Preface

The 8th Innovations in Theoretical Computer Science (ITCS) Conference was held between the 9th and 11th of January 2017 at the University of California at Berkeley, sponsored by the Simons Institute for the Theory of Computing. The role of ITCS is to complement the two major, prestigious, and very successful annual conferences of our field, STOC and FOCS by enabling a dialogue that is crucial and beneficial for the unity, vigor, and future of our field, and providing a forum for ideas that are novel and forward looking. ITCS conferences are typically small (about a hundred participants) with a well attended single track.

171 papers were submitted to the 8th ITCS, and from these the program committee selected for presentation at the conference and publication in these proceedings a total of 61 papers. Six papers were *invited,* meaning that they were of such quality that the program committee either explicitly invited their authors to submit them, or realized in retrospect that they should have done so: "Separators in region intersection graphs" by James R. Lee; "IRLS and Slime Mold" by Damian Straszak and Nisheeth Vishnoi; "Network coding in undirected graphs is either very helpful or not helpful at all" by Mark Braverman, Sumegha Garg and Ariel Schvartzman; "Nash Social Welfare, Matrix Permanent, and Stable Polynomials" by Nima Anari, Shayan Oveis Gharan, Amin Saberi and Mohit Singh; "Multiplayer parallel repetition for expander games" by Irit Dinur, Prahladh Harsha, Rakesh Venkat and Henry Yuen; and "The Journey from NP to TFNP Hardness" by Pavel Hubacek, Moni Naor and Eylon Yogev. Other than that, there is no best paper award at ITCS. The best student paper award was shared by these two papers: "Towards Hardness of Approximation for Polynomial Time Problems" by Amir Abboud and Arturs Backurs and "Detecting communities is hard and counting them is even harder," by Aviad Rubinstein.

Many heartfelt thanks are due to the stellar and hard working program committee, consisting of: Scott Aaronson, Elette Boyle, Mark Braverman, Alessandro Chiesa, Artur Czumaj, Costis Daskalakis, Shafi Goldwasser, Anna Karlin, Jon Kleinberg, Swastik Kopparty, Muthu Muthukrishnan, Noam Nisan, Georgios Piliouras, Toniann Pitassi, Tal Rabin, Alexander Razborov, Tim Roughgarden, Aviad Rubinstein, Nikhil Srivastava, Chris Umans, Paul Valiant, Virginia Vassilevska-Williams, Umesh Vazirani, Santosh Vempala, Mary Wootters, Nir Yosef, Henry Yuen, and Lisa Zhang. Of these, Ale Chiesa and Umesh Vazirani were also local organizers, and they worked very hard for the success of the conference. We are most grateful to the Simons Institute for hosting and supporting the conference. Finally, many thanks to all authors who submitted their work, and especially to all participants for making this a truly memorable event.

Separators in Region Intersection Graphs

James R. Lee

Computer Science, University of Washington, Seattle, USA
jrl@cs.washington.edu

Abstract

For undirected graphs $G = (V, E)$ and $G_0 = (V_0, E_0)$, say that G is a *region intersection graph over* G_0 if there is a family of connected subsets $\{R_u \subseteq V_0 : u \in V\}$ of G_0 such that $\{u, v\} \in E \iff R_u \cap R_v \neq \emptyset$.

We show if G_0 excludes the complete graph K_h as a minor for some $h \geq 1$, then every region intersection graph G over G_0 with m edges has a balanced separator with at most $c_h\sqrt{m}$ nodes, where c_h is a constant depending only on h. If G additionally has uniformly bounded vertex degrees, then such a separator is found by spectral partitioning.

A string graph is the intersection graph of continuous arcs in the plane. String graphs are precisely region intersection graphs over planar graphs. Thus the preceding result implies that every string graph with m edges has a balanced separator of size $O(\sqrt{m})$. This bound is optimal, as it generalizes the planar separator theorem. It confirms a conjecture of Fox and Pach (2010), and improves over the $O(\sqrt{m}\log m)$ bound of Matoušek (2013).

1 Introduction

Consider an undirected graph $G_0 = (V_0, E_0)$. A graph $G = (V, E)$ is said to be a *region intersection graph (rig) over* G_0 if the vertices of G correspond to connected subsets of G_0 and there is an edge between two vertices of G precisely when those subsets intersect. Concretely, there is a family of connected subsets $\{R_u \subseteq V_0 : u \in V\}$ such that $\{u, v\} \in E \iff R_u \cap R_v \neq \emptyset$. For succinctness, we will often refer to G as a *rig over* G_0.

Let $\mathsf{rig}(G_0)$ denote the family of all finite rigs over G_0. Prominent examples of such graphs include the intersection graphs of pathwise-connected regions on a surface (which are intersection graphs over graphs that can be drawn on that surface).

For instance, *string graphs* are the intersection graphs of continuous arcs in the plane. It is easy to see that every finite string graph G is a rig over some planar graph: By a simple compactness argument, we may assume that every two strings intersect a finite number of times. Now consider the planar graph G_0 whose vertices lie at the intersection points of strings and with edges between two vertices that are adjacent on a string (see Figure 1). Then $G \in \mathsf{rig}(G_0)$. It is not too difficult to see that the converse is also true; see Section 4.

To illustrate the non-trivial nature of such objects, we recall that there are string graphs on n strings that require $2^{\Omega(n)}$ intersections in any such representation [14]. The recognition problem for string graphs is NP-hard [13]. Decidability of the recognition problem was established in [25], and membership in NP was proved in [24]. We refer to the recent survey [22] for more of the background and history behind string graphs.

Even when G_0 is planar, the rigs over G_0 can be dense: Every complete graph is a rig over some planar graph (in particular, every complete graph is a string graph). It has been

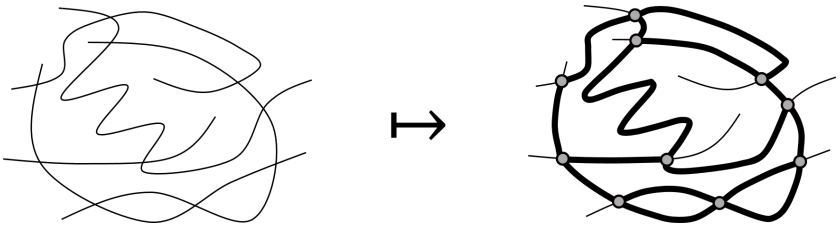

Figure 1 A string graph as a rig over a planar graph.

conjectured by Fox and Pach [5] that every m-edge string graph has a balanced separator with $O(\sqrt{m})$ nodes. Fox and Pach proved that such graphs have separators of size $O(m^{3/4}\sqrt{\log m})$ and presented a number of applications of their separator theorem. Matoušek [21] obtained a near-optimal bound of $O(\sqrt{m}\log m)$. In the present work, we confirm the conjecture of Fox and Pach, and generalize the result to include all rigs over graphs that exclude a fixed minor. This extended abstract contains mostly theorem statements; for detailed proofs and further arguments, we refer to the full paper [15].

▶ **Theorem 1.** *If $G \in \mathsf{rig}(G_0)$ and G_0 excludes K_h as a minor, then G has a $\frac{2}{3}$-balanced separator of size at most $c_h\sqrt{m}$ where m is the number of edges in G. Moreover, one has the estimate $c_h \leq O(h^3\sqrt{\log h})$.*

In the preceding statement, an ϵ-balanced separator of $G = (V, E)$ is a subset $S \subseteq V$ such that in the induced graph $G[V \setminus S]$, every connected component contains at most $\epsilon|V|$ vertices.

The proof of Theorem 1 is constructive, as it is based on solving and rounding a linear program; it yields a polynomial-time algorithm for constructing the claimed separator. In the case when there is a bound on the maximum degree of G, one can use the well-known spectral bisection algorithm (see Section 1.5).

Since planar graphs exclude K_5 as a minor, Theorem 1 implies that m-edge string graphs have $O(\sqrt{m})$-node balanced separators. Since the graphs that can be drawn on any compact surface of genus g exclude a K_h minor for $h \leq O(\sqrt{g+1})$, Theorem 1 also applies to string graphs over any fixed compact surface.

In addition, it implies the Alon-Seymour-Thomas [1] separator theorem[1] for graphs excluding a fixed minor, for the following reason. Let us define the *subdivision of a graph G* to be the graph $\dot{G}$ obtained by subdividing every edge of G into a path of length two. Then every graph G is a rig over $\dot{G}$, and it is not hard to see that for $h \geq 1$, G has a K_h minor if and only if $\dot{G}$ has a K_h minor.

1.1 Applications in topological graph theory

We mention two applications of Theorem 1 in graph theory. In [6], the authors present some applications of separator theorems for string graphs. In two cases, the tight bound for separators leads to tight bounds for other problems. The next two theorems confirm conjectures of Fox and Pach; as proved in [6], they follow from Theorem 1. Both results are tight up to a constant factor.

[1] Note that Theorem 1 is quantitatively weaker in the sense that [1] shows the existence of separators with $O(h^{3/2}\sqrt{n})$ vertices. Since every K_h-minor-free graph has at most $O(nh\sqrt{\log h})$ edges [12, 27], our bound is $O(h^{7/2}(\log h)^{3/4}\sqrt{n})$.

▶ **Theorem 2.** *There is a constant $c > 0$ such that for every $t \geq 1$, it holds that every $K_{t,t}$-free string graph on n vertices has at most $cnt(\log t)$ edges.*

A *topological graph* is a graph drawn in the plane so that its vertices are represented by points and its edges by curves connecting the corresponding pairs of points.

▶ **Theorem 3.** *In every topological graph with n vertices and $m \geq 4n$ edges, there are two disjoint sets, each of cardinality*

$$\Omega\left(\frac{m^2}{n^2 \log \frac{n}{m}}\right) \tag{1}$$

so that every edge in one set crosses all edges in the other.

This improves over the bound of $\Omega\left(\frac{m^2}{n^2(\log \frac{n}{m})^c}\right)$ for some $c > 0$ proved in [7], where the authors also show that the bound (1) is tight. Before we conclude this section, let us justify the observation made earlier.

▶ **Lemma 4.** *Finite string graphs are precisely finite region intersection graphs over planar graphs.*

Proof. We have already argued that string graphs are planar rigs. Consider now a planar graph $G_0 = (V_0, E_0)$ and a finite graph $G = (V, E)$ such that $G \in \mathsf{rig}(G_0)$. Let $\{R_u \subseteq V_0 : u \in V\}$ be a representation of G as a rig over G_0.

Since G is finite, we may assume that each region R_u is finite. To see this, for $v \in V_0$, let its *type* be the set $T(v) = \{u \in V : v \in R_u\}$. Then since G is finite, there are only finitely many types. For any region $R_u \subseteq V_0$, let $\tilde{R}_u$ be a finite set of vertices that exhausts every type in R_u, and let $\hat{R}_u$ be a finite spanning tree of $\tilde{R}_u$ in the induced graph $G_0[R_u]$. Then the regions $\{\hat{R}_u : u \in V\}$ are finite and connected, and also form a representation of G as a rig over G_0.

When each region R_u is finite, we may assume also that G_0 is finite. Now take a planar drawing of G_0 in $\mathbb{R}^2$ where the edges of G_0 are drawn as continuous arcs, and for every $u \in V$, let $T_u \subseteq \mathbb{R}^2$ be the drawing of the spanning tree of R_u. Each T_u can be represented by a string (simply trace the tree using an in-order traversal that begins and ends at some fixed node), and thus G is a string graph. ◀

1.2 Balanced separators and extremal spread

Since complete graphs are string graphs, we do not have access to topological methods based on the exclusion of minors. Instead, we highlight a more delicate structural theory. The following fact is an exercise.

Fact: If $\dot{G}$ is a string graph, then G is planar.

More generally, we recall that *H is a minor of G* if H can be obtained from G by a sequence of edge contractions, edge deletions, and vertex deletions. If H can be obtained using only edge contractions and vertex deletions, we say that *H is a strict minor of G.*

▶ **Lemma 5.** *If $G \in \mathsf{rig}(G_0)$ and $\dot{H}$ is a strict minor of G, then H is a minor of G_0.*

This topological structure of (forbidden) strict minors in G interacts nicely with "conformal geometry" on G. Consider the family of all pseudo-metric spaces that arise from a finite graph G by assigning non-negative lengths to its edges and taking the induced shortest path

distance. Certainly if we add an edge to G, the family of such spaces can only grow (since by giving the edge length equal to the diameter of the space, we effectively remove it from consideration). In particular, if $G = K_n$ is the complete graph on n vertices, then every n-point metric space is a path metric on G.

A significant tool will be the study of extremal conformal metrics on a graph G. Unlike in the edge-weighted case, the family of path distances coming from conformal metrics can be well-behaved even if G contains arbitrarily large complete graph minors. As a simple example, let $K_{\mathbb{N}}$ denote the complete graph on countably many vertices. Then every distance arising from a conformal metric on $K_{\mathbb{N}}$ is bi-Lipschitz to an ultrametric.

1.3 Vertex expansion and observable spread

Fix a graph $G = (V_G, E_G) \in \mathsf{rig}(G_0)$ with $n = |V_G|$ and $m = |E_G|$. Since the family $\mathsf{rig}(G_0)$ is closed under taking induced subgraphs, a standard reduction allows us to focus on finding a subset $U \subseteq V_G$ with small isoperimetric ratio: $\frac{|\partial U|}{|U|} \lesssim \frac{\sqrt{m}}{n}$, where

$$\partial U = \{v \in U : E_G(v, V_G \setminus U) \neq \emptyset\},$$

and $E_G(v, V_G \setminus U)$ is the set of edges between v and vertices outside U. Also define the interior $U^\circ = U \setminus \partial U$.

Let us define the *vertex expansion constant* of G as

$$\phi_G = \min\left\{\frac{|\partial U|}{|U|} : \emptyset \neq U \subseteq V_G, |U^\circ| \leq \frac{|V_G|}{2}\right\}. \tag{2}$$

In [4], it is shown that this quantity is related to the concentration function (in the sense of Lévy and Milman; see also Gromov's observable diameter [8]) of extremal conformal metrics on G .

For a finite metric space (X, dist), we define the *spread of* X as the quantity

$$\mathfrak{s}(X, \mathrm{dist}) = \frac{1}{|X|^2}\sum_{x,y\in X} \mathrm{dist}(x, y).$$

Define the *observable spread of* X by

$$\mathfrak{s}_{\mathrm{obs}}(X, \mathrm{dist}) = \sup_{f:X\to\mathbb{R}}\left\{\frac{1}{|X|^2}\sum_{x,y\in X}|f(x) - f(y)| : f \text{ is 1-Lipschitz}\right\}. \tag{3}$$

▶ Remark. We remark on the terminology: In general, it is difficult to "view" a large metric space all at once; this holds both conceptually and from an algorithmic standpoint. If one thinks of Lipschitz maps $f : X \to \mathbb{R}$ as "observations" then the observable spread captures how much of the spread can be "seen."

We then define the L^1*-extremal observable spread of* G as

$$\bar{\mathfrak{s}}_{\mathrm{obs}}(G) = \sup_{\omega:V_G\to\mathbb{R}_+}\left\{\mathfrak{s}_{\mathrm{obs}}(V_G, \mathrm{dist}_\omega) : \|\omega\|_{L^1(V_G)} \leq 1\right\}, \tag{4}$$

where $\|\omega\|_{L^1(V_G)} \coloneqq \frac{1}{|V_G|}\sum_{v\in V_G}\omega(v)$. We recall the following theorem from [4] that relates expansion to the observable spread.

▶ **Theorem 6** ([4]). *For every finite graph* G*,*

$$\tfrac{1}{2}\bar{\mathfrak{s}}_{\mathrm{obs}}(G) \leq \frac{1}{\phi_G} \leq 3\bar{\mathfrak{s}}_{\mathrm{obs}}(G).$$

▶ **Example 7.** If G is the subgraph of the lattice $\mathbb{Z}^d$ on the vertex set $\{0, 1, \ldots, L\}^d$, then $\phi_G \asymp 1/L$ and $\bar{\mathfrak{s}}(G) \asymp L$. This can be achieved by taking $\omega \equiv 1$ and defining $f : V_G \to \mathbb{R}$ by $f(x) = x_1$.

In light of Theorem 6, to prove Theorem 1, it suffices to give a lower bound on $\bar{\mathfrak{s}}_{\mathrm{obs}}(G)$. It is natural to compare this quantity to the *L^1-extremal spread of G*:

$$\bar{\mathfrak{s}}(G) \coloneqq \max \left\{ \frac{1}{|V_G|^2} \sum_{u,v \in V_G} \mathrm{dist}_\omega(u, v) : \|\omega\|_{L^1(V_G)} \le 1 \right\}. \tag{5}$$

Let us examine these two notions for planar graphs using the theory of circle packings.

▶ **Example 8** (Circle packings)**.** Suppose that G is a finite planar graph. The Koebe-Andreev-Thurston circle packing theorem asserts that G is the tangency graph of a family $\{D_v : v \in V_G\}$ of circles on the unit sphere $\mathbb{S}^2 \subseteq \mathbb{R}^3$. Let $\{c_v : v \in V_G\} \subseteq \mathbb{S}^2$ and $\{r_v > 0 : v \in V_G\}$ be the centers and radii of the circles, respectively. An argument of Spielman and Teng [26] (see also Hersch [9] for the analogous result for conformal mappings) shows that one can take $\sum_{v \in V_G} c_v = \mathbf{0}$.

If we define $\omega(v) = r_v$ for $v \in V_G$, then $\mathrm{dist}_\omega \ge \mathrm{dist}_{\mathbb{S}^2} \ge \mathrm{dist}_{\mathbb{R}^3}$ on the centers $\{c_v : v \in V_G\}$. (The latter two distances are the geodesic distance on $\mathbb{S}^2$ and the Euclidean distance on $\mathbb{R}^3$, respectively).

Using the fact that $\sum_{v \in V_G} c_v = \mathbf{0}$, we have

$$\sum_{u,v \in V_G} \|c_u - c_v\|_2^2 = 2n \sum_{u \in V_G} \|c_v\|^2 = 2n^2. \tag{6}$$

This yields

$$\sum_{u,v \in V_G} \mathrm{dist}_\omega(u, v) \ge \sum_{u,v \in V_G} \|c_u - c_v\| \ge \frac{n^2}{2}.$$

Moreover,

$$\|\omega\|_{L^1(V_G)} \le \|\omega\|_{L^2(V_G)} = \sqrt{\frac{1}{n} \sum_{v \in V_G} r_v^2} \le \sqrt{\frac{\mathrm{vol}(\mathbb{S}^2)}{\pi n}} = \sqrt{\frac{4}{n}}.$$

It follows that $\bar{\mathfrak{s}}(G) \ge \frac{\sqrt{n}}{4}$.

Observe that the three coordinate projections $\mathbb{R}^3 \to \mathbb{R}$ are all Lipschitz with respect to dist_ω, and one of them contributes at least a $1/3$ fraction to the sum (6). We conclude that $\bar{\mathfrak{s}}_{\mathrm{obs}}(G) \ge \frac{\sqrt{n}}{12}$. Combined with Theorem 6, this yields a proof of the Lipton-Tarjan separator theorem [18]. Similar proofs of the separator theorem based on circle packings are known (see [23]), and this one is not new (certainly it was known to the authors of [26]).

We will prove Theorem 1 in two steps: By first giving a lower bound $\bar{\mathfrak{s}}(G) \gtrsim n/\sqrt{m}$ and then establishing $\bar{\mathfrak{s}}_{\mathrm{obs}}(G) \gtrsim \bar{\mathfrak{s}}(G)$.

For the first step, we follow [21, 4, 2]. The optimization (5) is a linear program, and the dual optimization is a maximum multi-flow problem in G. Matoušek shows that a low-congestion multi-flow can be used to draw the complete graph in the plane with few edge crossings. Since this is impossible by a simple double-counting argument, one concludes that there is no low-congestion flow, providing a lower bound on $\bar{\mathfrak{s}}(G)$ via LP duality. We extend this argument to rigs over K_h-minor-free graphs using the flow crossing framework of [2].

1.4 Spread vs. observable spread

Our major departure from [21] comes in the second step: Rounding a fractional separator to an integral separator by establishing that $\bar{\mathfrak{s}}_{\mathrm{obs}}(G) \geq C_h \cdot \bar{\mathfrak{s}}(G)$ when G is a rig over a K_h-minor-free graph. Matoušek used the following result that holds for any metric space. It follows easily from the methods of [3] or [17] (see also [20, Ch. 15]).

▶ **Theorem 9.** *For any finite metric space (X, d) with $|X| \geq 2$, it holds that*

$$\mathfrak{s}_{\mathrm{obs}}(X, d) \geq \frac{\mathfrak{s}(X, d)}{O(\log |X|)} .$$

In particular, for any graph G on $n \geq 2$ vertices,

$$\bar{\mathfrak{s}}_{\mathrm{obs}}(G) \geq \frac{\bar{\mathfrak{s}}(G)}{O(\log n)} .$$

Instead of using the preceding result, we employ the graph partitioning method of Klein, Plotkin, and Rao [11]. Those authors present an iterative process for repeatedly partitioning a metric graph G until the diameter of the remaining components is bounded. If the partitioning process fails, they construct a K_h minor in G.

Since rigs over K_h-minor-free graphs do not necessarily exclude any minors, we need to construct a different sort of forbidden structure. This is the role that Lemma 5 plays in [15]. In order for the argument to work, it is essential that we construct induced partitions: We remove a subset of the vertices which induces a partitioning of the remainder into connected components. After constructing a suitable random partition of G, standard methods from metric embedding theory allow us to conclude

1.5 Eigenvalues and L^2-extremal spread

The methods presented here can be used to control eigenvalues of the discrete Laplacian on rigs. Consider the linear space $\mathbb{R}^{V_G} = \{f : V_G \to \mathbb{R}\}$. Let $\mathcal{L}_G : \mathbb{R}^{V_G} \to \mathbb{R}^{V_G}$ be the symmetric, positive semi-definite linear operator given by

$$\mathcal{L}_G f(v) = \sum_{u:\{u,v\} \in E_G} (f(v) - f(u)) .$$

Let $0 = \lambda_0(G) \leq \lambda_1(G) \leq \cdots \leq \lambda_{|V_G|-1}(G)$ denote the spectrum of $\mathcal{L}_G$.

Define the *L^p-extremal spread* of G as

$$\bar{\mathfrak{s}}_p(G) = \max_{\omega : V_G \to \mathbb{R}_+} \left\{ \frac{1}{|V_G|^2} \sum_{u,v \in V_G} \mathrm{dist}_\omega(u, v) : \|\omega\|_{L^p(V_G)} \leq 1 \right\} . \tag{7}$$

In [2], the L^2-extremal spread is used to give upper bounds on the first non-trivial eigenvalue of graphs that exclude a fixed minor. In [10], a stronger property of conformal metrics is used to bound the higher eigenvalues as well. Roughly speaking, to control the kth eigenvalue, one requires a conformal metric $\omega : V_G \to \mathbb{R}_+$ such that the spread on every subset of size $\geq |V_G|/k$ remains large. Combining their main theorems with our methods yields the following.

▶ **Theorem 10.** *Suppose that $G \in \mathsf{rig}(G_0)$ and G_0 excludes K_h as a minor for some $h \geq 3$. If $d_{\max}$ is the maximum degree of G, then for any $k = 1, 2, \ldots, |V_G| - 1$, it holds that*

$$\lambda_k(G) \leq O(d_{\max}^2 h^6 \log h) \frac{k}{|V_G|} .$$

In particular, the bound on $\lambda_1(G)$ shows that if $d_{\max}(G) \leq O(1)$, then recursive spectral partitioning (see [26]) finds an $O(\sqrt{n})$-vertex balanced separator in G.

1.6 Additional applications

Treewidth approximations. Bounding $\bar{\mathfrak{s}}_{\mathrm{obs}}(G)$ for rigs over K_h-minor-free graphs leads to some additional applications. Combined with the rounding algorithm implicit in Theorem 6 (and explicit in [4]), this yields an $O(h^2)$-approximation algorithms for the vertex uniform Sparsest Cut problem. In particular, it follows that if $G \in \mathsf{rig}(G_0)$ and G_0 excludes K_h as a minor, then there is a polynomial-time algorithm that constructs a tree decomposition of G with treewidth $O(h^2\mathrm{tw}(G))$, where $\mathrm{tw}(G)$ is the treewidth of G. This result appears new even for string graphs. We refer to [4].

Lipschitz extension. Our results on padded decomposability of conformal metrics on string graphs combine with the Lipschitz extension theory of [16] to show the following. Suppose that (G, ω) is a conformal graph, where G is a rig over some K_h-minor free graph. Then for every Banach space Z, subset $S \subseteq V_G$, and L-Lipschitz mapping $f : S \to Z$, there is an $O(h^2 L)$-Lipschitz extension $\tilde{f} : V_G \to Z$ with $\tilde{f}|_S = f$. See [19] for applications to flow and cut sparsifiers in such graphs.

Acknowledgements. The author thanks Noga Alon, Nati Linial, and Laci Lovász for helpful discussions, Janos Pach for emphasizing Jirka's near-optimal bound for separators in string graphs, and the organizers of the "Mathematics of Jiří Matoušek" conference, where much of this work was carried out.

Abstract

Given a twice continuously differentiable cost function f, we prove that the set of initial conditions so that gradient descent converges to saddle points where $\nabla^2 f$ has at least one strictly negative eigenvalue, has (Lebesgue) measure zero, even for cost functions f with non-isolated critical points, answering an open question in [12]. Moreover, this result extends to forward-invariant convex subspaces, allowing for weak (non-globally Lipschitz) smoothness assumptions. Finally, we produce an upper bound on the allowable step-size.

1 Introduction

The interplay between the structure of saddle points and the performance of gradient descent dynamics is a critical and not well understood aspect of non-convex optimization. Despite our incomplete theoretical understanding, in practice, the intuitive nature of the gradient descent method (and more generally gradient-like algorithms[1]) make it a basic tool for attacking non-convex optimization problems for which we have very little understanding of the geometry of their saddle points. In fact, these techniques become particularly useful as the equilibrium structure becomes increasingly complicated, e.g., such as in the cases of nonnegative matrix factorization [11] or congestion/potential games [25], where symmetries in the nature of non-convex optimization problems give rise to continuums of saddle points with complex geometry. In these cases, especially, the simplistic, greedy attitude of the gradient descent method, which is by design agnostic towards the global geometry of the cost function minimized, comes rather handy. As we move forward in time, the cost keeps decreasing and convergence is guaranteed.

This simplicity, however, comes at least seemingly at a significant cost. For example, it is well known that there exist instances where bad initialization of gradient descent converges to saddle points [18]. Despite the existence of such worst case instances in theory, practitioners have been rather successful at applying these techniques across a wide variety of problems [23]. Recently, Lee et. al. [12] have given a rather insightful interpretation of the effectiveness of gradient descent methods in terms of circumventing the saddle equilibrium problem using

[1] A gradient-like system is a system where for each non-equilibrium initial condition the dynamic will move towards a new state whose cost is strictly less than that of the initial state.

tools from topology of dynamical systems. At a glance, the paper argues the following intuitively clear message: *The instability of (locally unstable) saddle points translates to a global phenomenon and the probability of converging to such a saddle point given a randomly chosen (random not over a local neighborhood but over the whole state space) initial condition is zero.*

This message is clear, concise, and satisfying in the sense that it transcribes the practical success of the gradient descent method to a concrete theoretical guarantee. As is usually the case, such high level statements come with an asterisk of necessary technical conditions on the cost function f minimized.

Formally, a cost function f is said to satisfy the "strict saddle" property if each critical point[2] x of f is either a local minimizer, or a strict saddle, i.e., $\nabla^2 f(x)$ has at least one strictly negative eigenvalue. In this case, Lee et. al. argue that if $f : \mathbb{R}^d \to \mathbb{R}$ is a twice continuously differentiable function then gradient descent with constant step-size α (defined by $x_{k+1} = x_k - \alpha \nabla f(x_k)$) with a random initialization and sufficiently small constant step-size converges to a local minimizer or negative infinity almost surely.

Critically, for this result to apply, f is required to have isolated saddle points, ∇f is assumed to be globally L-Lipschitz[3] and the step-size α is taken to be less than $1/L$. These regularity conditions soften somewhat the impact of the statement both theoretically as well as in practice. First, although the assumption of isolated fixed points is indeed generic for abstract classes of cost functions, in several special cases of practical interest where the cost function has some degree of symmetry (e.g., due to scaling invariance) this assumption is not satisfied. For this reason, the question of whether the assumption of isolated equilibria is indeed necessary was explicitly raised in [12]. Moreover, the assumption of global Lipschitz continuity for ∇f is not satisfied even by low degree polynomials (e.g., cubic). Finally, a natural question is how tight is the assumption on the step-size?

In this work we provide answers to all the above questions. We show that the assumption of isolated saddle points is indeed not necessary to argue generic convergence to local minima. To argue this, we need to combine tools from dynamical systems, topology, analysis and optimization theory. Moreover, we show that the globally Lipschitz assumption can be circumvented as long as the domain is convex and forward invariant with respect to gradient descent. This proposition makes our results readily applicable to many standard settings. This extension holds even for non-coercive functions.[4] Finally, using linear algebra and eigenvalue analysis we provide an upper bound on the allowable step-size (for these results to hold).

It is important to clearly state that the focus of this work is more theoretical than applied. Specifically, although GD is guaranteed to converge to local minima this convergence can in the worst case (worst case initial conditions, instances) take exponential time as finding local minima of non-convex functions is an NP-hard problem. Nevertheless, we believe that this combination of topological techniques (standard in continuous-time dynamics) and discrete optimization techniques, besides solving an interesting open question, will hopefully be of use for other algorithmic problems as well. Deep learning, due to the singularity of the Hessian of the loss function in practice [24], is a domain where such techniques could lead to new insights and practical algorithms.

---

[2] x is a critical point of f if $\nabla f(x) = 0$.

[3] That is, f satisfies $\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\|_2 \leq L \|\mathbf{x} - \mathbf{y}\|_2$.

[4] As pointed out by a referee this extension of Lee et al. is relatively easy when a function is coercive, since the sublevel sets are compact.

1.1 Related work

First-order descent methods can indeed escape strict saddle points when assisted by near isotropic noise. [21] establishes convergence of the Robbins-Monro stochastic approximation to local minimizers for strict saddle functions, whereas [10] establishes convergence to local minima for perturbed versions of multiplicative weights algorithm in generic potential games. Recently, [7] quantified the convergence rate of perturbed stochastic gradient descent to local minima. The addition of isotropic noise can significantly slow down the convergence rate. In contrast, our setting is deterministic and corresponds to the simplest possible discrete-time implementation of gradient descent.

Numerous curvature-based optimization techniques have been developed in order to circumvent saddle points (e.g., trust-region methods [5, 28], modified Newton's method with curvilinear line search [17], cubic regularized Newton's method [19], and saddle-free Newton methods [6]). Unlike gradient descent, these methods have superlinear per-iteration implementation costs, making them impractical for high dimensional settings.

Gradient descent with carefully chosen initial conditions can bypass the problem of local minima altogether and converge to the global minimum for many practical non-convex optimization settings (e.g., dictionary learning [1], latent-variable models [29], matrix completion [9], and phase retrieval [2]). In contrast, we focus on the performance of gradient descent under generic initial conditions. Finally, some recent work has been focusing on the connections between stability and efficiency of fixed points in non-convex optimization (e.g., Gaussian random fields [4]).

Gradient-like dynamics, where the dynamic moves towards states of decreased cost but without necessarily moving in the direction of steepest decrease, is a generalization of gradient dynamics that arise in a number of applications including game theory and mathematical biology. Similar arguments about convergence to local minima for almost all initial conditions have been argued [10, 20, 13] for (variants of) replicator dynamics and multiplicative weights update algorithms when applied to games where the incentives of all agents are closely aligned.[5] From the perspective of biology and specifically evolution, (variants of) replicator/MWUA [3, 16] capture standard models of the evolution of the frequencies of different genotypes within a species (preferential survival of the fittest). By analyzing the properties of local minimum energy states we can derive completely different conclusions about the long term system behavior (in terms e.g., of the resulting genetic diversity) from the ones that follow from analyzing all saddle points [13]. In fact, understanding the properties of local minima raises interesting computational complexity questions [15]. Finally, examining the stability properties of equilibria can help us capture quantitatively the long term behavior of biologically inspired gradient-like systems even under time-evolving fitness landscapes [14]. Given the emergent overlapping interests between these areas and (non-convex) optimization theory, it seems that novel opportunities for cross-fertilization between these research communities arise.

1.2 Organization

In Section 2, we introduce the notation and definitions used throughout the paper and state formally our main theorems. In Section 3, we prove our results establishing the negligible probability of converging to saddle points, addressing the possibility of continuums

[5] Such games are known as potential/congestion games [10] and correspond to games where all agents act as if they share a common cost/potential function that they are trying to minimize.

of equilibria, forward-invariant subspaces, and establishing an upper bound on the step-size. In Section 4, we produce several examples showcasing the effectiveness of our methods. Finally, we conclude in Section 5 by suggesting directions for future work.

2 Preliminaries

Notation: We use boldface letters, e.g., $\mathbf{x}$, to denote column vectors. We denote by $\mathrm{sp}(A), \|A\|_2$ the spectral radius and spectral norm of a symmetric matrix A respectively. We also use $\|\mathbf{x}\|_2$ for the ℓ_2 norm of vector $\mathbf{x}$. By $\nabla^2 f(\mathbf{x})$ we denote the Hessian of a twice differentiable function $f : \mathcal{E} \to \mathbb{R}$, for some set $\mathcal{E} \subseteq \mathbb{R}^N$.

Assume a minimization problem of the form $\min_{\mathbf{x}\in\mathbb{R}^N} f(\mathbf{x})$ where $f : \mathbb{R}^N \to \mathbb{R}$ is a twice continuously differentiable function. Gradient descent is one of the most well-known algorithms (discrete dynamical system) to attack this generic optimization problem. It is defined by the equations below:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha\nabla f(\mathbf{x}_k),$$

or equivalently $\mathbf{x}_{k+1} = g(\mathbf{x}_k)$ with $g(\mathbf{x}) = \mathbf{x} - \alpha\nabla f(\mathbf{x})$, $g : \mathbb{R}^N \to \mathbb{R}^N$ and $\alpha > 0$.

It is easy to see that the fixed points of the dynamical system $\mathbf{x}_{k+1} = g(\mathbf{x}_k)$ are exactly the points $\mathbf{x}$ so that $\nabla f(\mathbf{x}) = \mathbf{0}$, called *critical points or equilibria*. The set of local minima of f is a subset of the set of critical points of f. These two sets do not coincide and this poses a serious obstacle for proving strong theoretical guarantees for gradient descent, since the dynamics may converge to a critical point which is not a local minimum, called a *saddle point*.

Lee et al. [12] argue, under technical conditions which include the assumption of isolated critical points, that the set of initial conditions that converge to *strict saddle points* is a zero measure set (for definition of strict saddle, see Definition 1). The paper leaves as an open question whether the condition of isolated equilibria is necessary. We prove that the set of initial conditions that converge to a strict saddle point is a zero measure set even in the case of non-isolated critical points[6]. Furthermore, one of the conditions for f is that ∇f is globally Lipschitz, which implies that the second derivative of f is bounded, i.e., there exists a $\beta > 0$ such that for all $\mathbf{x}$ we have $\left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq \beta$. However, even third degree polynomial functions are not globally Lipschitz. We provide a theorem which can circumvent this assumption as long as the domain $\mathcal{S}$ is *forward or positively invariant* with respect to g, i.e., $g(\mathcal{S}) \subseteq \mathcal{S}$. Finally, we provide an easy upper bound on the step-size α, via eigenvalue analysis of the Jacobian of g, i.e., $I - \alpha\nabla^2 f(\mathbf{x})$.

Below we give some necessary definitions as appeared in Lee et al. [12].

▶ **Definition 1.**

- A point $\mathbf{x}^*$ is a critical point of f if $\nabla f(\mathbf{x}^*) = \mathbf{0}$. We denote by $C = \{\mathbf{x} : \nabla f(\mathbf{x}) = \mathbf{0}\}$ the set of critical points (can be uncountably many).
- A critical point $\mathbf{x}^*$ is isolated if there is a neighborhood U around $\mathbf{x}^*$ and $\mathbf{x}^*$ is the only critical point in U.[7] Otherwise is called non-isolated.
- A critical point $\mathbf{x}^*$ of f is a saddle point if for all neighborhoods U around $\mathbf{x}^*$ there are $\mathbf{y}, \mathbf{z} \in U$ such that $f(\mathbf{z}) \leq f(\mathbf{x}^*) \leq f(\mathbf{y})$.

[6] Our arguments hence allow for cost functions f's with uncountably many critical points.
[7] If the critical points are isolated then they are countably many or finite.

- A critical point $\mathbf{x}^*$ of f is a strict saddle if $\lambda_{\min}(\nabla^2 f(\mathbf{x}^*)) < 0$ (minimum eigenvalue of matrix $\nabla^2 f(\mathbf{x}^*)$ is negative).
- A set $\mathcal{S}$ is called forward or positively invariant with respect to some function $h : \mathcal{E} \to \mathbb{R}^N$ with $\mathcal{S} \subseteq \mathcal{E} \subseteq \mathbb{R}^N$ if $h(\mathcal{S}) \subseteq \mathcal{S}$.

2.1 Main Results

In [12], the steps of the proof of their result are the following: Under the regularity assumption that ∇f is globally Lipschitz with some Lipschitz constant L, Lee et al. are able to show that $g(\mathbf{x}) = \mathbf{x} - \alpha \nabla f(\mathbf{x})$ is a diffeomorphism for $\alpha < 1/L$. Afterwards, using the center-stable manifold theorem (see theorem 8), they show that the set of initial conditions so that g converges to saddle points has measure zero under the assumption that the critical points are isolated. We generalize their result for non-isolated critical points, answering one of their open questions (see also the example in Section 4.1, where there is a line of critical points).

▶ **Theorem 2.** [**Non-isolated**] *Let $f : \mathbb{R}^N \to \mathbb{R}$ be a twice continuously differentiable function and $\sup_{\mathbf{x}\in\mathbb{R}^N} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L < \infty$. The set of initial conditions $\mathbf{x} \in \mathbb{R}^N$ so that gradient descent with step-size $0 < \alpha < 1/L$ converges to a strict saddle point is of (Lebesgue) measure zero, without the assumption that critical points are isolated.*

We can prove a stronger version of the theorem above, circumventing the globally Lipschitz condition for domains which are forward invariant (see also the example in Section 4.2).

