it satisfies equation 8. Hence our results hold for other matrix reconstruction algorithms as well, as long as we have a similar guarantee in the Frobenius norm.

▶ **Theorem 8.** *Let* $A \in \mathbb{R}^{m\times n}$ *be a matrix such that* $\max_{ij} A_{ij} = 1$. *Define the matrix* $\widehat{A}$ *to be a random matrix obtained by subsampling with probability* $p = 16n/\eta^2(\|A\|_F)^2$ *(for* $\eta > 0$*) and rescaling, that is* $\widehat{A}_{ij} = A_{ij}/p$ *with probability* p *and* 0 *otherwise. Let* $\mu > 0$ *a threshold parameter and denote* $\sigma = \sqrt{\frac{\mu}{k}}||\widehat{A}||_F$. *With probability at least* $1 - exp(-19(\log n)^4)$ *we have*

$$\|A - \widehat{A}_{\geq\sigma}\|_F \leq \|A - A_k\|_F + (3\sqrt{\eta}k^{1/4}\mu^{-1/4} + \sqrt{\mu/p})\|A\|_F. \tag{9}$$

If $\|A - A_k\|_F \leq \epsilon\|A\|_F$ *for some* $\epsilon > 0$ *and* $\|A\|_F \geq \frac{36\sqrt{2}(nk)^{1/2}}{\epsilon^3}$ *then we can choose* η, μ *such that* $\|A - \widehat{A}_{\geq\sigma}\|_F \leq 3\epsilon\|A\|_F$.

Proof. Let σ_i denote the singular values of $\widehat{A}$. Let ℓ the largest integer for which $\sigma_\ell \geq \sqrt{\frac{\mu}{k}}||\widehat{A}||_F$. Note that $\ell \leq \frac{k}{\mu}$. Then, by theorem 7, we have

$$\|A - \widehat{A}_{\geq\sigma}\|_F = \|A - \widehat{A}_\ell\|_F \leq \|A - A_\ell\|_F + 3\sqrt{\eta}\ell^{1/4}\|A\|_F.$$

Define the random variable $X = \sum_{i,j}\widehat{A}_{ij}^2$ so that $X = \|\widehat{A}\|_F^2$ and $E[X] = \|A\|_F^2/p$. The random variables $\widehat{A}_{ij}$ are independent, using the Chernoff bounds we have $\Pr[\|\widehat{A}\|_F^2 > (1+\beta)\|A\|_F^2/p] \leq e^{-\beta^2\|A\|_F^2/3p}$ for $\beta \in [0,1]$. The probability that $\|\widehat{A}\|_F^2 > 2\|A\|_F^2/p$ is exponentially small.

We distinguish two cases.

If $\ell \geq k$, then $\|A - A_\ell\|_F \leq \|A - A_k\|_F$, since A_ℓ contains more of the singular vectors of A.

If $k > \ell$, then $\|A - A_\ell\|_F \leq \|A - A_k\|_F + \|A_k - A_\ell\|_F$, which dominates the two cases. For the second term we have $\|A_k - A_\ell\|_F^2 = \sum_{i=\ell+1}^{k}\sigma_i^2 \leq k\frac{\mu}{k}\|\widehat{A}\|_F^2 \leq \frac{2\mu}{p}\|A\|_F^2$. Hence,

$$\|A - \widehat{A}_{\geq\sigma}\|_F \leq \|A - A_k\|_F + (3\sqrt{\eta}k^{1/4}\mu^{-1/4} + \sqrt{2\mu/p})\|A\|_F.$$

If $\|A - A_k\|_F \leq \epsilon\|A\|_F$, for some $\epsilon \geq 0$ then we choose $\mu = \epsilon^2 p/2$ and we can select any $\eta \leq \frac{2n^{1/4}\epsilon^{3/2}}{3(2k)^{1/4}\|A\|_F^{1/2}}$ so that $3\sqrt{\eta}k^{1/4}\mu^{-1/4} \leq \epsilon$ and the overall error $\|A - \widehat{A}_{\geq\sigma}\|_F \leq 3\epsilon\|A\|_F$. Indeed,

$$3\sqrt{\eta}k^{1/4}\mu^{-1/4} = \frac{3\eta^{1/2}(2k)^{1/4}}{\epsilon^{1/2}p^{1/4}} = \frac{3\eta\|A\|_F^{1/2}(2k)^{1/4}}{2\epsilon^{1/2}n^{1/4}} \leq \epsilon$$

Note that for this choice of μ and η, the sampling probability must be at least $p \geq \frac{36\sqrt{2}(nk)^{1/2}}{\|A\|_F\epsilon^3}$, the assumption in the theorem statement ensures that $p \leq 1$. ◀

Our quantum procedure will almost produce this projection. In fact, we will need to consider a family of matrices which denote the projection of the matrix A onto the space spanned by the union of the singular vectors whose corresponding singular value is bigger than σ and also some subset of singular vectors whose corresponding singular value is in the interval $[(1-\kappa)\sigma, \sigma)$. Think of κ as a constant, for example $1/3$. This subset could be empty, all such singular vectors, or any in-between subset. We denote by $A_{\geq\sigma,\kappa}$ any matrix in this family.

The final theorem we will need is the following

▶ **Theorem 9.** *Let $A \in \mathbb{R}^{m\times n}$ be a matrix and $\max_{ij} A_{ij} = 1$. Define the matrix $\widehat{A}$ to be a random matrix obtained by subsampling with probability $p = 16n/(\eta\|A\|_F)^2$ and rescaling, that is $\widehat{A}_{ij} = A_{ij}/p$ with probability p and 0 otherwise. Let $\mu > 0$ a threshold parameter and denote $\sigma = \sqrt{\frac{\mu}{k}}||\widehat{A}||_F$. Let $\kappa > 0$ a precision parameter. With probability at least $1 - exp(-19(\log n)^4)$,*

$$\|A - \widehat{A}_{\geq\sigma,\kappa}\|_F \leq 3\|A - A_k\|_F + \left(3\sqrt{\eta}k^{1/4}\mu^{-1/4}(2 + (1-\kappa)^{-1/2}) + (3-\kappa)\sqrt{2\mu/p}\right)\|A\|_F. \tag{10}$$

If $\|A - A_k\|_F \leq \epsilon\|A\|_F$ for some $\epsilon > 0$ and $\|A\|_F \geq \frac{36\sqrt{2}(nk)^{1/2}}{\epsilon^3}$ then we can choose η, μ such that $\|A - \widehat{A}_{\geq\sigma,\kappa}\|_F \leq 9\epsilon\|A\|_F$.

Proof. We have

$$\begin{aligned}
\|A - \widehat{A}_{\geq\sigma,\kappa}\|_F &\leq \|A - \widehat{A}_{\geq\sigma}\|_F + \|\widehat{A}_{\geq\sigma} - \widehat{A}_{\geq\sigma,\kappa}\|_F \\
&\leq \|A - \widehat{A}_{\geq\sigma}\|_F + \|\widehat{A}_{\geq\sigma} - \widehat{A}_{\geq(1-\kappa)\sigma}\|_F \\
&\leq \|A - \widehat{A}_{\geq\sigma}\|_F + \|A - \widehat{A}_{\geq\sigma}\|_F + \|A - \widehat{A}_{\geq(1-\kappa)\sigma}\|_F \\
&\leq 2\|A - \widehat{A}_{\geq\sigma}\|_F + \|A - \widehat{A}_{\geq(1-\kappa)\sigma}\|_F.
\end{aligned}$$

We use Theorem 8 to bound the first term as

$$\|A - \widehat{A}_{\geq\sigma}\|_F \leq \|A - A_k\|_F + (3\sqrt{\eta}k^{1/4}\mu^{-1/4} + \sqrt{2\mu/p})\|A\|_F$$

For the second term, we can reapply Theorem 8 where now we need to rename μ as $(1-\kappa)^2\mu$ and have

$$\|A - \widehat{A}_{\geq(1-\kappa)\sigma}\|_F \leq \|A - A_k\|_F + (3\sqrt{\eta}k^{1/4}(1-\kappa)^{-1/2}\mu^{-1/4} + (1-\kappa)\sqrt{2\mu/p})\|A\|_F.$$

Overall we have

$$\|A - \widehat{A}_{\geq\sigma,\kappa}\|_F \leq 3\|A - A_k\|_F + \left(3\sqrt{\eta}k^{1/4}\mu^{-1/4}(2 + (1-\kappa)^{-1/2}) + (3-\kappa)\sqrt{2\mu/p}\right)\|A\|_F.$$

Let $\|A - A_k\|_F \leq \epsilon\|A\|_F$, for some $\epsilon \geq 0$. We choose $\kappa = 1/3$, $\mu = \epsilon^2 p/2$ and we can select any $\eta \leq \frac{2n^{1/4}\epsilon^{3/2}}{3(2k)^{1/4}\|A\|_F^{1/2}}$ to have

$$\|A - \widehat{A}_{\geq\sigma,\kappa}\|_F \leq 3\epsilon\|A\|_F + \left(2\epsilon + \frac{\epsilon}{\sqrt{1-\kappa}} + (3-\kappa)\epsilon\right)\|A\|_F \leq 9\epsilon\|A\|_F. \tag{11}$$

As in theorem 8, the sampling probability must be at least $p \geq \frac{36\sqrt{2}(nk)^{1/2}}{\|A\|_F\epsilon^3}$. ◀

We have shown that the task of providing good recommendations for a user i reduces to being able to sample from the i-th row of the matrix $\widehat{T}_{\geq\sigma,\kappa}$, in other words sample from the projection of the i-th row of $\widehat{T}$ onto the space spanned by all row singular vectors with singular values higher than σ and possibly some more row singular vectors with singular values in the interval $[(1-\kappa)\sigma, \sigma)$.

In the following section, we show a quantum procedure, such that given a vector (e.g. the i-th row of $\widehat{T}$), a matrix (e.g. the matrix $\widehat{T}$), and parameters σ and κ, outputs the quantum state $|(\widehat{T}_{\geq\sigma,\kappa})_i\rangle$, which allows one to sample from this row by measuring in the computational basis. The algorithm runs in time polylogarihmic in the matrix dimensions and polynomial in k, since it depends inverse polynomially in σ, which in our case is inverse polynomial in k.

5 Quantum projections in polylogarithmic time

The main quantum primitive required for the recommendation system is a quantum projection algorithm that runs in time polylogarithmic in the matrix dimensions.

5.1 The data structure

The input to the quantum procedure is a vector $x \in \mathbb{R}^n$ and a matrix $A \in \mathbb{R}^{m\times n}$. We assume that the input is stored in a classical data structure such that an algorithm that has quantum access to the data structure can create the quantum state $|x\rangle$ corresponding to the vector x and the quantum states $|A_i\rangle$ corresponding to each row A_i of the matrix A, in time $\text{polylog}(mn)$.

It is in fact possible to design a data structure for a matrix A that supports the efficient construction of the quantum states $|A_i\rangle$. Moreover, we can ensure that the size of the data structure is optimal (up to polylogarithmic factors), and the data entry time, i.e. the time to store a new entry (i, j, A_{ij}) that arrives in the system is just $\text{polylog}(mn)$. Note that just writing down the entry takes logarithmic time.

▶ **Theorem 10.** *Let $A \in \mathbb{R}^{m\times n}$ be a matrix. Entries (i, j, A_{ij}) arrive in the system in an arbitrary order and w denotes the number of entries that have already arrived in the system. There exists a data structure to store the entries of A with the following properties:*

- **(i)** *The size of the data structure is $O(w \cdot \log^2(mn))$.*
- **(ii)** *The time to store a new entry (i, j, A_{ij}) is $O(\log^2(mn))$.*
- **(iii)** *A quantum algorithm that has quantum access to the data structure can perform the mapping $\widetilde{U} : |i\rangle|0\rangle \to |i\rangle|A_i\rangle$, for $i \in [m]$, corresponding to the rows of the matrix currently stored in memory and the mapping $\widetilde{V} : |0\rangle|j\rangle \to |\widetilde{A}\rangle|j\rangle$, for $j \in [n]$, where $\widetilde{A} \in \mathbb{R}^m$ has entries $\widetilde{A}_i = \|A_i\|$ in time $\text{polylog}(mn)$.*

The explicit description of the data structure is given in the appendix. Basically, for each row of the matrix, that we view as a vector in $\mathbb{R}^n$, we store an array of $2n$ values as a full binary tree of n leaves. The leaves hold the individual amplitudes of the vector and each internal node holds the sum of the squares of the amplitudes of the leaves rooted on this node. For each entry added to the tree, we need to update $\log(n)$ nodes in the tree. The same data structure can of course be used for the vector x as well. One need not use a fixed array of size $2n$ for this construction, but only ordered lists of size equal to the entries that have already arrived in the system.Alternative solutions for vector state preparation are possible, another solution based on a modified memory is described in [19].

5.2 Quantum Singular Value Estimation

The second tool required for the projection algorithm is an efficient quantum algorithm for singular value estimation. In the singular value estimation problem we are given a matrix A such that the vector states corresponding to its row vectors can be prepared efficiently. Given a state $|x\rangle = \sum_i \alpha_i |v_i\rangle$ for an arbitrary vector $x \in \mathbb{R}^n$ the task is to estimate the singular values corresponding to each singular vector in coherent superposition. Note that we take the basis $\{v_i\}$ to span the entire space by including singular vectors with singular value 0.

▶ **Theorem 11.** *Let $A \in \mathbb{R}^{m\times n}$ be a matrix with singular value decomposition $A = \sum_i \sigma_i u_i v_i^t$ stored in the data structure in theorem 10. Let $\epsilon > 0$ be the precision parameter. There is an algorithm with running time $O(\text{polylog}(mn)/\epsilon)$ that performs the mapping $\sum_i \alpha_i |v_i\rangle \to \sum_i \alpha_i |v_i\rangle |\overline{\sigma_i}\rangle$, where $\overline{\sigma_i} \in \sigma_i \pm \epsilon\|A\|_F$ for all i with probability at least $1 - 1/\text{poly}(n)$.*

Here, we present a quantum singular value estimation algorithm, in the same flavor as the quantum walk based algorithm by Childs [7] for estimating eigenvalues of a matrix, and show that given quantum access to the data structure from theorem 10, our algorithm runs in time $O(\text{polylog}(mn)/\epsilon)$. A different quantum algorithm for singular value estimation can be based on the work of [16] with running time $O(\text{polylog}(mn)/\epsilon^3)$, and for which a coherence analysis was shown in [19].

The idea for our singular value estimation algorithm is to find isometries $P \in \mathbb{R}^{mn\times m}$ and $Q \in \mathbb{R}^{mn\times n}$ that can be efficiently applied, and such that $\frac{A}{\|A\|_F} = P^tQ$. Using P and Q, we define a unitary matrix W acting on $\mathbb{R}^{mn}$, which is also efficiently implementable and such that the row singular vector v_i of A with singular value σ_i is mapped to an eigenvector Qv_i of W with eigenvalue $e^{\iota\theta_i}$ such that $\cos(\theta_i/2) = \sigma_i/\|A\|_F$ (note that $\cos(\theta_i/2) > 0$ as $\theta_i \in [-\pi, \pi]$). The algorithm consists of the following steps: first, map the input vector $\sum_i \alpha_i |v_i\rangle$ to $\sum_i \alpha_i |Qv_i\rangle$ by applying Q; then, use phase estimation as in theorem 3 with unitary W to compute an estimate of the eigenvalues θ_i and hence of the singular values $\sigma_i = \|A\|_F \cos(\theta_i/2)$; and finally undo Q to recover the state $\sum_i \alpha_i |v_i\rangle |\sigma_i\rangle$. This procedure is described in algorithm 1.

It remains to show how to construct the mappings P, Q and the unitary W that satisfy all the properties mentioned above that are required for the quantum singular value estimation algorithm.

▶ **Lemma 12.** *Let $A \in \mathbb{R}^{m\times n}$ be a matrix with singular value decomposition $A = \sum_i \sigma_i u_i v_i^t$ stored in the data structure in theorem 10. Then, there exist matrices $P \in \mathbb{R}^{mn\times m}, Q \in \mathbb{R}^{mn\times n}$ such that*

- **(i)** *The matrices P, Q are a factorization of A, i.e. $\frac{A}{\|A\|_F} = P^tQ$. Moreover, $P^tP = I_m$, $Q^tQ = I_n$, and multiplication by P, Q, i.e. the mappings $|y\rangle \to |Py\rangle$ and $|x\rangle \to |Qx\rangle$ can be performed in time $O(\text{polylog}(mn))$.*
- **(ii)** *The unitary $W = U \cdot V$, where U, V are the reflections $U = 2PP^t - I_{mn}$ and $V = 2QQ^t - I_{mn}$ can be implemented in time $O(\text{polylog}(mn))$.*
- **(iii)** *The isometry $Q : \mathbb{R}^n \to \mathbb{R}^{mn}$ maps a row singular vector v_i of A with singular value σ_i to an eigenvector Qv_i of W with eigenvalue $e^{\iota\theta_i}$ such that $\cos(\theta_i/2) = \sigma_i/\|A\|_F$.*

Proof. Let $P \in \mathbb{R}^{mn\times m}$ be a matrix with column vectors $e_i \otimes \frac{A_i}{\|A_i\|}$ for $i \in [m]$. In quantum notation multiplication by P can be expressed as

$$|Pe_i\rangle = |i, A_i\rangle = \frac{1}{\|A_i\|} \sum_{j\in[n]} A_{ij} |i, j\rangle , \quad \text{for } i \in [m].$$

Let $\widetilde{A} \in \mathbb{R}^m$ be the vector of Frobenius norms of the rows of the matrix A, that is $\widetilde{A}_i = \|A_i\|$ for $i \in [m]$. Let $Q \in \mathbb{R}^{mn \times n}$ be a matrix with column vectors $\frac{\widetilde{A}}{\|A\|_F} \otimes e_j$ for $j \in [n]$. In quantum notation multiplication by Q can be expressed as

$$|Qe_j\rangle = |\widetilde{A}, j\rangle = \frac{1}{\|A\|_F} \sum_{i \in [m]} \|A_i\| \, |i, j\rangle \,, \qquad \text{for } j \in [n].$$

The factorization $A = P^t Q$ follows easily by expressing the matrix product in quantum notation,

$$(P^t Q)_{ij} = \langle i, A_i | \widetilde{A}, j\rangle = \frac{\|A_i\|}{\|A\|_F} \frac{A_{ij}}{\|A_i\|} = \frac{A_{ij}}{\|A\|_F}.$$

The columns of P, Q are orthonormal by definition so $P^t P = I_m$ and $Q^t Q = I_n$. Multiplication by P and Q can be implemented in time polylog(mn) using quantum access to the data structure from theorem 10,

$$\begin{aligned} |y\rangle \to |y, 0^{\lceil \log n \rceil}\rangle = \sum_{i \in [m]} y_i \, |i, 0^{\lceil \log n \rceil}\rangle \xrightarrow{\widetilde{U}} \sum_{i \in [m]} y_i \, |i, A_i\rangle = |Py\rangle \\ |x\rangle \to |0^{\lceil \log m \rceil}, x\rangle = \sum_{j \in [n]} x_j \, |0^{\lceil \log m \rceil}, j\rangle \xrightarrow{\widetilde{V}} \sum_{j \in [n]} x_j \, |\widetilde{A}, j\rangle = |Qx\rangle \,. \end{aligned} \tag{12}$$

To show (ii), note that the unitary U is a reflection in $Col(P)$ and can be implemented as $U = \widetilde{U} R_1 \widetilde{U}^{-1}$ where $\widetilde{U}$ is the unitary in first line of equation (12) and R_1 is the reflection in the space $|y, 0^{\lceil \log n \rceil}\rangle$ for $y \in \mathbb{R}^m$. It can be implemented as a reflection conditioned on the second register being in state $|0^{\lceil \log n \rceil}\rangle$. The unitary V is a reflection in $Col(Q)$ and can be implemented analogously as $V = \widetilde{V} R_0 \widetilde{V}^{-1}$ where $\widetilde{V}$ is the unitary in the second line of equation (12) and R_0 is the reflection in the space $|0^{\lceil \log m \rceil}, x\rangle$ for $x \in \mathbb{R}^n$.

It remains to show that Qv_i is an eigenvector for W with eigenvalue $e^{\iota \theta_i}$ such that $\cos(\theta_i/2) = \sigma_i / \|A\|_F$. For every pair of singular vectors (u_i, v_i) of A, we define the two dimensional subspaces $\mathcal{W}_i = Span(Pu_i, Qv_i)$ and let $\theta_i/2 \in [-\pi/2, \pi/2]$ be the angle between Pu_i and $\pm Qv_i$. Note that $\mathcal{W}_i$ is an eigenspace for W which acts on it as a rotation by $\pm\theta_i$, since W is a reflection in the column space of Q followed by a reflection in the column space of P. Moreover, the relation $\cos(\theta_i/2) = \sigma_i / \|A\|_F$ is a consequence of the factorization in lemma 12, since we have

$$PP^t Qv_i = \frac{PAv_i}{\|A\|_F} = \frac{\sigma_i}{\|A\|_F} Pu_i \quad \text{and} \quad QQ^t Pu_i = \frac{QA^t u_i}{\|A\|_F} = \frac{\sigma_i}{\|A\|_F} Qv_i. \tag{13}$$

◀

Using the primitives from the preceding lemma, we next describe the singular value estimation algorithm and analyze it to prove theorem 11.

5.2.0.1 Analysis

The phase estimation procedure [12] with unitary W and precision parameter ϵ on input $|Qv_i\rangle$ produces an estimate such that $|\overline{\theta_i} - \theta_i| \leq 2\epsilon$. The estimate for the singular value is $\overline{\sigma_i} = \cos(\overline{\theta_i}/2)\|A\|_F$. The error in estimating $\sigma_i = \cos(\theta_i/2)\|A\|_F$ can be bounded as follows,

$$|\overline{\sigma_i} - \sigma_i| = |\cos(\theta_i/2) - \cos(\overline{\theta_i}/2)| \|A\|_F \leq \sin(\phi) \frac{|\overline{\theta_i} - \theta_i|}{2} \|A\|_F \leq \epsilon \|A\|_F \tag{14}$$

Algorithm 1 Quantum singular value estimation

Require: $A \in \mathbb{R}^{m\times n}$, $x \in \mathbb{R}^n$ in the data structure from theorem 10, precision parameter $\epsilon > 0$.

1. Create $|x\rangle = \sum_i \alpha_i |v_i\rangle$.
2. Append a first register $|0^{\lceil \log m \rceil}\rangle$ and create the state $|Qx\rangle = \sum_i \alpha_i |Qv_i\rangle$ as in eq. (12).
3. Perform phase estimation with precision parameter $2\epsilon > 0$ on the input $|Qx\rangle$ for the unitary $W = U \cdot V$ where U, V are the unitaries in lemma 12 and obtain $\sum_i \alpha_i |Qv_i, \overline{\theta_i}\rangle$.
4. Compute $\overline{\sigma_i} = \cos(\overline{\theta_i}/2)\|A\|_F$ where $\overline{\theta_i}$ is the estimate from phase estimation, and uncompute the output of the phase estimation.
5. Apply the inverse of the transformation in step 2 to obtain $\sum_i \alpha_i |v_i\rangle |\overline{\sigma_i}\rangle$.

where $\phi \in [\theta_i/2 - \epsilon, \theta_i/2 + \epsilon]$. Algorithm 1 therefore produces an additive error $\epsilon\|A\|_F$ estimate of the singular values, the running time is $O(\text{polylog}(mn)/\epsilon)$ by theorem 3 as the unitary W is implemented in time $O(\text{polylog}(mn))$ by lemma 12. This concludes the proof of theorem 11.

One can define an algorithm for singular value estimation with input $|y\rangle = \sum_i \beta_i |u_i\rangle$. where u_i are the column singular vectors, by using the operator P from lemma 12 instead of Q in algorithm 1. The correctness follows from the same argument as above.

5.3 Quantum projection with threshold

Let $A = \sum_i \sigma_i u_i v_i^t$. We recall that $A_{\geq\sigma} = \sum_{\sigma_i \geq \sigma} \sigma_i u_i v_i^t$ is the projection of the matrix A onto the space spanned by the singular vectors whose singular values are bigger than σ. Also, $A_{\geq\sigma,\kappa}$ is the projection of the matrix A onto the space spanned by the union of the singular vectors whose corresponding singular values is bigger than σ and some subset of singular vectors whose corresponding singular values are in the interval $[(1-\kappa)\sigma, \sigma)$.

Algorithm 2 presents a quantum algorithm that given access to vector state x, a matrix A and parameters σ, κ, outputs the state $|A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x\rangle$, namely the projection of x onto the subspace spanned by the union of the row singular vectors whose corresponding singular values are bigger than σ and some subset of row singular vectors whose corresponding singular values are in the interval $[(1-\kappa)\sigma, \sigma)$.

For simplicity, we present the algorithm without a stopping condition and we will compute the expected running time. By stopping the algorithm after a number of iterations which is $\log(n)$ times more than the expected one, we can easily construct an algorithm with worst-case running time guarantees and whose correctness probability has only decreased by a factor of $(1 - 1/\text{poly}(n))$.

Let $\{v_i\}$ denote an orthonormal basis for $\mathbb{R}^n$ that includes all row singular vectors of the matrix A. We think of κ as a constant, for example $1/3$.

For the running time, note that the singular value estimation takes time $O(\text{polylog}(mn)/\epsilon)$, while the probability we obtain $|0\rangle$ in step 5 is $\frac{||A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x||^2}{\|x\|^2} \geq \frac{||A^+_{\geq\sigma} A_{\geq\sigma} x||^2}{\|x\|^2}$.

▶ **Theorem 13.** *Algorithm 2 outputs $|A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x\rangle$ with probability at least $1 - 1/\text{poly}(n)$ and in expected time $O(\frac{\text{polylog}(mn)\|A\|_F \|x\|^2}{\sigma ||A_{\geq\sigma} A^+_{\geq\sigma} x||^2})$.*

It is important to notice that the running time of the quantum projection algorithm depends only on the threshold σ (which we will take to be of the order $\frac{\|A\|_F}{\sqrt{k}}$) and not on

Algorithm 2 Quantum projection with threshold

Require: $A \in \mathbb{R}^{m\times n}$, $x \in \mathbb{R}^n$ in the data structure from Theorem 10; parameters $\sigma, \kappa > 0$.

1. Create $|x\rangle = \sum_i \alpha_i |v_i\rangle$.
2. Apply the singular value estimation on $|x\rangle$ with precision $\epsilon \hat{=} \frac{\kappa}{2}\frac{\sigma}{\|A\|_F}$ to obtain the state
$$\sum_i \alpha_i |v_i\rangle |\overline{\sigma}_i\rangle$$
3. Apply on a second new register the unitary V that maps $|t\rangle|0\rangle \mapsto |t\rangle|1\rangle$ if $t < \sigma - \frac{\kappa}{2}\sigma$ and $|t\rangle|0\rangle \mapsto |t\rangle|0\rangle$ otherwise, to get the state
$$\sum_{i\in S} \alpha_i |v_i\rangle |\overline{\sigma}_i\rangle |0\rangle + \sum_{i\in\overline{S}} \alpha_i |v_i\rangle |\overline{\sigma}_i\rangle |1\rangle ,$$
where S is the union of all i's such that $\sigma_i \geq \sigma$ and some i's with $\sigma_i \in [(1-\kappa)\sigma, \sigma)$.
4. Apply the singular value estimation on the above state to erase the second register
$$\sum_{i\in S} \alpha_i |v_i\rangle |0\rangle + \sum_{i\in\overline{S}} \alpha_i |v_i\rangle |1\rangle = \beta |A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x\rangle |0\rangle + \sqrt{1-|\beta|^2}\, |A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x\rangle^{\perp} |1\rangle ,$$
with $\beta = \frac{||A^+_{\geq\sigma,\kappa} A_{\geq\sigma,\kappa} x||}{\|x\|}$.
5. Measure the second register in the standard basis. If the outcome is $|0\rangle$, output the first register and exit. Otherwise repeat step 1.

the condition number of A which may be very large. We will also show in the next section that in the recommendation systems, for most users the ratio $\frac{||A^+_{\geq\sigma} A_{\geq\sigma} x||^2}{\|x\|^2}$ is constant. This will conclude the analysis and show that the running time of the quantum recommendation system is polynomial in k and polylogarithmic in the matrix dimensions.

One could also use amplitude amplification to improve the running time of algorithm 2, once a careful error analysis is performed as the reflections are not exact. As we will see that the $\frac{||A^+_{\geq\sigma} A_{\geq\sigma} x||^2}{\|x\|^2}$ is constant for most users, this will not change asymptotically the running time of the algorithm and hence we omit the analysis.

6 Quantum recommendation systems

We have all the necessary ingredients to describe the quantum algorithm that provides good recommendations for a user i and that runs in time polylogarithmic in the dimensions of the preference matrix and polynomial in the rank k. As we said, in recommendation systems we assume that for the matrix T we have $\|T - T_k\|_F \leq \epsilon ||T||_F$ for some small approximation parameter ϵ and small rank k (no more than 100). In Algorithm 3, as in the classical recommendation systems, we assume we know k but in fact we just need to have a good estimate for it.

Note again that we do not put a stopping condition to the algorithm and we compute the expected running time. Again we can turn this into an algorithm with worst-case running time guarantees by stopping after running for $\log(n)$ times more than the expected running time, and the correctness probability has only decreased by a factor of $1 - 1/\text{poly}(n)$.

Algorithm 3 Quantum recommendation algorithm.

Require: A subsample matrix $\widehat{T} \in \mathbb{R}^{m\times n}$ (with sampling probability p) stored in the data structure from Theorem 10 and satisfying the conditions in Theorem 9; a user index i.

1: Apply the quantum projection procedure 2 with the matrix $\widehat{T}$, the vector corresponding to the i-th row $\widehat{T}_i$, with $\sigma = \sqrt{\frac{\epsilon^2 p}{2k}}\|\widehat{T}\|_F$ and $\kappa = 1/3$.
The algorithm runs in expected time $O(\text{polylog}(mn)\sqrt{k}\|\widehat{T}_i\|^2/\sqrt{p}\|\widehat{T}^+_{\geq\sigma}\widehat{T}_{\geq\sigma}\widehat{T}_i\|^2)$ and returns with probability at least $1 - 1/\text{poly}(n)$ the state $|\widehat{T}^+_{\geq\sigma,\kappa}\widehat{T}_{\geq\sigma,\kappa}\widehat{T}_i\rangle$.

2: Measure the above state in the computational basis to get a product j.

6.1 Analysis

Correctness

Let us check the correctness of the algorithm. Note that $\widehat{T}^+_{\geq\sigma,\kappa}\widehat{T}_{\geq\sigma,\kappa}\widehat{T}_i = (\widehat{T}_{\geq\sigma,\kappa})_i$, i.e. the i-th row of the matrix $\widehat{T}_{\geq\sigma,\kappa}$. Hence, the quantum projection procedure outputs with probability at least $1 - 1/\text{poly}(n)$ the state $|(\widehat{T}_{\geq\sigma,\kappa})_i\rangle$, meaning that our quantum recommendation algorithm with high probability outputs a product by sampling the i-th row of the matrix $\widehat{T}_{\geq\sigma,\kappa}$.

By Theorem 9, and by setting the parameters appropriately to get equation (11), we have that with probability at least $1 - exp(-19(\log n)^4)$,

$$\|T - \widehat{T}_{\geq\sigma,\kappa}\|_F \leq 9\epsilon\|T\|_F.$$

In this case, we can apply Theorem 6 with matrix $\widetilde{T} = \widehat{T}_{\geq\sigma,\kappa}$ to show that there exists a subset of users S' of size at least $(1-\delta-\zeta)m$ (for $\delta > 0$), such that on average over the users in S', the probability that our quantum algorithm provides a bad recommendation is

$$\Pr_{i\sim\mathcal{U}_{S'},j\sim(\widehat{T}_{\geq\sigma,\kappa})_i}[(i,j) \text{ bad}] \leq \frac{\left(\frac{9\epsilon(1+9\epsilon)}{1-9\epsilon}\right)^2}{\left(1/\sqrt{1+\gamma} - 9\epsilon/\sqrt{\delta}\right)^2 (1-\delta-\zeta)}.$$

Expected running time

We prove the following theorem

▶ **Theorem 14.** *For at least $(1-\xi)(1-\delta-\zeta)m$ users in the subset S', we have that the expected running time of Algorithm 3 is $O(\text{polylog}(mn)\text{poly}(k))$.*

Proof. First, by the conditions of Theorem 9, we must have $p \geq \frac{36\sqrt{2}(nk)^{1/2}}{\|A\|_F\epsilon^3}$. That is the theorem works even for a p which is sub-constant. However, in order to have the desired running time, we need to take p to be some constant, meaning that we need to subsample a constant fraction of the matrix elements. This is also the case for classical recommendation systems [5, 8].

Second, we need to show that for most users the term $W_i \equiv \frac{||\widehat{T}_i||^2}{||(\widehat{T}_{\geq\sigma,\kappa})_i||^2}$ that appears in the running time of the quantum projection algorithm is a constant. This is to be expected, since most typical rows of the matrix project very well onto the space spanned by the top singular vectors, since the spectrum of the matrix is well concentrated on the space of the top singular vectors.

As in Theorem 6, we focus on the users in the subset S', with $|S'| \geq (1-\delta-\zeta)m$, for which equations 4 and 6 hold. For these users we can use equation 6 with the matrix $\widetilde{T} = \widehat{T}_{\geq\sigma,\kappa}$ and error 9ϵ. We have

$$\begin{aligned} E_{i\in S'}[W_i] &= E_{i\in S'}[\frac{||\widehat{T}_i||^2}{||(\widehat{T}_{\geq\sigma,\kappa})_i||^2}] \leq \frac{E_{i\in S'}[||\widehat{T}_i||^2]}{\frac{||\widehat{T}||_F^2}{(1+\epsilon)^2 m}\left(\frac{1}{\sqrt{1+\gamma}}-\frac{9\epsilon}{\sqrt{\delta}}\right)^2} \leq \frac{\frac{||\widehat{T}||_F^2}{(1-\delta-\zeta)m}}{\frac{||\widehat{T}||_F^2}{(1+\epsilon)^2 m}\left(\frac{1}{\sqrt{1+\gamma}}-\frac{9\epsilon}{\sqrt{\delta}}\right)^2} \\ &\leq \frac{(1+\epsilon)^2}{(1-\delta-\zeta)\left(\frac{1}{\sqrt{1+\gamma}}-\frac{9\epsilon}{\sqrt{\delta}}\right)^2}. \end{aligned}$$

By Markov's inequality, for at least $(1-\xi)|S'|$ users in S' we have $W_i \leq \frac{(1+\epsilon)^2}{\xi(1-\delta-\zeta)\left(\frac{1}{\sqrt{1+\gamma}}-\frac{9\epsilon}{\sqrt{\delta}}\right)^2}$, which for appropriate parameters is a constant. Hence, for at least $(1-\xi)(1-\delta-\zeta)m$ users, the quantum recommendation algorithm has an expected running time of $O(\text{poly}(k)\text{polylog}(mn))$ and produces good recommendations with high probability. As we said we can easily turn this into a worst-case running time, by stopping after running $\log(n)$ times more than the expected running time and hence decreasing the correctness only by a factor of $1 - 1/\text{poly}(n)$. ◀

A The data structure

We prove the following theorem.

▶ **Theorem 15.** *(Theorem 10 restated) Let $A \in \mathbb{R}^{m\times n}$ be a matrix. Entries (i, j, A_{ij}) arrive in the system in some arbitrary order, and w denotes the number of entries that have already arrived in the system. There exists a data structure to store the matrix A with the following properties:*

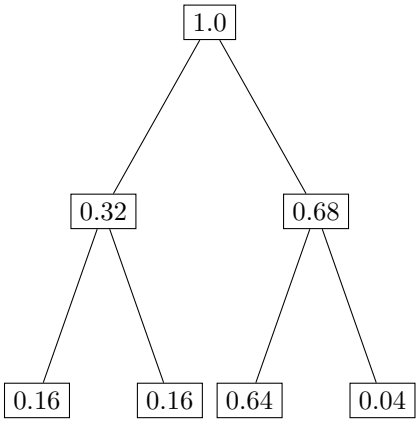
(i) *The size of the data structure is $O(w \log^2(mn))$.*

(ii) *The time to store a new entry (i, j, A_{ij}) is $O(\log^2(mn))$.*

(iii) *A quantum algorithm that has quantum access to the data structure can perform the mapping $\widetilde{U} : |i\rangle|0\rangle \to |i\rangle|A_i\rangle$, for $i \in [m]$, corresponding to the rows of the matrix currently stored in memory and the mapping $\widetilde{V} : |0\rangle|j\rangle \to |\widetilde{A}\rangle|j\rangle$, for $j \in [n]$, where $\widetilde{A} \in \mathbb{R}^m$ has entries $\widetilde{A}_i = \|A_i\|$ in time* $\mathrm{polylog}(mn)$.

Proof. The data structure consists of an array of m binary trees $B_i, i \in [m]$. The trees B_i are initially empty. When a new entry (i, j, A_{ij}) arrives the leaf node j in tree B_i is created if not present and updated otherwise. The leaf stores the value A_{ij}^2 as well as the sign of A_{ij}. The depth of each tree B_i is at most $\lceil \log n \rceil$ as there can be at most n leaves. An internal node v of B_i stores the sum of the values of all leaves in the subtree rooted at v, i.e. the sum of the square amplitudes of the entries of A_i in the subtree. Hence, the value stored at the root is $\|A_i\|^2$. When a new entry arrives, all the nodes on the path from that leaf to the tree root are also updated. The different levels of the tree B_i are stored as ordered lists so that the address of the nodes being updated can be retrieved in time $O(\log mn)$. The binary tree for a 4-dimensional unit vector for which all entries have arrived is illustrated in figure 1.

The time required to store entry (i, j, A_{ij}) is $O(\log^2 mn)$ as the insertion algorithm makes at most $\lceil \log n \rceil$ updates to the data structure and each update requires time $O(\log mn)$ to retrieve the address of the updated node.



Let $|\phi\rangle = 0.4\,|00\rangle + 0.4\,|01\rangle + 0.8\,|10\rangle + 0.2|11\rangle$.

- Rotation on qubit 1:
  $|0\rangle\,|0\rangle \to (\sqrt{0.32}\,|0\rangle + \sqrt{0.68}\,|1\rangle)\,|0\rangle$
- Rotation on qubit 2 conditioned on qubit 1:

$$(\sqrt{0.32}\,|0\rangle + \sqrt{0.68}\,|1\rangle)\,|0\rangle \to$$
$$\sqrt{0.32}\,|0\rangle\,\frac{1}{\sqrt{0.32}}(0.4\,|0\rangle + 0.4\,|1\rangle) +$$
$$\sqrt{0.68}\,|1\rangle\,\frac{1}{\sqrt{0.68}}(0.8\,|0\rangle + 0.2\,|1\rangle)$$

Figure 1 Vector state preparation illustrated for 4-dimensional state $|\phi\rangle$.

The memory requirement for the data structure is $O(w \log^2 mn)$ as for each entry (i, j, A_{ij}) at most $\lceil \log n \rceil$ new nodes are added, each node requiring $O(\log mn)$ bits.

We now show how to perform $\widetilde{U}$ in time polylog(mn) if an algorithm has quantum access to this classical data structure. The state preparation procedure using pre-computed amplitudes is well known in the literature, for instance see [9]. The method is illustrated for a 4-dimensional state $|\phi\rangle$ corresponding to a unit vector in figure 1. The amplitudes stored in the internal nodes of B_i are used to apply a sequence of conditional rotations to the initial state $|0\rangle^{\lceil \log n \rceil}$ to obtain $|A_i\rangle$. Overall, there are $\lceil \log n \rceil$ rotations applied and for each one of them we need two quantum queries to the data structure (from each node in the superposition we query its two children).

The amplitude stored at an internal node of B_i at depth t corresponding to $k \in \{0,1\}^t$ is,

$$B_{i,k} := \sum_{j \in [n], j_{1:t} = k} A_{ij}^2$$

where $j_{1:t}$ denotes the first t bits in the binary representation for j. Note that $B_{i,k}$ is the probability of observing outcome k if the first t bits of $|A_i\rangle$ are measured in the standard basis. Conditioned on the first register being $|i\rangle$ and the first t qubits being in state $|k\rangle$ the rotation is applied to the $(t+1)$ qubit as follows

$$|i\rangle\,|k\rangle\,|0\rangle \to |i\rangle\,|k\rangle\,\frac{1}{\sqrt{B_{i,k}}}\left(\sqrt{B_{i,k0}}\,|0\rangle + \sqrt{B_{i,k1}}\,|1\rangle\right).$$

The sign is included for rotations applied to the $\lceil \log n \rceil$-th qubit

$$|i\rangle\,|k\rangle\,|0\rangle \to |i\rangle\,|k\rangle\,\frac{1}{\sqrt{B_{i,k}}}\left(sgn(A_{k0})\sqrt{B_{i,k0}}\,|0\rangle + sgn(A_{k1})\sqrt{B_{i,k1}}\,|1\rangle\right).$$

Last, we show how to perform $\widetilde{V}$ in time polylog(mn). Note that the amplitudes of the vector $\widetilde{A}$ are equal to $\|A_i\|$, and the values stored on the roots of the trees B_i are equal to $\|A_i\|^2$. Hence, by a similar construction (another binary tree) for the m roots, we can perform the unitary $\widetilde{V}$ efficiently.

Abstract

We present a Gaussian random walk in a polytope that starts at a point inside and continues until it gets absorbed at a vertex. Our main result is that the probability distribution induced on the vertices by this random walk has strong negative dependence properties for matroid polytopes. Such distributions are highly sought after in randomized algorithms as they imply concentration properties. Our random walk is simple to implement, computationally efficient and can be viewed as an algorithm to round the starting point in an unbiased manner. The proof relies on a simple inductive argument that synthesizes the combinatorial structure of matroid polytopes with the geometric structure of multivariate Gaussian distributions. Our result not only implies a long line of past results in a unified and transparent manner, but also implies new results about constructing negatively associated distributions for *all* matroids.

1 Introduction

A basic problem that underlies a large number of approximation algorithms for combinatorial problems is: given a fractional point, how should it be rounded to an integral point? Typically, the fractional point is obtained by solving a linear program and has nice properties which one would like the integeral point to inherit. For instance, the fractional point might belong to the spanning tree polytope of a graph and the goal might be to round the point to a spanning tree whose cost is not much more and, in addition, satisfies some constraints satisfied by the fractional point; e.g., number of edges in the tree across each cut is small. A common approach towards this is to construct randomized rounding algorithms for such a problem which output an unbiased distribution over the underlying set of integral objects (spanning trees for the above example). Since in most interesting cases the set of integral objects is not a box, the distributions have correlations. These correlations end up being quite problematic when it comes to ensure that with high probability the integral point also satisfies the *additional* constraints the fractional point satisfies. The ultimate hope here is that the distribution essentially behaves like a product distribution so that one can apply concentration results such as Chernoff bounds. On the one hand, this has recently led TCS researchers to come up with a wide variety of ingenious rounding algorithms which have resulted in significant

progress on fundamental algorithmic problems [11, 2, 6, 7, 12, 19, 1] (see the book [8] for more examples). On the other hand, mathematicians have been investigating what kind of negative dependence properties result in the phenomena of measure concentration [17, 3]. Typically, it is non-trivial to both compute these distributions and prove their negative dependence properties.

In this paper we take a geometric approach and propose a very simple rounding algorithm and prove that it gives an unbiased distribution with *negative association* property for *all* matroids. Negative association is a significant strengthening of the negative correlation property. Roughly a set of random variables $(X_1, \ldots, X_n)$ is said to be negatively associated if for any two monotone functions f and g which act on distinct sets of coordinates S and T respectively, the corresponding random variables $f(X_i)_{i\in S}$ and $g(X_j)_{j\in T}$ are negatively correlated; see Definition 1 and Theorem 4.

A bit more formally, given a matroid over a universe of size n, consider the polytope in $\mathbb{R}^n$ that is the convex hull of all the bases of the matroid. Let θ be a given fractional point that lies inside this polytope and is to be rounded to one of the bases. Our algorithm starts at θ and keeps taking small Gaussian steps centered at the current point – thus maintaining the unbiasedness. If at some point the trajectory hits a constraint on the boundary of the polytope it never leaves it – meaning that the Gaussian in the next step is chosen so as to have no mass outside of this subspace. Thus, eventually, the trajectory gets absorbed at a vertex of the polytope. This rounding algorithm is inspired by the work of [15] on discrepancy and its simplicity is self-evident. At any given time, the algorithm has to keep track of the tight constraints and compute a Gaussian in the space corresponding to the intersection of these constraints.

Our proof synthesizes polyhedral properties about matroids with well-known properties of Gaussian distribution. Our key structural observation is that if F is a d-dimensional face of a matroid polytope and Σ_F is the covariance matrix of the d-dimensional Gaussian obtained by orthogonally projecting an n-dimensional Gaussian onto F, then all the off-diagonal entries of Σ are non-positive; see Theorem 5. The proof of this relies on an elementary *uncrossing* argument from matroid theory. *Thus, Gaussian distributions on faces of matroid polytopes have the negative correlation property.* This, in turn, immediately leads to an inductive argument that shows that from the beginning to the end of this random walk, the distribution has the negative correlation property. Finally, to go from negative correlation of Gaussian distributions to negative association, we employ a result that implies that for Gaussian distribution negative correlations implies negative association [13]. Roughly, this is a manifestation of the fact that all moments of Gaussian distributions are completely determined by their covariance matrix.

Negative dependence properties for distributions on bases of matroid have been extensively studied. Prior to our work, negatively associated distributions were known only for *balanced* matroids. In particular, [10] shows that the uniform distribution is negatively associated for balanced matroids and gives a Markov chain Monte Carlo method to sample from such a distribution. Unfortunately, the uniform, or more generally, an entropy maximizing distribution on general matroids does not give negative association property. For general matroids, the weaker negative cylindrical property (see Definition 3) was shown for the *pipage rounding* and *randomized swap rounding* [6]. The other two matroids that have been extensively studied are the uniform matroid, where bases are all sets of size k for integer k [20, 5] and the partition matroid [9, 8].

Lovett and Meka [15], who studied this random walk on the polytope obtained by intersecting the hypercube with few *discrepancy* constraints, were interested in the number

of integral coordinates of the output vertex. In our setting, we study the walk on integral polytopes, convex hull of bases of matroids, which are typically defined by exponentially many constraints and are interested in negative dependence properties of the output distribution.

While both the algorithm and the proof are simple and the reason for negative dependence is clear, several problems about the distribution remain open. First and foremost, what can we say about non-matroid polytopes? Do non-Gaussian distributions help? While we can understand the random walk locally, a global perspective seems hard. Concretely, can we prove that the distribution obtained by our random walk is the solution to some optimization problem? Finally, do much stronger forms of negative dependence, for example, Strongly Rayleigh property [3] holds for these distributions in specific matroids (see also [4])?

1.1 Preliminaries

We first give the following definition.

▶ **Definition 1** (Negative Association)**.** Let $X_1, \ldots, X_n$ be boolean random variables. Then X_i's are *negatively associated* if for every non-decreasing functions $f : \{0,1\}^n \to \mathbb{R}$ and $g : \{0,1\}^n \to \mathbb{R}$ we have

$$E[f(X_1, \ldots, X_n)g(X_1, \ldots, X_n)] \leq E[f(X_1, \ldots, X_n)]E[g(X_1, \ldots, X_n)] \tag{1}$$

if f and g depend on disjoint sets of coordinates.

While negative association is hard to verify, under very mild assumptions, it implies versions of the central limit theorems (see Yuan et al [21] and Pattersen et al [16]).

A much weaker notion of negative dependence is the negative correlation defined below.

▶ **Definition 2.** Let $X_1, \ldots, X_n$ be real valued random variables. Then X_i's are *negatively correlated* if for each $i \neq j \in [n]$, we have

$$E[X_i X_j] \leq E[X_i]E[X_j]. \tag{2}$$

Another notion of negative dependence is the negative cylindrical property that is stronger than negative correlation but weaker than negative association. This property is also well studied since it is enough to imply tail bounds ala Chernoff bounds.

▶ **Definition 3.** Let $X_1, \ldots, X_n$ be real valued random variables. Then X_i's have the *negatively cylindrical property* if for each $S \subseteq [n]$, we have

$$E[\prod_{i \in S} X_i] \leq \prod_{i \in S} E[X_i]. \tag{3}$$

A set system $\mathcal{M} = (U, \mathcal{I})$ is called a matroid if $\mathcal{I} \subseteq 2^U$ satisfies two axioms (i) $A \in \mathcal{I}$ and $B \subseteq A$ implies that $B \in \mathcal{I}$, (ii) $A, B \in \mathcal{I}$ such that $|A| > |B|$ implies that there exists $a \in A \backslash B$ such that $B \cup \{a\} \in \mathcal{I}$. Sets of $\mathcal{I}$ are called *independent* sets and the maximal sets in $\mathcal{I}$ are called *bases* of matroid $\mathcal{M}$. For a matroid $\mathcal{M}$, the corresponding *matroid polytope* is the convex hull of the indicator vectors of all the bases of $\mathcal{M}$.

2 Our Algorithm and Result

2.1 Algorithm

We present a discrete implementation of the random walk algorithm. We first introduce some notation. Let

$$P = \{\mathbf{x} \in \mathbb{R}^n : A\mathbf{x} \leq b\}$$

be the inequality description of P. Often we refer to individual inequalities or equalities as $\mathbf{a}_j^\top \mathbf{x} \leq b_j$ or $\mathbf{a}_j^\top \mathbf{x} = b_j$. For any face F of P defined by

$$F = \{\mathbf{x} \in P : A^= \mathbf{x} = b^=\},$$

let $d(F)$ denote the dimension of F. Let $C(F)$ denote the matrix whose columns form an orthonormal basis of the subspace

$$\{\mathbf{x} \in \mathbb{R}^n : A^= \mathbf{x} = 0\}.$$

Observe that the dimension of $C(F)$ is $n \times d(F)$.

Algorithm 1: Algorithm Random Walk

Input: θ, error parameter ε. Let $T = \frac{n^2}{\varepsilon^2}$.
Initialization $\mathbf{x}_0 \leftarrow \theta$. Let $t \leftarrow 0$, $F_0 = P$.
while dimension of $F_t > 0$ or $t \leq T$ **do**
  while there exists j such that $0 < b_j - \mathbf{a}_j^\top \mathbf{x}_t < n\varepsilon$, **do**
    Let $\mathbf{y}$ denote the point in $F_t \cap \{\mathbf{x}: \mathbf{a}_j^\top \mathbf{x} = b_j\}$ closest to $\mathbf{x}_t$.
    Let $\mathbf{x}_t \leftarrow \mathbf{y}$, $F_t \leftarrow F_t \cap \{\mathbf{x}: \mathbf{a}_j^\top \mathbf{x} = b_j\}$.
  end while
  Let d denote the dimension of F_t and let $\mathbf{g}$ be a normal Gaussian in d dimensions.
  Let $\mathbf{x}_{t+1} = \mathbf{x}_t + \varepsilon \cdot C(F_t)\mathbf{g}$ and let $F_{t+1} \leftarrow F_t$. If $\mathbf{x}_{t+1} \notin P$, then abort.
  Let $t \leftarrow t + 1$.
end while
Return $\mathbf{x}_t$.

If the algorithm ends at time $t^* \leq T$ with the vertex $\mathbf{x}_{t^*}$, we let $\mathbf{x}_t = \mathbf{x}_{t^*}$ for each $t^* \leq t \leq T$.

2.2 Main Result

Our main result is to show that the random walk algorithm described above gives a distribution over vertices of the matroid polytope that is negatively associated.

▶ **Theorem 4.** *Given any matroid $\mathcal{M} = (U, \mathcal{I})$, let P denote the convex hull of bases of $\mathcal{M}$ and let $n = |U|$. Given any $\theta \in P$ and error parameter $\varepsilon > 0$, the random walk algorithm returns a vertex of P before time $T = \frac{n^2}{\varepsilon^2}$ with probability at least $1 - e^{-n}$. Moreover, conditioned on algorithm returning a vertex of P, the output random vertex $\mathbf{x}_T$ satisfies the following properties.*

1. *For each $i \in U$,*

$$\theta(i) - n^2\varepsilon \leq E[\mathbf{x}_T(i)] \leq \theta(i) + n^2\varepsilon.$$

2. *For every 1-Lipschitz non-decreasing functions $f_1 : \mathbb{R}^U \to [0,1]$ and $f_2 : \mathbb{R}^U \to [0,1]$ depending on disjoint set of coordinates, we have*

$$E[f_1(\mathbf{x}_T) f_2(\mathbf{x}_T)] \leq E[f_1(\mathbf{x}_T)] E[f_2(\mathbf{x}_T)] + n\sqrt{n}\varepsilon \tag{4}$$

Moreover, the expected running time of the algorithm is polynomial in n and $\frac{1}{\varepsilon}$.

To prove the theorem, we rely on two crucial observations which also illustrate the crucial role of matroid polytopes. We show that for *every* face F of P, a standard Gaussian projected on F is negatively correlated; see Theorem 5. This result relies crucially on the facial structure of the matroid polytopes and a characterization of every face in terms of tight constraints defining the matroid polytope. Secondly, we use the classical result that for Gaussian random variables, negative correlation implies negative association (see Theorem 12). The above results use an inductive argument to show that the random walk algorithm leads to a distribution that is negatively associated.

▶ Remark. We mention that we describe the discrete version due to algorithmic implications but it naturally leads to error terms in Theorem 4. From a structural point of view, one can construct a Brownian motion that sticks to the face of the polytope as does our random walk and ends at a vertex of the polytope. The resulting distribution over bases of the polytope will satisfy the marginals and the inequality for negative association exactly.

3 Projected Gaussian in Matroids

In this section, we prove that standard Gaussian projected on any face of the matroid polytope is negatively correlated.

▶ **Theorem 5.** *Let $\mathcal{M} = (U, \mathcal{I})$ denote a matroid and P denote the convex hull of all bases of $\mathcal{M}$. Let F be the face of P and $g \in R^U$ be a standard Gaussian random variable. Then for any distinct $i, j \in U$ we have $E[(Cg)_i(Cg)_j] \leq 0$ where C is the projection matrix projecting onto F.*

Proof. Before we prove the general case, we prove the case when $\mathcal{M}$ is a uniform matroid. The convex hull of the bases of this matroid is well understood and has well characterized faces. The general case, whose facial structure is more complicated, will use this case as a building block.

Let k be an integer and $\mathcal{I} = \{S \subseteq U : |S| \leq k\}$. In this case, we have

$$P = \{x \in \mathbb{R}^U : \sum_{i \in U} x_i = k, \;\; 0 \leq x_i \leq 1 \;\; \forall i \in U\}.$$

First consider the face which is P itself. We let n denote the size of $|U|$.

▶ **Lemma 6.** *Let C denote the $n \times (n-1)$ matrix whose columns form the orthonormal basis of subspace $\{x \in \mathbb{R}^U : \sum_{i \in U} x_i = 0\}$. We have $CC^\top = I_n - \frac{1}{n} J_n$ where I_n denotes the identity matrix in n dimensions and J_n denotes the n dimensional matrix with all ones.*

Proof. Let $\hat{C}$ be $n \times n$ formed by adding the column $\frac{1}{\sqrt{n}}(1, \ldots, 1)$ to C. Then all columns of $\hat{C}$ form an orthonormal basis of $\mathbb{R}^n$. Then $\hat{C}\hat{C}^\top = I_n$. But $\hat{C}\hat{C}^\top = CC^\top + \frac{1}{n} J_n$ giving us that $CC^\top = I_n - \frac{1}{n} J_n$. ◀

Since all off-diagonal entries of $I_n - \frac{1}{n} J_n$ are negative, this implies that the standard Gaussian projected on P is negatively correlated. Any other face F is obtained by setting some of the variables to 0 or 1 in P. Thus the covariance matrix of the face will be a block matrix of the form $I_d - \frac{1}{n} J_d$ with the zero matrix. This completes the proof for the case when $\mathcal{M}$ is a uniform matroid.

We now consider the general case. Let $\mathcal{M} = (U, \mathcal{I})$ denote a matroid and P denote the convex hull of all independent sets of $\mathcal{M}$. In the next lemma, we characterize the possible covariance matrices for projections of normal Gaussians on any of the faces of the matroid

polytope. It shows that the covariance matrix is of block diagonal form where each block has the same structure as the covariance matrix for the uniform matroid as seen earlier.

▶ **Lemma 7.** *Let F be a face of P and X be a projection of a normal Gaussian on F. The covariance matrix of X (up to permuting indices of columns and rows) is $\Sigma = CC^\top$ where Σ is a block diagonal matrix with blocks of size $d_1, \ldots, d_r$ such that $\sum_i d_i = n$ and each block of size d_i is exactly $I_{d_i} - \frac{1}{d_i} J_{d_i}$ where I_{d_i} is the identity matrix and J_{d_i} is the all-ones matrix with sizes $d_i \times d_i$.*

Proof. The proof uses the characterization of any face of P by a maximal set of tight constraints which satisfy the chain structure. A collection of sets $A_1, A_2, \ldots, A_k \subseteq U$ form a *chain* if $A_1 \subseteq A_2 \subseteq \cdots \subseteq A_k$. The lemma is standard using the *uncrossing* technique (see Chapter 40 [18] or Lemma 5.2.4 [14]).

▶ **Claim 8.** *Given any face F of P, there exists a chain $S'_1 \subseteq S'_2 \subseteq \cdots \subseteq S'_r = U$ where $r = n - d$ and integers $k_j \geq 0$ for each $1 \leq j \leq r$ such that*

$$F = \{x \in P : \sum_{i \in S'_j} x_j = k_j \ \ \forall\, 1 \leq j \leq r\}.$$

Let $S_j = S'_j \setminus S'_{j-1}$ for each $1 \leq j \leq r$ where $S_0 = \emptyset$. Then the following two subspaces are equal

$$\{\mathbf{x} \in \mathbb{R}^n : \mathbf{x}(S'_j) = 0 \ \ \forall\, 1 \leq j \leq r\} = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{x}(S_j) = 0 \ \ \forall\, 1 \leq j \leq r\}.$$

Thus columns of C can be chosen to form an orthonormal basis of the subspace

$$\{\mathbf{x} \in \mathbb{R}^n : \mathbf{x}(S_j) = 0 \ \ \forall\, 1 \leq j \leq r\}.$$

Since $\{S_j : 1 \leq j \leq r\}$ form a partition of U, we can choose columns of C to be divided into groups of size $|S_j| - 1$ for each $1 \leq j \leq r$ where the j^{th} group is supported on the elements of S_j. Let C_j denote the submatrix with these $|S_j| - 1$ columns. Thus, we can apply Lemma 6 and $C_j^\top C_j$ has the property that the non-zero entries form a block matrix of $I_{d_i} - \frac{1}{d_i} J_{d_i}$ on the elements corresponding to S_j. Since $C'_j s$ have disjoint support, we have $CC^\top = \sum_{i=1}^r C_j C_j^\top$ as required. ◀

This completes the proof of Theorem 5. ◀

4 Negative Dependence Properties

In this section, we show the negative dependence properties of the random walk algorithm in matroid polytopes.

First, we have the following simple claim.

▶ **Lemma 9.** *The algorithm ends in $T = \frac{n^2}{\varepsilon^2}$ iterations with probability at least $1 - e^{-n}$. Conditioned on terminating, if the algorithm terminates with solution x_T, then $x_T = \theta + \sum_{t=1}^T \varepsilon C(F_t) g_t + \sum_{i=1}^n \zeta_i$ where g_t are independent Gaussians and $|\zeta_i| \leq n\varepsilon$ for each i. Here $C(F_t)$ is the projection matrix at time t and is also a random variable.*

Proof. The probability that the algorithm aborts in a single iteration is bounded by the probability of the event that a Gaussian with covariance at most εI is outside the ball of radius εn. Standard concentration result that this probability is bounded by e^{-n^2}. Thus the probability of aborting in the first T iterations is at most $\frac{n^2}{\varepsilon^2} e^{-n^2} \leq \frac{1}{2} e^{-n}$ for large enough n

and $\varepsilon < \frac{1}{n^2}$. Let us condition on the event that the algorithm does not abort. Now we bound the number of iterations. In each iteration, the expected distance squared from θ increases by at least ε^2. This follows since

$$E[\|\mathbf{x}_{t+1} - \theta\|_2^2 | x_t] = \varepsilon^2 E[gC(F_t)C(F_t)^\top g] \geq \varepsilon^2$$

where we use the fact that $C(F_t)^\top g$ is projection of a standard Gaussian in at least dimension one. Taking expectation over x_t, we get the squared distance increases by at least ε. Since the distance is bounded by diameter of P which is $\sqrt{n}$. Thus, with probability at least $1 - \frac{1}{2}e^{-n}$, the algorithm terminates in $n^2\varepsilon^2$ iterations with a vertex of P conditioned on the event that it doesn't terminate. Thus, we get the first claim.

Now consider the case that the algorithm succeeds and returns x_T. At each iteration t, we add $\varepsilon C(F_t)g_t$ to the current vector except when we project on a face. Since the dimension of the face reduces by one, there are at most n projection steps. The error term introduced by the projection is denoted by ζ_i where $|\zeta_i| \leq n\varepsilon$ for each $1 \leq i \leq n$. thus we obtain that

$$\mathbf{x}_T = \theta + \sum_{t=1}^{T} \varepsilon C(F_t)g_t + \sum_{i=1}^{n} \zeta_i. \qquad \blacktriangleleft$$

From now, we condition on the event that the algorithm does not abort and terminates with a vertex at iteration T. Thus all expectations stated from now on are conditioned on this event.

4.1 Negative Cylinder Property

We first show the negative cylinder property as defined in Definition 3. Recall that negative cylinder property is enough to obtain concentration results as given by Chernoff bounds.

▶ **Lemma 10.** *For any subset $R \subseteq U$,*

$$E[\prod_{i\in R} \mathbf{x}_T(i)] \leq \prod_{i\in R} E[\mathbf{x}_T(i)] + 2n^2\varepsilon = \prod_{i\in R} \theta(i) + 2n^2\varepsilon$$

Proof. We will show that $\prod_{i\in R} \mathbf{x}_t(i)$ forms a supermartingale (modulo the error terms). Since $\prod_{i\in R} \mathbf{x}_0(i) = \prod_{i\in R} \theta(i)$, we will have the claim. Let us verify the supermartingale property, by first ignoring the error term introduced due to fixing a constraint. Recall that

$$\mathbf{x}_{t+1} = \mathbf{x}_t(i) + \varepsilon C(F_t)g_t.$$

Let $h_t = C(F_t)g_t$. Consider any time $t+1$.

$$\begin{aligned}
E[\prod_{i\in R} \mathbf{x}_{t+1}(i) | \mathbf{x}_t] &= E[\prod_{i\in R} (\mathbf{x}_t(i) + \varepsilon h_t) \,|\mathbf{x}_t] \\
&= \prod_{i\in R} \mathbf{x}_t(i) + \varepsilon \sum_{j\in R} E[h_t(j)|\mathbf{x}_t] \cdot \left(\prod_{i\in R\setminus\{j\}} \mathbf{x}_t(i) \right) \\
&\quad + \varepsilon^2 \sum_{j,k\in R, j\neq k} E[h_t(j)h_t(k)|\mathbf{x}_t] \cdot \left(\prod_{i\in R\setminus\{j,k\}} \mathbf{x}_t(i) \right) \\
&\quad + \varepsilon^3 \sum_{j,k,l\in R, j\neq k\neq l} E[h_t(j)h_t(k)h_t(l)|\mathbf{x}_t] \cdot \left(\prod_{i\in R\setminus\{j,k,l\}} \mathbf{x}_t(i) \right) + \dots \\
&\leq \prod_{i\in R} \mathbf{x}_t(i) + 2\varepsilon^3 n^3
\end{aligned}$$

where we use the fact that $E[h_t(j)|\mathbf{x}_t] = 0$ for each $j \in R$ and $\varepsilon^2 \sum_{j,k \in R, j \neq k} E[h_t(j)h_t(k)|\mathbf{x}_t] \leq 0$ for each $j \neq k \in R$ from Theorem 5. The later terms have increasing powers of ε and thus we can bound the error terms using the fact that $\varepsilon \leq \frac{1}{n^2}$.