▶ **Theorem 3.** [**Non-isolated, forward invariant**] *Let $f : \mathcal{S} \to \mathbb{R}$ be twice continuously differentiable in an open convex set $\mathcal{S} \subseteq \mathbb{R}^N$ and $\sup_{\mathbf{x}\in\mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L < \infty$. If $g(\mathcal{S}) \subseteq \mathcal{S}$ (where $g(\mathbf{x}) = \mathbf{x} - \alpha\nabla f(\mathbf{x})$) then the set of initial conditions $\mathbf{x} \in \mathcal{S}$ so that gradient descent with step-size $0 < \alpha < 1/L$ converges to a strict saddle point is of (Lebesgue) measure zero, without the assumption that critical points are isolated.*

Finally, via eigenvalue analysis of $I - \alpha\nabla^2 f(\mathbf{x})$, we can find upper bounds on the step-size of gradient descent. A straightforward theorem is the following:

▶ **Theorem 4.** [**Upper bound on step-size**] *Let f be twice continuously differentiable in an open set $\mathcal{S} \subseteq \mathbb{R}^N$ and $\mathcal{C}^*$ be the set of local minima. Assume also that $\gamma < \inf_{\mathbf{x}\in\mathcal{C}^*} \left\|\nabla^2 f(\mathbf{x})\right\|_2 < \infty$. A necessary condition so that gradient descent converges to local minima for all but (Lebesgue) measure zero initial conditions in $\mathcal{S}$ is that the step-size satisfies $\alpha < \frac{2}{\gamma}$.*

3 Proving the theorems

Before we proceed with the proofs, let us argue that Theorem 3 is a generalization of Theorem 2. This can be checked by setting $\mathcal{S} := \mathbb{R}^N$ and observing that $g(\mathbb{R}^N) \subseteq \mathbb{R}^N$. We continue with the proofs of Theorems 3 and 4.

3.1 Proof of Theorem 3

In this section, we prove Theorem 3. We start by showing (for completeness) that the assumptions of Theorem 3 imply that $\nabla f(\mathbf{x})$ is Lipschitz in $\mathcal{S}$.

▶ **Lemma 5.** *Let $f : \mathcal{S} \to \mathbb{R}$ where $\mathcal{S}$ is an open convex set and f be twice continuously differentiable in $\mathcal{S}$. Also assume that $\sup_{\mathbf{x}\in\mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L < \infty$. Then ∇f satisfies the Lipschitz condition in $\mathcal{S}$ with Lipschitz constant L.*

Proof. Let $\mathbf{x}, \mathbf{y} \in \mathcal{S}$ (column vectors) and define the function $H : [0,1] \to \mathbb{R}^N$ as $H(t) = \nabla f(\mathbf{x} + t(\mathbf{y} - \mathbf{x}))$. By the chain rule we get that $H'(t) := \frac{dH}{dt} = (\nabla^2 f(\mathbf{x} + t(\mathbf{y} - \mathbf{x}))) \cdot (\mathbf{y} - \mathbf{x})$. It holds that

$$\begin{aligned}
\|\nabla f(\mathbf{y}) - \nabla f(\mathbf{x})\|_2 = \left\| \int_0^1 H'(t) dt \right\|_2 &\leq \int_0^1 \|H'(t)\|_2 \, dt \\
&= \int_0^1 \left\| (\nabla^2 f(\mathbf{x} + t(\mathbf{y} - \mathbf{x})))(\mathbf{y} - \mathbf{x}) \right\|_2 dt \\
&\leq \int_0^1 \left\| \nabla^2 f(\mathbf{x} + t(\mathbf{y} - \mathbf{x})) \right\|_2 \|\mathbf{y} - \mathbf{x}\|_2 \, dt \\
&\leq \int_0^1 L \|\mathbf{y} - \mathbf{x}\|_2 \, dt = L \|\mathbf{y} - \mathbf{x}\|_2 .
\end{aligned}$$

◀

▶ Remark. From Schwarz's theorem we get that $\nabla^2 f(\mathbf{x})$ is symmetric for $\mathbf{x} \in \mathcal{S}$, hence $\left\|\nabla^2 f(\mathbf{x})\right\|_2 = \text{sp}(\nabla^2 f(\mathbf{x}))$.

The assumption that $\sup_{\mathbf{x} \in \mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L < \infty$ implies that $\nabla f(x)$ is Lipschitz with constant L in the convex set $\mathcal{S}$, as stated by Lemma 5. We show that the converse holds as well, i.e., the Lipschitz condition for $\nabla f(\mathbf{x})$ with constant L in the main theorem in Lee et al. implies $\left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$ for all $\mathbf{x} \in \mathcal{S}$ and hence the assumption in our Theorems 2, 3 that $\sup_{\mathbf{x} \in \mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$ is satisfied.

▶ **Lemma 6.** *Let $f : \mathcal{S} \to \mathbb{R}$ where $\mathcal{S} \subseteq \mathbb{R}^N$ is an open convex set and f is twice continuously differentiable in $\mathcal{S}$. Assume $\nabla f(\mathbf{x})$ is Lipschitz with constant L in $\mathcal{S}$ then it holds $\sup_{\mathbf{x} \in \mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$.*

Proof. Fix an $\epsilon > 0$. By Taylor's theorem since f is twice differentiable with respect to some point $\mathbf{x}$ it holds that

$$\begin{aligned}
\|\nabla f(\mathbf{y}) - \nabla f(\mathbf{x})\|_2 &\geq \left\| (\nabla^2 f(\mathbf{x}))(\mathbf{y} - \mathbf{x}) \right\|_2 - o(\|\mathbf{y} - \mathbf{x}\|_2) \\
&\geq \left\| (\nabla^2 f(\mathbf{x}))(\mathbf{y} - \mathbf{x}) \right\|_2 - \epsilon \|\mathbf{y} - \mathbf{x}\|_2
\end{aligned}$$

for $\mathbf{y}$ sufficiently close to $\mathbf{x}$ (depends on ϵ). Therefore under the Lipschitz assumption we get that there exists a closed neighborhood $U(\epsilon)$ of $\mathbf{x}$ so that for all $\mathbf{y} \in U$ we get

$$\left\| (\nabla^2 f(\mathbf{x}))(\mathbf{x} - \mathbf{y}) \right\|_2 \leq \|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\|_2 + \epsilon \|\mathbf{y} - \mathbf{x}\|_2 \leq (L + \epsilon) \|\mathbf{x} - \mathbf{y}\|_2 . \tag{1}$$

We consider a closed ball B subset of U, with center $\mathbf{x}$ and radius r (in ℓ_2) and set $\mathbf{z} = \mathbf{x} - \mathbf{y}$. It is true that $\left\|\nabla^2 f(\mathbf{x})\right\|_2 = \sup_{\|\mathbf{z}\|_2 = r} \frac{\left\|(\nabla^2 f(\mathbf{x}))\mathbf{z}\right\|_2}{\|\mathbf{z}\|_2}$ by definition of spectral norm, scaled so that the length of the vectors is exactly r. Using 1 we get that $\left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L + \epsilon$. Since ϵ is arbitrary, we get that $\left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$. We conclude that $\sup_{\mathbf{x} \in \mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$. ◀

Lemmas 5 and 6 (which are provided for completeness) show that the smoothness assumptions in Lee et al. paper are equivalent to ours. We use the condition on the spectral norm of the matrix $\nabla^2 f(\mathbf{x})$ so that we can work with the eigenvalues in our theorems (e.g., in Remark 3.1 the spectral norm coincides with spectral radius for $\nabla^2 f(\mathbf{x})$). Below we prove that the update rule of gradient descent, i.e., function g is a diffeomorphism under the assumptions of Theorem 3 (similar approach appeared in [12]).

▶ **Lemma 7.** *Under the assumptions of Theorem 3, function g is a diffeomorphism in $\mathcal{S}$.*

Proof. First we prove that g is a injective. We follow the same argument as in [12]. Suppose $g(\mathbf{y}) = g(\mathbf{x})$, thus $\mathbf{y} - \mathbf{x} = \alpha(\nabla f(\mathbf{y}) - \nabla f(\mathbf{x}))$. We assume that $\mathbf{x} \neq \mathbf{y}$ and we will reach contradiction. From Lemma 5 we get $\|\nabla f(\mathbf{y}) - \nabla f(\mathbf{x})\|_2 \leq L \|\mathbf{y} - \mathbf{x}\|_2$ and hence $\|\mathbf{x} - \mathbf{y}\|_2 \leq \alpha L \|\mathbf{y} - \mathbf{x}\|_2 < \|\mathbf{y} - \mathbf{x}\|_2$ since $\alpha L < 1$ (contradiction).

We continue by showing that g is a local diffeomorphism. Observe that the Jacobian of g is $I - \alpha\nabla^2 f(\mathbf{x})$. It suffices to show that $\alpha\nabla^2 f(\mathbf{x})$ has no eigenvalue which is 1, because this implies matrix $I - \alpha\nabla^2 f(\mathbf{x})$ is invertible. As long as $I - \alpha\nabla^2 f(\mathbf{x})$ is invertible, from Inverse Function Theorem (see [27]) follows that g is a local diffeomorphism. Finally, since g is injective, the inverse g^{-1} is well defined and since g is a local diffeomorphism in $\mathcal{S}$, it follows that g^{-1} is smooth in $\mathcal{S}$. Therefore g is a diffeomorphism.

Let λ be an eigenvalue of $\nabla^2 f(\mathbf{x})$. Then $|\lambda| \leq \text{sp}(\nabla^2 f(\mathbf{x})) = \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$ where the equality comes from Remark 3.1 and first and last inequalities are satisfied by assumption. Therefore $\alpha\nabla^2 f(\mathbf{x})$ has as eigenvalue $\alpha\lambda$ and $|\alpha\lambda| \leq \alpha L < 1$. Thus all eigenvalues of $\alpha\nabla^2 f(\mathbf{x})$ are less than 1 in absolute value and the proof is complete. ◀

Proof of Theorem 3. We will use the Center-stable manifold theorem since $g(\mathbf{x}) = \mathbf{x} - \alpha\nabla f(\mathbf{x})$ is a diffeomorphism, where $\sup_{\mathbf{x}\in\mathcal{S}} \left\|\nabla^2 f(\mathbf{x})\right\|_2 \leq L$ and $\alpha < 1/L$. A modification of the proof of Theorem 3 appeared in [20] and [13] for replicator dynamics (not gradient descent).

▶ **Theorem 8** (Center and Stable Manifolds, p. 65 of [26]). *Let $\mathbf{p}$ be a fixed point for the C^r local diffeomorphism $h : U \to \mathbb{R}^n$ where $U \subset \mathbb{R}^n$ is an open neighborhood of $\mathbf{p}$ in $\mathbb{R}^n$ and $r \geq 1$. Let $E^s \oplus E^c \oplus E^u$ be the invariant splitting of $\mathbb{R}^n$ into generalized eigenspaces of $Dh(\mathbf{p})$[8] corresponding to eigenvalues of absolute value less than one, equal to one, and greater than one. To the $Dh(\mathbf{p})$ invariant subspace $E^s \oplus E^c$ there is an associated local h invariant C^r embedded disc W^{sc}_{loc} of dimension $dim(E^s \oplus E^c)$, and ball B around $\mathbf{p}$ such that:*

$$h(W^{sc}_{loc}) \cap B \subset W^{sc}_{loc}. \text{ If } h^n(\mathbf{x}) \in B \text{ for all } n \geq 0, \text{ then } \mathbf{x} \in W^{sc}_{loc}. \tag{2}$$

From this point on our approach deviates significantly from that of [12] and new ideas and tools need to be introduced.

Let $\mathbf{r}$ be a critical point of function $f(\mathbf{x})$ and $B_{\mathbf{r}}$ be the (open) ball that is derived from Theorem 8. We consider the union of these balls

$$A = \cup_{\mathbf{r}} B_{\mathbf{r}}.$$

The following property for $\mathbb{R}^N$ holds:

▶ **Theorem 9** (Lindelőf's lemma [8]). *For every open cover there is a countable subcover.*

Therefore due to Lindelőf's lemma, we can find a countable subcover for A, i.e., there exist fixed points $\mathbf{r}_1, \mathbf{r}_2, \ldots$ such that $A = \cup_{m=1}^{\infty} B_{\mathbf{r}_m}$. If gradient descent converges to a strict saddle point, starting from a point $\mathbf{v} \in \mathcal{S}$, there must exist a t_0 and m so that $g^t(\mathbf{v}) \in B_{\mathbf{r}_m}$ for all $t \geq t_0$. From Theorem 8 we get that $g^t(\mathbf{v}) \in W^{sc}_{loc}(\mathbf{r}_m) \cap \mathcal{S}$ where we used the fact that $g(\mathcal{S}) \subseteq \mathcal{S}$ (from assumption forward invariant), namely the trajectory remains in $\mathcal{S}$ for all times [9]. By setting $D_1(\mathbf{r}_m) = g^{-1}(W^{sc}_{loc}(\mathbf{r}_m) \cap \mathcal{S})$ and $D_{i+1}(\mathbf{r}_m) = g^{-1}(D_i(\mathbf{r}_m) \cap \mathcal{S})$ we get

[8] Jacobian of h evaluated at $\mathbf{p}$.
[9] $W^{sc}_{loc}(\mathbf{r}_m)$ denotes the center stable manifold of fixed point $\mathbf{r}_m$

that $\mathbf{v} \in D_t(\mathbf{r}_m)$ for all $t \geq t_0$. Hence the set of initial points in $\mathcal{S}$ so that gradient descent converges to a strict saddle point is a subset of

$$P = \cup_{m=1}^{\infty} \cup_{t=0}^{\infty} D_t(\mathbf{r}_m)). \tag{3}$$

Since $\mathbf{r}_m$ is strict saddle point, the Jacobian $I - \alpha\nabla^2 f(\mathbf{x})$ has an eigenvalue greater than 1, namely the dimension of the unstable eigenspace satisfies $dim(E^u) \geq 1$, and therefore the dimension of $W^{sc}_{loc}(\mathbf{r}_m)$ is at most $N-1$. Thus, the set $W^{sc}_{loc}(\mathbf{r}_m) \cap \mathcal{S}$ has Lebesgue measure zero in $\mathbb{R}^N$. Finally since g is a diffeomorphism (from Lemma 7), g^{-1} is continuously differentiable and thus it is locally Lipschitz (see [22] p.71). Therefore using Lemma 10 which we state below, g^{-1} preserves the null-sets and hence (by induction) $D_i(\mathbf{r}_m)$ has measure zero for all i. Thereby we get that P is a countable union of measure zero sets, i.e., is measure zero as well and the claim of Theorem 3 follows. ◀

▶ **Lemma 10.** *Let $h : \mathcal{S} \to \mathbb{R}^m$ be a locally Lipschitz function with $\mathcal{S} \subseteq \mathbb{R}^m$ then h is null-set preserving, i.e., for $E \subset \mathcal{S}$ if E has measure zero then $h(E)$ has also measure zero.*

Proof. The lemma is quite standard, but we provide a proof for completeness. Let B_γ be an open ball such that $\|h(\mathbf{y}) - h(\mathbf{x})\| \leq K_\gamma \|\mathbf{y} - \mathbf{x}\|$ for all $\mathbf{x}, \mathbf{y} \in B_\gamma$. We consider the union $\cup_\gamma B_\gamma$ which cover $\mathbb{R}^m$ by the assumption that h is locally Lipschitz. By Lindelőf's lemma we have a countable subcover, i.e., $\cup_{i=1}^{\infty} B_i$. Let $E_i = E \cap B_i$. We will prove that $h(E_i)$ has measure zero. Fix an $\epsilon > 0$. Since $E_i \subset E$, we have that E_i has measure zero, hence we can find a countable cover of open balls $C_1, C_2, ...$ for E_i, namely $E_i \subset \cup_{j=1}^{\infty} C_j$ so that $C_j \subset B_i$ for all j and also $\sum_{j=1}^{\infty} \mu(C_j) < \frac{\epsilon}{K_i^m}$. Since $E_i \subset \cup_{j=1}^{\infty} C_j$ we get that $h(E_i) \subset \cup_{j=1}^{\infty} h(C_j)$, namely $h(C_1), h(C_2), ...$ cover $h(E_i)$ and also $h(C_j) \subset h(B_i)$ for all j. Assuming that ball $C_j \equiv B(\mathbf{x}, r)$ (center $\mathbf{x}$ and radius r) then it is clear that $h(C_j) \subset B(h(\mathbf{x}), K_i r)$ (h maps the center $\mathbf{x}$ to $h(\mathbf{x})$ and the radius r to $K_i r$ because of Lipschitz assumption). But $\mu(B(h(\mathbf{x}), K_i r)) = K_i^m \mu(B(\mathbf{x}, r)) = K_i^m \mu(C_j)$, therefore $\mu(h(C_j)) \leq K_i^m \mu(C_j)$ and so we conclude that

$$\mu(h(E_i)) \leq \sum_{j=1}^{\infty} \mu(h(C_j)) \leq K_i^m \sum_{j=1}^{\infty} \mu(C_j) < \epsilon$$

Since ϵ was arbitrary, it follows that $\mu(h(E_i)) = 0$. To finish the proof, observe that $h(E) = \cup_{i=1}^{\infty} h(E_i)$ therefore $\mu(h(E)) \leq \sum_{i=1}^{\infty} \mu(h(E_i)) = 0$. ◀

A straightforward application of Theorem 3 is the following:

▶ **Corollary 11.** *Assume that the conditions of Theorem 3 are satisfied and all saddle points of f are strict. Additionally, let ν be a prior measure with support $\mathcal{S}$ which is absolutely continuous with respect to Lebesgue measure, and assume $\lim_{k\to\infty} g^k(x)$ exists[10] for all $\mathbf{x}$ in $\mathcal{S}$. Then*

$$\mathbb{P}_\nu[\lim_k g^k(\mathbf{x}) = \mathbf{x}^*] = 1,$$

where $\mathbf{x}^*$ is a local minimum.

Proof. Since the set of initial conditions whose limit point is a (strict) saddle point is a measure zero set and we have assumed $\lim_{k\to\infty} g^k(x)$ exists for all initial conditions in $\mathcal{S}$ then the probability of converging to a local minimizer is 1. ◀

[10] g^k denotes the composition of g with itself k times.

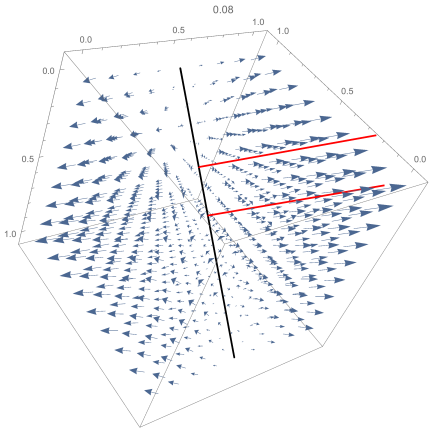

Figure 1 Example that satisfies the assumptions of Theorem 2. The black line represent critical points of f, all of which are strict. The red lines correspond to diverging trajectories of gradient descent with small step size.

▶ Remark. Arguing that $\lim_k g^k(\mathbf{x})$ exists follows from standard arguments in several settings of interest (e.g for analytic functions f that satisfy (Lojasiewicz Gradient Inequality)), see paper [12] and references therein.

The importance of Theorem 3 will become clear in the examples of Section 4. Specifically, in the example of Section 4.2, the function is not globally Lipschitz (we use the example that appears in [12]), nevertheless Theorem 3 applies and thus we have convergence to local minimizers with probability 1. In the example of Section 4.1 we see that simple functions may have non-isolated critical points.

3.2 Proof of Theorem 4

Proof. We proceed by contradiction. Consider any local minimum $\mathbf{x}^*$, and by assumption we get that $\text{sp}(\nabla^2 f(\mathbf{x}^*)) > \gamma$. Let $\alpha \geq \frac{2}{\gamma}$. Therefore the Jacobian $I - \alpha\nabla^2 f(\mathbf{x}^*)$ of g at $\mathbf{x}^*$ has spectral radius greater than 1 since $\text{sp}(I - \alpha\nabla^2 f(\mathbf{x}^*)) \geq \text{sp}(\alpha\nabla^2 f(\mathbf{x}^*)) - 1 > \alpha\gamma - 1 \geq 1$. This implies that the fixed point $\mathbf{x}^*$ of g is (Lyapunov) unstable. Since this is true for every local minimum, it cannot be true that gradient descent converges with probability 1 to local minima. ◀

4 Examples

4.1 Example for non-isolated critical points

Consider the simple example of the cost function $f : \mathbb{R}^3 \to \mathbb{R}$ with $f(x, y, z) = 2xy + 2xz - 2x - y - z$. Its gradient is $\nabla(f) = (2y + 2z - 2, 2x - 1, 2x - 1)$. Naturally, its saddle points correspond exactly to the line $(1/2, w, 1 - w)$ for $w \in \mathbb{R}$ and by computing their (common) eigenvalues we establish that they are all strict saddles (their minimum eigenvalue is $-2\sqrt{2}$). As we expect from our analysis effectively no trajectories converge to them (instead the value of practically all trajectories goes to $-\infty$). We plot in red some sample trajectories for small enough step sizes, starting in the local neighborhood of the equilibrium set.

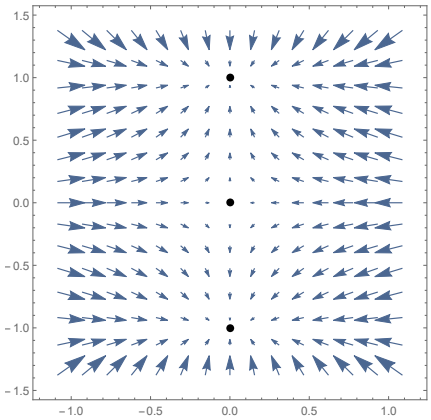

Figure 2 Example that satisfies the assumptions of Theorem 3. The three black dots represent the critical points. Function f is not Lipschitz.

4.2 Example for forward invariant set

We use the same function as in Lee et al. $f(x,y) = \frac{x^2}{2} + \frac{y^4}{4} - \frac{y^2}{2}$. As argued in previous sections, f is not globally Lipschitz so the main result in [12] cannot be applied here. We will use our Theorem 3 which talks about forward invariant domains.

The critical points of f are $(0,0),(0,1),(0,-1)$. $(0,0)$ is a strict saddle point and the other two are local minima. Observe that the Hessian $\nabla^2 f(x,y)$ is

$$J = \begin{pmatrix} 1 & 0 \\ 0 & 3y^2 - 1 \end{pmatrix}.$$

For $\mathcal{S} = (-1,1) \times (-2,2)$, so we get that $\sup_{(x,y)\in\mathcal{S}} \left\|\nabla^2 f(x,y)\right\|_2 \leq 11$ (for $y = 2$ gets the maximum value). We choose $\alpha = \frac{1}{12} < \frac{1}{11}$, and we have $g(x,y) = ((1-\alpha)x, (1+\alpha)y - \alpha y^3) = (\frac{11x}{12}, \frac{13y}{12} - \frac{y^3}{12})$. It is not difficult to see that $g(\mathcal{S}) \subseteq \mathcal{S}$ (easy calculations). The assumptions of Theorem 3 are satisfied, hence it is true that the set of initial conditions in $\mathcal{S}$ so that gradient descent converges to $(0,0)$ has measure zero. Moreover, by Corollary 11 it holds that if the initial condition is taken (say) uniformly at random in $\mathcal{S}$, then gradient descent converges to $(0,1),(0,-1)$ with probability 1. The figure below makes the claim clear, i.e. the set of initial conditions so that gradient descent converges to $(0,0)$ lie on the axis $y = 0$, which is of measure zero in $\mathbb{R}^2$. For all other starting points, gradient descent converges to local minima. Finally, from the figure one can see that $\mathcal{S}$ is forward invariant.

4.3 Example for step-size

We use the same function as in the previous example. Observe that for $(0,0),(0,1),(0,-1)$ we have that the spectral radius of $\nabla^2 f$ is $1,2,2$ respectively (so the minimum of all is 1). We choose $\alpha \geq 2$ and we get that $g(x,y) = (-x, 3y - 2y^3)$. It is not hard to see that gradient descent does not converge (in the first coordinate function g cycles between x and $-x$).

5 Conclusion

Our positive result cannot be improved without making explicit assumptions on the structure of the cost function f nor using beneficial random noise/well chosen initial conditions (as far as convergence is concerned, speed of convergence is not in the scope of this paper). Naturally,

all these directions are of key interest and are the object of recent work (see section 1.1). Keeping up with this simplest, deterministic implementation of gradient descent a natural hypothesis is that (in settings of practical interest) it converges not only to local minimizers but moreover the size of the region of attraction of each local minimizer is in a sense directly proportional to its quality.

Recently, in [20] there has been some progress in proving such statements in non-convex gradient-like systems that arise from learning in games. In such settings, (stable) fixed points correspond to Nash equilibria, but instead of having the typical system performance being dominated by the worst case Nash equilibria (as Price of Anarchy suggests) the regions of attractions of such bad (social) states prove to be minimal and the system works near optimally on average (given uniformly random initial conditions). Extending such statements to actual gradient-dynamics as well as comparing the average case performance of different heuristics even in restricted settings is a fascinating question that could shed more light into the in-many-cases surprising efficiency of the gradient descent method.

Abstract

First-order methods play a central role in large-scale machine learning. Even though many variations exist, each suited to a particular problem, almost all such methods fundamentally rely on two types of algorithmic steps: gradient descent, which yields primal progress, and mirror descent, which yields dual progress.

We observe that the performances of gradient and mirror descent are complementary, so that faster algorithms can be designed by *linearly coupling* the two. We show how to reconstruct Nesterov's accelerated gradient methods using linear coupling, which gives a cleaner interpretation than Nesterov's original proofs. We also discuss the power of linear coupling by extending it to many other settings that Nesterov's methods cannot apply to.

1 Introduction

The study of fast iterative methods for approximately solving convex problems is a central research focus in Machine Learning, Combinatorial Optimizations and many other areas of Computer Science and Mathematics. For large-scale programs, first-order iterative methods are usually the methods of choice due to their cheap and often highly parallelizable iterations.

First-order methods access the target optimization problem $\min_{x\in Q} f(x)$ in a black-box fashion: the algorithm queries a point $y \in Q$ at every iteration and receives the pair $\big(f(y), \nabla f(y)\big)$.[1] The complexity of a first-order method is usually measured in the number of queries necessary to produce an additive ε-approximate minimizer. First-order methods have recently experienced a renaissance in the design of fast algorithms for fundamental computer science problems, varying from discrete ones such as maximum flow problems [20], to continuous ones such as empirical risk minimization [39].

Despite the myriad of applications, first-order methods with provable convergence guarantees can be mostly classified as instantiations of two fundamental algorithmic ideas: *gradient*

* The authors would like to thank Silvio Micali for listening to our work and suggesting the name "linear coupling". The full version of this paper can be found on arXiv https://arxiv.org/abs/1407.1537.

[1] Here, variable x is constrained to lie in a convex set $Q \subseteq \mathbb{R}^n$, which is known as the *constraint set* of the problem.

descent and the *mirror descent*.[2] We argue that gradient descent takes a fundamentally primal approach, while mirror descent follows a complementary dual approach. In our main result, we show how these two approaches blend in a natural manner to yield a new and simple accelerated gradient method for smooth convex optimization problems, as well as lead to other applications where the classical accelerated gradient methods do not apply.

1.1 Understanding First-Order Methods: Gradient Descent and Mirror Descent

We now provide high-level descriptions of gradient and mirror descent. While this material is classical, our intuitive presentation of these ideas forms the basis for our main result in the subsequent sections. For a more detailed survey, we recommend the textbooks [9, 26].

Consider for simplicity the unconstrained minimization (i.e. $Q = \mathbb{R}^n$), but, as we will see in Section 2, the same intuition and a similar analysis extend to the constrained or even the proximal case. We use generic norms $\|\cdot\|$ and their duals $\|\cdot\|_*$. At a first reading, they can be both replaced with the Euclidean norm $\|\cdot\|_2$.

1.1.1 Primal Approach: Gradient Descent

A natural approach to iterative optimization is to decrease the objective function as much as possible at every iteration. To formalize the effectiveness of this idea, one usually introduces a smoothness assumption on the objective $f(x)$. Specifically, recall that an L-smooth function f satisfies $\|\nabla f(x) - \nabla f(y)\|_* \leq L\|x - y\|$ for every x, y. Such a smoothness condition yields a global quadratic upper bound on the function around a query point x:

$$\forall y, \quad f(y) \leq f(x) + \langle \nabla f(x), y - x \rangle + \frac{L}{2}\|y - x\|^2 \ . \tag{1.1}$$

Gradient-descent algorithms exploit this bound by taking a step that maximizes the guaranteed objective decrease (i.e., the primal progress) $f(x_k) - f(x_{k+1})$ at every iteration k. More precisely,

$$x_{k+1} \leftarrow \arg\min_y \left\{ \frac{L}{2}\|y - x_k\|^2 + \langle \nabla f(x), y - x_k \rangle \right\} \ .$$

Notice that here $\|\cdot\|$ is a generic norm. When this is the Euclidean ℓ_2-norm, the step takes the familiar additive form $x_{k+1} = x_k - \frac{1}{L}\nabla f(x_k)$. However, in other cases, e.g., for the non-Euclidean ℓ_1 or ℓ_∞ norms, the update step will not follow the direction of the gradient $\nabla f(x_k)$ (see for instance [18, 27]).

Under the smoothness assumption above, the magnitude of this primal progress is at least

$$f(x_k) - f(x_{k+1}) \geq \frac{1}{2L}\|\nabla f(x_k)\|_*^2 \ . \tag{1.2}$$

In general, this quantity will be larger when the gradient $\nabla f(x_k)$ has large norm. Classical convergence analysis of gradient descent usually combines (1.2) with a basic convexity argument to relate $f(x_k) - f(x^*)$ and $\|\nabla f(x_k)\|_*$: that is, $f(x_k) - f(x^*) \leq \|\nabla f(x_k)\|_* \|x_k - x^*\|$.

[2] We emphasize here that these two terms are sometimes used ambiguously in the literature; in this paper, we attempt to stick as close as possible to the conventions of the optimization community and in particular in the textbooks [9, 26] with one exception: we extend the definition of gradient descent to non-Euclidean norms in a natural way, following [18].

For L-smooth objectives, the final bound shows that gradient descent converges in $O\left(\frac{L}{\varepsilon}\right)$ iterations [26].

The limitation of gradient descent is that it does not make any attempt to construct a good lower bound to the optimum value $f(x^*)$. It essentially ignores the dual problem. In the next subsection, we review mirror descent, a method that focuses completely on the dual side.

1.1.2 Dual Approach: Mirror Descent

Mirror-descent methods (see for instance [9, 12, 24, 28, 44]) tackle the dual problem by constructing lower bounds to the optimum. Recall that each queried gradient $\nabla f(x)$ can be viewed as a hyperplane lower bounding the objective f: that is, $f(u) \geq f(x) + \langle \nabla f(x), u - x \rangle$ for all u. Mirror-descent methods attempt to carefully construct a convex combination of these hyperplanes in order to yield even a stronger lower bound. Formally, suppose one has queried points $x_0, \ldots, x_{k-1}$, then we form a linear combination of the k hyperplanes and obtain[3]

$$\forall u, \quad f(u) \geq \frac{1}{k}\sum_{t=0}^{k-1} f(x_t) + \frac{1}{k}\sum_{t=0}^{k-1} \langle \nabla f(x_t), u - x_t \rangle \ . \tag{1.3}$$

On the upper bound side, we consider a simple choice $\overline{x} = \frac{1}{k}\sum_{t=0}^{k-1} x_t$, i.e., the mean of the queried points. By straightforward convexity argument, we have $f(\overline{x}) \leq \frac{1}{k}\sum_{t=0}^{k-1} f(x_t)$. As a result, the distance between $f(\overline{x})$ and $f(u)$ for any arbitrary u can be upper bounded using (1.3):

$$\forall u, \quad f(\overline{x}) - f(u) \leq \frac{1}{k}\sum_{t=0}^{k-1} \langle \nabla f(x_t), x_t - u \rangle \stackrel{\text{def}}{=} R_k(u) \ . \tag{1.4}$$

Borrowing terminology from online learning, the right hand side $R_k(u)$ is known as the *regret* of the sequence $(x_t)_{t=0}^{k-1}$ with respect to point u. Now, consider a regularized version $\widetilde{R}_k(u)$ of the regret

$$\widetilde{R}_k(u) \stackrel{\text{def}}{=} \frac{1}{k} \cdot \Big(-\frac{w(u)}{\alpha} + \sum_{t=0}^{k-1} \langle \nabla f(x_t), x_t - u \rangle \Big) \ ,$$

where $\alpha > 0$ is a trade-off parameter and $w(\cdot)$ is some regularizer that is usually strongly convex. Then, mirror-descent methods choose the next iterate x_k by minimizing the maximum regularized regret at the next iteration: that is, choose $x_k \leftarrow \arg\max_u \widetilde{R}_k(u)$. This update rule can be shown to successfully drive $\max_u \widetilde{R}_k(u)$ down as k increases, and thus the right hand side of (1.4) decreases as k increases. This can be made into a rigorous analysis and show that mirror descent converges in $T = O(\rho^2/\varepsilon^2)$ iterations. Here, ρ^2 is the average value of $\|\nabla f(x_k)\|_*^2$ across the iterations.

To sum up, the smaller the queried gradients are (i.e. the smaller $\|\nabla f(x_k)\|_*$ is), the tighter the lower bound (1.3) becomes, and therefore the fewer iterations are needed for mirror descent to converge. (Note that the above mirror-descent analysis can also be used to derive the $1/\varepsilon$ convergence rate on smooth objectives similar to that in gradient descent [11]; since this adaption is not needed in our paper, we omit the details.)

[3] For simplicity, we choose uniform weights here. For the purpose of proving convergence results, the weights of individual hyperplanes are typically uniform or only dependent on k.

Remarks. Mirror descent admits several different algorithmic implementations, such as *Nemirovski's mirror descent* [24] and *Nesterov's dual averaging* [28].[4] Results based on one implementation can usually be transformed into another with some efforts. In this paper, we adopt Nemirovski's mirror descent as our choice of mirror descent, see Section 2.2.

One may occasionally find analyses that do not immediately fall into the above two categories. To name a few, solely using mirror descent and dual lower bounds, one can also obtain a convergence rate $1/\varepsilon$ for smooth objectives similar to that in gradient descent [11]. Conversely, one can deduce the mirror-descent guarantee by applying gradient descent on a dual objective (see Appendix A.3). Shamir and Zhang [40] obtained an algorithm that converges slightly slower than mirror descent, but has an error guarantee on the last iterate, rather than the average history.

1.2 Our Conceptual Question

Following this high level description of gradient and mirror descent, it is useful to pause and observe the complementary nature of the two procedures. Gradient descent relies on primal progress, uses local steps and makes faster progress when the norms of the queried gradients $\|\nabla f(x_k)\|$ are *large*. In contrast, mirror descent works by ensuring dual progress, uses global steps and converges faster when the norms of the queried gradients $\|\nabla f(x_k)\|$ are *small*.

This interpretation immediately leads to the question that inspires our work:

Can Gradient Descent and Mirror Descent be combined to obtain faster first-order methods?

In this paper, we initiate the formal study of this key conceptual question, and propose a *linear coupling* framework. To properly discuss our framework, we choose to mostly focus in the context of convex smooth minimization, and show how to reconstruct Nesterov's accelerated gradient methods using linear coupling. We also discuss the power of our framework by extending it to many other settings beyond Nesterov's original scope.

1.3 Accelerated Gradient Method Via Linear Coupling

In the seminal work [25, 26], Nesterov designed an accelerated gradient method for L-smooth functions with respect to ℓ_2 norms, and it performs quadratically faster than gradient descent – requiring $\Omega(L/\varepsilon)^{0.5}$ rather than $\Omega(L/\varepsilon)$ iterations. This is asymptotically tight [26]. Later in 2005, Nesterov generalizes his method to allow non-Euclidean norms in the definition of smoothness [27]. All these versions of methods are referred to as *accelerated gradient methods*, or sometimes as Nesterov's accelerated methods.

Although accelerated gradient methods have been widely applied (to mention a few, see [38, 39] for regularized optimizations, [19, 30] for composite optimization, [29] for cubic regularization, [31] for universal method, and [20] for an application on maxflow), they are often regarded as "analytical tricks" [17] because their convergence analyses are somewhat complicated and lack of intuitions.

In this paper, we provide a simple, alternative, but **complete** version of the accelerated gradient method. Here, by "complete" we mean our method works for any norm, and for both

[4] Other update rules can be viewed as specializations or generalizations of the mentioned implementations. For instance, the follow-the-regularized-leader (FTRL) step is a generalization of Nesterov's dual averaging step where the regularizers are can be adaptively selected (see [23]).

the constrained and unconstrained case.[5] Our key observation is to construct two sequences of updates: one sequence of gradient-descent updates and one sequence of mirror-descent updates.

Thought Experiment. Consider $f(x)$ that is unconstrained and L-smooth. For sake of demonstrating the idea, suppose $\|\nabla f(x)\|_2$, the norm of the observed gradient, is *either* always $\geq K$, or always $\leq K$, where the cut-off value K is determined later. Under such "wishful assumption", we propose the following algorithm: if $\|\nabla f(x)\|_2$ is always $\geq K$, we perform T gradient-descent steps; otherwise we perform T mirror-descent steps.

To analyze such an algorithm, suppose without loss of generality we start with some point x_0 whose objective distance $f(x_0) - f(x^*)$ is at most 2ε, and we want to find some x so that $f(x) - f(x^*) \leq \varepsilon$.[6] If T gradient-descent steps are performed, the objective decreases by at least $\frac{\|\nabla f(\cdot)\|_2^2}{2L} \geq \frac{K^2}{2L}$ per step according to (1.2), and we only need $T \geq \Omega(\frac{\varepsilon L}{K^2})$ steps to achieve an ε accuracy. If T mirror-descent steps are performed, we need $T \geq \Omega(\frac{K^2}{\varepsilon^2})$ steps according to the mirror-descent convergence. In sum, we need $T \geq \Omega\big(\max\big\{\frac{\varepsilon L}{K^2}, \frac{K^2}{\varepsilon^2}\big\}\big)$ steps to converge to an ε-minimizer. Setting K to be the "magic number" to balance the two terms, we only need $T \geq \Omega\big(\frac{L}{\varepsilon}\big)^{1/2}$ iterations as desired.

Towards an Actual Proof. To turn our thought experiment into an actual proof, we face the following obstacles. Although gradient-descent steps always decrease the objective, mirror-descent steps may sometimes increase the objective, cancelling the effect of the gradient descent. On the other hand, the mirror-descent steps are *only* useful when a large number of iterations are performed in a row; if any gradient-descent step stands in the middle, the convergence is destroyed.

For this reason, it is natural to design an algorithm that, in every single iteration k, performs *both* a gradient and a mirror descent step, and somehow ensure that the two steps are coupled together. However, the following additional difficulty arises: if from some starting point x_k, the gradient-descent step instructs us to go to y_k, while the mirror-descent step instructs us to go to z_k, then how do we continue? Do we look at the gradient at $\nabla f(y_k)$ or $\nabla f(z_k)$ in the next iteration?