Applying an inductive argument, and also incorporating the error term introduced due to fixing constraints, we obtain the lemma.

◀

4.2 Negative Association

We now prove the stronger negative dependence property of negative association. This relies on the following classical lemma about Gaussian distribution that says that pairwise negative correlation is enough to obtain negative association. The definition of negative association is extended to real random variables as well.

▶ **Definition 11** (Negative Association)**.** Let $X_1, \ldots, X_n$ be real valued random variables. Then X_i's are *negatively associated* if for every non-decreasing functions $f : \mathbb{R}^n \to \mathbb{R}$ and $g : \mathbb{R}^n \to \mathbb{R}$ we have

$$E[f(X_1, \ldots, X_n)g(X_1, \ldots, X_n)] \leq E[f(X_1, \ldots, X_n)]E[g(X_1, \ldots, X_n)] \tag{5}$$

if f and g depend on disjoint set of coordinates.

Observe that the definitions are consistent and if a set of boolean random variables are negatively associated as per Definition 1 then they are also negatively associated as per Definition 11. This follows since every non-decreasing $f : \{0,1\}^n \to \mathbb{R}$ which depends on $S \subseteq [n]$ can be extended to a non-decreasing function $\hat{f} : \mathbb{R}^n \to \mathbb{R}$ which depends on S. Indeed, for any $x \in [0,1]^n$, let

$$\hat{f}(x) = \sum_{T \subseteq [n]} f(T) \prod_{i \in T} x_i \prod_{i \notin T} (1 - x_i)$$

and for any other x, let

$$\hat{f}(x) = f(x \wedge 1)$$

where $(x \wedge 1)_i = \min\{x_i, 1\}$. A straightforward check shows that $\hat{f}$ and f agree on the boolean hypercube. Moreover, $\hat{f}$ is non-decreasing and only depends on S.

▶ **Theorem 12.** *[13] Let $f_1 : \mathbb{R}^n \to \mathbb{R}$ and $f_2 : \mathbb{R}^n \to \mathbb{R}$ be non-decreasing functions depending on a disjoint set of coordinates. Let $X = (X_1, \ldots, X_n)$ be a Gaussian random variable which is negatively correlated. Then we have*

$$E[f_1(X)f_2(X)] \leq E[f_1(X)]E[f_2(X)].$$

We now prove the following theorem.

▶ **Lemma 13.** *For any non-decreasing functions $f_1, f_2 : \mathbb{R}^n \to \mathbb{R}$ depending on disjoint set of coordinates that are 1-Lipschitz, we have for each $0 \leq t \leq T$,*

$$E[f_1(\mathbf{x}_t)f_2(\mathbf{x}_t)] \leq E[f_1(\mathbf{x}_t)]E[f_2(\mathbf{x}_t)] + 2n\sqrt{n}\varepsilon$$

Proof. We first ignore the errors introduced due to projection onto tight constraints and prove the inequality without the error term. We let $\mathbf{y}_t$ denote the corresponding fractional points. Thus $\mathbf{y}_t = \theta + \sum_{s=1}^{t-1} C(F_s)g_s$. We prove that

$$E[f_1(\mathbf{y}_t)f_2(\mathbf{y}_t)] \leq E[f_1(\mathbf{y}_t)]E[f_2(\mathbf{y}_t)]$$

by induction on t. For $t = 0$, $\mathbf{y}_0 = \theta$ and both sides are equal. Now, let the statement be true for $t \leq T-1$. We have $\mathbf{y}_{t+1} = \mathbf{y}_t + C_t g_t$ where we denote $C(F_t)$ by C_t. Thus we have

$$E[f_1(\mathbf{y}_{t+1}) f_2(\mathbf{y}_{t+1})|\mathbf{y}_t] = E[f_1(\mathbf{y}_t + C_t g_t) f_2(\mathbf{y}_t + C_t g_t)|\mathbf{y}_t]$$

But now observe that $C_t g_t$ is a Gaussian in $\mathbb{R}^n$ which is negatively correlated from Theorem 5. For any $\mathbf{y}_t$, we apply Theorem 12 to the functions $f_1(\mathbf{y}_t + \cdot)$ and $f_2(\mathbf{y}_t + \cdot)$, we obtain

$$\begin{aligned} E[f_1(\mathbf{y}_{t+1}) f_2(\mathbf{y}_{t+1})|\mathbf{y}_t] &= E[f_1(\mathbf{y}_t + C_t g_t) f_2(\mathbf{y}_t + C_t g_t)|\mathbf{y}_t] \\ &\leq E[f_1(\mathbf{y}_t + C_t g_t)|\mathbf{y}_t] E[f_2(\mathbf{y}_t + C_t g_t)|\mathbf{y}_t] \\ &= E[f_1(\mathbf{y}_{t+1})|\mathbf{y}_t] E[f_2(\mathbf{y}_{t+1})|\mathbf{y}_t]. \end{aligned}$$

Now taking expectations w.r.t. $\mathbf{y}_t$, we obtain that

$$E[f_1(\mathbf{y}_t) f_2(\mathbf{y}_t)] \leq E[f_1(\mathbf{y}_t)] E[f_2(\mathbf{y}_t)].$$

Now bound the distance between $\mathbf{x}_t$ and $\mathbf{y}_t$. We have

$$\|x_t - \mathbf{y}_t\|_2 = \|\sum_{i=1}^{t-1} \zeta_i\|_2 \leq \sqrt{n} \max_i \|\zeta_i\|_2 \leq n\sqrt{n}\varepsilon.$$

Since f_1 and f_2 are 1-Lipschitz, we have the result of the lemma. ◀

Abstract

This paper investigates the task of load balancing where the objective function is to minimize the p-norm of loads, for $p \geq 1$, in both static and incremental settings. We consider two closely related load balancing problems. In the bipartite matching problem we are given a bipartite graph $G = (C \cup S, E)$ and the goal is to assign each client $c \in C$ to a server $s \in S$ so that the p-norm of assignment loads on S is minimized. In the graph orientation problem the goal is to orient (direct) the edges of a given undirected graph while minimizing the p-norm of the out-degrees. The graph orientation problem is a special case of the bipartite matching problem, but less complex, which leads to simpler algorithms.

For the graph orientation problem we show that the celebrated Chiba-Nishizeki peeling algorithm provides a simple linear time load balancing scheme whose output is an orientation that is 2-competitive, in a p-norm sense, for all $p \geq 1$. For the bipartite matching problem we first provide an offline algorithm that computes an optimal assignment. We then extend this solution to the online bipartite matching problem with reassignments, where vertices from C arrive in an online fashion together with their corresponding edges, and we are allowed to reassign an amortized $O(1)$ vertices from C each time a new vertex arrives. In this online scenario we show how to maintain a single assignment that is 8-competitive, in a p-norm sense, for all $p \geq 1$.

1 Introduction

Online algorithms for load balancing have received much attention in recent years. There are many variants of load balancing, and in this paper we consider two closely related load balancing problems – bipartite matchings and graph orientations. These problems have many natural applications in areas such as internet advertising, social networks, and routing. In the standard online paradigm, an object such as a vertex or edge arrives online

* Research supported in part by NSF grants CCF-1421161, CCF-1514383, and CCF-1637546.

licensed under Creative Commons License CC-BY

and then a decision, such as orienting an edge or matching two vertices, must be made immediately. This decision is *irrevocable*. It is well understood that, for most problems, an online algorithm cannot perform as well as an offline algorithm which knows the future requests. Sometimes the gap can be quite large.

It is therefore natural to consider giving the online algorithm a small amount of additional power. This idea has taken many forms such as resource augmentation, randomization, advice, or knowledge of an input distribution. Here we study the idea of allowing the online algorithm to "redo" some of its earlier decisions. Since we are studying polynomial-time solvable problems such as matching and orientation, we have to be sure not to allow too many opportunities to redo decisions, as we would then just simulate an offline algorithm. In particular, we will allow edge reorientations or reassignments, but will focus on algorithms that allow only a small number of reassignments. Our results will, in general, show that by allowing a small number of reassignments, we can maintain a much better matching or orientation.

The p-norm

Typically one evaluates a matching by its size or total cost and one evaluates an orientation by its maximum edge out-degree, or load. In this paper, we consider a more general class of objective functions, evaluating the p-norm, for any $p \geq 1$. For a vector $X = (x_1, x_2, \ldots, c_k)$ the p-norm of X is denoted by $\|X\|_p = (\sum_{i=1}^{k} x_i^p)^{1/p}$. Often, with a load-balancing problem, there is a tension between finding a solution that minimizes the maximum load and one that fairly distributes load among various agents. Considering only the maximum load ignores fairness among the non-maximum load nodes and considering only the average ignores the possibility of a solution with one or more nodes of very high load. This tradeoff has been studied in various ways in previous work, e.g. [19, 24, 14, 25, 4]. We address this tradeoff by considering p-norms. By using a small constant $p > 1$, it is well understood that one balances these two competing objectives. In this paper, we will give algorithms that perform well on all norms simultaneously. This not only shows that the algorithm does not need to be specialized to the norm, but also shows that there exist solutions that perform well in all norms simultaneously.

1.1 Edge orientation and bipartite matching

We investigate the goal of minimizing the p-norm of loads by considering two closely related problems.

Graph orientations

In the graph orientation problem, the goal is to orient (direct) the edges of an undirected graph G while minimizing some function of the out-degrees, and in our case the p-norm. If we consider an *out-degree vector* X of length n where x_i is the out-degree of vertex v_i, then one can word this goal as minimizing $\|X\|_p$.

Bipartite matching

In the online bipartite matching with reassignments problem a bipartite graph contains two sets of vertices: there is a set of vertices S (*server* vertices) that is fixed in advance, and a set of vertices C (*client* vertices) that grows over time. In particular, at each time step, a new client c is inserted into C along with edges from c to some non-empty subset of S. We

say that a server $s \in S$ is a *neighbor* of c if edge (c, s) exists. Given any time t, we let C_t be the set of client vertices at time t. We always let C refer to the set of vertices at the *current* time t. Similarly, we let $G_t = (V_t, E_t)$ refer to the resulting bipartite graph at time t (so $V_t = C_t \bigcup S$), and G refer to the graph at the current time t.

The online algorithm must at all times maintain a *global assignment* function $A : C \to S$, which assigns each client $c \in C$ to some server $s \in S$. Whenever a new client c is inserted into C, it must immediately be *assigned* to one of its neighbors in S. However, unlike in standard online matching, we also allow the algorithm to reassign $O(1)$ vertices from C each time a client arrives. Given any $s \in S$, let $\text{LOAD}_A(s) = |\{c \in C : A(c) = s\}|$ refer to the number of client vertices assigned to s by A. Let $\overline{\text{LOAD}}_A = (\text{LOAD}_A(s_1), \text{LOAD}_A(s_2), \ldots, \text{LOAD}_A(s_k))$ where $S = \{s_1, s_2, \ldots, s_k\}$. The vector $\overline{\text{LOAD}}_A$ is is called the *load vector of* A. The goal is to maintain an assignment A that minimizes $\|\overline{\text{LOAD}}_A\|_p$.

Notice that if each client arrives with exactly two neighboring vertices in S, then the online bipartite matching problem corresponds to an incremental version of the graph orientation problem (where edges arrive online and orientations are allowed to be flipped) by considering S as the set of vertices and C as the set of edges.

1.2 Our results

Our main result is to show that for the online bipartite matching with reassignments problem we can maintain an 8-approximation to the optimal assignment, while reassigning a small number of clients. To do so, we first show how to find an optimal offline solution using an adaptation of augmenting paths as follows. Given a global assignment A we orient[1] the edges of G as follows: an edge (s, c) is oriented $s \to c$ if $A(c) = s$, and otherwise it is oriented $c \to s$. This oriented graph is denoted by G_A.

▶ **Definition 1.** For a bipartite graph $G = (C \cup S, E)$ and a global assignment A, a directed path P in G_A from server $x \in S$ to server $y \in S$ is an augmenting path if $\text{LOAD}_A(y) \leq \text{LOAD}_A(x) - 2$.

▶ **Theorem 2.** *For a bipartite graph $G = (S \cup C, E)$ and for any $1 \leq p < \infty$, a global assignment A is optimal with respect to the p-norm if and only if G_A has no augmenting paths.*

Our online algorithm will always keep track of the optimal offline solution in the background (Theorem 2 provides a simple algorithm for keeping track of OPT as new clients arrive), and use it to influence its online assignments. Note that even though the online algorithm knows OPT it does not directly use the same assignment as OPT because maintaining OPT as new vertices are inserted into C may require too many reassignments.

Let OPT_t be an optimal assignment at time t. We are now ready to state our main theorem for online assignment.

▶ **Theorem 3.** *There exists an algorithm for online assignment which only performs an amortized $O(1)$ reassignments per time step (i.e. $O(1)$ per new client vertex), and ensures that at every time t, for any $s \in S$, $\text{LOAD}_A(s) \leq 8 \cdot \text{LOAD}_{\text{OPT}_t}(s)$. Note that the resulting assignment is always 8-competitive to the optimal assignment for any p-norm where $p \geq 1$, including $p = \infty$.*

[1] Notice that this is not the same orientation as in the graph orientation problem, although the two are related.

Results for graph orientation

While Theorem 2 provides a method for finding an optimal orientation in G in polynomial time (since the graph orientation problem is a special case), the runtime (via a straightforward implementation) is $O(m^2)$ where m is the number of edges. Instead, based on the Chiba and Nishizeki [7] triangle enumeration algorithm, we provide a simple linear time algorithm for finding an orientation that is a 2-approximation to the optimal p-norm. For an orientation $\mathcal{O}$ and a vertex u Let $d^+_{\mathcal{O}}(u)$ be the out-degree of u in the graph oriented by $\mathcal{O}$.

▶ **Theorem 4.** *There exists a linear time algorithm for the graph orientation problem on a graph $G = (V, E)$ producing an orientation $\mathcal{O}$ such that for any $p \geq 1$ and any vertex $u \in V$, $d^+_{\mathcal{O}}(u) \leq 2 \cdot d^+_{\text{OPT}}(u)$ where* OPT *is an optimal orientation with respect to the p-norm.*

We emphasize that one can use Theorem 3 to solve an incremental/online version of the graph orientation problem with a constant number of edge flips to maintain an orientation with a close to optimal p-norm of the out-degrees. The nice benefit of the proof of Theorem 4 is that it introduces and investigates a new natural combinatorial measurement of graphs, called the *local degeneracy*, which may be of independent interest.

1.3 Overview and Techniques for Bipartite Matching

To prove Theorem 3 we start by proving a simpler theorem.

▶ **Theorem 5.** *Say that for some specific time t_f we know in advance an upper bound on $\text{LOAD}_{\text{OPT}_{t_f}}(s)$ for every $s \in S$: that is, we know some function $u : S \to \mathbb{N}$ such that $\text{LOAD}_{\text{OPT}_{t_f}}(s) \leq u(s)$ for every $s \in S$. Then, there is an online assignment protocol that performs an amortized $O(1)$ reassignments per time step, and guarantees that at time t_f, every server $s \in S$ has $\text{LOAD}_{t_f}(s) \leq 2u(s)$.*

The proof of Theorem 5 is based on a recent result of Gupta, Kumar, and Stein [16] that also studies the problem of online assignment with reassignments, but they solve a simpler problem of trying to minimize the *maximum* load (i.e. the L_∞ norm of the loads) while performing as few reassignments as possible. In particular, they achieve the following results (the second result is a combination of the first result and the standard guess and double technique):

▶ **Theorem 6.** *[16] Say that we know in advance that at some final time step t_f, there is a solution in which every server $s \in S$ has load at most k. Then, there is an online assignment protocol that performs an amortized $O(1)$ reassignments per time step, and achieves a maximum load of $2k$ at time t_f.*

▶ **Theorem 7.** *[16] There exists an algorithm for online assignment which performs $O(1)$ reassignments per time step and has the following guarantee: at every time step t, if there exists an offline solution in which every $s \in S$ has a load of at most k_t, then the online protocol achieves a maximum load of at most $8k_t$.*

Although there is a trivial extension from Theorem 6 to Theorem 5, there is no trivial extension from Theorem 7 to Theorem 3. The intuition for why not knowing the optimal maximum load in advance poses a problem is as follows. Loosely speaking, the analysis of Theorem 6 (where the optimal max load k is known in advance) relies on the fact that the server vertices are only getting more and more constrained: if we know in advance that the

final load should be k, then since the load on every server $s \in S$ can only increase over time, as more clients arrive less and less capacity remains before we reach load k. But if the loads are not known in advance, then the algorithm must occasionally increase the desired load on s from k to say $2k$, which effectively makes s *less* constrained, and destroys the analysis in Theorem 6.

Theorem 7 is able to very easily overcome this obstacle because as long as we only care about the maximum load, the desired load for all $s \in S$ changes at the same time: as more vertices are inserted into C, the algorithm sometimes realizes that max load k is no longer feasible, so it increases the max allowable load to $2k$ for all vertices $s \in S$. Such global changes are easy to handle by effectively restarting the entire algorithm every time the desired max load doubles. But this approach does not work for Theorem 3 because here the algorithm must aim for a different load on every server, and these loads will change at different times. This prevents us from applying a global restart, and locally changing the allowable load on one server ends up destroying the analysis for the not-yet-changed parts of the graph.

We show, however, that it is nonetheless possible to do a reduction from Theorem 3 (loads not known in advance) to Theorem 5 (loads known in advance), but the reduction is significantly more complicated, and requires a more careful analysis of how the optimal offline assignment OPT relates to our online assignment. The main idea is to create another graph G^* by carefully duplicating servers with exponentially increasing capacities. Once the first i servers are full we begin using the $i+1$'th server. We show that maintaining an optimal solution in G^* can be used to maintain a close to optimal solution in G, and then we show how to maintain a close-to-optimal solution in G^*.

1.4 Overview and Techniques for Graph orientations: The Local Degeneracy

When considering the ∞-norm of out-degrees, a natural parameter to consider is the *arboricity* or *degeneracy* of the graph. The degeneracy of an undirected graph $G = (V, E)$ is the largest minimum degree of any subgraph of G. Formally the degeneracy of G is $\delta(G) = \max_{U \subseteq V} \min_{u \in U} d_{G_U}(u)$ where d_{G_U} is the degree of u in the subgraph of G induced by U. The degeneracy is roughly equal (up to constant factors) to other well known graph parameters such as the arboricity, strength, or thickness of a graph. Of particular interest is the arboricity $\alpha(G)$ of G since the maximum out-degree of any orientation is at least $\alpha(G) - 1$, and $\alpha(G) \leq \delta(G) \leq 2\alpha(G)$-1.

Chiba and Nishizeki [7] gave a linear time algorithm, called the *CN-peeling* algorithm, that computes a $\delta(G)$-orientation as follows. Repeatedly remove a vertex u in (the current) G with smallest (current) degree, together with the edges E_u touching u at the time u is removed. For each u, all of the edges E_u are oriented as leaving u. The out-degree of each vertex is shown to be at most $\delta(G)$ using straightforward arguments. The CN-peeling algorithm provides an acyclic orientation of G, where for each vertex u all of the edges E_u are oriented as leaving u. This acyclic orientation is used to enumerate all triangles of the graph in time $O(m \cdot \delta(G))$ with the following observation: for each triangle v_1, v_2, v_3 in G there must be at least one vertex of the three with both edges oriented outwards. Thus, it suffices to consider, for each vertex, all pairs of outgoing edges.

Local versus global parameters

While the algorithm of [7] is essentially tight for worst-case inputs (see [21, 22]), for many graphs the runtime bound of $O(m \cdot \delta(G))$ is not tight. For example, consider a graph G composed of a clique on $n^{1/3}$ vertices, and a tree on the rest of the vertices, with the tree being connected to the clique with one edge. The degeneracy of G is $\Theta(n^{1/3})$ and so $O(m \cdot \delta(G)) = O(n^{4/3})$. However, it is obvious that triangle enumeration through the CN-peeling algorithm runs in $O(n)$ time.

Why is this analysis not tight enough? Because the degeneracy is a global parameter of G which is largely due to a small part of G being dense. However, in the analysis, this global parameter should not affect the time cost of other sparser parts in G. It would therefore be more beneficial to express the runtime using tighter graph parameters which are more appropriate in determining the local cost of each vertex.

Local degeneracy

We extend the notion of degeneracy by introducing a new local sparseness measurement. The *local degeneracy* (LD) of a vertex v in G is $\ell_v = \max_{U \subseteq V, v \in U} \min_{u \in U} d_{G_U}(u)$. In words, the LD of v is the largest minimum degree of any subgraph of G that contains v. It is straightforward to show that in the orientation obtained from the CN-peeling algorithm the out-degree d_u^+ of a vertex u is at most its LD ℓ_u. The runtime of the CN-peeling algorithm for triangle enumeration is then $\sum_{v \in V} (d_u^+)^2 \leq \sum_{v \in V} (\ell_u)^2$, which is always at most $O(m \cdot \delta(G))$, but could be much less. In the example graph G above, this turns out to be $O(n)$. So, at least in the example, LD captures a locality notion that better expresses the runtime of the peeling algorithm.

We prove that LD captures a fundamental property of graph orientations stated in the following theorem.

▶ **Theorem 8.** *For an undirected graph $G = (V, E)$ and for any $1 < p < 0$, let* OPT *be any optimal orientation of the edges with respect to the p-norm. Let $d^+_{\text{OPT}}(v)$ be the out-degree of $v \in V$ when G is oriented according to* OPT*. Then $d^+_{\text{OPT}}(v) > \ell_v/2 - 1$. For the ∞-norm, the same is true for some optimal orientation.*

Theorem 8 has two important consequences. The first is that the CN-peeling algorithm gives an orientation whose out-degrees are 2-competitive to the optimal orientation with respect to the p-norm (Theorem 4). The second implication is that any algorithm that uses an acyclic orientation for enumerating all triangles in a given graph, by separately considering for each vertex all pairs of its outgoing edges, cannot be asymptotically faster than the CN-peeling algorithm.

Local degeneracy and the k-core

The *k-core* of G is the maximum subgraph of G with minimum degree at least k, and is denoted by G_k. As it turns out, if $u \in G_k - G_{k+1}$ then $\ell_u = k$ (more on this in Section 4). While the notion of a k-core is certainly not new, the focus from an algorithmic perspective has mainly been on computing the k-core of a graph for a given k. In other words, the focus has been on the k-core from a global prospective of the graph. Our focus is on a local property of vertices, which is captured by the local degeneracy of each vertex. Thus, we find the terminology of *local degeneracy* to be more appropriate for our objectives.

1.5 Related work

There is a large body of work that deals with the tradeoff between reassignment and the quality of an online solution. E.g., consider the problem of load balancing, where each arriving task has a processing time but can run only on some subset of the servers. Here, Phillips and Westbrook [28] and Westbrook [33] showed that a small number of reassignments (linear in the number of tasks) improve the quality of the solution, getting a constant competetive ratio, compares to logarithmic lower bounds in the case without reassignments [3]. There has also been work on the case of identical machines [30, 13, 29, 32, 12] and reassignments for other online problems such as Steiner Tree [18, 26, 15].

Related work on online bipartite matching

For online matching, the maximization version has been studied extensively. In this model all arriving nodes do not need to be matched, and the goal is to maximize the reward accrued by successfully matching a large number/weight of these nodes. It is well known that the greedy algorithm is 1/2-competitive for maximum matching. There are many papers on variants including when the capacity on one side is large relative to the requests, or when there is stochastic information, or when randomization is allowed. These results are orthogonal to our line of investigation, and we omit a detailed discussion.

Most relevant to our work is a paper by Gupta, Kumar and Stein [16] that studies the problem of online assignment in the same model as this paper. For online bipartite matching, where the left vertices arrive online and must be matched to the right vertices, they give an algorithm that reassigns the left vertices an (amortized) constant number of times, and maintains a constant factor to the optimal load on the right vertices. They then extend this result in several ways. For restricted machine scheduling with arbitrary sized jobs, they give an algorithm that maintains load which is $O(\log \log mn)$ times the optimum, and reassigns each job only an (amortized) constant number of times. They also give an algorithm for online flow that reroutes flow an (amortized) constant number of times while achieving constant factor approximation to the congestion. The bounds in the SODA proceedings version of [16] are correct, but there is an error in the proof. Work on this paper revealed that proof, which the authors have since corrected (the corrected verion has not yet been made public). Our work generalizes the results in that paper.

Related work on graph orientations

The task of maintaining an edge orientation with the goal of minimizing the maximum out-degree has also received a lot of attention [5, 20, 17]. Edge orientations have many algorithmic applications including "color-coding" [1], adjacency queries [8, 5, 23, 20], short-path queries [24], load balancing [6], maximal matchings [27], pattern matching [2], counting subgraphs in sparse graphs [9], prize-collecting TSPs and Steiner Trees [10], reporting all maximal independent sets [11], answering dominance queries [11], subgraph listing problems (listing triangles and 4-cliques) in planar graphs [8], and computing the girth [24].

2 Optimal Offline Bipartite Matching

Proof of Theorem 2. If A is optimal with respect to the p-norm then clearly there are no augmenting paths since flipping an augmenting path leads to a new assignment with smaller p-norm, due to convexity. So we focus on proving that if there are no augmenting paths in

G_A then A must be optimal for any p-norm with $1 < p < \infty$. For the following let p be any p in the range.

Let OPT_p be the optimal global assignment with respect to p. We partition the set of vertices in S as follows. $S^< = \{u \in S | \text{LOAD}_A(u) < \text{LOAD}_{\text{OPT}_p}(u)\}, S^> = \{u \in S | \text{LOAD}_A(u) > \text{LOAD}_{\text{OPT}_p}(u)\}$, and $S^= = S - \{S^< \cup S^>\}$. Let $E^* = \{(c,s) \in E | A(c) = s \in A \wedge \text{OPT}_p(c) \neq s\}$ be the set of edges in the symmetric difference between G_A and G_{OPT_p}. Let A^* by a global assignment of $G^* = (S \cup C, E^*)$ where each assignment of a vertex from C is made according to its assignment in A. Notice that each vertex in C has either degree 0 or 2 in G^*.

Let C be a directed cycle in $G^*_{A^*}$. Notice that if we were to flip all of the edges of C in G_A, then the out-degree of each vertex would not change due to the flip, and so the p-norm of the corresponding assignment would remain the same. However, after flipping the edges in C these edges are oriented in the same direction in both G_A and G_{OPT_p}. So we may assume without loss of generality that $G^*_{A^*}$ contains no cycles, since otherwise we iteratively pick a cycle and flip it until no cycles are left.

Given that $G^*_{A^*}$ does not contain any directed cycles, then either E^* is empty, in which case we are done, or $G^*_{A^*}$ is a directed acyclic graph with some edges. We say a directed path from $u \in S$ to $v \in S$ in $G^*_{A^*}$ with length at least 1 is a maximal path if there is no edge entering u and no edge leaving v. Notice that a maximal path cannot start in S^- since every vertex in S^- has edges leaving it, and it cannot start in $S^=$ since every vertex in $S^=$ has the same number of incoming and outgoing edges. Similarly, a maximal path cannot end in S^+ or $S^=$. Thus, all maximal paths must begin in S^+ and end in S^-.

Consider a maximal path P from $u \in S^+$ to $v \in S^-$. We will prove that $\text{LOAD}_A(u) = \text{LOAD}_A(v) + 1$. From this it will follow that we can flip P in G_A thereby swapping the loads of u and v in A. So the p-norm of the loads of this new assignment is the same as the $\|\text{LOAD}_A\|_p$. We can then iteratively flip maximal paths until we obtain the assignment OPT_p, implying that $\|\text{LOAD}_A\|_p = \|\text{LOAD}_{\text{OPT}_p}\|_p$ as required.

If $\text{LOAD}_A(u) > \text{LOAD}_A(v) + 1$ then P is an augmenting path in G_A, which contradicts the assumption. If $\text{LOAD}_A(u) < \text{LOAD}_A(v) + 1$, then since $u \in S^+$ and $v \in S^-$ we have that $\text{LOAD}_{\text{OPT}_p}(u) \leq \text{LOAD}_A(u) + 1 \leq \text{LOAD}_A(v) + 1 \leq \text{LOAD}_{\text{OPT}_p}(v) + 2$. This implies that the reverse of P, which is a path in G_{OPT_p}, is an augmenting path, contradicting OPT_p being an optimal orientation with respect to the p-norm. ◀

By Theorem 2 an orientation that is optimal with respect to some $1 < p < \infty$ is optimal with respect to any such p, and so we denote any such orientation by OPT. We also call OPT the optimal orientation for G.

▶ **Corollary 9.** *If an orientation has no augmenting paths, then it is optimal for the ∞-norm.*

3 Online Matching with Reassignments: Preliminaries and Main Theorem Statement

Proof of 5. The proof shows how to reduce this problem to the one in Theorem 6. In particular, recall that $G = (V, E)$ always corresponds to the graph induced by $V = C \cup S$ at the current time t (so G changes as new clients are inserted). Instead of directly maintaining an online assignment in G, we create a slightly different graph $G' = (V', E')$ which is essentially equivalent to G, but where we only need to concern ourselves with the ∞-norm. We define $V' = S' \cup C$, where the set S' contains $u(s)$ copies of every vertex $s \in S$, labeled $s_1, s_2, ..., s_{u(s)}$. Then, for every edge $(c, s) \in E$, we add edges $(c, s_1), (c, s_2), ..., (c, s_{u(s)})$ to E'.

It is clear that since $\text{LOAD}_{\text{OPT}_{t_f}}(s) \leq u(s)$, at time t_f there is an assignment in G' in which every vertex $s_i \in S$ has load at most 1. But this means via applying Theorem 6 that there is an assignment protocol for G' that only requires an amortized $O(1)$ reassignments per time step, and that maintains an assignment in G' where at time t_f, every vertex s_i has load at most 2. This assignment for G' then translates directly to the desired assignment in G: assigning a client c to some copy $s_i \in V'$, corresponds to assigning c to $s \in V$. We only perform a reassignment in G when we perform one in G' (but not necessarily vice versa: a reassignment between two copies s_i and s_j in G' does not lead to a reassignment in G), so the number of reassignments in G will also be at most amortized $O(1)$ per time step. Since every copy $s_i \in V'$ has at most two client vertices assigned to it, and there are $u(s)$ copies of s in V', we will end up with $\text{LOAD}_{t_f}(s) \leq 2u(s)$, as desired. ◀

Defining a Capacity Function

Unlike Theorem 5, Theorem 3 does not specify a particular finish time t_f, so the online assignment must be a good approximation to OPT at *all* time steps. Thus, in order to rely on Theorem 5, we need to define a *fixed* capacity function $u : S \to \mathbb{N}$ such that at *all* times t we have that for every $s \in S$, $\text{LOAD}_{\text{OPT}_t}(s) \leq u(s)$.

This seems contradictory – how can u be an upper bound on $\text{LOAD}_{\text{OPT}_t}$ if the first is fixed and the latter increases with t – but the idea is to capture changes in $\text{LOAD}_{\text{OPT}_t}(s)$ by creating many copies of each $s \in S$, each with different capacities $u(s)$. (Note: these copies are unrelated to the copies used in the proof of Theorem 5.)

Recall that $G = (V, E)$ refers to the current version of the graph. We define another graph $G^* = (V^*, E^*)$ that also changes as new clients are inserted. We start by defining a new set of servers S^*, which contains an infinite number of copies for each vertex $s \in S$, labeled: $s_0, s_1, s_2, s_3...$, where copy s_i will have capacity $u(s_i) = 2^{i+1}$. Our algorithm will not have to actually handle an infinite number of copies because originally all the copies s_i of a vertex $s \in S$ are *closed*: there are no edges from C to a closed copy s_i, so s_i will never have any client vertices assigned to it and can be entirely ignored.

Recall that as new clients are inserted into the graph, we are always keeping track of an optimal offline solution OPT, and that by the proof of Theorem 2 $\text{LOAD}_{\text{OPT}}(s)$ never decreases for any $s \in S$. Let OPT_t be an optimal solution at time t. When a new vertex $c \in C$ arrives at time $t(c)$, we do the following to the graph G^*:

- If for some vertex $s \in S$, we have $\text{LOAD}_{\text{OPT}t(c)-1}(s) = 2^i - 1$ and $\text{LOAD}_{\text{OPT}t(c)}(s) = 2^i$, then we open copy $s_i \in S^*$.
- For every edge (c, s) in G, we add an edge (c, s_i) to E^* for every *open* copy s_i.

Note that our end goal is to apply Theorem 5 to G^*, so it is crucial that G^* evolves according to the definition of an online assignment problem given in Section 3: at each time step, a client arrives with all of its incoming edges, and no new edges are ever added or removed. In particular, when a new copy s_i opens up at time t, we do NOT add edges from (c, s_i) to G^* for client vertices $c \in C$ that arrived before time t. However, the lack of edges from opened server copies in S^* to older client vertices in C leads to the problem that G^* ends up being quite different from the main graph G. In particular, we can in theory imagine a situation where OPT assigns many client vertices $c_1, c_2, ..., c_q$ to some vertex $s \in S$, and yet in G^* we cannot assign all these c_i to copies of s in S^*, because even though there are many open copies of s (because $\text{LOAD}_{\text{OPT}}(s) = q$ is large), it might be the case that most of the copies s_i were created *after* the clients $c_1, ..., c_q$ arrived, so there no edges from these c_i to the copies of s in S^*. The following lemma shows that G^* is nonetheless a good

approximation to G: we first apply the Lemma to Theorem 3, and then proceed to prove the lemma.

▶ **Lemma 10.** *At all times t, there exists an assignment in G_t^* of vertices $c \in C$ to vertices $s_i \in S^*$ such that $\text{LOAD}(s_i) \leq 2^{i+1} = u(s_i)$.*

Proof of Theorem 3. The proof relies on using Theorem 5 to maintain an online assignment in G^*. Note that we do not need to specify a specific time t_f as in Theorem 5, because we know from Lemma 10 that at ALL times t there is an assignment from C to S^* in which every $s_i \in S^*$ has load at most $u(s_i) = 2^{i+1}$. Thus, by Theorem 5 we can maintain an assignment from C to S^* that only uses an amortized $O(1)$ reassignments per new client, and in which for all times t we have $\text{LOAD}(s_i) \leq 2u(s_i) = 2^{i+2}$.

The assignment from C to S^* in G^* then translates directly into an assignment from C to S in G: for every assignment $c \to s_i$, if $s_i \in S^*$ is a copy of $s \in S$, then we assign $c \to s$. The number of reassignments in G is also amortized $O(1)$ per new client, since every reassignment in G corresponds directly to one in G^* (the opposite is not necessarily true: a reassignment in G^* between two copies s_i and s_j does not translate to a reassignment in G). All we have left to show is that for each $s \in S$, and for all times t, we always have $\text{LOAD}_t(s) \leq 8\text{LOAD}_{\text{OPT}_t}(s)$. To see this, note that $\text{LOAD}_t(s) = \sum_i \text{LOAD}_t(s_i)$, where we know that $\text{LOAD}_t(s_i) \leq 2^{i+2}$ if copy i is open, and $\text{LOAD}_t(s_i) = 0$ if copy i is closed. But we only open copy s_i if $\text{LOAD}_{\text{OPT}_t}(s) \geq 2^i$, so letting j be an index for which $2^j \leq \text{LOAD}_{\text{OPT}_t}(s) < 2^{j+1}$, we have that

$$\text{LOAD}_t(s) = \sum_i \text{LOAD}_t(s_i) = \sum_{i \leq j} \text{LOAD}_t(s_i) \leq \sum_{i \leq j} 2^{i+2} < 2^{j+3} \leq 8\text{LOAD}_{\text{OPT}_t}(s). \qquad \blacktriangleleft$$

We now turn to the proof of Lemma 10, which requires a more careful analysis of the offline solution OPT in G.

▶ **Definition 11.** If at some time t OPT assigns $c \in C$ to $s \in S$ – whether because c just arrived, or because OPT chooses to reassign c at time t – we say that the assignment $c \to s$ has *level* k if $\text{LOAD}_{\text{OPT}_t}(s) = k$.

Note that if we look at all the different assignments of some $c \in C$, their level is monotonically increasing over time. This is because OPT always makes the lowest level assignment possible and LOAD_{OPT} is monotonically increasing. So if at time t_1 there was an assignment $c \to s_1$ of level k_1, and at time $t_2 > t_1$ there was an assignment $c \to s_2$ of level $k_2 < k_1$, then OPT would have instead assigned c to s_2 at time t_1.

▶ **Definition 12.** We say that a vertex $c \in C$ has *initial level* k if the assignment $c \to s$ performed by OPT when c first arrives is a level k assignment. Finally, we say that a vertex $s \in S$ is the *final level k server* of some $c \in C$ if the assignment $c \to s$ is the last level k assignment OPT performs on c.

▶ **Claim 13.** *Say that vertex $s \in S$ is the final level k server of vertex $c \in C$. Then, if at time t OPT reassigns c from s to s', we must have that $\text{LOAD}_{\text{OPT}_t}(s) > k$.*

Proof. OPT only has to reassign c from s to s' if it assigned some other c' to s. Now, we know that the assignment $c \to s'$ could not have been of level less than k because earlier c had a level k assignment to s, and the level of assignments of c is monotonically increasing. We also know that the reassignment $c \to s'$ cannot be of level k since s was the *final* level k server of c. Thus, the assignment $c \to s'$ is of level at least $k+1$, so by definition $\text{LOAD}_{\text{OPT}_t}(s') \geq k+1$. But this means that $\text{LOAD}_{\text{OPT}_t}(s) \geq k+1$, because otherwise OPT would not have reassigned c from s to s'. $\blacktriangleleft$

▶ **Claim 14.** *Let $s \in S$ be the final level k server for vertices $c_1, c_2, c_3, ..., c_q$; then $q \leq k$.*

Proof. Say, for contradiction, that $q \geq k+1$. Let t_i, for $1 \leq i \leq q$, be the time at which s became the final level k sever for c_i. Without loss of generality, let $t_1 < t_2 < ... < t_q$. We want to argue that at the end of time t_q we have $\text{LOAD}_{\text{OPT}t_q}(s) \geq k+1$, which contradicts s being the final k server for c_q. There are two cases to consider. The first case is that OPT still assigns all of $c_1, c_2, ..., c_{q-1}$ to s at the end of t_q; then, since OPT also assigns c_q to s at time t_q, we have that $\text{LOAD}_{\text{OPT}t_q}(s) \geq q \geq k+1$. The second case is that by time t_q some c_i is no longer assigned to s in OPT, in which case by Claim 13, we must have that $\text{LOAD}_{\text{OPT}t_q}(s) \geq k+1$. ◀

Proof of Lemma 10. We say that a vertex $c \in C$ has *priority* i if the initial level of c is in $(2^i, 2^{i+1}]$. We now argue the following: if vertex $c \in C$ has priority i, then for every edge $(c, s) \in E$, we have that E^* must contain edges $(c, s_0), (c, s_1), ...(c, s_i)$ (E^* might also contain edges from c to later copies of s). Let us say for the sake of contradiction that edge $(c, s_i) \notin E^*$. This can only happen if s_i was not yet open at time $t(c)$, where $t(c)$ is the arrival time of c, and so in particular if $\text{LOAD}_{\text{OPT}t(c)}(s) < 2^i$. Say that at time $t(c)$, c was assigned to $s' \in S$. Since c has priority i, we know that at the end of $t(c)$ we have $\text{LOAD}_{\text{OPT}t(c)}(s') > 2^i$. This inequality yields the desired contradiction, since OPT is not optimal, as it would have been better off assigning c to s instead of s' at time $t(c)$.

Let $C_t^i \subseteq C_t$ contain all vertices in C_t that have priority exactly i. We first observe that there is an assignment in G from all vertices $c \in C_t^i$ to vertices in S in which every $s \in S$ has load at most 2^{i+1}. In particular, we can simply assign each $c \in C_t^i$ to its final level 2^{i+1} server, and by claim 14, each $s \in S$ will end up with at most 2^{i+1} client vertices assigned to it. This implies that at all times t, there exists an assignment in G^* that assigns each vertex $c \in C_t^i$ to some ith copy $s_i \in S^*$, while maintaining $\text{LOAD}(s_i) \leq 2^{i+1} = u(s_i)$ (and $\text{LOAD}(s_j) = 0$ for all $j \neq i$.) The reason is that we can take the above assignment from C_t^i to S in the main graph G, and for every assignment $c \to s$ in G, we can simply assign $c \to s_i$ in G^*; we know from the above paragraph that edge (c, s_i) necessarily exists in G^* because c has priority i. This completes the proof of Lemma 10, since our final assignment in G^* from C_t to S^* is simply the union among all priorities i of all the assignments from C_t^i to the ith copies $s_i \in S^*$. ◀

4 Graph Orientation

Orienting with local degeneracy

We use Chiba and Nishizeki's peeling algorithm. Let $(v_1, \ldots, v_n)$ be the order of vertices as encountered by the peeling algorithm. Recall that E_u is the set of edges touching u at the time u is peeled.

▶ **Lemma 15.** $|E_{v_i}| \leq \ell_{v_i}$.

Proof. The subgraph of G at the point where v_i is peeled has a minimum degree of $|E_{v_i}|$ so ℓ_{v_i} must be at least $|E_{v_i}|$. ◀

Consider the k-core of G, denoted by G_k. Clearly, every vertex in G_k must have local degeneracy at least k. Seidman in [31] showed that by recursively deleting (peeling) vertices with degree less than k one obtains G_k.

▶ **Lemma 16.** *For v_i let $j \leq i$ be the smallest integer such that $|E_{v_j}| = \max_{1 \leq k \leq i}\{|E_{v_k}|\}$. Then $\ell_{v_i} = |E_{v_j}|$.*

Proof. When v_j is peeled, all vertices must have degree at least $|E_{v_j}|$ and so $\ell_{v_i} \geq |E_{v_j}|$. Furthermore, by the correctness of the process described in Seidman in [31], right before v_j is peeled the remaining graph must be a $|E_{v_j}|$-core of G, and if $\ell_{v_i} > |E_{v_j}|$ then the algorithm must encounter a vertex $v_{j'}$ where $j < j' \leq i$ such that $\ell_{v_i} = |E_{v_{j'}}| > |E_{v_j}|$ contradicting the definition of j. ◀

Proof of Theorem 4. The whole proof relies on the following simple claim: for $v, w \in V$, if there is a directed path in G oriented by OPT from w to v, then $d^+_{\mathrm{OPT}}(w) \leq d^+_{\mathrm{OPT}}(v) + 1$. This is because otherwise, OPT could be converted to a better solution by flipping the path from w to v.

Assume by contradiction that for some vertex $v \in V$, $d^+_{\mathrm{OPT}}(v) \leq \ell_v - 1$. For the rest of the proof, we ignore all vertices that are not in the ℓ_v-core. Now, clearly in G_{ℓ_v} as well we have that $d^+_{\mathrm{OPT}}(v) \leq \ell_v - 1$. On the other hand, we have that every vertex in the unoriented G_{ℓ_v} has degree at least ℓ_v.

Define S to be the set of all vertices that can reach v in G_{ℓ_v} by some directed path of oriented edges. Note that by the simple claim above, for any vertex $u \in S$ we have $d^+_{\mathrm{OPT}}(u) \leq \ell_v - 1 + 1 = \ell_v$. while $d^+_{\mathrm{OPT}}(u)$ itself is strictly less than $\ell_v/2$, so the average load in S is strictly less than $\ell_v/2$.

We will now prove a contradictory claim: S must have some edges directed into S from outside of S. This is contradictory because we defined S to be maximal. To yield the contradiction, let E_S be all edges incident in an undirected sense to S, and let E^*_S be all edges that are oriented outwards from vertices in S, possibly to some other vertex in S. We want to show that $E_S > E^*_S$, which implies that some edge is incoming into S. We know that E^*_S is the sum of the out-degrees of vertices in S, so given the upper bound on the average load in S, we have that $E^*_S < |S| \cdot \ell_v/2$. On the other hand, $E_S \geq |S| \cdot \ell_v/2$, because every vertex in S has degree at least ℓ_v. ◀

Abstract

Given a finite metric space (V, d), an approximate distance oracle is a data structure which, when queried on two points $u, v \in V$, returns an approximation to the the actual distance between u and v which is within some bounded stretch factor of the true distance. There has been significant work on the tradeoff between the important parameters of approximate distance oracles (and in particular between the size, stretch, and query time), but in this paper we take a different point of view, that of per-instance optimization. If we are given an particular input metric space and stretch bound, can we find the smallest possible approximate distance oracle for that particular input? Since this question is not even well-defined, we restrict our attention to well-known classes of approximate distance oracles, and study whether we can optimize over those classes.

In particular, we give an $O(\log n)$-approximation to the problem of finding the smallest stretch 3 Thorup-Zwick distance oracle, as well as the problem of finding the smallest Pătraşcu-Roditty distance oracle. We also prove a matching $\Omega(\log n)$ lower bound for both problems, and an $\Omega(n^{\frac{1}{k}-\frac{1}{2^{k-1}}})$ integrality gap for the more general stretch $(2k-1)$ Thorup-Zwick distance oracle. We also consider the problem of approximating the best TZ or PR approximate distance oracle *with outliers*, and show that more advanced techniques (SDP relaxations in particular) allow us to optimize even in the presence of outliers.

1 Introduction

Given a finite metric space (V, d), an approximate distance oracle is a data structure which can approximately answer distance queries. It is usually a combination of a preprocessing algorithm to compute a data structure, and a query algorithm which returns a distance $d'(u, v)$ whenever queried on a pair of vertices $u, v \in V$. An approximate distance oracle is said to have *stretch* t if $d(u, v) \leq d'(u, v) \leq t \cdot d(u, v)$. Note that there is a trivial stretch 1 distance oracle that uses $\Theta(n^2)$ space: we could just store the entire metric space. So the goal is to reduce the space, i.e., to build a small data structure that also has small stretch and small query time.

The seminal work on approximate distance oracles is due to Thorup and Zwick [19]. They showed that for every integer $k \geq 1$, every finite metric space has an approximate distance oracle with stretch $(2k-1)$ and query time $O(k)$ which uses only $O(kn^{1+\frac{1}{k}})$ space.

A significant fraction of more recent results have built off of the ideas developed in [19], and much of this follow-up work has stored the exact same (or very similar) data structure, just with improved query algorithms or slightly different information in the storage (see, e.g., [17, 21, 5, 6]). Most notably, Pătraşcu and Roditty [16] gave a different distance oracle (still using some of the basic ideas from [19]) that has multiplicative stretch of 2 and additive stretch of 1, with size $O(n^{\frac{5}{3}})$. This broke through the stretch 3 barrier from [19]. Later this result was improved to more general multiplicative/additive stretches [1].

In this paper we ask a natural but very different type of question about approximate distance oracles: can we find (or approximate) the *best* approximate distance oracle? If we are given an input metric space and a stretch bound, is it possible to find the *smallest* approximate distance oracle for that particular input? This is an unusual question in two ways. First, most data structures are by design forced to store all of the input data; the question is *how* to store it and what *extra* information should be stored. This is the case in other settings where instance-optimality of data structures has been considered, e.g., static or dynamic optimality of splay trees. Second, it is not clear whether this question is even well-defined: lower bounds on data structures are commonly arrived at through information or communication complexity (see, e.g., [15]) but when we ask for the optimal data structure on one particular instance this approach becomes meaningless.

However, approximate distance oracles are different in ways which allow us to make meaningful progress towards these optimization questions. First, since we are allowed to return only approximate distances (up to some stretch factor), we are allowed to store only part of the input (and indeed this is the entire point of such an oracle). The second problem is a bit more tricky: given an input, how can we optimize over "the space of all approximate distance oracles"? What does this mean, and what does this space look like?

To get around this issue, we make an observation: many modern distance oracles (and in particular Thorup-Zwick, Pătraşcu-Roditty, and almost all of their variants) have a similar structure. The preprocessing algorithm chooses a subset of the original distances to store which has some particular structure, and the query algorithm can return a valid distance estimate efficiently as long as the stored distances satisfy the required structure. Thus we can optimize for *these particular* distance oracles by choosing the *best possible* set of distances to remember subject to the required structure. By characterizing this structure for different types of distance oracles, we can optimize over those types.

For example, the stretch-3 Thorup-Zwick distance oracle uses a subtle but simple method to choose the set of distances to store. It randomly samples a subset of approximately $\sqrt{n}$ vertices, without using any information about the original metric space, and then creates a data structure which is related (in a well-defined, important way) to these vertices. The correctness of the query algorithm does not depend on the choice of the vertices. Thus instead of simply choosing the subset of vertices uniformly at random, we can instead try to optimize the set of chosen vertices with respect to the actual input metric space.

In this paper, we give matching $\Theta(\log n)$ upper and lower bounds for optimizing stretch-3 Thorup-Zwick distance oracles, and matching $\Theta(\log n)$ upper and lower bounds for optimizing the Pătraşcu-Roditty distance oracle. These upper bounds both use a similar LP relaxation, but by giving an $\Omega(n^{\frac{1}{k}-\frac{1}{2^{k-1}}})$ integrality gap for optimizing stretch-$(2k-1)$ Thorup-Zwick distance oracles, we show that this relaxation is not enough to give nontrivial approximations when extended to larger stretch values.

As an extension, we also study the problem of optimizing distance oracles *with outliers*: if we are allowed to not answer queries for some of the vertices (of our choosing), can we have much smaller storage space? We give an $(O(\log n), 1+\varepsilon)$-bicriteria approximation to

both stretch-3 Thorup-Zwick and Pătraşcu-Roditty distance oracles with outliers. We also give a true approximation to stretch-3 Thorup-Zwick distance oracle with outliers when the number of outliers is small.

1.1 Relationship to Spanners

It is worth noting that this paper is motivated by a similar line of research on *graph spanners* (subgraphs which approximately preserve distances). Spanners and distance oracles tend to be related (although there is no known formal connection between them), and the traditional questions asked of spanners (what is the tradeoff between the stretch and the size?) are similar to the traditional questions asked of distance oracles. Recently, there has been significant progress in looking at spanners from an optimization point of view: given an input graph and an allowed stretch bound, can we find the sparsest possible spanner meeting that stretch bound? In the last few years, upper and lower bounds have been developed for these problems in the basic case, the directed case, with a degree objective, with fault-tolerance, etc. See, e.g., [9, 2, 11, 8, 7].

It is natural to ask these kinds of optimization questions for distance oracles as well, but the definitions become much more difficult. For spanners, the space we are optimizing over (all subgraphs) is very clear and well-defined. But for distance oracles, as discussed, it is much harder to define the space of all data structures. Thus in this paper we optimize over restricted classes, where this space is more well-defined. We view our definitions of these restricted optimization questions as one of the major contributions of this work.

2 Definitions and Preliminaries

We begin with some basic definitions, including formal definitions of the problems that we will be working on.

▶ **Definition 1.** An approximate distance oracle with (m, a)-stretch, size s, preprocessing time g, and query time h is a pair of algorithms, *preprocess* and *query*, with the following properties.

- *preprocess* is a randomized preprocessing algorithm $preprocess(V, d, m, a, r)$ which takes as input a metric space (V, d), stretch bound (m, a), and random string r and outputs a data structure S where the expected output size is at most $\mathbb{E}_r[|S|] \leq s(|V|, m, a)$ and the expected preprocessing time is at most $g(|V|, m, a)$.
- *query* takes as input a data structure $S = preprocess(V, d, m, a, r)$ (the output of the preprocess algorithm) with two vertices $u, v \in V$, and outputs a value $d'(u, v) \in \mathbb{R}$ such that $d(u, v) \leq d'(u, v) \leq m \cdot d(u, v) + a$. The running time of *query* is at most $h(|V|, m, a)$.

We will frequently refer to these just as "distance oracles" rather than "approximate distance oracles" when the stretch bound is clear from context.

The query algorithm guarantees here are deterministic: the randomness only affects the size of the data structure. Note that one could easily define distance oracles so that either the correctness (with respect to the stretch bound) or the query running time (or both) hold only in expectation or with high probability, but as discussed in Section 1, essentially all existing distance oracles (and in particular the Thorup-Zwick distance oracle) have deterministic guarantees on the queries.

This naturally leads us to the following question: If we fix a particular distance oracle and metric space, can we find the *best* possible data structure? Here we will focus on the output size, not the preprocessing time (as long as the preprocessing time is polynomial). In

other words, since the query algorithm work on *any* of the possible data structures which the preprocessing algorithm might output, can we actually find the smallest such data structure? This gives the following natural optimization problem.

▶ **Definition 2.** Given an approximate distance oracle $\mathcal{A} = (preprocess, query)$, the $\mathcal{A}$-optimization problem takes as input a metric space (V, d) and a stretch bound (m, a), and the goal is to find a string r which minimizes $|preprocess(V, d, m, a, r)|$.

In this paper we will focus on two distance oracles (Thorup-Zwick [19] and Pătraşcu-Roditty [16]), so we now introduce these oracles.

2.1 Thorup-Zwick Distance Oracle

For every integer $k \geq 1$, Thorup and Zwick [19] provided an approximate distance oracle with $(2k-1, 0)$-stretch, size $O(n^{1+\frac{1}{k}})$, preprocessing time $O(kn^{2+\frac{1}{k}})$, and query time $O(k)$. We call this distance oracle TZ_k.

Their preprocessing algorithm first constructs a chain of subsets $\varnothing = A_k \subseteq A_{k-1} \subseteq \ldots \subseteq A_0 = V$ by repeated sampling. Each set A_i, where $i \in [k-1]$, is obtained by including each element of A_{i-1} independently with probability $n^{-\frac{1}{k}}$.

Let $R_{iu} = \{v \in A_{i-1} \mid d(u,v) < \min_{w \in A_i} d(u,w)\}$ for all $u \in V$ and $i \in [k]$ (where by convention $\min_{w \in \varnothing} d(u,w) = \infty$ for all $u \in V$ to handle the $i = k$ case). The output data structure is obtained by storing (in a 2-level hash table) the distance from each node u to each node in $\bigcup_{i=1}^{k} R_{iu}$.

The data structure also stores a little more information. Each vertex u remembers $k-1$ pivots: $\arg\min_{w \in A_i} d(u,w)$ for all $i \in [k-1]$, and the distance from u to these pivots. However, this is a fixed space cost, and also negligible, so when analyzing the size of the oracle we will ignore the cost of storing the pivots

Clearly the output data structure is determined once $A_1, \ldots, A_{k-1}$ are fixed. The size of the data structure is:

$$cost(A_1, \ldots, A_{k-1}, V, d) = \sum_{u \in V} \sum_{i=1}^{k} |R_{iu}| = \sum_{u \in V} \sum_{i=1}^{k} \left| \{v \in A_{i-1} \mid d(u,v) < \min_{w \in A_i} d(u,w)\} \right|.$$

We will refer to $\sum_{u \in V} |R_{iu}|$ as the cost in level i.

Let us look back on the definition of approximate distance oracle. The random string r is only used to generate A_i's, and the query algorithm will return a correct distance estimate no matter what the sets A_i are, but the size is determined by the sets. Therefore, the TZ_k-optimization problem is to find the subsets $\varnothing = A_k \subseteq A_{k-1} \subseteq \ldots \subseteq A_0 = V$ in order to minimize the total cost.

2.2 Pătraşcu-Roditty Distance Oracle

Pătraşcu and Roditty [16] provided an approximate distance oracle with $(2, 1)$-stretch, size $O(n^{\frac{5}{3}})$, preprocessing time $O(n^2)$, and query time $O(1)$. We call this distance oracle PR. Note that PR works only for metric spaces with integer distances.

Their preprocessing algorithm first construct a set $A \subseteq V$ via a complicated correlated sampling (informally, they sample a large set and a small set, and then define A to be everything in the large set and everything contained in a ball around the small set delimited by the large set). The data structure consists of a 2-level hash table for the distance from each node in A to each node in V, as well as a 2-level hash table storing the distance between each pair $\{u, v\} \subseteq V$ such that $d(u,v) < \min_{w \in A} d(u,w) + \min_{w \in A} d(v,w) - 1$.

As with Thorup-Zwick, the output data structure is completely determined once A is fixed. Let $R = \{\{u, v\} \subseteq V \mid d(u, v) < \min_{w \in A} d(u, w) + \min_{w \in A} d(v, w) - 1\}$. Then the size of the data structure is

$$\begin{aligned} cost(A, V, d) &= n \cdot |A| + |R| \\ &= n \cdot |A| + \left| \left\{ \{u, v\} \subseteq V : d(u, v) < \min_{w \in A} d(u, w) + \min_{w \in A} d(v, w) - 1 \right\} \right|. \end{aligned}$$

As before, the random string r is only used to generate the set A, and any $A \subseteq V$ gives a data structure on which the query algorithm works. Therefore, the PR-optimization problem is to find the subset $A \subseteq V$ in order to minimize the total cost.

2.3 Distance Oracles With Outliers

In some cases, a small set of outlier vertices may make the size of the data structure blow up. Yet in some applications it is acceptable to ignore these outliers. This was the motivation behind a line of work on distance oracles with slack ([3], [4]), in which the data structure could ignore the stretch bound on a small fraction of the distances.

In this paper, we consider the case that we can refuse to answer distance queries for some outlier vertices. In other words, we can essentially remove an outlier set F out of V when computing the distance oracle. This gives us the problem of optimizing distance oracle with outliers, in which we not only need to find the random string to determine the output data structure, we also need to find the set of outliers to minimize the final cost. More formally, we have the following type of problem.

▶ **Definition 3.** Given an approximate distance oracle $\mathcal{A} = (preprocess, query)$, the $\mathcal{A}$-optimization problem with outliers takes as input a metric space (V, d), a stretch bound (m, a), and a bound on the number of outliers $f \in \mathbb{N}$. The goal is to find a string r as well as a set $F \subseteq V$ where $|F| \leq f$, in order to minimize $|preprocess(V \backslash F, d, m, a, r)|$.

We will provide both true approximation results and (α, β)-bicriteria results, in which we slightly violate the bound on the number of outliers. Formally, an (α, β)-approximation algorithm for the $\mathcal{A}$-optimization problem with outliers is an algorithm which on any input $((V, d), (m, a), f)$ returns a solution with cost at most $\alpha \cdot OPT$ that has at most $\beta \cdot f$ outliers (where OPT is the minimum cost of any solution with at most f outliers).

2.4 Our Results and Techniques

With these definitions in hand, we can now formally state our results.

In Section 3 we discuss the problem of optimizing the 3-stretch Thorup-Zwick distance oracle, i.e., the TZ_2-optimization problem. It is straightforward to obtain an $O(\log n)$-approximation by reducing to the non-metric facility location problem.

▶ **Theorem 4.** *There is an $O(\log n)$-approximation algorithm for the TZ_2-optimization problem.*

To prove a matching lower bound, we use a reduction from Label Cover to the TZ_2-optimization problem. We use a proof which is similar to the proof of the hardness of Set Cover in [20] (based on [13]). However, we cannot use a reduction directly from Set Cover since we will need some extra properties of the starting instances, and thus are forced to start from Label Cover. We introduce a new notion of (m, l, δ)-set families and show that these can still be plugged into existing hardness results to get the extra structural properties that we need. This lets us prove the following theorem:

▶ **Theorem 5.** *Unless* $\mathbf{NP} \subseteq \mathbf{DTIME}(n^{O(\log\log n)})$*, the* TZ_2*-optimization problem does not admit a polynomial-time* $o(\log n)$*-approximation.*

For larger stretch values, a natural approach is to realize that a simple LP relaxation suffices to give Theorem 4 in the stretch 3 case, and try to extend this basic LP to larger stretches. In Section 4, we show that this does not work for the more general TZ_k-optimization problem: the integrality gap jumps up to become a polynomial. The instance is very simple: it is just the metric space formed by shortest paths on the n-cycle. It turns out to be straightforward to calculate the optimal fractional LP cost, but proving that the optimal integral solution is large is surprisingly involved.

▶ **Theorem 6.** *The basic LP relaxation for the* TZ_k*-optimization problem has an* $\Omega(n^{\frac{1}{k}-\frac{1}{2^{k-1}}})$ *integrality gap when* $k > 2$*.*

In Section 5 we discuss the problem of optimizing the Pătraşcu-Roditty distance oracle. The basic LP and a simple rounding algorithm gives us an $O(\log n)$-approximation algorithm.

▶ **Theorem 7.** *There is an* $O(\log n)$*-approximation algorithm for* PR*-optimization problem.*

A reduction from set cover problem also gives us a matching lower bound.

▶ **Theorem 8.** *Unless* $\mathbf{P} = \mathbf{NP}$*, the* PR*-optimization problem does not admit a polynomial-time* $o(\log n)$*-approximation.*

In Section 6 we move to the outliers setting. For both TZ_2- and PR-optimization problems, a semidefinite programming relaxation and a simple rounding algorithm gives us an $(O(\frac{\log n}{\varepsilon}), 1+\varepsilon)$-approximation algorithm. Here, using an SDP relaxation seems to be necessary – the corresponding LP relaxation requires violating the number of outliers by a factor of 2 rather than a factor of $1+\varepsilon$. We can also get a true approximation on TZ_2-optimization problem with outliers if the number of outliers is low. These results form the following theorems.

▶ **Theorem 9.** *There is an* $(O(\frac{\log n}{\varepsilon}), 1+\varepsilon)$*-approximation algorithm for the* TZ_2*-optimization problem with outliers.*

▶ **Theorem 10.** *There is an* $O(\log n)$*-approximation algorithm for* TZ_2*-optimization problem with outliers if the number of outliers is at most* $\sqrt{n}$*.*

▶ **Theorem 11.** *There is an* $(O(\frac{\log n}{\varepsilon}), 1+\varepsilon)$*-approximation algorithm for the* PR*-optimization problem with outliers.*

3 TZ_2-Optimization Problem

We first give an $O(\log n)$-approximation for TZ_2-optimization (Theorem 4), and follow this with a matching lower bound.

3.1 Upper Bound

We will prove our upper bound by a reduction to the non-metric facility location problem.

▶ **Definition 12.** In the *non-metric facility location* problem we are given a set F of facilities, a set D of clients, an opening cost function $f : F \to \mathbb{R}^+$, and a connection cost function $c : D \times F \to \mathbb{R}^+$. The goal is to find the set $S \subseteq F$ which minimizes $\sum_{i\in S} f(i) + \sum_{i\in D} \min_{j\in S} c(i,j)$ (i.e. the sum of the opening and connection costs).

Non-metric facility location is a classic problem, and much is known about it, including the following upper bound due to Hochbaum.

▶ **Theorem 13** ([14]). *There is a polynomial time algorithm which gives an $O(\log n)$-approximation to the non-metric facility location problem.*

Hochbaum's algorithm is a greedy algorithm, but it is also straightforward to design an algorithm with similar bounds using an LP relaxation. Since it is not necessary we do not present the relaxation here, but generalizations of the relaxation will prove its importance in the more general TZ_k setting (see Section 4).

We now show that the TZ_2-optimization problem is essentially a special case of non-metric facility location problem. First, simple arithmetic manipulation of the cost function of the TZ_2-optimization problem gives the following:

$$\begin{aligned} cost(A_1, V, d) &= \sum_{u \in V} |R_{1u}| + \sum_{u \in V} |R_{2u}| \\ &= \sum_{u \in V} \left| \{v \in V \mid d(u,v) < \min_{w \in A_1} d(u,w)\} \right| + \sum_{u \in V} |\{v \in A_1 \mid d(u,v) < \infty| \\ &= \sum_{u \in V} \left| \{v \in V \mid d(u,v) < \min_{w \in A_1} d(u,w)\} \right| + n|A_1| \\ &= \sum_{w \in A_1} n + \sum_{u \in V} \min_{w \in A_1} |\{v \in V \mid d(u,v) < d(u,w)\}| \,. \end{aligned}$$

Given an instance (V, d) of the TZ_2-optimization problem, we create an instance of non-metric facility location by setting $F = D = V$, opening costs $f(v) = n$ for all $v \in V$, and connection costs $c(u, w) = |\{v \in V \mid d(u, v) < d(u, w)\}|$ for all $u, w \in V$. Then the cost function of the TZ_2-optimization problem is exactly the same as the cost function of non-metric facility location problem. Therefore TZ_2 is a special case of non-metric facility location, which together with Theorem 13 implies Theorem 4.

3.2 Lower Bound

Proving an $\Omega(\log n)$ hardness of approximation (Theorem 5) turns out to be surprisingly difficult. Details appear in the full version [10]; here we provide an informal overview. Technically we reduce directly to TZ_2-optimization from a version of the Label Cover problem that corresponds to applying parallel repetition [18] to 3SAT-5, which is a standard starting point for hardness reductions. Informally, though, we are "really" reducing from Set Cover: given an instance of Set Cover, we show how to create an instance of TZ_2-optimization where the cost of the optimal solution is the same (up to a constant and a polynomial scaling factor). But in order for our reduction to work, we actually need more than just an arbitrary Set Cover instance: we need a version of Set Cover in which it is hard even to cover *most* of the elements, not just all of them.

So we have to also give a new reduction from Label Cover to Set Cover, showing that even this version of Set Cover is hard. It turns out that Feige's reduction [13], reinterpreted by Vazirani [20], essentially already gives us what we need. We just need to analyze it a bit more carefully. In particular, a key component of this reduction is what Vazirani called (m, l)*-set systems*, which can be thought of as nearly-unbiased sample spaces. We generalize this notion to (m, l, δ)-set systems, given in the following definition.

▶ **Definition 14.** A set B (the universe) and a collection of subsets $C_1, \ldots, C_m$ of B form an *(m, l, δ)-set system* if any collection of l sets in $\{C_1, \ldots, C_m, \overline{C_1}, \ldots, \overline{C_m}\}$ whose union contains at least $(1-\delta)|B|$ elements must include both C_i and $\overline{C_i}$ for some i.

An (m, l)-set system is just a $(m, l, 0)$-set system. While not all (m, l)-set systems are (m, l, δ)-set systems for larger δ, the construction of (m, l)-set systems in [20] actually does generalize directly to larger values of δ. With this tool in hand, we follow through the rest of the reduction and it gives us the type of Set Cover instances which we need. Technically our reduction skips this step by going directly from Label Cover to TZ_2-optimization, but generating these kinds of Set Cover instances is intuitively what the first part of the reduction is doing.

4 TZ_k-Optimization Problem

We now move to the more general TZ_k-optimization problem. While we are not able to give nontrivial upper bounds for this problem, we can at least show that the basic LP relaxation (as discussed in Section 3.1) does not give polylogarithmic bounds in this more general setting.

4.1 The LP

Let $B_u(v) = \{w \in V \mid d(u,w) \leq d(u,v)\}$. For every $v \in V$ and $i \in [k]$, let $x_v^{(i)}$ be a variable which is supposed to be an indicator for whether $v \in A_i$. Similarly, for all $u, v \in V$ and $i \in [k]$, let $y_{uv}^{(i)}$ be a variable which is supposed to be an indicator for whether $v \in R_{iu}$. (Recall that $R_{iu} = \{v \in A_{i-1} \mid d(u,v) < \min_{w \in A_i} d(u,w)\}$) We can easily write an LP relaxation for this problem:

$$\begin{array}{lll} (LP_{TZ_k}): \min & \sum_{i=1}^{k} \sum_{u,v \in V} y_{uv}^{(i)} & \\ s.t. & 0 = x_v^{(k)} \leq x_v^{(k-1)} \leq \ldots \leq x_v^{(1)} \leq x_v^{(0)} = 1 & \forall v \in V \\ & y_{uv}^{(i)} \geq x_v^{(i-1)} - \sum_{w \in B_u(v)} x_w^{(i)} & \forall u, v \in V, i \in [k] \\ & y_{uv}^{(i)} \geq 0 & \forall u, v \in V, i \in [k] \end{array}$$

It can easily be shown that this is a valid relaxation (the proof can be found in the full version [10]). When restricted to the special case of $k = 2$, it is not hard to see that this LP is essentially a special case of the basic LP relaxation for non-metric facility location, which can be used to prove the $O(\log n)$ bound of Theorem 4. But for larger values of k the behavior is different, and does not result in a polylogarithmic integrality gap.

4.2 Integrality Gap

The integrality gap instance is quite simple: the metric (V, d) induced by shortest-path distances in a cycle. Slightly more formally, we let $V = [n]$, and use the cycle distance $d(u,v) = \min\{|u-v|, n + \min\{u,v\} - \max\{u,v\}\}$.

Details can be found in the full version [10]. It turns out to be relatively easy to find a fractional solution to LP_{TZ_k} with cost $O(n^{1+\frac{1}{2^{k-1}}})$ on this instance. The tricky part is lower bounding the optimal solution, i.e., showing that the optimal integral solution has cost at least $\Omega(n^{1+\frac{1}{k}})$. Combining these two results gives us an $\Omega(n^{\frac{1}{k}-\frac{1}{2^{k-1}}})$ integrality gap, proving Theorem 6.

5 PR-Optimization Problem

We now move from Thorup-Zwick distance oracles to Pătraşcu-Roditty distance oracles. We show that from an optimization perspective, they are similar to TZ_2 in that we can find matching bounds: an $O(\log n)$-approximation, and $\Omega(\log n)$-hardness.

5.1 Upper Bound

In this section we prove Theorem 7 by using an LP and randomized rounding to give an $O(\log n)$-approximation to the PR-optimization problem.

Let $B_u(v) = \{w \in V \mid d(u,w) \leq d(u,v)\}$, and $B(u,r) = \{w \in V \mid d(u,w) \leq r\}$. We can see $B_u(v) = B(u, d(u,v))$. Now, let x_v be a variable which is supposed to be an indicator for whether $v \in A$, and let y_{uv} be a variable which is supposed to be an indicator for whether $\{u,v\} \in R$ (recall that $R = \{\{u,v\} \subseteq V \mid d(u,v) < \min_{w\in A} d(u,w) + \min_{w \in A} d(v,w) - 1\}$). We can write the following LP relaxation:

$$\begin{array}{rll} (LP_{PR}): \min & \sum_{v\in V} n \cdot x_v + \sum_{\{u,v\}\subseteq V} y_{uv} & \\ s.t. & y_{uv} \geq 1 - \sum_{w \in B(u,r) \cup B(v,d(u,v)-r)} x_w & \forall u,v \in V, \forall r \in [0, d(u,v)] \\ & x_v \in [0,1] & \forall v \in V \\ & y_{uv} \geq 0 & \forall u,v \in V \end{array}$$

At first blush it may not be obvious that the first type of constraint in this LP really captures the characterization of pairs in R. But it is actually not that hard to see that this is a valid relaxation (a formal proof can be found in the full version [10]). Note that while the number of constraints appears to be exponential (recall that we assume integer weights, but not necessarily unit weights, and hence $d(u,v)$ is not necessarily polynomial in the input size), it is in fact possible to solve this LP in polynomial time. We can do this by noting that for each $u,v \in V$, only at most n different value of r actually yield *different* constraints, so we can simply write the constraints for those values.

Our algorithm is relatively straightforward. We first solve LP_{PR} and get an optimal fractional solution (x^*_v, y^*_{uv}). We then use independent randomized rounding, adding each $v \in V$ to A independently with probability $\min\{4 \ln n \cdot x^*_v, 1\}$.

▶ **Lemma 15.** *If $y^*_{uv} \leq \frac{1}{2}$, then the probability that $\{u,v\} \in R$ is at most $\frac{1}{n}$.*

Proof. If $y^*_{uv} \leq \frac{1}{2}$, then the first constraint implies that $\sum_{w \in B(u,r) \cup B(v,d(u,v)-r)} x^*_w \geq \frac{1}{2}$ for all $r \in [0, d(u,v)]$. Therefore, the probability that $A \cap (B(u,r) \cup B(v, d(u,v) - r)) = \varnothing$ for a specific $r \in [0, d(u,v)]$ is at most

$$\prod_{w \in B(u,r) \cup B(v,d(u,v)-r)} (1 - \min\{4 \ln n \cdot x^*_w, 1\}) \leq e^{-\sum_{w \in B(u,r) \cup B(v,d(u,v)-r)} 4 \ln n \cdot x^*_w} \leq \frac{1}{n^2}$$

A union bound over all the different values of r we used in our LP implies that the probability that there exists an $r \in [0, d(u,v)]$ where $A \cap (B(u,r) \cup B(v, d(u,v) - r)) = \varnothing$ is at most $\frac{1}{n^2} \cdot n = \frac{1}{n}$. We claim that the existence of such an r is implied by $\{u,v\} \in R$, and hence the probability that $\{u,v\} \in R$ is at most $\frac{1}{n}$. To see this, suppose that $\{u,v\} \in R$, i.e. suppose that $d(u,v) < \min_{w\in A} d(u,w) + \min_{w \in A} d(v,w) - 1$. Then if we set $r = \min_{w \in A} d(u,w) - 1$, this implies that $\min_{w \in A} d(v,w) > d(u,v) - r$. But then this would imply that no element of A is in $B(u,r) \cup B(v, d(u,v) - r)$. ◀

Let $OPT_{LP_{PR}}$ denote the optimal cost of LP_{PR}. Then the above lemma implies that the expected cost of the rounding algorithm is at most

$$\begin{aligned}\mathbf{E}[n|A| + |R|] &\leq \sum_{v \in V} n \cdot x_v^* \cdot 4 \ln n + 2 \cdot \sum_{u,v \in V} y_{uv}^* + n^2 \cdot \frac{1}{n} \leq O(\log n) \cdot OPT_{LP_{PR}} + n \\ &\leq O(\log n) \cdot OPT\end{aligned}$$

(where we use the fact that $OPT \geq \Omega(n)$). This completes the proof of Theorem 7.

5.2 $\Omega(\log n)$-hardness

We now show a matching hardness bound for the PR-optimization problem by reducing from the Set Cover problem.

Consider a set cover instance $(\mathcal{U}, \mathcal{S})$ where $|\mathcal{U}| + |\mathcal{S}| = n$. For each $e \in \mathcal{U}$, we create a group of vertices G_e where $|G_e| = 3n$. For each $S \in \mathcal{S}$, we also create a group of vertices G_S where $|G_S| = 3n$.

Now we construct the following metric space: $V = (\bigcup_{e \in \mathcal{U}} G_e) \cup (\bigcup_{S \in \mathcal{S}} G_S)$ and

$$d(u,v) = \begin{cases} 1, & \text{if } u \in G_e, v \in G_e \\ 1, & \text{if } u \in G_S, v \in G_S \\ 1, & \text{if } u \in G_e, v \in G_S, e \in S \\ 2, & \text{otherwise.} \end{cases}$$

In the full version [10] we show that if there is a solution $\mathcal{S}^*$ to the set cover instance $(\mathcal{U}, \mathcal{S})$ where $|\mathcal{S}^*| = t$, then there is a set A where $cost(A, V, d) \leq t|V|$. We also show that if there is a set $A \subseteq V$ where $cost(A, V, d) \leq t|V|$, then there exists a solution $\mathcal{S}^*$ to the set cover instance $(\mathcal{U}, \mathcal{S})$ where $|\mathcal{S}^*| = t$. These two claims, together with an appropriate hardness theorem for Set Cover [12], imply Theorem 8.

6 Distance Oracles With Outliers

We now move to the more difficult outliers setting, where we can also optimize over a set of vertices to ignore. Recall that for an approximate distance oracle $\mathcal{A}$, our goal is now to find a set of vertices F (the outliers) where $|F| \leq f$ as well as a string r in order to minimize $|preprocess(V \setminus F, d, m, a, r)|$. In other words, we are going to try to solve the same problems as before, but where we can choose a set F to remove. We begin with TZ_2, and then move to PR.

6.1 TZ_2-Optimization Problem With Outliers

For this problem, it is easy to see that the cost function becomes:

$$\begin{aligned}cost(A, F, V, d) &= (n - f)|A| + \sum_{u \in V \setminus F} |R_{1u}| \\ &= (n - f)|A| + \sum_{u \in V \setminus F} \left| \{v \in V \setminus F \mid d(u,v) < \min_{w \in A} d(u,w)\} \right|.\end{aligned}$$

A natural approach is to use an LP which is similar to LP_{TZ_k} to solve this problem (but for TZ_2), suitably adapted to handle outliers. Let x_v be a variable which is supposed to be

an indicator for whether $v \in A$, let y_{uv} be a variable which is supposed to be an indicator for whether $v \in R_{1u}$, and let z_v be a variable which is supposed to be an indicator for whether $v \in F$. Then we can write the following natural LP relaxation:

$$\begin{array}{rll} (LP_{TZ_2O}): \min & \sum_{v\in V}(n-f)\cdot x_v + \sum_{u,v\in V} y_{uv} & \\ s.t. & y_{uv} \geq 1 - z_u - z_v - \sum_{w\in B_u(v)} x_w & \forall u,v \in V \\ & \sum_{v\in V} z_v \leq f & \\ & x_v \in [0,1] & \forall v \in V \\ & y_{uv} \geq 0 & \forall u,v \in V \\ & z_v \in [0,1] & \forall v \in V \end{array}$$

Unfortunately, this LP can not give an (α, β)-approximation with $\beta = 2 - \epsilon$. To see this, consider the case that $f = \frac{n}{2}$. Then the optimal solution to LP_{TZ_2O} is 0, by setting all z_v to $\frac{1}{2}$, all x_v to 0, and all $y_{uv} = 0$. Thus any integral solution, to be competitive with this fractional solution, must treat *all* nodes as outliers, requiring β to be at least 2.

Fortunately we can give a stronger semidefinite programming relaxation, allowing for a better approximation. As in LP_{TZ_2O}, let $\vec{x}_v$ be a variable which is supposed to be an indicator for whether $v \in A$, let $\vec{y}_{uv}$ be a variable which is supposed to be an indicator for whether $v \in R_{1u}$, and let $\vec{z}_v$ be a variable which is supposed to be an indicator for whether $v \in F$. We can then write this SDP:

$$\begin{array}{rll} (SDP_{TZ_2O}): \min & \sum_{v\in V}(n-f)\cdot \|\vec{x}_v\|^2 + \sum_{u,v\in V} \|\vec{y}_{uv}\|^2 & \\ s.t. & \|\vec{y}_{uv}\|^2 \geq 1 - \vec{z}_u \cdot \vec{z}_v - \sum_{w\in B_u(v)} \|\vec{x}_w\|^2 & \forall u,v \in V \\ & \sum_{v\in V} \|\vec{z}_v\|^2 \leq f & \\ & \|\vec{x}_v\|^2 \leq 1 & \forall v \in V \\ & \|\vec{y}_{uv}\|^2 \leq 1 & \forall u,v \in V \\ & \|\vec{z}_v\|^2 \leq 1 & \forall v \in V \end{array}$$

Our approximation algorithm first solves SDP_{TZ_2O} to get an optimal solution $(\vec{x}^*_v, \vec{y}^*_{uv}, \vec{z}^*_v)$. We then use independent randomized rounding to construct A, adding each $v \in V$ to A independently with probability $\min\{\frac{3\ln n}{\varepsilon} \cdot \|\vec{x}^*_v\|^2, 1\}$ where ε is a small constant. Finally, we use threshold rounding to construct F by adding each $v \in V$ to F if $\|\vec{z}^*_v\|^2 \geq \frac{1}{1+\varepsilon}$.

We want to show that this is an $(O(\log n), 1+\varepsilon)$-approximation. It is easy to see that $|F| \leq (1+\varepsilon)f$ because $\sum_{v\in V} \|\vec{z}^*_v\|^2 \leq f$. In order to prove Theorem 9 it only remains to prove that the expected cost is at most $O(\log n) \cdot OPT$. This proof can be found in the full version [10].

When $f \leq \sqrt{n}$ we can actually give a true $O(\log n)$-approximation (Theorem 10). The algorithm is almost the same; we just need to change the threshold rounding for outliers to instead pick the f vertices with largest $\|\vec{z}_v\|^2$ value. Details appear in the full version [10].

6.2 PR-Optimization Problem With Outliers

For this problem, the cost function becomes:

$$\begin{aligned} cost(A,F,V,d) &= (n-f)\cdot|A| + |R| \\ &= (n-f)\cdot|A| + \left|\{\{u,v\} \subseteq V\backslash F \mid d(u,v) < \min_{w\in A} d(u,w) + \min_{w\in A} d(v,w) - 1\}\right|. \end{aligned}$$

We will again use an SDP relaxation. Let $\vec{x}_v$ be a variable which is supposed to be an indicator for whether $v \in A$, let $\vec{y}_{uv}$ be a variable which is supposed to be an indicator for whether $\{u,v\} \in R$, and let $\vec{z}_v$ be a variable which is supposed to be an indicator for whether

$v \in F$. We have the following relaxation (which we call SDP_{PR}) which is similar to both LP_{PR} and SDP_{TZ_2O}:

$$\begin{array}{lll} \min & \sum_{v\in V}(n-f)\cdot\|\vec{x}_v\|^2 + \sum_{\{u,v\}\subseteq V}\|\vec{y}_{uv}\|^2 & \\ s.t. & \|\vec{y}_{uv}\|^2 \geq 1 - \vec{z}_u\cdot\vec{z}_v - \sum_{w\in B(u,r)\cup B(v,d(u,v)-r)}\|\vec{x}_w\|^2 & \forall u,v\in V, r\in[0,d(u,v)] \\ & \sum_{v\in V}\|\vec{z}_v\|^2 \leq f & \\ & \|\vec{x}_v\|^2 \leq 1 & \forall v\in V \\ & \|\vec{y}_{uv}\|^2 \leq 1 & \forall u,v\in V \\ & \|\vec{z}_v\|^2 \leq 1 & \forall v\in V \end{array}$$

Note that SDP_{PR} is solvable in polynimial time for the same reason that LP_{PR} is solvable: for each pair of (u,v), we can find n different values of r that give all of the distinct constraints.

The rounding algorithm is basically the same as the TZ_2-optimization problem with outliers. We first solve the SDP_{PR} and get an optimal solution $(\vec{x}^*_v, \vec{y}^*_{uv}, \vec{z}^*_v)$. We then use independent randomized rounding to get A, adding each $v \in V$ to A independently with probability $\min\{\frac{6\ln n}{\varepsilon}\cdot\|\vec{x}^*_v\|^2, 1\}$ where ε is a small constant. Then we use threshold rounding to get F, adding each $v \in V$ to F if $\|\vec{z}^*_v\|^2 \geq \frac{1}{1+\varepsilon}$.

This is an $(O(\log n), 1+\varepsilon)$-approximation. It is easy to see that $|F| \leq (1+\varepsilon)f$ because $\sum_{v\in V}\|\vec{z}^*_v\|^2 \leq f$. The proof that the expected cost is at most $O(\log n)\cdot OPT$ is in the full version [10], which completes the proof of Theorem 11.

7 Conclusion and Future Work

In this paper we initiate the study of *approximating* approximate distance oracles. This is a different take on the question of optimizing data structures, where we attempt to find the best data structure for a particular input, rather than for a class of inputs. In order to make this tractable (or even well-defined), we restrict our attention to known classes of distance oracles, and show that it is sometimes possible to find the best of these restricted oracles. We also extended our approaches to optimize in the presence of outliers.

For future work, the major question is clearly whether we can approximately optimize higher level (i.e., higher stretch) Thorup-Zwick distance oracles. Although we show an integrality gap for the basic LP, it is quite conceivable that a stronger LP or SDP could be used to give a logarithmic approximation ratio. Beyond this, there are other distance oracles which could be optimized – we chose Thorup-Zwick and Pătraşcu-Roditty since they are well-known and in some ways canonical, but it would be interesting to extend these ideas to other oracles. At a higher level, we believe that the definitions and ideas we have introduced here could lead to many interesting questions about optimizing data structures for given inputs: can we find near-optimal distance labels? Or compact routing schemes? Or connectivity oracles? Or fault-tolerant oracles? Essentially any data structure question in which there is a choice of *which* data to store, rather than how to store it, can be put into our optimization framework. Exploring this space is an exciting future direction.

Abstract

We provide a variant of cross-polytope locality sensitive hashing with respect to angular distance which is provably optimal in asymptotic sensitivity and enjoys $\mathcal{O}(d \ln d)$ hash computation time. Building on a recent result in [4], we show that optimal asymptotic sensitivity for cross-polytope LSH is retained even when the dense Gaussian matrix is replaced by a fast Johnson-Lindenstrauss transform followed by discrete pseudo-rotation, reducing the hash computation time from $\mathcal{O}(d^2)$ to $\mathcal{O}(d \ln d)$. Moreover, our scheme achieves the optimal *rate of convergence* for sensitivity. By incorporating a low-randomness Johnson-Lindenstrauss transform, our scheme can be modified to require only $\mathcal{O}(\ln^9(d))$ random bits.

1 Introduction

The nearest neighbor search problem is an essential algorithmic component to a wide variety of applications including data compression, information retrieval, image storage, computer vision, and pattern recognition. **Nearest neighbor search (NN)** can be stated as follows: given a metric space $(X, \mathcal{D})$ and a set of points $P = \{x_1, ..., x_n\} \subset X$, for a query point $x \in P$ find $y = \text{argmin}_{x_i \in P \setminus \{x\}} \mathcal{D}(x_i, x)$. In high dimensions, it is known that existing algorithms have poor performance (see [23]); that is, for a query point $x \in P$, any algorithm for NN must essentially compute the distances between x and each point in $P \setminus \{x\}$.

In order to improve on linear search, one may relax the problem to that of *approximate* nearest neighbors search. Precisely, the (R, c) **near neighbor problem (**(R, c)**-NN)** as introduced in [12] is as follows: given a query point $x \in P$ and the assurance of a point $y' \in P$ such that $\mathcal{D}(y', x) < R$, find $y \in P$ such that $\mathcal{D}(y, x) < cR$. In contrast to exact nearest neighbors search, the approximate nearest neighbor search problem can be solved in *sublinear* query time, and this is achieved using **locality sensitive hashing** (LSH). The idea in LSH is to specify a function from the domain X to a discrete set of hash values – a so-called *hash function* – which sends closer points to the same *hash value* with higher probability than points which are far apart. Then, for a set of points $P = \{x_1, ..., x_n\} \subset X$ and a query point $x \in P$, search within its corresponding hash bucket for a nearest neighbor.

From here on out, we fix the space $X = S^{d-1}$ endowed with the euclidean metric. We begin by recalling the standard notion of sensitivity for a hash family; intuitively, a hash family with higher sensitivity is much more likely to hash points that are close to the same hash value, and thus be a better candidate for locality sensitive hashing.

▶ **Definition 1.** For $r_1 \leq r_2$ and $p_2 \leq p_1$, a hash family $\mathcal{H}$ is (r_1, r_2, p_1, p_2)**-sensitive** if for all $x, y \in S^{d-1}$,

- If $\|x - y\|_2 \leq r_1$, then $\Pr_{\mathcal{H}}[h(x) = h(y)] \geq p_1$.
- If $\|x - y\|_2 \geq r_2$, then $\Pr_{\mathcal{H}}[h(x) = h(y)] \leq p_2$.

We primarily care about the case where $r_1 = R$, $r_2 = cR$, and to quantify sensitivity of a certain scheme, we study the parameter

$$\rho = \frac{\ln(p_1^{-1})}{\ln(p_2^{-1})}. \tag{1}$$

The key result linking the sensitivity of a hash family to its performance for $(R, c) - NN$ search is the following:[1]

▶ **Proposition 2** (Theorem 5 in [12])**.** *Given an (R, cR, p_1, p_2)-sensitive hash family $\mathcal{H}$, there exists a data structure that solves $(R, c) - NN$ with constant probability using $\mathcal{O}(dn + n^{1+\rho})$ space, $\mathcal{O}(n^\rho)$ query time, and $\mathcal{O}(n^\rho \ln_{1/p_1} n)$ evaluations of hash functions from $\mathcal{H}$.*

Since the parameter ρ quantifies the performance of a given LSH algorithm for $(R, c)-NN$, it is of interest to make this parameter as small as possible. It was shown in [20] that $\rho = \frac{1}{c^2}$ is asymptotically (in d) optimal for the case of unit sphere with the euclidean metric. Spherical LSH ([5], [6]) was shown to achieve this optimal sensitivity; however, the corresponding hash functions in spherical LSH are not practical to compute. Subsequently, Andoni, Indyk, Laarhoven, and Razenshteyn [4] showed the existence of an LSH scheme with optimally sensitive hash functions which are practical to implement; namely, the *cross-polytope* LSH scheme which has been previously proposed in [22] (see also [7], [20], [19]). Given a matrix $\mathcal{G} \in \mathbb{R}^{d \times d}$ with i.i.d. $\mathcal{N}(0, 1)$ entries, the cross polytope hash of a point $x \in S^{d-1}$ is defined as

$$h(x) = \operatorname*{argmin}_{u = \{\pm e_i\}} \left\| \frac{\mathcal{G}x}{\|\mathcal{G}x\|_2} - u \right\|_2, \tag{2}$$

where $\{e_i\}_{i=1}^d$ is the standard basis for $\mathbb{R}^d$. The paper [4] provided the following collision probability for cross-polytope LSH.

▶ **Proposition 3** (Theorem 1 in [4])**.** *Suppose $x, y \in S^{d-1}$ are such that $\|x - y\|_2 = R$, with $0 < R < 2$, and $\mathcal{H}$ is the hash family defined in (2). Then,*

$$\ln\left(\frac{1}{\Pr_{\mathcal{H}}[h(x) = h(y)]}\right) = \frac{R^2}{4 - R^2} \ln d + \mathcal{O}_R(\ln(\ln d)). \tag{3}$$

Consequently,

$$\rho = \frac{1}{c^2} \frac{4 - c^2 R^2}{4 - R^2} + o(1),$$

[1] In particular, the algorithm stores L hash tables from the family $\mathcal{G}$, where each $g \sim \mathcal{G}$ is given by $g(x) = (h_1(x), ..., h_k(x))$, and $h_i \sim \mathcal{H}, i = 1...k$. Then, given a query point $x \in S^{d-1}$, the algorithm looks for collisions in the buckets $g_1(x), ..., g_L(x)$. The choice of parameters $k = n^\rho$, $L = \ln_{1/p_1} n$ ensure that the algorithm solves $(R, c) - NN$ with constant probability.

where here and in the sequel, $o(1)$ means a parameter that goes to 0 as $d \to \infty$. This implies that the above scheme is asymptotically optimal with respect to ρ.[2] Still, this scheme is limited in efficiency by the $\mathcal{O}(d^2)$ computation required to compute a dense matrix-vector multiplication in (2). To reduce this computation, [4] proposed to to use a pseudo-random rotation in place of a dense Gaussian matrix, namely,

$$h(x) = \text{argmin}_{u=\{\pm e_i\}} \|HD_bHD_{b'}HD_{b''}x - u\|_2 , \tag{4}$$

where $H \in \mathbb{R}^{d\times d}$ is a Hadamard matrix and $D_b, D_{b'}, D_{b''} \in \mathbb{R}^{d\times d}$ are independent diagonal matrices with i.i.d. Rademacher entries on the diagonal. This scheme has the advantage of computing hash functions in time $\mathcal{O}(d \ln d)$, and was shown in [4] to *empirically* exhibit similar collision probabilities to cross-polytope LSH, but provable guarantees on the asymptotic sensitivity of this fast variant of the standard cross-polytope LSH remain open.

1.1 Our Contributions

1.1.1 Fast cross-polytope LSH with optimal asymptotic sensitivity

While we do not prove theoretical guarantees regarding the asymptotic sensitivity of the particular fast variant (4), we construct a different variant of the standard cross-polytope LSH (defined below in (5)) which also enjoys $\mathcal{O}(d \ln d)$ matrix-vector multiplication, and for which we are able to prove optimal asymptotic sensitivity $\rho = \frac{1}{c^2}$:

$$h_F(x) = \underset{u=\{\pm e_i\}}{\text{argmin}} \left\| \frac{\mathcal{G}(H_S D_b x)}{\|\mathcal{G}(H_S D_b x)\|_2} - u \right\|_2 ; \tag{5}$$

Here, $D_b : \mathbb{R}^d \to \mathbb{R}^d$ is a diagonal matrix with i.i.d. Rademacher entries on the diagonal, $H_S \in \mathbb{R}^{m\times d}$ is a partial Hadamard matrix restricted to a random subset $S \subset [d]$ of $|S| = m = \mathcal{O}(\log(d))$ rows, and $\mathcal{G} : \mathbb{R}^m \to \mathbb{R}^{d'}$ is a Gaussian matrix that lifts and rotates in dimension d' in the range $m \le d' \le d$. There is nothing special about lifting to dimension d, and indeed one could lift to dimension $d' > d$, but if d' grows faster than d, the hash computation no longer takes time $\mathcal{O}(d \ln d)$.

The embedding $H_S D_b x$ acts as a Johnson-Lindenstrauss (JL) transform[3], and embeds the points in dimension $m \approx \ln d$.

It is straightforward that the hash computation $x \to h_F(x)$ takes $\mathcal{O}(d'm)$ time from the Gaussian matrix multiplication and $\mathcal{O}(d \ln d)$ time from the JL transform. We will show that optimal asymptotic sensitivity is still achieved without lifting, $d' = m$, but we observe both empirically and theoretically that the *rate of convergence* to the asymptotic sensitivity improves by lifting to higher dimension; taking d' closer to d results in empirically closer results to the standard cross-polytope scheme (see section 5 for more details). Moreover, our scheme achieves the lower bound given by Theorem 2 in [4] for the fastest rate of convergence among all hash families which has to d' values.

---

[2] In fact, the coefficient $\frac{4-c^2R^2}{4-R^2} < 1$ for every choice of $c > 1$ and $0 < R < 2$, but this does not break the lower bound given in [20] since the lower bound $\rho = \frac{1}{c^2}$ only holds for a particular sequence $R = R(d)$. For cross-polytope LSH and the schemes proposed here, any sequence $R(d) \to 0$ suffices.

[3] Formally, given a finite metric space $(X, \|\cdot\|) \subset \mathbb{R}^d$, a JL transform is a linear map $\Phi : \mathbb{R}^d \to \mathbb{R}^m$ such that for all $x \in X$, $(1-\delta)\|x\|^2 \le \|\Phi x\|^2 \le (1+\delta)\|x\|^2$, with $m \ll d$ close to the optimal scaling $m = C\delta^{-2} \ln(|X|)$ [13, 2, 16].

Table 1 Various LSH Families and corresponding Hash Functions.

LSH Family	Hash Function
Cross-Polytope LSH	$h(x) = \underset{u=\{\pm e_i\}}{\operatorname{argmin}} \left\| \frac{\mathcal{G}x}{\|\mathcal{G}x\|_2} - u \right\|_2, \quad \mathcal{G} \in \mathbb{R}^{d\times d}$
Fast Cross-Polytope LSH	$h_F(x) = \underset{u=\{\pm e_i\}}{\operatorname{argmin}} \left\| \frac{\mathcal{G}(H_S D_b x)}{\|\mathcal{G}(H_s D_b x)\|_2} - u \right\|_2, \quad \mathcal{G} \in \mathbb{R}^{d'\times m}$
Fast Discrete Cross-Polytope LSH	$h_D(x) = \underset{u=\{\pm e_i\}}{\operatorname{argmin}} \left\| \frac{\widehat{\mathcal{G}}(Zx)}{\|\widehat{\mathcal{G}}(Zx)\|_2} - u \right\|_2, \quad \widehat{\mathcal{G}} \in \mathbb{R}^{d'\times m}$

1.1.2 Fast cross-polytope LSH with optimal asymptotic sensitivity and few random bits

Aiming to construct a hash family with similar guarantees which also uses as little randomness as possible, we also consider a discretized version of the fast hashing scheme (5) in which the Gaussian matrix $\mathcal{G} \in \mathbb{R}^{d'\times m}$ is replaced by a matrix $\widehat{\mathcal{G}} \in \mathbb{R}^{d'\times m}$ whose entries are i.i.d. discrete approximations of a Gaussian; in place of the "standard" fast JL transform $H_S D_b$, we consider $Z \in \mathbb{R}^{d\times m}$ a low-randomness JL transform that we will clarify later. Then, the discrete fast hashing scheme we consider is

$$h_D(x) = \underset{u=\{\pm e_i\}}{\operatorname{argmin}} \left\| \frac{\widehat{\mathcal{G}}(Zx)}{\|\widehat{\mathcal{G}}(Zx)\|_2} - u \right\|_2. \tag{6}$$

Also for this scheme, the hash computation $x \to h(x)$ takes $\mathcal{O}(d'm)$ time from the Gaussian matrix multiplication and $\mathcal{O}(d \ln d)$ time from the JL transform. Our scheme has several advantages, due to the fact that the choice of d' in the range $d \le d' \le m$ is flexible: To summarize our main contributions, we prove for both the fast cross-polytope LSH and the fast discrete cross-polytope LSH,

- For each d' in the range $m \le d' \le d$, this scheme achieves the asymptotically optimal ρ. Moreover, for $d' = d$, the rate of convergence to this ρ is optimal over all hash families with d hash values.
- With the choice $d' = d$, the scheme computes hashes in time $\mathcal{O}(d \ln d)$ and performs well empirically compared to the standard cross-polytope with dense Gaussian matrix (see section 5).
- With the choice $d' = m$, and by discretizing the Gaussian matrix, we arrive at a scheme that has only $\mathcal{O}(\ln^9(d))$ bits of randomness and still has optimal asymptotic sensitivity.

Table 1 contains the construction of the original cross-polytope LSH scheme, our fast cross-polytope scheme, as well as the discretized version.

1.2 Related work

Many of our results hinge on the careful analysis of collision probabilities for the cross-polytope LSH scheme given in [4]. Additionally, various ways to reduce the runtime of cross-polytope LSH, specifically using fast, structured projection matrices, are mentioned

in [8]. They also define a generalization of cross-polytope lsh that first projects to a low dimensional subspace, but they never consider lifting back up to a high dimensional subspace again. Johnson-Lindenstrauss transforms have previously been used in many approximate nearest neighbors algorithms, (see [12], [18], [1], [21], [5], and [9], to name a few), primarily as a preprocessing step to speed up computations that have some dependence on the dimension. LSH with p-stable distributions, as introduced in [10], uses a random projection onto a single dimension, which is later generalized in [3] to random projection onto $o(\ln d)$ dimensions, with the latter having optimal exponent $\rho = \frac{1}{c^2} + \mathcal{O}(\ln(\ln d)/\ln^{1/3} d)$. We make a note that our scheme uses dimension reduction slightly differently, as an intermediate step before lifting the vectors back up to a different dimension.

Similar dimension reduction techniques have been used in [17], where the data is sparsified and then a random projection matrix is applied. The authors exploit the fact that the random projection matrix will have the restricted isometry property, which preserves pairwise distances between any two sparse vectors. This result is notable in that the reduced dimension has no dependence on n, the number of points. See section 4 for more discussion.

2 Notation

We now establish notation that will be used in the remainder. $\mathcal{O}_R(f(d))$ is to mean $\mathcal{O}_R(f(d)) = \mathcal{O}(f(d)g(R))$ for some finite valued function $g : (0, 2) \to \mathbb{R}$. The expression $o(1)$ is a quantity such that $\lim_{d\to\infty} o(1) = 0$. $H \in \mathbb{R}^{d\times d}$ is the Hadamard matrix. $D_b \in \mathbb{R}^{d\times d}$ is a diagonal matrix whose entries are i.i.d. Rademacher variables. For a matrix $M \in \mathbb{R}^{d\times d}$, M_S will denote the restriction of M to its rows indexed by the set $S \subset \{1, ..., d\}$. The variable $\mathcal{G}$ will always denote a matrix with i.i.d. standard normal Gaussian entries, where the matrix may vary in size. The variable $\widehat{\mathcal{G}}$ will always denote a matrix with i.i.d. copies of a discrete random variable X which roughly models a Gaussian. C will denote various constants that are bounded independent of the dimension. We will use m to denote the projected dimension of our points, where $m \ll d$, and d' the lifted dimension, where $m \leq d' \leq d$. For a vector $x \in S^{d-1}$ we will denote $\tilde{x} = H_S D_b x$.

3 Main Results

We now formalize the intuition about how our scheme behaves relative to cross-polytope LSH.

▶ **Theorem 4.** *Suppose $\mathcal{H}$ is the family of hash functions defined in (5) with the choice $m = \mathcal{O}(\ln^5(d)\ln^4(\ln d))$, and ρ is as defined in (1) for this particular family. Then we have (i-)*

$$\rho = \frac{1}{c^2}\frac{4 - c^2R^2}{4 - R^2} + o(1).$$

and this hashing scheme runs in time $\mathcal{O}(d \ln d)$.

Moreover, we have the optimal rate of convergence,
(ii-)

$$\rho = \frac{1}{c^2}\frac{4 - c^2R^2}{4 - R^2} + \mathcal{O}\left(\frac{1}{\ln d'}\right).$$

The lower bound given by Theorem 2 in [4] verifies the above rate of convergence is in fact optimal. We remark that when hashing n points simultaneously, the embedded dimension m

picks up a factor of $\ln(n)$. Assuming that n is polynomial in d, the result in Theorem 4 still holds simultaneously over all pairs of points.

In addition to creating a fast hashing scheme, one can reduce the amount of randomness involved. In particular, we show that a slight alteration of the scheme still achieves the optimal ρ-value while using only $\mathcal{O}(\ln^9 d)$ bits of randomness. The idea is to replace the Gaussian matrix by a matrix of i.i.d. discrete random variables. Some care is required in tuning the size of this matrix so that the correct number of bits is achieved. As a consequence the number of hash values for this scheme is of order $\mathcal{O}(m)$ (i.e. we lift up to a smaller dimension), which lowers performance in practice, but does not affect the asymptotic sensitivity ρ. We additionally use a JL transform developed by Kane and Nelson [14] that only uses $\mathcal{O}(\ln(d)\ln(\ln d))$ bits of randomness. Specifically, the hash function for this scheme is

$$h_D(x) = \operatorname*{argmin}_{u=\{\pm e_i\}} \left\| \frac{\widehat{\mathcal{G}}(Zx)}{\|\widehat{\mathcal{G}}(Zx)\|_2} - u \right\|_2$$

where $\widehat{\mathcal{G}} \in \mathbb{R}^{d' \times m}$ is a matrix with i.i.d. copies of a discrete random variable X which roughly models a Gaussian, and $Z \in \mathbb{R}^{d \times m}$ is the JL transform constructed in [14]. Our analysis allows us to pick the threshold value $d' = m$ to minimize the number of random bits.

▶ **Theorem 5.** *There is a hash family $\mathcal{H}$ with $\mathcal{O}(\ln^9 d)$ bits of randomness that achieves the bound*

$$\rho = \frac{1}{c^2}\frac{4 - c^2R^2}{4 - R^2} + o(1),$$

and runs in time $\mathcal{O}(d \ln d)$.

3.1 Theorem 4 Part (i-) Proof Outline

First we state an elementary limit result that we will apply to the proofs of both Theorem 4 and Theorem 5.

▶ **Lemma 6.** *Suppose $m_d(a), m_d(b)$ are positive functions, $\lim_{d\to\infty} m_d(a) = a$, $\lim_{d\to\infty} m_d(b) = b$, and that $f(d), g(d)$ are also positive, $\lim_{d\to\infty} f(d) = \lim_{d\to\infty} g(d) = \infty$, $\lim_{d\to\infty} \frac{f(d)}{g(d)} = \infty$. Then,*

$$\lim_{d\to\infty} \frac{m_d(a)f(d) + g(d)}{m_d(b)f(d) + g(d)} = \frac{a}{b}$$

Proceeding to the proof of Theorem 4, the key observation is that for $x, y \in S^{d-1}$, $\mathcal{G}\tilde{x} = \mathcal{G}_0 \begin{bmatrix} \tilde{x} \\ 0 \end{bmatrix}$, where $\mathcal{G}_0 \in \mathbb{R}^{d' \times d'}$ is a square Gaussian matrix. Thus,

$$\Pr[h_f(x) = h_f(y)] = \Pr\left[h\left(\begin{bmatrix} \tilde{x} \\ 0 \end{bmatrix}\right) = h\left(\begin{bmatrix} \tilde{y} \\ 0 \end{bmatrix}\right)\right],$$

recalling that h_f is the fast cross-polytope hash function and h is the standard version. It then follows that, provided the distance between $\tilde{x}$ and $\tilde{y}$ is close to the distance between x and y, we can apply proposition 3 to control the above probability. We start with a lemma for our chosen JL transform that combines a recent improvement on the *restricted isometry property* (RIP) for partial Hadamard matrices [11] with a reduction from RIP to Johnson-Lindenstrauss transforms in [15]; we defer the proof to the appendix.

▶ **Lemma 7.** *Suppose $\gamma > 0$, $x, y \in S^{d-1}$, $\widetilde{x} = H_S D_b x$, $\widetilde{y} = H_S D_b y$ and $H_S \in \mathbb{R}^{m\times d}$ is such that $m = \mathcal{O}(\gamma \ln^4(d) \ln^4(\ln d))$. Then with probability $1 - \mathcal{O}(d^{-\gamma})$,*

$$\left(1 - \frac{1}{\ln d}\right) \leq \|\widetilde{x}\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right), \tag{7}$$

$$\left(1 - \frac{1}{\ln d}\right) \leq \|\widetilde{y}\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right), \tag{8}$$

$$\left(1 - \frac{1}{\ln d}\right) \|x - y\|_2^2 \leq \|\widetilde{x} - \widetilde{y}\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right) \|x - y\|_2^2 \tag{9}$$

We apply the above lemma with the choice $\gamma = \ln d$ to get that

$$\frac{\|x-y\|_2^2}{(1-\frac{1}{\ln d})} - \frac{5}{\ln d - 1} \leq \left\| \frac{\widetilde{x}}{\|\widetilde{x}\|_2} - \frac{\widetilde{y}}{\|\widetilde{y}\|_2} \right\|_2^2 \leq \frac{\|x-y\|_2^2}{(1+\frac{1}{\ln d})} + \frac{5}{\ln d + 1}. \tag{10}$$

with probability $1 - \mathcal{O}(d^{-\ln d})$. Combining this fact with proposition 3 we get that

$$\Pr[h_f(x) = h_f(y)] = C(d')^{\frac{-\tilde{R}^2}{4-\tilde{R}^2}} \ln^{-1}(d'),$$

where $\tilde{R} = \|\tilde{x} - \tilde{y}\|^2$ (by equation (10)) goes to R as $d \to \infty$, and C is bounded in the dimension. We then apply lemma 6 to see that

$$\begin{aligned}\rho &= \frac{\frac{\tilde{R}^2}{4-\tilde{R}^2} \ln(d') + \ln\ln(d') + C}{\frac{c^2\tilde{R}^2}{4-c^2\tilde{R}^2} \ln(d') + \ln\ln(d') + C} \\ &= \frac{1}{c^2} \frac{4 - c^2R^2}{4 - R^2} + o(1).\end{aligned}$$

We defer the proof of Theorem 4 part (ii-) to the appendix.

3.2 Theorem 5 Proof Outline

We will use the following result (formulated as an analogue to lemma 7) , due to Kane and Nelson, that reduces the amount of randomness required to perform a JL transform.

▶ **Proposition 8.** *(Theorem 13 and Remark 14 in [14]) Suppose $\gamma > 0$, $x, y \in S^{d-1}$. Then, there is a random matrix $Z \in \mathbb{R}^{d\times m}$ with $m = \mathcal{O}(\gamma \ln^3(d))$ and sampled with $\mathcal{O}(\gamma \ln^2(d))$ random bits such that with probability $1 - \mathcal{O}(d^{-\gamma})$,*

$$\left(1 - \frac{1}{\ln d}\right) \leq \|Zx\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right),$$

$$\left(1 - \frac{1}{\ln d}\right) \leq \|Zy\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right),$$

$$\left(1 - \frac{1}{\ln d}\right) \|x - y\|_2^2 \leq \|Z(x-y)\|_2^2 \leq \left(1 + \frac{1}{\ln d}\right) \|x - y\|_2^2$$

Now we want to construct a hash scheme that uses a Gaussian rotation with which to compare our discretized scheme. Define

$$h'_D(x) = \operatorname*{argmin}_{u=\{\pm e_i\}} \left\| \frac{\mathcal{G}'Zx}{\|\mathcal{G}'Zx\|_2} - u \right\|_2, \tag{11}$$

where $\mathcal{G}' \in \mathbb{R}^{m\times m}$ is a standard i.i.d. Gaussian matrix. The following elementary lemma gives us a suitable replacement for each Gaussian in the matrix $\mathcal{G}'$.

▶ **Lemma 9.** *Suppose $g \sim \mathcal{N}(0,1)$. Then, there is a symmetric, discrete random variable X taking 2^b values such that for any $x \in \mathbb{R}$,*

$$\Pr[g \leq x] = \Pr[X \leq x] + \mathcal{O}(2^{-b}) \tag{12}$$

The discretized scheme can now be constructed by

$$h_D(x) = \underset{u=\{\pm e_i\}}{\operatorname{argmin}} \left\| \frac{\widehat{\mathcal{G}}Zx}{\|\widehat{\mathcal{G}}Zx\|_2} - u \right\|_2, \tag{13}$$

where the entries of $\widehat{\mathcal{G}} \in \mathbb{R}^{d' \times m}$ are i.i.d. copies of the random variable X in Lemma 9. Note that each discrete random variable has b bits of randomness, so the hashing scheme has minimial randomness when $d' = m$, thus there are $m \times m \times b + \mathcal{O}(\gamma \ln^2(d)) = \mathcal{O}(\gamma^2 \ln^6(d) b + \gamma \ln^2(d))$ bits of randomness. As we will see, we can choose γ and b to be a power of $\ln(d)$ while still achieve the optimal asymptotic ρ. For this we have the following lemma.

▶ **Lemma 10.** *Let $x, y \in \mathbb{R}^d$ be such that $\|x - y\|_2 = R$, $\widetilde{x} = Zx$, and let h, h' be as defined in (13) and (11) respectively with $m = \mathcal{O}(\ln^4(d))$, $b = \log_2(d)$ where $\widetilde{R} = \|\widetilde{x} - \widetilde{y}\|_2$. Then,*

$$\ln(\Pr[h_D(x) = h_D(y)]) = \ln(\Pr[h'_D(x) = h'_D(y)]) + \mathcal{O}_{\widetilde{R}}(1) \tag{14}$$

We defer the proof of lemma 10 to the appendix, but the idea is as follows. We can first write

$$\Pr[h'_D(x) = h'_D(y)] = 2d' \Pr[h'_D(x) = h'_D(y) = e_1].$$

Note that the set $\{h'_D(x) = h'_D(y) = e_1\} = \{(\mathcal{G}'\widetilde{x})_1 \geq |(\mathcal{G}'\widetilde{x})_2|, (\mathcal{G}'\widetilde{y})_1 \geq |(\mathcal{G}'\widetilde{y})_2|\}$, which is the Gaussian measure of a convex polytope, so we can write the above probability as the integral over m intervals of the m-dimensional Gaussian probability distribution. We can then use equation (12) to replace the Gaussian pdf with the discrete Gaussian pdf in each coordinate succesively, and (keeping track of parameters), the lemma follows.

We now run the same argument as in Theorem 4 by setting $\gamma = \ln d$, so combining lemma 10 and proposition 3 applied to $h'_D(x)$, we have that

$$\begin{aligned}
\rho &= \frac{\ln(\Pr[h_D(x) = h_D(y)])}{\ln(\Pr[h_D(cx) = h_D(cy)])} \\
&= \frac{\ln(\Pr[h'_D(x) = h'(y)]) + \mathcal{O}_{\widetilde{R}}(1)}{\ln(\Pr[h'_D(cx) = h'(cy)]) + \mathcal{O}_{\widetilde{R}}(1)} \\
&= \frac{\frac{R_+^2}{4 - R_+^2} \ln(d') + \ln\ln(d') + C + \mathcal{O}_{\widetilde{R}}(1)}{\frac{c^2 R_-^2}{4 - c^2 R_-^2} \ln(d') + \ln\ln(d') + C + \mathcal{O}_{\widetilde{R}}(1)} \\
&= \frac{\frac{R_+^2}{4 - R_+^2} \ln(d') + \ln\ln(d') + C}{\frac{c^2 R_-^2}{4 - c^2 R_-^2} \ln(d') + \ln\ln(d') + C} \\
&= \frac{1}{c^2} \frac{4 - c^2 R^2}{4 - R^2} + o(1), \text{ by lemma 6.}
\end{aligned}$$

Finally, by our choice of γ and b in the above lemma, we know that there are $\mathcal{O}(\ln^9(d))$ bits of randomness.

4 Open Problems

Although we achieve a logarithmic number of bits of randomness in Theorem 5, there is no reason to believe this is optimal among all hash families. More generally, given a particular rate of convergence to the optimal asymptotic sensitivity we would like to know the minimal number of required bits of randomness. Note that by the result in [20], for each dimension d, $c > 0$, and $q > 0$, there is some distance $R > 0$ such that the sensitivity parameter $\rho \geq \frac{1}{c^2} - \mathcal{O}_q\left(\frac{1}{\ln d}\right)$. In light of this result, we would like to know, for a given rate of convergence, whether it gets close to the lower bound $\frac{1}{c^2}$ for all sequences of distances $R = R(d)$. Note that this condition holds for cross-polytope lsh with $f(d) = \mathcal{O}\left(\frac{1}{\ln d}\right)$.

▶ **Problem 11.** *Given a rate of convergence $f(d)$ such that $\lim_{d\to\infty} f(d) = 0$, find the minimal number of bits $\mathcal{O}_f(d)$ such that any hash family $\mathcal{H}$ over the sphere S^{d-1} with $\mathcal{O}_f(d)$ bits of randomness satisfies $\rho = \frac{1}{c^2} + f(d)$ for all sequences $R = R(d)$.*

A more practical question is, given a rate of convergence for ρ, what is the fastest one could compute a hash family achieving this rate.

▶ **Problem 12.** *Given a rate of convergence $f(d)$ as in Problem 11, find the hash family $\mathcal{H}$ over S^{d-1} such that $\rho = \frac{1}{c^2} + f(d)$ for all sequences $R = R(d)$, that also has the fastest hash computations.*

It would be natural to extend our theoretical analysis to the case of hashing a collection of n points simultaneously. In this setting, the embedding dimension of the JL matrix would inherit an additive factor depending on $\ln(n)$. Inspired by the construction in [17] which first sparsifies the data then exploits the restricted isometry property which applies uniformly over all sparse vectors, we can aim for a construction that doesn't depend on the number of data points.

5 Numerical Experiments

To illustrate our theoretical results in the low dimensional case, we ran Monte Carlo simulations to compare the collision probabilities for regular cross-polytope LSH as well as the fast and discrete versions for various values of the original and lifted dimension. We refer to [4] for an in depth comparison of run times for cross-polytope LSH and other popular hashing schemes.

The experiments were run with $N = 20000$ trials. For each trial, two points were fixed at the given distance threshold on the unit sphere (in the plane given by the first two coordinates) and then rotated uniformly at random on the sphere. The discretized scheme used 10 bits of randomness for each entry. The fast, discrete, and regular cross-polytope LSH schemes exhibit similar collision probabilities for small distances, with fast/discrete cross-polytope having marginally higher collision probabilities for larger distances. It is clear that as the lifted dimension decreases, the fast and discrete versions have higher collision probabilities at further distances, which decreases the sensitivity of those schemes.

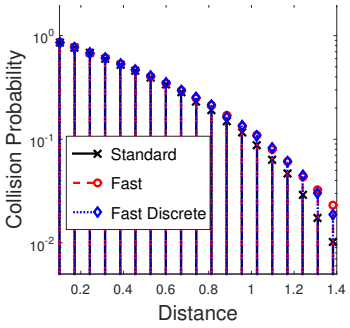

Figure 1 $d = 128$, $d' = 128$.

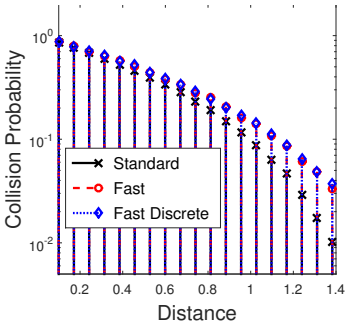

Figure 2 $d = 128$, $d' = 64$.

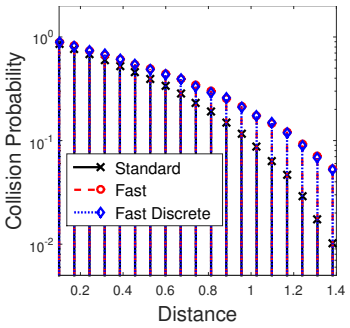

Figure 3 $d = 128$, $d' = 32$.

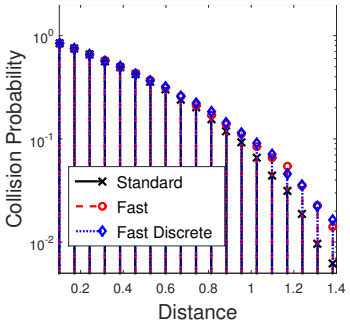

Figure 4 $d = 256$, $d' = 256$.

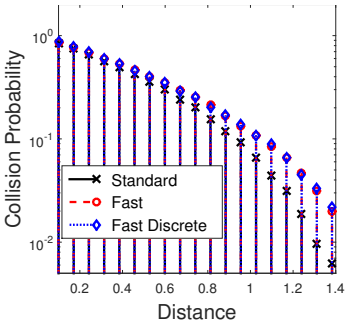

Figure 5 $d = 256$, $d' = 128$.

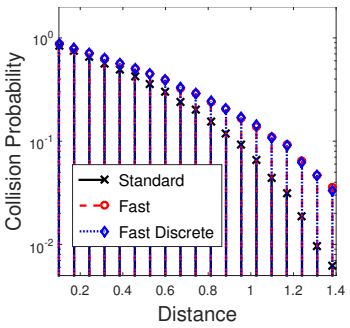

Figure 6 $d = 256$, $d' = 64$.

The following figures illustrate the rate of convergence to the optimal collision probability as $d \to \infty$, as well as various lines that illustrate the optimal rate of convergence $C \setminus \ln(d)$, where C varies for illustrative purposes. The experiments were run with varying distances and clearly show the same rate of convergence for the collision probability between the standard and fast cross-polytope schemes. We note that at low dimensions, the schemes behave even more similarly because the embedded dimension is much closer to the original dimension in this case.

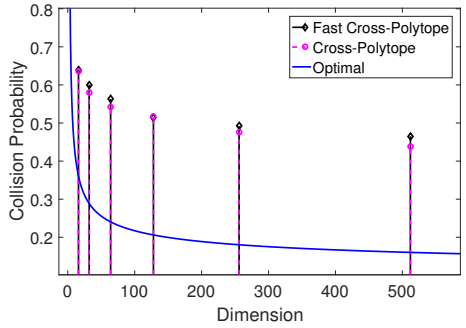

Figure 7 $R = 0.4$.

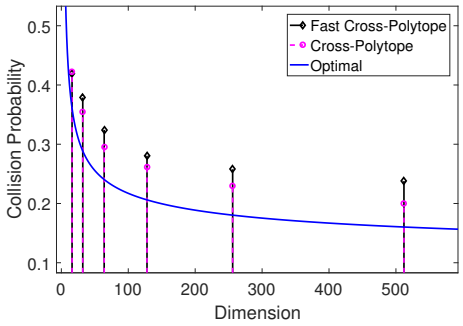

Figure 8 $R = 0.7$.

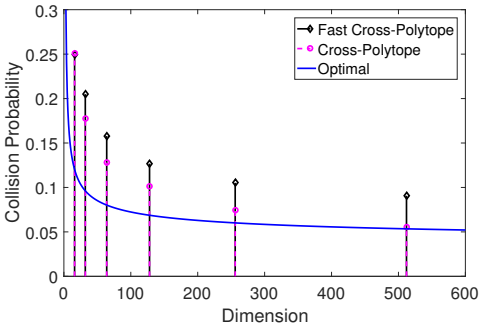

Figure 9 $R = 1$.

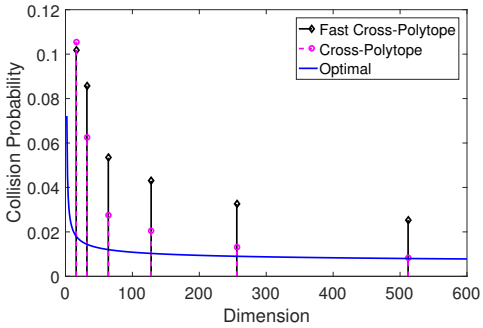

Figure 10 $R = 1.3$.

6 Appendix

6.1 Proof of Theorem 4 Part (ii-)

Let $\rho_{R,c}$ be the exponent for standard cross-polytope lsh in dimension d', and $\rho_{R,c}^{fast}$ be the exponent for fast cross-polytope lsh lifted to dimension d'. Suppose that

$$\rho_{R,c} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2} \leq C(R,c)F(d'),$$

where $F(d') \to 0$ as $d' \to \infty$ and $C(r,c)$ is constant in the dimension d'.
Assume that $H_sD_b : \mathbb{R}^d \to \mathbb{R}^m$ is a δ-isometry on $x-y$, i.e.

$$||x-y||_2^2 \leq R^2 \implies ||\tilde{x}-\tilde{y}||_2^2 \leq (1+\delta)R^2 \tag{15}$$

$$||x-y||_2^2 \geq c^2R^2 \implies ||\tilde{x}-\tilde{y}||_2^2 \geq (1-\delta)c^2R^2. \tag{16}$$

The next observation is that $h_f(x)$ applies the standard cross-polytope lsh scheme on H_sD_bx, so conditioned on H_sD_bx being a δ-isometry, we can analyze the fast scheme in terms of the standard scheme as follows:

$$\rho_{R,c}^{fast} \leq \rho_{R',c'},$$

where $R' = R\sqrt{1+\delta}$, $c' = \sqrt{\frac{1-\delta}{1+\delta}}c$. Now, we can say

$$\begin{aligned}\rho_{R,c}^{fast} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2} &\leq [\rho_{R,c}^{fast} - \rho_{R',c'}] + \left[\rho_{R',c'} - \frac{1}{(c')^2}\frac{4-(c')^2(r')^2}{4-(R')^2}\right] \\ &\quad + \left[\frac{1}{(c')^2}\frac{4-(c')^2(R')^2}{4-(R')^2} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2}\right] \\ &\leq C(R',c')F(d) + \left[\frac{1}{(c')^2}\frac{4-(c')^2(R')^2}{4-(R')^2} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2}\right].\end{aligned}$$

The difference in the last equation can be bounded as

$$\begin{aligned}
&\frac{1}{(c')^2}\frac{4-(c')^2(R')^2}{4-(R')^2} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2} = \left(\frac{1+\delta}{c^2(1-\delta)}\right)\frac{4-(1-\delta)c^2R^2}{4-(1-\delta)R^2} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2} \\
&\leq \frac{(1+\delta)(4-(1-\delta)c^2R^2)(4-R^2) - (4-c^2R^2)(1-\delta)(4-(1-\delta)R^2)}{\frac{c^2}{2}(4-R^2)^2} \\
&= \delta\mathcal{O}(R,c) + \frac{(1+\delta)(4-c^2R^2)(4-R^2) - (1-\delta)(4-c^2R^2)(4-R^2)}{\frac{c^2}{2}(4-R^2)^2} \\
&= \delta D(R,c),
\end{aligned}$$

so it follows that $\rho^{fast}_{R,c} - \frac{1}{c^2}\frac{4-c^2R^2}{4-R^2} \leq \delta D(R,c) + C(R',c')F(d')$ conditioned on the fact that H_sD_b is a δ-isometry on $x-y$. Note that for d' large enough, $C(R',c')$ is bounded above by a constant independent of the dimension. We can make the choice $\delta = \frac{1}{\ln(d)}$, so that the isometry condition holds with probability $1-\mathcal{O}(d^{-\ln d})$, so if ρ is the true exponent without conditioning, we get that

$$\begin{aligned}
\rho &\leq \frac{p_1}{p_2 + C\ln(1-d^{-\ln d})} \\
&\leq \frac{p_1}{p_2 - Cd^{-\ln d}} \\
&\leq \frac{p_1}{p_2}(1 + Cd^{-\ln d}/p_1),
\end{aligned}$$

where $C>0$ is an constant that changes by line but is independent of the dimension. From this expression it is easy to see that the error term decays at least like $1/\ln d'$ (recall that $d' \leq d$).
Finally, provided $F(d')$ decays as fast as than $\frac{1}{\ln(d')}$, the result will hold. This follows from Theorem 1 in [4].