This problem is implicitly solved by Nesterov using the following simple idea[7]: in the k-th iteration, we choose a linear combination $x_{k+1} \leftarrow \tau z_k + (1-\tau)y_k$, and use this same gradient $\nabla f(x_{k+1})$ to continue the gradient and mirror steps of the next iteration. Whenever τ is carefully chosen (just like the "magic number" K), the two descent sequences provide a coupled bound on the error guarantee, and we recover the same convergence as [27].

Roadmap. We review the key lemmas of gradient and mirror descent in Section 2. We propose a simple method with fixed step length to recover Nesterov's accelerated methods for the unconstrained case in Section 3, and generalize it to the full-setting in Section 4. We

[5] Some authors have regarded the result in [26] as "momentum analysis" [32, 41] or "ball method" [10]. These analyses only apply to Euclidean spaces. We point out the importance of allowing non-Euclidean norms in Appendix A.1. In addition, our proof in this paper extends naturally to the proximal version of first-order methods, but for simplicity, we choose to include only the constrained version.

[6] For all first-order methods, the heaviest computation always happens in this 2ε to ε process.

[7] We wish to point out that Nesterov has phrased his method differently from ours, and little is known on why this linear combination is needed from his proof, except for being used as an algebraic trick to cancel specific terms.

discuss several important applications of linear coupling that Nesterov's original methods do not solve in Section 5.

2 Key Lemmas of Gradient and Mirror Descent

2.1 Review of Gradient Descent

Consider a function $f(x)$ that is convex and differentiable on a closed convex set $Q \subseteq \mathbb{R}^n$, and assume that f is *L-smooth* with respect to $\|\cdot\|$, that is, for every $x, y \in Q$, it satisfies $\|\nabla f(x) - \nabla f(y)\|_* \le L\|x - y\|$. Here, $\|\cdot\|_*$ is the dual norm of $\|\cdot\|$.[8]

▶ **Definition 2.1.** For any $x \in Q$, the *gradient (descent) step* (with step length $\frac{1}{L}$) is

$$\widetilde{x} = \mathsf{Grad}(x) \stackrel{\text{def}}{=} \arg\min_{y \in Q} \left\{ \frac{L}{2}\|y - x\|^2 + \langle \nabla f(x), y - x \rangle \right\}$$

and we let $\mathsf{Prog}(x) \stackrel{\text{def}}{=} -\min_{y \in Q} \left\{ \frac{L}{2}\|y - x\|^2 + \langle \nabla f(x), y - x \rangle \right\} \ge 0$.

In particular, when $\|\cdot\| = \|\cdot\|_2$ is the ℓ_2-norm and $Q = \mathbb{R}^n$ is unconstrained, the gradient step can be simplified as $\mathsf{Grad}(x) = x - \frac{1}{L}\nabla f(x)$. Or, slightly more generally, when $\|\cdot\| = \|\cdot\|_2$ is the ℓ_2-norm but Q may be constrained, we have $\mathsf{Grad}(x) = x - \frac{1}{L} g_Q(x)$ where $g_Q(x)$ is the gradient mapping of f at x (see Chapter 2.2.3 of [26]).

The classical theory on smooth convex programming gives rise to the following lower bound on the amount of objective decrease (proved in Appendix B for completeness):

$$f(\mathsf{Grad}(x)) \le f(x) - \mathsf{Prog}(x) \tag{2.1}$$

$$\text{or in the special case when } Q = \mathbb{R}^n \qquad f(\mathsf{Grad}(x)) \le f(x) - \frac{1}{2L}\|\nabla f(x)\|_*^2 \ .$$

From the above descent guarantee, one can deduce the convergence rate of gradient descent. For instance, if $\|\cdot\| = \|\cdot\|_2$ is the Euclidean norm, and if gradient step $x_{k+1} = \mathsf{Grad}(x_k)$ is applied T times, we obtain the following convergence guarantee (see [26])

$$f(x_T) - f(x^*) \le O\Big(\frac{L\|x_0 - x^*\|_2^2}{T}\Big) \quad \text{or equivalently} \quad T \ge \Omega\Big(\frac{L\|x_0 - x^*\|_2^2}{\varepsilon}\Big) \Rightarrow f(x_T) - f(x^*) \le \varepsilon \ .$$

Here, x^* is any minimizer of $f(x)$. If $\|\cdot\|$ is a general norm, but $Q = \mathbb{R}^n$ is unconstrained, the above convergent rate becomes $f(x_T) - f(x^*) \le O\big(\frac{LR^2}{T}\big)$, where $R = \max_{x: f(x) \le f(x_0)} \|x - x^*\|$. We provide the proof of this later case in Appendix B because it is less known and we cannot find it in the optimization literature.

Note that, we are unaware of any universal convergence proof for both the general norm and the unconstrained case. As we shall see later in Section 4, this convergence rate can be improved by accelerated gradient methods, even for the general norm $\|\cdot\|$ and the constrained case.

2.2 Review of Mirror Descent

Consider some function $f(x)$ that is convex on a closed convex set $Q \subseteq \mathbb{R}^n$, and assume that f is *ρ-Lipschitz continuous* with respect to norm $\|\cdot\|$, that is, for every $x, y \in Q$, it satisfies $|f(x) - f(y)| \le \rho\|x - y\|$. This is equivalent to saying that f admits a subgradient

[8] $\|\xi\|_* \stackrel{\text{def}}{=} \max\{\langle \xi, x \rangle : \|x\| \le 1\}$. For instance, ℓ_p norm is dual to ℓ_q norm if $\frac{1}{p} + \frac{1}{q} = 1$.

$\partial f(x)$ at every point $x \in Q$, and satisfies $\|\partial f(x)\|_* \le \rho$. (Recall that $\partial f(x) = \nabla f(x)$ if f is differentiable.)

Mirror descent requires one to choose a regularizer (also referred to as a distance generating function):

▶ **Definition 2.2.** We say that $w\colon Q \to \mathbb{R}$ is a *distance generating function (DGF)*, if w is 1-strongly convex with respect to $\|\cdot\|$, or in symbols, $\forall x \in Q \setminus \partial Q$, $\forall y \in Q$: $w(y) \ge w(x) + \langle \nabla w(x), y - x\rangle + \frac{1}{2}\|x-y\|^2$. Accordingly, the *Bregman divergence* is given as

$$V_x(y) \stackrel{\text{def}}{=} w(y) - \langle \nabla w(x), y - x\rangle - w(x) \quad \forall x \in Q \setminus \partial Q, \forall y \in Q \ .$$

The property of DGF ensures that $V_x(x) = 0$ and $V_x(y) \ge \frac{1}{2}\|x-y\|^2 \ge 0$.

Common examples of DGFs include `(i)` $w(y) = \frac{1}{2}\|y\|_2^2$, which is strongly convex with respect to the ℓ_2-norm over every Q, and the corresponding $V_x(y) = \frac{1}{2}\|x-y\|_2^2$, and `(ii)` the entropy function $w(y) = \sum_i y_i \log y_i$, which is strongly convex with respect to the ℓ_1-norm over any $Q \subseteq \Delta \stackrel{\text{def}}{=} \{x \ge 0 : \mathbb{1}^T x = 1\}$. and the corresponding $V_x(y) = \sum_i y_i \log(y_i/x_i) \ge \frac{1}{2}\|x-y\|_1^2$.

▶ **Definition 2.3.** The *mirror (descent) step* with step length α can be described as

$$\widetilde{x} = \mathsf{Mirr}_x(\alpha \cdot \partial f(x)) \quad \text{where} \quad \mathsf{Mirr}_x(\xi) \stackrel{\text{def}}{=} \arg\min_{y \in Q} \left\{ V_x(y) + \langle \xi, y - x\rangle \right\} \ .$$

Mirror descent's core lemma is the following inequality (proved in Appendix B for completeness):

If $x_{k+1} = \mathsf{Mirr}_{x_k}\big(\alpha \cdot \partial f(x_k)\big)$, then

$$\forall u \in Q, \quad \alpha(f(x_k) - f(u)) \le \alpha\langle \partial f(x_k), x_k - u\rangle \le \frac{\alpha^2}{2}\|\partial f(x_k)\|_*^2 + V_{x_k}(u) - V_{x_{k+1}}(u) \ . \tag{2.2}$$

The term $\langle \partial f(x_k), x_k - u\rangle$ features prominently in online optimization, and is known as the *regret* at iteration k with respect to u (see Appendix A.2 for the folklore relationship between mirror descent and regret minimization). It is not hard to see that, telescoping (2.2) for $k = 0, \dots, T-1$, setting $\overline{x} \stackrel{\text{def}}{=} \frac{1}{T}\sum_{k=0}^{T-1} x_k$ to be the average of the x_k's, and choosing $u = x^*$, we have

$$\alpha T(f(\overline{x}) - f(x^*)) \le \sum_{k=0}^{T-1} \alpha\langle \partial f(x_k), x_k - x^*\rangle \le \frac{\alpha^2}{2}\sum_{k=0}^{T-1}\|\partial f(x_k)\|_*^2 + V_{x_0}(x^*) - V_{x_T}(x^*) \ . \tag{2.3}$$

Finally, letting Θ be any upper bound on $V_{x_0}(x^*)$ (recall $\Theta = \frac{1}{2}\|x_0 - x^*\|_2^2$ when $\|\cdot\|$ is the Euclidean norm), and $\alpha = \frac{\sqrt{2\Theta}}{\rho\cdot\sqrt{T}}$ be the step length, inequality (2.2) can be re-written as

$$f(\overline{x}) - f(x^*) \le \frac{\sqrt{2\Theta}\cdot\rho}{\sqrt{T}} \quad \text{or equivalently} \quad T \ge \frac{2\Theta\cdot\rho^2}{\varepsilon^2} \Rightarrow f(\overline{x}) - f(x^*) \le \varepsilon \ . \tag{2.4}$$

Remark. While their analyses share some similarities, mirror and gradient steps are often very different. For example, if the optimization problem is over the simplex with ℓ_1 norm, then gradient step gives $x' \leftarrow \arg\min_y\{\frac{1}{2}\|y-x\|_1^2 + \alpha\langle \nabla f(x), y - x\rangle\}$, while the mirror step with entropy regularizer gives $x' \leftarrow \arg\min_y\{\sum_i y_i \log(y_i/x_i) + \alpha\langle \nabla f(x), y - x\rangle\}$. We point out in Appendix A.1 that non-Euclidean norms are very important for certain applications.

In the special case of $w(x) = \frac{1}{2}\|x\|_2^2$ and $\|\cdot\|$ is ℓ_2-norm, gradient and mirror steps are indistinguishable from each other. However, as we have discussed earlier, these two update rules are often equipped with very different convergence analyses, even if they 'look the same'.

3 Warm-Up Method with Fixed Step Length

Consider the same setting as Section 2.1: that is, $f(x)$ is convex and differentiable on its domain Q, and is L-smooth with respect to some norm $\|\cdot\|$. (Note that $f(x)$ may not have a good Lipschitz continuity parameter ρ, but we do not need such a property.) In this section, we focus on the unconstrained case $Q = \mathbb{R}^n$, and combine gradient and mirror descent to produce a very simple accelerated method. We explain this method first because it avoids the mysterious choices of step lengths as in the full setting, and carries our conceptual message in a very clean way.

Design an algorithm that, in every step k, performs *both* a gradient and a mirror step, and ensures that the two steps are linearly coupled. More specifically, starting from $x_0 = y_0 = z_0$, in each iteration $k = 0, 1, \ldots, T-1$, we first define $x_{k+1} \leftarrow \tau z_k + (1-\tau) y_k$ and then

- perform a gradient step $y_{k+1} \leftarrow \mathsf{Grad}(x_{k+1})$, and
- perform a mirror step $z_{k+1} \leftarrow \mathsf{Mirr}_{z_k}\big(\alpha \nabla f(x_{k+1})\big)$.[9]

Above, α is the (fixed) step length of the mirror step, while τ is the parameter controlling the coupling rate. The choices of α and τ will become clear at the end of this section, but from a high level,

- α will be determined from the mirror-descent analysis, similar to that in (2.3), and
- τ will be determined as the best parameter to balance the gradient and mirror steps, similar to the "magic number" K in our thought experiment discussed in Section 1.3.

Classical gradient-descent and mirror-descent analyses immediately imply the following:

▶ **Lemma 3.1.** *For every $u \in Q = \mathbb{R}^n$,*

$$\begin{aligned} \alpha \langle \nabla f(x_{k+1}), z_k - u \rangle &\overset{①}{\le} \frac{\alpha^2}{2} \|\nabla f(x_{k+1})\|_*^2 + V_{z_k}(u) - V_{z_{k+1}}(u) \\ &\overset{②}{\le} \alpha^2 L \big(f(x_{k+1}) - f(y_{k+1}) \big) + V_{z_k}(u) - V_{z_{k+1}}(u) \ . \end{aligned} \tag{3.1}$$

Proof. To deduce ①, we note that our mirror step $z_{k+1} = \mathsf{Mirr}_{z_k}(\alpha \nabla f(x_{k+1}))$ is essentially identical to that of $x_{k+1} = \mathsf{Mirr}_{x_k}(\alpha \nabla f(x_k))$ in (2.2), with only changes of variable names. Therefore, inequality ① is a simple copy-and-paste from (2.2) after changing the variable names (see the proof of (2.2) for details). The second inequality ② is from the gradient step guarantee $f(x_{k+1}) - f(y_{k+1}) \ge \frac{1}{2L} \|\nabla f(x_{k+1})\|_*^2$ in (2.1). ◀

One can immediately see from Lemma 3.1 that, although the mirror step introduces an error $\frac{\alpha^2}{2} \|\nabla f(x_{k+1})\|_*^2$, this error is proportional to the amount of the gradient-step progress $f(x_{k+1}) - f(y_{k+1})$. This captures the observation we stated in the introduction: if $\|\nabla f(x_{k+1})\|_*$ is large, we can make a large gradient step, or if $\|\nabla f(x_{k+1})\|_*$ is small, the mirror step suffers from a small loss.

If we choose $\tau = 1$ or equivalently $x_{k+1} = z_k$, the left hand side of inequality (3.1) becomes $\langle \nabla f(x_{k+1}), x_{k+1} - u \rangle$, the regret at iteration x_{k+1}. In such a case we wish to telescope it for all iterations k in the spirit of mirror descent (see (2.3)). However, we face the problem that the terms $f(x_{k+1}) - f(y_{k+1})$ do not telescope. [10] On the other hand, if we choose $\tau = 0$ or

[9] Here, the mirror step Mirr is defined by specifying any DGF $w(\cdot)$ that is 1-strongly convex over Q.

[10] In other words, although a gradient step may decrease the objective from $f(x_{k+1})$ to $f(y_{k+1})$, it may also get the objective increased from $f(y_k)$ to $f(x_{k+1})$.

equivalently $x_{k+1} = y_k$, then the terms $f(x_{k+1}) - f(y_{k+1}) = f(y_k) - f(y_{k+1})$ telescope, but the left hand side of (3.1) is no longer the regret. [11]

To overcome this issue, we use linear coupling. We compute and upper bound the difference between the left hand side of (3.1) and the actual "regret":

$$\begin{aligned}&\alpha\langle\nabla f(x_{k+1}), x_{k+1} - u\rangle - \alpha\langle\nabla f(x_{k+1}), z_k - u\rangle \\ &= \alpha\langle\nabla f(x_{k+1}), x_{k+1} - z_k\rangle = \frac{(1-\tau)\alpha}{\tau}\langle\nabla f(x_{k+1}), y_k - x_{k+1}\rangle \le \frac{(1-\tau)\alpha}{\tau}(f(y_k) - f(x_{k+1})). \quad (3.2)\end{aligned}$$

Above, we used the fact that $\tau(x_{k+1} - z_k) = (1-\tau)(y_k - x_{k+1})$, as well as the convexity of $f(\cdot)$. It is now immediate that by choosing $\frac{1-\tau}{\tau} = \alpha L$ and combining (3.1) and (3.2), we have

▶ **Lemma 3.2** (Coupling). *Letting $\tau \in (0,1)$ satisfy that $\frac{1-\tau}{\tau} = \alpha L$, we have that*

$$\forall u \in Q = \mathbb{R}^n, \quad \alpha\langle\nabla f(x_{k+1}), x_{k+1} - u\rangle \le \alpha^2 L\big(f(y_k) - f(y_{k+1})\big) + \big(V_{z_k}(u) - V_{z_{k+1}}(u)\big).$$

It is clear from the above proof that τ is introduced to precisely balance the objective decrease $f(x_{k+1}) - f(y_{k+1})$, and the (possible) objective increase $f(y_k) - f(x_{k+1})$. This is similar to the "magic number" K discussed in the introduction.

Finally Convergence Rate. We telescope inequality Lemma 3.2 for $k = 0, 1, \ldots, T-1$. Setting $\overline{x} \stackrel{\text{def}}{=} \frac{1}{T}\sum_{k=0}^{T-1} x_k$ and $u = x^*$, we have

$$\alpha T(f(\overline{x}) - f(x^*)) \le \sum_{k=0}^{T-1} \alpha\langle\partial f(x_k), x_k - x^*\rangle \le \alpha^2 L\big(f(y_0) - f(y_T)\big) + V_{x_0}(x^*) - V_{x_T}(x^*) \ . \quad (3.3)$$

Suppose our initial point is of error at most d, that is $f(y_0) - f(x^*) \le d$, and suppose $V_{x_0}(x^*) \le \Theta$, then (3.3) gives $f(\overline{x}) - f(x^*) \le \frac{1}{T}\big(\alpha L d + \Theta/\alpha\big)$. Choosing $\alpha = \sqrt{\Theta/Ld}$ to be the value that balances the above two terms,[12] we obtain that $f(\overline{x}) - f(x^*) \le \frac{2\sqrt{L\Theta d}}{T}$. In other words,

$$\text{in } T = 4\sqrt{L\Theta/d} \text{ steps, we can obtain some } \overline{x} \text{ satisfying } f(\overline{x}) - f(x^*) \le d/2,$$

halving the distance to the optimum. If we restart this entire procedure a few number of times, halving the distance for every run, then we obtain an ε-approximate solution in

$$T = O\big(\sqrt{L\Theta/\varepsilon} + \sqrt{L\Theta/2\varepsilon} + \sqrt{L\Theta/4\varepsilon} + \cdots\big) = O\big(\sqrt{L\Theta/\varepsilon}\big)$$

iterations, matching the same running time of Nesterov's accelerated methods [25, 26, 27]. It is important to note here that $\alpha = \sqrt{\Theta/Ld}$ increases as time goes (i.e., as d goes down), and therefore $\tau = \frac{1}{\alpha L + 1}$ decreases as time goes. This lesson instructs us that gradient steps should be given more weights than mirror steps, when it is closer to the optimum.[13]

[11] Indeed, our "thought experiment" in the introduction is conducted *as if* we both had $x_{k+1} = z_k$ and $x_{k+1} = y_k$, and therefore we could arrive at the upcoming (3.3) directly.

[12] This is essentially the same way to choose α in mirror descent, see (2.3).

[13] One may find this counter-intuitive because when it is closer to the optimum, the observed gradients will become smaller, and therefore mirror steps should perform well due to our conceptual message in the introduction. This understanding is incorrect for two reasons. First, when it is closer to the optimum, the threshold between "large" and "small" gradients also become smaller, so one cannot rely only on mirror steps. Second, when it is closer to the optimum, mirror steps are more 'unstable' and may increase the objective more (in comparison to the current distance to the optimum), and thus should be given less weight.

Algorithm 1 $\texttt{AGM}(f, w, x_0, T)$

Input: f a differentiable and convex function on Q that is L-smooth with respect to $\|\cdot\|$; w the DGF function that is 1-strongly convex with respect to the same $\|\cdot\|$ over Q; x_0 some initial point; and T the number of iterations.

Output: y_T such that $f(y_T) - f(x^*) \le \frac{4\Theta L}{T^2}$.

$V_x(y) \stackrel{\text{def}}{=} w(y) - \langle \nabla w(x), y - x\rangle - w(x)$.
$y_0 \leftarrow x_0, \quad z_0 \leftarrow x_0$.
for $k \leftarrow 0$ **to** $T-1$ **do**
  $\alpha_{k+1} \leftarrow \frac{k+2}{2L}$, and $\tau_k \leftarrow \frac{1}{\alpha_{k+1}L} = \frac{2}{k+2}$.
  $x_{k+1} \leftarrow \tau_k z_k + (1-\tau_k) y_k$.
  $y_{k+1} \leftarrow \mathsf{Grad}(x_{k+1})$ $\quad \diamond = \arg\min_{y\in Q}\left\{\frac{L}{2}\|y - x_{k+1}\|^2 + \langle \nabla f(x_{k+1}), y - x_{k+1}\rangle\right\}$
  $z_{k+1} \leftarrow \mathsf{Mirr}_{z_k}\big(\alpha_{k+1}\nabla f(x_{k+1})\big)$ $\quad \diamond = \arg\min_{z\in Q}\left\{V_{z_k}(z) + \langle \alpha_{k+1}\nabla f(x_{k+1}), z - z_k\rangle\right\}$
end for
return y_T.

Conclusion. Equipped with the basic knowledge of gradient descent and mirror descent, the above proof is quite straightforward and gives intuition on how the two "magic numbers" α and τ are selected. However, this simple algorithm has several caveats. First, the value α depends on the knowledge of Θ; second, a good initial distance bound d has to be specified; and third, the algorithm has to be restarted. In the next section, we let α and τ change gradually across iterations. This overcomes the mentioned caveats, and also extends the above analysis to allow Q to be constrained.

4 Final Method with Variable Step Lengths

In this section, we recover the main result of [27] in the constrained case, that is

▶ **Theorem 4.1.** *If $f(x)$ is L-smooth w.r.t. $\|\cdot\|$ on Q, and $w(x)$ is 1-strongly convex w.r.t. $\|\cdot\|$ on Q, then* AGM *outputs y_T satisfying $f(y_T) - f(x^*) \le 4\Theta L/T^2$, where Θ is any upper bound on $V_{x_0}(x^*)$.*

We remark here that it is very important to allow the norm $\|\cdot\|$ to be general, rather than focusing on the ℓ_2-norm as in [26]. See our discussion in Appendix A.1.

Our algorithm AGM (see Algorithm 1) starts from $x_0 = y_0 = z_0$. In each step $k = 0, 1, \ldots, T-1$, it computes $x_{k+1} \leftarrow \tau_k z_k + (1-\tau_k) y_k$ and then

- performs gradient step $y_{k+1} \leftarrow \mathsf{Grad}(x_{k+1})$, and
- performs mirror step $z_{k+1} \leftarrow \mathsf{Mirr}_{z_k}\big(\alpha_{k+1}\nabla f(x_{k+1})\big)$.

Here, α_{k+1} is the step length of mirror descent and will be chosen at the end of this section. The value τ_k is $\frac{1}{\alpha_{k+1}L}$ which is slightly different from $\frac{1}{\alpha L+1}$ used in the warm-up case. (This is necessary to capture the constrained case.) Our choice of α_{k+1} will ensure that $\tau_k \in (0, 1]$ for each k.

Convergence Analysis. We state the analogue of Lemma 3.1 whose proof is in Appendix C:

▶ **Lemma 4.2.** *If $\tau_k = \frac{1}{\alpha_{k+1}L}$, then it satisfies that for every $u \in Q$,*

$$\begin{aligned}\alpha_{k+1}\langle \nabla f(x_{k+1}), z_k - u\rangle &\le \alpha_{k+1}^2 L\,\mathsf{Prog}(x_{k+1}) + V_{z_k}(u) - V_{z_{k+1}}(u)\\ &\le \alpha_{k+1}^2 L\big(f(x_{k+1}) - f(y_{k+1})\big) + V_{z_k}(u) - V_{z_{k+1}}(u)\ .\end{aligned}$$

We state the analogue of Lemma 3.2, whose proof is slightly different and in Appendix C:

▶ **Lemma 4.3** (Coupling). *For any $u \in Q$,*

$$\big(\alpha_{k+1}^2 L\big) f(y_{k+1}) - \big(\alpha_{k+1}^2 L - \alpha_{k+1}\big) f(y_k) + \big(V_{z_{k+1}}(u) - V_{z_k}(u)\big) \le \alpha_{k+1} f(u) \ .$$

We are now ready to prove Theorem 4.1:

Proof of Theorem 4.1. In order to telescope Lemma 4.3, we only need to set the sequence of α_k so that $\alpha_k^2 L \approx \alpha_{k+1}^2 L - \alpha_{k+1}$ as well as $\tau_k = 1/\alpha_{k+1} L \in (0,1]$. In our `AGM`, we let $\alpha_k = \frac{k+1}{2L}$ so that $\alpha_k^2 L = \alpha_{k+1}^2 L - \alpha_{k+1} + \frac{1}{4L}$. Summing up Lemma 4.3 for $k = 0, 1, \dots, T-1$, we obtain

$$\alpha_T^2 L f(y_T) + \sum_{k=1}^{T-1} \frac{1}{4L} f(y_k) + \big(V_{z_T}(u) - V_{z_0}(u)\big) \le \sum_{k=1}^{T} \alpha_k f(u) \ .$$

By choosing $u = x^*$, we notice that $\sum_{k=1}^{T} \alpha_k = \frac{T(T+3)}{4L}$, $f(y_k) \ge f(x^*)$, $V_{z_T}(u) \ge 0$ and $V_{z_0}(x^*) \le \Theta$. Therefore, we obtain

$$\frac{(T+1)^2}{4L^2} L f(y_T) \le \Big(\frac{T(T+3)}{4L} - \frac{T-1}{4L}\Big) f(x^*) + \Theta \ ,$$

which after simplification implies $f(y_T) \le f(x^*) + \frac{4\Theta L}{(T+1)^2}$. ◀

Let us make three remarks.

- `AGM` is slightly different from [27]: (1) we use Nemirovski's mirror steps instead of dual averaging steps, (2) we allow arbitrary starting points x_0, and (3) we use $\tau_k = \frac{2}{k+2}$ rather than $\tau_k = \frac{2}{k+3}$.
- `AGM` is very different from the perhaps better-known version [26], which is known by some authors as the "momentum method" [32, 41]. Momentum methods do not apply to non-Euclidean settings.
- In Appendix D, we also recover the strong convexity version of accelerated gradient methods [26], and thus linear coupling provides a complete proof of all existing accelerated gradient methods.

5 Beyond Accelerated Gradient Methods

Providing an intuitive, yet complete interpretation of accelerated gradient methods is an open question in Optimization [17]. Our result in this paper is one important step towards this general goal. Linear coupling not only gives a reinterpretation of Nesterov's accelerated methods, more importantly, it provides a framework for designing first-order methods in a *bigger agenda*. Since the original version of this paper appeared online, our linear-coupling framework has led to breakthroughs for several problems in computer science. In all such problems, the original Nesterov's accelerated methods do not apply. We illustrate a few examples in this line of research, in order to demonstrate the power and generality of linear coupling.

Recall the key lemmas of gradient and mirror descent in linear coupling (see (3.1)):

$$\text{gradient descent:} \quad f(x_{k+1}) - f(y_{k+1}) \ge \frac{1}{2L} \|\nabla f(x_{k+1})\|_*^2 \tag{5.1}$$

$$\text{mirror descent:} \quad \alpha \langle \nabla f(x_{k+1}), z_k - u \rangle \le \frac{\alpha^2}{2} \|\nabla f(x_{k+1})\|_*^2 + V_{z_k}(u) - V_{z_{k+1}}(u) \tag{5.2}$$

Extension 1: Strengthening (5.2) and (5.1). If f satisfies good properties other than smoothness, one can also develop objective decrease lemma to replace (5.1). In addition, if necessary, a non-strongly convex regularizer can be used in mirror descent to replace (5.2). In either or both such cases, linear coupling can still be used to combine the two methods and obtain faster running times; in contrast, Nesterov's original accelerated methods do not apply.

For example, recent breakthroughs on *positive linear programming (positive LP)* are all based on the above extension of linear coupling [3, 4, 5, 22, 42, 43]. For such LPs, the corresponding objective f is intrinsically non-smooth. Some authors including Nesterov himself have applied simple smoothing to turn f into a smooth variant f', and then minimized f' [27]; however, even if Nesterov's accelerated methods are used to minimize f', the resulting running time scales with the problem's *width*, a parameter that can be exponential in input size.[14] In contrast, if linear coupling is used, one can show that $f(x_{k+1}) - f(y_{k+1})$ is lower bounded by a constant times $\sum_j \max\{|\nabla_j f(x_{k+1})|, 1\}^2$ for the original objective f (see [4]). This is a weaker version of (5.1). However, after linear coupling, it leads to a faster algorithm than naively applying Nesterov's accelerated methods on f' *in all parameter regimes.*

Extension 2: Three-Point Coupling. One may naturally consider linearly coupling for more than two vectors. While this is provably unnecessary for minimizing a smooth objective in the full-gradient setting (because accelerated gradient methods are already optimal), it can be very helpful in the *stochastic-gradient* setting.

More specifically, it was a known obstacle in Nesterov's accelerated methods (including our `AGM`) that if the full gradient $\nabla f(x_{k+1})$ is replaced with a random estimator $\widetilde{\nabla}$ whose expectation $\mathbf{E}[\widetilde{\nabla}] = \nabla f(x_{k+1})$, then acceleration disappears in the worst case. Using linear coupling, we can fix this issue by providing the first direct accelerated *stochastic* gradient method. In [1], the author replaced the coupling step $x_{k+1} \leftarrow \tau z_k + (1-\tau) y_k$ with $x_{k+1} \leftarrow \tau_1 z_k + \tau_2 \widetilde{x} + (1-\tau_2-\tau_1) y_k$, where $\widetilde{x}$ is a snapshot point whose full gradient is computed exactly but very infrequently. Such a "three-point" linear coupling provides an accelerated running time because one can combine (5.1), (5.2), together with a so-called variance-reduction inequality [16] all three at once.

Extension 3: Optimal Sampling Probability. Nesterov's accelerated methods generalize to coordinate-descent settings, that is, to minimize f that is L_i-smooth for each coordinate i. The best known coordinate-descent method [21] samples each coordinate i with probability proportional to L_i, and is based on a randomized version of Nesterov's original analysis. Using linear coupling, the authors of [6] discovered that one should select i with probability proportional to $\sqrt{L_i}$ for an even faster running time.

To illustrate the reasoning behind this, let us revisit (5.1) and (5.2). In the coordinate-descent setting, if we abbreviate x_{k+1} with x, the right hand side of (5.1) simply becomes $\frac{1}{2L_i}(\nabla_i f(x))^2$ if coordinate i is selected. As for (5.2), to ensure its left hand side stays the same in expectation, one should replace $\nabla f(x)$ with $\frac{1}{p_i}\nabla_i f(x)$, where p_i is the probability to select i. As a result, the first term on the right hand side of (5.2) becomes $\frac{\alpha^2}{2p_i^2}(\nabla_i f(x))^2$. By comparing these two new terms $\frac{1}{2L_i}(\nabla_i f(x))^2$ and $\frac{\alpha^2}{2p_i^2}(\nabla_i f(x))^2$, we immediately notice

[14] We recommend interested readers to find detailed discussions in [4] regarding the importance of designing *width-independent* solvers for positive LP. As an illustrative example, in the problem of maximum matching (which can be written as positive LP), the width of the problem is the number of edges in the graph.

that p_i had better be proportional to $\sqrt{L_i}$ in order for the two terms to cancel. This simple idea, fully motivated from linear coupling, leads to the fastest accelerated coordinate-descent method [6].

Extension 4: Supporting Non-Convexity. Consider objectives f that are not even convex but still smooth. For instance, neural network training objectives fall into this class if smoothed activation functions are used. In such a case, both (5.1) and (5.2) remain true. However, when coupling the two steps, we cannot claim $\langle \nabla f(x_{k+1}), x_{k+1} - u \rangle \geq f(x_{k+1}) - f(u)$ because there is no convexity. In [2], the authors discovered that one can use the quadratic lower bound $\langle \nabla f(x_{k+1}), x_{k+1} - u \rangle \geq f(x_{k+1}) - f(u) - \frac{L}{2}\|x_{k+1} - u\|^2$ to replace convexity arguments, and still perform a weaker version of linear coupling. This leads to a stochastic algorithm that converges to approximate saddle-points,[15] outperforming both gradient descent and stochastic gradient descent, the only two known first-order methods with provably convergence guarantees.

Acknowledgements. We thank Jon Kelner and Yin Tat Lee for helpful conversations, and Aaditya Ramdas for pointing out a typo in the previous version of this paper.

A Several Remarks on First-Order Methods

A.1 Importance of Non-Euclidean Norms

Let us use a simple example to illustrate the importance of allowing arbitrary norms in studying first-order methods.

Consider the saddle point problem of $\min_{x\in\Delta_n}\max_{y\in\Delta_m} y^TAx$, where A is an $m\times n$ matrix, $\Delta_n=\{x\in\mathbb{R}^n : x\geq 0\wedge \mathbb{1}^Tx=1\}$ is the unit simplex in $\mathbb{R}^n$, and $\Delta_m=\{y\in\mathbb{R}^m : y\geq 0\wedge \mathbb{1}^Ty=1\}$. This problem is important to study because it captures packing and covering linear programs that have wide applications in many areas of computer science (see the survey of [8]).

Letting $\mu=\frac{\varepsilon}{2\log m}$, Nesterov has shown that the following objective

$$f_\mu(x)\stackrel{\text{def}}{=}\mu\log\left(\frac{1}{m}\sum_{j=1}^m \exp^{\frac{1}{\mu}(Ax)_j}\right)\ ,$$

when optimized over $x \in \Delta_n$, can yield an additive $\varepsilon/2$ solution to the original saddle point problem [27].

This $f_\mu(x)$ is proven to be $\frac{1}{\mu}$-smooth with respect to the ℓ_1-norm over Δ_n, if all the entries of A are between $[-1, 1]$. Instead, $f_\mu(x)$ is $\frac{1}{\mu}$-smooth with respect to the ℓ_2-norm over Δ_n, *only if* the sum of squares of every row of A is at most 1. This ℓ_2 condition is certainly stronger and less natural than the ℓ_1 condition, and the ℓ_1 condition one leads to the fastest (approximate) width-dependent positive LP solver [27].

Different norm conditions also yield different gradient and mirror descent steps. For instance, in the ℓ_1-norm case, the gradient step is $x' \leftarrow \arg\min_{x' \in \Delta_n} \left\{ \frac{1}{2}\|x' - x\|_1^2 + \alpha\langle \nabla f_\mu(x), x' - x\rangle \right\}$, and the mirror step is $x' \leftarrow \arg\min_{x' \in \Delta_n} \left\{ \sum_{i \in [n]} x'_i \log \frac{x'_i}{x_i} + \alpha\langle \nabla f_\mu(x), x' - x\rangle \right\}$. In the ℓ_2-norm case, gradient and mirror steps are both of the form $x' \leftarrow \arg\min_{x' \in \Delta_n} \left\{ \frac{1}{2}\|x' - x\|_2^2 + \alpha\langle \nabla f_\mu(x), x' - x\rangle \right\}$.

As another example, [35] has shown that the ℓ_1 norm, instead of the ℓ_2 one, is crucial when computing the minimum enclosing ball of points. One can find other applications as well in [27] for the use of non-Euclidean norms, and an interesting example of ℓ_∞-norm gradient descent for nearly-linear time maximum flow in [18].

It is now important to note that, the methods in [25, 26] work only for the ℓ_2-norm case, and it is not clear how the proof can be generalized to other norms until [27]. Some other proofs (such as [13]) only work for the ℓ_2-norm because the mirror steps are described as (a scaled version of) gradient steps.

A.2 Folklore Relationship Between Multiplicative Weight Updates and Mirror Descent

The multiplicative weight update (MWU) method (see the survey of Arora, Hazan and Kale [8]) is a simple method that has been repeatedly discovered in theory of computation, machine learning, optimization, and game theory. The setting of this method is the following.

Let $\Delta_n = \{x \in \mathbb{R}^n : x \geq 0 \wedge \mathbb{1}^T x = 1\}$ be the unit simplex in $\mathbb{R}^n$, and we call any vector in Δ_n an *action*. A player is going to play T actions $x_0, \ldots, x_{T-1} \in \Delta_n$ in a row; only after playing x_k, the player observes a loss vector $\ell_k \in \mathbb{R}^n$ that may depend on x_k, and suffers from a loss value $\langle \ell_k, x_k\rangle$. The MWU method ensures that, if $\|\ell_k\|_\infty \leq \rho$ for all $k \in [T]$, then the player has an (adaptive) strategy to choose the actions such that the average *regret* is bounded:

$$\frac{1}{T}\Big(\sum_{i=0}^{T-1} \langle \ell_k, x_k\rangle - \min_{u \in \Delta_n} \sum_{i=0}^{T-1} \langle \ell_k, u\rangle \Big) \leq O\Big(\frac{\rho\sqrt{\log n}}{\sqrt{T}} \Big) \ . \tag{A.1}$$

The left hand side is called the average regret because it is the (average) difference between the suffered loss $\sum_{i=0}^{T-1} \langle \ell_k, x_k\rangle$, and the loss $\sum_{i=0}^{T-1} \langle \ell_k, u\rangle$ of the best action $u \in \Delta_n$ in hindsight. Another way to interpret (A.1) is to state that we can obtain an average regret of ε using $T = O(\frac{\rho^2 \log n}{\varepsilon^2})$ rounds.

The above result can be proven directly using mirror descent. Letting $w(x) \stackrel{\text{def}}{=} \sum_i x_i \log x_i$ be the entropy DGF over the simplex $Q = \Delta_n$, and its corresponding Bregman divergence $V_x(x') \stackrel{\text{def}}{=} \sum_{i \in [n]} x'_i \log \frac{x'_i}{x_i}$, we consider the following update rule.

Start from $x_0 = (1/n, \ldots, 1/n)$, and update $x_{k+1} = \mathsf{Mirr}_{x_k}\big(\alpha \ell_k\big)$, or equivalently, $x_{k+1,i} = x_{k,i} \cdot \exp^{-\alpha \ell_{k,i}} / Z_k$, where $Z_k > 0$ is the normalization factor that equals to $\sum_{i=1}^n x_{k,i} \cdot$

$\exp^{-\alpha\ell_{k,i}}$.[16] Then, the mirror-descent guarantee (2.2) implies that[17]

$$\forall u \in \Delta_n, \quad \alpha\langle \ell_k, x_k - u\rangle \le \frac{\alpha^2}{2}\|\ell_k\|_\infty^2 + V_{x_k}(u) - V_{x_{k+1}}(u) \ .$$

After telescoping the above inequality for all $k = 0, 1, \ldots, T-1$, and using the upper bounds $\|\ell(x_k)\|_\infty \le \rho$ and $V_{x_0}(u) \le \log n$, we obtain that for all $u \in \Delta_n$,

$$\frac{1}{T}\sum_{k=0}^{T-1}\langle \ell_k, x_k - u\rangle \le \frac{\alpha\rho^2}{2} + \frac{\log n}{\alpha T} \ .$$

Setting $\alpha = \frac{\sqrt{\log n}}{\rho\sqrt{T}}$ we arrive at the desired average regret bound (A.1).

In sum, we have re-deduced the MWU method from mirror descent, and the above proof is quite different from most of the classical analysis of MWU (e.g., [7, 8, 14, 34]). It can be generalized to solve the matrix version of MWU [8, 33], as well as to incorporate the width-reduction technique [8, 34]. We ignore such extensions here because they are outside the scope of this paper.

A.3 Deducing the Mirror-Descent Guarantee via Gradient Descent

In this section, we re-deduce the convergence rate of mirror descent from gradient descent. In particular, we show that the dual averaging steps are equivalent to gradient steps on the Fenchel dual of the regularized regret, and deduce the same convergence bound as (2.4). (Similar proof can also be obtained for mirror steps but is notationally more involved.)

Given a sequence of points $x_0, \ldots, x_{T-1} \in Q$, the (scaled) regret with respect to any point $u \in Q$ is $R(x_0, \ldots, x_{T-1}, u) \stackrel{\text{def}}{=} \sum_{i=0}^{T-1} \alpha\langle \partial f(x_i), x_i - u\rangle$. Since it satisfies that $\alpha T \cdot (f(\overline{x}) - f(u)) \le R(x_0, \ldots, x_{T-1}, u)$, the average regret (after scaling) upper bounds on the distance between any point $f(u)$ and the average $\overline{x} = \frac{1}{T}(x_0 + \cdots + x_{T-1})$. Consider now the regularized regret

$$\widehat{R}(x_0, \ldots, x_{T-1}) \stackrel{\text{def}}{=} \max_{u\in Q}\Big\{ \sum_{i=0}^{T-1} \alpha\langle \partial f(x_i), x_i - u\rangle - w(u)\Big\} \ ,$$

and we can rewrite it using the Fenchel dual $w^*(\lambda) \stackrel{\text{def}}{=} \max_{u\in Q}\{\langle \lambda, u\rangle - w(u)\}$ of $w(\cdot)$:

$$\widehat{R}(x_0, \ldots, x_{T-1}) = w^*\Big(-\alpha \sum_{i=0}^{T-1} \partial f(x_i)\Big) + \sum_{i=0}^{T-1} \alpha\langle \partial f(x_i), x_i\rangle \ .$$

The classical theory of Fenchel duality tells us that $w^*(\lambda)$ is 1-smooth with respect to the dual norm $\|\cdot\|_*$, because $w(\cdot)$ is 1-strongly convex with respect to $\|\cdot\|$. We also have $\nabla w^*(\lambda) = \arg\max_{u\in Q}\{\langle \lambda, u\rangle - w(u)\}$. (See for instance [36].)

With enough notations introduced, let us now minimize $\widehat{R}$ by intelligently selecting $x_0, \ldots, x_{T-1}$. Perhaps a little counter-intuitively, we start from $x_0 = \cdots = x_{T-1} = x^*$ and accordingly $\partial f(x^*) = 0$ (if there are multiple subgradients at x^*, choose the zero one).

[16] This version of the MWU is often known as the Hedge rule [14]. Another commonly used version is to choose $x_{k+1,i} = \frac{x_{k,i}(1-\alpha\ell_{k,i})}{Z_k}$. Since $e^{-t} \approx 1 - t$ whenever $|t|$ is small and our choice of α will make sure that $|\alpha\ell_{k,i}| \ll 1$, this is essentially identical to the Hedge rule.

[17] To be precise, we have replaced $\partial f(x_k)$ with ℓ_k. It is easy to see from the proof of (2.2) that this loss vector ℓ_k does not need to come from the subgradient of some objective $f(\cdot)$.

This corresponds to a regret value of zero and a regularized regret $\widehat{R}(x^*,\dots,x^*) = w^*(0) = -\min_{u\in Q}\{w(u)\}$.

Next, we choose the values of $x_0,\dots,x_{T-1}$ one by one. We choose $x_0 = \arg\min_{u\in Q}\{w(u)\}$ as the starting point.[18] Suppose that the values of $x_0,\dots,x_{k-1}$ are already determined, and we are ready to pick $x_k \in Q$. Let us compute the changes in the regularized regret as a function of x_k:

$$\begin{aligned}\Delta\widehat{R} &= \widehat{R}(x_0,\dots,x_k,x^*,\dots,x^*) - \widehat{R}(x_0,\dots,x_{k-1},x^*,\dots,x^*)\\ &= w^*\Big(-\alpha\sum_{i=0}^{k}\partial f(x_i)\Big) - w^*\Big(-\alpha\sum_{i=0}^{k-1}\partial f(x_i)\Big) + \alpha\langle\partial f(x_k),x_k\rangle\\ &\le \Big\langle\nabla w^*\Big(-\alpha\sum_{i=0}^{k-1}\partial f(x_i)\Big), -\alpha\partial f(x_k)\Big\rangle + \frac{1}{2}\big\|\alpha\partial f(x_k)\big\|_*^2 + \alpha\langle\partial f(x_k),x_k\rangle\ . \qquad \text{(A.2)}\end{aligned}$$

Here, the last inequality is because $w^*(a) - w^*(b) \le \langle\nabla w^*(b), a-b\rangle + \frac{1}{2}\|a-b\|_*^2$, owing to the smoothness of $w^*(\cdot)$. At this moment, it is clear to see that if one chooses

$$x_k = \nabla w^*\Big(-\alpha\sum_{i=0}^{k-1}\partial f(x_i)\Big) = \arg\min_{u\in Q}\Big\{w(u) + \sum_{i=0}^{k-1}\alpha\langle\partial f(x_i),u\rangle\Big\}\ ,$$

the first and third terms in (A.2) cancel out, and we obtain $\Delta\widehat{R} \le \frac{1}{2}\big\|\alpha\partial f(x_k)\big\|_*^2$. In other words, the regularized regret increases by no more than $\frac{1}{2}\big\|\alpha\partial f(x_k)\big\|_*^2 \le \alpha^2\rho^2/2$ in each step, so in the end we have $\widehat{R}(x_0,\dots,x_{T-1}) \le -w(x_0) + \alpha^2\rho^2 T/2$.

In sum, by the definition of the regularized regret, we have

$$\begin{aligned}\alpha T\cdot(f(\overline{x}) - f(x^*)) - w(x^*) &\le \sum_{i=0}^{T-1}\alpha\langle\partial f(x_i), x_i - x^*\rangle - w(x^*)\\ &\le \widehat{R}(x_0,\dots,x_{T-1})\\ &\le -w(x_0) + \frac{\alpha^2\rho^2 T}{2}\ .\end{aligned}$$

This implies the following upper bound on the optimality of $f(\overline{x})$

$$f(\overline{x}) - f(x^*) \le \frac{\alpha\rho^2}{2} + \frac{w(x^*)-w(x_0)}{\alpha T} = \frac{\alpha\rho^2}{2} + \frac{V_{x_0}(x^*)}{\alpha T} \le \frac{\alpha\rho^2}{2} + \frac{\Theta}{\alpha T}\ .$$

Finally, choosing $\alpha = \frac{\sqrt{2\Theta}}{\rho\cdot\sqrt{T}}$ to be the step length, we arrive at $f(\overline{x}) - f(x^*) \le \frac{\sqrt{2\Theta}\cdot\rho}{\sqrt{T}}$, which is the same convergence rate as (2.4).

B Missing Proof of Section 2

For the sake of completeness, we provide self-contained proofs of the mirror descent and mirror descent guarantees in this section.

[18] Dual averaging steps typically demand the first point x_0 to be at the minimum of the regularizer $w(\cdot)$, because that leads to the cleanest analysis. This can be relaxed to allow an arbitrary starting point.

B.1 Missing Proof for Gradient Descent

Gradient Descent Guarantee

$$f(\mathsf{Grad}(x)) \le f(x) - \mathsf{Prog}(x) \qquad (2.1)$$

or in the special case when $Q = \mathbb{R}^n$ $\quad f(\mathsf{Grad}(x)) \le f(x) - \frac{1}{2L}\|\nabla f(x)\|_*^2$.

Proof. [19] Letting $\widetilde{x} = \mathsf{Grad}(x)$, we prove the first inequality by

$$\mathsf{Prog}(x) = -\min_{y\in Q}\Big\{\frac{L}{2}\|y-x\|^2 + \langle \nabla f(x), y-x\rangle\Big\} = -\Big(\frac{L}{2}\|\widetilde{x}-x\|^2 + \langle \nabla f(x), \widetilde{x}-x\rangle\Big)$$
$$= f(x) - \Big(\frac{L}{2}\|\widetilde{x}-x\|^2 + \langle \nabla f(x), \widetilde{x}-x\rangle + f(x)\Big) \le f(x) - f(\widetilde{x}) \ .$$

Here, the last inequality is a consequence of the smoothness assumption: for any $x, y \in Q$,

$$\begin{aligned} f(y) - f(x) &= \int_{\tau=0}^{1} \langle \nabla f(x+\tau(y-x)), y-x\rangle d\tau \\ &= \langle \nabla f(x), y-x\rangle + \int_{\tau=0}^{1} \langle \nabla f(x+\tau(y-x)) - \nabla f(x), y-x\rangle d\tau \\ &\le \langle \nabla f(x), y-x\rangle + \int_{\tau=0}^{1} \|\nabla f(x+\tau(y-x)) - \nabla f(x)\|_* \cdot \|y-x\| d\tau \\ &\le \langle \nabla f(x), y-x\rangle + \int_{\tau=0}^{1} \tau L\|y-x\| \cdot \|y-x\| d\tau \\ &= \langle \nabla f(x), y-x\rangle + \frac{L}{2}\|y-x\|^2 \end{aligned}$$

The second inequality follows because in the special case of $Q = \mathbb{R}^n$, we have

$$\mathsf{Prog}(x) = -\min_{y\in Q}\Big\{\frac{L}{2}\|y-x\|^2 + \langle \nabla f(x), y-x\rangle\Big\} = \frac{1}{2L}\|\nabla f(x)\|_*^2 \ . \qquad \blacktriangleleft$$

▶ **Fact 2.1** (Gradient Descent Convergence). *Let $f(x)$ be a convex, differentiable function that is L-smooth with respect to $\|\cdot\|$ on $Q = \mathbb{R}^n$, and x_0 any initial point in Q. Consider the sequence of T gradient steps $x_{k+1} \leftarrow \mathsf{Grad}(x_k)$, then the last point x_T satisfies that*

$$f(x_T) - f(x^*) \le O\big(\frac{LR^2}{T}\big) \ ,$$

where $R = \max_{x:f(x)\le f(x_0)} \|x - x^*\|$, and x^* is any minimizer of f.

Proof. [20] Recall that we have $f(x_{k+1}) \le f(x_k) - \frac{1}{2L}\|\nabla f(x_k)\|_*^2$ from (2.1). Furthermore, by the convexity of f and Cauchy-Schwarz we have

$$f(x_k) - f(x^*) \le \langle \nabla f(x_k), x_k - x^*\rangle \le \|\nabla f(x_k)\|_* \cdot \|x_k - x^*\| \le R \cdot \|\nabla f(x_k)\|_* \ .$$

Letting $D_k = f(x_k) - f(x^*)$ denote the distance to the optimum at iteration k, we now obtain two relationships $D_k - D_{k+1} \ge \frac{1}{2L}\|\nabla f(x_k)\|_*^2$ as well as $D_k \le R \cdot \|\nabla f(x_k)\|_*$. Combining these two, we get

$$D_k^2 \le 2LR^2(D_k - D_{k+1}) \implies \frac{D_k}{D_{k+1}} \le 2LR^2\Big(\frac{1}{D_{k+1}} - \frac{1}{D_k}\Big) \ .$$

[19] This proof can be found for instance in the textbook [26].
[20] Our proof follows almost directly from [26], but he only uses the Euclidean ℓ_2 norm.

Noticing that $D_k \geq D_{k+1}$ because our objective only decreases at every round, we obtain that $\frac{1}{D_{k+1}} - \frac{1}{D_k} \geq \frac{1}{2LR^2}$. Finally, we conclude that at round T, we must have $\frac{1}{D_T} \geq \frac{T}{2LR^2}$, finishing the proof that $f(x_T) - f(x^*) \leq \frac{2LR^2}{T}$. ◀

B.2 Missing Proof for Mirror Descent

Mirror Descent Guarantee

If $x_{k+1} = \mathsf{Mirr}_{x_k}\big(\alpha \cdot \partial f(x_k)\big)$, then

$$\forall u \in Q, \quad \alpha(f(x_k) - f(u)) \leq \alpha\langle \partial f(x_k), x_k - u\rangle \leq \frac{\alpha^2}{2}\|\partial f(x_k)\|_*^2 + V_{x_k}(u) - V_{x_{k+1}}(u) \ . \quad (2.2)$$

Proof. [21] we compute that

$$\begin{aligned}
\alpha\langle \partial f(x_k), x_k - u\rangle &= \langle \alpha\partial f(x_k), x_k - x_{k+1}\rangle + \langle \alpha\partial f(x_k), x_{k+1} - u\rangle \\
&\overset{①}{\leq} \langle \alpha\partial f(x_k), x_k - x_{k+1}\rangle + \langle -\nabla V_{x_k}(x_{k+1}), x_{k+1} - u\rangle \\
&\overset{②}{=} \langle \alpha\partial f(x_k), x_k - x_{k+1}\rangle + V_{x_k}(u) - V_{x_{k+1}}(u) - V_{x_k}(x_{k+1}) \\
&\overset{③}{\leq} \Big(\langle \alpha\partial f(x_k), x_k - x_{k+1}\rangle - \frac{1}{2}\|x_k - x_{k+1}\|^2\Big) + \big(V_{x_k}(u) - V_{x_{k+1}}(u)\big) \\
&\overset{④}{\leq} \frac{\alpha^2}{2}\|\partial f(x_k)\|_*^2 + \big(V_{x_k}(u) - V_{x_{k+1}}(u)\big)
\end{aligned}$$

Here, ① is due to the minimality of $x_{k+1} = \arg\min_{x\in Q}\{V_{x_k}(x) + \langle \alpha\partial f(x_k), x\rangle\}$, which implies that $\langle \nabla V_{x_k}(x_{k+1}) + \alpha\partial f(x_k), u - x_{k+1}\rangle \geq 0$ for all $u \in Q$. ② is due to the triangle equality of Bregman divergence.[22] ③ is because $V_x(y) \geq \frac{1}{2}\|x - y\|^2$ by the strong convexity of the DGF $w(\cdot)$. ④ is by Cauchy-Schwarz. ◀

C Missing Proofs of Section 4

▶ **Lemma 4.2.** *If $\tau_k = \frac{1}{\alpha_{k+1}L}$, then it satisfies that for every $u \in Q$,*

$$\begin{aligned}
\alpha_{k+1}\langle \nabla f(x_{k+1}), z_k - u\rangle &\overset{①}{\leq} \alpha_{k+1}^2 L\mathsf{Prog}(x_{k+1}) + V_{z_k}(u) - V_{z_{k+1}}(u) \\
&\overset{②}{\leq} \alpha_{k+1}^2 L\big(f(x_{k+1}) - f(y_{k+1})\big) + V_{z_k}(u) - V_{z_{k+1}}(u) \ .
\end{aligned}$$

Proof. The second inequality ② is again from the gradient descent guarantee $f(x_{k+1}) - f(y_{k+1}) \geq \mathsf{Prog}(x_{k+1})$. To prove ①, we first write down the key inequality of mirror-descent

[21] This proof can be found for instance in the textbook [9].

[22] That is,

$$\begin{aligned}
\forall x, y \geq 0, \quad \langle -\nabla V_x(y), y - u\rangle &= \langle \nabla w(x) - \nabla w(y), y - u\rangle \\
&= (w(u) - w(x) \\
&\quad - \langle \nabla w(x), u - x\rangle) - (w(u) - w(y) - \langle \nabla w(y), u - y\rangle) \\
&\quad - (w(y) - w(x) - \langle \nabla w(x), y - x\rangle) \\
&= V_x(u) - V_y(u) - V_x(y) \ .
\end{aligned}$$

analysis (whose proof is identical to that of (2.2))

$$\begin{aligned}\alpha_{k+1}\langle\nabla f(x_{k+1}), z_k - u\rangle &= \langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle + \langle\alpha_{k+1}\nabla f(x_{k+1}), z_{k+1} - u\rangle \\ &\overset{①}{\leq} \langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle + \langle -\nabla V_{z_k}(z_{k+1}), z_{k+1} - u\rangle \\ &\overset{②}{=} \langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle + V_{z_k}(u) - V_{z_{k+1}}(u) - V_{z_k}(z_{k+1}) \\ &\overset{③}{\leq} \Big(\langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle - \frac{1}{2}\|z_k - z_{k+1}\|^2\Big) \\ &\quad + \big(V_{z_k}(u) - V_{z_{k+1}}(u)\big)\end{aligned}$$

Here, ① is due to the minimality of $z_{k+1} = \arg\min_{z\in Q}\{V_{z_k}(z) + \langle\alpha_{k+1}\nabla f(x_{k+1}), z\rangle\}$, which implies that $\langle\nabla V_{z_k}(z_{k+1}) + \alpha_{k+1}\nabla f(x_{k+1}), u - z_{k+1}\rangle \geq 0$ for all $u \in Q$. ② is due to the triangle equality of Bregman divergence (see Footnote 22 in Appendix B). ③ is because $V_x(y) \geq \frac{1}{2}\|x-y\|^2$ by the strong convexity of the $w(\cdot)$.

If one stops here and uses Cauchy-Shwartz $\langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle - \frac{1}{2}\|z_k - z_{k+1}\|^2 \leq \frac{\alpha_{k+1}^2}{2}\|\nabla f(x_{k+1})\|_*^2$, he will get the desired inequality in the special case of $Q = \mathbb{R}^n$, because $\mathsf{Prog}(x_{k+1}) = \frac{1}{2L}\|\nabla f(x_{k+1})\|_*^2$ from (2.1).

For the general unconstrained case, we need to use the special choice of $\tau_k = 1/\alpha_{k+1}L$ follows. Letting $v \overset{\text{def}}{=} \tau_k z_{k+1} + (1-\tau_k)y_k \in Q$ so that $x_{k+1} - v = (\tau_k z_k + (1-\tau_k)y_k) - v = \tau_k(z_k - z_{k+1})$, we have

$$\begin{aligned}&\langle\alpha_{k+1}\nabla f(x_{k+1}), z_k - z_{k+1}\rangle - \frac{1}{2}\|z_k - z_{k+1}\|^2 \\ &= \langle\frac{\alpha_{k+1}}{\tau_k}\nabla f(x_{k+1}), x_{k+1} - v\rangle - \frac{1}{2\tau_k^2}\|x_{k+1} - v\|^2 \\ &= \alpha_{k+1}^2 L\left(\langle\nabla f(x_{k+1}), x_{k+1} - v\rangle - \frac{L}{2}\|x_{k+1} - v\|^2\right) \leq \alpha_{k+1}^2 L\mathsf{Prog}(x_{k+1})\end{aligned}$$

where the last inequality is from the definition of $\mathsf{Prog}(x_{k+1})$. ◀

▶ **Lemma 4.3** (Coupling). *For any $u \in Q$,*

$$\big(\alpha_{k+1}^2 L\big)f(y_{k+1}) - \big(\alpha_{k+1}^2 L - \alpha_{k+1}\big)f(y_k) + \big(V_{z_{k+1}}(u) - V_{z_k}(u)\big) \leq \alpha_{k+1}f(u)\ .$$

Proof. We deduce the following sequence of inequalities

$$\begin{aligned}&\alpha_{k+1}\big(f(x_{k+1}) - f(u)\big) \\ &\leq \alpha_{k+1}\langle\nabla f(x_{k+1}), x_{k+1} - u\rangle \\ &= \alpha_{k+1}\langle\nabla f(x_{k+1}), x_{k+1} - z_k\rangle + \alpha_{k+1}\langle\nabla f(x_{k+1}), z_k - u\rangle \\ &\overset{①}{=} \frac{(1-\tau_k)\alpha_{k+1}}{\tau_k}\langle\nabla f(x_{k+1}), y_k - x_{k+1}\rangle + \alpha_{k+1}\langle\nabla f(x_{k+1}), z_k - u\rangle \\ &\overset{②}{\leq} \frac{(1-\tau_k)\alpha_{k+1}}{\tau_k}(f(y_k) - f(x_{k+1})) + \alpha_{k+1}\langle\nabla f(x_{k+1}), z_k - u\rangle \\ &\overset{③}{\leq} \frac{(1-\tau_k)\alpha_{k+1}}{\tau_k}(f(y_k) - f(x_{k+1})) + \alpha_{k+1}^2 L\big(f(x_{k+1}) - f(y_{k+1})\big) + V_{z_k}(u) - V_{z_{k+1}}(u) \\ &\overset{④}{=} \big(\alpha_{k+1}^2 L - \alpha_{k+1}\big)f(y_k) - \big(\alpha_{k+1}^2 L\big)f(y_{k+1}) + \alpha_{k+1}f(x_{k+1}) + \big(V_{z_k}(u) - V_{z_{k+1}}(u)\big)\end{aligned}$$

Here, ① uses the choice of x_{k+1} that satisfies $\tau_k(x_{k+1} - z_k) = (1-\tau_k)(y_k - x_{k+1})$; ② is by the convexity of $f(\cdot)$ and $1 - \tau_k \geq 0$; ③ uses Lemma 4.2; and ④ uses the choice of $\tau_k = 1/\alpha_{k+1}L$. ◀

D Strong Convexity Version of Accelerated Gradient Method

When the objective $f(\cdot)$ is both σ-strongly convex and L-smooth with respect to the same norm $\|\cdot\|_2$, another version of accelerated gradient method exists and achieves a $\log(1/\varepsilon)$ convergence rate [26]. We show in this section that, our method $\texttt{AGM}(f, w, x_0, T)$ can be used to recover that strong-convexity accelerated method in one of the two ways. Therefore, the gradient-mirror coupling interpretation behind our paper still applies to the strong-convexity accelerated method.

One way to recover the strong-convexity accelerated method is to replace the use of the mirror-descent analysis on the regret term by its strong-convexity counterpart (also known as logarithmic-regret analysis, see for instance [15, 37]). This would incur some different parameter choices on α_k and τ_k, and results in an algorithm similar to that of [26].

Another, but simpler way is to recursively apply Theorem 4.1. In light of the definition of strong convexity and Theorem 4.1, we have

$$\frac{\sigma}{2}\|y_T - x^*\|_2^2 \le f(y_T) - f(x^*) \le \frac{4\cdot\frac{1}{2}\|x_0 - x^*\|_2^2 \cdot L}{T^2} \ .$$

In particular, in every $T = T_0 \stackrel{\text{def}}{=} \sqrt{8L/\sigma}$ iterations, we can halve the distance $\|y_T - x^*\|_2^2 \le \frac{1}{2}\|x_0 - x^*\|_2^2$. If we repeatedly invoke $\texttt{AGM}(f, w, \cdot, T_0)$ a sequence of ℓ times, each time feeding the initial vector x_0 with the previous output y_{T_0}, then in the last run of the T_0 iterations, we have

$$f(y_{T_0}) - f(x^*) \le \frac{4\cdot\frac{1}{2^\ell}\|x_0 - x^*\|_2^2 \cdot L}{T_0^2} = \frac{1}{2^{\ell+1}}\|x_0 - x^*\|_2^2 \cdot \sigma \ .$$

By choosing $\ell = \log\big(\frac{\|x_0 - x^*\|_2^2 \cdot \sigma}{\varepsilon}\big)$, we conclude that

▶ **Corollary 4.1.** *If $f(\cdot)$ is both σ-strongly convex and L-smooth with respect to $\|\cdot\|_2$, in a total of $T = O\big(\sqrt{\frac{L}{\sigma}} \cdot \log\big(\frac{\|x_0 - x^*\|_2^2 \cdot \sigma}{\varepsilon}\big)\big)$ iterations, we can obtain some x such that $f(x) - f(x^*) \le \varepsilon$.*

This is slightly better than the result $O\big(\sqrt{\frac{L}{\sigma}} \cdot \log\big(\frac{\|x_0 - x^*\|_2^2 \cdot L}{\varepsilon}\big)\big)$ in Theorem 2.2.2 of [26].

We remark here that O'Donoghue and Candès [32] have studied some heuristic adaptive restarting techniques which suggest that the above (and other) restarting version of the accelerated method practically outperforms the original method of Nesterov.

High Dimensional Random Walks and Colorful Expansion*

Tali Kaufman[1] **and David Mass**[2]

Abstract

Random walks on bounded degree expander graphs have numerous applications, both in theoretical and practical computational problems. A key property of these walks is that they converge rapidly to their stationary distribution.

In this work we *define high order random walks*: These are generalizations of random walks on graphs to high dimensional simplicial complexes, which are the high dimensional analogues of graphs. A simplicial complex of dimension d has vertices, edges, triangles, pyramids, up to d-dimensional cells. For any $0 \leq i < d$, a high order random walk on dimension i moves between neighboring i-faces (e.g., edges) of the complex, where two i-faces are considered neighbors if they share a common $(i+1)$-face (e.g., a triangle). The case of $i = 0$ recovers the well studied random walk on graphs.

We provide a *local-to-global criterion* on a complex which implies *rapid convergence of all high order random walks* on it. Specifically, we prove that if the 1-dimensional skeletons of all the links of a complex are spectral expanders, then for *all* $0 \leq i < d$ the high order random walk on dimension i converges rapidly to its stationary distribution.

We derive our result through a new notion of high dimensional combinatorial expansion of complexes which we term *colorful expansion*. This notion is a natural generalization of combinatorial expansion of graphs and is strongly related to the convergence rate of the high order random walks.

We further show an explicit family of *bounded degree* complexes which satisfy this criterion. Specifically, we show that Ramanujan complexes meet this criterion, and thus form an explicit family of bounded degree high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution.

1 Introduction

Expander graphs play a fundamental role in computer science, mathematics, physics and more (see e.g. [8] and [12]). In particular, random walks on bounded degree expander graphs have been proven to be very useful in many applications. A key property of these walks is that they converge rapidly to their stationary distribution. This property allows one to

efficiently sample points from some huge space while investing only a few random bits, which is necessary in many theoretical and practical computational problems.

In recent years a generalization of expander graphs to higher dimensions has emerged. The high dimensional analogue of a graph is called a *simplicial complex*. It can be viewed as a hypergraph with a closure property, namely, for any hyperedge in the hypergraph all of its subsets are also in the hypergraph. An hyperedge of size i is called an $(i-1)$-*face* of the complex. Thus, the vertices of the complex are the 0-faces, the edges are the 1-faces, the triangles are the 2-faces, etc. A complex is termed *bounded degree* if the number of faces of any dimension which are incident to any vertex is bounded by a constant, independent of the number of vertices in the complex.

On high dimensional expanders

The study of high dimensional expanders gains a lot of interest recently. They were proven to be a bridge between deep questions in topology (such as topological overlapping, see [6]) and important questions in theoretical computer science (such as property testing and error-correcting codes, see [10]). The interested reader is referred to [13] for a recent survey on high dimensional expanders. The general hope is that high dimensional expanders could be used in places where expander graphs were not good enough.

Expander graphs have had an enormous effect on computer science. However, there are some striking applications in which expanders yield good results but not good enough. For example, by the celebrated result of Sipser and Spielman [19], expanders imply good error-correcting codes. However, the codes obtained by [19] are not locally testable, namely, the very desired property of local testability (which in fact was the motivating goal in the construction of error-correcting codes from expanders, as discussed in Spielman's thesis [20]) is not known to be achieved by codes based on expanders.

Another canonical example where we have seen the limit of expanders is the new proof of the PCP theorem obtained by Dinur [2]. Dinur builds on properties of expanders and achieves a simpler proof of the celebrated PCP theorem. However, the PCP obtained by expanders is not strong enough to yield good hardness of approximation results.

The thesis we try to pursue here is that high dimensional expanders could potentially be used in applications as above, where (one-dimensional) expanders were not strong enough. We expect high dimensional expanders to yield better results than the well studied (one-dimensional) expanders since they are stronger objects: They expand at *all* dimensions, i.e., with respect to vertices, edges, triangles, etc., and not just with respect to vertices as expander graphs.

Dinur's proof of the PCP theorem builds heavily on random walks on expander graphs. In the following we study high dimensional analogues of random walks in high dimensional simplicial complexes.

On high dimensional random walks

In this paper we define high order random walks on simplicial complexes. Our definition generalizes the well studied random walk on graphs to high dimensional simplicial complexes.

For a d-dimensional simplicial complex, we define the high order random walk on it for any dimension $0 \leq i < d$. This walk moves at random between neighboring i-faces (e.g., edges) of the complex, where two i-faces are considered neighbors if they share a common $(i+1)$-face (e.g., a triangle).

The question we address in this paper is the following.

▶ **Question.** *Are there bounded degree high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution.*

In a nutshell, our answer is the following. We provide a local criterion on a complex which implies the rapid convergence of all high order random walks on it. Moreover, we show an explicit family of bounded degree complexes which satisfy this criterion, and hence are bounded degree high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution.

The convergence rate of random walks on graphs is known to be deduced from the spectrum of the graph's adjacency matrix (for more about random walks on graphs see [11]). Similarly, for a d-dimensional simplicial complex and any $0 \leq i < d$ we define the matrix A_i to be the adjacency matrix of dimension i of the complex. This matrix is indexed by the i-faces of the complex, where $A_i(\sigma, \tau)$ indicate if σ and τ are neighbors. The question we address here is how one could construct a bounded degree d-dimensional simplicial complex (for any $d \in \mathbb{N}$) whose *all* adjacency matrices A_i, $0 \leq i < d$, have a concentrated spectrum, and thus its associated high order random walks (on all of its dimensions) converge rapidly to their stationary distribution.

Bounded versus unbounded

It is easy to obtain an unbounded degree graph in which the random walk will converge rapidly to its stationary distribution. This case is less useful as in most applications it is crucial to have a constant bound on the number of neighbors of any vertex in the graph. In a same way, the case of having an unbounded degree complex so the high order random walks on it will converge rapidly to their stationary distribution is less interesting. The complete high dimensional analogue of the most useful random walks on expander graphs are *bounded degree* high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution.

Better than random

In the case of graphs, a random walk on a random bounded degree graph is known to converge rapidly to its stationary distribution. The constructions of explicit expander graphs seem to try and simulate the behavior of these random objects as much as possible, i.e., the philosophy is that a random graph is the best one can get and with explicit constructions we try to get as close as we can to random graphs. In the case of high dimensional simplicial complexes, a high order random walk on a random bounded degree complex *does not* converge rapidly to its stationary distribution. Thus, this phenomenon we study here is very special as it is something we *cannot achieve with a random object*.

Colorful expansion

Our method in asserting the rapid convergence of the high order random walks is as follows. We introduce a new notion of high order combinatorial expansion of complexes which we term colorful expansion: A d-dimensional simplicial complex is said to be a colorful expander if for any $0 \leq i < d$ and any subset S of i-faces there is a large set of *expanding* $(i+1)$-faces, i.e., faces which are hit by S but are not fully covered by S. The term colorful expansion comes from the fact that if we color the faces in S with one color and the faces not in S with another color, then we get many colorful $(i+1)$-faces. This notion is of an independent interest as it is a natural generalization of combinatorial expansion of graphs to higher dimensions, which

is not implied by previously studied notions such as coboundary or cosystolic expansion (see [4]). We show that colorful expansion of a complex implies that *all* of its adjacency matrices A_i, $0 \leq i < d$, have a concentrated spectrum, and hence all of the high order random walks on it converge rapidly to their stationary distribution.

We provide a local-to-global criterion on a complex which implies colorful expansion. For any face σ in the complex, its *link* is the local view of σ, which is obtained by taking all the faces containing σ and removing σ from all of them. We prove that if the 1-dimensional skeleton (i.e., the underlying graph) of every link in the complex is a spectral expander graph, then the entire complex is a colorful expander.

We conclude by showing that Ramanujan complexes satisfy this criterion, and hence are colorful expanders. We then use the explicit construction of Ramanujan complexes from [14] in order to achieve an explicit family of bounded degree complexes in which all of the high order random walks converge rapidly to their stationary distribution.

1.1 Expander graphs and random walks

Let $G = (V, E)$ be an undirected graph. Denote by A the adjacency matrix of G, where $A(u, v)$ equals the number of edges between u and v (we allow multiple edges). The *degree* of a vertex is the number of edges containing it. Throughout this section assume for simplicity that G is k-regular, i.e., the degree of any vertex is k (we deal with the non-regular case at Section 1.5). The *Cheeger constant* of G is defined as

$$h(G) = \min_{\substack{\emptyset \neq S \subset V \\ |S| \leq |V|/2}} \frac{|E(S, \bar{S})|}{k|S|},$$

where $E(S, \bar{S})$ is the set of edges with one endpoint in S and one endpoint in $\bar{S}$.

If $h(G) \geq \epsilon$ for some constant $\epsilon > 0$, then G is said to be an *ϵ-combinatorial expander*. A family of graphs $\{G_i\}_{i \in \mathbb{N}}$ is called a family of ϵ-combinatorial expanders if there exists a constant $\epsilon > 0$ such that $h(G_i) \geq \epsilon$ for every $i \in \mathbb{N}$. Intuitively, it means that the graph is very well connected, and hence the random walk on it is not likely to "get stuck" in a small subset of vertices.

A *random walk* on G can be described by the following process. We start at a random vertex $v_0 \in V$. Then, if after t steps we are at vertex v_t, we choose one of the edges containing v_t uniformly at random and move to its other endpoint. Thus, for any $u, v \in V$

$$\Pr[v_{t+1} = v \mid v_t = u] = \frac{A(u, v)}{k}.$$

Denote by $\pi_0 \in \mathbb{R}^V$ the probability distribution from which v_0 is chosen. Then the random walk on G yields a sequence of probability distributions $\pi_0, \pi_1, \ldots \in \mathbb{R}^V$. The transition from π_t to π_{t+1} is given by $\pi_{t+1} = \pi_t \widetilde{A}$, where $\widetilde{A} = (1/k)A$ is the *normalized adjacency matrix* of G. Note that $\widetilde{A}(u, v)$ is the probability to move from u to v in a single step, and $\widetilde{A}^t(u, v)$ is the probability that a walk starting at u will be at v after t steps. It follows that for any $t \in \mathbb{N}$, $\pi_t = \pi_0 \widetilde{A}^t$.

Denote by $\mathbf{u} = (1/|V|, \ldots, 1/|V|)$ the uniform distribution on the vertices. If G is connected and non-bipartite, then $\pi_0 \widetilde{A}^t \to \mathbf{u}$ as $t \to \infty$ for any initial probability distribution $\pi_0 \in \mathbb{R}^V$. The random walk on G is said to be *μ-rapidly mixing*, $0 < \mu < 1$, if for any initial probability distribution $\pi_0 \in \mathbb{R}^V$ and any $t \in \mathbb{N}$

$$\|\pi_t - \mathbf{u}\|_2 \leq \mu^t.$$

The common way to deduce the mixing rate of a random walk is by the spectrum of the normalized adjacency matrix of G. Denote by $1 = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{|V|} \geq -1$ the eigenvalues of $\widetilde{A}$. Then the random walk on G is μ-rapidly mixing for $\mu \leq \max\{|\lambda_2|, |\lambda_{|V|}|\}$. (A proof for this assertion can be found in many places, see [8] for instance.)

Here comes the relation between expanders and rapid mixing of random walks. Since combinatorial expanders are very strongly connected, we expect that random walks on them would mix rapidly. This is indeed true and it is given formally by Cheeger's inequality [1] which states that

$$\lambda_2 \leq 1 - \frac{h(G)^2}{2}.$$

Thus, it suffices to show that a graph is an ϵ-combinatorial expander for some constant $\epsilon > 0$ in order to deduce that the random walk on it converges rapidly to the uniform distribution.

▶ Remark. The cautious reader would note that combinatorial expansion gives us a bound only on λ_2, but for rapid mixing we need to bound $\lambda_{|V|}$ as well. This is not a problem since $\lambda_{|V|} = -1$ if and only if the graph is bipartite. Thus, in most applications it is possible just to add self-loops at each vertex which "destroys the bipartiteness" of the graph and does not slow down the convergence rate too much. Nevertheless, we show at section 1.6 that when dealing with high order random walks the smallest eigenvalue of the normalized adjacency matrix is bounded away from -1. In any case, combinatorial expansion is the crucial condition for rapid mixing of random walks.

1.2 High dimensional simplicial complexes

A *simplicial complex* X with a set of vertices V is a collection of subsets of V with a closure property, namely, for any subset $\sigma \in X$, all of its subsets $\tau \subset \sigma$ are also in X. Each such subset is called a *face* of the complex. The *dimension* of a face $\sigma \in X$ is one less than the number of vertices in it, i.e., $\dim(\sigma) = |\sigma| - 1$. We also define the empty set as a face of the complex, which is the unique face of dimension -1. The dimension of the entire complex is defined as the maximal dimension of a face in it. The complex is said to be *pure* if for any face $\sigma \in X$ with $\dim(\sigma) < \dim(X)$ there is a face of maximal dimension $\tau \in X$, $\dim(\tau) = \dim(X)$, such that $\sigma \subset \tau$. We only deal with pure simplicial complexes.

We denote by $X(i)$ the faces of the complex of dimension i, which are called in short the i-faces of the complex. In the terminology of simplicial complexes, an *i-cochain* is a function $W : X(i) \to \{0, 1\}$. For us it is convenient to view an i-cochain as defining a subset of i-faces, where $\sigma \in W \Leftrightarrow W(\sigma) = 1$. The space of all the i-cochains is denoted by $C^i(X)$.

The *degree* of a face $\sigma \in X$ is the number of faces of maximal dimension which contain σ. Again, we assume for simplicity that the complex is regular, i.e., for any $0 \leq i < d$ and any two i-faces $\sigma, \tau \in X(i)$ it holds that $\deg(\sigma) = \deg(\tau)$ (we deal with non-regularity at Section 1.5). For any i-cochain $W \in C^i(X)$ we define its norm to be the fraction of i-faces which are in W (this definition will be refined at Section 1.5), i.e.,

$$\|W\| = \frac{|W|}{|X(i)|}.$$

The *link* of a face $\sigma \in X$, denoted by X_σ, is the complex obtained by taking all the faces which contain σ, and removing σ from all of them. Intuitively, it is the local view of X "from the eyes of σ". Formally it is given by $X_\sigma = \{\tau \setminus \sigma \mid \tau \in X, \tau \supseteq \sigma\}$. If X is of dimension d, then X_σ is a complex of dimension $d - |\sigma|$. We denote by $\|\cdot\|_\sigma$ the norm associated with the link of σ.

Let us demonstrate the above definitions with a simple example.