6.2 Proof of Lemma 6

We know that for any $\epsilon > 0$ and d large enough, $m_d(b) \geq b - \epsilon$, so that

$$\begin{aligned}
\lim_{d\to\infty}\frac{g(d)}{m_d(b)f(d)+g(d)} &\leq \lim_{d\to\infty}\frac{g(d)}{(b-\epsilon)f(d)+g(d)} \\
&= \lim_{d\to\infty}\frac{1}{(b-\epsilon)\frac{f(d)}{g(d)}+1} = 0,
\end{aligned}$$

and by positivity the inequality is an equality. This implies that

$$\lim_{d\to\infty}\frac{m_d(a)f(d)+g(d)}{m_d(b)f(d)+g(d)} = \lim_{d\to\infty}\frac{m_d(a)f(d)}{m_d(b)f(d)+g(d)}.$$

The same argument on the reciprocal shows that

$$\lim_{d\to\infty}\frac{m_d(a)f(d)}{m_d(b)f(d)+g(d)} = \lim_{d\to\infty}\frac{m_d(a)f(d)}{m_d(b)f(d)} = \frac{a}{b}$$

6.3 Proof of Lemma 7

Define the event

$$E_{v,\delta} := \{v \in \mathbb{R}^n : (1-\delta)\|v\|_2 \leq \|\widetilde{v}\|_2 \leq (1+\delta)\|v\|_2\}.$$

sCombining Theorem 4.5 of [11] and Theorem 3.1 of [15], we know that for any $\eta \in (0,1)$, any $s \geq 40\ln(12/\eta)$, some $C_0 > 0$, and provided $m = \mathcal{O}(\delta^{-2}\ln^2(1/\delta)s\ln^2(s/\delta)\ln(d))$,

$$\Pr[E_{x,\delta} \cap E_{y,\delta} \cap E_{x-y,\delta}] \geq (1-\eta)(1-2^{-C_0\ln(d)\ln(s/\delta)})$$

Setting $\delta = 1/\ln(d)$, $\eta = d^{-\gamma}$, $s = 40C\ln(12d)$, we get

$$\Pr[E_{x,\delta} \cap E_{y,\delta} \cap E_{x-y,\delta}] \geq (1-d^{-\gamma})(1-2^{-C_0\ln(d)\ln(40\gamma\ln(12d)\ln(d))}),$$

and the lemma follows.

6.4 Proof of Lemma 10

Note that since the entries of $\widehat{\mathcal{G}}\widetilde{x}$ are symmetric and i.i.d., the probability of hashing to one value is equal for all hash values, so we get

$$\begin{aligned}\Pr[h_D(x) = h_D(y)] &= 2d'\Pr[h_D(x) = h_D(y) = e_1] \\ &= 2d'\Pr[\cap_{j=2}^{d'}(\widehat{\mathcal{G}}\widetilde{x})_1 \geq |(\widehat{\mathcal{G}}\widetilde{x})_j|, (\widehat{\mathcal{G}}\widetilde{y})_1 \geq |(\widehat{\mathcal{G}}\widetilde{y})_j|] \\ &= 2d'\mathbb{E}_{(\widehat{\mathcal{G}}\widetilde{x})_1,(\widehat{\mathcal{G}}\widetilde{y})_1}(\Pr[(\widehat{\mathcal{G}}\widetilde{x})_1 \geq |(\widehat{\mathcal{G}}\widetilde{x})_2|, (\widehat{\mathcal{G}}\widetilde{y})_1 \geq |(\widehat{\mathcal{G}}\widetilde{y})_2|]^{d'-1}). \qquad (17)\end{aligned}$$

Our goal is to bound the probability $\Pr[(\widehat{\mathcal{G}}\widetilde{x})_1 \geq |(\widehat{\mathcal{G}}\widetilde{x})_2|, (\widehat{\mathcal{G}}\widetilde{y})_1 \geq |(\widehat{\mathcal{G}}\widetilde{y})_2|]$ in terms of the probability $\Pr[(\mathcal{G}'\widetilde{x})_1 \geq |(\mathcal{G}'\widetilde{x})_2|, (\mathcal{G}'\widetilde{y})_1 \geq |(\mathcal{G}'\widetilde{y})_2|]$. Define $E_{\mathcal{G}'} = \{(\mathcal{G}'\widetilde{x})_1 \geq |(\mathcal{G}'\widetilde{x})_2|, (\mathcal{G}'\widetilde{y})_1 \geq |(\mathcal{G}'\widetilde{y})_2|\}$ and similarly for $\widehat{\mathcal{G}}$. Since $E_{\mathcal{G}'}$ is a convex polytope, we can write

$$\Pr[E_{\mathcal{G}'}] = \int_{I_1}\int_{I_2(x_1)}\dots\int_{I_m(x_1,x_2,\dots,x_{m-1})}\frac{1}{(2\pi)^m}e^{-(x_1^2+\dots+x_m^2)/2}dx_m\dots dx_1,$$

where each $I_j(x_1,\dots,x_j)$ is a (possibly unbounded) interval. By construction of X,

$$\int_{I_j(x_1,\dots,x_j)}\frac{1}{2\pi}e^{-x_{j+1}^2/2}dx_{j+1} = \int_{I_j(x_1,\dots,x_j)}p_X(x_{j+1})dx_{j+1} + \mathcal{O}(2^{-b})$$

where $p_X(x)$ is the pdf of X. This implies that

$$\begin{aligned}&\Pr[E_{\mathcal{G}'}] \\ &= \int_{I_1}\int_{I_2(x_1)}\dots\int_{I_m(x_1,\dots,x_{m-1})}\frac{1}{(2\pi)^{m-1}}e^{-(x_1^2+\dots+x_{m-1}^2)/2}p_X(x_m)dx_m\dots dx_1 + \mathcal{O}(2^{-b}) \\ &\dots = \int_{I_1}\int_{I_2(x_1)}\dots\int_{I_m(x_1,\dots,x_{m-1})}p_X(x_1)\dots p_X(x_m)dx_m\dots dx_1 + \mathcal{O}(m2^{-b}) \\ &= \Pr[E_{\widehat{\mathcal{G}}}] + \mathcal{O}(m2^{-b}).\end{aligned}$$

Plugging this into (17), we get

$$\begin{aligned}\Pr[h_D(x) = h_D(y)] &= 2d'\mathbb{E}_{(\widehat{\mathcal{G}}\widetilde{x})_1,(\widehat{\mathcal{G}}\widetilde{y})_1}(\Pr[E_{\mathcal{G}'}] + \mathcal{O}(m2^{-b})))^{d'-1} \\ &= 2d'\mathbb{E}_{(\widehat{\mathcal{G}}\widetilde{x})_1,(\widehat{\mathcal{G}}\widetilde{y})_1}\left[\sum_{k=1}^{d'-1}\binom{d'-1}{k}\Pr[E_{\mathcal{G}'}]^k(\mathcal{O}(m2^{-b}))^{d'-1-k}\right].\end{aligned}$$

We now make the choice $m = C\ln^4(d)$, $b = \log_2(d)\ln(d)$, so that the above summation becomes

$$\begin{aligned}&\sum_{k=1}^{d'-1}\binom{d'-1}{k}\Pr[E_{\mathcal{G}'}]^{d'-1-k}(C\ln^4(d)d^{-\ln(d)})^k \\ &\qquad = \sum_{k=1}^{d'-1}\binom{d'-1}{k}\Pr[E_{\mathcal{G}'}]^{d'-1-k}(C\ln^4(d)d^{-\ln(d)})^k\end{aligned}$$

This first term in the summation is the main term $\Pr[E_{\mathcal{G}'}]^{d'-1}$ and the other terms can be bounded using Sterling's approximation as follows,

$$\binom{d'-1}{k}\Pr[E_{\mathcal{G}'}]^{d'-1-k}(C\ln^4(d)d^{-\ln(d)})^k \leq \left(\frac{d'e}{k}\right)^k (C\ln^4(d)d^{-\ln(d)})^k.$$

For $k \geq 1$ this is certainly bounded by $\mathcal{O}(d^{-\ln(d)+1})$, and we have

$$\begin{aligned}\sum_{k=1}^{d'-1}\binom{d'-1}{k}&\Pr[E_{\mathcal{G}'}]^{d'-1-k}(C\ln^4(d)d^{-\ln(d)})^k \\ &= \Pr[E_{\mathcal{G}'}]^{d'-1} + \mathcal{O}(d^{-\ln(d)+2})\end{aligned}$$

We note that the last asymptotic approximation is very rough but sufficient for our purposes. This means that

$$\Pr[h_D(x) = h_D(y)] = 2d'\mathbb{E}_{(\widehat{\mathcal{G}\widetilde{x}})_1,(\widehat{\mathcal{G}\widetilde{y}})_1}(\Pr[E_{\mathcal{G}'}]^{d'-1}) + \mathcal{O}(md^{-\ln(d)+2}). \tag{18}$$

Using the same technique as above where we replace the Gaussian density function with $P_X(x)$, we have

$$\begin{aligned}\Pr[h'_D(x) = h'_D(y)] &= 2d'\mathbb{E}_{(\mathcal{G}'\widetilde{x})_1,(\mathcal{G}'\widetilde{y})_1}(\Pr[E_{\mathcal{G}'}]^{d'-1}) \\ &= 2d'\mathbb{E}_{(\widehat{\mathcal{G}\widetilde{x}})_1,(\widehat{\mathcal{G}\widetilde{y}})_2}(\Pr[E_{\mathcal{G}'}] + \mathcal{O}(m2^{-b}))^{d'-1} \\ &= 2d'\mathbb{E}_{(\widehat{\mathcal{G}\widetilde{x}})_1,(\widehat{\mathcal{G}\widetilde{y}})_2}(\Pr[E_{\mathcal{G}'}]^{d'-1}) + \mathcal{O}(md^{-\ln(d)+2})\end{aligned}$$

Finally, plugging this into (18), we get

$$\begin{aligned}\Pr[h_D(x) = h_D(y)] &= \Pr[h'_D(x) = h'_D(y)] + \mathcal{O}(md^{-\ln(d)+2}) \\ &= \Pr[h'_D(x) = h'_D(y)] + \mathcal{O}(d^{-\ln(d)+3}).\end{aligned}$$

Now, we know that by Theorem 3, $\ln(\Pr[h_D(x) = h_D(y)]) = -\frac{\widetilde{R}^2}{4-\widetilde{R}^2}\ln(d') + \mathcal{O}_{\widetilde{R}}(\ln(\ln d'))$, so provided d is large enough that $\ln(d) - 2 > \frac{\widetilde{R}^2}{4-\widetilde{R}^2}$, the lemma follows.

The Distortion of Locality Sensitive Hashing

Abstract

Given a pairwise similarity notion between objects, locality sensitive hashing (LSH) aims to construct a hash function family over the universe of objects such that the probability two objects hash to the same value is their similarity. LSH is a powerful algorithmic tool for large-scale applications and much work has been done to understand LSHable similarities, i.e., similarities that admit an LSH.

In this paper we focus on similarities that are provably non-LSHable and propose a notion of distortion to capture the approximation of such a similarity by a similarity that is LSHable. We consider several well-known non-LSHable similarities and show tight upper and lower bounds on their distortion.

1 Introduction

The notion of similarity finds its use in a large variety of fields above and beyond computer science. Often, the notion is tailored to the actual domain and the application for which it is intended. Locality sensitive hashing (henceforth LSH) is a powerful algorithmic paradigm for computing similarities between data objects in an efficient way. Informally, an LSH scheme for a similarity is a probability distribution over a family of hash functions such that the probability the hash values of two objects agree is precisely the similarity between them. In many applications, computing similar objects (i.e., finding nearest neighbors) can be computationally very demanding and LSH offers an elegant and cost-effective alternative.

Intuitively, large objects can be represented compactly and yet accurately from the point of view of similarity, thanks to LSH. Thus, the similarity between two objects can be quickly estimated by picking a few random hash functions from the family and estimating the fraction of times the hash functions agree on the two objects. This paradigm has been very successful in a variety of applications dealing with large volumes of data, from near-duplicate estimation in text corpora to nearest-neighbor search in a multitude of domains.

Given its success and importance[1], researchers have looked for LSH schemes for more and more similarities. Thus a natural question arises: which similarities admit an LSH scheme? In [12] Charikar introduced two necessary criteria (the former weaker than the latter) for a similarity S to admit an LSH:

(T1) $1 - S$ must be a metric;

(T2) $1 - S$ must be isometrically embeddable in ℓ_1.

These two tests can be used to rule out the existence of LSH schemes for various similarities, for instance, the Sørensen–Dice and Sokal–Sneath similarities (see Table 1 or [15] for definitions).

This brings us to a very natural question, and the one we address in this paper: *if a similarity S does not admit an LSH scheme, then how well can it be approximated by another similarity S' that admits an LSH?*

Locality sensitive distortion. The two criteria (T1) and (T2) are one of the many points of contact between LSH schemes and the theory of embeddability in metric spaces, where the natural notion of "closeness" is distortion. We say that a similarity S has a *distortion* not larger than δ if there is a similarity S' defined on the same universe that admits an LSH and such that

$$\frac{S}{\delta} \leq S' \leq S.$$

The distortion is 1 if and only if S admits an LSH.

In this paper we begin a systematic investigation of the notion of distortion for LSH schemes and prove optimal distortion bounds for several well-known and widely used similarities such as cosine, Simpson, Braun–Blanquet (also known as "all-confidence"), Sørensen–Dice and several others (see Table 1). We obtain our lower bounds by introducing two new combinatorial tools dubbed the *center method* and the *k-sets method*. In nearly all cases, we also exhibit matching distortion upper bounds by explicitly constructing an LSH. As concrete examples, we show that the distortion of cosine similarity is $\Theta(\sqrt{n})$ and that of Braun–Blanquet and Sørensen–Dice similarities is two (the full picture is given in Table 1).

Our framework also greatly expands the outreach of the tests (T1) and (T2). We demonstrate its applicability by means of a few notable examples, in particular the Braun–Blanquet similarity whose distortion is proven to be exactly two. This similarity is particularly noteworthy because not only it passes test (T1) but also (T2). To show this we prove that this similarity is embeddable isometrically in ℓ_1, a result that may be of independent interest. Besides the two general methods discussed, we also provide ad hoc distortion bounds for Sokal–Sneath 1 and Forbes similarities.

Of the two methods introduced in our work, the center method is easier to apply than the k-sets method. The former is applicable to many instances of similarity but the latter is unavoidable in the following sense. Braun–Blanquet similarity not only, as remarked, passes (T1) and (T2), but also the test provided by the center method. However, the more powerful k-sets method can instead be used to show a distortion bound of two. Other similarities to which the k-sets method applies are Sørensen–Dice and the family SORENSEN_γ.

[1] The 2012 Paris Kanellakis Theory and Practice Award was given to Broder, Charikar, and Indyk for their work on LSH.

Table 1 A list of similarities and of their lower and upper distortion bounds. The value n refers to the cardinality of the ground set or to the number of dimensions.

Name	$S(X,Y)$ $X \neq Y$	Distortion LB	Distortion UB
Jaccard	$\frac{\lvert X\cap Y\rvert}{\lvert X\cap Y\rvert+\lvert X\triangle Y\rvert}$	1	1 (Shingles [8])
Hamming	$\frac{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert}{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert+\lvert X\triangle Y\rvert}$	1	1 (folklore)
Anderberg	$\frac{\lvert X\cap Y\rvert}{\lvert X\cap Y\rvert+2\lvert X\triangle Y\rvert}$	1	1 (RSS [13])
Rogers–Tanimoto	$\frac{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert}{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert+2\lvert X\triangle Y\rvert}$	1	1 (RSS [13])
Cosine	$\frac{X\cdot Y}{\ell_2(X)\cdot\ell_2(Y)}$	$\sqrt{n}$ (Theorem 6)	$3\sqrt{n}$ (Theorem 7)

Braun–Blanquet	$\frac{\lvert X\cap Y\rvert}{\max\{\lvert X\rvert,\lvert Y\rvert\}}$	2 (Theorem 16)	2 (Shingles [8])
Sørensen–Dice	$\frac{\lvert X\cap Y\rvert}{\lvert X\cap Y\rvert+1/2\lvert X\triangle Y\rvert}$	2 (Theorem 5)	2 (Shingles [8])
Sokal–Sneath 1	$\frac{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert}{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert+1/2\lvert X\triangle Y\rvert}$	4/3 (Theorem 8)	2 (RSS [13])
Forbes	$\frac{n\lvert X\cap Y\rvert}{\lvert X\rvert\lvert Y\rvert}$	n (Theorem 18)	n (Theorem 18)
SORENSEN$_\gamma$	$\frac{\lvert X\cap Y\rvert}{\lvert X\cap Y\rvert+\gamma\lvert X\triangle Y\rvert}$	$\max(1,1/\gamma)$ (Theorem 5)	$\max(1,1/\gamma)$ (Shingles [8], RSS [13])
SOKAL-SNEATH$_\gamma$	$\frac{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert}{\lvert X\cap Y\rvert+\lvert\overline{X\cup Y}\rvert+\gamma\lvert X\triangle Y\rvert}$	$\max(1,2/(1+\gamma))$ (Theorem 8)	$\max(1,1/\gamma)$ (RSS [13])

Upper bounds: worst-case vs. practice. The main motivation behind our work is to extend the range of applicability of LSH as far as possible and our concept of distortion should be understood in these terms. For instance, even if a similarity is shown not to admit an LSH scheme it might be possible to approximate it efficiently by means of LSH schemes of other similarities that are close to it. Our results show that some cases, such as cosine, are a forlorn hope (since the distortion is not a constant), but in other instances, such as Sørensen–Dice and Braun–Blanquet, our bounds give reasons to be optimistic. As a first "proof of concept" of the notion of distortion we performed a series of experiments with real-world text corpora. The results are encouraging, for they show that the distortion of real data sets is smaller than the worst case. In our tests the average distortion turned out to be approximately 1.4 as opposed to the worst-case bound of two.

In the same vein we also investigate experimentally for the first time the effectiveness of two recent LSH schemes for Anderberg and Rogers–Tanimoto similarities. Until the work in [13] it was not known whether these similarities admitted LSH schemes. That paper shows that they do, in a somewhat peculiar way—strictly speaking they might need exponentially many bits (albeit with low probability)! In this paper we report on experiments with real text corpora that show that in practice these schemes are quite efficient.

2 Related Work

LSH was formally developed over a series of papers [8, 9, 25, 26]. Broder et al. [8, 9] showed that min-wise independent permutations form an LSH for the Jaccard similarity. Indyk and Motwani [25] introduced sampling hash as an LSH scheme for the Hamming similarity. Pursuing the work of characterizing similarities that admit an LSH, Charikar [12] introduced (T1) and (T2) as necessary criteria. Chierichetti and Kumar [13] proposed the concept of LSH-preserving functions, which are probability generating functions that preserve the LSH property of a similarity. From applications point of view, LSH has been widely used for solving the approximate or exact near-neighbor search [2] and similarity search [22, 30, 38] in high dimensional spaces. For a detailed bibliography on LSH, including pointers to implementations, see Alex Andoni's LSH page (`www.mit.edu/~andoni/LSH/`) and the surveys of Andoni and Indyk [3] and Wang et al. [43].

Similarities are extensively used in various areas of computer science. Hamming similarity, for instance, is widely used in information theory [5, 6, 18]. Areas like data mining and data management have seen the usage of Anderberg similarity [1], Cosine similarity [10, 37], and Sokal–Sneath [40] similarity. Cosine similarity is also ubiquitous in information retrieval [21, 32, 36, 46] and bioinformatics [11] whereas Sokal–Sneath is used in image processing [4]. We should note here that the success of similarity algorithms/functions is not limited only within computer science. For instance, Sørensen–Dice is commonly used in ecology [16, 28, 29], phytosociology [27, 42], plant taxonomy [44], biology [39] and even in lexicography [35]. Biology has also seen the usage of Sokal–Sneath [41, 45], mentioned above. Other interesting examples are Simpson similarity used in microscopy [31] and biology [17], Braun–Blanquet in phytosociology [7] and ecology [33], and Rogers–Tanimoto used in taxonomy [34].

The notion of distortion is studied in various areas of computer science and mathematics, especially in metric embedding problems. Here, we are given a source metric space (X, d), and a target metric space (X', d'), and we wish to find a map $f : X \to X'$ from points in X to points in X' that minimizes the distortion

$$\max_{\{a,b\}\in\binom{X}{2}} \max\left(\frac{d(a,b)}{d'(f(a),f(b))}, \frac{d'(f(a),f(b))}{d(a,b)}\right).$$

Problems of this form have been studied for many source and target metric spaces (cf. [24]). Examples include embeddings into the Euclidean (ℓ_2) metric, into the ℓ_1 metric, or into tree metrics from shortest-path metrics on graphs or from normed spaces of large dimensionality. Even though the LSH distortion problem seems to resemble distorted metric embedding problems, an important difference is that we want to guarantee a multiplicative approximation to the "similarity" (as opposed to the "distance").

3 Preliminaries

We use the notation 2^A to represent the set of all subsets of a set A. Also, for any set A, $\binom{A}{2}$ is the set of all pairs $\{a, b\}$ such that $a \neq b$ and $a, b \in A$. For a positive integer n, let $[n] = \{1, 2, \ldots, n\}$.

Let $\mathcal{U}$ be a (finite) universe of objects. A symmetric function $S : \mathcal{U} \times \mathcal{U} \to [0, 1]$ such that $S(X, X) = 1$ for all $X \in \mathcal{U}$ is called a *similarity*. See [15] for a rather complete illustration of the different types of similarities that are used in a practical context.

We first define what it means for a similarity to admit a locality sensitive hash (LSH).

▶ **Definition 1** (LSH [12]). An *LSH* for a similarity function $S : \mathcal{U} \times \mathcal{U} \to [0,1]$ is a probability distribution over a set $\mathcal{H}$ of (hash) functions defined on $\mathcal{U}$ such that, for each $X, Y \in \mathcal{U}$, we have

$$\Pr_{h \in \mathcal{H}}[h(X) = h(Y)] = S(X,Y).$$

(See [25] for a somewhat different definition of LSH in the same spirit.) A similarity is *LSHable* if there exists an LSH for it. The basic notion we introduce in this paper is defined next.

▶ **Definition 2** (LSH distortion). The *LSH distortion*, or *distortion*, of a similarity $S : \mathcal{U} \times \mathcal{U} \to [0,1]$ is the minimum[2] $\delta \geq 1$ such that there exists an LSHable similarity $S' : \mathcal{U} \times \mathcal{U} \to [0,1]$ for which

$$\frac{1}{\delta} \cdot S(X,Y) \leq S'(X,Y) \leq S(X,Y) \quad \forall X, Y \in \mathcal{U}.$$

We denote $\mathsf{distortion}(S) = \delta$.

At first blush a more general definition seems possible. One could define the distortion of S as the minimum δ such that there exist an LSHable similarity S' and $\alpha, \beta \geq 1$, with $\alpha\beta = \delta$, such that, for all $X, Y \in \mathcal{U}$,

$$\frac{1}{\alpha} \cdot S(X,Y) \leq S'(X,Y) \leq \beta \cdot S(X,Y).$$

The next lemma however implies that Definition 2 can be adopted without loss of generality.

▶ **Lemma 3.** *Let $S : \mathcal{U} \times \mathcal{U} \to [0,1]$ be an LSHable similarity. Then, for each $\gamma \in [0,1]$, the similarity*

$$S'(X,Y) = \begin{cases} \gamma \cdot S(X,Y) & X \neq Y \\ 1 & X = Y \end{cases}$$

is also LSHable.

Proof. Let $\mathcal{H}$ be the hash function family for S given by Definition 1. We will build a family $\mathcal{H}'$ for S' by bijectively obtaining an h' for each $h \in \mathcal{H}$. To define h', consider the following procedure: with probability γ, let $h'(X) = (0, h(X))$ for each $X \in \mathcal{U}$, while with probability $1 - \gamma$, let $h'(X) = (1, X)$, for each $X \in \mathcal{U}$. Then, for each $X \neq Y$, $\Pr[h'(X) = h'(Y)] = \gamma \cdot S'(X,Y)$. ◀

Now, suppose that for a given similarity S, we have an LSHable similarity S' satisfying $\frac{1}{\alpha} \cdot S(X,Y) \leq S'(X,Y) \leq \beta \cdot S(X,Y)$ with $\alpha\beta = \delta$. By applying Lemma 3 to S' we obtain an LSH for the similarity $S''(X,Y) = \frac{1}{\beta} \cdot S'(X,Y)$ (when $X \neq Y$) which satisfies

$$\frac{1}{\alpha\beta} \cdot S(X,Y) \leq \frac{1}{\beta} \cdot S'(X,Y) = S''(X,Y) \leq S(X,Y).$$

Hence Definition 2 is robust.

[2] A minimum δ exists because it is equal to the solution of a linear program (see, e.g., [14]) of size polynomial in $|\mathcal{U}|$.

Known LSH for set similarities. Set similarities are those similarities whose universe $\mathcal{U}$ satisfies $\mathcal{U} = 2^U$, for some finite ground set U. To give upper bounds on the distortions of various similarities we employ a number of LSH schemes for set similarities proposed in the literature. First and foremost, we employ *shingles* [8, 9], which is an LSH scheme for the Jaccard similarity over sets ($\textsc{jaccard}(X, Y) = |X \cap Y|/|X \cup Y|$), over the universe $\mathcal{U} = 2^U$. To sample a hash function $h \in \mathcal{H}$ from this scheme, one picks a permutation π of the ground set U uniformly at random. Then, $h(X)$, for a set $X \neq \varnothing$, is equal to the element in X with smallest rank in π. (And, $h(\varnothing)$ is identically equal to $\perp$.) A simple calculation shows that $\Pr_{h\in\mathcal{H}}[h(X) = h(Y)] = \frac{|X\cap Y|}{|X\cup Y|}$ if $X \cup Y \neq \varnothing$, and $\Pr_{h\in\mathcal{H}}[h(\varnothing) = h(\varnothing)] = 1$.

We also use a generalization of shingles given in [12] for the weighted Jaccard similarity. Finally, we use some of the LSH schemes given in [13] for the various rational set similarities. We will use these results as black-boxes and hence we will not describe them.

4 The Center Method

In this section we introduce our first lower bound tool for LSH distortion. It will be used to get tight bounds for the distortion of Simpson, and two infinite families of similarities, namely, S_γ and ℓ_p-norm dot product, that contain well-known similarities such as Sørensen–Dice and Cosine as special cases. The main workhorse is given by the next theorem. Roughly, it says that if we can find a set of points in our universe that are mutually far apart, then its "center" is far apart from some point in the set. Later in this section, we will also present matching distortion upper bounds for these similarities.

▶ **Theorem 4.** *Suppose that $S : \mathcal{U} \times \mathcal{U} \to [0, 1]$ is a similarity admitting an LSH such that there exists $\varnothing \neq \mathcal{X} \subseteq \mathcal{U}$, with $S(X, X') = 0$ for each $\{X, X'\} \in \binom{\mathcal{X}}{2}$. Then, for each $Y \in \mathcal{U}$, there exists at least one $X^\star \in \mathcal{X}$ such that $S(X^\star, Y) \leq 1/|\mathcal{X}|$.*

Proof. Let $\mathcal{H}$ be the hash function family for S. Observe that no LSH with a finite distortion can assign a non-zero probability to any of the pairs in $\binom{\mathcal{X}}{2}$, since their pairwise similarities are zero. Therefore each $Y \in \mathcal{U}$ can be hashed to the same value of at most one element of $\mathcal{X}$ for each hash function. In other words, each hash function $h \in \mathcal{H}$ must satisfy $|\{h(X) \mid X \in \mathcal{X}\}| = |\mathcal{X}|$. Therefore,

$$\sum_{X\in\mathcal{X}} S(X, Y) = \Pr[h(Y) \in \{h(X) \mid X \in \mathcal{X}\}] \leq 1.$$

By averaging, it follows that there must exists at least one $X^\star \in \mathcal{X}$ such that $S(X^\star, Y) \leq 1/|\mathcal{X}|$. ◀

We will use this characterization in the following way. For a given similarity, we will find a set $\mathcal{X} \subseteq \mathcal{U}$ of objects that are entirely dissimilar from one another (i.e., all their pairwise similarities are zero) and an additional object $Y \in \mathcal{U} \setminus \mathcal{X}$ (i.e., the *center*) that is more similar than $1/|\mathcal{X}|$ to each of the elements in $\mathcal{X}$. If we can prove a lower bound of $\alpha/|\mathcal{X}|$, $\alpha > 1$, on the similarities $S(Y, X)$ for each $X \in \mathcal{X}$, then we can conclude that the similarity S has to be distorted by at least α to admit an LSH. In the remainder of this section we apply Theorem 4 to a few notable examples.

4.1 Simpson and generalized Sørensen–Dice

Let us begin by recalling the definition of the similarities to be discussed in this section. The Simpson similarity, operating on the subsets of the ground set $[n]$, is defined as

$$\textsc{simpson}(X,Y) = \frac{|X \cap Y|}{\min(|X|,|Y|)},$$

if $|X|, |Y| \geq 1$, as $\textsc{simpson}(X, \varnothing) = 0$ if $|X| \geq 1$ and as $\textsc{simpson}(\varnothing, \varnothing) = 1$. The infinite family $\textsc{sorensen}_\gamma$, for $\gamma > 0$, operating on the subsets of $[n]$, is defined as

$$\textsc{sorensen}_\gamma(X,Y) = \frac{|X \cap Y|}{|X \cap Y| + \gamma |X \triangle Y|},$$

if $|X| + |Y| \geq 1$, and $\textsc{sorensen}_\gamma(\varnothing, \varnothing) = 1$. The $\textsc{sorensen}_\gamma$ family subsumes as special cases several well-known similarities, for instance, Sørensen–Dice ($\gamma = \frac{1}{2}$), Jaccard ($\gamma = 1$), and Anderberg ($\gamma = 2$).

▶ **Theorem 5.** *For a ground set of n elements,*

$$\begin{aligned} \mathsf{distortion}(\textsc{simpson}) &= n, \text{ and} \\ \mathsf{distortion}(\textsc{sorensen}_\gamma) &= \max(1/\gamma, 1) - O(1/n). \end{aligned}$$

Proof. First, we show the lower bound by exhibiting an instance on a ground set of n elements. Let $U = [n]$, $Y = U$, and $\mathcal{X} = \{X_1, \ldots, X_n\}$, where $X_i = \{i\}$ for $i \in [n]$. Observe that, for each $\{X_i, X_j\} \in \binom{\mathcal{X}}{2}$, we have that $\textsc{simpson}(X_i, X_j) = \textsc{sorensen}_\gamma(X_i, X_j) = 0$, while, for each $X_i \in \mathcal{X}$, we have $\textsc{simpson}(X_i, Y) = 1$ and $\textsc{sorensen}_\gamma(X_i, Y) = \frac{1}{\gamma n + (1-\gamma)}$.

By Theorem 4 we know that for every similarity S with an LSH that finitely distorts $\textsc{simpson}$ or $\textsc{sorensen}_\gamma$, there must exist at least one X_i such that $S(X_i, Y) \leq \frac{1}{|\mathcal{X}|} = \frac{1}{n}$. The lower bounds follow.

Next we show matching upper bounds for the distortion. Recall the definition of the Jaccard similarity:

$$\textsc{jaccard}(X,Y) = \frac{|X \cap Y|}{|X \cup Y|}.$$

Broder's shingles [8] and minwise independent permutations [9] are a well-known LSH scheme for Jaccard similarity (see § 2). We use this to prove matching upper bounds for Theorem 5.

Minwise independent permutations form an LSH scheme with distortion n for Simpson similarity since

$$\min(|X|,|Y|) \leq |X \cup Y| \leq n \cdot \min(|X|,|Y|),$$

as long as $|X|, |Y| \geq 1$. They also provide a distortion of $1/\gamma$ for $\textsc{sorensen}_\gamma$, for every $\gamma \in (0, 1]$ since

$$\gamma |X \cup Y| \leq |X \cap Y| + \gamma |X \triangle Y| \leq |X \cup Y|.$$

Finally, recall that a result in [13] proves that the similarity H_γ admits an LSH scheme as long as $\gamma \geq 1$. ◀

Figure 1 plots the minimum distortion of $\textsc{sorensen}_\gamma$, as γ varies.

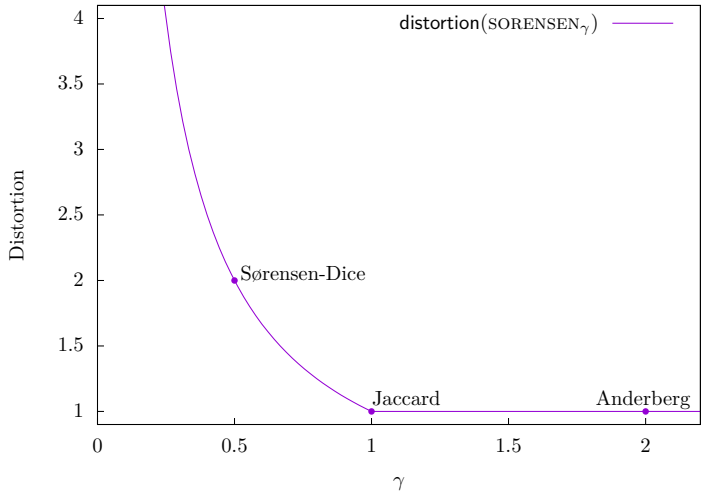

Figure 1 The minimum distortion of SORENSEN$_\gamma$.

4.2 Cosine and unit ℓ_p-norm dot product

Recall that given any $p \geq 1$, the ℓ_p norm of a vector $x \in \mathbf{R}^n$ is $\ell_p(x) = \left(\sum_{i=1}^n |x(i)|^p\right)^{1/p}$ and that the cosine similarity of two non-negative vectors $x, y \in \mathbf{R}^n_+$ having unit ℓ_2 norm is $\sum_{i=1}^n x(i) \cdot y(i)$.

Furthermore, given $p \geq 1$, let

$$B_{p,n} := \left\{ x \in \mathbf{R}^n_+ \mid \sum_{i=1}^n x(i)^p \leq 1 \right\} \text{ and } S_{p,n} := \left\{ x \in \mathbf{R}^n_+ \mid \sum_{i=1}^n x(i)^p = 1 \right\},$$

be, respectively, the set of points contained in the p-ball of p-radius 1 with non-negative coordinates and the set of points lying on the p-sphere of p-radius 1 with non-negative coordinates.

The universe of the dot product similarity (that we define next) is $B_{p,n}$, which is uncountably infinite. To avoid technical issues in giving a minimally distorted LSH for this similarity, we restrict the universe $B_{p,n}$ to any finite subset $F_{p,n}$ of $B_{p,n}$. Given any such subset, the similarity $\text{DOT}_{p,n} : F_{p,n} \times F_{p,n} \to [0, \infty)$ is

$$\text{DOT}_{p,n}(x, y) = \sum_{i=1}^n x(i) \cdot y(i).$$

Notice that $\text{DOT}_{2,n}$ is the well-known cosine similarity (defined on the points of $S_{2,n}$). (Note that we have relaxed the notion of similarity to have range outside $[0, 1]$; the distortion bounds will take care of this issue. However, for the cosine similarity, the range is still $[0, 1]$.) We first show an upper bound on distortion and follow that with a matching lower bound.

▶ **Theorem 6.** *For $p \geq 2$,* $\text{distortion}(\text{DOT}_{p,n}) \leq 3n^{1-\frac{1}{p}}$.

Proof. The proof is omitted from this extended abstract. ◀

Now we show that the distortion of Theorem 6 is close to optimal using, once again, the center method.

▶ **Theorem 7.** *For $p \geq 1$,* $\mathsf{distortion}(\text{DOT}_{p,n}) \geq n^{1-\frac{1}{p}}$.

Proof. Consider the n vectors u_i defined as $u_i(i) = 1$, and $u_i(j) = 0$ for each $i \in [n]$ and for each $j \in [n] \setminus \{i\}$. Also, let $u_\star$ be the vector such that $u_\star(i) = n^{-\frac{1}{p}}$, for each $i \in [n]$, and let $X = \{u_1, u_2, \ldots, u_n\}$. Observe that for each $x \in X$, we have $\ell_p(x) = 1$ and $\ell_p(u_\star) = 1$.

Suppose that S is an LSHable similarity that distorts $\text{DOT}_{p,n}$ by the minimum possible amount. Since $S(u_i, u_j) = 0$ for every $i \neq j$, by Theorem 4 we know that there exists $u_i \in X$ such that $S(u_i, u_\star) \leq \frac{1}{n}$. Since $\text{DOT}_{p,n}(u_i, u_\star) = n^{-\frac{1}{p}}$, the distortion is at least $n^{1-\frac{1}{p}}$. ◀

As a simple corollary, we observe that the distortion for the cosine similarity is $\Theta(\sqrt{n})$ and that the distortion bound is tight for $p \geq 2$. We conjecture that it is generally tight for all $p \geq 1$, i.e., that Theorem 6 could be strengthened to all $p \geq 1$.

4.3 Sokal–Sneath similarities

Finally, we look at the Sokal–Sneath similarities. For $\gamma > 0$, let

$$\text{SOKAL-SNEATH}_\gamma(X, Y) = \frac{|X \cap Y| + \left|\overline{X \cup Y}\right|}{|X \cap Y| + \left|\overline{X \cup Y}\right| + \gamma\,|X \triangle Y|}.$$

Observe that SOKAL-SNEATH_1 is the Hamming similarity, $\text{SOKAL-SNEATH}_{1/2}$ is the Sokal–Sneath 1 similarity, and SOKAL-SNEATH_2 is the Rogers–Tanimoto similarity.

Rational set similarities [13] prove that $\text{SOKAL-SNEATH}_\gamma$ has an LSH iff $\gamma \geq 1$. Thus, the Hamming similarity and the Rogers–Tanimoto similarity admit an LSH, while the Sokal–Sneath 1 similarity does not admit an LSH.

We use the center method to prove a lower bound on the LSH-distortion of $\text{SOKAL-SNEATH}_\gamma$.

▶ **Theorem 8.** *For any $0 < \gamma < 1$,*

$$\frac{2}{1+\gamma} \leq \mathsf{distortion}(\text{SOKAL-SNEATH}_\gamma) \leq \frac{1}{\gamma}.$$

Proof. We begin with the lower bound. Given any ground set $[n]$ of even cardinality, consider the three sets $X = [n/2]$, $X' = [n] \setminus [n/2]$ and $Y = [n]$. We have, $\text{SOKAL-SNEATH}_\gamma(X, X') = 0$, $\text{SOKAL-SNEATH}_\gamma(X, Y) = \text{SOKAL-SNEATH}_\gamma(X', Y)$, and

$$\text{SOKAL-SNEATH}_\gamma(X, Y) = \frac{1/2}{1/2 + \gamma/2} = \frac{1}{1+\gamma}.$$

Consider any set similarity S on the ground set $[n]$ that admits an LSH, and that guarantees that $S(X, X') = 0$. By Theorem 4, there must exists $X^\star \in \{X, X'\}$ such that $S(X^\star, Y) \leq 1/2$. It follows that the distortion is at least $\frac{\frac{1}{1+\gamma}}{\frac{1}{2}} = \frac{2}{1+\gamma}$.

As for the upper bound, observe that for $0 < \gamma < 1$, we can approximate $\text{SOKAL-SNEATH}_\gamma$ with SOKAL-SNEATH_1 by introducing a distortion of $1/\gamma$. Since SOKAL-SNEATH_1 admits an LSH [13], it follows that $\mathsf{distortion}(\text{SOKAL-SNEATH}_\gamma) \leq 1/\gamma$. ◀

5 The k-sets Method

In this section we introduce our second tool for lower bounding the distortion of LSH. This method is geared towards set similarities. The main tool is the following theorem. Let $\mathcal{U}_{n,k}$ denote $\binom{[n]}{k}$.

▶ **Theorem 9.** *Let $k = o(\sqrt{n})$, and let $S : \mathcal{U}_{n,k} \times \mathcal{U}_{n,k} \to [0,1]$ be a similarity such that $S(X,Y) = 0$ if $X \cap Y = \varnothing$. If S admits an LSH, then*

$$f(S) := \operatorname*{avg}_{\substack{\{X,Y\} \in \binom{\mathcal{U}_{n,k}}{2} \\ |X \cap Y| = 1}} S(X,Y) \quad \leq \quad \alpha_k + O\left(\frac{k}{n}\right), \quad \text{where} \quad \alpha_k := \frac{1}{2k-1}.$$

This will be used in the following way. Suppose that we have a similarity S' defined on sets such that $S'(X,Y) = 0$ whenever X and Y are disjoint (not all, but many set similarities satisfy this property), and suppose also that $S'(X,Y) \geq d \cdot \alpha_k$ whenever X and Y are such that $|X| = |Y| = k$ and $|X \cap Y| = 1$. If S is LSHable, how small can its distortion be with respect to S'? By Theorem 9, there must exist a pair of sets such that $S(X,Y) \leq \alpha_k + O(k/n)$ which implies that the distortion of any LSHable S with respect to S' is at least $d - O(k^2/n)$.

In what follows, we begin with some technical Lemmas (§ 5.1) to prove Theorem 9 (§ 5.2) and then apply it, in § 5.3, to Braun–Blanquet similarity, establishing optimal distortion bounds for it.

5.1 Extremal partitions

A hash function h on $\mathcal{U}$ naturally induces a partition in the following sense: two objects $X, Y \in \mathcal{U}$ belong to the same side of the partition if $h(X) = h(Y)$. This view is particularly useful for our purposes and from now on we will identify a hash function with the partition that it induces.

▶ **Definition 10** (Acceptable partition)**.** A partition $\mathcal{P}$ of $\mathcal{U}_{n,k}$ *induces a pair* $\{X,Y\}$ (with $X \neq Y$) if X, Y belong to the same part of $\mathcal{P}$. A partition is *acceptable* if it induces no pair $\{X,Y\}$ such that X and Y are disjoint. The *value* of a partition is the number of pairs induced by it.

Our first goal is to prove that no acceptable partition of $\mathcal{U}_{n,k}$ has value greater than

$$\left(1 + O\left(k^2/n\right)\right) \cdot \frac{n^{2k-1}}{2(2k-1)((k-1)!)^2}.$$

▶ **Definition 11** (Nice partition)**.** An acceptable partition $\mathcal{P}$ of $\mathcal{U}_{n,k}$ is *nice* if it contains n parts $P_1, \ldots, P_t$, and if there exists a partition $I_1, \ldots, I_t$ of $[n]$ (with $I_i \neq \varnothing$ for $i \in [t]$, $\cup_{i=1}^{t} I_i = [n]$ and $I_i \cap I_j = \varnothing$ for each $\{i,j\} \in \binom{[t]}{2}$) such that, for each $i \in [t]$,

$$P_i = \left\{X \in \mathcal{U}_{n,k} \mid I_i \subseteq X \text{ and } X \cap \left(\cup_{j=1}^{i-1} I_j\right) = \varnothing\right\}.$$

We first show that nice partitions satisfy a slightly stronger version of the the above bound; we will then reduce any partition to a nice one.

▶ **Lemma 12.** *The value of a nice partition of $\mathcal{U}_{n,k}$ is at most*

$$\frac{n^{2k-1}}{2(2k-1)\left((k-1)!\right)^2}.$$

Proof. The proof is omitted from this extended abstract. ◀

We now make use of the following theorem of Hilton and Milner [23] (see [20] for a short proof), which bounds the maximum cardinality of an Erdös–Ko–Rado [19] family that is not a star.

▶ **Theorem 13** (Hilton–Milner [23]). *Let $\mathcal{F} \subseteq \mathcal{U}_{n,k}$ be a family of sets with pairwise non-empty intersection with $n \geq 2k$. If $\bigcap_{F\in\mathcal{F}} F = \varnothing$ then $|\mathcal{F}| \leq \binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1$.*

▶ **Fact 14.** $\binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1 \leq O\left(k \cdot \frac{n^{k-2}}{(k-2)!}\right)$.

▶ **Lemma 15.** *The value of an acceptable partition of $\mathcal{U}_{n,k}$ is at most*

$$\left(1 + O\left(\frac{k^2}{n}\right)\right) \cdot \frac{n^{2k-1}}{2(2k-1)\left((k-1)!\right)^2}.$$

Proof. The proof is omitted from this extended abstract. ◀

5.2 Proof of Theorem 9

Proof. Let $\alpha = \operatorname{avg}_{\substack{\{X,Y\}\in\binom{\mathcal{U}_{n,k}}{2} \\ |X\cap Y|=1}} S(X,Y)$ be the average similarity between pairs of sets of cardinality k having an intersection of cardinality 1. Let σ be the total amount of similarity between unordered pairs of sets of cardinality k having intersection 1. It is equal to:

$$\sigma = n\frac{\binom{n-1}{k-1}\binom{n-k}{k-1}}{2}\alpha.$$

Recall that, in general, we have that

$$\binom{n}{\ell} \geq \frac{(n-\ell)^\ell}{\ell!} = \frac{n^\ell\left(1-\frac{\ell}{n}\right)^\ell}{\ell!} \geq \frac{n^\ell}{\ell!}\left(1-\frac{\ell^2}{n}\right).$$

Substituting k for ℓ, we obtain:

$$\sigma \geq \left(1 - O\left(\frac{k^2}{n}\right)\right)\frac{n^{2k-1}}{2((k-1)!)^2}\cdot\alpha,$$

where the $O(\cdot)$ term tends to 0, since $k = o(\sqrt{n})$. Since $S(X,Y) = 0$ whenever $|X\cap Y| = 0$, we cannot give positive probability to a hash function placing two such sets X and Y in the same part, for otherwise we would have infinite distortion. Hence, we can only use acceptable partitions. Suppose that the S has an LSH and assume wlog that this LSH gives positive probabilities $p_1,\ldots,p_h > 0$ to partitions $P_1,\ldots,P_h$, and that it gives probability 0 to other partitions. Let $v_1,\ldots,v_h$ be the values of partitions $P_1,\ldots,P_h$, and observe that $\sum_{i=1}^h p_i = 1$. Then, we have

$$\sigma = \sum_{\substack{\{X,Y\}\in\binom{\mathcal{U}_{n,k}}{2} \\ |X\cap Y|=1}} S(X,Y) = \sum_{i=1}^{h}(p_i v_i),$$

i.e., the total amount of similarity mass that an acceptable partition brings to our similarity's values is equal to the probability that the LSH assigns to the partition times the number of the partition's pairs, equivalently, its own value. By Lemma 15, the value of an acceptable partition is at most

$$\tau = \left(1 + O\left(\frac{k^2}{n}\right)\right)\frac{n^{2k-1}}{2(2k-1)\left((k-1)!\right)^2}.$$

Therefore, $\sigma \leq \sum_{i=1}^{h} (\tau p_h) = \tau$. I.e., if S admits an LSH, then $\tau \geq \sigma$. Thus, we must have

$$1 \geq \frac{\sigma}{\tau} \geq \left(1 - O\left(\frac{k^2}{n}\right)\right) \frac{\frac{n^{2k-1}}{2((k-1)!)^2} \cdot \alpha}{\frac{n^{2k-1}}{2(2k-1)((k-1)!)^2}} = \left(1 - O\left(\frac{k^2}{n}\right)\right) \alpha \cdot (2k-1),$$

which implies

$$\alpha \leq \left(1 + O\left(\frac{k^2}{n}\right)\right) \frac{1}{2k-1} = \frac{1}{2k-1} + O\left(\frac{k}{n}\right). \quad \blacktriangleleft$$

5.3 The distortion of Braun–Blanquet

Recall the definition of Braun–Blanquet, that operates on the subsets of the ground set $[n]$:

$$\text{BRAUN-BLANQUET}(X, Y) = \frac{|X \cap Y|}{\max(|X|, |Y|)},$$

if $|X| + |Y| \geq 1$, and $\text{BRAUN-BLANQUET}(X, Y) = 1$ if $X = Y = \varnothing$.

Observe that, for sets $X, Y \subseteq [n]$ such that $|X| = |Y| = k \geq 1$, both Braun–Blanquet and Sørensen–Dice evaluate to $1/k$ if $|X \cap Y| = 1$, and that they evaluate to 0 when $|X \cap Y| = 0$. Therefore, Theorem 9 implies that they have to be distorted by at least $(1 - o_n(1)) \cdot (2 - 1/k)$ when applied on such pairs of k-sets. By letting k grow to infinity, we obtain an asymptotically tight lower bound of 2 on their distortions. More precisely, by selecting $k = \Theta\left(n^{1/3}\right)$, and by letting n grow to infinity, their distortion is at least $2 - \Theta\left(n^{-1/3}\right)$. If we denote with S any of the two similarities, with S' any LSHable similarity with the same domain, and with X, Y any two sets that minimize $S'(X, Y)$, we obtain,

$$\frac{S(X,Y)}{S'(X,Y)} \geq \frac{\frac{1}{k}}{\frac{1}{2k-1} + O(\frac{k}{n})} = \frac{2 - \frac{1}{k}}{1 + O(\frac{k^2}{n})} = 2 - O(n^{-1/3}).$$

We finally observe that min-wise independent permutations [8, 9] achieve a distortion of $2 - \Theta\left(n^{-1}\right)$ for Braun–Blanquet. Thus, we have the following theorem:

▶ **Theorem 16.** $\text{distortion}(\text{BRAUN-BLANQUET}) = 2 - o(1)$.

▶ **Theorem 17.** $1 - \text{BRAUN-BLANQUET}$ *can be isometrically embedded into* ℓ_1.

Proof. The proof is omitted from this extended abstract. ◀

Thus, BRAUN-BLANQUET passes both (T1) and (T2) (see the introduction), and yet it is not LSH-able.

6 Ad hoc Approaches

In this section we discuss another similarity, whose distortion bound we prove through a simple ad hoc approach.

6.1 Forbes similarity

The Forbes similarity is defined as $\text{FORBES}(X, Y) = n \cdot \frac{|X \cap Y|}{|X|\,|Y|}$ if $|X|, |Y| \geq 1$, $\text{FORBES}(X, \varnothing) = 0$ if $|X| \geq 1$, and if $\text{FORBES}(\varnothing, \varnothing) = 1$. Since $F(\{1\}, \{1\}) = n$, we have the following simple observation.

▶ **Theorem 18.** distortion(FORBES) $= n$.

Proof. The lower bound is trivial since FORBES$(\{1\},\{1\}) = n$ and no LSH can assign a value larger than 1 to a pair of sets.

We give an LSH for the similarity FORBES$/n$, thus proving an upper bound of n on its distortion. The hash function h will be chosen as follows: $h(\varnothing) = \varnothing$ and, for each $X \neq \varnothing$ independently, $h(X)$ will be chosen uniformly at random from the elements of X. Then, if $X \neq Y$, we have $\Pr[h(X) = h(Y)] = \frac{|X \cap Y|}{|X| \cdot |Y|}$. ◀

7 Experiments

In this section we report on the outcome of two types of experiments. As we have seen in the previous sections the distortion of Braun–Blanquet and of Sørensen–Dice is $2 - o(1)$ and this bound can be matched by Jaccard, which is LSHable. Distortion being a worst-case notion, it is conceivable that the typical behavior of Jaccard with real-world datasets could be somewhat better. This is exactly what our experiments with three real world data sets show. We stress that our results are preliminary, but they give reasons for hope and might justify a more comprehensive experimental assessment. The average distortion turns out to be as low as 1.3 for some of our data sets and always less than two. The second set of experiments is a feasibility study of the LSH scheme for Anderberg and Rogers–Tanimoto, similarities that until recently were not known to be LSHable. As shown in [13] they are, but in a somewhat peculiar way, for the LSH schemes might need exponentially many bits (with low probability). The goal of our tests is to see whether such schemes are practical. Our study shows that they are and that in fact they can be very effective with very few bits. We begin by describing our data sets.

7.1 Datasets

We use three publicly available datasets: (i) a collection of more than 110K scientific papers downloaded from CiteSeerX, (ii) 29K scientific articles downloaded from ArXiv, and (iii) 104K Wikipedia articles. The collection of XML metadata of CiteSeerX and ArXiv where accessed using the OAI protocol for metadata harvesting, which is supported by both digital libraries. The Wikipedia collection was obtained from `en.wikipedia.org/wiki/Wikipedia:Database_download`. The words in each paper were transformed into lowercase and each document became a bag of words (no repetitions).

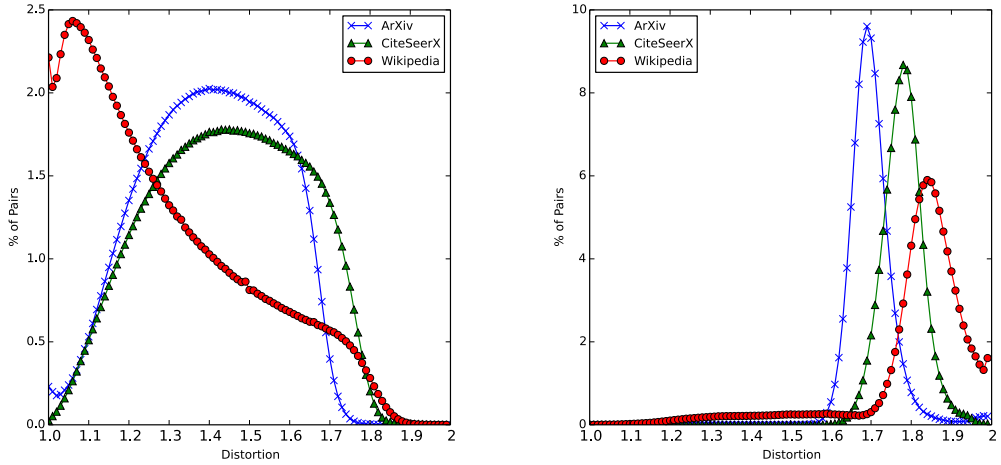
For the experiments of § 7.3 the documents underwent the following "cleaning" procedure: (i) all words not included in top 1000 most frequent words of the whole dataset were removed and, (ii) every word was hashed to a unique integer. As a result, the papers are represented as vectors containing integers in the range $[1000] = \{1, 2, \ldots, 1000\}$.

7.2 Distortion on real data

From each corpus, we selected 50 million random pairs of documents and computed the distortion, i.e., the ratio between the Jaccard value (computed exactly) and the two similarities Braun–Blanquet and Sørensen–Dice. Figure 2a shows the distortion w.r.t. Braun–Blanquet for our three datasets ArXiv, CiteSeer, and Wikipedia. For each value of the distortion on the x-axis, the plot gives, on the y-axis, the fraction of pairs with that distortion. Similarly, Figure 2b shows the distortion w.r.t. Sørensen–Dice. Table 2 displays the average distortion and the variance of these experiments.

Table 2 Experimental results.

	Braun–Blanquet		Sørensen–Dice	
	μ	σ	μ	σ
ArXiv	1.45	0.2	1.78	0.09
CiteSeerX	1.4	0.16	1.7	0.05
Wikipedia	1.29	0.21	1.81	1.14



(a) Braun–Blanquet similarity. **(b)** Sørensen–Dice similarity.

Figure 2 Percentage of document pairs with distortion δ with respect to shingles as δ increases.

Overall, these tests show that in real-world scenarios the average distortion of Braun–Blanquet and Sørensen–Dice can be significantly smaller than the worst case bound.

7.3 LSH schemes for rational set similarities

Let us start by recalling the definitions of the similarities we deal with in this section. The Anderberg similarity is defined as follows. Given two nonempty sets X, Y of n elements,

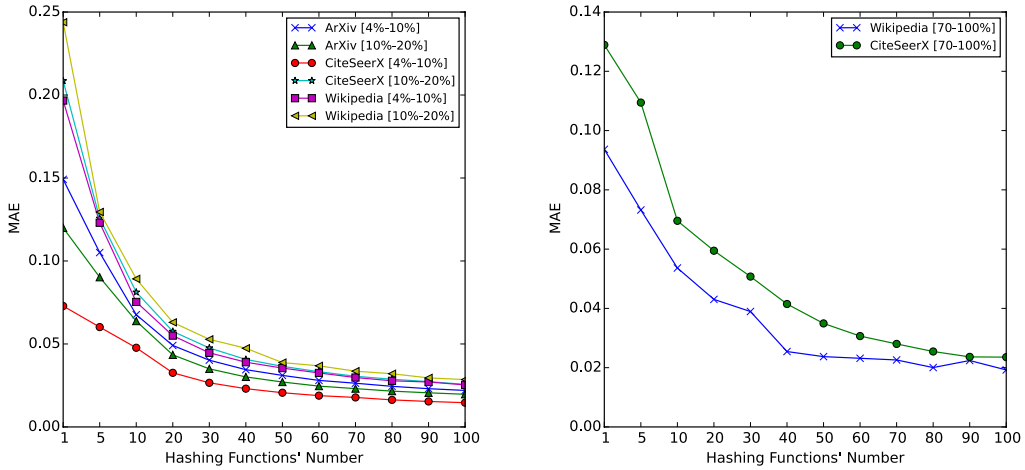
$$\text{ANDERBERG}(X,Y) = \frac{|X \cap Y|}{|X \cap Y| + 2|X \triangle Y|},$$

where $\triangle$ is the symmetric difference. (Note that S_2 is the Anderberg similarity.) The value is zero if exactly one of the two sets is empty, and it is 1 whenever $X = Y$. In [13] it is proven that the following is an LSH scheme for it. Pick a positive integer r at random with probability 2^{-r}. Let $h_1, \ldots, h_r$ be r shingles picked independently. Then, $h(X) := (h_1(X), \ldots, h_r(X))$ is an LSH scheme for A, i.e., $\text{ANDERBERG}(X,Y) = \Pr[h(X) = h(Y)]$.

The Rogers–Tanimoto similarity is defined as

$$\text{ROGERS-TANIMOTO}(X,Y) = \frac{|X \cap Y| + \left|\overline{X \cup Y}\right|}{|X \cap Y| + \left|\overline{X \cup Y}\right| + 2|X \triangle Y|}.$$

(Note that H_2 is the Rogers–Tanimoto similarity.) The following is the LSH scheme for Rogers–Tanimoto proposed in [13]. Pick r as before, and then pick r elements $e_1, e_2, \ldots, e_r$



(a) Anderberg similarity. **(b)** Rogers-Tanimoto similarity.

Figure 3 Mean Average Error as number of hash functions applied varies.

from the ground set independently at random. The random hash function h is defined as follows. For a set X, we let $h(X) := (e_1 \in X, \ldots, e_r \in X)$ (where $e_i \in X$ is a boolean value). Given two sets X and Y, $h(X) = h(Y)$ iff the two vectors coincide on each coordinate (for each element $e = e_1, e_2, \ldots, e_r$, either both sets have it or they both do not).

Recall that in this experiment our corpora consists of bag of words in which only the one thousand most popular words are retained. So each document can be thought of as binary vector of one thousand coordinates (coordinate i is one iff the ith most popular word is in the document).

The experiment is as follows. Let h denote a generic hash function of the LSH scheme that we are testing. From each corpus, we picked one hundred thousand random pairs of documents. Then, for every $k \in [100]$, we selected k hash functions $h_1, \ldots, h_k$ and estimated the similarity of the random pair in the usual fashion, i.e., as the fraction of times that $h_i(X) = h_i(Y)$, for $i \in [k]$.

Figure 3a shows, for each value of k on the x-axis, the mean absolute error (MAE) w.r.t. the real value of Anderberg. Note that already for $k = 20$ the MAE is below 0.05. Since the expected number of shingles used in each h is two (with very small variance) this shows the LSH scheme is inexpensive both time-wise and space-wise. Similar conclusions apply to Rogers–Tanimoto, as Figure 3b shows.

The experimental results show that the MAE decreases as the number of hashing functions applied increase for each of the databases and similarities tested, reinforcing the theoretical aspects of LSH applied to specific group of similarities that admit such an LSH.

8 Conclusions

In this paper we studied the notion of distorted locality sensitive hashing schemes for a number of widely-used similarities that do not admit exact such schemes. For most of them, we have obtained tight bounds on the minimum distortion required for obtaining an LSH. In doing so, we developed two lower bounding tools that could be useful for bounding the distortion of other similarities that are not LSHable.

To complement our theoretical bounds, we also studied the behavior of our proposed distorted LSH schemes on real datasets. Our main observation is that in practice, the average distortion is milder than what is dictated by the worst-case bounds.

It will be interesting to consider other non-LSHable similarities and study their distortion. The encyclopedia [15] is a rich source for such similarities.

Acknowledgments. We thank the anonymous reviewers for several useful comments and suggestions.

Abstract

Let $\mathcal{B}$ be a linear space of matrices over a field $\mathbb{F}$ spanned by $n \times n$ matrices $B_1, \ldots, B_m$. The non-commutative rank of $\mathcal{B}$ is the minimum $r \in \mathbb{N}$ such that there exists $U \leq \mathbb{F}^n$ satisfying $\dim(U) - \dim(\mathcal{B}(U)) \geq n - r$, where $\mathcal{B}(U) := span(\cup_{i\in[m]} B_i(U))$.

Computing the non-commutative rank generalizes some well-known problems including the bipartite graph maximum matching problem and the linear matroid intersection problem.

In this paper we give a deterministic polynomial-time algorithm to compute the non-commutative rank over any field $\mathbb{F}$. Prior to our work, such an algorithm was only known over the rational number field $\mathbb{Q}$, a result due to Garg et al, [20]. Our algorithm is constructive and produces a witness certifying the non-commutative rank, a feature that is missing in the algorithm from [20].

Our result is built on techniques which we developed in a previous paper [24], with a new reduction procedure that helps to keep the blow-up parameter small. There are two ways to realize this reduction. The first involves constructivizing a key result of Derksen and Makam [12] which they developed in order to prove that the null cone of matrix semi-invariants is cut out by generators whose degree is polynomial in the size of the matrices involved. We also give a second, simpler method to achieve this. This gives another proof of the polynomial upper bound on the degree of the generators cutting out the null cone of matrix semi-invariants.

Both the invariant-theoretic result and the algorithmic result rely crucially on the regularity lemma proved in [24]. In this paper we improve on the constructive version of the regularity lemma from [24] by removing a technical coprime condition that was assumed there.

1 Introduction

1.1 From the bipartite perfect matching problem to the commutative and non-commutative rank problems

Given a bipartite graph $G = (L \cup R, E)$ where $|L| = |R|$, the celebrated Hall's marriage theorem states that G has a perfect matching if and only if G has no *shrunk subsets*: $S \subseteq L$ is called a shrunk subset, if $|N(S)| < |S|$ where $N(S)$ denotes the set of neighbours of S.

Consider the following linear algebraic analogue of the bipartite perfect matching problem. Let $\mathbb{F}$ be a field, and let $U \cong V \cong \mathbb{F}^n$ be two vector spaces. We assume $\mathbb{F}$ is large (larger than a fixed polynomial in n is enough). U and V may be thought of as corresponding to sets of vertices. In a bipartite graph, each edge may be viewed as a "partial function" from the left vertex set to the right vertex set. Carrying out this analogue, in the linear algebraic setting we shall think of one linear map from U to V as one edge. After fixing bases of U and V this linear map is represented as a matrix. Let $M(n, \mathbb{F})$ denote the linear space of $n \times n$ matrices over $\mathbb{F}$. Then the edge set in the linear algebraic setting is just a set of matrices, and suppose we have m matrices $\{B_1, \ldots, B_m\} \subseteq M(n, \mathbb{F})$.

In a bipartite graph, a perfect matching is a subset of edges that form a bijective function from the left vertex set to the right vertex set. Choosing a subset of edges can be viewed as assigning 0 and 1 to the edges and then selecting those edges with 1's. This leads us to consider linear combinations of the matrices in the linear algebraic setting. That is, we are interested in the linear span of the given matrices $B_1, \ldots, B_m \in M(n, \mathbb{F})$, denoted as $\mathcal{B} = \text{span}(B_1, \ldots, B_m) \leq M(n, \mathbb{F})$. We call a linear subspace of $M(n, \mathbb{F})$ a *matrix space*. A "perfect matching" in the linear algebraic setting is then naturally a full-rank (non-singular) matrix as it is a bijective linear map between the left and the right vector spaces. A matrix space is *non-singular* if it contains a non-singular matrix, and *singular* otherwise.

It is also easy to obtain an analogue of shrunk subsets as in the Hall's marriage theorem. For $c \in \mathbb{N}$, we call $W \leq U$ a *c-shrunk subspace* of $\mathcal{B} = \text{span}(B_1, \ldots, B_m) \leq M(n, \mathbb{F})$, if $\dim(W) - \dim(\mathcal{B}(W)) \geq c$ where $\mathcal{B}(W) := \text{span}(\cup_{i \in [m]} B_i(W))$. We also call $W \leq U$ a shrunk subspace if it is a c-shrunk subspace for some $c \geq 1$. Clearly, if $\mathcal{B}$ possesses a shrunk subspace then it is singular.

A natural question is then whether the analogue of Hall's theorem holds, that is, whether every singular matrix space has a shrunk subspace. A counter-example is not hard to find, as evidenced by the linear space of 3×3 skew-symmetric matrices. That is, while perfect matchings and shrunk subsets are two sides of the same coin for bipartite graphs, non-singular matrices and shrunk subspaces are not in the linear algebraic setting. This gives rise to two natural algorithmic problems.

Input Given $B_1, \ldots, B_m \in M(n, \mathbb{F})$, let $\mathcal{B}$ be the matrix space spanned by these matrices.

The commutative rank problem Call the maximum rank over matrices in $\mathcal{B}$ the *commutative rank* of $\mathcal{B}$, denoted as $\text{crk}(\mathcal{B})$. The commutative rank problem asks to compute $\text{crk}(\mathcal{B})$.

The non-commutative rank problem Define the non-commutative corank to be the maximum $c \in \mathbb{N}$ such that there exists a c-shrunk subspace of $\mathcal{B}$, and the *non-commutative rank* to be $n - c$, denoted as $\text{ncrk}(\mathcal{B})$. The non-commutative rank problem asks to compute $\text{ncrk}(\mathcal{B})$.

The names of these problems were coined in Fortin and Reutenauer [19],[1] though both problems have been around since 1970's (see Section 1.2).

While these two problems are different in general, as suggested by the 3×3 skew-symmetric matrix space, they do coincide in some special cases. For this let us recall how the bipartite perfect matching problem and the linear matroid intersection problem can be cast as special instances of both problems.

Given a bipartite graph $G = (L \cup R, E)$ where $L = R = \{1, 2, \ldots, n\}$, for each edge $e = (i, j) \in E$ construct the elementary matrix $E_{i,j}$, which span a matrix space $\mathcal{B}$.

It is easy to see that the size of a maximum matching equals the maximum rank over matrices in $\mathcal{B}$ (over a large enough field). Hall's marriage theorem then implies that if the maximum rank is $n - c$ then there exists a c-shrunk subspace, and it is clear that if there exists a c-shrunk subspace then the maximum rank can be no larger than $n - c$. This shows that the commutative rank and the non-commutative rank coincide in this special case.

Lovász [27] observed that the linear matroid intersection problem (LMIP) can be cast as an instance of both the commutative and the non-commutative rank problems as follows. The input to LMIP is two tuples of vectors $(a_1, \ldots, a_m)$ and $(b_1, \ldots, b_m)$ where $a_i, b_j \in \mathbb{F}^n$. It asks to compute the maximum $s \in \mathbb{N}$ such that there exist $1 \le i_1 < \cdots < i_s \le m$ with both $\{a_{i_1}, \ldots, a_{i_s}\}$ and $\{b_{i_1}, \ldots, b_{i_s}\}$ being linearly independent. Construct m rank-1 matrices $a_i b_i^t$ spanning a matrix space $\mathcal{B}$. Using Edmonds' matroid intersection theorem, Lovász showed that in this case the commutative rank and the non-commutative rank of $\mathcal{B}$ coincide, and both are equal to the matroid intersection number.

1.2 Backgrounds to the commutative and non-commutative rank problems

As far as we are aware the commutative rank problem was first proposed by Edmonds [17] in 1967. It was then realized that it admits an efficient randomized algorithm via the Schwartz-Zippel lemma. Lovász [27] cast several problems from matroid theory, including the linear matroid intersection problem and the linear matroid parity problem, as special instances of the commutative rank problem. To decide whether the commutative rank is full is now better known as the *symbolic determinant identity testing* (SDIT) problem.

At present, SDIT stands at the frontier of proving arithmetic circuit lower bounds due to the celebrated work of Kabanets and Impagliazzo [25], which was recently improved by Carmosino et al [5]. They show that a deterministic efficient algorithm for SDIT implies the existence of a polynomial family such that its graph is in NE, but it cannot be computed by polynomial-size arithmetic circuits. Also, since determinants with affine entries are equivalent[33] to weakly-skew arithmetic circuits,[2], up to a polynomial overhead, SDIT is just another way of formulating the more well-known *polynomial identity testing* (PIT) problem for weakly-skew arithmetic circuits. The research into PIT has received a lot of attention since early 2000 (see the surveys [32, 30]).

[1] We explain the name choices here: from $B_1, \ldots, B_m \in M(n, \mathbb{F})$ one can construct a symbolic matrix $T = x_1B_1 + \cdots + x_mB_m$ where each entry is a linear form. When the variables x_i's commute, the rank of T over the rational function field is equal to the commutative rank (as we assumed $\mathbb{F}$ is large enough). If x_i's are non-commutative, there exists a non-commutative analogue of the rational function field, called the free skew field. Fortin and Reutenauer [19] (building on [8]) proved that the rank of T over the free skew field is equal to the non-commutative rank defined above.

[2] An arithmetic circuit is weakly skew if each product gate is of fan-in 2 and has at least one child labelled by a variable or a field element. The computation power of weakly skew circuit is between arithmetic formulas and arithmetic circuits.

The non-commutative rank problem can be traced back to 1970's, when Cohn[6, 7] raised this problem in his research on the free skew field.[3] There Cohn showed that this problem is decidable. This is already non-trivial, partly because his starting point was the free skew field, which itself is a complex object. This was improved to PSPACE by Cohn and Reutenauer [9] by reducing to testing the solvability of a system of multivariate polynomial equations. Fortin and Reutenauer [19] realized the connection between the non-commutative rank problem and the structure of matrix spaces,[4] and the definition of the non-commutative rank in terms of shrunk subspaces we have given above is due to them. Around the same time, Gurvits [21] came to the non-commutative rank problem in his study of the commutative rank problem, and endowed both the commutative and non-commutative rank problems with quantum information theoretic interpretations. In 2014, Hrubeš and Wigderson [22] studied non-commutative arithmetic formulas with divisions, and reduced the identity testing problem in this model to the non-commutative rank problem. In particular, they discovered that a good upper bound of a quantity in invariant theory (which will be explained below) implies the efficient elimination of divisions in arithmetic formulas with divisions, as well as an efficient randomized algorithm for the non-commutative rank problem.

We refer readers to [24, 20] for an introduction to the various avatars of the non-commutative rank problem.

Our main motivation to examine the non-commutative rank problem comes from its relation with the commutative one. For the purpose of getting arithmetic circuit lower bounds following [5], it is actually enough to put SDIT in NP, that is, to find a short witness which testifies the singularity of singular matrix spaces. Shrunk subspaces just form one natural class of singularity witnesses, as evidenced in its analogue with the shrunk subsets in Hall's marriage theorem and its crucial role in the linear matroid intersection problem. If we can efficiently distinguish matrix spaces with shrunk subspaces from those without then, for SDIT it would be enough to focus on singular matrix spaces without shrunk subspaces. While such spaces are known to have a rich structure, see [2, 18, 16], to further understand them and see how they can be efficiently recognized, is a natural approach to study SDIT.

1.3 Certifying matrix spaces without shrunk subspaces

Since 2015 there has been impressive progress on the non-commutative rank problem and the relevant invariant theoretic problem. To introduce this progress, let us review the link between the non-commutative rank problem and invariant theory.

Recall that the non-commutative rank problem asks to compute, given a matrix space $\mathcal{B} \leq M(n, \mathbb{F})$, the maximum c such that $\mathcal{B}$ has a c-shrunk subspace. For convenience, let us consider a decision version of this problem, that is to decide whether $\mathcal{B}$ has a shrunk subspace. One conceptual difficulty in tackling this problem is to find a short witness certifying that a matrix space $\mathcal{B}$ has no shrunk subspaces. It is clear that, if $\mathcal{B}$ has a non-singular matrix, then this non-singular matrix can be used to certify that $\mathcal{B}$ has no shrunk subspaces. But we've seen that, the space of 3×3 skew-symmetric matrices sk_3, has no non-singular matrices, nor shrunk subspaces. Our approach to resolving this difficulty is to introduce the following blow-up operation for matrix spaces. Given a matrix space $\mathcal{B} \leq M(n, \mathbb{F})$, the dth *blow-up* of

[3] The free skew field may be thought of as the non-commutative analogue of the rational function field.

[4] Fortin and Reutenauer were inspired by a paper by Eisenbud and Harris [18] in algebraic geometry. In fact matrix spaces with commutative rank bounded from above roughly correspond to certain torsion-free sheaves on projective spaces.

$\mathcal{B}$, denoted as $\mathcal{B}^{[d]}$, is defined to be the matrix space $M(d,\mathbb{F})\otimes\mathcal{B}\leq M(nd,\mathbb{F})$. It is easy to show the following.

▶ **Proposition 1.** *If $\mathcal{B}\leq M(n,\mathbb{F})$ has a c-shrunk subspace, then $\mathcal{B}^{[d]}$ has a cd-shrunk subspace.*

That is, the blow-up operation preserves shrunk subspaces. On the other hand, it is not immediately clear what the blow-up operation's effect is on matrix spaces without shrunk subspaces, though it can be shown that for sk_k, the space of skew-symmetric matrices of an odd size k, $\mathrm{sk}_k{}^{[2]}$ contains a non-singular matrix. Therefore the first question is whether for any matrix space $\mathcal{B}\leq M(n,\mathbb{F})$ without shrunk subspaces, $\mathcal{B}^{[d]}$ contains a non-singular matrix for some finite d. This turns out to be true, but to see it we need to go through several results in invariant theory and algebraic geometry.

Consider the group action of $(A,C)\in \mathrm{SL}(n,\mathbb{F})\times\mathrm{SL}(n,\mathbb{F})$ on $M(n,\mathbb{F})^{\oplus m}$ sending $(B_1,\ldots,B_m)$ to $(AB_1C^t,\ldots,AB_mC^t)$. This induces an action on the ring of polynomial functions on $M(n,\mathbb{F})^{\oplus m}$. Let $R(n,m)$ be the ring of those polynomials invariant under this action. $R(n,m)$ is called *the ring of matrix semi-invariants* (for m matrices of size $n\times n$) [24, 12]. The common zeros of all polynomials in $R(n,m)$, denoted as $N(R(n,m))$, is called the *nullcone* of this invariant ring in the invariant theory literature. The first link is the following result from invariant theory, proved using the celebrated Hilbert-Mumford criterion.

▶ **Theorem 2** ([4, 1]). *$(B_1,\ldots,B_m)$ is in $N(R(n,m))$ if and only if* $\mathrm{span}(B_1,\ldots,B_m)$ *has a shrunk subspace.*

Theorem 2 shows that matrix spaces with shrunk subspaces are characterized by those polynomials in $R(n,m)$. It is then desirable to know what polynomials in $R(n,m)$ look like. This task is usually resolved in the so-called first fundamental theorem for $R(n,m)$. In fact, it is this theorem that leads to the use of the blow-up operation.

▶ **Theorem 3** ([14, 31, 15, 1]). *Every homogeneous polynomial in $R(n,m)$ is of degree dn for some $d\in\mathbb{N}$, and is a linear combination of polynomials of the form* $\det(A_1\otimes X_1+\cdots+A_m\otimes X_m)$ *where X_i's are $n\times n$ variable matrices, and A_i's are $d\times d$ matrices over $\mathbb{F}$.*

Therefore, if $\mathrm{span}(B_1,\ldots,B_m)$ does not possess a shrunk subspace, then $(B_1,\ldots,B_m)$ is not in the null cone of $R(n,m)$ (Theorem 2). This implies that there exists some $(A_1,\ldots,A_m)\in M(d,\mathbb{F})^{\oplus m}$ such that $\det(A_1\otimes B_1+\cdots+A_m\otimes B_m)\neq 0$ (Theorem 3), which just says that $\mathcal{B}^{[d]}$ contains a non-singular matrix. This almost suggests that the blow-up operation would resolve the difficulty of certifying matrix spaces without shrunk subspaces, except that it is not immediately clear how large d needs to be for $\mathcal{B}^{[d]}$ to contain a non-singular matrix. To see that d is finite is classical: by Hilbert's basis theorem, $N(R(n,m))$ can be defined by finitely many polynomials, so d is also finite.

But if our hope is that the blow-up operation would *efficiently* certify matrix spaces without shrunk subspaces, just knowing d to be finite is not very useful – in fact, for this purpose we would require d to be upper bounded by a polynomial in n. Let $\sigma(R(n,m))$ be the smallest d such that $N(R(n,m))$ is defined by polynomials in $R(n,m)$ of degree no more than d. (This definition is valid for any invariant ring S, and to get an explicit upper bound on $\sigma(S)$ for invariant rings satisfying certain general conditions is an important research topic in invariant theory [28, 11].) Digging into the literature, from Derksen's work [11] it follows that $\sigma(R(n,m))\leq 1/4\cdot n^2\cdot 4^{n^2}$ for algebraically closed fields of characteristic 0.

Since 2015 there has been considerable progress towards a better upper bound on $\sigma(R(n,m))$. In [24] we show that $\sigma(R(n,m))\leq n!$ for all large enough fields. The key is the following so-called regularity lemma.

▶ **Lemma 4** (Regularity lemma for blow-ups, [24, Lemma 5.6]). *For $\mathcal{B} \leq M(n, \mathbb{F})$, assume that $|\mathbb{F}| > (nd)^{\Omega(1)}$. Then $\mathrm{crk}(\mathcal{B}^{[d]})$ is divisible by d.*

After [24] appeared, Derksen and Makam [12] discovered a concavity property of blow-ups, and showed that combining the regularity lemma with this property gives the following surprising result.

▶ **Theorem 5** ([12]). *Suppose $|\mathbb{F}| > n^{\Omega(1)}$. Then $\sigma(R(n,m)) \leq n^2 - n$.*

Theorem 5 immediately suggests an efficient approach to certify matrix spaces without shrunk subspaces: if $\mathcal{B}$ has no shrunk subspace, to see it we only need to exhibit a non-singular matrix in $\mathcal{B}^{[d]}$ for some $d \leq n-1$. A slightly more careful analysis suggests that if $\mathrm{ncrk}(\mathcal{B}) \geq r$, then to certify this we can exhibit a matrix in $\mathcal{B}^{[d]}$ of rank dr for some $d \leq r-1$.

By [11], this implies that $R(n,m)$ can be generated as a ring by those polynomials of degree $\leq O(n^8)$. Further consequences include improved degree bounds for generating semi-invariants of quivers (see [12]), since semi-invariants of quivers can be described as determinants of block matrices in general [15].

Soon after Derksen and Makam[12] announced their result, we discovered another argument based on the regularity lemma which gives $\sigma(R(n,m)) \leq n^2 + n$. While slightly worse in parameters, our argument is simpler than the one using the concavity property discovered by Derksen and Makam. We shall present this in Section 2.

1.4 Deterministic efficient algorithms for the non-commutative rank problem

As mentioned in Section 1.2, before 2015 it was only known that the non-commutative rank problem is in PSPACE. We gave a $\mathrm{poly}((n+1)!)$-time algorithm for this problem in 2015 [24]. Our algorithm can be viewed as a linear algebraic analogue of the augmenting path algorithm for the bipartite maximum matching problem, and relies heavily on a constructive proof of the regularity lemma.

Later that year Garg et al [20] showed that a careful analysis of an algorithm of Gurvits from 2003, [21], puts the non-commutative rank problem in P over $\mathbb{Q}$.

▶ **Theorem 6** ([20]). *Over $\mathbb{Q}$, the non-commutative rank problem is in* P.

Interestingly, Gurvits' algorithm is a quantum generalization of an algorithm for the bipartite maximum matching problem proposed by Linial et al,[26]: given the bipartite adjacency matrix of a bipartite graph, perform the row averaging and the column averaging operations alternatively. In [26] the authors proved that after a polynomially number of rounds, the resulting matrix is close to the identity matrix if and only if the bipartite graph has a perfect matching. Gurvits' algorithm is a beautiful and far-reaching generalization of the above idea to the setting of matrix spaces. It was originally used to tackle the commutative rank problem when the matrix space satisfies what Gurvits called the *Edmonds-Rado property*, namely those matrix spaces that are either non-singular, or have a shrunk subspace. The main innovation of Garg et al. in [20] is to realize that, by combining the exponential bounds on $\sigma(R(n,m))$ (either from [11] or [24]) with the capacity of operators introduced by Gurvits [21], Gurvits' algorithm actually solves the non-commutative rank problem over $\mathbb{Q}$. However, their algorithm fails to output a c-shrunk subspace and a matrix of rank $(n-c)d$ in $\mathcal{B}^{[d]}$ which together certify that the non-commutative rank is $n-c$.

We observed that Derksen and Makam's [12] concavity property of blow-ups can be constructivized, and this boosted our previous $\mathrm{poly}((n+1)!)$-time algorithm to polynomial

time. As mentioned later we discovered another, simpler, constructive argument, which also achieves the same bound. This leads to our main result.

▶ **Theorem 7** (Main theorem). *Let $\mathcal{B} \leq M(n, \mathbb{F})$ be a matrix space given by a linear basis, and suppose $|\mathbb{F}| = n^{\Omega(1)}$.*

Suppose that $\mathcal{B}$ has (a priori unknown) non-commutative rank r. Then there is a deterministic algorithm using $n^{O(1)}$ arithmetic operations over $\mathbb{F}$ that constructs a matrix of rank rd in a blow-up $\mathcal{B}^{[d]}$ for some $d \leq r + 1$ as well as an $(n - r)$-shrunk subspace of $\mathbb{F}^n$ for $\mathcal{B}$. When $\mathbb{F} = \mathbb{Q}$, the final data as well as all the intermediate data have size polynomial in the size of the input data and hence the algorithm runs in polynomial time.

Compared with the algorithm in [20], our algorithm has the advantages of working with arbitrary large enough fields, and outputting a shrunk subspace and a matrix in a blow-up space certifying that the non-commutative rank is r. Note that the second feature is new even over $\mathbb{Q}$. In section 1.5 we show that the small finite fields case can also be handled.

▶ Remark.

(a) If the constructivized version of Derksen and Makam [12] is used (see Appendix A), then d in the above theorem can be improved to $d \leq r - 1$ instead of $d \leq r + 1$.

(b) Polynomial running time of the algorithm can also be proved for a wide range "concrete" base fields $\mathbb{F}$. These include sufficiently large finite fields, and also number fields and transcendental extensions of constant degree over finite fields and over number fields.

(c) In particular, the non-commutative rank can be computed in deterministic polynomial time in positive characteristic as well, assuming that the ground field is sufficiently large.

Our result also settles a question of Gurvits [21], asking if it is possible to decide efficiently, over fields of positive characteristics, whether or not there exists a non-singular matrix in a matrix space having the Edmonds-Rado property. Since the algorithm in Theorem 7 efficiently tells whether the given matrix space has a shrunk subspace (e.g. the non-commutative rank is not full), it settles Gurvits' question, when the field size is as stated in the hypothesis.

1.5 Over small finite fields

From the above, we have seen a polynomial upper bound on $\sigma(R(n, m))$, and settled the non-commutative rank problem as well as SDIT for the Edmonds-Rado class, provided that the underlying field is large enough. However we can say more, even when the base field is a "too small" finite field.

▶ **Corollary 8.** *Let $\mathbb{F}$ be a finite field of size $s < n^{O(1)}$.*

1. *Let $R(n, m)$ be the ring of matrix semi-invariants over $\mathbb{F}$. Then $\sigma(R(n, m)) \leq O((n^2 - n) \log_s n)$.*
2. *Let $\mathcal{B} \leq M(n, \mathbb{F})$ be a matrix space given by a linear basis with a priori unknown non-commutative rank r. There is a deterministic polynomial-time algorithm that constructs a matrix of rank rd in a blow-up $\mathcal{B}^{[d]}$ for some $d \leq O(r \log_s n)$, as well as an $(n - r)$-shrunk subspace of $\mathbb{F}^n$ for $\mathcal{B}$.*
3. *Let $\mathcal{B} \leq M(n, \mathbb{F})$ be a matrix space given by a linear basis satisfying the Edmonds-Rado property. Then there exists a deterministic polynomial-time algorithm that decide whether $\mathcal{B}$ has a non-singular matrix, or a shrunk-subspace.*

1.6 A technical improvement of the regularity lemma

As mentioned in Section 1.3, the regularity lemma from [24] (Lemma 4) is the key to the polynomial bound on $\sigma(R(n, m))$. Furthermore, a constructive version of it from [24] is crucial

for our algorithm for the non-commutative rank problem. Specifically, we use the regularity lemma in the algorithm in the following situation: given $A \in \mathcal{B}^{[d]}$ of rank $(r-1)d+k$ where $1 < k < d$, we wish to construct $A' \in \mathcal{B}^{[d]}$ of rank $\geq rd$ efficiently. In [24, Lemma 5.7], this was achieved under the condition that, if $\mathrm{char}(\mathbb{F}) = p > 0$, then $p \nmid d$. In this paper, we remove this coprime condition. Roughly speaking, the proof of the regularity lemma in [24] made crucial use of central division algebras, and a classical construction of such algebras is based on cyclic field extensions. Therefore an efficient construction of cyclic field extensions is the basis of the constructive regularity lemma. In [24] an efficient construction of cyclic field extensions is presented assuming that the extension degree and the field characteristic are coprime. We remove this coprime condition to get a complete constructive proof of the regularity lemma. The technical details of this construction are given in Appendix B.

We note that recently Derksen and Makam obtained another proof of the regularity lemma in [13]. However they remark [13] that their proof is "less constructive".

Organization of the article

In Section 2 we present our proof of the n^2+n upper bound on $\sigma(R(n,m))$. In Section 3 we outline the algorithm in [24] and explain how the idea in Section 2 can be used to bring down its time complexity from exponential to polynomial, both intuitively (Section 3.1) and rigorously (Section 3.2). Section 4 contains the proof of Corollary 8. A proof of the full constructive regularity lemma is given in section 5. In Appendix A we show how the concavity property of Derksen and Makam can be constructivized. In Appendix B, we give an efficient construction of cyclic field extensions.

2 Another proof of a polynomial upper bound on defining the nullcone of matrix semi-invariants

In this short section we show how a simple argument based on the regularity lemma (Lemma 4) proves that $\sigma(R(n,m)) \leq n^2+n$. Let us remark again that Derksen and Makam [12] were the first to prove that $\sigma(R(n,m)) \leq n^2-n$. They too relied crucially on the regularity lemma from [24]. Here we present a simpler proof, albeit with a slightly worse parameter.

▶ **Theorem 9.** *Suppose* $|\mathbb{F}| > n^{\Omega(1)}$. *Then* $\sigma(R(n,m)) \leq n^2+n$.

Proof. Suppose $\mathcal{B} \leq M(n,\mathbb{F})$ is of dimension m. To prove the statement, we need to show that for any such $\mathcal{B}$, $\mathcal{B}^{[d]}$ contains a non-singular matrix for some $d \leq n+1$. As explained in Section 2, by Theorem 2 and 3, as well as Hilbert's basis theorem, $\mathcal{B}^{[d]}$ contains a non-singular matrix A for some $d \in \mathbb{N}$. If $d > n+1$, then note that $A \in \mathcal{B}^{[d]} \leq M(d,\mathbb{F}) \otimes M(n,\mathbb{F})$ is a $d \times d$ block matrix where each block is of size $n \times n$. Let A' be the right lower $(d-1) \times (d-1)$ block matrix of A; note that $A' \in \mathcal{B}^{[d-1]}$. Since A' is obtained from A by removing n rows and n columns, we have $\mathrm{rk}(A') \geq dn-2n = dn-n+1-(n+1) > dn-n+1-d = (d-1)(n-1)$, which gives $\mathrm{crk}(\mathcal{B}^{[d-1]}) > (d-1)(n-1)$. By Lemma 4, $\mathrm{crk}(\mathcal{B}^{[d-1]})$ has to be divisible by $(d-1)$, so $\mathrm{crk}(\mathcal{B}^{[d-1]}) = (d-1)n$ is of full rank. Continuing this way we can reduce d to be no more than $n+1$. ◀

3 Proof of the main theorem

As mentioned in Section 1.4, the algorithm for Theorem 7 is obtained by combining the algorithm in [24] with the idea in the proof of Theorem 9. For the readers convenience we give an intuitive explanation of the algorithm from [24] in Section 3.1; the reader is referred

to [24] for a rigorous treatment. We also explain why it runs in exponential time and how the idea in the proof of Theorem 9 can reduce its complexity to polynomial. Section 3.2 gives a rigorous treatment of the algorithm that proves Theorem 9.

3.1 Outline of the algorithm in [24]

The algorithm in [24] can be viewed as an analogue of the augmenting path algorithm for the bipartite matching problem. However, due to the failure of the analogue of Hall's marriage theorem in the matrix space setting, there are a couple of new and sophisticated components.

Given a matching T for the input bipartite graph $G = (L \cup R, E)$, the algorithm tries to find an augmenting path for T. If an augmenting path is found, T is replaced by a larger matching T'. If no augmenting paths can be found, the algorithm can output a shrunk subset as the certificate of the maximality of T.

We hope to implement the above idea for the non-commutative rank problem. Given a matrix $A \in \mathcal{B} = \mathrm{span}(B_1, \ldots, B_m) \leq M(n, \mathbb{F})$, we would like to either find an "augmenting path" for it and increase its rank, or output a c-shrunk subspace where $c = \mathrm{cork}(A)$.

A linear algebraic analogue of augmenting paths has been developed in [23]. Given a subspace $U \leq \mathbb{F}^n$, let $A^{-1}(U)$ be the preimage of U under A, namely the subspace $\{v \in \mathbb{F}^n : A(v) \in U\}$. We also define $\mathcal{B}(U) := \mathrm{span}(\cup_{i\in[m]} B_i(U))$. Given $A \in \mathcal{B} \leq M(n, \mathbb{F})$, we apply $\mathcal{B}$ and A^{-1} iteratively to $V_0 = \ker(A)$, to get $W_1 = \mathcal{B}(V_0)$, $V_1 = A^{-1}(W_1)$, $W_2 = \mathcal{B}(V_1)$, $\ldots$, $V_i = A^{-1}(W_i)$, $W_{i+1} = \mathcal{B}(V_i)$, $\ldots$. It can be shown that for some $\ell \in [n]$, $W_1 < W_2 < \cdots < W_\ell = W_{\ell+1} = \ldots$, and this is called *the second Wong sequence* of $(A, \mathcal{B})$.[5][6] W_ℓ is called the *limit subspace* of this sequence.

In [23], it was proved that $W_\ell \leq \mathrm{im}(A)$ if and only if $\mathcal{B}$ has a $\mathrm{cork}(A)$-shrunk subspace[7]. Therefore when $W_\ell \leq \mathrm{im}(A)$, we can conclude that the non-commutative rank is $\mathrm{rk}(A)$. On the other hand, when $W_\ell \not\leq \mathrm{im}(A)$, following the bipartite maximum matching algorithm it seems natural to try to obtain $A' \in \mathcal{B}$ with $\mathrm{rk}(A') > \mathrm{rk}(A)$. However this is not always possible, as it can be the case that $\mathrm{rk}(A) = \mathrm{crk}(\mathcal{B})$ and $\mathrm{crk}(\mathcal{B}) < \mathrm{ncrk}(\mathcal{B})$. Thanks to Theorem 9, the key to resolve this difficulty is to find $A' \in \mathcal{B}^{[d]}$ of rank $\geq (r+1)d$ for some not too large d. (So that the scaled-down rank $\mathrm{rk}(A')/d$ is larger than r.) This is accomplished in two steps.

The first step is to obtain a matrix $\widehat{A} \in \mathcal{B}^{[d]}$ of rank $\geq rd + 1$ where $d = r + 1$. To see how this step works, notice first that by multiplying A and $\mathcal{B}$ with an appropriate matrix, one can arrange A to be idempotent. In that case, as long as $W_1, \ldots, W_{j-1}$ remain inside $\mathrm{im}(A)$, we have $W_j = \mathcal{B}^j \ker(A)$. Let k be the smallest index j with $W_j \not\leq \mathrm{im}(A)$. Obviously $k \leq r + 1$. Then there exist indices $1 \leq i_1, \ldots, i_k \leq m$ such that $B_1 \cdots B_k \ker(A) \not\leq \mathrm{im}(A)$. It would be nice if one could find a *single* matrix $B \in \mathcal{B}$ such that $B^k \ker(A) \not\leq \mathrm{im}(A)$: if this indeed happens, then for some λ and μ from a subset of the base field of size at least $r + 1$ one would have $\mathrm{rk}(\mu A + \lambda B) > \mathrm{rk}(A)$. This is because of the result from [3], where it is proved that for two-dimensional matrix spaces the commutative and the non-commutative ranks coincide.

---

[5] The first Wong sequence is the dual of the second one. This naming convention is due to Wong [34] who defined the two sequences for the special case when $\mathcal{B}$ is of dimension 1. See [23] for more details.

[6] Over $\mathbb{Q}$ the straightforward implementation of the second Wong sequence may lead to a bit size explosion. To avoid that some tricks are needed; see [23].

[7] At the time of writing the first version of [23], the authors were unaware of [19] where actually this statement has already appeared. The real value added in [23] was that, in certain special cases, when $W_\ell \not\leq \mathrm{im}(A)$ the second Wong sequence could be used to find an "augmenting" matrix B from $\mathcal{B}$ such that $\mathrm{rk}(\mu A + \lambda B) > \mathrm{rk}(A)$ for some scalars λ and μ.

The main ingredient of the algorithm in [23] was a method to find such a $B \in \mathcal{B}$ in certain special cases. The idea in [24] is that if we relax our requirement and instead work in $\mathcal{B}^{[d]}$, then this can be achieved in a simple way, for every matrix space $\mathcal{B}$. Observe that $A \otimes I_d$ is a matrix from $\mathcal{B}^{[d]}$ of rank rd. Let $E_{i,j}$ be the elementary matrix with the (i,j)th entry being 1 and others 0. Put $\widehat{B} = B_1 \otimes E_{1,2} + B_2 \otimes E_{2,3} + \ldots B_{k-1} \otimes E_{k-1,k} + B_k \otimes E_{k,1} \in \mathcal{B}^{[d]}$. Then $\widehat{B}^k = (B_1 \cdots B_k) \otimes E_{1,1} + (B_2 \cdots B_k B_1) \otimes E_{2,2} + \ldots + (B_k B_1 \cdots B_{k-1}) \otimes E_{k,k}$, whence $\widehat{B}^k \ker(A \otimes I_d) \not\leq \mathrm{im}(A \otimes I_d)$. Therefore $\widehat{A} = \mu(A \otimes I_d) + \lambda \widehat{B}$ will have rank larger than rd for some λ and μ from a subset of the base field of size $rd + 1$.

For the second step, starting with $\widehat{A}$, we wish to get the desired $A' \in \mathcal{B}^{[d]}$ of rank $\geq (r+1)d$. This is accomplished by the constructive regularity lemma ([24, Lemma 5.7]; see Lemma 11 in Section 3.2).

This $A' \in \mathcal{B}^{[d]}$ of rank $\geq (r+1)d$ where $d = r + 1$ certifies that $\mathrm{ncrk}(\mathcal{B}) \geq r + 1$. (If $\mathrm{ncrk}(\mathcal{B}) \leq r$ then $\mathrm{crk}(\mathcal{B}^{[d]}) \leq rd$ for any d by Proposition 1.) So after these two steps we obtain A' of rank $r'd$ where $r' > r$.

In the next phase, we need to use A' and $\mathcal{B}^{[d]}$ to restart the above procedure, hoping either to find a $\mathrm{cork}(A')$-shrunk subspace, or to obtain some A'' in $\mathcal{B}^{[dd']}$ of rank $r''dd'$ where $r'' > r'$. We then apply the second Wong sequence to work with the blow-up space $\mathcal{B}^{[d]}$ and A'.[8] If $\mathrm{cork}(A')$-shrunk subspace U' is found for $\mathcal{B}^{[d]}$, then this naturally induces a $\mathrm{cork}(A')/d$-shrunk subspace U for $\mathcal{B}$ [24, Proposition 5.2]. In this case we conclude that the non-commutative rank is r', and A' and U together serve as witnesses for this fact. If the limit subspace goes out of $\mathrm{im}(A')$ we need to go to an even larger blow-up space $(\mathcal{B}^{[d]})^{[d']} \cong \mathcal{B}^{[dd']}$ where $d' = r' + 1$ to find a matrix $A'' \in \mathcal{B}^{[dd']}$ of rank $r''dd'$ for some $r'' > r'$.

So the right approach to carrying out the augmenting path idea in this setting is to play with shrunk subspaces on one hand, and matrices in the blow-up spaces on the other.

The alert reader may now notice that the above strategy leads to an exponential-time algorithm. Recall that we start with $A \in \mathcal{B}$ of rank r. If $\mathrm{ncrk}(\mathcal{B}) = n$, then we may end up finding $A^* \in \mathcal{B}^{[d^*]}$ of rank nd^* where d^* can be as large as $n!/r!$. This is because, increasing the scaled-down rank from r' to $r' + 1$ would lead to a multiplicative factor of $r' + 1$ in the size of the blow-up space. This is why the algorithm in [24] runs in time $\mathrm{poly}(n!)$.

However, the idea in the proof of Theorem 9 readily implies that, once we find A' of rank $r'd$ in $\mathcal{B}^{[d]}$, we can efficiently reduce d to be no more than $r' + 1$. This means that we can always ensure that the blow-up factor is small, which is the key to reducing the complexity from exponential time to polynomial time. We make the above idea rigorous.

3.2 The algorithm for the main theorem

In this subsection we prove Theorem 7. Here it is easier to work with $\mathcal{B}^{\{d\}} := \mathcal{B} \otimes M(d, \mathbb{F})$ instead of $\mathcal{B}^{[d]} = M(d, \mathbb{F}) \otimes \mathcal{B}$. This does not change anything, as $\mathcal{B}^{[d]}$ is isomorphic to $\mathcal{B}^{\{d\}}$. The point is that we now think of matrices in the blow-up space as $n \times n$ block matrices with blocks of size $d \times d$. We first recall some notions from [24].

Finding an sd-shrunk subspace for the $\mathcal{B}^{\{d\}}$ is equivalent to finding an s-shrunk subspace for $\mathcal{B}$ because of the following simple observations ([24, Proposition 5.2]). Firstly, for every s-shrunk subspace U of $\mathbb{F}^n$ the subspace $U \otimes \mathbb{F}^d$ for $\mathcal{B}$ is an sd-shrunk subspace for $\mathcal{B}^{\{d\}}$. Conversely, a s'-shrunk subspace for $\mathcal{B}^{\{d\}}$ can be embedded into a subspace of the form $U \otimes \mathbb{F}^d$ where U is an s-shrunk subspace for $\mathcal{B}$ with $sd \geq s'$.

[8] When the second Wong sequence is applied to such blow-up spaces then it has some nice properties; cf. the proof for Theorem 5.10 in [24].

We shall also need the following useful lemma.

▶ **Lemma 10** (Data reduction, [10] and [24, Lemma 5.3]). *Let $\mathcal{B} \leq M(k \times \ell, \mathbb{F})$ be given by a basis $B_1, \ldots, B_m$, and let $\mathbb{K}$ be an extension field of $\mathbb{F}$. Let S be a subset of $\mathbb{F}$ of size at least $r+1$. Suppose that we are given a matrix $A' = \sum_i a'_i B_i \in \mathcal{B} \otimes_{\mathbb{F}} \mathbb{K}$ of rank at least r. Then we can find $A = \sum_i a_i B_i$ of rank also at least r with $a_i \in S$. The algorithm uses* $\mathrm{poly}(k, \ell, r)$ *rank computations for matrices of the form $\sum \sigma_i A_i$ where $a''_i \in \{a'_1, \ldots, a'_m\} \cup S$.*

We now present the formal statement of the constructive regularity lemma in its full generality, with an addition of a technical notion that will be useful for the proof of Theorem 7. Let $n \in \mathbb{N}$, and let $\mathbf{i} = (i_1, \ldots, i_r)$, $\mathbf{j} = (j_1, \ldots, j_r)$ be two sequences of integers, where $1 \leq i_1 < \cdots < i_r \leq n$ and $1 \leq j_1 < \cdots < j_r \leq n$. For a matrix $A \in M(n, \mathbb{F}) \otimes M(d, \mathbb{F})$, the $r \times r$ *window* indexed by $\mathbf{i}, \mathbf{j}$ is the sub-matrix of A consisting of the blocks indexed by (i_k, j_ℓ), $k, \ell \in [r]$.

▶ **Lemma 11** (The complete constructive regularity lemma). *For $\mathcal{B} \leq M(n, \mathbb{F})$ and $\mathcal{A} = \mathcal{B}^{\{d\}}$, assume that $|\mathbb{F}| = (rd)^{\Omega(1)}$. Given a matrix $A \in \mathcal{A}$ with $\mathrm{rk} A > (r-1)d$, there exists a deterministic algorithm that returns $\widetilde{A} \in \mathcal{A}$ and an $r \times r$ window W in $\widetilde{A}$ such that W is non-singular (of rank rd). This algorithm uses* $\mathrm{poly}(nd)$ *arithmetic operations and, over $\mathbb{Q}$, the algorithm runs in polynomial time (in particular, all intermediate numbers have bit lengths polynomial in the input size).*

The cases (a) $\mathrm{char}(\mathbb{F}) = 0$, (b) $\mathrm{char}(\mathbb{F})$ and d are coprime, and $|\mathbb{F}| = (rd)^{\Omega(1)}$ were settled in [24, Lemma 5.7]. We will remove this coprime condition in .

The main technical ingredient of our algorithm will be the following result,[24, Theorem 5.10] based on Lemma 11, and the second Wong sequences introduced in [19] and [23]. It states that either a shrunk subspace witnessing that the (scaled-down) rank of a matrix in a blow-up reaches the non-commutative rank or a matrix in a larger blow-up having larger scaled-down rank can be efficiently constructed.

▶ **Theorem 12** ([24, Theorem 5.10]). *Let $\mathcal{B} \leq M(n, \mathbb{F})$ and let $\mathcal{A} = \mathcal{B}^{\{d\}}$. Assume that we are given a matrix $A \in \mathcal{A}$ with $\mathrm{rk}(A) = rd$, and $|\mathbb{F}|$ is $(ndd')^{\Omega(1)}$, where $d' > r$ is any positive integer.*

There exists a deterministic algorithm that returns either an $(n-r)d$-shrunk subspace for $\mathcal{A}$ (equivalently, an $(n-r)$-shrunk subspace for $\mathcal{B}$), or a matrix $B \in \mathcal{A} \otimes M(d', \mathbb{F})$ of rank at least $(r+1)dd'$. Furthermore, in the latter case an $(r+1) \times (r+1)$ window is also found such that the corresponding $(r+1)dd' \times (r+1)dd'$ sub-matrix of B has full rank. This algorithm uses $\mathrm{poly}(ndd')$ *arithmetic operations and, over $\mathbb{Q}$, all intermediate numbers have bit lengths polynomial in the input size.*

The sentence on the $(r+1) \times (r+1)$ window was not explicitly stated in [24]. However, the algorithm in its proof contains, as a last step, a call to the method behind Lemma 11. Also, the theorem was stated only under the assumption that d was not divisible by $\mathrm{char}(\mathbb{F})$ because of this last call. As the algorithm up to this step constructs a matrix of rank greater than rdd', the complete constructive regularity lemma, as stated in Lemma 11, makes it possible to dispense with that assumption.

To complete the proof Theorem 7, the regularity lemma needs to be accompanied with a reduction procedure that keeps the blow-up parameter small. In this section we use our method, which follows immediately from the proof of Theorem 9. The method based on the Derksen-Makam idea is presented in Appendix A.

▶ **Lemma 13.** *Let $\mathcal{B} \leq M(n,\mathbb{F})$, and $d > n+1$. Assume we are given a matrix $A \in \mathcal{B}^{\{d\}}$ of rank dn. Then there exists a deterministic polynomial-time procedure that constructs $A' \in \mathcal{B}^{\{d-1\}}$ of rank $(d-1)n$.*

Proof. Let A'' be an appropriate $(d-1)n \times (d-1)n$ submatrix of A corresponding to a matrix in $\mathcal{B}^{\{d-1\}}$. We claim A'' is of rank $> (d-1)(n-1)$. Suppose not, as A is obtained from A'' from adding n rows and then n columns, and $d > n+1$, we have $\mathrm{rk}(A) \leq \mathrm{rk}(A'') + 2n \leq dn - d - n + 1 + 2n < dn$, a contradiction. Now that $\mathrm{rk}(A'') > (d-1)(n-1)$, using Lemma 11, we obtain $A' \leq \mathcal{B}^{\{d-1\}}$ of rank $(d-1)n$. ◀

Proof of Theorem 7. Let $B_1, \ldots, B_m$ be the input basis for $\mathcal{B}$. The algorithm is an iteration based on Theorem 12. In each round we start with a matrix $A = \sum_i B_i \otimes T_i \in \mathcal{B}^{\{d\}}$ of rank rd for some integer $d \leq r+1$.

In the first round, $d = 1$ and A can be taken as any matrix in $\mathcal{B}$. The procedure behind Theorem 12 either returns an $(n-r)$-shrunk subspace (in which case we are done), or a new matrix (denoted also by A) in a blow-up $\mathcal{B}^{\{d'\}}$ of rank $\geq (r+1)d'$ for some $d' \leq (r+1)^2$, together with a square window of size $r+1$ so that the corresponding sub-matrix of A is of rank $(r+1)d'$.

If $d' > r+2$ then we apply Lemma 13 as follows. The n in the statement of Lemma 13 will be $r+1$, and we use it repeatedly to get a matrix in the $(r+2)$-blow-up, the main content of which consists of $(r+2) \times (r+2)$ matrices $T'_1, \ldots, T'_m$ such that the corresponding $(r+1)(r+2) \times (r+1)(r+2)$ sub-matrix of $A' = \sum_i B_i \otimes T'_i$ has full rank. Then we replace A with A' and apply the size reduction procedure in Lemma 10 to ensure that the entries of T_i are from the prescribed subset of $\mathbb{F}$, and continue the iteration with this new matrix A. ◀

4 Proof of Corollary 8: the case of small finite fields

We only need to prove Corollary 8 (2), from which (1) and (3) are immediate.

Given a matrix space $\mathcal{B} \leq M(n,\mathbb{F})$ and a field extension $\mathbb{K}/\mathbb{F}$, $\mathcal{B}$ can be viewed naturally as a matrix space in $M(n,\mathbb{K})$. For convenience we use $\mathrm{ncrk}_{\mathbb{F}}(\mathcal{B})$ to signal that we consider the non-commutative rank of $\mathcal{B}$ over $\mathbb{F}$. Observe first that the non-commutative rank does not change under field extensions. This is classical, and can be seen from the perspective of the second Wong sequences (see e.g. [23, Section 2]). Note that unlike the non-commutative rank the commutative rank may get larger if we go to an extension field of a too-small field.

▶ **Lemma 14.** *Given $\mathcal{B} \leq M(n,\mathbb{F})$ and a field extension $\mathbb{K}/\mathbb{F}$, we have $\mathrm{ncrk}_{\mathbb{F}}(\mathcal{B}) = \mathrm{ncrk}_{\mathbb{K}}(\mathcal{B})$.*

Suppose $\mathcal{B} \leq M(n,\mathbb{F})$ is given by a linear basis $\{B_1, \ldots, B_m\}$. Let $\mathbb{K}/\mathbb{F}$ be a field extension of degree g so that $|\mathbb{K}| = n^{\Omega(1)}$ satisfies the field size condition of Theorem 7. Note that $g \leq O(\log_{|\mathbb{F}|} n)$. Viewing $\mathcal{B}$ as a matrix space over $\mathbb{K}$, we apply Theorem 7 to compute $\mathrm{ncrk}_{\mathbb{K}}(\mathcal{B})$, which is equal to $r = \mathrm{ncrk}_{\mathbb{F}}(\mathcal{B})$ by Lemma 14. We also obtain the following: (1) $A_1, \ldots, A_m \in M(d,\mathbb{K})$ such that $A = \sum_{i\in[m]} A_i \otimes B_i$ is of rank rd, and (2) $U \leq \mathbb{K}^n$ such that U is a shrunk subspace of $\mathcal{B}$ a matrix space in $M(n,\mathbb{K})$. We fix an embedding ϕ of $\mathbb{K}$ into $M(g,\mathbb{F})$ using the regular representation. For $i \in [m]$, construct $\widetilde{A_i} \in M(gd,\mathbb{F})$ by replacing each entry α of A_i with $\phi(\alpha)$, and form $\widetilde{A} = \sum_{i\in[m]} \widetilde{A_i} \otimes B_i$. Note that $\widetilde{A}$ is in $M(gd,\mathbb{F}) \otimes \mathcal{B}$, and it can be seen easily that $\mathrm{rk}(\widetilde{A}) = g \cdot \mathrm{rk}(A)$. Since $\mathrm{rk}(\widetilde{A})/gd = r = \mathrm{ncrk}_{\mathbb{F}}(\mathcal{B})$, we have $\mathrm{crk}_{\mathbb{F}}(M(gd,\mathbb{F}) \otimes \mathcal{B}) = \mathrm{ncrk}_{\mathbb{F}}(M(gd,\mathbb{F}) \otimes \mathcal{B})$. This implies that we can apply the second Wong sequence to $(\widetilde{A}, M(gd,\mathbb{F}) \otimes \mathcal{B})$ to obtain an $(n-r)gd$-shrunk subspace of $M(gd,\mathbb{F}) \otimes \mathcal{B}$ which then induces an $(n-r)$-shrunk subspace of $\mathcal{B}$.

5 The full constructive regularity lemma

In this section we prove Lemma 11. The proof makes use of the following two results from [24], which we reproduce here as Proposition 15 and Lemma 16. Roughly speaking, Proposition 15 states that from cyclic field extensions one can construct central division algebras. Lemma 16 is the conditional constructive regularity lemma, where the condition required there is an efficient construction of central division algebras.

▶ **Proposition 15** ([24, Proposition 4.4]). *Let $\mathbb{L}$ be a cyclic extension of degree d of a field $\mathbb{K}$, and suppose that $\mathbb{L}$ is given by structure constants w.r.t. a $\mathbb{K}$-basis $A_1, \ldots, A_d$. Similarly, a generator σ for the Galois group is assumed to be given by its matrix in terms of the same basis. Let Y be a formal variable. Then one can construct a $\mathbb{K}(Y)$-basis σ of $M(d, \mathbb{K}(Y))$ such that the $\mathbb{K}(Y^d)$-linear span of σ is a central division algebra over $\mathbb{K}(Y^d)$ of index d, using* $\mathrm{poly}(d)$ *arithmetic operations in $\mathbb{K}$. Furthermore for $\mathbb{K} = \mathbb{Q}[\sqrt[d]{1}]$, the bit complexity of the algorithm, as well as the size of the output, are also* $\mathrm{poly}(d)$.

▶ **Lemma 16** (Conditional regularity [24, Lemma 5.4]). *Assume that we are given a matrix $A \in \mathcal{B}^{\{d\}} \leq M(dn, \mathbb{F})$ with $\mathrm{rk}(A) = (r-1)d + k$ for some $1 < k < d$. Let X and Y be formal variables and put $\mathbb{K} = \mathbb{F}'(X)$, where $\mathbb{F}'$ is a finite extension of $\mathbb{F}$ of degree at most d. Suppose further that $|\mathbb{F}| > (nd)^{O(1)}$ and that we are also given a $\mathbb{K}(Y)$-basis σ of $M(d, \mathbb{K}(Y))$ such that the $\mathbb{K}(Y^d)$-linear span of σ is a central division algebra D' over $\mathbb{K}(Y^d)$. Let δ be the maximum of the degrees of the polynomials appearing as numerators or denominators of the entries of the matrices in σ. Then, using $(nd + \delta)^{O(1)}$ arithmetic operations in $\mathbb{F}$, one can find a matrix $A'' \in \mathcal{B}^{\{d\}}$ with $\mathrm{rk}(A'') \geq rd$. Furthermore, over $\mathbb{Q}$ the bit complexity of the algorithm is polynomial in the size of the input data (that is, the total number of bits describing the entries of matrices and in the coefficients of polynomials).*

From the above two results, the missing piece is just an efficient construction of cyclic field extensions. In [24] such a construction based on Kummer extensions was presented assuming $\mathrm{char}(\mathbb{F})$ and d are coprime. The main issue with the case when d is divisible by $\mathrm{char}(\mathbb{F})$ is that the proof requires an efficient construction of an appropriate Artin-Schreier-Witt extension of $\mathbb{F}_p(x)$, not known to us when writing [24]. Now we have such a construction leading to the following lemma whose proof we give in appendix B.

▶ **Lemma 17.** *Let $\mathbb{F}'$ be a field. Let d be any non-negative integer. If $\mathrm{char}(\mathbb{F}') = 0$ then $d_1 = d$. If $\mathrm{char}(\mathbb{F}') = p > 0$ then let d_1 be the p-free part of d, that is, $d = d_1 p^s$, where $p \nmid d_1$ and $s \in \mathbb{N}$.*

Assume that $\mathbb{F}'$ contains a known d_1th root of unity ζ. Then a cyclic extension $\mathbb{L}$ degree d of $\mathbb{K} := \mathbb{F}'(X)$ can be computed using $\mathrm{poly}(d)$ *arithmetic operations. $\mathbb{L}$ will be given by structure constants with respect to a basis, and the matrix for a generator of the Galois group in terms of the same basis will also be given. All the output entries (the structure constants as well as the entries of the matrix representing the Galois group generator) will be polynomials of degree* $\mathrm{poly}(d)$ *in $\mathbb{F}'[X]$. Furthermore for $\mathbb{F}' = \mathbb{Q}[\sqrt[d_1]{1}]$, the bit complexity of the algorithm (as well as the size of the output) is* $\mathrm{poly}(d)$.

Proof of Lemma 11. The statement, except the window part, readily follows by plugging Lemma 17 and Proposition 15 to Lemma 16.

To see that such a window can be computed, we first observe that the lemma applies to d-blow-ups of rectangular matrices, by simple zero padding. Second, apply the lemma and find an $rd \times rd$ nonsingular sub-matrix of the given matrix A. If the column indices include some such that not all of its $d-1$ siblings are included, then (1) delete the corresponding

column from the original matrix space; (2) let A' be the matrix obtained by deleting the corresponding d columns from A. Then $\mathrm{rk}(A') > \mathrm{rk}(A) - (d-1)$. So we apply the regularity lemma in the rectangular space with A', to round up the rank to $\mathrm{rk}(A)$ again. Do the same for row indices. Iterate until we obtain a full window. ◀

Acknowledgements. We would like to thank the authors of [20] and of [12] for sharing their ideas with us and making it possible for us to read early versions of their manuscripts. Part of the work was done when Gábor and Youming were visiting the Centre for Quantum Technologies at the National University of Singapore.

A Constructivizing the result of Derksen and Makam

Here is an algorithmic version of Lemma 2.7 of [12]. Let $M(k \times \ell, \mathbb{F})$ be the space of $k \times \ell$ matrices over $\mathbb{F}$, and define $\mathcal{B}^{\{k,\ell\}} := \mathcal{B} \otimes M(k \times \ell, \mathbb{F})$.

▶ **Lemma 18.** *Let $\mathcal{B} \leq M(n, \mathbb{F})$. Assume that for $k, \ell = 1, \ldots, N$ we are given matrices $M_0(k, \ell) \in \mathcal{B}^{\{k,\ell\}}$ of rank $r_0(k, \ell)$, and suppose that $|\mathbb{F}| \geq 2nN + 1$. Then for every $k, \ell = 0, \ldots, N$ we can efficiently (that is, by an algorithm that uses $\mathrm{poly}(Nn)$ arithmetic operations and, over e.g. $\mathbb{Q}$, produces intermediate and final data of size polynomial in the input size) construct matrices $M(k, \ell) \in \mathcal{B}^{\{k,\ell\}}$ of rank $r(k, \ell) \geq r_0(k, \ell)$ such that*

(1) $r(k, \ell + 1) \geq r(k, \ell)$ $(0 \leq \ell < N)$;
(2) $r(k + 1, \ell) \geq r(k, \ell)$ $(0 \leq k < N)$;
(3) $r(k, \ell + 1) \geq \frac{1}{2}(r(k, \ell) + r(k, \ell + 2))$ $(0 \leq \ell < N - 1)$;
(4) $r(k + 1, \ell) \geq \frac{1}{2}(r(k, \ell) + r(k + 2, \ell))$ $(0 \leq k < N - 1)$;
(5) $r(k, k)$ is divisible by k.

For $k = 0$ (resp. $\ell = 0$) we assume that $M_0(k, \ell)$ is the empty matrix having ℓ columns (resp. k rows), and $r(k, \ell) = 0$.

Proof. Initially put $M(k, \ell) = M_0(k, \ell)$ for every pair (k, ℓ). For a $k \times \ell$ matrix T let T^+ denote the $(k + 1) \times \ell$ matrix obtained form T by appending a zero ($(k + 1)$st) row, T^{++} is obtained by appending two zero rows.

For $M = \sum_{i=1}^{m} B_i \otimes T_i$ we use M^+ for $\sum_{i=1}^{m} B_i \otimes T_i^+$, while $M^{++} = \sum_{i=1}^{m} B_i \otimes T_i^{++}$.

Let (k, ℓ) be a pair such that any of (1)–(5) is violated. Then we will replace some of the matrices $M(k', \ell')$ with matrices having larger rank. Over an infinite base field like $\mathbb{Q}$, each such replacement step (or each small group consisting of a few them) can be followed by an application of the data reduction procedure from [10] to keep intermediate (as well as the final) data small.

If (1) is violated then, like in [12], replace $M(k + 1, \ell)$ with $M(k, \ell)^+$. We can treat a violation of (2) symmetrically.

When (3) is violated we consider the matrix $A = A(t) = M(k + 2, \ell) + tM(k, \ell)^{++}$ as a $(k + 2) \times \ell$ block matrix consisting of square blocks of size n from $\mathcal{B}$. We can choose t from any subset S of size $2nN + 1$ of the base field so that A has rank at least $r(k + 2, \ell)$, while the first kn rows form a matrix of rank at least $r(k, \ell)$. This is because a necessary condition for violating either of these two conditions is that the determinant of an appropriate (but unknown) sub-matrix vanishes which determinant is, as a polynomial of degree at most nN in t is not identically zero. The product of these polynomials has degree at most $2nN$ therefore it cannot have more that $2nN$ zeros.

If A has rank larger than $r(k+2, \ell)$ then we replace $M(k+2, \ell)$ with A. Otherwise, like in [12], let U be the span of the first kn rows of A, V be the span of the first $(k+1)n$ rows and W be the span of the first kn rows and the last n rows. Note that these collections rows correspond to matrices of the form $A_0 = \sum B_i \otimes T_i$, $A_1 = \sum B_i \otimes T_i'$ and $A_2 = \sum B_i \otimes T_i''$ where T_i are $k \times \ell$ matrices, while T_i' and T_i'' have $(k+1)$ rows and ℓ columns. As $U \leq V \cap W$ and the row space of A is $V + W$, we have $r(k, \ell) \leq \dim U \leq \dim(V \cap W) = \dim V + \dim W - \dim V + W = \dim V + \dim W - r(k + 2, \ell)$. It follows that $\dim V + \dim W \geq r(k, \ell) + r(k + 2, \ell)$, whence violation of (3) is only possible if either $\dim V$ or $\dim W$ is strictly larger than $\frac{1}{2}(r(k, \ell) + r(k + 2, \ell))$. Then we replace $M(k + 1, \ell)$ with A_1 or A_2, according to which one has larger rank. A violation of (4) is treated symmetrically.

When (5) is violated then we can apply Lemma 11.

As in each round when violation of (1),. . .,(4) or (5) occurs the rank of at least one of the matrices $M(k,\ell)$ is incremented, the total number of rounds for achieving (1)–(5) is at most $N^3 n$. ◀

And here is essentially Proposition 2.10 of [12]. We include a proof (which is almost literally the same as the proof in [12]) here for completeness. We note that this lemma deals only with the property of certain families of functions, without referring to matrices.

▶ **Lemma 19** ([12, Proposition 2.10]). *Assume that $N > n > 0$, $r : \{0,1,\ldots,N\}^2 \to \mathbb{Z}$ is a function with $0 \le r(k,\ell) \le \min(k,\ell)n$ for $k,\ell \in \{0,1,\ldots,N\}$ also satisfying (1)–(5) of Lemma 18. Suppose further that $r(1,1) > 1$, and there exists d such that $n \le d+1 \le N$ and $r(d+1,d+1) = n(d+1)$. Then, $r(d,d) = nd$ as well.*

Proof. By $r(d+1,d+1) = n(d+1)$, for $1 \le a < d+1$,

$$r(d+1,a) \ge \frac{(d+1-1)\cdot r(d+1,0) + a \cdot r(d+1,d+1)}{d+1} = an.$$

As by assumption $r(d+1,a) \le an$, we have $r(d+1,a) = an$. Similarly $r(a,d+1) = an$ for $1 \le a < d+1$.

Then we bound $r(1,d)$ as follows:

$$\begin{aligned} r(1,d) &\ge \frac{(d-1)\cdot r(1,d+1) + 1 \cdot r(1,1)}{d} \\ &\ge \frac{(d-1)n+2}{d} = n - \frac{n-2}{d} > n-1. \end{aligned}$$

Note that we use $r(1,1) > 1$ and $d \ge n-1$. Since $r(1,d) \in \mathbb{Z}$, $r(1,d) = n$.

We are ready to bound $r(d,d)$ then.

$$\begin{aligned} r(d,d) &\ge \frac{(d-1)\cdot r(d+1,d) + 1 \cdot r(1,d)}{d} \\ &= \frac{(d-1)dn+n}{d} = nd - n + \frac{n}{d}. \end{aligned}$$

From $d \ge n-1$ it is inferred easily that $-n + \frac{n}{d} > -d$. Therefore $nd - n + \frac{n}{d} > (n-1)d$. By (5) we conclude that $r(d,d) = nd$. ◀

We finally remark that, if we use Lemma 18 in the proof of Theorem 7, then n in the statement of the lemma will be $r+1$, N will be d', $M_0(d',d')$ is the nonsingular $(r+1)d' \times (r+1)d'$ block of A and $M_0(p,q)$ can be actually even the zero matrix for $(p,q) \ne (d',d')$. It will prepare matrices in several not necessarily square blow-ups, among others, most importantly, one in an (r,r)-blow-up with a similar content as described in the proof of Theorem 7.

B Efficient construction of cyclic field extensions of arbitrary degrees

A cyclic extension of a field $\mathbb{K}$ is a finite Galois extension of $\mathbb{K}$ having a cyclic Galois group. By constructing a cyclic extension $\mathbb{L}$ we mean constructing the extension as an algebra over $\mathbb{K}$, e.g., by giving an array of *structure constants* with respect to a $\mathbb{K}$-basis for $\mathbb{L}$ defining the multiplication on $\mathbb{L}$ as well as specifying a generator of the Galois group, e.g, by its matrix with respect to a $\mathbb{K}$-basis.

▶ **Lemma 20.** *Given a prime p and an integer $s \geq 1$, one can construct in time* $\mathrm{poly}(p^s)$ *a cyclic extension K_s of $\mathbb{F}_p(Z)$ of degree p^s such that $\mathbb{F}_p$ is algebraically closed in K_s. The field K_s will be given in terms of structure constants with respect to a basis over $\mathbb{F}_p(Z)$, and the generator σ for the Galois group will be given by its matrix in terms of the same basis. The structure constants as well as the entries of the matrix for σ will be polynomials in $\mathbb{F}_p[Z]$ of degree* $\mathrm{poly}(p^s)$.

Proof. First we briefly recall the general construction given in Section 6.4 of [29]. This, starting from a field K_0 of characteristic p, recursively builds a tower $K_0 < K_1 < \ldots < K_s$ of fields such that K_j is a cyclic extension of K_0 of degree p^j. Assume that K_s together with a K_0-automorphism σ_s of order p^s has already been constructed. (Initially let σ_0 be the identity map on K_0.) Then for any element $\beta_s \in K_s$ with $\mathrm{Tr}_{K_s:K_0}(\beta_s) = 1$ and for any $\alpha_s \in K_s$ such that $\alpha_s^{\sigma_s} - \alpha_s = \beta_s^p - \beta_s$ the polynomial $X^p - X - \alpha_s$ is irreducible in $K_s[X]$. (Existence of α_s with the required property follows from the additive Hilbert 90.) Put $K_{s+1} = K_s[X]/(X^p - X - \alpha_s)$ and let $\omega_{s+1} \in K_{s+1}$ be the image of of X under the projection $K_s[X] \to K_{s+1}$. Then σ_s extends to a K_0-automorphism σ_{s+1} of degree p^{s+1} of K_{s+1} such that $\omega_{s+1}^{\sigma_{s+1}} = \omega_{s+1} + \beta_s$. This gives a cyclic extension of degree p^{s+1}.

Now we specify some details of a polynomial time construction for $K_0 = \mathbb{F}_p(Z)$. In the first step we take $\beta_0 = 1$, and, in order to guarantee that the only elements in K_1 which are algebraic over $\mathbb{F}_p$ is F_p (we also use the phrase F_p is algebraically closed in K_1 when this property holds), we take $\alpha_0 = Z$. Then K_1 is a pure transcendental extension of $\mathbb{F}_p$. As K_s/K_0 is a cyclic extension of oder p^s, it has a unique subfield which is an order p extension of K_0. This must be K_1. Then $\mathbb{F}_p$ has no proper finite extension in K_s as otherwise K_0 would also have another degree p extension.