▶ **Example 1.1.** Let X be a 2-dimensional simplicial complex. The complex contains faces of dimensions $0, 1$ and 2, which can be viewed as vertices, edges and triangles. $X(0)$ denotes the vertices, $X(1)$ the edges, and $X(2)$ the triangles. The degree of any vertex $u \in X(0)$ is the number of triangles containing it, i.e., $\deg(u) = |\{t \in X(2) \mid u \in t\}|$. The link of a vertex $u \in X(0)$ is a 1-dimensional simplicial complex defined as follows. Any edge of the form $\{u, v\} \in X(1)$ becomes a vertex in the link, i.e., $v \in X_u(0)$, and any triangle of the form $\{u, v, w\} \in X(2)$ becomes an edge in the link, i.e., $\{v, w\} \in X_u(1)$. Thus, the link of u contains vertices and edges, which correspond to edges and triangles of the complex, respectively.

1.3 Our contribution

In this work we introduce a new notion of random walks on high dimensional simplicial complexes. Our main result is a local criterion on a complex which implies the rapid mixing of all of its associated high order random walks. In order to assert their rapid mixing we introduce a new definition for combinatorial expansion of high dimensional simplicial complexes, which we term colorful expansion. We prove that this local criterion on a complex implies colorful expansion, which in turn implies the rapid convergence of all high order random walks on it. We then show an explicit construction of bounded degree complexes which satisfy this criterion, and hence are bounded degree complexes in which all of the high order random walks converge rapidly to their stationary distribution.

1.3.1 High order random walks

Let X be a d-dimensional simplicial complex. We generalize the notion of random walks on graphs to higher dimensions by letting the walk to move on any dimension of the complex. For any $0 \leq i < d$ we define the walk on dimension i of the complex as follows. We start from an initial i-face $\sigma_0 \in X(i)$. Then, if after t steps we are at σ_t, the process of choosing σ_{t+1} can be described by the following two steps:

1. Choose an $(i+1)$-face $\tau \supset \sigma_t$ uniformly at random.
2. Choose an i-face $\sigma_{t+1} \subset \tau$, $\sigma_{t+1} \neq \sigma_t$, uniformly at random and move to it.

We say that $\sigma, \sigma' \in X(i)$ are neighbors, denoted by $\sigma \sim \sigma'$, if they share a common $(i+1)$-face, i.e., $\sigma \cup \sigma' \in X(i+1)$. In order to analyze this walk, we define the following auxiliary graphs.

▶ **Definition 1.2.** Let X be a d-dimensional simplicial complex. For any $0 \leq i < d$ the *i-graph* $G_i = (V_i, E_i)$ (with adjacency matrix A_i) is defined as follows.

- The vertices of G_i are the i-faces of X, i.e., $V_i = X(i)$.
- For any two i-faces $\sigma, \sigma' \in X(i)$ such that $\sigma \sim \sigma'$, there is an edge between the corresponding vertices in G_i, i.e., $E_i = \left\{\{\sigma, \sigma'\} \in \binom{X(i)}{2} \mid \sigma \sim \sigma'\right\}$.

Denote by $\pi_0 \in \mathbb{R}^{X(i)}$ the probability distribution from which σ_0 is chosen. As in graphs, the random walk on dimension i of X yields a sequence of probability distributions $\pi_0, \pi_1, \ldots, \in \mathbb{R}^{X(i)}$. Note that the transition from π_t to π_{t+1} is given by $\pi_{t+1} = \pi_t \widetilde{A}_i$, where $\widetilde{A}_i$ is the normalized adjacency matrix of G_i. In other words, the random walk on dimension i of the complex is equivalent to a random walk on the i-graph as above. Thus, our goal is to construct a complex X such that the random walks on *all* of its induced i-graphs, $0 \leq i < d$, will converge rapidly to the uniform distribution.

1.3.2 Rapid mixing criterion

Recall that the link of any face $\sigma \in X$ is a smaller complex which corresponds to the local view of σ. We essentially show that if every link is expanding in some sense, then all of the high order random walks on X converge rapidly to their stationary distribution.

For any face $\sigma \in X$ the 1-dimensional skeleton of X_σ is defined as $X_\sigma(0) \cup X_\sigma(1)$, i.e., the underlying graph of X_σ. We say that X is a *skeleton expander* if the 1-dimensional skeleton of every link behaves pseudorandomly.

▶ **Definition 1.3** (Skeleton expansion)**.** Let X be a d-dimensional simplicial complex. X is called an *α-skeleton expander*, $\alpha > 0$, if for any face $\sigma \in X$ (including $\sigma = \emptyset$) and any subset of vertices $S \subseteq X_\sigma(0)$ it holds that

$$\|E(S)\|_\sigma \leq \|S\|_\sigma(\|S\|_\sigma + \alpha),$$

where $E(S) \subseteq X_\sigma(1)$ denotes the set of edges with both endpoints in S.

We note that in the above definition we can replace the requirement of α-skeleton expansion for $\sigma = \emptyset$ with the weaker requirement that the complex is connected. This could be done since by [16] if the complex is connected, then the α-skeleton expansion of $\sigma = \emptyset$ follows from the α-skeleton expansion of all $\sigma \in X$, $\sigma \neq \emptyset$.

For some intuition regrading the above definition, consider a random graph $G = (V, E)$ whose edges are distributed uniformly. Let $S \subseteq V$ be any subset of vertices of size $\gamma|V|$. Then the probability for any edge to have both endpoints in S is γ^2, and hence the expected size of $E(S)$ is $\gamma^2|E|$. From this point of view, the α-skeleton expansion property means that the underlying graph of every link "looks like" a random graph, up to an error of α.

The main result of this paper is the following theorem.

▶ **Theorem 1.4** (Rapid mixing criterion, informal, for formal see Theorem 3.2)**.** *If a complex is an α-skeleton expander for small enough α, then all of the high order random walks on it converge rapidly to their stationary distribution.*

1.3.3 Colorful expansion

Our new definition for combinatorial expansion of high dimensional simplicial complexes is the main building block in the rapid mixing proof. For an i-cochain $W \in C^i(X)$, we say that an $(i+1)$-face is *expanding* if it hits W but not fully covered by W.

▶ **Definition 1.5** (Expanding faces)**.** Let X be a d-dimensional simplicial complex. For any i-cochain $W \in C^i(X)$, $0 \leq i < d$, the *expanding faces* of W are defined as

$$\psi(W) = \{\tau \in X(i+1) \mid \exists\, \sigma, \sigma' \subset \tau : \sigma \in W, \sigma' \in X(i) \setminus W\}.$$

Then we define colorful expansion as follows.

▶ **Definition 1.6** (Colorful expander)**.** Let X be a d-dimensional simplicial complex. X is called an *ϵ-colorful expander*, $\epsilon > 0$, if for any i-cochain $W \in C^i(X)$, $0 \leq i < d$, $0 < \|W\| \leq 1/2$,

$$\frac{\|\psi(W)\|}{\|W\|} \geq \epsilon.$$

Our main result is then a corollary of the following two theorems.

▶ **Theorem 1.7** (Colorful expansion criterion, informal, for formal see Theorem 2.1)**.** *If a complex is an α-skeleton expander for small enough α, then it is a colorful expander.*

▶ **Theorem 1.8** (Colorful expansion implies rapid mixing, informal, for formal see Theorem 3.1)**.** *If a complex is a colorful expander, then all of the high order random walks on it converge rapidly to their stationary distribution.*

Since Theorem 1.7 is the main technical part of this paper, we provide here a short overview of the proof.

Informal overview of the proof of Theorem 1.7

We need to show that for any dimension i and any non-empty i-cochain with norm up to $1/2$ there are many expanding faces.

Consider an arbitrary i-cochain W. From a very high level point of view, the proof can be divided into three steps:

1. Mark "selected" faces in dimensions $i, i-1, \ldots, -1$.
2. Find a "good" dimension $j \leq i$.
3. "Climb up" from dimension j to deduce many expanding faces in dimension $i+1$.

In more details, we start by marking all of the i-faces which are in W. Then we mark $(i-1)$-faces, where the rule for marking a face is if many (above some threshold) of the i-faces which contain it are marked. We continue this way down to the lowest dimension of the complex, where each dimension is marked with regard to one dimension above. We term these marked faces as *fat faces* since each marked face contains in its link many i-faces which are in W.

The next step is to look for the highest dimension $j \leq i$ with the property that many fat j-faces contain many non-fat $(j-1)$-faces. By setting a large enough threshold for marking faces we can make sure that the empty set is never fat, which implies that such dimension must exist (Proposition 2.6).

The last step is to deduce from the links of the non-fat $(j-1)$-faces that there exist many expanding $(i+1)$-faces. We already know, by the existence of many fat j-faces in these links, that a large part of W is seen in them (Proposition 2.7). It is left to show that many of the $(i+1)$-faces in these links contain at least one i-face which is not in W (Proposition 2.8).

For that we define *full faces* for any dimension of the complex, where a k-face is full if it contains only fat $(k-1)$-faces. By this definition it follows that a full k-face is seen in the link of any $(k-2)$-face as an edge between two fat vertices. So when considering the link of a non-fat $(k-2)$-face, which by definition contains only a few fat vertices, by the skeleton expansion it contains only a few full k-faces. Thus, the number of the full $(j+1)$-faces in the links of the non-fat $(j-1)$-faces is very small. Then again, by the skeleton expansion and the maximality of j we can deduce that for any $k > j+1$ most of the full k-faces contain only full $(k-1)$-faces. This implies that the fraction of full $(i+1)$-faces is about the same as the fraction of the full $(j+1)$-faces. This actually finishes the proof, since we get many $(i+1)$-faces that are not full, i.e., contain at least one i-face which is not in W.

1.3.4 Explicit construction

As proven in [4], Ramanujan complexes are excellent skeleton expanders. Since our definition of skeleton expansion is slightly different than the one appearing in [4], we modify their proof so the requirement of our definition follows. We show that Ramanujan complexes with thickness large enough are α-skeleton expanders with α as small as we want. Then by the explicit construction of Ramanujan complexes from [14] we achieve the following theorem.

▶ **Theorem 1.9** (Explicit construction, informal, for formal see Theorem 4.1)**.** *There exists an explicit family of bounded degree high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution.*

1.4 Related work

In a recent work Oppenheim [16] has shown that if all the links of a d-dimensional simplicial complex are good spectral expanders and the complex is connected, then the 1-dimensional skeleton of the complex is an expander graph, or in other words, that the graph G_0 is a spectral expander. In this paper we show that the spectral expansion of the links, including the spectral expansion of the 1-dimensional skeleton of the complex, imply the spectral expansion of G_i for *all* $0 < i < d$.

Parzanchevski and Rosenthal in [17] study a different notion of high order random walk. The high order random walk of [17] is designed to expose the topological properties of the complex. Parzanchevski and Rosenthal define a variant of the stationary distribution of the random walk and show its relation to the spectrum of the high order laplacian on the space that is *orthogonal to the coboundaries*. In our work, the stationary distribution of the random walks is already known. Moreover, it is already known that the convergence rate is controlled by the spectrum of the high order normalized adjacency matrices on the space that is *orthogonal to the constant functions*. We show that the expansion of the links implies the concentration of the spectrum of the high order normalized adjacency matrices, a thing that cannot be deduced in any way from [17].

We study the spectrum of the high order normalized adjacency matrices of the complex and derive some good bounds on it from the spectrum of the links. Garland in a seminal work [5] has studied the spectrum of high order laplacians associated with a d-dimensional simplicial complex. Garland has shown that if all the links of a complex are good spectral expanders, then the eigenspace of the weighted oriented laplacian that is orthogonal to the coboundaries has a concentrated spectrum. This is somewhat in the spirit of what we get here. However, Garland could only obtain bounds on the eigenspace orthogonal to the coboundaries, while here we want to get a bound on all the eigenvalues besides the first trivial one corresponding to the constant functions. There is no known way to obtain our result from Garland's argument. See also [7] for more discussion on Garland's work and the fact that it does not imply the required spectrum bound for the eigenvalues on the space that is orthogonal to the constant functions.

In a recent work of the first coauthor and Evra [4] a different notion of high order expansion has been studied, which is called cosystolic expansion. It was shown in [4] that if all the links of a d-dimensional simplicial complex are good spectral expanders and good coboundary expanders, then the $(d-1)$-skeleton of the complex is a cosystolic expander. Though the spirit of the proof there might resemble at first glance the method of the proof that we use here, the obstacles and the solutions are different. They could only show cosystolic expansion of *small* sets. Then they use a reduction of [9] showing that cosystolic expansion of small sets implies cosystolic expansion of the $(d-1)$-skeleton of a given d-dimensional simplicial complex. In our work it is crucial for us to obtain expansion of large sets, whose norm is up to $1/2$, and the reduction of [9] could not work here since it does not imply colorful expansion. Thus, the expansion here is achieved in a method which is different than the one used in [4].

1.5 Dealing with non-regularity

Up to now we assumed that the complexes are regular. In this section we describe the necessary modifications for the general case, where we are not guaranteed to have regularity. We start with non-regular graphs (for more about random walks on non-regular graphs see [18]).

Let $G = (V, E)$ be an undirected graph. Instead of using the Cheeger constant we use the *conductance*, which is its generalized version. For any subset of vertices $S \subseteq V$, its *volume* is defined as $\mathrm{vol}(S) = \sum_{v \in S} \deg(v)$. Then the conductance of any subset of vertices $S \subseteq V$ is defined as

$$\Phi(S) = \frac{|E(S, \bar{S})|}{\mathrm{vol}(S)},$$

and the conductance of the graph is defined as

$$\Phi(G) = \min_{\substack{\emptyset \neq S \subseteq V \\ \mathrm{vol}(S) \leq \mathrm{vol}(V)/2}} \Phi(S).$$

When considering a random walk on G, then for any $u, v \in V$ and any $t \in \mathbb{N}$

$$\Pr[v_{t+1} = v \mid v_t = u] = \frac{A(u, v)}{\deg(u)}.$$

So the transition from π_t to π_{t+1} is given by $\pi_{t+1} = \pi_t(DA)$, where D is the diagonal matrix defined by

$$D(u, v) = \begin{cases} \dfrac{1}{\deg(u)} & \text{if } u = v, \\ 0 & \text{otherwise.} \end{cases}$$

The *stationary distribution* of the walk is the probability distribution $\pi \in \mathbb{R}^V$ for which $\pi(DA) = \pi$. When G is connected and non-bipartite, then for any $v \in V$

$$\pi(v) = \frac{\deg(v)}{\sum_{u \in V} \deg(u)},$$

and for any initial probability distribution $\pi_0 \in \mathbb{R}^V$ it holds that $\pi_0(DA)^t \to \pi$ as $t \to \infty$. The random walk is said to be *μ-rapidly mixing*, $0 < \mu < 1$, if for any initial probability distribution $\pi_0 \in \mathbb{R}^V$ and any $t \in \mathbb{N}$

$$\|\pi_t - \pi\|_2 \leq \sqrt{\frac{d_{max}}{d_{min}}} \mu^t,$$

where $d_{max} = \max_{v \in V}\{\deg(v)\}$ and $d_{min} = \min_{v \in V}\{\deg(v)\}$.

The mixing rate of the random walk on G can be deduced from the spectrum of its normalized adjacency matrix, which is defined in the general case as $\widetilde{A} = D^{1/2} A D^{1/2}$. The largest eigenvalue of $\widetilde{A}$ satisfies $\lambda_1 = 1$ (with corresponding eigenvector $\left(\sqrt{\pi(v)}\right)_{v \in V}$) and the smallest eigenvalue satisfies $\lambda_{|V|} \geq -1$. Similar to the regular case, the random walk on G is μ-rapidly mixing for $\mu \leq \max\{|\lambda_2|, |\lambda_{|V|}|\}$. (We prove this assertion in the appendix.)

The following lemma of Sinclair and Jerrum [18] generalizes Cheeger's inequality to non-regular graphs.

▶ **Lemma 1.10.** *Let $G = (V, E)$ be an undirected graph where multiple edges are allowed, $\widetilde{A}$ its normalized adjacency matrix and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{|V|}$ the eigenvalues of $\widetilde{A}$. Then*

$$\lambda_2 \leq 1 - \frac{\Phi(G)^2}{2}.$$

We describe now the modifications required for non-regular complexes. Let X be a d-dimensional simplicial complex. For any i-cochain $W \in C^i(X)$ we refine the definition of the norm to the general case as

$$\|W\| = \frac{\sum_{\sigma \in W} deg(\sigma)}{\sum_{\tau \in X(i)} deg(\tau)}.$$

An alternative view of this norm, which is very useful for further calculations, is the following. Let $P_d \in X(d)$ be a uniformly random d-face of the complex. For any $i = d-1, \ldots, -1$, let $P_i \in X(i)$ be a random i-face which is obtained by removing a uniformly random vertex from P_{i+1}. Then we get a sequence of random variables $\{P_i\}_{i=-1}^{d}$ such that for any i-cochain $W \in C^i(X)$

$$\|W\| = \Pr[P_i \in W].$$

Now when considering a random walk on dimension i of X, we take into consideration the degrees of the faces. Assuming the walk is now at σ_t, then the process of choosing σ_{t+1} is given as follows:

1. Choose an $(i+1)$-face $\tau \supset \sigma_t$ with probability *proportional to its degree.*
2. Choose an i-face $\sigma_{t+1} \subset \tau$, $\sigma_{t+1} \neq \sigma_t$, uniformly at random and move to it.

So the exact probability for moving from σ to σ', where $\sigma \sim \sigma'$, is given by

$$\Pr[\sigma_{t+1} = \sigma' \mid \sigma_t = \sigma] = \frac{\deg(\sigma \cup \sigma')}{\sum_{\sigma'' \sim \sigma} \deg(\sigma \cup \sigma'')}.$$

The last generalization required is for the auxiliary graphs G_i, $0 \leq i < d$ (Definition 1.2). For any two i-faces $\sigma, \sigma' \in X(i)$ such that $\sigma \sim \sigma'$, instead of having one edge between the corresponding vertices in G_i, we put $\deg(\sigma \cup \sigma')$ edges between them. Now the random walk on G_i is equivalent to the random walk on dimension i of X, i.e., for any $t \in \mathbb{N}$ it holds that $\pi_{t+1} = \pi_t(D_i A_i)$, where π_t is the probability distribution after t steps of the random walk on dimension i of X, and D_i, A_i are the diagonal and adjacency matrices of G_i, respectively.

1.6 Bounding the smallest eigenvalue

The last technical issue, mentioned in remark 1.1, is to make sure that $\lambda_{|V|}$ is bounded away from -1. For random walks on dimension $i \geq 1$ we can do that by another combinatorial measure of the graph, which we describe in this section.

Let $G = (V, E)$ be an undirected graph. A *bipartite component* in G is a non-empty subset of vertices $\emptyset \neq S \subseteq V$ and a partition of S into two disjoint subsets $S_1 \cup S_2 = S$ such that $|E(S, \bar{S})| = |E(S_1)| = |E(S_2)| = 0$. ($E(S_i)$ denotes the set of edges with both endpoints in S_i.) It is known that $\lambda_{|V|} = -1$ if and only if the graph has a bipartite component. Trevisan [21] has proven that when the graph is "far" from having a bipartite component, then $\lambda_{|V|}$ is bounded away from -1.

For any tuple (S, S_1, S_2), $\emptyset \neq S \subseteq V$, $S_1 \cup S_2 = S$, the *bipartiteness ratio* of (S, S_1, S_2) is defined as

$$\beta(S, S_1, S_2) = \frac{|E(S, \bar{S})| + 2(|E(S_1)| + |E(S_2)|)}{\mathrm{vol}(S)},$$

and the bipartiteness ratio of the graph is defined as

$$\beta(G) = \min_{\substack{\emptyset \neq S \subseteq V \\ S_1 \cup S_2 = S}} \beta(S, S_1, S_2).$$

It is easy to see that $\beta(G) = 0$ if and only if G has a bipartite component. Moreover, when $\beta(G)$ is close to 0, then G has a component which is "almost" bipartite. As $\beta(G)$ is bounded away from 0, G is further away from having a bipartite component. The following lemma of Trevisan [21] formalizes it.

▶ **Lemma 1.11.** *Let $G = (V, E)$ be an undirected graph where multiple edges are allowed, $\widetilde{A}$ its normalized adjacency matrix and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{|V|}$ the eigenvalues of $\widetilde{A}$. Then*

$$\lambda_{|V|} \geq -1 + \frac{\beta(G)^2}{2}.$$

When dealing with a random walk dimension 0, i.e., the vertices of the complex, we cannot guarantee that the graph is far from being bipartite. In this case we add $\deg(v)$ self-loops to any vertex $v \in V_0$. Then we get a *lazy* random walk on the vertices of the complex, where at each step we stay put with probability 1/2. It turns out that this technique cancels the negative eigenvalues of the complex. The following proposition follows from elementary linear algebra and can also be found at [18].

▶ **Proposition 1.12.** *Let $G = (V, E)$ be an undirected graph where multiple edges are allowed, $\widetilde{A}$ its normalized adjacency matrix and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{|V|}$ the eigenvalues of $\widetilde{A}$. Denote by $G' = (V, E')$ the modified graph after adding $\deg(v)$ self-loops to any vertex $v \in V$. Then the eigenvalues λ'_2 and $\lambda'_{|V|}$ of the modified normalized adjacency matrix $\widetilde{A}'$ satisfy $\lambda'_2 = (1+\lambda_2)/2$ and $\lambda'_{|V|} \geq 0$.*

1.7 Organization of this paper

The paper is organized as follows. In Section 2 we prove that the expansion of the links imply colorful expansion (Theorem 1.7). In Section 3 we prove the rapid mixing criterion for the high order random walks (Theorems 1.8 and 1.4). In Section 4 we show that Ramanujan complexes satisfy this criterion and hence form an explicit family of bounded degree high dimensional simplicial complexes in which all of the high order random walks converge rapidly to their stationary distribution (Theorem 1.9).

2 Colorful expansion

In this section we prove that the expansion of all the links of a complex imply its colorful expansion. The following is the formal version of Theorem 1.7 from the introduction.

▶ **Theorem 2.1** (Colorful expansion criterion)**.** *Let X be a d-dimensional α-skeleton expander. If $\alpha < (\sqrt[2^d]{2} - 1)/\sqrt{2}$, then there exists an $\epsilon = \epsilon(d, \alpha)$ such that X is an ϵ-colorful expander. Specifically, it holds for*

$$\epsilon = \left(\frac{\sqrt[2^d]{2} - 1 - \sqrt{2}\alpha}{2\sqrt{2}d} \right)^d.$$

This section is organized as follows. In Section 2.1 we define the required ingredients of the proof in a formal way. In Section 2.2 we just state the three propositions which are the main building blocks in the proof of the theorem. In Section 2.3 we prove the theorem assuming these propositions hold, and then in Section 2.4 we prove the main propositions which we stated earlier.

2.1 Definitions

Since we prove a global expansion property from the local expansion of the links, it is useful for us to relate cochains in the complex to their local views in the links.

▶ **Definition 2.2** (Localization)**.** Let X be a d-dimensional simplicial complex. For any i-cochain $W \in C^i(X)$, $0 \leq i \leq d$, and any j-face $\sigma \in X(j)$, $j < i$, the *localization* of W to the link of σ is defined as

$$W_\sigma = \{\tau \in X_\sigma \mid \tau \cup \sigma \in W\}.$$

Recall that for any i-cochain $W \in C^i(X)$ it holds that $\|W\| = \Pr[P_i \in W]$. When considering the localization of W to a link of some j-face $\sigma \in X(j)$ $(j < i)$ we have

$$\|W_\sigma\|_\sigma = \Pr[P_i \in W \mid P_j = \sigma].$$

This holds because the condition $P_j = \sigma$ implies that P_d is uniformly distributed on the d-faces containing σ, which are the maximal faces in the link of σ.

For any i-cochain $W \in C^i(X)$ and any dimension $j \leq i$ we define the j-cochain of fat faces. These faces are defined recursively such that any i-face in W is fat, and any j-face, $j < i$, is fat if many of the $(j+1)$-faces which contain it are fat.

▶ **Definition 2.3** (Fat faces)**.** Let X be a d-dimensional simplicial complex, $0 \leq i \leq d$, $W \in C^i(X)$ an arbitrary i-cochain and $0 < \eta < 1$ a fatness constant. The i-cochain of fat faces is defined as $S^i(W) = W$, and for any $-1 \leq j < i$

$$S^j(W) = \left\{\sigma \in X(j) \mid \left\|S^{j+1}(W)_\sigma\right\|_\sigma \geq \eta^{2^{i-j-1}}\right\}.$$

Recall that the expanding faces of any i-cochain $W \in C^i(X)$ are the $(i+1)$-faces which contain at least one face in W and one face not in W. For a simple representation of the expanding faces we define the following cochains.

▶ **Definition 2.4** (Container)**.** Let X be a d-dimensional simplicial complex. For any i-cochain $W \in C^i(X)$, $0 \leq i \leq d$, the *container* of W is defined as

$$\Gamma(W) = \{\tau \in X(i+1) \mid \exists\, \sigma \subset \tau : \sigma \in W\}.$$

▶ **Definition 2.5** (Full faces)**.** Let X be a d-dimensional simplicial complex. For any i-cochain $W \in C^i(X)$, $0 \leq i < d$, the *full faces* of dimension j, $0 \leq j \leq i+1$, are defined as

$$F^j(W) = \{\tau \in X(j) \mid \forall\, \sigma \subset \tau,\ \dim(\sigma) = j-1 : \sigma \in S^{j-1}(W)\}.$$

In words, the container of W is the $(i+1)$-cochain of faces which contain at least one i-face in W. The full faces are defined for any dimension $j \leq i+1$ and they are the j-faces which all of their $(j-1)$-faces are fat. Then we get

$$\psi(W) = \Gamma(W) \setminus F^{i+1}(W).$$

2.2 Main propositions

The first proposition ensures that, with the right parameters, there exists some dimension $j \leq i$ in which many fat j-faces contain many non-fat $(j-1)$-faces.

▶ **Proposition 2.6** (Existence of dimension in which many fat faces contain many non-fat faces)**.** *Let X be a d-dimensional simplicial complex, $0 \le i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$, $\|W\| < \eta^{2^{i+1}-1}$, and any $c \le 1/2$ there exists $0 \le j \le i$ such that*

$$\Pr\left[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)\right] \ge \frac{c^j}{i+1}\|W\|.$$

We relate to these non-fat $(j-1)$-faces as faces with a large "potential" since they have many fat j-faces in their links. We show that this potential can be "lifted" up to dimension $i+1$ in order to deduce that many faces of W contain these non-fat $(j-1)$-faces.

▶ **Proposition 2.7** (Large norm of fat faces implies large norm of the container of W)**.** *Let X be a d-dimensional simplicial complex, $0 \le i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $0 \le j \le i$*

$$\Pr[P_{i+1} \in \Gamma(W) \wedge P_{j-1} \notin S^{j-1}(W)] \ge \eta^{2^{i-j}-1} \Pr[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)].$$

The last proposition shows that, in a skeleton expander complex, the non-fat $(j-1)$-faces can be "lifted" up to dimension $i+1$ in order to deduce that many of the $(i+1)$-faces, which contain these non-fat $(j-1)$-faces, are not full.

▶ **Proposition 2.8** (Large norm of non-fat faces implies large norm of non-full faces)**.** *Let X be an α-skeleton expander, $0 \le i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $0 \le j \le i$*

$$\begin{aligned}\Pr[P_{i+1} \in F^{i+1}(W) \wedge P_{j-1} \notin S^{j-1}(W)] \le \\ \left(\eta^{2^{i-j}} + \alpha\right) \Pr[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)] + \\ \sum_{k=j+1}^{i} (k+1)\left(\eta^{2^{i-k}} + \alpha\right) \Pr[P_k \in S^k(W) \wedge P_{k-1} \notin S^{k-1}(W)]\end{aligned}$$

2.3 Proof of Theorem 2.1

Recall that for colorful expansion we need that any i-cochain with norm up to $1/2$ (of any dimension $i < d$) will have many expanding faces. Let $W \in C^i(X)$, $0 \le i < d$, be an arbitrary i-cochain with $\|W\| \le 1/2$. Set $\eta = \sqrt[2^{i+1}]{1/2}$ and

$$c = \frac{(\eta^{-1}-1)\eta^{2^i} - \alpha}{2(i+1)}.$$

By Proposition 2.6 there exists a dimension $0 \le j \le i$ in which many fat j-faces contain many non-fat $(j-1)$-faces, i.e.,

$$\Pr[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)] \ge \frac{c^j}{i+1}\|W\|. \tag{1}$$

Let j be the maximal which satisfies (1), so for any $k \in \{j+1, \ldots, i\}$

$$\Pr[P_k \in S^k(W) \wedge P_{k-1} \notin S^{k-1}(W)] < \frac{c^k}{i+1}\|W\|. \tag{2}$$

We are going to show that the non-fat $(j-1)$-faces imply many expanding $(i+1)$-faces. By definition we have

$$\begin{aligned}\|\psi(W)\| = \left\|\Gamma(W) \setminus F^{i+1}(W)\right\| = \Pr[P_{i+1} \in \Gamma(W) \setminus F^{i+1}(W)] \geq \\ \Pr[P_{i+1} \in \Gamma(W) \setminus F^{i+1}(W) \wedge P_{j-1} \notin S^{j-1}(W)] \geq \\ \Pr[P_{i+1} \in \Gamma(W) \wedge P_{j-1} \notin S^{j-1}(W)] - \Pr[P_{i+1} \in F^{i+1}(W) \wedge P_{j-1} \notin S^{j-1}(W)], \quad (3)\end{aligned}$$

where both of the inequalities follow from laws of probability. The meaning of this is that the expanding faces of W are at least the difference between the container of W and the full $(i+1)$-faces, when both are restricted to the non-fat $(j-1)$-faces.

By the existence of many fat j-faces in the links of the non-fat $(j-1)$-faces we know that a large part of W is seen in these links, or in other words, we can "lift" the fat j-faces in order to deduce a lower bound on the container of W. This lower bound is given formally by Proposition 2.7:

$$\Pr[P_{i+1} \in \Gamma(W) \wedge P_{j-1} \notin S^{j-1}(W)] \geq \eta^{2^{i-j}-1} \Pr[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)]. \quad (4)$$

By the skeleton expansion of X we can "lift" the non-fat $(j-1)$-faces in order to deduce an upper bound on the full $(i+1)$-faces. So by Proposition 2.8 we have

$$\begin{aligned}\Pr[P_{i+1} \in F^{i+1}(W) \wedge P_{j-1} \notin S^{j-1}(W)] \leq \\ (\eta^{2^{i-j}} + \alpha) \Pr[P_j \in S^j(W) \wedge P_{j-1} \notin S^{j-1}(W)] + \\ \sum_{k=j+1}^{i} (k+1)(\eta^{2^{i-k}} + \alpha) \Pr[P_k \in S^k(W) \wedge P_{k-1} \notin S^{k-1}(W)] \quad (5)\end{aligned}$$

Substituting (4) and (5) in (3) yields

$$\begin{aligned}\|\psi(W)\| \geq \left((\eta^{-1}-1)\eta^{2^{i-j}} - \alpha\right) \Pr[P_j \in S^j \wedge P_{j-1} \notin S^{j-1}(W)] - \\ \sum_{k=j+1}^{i} (k+1)(\eta^{2^{i-k}} + \alpha) \Pr[P_k \in S^k \wedge P_{k-1} \notin S^{k-1}(W)]. \quad (6)\end{aligned}$$

Now by substituting (1) and (2) in (6) we get

$$\begin{aligned}\|\psi(W)\| \geq \left(\frac{(\eta^{-1}-1)\eta^{2^{i-j}} - \alpha}{i+1} c^j - \sum_{k=j+1}^{i} \frac{k+1}{i+1} (\eta^{2^{i-k}} + \alpha) c^k \right) \|W\| \\ \geq c^j \left(\frac{(\eta^{-1}-1)\eta^{2^i} - \alpha}{i+1} - \sum_{k=1}^{i-j} \frac{k+j+1}{i+1} c^k \right) \|W\| \geq c^j (2c-c) \|W\| = c^{j+1} \|W\|,\end{aligned}$$

where the second inequality holds since

$$\eta^{2^{i-k}} + \alpha \leq \eta + \alpha < \sqrt[2^{i+1}]{1/2} + \frac{\sqrt[2^{i+1}]{2} - 1}{\sqrt{2}} = 2^{-x} + \frac{2^x - 1}{\sqrt{2}} \leq 1$$

for $x = (1/2)^{i+1} \in \left(0, 1/2\right]$, and the last inequality holds trivially for $j = i$, and for $j < i$ it holds since

$$\begin{aligned}\sum_{k=1}^{i-j} \frac{k+j+1}{i+1} c^k \leq c \left(\frac{i+1-(i-j-1)}{i+1} + \sum_{k=2}^{i-j} c^{k-1} \right) \\ \leq c \left(\frac{i+1-(i-j-1)}{i+1} + (i-j-1)\frac{1}{i+1} \right) \leq c.\end{aligned}$$

Since $j \leq i < d$ it follows that for any i-cochain $W \in C^i(X)$, $0 \leq i < d$, $\|W\| \leq 1/2$,

$$\frac{\|\psi(W)\|}{\|W\|} \geq c^{i+1} \geq \epsilon$$

for ϵ as in the theorem. ◀

2.4 Proofs of the main propositions

For ease of notation, in this section we use the following shortcuts.

- When the cochain W is clear from the context we write just S^j instead of $S^j(W)$ to denote the fat j-faces, as well as F^j and Γ instead of $F^j(W)$ and $\Gamma(W)$, respectively.
- We relate to each cochain as the event that the matching random variable is in the cochain. For instance, instead of writing $\Pr[P_j \in S^j]$ and $\Pr[P_j \notin S^j]$ we write just $\Pr[S^j]$ and $\Pr[\overline{S^j}]$, respectively.

2.4.1 Proof of Proposition 2.6

Our aim is to show that there exists a dimension $j \leq i$ in which many fat j-faces contain many non-fat $(j-1)$-faces. We first show that a large norm of fat faces of any dimension imply a large norm of W.

▶ **Lemma 2.9** (Large norm of fat faces implies large norm of W)**.** *Let X be a d-dimensional simplicial complex, $0 \leq i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $-1 \leq j \leq i$*

$$\|W\| \geq \eta^{2^{i-j}-1} \big\|S^j\big\|.$$

Proof. Fix an i-cochain $W \in C^i(X)$ and some $-1 \leq j \leq i$. By laws of probability, for any $k \leq i$

$$\begin{aligned} \big\|S^k\big\| &= \Pr\big[S^k\big] \geq \Pr\big[S^k \wedge S^{k-1}\big] = \Pr\big[S^k \mid S^{k-1}\big] \Pr\big[S^{k-1}\big] \\ &\geq \eta^{2^{i-k}} \Pr\big[S^{k-1}\big] = \eta^{2^{i-k}} \big\|S^{k-1}\big\|, \end{aligned} \tag{7}$$

where the last inequality follows from the definition of fat faces.

Applying (7) iteratively for $k = i, i-1, \ldots, j+1$ yields

$$\|W\| \geq \eta\, \eta^2 \cdots \eta^{2^{i-j-1}} \big\|S^j\big\| = \eta^{2^{i-j}-1} \big\|S^j\big\|,$$

◀

Now we show that for any dimension $j \leq i$ the norm of W is bounded by the norm of the fat j-faces (which represent fat i-faces on fat $(i-1)$-faces on fat $(i-2)$-faces and all the way down to fat j-faces) plus the norm of fat k-faces which contain non-fat $(k-1)$-faces for all $k \in \{j+1, \ldots, i\}$.

▶ **Lemma 2.10** (Norm of W as fat faces on fat faces plus fat faces on non-fat faces)**.** *Let X be a d-dimensional simplicial complex, $0 \leq i < d$. Then for any i-cochain $W \in C^i(X)$ and any $-1 \leq j \leq i$*

$$\|W\| \leq \big\|S^j\big\| + \sum_{k=j+1}^{i} \Pr\big[S^k \wedge \overline{S^{k-1}}\big].$$

Proof. Fix an i-cochain $W \in C^i(X)$ and some $-1 \leq j \leq i$. By laws of probability, for any $k \leq i$

$$\begin{aligned}\left\|S^k\right\| &= \Pr\left[S^k\right] = \Pr\left[S^k \wedge S^{k-1}\right] + \Pr\left[S^k \wedge \overline{S^{k-1}}\right] \\ &\leq \Pr\left[S^{k-1}\right] + \Pr\left[S^k \wedge \overline{S^{k-1}}\right] = \left\|S^{k-1}\right\| + \Pr\left[S^k(W) \wedge \overline{S^{k-1}}\right]. \end{aligned} \tag{8}$$

Applying (8) iteratively for $k = i, i-1, \ldots, j+1$ finishes the proof. ◀

Now we use the above two lemmas in order to prove the proposition.

Proof of Proposition 2.6. Fix an i-cochain $W \in C^i(X)$, $\|W\| < \eta^{2^{i+1}-1}$. First we show that the empty set is not fat. By Lemma 2.9 it holds that

$$\|W\| \geq \eta^{2^{i+1}-1}\left\|S^{-1}\right\|.$$

Since $\|W\| < \eta^{2^{i+1}-1}$ it follows that $\left\|S^{-1}\right\| < 1$, which implies that $\left\|S^{-1}\right\| = 0$ because there is only one (-1)-face (the empty set). Now, if for any $0 \leq j \leq i$

$$\Pr\left[S^j \wedge \overline{S^{j-1}}\right] < \frac{c^j}{i+1}\|W\|,$$

then by Lemma 2.10

$$\|W\| \leq \sum_{j=0}^{i} \Pr\left[S^j \wedge \overline{S^{j-1}}\right] < \sum_{j=0}^{i} \frac{c^j}{i+1}\|W\| \leq \|W\|,$$

which leads to a contradiction. ◀

2.4.2 Proof of Proposition 2.7

Fix an i-cochain $W \in C^i(X)$ and some $0 \leq j \leq i$. By laws of probability it follows that

$$\Pr\left[\Gamma \wedge \overline{S^{j-1}}\right] \geq \Pr\left[\Gamma \wedge \overline{S^{j-1}} \wedge W\right] = \Pr\left[\Gamma \mid \overline{S^{j-1}} \wedge W\right] \Pr\left[\overline{S^{j-1}} \wedge W\right] = \Pr\left[\overline{S^{j-1}} \wedge W\right], \tag{9}$$

where the last equality holds since $\Pr[\Gamma \mid W] = 1$.

By an argument similar to Lemma 2.9 (just add the event $\overline{S^{j-1}}$ to each step) we get that

$$\Pr\left[W \wedge \overline{S^{j-1}}\right] \geq \eta^{2^{i-j}-1} \Pr\left[S^j \wedge \overline{S^{j-1}}\right]. \tag{10}$$

Combining (9) and (10) finishes the proof. ◀

2.4.3 Proof of Proposition 2.8

We want to show that many of the $(i+1)$-faces, which contain non-fat $(j-1)$-faces, are not full. First we count the full $(i+1)$-faces by two terms: Full $(i+1)$-faces which contain only full faces, and full $(i+1)$-faces which contain a non-full k-face for some $k \in \{j, \ldots, i\}$.