We consider the following K_0-basis for K_s:

$$\sigma_s = \left\{ \prod_{j=1}^{s} \omega_j^k, \quad (k = 0, \ldots, p-1) \right\},$$

where ω_j is a root of $X^p - X - \alpha_{j-1}$ in K_j. We claim that $\mathrm{Tr}_{K_j:K_{j-1}}(\omega_j^{p-1}) = -1$. Indeed, in the K_{j-1}-basis $\omega_j^0, \ldots, \omega_j^{p-1}$ for K_j, in the matrix of multiplication by ω_j^{p-1} the diagonal entries consist of $p-1$ ones and one zero. Therefore $\mathrm{Tr}_{K_j:K_{j-1}}(\omega_j^{p-1}\sigma) = -\sigma$ for every $\sigma \in K_{j-1}$, whence $\mathrm{Tr}_{K_j:K_0}(\omega_j^{p-1}\sigma) = -\mathrm{Tr}_{K_{j-1}:K_0}(\sigma)$. Now by induction we obtain $\mathrm{Tr}_{K_j:K_0} \prod_{i=1}^{j} \omega_i^{p-1} = (-1)^j$. Therefore in each step (when $j > 0$) we can choose $\beta_j = (-1)^j \prod_{i=1}^{j} \omega_i^{p-1}$ and α_j thereafter, following the construction in the standard proof of the additive Hilbert 90. Specifically, we set

$$\alpha_j = (-1)^{j+1} \sum_{k=1}^{p^j-1} \beta_j^{\sigma_j^k} \left(\sum_{\ell=0}^{k-1} (\beta_j^p - \beta_j)^{\sigma_j^\ell} \right). \tag{B.1}$$

Then $\alpha_j^{\sigma_j} - \alpha_j = \beta_j^p - \beta_j$. Notice that α_j is a sum of terms with each of which, up to a sign, is a product of at most $p+1$ conjugates $\beta_j^{\sigma_j^\ell}$ (with various ℓs) of β_j ($\ell \leq p^j$)

Assume by induction that the structure constants of K_j with respect to the basis σ_j are polynomials from $\mathbb{F}_p[Z]$ of degree at most Δ_j and the same holds for the entries of the matrix of σ_j^ℓ for every $1 \leq \ell < p^j$ (written in the same basis). For $j = 1$ this holds with $\Delta_1 = 1$. (To see this, observe that for $0 \leq k, \ell < p$, the product $\omega_1^k \omega_1^\ell$ is the basis element of $\omega_1^{k+\ell}$ if $k + \ell < p$, while otherwise it equals the sum $\omega_1^{k+\ell-p+1} + Z\omega_1^{k+\ell-p}$.) Then, if we express α_j in terms of the basis σ_j using Eq. B.1, we obtain that its coordinates are polynomials of

degree at most $(2p+1)\Delta_j$. This is because $(-1)^j\beta_j \in \sigma_j$, whence $\beta_j^{\sigma^\ell}$ has coordinates of polynomials of degree bounded by Δ_j. In Eq. B.1, we have the products of at most $p+1$ such elements, so the result will have polynomial coordinates of degree at most $(2p+1)\Delta_j$.

Now consider the product of two elements $\omega_{j+1}^k\sigma_1$ and $\omega_{j+1}^\ell\sigma_2$ of σ_{j+1}. Here $k,\ell < p$ and $\sigma_1,\sigma_2 \in \sigma_j$. The coordinates of the product $\sigma_1\sigma_2$ with respect to σ_j are polynomials of degree at most Δ_j. The same holds for the product $\omega_{j+1}^{k+\ell}\sigma_1\sigma_2$ if $k+\ell < p$. If $k+\ell > p$, then $\omega_{j+1}^{k+\ell} = \omega_{j+1}^p\omega_{j+1}^{k+\ell-p} = (\omega_{j+1}+\alpha_j)\omega_{j+1}^{k+\ell-p}$, whence $\omega_{j+1}^{k+\ell}\sigma_1\sigma_2$ is the sum of $\omega_{j+1}^{1+k+\ell-p}\sigma_1\sigma_2$ and $\alpha_j\sigma_1\sigma_2$. The former term has coordinates of degree at most Δ_j, the coordinates of the latter are polynomials of degree at most $(2p+1)\Delta_j + \Delta_j + \Delta_j = (2p+3)\Delta_j$.

Now consider the conjugate of $\omega_{j+1}^k\sigma$ by σ_{j+1}^ℓ, where $1 \le \ell < p^{j+1}$, $1 \le k \le p-1$ and $\sigma \in \sigma_j$. This conjugate is $(\omega_{j+1}^{\sigma_{j+1}^\ell})^k\sigma^{\sigma_{j+1}^\ell}$. The second term equals $\sigma^{\sigma_j^\ell}$ which has coordinates of degree at most Δ_j. To investigate the first term, recall that $\omega_{j+1}^{\sigma_{j+1}} = \omega_{j+1} + \beta_j$, whence

$$\omega_{j+1}^{\sigma_{j+1}^\ell} = \omega_{j+1} + \sum_{r=0}^{\ell-1}\beta_j^{\sigma_j^r}$$

The element $\delta = \sum_{r=0}^{\ell-1}\beta_j^{\sigma_j^r}$, expressed in terms of σ_j, has again polynomial coordinates of degree at most Δ_j. Then $(\omega_{j+1}^{\sigma_{j+1}^\ell})^k$ is the sum (with binomial coefficients) of terms of the form $\omega_{j+1}^r\delta^{k-r}$. The power δ^{k-r} has coordinates of degree at most $(k-r)\Delta_j + (k-r-1)\Delta_j \le (2p-1)\Delta_j$ in terms of σ_j, whence we conclude that $(\omega_{j+1}^{\sigma_{j+1}^\ell})^k$ has, in terms of σ_{j+1} polynomial coordinates of degree at most $(2p-1)\Delta_j$. It follows that the matrix of any power of σ_{j+1} has polynomial entries of degree at most $2p\Delta_j$.

We obtained that the function $(2p+3)^s = \mathrm{poly}(p^s)$ is an upper bound for both the structure constants and for the matrices of the powers of σ_s. ◀

▶ **Lemma 17** (restated). *Let $\mathbb{F}'$ be a field. Let d be any non-negative integer. If $\mathrm{char}(\mathbb{F}') = 0$ then $d_1 = d$. If $\mathrm{char}(\mathbb{F}') = p > 0$ then let d_1 be the p-free part of d, that is, $d = d_1p^s$, where $p \nmid d_1$ and $s \in \mathbb{N}$. Assume that $\mathbb{F}'$ contains a known d_1th root of unity ζ. Then a cyclic extension $\mathbb{L}$ degree d of $\mathbb{K} := \mathbb{F}'(X)$ can be computed using $\mathrm{poly}(d)$ arithmetic operations. $\mathbb{L}$ will be given by structure constants with respect to a basis, and the matrix for a generator of the Galois group in terms of the same basis will also be given. All the output entries (the structure constants as well as the entries of the matrix representing the Galois group generator) will be polynomials of degree $\mathrm{poly}(d)$ in $\mathbb{F}'[X]$. Furthermore for $\mathbb{F}' = \mathbb{Q}[\sqrt[d_1]{1}]$, the bit complexity of the algorithm (as well as the size of the output) is $\mathrm{poly}(d)$.*

Proof. Put $\mathbb{L}_1 = \mathbb{F}'(Y)$ and $X = Y_1^{d_1}$. Then $1, Y_1, \ldots, Y_1^{d_1}$ are a $\mathbb{F}'(X)$-basis for $\mathbb{L}_1$ with $Y_1^iY_1^j = Y_1^{i+j}$ if $i+j \le d_1$ and $XY_1^{i+j-d_1}$ otherwise. Further note that the linear extension σ_1 of the map sending Y_1^j to $\zeta^jY_1^j$ is an automorphism of degree d_1. Then $\mathbb{L}_1$ is a cyclic extension of $\mathbb{F}'(X)$ of degree d_1. This procedure has been used in [24].

We can compute whether $\mathrm{char}(\mathbb{F}')$ is a divisor of d by testing the multiples of the identity element up to d. If $\mathrm{char}(\mathbb{F}') = 0$, or if $\mathrm{char}(\mathbb{F}') = p > 0$ and $p \nmid d$, we are done. Note that in the following $p \le d$.

If $\mathrm{char}(\mathbb{F}') = p > 0$ and $p \mid d$, let d_1 be in the statement, so $d = d_1p^s$. Let $d_2 = p^s$, and $\mathbb{F}_p$ be the prime field of $\mathbb{F}'$. Construct the cyclic extension of degree d_2 of $\mathbb{F}_p(X)$ over $\mathbb{F}_p$ by Lemma 20, and let the resulting field be $\mathbb{L}_2$. We also obtain the matrix a generator σ_2 of the Galois group. Then put $\mathbb{L} = \mathbb{L}_1 \otimes_{\mathbb{F}_p(X)} \mathbb{L}_2$. It contains a copy of $\mathbb{K} = \mathbb{F}'(X) \cong \mathbb{F}'(X) \otimes_{\mathbb{F}_p(X)} \mathbb{F}_p(X)$. We take the product basis for the structure constants and for matrix representation of the automorphism $\sigma_1 \otimes \sigma_2$. ◀

The Duality Gap for Two-Team Zero-Sum Games

Leonard J. Schulman[*1] **and Umesh V. Vazirani**[2]

vazirani@eecs.berkeley.edu

Abstract

We consider multiplayer games in which the players fall in two teams of size k, with payoffs equal within, and of opposite sign across, the two teams. In the classical case of $k = 1$, such zero-sum games possess a unique value, independent of order of play, due to the von Neumann minimax theorem. However, this fails for all $k > 1$; we can measure this failure by a duality gap, which quantifies the benefit of being the team to commit last to its strategy. In our main result we show that the gap equals $2(1 - 2^{1-k})$ for $m = 2$ and $2(1 - m^{-(1-o(1))k})$ for $m > 2$, with m being the size of the action space of each player. At a finer level, the cost to a team of individual players acting independently while the opposition employs joint randomness is $1 - 2^{1-k}$ for $k = 2$, and $1 - m^{-(1-o(1))k}$ for $m > 2$.

This class of multiplayer games, apart from being a natural bridge between two-player zero-sum games and general multiplayer games, is motivated from Biology (the weak selection model of evolution) and Economics (players with shared utility but poor coordination).

1 Introduction

Games between *teams* of players are ubiquitous; in the economy this occurs most prominently in competition between firms. Another case of significance is that in which a team is a biological species and the players on the team are the genes of the species. What makes a set of players a team, in our idealization, is that in any outcome the players in the set receive identical payoffs.

Competition among firms or species need not be zero-sum; however, the zero-sum case will be the focus of this paper, being the most basic form of competition, and often an approximation to reality. Specifically, a two-team zero-sum game is a multiplayer game in which the players are partitioned into two sets A and B, and a real-valued payoff tensor (of dimension equal to the number of players) specifies the payoff conditional on player actions; this payoff accrues positively to each player of Team B and negatively to each player of Team A.

If perfect coordination within each team can be achieved, then a zero-sum interaction between two teams is nothing but a zero-sum interaction between two "virtual" players. In the biological setting, the opposite extreme is relevant: an important model in evolutionary theory is the *weak selection* model (see [8, 1, 10, 9, 13, 14, 3, 7]), in which a species is a team, the genes are the players, the alleles of the gene are the possible actions of a player, and the

allele frequencies are independent across genes. Likewise, the difficulty of coordination has long been treated in the economic literature as one of the forces limiting the size of firms [4].

This raises a natural question: does von Neumann's minimax theorem for zero-sum games continue to hold for a zero-sum team game where the individual members of the team play independently, and if not can the deviation be bounded? Formally, this deviation is expressed through the *duality gap* between the values of the game (always expressed as the payoff to Team B) under two scenarios: when all members of Team A must first commit to their randomized strategies, and then Team B gets to respond; and when all members of Team B must commit, and then Team A gets to respond. Surprisingly, this natural question does not seem to have been asked before.

In Section 3 we determine the range of this duality gap: for action spaces of size 2 we give the exact answer for all k (the size of the teams); for action spaces of any size $m > 2$ we determine the asymptotics of the answer as a function of k.

The key lemma in the lower bound on the duality gap for $m > 2$ may be of independent interest: fix a random set S of $g(m)$ m-ary strings of any length k. Then with high probability, any product distribution may place probability more than $m^{-k(1-o(1))}$ (i.e. much more than the uniform distribution would) on at most $O(\log g(m))$ strings in S.

Another interesting quantity is the *defensive gap*: the defensive gap of Team B is the difference between the payoff to Team B if Team A must play a product strategy, and the payoff to Team B if Team A can use a joint (but hidden from B) source of randomness. The defensive gap quantifies the reduced effectiveness of a team when its members are constrained to choose their actions from a product distribution. Note that the duality gap is the sum of the two teams' defensive gaps.

The defensive gap may be compared to two notions in the existing literature. Assume Team A goes first, and think just of the multiplayer game being played by the k players of Team A. (Since Team B can respond optimally, even deterministically, once the strategies of Team A have been fixed, we may ignore the players of Team B and consider their response merely part of the definition of the game being played by Team A.) Then, since the payoffs to all players in Team A are identical, the defensive gap is the difference between the value of the best correlated equilibrium [2] and the best Nash equilibrium [12]. It quantifies, if you will, the penalty for not coordinating. Again, since the payoffs are identical within the team, social welfare agrees with individual welfare, and so the defensive gap is, conceptually, a Price of Stability [11] (although that "price" is normally defined as a ratio and not a difference).

Finally, in Section 4 we go on to investigate how the value of a game can be affected by more incremental changes, specifically, by exchanging the order of play of two players of opposing teams who were playing (committing to their randomized strategy) in immediate succession. There are games with duality gap bounded away from 0, in which all these value changes tend to 0 in k; whereas there are other games, including games symmetric within each team, in which the largest such value change is bounded away from 0 as a function of k.

2 Preliminaries

We consider two-team zero-sum games in which Team A has k players each with m choices in its action space; likewise for Team B. The payoff (to Team B) is specified by a tensor T in $(\mathbb{R}^m)^{\otimes 2k}$. (In the biological setting, each of A and B is a species with a genome of k genes, each taking on one of m possible alleles.) More formally to each player A_i, $i = 1, \ldots k$ of Team A corresponds a vector space $U_i \cong \mathbb{R}^m$, and to each player B_j, $j = 1, \ldots k$ of Team

B, a vector space $V_j \cong \mathbb{R}^m$. Space U_i is spanned by a basis which we denote $u_{i0}, \ldots, u_{i,m-1}$. Similarly for V_j. In this setting $T \in U_1^* \otimes \ldots \otimes U_k^* \otimes V_1^* \otimes \ldots \otimes V_k^*$. (With $*$ denoting dualization.) Letting $\boldsymbol{I} = (i_1, \ldots, i_k) \in \{0, \ldots, m-1\}^k$ represent an action of the players of Team A, and $\boldsymbol{J} = (j_1, \ldots, j_k) \in \{0, \ldots, m-1\}^k$ an action of the players of Team B, $T_{\boldsymbol{I}}^{\boldsymbol{J}}$ is the payoff to players of Team B (and minus the payoff to players of Team A).

In the case $m = 2$, the strategy of player A_i is specified by a parameter $0 \le p_i \le 1$ which is the probability with which he plays choice 0, i.e., vector u_{i0}. Likewise player B_j has a parameter $0 \le q_j \le 1$ which is the probability with which he plays choice 0, i.e., vector v_{j0}. For $m > 2$, the strategy of player A_i is specified by a probability distribution $(p_{i0}, \ldots, p_{i,m-1})$ and the strategy of player B_j is specified by a probability distribution $(q_{j0}, \ldots, q_{j,m-1})$. (Thus for $m = 2$, $(p_i, 1-p_i)$ is shorthand for (p_{i0}, p_{i1}).)

We let T_p^q denote the expected payoff to Team B when the players of Team A use distributions p_i and those of Team B use distributions q_j. This notation generalizes the notation $T_{\boldsymbol{I}}^{\boldsymbol{J}}$, if one interprets $\boldsymbol{I}$ as the probability distribution on $\{0, \ldots, m-1\}^k$ supported solely on $\boldsymbol{I}$ (and similarly for $\boldsymbol{J}$). Equivalently, T_p^q equals the scalar given by contracting T with the tensor product of the vectors $(p_{i0}, \ldots, p_{i,m-1})$ (ranging over i) and $(q_{j0}, \ldots, q_{j,m-1})$ (ranging over j).

By a standard argument, $\min_p \max_q T_p^q \ge \max_q \min_p T_p^q$. (We write everywhere min or max rather than inf or sup since the spaces are compact.) However, apart from the linear ($k = 1$) case, the gap $\min_p \max_q T_p^q - \max_q \min_p T_p^q$ can be positive.

Our purpose is to quantify this gap relative to the uniform norm $\|T\|_\infty = \max_{\boldsymbol{I},\boldsymbol{J}} |T_{\boldsymbol{I}}^{\boldsymbol{J}}|$. We define the duality gap of tensor T:

$$\mathrm{gap}(T) = \frac{\min_p \max_q T_p^q - \max_q \min_p T_p^q}{\|T\|_\infty} = \frac{\min_p \max_{\boldsymbol{J}} T_p^{\boldsymbol{J}} - \max_q \min_{\boldsymbol{I}} T_{\boldsymbol{I}}^q}{\|T\|_\infty} \tag{2.1}$$

where as above, $\boldsymbol{I}$ or $\boldsymbol{J}$ represent the pure strategy choosing that action.

The principal quantity of interest is

$$\mathrm{gap}_{m,k} = \max_T \mathrm{gap}(T) \tag{2.2}$$

ranging over games T for teams of size k and action spaces of size m. It is trivial that $\mathrm{gap}_{m,k} \le 2$. Moreover $\mathrm{gap}_{m,k}$ is nondecreasing in k (because one may ignore the actions of players after the k'th player on each team), and in m (because one may map all actions $\ge m-1$ to action $m-1$).

Here and throughout the paper, upper-case P and Q denote mixed strategies of virtual players; that is to say, each is a general probability tensor (a tensor with nonnegative entries summing to 1), $P \in U_1 \otimes \ldots \otimes U_k$ and $Q \in V_1 \otimes \ldots \otimes V_k$. Lower-case p and q denote product distributions, i.e., rank-one probability tensors.

Extending the existing notation, T_P^Q is the expected payoff to B when A (as a virtual player) uses distribution P and B uses distribution Q. It is also useful to employ the standard convention that a repeated index indicates tensor contraction over that index, so $P^{\boldsymbol{I}} T_{\boldsymbol{I}}^{\boldsymbol{J}} = T_P^{\boldsymbol{J}} \in V_1^* \otimes \ldots \otimes V_k^*$ and $Q_{\boldsymbol{J}} T_{\boldsymbol{I}}^{\boldsymbol{J}} = T_{\boldsymbol{I}}^Q \in U_1^* \otimes \ldots \otimes U_k^*$.

By strong LP duality we can define the value of the virtual player game by

$$\mathrm{Val}\, T = \min_P \max_{\boldsymbol{J}} \{P^{\boldsymbol{I}} T_{\boldsymbol{I}}^{\boldsymbol{J}}\} = \max_Q \min_{\boldsymbol{I}} \{Q_{\boldsymbol{J}} T_{\boldsymbol{I}}^{\boldsymbol{J}}\}. \tag{2.3}$$

Let P and Q be strategies achieving equality in (2.3). We can usefully refine the study of $\mathrm{gap}(T)$ by defining the *defensive gap* of Team A in tensor T as

$$\mathrm{gap}_A(T) = \frac{\min_p \max_{\boldsymbol{J}} \{p^{\boldsymbol{I}} T_{\boldsymbol{I}}^{\boldsymbol{J}}\} - \max_{\boldsymbol{J}} \{P^{\boldsymbol{I}} T_{\boldsymbol{I}}^{\boldsymbol{J}}\}}{\|T\|_\infty} = \frac{\min_p \max_{\boldsymbol{J}} \{p^{\boldsymbol{I}} T_{\boldsymbol{I}}^{\boldsymbol{J}}\} - \mathrm{Val}\, T}{\|T\|_\infty}$$

where, of course, p ranges over product distributions. Likewise the defensive gap of Team B is

$$\mathrm{gap}_B(T) = \frac{\min_{\boldsymbol{I}}\{Q_{\boldsymbol{J}} T^{\boldsymbol{J}}_{\boldsymbol{I}}\} - \max_q \min_{\boldsymbol{I}}\{q_{\boldsymbol{J}} T^{\boldsymbol{J}}_{\boldsymbol{I}}\}}{\|T\|_\infty} = \frac{\mathrm{Val}\, T - \max_q \min_{\boldsymbol{I}}\{q_{\boldsymbol{J}} T^{\boldsymbol{J}}_{\boldsymbol{I}}\}}{\|T\|_\infty}$$

The defensive gap quantifies the reduced effectiveness of a team of players (when forced to commit to a mixed strategy to which the other team has a chance to respond), as compared with a virtual player (in the same situation).

3 The Defensive Gaps and the Duality Gap

▶ **Theorem 1.** $\mathrm{gap}_{2,k} = 2(1-2^{1-k})$, *and for every* $m > 2$, $2(1-m^{-(1-o(1))k}) \le \mathrm{gap}_{m,k} \le 2(1-m^{1-k})$. *(The "*$o(1)$*" being w.r.t.* k*.) More specifically:*

1. *Upper bound on the defensive gaps and duality gap:*
   For any $m \ge 2$, *and for any* T *having action spaces of size* m, $\mathrm{gap}_A(T) \le (1 - \mathrm{Val}\, T/\|T\|_\infty)(1-m^{1-k})$ *and* $\mathrm{gap}_B(T) \le (1+\mathrm{Val}\, T/\|T\|_\infty)(1-m^{1-k})$.
2. *Lower bound on the duality gap:*
   (a) $\mathrm{gap}_{2,k} \ge 2(1-2^{1-k})$.
   (b) *For every* $m > 2$ *there is a function* $\varepsilon(k)$ *tending to* 0 *as* $k \to \infty$, *such that* $\mathrm{gap}_{m,k} \ge 2(1-m^{-(1-\varepsilon(k))k})$.

Henceforth scale any $T \neq 0$ so that $\|T\|_\infty = 1$.

Proof.

Part (1): Upper Bounds on $\mathrm{gap}_A(T)$, $\mathrm{gap}_B(T)$ and $\mathrm{gap}_{m,k}$.

It suffices to show the claim for gap_A. The claim for gap_B follows by negating all entries of T, reversing the roles of the teams and applying the claim for gap_A. The claim for the duality gap follows because $\mathrm{gap}(T) = \mathrm{gap}_A(T) + \mathrm{gap}_B(T)$.

We start with the case $m = 2$. Given an arbitrary coordinated mixed strategy P for team A, we wish to "round" it to a rank-one probability tensor (a product distribution) that does no worse than the claimed defensive gap. The natural candidate for rounding would be the approximation by independent random variables having the same marginals as P. That is, set

$$p_1 = \sum_{i_2,\ldots,i_k} P^{0,i_2,\ldots,i_k}, \quad p_2 = \sum_{i_1,i_3,\ldots,i_k} P^{i_1,0,i_3,\ldots,i_k}, \quad \text{etc.} \tag{3.1}$$

and, letting

$$p = (p_1, 1-p_1) \otimes \ldots \otimes (p_k, 1-p_k), \tag{3.2}$$

use p as the rank-one strategy replacing P, and use it to bound the defensive gap. It turns out that this approach cannot be used to prove any bound on the defensive gap. Surprisingly, there is a less obvious rank-one strategy which can be obtained from P and which provides a tight bound on the defensive gap.

For $0 \le x \le 1/2$ set

$$\beta(x) = \frac{(2x)^{1/k}}{2} \tag{3.3}$$

and for $1/2 < x \le 1$ set $\beta(x) = 1 - \beta(1-x)$. (Observe that β is increasing.)

Then use the rank-one strategy:

$$\tilde{p} = (\beta(p_1), \beta(1-p_1)) \otimes \ldots \otimes (\beta(p_k), \beta(1-p_k)) \tag{3.4}$$

We now claim that for every $\boldsymbol{I}$, $\tilde{p}^{\boldsymbol{I}} \geq 2^{1-k} P^{\boldsymbol{I}}$. We show this for $\boldsymbol{I} = \mathbf{0}$; all other $\boldsymbol{I}$ follow by the same argument. First note that for every $1 \leq i \leq k$, $p_i \geq P^{\mathbf{0}}$, and therefore $\beta(p_i) \geq \beta(P^{\mathbf{0}})$. So $\tilde{p}^{\mathbf{0}} = \beta(p_1) \cdots \beta(p_k) \geq \beta(P^{\mathbf{0}})^k$. Now there are two cases. If $P^{\mathbf{0}} \leq 1/2$ then $\beta(P^{\mathbf{0}})^k = 2^{1-k} P^{\mathbf{0}}$ as desired. If $P^{\mathbf{0}} > 1/2$ then $\beta(P^{\mathbf{0}})^k = (1 - \frac{1}{2}(2 - 2P^{\mathbf{0}})^{1/k})^k$. Showing this is $\geq 2^{1-k} P^{\mathbf{0}}$ is equivalent to showing that

$$(2 - (2P^{\mathbf{0}})^{1/k})^k \geq 2 - 2P^{\mathbf{0}}. \tag{3.5}$$

Let $\varepsilon = (2P^{\mathbf{0}})^{1/k} - 1$ and note $0 \leq \varepsilon \leq 1$. Then (3.5) is equivalent to $(1-\varepsilon)^k + (1+\varepsilon)^k \geq 2$ which holds by the power-mean inequality (for k vs. 1).
From $\tilde{p}^{\boldsymbol{I}} \geq 2^{1-k} P^{\boldsymbol{I}}$ for every $\boldsymbol{I}$ and from $\|T\|_\infty \leq 1$, we have that for every $\boldsymbol{J}$:

$$\tilde{p}^{\boldsymbol{I}} T^{\boldsymbol{J}}_{\boldsymbol{I}} \leq 1 - 2^{1-k} + 2^{1-k} P^{\boldsymbol{I}} T^{\boldsymbol{J}}_{\boldsymbol{I}} \tag{3.6}$$

which (upper bounding $P^{\boldsymbol{I}} T^{\boldsymbol{J}}_{\boldsymbol{I}}$ by $\operatorname{Val} T$, and subtracting $\operatorname{Val} T$ from each side) completes the proof for $m = 2$.
The same proof technique works for $m > 2$, only there is more flexibility in the function β. Given that in an optimal virtual-player distribution P for Team A, the marginal distribution of player i is $p_i(0), \ldots, p_i(m-1)$, we require a new distribution $\beta_i(0), \ldots, \beta_i(m-1)$ for player i such that for every ℓ, $\beta_i(\ell)^k \geq m^{1-k} p_i(\ell)$, which is to say, $\beta_i(\ell) \geq (m p_i(\ell)^{1/k})/m$. Such a distribution exists due to the inequality $\sum_\ell (m p_i(\ell))^{1/k}/m \leq 1$, which holds because by the power-mean inequality $(\sum_\ell (m p_i(\ell))^{1/k}/m)^k \leq \sum_\ell (m p_i(\ell))/m = 1$. The rest of the details are as for $m = 2$.

Part (2a): Lower Bound on $\mathrm{gap}_{2,k}$.

Write $\mathbf{0} = (0, \ldots 0)$ and $\mathbf{1} = (1, \ldots 1)$.
Consider the following tensor.

▶ **Example 2.**

$$\begin{cases} G^{\mathbf{0}}_{\boldsymbol{I}} & = \begin{cases} -1 & \text{if } \boldsymbol{I} = \mathbf{0} \\ 1 & \text{otherwise} \end{cases} \\ G^{\mathbf{1}}_{\boldsymbol{I}} & = \begin{cases} -1 & \text{if } \boldsymbol{I} = \mathbf{1} \\ 1 & \text{otherwise} \end{cases} \\ G^{\boldsymbol{J}}_{\mathbf{0}} & = \begin{cases} 1 & \text{if } \boldsymbol{J} = \mathbf{1} \\ -1 & \text{otherwise} \end{cases} \\ G^{\boldsymbol{J}}_{\mathbf{1}} & = \begin{cases} 1 & \text{if } \boldsymbol{J} = \mathbf{0} \\ -1 & \text{otherwise} \end{cases} \\ G^{\boldsymbol{J}}_{\boldsymbol{I}} & = 0 \text{ for all other } \boldsymbol{I}, \boldsymbol{J} \end{cases} \tag{3.7}$$

An informal description of this game is that if both Team A and Team B choose actions in $\{\mathbf{0}, \mathbf{1}\}$, then the outcome is as it would be in the "matching pennies" game. If just one of the teams chooses an action in $\{\mathbf{0}, \mathbf{1}\}$, then that team wins. If neither team chooses an action in $\{\mathbf{0}, \mathbf{1}\}$, then the game is a tie.
(We incidentally note that the proof of Part (2a) does not depend on setting entries to 0 in the last line of 3.7; the argument will go through with each entry taking any value in $[-1, 1]$.)

Now consider any strategy $p = (p_1, \ldots, p_k)$ for Team A (recall these are the probabilities of action 0). The expected payoff for action $\boldsymbol{J} = \mathbf{0}$ of Team B is

$$G_p^{\mathbf{0}} = 1 - 2p_1 \cdots p_k$$

The expected payoff for $\boldsymbol{J} = \mathbf{1}$ is

$$G_p^{\mathbf{1}} = 1 - 2(1 - p_1) \cdots (1 - p_k)$$

By the arithmetic-geometric mean inequality, $G_p^{\mathbf{0}} \geq 1 - 2(\frac{1}{k}\sum p_i)^k$ and $G_p^{\mathbf{1}} \geq 1 - 2(\frac{1}{k}\sum(1-p_i))^k$. So

$$\frac{1 - \max\{G_p^{\mathbf{0}}, G_p^{\mathbf{1}}\}}{2} \leq \min\{(\frac{1}{k}\sum p_i)^k, (\frac{1}{k}\sum(1-p_i))^k\}$$

equivalently

$$\left(\frac{1 - \max\{G_p^{\mathbf{0}}, G_p^{\mathbf{1}}\}}{2}\right)^{1/k} \leq \min\{\frac{1}{k}\sum p_i, \frac{1}{k}\sum(1-p_i)\}$$

The RHS is at most $1/2$. So $\min_p \max\{G_p^{\mathbf{0}}, G_p^{\mathbf{1}}\} \geq 1 - 2^{1-k}$.
A similar argument applied to the strategy q of Team B establishes that
$\max_q \min\{G_{\mathbf{0}}^q, G_{\mathbf{1}}^q\} \leq -1 + 2^{1-k}$. Adding the two contributions, Part (2a) of the theorem follows.

Part (2b): Lower Bound on $\mathbf{gap}_{m,k}$, $m > 2$.

Proof: We non-constructively exhibit a game establishing the lower bound. We start by selecting, for a function $g(m)$ to be specified, $g(m)$ strings $S = (s^1, \ldots, s^{g(m)})$, each s^j chosen independently and uniformly in $\{0, \ldots, m-1\}^k$ (Think of m as arbitrary but fixed while $k \to \infty$). The first idea of the proof lies in the interesting fact that with high probability, this set (whose size is independent of k) has the property that any product distribution may place probability more than $m^{-k(1-o(1))}$ on at most $\sim \log g(m)$ strings in S.

To describe the second idea, we start by associating the strings of S with players in a tournament. (A tournament is a digraph in which there is one directed edge between every pair of distinct vertices.) The game is then as follows. Associate the strings of S with the vertices of the tournament in an arbitrary way. If neither team chooses a string in S, the game is a tie. If one team chooses a string in S and the other does not, the first team wins. If both teams choose strings in S, the winning vertex is that which points toward the other (with a tie for identical strings). In all cases a win means a payoff of 1 and a tie a payoff of 0.

Key to the second idea is that by a result of Erdös [5] (later constructively in [6]) it is possible to choose the tournament so that it has no dominating set of size $\sim \log g(m)$. (A set of vertices is dominating if every vertex outside the set is pointed to by at least one vertex in the set.)

Now we claim that whichever team goes second can achieve payoff $1 - m^{-(1-o(1))k}$. The argument is the same for both teams, so say Team A goes first and let p be its product strategy. Let R be the $\sim \log g(m)$ strings in S accorded highest probability in p; all other strings of S have probability less than $m^{-(1-o(1))k}$. Team B responds to p with an $s \in S$ which dominates all of R. Team B wins unless Team A selects an $s' \in S - R$ (and sometimes even then). The payoff to Team B is therefore at least $1 - g(m)m^{-(1-o(1))k}$ which is at least $1 - m^{-(1-o(1))k}$. ◀

4 Order Refinements

It is natural to consider a more general scenario in which players of the two teams commit to their strategies in some (not necessarily strict) alternation. That is to say, let π be any bijection from $\{1,\ldots,2k\}$ to $\{A_1,\ldots,A_k,B_1,\ldots,B_k\}$. If $\pi(\ell)=A_i$ for some i then let $M(\ell)$ be the quantifier $\min_{p_i}$; if $\pi(\ell)=B_j$ for some j then let $M(\ell)=\max_{q_j}$. Then the value of game T with respect to order π is defined to be

$$V(T,\pi)=M(1)\ldots M(2k)T_p^q.$$

In particular, let π^{AB} be an order in which all the members of Team A go first, that is, $\pi^{AB}(\ell)=A_\ell$ for $\ell\le k$, and $\pi^{AB}(\ell)=B_{\ell-k}$ for $\ell>k$. (Note that V is invariant under exchange of same-team players with adjacent quantifiers.) Likewise let π^{BA} be an order in which Team B goes first. Then the duality gap of game T is

$$\mathrm{gap}(T)=V(T,\pi^{AB})-V(T,\pi^{BA}).$$

We now ask how much V may change when we change π by a single adjacent transposition.

A natural place to study this question is in *symmetric games*, by which we mean games invariant under permutation of the actions taken by members of a team. Even in this restrictive setting, a wide range of behaviors can occur.

For one extreme, we return to the game G of Example 2. We show that for any k, the order of the first three players can affect the outcome decisively.

▶ **Lemma 3.** *If $\ell\ge 3$ is the first time that Team B plays in π, then $V(G,\pi)\ge 1/2$. Likewise if $\ell\ge 3$ is the first time that Team A plays in π, then $V(G,\pi)\le -1/2$.*

For the other extreme, we have:

▶ **Theorem 4.** *There exist symmetric team games with any $k\ge 1$ players per team, with duality gap bounded away from 0 (as a function of k), but in which any adjacent transposition in the order of play changes the value of the game only by $O(1/k)$.*

Proofs of the lemma and theorem will be provided in the journal version of the paper.

5 Discussion

We have characterized the possible range of the duality gap. The examples which achieved large gap were highly structured. It would be interesting to find natural conditions on a game (particularly a symmetric game) that ensure small duality gap.

It would be interesting to extend our inquiry to teams (possibly more than two) competing in non-zero-sum games.

Abstract

In this paper we present a generic reduction from the problem of finding an ϵ-well-supported Nash equilibrium (WSNE) to that of finding an $\Theta(\epsilon)$-approximate Nash equilibrium (ANE), in large games with n players and a bounded number of strategies for each player. Our reduction complements the existing literature on relations between WSNE and ANE, and can be applied to extend hardness results on WSNE to similar results on ANE. This allows one to focus on WSNE first, which is in general easier to analyze and control in hardness constructions.

As an application we prove a $2^{\Omega(n/\log n)}$ lower bound on the randomized query complexity of finding an ϵ-ANE in binary-action n-player games, for some constant $\epsilon > 0$. This answers an open problem posed by Hart and Nisan [23] and Babichenko [2], and is very close to the trivial upper bound of 2^n. Previously for WSNE, Babichenko [2] showed a $2^{\Omega(n)}$ lower bound on the randomized query complexity of finding an ϵ-WSNE for some constant $\epsilon > 0$. Our result follows directly from combining [2] and our new reduction from WSNE to ANE.

1 Introduction

The celebrated theorem of Nash [29] states that every finite game has an equilibrium point. The solution concept of Nash equilibrium (NE) has been tremendously influential in economics and social sciences ever since (e.g. see [24]). The complexity and efficient approximation of NE have been studied intensively during the past decade, and much progress has been made (e.g., see [27, 1, 6, 26, 34, 13, 9, 16, 28, 14, 4, 10, 32, 7, 12, 15, 33, 11, 5]).

In this paper, we study the randomized query complexity of finding an *ϵ-approximate Nash equilibrium* (ANE) in large games, for some *constant* $\epsilon > 0$. Given a game $\mathcal{G}$ with n players and α actions for each player, we index the players by the set $[n] = \{1, \ldots, n\}$ and index the actions by the set $[\alpha] = \{1, \ldots, \alpha\}$. Recall that an ϵ-ANE of $\mathcal{G}$ is a mixed strategy profile $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$, where each $\boldsymbol{x}_i \in [0,1]^\alpha$ sums to 1 and is an ϵ-best response

of player i to other players' strategies $\boldsymbol{x}_{-i}$[1] (see Section 2 for the formal definitions). Since the notion of ANE is additive, we always assume that payoff functions of games considered in this paper take values between 0 and 1.

We consider the payoff query model, where an oracle algorithm with unlimited computational power is given an approximation parameter ϵ, the number of players n and the number of actions α in an unknown game $\mathcal{G}$, and needs to find an ϵ-ANE of $\mathcal{G}$. The algorithm has oracle access to the payoff functions of players in $\mathcal{G}$: For each round, the algorithm can adaptively query a pure strategy profile $\boldsymbol{a} \in [\alpha]^n$, and receives the payoff of each player with respect to $\boldsymbol{a}$. We are interested in the number of queries needed by any randomized oracle algorithm for this task. Note that a trivial upper bound is α^n by simply querying all the pure strategy profiles.

1.1 Prior Results and Related Work

The query complexity of (approximate) Nash equilibria and related solution concepts has received considerable attention recently, e.g., see [17, 23, 18, 19, 2, 3, 20, 33]. Below we review results that are most relevant to our work.

The query complexity of (approximate) correlated equilibria (CE) [2] is well understood. For the payoff query model considered here, randomized algorithms exist (e.g., regret-minimizing algorithms [22, 21, 8]) for finding an ϵ-CE using $\text{poly}(1/\epsilon, \alpha, n)$ many queries. It turns out that both randomization and approximation are necessary. [3] showed that every deterministic algorithm that finds an exact CE requires exponentially many queries in n. [23] then showed that the same exponential lower bound holds for any deterministic algorithm for (1/2)-CE and any randomized algorithm for exact CE. For the stronger (expected payoff) query model, where the oracle returns the expected payoffs of any mixed strategy profile [3], [30] and [25] obtained a deterministic algorithm that computes an exact CE in polynomial time using polynomially many queries (both in α and n).

Now turning to the harder, but perhaps more interesting, problem of approximating Nash equilibria under the payoff query model, the deterministic lower bound of [23] for (1/2)-CE directly implies the same bound for (1/2)-ANE, because any ϵ-ANE by definition is an ϵ-CE as well. For the randomized query complexity, Babichenko [2] showed that any randomized algorithm requires $2^{\Omega(n)}$ queries to find an ϵ-well-supported Nash equilibrium (WSNE), in a binary-action, n-player game. Recall that an ϵ-WSNE of a game is a mixed strategy profile $\boldsymbol{x}$ in which the probability of player i playing action j is positive only when action j is an ϵ-best response with respect to $\boldsymbol{x}_{-i}$. By definition, an ϵ-WSNE is also an ϵ-ANE but the inverse is not true. Following a well-known connection between WSNE and ANE [13] (and using random samples to approximate expected payoffs), [2] showed that the same $2^{\Omega(n)}$ bound holds for the randomized query complexity of ϵ-ANE, but only when $\epsilon = O(1/n)$. Before our work, the randomized query complexity of ϵ-ANE in large games remains an open problem when $\epsilon > 0$ is a constant.

In this paper we prove a $2^{\Omega(n/\log n)}$ lower bound on the randomized query complexity of finding an ϵ-ANE, for some constant $\epsilon > 0$. Subsequently, Rubinstein [33] showed a tight $2^{\Omega(n)}$ lower bound on the randomized query complexity of ϵ-ANE, using more sophisticated machinery in coding theory to remove the $\log n$ factor in the exponent. However, our

[1] We use $\boldsymbol{x}_{-i} := (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{i-1}, \boldsymbol{x}_{i+1}, \ldots, \boldsymbol{x}_n)$ to denote the strategies of players other than i in $\boldsymbol{x}$.

[2] An ϵ-correlated equilibrium is a probability distribution over pure strategy profiles, such that any player unilaterally deviating from strategies drawn from it can increase her expected payoff by no more than ϵ.

[3] Such an oracle can be implemented in polynomial time for many classes of succinct games; see [30].

reduction from ANE to WSNE is much simpler and could be used to obtain hardness results on ANE in other applications (e.g. [31]). It remains an interesting open question if there is a more efficient reduction from WSNE to ANE, without paying the extra factor of $\log n$.

1.2 Our Results

For binary-action, n-player games, we show that $2^{\Omega(n/\log n)}$ queries are required for any randomized algorithm to find an ϵ-ANE, for some constant $\epsilon > 0$. To state the result we use $\mathrm{QC}_p(\mathbf{ANE}(n,\epsilon))$, for some $p > 0$, to denote the smallest T such that there exists a randomized oracle algorithm that uses no more than T queries and outputs an ϵ-ANE with probability at least p, given any unknown binary-action, n-player game. Our main result is the following lower bound on $\mathrm{QC}_p(\mathbf{ANE}(n,\epsilon))$:

▶ **Theorem 1** (Main). *There exist two constants $\epsilon > 0$ and $c > 0$ such that*

$$\mathrm{QC}_p(\mathbf{ANE}(n,\epsilon)) = 2^{\Omega(n/\log n)}, \quad \text{where } p = 2^{-cn/\log n}.$$

Our lower bound answers an open problem posed in [23] and in [2]. Our result shows that, in terms of their query complexities, finding an ϵ-ANE is almost as hard as finding an ϵ-WSNE in a large game, even for constant $\epsilon > 0$. It also directly implies the following corollary regarding the rate of convergence of k-queries dynamics (see [2] for the definition).

▶ **Corollary 2.** *There exist constants $\epsilon, c > 0$ such that no k-queries dynamic can converge to an ϵ-ANE in $2^{\Omega(n/\log n)}/k$ steps with probability at least $2^{-cn/\log n}$ for every binary-action and n-player game.*

Our proof of Theorem 1 relies on a polynomial-time reduction [4] from the problem of finding an ϵ-WSNE to that of finding an $(\epsilon' = \Omega(\epsilon))$-ANE in a *succinct game* with a fixed number of actions. As defined in [30], an α-action succinct game is a pair (n, U), where n is the number of players and U is a (multi-output) Boolean circuit that, given a pure strategy profile $\boldsymbol{a} \in [\alpha]^n$ (encoded in binary), outputs the payoffs of all n players with respect to $\boldsymbol{a}$.

▶ **Theorem 3.** *Let $\epsilon \geq 0$ and $\alpha \in \mathbb{N}$ be two constants. The problem of finding an ϵ-WSNE is polynomial-time reducible to that of finding an $\epsilon/(4\alpha)$-ANE, both in α-action succinct games.*

1.3 Approximate vs. Well-Supported Nash Equilibria

Let $\mathrm{QC}_p(\mathbf{WSNE}(n,\epsilon))$ denote the smallest T such that there exists a randomized oracle algorithm that uses no more than T queries and outputs an ϵ-WSNE with probability at least p, given any unknown binary-action, n-player game. Babichenko [2] showed that

▶ **Theorem 4** ([2]). *There exist constants $\epsilon, c > 0$ such that*

$$\mathrm{QC}_p(\mathbf{WSNE}(n,\epsilon)) = 2^{\Omega(n)}, \quad \text{where } p = 2^{-cn}.$$

Given Theorem 4, the same exponential lower bound follows directly for the randomized query complexity of ϵ-ANE, for certain small enough constant $\epsilon > 0$, if

[4] Recall that a polynomial-time reduction from a total search problem A to a total search problem B is a pair (f, g) of polynomial-time computable functions such that: 1) for every input instance x of A, $f(x)$ is an input instance of B; and 2) for every solution y to $f(x)$ in B, $g(y)$ is a solution to x in A.

Given oracle access to $\mathcal{G}$ and any ϵ'-ANE of $\mathcal{G}$, where $\epsilon' = c(\alpha) \cdot \epsilon$ for some constant $c > 0$ that only depends on α, there is a query-efficient procedure that outputs an ϵ-WSNE of $\mathcal{G}$.

However, the best such procedure known is the following result from [13]. The parameters are subsequently improved in [2], where the number of queries needed is also analyzed:

Given oracle access to $\mathcal{G}$ and any $\epsilon^2/(16n)$-ANE of $\mathcal{G}$, there is a procedure that outputs an ϵ-WSNE of $\mathcal{G}$ using poly$(\alpha, n, 1/\epsilon)$ payoff queries, where n denotes the number of players.

The procedure is very natural: For each player, reallocate probabilities on actions with a relatively low expected payoff to a best-response action. Using Theorem 4, such a procedure implies the same exponential lower bound for ϵ-ANE [2] but only when ϵ is $O(1/n)$.

Before our work, no better procedure is known. By definition, an ANE poses a slightly weaker condition on each player compared to that of a WSNE. More specifically, given the mixed strategies of other players $\boldsymbol{x}_{-i}$, for an ϵ-WSNE, $\boldsymbol{x}_i$ must be supported on actions that are ϵ-best responses to $\boldsymbol{x}_{-i}$, while in an ϵ-ANE, $\boldsymbol{x}_i$ can be any mixed strategy that yields an overall ϵ-best response to $\boldsymbol{x}_{-i}$. For example, $\boldsymbol{x}_i$ may allocate $1 - \epsilon$ probability on best-response actions while putting ϵ probability on any other actions. This makes WSNE much easier to analyze and control in hardness reductions, which is why it played a critical role in characterizing the complexity of Nash equilibria, starting with the work of [13], later in [9] and subsequent works. The reason that Babichenko's lower bound (Theorem 4) does not hold for ϵ-ANE is that, if every player places a tiny probability on a suboptimal action, in aggregate there are always some players who play suboptimally, which makes the outcome quite unpredictable.

1.4 Our Approach

We prove Theorem 1 via a *query-efficient* reduction from the problem of finding an ϵ-WSNE to that of finding an $\Theta(\epsilon)$-ANE:

Given any α-action, n-player game $\mathcal{G}$ and any parameter $\epsilon > 0$, one can define a new α-action game $\mathcal{G}'$ with a slightly larger set of $O(\alpha^2 \log(n/\epsilon) \cdot n)$ players such that

1. *To answer each payoff query on $\mathcal{G}'$, it suffices to make αn payoff queries on $\mathcal{G}$;*
2. *There is a procedure that, given any ϵ-ANE $\boldsymbol{x}$ of $\mathcal{G}'$, outputs a $(4\alpha\epsilon)$-WSNE $\boldsymbol{y}$ of $\mathcal{G}$, with no payoff oracle access to $\mathcal{G}$ or $\mathcal{G}'$.*

Our reduction is presented in Section 3. Theorem 1 then follows immediately from the lower bound of [2] on the randomized query complexity of WSNE (in Theorem 4). Theorem 3 follows from the fact that: 1) the payoff entries of $\mathcal{G}'$ are easy to compute; and 2) the procedure to obtain $\boldsymbol{y}$ from $\boldsymbol{x}$ runs in time polynomial in the length of the binary representation of $\boldsymbol{x}$, when the number of actions α is bounded. We first give the intuition behind our reduction.

Recall that in the procedure of [13] and [2], an ϵ-WSNE is obtained from an ϵ'-ANE with $\epsilon' = \epsilon^2/(16n)$ by reallocating probabilities on actions with relatively low expected payoff (formally, actions with payoff $\Omega(\epsilon)$ lower than the best response) to best-response actions. From the definition of ANE, no player can have probability more than $O(\epsilon'/\epsilon) = O(\epsilon/n)$ on actions with low payoff in any ϵ'-ANE. Thus, the procedure changes the expected payoff of each player on each action by at most $n \cdot O(\epsilon/n) = O(\epsilon)$ since it changes the mixed strategy of each player by $O(\epsilon/n)$. It follows that the new mixed strategy profile is an ϵ-WSNE. The blow up of a factor of n from ϵ' to ϵ is precisely due to the cumulative impact on a player's expected payoff imposed by small changes to all other players' mixed strategies.

Our reduction from WSNE to ANE overcomes this obstacle by constructing from $\mathcal{G}$ a new and slightly larger game $\mathcal{G}'$ with $O(n \log n)$ players, where each player i in the original n-player game $\mathcal{G}$ is simulated by a group of $O(\log n)$ players indexed by (i, j) in the new game $\mathcal{G}'$, and we use the *majority* strategy in group i to decide the strategy of player i in the original game. The payoff function of the player (i, j) in $\mathcal{G}'$ is exactly the same as that of player i in $\mathcal{G}$, but is now defined with respect to the *aggregate* action (by plurality voting) of each group of players in $\mathcal{G}'$.

We show that an ϵ-WSNE of $\mathcal{G}$ can be recovered from any ϵ'-ANE of $\mathcal{G}'$, where $\epsilon' = \Omega(\epsilon)$, by (1) computing the distribution of the majority action of each group and (2) truncating the small entries in each distribution. Intuitively, by focusing on the aggregate behavior of each group of $O(\log n)$ *independent* players in $\mathcal{G}'$, we make sure that the mixed strategies obtained from Step (1) are highly concentrated on actions with close-to-best expected payoffs, and actions with low payoffs can only appear as the majority action of a group with probability $O(\epsilon/n)$. Therefore, in Step (2) we only need to truncate entries with probability $O(\epsilon/n)$, and the remaining positive entries would correspond to close-to-best actions. We can also control the effect of this truncation at the same time, because when the number of actions is bounded, the aggregate behavior of each group changes by at most $O(\epsilon/n)$, which allows us to show that the result is an ϵ-WSNE of the original game $\mathcal{G}$.

1.5 Organization

The rest of the paper is organized as follows. We first give formal definitions of ANE and WSNE in Section 2. In Section 3 we present the reduction from WSNE to ANE for large games, and then use it to prove Theorem 1 and Theorem 3 in Section 4.

2 Preliminaries

A game $\mathcal{G}$ is a triple $(n, \alpha, \boldsymbol{u})$, where n is the number of players, α is the number of actions for each player, and $\boldsymbol{u} = (u_1, \ldots, u_n)$ are the payoff functions, one for each player. We always use $[n] = \{1, \ldots, n\}$ to denote the set of players and $[\alpha] = \{1, \ldots, \alpha\}$ to denote the set of actions for each player. Since we are interested in additive approximations, each u_i maps $[\alpha]^n$ to $[0, 1]$.

Let Δ_α denote the set of probability distributions over $[\alpha]$. A mixed strategy profile of $\mathcal{G}$ is then a tuple $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ of mixed strategies, where $\boldsymbol{x}_i \in \Delta_\alpha$ denotes the mixed strategy of player i. Given $\boldsymbol{x}$, we use $\boldsymbol{x}_{-i}$ to denote the tuple of mixed strategies of all players other than i. As a shorthand, we write $u_i(\boldsymbol{x})$ to denote the expected payoff of player i with respect to $\boldsymbol{x}$, and write $u_i(a, \boldsymbol{x}_{-i})$ to denote the expected payoff of player i playing action $a \in [\alpha]$ with respect to $\boldsymbol{x}_{-i}$:

$$u_i(\boldsymbol{x}) = \mathop{\mathbb{E}}_{\boldsymbol{a} \sim \boldsymbol{x}} [u_i(\boldsymbol{a})] \quad \text{and} \quad u_i(a, \boldsymbol{x}) = \mathop{\mathbb{E}}_{\boldsymbol{b} \sim \boldsymbol{x}_{-i}} \big[u_i(a, \boldsymbol{b})\big].$$

Next we define approximate and well-supported Nash equilibria.

▶ **Definition 5.** Given $\epsilon > 0$, an ϵ-approximate Nash equilibrium of an α-action and n-player game $\mathcal{G}(n, \alpha, \boldsymbol{u})$ is a mixed strategy profile $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ such that for every player $i \in [n]$:

$$u_i(\boldsymbol{x}) \geq u_i(a', \boldsymbol{x}_{-i}) - \epsilon, \quad \text{for all } a' \in [\alpha].$$

▶ **Definition 6.** Given $\epsilon > 0$, an ϵ-well-supported Nash equilibrium of $\mathcal{G}(n, \alpha, \boldsymbol{u})$ is a mixed strategy profile $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ such that for all $i \in [n]$ and action a in the support of $\boldsymbol{x}_i$:

$$u_i(a, \boldsymbol{x}_{-i}) \geq u_i(a', \boldsymbol{x}_{-i}) - \epsilon, \quad \text{for all } a' \in [\alpha].$$

Finally, we give a formal definition of succinct games [30].

▶ **Definition 7.** An α-action succinct game is a pair (n, U), where n is the number of players and U is a (multi-output) Boolean circuit that, given any pure strategy profile $\boldsymbol{a} \in [\alpha]^n$ (encoded in binary), outputs the payoffs of all n players with respect to $\boldsymbol{a}$ in the game. Note that the input size of (n, U) is the size of the circuit U.

3 A Reduction from WSNE to ANE

Given an α-action, n-player game $\mathcal{G}(n, \alpha, \boldsymbol{u})$ and a parameter $\epsilon \in (0, 1)$, we now define a new game $\mathcal{G}'(sn, \alpha, \boldsymbol{u}')$ with sn players, where $s = 2\alpha^2 \cdot \lceil \ln(n/\epsilon) \rceil$. We prove that given an ϵ-ANE $\boldsymbol{x}$ of the new game $\mathcal{G}'$, one can compute a $(4\alpha\epsilon)$-WSNE $\boldsymbol{y}$ of $\mathcal{G}$ without making any payoff queries to $\mathcal{G}$ or $\mathcal{G}'$.

For each player $i \in [n]$ in $\mathcal{G}$, we introduce a group of s players in $\mathcal{G}'$, indexed by (i, j) with $j \in [s]$, and use $u'_{i,j}$ to denote the payoff function of player (i, j). Given any pure strategy profile $\boldsymbol{a} = (a_{i,j} : i \in [n], j \in [s])$, we define the payoff $u'_{i,j}(\boldsymbol{a})$ of player (i, j) as follows. First, for each $i \in [n]$, let $\bar{a}_i \in [\alpha]$ denote the *majority* action played by the i-th group (players (i, j), $j \in [s]$) in the pure strategy profile $\boldsymbol{a}$ (break ties by choosing the action with the smallest index). Write $\bar{\boldsymbol{a}} = (\bar{a}_1, \ldots, \bar{a}_n)$. Next, the payoff of player (i, j) under $\boldsymbol{a}$ is defined as

$$u'_{i,j}(\boldsymbol{a}) = u_i(a_{i,j}, \bar{\boldsymbol{a}}_{-i}). \tag{1}$$

This completes the definition of $\mathcal{G}'$. The next lemma follows from the definition.

▶ **Lemma 8.** *To answer a payoff query on $\mathcal{G}'$, it suffices to make αn queries on $\mathcal{G}$.*

Proof. By the definition of $\mathcal{G}'$, $u'_{i,j}(\boldsymbol{a})$'s for all (i, j), are determined by

$$\big(u_i(a', \bar{\boldsymbol{a}}_{-i}) : i \in [n], a' \in [\alpha]\big),$$

for which αn payoff queries on $\mathcal{G}$ suffice. ◀

We conclude our reduction by proving the following lemma:

▶ **Lemma 9.** *Given any ϵ-ANE $\boldsymbol{x}$ of $\mathcal{G}'$, one can compute a $(4\alpha\epsilon)$-WSNE $\boldsymbol{y}$ of G without making any payoff queries on $\mathcal{G}$ or $\mathcal{G}'$. Moreover, when α is a constant, the computation of $\boldsymbol{y}$ from $\boldsymbol{x}$ can be done in time polynomial in the number of bits needed in the binary representation of $\boldsymbol{x}$ and $1/\epsilon$.*

Proof. Let $\boldsymbol{x} = (\boldsymbol{x}_{i,j})$ be an ϵ-ANE of $\mathcal{G}'$. For each group i and action $k \in [\alpha]$, let

$$\bar{x}_{i,k} = \Pr_{\boldsymbol{a} \sim \boldsymbol{x}} [\bar{a}_i = k]. \tag{2}$$

Recall that $\bar{a}_i$ is the majority action played by players (i, j), $j \in [s]$, in the pure strategy profile $\boldsymbol{a}$. By definition, each $\bar{\boldsymbol{x}}_i = (\bar{x}_{i,1}, \ldots, \bar{x}_{i,\alpha})$ is a probability distribution over $[\alpha]$.

Next, we define a mixed strategy $\boldsymbol{y} = (\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n)$ of $\mathcal{G}$, and show that $\boldsymbol{y}$ is a $(4\alpha\epsilon)$-WSNE. We zero out entries smaller than ϵ/n in $\bar{\boldsymbol{x}}_i$ and rescale it, formally

$$c_{i,k} = \begin{cases} \bar{x}_{i,k} & \text{if } \bar{x}_{i,k} \le \epsilon/n \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad y_{i,k} = \frac{\bar{x}_{i,k} - c_{i,k}}{1 - \sum_{j \in [\alpha]} c_{i,k}}. \tag{3}$$

It is easy to verify that $\boldsymbol{y}_i = (y_{i,1}, \ldots, y_{i,\alpha})$ is indeed a probability distribution over $[\alpha]$.

Now assume for contradiction that $\boldsymbol{y}$ is not a $(4\alpha\epsilon)$-WSNE, i.e. for some player $i \in [n]$ there exists an action $\ell \in [\alpha]$ such that $y_{i,\ell} > 0$ but

$$\max_{k\in[\alpha]} u_i(k, \boldsymbol{y}_{-i}) > u_i(\ell, \boldsymbol{y}_{-i}) + 4\alpha\epsilon. \tag{4}$$

But note that, the total variation distance between $\bar{\boldsymbol{x}}_j$ and $\boldsymbol{y}_j$ for each $j \in [n]$ is at most $\alpha\epsilon/n$. So by coupling and applying union bound, we have that

$$\left|u_i(k, \bar{\boldsymbol{x}}_{-i}) - u_i(k, \boldsymbol{y}_{-i})\right| \le (n-1)\cdot(\alpha\epsilon/n) < \alpha\epsilon, \quad \text{for all } k \in [\alpha]. \tag{5}$$

It then follows from (4) and (5) that

$$\max_{k\in[\alpha]} u_i(k, \bar{\boldsymbol{x}}_{-i}) > u_i(\ell, \bar{\boldsymbol{x}}_{-i}) + 2\alpha\epsilon. \tag{6}$$

By the definition (1) of the payoff function $u'_{i,j}$, we have

$$u'_{i,j}(k, \boldsymbol{x}_{-i}) = u_i(k, \bar{\boldsymbol{x}}_{-i}), \quad \text{for all } j \in [s] \text{ and } k \in [\alpha]. \tag{7}$$

Combining (6) and (7), we have that for every player (i,j), $j \in [s]$:

$$\max_{k\in[\alpha]} u'_{i,j}(k, \boldsymbol{x}_{-i}) - u'_{i,j}(\ell, \boldsymbol{x}_{-i}) \ge 2\alpha\epsilon.$$

Since $\boldsymbol{x}$ is an ϵ-ANE of $\mathcal{G}'$, $x_{i,j,\ell} \le 1/(2\alpha)$. By Hoeffding bound and our choice of s,

$$\begin{aligned}\bar{x}_{i,\ell} &= \Pr\left[\ell \text{ is the majority action among players } (i,j),\ j \in [s]\right] \\ &\le \Pr\left[\text{the number of players } (i,j) \text{ playing } \ell \text{ is at least } s/\alpha\right] \le e^{-s/(2\alpha^2)} \le \epsilon/n.\end{aligned}$$

By (3), this implies that $y_{i,\ell} = 0$, which contradicts our assumption and proves that $\boldsymbol{y}$ is indeed a $(4\alpha\epsilon)$-WSNE of $\mathcal{G}$.

It is clear that from the definition of $\boldsymbol{y}$, the computation of $\boldsymbol{y}$ from $\boldsymbol{x}$ does not require any payoff queries. For the running time, when α is a constant, to compute $\bar{x}_{i,k}$ in (2) one needs to go through

$$\alpha^s = \alpha^{2\alpha^2\cdot\lceil\ln(n/\epsilon)\rceil} = (n/\epsilon)^{O(1)}$$

many pure strategy profiles of players (i,j), $j \in [s]$. Therefore $\boldsymbol{y}$ can be computed in time polynomial in the number of bits needed in the binary representation of $\boldsymbol{x}$ and $1/\epsilon$. ◀

4 Proofs of Theorems 1 and 3

We use our query-efficient reduction to prove Theorem 1 and Theorem 3.

Proof of Theorem 1. By Theorem 4 there exist constants $\epsilon', c' > 0$ such that

$$\mathrm{QC}_{p'}(\mathbf{WSNE}(n', \epsilon)) = 2^{\Omega(n')}, \quad \text{where } p' = 2^{-c'n'}.$$

Let $n = 8n' \cdot \lceil\ln(n'/\epsilon')\rceil$ and $\epsilon = 8\epsilon'$. It follows from Lemma 8 and Lemma 9 that

$$\mathrm{QC}_{p'}(\mathbf{ANE}(n, \epsilon)) \ge \mathrm{QC}_{p'}(\mathbf{WSNE}(n', \epsilon)) = 2^{\Omega(n')}.$$

The theorem then follows from $n' = \Omega(n/\log n)$. ◀

Proof of Theorem 3. Using Lemma 9, it suffices to prove that, given any α-action succinct game $\mathcal{G} = (n, U)$, we can construct in polynomial time a Boolean circuit U' that implements the payoff functions of players in $\mathcal{G}'$. This can be done by following the definition of $\mathcal{G}'$ in the previous section since the payoffs of a pure strategy profile $\boldsymbol{a}$ in $\mathcal{G}'$ only depends (in a straight-forward fashion) on the payoffs of $\alpha n = O(n)$ easy-to-compute profiles of $\mathcal{G}$. ◀

Abstract

We consider the maximum weight matching (MWM) problem in dynamic graphs. We provide two reductions. The first reduces the dynamic MWM problem on m-edge, n-node graphs with weights bounded by N to the problem with weights bounded by $(n/\varepsilon)^2$, so that if the MWM problem can be α-approximated with update time $t(m, n, N)$, then it can also be $(1+\varepsilon)\alpha$-approximated with update time $O(t(m, n, (n/\varepsilon)^2)\log^2 n + \log n \log\log N))$. The second reduction reduces the dynamic MWM problem to the dynamic maximum cardinality matching (MCM) problem in which the graph is unweighted. This reduction shows that if there is an α-approximation algorithm for MCM with update time $t(m, n)$ in m-edge n-node graphs, then there is also a $(2+\varepsilon)\alpha$-approximation algorithm for MWM with update time $O(t(m, n)\varepsilon^{-2}\log^2 N)$. We also obtain better bounds in our reductions if the ratio between the largest and the smallest edge weight is small. Combined with recent work on MCM, these two reductions substantially improve upon the state-of-the-art of dynamic MWM algorithms.

1 Introduction

The maximum matching problem is one of the most basic problems in algorithms. Starting from the 1950s, a series of influential papers (among others, [15, 13, 20, 23, 9, 14, 17, 19]) culminated in very efficient algorithms for the problem in n node m edge graphs. There are two versions of the problem: the unweighted version in which one needs to return a maximum cardinality matching (MCM), and the weighted version, in which the input graph has weights on its edges and one seeks a matching of maximum weight (MWM).

For MCM in general graphs, the best known algorithms are the Micali-Vazirani [18] $O(m\sqrt{n})$ algorithm and the $O(n^\omega)$ time algorithm of Mucha and Sankowski [19] (see also [12, 23, 20]), where $\omega < 2.373$ is the matrix multiplication exponent [26, 16]. For the special case of bipartite graphs, a recent breakthrough result of Madry [17] achieved a runtime of $\tilde{O}(m^{10/7})$. For the maximum weight matching problem, the best known running times are $O(m\sqrt{n}\log(nN))$ [9, 10] and $\tilde{O}(Nn^\omega)$ [25] where N is the largest edge weight.

Graphs in applications, however, are dynamic by nature. Edges and vertices fail and new ones are introduced. Because of this, more resilient, *dynamic* algorithms are desired. Such algorithms can update the solution efficiently when an edge insertion or deletion occurs.

Maintaining an exact solution to the maximum matching problem, however, turns out to be a difficult problem. Utilizing fast matrix multiplication, Sankowski [24] gave an algorithm with update time $O(N^{2.495}n^{1.495})$ that can maintain the weight of a maximum weight matching; his algorithm is also the best known in the unweighted case when $N = 1$. Abboud and Vassilevska Williams [1] showed in a formal sense that the use of fast matrix multiplication is inherent even for dynamic bipartite MCM, as fast enough updates would imply a faster Boolean matrix multiplication algorithm.

Because exact dynamic algorithms seem to be doomed to be inefficient, the majority of research on dynamic matching has been on maintaining approximate matchings. Following work by Onak and Rubinfeld [22], Baswana et al. [3] obtained a randomized fully dynamic algorithm that maintains a maximal (and hence 2-approximate) matching with expected amortized update time $O(\log n)$. Obtaining a fast deterministic algorithm has been a much more difficult task. Following Neiman and Solomon [21], Gupta and Peng [11] showed how to obtain a $(1+\varepsilon)$-approximation algorithm to the MCM with update time $O(\sqrt{m}/\varepsilon^2)$. Bernstein and Stein [5, 4] developed dynamic algorithms that achieve a $(3/2 + \epsilon)$-approximation in amortized update time $O(m^{1/4}\epsilon^{-2.5})$. Just recently Bhattacharya et al. [7] gave a very fast deterministic algorithm: for every $\epsilon > 0$, their algorithm achieves a $(2 + \epsilon)$-approximation algorithm with update time $\text{polylog}(n, 1/\epsilon)$.

For maintaining an approximate MWM, only two results are known. Anand et al. [2] obtained a randomized 4.911-approximation to the MWM in $O(\log n \log C + \log N)$ expected amortized update time[1], where N is the maximum edge weight and C is the ratio between N and the lowest edge weight. Gupta and Peng [11] obtained a $(1 + \varepsilon)$ approximation in deterministic worst case $O(\sqrt{m}\varepsilon^{-2-O(1/\varepsilon)} \log N)$ update time, where N is the largest edge weight in the graph.

There are two main questions that emerge:

1. *Can one get improved dynamic algorithms for MWM?* E.g., is there a faster than $O(\sqrt{m})$ deterministic worst case update algorithm for any constant approximation ratio? Is there a polylogarithmic update time dynamic algorithm with a better than 4.911-approximation guarantee? Can one use the recent techniques developed for dynamic MCM algorithms here?
2. All known dynamic MWM algorithms have update times that depend logarithmically on N. If N can be exponential in n, this causes a polynomial overhead in the running time. *Can the dependence on N be decreased?*
   If the algorithm had to be exact, then clearly the algorithm has to read the entire edge weights, so it is natural to have a dependence on $\log N$. However, here the answers can be approximate, so perhaps one can get away with reading only a few of the bits of the weight. If this is possible, then the algorithm would be fast even if the edge weights were exponential in the number of vertices. In particular, a truly polylogarithmic in n update time for approximate MWM would be possible.

1.1 Our results

In this paper we address both questions above.

Our first contribution is an efficient black-box reduction from dynamic approximate MWM to dynamic approximate MCM. Applying this reduction, we are able to improve the

[1] The update time stated in [2] is $O(\log n \log C)$, however, taking into account reading the edge weights on edge insertion actually adds a $\log N$ to the running time.

current best algorithms for dynamic MWM. The second contribution is a black-box reduction from dynamic approximate MWM on an exponential weight range to the same problem on a polynomial weight range, giving rise to the first algorithm for exponential range dynamic approximate MWM with truly polylogarithmic update time.

Let C be the ratio between the largest edge weight N and smallest edge weight L. Let n be the number of nodes and m the number of edges. The two theorems we prove are as follows:

▶ **Theorem 1.** *Let A be a dynamic algorithm that maintains an α-approximate MCM with update time $t(m,n)$. Then, for all $\varepsilon > 0$, there is a dynamic algorithm that maintains a $2\alpha \cdot (1+\varepsilon)$-approximate MWM with update time $O(t(m,n)\varepsilon^{-2}\log^2 C + \log N)$.*

If the original MCM algorithm was fully dynamic, so is the MWM algorithm, and if the original MCM algorithm is partially dynamic (incremental or decremental), so is the MWM one. If the MCM update time was worst case, then so is the MWM one, and if the original one was deterministic, so is the MWM one.

▶ **Theorem 2.** *Suppose that there is an algorithm that maintains an α-approximate MWM with update time $T(m,n,N)$. Then, for every constant $\varepsilon > 0$, one can convert it into an algorithm that maintains an $\alpha \cdot (1+\varepsilon)$-approximate MWM with asymptotic update time*

$$T(m,n,n^2\varepsilon^{-2})\log^2 n + \log n \log\log C + \log\log N.$$

The new algorithm enjoys the same properties as the old one (worst-case, deterministic etc).

Composing Theorems 1 and 2 we get that a $t(m,n)$-update time α-approximate MCM algorithm can be converted into a $(2+\varepsilon)\alpha$-approximate MWM algorithm with update time $O(t(m,n)\varepsilon^{-2}\log^4 n + \log n \log\log C + \log\log N)$.[2]

Applying Theorems 1 and 2 to the algorithms of Baswana et al. [3], Bhattacharya et al. [6, 7] and Bernstein and Stein [5, 4], we obtain the following immediate corollary.

▶ **Corollary 3.** *The following dynamic algorithms exist for MWM for all $\varepsilon > 0$:*

- *a $(4+\varepsilon)$-approximation with deterministic worst case update time $O(\ poly(\log n, 1/\varepsilon) + \log n \log\log C + \log\log N)$*
- *a $(4+\varepsilon)$-approximation with expected amortized update time $O(\varepsilon^{-2}\log^5 n + \log n \log\log C + \log\log N)$, and*
- *a $(3+\varepsilon)$-approximation in deterministic amortized update time $O(m^{1/4}\varepsilon^{-4.5}\log^4 n + \log n \log\log C + \log\log N)$.*

The above Corollary significantly improves upon the state of the art of dynamic MWM algorithms. In particular, it presents the first *truly polylogarithmic* update time for approximate dynamic MWM in the case when the edge weights can be exponential in n. Note that since our algorithm works on subsets of the edges of the original graph, we can derive dynamic weighted matching algorithms from dynamic maximum cardinality matching algorithms for *special classes of graphs* closed under edge deletions, such as the low-arboricity result of Neiman and Solomon [21].

A big advantage of our meta-algorithms is that they are simple, clean and combinatorial. Thus, if the original dynamic MCM algorithm is practical, then the MWM algorithms resulting from our theorems would likely also be practical.

[2] The composition gives this runtime for any $\varepsilon > 1/n^3$. Of course, if $\varepsilon \leq 1/n^3$, the trivial algorithm that recomputes the matching from scratch has update time $O(1/\varepsilon)$.

1.1.1 Overview of the reduction from dynamic MWM to MCM

Here we give an overview of our approach to proving Theorem 1. Our starting point is a result by Crouch and Stubbs [8] that reduced MWM to MCM in the streaming setting. This reduction shows how to reduce approximate MWM to a small number of instances of approximate MCM, but does not show how to maintain the output approximate MWM efficiently under arbitrary edge updates. Here we show how to make the reduction work in the dynamic setting.

Suppose that we are given a graph with integer edge weights between L and N and we want to compute an approximate MWM; let $C = N/L$. The basic idea of the Crouch and Stubbs reduction is to take maximal matchings from weight-threshold-based subgraphs of the underlying graph, and then merge the resulting maximal matchings together greedily. In particular, one computes an approximate MCM on all edges of weight at least $(1+\epsilon)^i$, for $i \in \{\lfloor(\log_{1+\epsilon} L\rfloor, \lfloor\log_{1+\epsilon} L\rfloor + 1, \ldots, \lfloor\log_{1+\epsilon} N\rfloor\}$. One produces the output matching from the approximate MCMs by including all edges from the matching in the weight class with the highest threshold, and then adding edges in descending order of the height of their weight class, as long as they are node-disjoint from the edges added so far.

Since we have $O(\epsilon^{-1} \log C)$ different weight classes, maintaining the approximate MCMs only incurs a small overhead, over any dynamic matching algorithm for approximate MCM. The only remaining concern, then, is how much time it takes to maintain the output matching by merging these together. This is our contribution on top of the result of Crouch and Stubbs: we show that the greedy merge of the MCMs can be *updated* efficiently.

We begin by assuming that we have approximate maximum cardinality matchings for each of the weight classes and an output matching M constructed *statically* by merging these matchings greedily in decreasing order of class height. When an update to the underlying graph occurs, it might cause some number of the edges in each of the matchings to change. This number in a weight class is at most the update time of the corresponding MCM data structure. Assuming that the dynamic algorithm for approximate MCM has update time $T(m, n)$, the number of changed edges in any one of the matchings is at most $T(m, n)$.

When edges change in an approximate MCM, we fold those changes into M one level at a time, in order of decreasing class height. If an edge in the output matching was deleted, we mark its endpoints as "newly free," so that we can look for new edges that cover those endpoints in lower classes – note that we needn't check the higher classes, since any such edge would have precluded the just-deleted edge from being in the output matching. If an edge was newly added, we add it to the output matching iff neither of its endpoints is covered by a higher class edge; if any edges are deleted in the process, we mark their endpoints as "newly free" and check for edges that cover these newly free nodes in lower classes, as before.

The process of checking for edges to cover a newly free node v is simple: in each lower class, as we're rolling in the changes to the current MCM, we also check whether v is matched in the updated MCM. If it is and its match u is not covered by an edge in the current output matching from a higher class, we add (u, v) to the output matching and v is no longer newly free. If u were already matched in the output matching to some node via a less exclusive edge e, we remove e from the output matching and make its other endpoint newly free.

The main part of the efficiency argument is as follows. The changes in the MCMs cause at most $O(T(m, n)\varepsilon^{-1} \log C)$ edges in our matching data structure to change. For each such changed edge, we carry out constant immediate processing, and also possibly create up to two "newly free" nodes. The crucial point is that if a newly free node is matched, then it can create at most one new newly free node, and so the total number of newly free nodes that have cascaded down the classes starting from a particular changed edge is at most 2.

For each weight class, we might need to consider up to $O(T(m,n)\varepsilon^{-1}\log C)$ newly free nodes from the classes above it, performing a constant time operation for each. Therefore the total time it takes to handle the entire merger is $O(\epsilon^{-2}\log^2(C)T(m,n))$. This process is sufficient to produce an output graph identical to one created by the static merge described above, since edges from higher classes are allowed to preempt ones from lower classes, just as if we'd greedily merged them in first. For the actual update time, we need to read in the weight of any inserted edge, and for this we pay an additional $O(\log N)$.

In Section 3 we provide the full details of the algorithm and the proofs of runtime, correctness and approximation guarantee.

1.1.2 Overview of improving the dependence on the weights

Here we provide an overview of our proof of Theorem 2 presented in Section 4.

A useful fact about weighted matching is that the maximum weight matching of the restriction of the graph to edges of weight at least a $2\epsilon/n$ fraction of the weight of the largest edge (so at least $2\epsilon N/n$, in our case) has weight at least $1/(1+\epsilon)$ times the true maximum weight matching, even if there are no edges other than the unique edge of weight N in this subgraph. The reason is simple: a matching has at most $n/2$ edges, and if none of these weigh more than $2\epsilon N/n$, the whole matching weighs only $(n/2)(2\epsilon N/n) = \epsilon N$, meaning the whole matching including the top edge weighs at most $(1+\epsilon)N$, as desired. Adding more edges above the threshold only makes the "best-only" matching a better approximation of the true matching.

It would be natural to want to apply this principle to fully dynamic weighted matching algorithms (like ours above) in order to reduce the dependence on the – potentially quite large – weight range to a dependence on $O(\epsilon^{-1}n)$. Unfortunately, N can potentially change in the fully dynamic setting: in particular, if we were relying on a single high-weight edge to carry our matching and that edge is deleted, we would have no approximation at all!

Our solution is to maintain enough copies of a dynamic maximum weight matching algorithm on a small range of weights, to guarantee that any two edges whose weights are within a factor of $2\epsilon/n$ of one another appear in the same data structure somewhere. In particular, the highest weight edge appears in the same data structure with any edge with weight within a $2\epsilon/n$ factor of the maximum weight. At the same time, we keep the weight ranges nearly disjoint so that only two of the data structures need to be altered by any update to the underlying graph.

To accomplish both goals, we take weight ranges of the form $((n\varepsilon^{-1})^i, (n\varepsilon^{-1})^{i+2}]$ for $\log_{n\varepsilon^{-1}} L \le i \le \log_{n\varepsilon^{-1}} N$ where L and N are the minimum and maximum edge weight in the data structure throughout its existence. The number of these ranges is now $O(\log_{n\varepsilon^{-1}} C)$ (where $C = N/L$), and we have guaranteed that the MWM in one of these classes is a $(1+\epsilon)\alpha$ approximation to the true MWM, and that the weight range in each class can be reduced to $n\varepsilon^{-1}$. However, we would like to have a persistent output matching that always contains a $(1+\epsilon)\alpha$ approximation of the maximum weight matching, that doesn't change dramatically in a single time step just because the highest weight edge was deleted from the graph.

To this end, we define and maintain a specially constructed output matching M that we call the *census matching*. The idea is as follows. M will contain a certain number of edges from the matchings in each weight class as follows. Consider some weight class $((n\varepsilon^{-1})^i, (n\varepsilon^{-1})^{i+2}]$ and suppose that the number of edges in its matching is n_i. Let $N_i = \sum_{j>i} n_j$ be the sum of cardinalities of matchings in classes above i. If $n_i > N_i$, we will have $n_i - N_i$ matching edges R_i from class i that the census matching M will consider. M is constructed by greedily merging R_i similar to our algorithm from the MWM to MCM reduction.

In particular, the census matching always contains all the edges of weight within $n\varepsilon^{-1}$ of the current maximum weight. Further, since the total number of edges in matchings that have any edges considered by the output matching doubles with each lower class that still has nonempty R_i, and since no matching has more than $n/2$ edges, the total number of classes with any edges considered is $O(\log n)$.

The output matching itself is relatively simple and behaves like the output matching of our first algorithm, except that it's drawing from these "representative sets" R_i, rather than from approximate maximum cardinality matchings. Fortunately, we can show that only two representative sets can change at a time, so it only takes $O(t(n, m, (n\varepsilon^{-1})^2, (n\varepsilon^{-1})^2) \log n)$ time to do the updates, where $t(n, m, N, C)$ is the update time of the underlying MWM algorithm, and thus the maximum number of edges that can be added or removed from a single MWM in a single time step.

We show that when an edge is to be updated, to figure out which pair of classes it belongs to, we only need to read $O(\log \log N)$ bits of its weight. To make everything work efficiently, we introduce a complete binary tree data structure (with the weight classes as leaves) that helps us maintain the representative sets R_i efficiently, though the tree is only conceptually complete, as we only add edges and nodes on paths from the root to leaves of non-empty weight classes to avoid wasting time when a new edge appears of much higher or lower weight than all previous edges. In particular, the $O(\log \log C)$ overhead in our running time is due to the tree having depth $O(\log \log C)$. The $\log \log N$ dependence is due to various pointers to positions in the bits of the weight. The details are in Section 4.

2 Merging matchings greedily

Here we prove a technical lemma used in both of our algorithms.

Let $S_1, \ldots, S_k$ be matchings in a graph G. For any edge (u, v), let $\ell(u, v) = \max\{i \mid (u, v) \in S_i\}$. Call a matching M a *Greedy Census* matching if for any edge $(u, v) \in S_i \setminus M$, there exists either (u, u') or $(v, v') \in M \cap S_j$, for some $j \geq i$. This property is equivalent to saying that M could have been constructed by greedily adding edges from each level from k down to 1, ensuring that the added edges are maximal within the current level before moving down. Thus, we have $\forall j : M \cap (\cup_{i>j} S_i)$ is maximal in $\cup_{i>j} S_i$

For an edge (u, v) let $L(u, v)$ be a decreasing set of indices $\{i_1, i_2, \ldots\}$ such that $(u, v) \in S_{i_j}$ for each j and $i_j > i_{j+1}$. In particular, $i_1 = \ell(u, v)$.

▶ **Lemma 4.** *Suppose we are given any collection of edge sets $In_1, In_2, \ldots, In_k$ and $Del_1, \ldots, Del_k$, the sets $L(u, v)$ for all (u, v) and a Greedy Census matching M of $S_1, \ldots, S_k$. Then one can insert all edges of In_j into S_j and delete all edges of Del_j from S_j and update M and all $L(u, v)$ so that M is a Greedy Census of the modified sets S_j, all in time*

$$\sum_{j=1}^{k} j \cdot \big(|In_j| + |Del_j|\big).$$

In our reduction from MWM to MCM, the sets S_j will correspond to the approximate maximum cardinality matchings of different weight classes, and in our algorithm for decreasing the dependence on the edge weight, they will correspond to the sets of representative edges of different weight classes.

Before we prove Lemma 4, let us introduce some notation.

For each $j \in [k]$, let NewFree(j), initially empty, be the set of newly free nodes created for level j. A newly free node u is any node that was covered by some edge in M, and then

became uncovered after a change to that matching. Specifically, u becomes newly free by the deletion of an edge (u, v) from M. This deletion could happen for one of two reasons: either because (u, v) was in $Del(j)$, meaning it was removed by an update to the underlying graph or some activity at a lower level of the algorithm, and is no longer in consideration for inclusion in M, or because $\ell(u, v) \leq j$ and (u, v) was deleted so that v can be matched via an edge of level greater than j; that is, we found another better edge for M to use in place of (u, v) and u was left uncovered.

Now the procedure is as follows. We set $\textsc{NewFree}(j) = \emptyset$ for all j. We iterate through all levels j from k down to 1. Fix a level j. Then, for each edge $(x, y) \in Del_j$, remove it from S_j, and remove j from $L(x, y)$. If now $\ell(x, y) < j$, and if $(x, y) \in M$, remove (x, y) from M and add x and y to $\textsc{NewFree}(j)$. For each $(x, y) \in In_j$, insert it into S_j, add j to $L(x, y)$. For each $(x, y) \in In_j$, in a second loop, check whether x and y are matched in M. Suppose that either x is not matched or x is matched to x' with $\ell(x, x') < j$. Suppose further that either y is not matched or it is matched to y' with $\ell(y, y') < j$. Then, remove (x, x') and (y, y') from M, add x' and y' to $\textsc{NewFree}(j)$ and insert (x, y) into M. If x or y are in $\textsc{NewFree}(j)$, remove them from $\textsc{NewFree}(j)$.

Now, for each $u \in \textsc{NewFree}(j)$, let v be its match in S_j (recall S_j is a matching). If v is matched to a node v' such that $\ell(v, v') \geq j$, then just move u to $\textsc{NewFree}(j-1)$ and move to the next u. Else if v is unmatched in M or if v is matched to some v' with $\ell(v, v') < j$, then remove (v, v') from M, add v' to $\textsc{NewFree}(j-1)$ and add (u, v) to M. This completes stage j.

Now we prove the following claims:

▶ **Claim 1.** *The runtime of the above algorithm is* $O(\sum_{j=1}^{k} j(|In_j| + |Del_j|))$.

Proof. Each deletion in Del_j can create at most 2 newly free nodes. Each insertion in In_j can cause the creation of at most 2 newly free nodes as well. If a newly free node is matched in some stage j, then it can create at most one new newly free node, and this one is put in $\textsc{NewFree}(j-1)$. Thus, the total cost of processing newly free nodes is $O(\sum_{j=1}^{k} j(|In_j| + |Del_j|))$. ◀

▶ **Claim 2.** *Let* $S'_i = S_i \cup In_i \setminus Del_i$. *$M$ is a greedy census matching of the updated matchings* $S'_1, \ldots, S'_k$.

Proof. Consider for contradiction an edge $(u, v) \in S_i \setminus M$ such that neither u nor v are matched with edges of level at least i. Before updating, one of the following was true, since M was a census matching: 1) $(u, v) \notin S_i$, 2) $(u, v) \in S_i \cap M$ or 3) (wlog) $(u, u') \in S_j \cap M$, for some $j > 1$. In case 1, (u, v) must have been in In_i, and, since neither u nor v are matched at a level above i, (u, v) would have been added to M, and then it's not true that $(u, v) \in S_i \setminus M$. In case 2, (u, v) left M with the update, but is still in S_i, so it wasn't in Del_i. This can only have happened because a higher level edge, wlog (u, u') was in $In_{\ell(u,u')}$, causing (u, v) to be removed from M. Since the In_i are processed in descending order, and the edges in $Del_{\ell(u,u')}$ get deleted before the edges from $In_{\ell(u,u')}$ get inserted, (u, u') will not be deleted by anything in this batch of updates, and so (u, u') is in M, and u is matched, violating the second part of the assertion. In case 3, the higher level edge, (u, u') must have been deleted in the update, either directly by being in Del_i or indirectly by having a higher level edge claim u'. In either case, u would be added to $\textsc{NewFree}(\ell(u', u))$, and it would either get matched to v, putting $(u, v) \in M$, or it would get matched to some (u, u'') of higher level than (u, v), both of which invalidate the assertion. ◀

3 A meta-algorithm for approximating MWM

Let $\varepsilon > 0$ be fixed. For every integer i, let E_i contain all edges of G that have weight $\geq (1+\varepsilon)^i$. Let D_i be a data structure that maintains an α-approximate MCM of E_i with update time $t(m,n)$.

Let ℓ be the smallest i such that $E_i \neq E_{i+1}$. During each stage of the dynamic algorithm we have a pointer to D_ℓ, for the current value of ℓ. Let M be the approximate MWM that we are maintaining. Let $\tilde{M}_i$ be the approximate MCM maintained by D_i, and let $M_i := M \cap \tilde{M}_i$. We will actually maintain M so that $M_i = M \cap E_i$.

We define the level $\ell(u,v)$ of edge (u,v) to be i such that $w(u,v) \in [(1+\varepsilon)^i, (1+\varepsilon)^{i+1})$.

We use Lemma 4 and its algorithm from Section 2 with $S_i = \tilde{M}_i$ to maintain the greedy census matching M. To do this, when a weighted edge (u,v) is inserted or deleted, we insert or delete it from all data structures D_j with $j \leq \ell(u,v)$. If $\ell(u,v) = \ell$ and $D_\ell \setminus D_{\ell+1}$ became empty, update ℓ. Now, after the D_j are updated, we figure out all the sets In_j and Del_j to feed into the data structure from Section 2.

We immediately obtain:

▶ **Lemma 5.** *M is a maximal matching in the graph $\cup_i \tilde{M}_i$.*

▶ **Lemma 6.** *The update time is $O(t(m,n)(\log_{1+\varepsilon} N/L)^2)$.*

Proof. Let $\mu = \log_{1+\varepsilon} N/L$. $|Del_j|$ and $|In_j|$ for each j are at most $O(t(m,n))$ since the (amortized/expected/worst case) number of deletions or insertions performed by each D_j is $\leq t(m,n)$. By the proofs in Section 2, the running time should be asymptotically $\sum_j j \cdot |In_j| + |Del_j| \leq t(m,n) \sum_{j=1}^{\mu} j \leq O(\mu^2 t(m,n))$. ◀

The proof of the Lemma below directly follows from Claim 2 from Section 2.

▶ **Lemma 7.** *For every j, $M \cap E_j$ is maximal matching in the graph $\cup_{i \geq j} \tilde{M}_i$*

Now we can prove the approximation guarantee part of our result.

▶ **Lemma 8.** *If each $\tilde{M}_j$ is an α-approximate MCM, then M is a $2\alpha(1+\varepsilon)$-approximate MWM.*

Proof. Consider a fixed optimal MWM M^*, and let m_i be the cardinality of the MCM on edges of level i, and note that $|M^* \cap E_i| \leq m_i$. Clearly $\alpha|\tilde{M}_i| \geq m_i \geq |M^* \cap E_i|$. Further, $2|M \cap E_i| \geq |\tilde{M}_i|$ by Lemma 7, since $M \cap E_i$ is a maximal matching on a superset of the edges in $\tilde{M}_i$, meaning $|M \cap E_i| \geq \frac{1}{2\alpha}|M^* \cap E_i|$. This means that for each i, every 2α edges of M^* can be assigned to a single "babysitter" edge of M of equal or higher level – this is perhaps easier to see by subtracting out all of the already assigned "pairs" from higher levels, giving $|M \cap E_i| - \frac{1}{2\alpha}|M^* \cap E_{i+1}| \geq \frac{1}{2\alpha}(|M^* \cap E_i| - |M^* \cap E_{i+1}|)$. Since the babysitter edge e is of at least as high a level as all of its charges, $(1+\varepsilon)w(e) \geq w(e^*)$, and, in general, $2(1+\varepsilon)\alpha w(M \cap E_i) \geq w(M^* \cap E_i)$, which, taking $i = L$, proves the lemma. ◀

4 A Meta-meta-algorithm for approximating MWM

4.1 The Census Matching

We maintain a matching using the process from Section 2, partitioning the weight range, running a matching algorithm on each partition, and merging the results, just like in Section 3. However, we keep weighted (rather than unweighted) matchings in each class, and we only consider some of the edges from a few of these classes, rather than merging all of the edges.

In particular, we "semi-partition" the weight range, such that every value within that range falls into exactly two of our semi-partition intervals. Each interval is of the form $((n/\varepsilon)^i, (n/\varepsilon)^{i+2}]$, for $i \in \mathbb{Z}$ such that $\log(w_o) - 1 \leq i \leq \log(w^*) - 1$, where w_o and w^* are the highest and lowest weights that have appeared on any edge in the matching, even if that edge was later deleted. For each of these semi-partitions, we maintain a maximum weight matching algorithm on the subgraph defined by the edges in the underlying graph whose weights fall within that interval. We denote by W_i the approximate MWM maintained on the interval $((n/\varepsilon)^i, (n/\varepsilon)^{i+2}]$.

To merge the W_is together, we maintain a single census matching C, which uses the algorithm from Section 2 to combine a subset of the edges from $O(\log n)$ specific W_is, as determined by a binary tree data structure that we will call the "responsibility tree", T. We will describe this below.

As described in the introduction, we strive to select from each W_i a number of representative edges. Let n_i be the cardinality of W_i, and let $N_i = \sum_{j>i} n_j$ be the total sum of the cardinalities of the matchings in classes above i. If $n_i > N_i$, we will have $n_i - N_i$ matching edges R_i from class i that the census matching M will consider. The tree data structure T will facilitate maintaining the cardinalities that the R_is need to have.

4.2 The Responsibility Tree

We build a near-complete binary tree with leaves corresponding to the W_is to efficiently determine which edges should be sent to the census matching to ensure the desired properties. The W_is are arranged in descending order from left to right, with the leftmost leaf corresponding to $W_{\log_{n/\varepsilon}(w^*)}$ and the rightmost to $W_{\log_{n/\varepsilon}(w_o)}$. The leaves track the number of edges in the matchings and the number of those edges which are represented, and the internal nodes have attributes which depend on the attributes of their children. Whether or not each W_i has the correct number of represented edges can be determined just by looking at the attributes of the root, and if those attributes are wrong, the incorrectly represented classes/leaves can each be tracked down in a single traversal from root to leaf.

Every node in the tree has three attributes: mass, high, and low. The mass attribute is a running tally of the total number of edges among matchings in the classes associated with the leaves of this subtree. The "high" and "low" attributes validate the number of representatives that classes in this subtree have: if the "high" indicator $h(v)$ on any node v is negative, some class in that node's subtree $t(v)$ has too *many* representatives, and if the "low" indicator $l(v)$ on any node v in the left-most branch (the "spine") is positive, then some class in that node's subtree $t(v)$ has too *few* representatives.

We refer to edges that are in the selection pool for the census matching as "representatives," and we record the number of representatives for each class as $R(v)$.

We refer to the high indicator for a vertex v as $h(v)$, its left child as $v.l$, and its right child as $v.r$.

$$h(v) := \begin{cases} \min(h(v.l), h(v.r) - m(v.l)) & \text{if } v \text{ is not a leaf} \\ \infty & \text{if } leaf(v) \wedge R(v) = 0 \\ m(v) - R(v) & \text{if } leaf(v) \wedge R(v) > 0 \end{cases}$$

Similarly for the low indicator, $\ell(v)$,

$$\ell(v) := \begin{cases} m(v) - R(v) & \text{if } v \text{ is a leaf} \\ \max(h(v.l), h(v.r) - m(v.l)) & \text{otherwise} \end{cases}$$

Finally, mass, $m(v)$, is simply

$$m(v) := \begin{cases} \#\text{ edges in matching} & \text{if } v \text{ is a leaf} \\ m(v.l) + m(v.r) & \text{otherwise} \end{cases}$$

4.2.1 Tree Properties

▶ **Lemma 9.** *If the root r has $h(r) = l(r) = 0$, then for every class ℓ_i, $m(\ell_i) = R(\ell_i) + \sum_{j>i} m(\ell_j)$ if $R(\ell_i)$ is positive, and $m(\ell_i) \leq \sum_{j>i} m(\ell_j)$ otherwise. That is, if the root's high and low indicators are both 0, then no class has too many or too few representatives.*

We will prove the lemma using two claims below.

▶ **Claim 3** (No Class has Too Many Representatives.)**.** *For any node v,*

$$h(v) = \min_{\{a_i \in t(v) | R(a_i) \neq 0\}} \left(m(a_i) - R(a_i) - \sum_{j>i \in t(v)} m(a_j) \right).$$

Proof. By induction. For a leaf a, the subtree $t(a)$ is trivial, and this is the definition of $h(a)$. For an internal node v, $h(v) = \min(h(v.l), h(v.r) - m(v.l))$. $v.l$ has no higher classes to account for in $t(v)$, and subtracting $m(v.l)$ from $h(v.r)$ subtracts the masses of all previously unaccounted for classes, meaning both children fit the conditions, and $h(v)$ is simply the minimum of these, as desired. ◀

Consider a class a_i such that its number of represented edges is greater than it should be, i.e., the total number of edges in classes above it $\sum_{j>i}(m(a_j))$, plus the number of its representatives $R(a_i)$, is greater than its own mass $m(a_i)$. Then by Claim 3, $h(r)$ will be negative.

Thus, if $h(r) = 0$, there is no class with too many representatives.

▶ **Claim 4** (No Class has Too Few Representatives.)**.** *For any node v,*

$$\ell(v) = \max_{a_i \in t(v)} \left(m(a_i) - R(a_i) - \sum_{j>i \in t(v)} m(a_j) \right).$$

Proof. By induction, symmetrical to proof of Claim 3. ◀

Consider a class a_i such that its number of represented edges is less than it should be, i.e., $m(a_i) - R(a_i) - \sum_{j>i}(m(a_j)) > 0$. Then by Claim 4, $\ell(r) > 0$.

Thus, if $\ell(r) = 0$, no node has too few representatives.

4.3 The Census Matching is Nearly as Good as The Underlying MWM

We define the "Census matching" to be the resultant matching from combining the representative edges from each class in a way that mimics a static greedy merge, that is, using the algorithm of Section 2.

4.3.1 The Best is Good Enough

▶ **Lemma 10.** *There exists a matching, M_B, such that 1) the ratio between the lowest and highest weight edges in M_B is at most $\epsilon^{-1}n/2$ and 2) $(1+\epsilon)w(M_B) \geq w(M^*)$*

Proof. Consider the lowest interval of width $\epsilon^{-1}n/2$ such that there are no edges above that interval; thus, the interval will contains the highest weight edge(s) in the underlying graph at the top, as well as all edges that weigh at least $2\epsilon/n$ times as much as those edges. We call this interval $B = [2\epsilon/nw^*, w^*]$, where w^* is the highest weight of any edge in the underlying graph.

Consider the optimal matching on edges with weights that fall within B, $\textsc{Opt}_b$. Clearly, its weight is at least w^*, since the trivial matching formed by taking just the single highest weight edge has that weight, and is a matching on edges in B. Now consider the amount by which the true optimum matching, $\textsc{Opt}$, exceeds the weight of $\textsc{Opt}_b$. Any gains the true optimum makes must be from the inclusion of edges outside of (hence, below) B, each of which weighs at most $2\epsilon w^*/n$. Further, the optimum matching can only include $n/2$ such edges (because it is a matching), meaning

$$\begin{aligned} w(\textsc{Opt}) - w(\textsc{Opt}_b) &\leq \frac{n}{2}\frac{2\epsilon w^*}{n} && (1)\\ &= \epsilon w^* && (2)\\ &\leq \epsilon w(\textsc{Opt}_b) && (3) \end{aligned}$$

which tells us that

$$w(\textsc{Opt}) \leq (1+\epsilon)w(\textsc{Opt}_b) \quad (4)$$

◀

So if we have a maximum weight matching algorithm that gives an α-approximation, and run it on just edges with weights in B, we get a $(1+\epsilon)\alpha$-approximation to the overall maximum weight matching. Moreover, if we run it on edges from some interval containing B, we get the same guarantees.

▶ **Corollary 11.** *For any graph G, there exists an interval $I = [(\epsilon^{-1}n/2)^i, (\epsilon^{-1}n/2)^{i+2})]$ such that for any MWM algorithm A, $(1+\epsilon)w(A(G_I)) \geq w(A(G))$, where G_I is the restriction of G to edges with weights in I.*

4.3.2 The Census Displays the Best

▶ **Lemma 12.** $w(M) \geq w(M_B)$

Proof. Since we have a copy of our MWM algorithm running for each non-empty interval of the form $((\epsilon^{-1}n)^i, (\epsilon^{-1}n)^{i+2}]$, we have a MWM covering a superset of every interval of "width" $\epsilon^{-1}n/2$, and, in particular, B. By Lemma 1, the top non-empty class (which contains B) has all of its edges represented, and by the fact that the census matching prioritizes higher weight edges, all of these representatives will, in fact, be included in the final census matching. This means that the census matching is a superset of MWM_B, meaning its weight is at least $(1+\epsilon)\alpha w(\textsc{Opt})$. ◀

4.4 Maintaining the Census is Fast

▶ **Lemma 13.** *Given an underlying MWM running in time $T(n, m, C, N)$, the census matching can be maintained in $O(\log^2(n)T(n, m, (n/\varepsilon)^2, (n/\varepsilon)^2))$ time.*

Proof. By Lemma 9, any class with 1 or more representatives has more edges in its underlying matching than every class above it. Clearly, this means that each class with any representatives has twice as many edges in its matching than the last. Combined with the fact that no matching can have more than $n/2$ matchings, this means there are at most $O(\log n)$ represented classes, and consequently only $O(\log n)$ levels in the census matching. Then the proof follows from the Lemma in Section 2.

Within each of the classes, an instance of the underlying MWM is being run with weights between 1 and $(n/\varepsilon)^2$, and so the maximum number of edges that can change in any given matching (and thus the cardinality of Del_i and In_i) is bounded above by the running time of the MWM on that interval, i.e. $T(n, m, (n/\varepsilon)^2, (n/\varepsilon)^2)$ ◀

4.5 Maintaining the Tree is Fast

▶ **Lemma 14.** *Updating the tree after an insertion or deletion takes $O(\log n \log\log C)$ time*

Proof. Since the Responsibility Tree is a near-complete binary tree with $O(\log C)$ leaves, the length of the path from a leaf to the root is $O(\log\log C)$, meaning only $O(\log\log C)$ nodes need to be changed for each leaf whose underlying matching had a change in cardinality or represenatives. Since any edge is within the purview of only two W_is, only two classes can have a change in the cardinality of their underlying matchings.

By the proof of Lemma 13, $O(\log n)$ classes have a non-zero number of representatives before and after the update, meaning that for all but $O(\log n)$ classes, the number of representatives was 0 before and after the change. So the total number of classes which had a change in number of representatives or cardinality is at most $O(\log n)$, which, combined with the fact that updating each one takes $O(\log\log C)$ time, gives us the desired time complexity. ◀

4.6 Numerical Considerations (reading an update is fast)

We assume that updates arrive with weights w that are organized like standard floating point numbers: a significand s, a base b, and an exponent x such that $1 \leq s < b$ and $sb^x = w$, along with pointers to where in the number these segments begin and end. Note that s will be $O(\log w)$ bits long, b will be a constant number of bits, and x will be $O(\log\log w)$ bits.

We want two pieces of information from this update: the pair of W_is that the edge should be processed by, and enough information about the edge's weight to maintain those W_is without too much error. The first piece of information is easy to approximate from reading just the exponent and the base, since the significand only changes the weight of w by a factor of at most b. Then we can send the edges to class i and $i+1$ for $i = x/\log_b(n/\varepsilon)$. The only concern then is if $x/\log_b(n/\varepsilon) < i+1$ but $sx/\log_b(n/\varepsilon) = \log_{n/\varepsilon} w \geq i+1$, in which case the edge "belonged" in classes $i+1$ and $i+2$ but was sent to i and $i+1$ instead. Fortunately, if w is on the border in this way, and $i+2$ is the highest non-empty class, w would be on one of the lowest weight edges in that class, meaning that its weight is at most $\varepsilon b/n$ times the weight of the largest edge in the matching, and the error incurred is only $O(\varepsilon)$ times that weight, even if a full $n/2$ edges of this type are missed, and so the error is subsumed into the rounding error.

The second piece of information does require us to read the significand, but fortunately only very few bits of it. Since all of the edges within class i have weights between $(n/\varepsilon)^i$ and $(n/\varepsilon)^{i+2}$, and because misreporting the lower order bits of the weights only causes multiplicative $(1-\varepsilon/n)$ error in each edge weight, for a total error of ε from all edges in the matching, we can divide the weights of the edges by the lower bound of their classes, resulting in needing to send weights that can be described in only $O(\log(n/\varepsilon))$ bits. Further, since we can just truncate off the trailing bits of the significand rather than performing a true division, we only need to read the first $O(\log(n/\varepsilon))$ bits of the significand to determine which values to send.

SOS Is Not Obviously Automatizable, Even Approximately*

Ryan O'Donnell

Computer Science Department, Carnegie Mellon University, Pittsburgh, USA
odonnell@cs.cmu.edu

Abstract

Suppose we want to minimize a polynomial $p(x) = p(x_1, \ldots, x_n)$, subject to some polynomial constraints $q_1(x), \ldots, q_m(x) \geq 0$, using the Sum-of-Squares (SOS) SDP hierarachy. Assume we are in the "explicitly bounded" ("Archimedean") case where the constraints include $x_i^2 \leq 1$ for all $1 \leq i \leq n$. It is often stated that the degree-d version of the SOS hierarchy can be solved, to high accuracy, in time $n^{O(d)}$. Indeed, I myself have stated this in several previous works.

The point of this note is to state (or remind the reader) that this is not obviously true. The difficulty comes not from the "r" in the Ellipsoid Algorithm, but from the "R"; a priori, we only know an exponential upper bound on the number of bits needed to write down the SOS solution. An explicit example is given of a degree-2 SOS program illustrating the difficulty.

1 Introduction

Suppose you want to approximately minimize a real polynomial $p(x) = p(x_1, \ldots, x_n)$ over the set $K = \{x \in \mathbb{R}^n : q_1(x) \geq 0, \ldots, q_m(x) \geq 0\}$, where $q_1, \ldots, q_m$ are real polynomials. All of the examples I'll consider will be quite simple: m will be at most $O(n)$; and, the polynomials $p, q_1, \ldots, q_m$ will be of degree at most 2 and will have small integer coefficients (magnitude at most poly(n), say; often at most 2). A good example to keep in mind arises from the "Balanced Separator" problem in combinatorial optimization. There, you're given an n-vertex graph $G = (V, E)$ and the goal is to partition its vertices into two parts, neither of size more than $\frac{2}{3}n$, such that the number of edges crossing between the parts is minimized. Introducing a variable x_i for each vertex, this is equivalent to solving

$$\min \sum_{\{i,j\} \in E} \tfrac{1}{4}(x_i - x_j)^2 \quad \text{subject to} \quad \{x_i^2 = 1 \ \forall i, \ -\tfrac{1}{3}n \leq x_1 + \cdots + x_n \leq \tfrac{1}{3}n\}.$$

Here $x_i^2 = 1$ can be treated as the two inequalities $1 - x_i^2 \geq 0$, $-1 + x_i^2 \geq 0$. Another good example arises from the "Maximum Independent Set" problem on G:

$$\max \sum_{i=1}^{n} x_i \quad \text{subject to} \quad \{x_i^2 = x_i \ \forall i, \ x_i x_j = 0 \ \forall \{i,j\} \in E\}.$$

A powerful technique for trying to certify that the minimum is at least $\theta \in \mathbb{R}$ is to find a formal polynomial identity of the form

$$p(x) - \theta = u_0(x) + u_1(x)q_1(x) + \cdots + u_m(x)q_m(x), \tag{1}$$

where each $u_j(x)$ is SOS; i.e., a sum of squares of polynomials. We will refer to this as "SOS-proving" or "SOS-certifying" the statement "$p(x) \geq \theta$". A variation of this technique ("SOS-refutation") is to take $q_{m+1}(x) = (\theta - \epsilon) - p(x) \geq 0$ as an additional constraint, and then try to SOS-prove the statement "$-1 \geq 0$". It's easy to check that we can do this for every $\epsilon > 0$ provided that "$p(x) \geq \theta$" is SOS-provable. So if we aren't concerned with very small additive errors — and I won't be, in this note — the refutation technique is fundamentally stronger (see, e.g., [22] for further discussion). In any case, I'll use the "SOS-certifying" terminology in the rest of the note, since SOS-refutation is just a special case with one extra constraint.

Suppose we now bound the degree of the $u_j(x)$'s, insisting that $\deg(u_0), \deg(u_1 q_1), \cdots \leq d$. Then the question of whether the certifying $u_j(x)$'s exist is equivalent to the feasibility of a certain semidefinite program (SDP). This is the "degree-d SOS relaxation", pioneered by Shor [28], Nesterov [20], Grigoriev and Vorobjov [9], Lasserre [16, 17] and Parrilo [23]. See, e.g., [18, 3] for many more details.

Under the simple assumptions I mentioned (namely, $m \leq O(n)$, p and q_j's having small coefficients and degree at most 2), the degree-d SOS SDP for (1) can be written down using $N = n^{O(d)}$ bits. It is then quite commonly stated that feasibility can be tested in $\text{poly}(N)$ time, using, say the Ellipsoid Algorithm [15, 11]. This is sometimes referred to as the SOS proof system being "automatizable". Unfortunately, I will now explain why it's not clear whether this is truly the case.

Approximation, and the explicitly bounded case. I should emphasize that I am *not* worried about very small additive errors; i.e., the difference between testing feasibility and near-feasibility. Indeed, most often the caveat is correctly added that semidefinite programming only tests feasibility up to a very small additive error. This caveat is related to the fact that the Ellipsoid Algorithm has a technical requirement, that if the SDP is feasible then it contains a feasible ball of some small radius $r = 2^{-\text{poly}(N)} > 0$. Actually, to talk about additive error only makes sense if there is some notion of "scaling". To continue keeping things simple, I'll henceforth assume that the variables are intended to be in the range $[-1, 1]$; i.e., that K always includes the constraints $x_i^2 \leq 1$ for $1 \leq i \leq n$. (It would actually be fine if we even just had $x_i^2 \leq 2^{\text{poly}(N)}$ for all i.) This is sometimes called the "explicitly bounded" or "Archimedean" case, and it's also known to imply that the SDP has no duality gap [13].

With this issue discussed, let's now again pose the question:

Question. *Suppose there is a degree-d SOS proof that $p(x) \geq \theta$ subject to constraints $x_1^2, \ldots, x_n^2 \leq 1$ and $q_1(x), \ldots, q_m(x) \geq 0$, of the form (1). Is there a $\text{poly}(N)$-time algorithm (presumably, a version of the Ellipsoid Algorithm) that finds SOS polynomials $u_0(x), \ldots, u_m(x)$ certifying $p(x) \geq \theta - o_N(1)$?*

In a joint work with Yuan Zhou [22, Footnote 2], I wrote that the answer is "yes".[1] However I now see that my reasoning was incomplete, and that the answer is unclear. In fact, I would now guess that the answer is probably "no". Although it's true that the technical "r" parameter in the Ellipsoid Algorithm does not cause real problems in the explicitly bounded case, there is another technical parameter, "R" — and it *does* seem to cause real problems. The Ellipsoid Algorithm is only guaranteed to work correctly in $\text{poly}(N)$ time if the SDP's

[1] Sorry for talking you into that footnote, Yuan.

feasible region (should it exist) intersects a ball of radius $R = 2^{\mathrm{poly}(N)}$. In other words, algorithmically speaking it's not enough for an SOS proof to exist; we also need one to exist in which all the SOS polynomials can be written down with $\mathrm{poly}(N)$ bits. However, in the next section I'll show a simple, explicitly bounded example where an inequality is SOS-provable, but any approximate SOS proof requires integers of size roughly 2^{2^n}. This example is based on the well-known fact (attributed to J. Ramana in [1] and to Khachiyan in [25]) that there are SDPs with n variables and $O(n)$ constraints that are feasible, yet for which every feasible solution requires exponential bit-complexity.

In fact, as pointed out to me by Pablo Parrilo, *every* SDP-feasibility problem can be viewed as an SOS-feasibility problem modulo an ideal; thus, if we ignore the insistence on $x_i^2 \le 1$ constraints, the above **Question** is tantamount to simply asking if the Semidefinite Feasibility Problem (SDFP) is in P. This is a well-known open question; see [25, 24, 30]. The best current upper bound known is PSPACE, by reduction to the existential theory of the reals.[2]

2 SOS-provable, but only with huge coefficients

Let's say we have $2n$ indeterminates $x_1, x_2, \dots, x_n, y_1, \dots, y_n$, and the following constraints.

$$\begin{array}{llll} 2x_1y_1 = y_1, & 2x_2y_2 = y_2, & 2x_3y_3 = y_3, & 2x_ny_n = y_n, \\ x_1^2 = x_1, & x_2^2 = x_2, & x_3^2 = x_3, \quad \cdots & x_n^2 = x_n, \\ y_1^2 = y_2, & y_2^2 = y_3, & y_3^2 = y_4, & y_n^2 = 0. \end{array} \tag{K}$$

(These should be read column-wise. Notice the very last constraint, $y_n^2 = 0$, breaks the pattern.)

At first, I won't include the constraints $x_i^2 \le 1$, $y_i^2 \le 1$; we'll analyze their inclusion later.

We wish to know whether

$$p_n(x, y) = x_1 + x_2 + x_3 + \cdots + x_n - 2y_1$$

is nonnegative subject to these constraints. It's easy for the human mathematician to see the answer is "yes", because "solving" the constraints shows that they are equivalent to $x_1, \dots, x_n \in \{0, 1\}$ and $y_1 = \cdots = y_n = 0$; hence the minimum of $p_n(x)$ is 0. However SOS algorithms do not first try to "solve" or "simplify" the constraints.[3] So we have to see what happens when SOS algorithms are run "generically" on this input.

For simplicity, let's consider the degree-2 SOS algorithm. In this case, whether we consider the constraints as equalities or two-inequalities amounts to the same thing: we get to multiply

[2] Even the special case of deciding whether a given rational multivariate polynomial is SOS is not known to be in P or even in NP. I do not know if the "R" problem is relevant here, but the "r" problem certainly is; according to Scheiderer [26] there are rational polynomials such as $x^4 + xy^3 + y^4 - 3x^2yz - 4xy^2z + 2x^2z^2 + xz^3 + yz^3 + z^4$ that are SOS but don't have a rational SOS representation. However in this work I am less concerned with this kind of example, because I would like to consider the "bounded case" and allow approximation.

[3] Otherwise, the well-known SOS lower bounds for "Knapsack" [8] and "kXOR" [7, 27] would be invalid. In particular, applying a Gröbner basis algorithm to the constraints is not a good idea in general, since it has exponential complexity even for zero-dimensional ideals [12]. For example, the size of the Gröbner basis for the very simple "Max-Bisection" ideal, $\{x_1^2 = \cdots = x_{2n}^2 = 1, x_1 + \cdots + x_{2n} = 0\}$, is $\widetilde{\Theta}(2^n)$.

them by nonnegative reals. Thus the question becomes:

$$p_n(x,y) = \big[\text{degree-2 SOS}\big] \bmod (\text{K})? \tag{2}$$

where the "mod" refers to adding linear multiples of the constraint equations — i.e., adding $a(2x_1y_1-y_1)+b(x_1^2-x_1)+c(y_1^2-y_2)+d(2x_2y_2-y_2)+\cdots$ for some real constants $a,b,c,d,\ldots$. The answer to this question is *also* "yes":

$$p_n(x,y) = (x_1-2y_1)^2+(x_2-4y_2)^2+(x_3-16y_3)^2+(x_4-256y_4)^2+\cdots+(x_n-2^{2^{n-1}}y_n)^2 \bmod (\text{K}).$$

However, it turns out that *every* way of expressing $p_n(x,y)$ as in (2) has exponential-in-n bit-complexity. This shows that no matter how exactly we formulate the SOS problem as an SDP (e.g., whether we look for homogeneous or non-homogeneous sums of squares, whether we explicitly introduce variables $a,b,c,d,\ldots$ to multiply against the constraints or instead work "mod the ideal", etc.), no generic polynomial-time SDP-solving algorithm will find a degree-2 SOS proof of $p_n(x,y) \geq 0$.[4]

Before proving this, two comments: First, this example and its proof are nothing more than a slight rearrangement of the standard example of a feasible SDP whose only feasible solutions are doubly exponential. I'm only putting an SOS spin on it. Second, this argument doesn't really give a negative example for the **Question** from Section 1, because it's conceivable that there is a degree-2 SOS proof with polynomial bit-complexity of "$p_n(x,y) \geq -\epsilon_n$", where $\epsilon_n = o_n(1)$. In Subsections 2.1, 2.2, I'll show that even this is impossible, even when the constraints $x_i^2 \leq 1$, $y_i^2 \leq 1$ are added.

So let's suppose we have an SOS representation of $p_n(x,y)$ as in (2):

$$x_1 + x_2 + \cdots + x_n - 2y_1 = \sum_j \ell_j(x,y)^2 \bmod (\text{K}), \tag{3}$$

where the ℓ_j's denote linear polynomials. In fact, the ℓ_j's must be homogeneous of degree 1. The reason is that if we set all x_i's and y_i's to 0 in (3), the LHS becomes 0 and the RHS becomes the sum of the squares of the constant coefficients of the ℓ_j's. Hence all these constant coefficients must be 0.

Next, let us express each ℓ_j as $\sum_{k=1}^n \ell_{jk}$, where each ℓ_{jk} is of the form $a_{jk}x_k + b_{jk}y_k$. It would of course be incorrect to say that $\ell_j^2 = \sum_{k=1}^n \ell_{jk}^2$ — to neglect the cross-terms is the so-called "freshman's dream". Notice, though, that any nonzero cross-term contains a monomial of the form $x_kx_{k'}$, $x_ky_{k'}$, or $y_ky_{k'}$ ($k \neq k'$), and no such monomial appears on the left in (3). Furthermore, such monomials are not affected by the "mod (K)", and thus they must be canceled via cross-terms arising from other squares $\ell_{j'}^2$ in the sum. Hence following the "freshman's dream" in $\sum_j \ell_j^2$ actually gives the same identity in (3). In other words, we may assume without loss of generality that (3) is of the form

$$\sum_{i=1}^n \sum_j (a_{ij}x_i + b_{ij}y_i)^2 = \sum_{i=1}^n (A_i^2x_i^2 + 2M_ix_iy_i + B_i^2y_i^2), \tag{4}$$

where $A_i = \sqrt{\sum_j a_{ij}^2}$, $B_i = \sqrt{\sum_j b_{ij}^2}$, and $M_i = \sum_j a_{ij}b_{ij}$. Cauchy–Schwarz implies

$$|M_i| = \sum_j a_{ij}b_{ij} \leq A_iB_i. \tag{5}$$

[4] Note that it doesn't matter whether we ask the algorithm to find a PSD matrix representing the SOS polynomial, or the actual sums of squares. Since Cholesky (LDL) decomposition can be done in polynomial time (see Section 4), if there were a rational PSD matrix of polynomial bit-complexity representing the SOS polynomial, we could extract from it an explicit rational sum-of-squares representation with polynomial bit-complexity.

For (4) to equal the LHS of (3) mod (K), we'll need to use all of the equality constraints, thereby obtaining

$$\sum_{i=1}^{n}(A_i^2 x_i + M_i y_i + B_i^2 y_{i+1}),$$

with y_{n+1} denoting 0. Equating coefficients with LHS(3), we deduce

$$A_i = 1 \ \forall i, \quad M_1 = -2, \quad M_{i+1} = -B_i^2 \ \forall 1 < i < n.$$

Combining this with (5), we get $B_i \geq |M_i|$ for all i, and hence

$$B_1 \geq 2, \quad B_{i+1} \geq B_i^2 \ \forall 1 < i < n.$$

Thus $B_n \geq 2^{2^{n-1}}$; i.e., the sum of the squares of the coefficients on y_n in any representation (3) is at least 2^{2^n}. So indeed any solution to (2) has exponential bit-complexity.

2.1 Even approximately

I'll now show that even getting a degree-2 SOS proof of $p_n(x, y) \geq -o_n(1)$ is impossible without exponential bit-complexity. So suppose we have

$$x_1 + x_2 + \cdots + x_n - 2y_1 + \epsilon = \sum_j \ell_j(x, y)^2 \text{ mod (K)}, \tag{6}$$

where $\epsilon \leq .01$, say. Now we can't deduce that the ℓ_j's are homogeneous, but the reasoning concerning the "freshman's dream" still holds. So the SOS part must be of the form

$$\sum_{i=1}^{n}\sum_j (a_{ij}x_i + b_{ij}y_i + c_{ij})^2 = \sum_{i=1}^{n}(A_i^2 x_i^2 + 2M_i x_i y_i + B_i^2 y_i^2 + 2U_i x_i + 2V_i y_i + C_i^2),$$

where we're now introducing the notation $U_i = \sum_j a_{ij}c_{ij}$, $V_i = \sum_j b_{ij}c_{ij}$, and $C_i = \sqrt{\sum_j c_{ij}^2}$. Cauchy–Schwarz still implies (5), and also

$$|U_i| \leq A_i C_i, \quad |V_i| \leq B_i C_i. \tag{7}$$

Again, equating coefficients and reducing mod (K) yields

$$\epsilon = \sum_i C_i^2, \quad A_i^2 + 2U_i = 1 \ \forall i, \quad M_1 + 2V_1 = -2, \quad M_{i+1} + 2V_{i+1} = -B_i^2 \ \forall 1 < i < n. \tag{8}$$

As $\epsilon \leq .01$, the first equation implies $C_i \leq .1$ for all i. Thus (7) implies $|U_i| \leq .1A_i$, $|V_i| \leq .1B_i$. Substituting these into the above yields the following:

$$A_i^2 - .2A_i \leq 1 \implies A_i \leq 1.2 \ \forall i; \qquad |M_1| \geq 2 - .2B_1; \qquad |M_{i+1}| \geq B_i^2 - .2B_{i+1} \ \forall 1 < i < n.$$

As we still have (5), the first inequality above yields $1.2B_i \geq |M_i|$ for all i. Combining this with the second and third inequalities above gives:

$$1.4B_1 \geq 2 \implies B_1 \geq 1.42;$$
$$1.2B_{i+1} \geq |M_{i+1}| \geq B_i^2 - .2B_{i+1} \implies 1.4B_{i+1} \geq B_i^2 \ \forall 1 < i < n.$$

Together, the above yield $B_n \geq 1.4(1.42/1.4)^{2^{n-1}}$, and we again see that exponential bit-complexity is required for a degree-2 SOS proof of $p_n(x, y) \geq -.01$ mod (K). (Incidentally, this also rules out the possibility of "SOS-refuting" the statement $p_n(x, y) < -o_n(1)$ with degree 2.)

2.2 Even with the "Archimedean" constraints

Finally, it's easy to see that the conclusion doesn't change even if we add to (K) the additional constraints $x_i^2 \leq 1$ and $y_i^2 \leq 1$ for all i, making the domain "Archimedean" ("explicitly bounded"). We know these constraints are actually redundant, so still $p_n(x,y)$ has minimal value 0. As for the effect on degree-2 SOS proofs, the new constraints allow us to also add terms $D_i(1-x_i^2)$ and $E_i(1-y_i^2)$ on the RHS of (6) for nonnegative constants D_i, E_i. In turn, this changes (8) to

$$\epsilon = \sum_i (C_i^2 + D_i + E_i), \quad A_i^2 + 2U_i - D_i = 1 \ \forall i, \quad M_1 + 2V_1 = -2,$$
$$M_{i+1} + 2V_{i+1} = -B_i^2 + E_i \ \forall 1 < i < n.$$

The first constraint implies $D_i, E_i \leq .01$ for all i. Given $D_i \leq .01$, we can still deduce $A_i^2 - .2A_i \leq 1.01$, which still implies $A_i \leq 1.2$. The condition $E_i \leq .01$ changes $|M_{i+1}| \geq B_i^2 - .2B_{i+1}$ to $|M_{i+1}| \geq B_i^2 - .2B_{i+1} - .01$, and hence we only get $1.4B_{i+1} \geq B_i^2 - .01$ for all $1 < i < n$. But this is still enough to conclude B_n is doubly-exponential in n, as before. In summary:

▶ **Theorem 1.** *Subject to* (K) *and* $x_i^2 \leq 1$, $y_i^2 \leq 1$, *there is a degree-2 SOS proof that* $p_n(x,y) \geq 0$. *However any degree-2 SOS proof even of* $p_n(x,y) \geq -.01$ *requires bit-complexity* $\Theta(2^n)$.

As a further remark, in the "explicitly bounded" case it's known that there is no SDP duality gap. So instead of trying to use semidefinite programming to get an SOS proof of $p_n(x,y) \geq -o_n(1)$, we might try using it to find a "pseudoexpectation" $\widetilde{\mathbf{E}}[\cdot]$ that satisfies the constraints and minimizes $\widetilde{\mathbf{E}}[p_n(x,y)]$. (See [3] for more on this terminology.) In this dual case, there won't be any "R problem", but instead we'll get an "r problem". The Ellipsoid Algorithm might be used to produce an $\widetilde{\mathbf{E}}[\cdot]$ that satisfies all the constraints up to doubly-exponentially small tolerance; e.g., the *genuine* distribution $x_i \equiv 0$, $y_i \equiv 2^{-2^i}$ satisfies all constraints except for $y_n^2 = 0$, which it satisfies to doubly-exponentially small tolerance. As constructors of SDP hierarchy integrality gaps know, the step of massaging an almost-satisfying solution to an exactly-satisfying solution is often non-obvious and problem-specific.

3 Discussion

I think that Theorem 1 gives a particularly simple example of things going wrong. It's not too much different from, say, the SOS formulation of Maximum Independent Set. Undoubtedly there are generic extensions of the SOS method that will handle this one specific example. For example, the Gröbner basis technique will not have exponential complexity in this case, and will in fact lead to an efficient degree-2 SOS-proof of $p_n(x,y) \geq 0$. We also did not analyze how degree-*four* SOS behaves on this instance. But the point is that it's not so easy to think of generic SOS extensions that will always work in polynomial time. Nor is it easy to think of additional structural constraints on instances that may help, yet that are not too restrictive.

An obvious candidate for additional structure is the constraint that every variable is not just bounded in $[-1,1]$ but *Boolean*. This is at least a common scenario in combinatorial optimization. One still has to be careful though. For example, there is a well-known trick for converting inequality constraints to equality constraints in SOS: replace $q_i(x) \geq 0$ with

$q_i(x) = z^2$ where z is a new variable. However this new variable wouldn't be constrained to be Boolean.

I don't know whether constraining every variable to be Boolean will cause feasible SOS SDPs to always have solutions of polynomial bit-complexity. However in the next section I'll observe that if these are the *only* constraints, we are in good shape. Nevertheless, this seems to me a somewhat rare situation; e.g., it's not satisfied in the Balanced Separator or Independent Set examples. And as noted earlier, although you may succeed in SOS-proving $p(x) \geq \theta$ subject to $x_i^2 = 1\ \forall i$, it's always fundamentally better to try SOS-proving $-1 \geq 0$ subject to the extra constraint $p(x) \leq \theta - \epsilon$. But then you have an additional constraint-inequality in addition to Booleanness.

4 Automatizing SOS proofs subject only to Booleanness

Here I'll record the known observation that, in $n^{O(d)}$ time, we can approximately test if some $p(x)$ is a degree-d sum of squares, modulo $\{x_i^2 = 1,\ \forall i\}$. (To avoid an extra parameter, I'll assume the coefficients of $p(x)$ are rationals expressible with $n^{O(d)}$ bits.) Specifically, if indeed $p(x)$ is degree-d SOS, then the algorithm will find a degree-d SOS representation of $p(x) + \epsilon$ for some $0 \leq \epsilon \leq 2^{-N^{O(d)}}$. I emphasize that there is no mathematical innovation in this section; all the details herein are known.

The typical way to formulate this problem as an SDP is to consider real symmetric matrices X with rows and columns indexed by the $N = n^{O(d)}$ subsets $S \subseteq [n]$, $|S| \leq d/2$. Then $p(x)$ is degree-d SOS mod $\{x_i^2 = 1,\ \forall i\}$ if and only if

$$\exists X \succeq 0 \quad \text{such that} \quad \sum_{\substack{|S|,|T| \leq d/2 \\ S \Delta T = U}} X_{S,T} = p_U \ \forall\ U \subseteq [n],\ |U| \leq d, \tag{SDP}$$

where p_U denotes the coefficient of $p(x)$ on $\prod_{i \in U} x_i$. (We may assume without loss of generality that $p(x)$ is multilinear.) This SDP feasibility problem can be written down using $\mathrm{poly}(N)$ bits, and we want to argue it can be decided (approximately) in $\mathrm{poly}(N)$ time.

The key observation is that the $U = \emptyset$ constraint of (SDP) is precisely "$\mathrm{tr}(X) = p_\emptyset$". The bit-complexity of $p_\emptyset$ is $\mathrm{poly}(N)$, by assumption (in general, it's bounded by the input size). Thus any feasible PSD solution X has the sum of its eigenvalues at most $\mathrm{poly}(N)$, and hence squared Frobenius norm at most $\mathrm{poly}(N)$. This means we can take the "R" in the Ellipsoid Algorithm to be $\mathrm{poly}(N)$, overcoming the main difficulty described in this note. (Note that we could still run in $\mathrm{poly}(N)$ time even if R were $2^{\mathrm{poly}(N)}$.)

We now recall how to take care of the "r" for the Ellipsoid Algorithm. The linear constraints in (SDP) obviously preclude any feasible region from containing a ball of positive radius. So we relax the "$= p_U$" equality constraints to two-sided "$\in [p_U - \epsilon', p_U + \epsilon']$" inequalities, where $\epsilon' = 2^{-N^c}$ for some constant c. (Note that this preserves feasibility, and the bit-complexity of ϵ' is just $\mathrm{poly}(N)$.) Actually, we're still not done because of the additional symmetry requirement $X_{S,T} = X_{T,S}$, but we can take care of this as in the original paper by Grötschel, Lovász, and Schrijver [10] by not introducing variables for the below-diagonal elements of X, treating them implicitly. We can now take the Ellipsoid Algorithm's "r" parameter to be $2^{-\mathrm{poly}(N)}$, as needed.