▶ **Lemma 2.11** (Full $(i+1)$-faces as full faces on full faces plus full faces on non-full faces)**.** *Let X be a d-dimensional simplicial complex, $0 \leq i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $0 \leq j \leq i$*

$$\Pr\left[F^{i+1} \wedge \overline{S^{j-1}}\right] \leq \Pr\left[F^{j+1} \wedge \overline{S^{j-1}}\right] + \sum_{k=j+2}^{i+1} \Pr\left[F^k \wedge \overline{F^{k-1}}\right].$$

Proof. Fix an i-cochain $W \in C^i(X)$ and some $0 \leq j < i$. By laws of probability, for any $k > j$

$$\begin{aligned}\Pr\left[F^k \wedge \overline{S^{j-1}}\right] &= \Pr\left[F^k \wedge \overline{S^{j-1}} \wedge F^{k-1}\right] + \Pr\left[F^k \wedge \overline{S^{j-1}} \wedge \overline{F^{k-1}}\right] \\ &\leq \Pr\left[F^{k-1} \wedge \overline{S^{j-1}}\right] + \Pr\left[F^k \wedge \overline{F^{k-1}}\right]. \end{aligned} \tag{11}$$

Applying (11) iteratively for $k = i+1, i, \ldots, j+2$ finishes the proof. ◀

Now we want to bound the second term of Lemma 2.11, so we relate the norm of full k-faces which contain a non-full $(k-1)$-face to the norm of full k-faces which contain a non-fat $(k-2)$-face.

▶ **Lemma 2.12** (Full k-faces with a non-full $(k-1)$-face related to full k-faces with a non-fat $(k-2)$-face)**.** *Let X be a d-dimensional simplicial complex, $0 \leq i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $1 \leq k \leq i+1$*

$$\Pr\left[F^k \wedge \overline{F^{k-1}}\right] \leq k \Pr\left[F^k \wedge \overline{S^{k-2}}\right].$$

Proof. Fix an i-cochain $W \in C^i(X)$ and some $1 \leq k \leq i+1$. Note that if a $(k-1)$-face $\sigma \in X(k-1)$ is not full, then by definition it contains a non-fat $(k-2)$-face $\tau \subset \sigma$, $\tau \in X(k-2) \setminus S^{k-2}$. Since each $(k-1)$-face contains k vertices, by removing one vertex from σ uniformly at random there is a probability of $1/k$ to hit τ. It follows that

$$\begin{aligned} 1 &= \Pr\left[\overline{F^{k-1}} \mid F^k \wedge \overline{S^{k-2}}\right] = \frac{\Pr\left[\overline{F^{k-1}} \wedge F^k \wedge \overline{S^{k-2}}\right]}{\Pr\left[F^k \wedge \overline{S^{k-2}}\right]} \\ &= \frac{\Pr\left[\overline{S^{k-2}} \mid F^k \wedge \overline{F^{k-1}}\right] \Pr\left[F^k \wedge \overline{F^{k-1}}\right]}{\Pr\left[F^k \wedge \overline{S^{k-2}}\right]} \geq \frac{\Pr\left[F^k \wedge \overline{F^{k-1}}\right]}{k \Pr\left[F^k \wedge \overline{S^{k-2}}\right]}, \end{aligned} \tag{12}$$

where the first equality holds since if $P_{k-2} \in \overline{S^{k-2}}$, then by definition P_{k-1} must have been not full, the second and third equalities follow from laws of probability and the inequality follows from the explanation above. ◀

The next lemma is the *only* place where we use the skeleton expansion of the complex. We use it in order to bound the norm of full k-faces which contain a non-fat $(k-2)$-face with relation to the norm of fat $(k-1)$-faces which contain a non-fat $(k-2)$-face.

▶ **Lemma 2.13** (Full k-faces with a non-fat $(k-2)$-face related to fat $(k-1)$-faces with a non-fat $(k-2)$-face)**.** *Let X be a d-dimensional α-skeleton expander, $0 \leq i < d$, $0 < \eta < 1$ a fatness constant. Then for any i-cochain $W \in C^i(X)$ and any $1 \leq k \leq i+1$*

$$\Pr\left[F^k \wedge \overline{S^{k-2}}\right] \leq \left(\eta^{2^{i-k+1}} + \alpha\right) \Pr\left[S^{k-1} \wedge \overline{S^{k-2}}\right].$$

Proof. Fix an i-cochain $W \in C^i(X)$ and some $1 \leq k \leq i+1$. Recall that a k-face is full if all of its $(k-1)$-faces are fat. Thus, at the link of any $(k-2)$-face, a full k-face seems as an edge between two fat vertices. It follows that for any non-fat $(k-2)$-face $\sigma \in X(k-2) \setminus S^{k-2}$

$$\left\|F^k_\sigma\right\|_\sigma \leq \left\|E(S^{k-1}_\sigma)\right\|_\sigma \leq \left(\eta^{2^{i-k+1}} + \alpha\right) \left\|S^{k-1}_\sigma\right\|_\sigma,$$

where the second inequality follows from the skeleton expansion of X and that σ is not fat. Then by the law of total probability

$$\begin{aligned}
\Pr\left[F^k \wedge \overline{S^{k-2}}\right] &= \sum_{\sigma \in X(k-2)\setminus S^{k-2}} \Pr\left[F^k \mid \sigma\right] \Pr[\sigma] \\
&= \sum_{\sigma \in X(k-2)\setminus S^{k-2}} \left\|F_\sigma^k\right\|_\sigma \Pr[\sigma] \\
&\leq \sum_{\sigma \in X(k-2)\setminus S^{k-2}} \left(\eta^{2^{i-k+1}} + \alpha\right) \left\|S_\sigma^{k-1}\right\|_\sigma \Pr[\sigma] \\
&= \left(\eta^{2^{i-k+1}} + \alpha\right) \sum_{\sigma \in X(k-2)\setminus S^{k-2}} \Pr\left[S^{k-1} \mid \sigma\right] \Pr[\sigma] \\
&= \left(\eta^{2^{i-k+1}} + \alpha\right) \Pr\left[S^{k-1} \wedge \overline{S^{k-2}}\right]. \qquad \blacktriangleleft
\end{aligned}$$

Now the proposition follows as an immediate corollary of the above lemmas.

Proof of Proposition 2.8. Fix an i-cochain $W \in C^i(X)$ and some $0 \leq j \leq i$. Then by the above lemmas

$$\begin{aligned}
\Pr\left[F^{i+1} \wedge \overline{S^{j-1}}\right] &\leq \Pr\left[F^{j+1} \wedge \overline{S^{j-1}}\right] + \sum_{k=j+2}^{i+1} \Pr\left[F^k \wedge \overline{F^{k-1}}\right] \\
&\leq \Pr\left[F^{j+1} \wedge \overline{S^{j-1}}\right] + \sum_{k=j+2}^{i+1} k \Pr\left[F^k \wedge \overline{S^{k-2}}\right] \\
&\leq \left(\eta^{2^{i-j}} + \alpha\right) \Pr\left[S^j \wedge \overline{S^{j-1}}\right] + \sum_{k=j+1}^{i} (k+1)\left(\eta^{2^{i-k}} + \alpha\right) \Pr\left[S^k \wedge \overline{S^{k-1}}\right],
\end{aligned}$$

where the inequalities follow from Lemma 2.11, Lemma 2.12 and Lemma 2.13, in that order. $\blacktriangleleft$

3 Rapid mixing of high order random walks

In this section we prove the following two theorems.

▶ **Theorem 3.1** (Colorful expansion implies rapid mixing). *Let X be a d-dimensional ϵ-colorful expander, $d > 1$. Then all of the high order random walks on X are μ-rapidly mixing for*

$$\mu = 1 - \frac{\epsilon^2}{2(d+1)^2}.$$

▶ **Theorem 3.2** (Rapid mixing criterion). *Let X be a d-dimensional α-skeleton expander, $d > 1$. If $\alpha < (\sqrt[2^d]{2} - 1)\sqrt{2}$, then all of the high order random walks on X are μ-rapidly mixing for*

$$\mu = 1 - \frac{1}{2(d+1)^2}\left(\frac{\sqrt[2^d]{2} - 1 - \sqrt{2}\alpha}{2\sqrt{2}d}\right)^{2d}.$$

We note that by following the steps of the proof carefully we actually get a stronger theorem, which we state here without proving it.

▶ **Theorem 3.3** (Stronger rapid mixing). *Let X be a d-dimensional α-skeleton expander, $d > 1$. Then for any $0 \leq i < d$ such that $\alpha < (\sqrt[2^{i+1}]{2} - 1)/\sqrt{2}$ the high order random walk on dimension i of X is μ-rapidly mixing for*

$$\mu = 1 - \frac{1}{2(i+2)^2}\left(\frac{\sqrt[2^{i+1}]{2} - 1 - \sqrt{2}\alpha}{2\sqrt{2}(i+1)}\right)^{2(i+1)}.$$

Recall that the mixing rate of a random walk is deduced from the spectrum of its normalized adjacency matrix. We show in the following lemmas that all of the induced i-graphs, $0 \leq i < d$, have a large conductance and a large bipartiteness ratio, which imply the concentration of the spectrum of the normalized adjacency matrices $\widetilde{A}_i$ for all $0 \leq i < d$.

▶ **Lemma 3.4.** *Let X be a d-dimensional ϵ-colorful expander. Then for any $0 \leq i < d$ the conductance of $G_i(X)$ satisfies*

$$\Phi(G_i(X)) \geq \frac{\epsilon}{i+2}.$$

Proof. Fix $0 \leq i < d$ and denote by $G_i = (V_i, E_i)$ the induced i-graph of X. For any i-face $\sigma \in X(i)$ and its corresponding vertex $v \in V_i$ it holds that

$$\deg(\sigma) = \frac{1}{d-i}\sum_{\substack{\tau \supset \sigma \\ |\tau| = |\sigma|+1}} \deg(\tau) = \frac{1}{(d-i)(i+1)}\sum_{\sigma' \sim \sigma} \deg(\sigma \cup \sigma') = \frac{\deg(v)}{(d-i)(i+1)}, \quad (13)$$

where the first equality holds since each d-face which contains σ contains $d-i$ $(i+1)$-faces $\tau \supset \sigma$, and hence is counted $d-i$ times. And the second equality holds since each $(i+1)$-face which contains σ contains $i+1$ neighbors of σ.

Now let $\emptyset \neq S \subseteq V_i$, $\mathrm{vol}(S)/\mathrm{vol}(V_i) \leq 1/2$, be an arbitrary subset of vertices in G_i and denote by $W \in C^i(X)$ the corresponding i-cochain in X. By (13) it follows that

$$\|W\| = \frac{\sum_{\sigma \in W}\deg(\sigma)}{\sum_{\sigma \in X(i)}\deg(\sigma)} = \frac{\sum_{v \in S}\deg(v)}{\sum_{v \in V_i}\deg(v)} = \frac{\mathrm{vol}(S)}{\mathrm{vol}(V_i)} \leq \frac{1}{2},$$

and thus by the ϵ-colorful expansion of X we get that

$$\frac{\|\psi(W)\|}{\|W\|} \geq \epsilon. \quad (14)$$

We claim that any expanding face $\tau \in \psi(W)$ contributes at least $(i+1)\deg(\tau)$ edges between S and $\bar{S}$. In order to see this, consider an expanding face $\tau \in \psi(W)$ and let $j = |\{\sigma \subset \tau \mid \sigma \in W\}|$ denote the number of i-faces of τ which are in W. Since the total number of i-faces in τ is $i+2$, then τ has $(i+2-j)$ i-faces which are not in W. It follows that there are $j(i+2-j)$ pairs of i-faces $\sigma, \sigma' \subset \tau$ such that $\sigma \in W$, $\sigma' \notin W$. Recall that for each such pair, there are $\deg(\tau)$ edges between the corresponding vertices in G_i, so τ contributes $j(i+2-j)\deg(\tau)$ edges between S and $\bar{S}$. The last thing to note is that τ is an expanding face so $1 \leq j \leq i+1$, which yields that $j(i+2-j) \geq i+1$. Therefore,

$$|E(S, \bar{S})| \geq (i+1)\sum_{\tau \in \psi(W)}\deg(\tau). \quad (15)$$

It follows that

$$\begin{aligned}\frac{\|\psi(W)\|}{\|W\|} &= \frac{\sum_{\tau \in \psi(W)}\deg(\tau)}{\sum_{\tau \in X(i+1)}\deg(\tau)} \cdot \frac{\sum_{\sigma \in X(i)}\deg(\sigma)}{\sum_{\sigma \in W}\deg(\sigma)} = \frac{i+2}{d-i} \cdot \frac{\sum_{\tau \in \psi(W)}\deg(\tau)}{\sum_{\sigma \in W}\deg(\sigma)} \\ &\leq (i+2)\frac{|E(S, \bar{S})|}{\mathrm{vol}(S)} = (i+2)\Phi(S), \end{aligned} \quad (16)$$

where the second equality holds since

$$\frac{\sum_{\sigma\in X(i)}\deg(\sigma)}{\sum_{\tau\in X(i+1)}\deg(\tau)}=\frac{\binom{d+1}{i+1}|X(d)|}{\binom{d+1}{i+2}|X(d)|}=\frac{i+2}{d-i},$$

and the inequality holds by (13) and (15).

Combining (14) and (16) finishes the proof. ◀

▶ **Lemma 3.5.** *Let X be a d-dimensional simplicial complex. Then for any $1\le i<d$ the bipartiteness ratio of $G_i(X)$ satisfies*

$$\beta(G_i(X))\ge\frac{1}{i+2}.$$

Proof. Fix $1\le i<d$ and denote by $G_i=(V_i,E_i)$ the induced i-graph of X. Let $S,S_1,S_2\subseteq V_i$ be arbitrary subsets of vertices such that $S_1\uplus S_2=S$ and denote by $W,W_1,W_2\in C^i(X)$ the corresponding i-cochains in X.

For any $(i+1)$-face $\tau\in\Gamma(W)$ denote by $j_1(\tau)=|\{\sigma\subset\tau\mid\sigma\in W_1\}|$ the number of i-faces of τ which are in W_1. Similarly denote by $j_2(\tau)$ the number of i-faces of τ which are in W_2. Since the total number of i-faces in τ is $i+2$, then τ contains $(i+2-j_1(\tau)-j_2(\tau))$ i-faces which are not in W. It follows that

$$|E(S,\bar{S})|=\sum_{\tau\in\Gamma(W)}(j_1(\tau)+j_2(\tau))(i+2-j_1(\tau)-j_2(\tau))\deg(\tau),\tag{17}$$

and for any $k=1,2$

$$2|E(S_k)|=\sum_{\tau\in\Gamma(W)}2\binom{j_k(\tau)}{2}\deg(\tau).\tag{18}$$

Combining (17) and (18) yields

$$|E(S,\bar{S})|+2(|E(S_1)|+|E(S_2)|)=\sum_{\tau\in\Gamma(W)}\Big(\big(j_1(\tau)+j_2(\tau)\big)(i+1)-2j_1(\tau)j_2(\tau)\Big)\deg(\tau).\tag{19}$$

Consider an arbitrary $(i+1)$-face $\tau\in\Gamma(W)$. If $j_1(\tau)=0$ or $j_2(\tau)=0$, then

$$\big(j_1(\tau)+j_2(\tau)\big)(i+1)-2j_1(\tau)j_2(\tau)\ge i+1.\tag{20}$$

Otherwise,

$$\big(j_1(\tau)+j_2(\tau)\big)(i+1)-2j_1(\tau)j_2(\tau)\ge\big(j_1(\tau)+j_2(\tau)\big)\left(i+1-\frac{j_1(\tau)+j_2(\tau)}{2}\right)\ge i+1,\tag{21}$$

where the first inequality holds since $j_1(\tau)j_2(\tau)\le((j_1(\tau)+j_2(\tau))/2)^2$, and the second inequality holds since $2\le j_1(\tau)+j_2(\tau)\le i+2$.

Substituting (20) and (21) in (19) yields

$$|E(S,\bar{S})|+2(|E(S_1)|+|E(S_2)|)\ge(i+1)\sum_{\tau\in\Gamma(W)}\deg(\tau).\tag{22}$$

It also holds that

$$\begin{aligned}\mathrm{vol}(S) &= \sum_{v\in S}\deg(v) = \sum_{\sigma\in W}\sum_{\sigma'\sim\sigma}\deg(\sigma\cup\sigma')\\ &= \sum_{\tau\in\Gamma(W)}\big(j_1(\tau)+j_2(\tau)\big)(i+1)\deg(\tau) \le (i+2)(i+1)\sum_{\tau\in\Gamma(W)}\deg(\tau). \qquad (23)\end{aligned}$$

Combining (22) and (23) yields

$$\beta(S,S_1,S_2) = \frac{|E(S,\bar{S})| + 2(|E(S_1)|+|E(S_2)|)}{\mathrm{vol}(S)} \ge \frac{1}{i+2}.$$

Since S, S_1, S_2 were arbitrary it follows that

$$\beta(G_i(X)) \ge \frac{1}{i+2},$$

which finishes the proof. ◀

Proof of Theorem 3.1. The proof follows from the previous lemmas. For any $0 \le i < d$ the combination of Lemma 1.10 and Lemma 3.4 yields

$$\lambda_2(\widetilde{A}_i) \le 1 - \frac{\Phi(G_i)^2}{2} \le 1 - \frac{\epsilon^2}{2(i+2)^2} \le 1 - \frac{\epsilon^2}{2(d+1)^2}. \qquad (24)$$

For $1 \le i < d$ the combination of Lemma 1.11 and Lemma 3.5 yields

$$\lambda_{|V_i|}(\widetilde{A}_i) \ge -1 + \frac{\beta(G_i)^2}{2} \ge -1 + \frac{1}{2(i+2)^2} \ge -1 + \frac{1}{2(d+1)^2} \ge -1 + \frac{\epsilon^2}{2(d+1)^2}, \qquad (25)$$

where the last inequality holds since $\epsilon < 1$.

For $i = 0$ denote by G_0' the graph obtained by adding $\deg(v)$ self-loops to any vertex $v \in V_0$. Then by Proposition 1.12

$$\lambda_2(\widetilde{A}_0') = \frac{1}{2}(1+\lambda_2(\widetilde{A}_0)) \le \frac{1}{2}\left(1+1-\frac{\Phi(G_0)^2}{2}\right) \le 1 - \frac{\epsilon^2}{4\cdot 2^2} \le 1 - \frac{\epsilon^2}{2(d+1)^2}, \qquad (26)$$

where the first and second inequalities follow from Lemma 1.10 and Lemma 3.4, respectively, and the last inequality holds since $d > 1$. By the same proposition it also holds that $\lambda_{|V_0|}(\widetilde{A}_0') \ge 0$.

By (24), (25) and (26) it follows that for any $0 \le i < d$ the high order random walk on dimension i of X is μ-rapidly mixing for

$$\mu = 1 - \frac{\epsilon^2}{2(d+1)^2}.$$ ◀

Proof of Theorem 3.2. The proof follows immediately as a corollary of Theorem 2.1 and Theorem 3.1. ◀

4 Explicit construction

Ramanujan complexes were first defined in [15] and were explicitly constructed in [14]. For details on Ramanujan complexes we refer the readers to [13].

In this section we prove the following theorem.

▶ **Theorem 4.1** (Explicit construction). *For any $d \in \mathbb{N}$ there exists a constant $q_0 = q_0(d)$ such that if X is a d-dimensional q-thick Ramanujan complex with $q > q_0$, then there exists a constant $\mu = \mu(d, q)$ such that all of the high order random walks on X are μ-rapidly mixing.*

As been proven in [4], Ramanujan complexes are excellent skeleton expanders. Though, we need a stronger claim for the mixing of their 1-dimensional skeletons than the one appears in [4]. We can get a better bound since we need a good mixing behavior only inside a subset of vertices and not between every two subsets. We start by defining a special type of complexes.

▶ **Definition 4.2** (Partite regular complex). Let X be a d-dimensional simplicial complex. X is said to be *partite regular* if there exists a partition of its vertices to disjoint subsets $V_0 \cup V_1 \cup \cdots \cup V_d = X(0)$ such that:

- For any d-dimensional face $\sigma \in X(d)$ it holds that $\sigma \in V_0 \times V_1 \times \cdots \times V_d$.
- For any $I \subset J \subset \{0, 1, \ldots, d\}$ there exists $k_I^J \in \mathbb{N}$ such that any face $\sigma \in X \cap \prod_{i \in I} V_i$ is contained in k_I^J faces from $X \cap \prod_{j \in J} V_j$.

For a partite regular complex X, denote by $X_{(i,j)} = (V_i \cup V_j, X(1) \cap (V_i \times V_j))$ the induced graph by partitions i and j. Note that by the regularity of the complex, $X_{(i,j)}$ is a bipartite biregular graph, i.e., there exists $k_i^j, k_j^i \in \mathbb{N}$, such that any vertex $v \in V_i$ is contained in k_i^j edges and any vertex $u \in V_j$ is contained in k_j^i edges. It is known that $\lambda_1(X_{(i,j)}) = (k_i^j k_j^i)^{1/2}$, where $\lambda_1(X_{(i,j)})$ is the largest eigenvalue of the graph's adjacency matrix (see [3, Lemma 3.1] for a proof). Denote by $\widetilde{\lambda}_2(X_{(i,j)}) = \lambda_2(X_{(i,j)})/(k_i^j k_j^i)^{1/2}$ the normalized second largest eigenvalue. The following mixing lemma for bipartite biregular graphs is proven in [3].

▶ **Lemma 4.3.** *[3, Corollary 3.4] Let $G = (V_1 \cup V_2, E)$ be a bipartite biregular graph, $\widetilde{\lambda}_2(G)$ its normalized second largest eigenvalue. Then for any $S \subseteq V_1, T \subseteq V_2$*

$$\frac{|E(S,T)|}{|E|} \leq \sqrt{\frac{|S||T|}{|V_1||V_2|}}\left(\sqrt{\frac{|S||T|}{|V_1||V_2|}} + \widetilde{\lambda}_2(G)\right).$$

We use this lemma in order to prove the following proposition.

▶ **Proposition 4.4** (Skeleton mixing lemma). *Let X be a partite regular d-dimensional complex, $\widetilde{\lambda}_2(X) = \max_{0 \leq i < j \leq d} \widetilde{\lambda}_2(X_{(i,j)})$. Then for any subset of vertices $S \subseteq X(0)$*

$$\|E(S)\| \leq \|S\|(\|S\| + \widetilde{\lambda}_2(X)).$$

Proof. Let $V_0 \cup V_1 \cup \cdots \cup V_d$ be the partition of $X(0)$. Note that since X is a partite regular complex, then for any $0 \leq i \leq d$ and any two vertices $u, v \in V_i$ it holds that $\deg(u) = \deg(v)$. It is achieved by the regularity property of the complex and by setting $I = \{i\}$ and $J = [d] = \{0, 1, \ldots, d\}$. This implies that for any $0 \leq i \leq d$

$$\sum_{v \in X(0)} \deg(v) = (d+1)|X(d)| = (d+1) \sum_{v \in V_i} deg(v) = (d+1)|V_i| k_{\{i\}}^{[d]}.$$

Therefore, for any subset of vertices $S_i \subseteq V_i$

$$\|S_i\| = \frac{\sum_{v \in S_i} deg(v)}{\sum_{u \in X(0)} deg(u)} = \frac{|S_i|}{(d+1)|V_i|} \tag{27}$$

In a same way, for any $0 \leq i < j \leq d$

$$\sum_{e \in X(1)} \deg(e) = \binom{d+1}{2}|X(d)| = \binom{d+1}{2} \sum_{e \in X(1) \cap (V_i \times V_j)} deg(e)$$
$$= \binom{d+1}{2}|X(1) \cap (V_i \times V_j)|k^{[d]}_{\{i,j\}}.$$

And again for any subset of edges $S_{ij} \subseteq X(1) \cap (V_i \times V_j)$

$$\|S_{ij}\| = \sum_{e \in S_{ij}} w(e) = \frac{\sum_{e \in S_{ij}} deg(e)}{\sum_{f \in X(1)} deg(u)} = \frac{2|S_{ij}|}{d(d+1)|X(1) \cap (V_i \times V_j)|}. \tag{28}$$

Now let $S \subseteq X(0)$ be an arbitrary subset of vertices in the complex. For any $0 \leq i \leq d$ denote by $S_i = S \cap V_i$ the vertices in partition i. For any $0 \leq i < j \leq d$, (27) yields

$$\sqrt{\frac{|S_i||S_j|}{|V_i||V_j|}} = \sqrt{(d+1)^2\|S_i\|\|S_j\|} = (d+1)\sqrt{\|S_i\|\|S_j\|},$$

and (28) yields

$$\frac{|E(S_i, S_j)|}{|X(1) \cap (V_i \times V_j)|} = \frac{d(d+1)}{2}\|E(S_i, S_j)\|.$$

By Lemma 4.3 it follows that for any $0 \leq i < j \leq d$

$$\|E(S_i, S_j)\| \leq \frac{2}{d}\sqrt{\|S_i\|\|S_j\|}\left((d+1)\sqrt{\|S_i\|\|S_j\|} + \widetilde{\lambda}_2(X)\right).$$

Note that since $S = S_0 \cup S_1 \cup \cdots \cup S_d$, then $\|S\| = \sum_{i=0}^{d}\|S_i\|$. Thus, the sum $\sum_{i \neq j}\|S_i\|\|S_j\|$ is maximized when all of the subsets are equal, i.e., $\|S_i\| = \|S\|/(d+1)$ for all $0 \leq i \leq d$. It follows that

$$\|E(S)\| = \sum_{i \neq j}\|E(S_i, S_j)\| \leq \sum_{i \neq j}\frac{2}{d}\sqrt{\|S_i\|\|S_j\|}\left((d+1)\sqrt{\|S_i\|\|S_j\|} + \widetilde{\lambda}_2(X)\right)$$
$$\leq \sum_{i \neq j}\frac{2}{d}\sqrt{\frac{\|S\|^2}{(d+1)^2}}\left((d+1)\sqrt{\frac{\|S\|^2}{(d+1)^2}} + \widetilde{\lambda}_2(X)\right)$$
$$= \binom{d+1}{2}\frac{2}{d(d+1)}(\|S\| + \widetilde{\lambda}_2(X)) = \|S\|(\|S\| + \widetilde{\lambda}_2(X)), \tag{29}$$

which finishes the proof. ◀

Now, as been proven in [4], all of the links of a Ramanujan complex are partite regular and the normalized second largest eigenvalue of every induced bipartite biregular graph approaches 0 as a function of the dimension and the thickness of the complex. So we state the following lemma which is proven in [4].

▶ **Lemma 4.5.** *Let X be a d-dimensional q-thick Ramanujan complex. Then there exists a constant $C = C(d)$ such that*

$$\max_{\substack{\sigma \in X \\ i \neq j}} \widetilde{\lambda}_2((X_\sigma)_{(i,j)}) \leq \frac{C}{\sqrt{q}}.$$

We are now ready to prove the theorem of this section.

Proof of Theorem 4.1. Let $d \in \mathbb{N}$ be any dimension we want. Let $C = C(d)$ be the constant from Lemma 4.5 and set

$$q_0 = \left(\frac{\sqrt{2}C}{\sqrt[2^d]{2} - 1} \right)^2.$$

Now if X is a d-dimensional q-thick Ramanujan complex with $q > q_0$, then by Proposition 4.4 and Lemma 4.5 X is an α-skeleton expander for

$$\alpha = \frac{C}{\sqrt{q}} < \frac{\sqrt[2^d]{2} - 1}{\sqrt{2}}. \tag{30}$$

Then applying Theorem 3.2 finishes the proof. ◀

Acknowledgements. We would like to thank Roei Tell for introducing us to the probabilistic view of the norm, it made the proofs much simpler.

A Mixing rate for general graphs

We show here that the mixing rate of random walks on a general graph can be deduced from the spectrum of its normalized adjacency matrix. The idea is similar to the proof for regular graphs, but the details require some more carefulness.

▶ **Proposition 1.1.** *Let $G = (V, E)$ be an undirected graph on n vertices, $\widetilde{A}$ its normalized adjacency matrix, $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ the eigenvalues of $\widetilde{A}$ and $\lambda = \max\{|\lambda_2|, |\lambda_n|\}$. Then for any initial probability distribution $\pi_0 \in \mathbb{R}^V$ and any $t \in \mathbb{N}$*

$$\|\pi_t - \pi\|_2 \leq \sqrt{\frac{d_{max}}{d_{min}}}\lambda^t,$$

where π_t is the probability distribution after t steps of the random walk, π is the stationary distribution, $d_{max} = \max_{v\in V}\{\deg(v)\}$ and $d_{min} = \min_{v\in V}\{\deg(v)\}$.

Proof. Recall that $\widetilde{A} = D^{1/2}AD^{1/2}$, where $D = \mathrm{diag}(1/\deg(v))_{v\in V}$ and A is the adjacency matrix of G. It follows that for any initial probability distribution $\pi_0 \in \mathbb{R}^V$ and any $t \in \mathbb{N}$

$$\pi_t = \pi_0(DA)^t = \pi_0(D^{1/2}\widetilde{A}D^{-1/2})^t = \pi_0 D^{1/2}\widetilde{A}^t D^{-1/2}.$$

We show first that the claim holds for a random walk starting from any fixed vertex and then we extend it to any initial probability distribution on the vertices.

Fix a starting vertex $v \in V$ and denote by $\mathbf{1}_v$ the probability distribution which is fixed on v, i.e., $\mathbf{1}_v(v) = 1$ and for any other vertex $u \neq v$, $\mathbf{1}_v(u) = 0$. Since $\widetilde{A}$ is a symmetric matrix, its eigenvectors $\{\mathbf{e}_1, \ldots, \mathbf{e}_n\}$ form an orthonormal basis for $\mathbb{R}^n$, and $\widetilde{A}$ has the spectral representation

$$\widetilde{A} = \sum_{i=1}^{n} \lambda_i \mathbf{e}_i^T \mathbf{e}_i = \sum_{i=1}^{n} \lambda_i E_i,$$

where $E_i = \mathbf{e}_i^T\mathbf{e}_i$. Note that for any i, $E_i^2 = E_i$ and for any $i \neq j$, $E_iE_j = 0$. It follows that

$$\mathbf{1}_v(DA)^t = \mathbf{1}_v D^{1/2}\widetilde{A}^t D^{-1/2} = \mathbf{1}_v D^{1/2}\Big(\sum_{i=1}^{n}\lambda_i^t E_i\Big)D^{-1/2} = \sum_{i=1}^{n}\lambda_i^t \mathbf{1}_v D^{1/2}E_i D^{-1/2}. \tag{31}$$

The first eigenvalue of $\widetilde{A}$ is the trivial one, i.e., $\lambda_1 = 1$, with corresponding eigenvector

$$\mathbf{e}_1 = \left(\sqrt{\frac{\deg(u)}{\sum_{w\in V}\deg(w)}}\right)_{u\in V}.$$

Note that for any $1 \le i \le n$, $\mathbf{1}_v E_i = \mathbf{e}_i(v)\mathbf{e}_i$. Then by substitution we get

$$\lambda_1^t \mathbf{1}_v D^{1/2} E_1 D^{-1/2} = \frac{\mathbf{1}_v E_1 D^{-1/2}}{\sqrt{\deg(v)}} = \frac{\mathbf{e}_1(v)\mathbf{e}_1 D^{-1/2}}{\sqrt{\deg(v)}} = \pi. \tag{32}$$

Combining (31) and (32) yields

$$\begin{aligned}
\left\|\mathbf{1}_v(DA)^t - \pi\right\|_2 &= \left\|\sum_{i=2}^{n} \lambda_i^t \mathbf{1}_v D^{1/2} E_i D^{-1/2}\right\|_2 \le \sqrt{\frac{d_{max}}{d_{min}}}\left\|\sum_{i=2}^{n}\lambda_i^t \mathbf{1}_v E_i\right\|_2 \\
&= \sqrt{\frac{d_{max}}{d_{min}}}\left\|\sum_{i=2}^{n}\lambda_i^t \mathbf{e}_i(v)\mathbf{e}_i\right\|_2 = \sqrt{\frac{d_{max}}{d_{min}}}\sqrt{\left\langle\sum_{i=2}^{n}\lambda_i^t \mathbf{e}_i(v)\mathbf{e}_i, \sum_{j=2}^{n}\lambda_j^t \mathbf{e}_j(v)\mathbf{e}_j\right\rangle} \\
&= \sqrt{\frac{d_{max}}{d_{min}}}\sqrt{\sum_{i=2}^{n}\lambda_i^{2t}\mathbf{e}_i(v)^2} \le \sqrt{\frac{d_{max}}{d_{min}}}\lambda^t\sqrt{\sum_{i=2}^{n}\mathbf{e}_i(v)^2} \le \sqrt{\frac{d_{max}}{d_{min}}}\lambda^t,
\end{aligned}$$

where the last equality and the last inequality follow from the orthonormality of the eigenvectors.

Now let $\pi_0 \in \mathbb{R}^V$ be any initial probability distribution on the vertices. We can write π_0 as a convex combination $\pi_0 = \sum_{v\in V}\alpha_v \mathbf{1}_v$, where $\sum_{v\in V}\alpha_v = 1$. Similarly, the stationary distribution can be written as $\pi = \sum_{v\in V}\alpha_v \pi$. Then by the triangle inequality we get

$$\begin{aligned}
\|\pi_t - \pi\|_2 = \left\|\pi_0(DA)^t - \pi\right\|_2 &= \left\|\sum_{v\in V}\alpha_v\left(\mathbf{1}_v(DA)^t - \pi\right)\right\|_2 \\
&\le \sum_{v\in V}\alpha_v\left\|\mathbf{1}_v(DA)^t - \pi\right\|_2 \le \sqrt{\frac{d_{max}}{d_{min}}}\lambda^t,
\end{aligned}$$

which finishes the proof. ◀

Real Stability Testing*

Abstract

We give a strongly polynomial time algorithm which determines whether or not a bivariate polynomial is real stable. As a corollary, this implies an algorithm for testing whether a given linear transformation on univariate polynomials preserves real-rootedness. The proof exploits properties of hyperbolic polynomials to reduce real stability testing to testing nonnegativity of a finite number of polynomials on an interval.

1 Introduction

A univariate polynomial with real coefficients is called *real-rooted* if all of its roots are real. Multivariate generalizations of this concept, known as *hyperbolic* and *real stable* polynomials, were defined in the 50's and in the 80's in the context of Partial Differential Equations and Control Theory, respectively[1], and have since made contact with several areas of mathematics. In particular, a polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ is called *real stable* if it has no zeros with all coordinates in the open upper half of the complex plane. These polynomials have played a central role in several recent advances in theoretical computer science and combinatorics — for instance, [1, 14, 13, 7, 5]. Each of these works relies in a critical way on (1) understanding which polynomials are real stable (2) understanding which linear operators *preserve* real-rootedness and real stability. Motivated by (1) and (2), this paper studies the following two fundamental algorithmic problems:

Problem 1. Given a bivariate polynomial[2] $p \in \mathbb{R}_n[x, y]$, is p real stable?

Problem 2. Given a linear operator $T : \mathbb{R}_n[x] \to \mathbb{R}_m[x]$, does T preserve real-rootedness?

The main result of this paper is a strongly polynomial time algorithm that solves Problem 1.

▶ **Theorem 1** (Main). *Given the coefficients of a bivariate polynomial $p \in \mathbb{R}_n[x, y]$, there is a deterministic algorithm which decides whether or not p is real stable in at most $O(n^5)$ arithmetic operations, assuming exact arithmetic.*

Part of the motivation for solving Problem 1 is the following theorem of Borcea and Branden, which shows that Problem 2 can be reduced to Problem 1.

▶ **Theorem 2** (Borcea-Branden [4]). *For every linear transformation $T : \mathbb{R}_n[x] \to \mathbb{R}_m[x]$, there is a bivariate polynomial $p \in \mathbb{R}_{\max(n,m)}[x, y]$ such that T preserves real-rootedness if and only if p is real stable. Moreover, the coefficients of p can be computed from the matrix of T in linear time.*

Thus, our main theorem immediately implies a solution to Problem 2 as well.

To give the reader a feel for the objects at hand, we remark that the set of real stable polynomials in any number of variables is a nonconvex set with nonempty interior [16]. In the univariate case, the interior of the set of real-rooted polynomials simply corresponds to polynomials with distinct roots, and its boundary contains polynomials which have roots with multiplicity greater than one. With regards to Problem 2, the prototypical example of an operator which preserves real rootedness is differentiation. Recent applications such as [15] rely on finding more elaborate differential operators with this property.

We now describe the main ideas in our algorithm. It turns out that testing bivariate real stability is equivalent to testing whether a certain *two parameter* family of polynomials is real rooted. It is not clear how to check this continuum of real-rootedness statements in strongly polynomial, or even in exponential time. To circumvent this, we use a deep convexity result from the theory of hyperbolic polynomials to reduce the two parameter family to a one parameter family of degree n polynomials, whose coefficients are themselves polynomials of degree n in the parameter. We then use a characterization of real-rootedness as postive semidefiniteness of certain moment matrices to further reduce this to checking that a finite number of univariate polynomials are *nonnegative* an interval. Finally, we solve each instance of the nonnegativity problem using Sturm sequences and a bit of algebra.

The set of polynomials nonnegative on an interval forms a closed convex cone, so the last step of our algorithm may be viewed as a strongly polynomial time membership oracle for this cone. We would not be surprised if such a result is already known (at least as folklore) but we were unable to find a concrete reference in the literature, so this component of our method may be of independent interest.

We see this result as being both mathematically fundamental, as well as useful for researchers who work with stable polyomials, particularly since many of their known applications so far (e.g.[14]) put special emphasis on properties of bivariate restrictions. More speculatively, it is possible that being able to test membership in the set of real stable polynomials is a step towards being able to optimize over them.

1.1 Related Work

Problem 1 was solved in the univariate case by C. Sturm in 1835 [19], who described a now well-known method that can be turned into a strongly polynomial quadratic time algorithm given the coefficients of p [2]. We are unaware of any published work regarding algorithms for the bivariate case or for Problem 2. We remark that following the release of this paper, Thorsten Theobald has observed (informal communication) that the quantifier elimination techniques of [3] can be used to obtain *weakly* polynomial time algorithms for Problems 1 and 2.

The paper [9] studied the problem of testing whether a bivariate polynomial is *real zero* (a special case of real stability). It reduced that problem to testing PSDness of a one-parameter family of matrices which it then suggested could be solved using semidefinite programming, but without quite proving a theorem to that effect. This work is partly inspired by ideas in [9].

The paper [12] gives semidefinite programming based algorithms that can test whether certain restricted classes of *multiaffine* polynomials are real stable (in more than 2 variables).