Finally, we have a $\mathrm{poly}(N)$-time "strong separation oracle" for the relaxed form of (SDP). This follows immediately from the fact that testing whether a matrix of rationals is PSD can be done exactly in polynomial time, as noted in [10].[5] Thus the Ellipsoid Method, as

[5] I've found that the correct proof of this fact appears extremely rarely in the literature; indeed, I've only

described thoroughly in [11], will find a solution to the relaxed form of (SDP) in poly(N) time, provided one exists.

By performing $LDL^\top$ decomposition on the solution (see, e.g., [21]), in poly(N) time we get an exact SOS representation $p'(x) = \sum_{j=1}^{n} c_j r_j(x)^2$, where $p'(x)$ is a polynomial with the property that $|p_U - p'_U| \leq 2^{-N^c}$ for all U. (Here c_j and the coefficients of $r_j(x)$ are rational, and the degree of each $r_j(x)$ is at most $d/2$.) Writing $\Delta(x) = p'(x) - p(x)$, we have a degree-d SOS representation of $p(x) + \Delta(x)$, where Δ has degree at most d and all coefficients bounded by ϵ. Now for each monomial δx^U in $\Delta(x)$, we can get a degree-d SOS proof of $\delta x^U \leq |\delta|$ by using either $x^U = -1 + \frac{1}{2}(x^V + x^W)^2$ or $x^U = 1 - \frac{1}{2}(x^V - x^W)^2$, where V and W partition U into two sets, each of cardinality at most $d/2$. Adding these in for each of the roughly N^2 potential monomials of $\Delta(x)$ therefore gives a degree-$2d$ SOS representation of $p(x) + \epsilon$ for $\epsilon \lessapprox N^2 2^{-N^c}$, and we can make the constant c as large as we want.

5 Conclusion

Several papers have shown that certain "hard-seeming instances" of combinatorial optimization problems — like Unique-Games or Balanced-Separator — are not hard for the constant-degree SOS proof system. Optimistically, this might be evidence that there are better polynomial-time approximation algorithms for the problems than those currently known. But in the end, if we want to show that certain approximation tasks are literally in P in the Turing machine model, we'll have to treat some of the details discussed in this paper.

A good open problem is to establish useful conditions under which this treatment can be done automatically. E.g., does the **Question** from Section 1 have a positive answer if the constraints $x_i^2 \leq 1$ are upgraded to $x_i^2 = 1$?

Regarding errata for my own works: In [22, 14] we showed that certain explicit families of combinatorial optimization instances have low-degree SOS analyses. I did not yet verify that these SOS proofs also have the necessarily small bit-complexity that would allow an efficient algorithm to (approximately) find them. However we didn't formally claim that these algorithms exist; the theorems in these works were just evidence that SOS *might* be successful on all instances. In [2] we claimed that SOS algorithms could efficiently refute random instances of certain CSPs with certain parameters. I'm confident that this statement is true, but rather than prove it I'll simply say that the SOS-ability here is essentially just a side comment. It's clear that there is *some* efficient algorithm: all that's ultimately needed for refutation is the certification that a certain symmetric matrix A has $\|A\| \leq O(\text{small})$. This is equivalent to $O(\text{small}) \cdot I - A \succeq 0$, and as noted in Section 4, testing semidefiniteness of rational matrices can be done efficiently.

Acknowledgments. I would like to thank Boaz Barak, Sangxia Huang, Etienne de Klerk, Pravesh Kothari, James Lee, Pablo Parrilo, Dima Pasechnik, David Steurer, and especially

seen it in the work of Grötschel, Lovász, and Schrijver [10, 11] and in a survey article by Lovász [19]. You certainly can't just "compute the eigenvalues of the matrix and check if they're nonnegative". It's also a somewhat common misconception [29, 4] that X is PSD if and only if its N leading principal minors are nonnegative. The correct proof from [19] involves seeing whether the Cholesky (LDL) decomposition on X succeeds. (This is essentially the same as the proof in [10], which involves finding the image of X, then checking if X is strictly positive definite on the image by testing if the leading principal minors are strictly positive.) In turn, this relies on the old but nonobvious [6] fact due to Edmonds [5] that Gaussian Elimination is in polynomial time.

David Witmer for discussions. I would also like to thank Dieter van Melkebeek for pointing out the incorrect justification of (4) in an earlier draft of this work.

Abstract

The class TFNP is the search analog of NP with the additional guarantee that any instance has a solution. TFNP has attracted extensive attention due to its natural syntactic subclasses that capture the computational complexity of important search problems from algorithmic game theory, combinatorial optimization and computational topology. Thus, one of the main research objectives in the context of TFNP is to search for efficient algorithms for its subclasses, and at the same time proving hardness results where efficient algorithms cannot exist.

Currently, no problem in TFNP is known to be hard under assumptions such as NP hardness, the existence of one-way functions, or even public-key cryptography. The only known hardness results are based on less general assumptions such as the existence of collision-resistant hash functions, one-way permutations less established cryptographic primitives (e.g., program obfuscation or functional encryption).

Several works explained this status by showing various barriers to proving hardness of TFNP. In particular, it has been shown that hardness of TFNP hardness cannot be based on worst-case NP hardness, unless NP = coNP. Therefore, we ask the following question: What is the weakest assumption sufficient for showing hardness in TFNP?

In this work, we answer this question and show that hard-on-average TFNP problems can be based on the weak assumption that there exists a *hard-on-average* language in NP. In particular, this includes the assumption of the existence of one-way functions. In terms of techniques, we show an interesting interplay between problems in TFNP, derandomization techniques, and zero-knowledge proofs.

1 Introduction

The class NP captures all *decision* problems for which the "yes" instances have efficiently verifiable proofs. The study of this class and its computational complexity are at the heart of theoretical computer science. Part of the effort has been to study the *search* analog of NP which is defined by the class FNP (for Function NP) and captures all search problems for which verifying a solution can be done efficiently. Megiddo and Papadimitriou [43] introduced

the complexity class TFNP (for Total Function NP) which is a subclass of FNP with the additional property of the problem being *total*, i.e., for any instance a solution is guaranteed to exist. For this reason, the class TFNP is usually considered as the search variant containing NP ∩ coNP: in particular, for any language $L \in \mathsf{NP} \cap \mathsf{coNP}$, the corresponding search problem is given by an instance x and a solution is either a witness verifying that $x \in L$ or a witness verifying that $x \notin L$. Since $L \in \mathsf{NP} \cap \mathsf{coNP}$, such a solution must always exist.

Beyond its natural theoretical appeal, TFNP attracted extensive attention due to its important syntactic subclasses. The common way of defining such subclasses is via various non-constructive arguments used for proving totality of search problems. For example, the *parity argument for directed graphs*: "If a directed graph has an unbalanced node (a vertex with unequal in-degree and out-degree), then it must have another unbalanced node," gives rise to the class PPAD (for Polynomial Parity Argument on Directed graphs [47]). This might be the most famous subclass of TFNP due to the fact that one of its complete problems is finding Nash equilibria in strategic games [19, 18]. Other known subclasses are PPP (for Polynomial Pigeonhole Principle [47]), PLS (for Polynomial Local Search [36]), and CLS (for Continuous Local Search [20]).

It is easy to see that if P = NP then all search problems in TFNP can be solved efficiently. Therefore, the study of the hardness of TFNP classes must rely on some hardness assumptions (until the $\mathsf{P} \stackrel{?}{=} \mathsf{NP}$ question is resolved). A related issue is to establish hard distributions for problems in TFNP. Here it is natural to use hardness of cryptographic assumptions, and therefore the goal is to base TFNP hardness on different cryptographic primitives. For instance, the (average-case) hardness of the subclass PPP has been based on the existence of either one-way permutations[1] [47] or collision-resistant hash[2] [35]. For other subclasses even less standard assumptions have been used. The hardness of PPAD, PLS and even CLS (a subclass of their intersection) has been based on strong cryptographic assumptions, e.g., indistinguishability obfuscation and functional encryption [13, 26, 29].

To understand the hierarchy of cryptographic assumptions it is best to turn to Impagliazzo's worlds [30]. He described five possible worlds: `Algorithmica` (where P = NP), `Heuristica` (where NP is hard in the worst case but easy on average, i.e., one simply does not encounter hard problems in NP), `Pessiland` (where hard-on-average problems in NP exist, but one-way functions do not exist), `Minicrypt` (where one-way functions exist[3]), and `Cryptomania` (where Oblivious Transfer exists[4]). Nowadays, it is possible to add a sixth world, `Obfustopia` where indistinguishability obfuscation for all of P is possible [7, 25, 51]. Our goal is to connect these worlds to the world of TFNP.

So far the hardness of TFNP was only based either on `Obfustopia` or strong versions of `Minicrypt` (e.g. one-way permutations). None of the assumptions used to show TFNP hardness are known to be implied simply by the existence of one-way functions, or even from public-key encryption. It is known that one-way permutations cannot be constructed in a black-box way from one-way functions [50, 37]. Moreover, indistinguishability obfuscation is a relatively new notion that has yet to find solid ground (see [1, Appendix A] for a summary

[1] A permutation is one-way if it is easy to compute on every input, but hard to invert on a random image. Such permutations exist only if $\mathsf{P} \neq \mathsf{NP} \cap \mathsf{coNP}$ [16].

[2] A collision-resistant hash is a hash function such that it is hard to find two inputs that hash to the same output. Simon [52] showed a *black-box separation* between one-way functions and collision-resistant hashing.

[3] For many primitives such as shared-key encryption, signatures, and zero-knowledge proofs for NP it is known that their existence is equivalent to the existence of one-way functions.

[4] Roughly speaking, this world is where public-key cryptography resides.

of known attacks as of August 2016). Moreover, while indistinguishability obfuscation implies the existence of one-way functions [39], it has been shown that it cannot be used to construct either one-way permutations or collision-resistant hash in a black-box manner [5, 6]. Other hardness results for TFNP rely on specific number theoretic assumptions such as factoring or discrete log.

Barriers for proving TFNP hardness. Given the lack of success in establishing hardness of TFNP under general assumptions, there has been some effort in trying to explain this phenomenon. From the early papers on PLS and TFNP by Johnson et al. [36] and Megiddo and Papadimitiriou [43] we know that TFNP hardness cannot be based on worst-case NP hardness, unless NP = coNP.[5] Mahmoody and Xiao [42] showed that even a *randomized* reduction from TFNP to worse-case NP would imply that SAT is "checkable" (which is a major open question [15]). Buhrman et al. [17] exhibited an oracle under which all TFNP problems are easy but the polynomial hierarchy is infinite, thus, explaining the failure to prove TFNP hardness based on worst-case problems in the polynomial hierarchy. In a recent work, Rosen et al. [49] showed that any attempt to base TFNP hardness on (trapdoor) one-way functions (in a black-box manner) must result in a problem with exponentially many solutions. This leads us to ask the following natural question:

What is the weakest assumption under which we can show hardness of TFNP*?*

A possible approach to answering this question is to try to put TFNP hardness in the context of the Impagliazzo's five worlds. In the light of this classification, one can argue that an equally, if not more interesting, question is:

What is the weakest assumption for hardness on average of TFNP*?*

In this work, we give an (almost) tight answer to this question. Given the negative results discussed above, our results are quite unexpected. While the barriers imply that it is very unlikely to show TFNP hardness under *worst-case* NP hardness, we are able to show that *hard-on-average* TFNP can be based on any *hard-on-average* language in NP (and in particular on the existence of one-way functions). In the terminology of the worlds of Impagliazzo, our results show that hard-on-average TFNP problems exist in `Pessiland` (and beyond), a world in which none of the assumptions previously used to show TFNP hardness exist (not even one-way functions). On the other hand, the barriers discussed above indicate that it would be unlikely to prove worse-case TFNP hardness in `Heuristica`, as in that world the only available assumption is $\mathsf{P} \neq \mathsf{NP}$.

As for techniques, we show an interesting interplay between TFNP and derandomization. We show how to "push" problems into TFNP while maintaining their hardness using derandomization techniques. In the non-uniform settings, our results can be established with no further assumptions. Alternatively, we show how to get (standard) uniform hardness via further derandomization assuming the existence of a Nisan-Wigderson type pseudorandom generator (discussed below).

In correspondence with the black-box impossibility of Rosen et al. [49], the problem we construct might have instances with an exponential number of solutions. Nevertheless, we

[5] The argument is quite simple: Suppose there is a reduction from SAT (for example) to TFNP, in a way that every solution to the TFNP problem translates to a resolution of the SAT instance. This would yield an efficient way to refute SAT: guess a solution of the TFNP problem, and verify that it indeed implies that the SAT instance has no solution.

show that there exists a different problem in TFNP such that its hardness can be based on the existence of one-way functions and *Zaps* (discussed below), and has *either one or two* solutions for any instance. The reason our result does not contradict the impossibility results is (i) that it is not black-box, and (ii) we use an extra object, Zaps; it is unknown whether the latter exists solely under the assumption that one-way functions exist (but it can be shown to exist relative to random oracles). We observe that the fact that our problem has either one or two solutions for every instance is (in some sense) tight: any hard problem with a single solution for every instance would imply hardness of $\mathsf{NP} \cap \mathsf{coNP}$ (by taking a hardcore bit of the unique solution), and thus would have to face the limitations of showing $\mathsf{NP} \cap \mathsf{coNP}$ hardness from unstructured assumptions [12].

Nisan-Wigderson PRGs. Nisan and Wigderson showed how the assumption of a very hard language can be used to construct a specific type of pseudorandom generators (henceforth NW-type PRG) benefitial for tasks of derandomization and in particular to derandomize BPP algorithms [46]. Impagliazzo and Wigderson [34] constructed a NW-type PRG under the (relatively modest) assumption that E (i.e., $\mathsf{DTIME}(2^{O(n)})$) has a problem of circuit complexity $2^{\Omega(n)}$. Although used mainly in computational complexity, (strong versions of) these generators have found applications in cryptography as well: Barak, Lindell, and Vadhan [8] used them to prove an impossibility for two-round zero-knowledge proof systems, Barak, Ong, and Vadhan [9] showed how to use them to construct a witness indistinguishable proof system for NP, and Bitansky and Vaikuntanathan [14] showed how to completely immunize a large class of cryptographic algorithms from making errors. In the examples above, the PRG was constructed to fool polynomial sized (co)non-deterministic circuits. Such NW-type PRGs follow from (relatively modest) assumption that E has a problem of (co)non-deterministic circuit complexity $2^{\Omega(n)}$.

We show that NW-type PRGs have an interesting interplay with TFNP as well. We use strong versions of these generators to show that several different problems can be "pushed" into TFNP by eliminating instances with no solutions (in the uniform setting). Our notion of strong NW-type PRG requires fooling polynomial-sized Π_2-circuits. Again, such PRGs follow from the assumption that E has a problem of Π_2-circuit complexity $2^{\Omega(n)}$ (see [4] for an example of a use of such PRGs).

Zaps. Feige and Shamir [24] suggested a relaxed notion of zero-knowledge called *witness indistinguishability* where the requirement is that any two proofs generated using two different witnesses are computationally indistinguishable. They showed how to construct three-message witness indistinguishable proofs for any language in NP assuming the existence of one-way functions. A Zap, as defined by Dwork and Naor [21], is a two-message public-coin witness indistinguishable scheme where the first message can be reused for all instances. They showed that (assuming one-way functions) Zaps are existentially equivalent to NIZKs (non-interactive zero-knowledge proofs), and hence one can use the known constructions (e.g., based on trapdoor permutations). Dwork and Naor also showed that the interaction could be further reduced to a single message witness indistinguishable proof system in the non-uniform setting (i.e., the protocol has some polynomial sized advice). In the uniform setting, Barak et al. [9] showed the same result by leveraging a NW-type PRG for derandomizing the known constructions of Zaps. Our proofs make use of such witness indistinguishable proof systems both in the uniform and non-uniform setting.

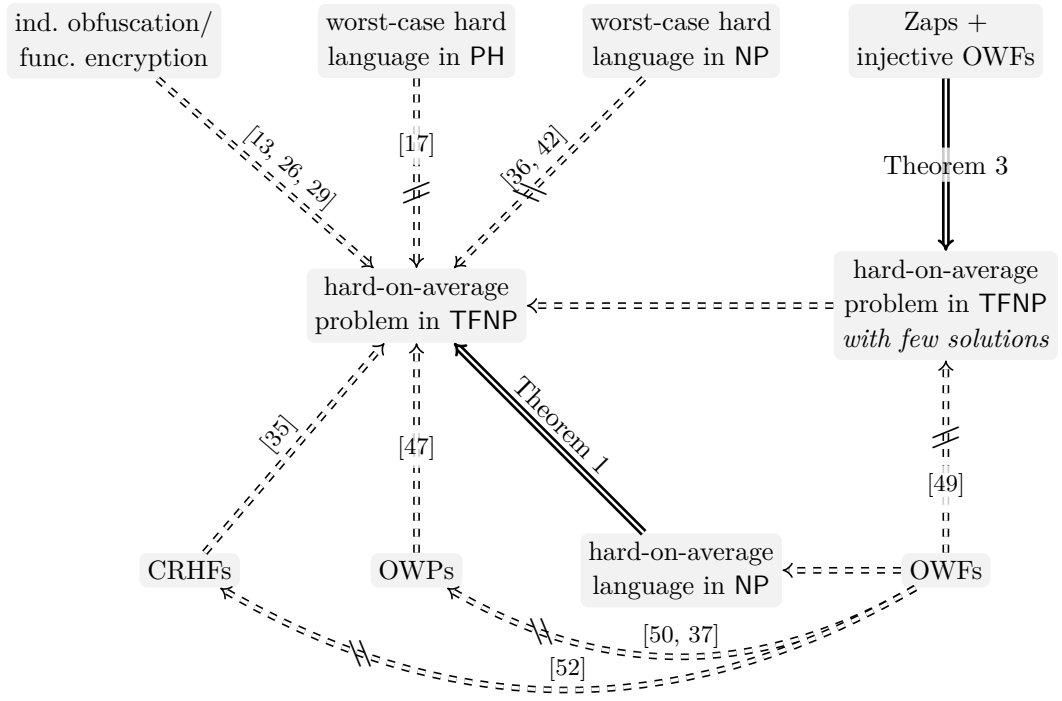

Figure 1 An illustration of our results (solid implications) in the context of previously known positive results (dashed implications) and negative results (crossed out dashed implications).

1.1 Our results

Some of our results use a derandomization assumption in the form "assume that there exists a function with deterministic (uniform) time complexity $2^{O(n)}$, and Π_2-circuit complexity $2^{\Omega(n)}$". In the description of our results below, we simply call this the *fooling assumption*. Alternatively, instead of this assumption we can consider the non-uniform setting, and get the same results for TFNP/poly (see Definition 10). Some of our results are summarized in Figure 1.

▶ **Theorem 1** (Informal). *Any hard-on-average* NP *language (e.g., random SAT, hidden clique, or any one-way function) implies a non-uniform* TFNP *problem which is hard-on-average.*

Then, using derandomization we get the following corollary for the uniform setting.

▶ **Corollary 2** (Informal). *Under the fooling assumption, any hard-on-average* NP *language implies a (uniform)* TFNP *problem which is hard-on-average.*

Furthermore, we present an alternative approach for proving totality of search problems using zero-knowledge proofs which allows to build more structured TFNP problems. Specifically, if injective one-way functions exist, and Zaps exist then we construct a total search problem with at most two solutions.

▶ **Theorem 3** (Informal). *Assume the existence of Zaps and injective one-way functions. Then, there exists a hard-on-average problem (either non-uniform, or uniform under the fooling assumption) in* TFNP *such that any instance has at most two solutions.*

1.2 Related work (search vs. decision)

The question of the complexity of search when the solution is guaranteed to exist has been discussed in various scenarios. Even et al. [23] considered the complexity of promise problems and the connection to cryptography. They raised a conjecture which implies that public-key cryptography based on NP-hard problems does not exist. Impagliazzo and Naor [33] and Lovasz et al. [41] considered search in the query complexity model where a solution is guaranteed to exist, similarly to the class TFNP. They showed a separation between the classes of deterministic, randomized, and the size of the object of the search. Bellare and Goldwasser [10] considered the issue of self reducibility, i.e. are there languages in NP where given a decision oracle it is hard to solve *any* corresponding FNP search problem. They showed that such languages exist under the assumption that EE $\neq$ NEE (double exponential time is not equal the non-deterministic version of it).

2 Our Techniques

2.1 TFNP hardness based on average-case NP hardness

Let L be a hard-on-average NP language for an efficiently samplable distribution $\mathcal{D}$, associated with a relation R_L. That is, $(L, \mathcal{D})$ is a pair such that no efficient algorithm can decide L with high probability when instances are drawn from $\mathcal{D}$. Our goal is to construct a (randomized) reduction from an instance for L sampled from $\mathcal{D}$ to a TFNP problem, such that every solution to the TFNP problem can be used to decide the instance given for L. As discussed above, such a reduction cannot rely on worst-case complexity ([36, 43]), and hence it must use the fact that we have a hard distribution for L.

The first thing to note is that since $(L, \mathcal{D})$ is hard to decide, then it is also hard to find a valid witness. Thus, the corresponding search problem, i.e., given an instance x to find a witness w such that $(x, w) \in R_L$, is hard directly based on the hardness of $(L, \mathcal{D})$. However, this is not sufficient for establishing hardness in TFNP. The issue is that not all instances indeed have a solution, and furthermore, determining whether an instance has a solution is by itself NP-hard.

To show that a problem is in TFNP we need to prove that there exists a solution for *every* instance. Therefore, our goal is to start with $(L, \mathcal{D})$ and end up with $(L', \mathcal{D}')$, such that the distribution $\mathcal{D}'$ always outputs instances in L', but remains a hard distribution nevertheless. We employ a method called *reverse randomization*, which has been used in the context of complexity (for proving that BPP is in the polynomial hierarchy [40]) and in the context of cryptography (for constructing Zaps, commitment schemes, and immunizing cryptographic schemes from errors [44, 21, 22, 14]). For a string s, let the distribution $\mathcal{D}_s$ be the one that on random coins r samples both $x \leftarrow \mathcal{D}(1^n; r)$ and $x' \leftarrow \mathcal{D}(1^n; r \oplus s)$. We define L_s accordingly as containing the instance (x, x') if *at least one* of x or x' is in L. Since D is a hard distribution, we know that for x' sampled from D the probability that $x' \in L$ is non-negligible. Therefore, we get that for any instance $x \notin L$ with non-negligible probability over the choice of s the shifted version x' of x is such that $x' \in L$. We perform several such random shifts, such that for any $x \notin L$ the probability that *one* of its shifts is an element in L is very high, and define the new language to accept any instance where *at least one of the shifts* is in L. Moreover, we show that for any such collection of shifts, the resulting distribution is still hard even when the shift is given to the solving algorithm.

The result is that there *exists* a collection of shifts such that applying them to $\mathcal{D}$ yields a pair $(L', \mathcal{D}')$ with the following two properties: (1) the support of $\mathcal{D}'$ is entirely contained in

L', and (2) the pair $(L', \mathcal{D}')$ is a hard *search* problem, i.e., given a random instance x sampled from $\mathcal{D}'$ the probability of finding a valid witness for x in polynomial-time is negligible. To construct our hard TFNP problem there are a few difficulties we ought to address.

We have merely proven the existence of such a shift for every input length. However, finding such a shift might be a hard task on its own. One possible way to circumvent this issue is to consider non-uniform versions of the problem, where this shift is hardwired into the problem's description (for each input size). Notice that in this case the shift is public and thus it is important that we have proven hardness even given the shift. If we want to stay in the uniform setting, we need to show how to find such shifts efficiently for every n. The main observation here is that we can show that a random shift will be good enough with high probability, and verifying if a given shift is good can be done in the complexity class Π_2. Thus, using a Nisan-Wigderson type pseudorandom generators against Π_2-circuits we show how to (completely) derandomize this process and find the collection of shifts efficiently and deterministically. Such NW-type PRGs were shown to exist under the assumption that E is hard for Π_2 circuits.

At this point, we have an (efficiently) samplable distribution $\mathcal{D}'$ such that its support provably contains only instances in L', and finding any valid witness is still hard for any polynomial-time algorithm. However, how can we use $\mathcal{D}'$ to create a hard TFNP problem? Indeed, we can use $(L', \mathcal{D}')$ to construct a hard search problem. Since any instance in the support of $\mathcal{D}'$ is satisfiable we would claim that the problem is indeed in TFNP. However, this is actually not the case, since it is infeasible to verify that an instance has actually been sampled from $\mathcal{D}'$! Therefore, the resulting search problem is not in TFNP. To solve this, we need a way to prove that an instance x is in the support of $\mathcal{D}'$ without hurting the hardness of the distribution.

On distributions with public randomness. The straightforward solution to the above problem is to publish the randomness r used to sample the instance. This way, it is easy to verify that the instance is indeed in the support of $\mathcal{D}'$ and thus any instance must have a solution and our problem is in TFNP. But what about hardness? Is the distribution hard even when given the randomness used to sample from it? Note that in many cases the randomness might even explicitly contain a satisfying assignment (e.g., a planted clique or factorization of a number). Thus, we must rely on distributions which remain hard even when given the random coins used for sampling. We denote such distributions as *public-coin distributions*.

If the original distribution $\mathcal{D}$ was public-coin to begin with, then we show that our modifications maintain this property. Thus, assuming that $\mathcal{D}$ is public-coin we get a problem that is provably in TFNP and is as hard as $\mathcal{D}$ (see Section 4.1 for the full proof). Then, we show that in fact any hard distribution can be modified to construct a public-coin distribution while maintaining its hardness, with no additional assumptions. This lets us construct a hard TFNP problem using any hard-on-average language L, even one with a distribution that is not public-coin (see Section 4.2 for discussion of the transformation).

The number of solutions of the TFNP problem we constructed is polynomial in the number of witnesses of the language L we begin with (each shift introduces new solutions). In particular, if we start from a hard decision problem $(L, \mathcal{D})$ where $\mathcal{D}$ is public-coin and every $x \in L$ has a single witness, then our TFNP problem will have only a polynomial number of witnesses. Our transformation from any distribution to a public-coin one increases the number of witnesses (for some instances). In the next section, we discuss an alternative method for proving totality of search problems which, moreover, results in a small number of solutions.

2.2 Using zero-knowledge for TFNP hardness

We demonstrate the power of zero-knowledge proofs in the context of TFNP in order to assure totality of search problems. This enables us to get more structured problems in TFNP.

Suppose we have a one-way function f, and we try to construct a hard TFNP problem where any solution can be used to invert f on a random challenge y. The difficulty is that we need to prove that the search problem is total while not ruining its hardness. In particular, we have to prove that given y there exists an inverse x such that $f(x) = y$ without "revealing anything" beyond the existence of x. If f is a permutation this task is trivial, since every y has an inverse by definition. However, for a general one-way function this is not the case.

To solve this issue, we employ as our main tool a Zap: a two-message witness indistinguishable proof system for NP (discussed in Section 1). We construct a problem where an instance contains an image y and a Zap proof π of the statement "y has an inverse under f". The first message of the proof is either non-uniformly hardwired in the problem description, or uniformly derandomized (see discussion in the introduction). This way, any instance has a solution: if π is a valid proof then by the perfect soundness of the Zap we know that y indeed has an inverse, and otherwise, we consider the all-zero string to be a solution. Our goal is to show that this problem is still hard. However, the Zap proof only guarantees that for any two x, x' the proof π is indistinguishable, which does not suffice. In fact, if f is injective, then y has only a single inverse and π might simply be the inverse x without violating the witness indistinguishability property of the Zap.

Therefore, an instance of our problem will consist of two images y, y' and a Zap proof π that *one* of the images has an inverse under f. The goal is to find an inverse of y or y', where one is guaranteed to exist as long as the proof π is valid. This way, we are able to ensure that the proof π does not reveal any useful information about the inverse x. Finally, by randomly embedding an instance y of a challenge to f we show that any adversary that solves this problem can be used to invert the one-way function f. Thus, we get a total problem that is hard assuming one-way functions, and Zaps. Moreover, notice that when the underlying one-way function is *injective* the problem we constructed has *exactly one or two solutions* for any instance. See Theorem 21 and Section 5 for details of the full proof.

3 Preliminaries

We present the basic definitions and notation used in this work. For a distribution X we denote by $x \leftarrow X$ the process of sampling a value x from the distribution X. For an integer $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1, \ldots, n\}$. A function $\mathsf{neg}\colon \mathbb{N} \to \mathbb{R}$ is negligible if for every constant $c > 0$ there exists an integer N_c such that $\mathsf{neg}(n) < n^{-c}$ for all $n > N_c$.

▶ **Definition 4** (Computational Indistinguishability)**.** Two sequences of random variables $X = \{X_n\}_{n\in\mathbb{N}}$ and $Y = \{Y_n\}_{n\in\mathbb{N}}$ such that X_n's and Y_n's lengths are polynomially bounded are computationally indistinguishable if for every probabilistic polynomial time algorithm A there exists an integer N such that for all $n \geq N$,

$$|\Pr[A(X_n) = 1] - \Pr[A(Y_n) = 1]| \leq \mathsf{neg}(n) \ ,$$

where the probabilities are over X_n, Y_n and the internal randomness of A.

▶ **Definition 5** (One-Way Functions)**.** A polynomial time computable function $f : \{0,1\}^* \to \{0,1\}^*$ is called *one-way* if for any PPT inverter A (the non-uniform version is polysize circuit) there exists a negligible function $\mu(\cdot)$, such that

$$\Pr\left[A(f(x)) \in f^{-1}(f(x)) : x \leftarrow \{0,1\}^n\right] \leq \mu(n) \ .$$

We say that $\mathcal{F}$ is a family of injective one-way functions if every function in $\mathcal{F}$ is injective.

3.1 Average-case complexity

For a language L and an instance x we write $L(x) = 1$ if $x \in L$ and $L(x) = 0$ otherwise.

▶ **Definition 6** (Probability distributions)**.** A probabilistic randomized algorithm $\mathcal{D}$ is said to be a probability distribution if on input 1^n it outputs a string of length n. We denote by $\mathcal{D}(1^n; r)$ the evaluation of $\mathcal{D}$ on input 1^n using the random coins r. We say that $\mathcal{D}$ is efficient if it runs in polynomial time.

▶ **Definition 7** (Hard distributional problem)**.** Let $L \in \mathsf{NP}$ and let $\mathcal{D}$ be an efficient probability distribution. We say that $(L, \mathcal{D})$ is a hard distributional problem if for any probabilistic polynomial time-algorithm A there exist a negligible function $\mathsf{neg}(\cdot)$ such that for all large enough n it holds that:

$$\Pr_{r,A}[A(x) = L(x) : x \leftarrow \mathcal{D}(1^n; r)] \leq 1/2 + \mathsf{neg}(n) \ ,$$

where the probability is taken over r and the randomness of A.

▶ Remark. We say that a language $L \in \mathsf{NP}$ is hard-on-average if there exists an efficient probability distribution $\mathcal{D}$ such that $(L, \mathcal{D})$ is a hard distributional problem.

▶ **Definition 8** (Hard public-coin distributional problem)**.** Let $L \in \mathsf{NP}$ and let $\mathcal{D}$ be an efficient probability distribution. We say that $(L, \mathcal{D})$ is a hard public-coin distributional problem if for any probabilistic polynomial time-algorithm A there exists a negligible function $\mathsf{neg}(\cdot)$ such that for all large enough n it holds that:

$$\Pr_{r,A}[A(r, x) = L(x) : x \leftarrow \mathcal{D}(1^n; r)] \leq 1/2 + \mathsf{neg}(n) \ ,$$

where the probability is taken over r and the randomness of A. (Notice that in this case, A gets both the instance x and the random coins r used to sample x.)

3.2 Total search problems

The class TFNP of "total search problems" contains a host of non-trivial problems for which a solution always exists.

▶ **Definition 9** (TFNP)**.** A *total* NP *search problem* is a relation $\mathcal{S}(x, y)$ such that it is (i) computable in polynomial (in $|x|$ and $|y|$) time (ii) *total*, i.e. there is a polynomial q such that for every x there exists a y such that $\mathcal{S}(x, y)$ and $|y| \leq q(|x|)$.

The set of all total NP search problems is denoted by TFNP.

The class $\mathsf{TFNP/poly}$ is the non-uniform circuit version of TFNP, similar to $\mathsf{NP/poly}$ with respect to NP.

▶ **Definition 10** ($\mathsf{TFNP/poly}$)**.** A *total* $\mathsf{NP/poly}$ *search problem* is a relation $\mathcal{S}(x, y)$ such that it is (i) computable polynomial (in $|x|$ and $|y|$) time with polynomial advice or equivalently there exists a family of polynomial sized circuits that computes $\mathcal{S}$ (ii) *total*, i.e. there is a polynomial q such that for every x there exists a y such that $\mathcal{S}(x, y)$ and $|y| \leq q(|x|)$.

The set of all total $\mathsf{NP/poly}$ search problems is denoted by $\mathsf{TFNP/poly}$.

3.3 Witness indistinguishable proof systems

We consider witness indistinguishable proof systems for NP. In particular, these are derandomized versions of Zaps and can be constructed from any Zap by fixing the first message non-uniformly (see [21, Section 3]). In the uniform setting, Barak et al. [9] showed that by leveraging a NW-type PRG, they can derandomize the Zap construction and get the same result. In both cases, we get a witness indistinguishable proof system which is defined as follows:

▶ **Definition 11.** Let L be an NP language with relation R. A scheme $(\mathsf{Prove}, \mathsf{Verify})$ is a witness indistinguishable proof system between a verifier and a prover if:

1. **Completeness**: for every $(x, w) \in R$ we have that:

$$\Pr\left[\mathsf{Verify}(x, \pi) = 1 \mid \pi \leftarrow \mathsf{Prove}(x, w)\right] = 1 \ .$$

2. **Perfect Soundness**: for every $x \notin L$ and for every π it holds that:

$$\Pr\left[\mathsf{Verify}(x, \pi) = 1\right] = 0 \ .$$

3. **Witness Indistinguishability**: for any sequence of $\{x, w, w'\}$ such that $(x, w) \in R$ and $(x, w') \in R$ it holds that:

$$\{\mathsf{Prove}(x, w)\} \approx_c \{\mathsf{Prove}(x, w')\} \ .$$

3.4 Nisan-Wigderson type pseudorandom generators

We define Nisan-Wigderson type pseudorandom generators [46] that fool circuits of a given size.

▶ **Definition 12** (NW-type PRGs.)**.** A function $\mathsf{G}\colon \{0,1\}^{d(n)} \to \{0,1\}^n$ is an *NW-type* PRG *against circuits of size* $t(n)$ if it is (i) computable in time $2^{O(d(n))}$ and (ii) any circuit C of size at most $t(n)$ distinguishes $U \leftarrow \{0,1\}^n$ from $\mathsf{G}(s)$, where $s \leftarrow \{0,1\}^{d(n)}$, with advantage at most $1/t(n)$.

▶ **Theorem 13** ([34])**.** *Assume there exists a function in* $\mathsf{E} = \mathsf{DTIME}(2^{O(n)})$ *with circuit complexity* $2^{\Omega(n)}$*. Then, for any polynomial* $t(\cdot)$*, there exists a NW-type generator* $\mathsf{G}\colon \{0,1\}^{d(n)} \to \{0,1\}^n$ *against circuits of size* $t(n)$*, where* $d(n) = O(\log n)$*.*

Note that one can find a specific function f satisfying the above condition. In general, any function that is E-complete under linear-time reductions will suffice, and in particular, one can take the bounded halting function.[6]

The above theorem was used in derandomization to fool polynomial sized circuits. It was observed in [4] that Theorem 13 can be extended to more powerful circuits such as non-uniform circuits. In particular, they gave the following theorem that is used in this work.

▶ **Definition 14** (oracle circuits and Σ_i/Π_i-circuits)**.** Given a boolean function $f(\cdot)$, an f-circuit is a circuit that is allowed to use f gates (in addition to the standard gates). A Σ_i-circuit (resp., Π_i-circuit) is an f-circuit where f is the canonical Σ_i^p-complete (resp., Π_i^p-complete) language. The size of all circuits is the total number of wires and gates (see [3, Chapter 5] for a formal definition of the classes Σ_i^p and Π_i^p).

[6] The function is defined as follows: $\mathrm{BH}(M, x, t) = 1$ if the Turing machine M outputs 1 on input x after at most t steps (where t is given in binary), and $\mathrm{BH}(M, x, t) = 0$ otherwise.

▶ **Theorem 15** (cf., [4, Theorem 1.7]). *For every $i \geq 0$, the statement of Theorem 13 also holds if we replace every occurrence of the word "circuits" by "Σ_i-circuits" or alternatively by "Π_i-circuits".*

The assumption underlying the above theorem is a worst-case assumption and it can be seen as a natural generalization of the assumption that $\mathsf{E} \subsetneq \mathsf{NP}$. For a further discussion about this type of assumptions see [4, 2].

4 TFNP Hardness from Average-Case NP Hardness

We show that there exists a search problem in TFNP that is hard-on-average under the assumption of existence of a hard-on-average NP language and a Nisan-Wigderson type complexity assumption. An overview of the proof is given in Section 2.1. Formally, we prove:

▶ **Theorem 16.** *If there exists a hard-on-average language in* NP *then there exists a hard-on-average problem in non-uniform* TFNP.

Under an additional (worst-case) complexity assumption (as discussed in Section 1.1), we also give a uniform version of this result.

▶ **Corollary 17.** *Assume that there exist functions with deterministic (uniform) time complexity $2^{O(n)}$, and Π_2-circuit complexity $2^{\Omega(n)}$. If there exists a hard-on-average language in* NP *then there exists a hard-on-average problem in* TFNP.

We split the proof of Theorem 16 and Corollary 17 into two parts. First, we prove the results under the assumption that the distribution $\mathcal{D}$ has a special property we call *public-coin*, i.e., when the distribution remains hard even given the random coins used to sample from it (see Definition 8). Second, we show that this assumption does not hurt the generality of the statement, since the existence of hard distributional decision problems implies the existence of hard *public-coin* distributional decision problems.

4.1 Hardness based on public-coin distributions

We begin with the proof of the non-uniform version of our result.

Proof (Theorem 16). Fix an input size n. For simplicity of presentation (and without loss of generality), assume that to sample an instance $x \in \{0,1\}^n$ the number of random coins needed is n (otherwise, one can pad the instances to get the same effect). We begin by showing that any hard distributional decision problem $(L, \mathcal{D})$ implies the existence of a hard distributional search problem. In general, this problem will not be a total one but we will be able to use its structure to devise a total problem.

Let $\mathcal{D}$ be a hard distribution for some NP language L with associated relation R_L. The distributional search problem associated to $(L, \mathcal{D})$, i.e., given $x \leftarrow \mathcal{D}(1^n)$ to find a w such that $R_L(x, w) = 1$, is also hard. Moreover, there exists a polynomial $p(\cdot)$ such that $\Pr_{x \leftarrow \mathcal{D}}[L(x) = 1] \geq p(n)$, as otherwise, the "constant no" algorithm would contradict $\mathcal{D}$ being a hard distribution for L. For any set of $k = n^2 \cdot p(n)$ strings $s_1, \ldots, s_k \in \{0,1\}^n$, we define a distributional problem $(L_{s_1,\ldots,s_k}, \mathcal{D}')$, where the language $L_{s_1,\ldots,s_k}$ is defined by the relation

$$R_{L_{s_1,\ldots,s_k}}(r, w) = \bigvee_{i \in [k]} R_L(x_i, w), \text{ where } x_i \leftarrow \mathcal{D}(1^n; r \oplus s_i) \ ,$$

and $\mathcal{D}'$ is the uniform distribution on $\{0,1\}^n$.

First, we use the following general lemma to argue that the distributional search problem associated with $(L_{s_1,\ldots,s_k}, \mathcal{D}')$ is hard.

▶ **Lemma 18.** *Let $(L, \mathcal{D})$ be a hard distributional search problem. Let $(L', \mathcal{D}')$ be a distributional search problem related to $(L, \mathcal{D})$ that satisfies the following conditions:*

1. *L' is in an "OR" form, i.e., there exist efficiently computable functions $f_1, \ldots, f_k$ such that $R_{L'}(x', w) = \bigvee_{i \in [k]} R_L(f_i(x'), w)$ where k is some polynomially bounded function of n.*
2. *For every $i \in [k]$, the marginal distribution of $f_i(x')$ under $x' \leftarrow \mathcal{D}'$ is identical to the distribution of $x \leftarrow \mathcal{D}(1^n)$.*
3. *For any fixed instance $x^* = \mathcal{D}(1^n; r)$, the distribution $x' \leftarrow \mathcal{D}'(1^n)$ conditioned on $f_i(x') = x^*$ is efficiently sampleable (given r).*

Then $(L', \mathcal{D}')$ is a hard distributional search problem.

The proof of Lemma 18 follows by a reduction to solving the original distributional search problem $(L, \mathcal{D})$, and is deferred to Appendix A.1. Notice that $(L_{s_1,\ldots,s_k}, \mathcal{D}')$ satisfies the three conditions of Lemma 18 with respect to $(L, \mathcal{D})$: (1) the instances are in the "OR" form (where $x_i = f_i(r) = r \oplus s_i$), (2) for any $i \in [k]$ it holds that x_i is distributed as $\mathcal{D}$ since $r \oplus s_i$ is uniformly random, and (3) for any $x^* = \mathcal{D}(1^n; r^*)$, sampling from $\mathcal{D}'$ conditioned on $x_i = x^*$ can be done by setting $r = s_i \oplus r^*$. We say that $L_{s_1,\ldots,s_k}$ *is good* if it is total, i.e., if it holds that

$$\forall r \in \{0,1\}^n : L_{s_1,\ldots,s_k}(r) = 1 \ .$$

We prove that for a random choice of $s_1, \ldots, s_k$ the language $L_{s_1,\ldots,s_k}$ is good with high probability.

▶ **Lemma 19.** $\Pr_{s_1,\ldots,s_k \leftarrow \{0,1\}^{kn}}[L_{s_1,\ldots,s_k} \textit{ is good }] \geq 3/4$.

Proof. Fix any string r. If we pick s at random we get that

$$\Pr_{s \leftarrow \{0,1\}^n}[L(x) = 1 \mid x \leftarrow \mathcal{D}(1^n; r \oplus s)] \geq 1/p(n) \ .$$

This follows since for any string r the string $r \oplus s$ is uniformly random. Moreover, since for any s_i this event is independent, we get that for any fixed r (and for $k = n^2 \cdot p(n)$) it holds that:

$$\Pr_{s_1,\ldots,s_k \leftarrow \{0,1\}^{kn}}[\forall i : L(x_i) = 0 \mid x_i \leftarrow \mathcal{D}(1^n; r \oplus s_i)] \leq (1 - 1/p(n))^k \leq 2^{-n^2} \ .$$

Thus, taking a union bound over all possible $r \in \{0,1\}^n$ we get that

$$\Pr_{s_1,\ldots,s_k \leftarrow \{0,1\}^{kn}}[L_{s_1,\ldots,s_k} \text{ is not good }] \leq 2^n \cdot 2^{-n^2} \leq 1/4 \ ,$$

and thus the statement of the claim follows. ◀

Thus, for any n we fix a set of k strings non-uniformly to get a good $L_{s_1,\ldots,s_k}$, and get a language L^*, that is a hard-on-average search problem under the uniform distribution $\mathcal{D}^*$. Moreover, we get that the problem is total: for every n, every instance $r \in \{0,1\}^n$ must have a solution since we choose a good $L_{s_1,\ldots,s_k}$ for every n.[7] ◀

[7] Actually, this claim works only for large enough input sizes n. For small values of n we simply define the language to accept all instances, and thus to remain total. Notice that this does not harm the hardness of the problem.

Getting a uniform version. In the above proof of Theorem 16 we constructed a problem in non-uniform TFNP, i.e., a problem in TFNP/poly (see Definition 10). To get a uniform version of the problem (i.e., a problem in TFNP) we show how to employ derandomization techniques to find $s_1, \ldots, s_k$.

Proof (Corollary 17). Recall the definition of the language $L_{s_1,\ldots,s_k}$ from the proof of Theorem 16. Consider a circuit C that on input $s_1, \ldots, s_k$ outputs 1 if and only if $L_{s_1,\ldots,s_k}$ is good. Notice that C can be implemented by a polynomial-sized Π_2-circuit, since $s_1, \ldots, s_k$ is good if for all $r \in \{0,1\}^n$ there exists a witness (s_i, w) such that $R_L(r \oplus s_i, w) = 1$. Let G be a Nisan-Wigderson type PRG (see Definition 12) against Π_2-circuits of size $|C|$ with seed length $m = O(\log n)$. For any seed $j \in [2^m]$, let $(s_1^j, \ldots, s_k^j) = \mathsf{G}(j)$ and write $L^j = L_{s_1^j,\ldots,s_k^j}$. By Claim 19 and by pseudorandomness of G we get that

$$\Pr_{j \in [2^m]}[L^j \text{ is good}] \geq 3/4 - 1/|C| \geq 2/3 \ .$$

To derandomize the choice of $s_1, \ldots, s_k$ we define

$$L^*(r_1, \ldots, r_{2^m}) = \bigvee_{j \in [2^m]} L^j(r_j) \ ,$$

where every r_j is of length n. Accordingly, define $\mathcal{D}^*$ to sample $\bar{r} = r_1, \ldots, r_{2^m}$ uniformly at random where $r_j \in \{0,1\}^n$. Notice that $(L^*, \mathcal{D}^*)$ satisfies the following:

1. $\Pr_{\bar{r} \leftarrow \mathcal{D}^*}[L^*(\bar{r}) = 1] = 1$.
2. For any PPT A for large enough n we have: $\Pr_{\bar{r} \leftarrow \mathcal{D}^*}[L^*(\bar{r}, A(\bar{r})) = 1] \leq \mathsf{neg}(n)$.

The first item follows by the derandomization. The second item follows, since for all $j \in [2^m]$, the search problem $(L^j, \mathcal{D}')$ is hard (which follows from Lemma 18). In particular, any adversary A solving the search problem associated to $(L^*, \mathcal{D}^*)$ with noticeable probability $1/p(n)$ must solve one of he $(L^j, \mathcal{D}')$ with probability at least $1/(2^m p(n)) = 1/\mathsf{poly}(n)$, a contradiction. We get that $(L^*, \mathcal{D}^*)$ is a hard-on-average search problem, which is total, and thus in TFNP. ◀

Note that it was crucial that $\mathcal{D}$ was a public-coin distribution in order to construct $\mathcal{D}^*$ to be the uniform while maintaining hardness. This, in turn, let us define a total problem since any string is in the support of $\mathcal{D}^*$. In the next section, we show that the assumption that $\mathcal{D}$ is public-coin can be made without loss of generality.

4.2 From private coins to public coins

We prove that we can assume that our underlying distribution is public-coin without loss of generality. That is, we show that it can be (efficiently) converted to a public-coin distribution with same hardness with no additional assumptions.

▶ **Theorem 20.** *If hard-on-average* NP *languages exist then public-coin hard-on-average* NP *languages exist.*

Here we discuss two alternative versions of the proof. Though not discussed explicitly, one can see that Impagliazzo anad Levin [31] actually proved a similar statement. Their work in the context of average-case complexity showed that problems with natural hard distributions give rise to problems with *simple* hard distributions. Specifically, they showed that any problem with efficiently samplable hard distribution can be reduced to a problem with an efficiently computable hard distribution, i.e., where the cumulative distribution function is efficiently

computable. An alternative presentation of this result by Goldreich [28, Sec. 10.2.2.2] provides a step towards reducing simple distributions to hard public-coin distribution. In particular, any problem with a simple distribution can be reduced to a problem with a distribution samplable via a monotone mapping, as shown in [28, Exercise 10.14]. Given the monotonicity property, we can turn any simple distribution into a public-coin distribution. Thus, we get that decision problems with samplable distributions imply decision problems with public-coin distributions.

We provide also a self-contained proof that does not rely on the notions of samplable and simple distributions. Our approach is to use the construction of universal one-way hash functions (UOWHFs) from one-way functions [45, 48, 38]. A UOWHF is a weaker primitive than a collision resistant hash function, where an adversary chooses an input x, then it is given a hash function h sampled from the UOWHF family, and its task is to find an input $x' \neq x$ such that $h(x) = h(x')$. Therefore, any UOWHF gives rise to a hard distributional search problem (in fact, a distributional decision problem by [11]) which is public-coin: given random sample x, h find a colliding x'. We conclude the proof by showing that for any input length, a hard distribution is either already public-coin or it gives rise to a one-way function for this length. See Appendix A.2 for the complete proof.

5 Using Zero-Knowledge for TFNP Hardness

In the previous section, we have shown how to get TFNP hardness from average-case NP hardness. We either settled for a non-uniform version with no additional assumptions or used a NW-type PRG to get a uniform version. In this section we show a different approach to proving hardness of problems in TFNP. Our main technique uses Zap, a two-message witness indistinguishable proof for NP. As discussed in Section 1, the Zap can be further reduced to a single message by either fixing the first message non-uniformly or by using a NW-type PRG. In both cases, we get non-interactive witness indistinguishable proof system for NP (see Definition 11), and thus we write the proof in terms of this primitive.

The advantage of this technique is twofold. First, it is a general technique that might be used to "push" other problems inside TFNP. Second, it allows us to construct a hard problem in TFNP from injective one-way functions (see Definition 5) with at most two solutions. Formally, we prove the following theorem:

▶ **Theorem 21.** *If injective one-way functions and non-interactive witness-indistinguishable proof systems for* NP *exist, then there exists a hard-on-average problem in* TFNP *such that any instance has at most two solutions.*

Proof. We define a new total search problem and call it Invert-Either.

▶ **Definition 22** (Invert-Either)**.** Let $f\colon \{0,1\}^m \to \{0,1\}^n$ be an efficiently computable function. Let L be an NP language defined by the following relation: $R((y,y'),x) = 1$ if and only if $f(x) \in \{y,y'\}$. Let $(\mathsf{Prove},\mathsf{Verify})$ be a witness indistinguishable proof system for L. The input to the Invert-Either problem is a tuple (y,y',π), where $y,y' \in \{0,1\}^n$, and $\pi \in \{0,1\}^{\mathsf{poly}(n)}$. We ask to find a string $x \in \{0,1\}^m$ satisfying one of the following:

1. $x = 0^m$ if $\mathsf{Verify}((y,y'),\pi) = 0$.
2. $f(x) \in \{y,y'\}$ if $\mathsf{Verify}((y,y'),\pi) = 1$.

We now show that Invert-Either is a total search problem.

▶ **Lemma 23.** *The* Invert-Either *problem is in* TFNP.

Proof. Let (y, y', π) be an instance of Invert-Either. If $\mathsf{Verify}((y, y'), \pi) = 0$ then $x = 0^n$ is a solution. Otherwise if $\mathsf{Verify}((y, y'), \pi) = 1$ then, by the perfect soundness of the witness indistinguishable proof system $(\mathsf{Prove}, \mathsf{Verify})$, it follows that $(y, y') \in L$. Thus, there exists an $x \in \{0,1\}^n$ such that $f(x) = y$ or $f(x) = y'$ which is a solution for the Invert-Either instance (y, y', π). In either case there exists a solution and Invert-Either is in TFNP. ◀

We move on to show that the existence of one-way functions implies a hard on average distribution of instances of Invert-Either. Assume that there exists an efficient algorithm A that solves in polynomial time instances of Invert-Either defined relative to some one-way function f. We construct A' that inverts an image of f evaluated on a random input with noticeable probability. Given $y = f(x)$, a challenge for inverting the function f, the inverter A' proceeds as follows:

$\underline{\boldsymbol{A'(y)}}$

1. choose $x' \leftarrow \{0,1\}^n$ at random and compute $y' = f(x')$.
2. choose $b \leftarrow \{0,1\}$ at random and set $y_b = y$ and $y_{1-b} = y'$.
3. compute $\pi \leftarrow \mathsf{Prove}((y_0, y_1), x')$.
4. compute $w \leftarrow A(y_0, y_1, \pi)$.
5. output w.

Since A' computes the proof π honestly, any solution w for the Invert-Either instance (y_0, y_1, π) must be a preimage of either y or y', i.e., either $f(w) = y$ or $f(w) = y'$. If A outputs a preimage of y then A' will succeed in inverting f. However, A might output a w which is a preimage of y' which was chosen by A' and it does not help in inverting the challenge y. Our claim is that A must output a preimage of y with roughly the same probability as a preimage of y'. Formally, we show that

$$|\Pr[f(A(y_0, y_1, \pi)) = y'] - \Pr[f(A(y_0, y_1, \pi)) = y]| \leq \mathsf{neg}(n) \ .$$

It is sufficient to argue that the input tuple (y_0, y_1, π) for A produced by A' is computationally indistinguishable from an input triple produced using the actual pre-image x of the challenge y, i.e.,

$$\{y_0, y_1, \pi \leftarrow \mathsf{Prove}((y_0, y_1), x')\} \approx_c \{y_0, y_1, \pi \leftarrow \mathsf{Prove}((y_0, y_1), x)\} \ .$$

Since x and x' are chosen according to the same distribution, and y_0 and y_1 are random labels of y and y', the only way to distinguish between the two ensembles is using the proof π. However, from the witness-indistinguishability property of the proof system we get that $\mathsf{Prove}((y_0, y_1), x)$ is computationally indistinguishable from $\mathsf{Prove}((y_0, y_1), x')$ even given x and x' (and thus also given y_0 and y_1). Altogether, we get that the probability that A outputs a preimage of y is about the same probability as the probability that A outputs a preimage of y'. By our assumption, A must output either type of solution with noticeable probability. Therefore, A' succeeds in inverting the challenge y with noticeable probability. ◀

▶ Remark. We note that we get hardness of Invert-Either from any one-way function, however, the number of solutions is guaranteed to be at most two only when the one-way function is injective.

6 Open Problems

The most immediate open problem is whether it is possible to base the hardness of any of the known subclasses of TFNP on the assumption that one-way functions exist[8]. Perhaps the most plausible one is PPP: its canonical problem is given by a circuit $C\colon \{0,1\}^n \to \{0,1\}^n$ where the goal is to find a collision under C or an input x such that $C(x) = 0$. Notice that by the pigeonhole principle we get that this problem is total. The hardness of PPP was shown from one-way permutations or collision-resistant hash functions. Thus, it is a prime candidate for showing hardness from one-way functions.

Recall that Bellare and Goldwasser [10] considered the issue of self reducibility, i.e. are there languages in NP where given a decision oracle it is hard to solve *any* corresponding FNP search problem. They showed that such languages exist under the assumption that EE $\neq$ NEE (double exponential time is not equal the non-deterministic version of it). In particular the language they constructed is in P/Poly. Can standard cryptographic type assumptions and techniques be used to show such separation results?

We have shown how to use derandomization and also zero-knowledge to prove that some (hard) problems are in TFNP. Another interesting direction is to use our techniques to push into TFNP (variants of) other natural search problems which are not known to be total.

Acknowledgements. We wish to thank Oded Goldreich and Roei Tell for their invaluable help and comments.

A Detailed Proofs

A.1 Proof of Lemma 18

We give the full proof of Lemma 18 that we use in the proof of Section 4.1. The proof follows by a reduction to the original distributional problem $(L, \mathcal{D})$. Given a challenge x^* for $(L, \mathcal{D})$ we can create an instance σ of the search problem associated with $(L', \mathcal{D}')$ such that the challenge x^* is embedded in a random location among the "ORed" instances in σ. This can be done efficiently by the first and the third item. Then, by the second item we get that if $x^* \in L$ then a solution for σ will contain a solution for x^* with probability at least $1/k$. Overall, we gain a polynomial advantage for solving x^* which contradicts the hardness of $(L, \mathcal{D})$.

▶ Lemma 18 (restated). *Let $(L, \mathcal{D})$ be a hard distributional search problem. Let $(L', \mathcal{D}')$ be a distributional search problem related to $(L, \mathcal{D})$ that satisfies the following conditions:*

1. *L' is in an "OR" form, i.e., there exist efficiently computable functions $f_1, \ldots, f_k$ such that $R_{L'}(x', w) = \bigvee_{i \in [k]} R_L(f_i(x'), w)$ where k is some polynomially bounded function of n.*
2. *For every $i \in [k]$, the marginal distribution of $f_i(x')$ under $x' \leftarrow \mathcal{D}'$ is identical to the distribution of $x \leftarrow \mathcal{D}(1^n)$.*
3. *For any fixed instance $x^* = \mathcal{D}(1^n; r)$, the distribution $x' \leftarrow \mathcal{D}'(1^n)$ conditioned on $f_i(x') = x^*$ is efficiently sampleable (given r).*

Then $(L', \mathcal{D}')$ is hard distributional search problem.

Proof. Assume towards contradiction that there exist an adversary A and a polynomial $p(\cdot)$ such that

$$\Pr_{x \leftarrow D'(1^n; r)}[R_{L'}(x, A(x, r)) = 1] \geq 1/p(n) \ .$$

Then, we construct an adversary A' that solves the search problem $(L, \mathcal{D})$.

$\underline{A'(x)}$

1. Choose $i \in [k]$ at random.
2. Sample $x' \leftarrow \mathcal{D}'$ conditioned on $f_i(x') = x$ (this can be performed efficiently due to item 3.).
3. Output $w \leftarrow A(x')$.

Notice that since x is sampled from $\mathcal{D}$ and the marginal distribution of $f_i(x')$ is identical to that of $\mathcal{D}$ (item 2.), we get that x' is distributed exactly as a sample from $\mathcal{D}'$. Therefore, when computing w we have that A sees exactly the distribution it expects, and it will find a valid solution to x' with probability at least $1/p(n)$.

If $x \in L$, then with probability $1/p(n)$ we have that A will give us a solution to x' and since x' is in the "OR" form (item 1.), with probability $1/k$ that solution will solve x (and otherwise it answers at random). Thus, the probability for A' to solve x is at least $1/(k \cdot p(n))$ which contradicts $(L, \mathcal{D})$ being a hard distributional search problem. ◀

A.2 Proof of Theorem 20

We give the proof of the following theorem establishing that private-coin distributional decision problems imply existence of public-coin distributional decision problems.

▶ Theorem 20 (restated). *If hard-on-average* NP *languages exist then public-coin hard-on-average* NP *languages exist.*

Proof. We begin by showing that if one-way functions exist then there are hard-on-average distributions that are public-coin. This part of the proof follows by combining known transformations. First, it is known that if one-way functions exist then universal one-way hash functions (UOWHFs) exist [45, 48, 38]. A UOWHF is a family of compressing functions $\mathcal{H}$ that have the following security requirement: for a random x and $h \in \mathcal{H}$ it is hard for any PPT algorithm to find an $x \neq x'$ such that $h(x) = h(x')$. We note that the constructions of such families are in fact public-coin: to sample h no private coins are used. Thus, we can define the following search problem: given x, h find an appropriate collision x'.[9] Second, we can apply to this search problem a transformation of Ben-David et al. [11] for converting any average-case search problem into an average-case decision problem. Although it was not mentioned explicitly in their work, we observe when applied to a search problem that has a public-coin distribution the resulting decision problem is public-coin as well.

We have shown how to get a hard public-coin distributional problem from one-way function. We want to show how to get the same result from any hard distributional problem. Let $\mathcal{D}$ be a hard-on-average NP distribution for some language L. If $\mathcal{D}$ is public-coin, then we are done. Assume that $\mathcal{D}$ is not public-coin.

If we were able to prove a statement of the form "private-coin distributions imply one-way functions", then by applying the above two transformations we would be done. But what exactly is a "private-coin" distribution? Our only assumption is that $\mathcal{D}$ is not public-coin. It might be the case that for some (infinitely many) input sizes the distribution is public-coin and for some (infinitely many) it is not. Thus, the function that we get will be hard to invert only on the input sizes that the distribution is not public-coin. Then, the distribution that we get from this function will be public-coin only for the same input sizes. However, for the

[9] Notice that this search problem problem is not in TFNP since no such collision x' might exist.

rest of the input sizes, the distribution was already public-coin! Thus, by combining the two we can get a hard public-coin distribution for any input size.

One subtle issue is that we do not necessarily know for which input sizes is the distribution public-coin and for which not. Thus, for any input size n we apply both methods: we two samples using randomness r_1 and r_2. For r_1 we release $r_1, \mathcal{D}(1^n, r_1)$, and we r_2 to sample from the distribution constructed from the one-way function, as described above. Finally, we take the "AND" of the both. For any n we know that one of the two will be hard, and thus overall we get hardness for any input size.

We are left to show how to construct one-way functions that are hard to invert for the non-public input sizes of the distribution. Assume that $\mathcal{D}$ is not public-coin. Then, there exist an efficient algorithm A, and a polynomial p such that for infinitely many input sizes it holds that:

$$\Pr_{r,A}[A(r,x) = L(x) : x \leftarrow D_n(r)] \geq 1/2 + 1/p(n) \ . \tag{A.1}$$

Let $\mathcal{N}$ be the infinite set of $n \in \mathbb{N}$ such that (A.1) holds. We define the function family $f = \{f_n(r) = D_n(r)\}_{n\in\mathbb{N}}$. We claim that it is infeasible to invert f for the input sizes in $\mathcal{N}$:

▶ **Lemma 24.** *For any PPT A there exists a negligible function $\mathsf{neg}(\cdot)$ such that for all $n \in \mathcal{N}$:*

$$\Pr_{r\in\{0,1\}^n}[A(f_n(r)) \in f_n^{-1}(f_n(r))] \leq \mathsf{neg}(n) \ .$$

Proof. Impagliazzo and Luby [32] showed that if one-way functions do not exist, then it is not only possible to invert a function f, but also to get a close to uniform inverse. Formally, if A is an adversary that inverts f then there exists a constant $c > 0$ such that A outputs a distribution that is $1/n^c$-close to a uniform distribution over the inverses.

Thus, suppose that f is not one-way as stated in the Lemma. Then, given $y = f(r)$ we can run the inverter on y and get r' such that $f(r) = f(r')$ with probability $1/p(n)$ for some polynomial p. Moreover, there exists a constant c such that the distribution of r' is $1/n^c$ close to a uniform one. The high-level idea is that if we run $A(r', x)$ then we get the correct answer with high probability, thus we are able to decide L relative to $\mathcal{D}$ with high probability.

Formally, we verify that $\mathcal{D}(r) = \mathcal{D}(r')$. If this is not the case then we answer randomly. Assume that $\mathcal{D}(r) = \mathcal{D}(r')$. Let

$$\mathcal{R}_x = \{r : \Pr_A[A(r,x) = L(x)] \geq 1/2 + 1/p(n)\}.$$

We say that x is good if $\Pr_r[r \in \mathcal{R}_x] \geq 1/2$. By (A.1) we get that the probability that x is good is at least half. If x is good, then we get that $A(r', x) = L(x)$ with probability at least $1/2 + 1/p(n) - 1/n^c$. Altogether, we get a polynomial advantage above $1/2$ in deciding L. ◀

The above Lemma concludes the proof. ◀