The problem of certifying that a univariate polynomial is nonnegative is typically stated (for instance, in lecture notes) as being the solution to a semidefinite program. If one were able to work out the appropriate error to which the SDP has to be solved, this could give a weakly polynomial time algorithm for nonnegativity, which we suspect must be known as folklore. The paper [18] analyzes a semidefinite programming based algorithm in the special case when the polynomial is nondegenerate in an appropriate sense.

2 Real Stable and Hyperbolic Polynomials

We recall below the definition of a real stable polynomial in an arbitrary number of variables.

▶ **Definition 3.** A polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ is called *real stable* if it is identically zero[3] or if $p(z_1, \ldots, z_n) \neq 0$ whenever $\mathrm{Im}(z_i) > 0$ for all $i = 1, \ldots, n$. Equivalently, p is real stable if and only if the univariate restrictions

$$t \mapsto p(te_1 + x_1, te_2 + x_2, \ldots, te_n + x_n)$$

are real rooted whenever $e_1, \ldots, e_n > 0$ and $x_1, \ldots, x_n \in \mathbb{R}$.

The equivalence between the two formulations above is an easy exercise. Note that a univariate polynomial is real stable if and only if it is real rooted. Note that we consider the zero polynomial to be real-rooted.

We will frequently use the elementary fact that a limit of real-rooted polynomials is real-rooted, which follows from Hurwitz's theorem (see, e.g. [20, Sec. 2]), or from the argument principle.

Real Stable polynomials are closely related to the following more general class of polynomials.

▶ **Definition 4.** A homogeneous polynomial $p \in \mathbb{R}[x_1, \ldots, x_n]$ is called *hyperbolic* with respect to a point $e = (e_1, \ldots, e_n) \in \mathbb{R}^n$ if $p(e) > 0$ and the univariate restrictions

$$t \mapsto p(te + x)$$

are real rooted for all $x \in \mathbb{R}^n$. The connected component of $\{x \in \mathbb{R}^n : p(x) \neq 0\}$ containing e is called the *hyperbolicity cone* of p with respect to e, and will be denoted $K(p, e)$.

Perhaps the most familiar example of a hyperbolic polynomial is the determinant of a symmetric matrix:

$$X \mapsto \det(X)$$

[3] Some works (e.g. [4]) consider only nonzero polynomials to be stable, while others [20] include the zero polynomial. We find the latter convention more convenient.

for real symmetric X, which is hyperbolic with respect to the identity matrix since the characteristic polynomial of a symmetric matrix is always real rooted. The corresponding hyperbolicity cone is the cone of positive semidefinite matrices.

The most important theorem regarding hyperbolic polynomials says that hyperbolicity cones are *always* convex, and that hyperbolicity at one point in the cone implies hyperbolicity at every other point. Thus, hyperbolic polynomials and hyperbolicity cones may be viewed as generalizing determinants and PSD cones.

▶ **Theorem 5** (Garding [6]). *If $p \in \mathbb{R}[x_1, \ldots, x_n]$ is hyperbolic with respect to $e \in \mathbb{R}^n$ then:*

1. *$K(p, e)$ is an open convex cone.*
2. *p is hyperbolic with respect to every point $y \in K(p, e)$.*

The reason hyperbolic polynomials are relevant in this work is that real stable polynomials are essentially a special case of them.

▶ **Theorem 6** (Borcea-Branden [4]). *A nonzero bivariate polynomial $p(x, y)$ of total degree at most m is real stable if and only if its homogenization*

$$p_H(x, y, z) := z^m p(x/z, y/z)$$

is hyperbolic with respect to every point in

$$\mathbb{R}^2_{>0} \times \{0\} = \{(e_1, e_2, 0) : e_1, e_2 > 0\}.$$

Thus, real stable polynomials enjoy the strong structural properties guaranteed by Theorem 5 as well, and we exploit these in our algorithm.

3 Parameter Reduction via Hyperbolicity

In this section we use the properties of hyperbolic polynomials to reduce real stability of a bivariate polynomial to testing real rootedness of a one parameter family of polynomials.

▶ **Theorem 7** (Reduction to One-Parameter Family). *A nonzero bivarite polynomial $p \in \mathbb{R}_n[x, y]$ ofis real stable if and only if following two conditions hold:*

1. *The one-parameter family of univariate polynomials $q_\gamma \in \mathbb{R}[t]$ given by,*

$$q_\gamma(t) = p(\gamma + t, t) \in \mathbb{R}[t]$$

   are real rooted for all $\gamma \in \mathbb{R}$.
2. *The univariate polynomial*

$$t \mapsto p_H(t, 1 - t, 0)$$

   is strictly positive on the interval $(0, 1)$,

Proof. (*real-stability of p* $\implies$ (1) & (2))

By Theorem 6, p_H is hyperbolic with respect to the positive orthant $\mathbb{R}^2_{>0} \times \{0\}$. Since $(1, 1, 0) \in \mathbb{R}^2_{>0} \times \{0\}$, this implies that for all $(x, y, z) \in \mathbb{R}^3$,

$$q(t) = p_H(x + t, y + t, z)$$

is real-rooted. Setting $x = \gamma$, $y = 0$ and $z = 1$ we get that $q_\gamma(t) = p_H(\gamma + t, t, 1) = p(\gamma + t, t)$ is real-rooted for all $\gamma \in \mathbb{R}$ which is condition (1). Finally, since

$$\{(t, 1 - t, 0) | t \in (0, 1)\} \subset \mathbb{R}^2_{>0} \times \{0\}$$

and p_H is hyperbolic with respect to $\mathbb{R}^2_{>0} \times \{0\}$, it follows that $p_H(t, 1-t, 0) > 0$ for all $t \in (0, 1)$.

((1) & (2) $\implies$ *real-stability of* p)

First, we claim that the polynomial p_H is hyperbolic with respect to $(1, 1, 0)$. By (2) we have $p_H(1/2, 1/2, 0) > 0$ so homogeneity implies that $p_H(1, 1, 0) > 0$. It remains to show that $q_{x,y,z}(t) = p_H(x + t, y + t, z)$ is real-rooted for all $(x, y, z) \in \mathbb{R}^3$. First, consider the case of $(x, y, z) \in \mathbb{R}^3$ with $z \neq 0$.

$$
\begin{aligned}
&\forall (x, y, z) \in \mathbb{R}^3 \text{ with } z \neq 0, p_H(x + t, y + t, z) \text{ is real-rooted} \\
&\iff \forall (x, y, z) \in \mathbb{R}^3 \text{ with } z \neq 0, p_H(\frac{x}{z} + \frac{t}{z}, \frac{y}{z} + \frac{t}{z}, 1) \text{ is real-rooted} \\
&\iff \forall (x, y, z) \in \mathbb{R}^3 \text{ with } z \neq 0, p_H(\frac{x}{z} + t, \frac{y}{z} + t, 1) \text{ is real-rooted (replacing } t/z \text{ with } t) \\
&\iff \forall (x, y) \in \mathbb{R}^2, p_H(x + t, y + t, 1) \text{ is real-rooted} \\
&\iff \forall (x, y) \in \mathbb{R}^2, p_H(x + t, t, 1) \text{ is real-rooted (replacing } t \text{ with } t - y) \\
&\iff \forall \gamma \in \mathbb{R}, p(\gamma + t, t) \text{ is real-rooted}
\end{aligned}
$$

By Hurwitz's theorem, the limit of any sequence of real-rooted polynomials is real-rooted. Therefore, if $q_{x,y,z}(t)$ is real-rooted for all $(x, y, z) \in \mathbb{R}^3$ with $z \neq 0$ then $q_{x,y,z}(t)$ is real-rooted for all $(x, y, z) \in \mathbb{R}^3$.

Given that p_H is hyperbolic with respect to $e = (\frac{1}{2}, \frac{1}{2}, 0)$, its hyperbolicity cone $K(p_H, e)$ is a convex cone containing $(1, 1, 0)$. Condition (2) implies that the connected component of $\{x | p(x) \neq 0\}$ containing $(1, 1, 0)$ contains the open line segment from $(1, 0, 0)$ to $(0, 1, 0)$. Together, this implies that the positive quadrant $\mathbb{R}^2 \times \{0\} \subseteq K(p_H, e)$. By Theorem 6, this implies that p is real-stable. ◀

Thus, our algorithmic goal is reduced to testing whether a one-parameter family is real-rooted, and whether a given univariate polynomial is positive on an interval. We solve these problems in the sequel.

4 Real-rootedness of one-parameter families

In this section we present two algorithms for testing real-rootedness of a one-parameter family of polynomials. Both algorithms reduce this problem to verifying nonnegativity of a finite number of polynomials on the real line. The first algorithm produces n polynomials of degree roughly $O(n^3)$, and has the advantage of being very simple, relying only on elementary techniques and standard algorithms such as fast matrix multiplication and the discrete Fourier transform. The second algorithm produces n polynomials of degree roughly $O(n^2)$ and runs significantly faster, but uses somewhat more specialized (but nonetheless classical) machinery from the theory of resultants.

4.1 A Simple $O(n^{3+\omega})$ Algorithm

The first algorithm is based on the observation that real-rootedness of a single polynomial is equivalent to testing positive semidefiniteness of its moment matrix, which in turn is equivalent to testing nonnegativity of the elementary symmetric polynomials of that matrix. In the more general case of a one-parameter family, the latter polynomials turn out to be polynomials of bounded degree in the parameter, and it therefore suffices to verify that these are nonnegative everywhere.

We begin by recalling the Newton Identities, which express the moments of a polynomial in terms of its coefficients.

▶ **Lemma 8** (Newton Identities). *If*

$$p(x) = \sum_{k=0}^{n} (-1)^k x^{n-k} c_k = c_0 \prod_{i=1}^{n} (x - x_i) \in \mathbb{R}[x]$$

with $c_0 \neq 0$ is a univariate polynomial with roots $x_1, \ldots, x_n$, then the moments

$$m_k := \sum_{i=1}^{n} x_i^k$$

satisfy the recurrence:

$$m_k = (-1)^{k-1} \frac{c_k}{c_0} + \sum_{i=1}^{k-1} (-1)^{k-1+i} \frac{c_{k-i}}{c_0} m_i \qquad 0 \leq k \leq n,$$

$$m_k = \sum_{k-n}^{k-1} (-1)^{k-1+i} \frac{c_{k-i}}{c_0} m_i \qquad k > n,$$

$$m_0 = n.$$

The following consequences of Lemma 8 will be relevant to analyzing our algorithm.

▶ **Corollary 9.**

1. *The moments $m_0, \ldots, m_{2n-2}$ of a degree n polynomial can be computed from its coefficients in $O(n^2)$ arithmetic operations.*
2. *Suppose $p(x) = \sum_{k=0}^{n} (-1)^k x^{n-k} c_k(\gamma)$ is a polynomial whose coefficients are polynomials $c_0(\gamma), \ldots, c_n(\gamma) \in \mathbb{R}_d[\gamma]$ in a parameter γ. Then the moments of p are given by*

$$m_k(\gamma) = r_k(\gamma)/c_0(\gamma)^k,$$

for some polynomials $r_k \in \mathbb{R}_{dk}[\gamma]$.

Proof. The first claim follows because each application of the recurrence requires at most n arithmetic operations. For the second claim, observe that each ratio $c_{k-i}(\gamma)/c_0(\gamma)$ is a rational function with a numerator of degree at most d and denominator $c_0(\gamma)$. Thus, each application of the recurrence increases the degree of the numerator by at most d and introduces an additional c_0 in the denominator. ◀

As a subroutine, we will also need the following standard result in linear algebra.

▶ **Theorem 10** (Keller-Gehrig [11]). *Given an $n \times n$ complex matrix A, there is an algorithm which computes the characteristic polynomial of A in time $O(n^\omega \log n)$.*

We now specify the algorithm and prove its correctness.

▶ **Theorem 11.** *A polynomial $p_\gamma(x) = \sum_{k=0}^{n} (-1)^k x^{n-k} c_k(\gamma)$ is real-rooted for all $\gamma \in \mathbb{R}$ if and only if the polynomials $q_0, \ldots, q_n$ output by **SimpleRR** are nonnegative on $\mathbb{R}$. Moreover, **SimpleRR** runs in time $\tilde{O}(dn^{2+\omega} + d^2 n^3)$.*

Proof. We first show correctness. Let $m_k(p)$ denote the k^{th} moment of the roots of a polynomial. By Sylvester's theorem [2, Theorem 4.58], a real polynomial

$$p_\gamma(x) = \sum_{k=0}^{n} (-1)^k x^{n-k} c_k(\gamma)$$

is real-rooted if and only if the corresponding moment matrix

$$M(\gamma)_{k,l} := m_{k+l-2}(p_\gamma)$$

is positive semidefinite. Since ν is even and c_0 has real coefficients, we have for every $\gamma \in \mathbb{R}$ that is not a root of c_0:

$$M(\gamma) \succeq 0 \iff c_0(\gamma)^\nu M(\gamma) = H(\gamma) \succeq 0.$$

Since c_0 has only finitely many roots and a limit of PSD matrices is PSD, we conclude that

$$M(\gamma) \succeq 0 \quad \forall \gamma \in \mathbb{R} \iff H(\gamma) \succeq 0 \forall \gamma \in \mathbb{R}.$$

Note that by Corollary 9 the entries of $H(\gamma)$ are polynomials of degree at most $d(\nu + 2n - 2)$ in γ.

We now recall a well-known[4] (e.g., [10]) characterization of positive semidefiniteness as a semialgebraic condition: an $n \times n$ real symmetric matrix A is PSD if and only if $e_k(A) \geq 0$ for all $k = 1, \ldots, n$, where

$$e_k(A) = \sum_{|S|=k} \det(A_{S,S})$$

is the sum of all $k \times k$ principal minors of A. Thus, p_γ is real-rooted for all $\gamma \in \mathbb{R}$ if and only if the polynomials

$$q_k(\gamma) := e_k(H(\gamma))$$

for $k = 1, \ldots, n$ are nonnegative on $\mathbb{R}$.

Since each q_k is a sum of determinants of order at most n in $H(\gamma)$ it has degree at most n in the entries of $H(\gamma)$, and we conclude that $q_1, \ldots, q_n \in \mathbb{R}_N[\gamma]$. Thus, the q_k can be recovered by interpolating them at the N^{th} roots of unity. Since the k^{th} elementary symmetric function of a matrix is the coefficient of z^{n-k} in its characteristic polynomial, this is precisely what is achieved in Step 2.

For the complexity analysis, it is clear that Step 1 takes $O(dn^2)$ time. Constructing each Hankel matrix $H(s_i)$ takes time $O(dn + n^2)$ by Corollary 9, and computing its elementary symmetric functions via the characteristic polynomial takes time $O(n^\omega \log n)$, according to Theorem 10. Thus, the total time for each iteration is $O(n^\omega \log n + dn)$, so the time for all iterations is $O(dn^{2+\omega} \log n + d^2 n^3)$. The final step requires $O(N \log N)$ time for each e_k using fast polynomial interpolation via the discrete Fourier transform, for a total of $O(dn^3 \log n)$. Thus, the total running time is $\tilde{O}(dn^{2+\omega} + d^2 n^3)$, suppressing logarithmic factors. ◀

[4] Here is a short proof: A is PSD iff $\det(zI - A)$ has only nonnegative roots. Since A is symmetric we know the roots are real. We now observe that a real-rooted polynomial has nonnegative roots if and only if its coefficients alternate in sign.

Algorithm 1: SimpleRR

Input: $(n+1)$ univariate polynomials $c_0, \ldots, c_n \in \mathbb{R}_d[\gamma]$ with $c_0 \not\equiv 0$.
Output: n univariate polynomials $q_1, \ldots, q_n \in \mathbb{R}_{3n^2d}[\gamma]$

1. Let ν be the first even integer greater than or equal to n and let $N = nd(2n-2+\nu) = O(dn^2)$. Let $s_1, \ldots, s_N \in \mathbb{C}$ be the N^{th} roots of unity.
2. For each $i = 1, \ldots N$:
   - Compute the $n \times n$ Hankel matrix $H(s_i)$ with entries

     $$H(s_i)_{k,l} := c_0(s_i)^\nu m_{k+l-2}(p_{s_i}),$$

     by applying the Newton identities (Lemma 8).
   - Compute the characteristic polynomial

     $$\det(zI - H(s_i)) = \sum_{k=0}^{n} (-1)^k z^{n-k} e_k(H(s_i))$$

     using the Keller-Gehrig algorithm (Theorem 10).
3. For each $k = 1, \ldots, n$: Use the points $e_k(H(s_1)), \ldots, e_k(H(s_N))$ to interpolate the coefficients of the polynomial

   $$q_k(\gamma) := e_k(H(\gamma)).$$

Output $q_1, \ldots, q_n$.

4.2 A Faster $O(n^4)$ Algorithm Using Subresultants

The algorithm of the previous section is based on the generic fact that a matrix is PSD if and only if its elementary symmetric polynomials are nonnegative. In this section we exploit the fact that our matrices have a special structure – namely, they are moment matrices – to find a different finite set of polynomials whose nonnegativity suffices to certify their PSDness. These polynomials are called *subdiscriminants*, and turn out to be related to another class of polynomials called *subresultants*, for which there are known fast symbolic algorithms.

Let M_p denote the $n \times n$ moment matrix corresponding to a polynomial p of degree n. Recall that $M_p = VV^T$ where V is the Vandermonde matrix formed by the roots of p. Let $(M_p)_i$ denote the leading principal $i \times i$ minor of M_p. We define subdiscriminants of a polynomial, and then show their relation to the leading principal minors of the moment matrix. For the remainder of this section it will be more convenient to use the notation

$$p(x) = \sum_{k=0}^{n} a_k x^k$$

for the coefficients of a polynomial, with roots $x_1, \ldots, x_n$ and $a_n \neq 0$.

▶ **Definition 12.** The k^{th} *subdiscriminant* of a polynomial p is defined as

$$\texttt{sDisc}_k(p) = a_n^{2k-2} \sum_{S \subset \{1,\ldots,n\}, |S|=k} \prod_{\{i,j\} \subset S} (x_i - x_j)^2$$

▶ **Lemma 13.** *The leading principal minors of the moment matrix are multiples of the*

subdiscriminants,

$$(M_p)_i = a_n^{2-2k}\mathtt{sDisc}_k(p) = \sum_{S\subset\{1,\ldots,n\},|S|=k}\prod_{\{i,j\}\subset S}(x_i-x_j)^2$$

Proof. Let

$$V_i = \begin{bmatrix} 1 & \ldots & 1 \\ x_1 & \ldots & x_n \\ \vdots & \vdots & \vdots \\ x_1^{i-1} & \ldots & x_n^{i-1} \end{bmatrix}.$$

Then $(M_p)_i = \det(V_iV_i^T)$. By Cauchy-Binet, this determinant is the sum over the determinants of all submatrices of size $i \times i$. These submatrices are exactly the Vandermonde matrices formed by subsets of the roots of size i. Then the identity follows from the formula for the determinant of a Vandermonde matrix. ◀

Equipped with this we can provide an alternative characterization of real rootedness. Define the sign of a number, denoted $\mathtt{sgn}$ to be $+1$ if it is positive, -1 if it is negative, and 0 otherwise.

▶ **Lemma 14.** *p is real-rooted if and only if the sequence $\mathtt{sgn}(\mathtt{sDisc}_1(p)),\ldots,\mathtt{sgn}(\mathtt{sDisc}_n(p))$ is first 1's and then 0's.*

Proof. Note that since $a_n \neq 0$ we have $\mathtt{sgn}(Disc_k) = \mathtt{sgn}(a_n^{2(1-k)}Disc_k) = \mathtt{sgn}((M_p)_i)$. It is clear from the definition of the subdiscriminants that if p is real-rooted with k distinct roots then $\mathtt{sDisc}_i$ is positive if $i \leq k$ and $\mathtt{sDisc}_i = 0$ if $i > k$.

Conversely, given a polynomial p with k distinct roots, then if $i > k$ we have all the minors of size i in V_i^T contain two identical rows, and hence V_i^T does not have full rank, so $V_iV_i^T$ is singular. Let $x_1, x_2, \ldots, x_j$ be the real distinct roots of p and $y_1, \bar{y_1}, \ldots, y_l, \bar{y_l}$ be the distinct complex conjugate pairs of p where $j + l = k$. Suppose the multiplicities of x_i are n_i and y_i are m_i. Then the top left $k \times k$ submatrix of M_p is

$$= \sum_i n_i \begin{bmatrix} 1 \\ x_i \\ \vdots \\ x_i^{k-1} \end{bmatrix} \begin{bmatrix} 1 & x_i & \cdots & x_i^{k-1} \end{bmatrix} + \sum_i m_i \begin{bmatrix} 1 \\ y_i \\ \vdots \\ y_i^{k-1} \end{bmatrix} \begin{bmatrix} 1 & y_i & \cdots & y_i^{k-1} \end{bmatrix} + \begin{bmatrix} 1 \\ \bar{y_i} \\ \vdots \\ \bar{y_i}^{k-1} \end{bmatrix} \begin{bmatrix} 1 & \bar{y_i} & \cdots & \bar{y_i}^{k-1} \end{bmatrix}$$

$$= \sum_i n_i \begin{bmatrix} 1 \\ x_i \\ \vdots \\ x_i^{k-1} \end{bmatrix} \begin{bmatrix} 1 & x_i & \cdots & x_i^{k-1} \end{bmatrix} + \sum_i m_i \begin{bmatrix} 1 & 1 \\ \mathrm{Re}(y_i) & \mathrm{Im}(y_i) \\ \vdots & \vdots \\ \mathrm{Re}(y_i^{k-1}) & \mathrm{Im}(y_i^{k-1}) \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ \mathrm{Re}(y_i) & \mathrm{Im}(y_i) \\ \vdots & \vdots \\ \mathrm{Re}(y_i^{k-1}) & \mathrm{Im}(y_i^{k-1}) \end{bmatrix}^T$$

This shows that this submatrix is positive definite if and only if the distinct roots are all real. Note that by Sylvester's criterion this submatrix is positive definite if and only if all the leading principal minors of size $\leq k$ are positive. ◀

We now obtain a formula for the subdiscriminants of a polynomial in terms of its coefficients. The connection is provided by another family of polynomials called the *subresultants.*

▶ **Definition 15.** Let $p = \sum_{k=0}^{n} a_k x^k$ where $a_n \neq 0$. The *kth subresultant* of p, denoted $\mathtt{sRes}_k(p, p')$ is the determinant of the submatrix obtained from the first $2n-1-2k$ columns of the following $(2n-1-2k) \times (2n-1-k)$ matrix:

$$\begin{bmatrix} a_n & \cdots & \cdots & \cdots & \cdots & a_0 & 0 & 0 \\ 0 & \ddots & & & & & \ddots & 0 \\ \vdots & \ddots & a_n & \cdots & \cdots & \cdots & \cdots & a_0 \\ \vdots & & 0 & na_n & \cdots & \cdots & \cdots & a_1 \\ \vdots & \iddots & \iddots & & & & \iddots & 0 \\ 0 & \iddots & & & & \iddots & \iddots & \vdots \\ na_n & \cdots & \cdots & \cdots & a_1 & 0 & \cdots & 0 \end{bmatrix}$$

We will use two properties of subresultants. The first is a good bound on their degree as a consequence of the determinantal formula above. The second is quick algorithm to compute them. We refer the reader to [2] for a more detailed discussion of subresultants.

In this paper we will only be interested in subresultants of a polynomial with its derivative We are interested in this because of its relation to our leading principal minors:

▶ **Lemma 16** ([2] Proposition 4.27)**.** *Let* $p(x) = \sum_{k=0}^{n} a_k x^k$ *where* $a_n \neq 0$

$\mathtt{sRes}_k(p, p') = a_n \mathtt{sDisc}_{n-k}(p)$

▶ **Corollary 17.** *Since the first column of the determinant used to define the subresultant is divisible by* a_n*, we get* $\mathtt{sDisc}_k(p)$ *is a polynomial in our coefficients* $a_n, \ldots, a_0$ *of degree at most* $2n$*.*

The benefit of studying the principal minors instead of the coefficients of the characteristic polynomial for our moment matrix is that we can use an algorithm from subresultant theory to quickly calculate all the minors at once.

▶ **Theorem 18** ([2] Algorithm 8.21)**.** *There exists an algorithm which, given a polynomial* p *of degree* n *returns a list of all of its subresultants* $\mathtt{sRes}_k(p, p')$ *for* $k = 1, \ldots, n$ *in* $O(n^2)$ *time.*

▶ Remark. Many computer algebra systems (e.g., Mathematica, Macaulay2) have built-in efficient algorithms to compute subresultants.

We now combine the above facts to obtain a crisp condition for real-rootedness of a one-parameter family. Recall that by Theorem 7, we are interested in testing when a family of polynomials $p_\gamma(x)$ are real-rooted for all $\gamma \in \mathbb{R}$, where

$$p_\gamma(x) = \sum_{k=0}^{n} a_k(\gamma) x^k$$

with $c_k \in \mathbb{R}_n[\gamma]$. Let $c_m(\gamma)$ be the highest coefficient that is not identically zero. We are only interested in the case when $m \geq 2$.

▶ **Proposition 19.** *If* $p_\gamma(x) = \sum_{k=0}^{n} x^k c_k(\gamma)$ *with* $c_k \in \mathbb{R}_d[\gamma]$*, then* $\mathtt{sDisc}_k(p_\gamma)$ *is a polynomial in* γ *of degree at most* $2dn$*.*

Proof. From our previous lemma, we know that $\mathtt{sDisc}_k$ is a polynomial in the coefficients of p of degree at most $2n$. Since each of these coefficients $c_k(\gamma)$ is a polynomial in γ of degree at most d, our result follows. ◀

We now extend our characterization of real-rootedness in terms of the signs of the principal minors of a fixed polynomial to a characterization for coefficients which are polynomials in γ.

▶ **Theorem 20.** *$p_\gamma(x)$ is real-rooted for all $\gamma \in \mathbb{R}$ if and only if there exists a k such that $\mathtt{sDisc}_i(p_\gamma)$ is a nonnegative polynomial which is not identically zero for all $i \leq k$ and $\mathtt{sDisc}_i(p_\gamma)$ is identically zero for $i > k$.*

Proof. First suppose that $p_\gamma(x)$ is real rooted for all $\gamma \in \mathbb{R}$. Observe that $c_m(\gamma)$ vanishes for at most finitely many points Z_1. Moreover, the degree m discriminant of p_γ is a polynomial in γ, and is zero for at most finitely many points — call them Z_2. Thus, for $\gamma \notin Z_1 \cup Z_2$, we know that p_γ has exactly m distinct real roots, so by Lemma 14 $\mathtt{sDisc}_i(p_\gamma)$ is strictly positive for $i \leq m$ and zero for $i > m$ on this set. By continuity this implies that $\mathtt{sDisc}_i(p_\gamma)$ is nonnegative and not identically zero on $\mathbb{R}$ for $i \leq m$, and $\mathtt{sDisc}_i(p_\gamma)$ is identically zero for $i > m$, as desired.

To prove the converse, note that for $i \leq k$, $\mathtt{sDisc}_i(p_\gamma(t))$ is not identically zero, and hence there are finitely many γ away from which $\mathtt{sDisc}_i(p_\gamma)$ is positive for all $i \leq k$, and then all zero. By Lemma 14 we get that $p_\gamma(x)$ is real rooted for all these γ. Since real-rootedness is preserved by taking limits (by Hurwitz's theorem), we conclude that $p_\gamma(x)$ is real rooted for all $\gamma \in \mathbb{R}$. ◀

Combining these observations, and using the $O(n^2)$ time algorithm to compute the subdiscriminants, we arrive at the following $O(n^4)$ time algorithm for computing all the subdiscriminants.

Algorithm 2: FastRR

Input: $(n+1)$ univariate polynomials $c_0, \ldots, c_n \in \mathbb{R}_d[\gamma]$ with $c_0 \not\equiv 0$.

Output: n univariate polynomials $q_1, \ldots, q_n \in \mathbb{R}_{2dn}[\gamma]$

1. Find distinct points $\gamma_1, \ldots, \gamma_{2dn} \in$ such that $c_m(\gamma_i) \neq 0$.
2. For each γ_i use the subresultant algorithm (Theorem 18) to compute all of the $\mathtt{sRes}_k(p_{\gamma_i})$, with $k = 1, \ldots, n$.
3. Use the above values to compute $2dn$ different values $q_k(\gamma_1), \ldots, q_k(\gamma_{2dn})$ for each of the polynomials

$$q_k(\gamma) := \mathtt{sDisc}_k(p_\gamma) = c_m(\gamma)^{-1}\mathtt{sRes}_{m-k}(p_\gamma)),$$

$k = 1, \ldots, n$.

4. Use fast interpolation to compute the coefficients of $q_1, \ldots, q_n$.

Output $q_1, \ldots, q_n$.

▶ **Theorem 21.** ***FastRR*** *runs in $O(n^4)$ time.*

Proof. Since $c_n(\gamma)$ is of degree at most d we can test $2dn + d$ points to find $2dn$ points on which $c_n(\gamma)$ doesnt vanish. Each evaluation takes $O(d)$ times, so total this takes $O(d^2 n)$ time. To compute $\mathtt{sRes}_k(p_{\gamma_i})$ for each $0 \leq k \leq n-1$ and $1 \leq i \leq 2dn$ takes $O(dn^3)$ time by Theorem 18. Then to scale all the subresultants, since we have $O(dn^2)$ data points and have already computed $c_n(\gamma_i)$ takes $O(dn^2)$ time. Finally, since the degrees of the q_k are at most $2dn$, the total time to interpolate all of them is $O(dn^2 \log n)$. ◀

5 Univariate Nonnegativity Testing

In this section, we describe an algorithm to test non-negativity of a univariate polynomial over the real line.

Let $p \in \mathbb{R}[x]$ denote a univariate polynomial of degree d. The goal of the algorithm is to test if $p(x) \geq 0$ for all $x \in \mathbb{R}$. A canonical approach for the problem would be to use a Sum-of-Squares semidefinite program to express p as a sum of squares of low-degree polynomials. Unfortunately, the resulting algorithm is not a symbolic algorithm, i.e., its runtime is not strongly polynomial in the degree d, since semidefinite programming is not known to be strongly polynomial.

We will now describe a strongly polynomial time algorithm to test non-negativity of the polynomial p. Our starting point is an algorithm to count the number of real roots of a polynomial using Sturm sequences. We refer the reader to Basu et al. [2] for a detailed presentation of Sturm sequences and algorithms to compute them. For our purposes, we will need the following lemma.

▶ **Lemma 22.** *Given a univariate polynomial $p \in \mathbb{R}[x]$, the algorithm based on computing Sturm sequences uses $O(\deg(p)^2)$ arithmetic operations to determine the number of real roots of p.*

The polynomial p is positive, i.e., $p(x) > 0$ for all $x \in \mathbb{R}$, if and only if it has no real roots. Therefore, Lemma 22 yields an algorithm to test positivity using in $O(d^2)$ arithmetic operations. To test non-negativity, the only additional complication stems from the roots of the polynomial p. We begin with a simple observation.

▶ **Fact 23.** *If $p \in \mathbb{R}[x]$ is monic then $p(x) \geq 0$ for all $x \in \mathbb{R}$ if and only if p has no real roots of odd multiplicity.*

▶ **Definition 24.** A square-free decomposition of a polynomial $p \in \mathbb{R}[x]$ of degree d, is a set of polynomials $\{a_1, \ldots, a_d\} \in \mathbb{R}[x]$ such that

$$p(x) = \prod_{i=1}^{d} a_i(x)^i \ ,$$

and each a_i has no roots with multiplicity greater than one. Alternately, for each $i \in [d]$, $a_i(x)^i$ consists of all roots of p with multiplicity exactly i.

Square-free decompositions can be computed efficiently using gcd computations. Yun [21] carries out a detailed analysis of square-free decomposition algorithms. In particular, he shows that an algorithm due to Musser can be used to compute square-free decompositions at the cost of constantly many gcd computations.

Now, we are ready to describe an algorithm to test non-negativity.

Algorithm 3: Nonnegative

Input: A monic polynomial $p \in \mathbb{R}[x]$, $\deg(p) = d$

Goal: Test if $p(x) \geq 0$ for all $x \in \mathbb{R}$.

1. Using Musser's algorithm, compute the square-free decomposition of p given by,

$$p = \prod_{i \in [d]} a_i^i$$

where $a_i \in \mathbb{R}[x]$ has no roots with multiplicity greater than 1.

2. For each $i \in [\lceil \frac{d}{2} \rceil]$
   - Using Sturm sequences, test if a_{2i-1} has real roots. If a_{2i-1} has real roots p is NOT non-negative.

Runtime

Let $T_{gcd}(d)$ denote the time-complexity of computing the gcd of two univariate polynomials of degree d. The runtime of Musser's square-free decomposition algorithm is within constant factors of $T_{gcd}(d)$. Let $S_{real}(\ell)$ denote the time-complexity of determining if a degree ℓ polynomial has no real roots. Observe that

$$\sum_i \deg(a_i) \leq \deg(p) = d$$

Since $S_{real}(\ell)$ is super-linear in ℓ, we have $\sum_{i \in [d]} S_{real}(a_i) \leq S_{real}(d)$. The run-time of the algorithm is given by $O(T_{gcd}(d) + S_{real}(d))$. Using Sturm sequences, $S_{real}(d) = O(d^2)$ elementary operations on real numbers (see [2]). Using Euclid's algorithm, $T_{gcd}(d) = O(d^2)$ elemenetary operations on real numbers. This yields an algorithm for non-negativity that incurs at most $O(d^2)$ elementary operations.

6 Conclusion and Discussion

Finally, we combine the ingredients from sections 3, 4, and 5 to obtain the proof of our main theorem.

Proof of Theorem 1. Given the coefficients of p, we can compute the coefficients of the one-parameter family in (1) of Theorem 7 in time at most $O(n^3)$. By Theorem 21, **FastRR** produces the polynomials $q_1, \ldots, q_n$ in time $O(n^4)$. We check that some final segment of these polynomials are identically zero by evaluating each one at $O(n^2)$ points. These polynomials have degree $O(n^2)$, so **Nonnegative** requires time $O(n^4)$ to check nonnegativity of each remaining one, for a total running time of $O(n^5)$.

For part (2) of Theorem 7, we simply use a Sturm sequence to ensure that there are no roots in $(0, 1)$, and then evaluate the polynomial at a single point to check that the sign is positive. ◀

The algorithm in this paper offers a starting point in the area of polynomial time algorithms for real stability. In addition to the obvious possibility of improving the running time to say $O(n^4)$ or below, several natural open questions remain:

- Can the algorithm be generalized to 3 or more variables? The bottleneck to doing this is that we do not know how to check real rootedness of 2-parameter families, or equivalently, nonnegativity of bivariate polynomials.

- Is there an algorithm for testing whether a given polynomial is hyperbolic with respect to *some* direction, without giving the direction as part of the input?
- Is there an algorithm for testing stability of bivariate polynomials with *complex* coefficients?

Perhaps leaving the realm of strongly polynomial time algorithms, the major open question in this area is the following: a famous theorem of Helton and Vinnikov [8] asserts that every bivariate real stable polynomial can be written as

$$p(x, y) = \det(xA + yB + C)$$

for some positive semidefinite matrices A, B and real symmetric C. Unfortunately, their proof does not give an efficient algorithm for finding these matrices. Can the ideas in this paper, perhaps via using SDPs to find sum-of-squares representations of certain nonnegative polynomials derived from p, be used to obtain such an algorithm?

Acknowledgments. We thank Eric Hallman, Navin Goyal, Jonathan Leake, and Bernd Sturmfels for valuable discussions. We also thank Didier Henrion for valuable correspondence regarding other algorthimic approaches to these problems, and Thorsten Theobald for pointing out the reference [3].

Very Simple and Efficient Byzantine Agreement

Silvio Micali

CSAIL, MIT, Cambridge, USA
silvio@csail.mit.edu

Abstract

We present a very simple, cryptographic, binary Byzantine-agreement protocol that, with $n \geq 3t + 1 \geq 3$ players, at most t of which are malicious, halts in expected 9 rounds.

1998 ACM Subject Classification C2.2 Network Protocols, F.0 General

Keywords and phrases Byzantine Agreement

Digital Object Identifier 10.4230/LIPIcs.ITCS.2017.6

1 Set Up

The players communicate, in rounds, in a synchronous, point-to-point network with full connectivity. Each player i has a public key PK_i, and a corresponding secret key SK_i, of a verifiable random function. (For simplicity, we may rely on a unique-signature digital signature scheme and a hash-function H modelled as a random oracle. This way, i univocally associates to each message m the random string $H(SIG_i(m))$.) There is also a random string R, independent of the n public keys. The players, their public keys, and the string R are common knowledge to all players.

2 Adversarial Model

A honest player follows all his protocol instructions. Initially all players are honest, and remain so until he made malicious (corrupted) by a polynomial-time Adversary. At the start of *any round*, the Adversary may secretly corrupt *any player* he wants, provided that he corrupts less than $n/3$ players in total. The Adversary totally controls, and perfectly coordinates, the actions of all corrupted players, who thus may arbitrarily deviate from their protocol instructions. At each round, the Adversary immediately learns all messages sent by the honest players, and then chooses the messages sent in the same round by all currently corrupted players. However, the Adversary cannot interfere (block, alter, etc.) the messages the currently honest players send to each other. In addition, since he is computationally bounded, he cannot successfully forge the digital signature of an honest player, except with negligible probability.

3 Further Information

For more details, see https://people.csail.mit.edu/silvio/Selected Scientific Papers Distributed Computation.

Also, the author and Vinod Vikuntanathan have modified the protocol so as as to work also when the Adversary corrupt any number of players less than $n/2$. Stay tuned!

Low-Complexity Cryptographic Hash Functions*†

Abstract

Cryptographic hash functions are efficiently computable functions that shrink a long input into a shorter output while achieving some of the useful security properties of a random function. The most common type of such hash functions is *collision resistant* hash functions (CRH), which prevent an efficient attacker from finding a pair of inputs on which the function has the same output.

Despite the ubiquitous role of hash functions in cryptography, several of the most basic questions regarding their computational and algebraic complexity remained open. In this work we settle most of these questions under new, but arguably quite conservative, cryptographic assumptions, whose study may be of independent interest. Concretely, we obtain the following results:

- **Low-complexity CRH.** Assuming the intractability of finding short codewords in natural families of linear error-correcting codes, there are CRH that shrink the input by a constant factor and have a *constant algebraic degree* over $\mathbb{Z}_2$ (as low as 3), or even *constant output locality and input locality.* Alternatively, CRH with an arbitrary polynomial shrinkage can be computed by *linear-size* circuits.
- **Win-win results.** If low-degree CRH with good shrinkage *do not* exist, this has useful consequences for learning algorithms and data structures.

- **Degree-2 hash functions.** Assuming the conjectured intractability of solving a random system of quadratic equations over $\mathbb{Z}_2$, a uniformly random degree-2 mapping is a *universal one-way hash function* (UOWHF). UOWHF relaxes CRH by forcing the attacker to find a collision with a random input picked by a challenger. On the other hand, a uniformly random degree-2 mapping is *not* a CRH. We leave the existence of degree-2 CRH open, and relate it to open questions on the existence of degree-2 randomized encodings of functions.

1 Introduction

This work studies the problem of minimizing the complexity of cryptographic hash functions. We start with some relevant background.

Cryptographic hash functions are efficiently computable functions that shrink a long input into a shorter output while achieving some of the useful security properties of a random function. The main focus of this work is on *collision resistant* hash functions (CRH), which prevent an efficient attacker from finding a pair of distinct inputs x, x' on which the function has the same output.[1] However, we will also consider *universal one-way hash function* (UOWHF) [63], which relax CRH by forcing the attacker to find a collision with a random input x picked by a challenger.

CRH are among the most useful and well studied cryptographic primitives. They are commonly used in cryptographic protocols, with applications ranging from sublinear-communication and statistically hiding commitments [29, 47], via succinct and efficiently verifiable arguments for NP [54, 62], to protocols that bypass black-box simulation barriers [7]. More directly, they can be used via the "hash and sign" paradigm to reduce the task of digitally signing a long message x to the easier task of signing a short hash $h(x)$ [28, 61]. Analogously, they can reduce the cost of verifying the correctness of a long NP-statement x to that of verifying the correctness of a short NP-statement $y = h(x)$ by having the prover argue that she knows some x' such that $h(x') = y$ and x' is a true statement. Thus, the amortized cost of signing a long message or verifying a long NP-statement is essentially the cost of computing a CRH.

While the *feasibility* of CRH can be based on a variety of standard cryptographic assumptions, including the conjectured intractability of factoring, discrete logarithms, and lattice problems [28, 42, 65, 58], questions about the *efficiency* of CRH are still quite far from being settled. In particular, recent progress on the efficiency of other "symmetric" cryptographic primitives, such as pseudorandom generators, [20, 75], pseudorandom functions [43], and even UOWHFs, does not seem relevant in light of the known black-box separation between CRH and these primitives [69, 45]. The goal of the present work is to close some of the remaining gaps in our understanding of the complexity of CRH and related primitives.

[1] Technically speaking, a CRH is defined by a collection of input-shrinking functions h_z, where z is a public evaluation key, and where the security requirement should hold with respect to a randomly chosen z. This has the advantage of allowing security against non-uniform attackers. In the following presentation we will treat a CRH as a single deterministic function for simplicity.

We study the following natural complexity measures:

- **Degree.** We say that $h : \{0,1\}^k \to \{0,1\}^m$ has algebraic degree d if each output can be written as a multivariate polynomial over $\mathbb{Z}_2$ in the inputs of degree at most d. Ideally, we would like the degree to be constant, where 2 is the best one could hope for.
- **Locality.** We say that h has *output locality* d if each output depends on at most d inputs. Ideally, we would like the output locality to be constant, where output locality 3 is the best one could hope for [41]. If h has output locality d then its degree is at most d. Similarly, h has *input locality* d if every input influences at most d outputs.
- **Circuit size.** We say that h has circuit size S if it can be computed by a boolean circuit of size S over the standard AND/OR/NOT basis (with AND/OR gates of fan-in 2).[2] Ideally, we would like the circuit size to be *linear* in the input length. Linear size is implied by constant output locality.

The goals of minimizing circuit size and locality can be directly motivated by the goals of reducing the sequential and parallel time complexity of hashing. Minimizing algebraic degree, other than being of theoretical interest, is motivated by applications in which hashing is computed in the encrypted or secret-shared domain. Indeed, it is typically the case that techniques for secure multiparty computation [12, 26, 66], homomorphic encryption [39, 22, 40], or homomorphic secret sharing [27, 21] are much more efficient when applied to low-degree computations over a small field. See [46] for further discussion.

The prior state of the art can be summarized as follows. Standard algebraic or number theoretic constructions of CRH, as well as (asymptotic versions of) the commonly used practical designs, do not achieve constant degree or locality, and their circuit size is quasi-linear or worse. General techniques for randomized encoding of functions can be used to convert any standard CRH h in NC^1 into a CRH $\hat{h}$ with constant output locality [1]. However, even if h has very good shrinkage, $\hat{h}$ only shrinks the input by a sublinear amount, which limits its usefulness. From here on, we will restrict the attention by default to hash functions that have linear (or better) shrinkage, namely $h : \{0,1\}^k \to \{0,1\}^{ck}$ for some $0 < c < 1$. Every such h with linear circuit size can be converted into a linear-size CRH with polynomial shrinkage, namely $h' : \{0,1\}^k \to \{0,1\}^{k^\epsilon}$ for an arbitrary $\epsilon > 0$, using a tree of invocations of h [60]. Linear-size UOWHFs were constructed in [52] under strong assumptions. The assumptions were later improved in [3], who also achieved constant locality. The question of obtaining similar results for CRH was left open by both works. Finally, heuristic constructions of CRH with constant algebraic degree have been proposed in the literature [30]. However, the security of these proposals has not been reduced to a well studied problem.

To summarize, prior to our work, linear-shrinkage CRH candidates with constant algebraic degree were only proposed as heuristics, and no candidate CRH construction with constant locality or linear circuit size has been proposed.

1.1 Our Contribution

In this work we settle most of the open questions concerning the complexity of CRH and related primitives under new, but arguably clean and conservative, cryptographic assumptions.

Concretely, we put forward the following class of *binary SVP* assumptions. For a distribution $\mathcal{M}$ over $m \times n$ binary matrices and a parameter $0 < \delta < 1/2$, the $(\mathcal{M}, \delta) - \mathsf{bSVP}$ assumption asserts that given a matrix M drawn from $\mathcal{M}$, no efficient algorithm can find

[2] One could alternatively consider *running time* on a RAM machine; our upper bounds on circuit size apply to this model as well.

a nonzero vector in the kernel of M whose Hamming weight is at most δn, except with negligible success probability. The matrix M can be thought of as the parity-check matrix of a binary linear error-correcting code. Thus, bSVP can be viewed as a binary field analogue of the lattice Shortest Vector Problem (SVP), replacing an integer lattice by a binary code.

We construct low-complexity CRH based on instances of the bSVP assumption with matrix distributions $\mathcal{M}$ that correspond to uniform distributions over natural classes of linear codes. The parameter δ is chosen such that there are exponentially many codewords whose relative weight is close to δ, but where such codewords are only an exponentially small fraction of the set of all codewords, thus ruling out "guessing attacks." When $m = \alpha n$ and $\mathcal{M}$ is sufficiently rich (in particular, when it is uniform over *all* $m \times n$ matrices), the assumption is plausible whenever $\delta < \alpha/2$. The assumption does *not* hold when $\delta > \alpha/2$, since in this case a codeword of weight δn can be found by solving a system of linear equations.

Despite being a simple and natural cryptographic assumption, we are not aware of any explicit study or even precise formulation of the bSVP assumption in the literature. While we were not able to reduce useful instances of bSVP to any standard cryptographic assumption, we do show that such instances have a "win-win" flavor in the sense that if they are broken, this would necessarily have useful algorithmic consequences. Natural instances of the bSVP assumption are likely to find additional applications in cryptography, and their further study may be of independent interest from both a cryptography and coding theory points of view.

We now give a more detailed account of our results.

Low-complexity CRH

Assuming bSVP for a random linear code with $\delta > 2H_2^{-1}(\alpha)$ (where H_2 denotes the binary entropy function), there are CRH that shrink the input by a constant factor and have a *constant algebraic degree*. We give a direct construction of degree-5 CRH, and then reduce the degree to 3 by using a new optimized randomized encoding construction for constant-degree functions (previous randomized encoding methods from [1] can also reduce the degree to 3, but at the expense of compromising the linear shrinkage feature).

Assuming bSVP for a random low-density parity-check code (LDPC), we can also get *constant output and input locality*, which imply CRH with an arbitrary polynomial shrinkage that can be computed by *linear-size* circuits. The assumption that bSVP holds for LDPCs may look too strong in light of the fact that LDPCs admit efficient decoding algorithms. However, known decoding techniques seem to have only limited relevance to bSVP. Indeed, the known reductions from bSVP to unique decoding introduce exponential overhead (cf. [32]). Moreover, there is a gap between the noise level p for which LDPC's admit efficient decoding and the relative distance Δ of LDPC's which essentially corresponds to our parameter δ. This gap grows with the (constant) locality parameter [23], and the LDPC becomes similar to random linear code both combinatorially [37, 57], and, presumably, in terms of its intractability.[3]

Our constructions take the following natural high level approach. First the input is deterministically encoded into a longer vector that has a low weight. This encoding is done via a simple function Expand that has constant input and output locality. Then the encoded

[3] We further mention that the problem of finding (many) w-weight codewords in LDPC with sub-constant rate (e.g., when the parity check matrix has m rows and $n = O(m^{7/5})$ columns and $w = O(m^{0.2})$) was implicitly considered by Feige, Kim and Ofek [34]. In particular, it was shown that if the problem is easy (for randomly chosen 3-sparse ,matrices) then one can efficiently *refute* random 3-CNF's with m variables and $m^{1.4}$, beating the state-of-the-art refutation algorithms.

input is shrunk by applying a random linear mapping M sampled from $\mathcal{M}$, where M is used as a key specifying the CRH. Finding a collision implies finding a low-weight vector in the kernel of M (namely, the sum of two images of Expand), which is intractable if the appropriate instance of the bSVP assumption holds. A practically-oriented hash function candidate with a similar structure was proposed by Augot et al. [4] (see also [35]). In fact, our degree-5 construction can be obtained as an instance of their construction (with a specific choice of parameters). Our other instantiations of this approach are different and are tailored to different optimization goals.

As an application, our linear-size CRH imply (together with other cryptographic assumptions, cf. [16]) the first succinct non-interactive argument system for NP in which the verifier's algorithm can be implemented by a linear-size circuit in the statement length. They also imply the first linear-size implementations of non-interactive *statistically hiding commitments* (SHC), a randomized variant of CRH that can be used to hide the input. This follows from the known constructions of SHC from CRH [29, 47].

Win-win results

To gain more insight on the instances of the bSVP assumption on which we rely, we show that refuting them would have useful algorithmic consequences. Concretely, we show two types of such results. First, we show that either (1) there is a linearly-shrinking CRH with logarithmic degree (a non-trivial object that does not seem to follow from standard assumptions) or (2) one can achieve an arbitrary polynomial speedup over the celebrated BKW algorithm for Learning Parities with Noise (LPN) [19]. The latter would be considered a breakthrough in light of the large body of work on algorithms for LPN and its variants. Second, we show that breaking useful instances of bSVP, on which a degree-3 linearly-shrinking CRH can be based, leads to a surprisingly good *data structure* for learning parities from random (noiseless) examples in a natural distributed learning model.

Degree-2 hash functions

Finally, we study the case of hash functions that have the minimal possible degree. We first address the case of UOWHFs, showing that a random shrinking degree-2 mapping is a UOWHF assuming that it is one-way. The latter is equivalent to a fairly well studied assumption, known as the "MQ assumption" [59, 73], which asserts that solving a random system of quadratic equations is intractable.

We then show several results on the existence of a degree-2 CRH. We show that a *random* degree-2 shrinking function is not collision resistant, strengthening a claim from [30] that was restricted to the case of linear-shrinkage. This result can be extended to the case of SHC, leaving open the possibility of constructing degree-2 CRH and SHC by using other distributions over degree-2 mappings.

We relate this question to questions on the existence of degree-2 randomized encodings of functions that were left open by [51]. The high level idea is that while for strong version of randomized encoding the existence of degree-2 encodings for general functions can be ruled out, there are relaxed versions for which this question is still open, yet these relaxed versions are strong enough to respect the security properties of CRH and SHC. Thus, ruling out a degree-2 implementation of these primitives would require settling the above open questions in the negative.

Organization

Following some preliminaries (Section 2), in Section 3 we discuss the assumptions on which we rely, including the bSVP assumption we introduce and the MQ assumption. In Section 4 we present constructions of low-complexity CRH from variants of bSVP. In Section 5 we present our positive and negative results for degree-2 hash functions. Finally, in Section 6 we present the "win-win" results showing that if low-complexity CRH do not exist, this has useful algorithmic consequences.

2 Preliminaries

General

We let $[n]$ denote the set $\{1, \ldots, n\}$. We naturally view n-bit strings as (column) vectors over the binary field $\mathbb{Z}_2$. For a pair of strings $x, x' \in \{0,1\}^n$, we let $\Delta(x, x')$ denote the relative Hamming distance between x and x', i.e., $|\{i \in [n] : x_i \neq x'_i\}|/n$. We let $\Delta(x)$ denote the (relative) Hamming weight of x, i.e., $\Delta(x) = \Delta(x, 0^n)$. By default, logarithms are taken to base 2. For real $p \in [0,1]$ we let $H_2(p) := -p\log(p) - (1-p)\log(1-p)$ denote the binary entropy function where $0 \log 0$ is taken to be 0. The inverse of the binary entropy function, $H_2^{-1} : [0,1] \to [0, \frac{1}{2}]$, maps $y \in [0,1]$ to the unique $x \in [0, \frac{1}{2}]$ for which $H_2(x) = y$. It is well known (cf. [44, Chapter 3]) that for every constant $\delta \in (0, 1/2)$

$$2^{nH_2(\delta)-o(n)} \leq \binom{n}{\delta n} \quad \text{and} \quad \sum_{i=1}^{\delta n} \binom{n}{i} \leq 2^{nH_2(\delta)}. \tag{2.1}$$

We also use the following approximation taken from [24, Theorem 2.2]:

$$\frac{x}{2\log(6/x)} \leq H_2^{-1}(x) \leq \frac{x}{\log(1/x)}. \tag{2.2}$$

A function $\epsilon(\cdot)$ is said to be negligible if $\epsilon(k) < k^{-c}$ for any constant $c > 0$ and sufficiently large k. We will sometimes use $\mathrm{neg}(\cdot)$ to denote an unspecified negligible function. The statistical distance between two probability distributions X and Y, denoted $\mathsf{SD}(X;Y)$, is defined as the maximum, over all functions A, of the distinguishing advantage $|\Pr[A(X) = 1] - \Pr[A(Y) = 1]|$. A pair of distribution ensembles $X = \{X_k\}$ and $Y = \{Y_k\}$ is *statistically indistinguishable* if $\mathsf{SD}(X_k; Y_k) \leq \mathrm{neg}(k)$.

Locality and Degree

Let $f : \{0,1\}^k \to \{0,1\}^m$ be a function. We say that the i-th output variable y_i *depends* on the j-th input variable x_j (or equivalently, x_j *affects* the output y_i) if there exists a pair of input strings which differ only on the j-th location whose images differ on the i-th location. The locality of an output variable (resp., input variable) is the number of input variables on which it depends (resp., the number of output variables which it affects). We say that an output has degree d if it can be expressed as a multivariate polynomial of degree d in the inputs over the binary field $\mathbb{Z}_2$. The locality of an output variable trivially upper bounds its degree. The output locality (resp., degree) of f is the maximum output locality (resp., degree) over all outputs of f. Similarly, the input locality of f is the maximal input locality over all inputs of f.

▶ **Definition 1** (Collision-Resistant Hash Functions)**.** A collection of functions

$$\mathcal{H} = \left\{ h_z : \{0,1\}^k \to \{0,1\}^{m(k)} \right\}_{z \in \{0,1\}^{s(k)}}$$

is a *collision-resistance hash* (CRH) function if the following hold:

- (Shrinkage) The output length is smaller than the input length: $m(k) < k$ for every k.
- (Efficient evaluation and sampling) There exists a pair of efficient algorithms: (a) an *evaluation algorithm* H which given $(z \in \{0,1\}^s, x \in \{0,1\}^k)$ outputs $h_z(x)$; and (b) a key-sampling algorithm $\mathcal{K}$ which given 1^k samples an index $z \in \{0,1\}^{s(k)}$.
- (Collision resistance) For every probabilistic polynomial-time adversary Adv it holds that

$$\Pr_{z \xleftarrow{R} \mathcal{K}(1^k)} [\mathsf{Adv}(z) = (x, x') \text{ s.t. } x' \neq x \text{ and } h_z(x) = h_z(x')] \tag{2.3}$$

  is negligible in k.

The *shrinking factor* of $\mathcal{H}$ is the ratio m/k. We say that $\mathcal{H}$ is *linearly shrinking* if m/k is upper-bounded by a constant $c < 1$. Similarly, $\mathcal{H}$ is *polynomially shrinking* if $m/k < 1/k^c$ for some constant $c \in (0,1)$.

The weaker variant of *universal one-way hash function* (UOWHF) [63] is defined by relaxing the third item (collision resistance) with the following requirement (also known as *target collision resistance* [11]):

- (Target collision resistance) For every pair of probabilistic polynomial-time adversaries $\mathsf{Adv} = (\mathsf{Adv}_1, \mathsf{Adv}_2)$ it holds that

$$\Pr_{\substack{(x,r) \xleftarrow{R} \mathsf{Adv}_1(1^k) \\ z \xleftarrow{R} \mathcal{K}(1^k)}} [\mathsf{Adv}_2(z, x, r) = x' \text{ s.t. } x' \neq x \text{ and } h_z(x) = h_z(x')] \leq \mathrm{neg}(k).$$

That is, first the adversary Adv_1 specifies a target string x and a state information r, then a random hash function h_z is selected, and then Adv_2 tries to form a collision x' with x under h_z.

▶ Remark (Measuring efficiency). When saying that a collection $\mathcal{H}$ of hash functions enjoys some level of efficiency we refer to the complexity of *every fixed* function h_z in the collection $\mathcal{H}$. For example, $\mathcal{H}$ has constant output locality of d if every function $h_z \in \mathcal{H}$ has output locality of at most d. A stronger form of efficiency guarantees that given the index z and the input x the function $H(z,x) = h_z(x)$ has the required level of efficiency (e.g., constant locality). Since the index z is selected once and for all we adopt the former (weaker) variant as our default notion. However, some of our constructions also guarantee the stronger form of efficiency.

▶ Remark (Public coins). Our constructions are all in the "public-coin" setting [49], and so they remain secure even if the adversary gets the coins used to sample the index of the collection.

2.1 Randomized Encoding of Functions

Roughly speaking, a *randomized encoding* [51, 1] of a function $f(x)$ is a randomized mapping $\hat{f}(x;r)$ such that for every input x the output distribution $\hat{f}(x;r)$ (induced by a random choice of r) depends only on the output of $f(x)$. Throughout the paper we employ *perfect randomized encoding* as defined below.

▶ **Definition 2** (Perfect Randomized Encoding). Let $f : \{0,1\}^n \to \{0,1\}^m$ be a function. We say that a function $\hat{f} : \{0,1\}^n \times \{0,1\}^\rho \to \{0,1\}^s$ is a *perfect randomized encoding* (PRE) of f if there exists a deterministic decoding algorithm C and a randomized simulator S which satisfy the following:

- (Perfect correctness) For every input $x \in \{0,1\}^n$ and $r \in \{0,1\}^\rho$, it holds that $C(\hat{f}(x;r)) = f(x)$.
- (Perfect privacy) For every $x \in \{0,1\}^n$, the distribution $\hat{f}(x;r)$, induced by a uniform choice of $r \xleftarrow{R} \{0,1\}^\rho$, is identical to the distribution $S(f(x))$.
- (Balanced simulation) The distribution $S(y)$ induced by choosing $y \xleftarrow{R} \{0,1\}^m$ is identical to the uniform distribution over $\{0,1\}^s$.
- (Length preserving) The difference between the output length and the total input length of the encoding $s - (n + \rho)$ is equal to the difference $m - n$ between the output length and the input length of f.

We refer to the second input of $\hat{f}$ as its *random input* and to ρ and s as the *randomness complexity* and *output complexity* of $\hat{f}$, respectively.

The definition naturally extends to collections of functions $\mathcal{F} = \left\{f_z : \{0,1\}^{n(z)} \to \{0,1\}^{m(z)}\right\}_{z\in\{0,1\}^*}$. In particular, we say that $\hat{\mathcal{F}} = \left\{\hat{f}_z : \{0,1\}^{n(z)} \times \{0,1\}^{\rho(z)} \to \{0,1\}^{s(z)}\right\}_{z\in\{0,1\}^*}$ perfectly encodes $\mathcal{F}$ if for every z, $\hat{f}_z$ perfectly encodes f_z. Furthermore, we always assume that the encoding is uniform in the sense that there exists a polynomial-time algorithm which given z outputs a description (say as a boolean circuit) of the encoding $\hat{f}_z$, its decoder C_z and its simulator S_z.

In [1] it is shown that a PRE of a CRH is also CRH.

▶ **Lemma 3** ([1, Lemma 7.2]). *If $\mathcal{H} = \left\{h_z : \{0,1\}^k \to \{0,1\}^m\right\}$ is a CRH then its perfect encoding $\hat{\mathcal{H}} = \left\{\hat{h}_z : \{0,1\}^k \times \{0,1\}^\rho \to \{0,1\}^s\right\}$ is also a CRH, where $\hat{\mathcal{H}}$ is viewed as a collection of single-input functions (of input length $k + \rho$) which uses the key-sampling algorithm of $\mathcal{H}$.*

Observe that if the collection $\mathcal{H}$ has linear-shrinkage and the perfect encoding $\hat{\mathcal{H}}$ has randomness complexity of $O(k)$, then the collection $\hat{\mathcal{H}}$ also has linear shrinkage.

The following proposition follows from [1, Section 4].

▶ **Proposition 4.** Let $f : \{0,1\}^n \to \{0,1\}^\ell$ be a function that each of its outputs can be computed by a formula of size at most t. Then, f can be encoded by a PRE $\hat{f}$ with degree 3, output locality 4, randomness/output complexity of $\ell \cdot \mathrm{poly}(t)$ and input locality of at most $c \cdot \mathrm{poly}(t)$ where c is the input locality of f. In particular, if f has constant output locality then the randomness complexity of $\hat{f}$ is $O(\ell)$, and if, in addition, f has constant input locality, then $\hat{f}$ also has constant input locality.

We will also need two standard closure properties of PREs. First, just like in the case of string-encodings, if we take an encoding $\hat{f}$ of f, and re-encode it by $\hat{\hat{f}}$, then the resulting encoding also encodes the original function f. Second, given an encoding $\hat{f}(y;r)$ of $f(y)$ we can encode a function of the form $f(g(x))$ by encoding the outer function and substituting y with $g(x)$, i.e., $\hat{f}(g(x);r)$. We summarize these properties via the following lemmas (taken from [1, Lemma 4.11] and [2, Fact 3.1]).

▶ **Lemma 5** (Composition lemma). *Suppose that $g(x;r_g)$ is a PRE of $f(x)$ and $h((x,r_g);r_h)$ is a PRE of $g((x,r_g))$ (viewed as a single-argument function). Then, the function $\hat{f}(x;(r_g,r_h)) \triangleq h((x,r_g);r_h)$ is a PRE of f.*

▶ **Lemma 6** (Substitution lemma). *Suppose that the function $\hat{f}(x;r)$ is a PRE of $f(x)$. Let $h(z)$ be a function of the form $f(g(z))$ where $z \in \{0,1\}^k$ and $g : \{0,1\}^k \to \{0,1\}^n$. Then, the function $\hat{h}(z;r) \triangleq \hat{f}(g(z);r)$ is a PRE of h.*

3 Our Assumptions

3.1 The Binary Shortest Vector Problem

In the following the term *matrix sampler* refers to an algorithm $\mathcal{M}$ which, given 1^n, samples $m(n) \times n$ binary matrix for some integer-valued function $m(n)$.

▶ **Definition 7** (binary SVP)**.** For a weight parameter $\delta(n) : \mathbb{N} \to (0, 1/2)$, and an efficient sampler $\mathcal{M}(1^n)$ which samples $m(n) \times n$ binary matrices, the $(\mathcal{M}, \delta)$-bSVP assumption asserts that for every efficient algorithm Adv the probability

$$\Pr_{\mathbf{M} \stackrel{R}{\leftarrow} \mathcal{M}(1^n)} [\mathsf{Adv}(\mathbf{M}) = \mathbf{x} \text{ such that } \mathbf{x} \neq \mathbf{0}, \mathbf{Mx} = \mathbf{0} \text{ and } \Delta(\mathbf{x}) \leq \delta]$$

is negligible in n. If $m(n)/n \leq \alpha(n)$, then we refer to the distribution sampled by $\mathcal{M}$ as (α, δ)-bSVP *hard distribution*.

Using a coding-theoretic terminology, we can think of $\mathcal{M}$ as specifying an ensemble of binary linear codes which are represented by their $m \times n$ parity-check matrices. We will always assume that, except with negligible probability, the rows of $M \stackrel{R}{\leftarrow} \mathcal{M}(1^n)$ are linearly independent and so the code has rate of $1 - m/n$. The binary SVP assumption asserts that it is hard to find a short codeword (of weight at most δ) in a random member of this ensemble. For the purpose of constructing hash functions, we will choose $\delta(n)$ such that a code sampled from $\mathcal{M}(1^n)$ is likely to contain (exponentially) many codewords of weight at most $\delta(n)$ (but such light codewords capture only exponentially-small fraction of all codewords). Intuitively, this setting corresponds to the list-decoding regime of the code.[4] We mention that in the worst case, it is NP-hard to compute the distance of a linear code [72] or even to approximate it by a constant factor [33]. Currently, the best known algorithms run in exponential time (cf. [71, 31, 8, 36, 14, 10]). Let us present the main distributions used in the paper.

3.1.1 The Random Linear Code Ensemble

The ensemble of *random linear codes* is probably the most natural choice for bSVP. Formally, for a length parameter $\alpha(n) : \mathbb{N} \to (0, 1)$ and weight parameter $\delta(n)$, we let (α, δ)-bSVP denote the $(\mathcal{M}, \delta)$-bSVP assumption where $\mathcal{M}(1^n)$ uniformly samples a matrix from $\mathbb{Z}_2^{\lceil \alpha(n) \cdot n \rceil \times n}$. It is well known that a random linear code of rate $R = (1 - \alpha)$ achieves the Gilbert—Varshamov bound (cf. [44]). Specifically, for any constants δ, α for which $\delta < H_2^{-1}(\alpha)$, a uniformly chosen matrix $\mathbf{M} \stackrel{R}{\leftarrow} \mathbb{Z}_2^{\alpha n \times n}$ has no codewords of weight less than δ (except with exponentially small probability $\exp(-\Omega(n))$). Accordingly, we will be interested in the regime where $\delta > H_2^{-1}(\alpha)$. For this regime we make the following simple observations. For simplicity, we restrict our attention to the case where α and δ are constants which do not depend on n.

▶ **Observation 8** (Attack based on linear algebra)**.** *If $\delta > \alpha/2$ the (α, δ)-bSVP assumption does not hold. In particular, there is a polynomial-time algorithm that solves the problem with probability $\frac{1}{2}$.*

Proof. Given $\mathbf{M}$, we can always find a set S of $m(n) = \lceil \alpha n \rceil$ linearly-independent columns which span the column space (since the matrix has only $m(n)$ rows). We can therefore find a solution $\mathbf{x}$ of weight αn to the original system by letting $\mathbf{x}_S$ be the unique vector in the kernel of the restricted matrix $\mathbf{M}_S$, and by letting $\mathbf{x}_{[n] \setminus S}$ be the all zero vector.

[4] In fact, we show that, over random linear codes, a variant of the list-decoding problem reduces to bSVP (see Lemma 29).

To do better, we choose S so that the random variable M_S (induced by M) is a random full rank square matrix (e.g., by choosing the lexicographically-first S). In this case, the (unique) vector $\mathbf{x}_S$ in $\ker(\mathbf{M}_S)$ is uniformly distributed over $\mathbb{Z}_2^{\alpha n}$ and so with probability $\frac{1}{2}$ its relative weight is at most $\frac{1}{2}$. It follows that, with probability $\frac{1}{2}$, the algorithm outputs a vector in the kernel of $\mathbf{M}$ whose Hamming weight is at most $\alpha/2$. ◀

We do not know of any polynomial-time attack for the case $\delta < \alpha/2$.

▶ **Observation 9.** *If (α, δ)-bSVP holds for $\delta > H_2^{-1}(\alpha)$ then one-way functions exist.*

Proof. Let $m(n) = \lceil \alpha n \rceil$. Consider the algorithm S which samples a random $\mathbf{x} \in \mathbb{Z}_2^n$ of weight $\lfloor \delta n \rfloor$ and then samples a random matrix $\mathbf{M} \in \mathbb{Z}_2^{m(n) \times n}$ subject to $\mathbf{M} \cdot \mathbf{x} = \mathbf{0}$. We claim that the mapping f that takes the random coins of the algorithm and outputs $\mathbf{M}$ is one-way. Indeed, assume, towards a contradiction, that the mapping can be inverted efficiently by an adversary Adv with probability ϵ, then, we can break (α, δ)-bSVP by applying Adv on $\mathbf{M} \xleftarrow{R} \mathbb{Z}_2^{m(n) \times n}$, get r, and apply the sampler in the forward direction to recover a solution $\mathbf{x}$.

To analyze the success probability it suffices to show that the distribution sampled by S (on which Adv is promised to succeed) is statistically close to the uniform distribution over $\mathbb{Z}_2^{m(n) \times n}$. Indeed, this follows by noting that (1) S samples the uniform distribution over all matrices whose kernel contains a vector of relative weight δ; and (2) The probability that a uniformly chosen parity-check matrix $\mathbf{M} \xleftarrow{R} \mathbb{Z}_2^{m(n) \times n}$ will not have a vector of weight δ in its kernel is exponentially small (cf. [9]). This completes the proof. ◀

We will later show (Theorem 14) that hardness for $\delta > 2H_2^{-1}(\alpha)$ implies the existence of collision-resistance hash functions. Due to the above attack, this means that the weight parameter δ should be in the interval

$$(2H_2^{-1}(\alpha), \alpha/2).$$

Plugging in the approximation from Eq. (2.2), and letting $\alpha = 2^{-k}$, we conclude that δ should live in the interval

$$(2^{-k+1}/k, 2^{-k-1}),$$

so the ratio between the upper-bound and the lower-bound grows when $\alpha = 2^{-k}$ decreases.

3.1.2 Random LDPC Ensemble

Instead of taking a uniformly-chosen parity-check matrix, one can use an ensemble of Low-Density Parity-Check Codes (LDPC) [37]. Concretely, for constant $\alpha \in (0, 1)$ and constant $d \in \mathbb{N}$ for which $c = \alpha d$ is an integer, we let (d, α, δ)-bSVP denote the $(\mathcal{M}_{\alpha,d}, \delta) - \mathsf{bSVP}$ assumption where $\mathcal{M}_{\alpha,d}(1^n)$ samples a uniformly chosen $\alpha \cdot n \times n$ matrix subject to the constraint that each column contains exactly c ones and each row contains exactly d ones.[5]

This ensemble of codes is well studied in the coding theory literature. Most notably, it is known that, for any fixed α and $d > 2$, a typical code in the ensemble can be efficiently decoded in the presence of constant noise rate of $p(\alpha, d) > 0$ (say over the binary symmetric channel) [37]. So in some regime of parameters, the unique decoding problem over LDPCs

[5] We implicitly restrict our attention to n's for which $(c/d) \cdot n$ is an integer, and, correspondingly, assume hardness only for these input lengths. Nevertheless, since this set of inputs is sufficiently dense, we can derive collision resistant hash functions for all input lengths via standard padding.

can be solved efficiently. Interestingly, for a fixed α, larger sparsity d reduces the noise rate $p(\alpha, d)$ for which known efficient decoding techniques work [23], whereas, combinatorially, when d grows the code becomes better and approaches the performance of a random linear code [37, 57].

Several methods for finding codewords of minimal weight in LDPC's have been proposed (see [48, 50, 74, 53, 32] and references therein). It is typically unknown how to analyze the complexity of these heuristics but an experimental study seems to suggest that the complexity grows exponentially with the distance of the code which is linear in the block length n (see also the discussion in [32]).

Overall, one may conjecture that when sparsity grows the intractability of binary SVP over LDPC codes "approaches" the intractability of SVP over the random linear code ensemble. Specifically, it seems plausible that for some constant α and every $\delta < \alpha/2$ there exists a (sufficiently large) constant d for which (d, α, δ)-bSVP holds.

3.2 Multivariate Quadratic Assumptions

We first define the multivariate quadratic (MQ) assumption that we use in this work.

▶ **Definition 10.** Let $\mathcal{D} = \{\mathcal{D}_{n(\lambda),m(\lambda),p(\lambda)}\}_{\lambda\in\mathbb{N}}$ be an ensemble of probability distributions that output a sequence of $m = m(\lambda)$ *upper triangular* matrices $\mathbf{Q}_1, \ldots, \mathbf{Q}_m \in \mathbb{Z}_p^{n\times n}$ (where we will write p for $p(\lambda)$ and n for $n(\lambda)$ from now on), and m vectors $\mathbf{L}_1, \ldots, \mathbf{L}_m \in \mathbb{Z}_p^n$. The $\mathcal{D}$-multivariate quadratic assumption (which we will refer to simply as the MQ assumption, when the parameter $\mathcal{D}$ is obvious from the context) states that it is computationally hard to find a *non-zero* solution to a given set of m quadratic equations

$$\left\{ q_i(\mathbf{x}) \stackrel{\Delta}{=} \mathbf{x}^T\mathbf{Q}_i\mathbf{x} + \mathbf{L}_i^T\mathbf{x} \stackrel{\Delta}{=} \sum_{j,k\in[n]} q_{i,j,k}x_jx_k + \sum_{j\in[n]} \ell_{i,j}x_j = 0 \pmod p \right\}_{i\in[m]}$$

where $q_{i,j,k}$ are the (j,k)-th entries of the matrix $\mathbf{Q}_i$ and $\ell_{i,j}$ are the j-th entries of the vector $\mathbf{L}_i$.

3.2.1 Previous Work on the MQ Problem

It is well-known that the multivariate quadratic (MQ) problem is NP-hard in the worst case [38]. To the best of our knowledge, the best algorithms for the *random* MQ problem with $m = O(n)$ run in $2^{\Omega(n)}$ time. Kipnis, Patarin and Goubin [55] showed that a random instance of MQ can be solved in polynomial time if $m(n) = O(\sqrt{n})$. Kipnis and Shamir [56] showed that the MQ problem can be solved in polynomial time when $m(n) = \Omega(n^2)$. The hardness of the MQ function for a randomly chosen instance is not known to follow from any well-studied intractability assumption.

Regarding cryptographic usefulness, it is easy to see that the average-case hardness of the MQ problem immediately gives us a one-way function. In the regime where $m > n$, the same assumption also gives us a pseudorandom generator [13].

The early work using the MQ assumption, starting from Matsumoto and Imai [59], focused on the (much) harder task of constructing public-key encryption schemes. The hardness of the MQ problem was necessary but not sufficient for the semantic security of their encryption scheme. Indeed, their proposal was attacked [64, 56] and fixed many times. However, none of the attacks break the MQ assumption, but rather were the result of the additional structure introduced into the assumption to obtain public-key cryptography. We do not go into the details of this long line of work as public-key cryptography is not the focus of our paper.

However, a reader interested in the history of this early work is referred to Christopher Wolf's Ph.D. thesis [73].

Moving on to hashing, the topic of this paper, Aumasson and Meier [5] showed that a *random* and *sparse* degree-2 function is not collision-resistant. Ding and Yang [30] claim that the sparsity condition can be removed, namely that a random degree-2 function with compression level $m(n) = n/2$ is not collision-resistant; however, no formal proof of this claim was provided. (Jumping ahead, we will show that indeed, their intuition was correct and that one can find in polynomial time collisions in the random MQ function with *any* non-trivial compression.) Ding and Yang [30] also conjectured that a random degree-3 function with the same compression level is a CRH. Billet, Robshaw and Peyrin [15] observed that given the difference between a possible colliding inputs of degree-2 function, the collision can be found in polynomial time. This method was first presented by Patarin in [64].

We are not aware of any results on universal one-way hashing from MQ-type assumptions.

4 Hash Functions from the Binary SVP Assumption

4.1 A General Template

We show how to construct CRH based on the bSVP assumption. Our CRH is keyed with a matrix $\mathbf{M} \in \mathbb{Z}_2^{m \times n}$, it first takes an input $\mathbf{x} \in \{0,1\}^k$ and expand it into an n-bit vector $\mathbf{y}$ via some preprocessing mapping Expand, and then compresses $\mathbf{y}$ to an m-bit vector $\mathbf{z}$ by computing $\mathbf{My}$. Formally, the construction has the following structure.

▶ **Construction 11.** Let $n = n(k)$ and $m = m(k)$ be integer valued functions. For a mapping $\mathsf{Expand} : \{0,1\}^k \to \{0,1\}^n$, and a matrix-sampler $\mathcal{M}(1^n)$ which samples $m \times n$ matrices, we define the collection of functions $\mathcal{H}_{k,m} = \{h_{\mathbf{M}} : \{0,1\}^k \to \{0,1\}^m \ : \ \mathbf{M} \in \mathbb{Z}_2^{m \times n}\}$ where

$$h_{\mathbf{M}}(\mathbf{x}) = \mathbf{M} \cdot \mathsf{Expand}(\mathbf{x}),$$

and the key-sampling algorithm $\mathcal{K}(1^k)$ outputs $\mathbf{M} \xleftarrow{R} \mathcal{M}(1^n)$.

We say that a function $\mathsf{Expand} : \{0,1\}^k \to \{0,1\}^n$ is (b,β)-*expanding* if (1) the function is injective; (2) the expansion factor n/k is at most b; and (3) the function outputs strings whose relative Hamming weight is at most β.

▶ **Lemma 12.** *Suppose that Construction 11 is instantiated with a matrix sampler $\mathcal{M}(1^n)$ which samples an (α,δ)-*bSVP *hard distribution and with a (b,β)-expanding algorithm* Expand *where $b\alpha < 1$ and $2\beta \leq \delta$. Then, the resulting collection $\mathcal{H}$ is a collision-resistance hash function with shrinkage factor of $b\alpha$.*

Proof. First observe that since $b\alpha < 1$ the function $h_{\mathbf{M}}$ is shrinking, as required. Next, we show that a collision finder Adv can be used to find a short vector in the kernel of $\mathbf{M}$. Assume, towards a contradiction, that there exists an efficient collision-finder Adv that given an $m(k) \times n(k)$ matrix $\mathbf{M} \xleftarrow{R} \mathcal{K}(1^k)$ outputs a collision $\mathbf{x} \neq \mathbf{x}' \in \mathbb{Z}_2^k$ with non-negligible probability $\epsilon(k)$. We show that the vector $\mathbf{y} = \mathsf{Expand}(\mathbf{x}) \oplus \mathsf{Expand}(\mathbf{x}')$ is (1) non-zero vector (2) it has relative weight of at most δ, and (3) it is in $\ker(\mathbf{M})$. Indeed, (1) follows since Expand is injective, (2) follows since the image of Expand contains only strings whose relative Hamming is at most β and so the vector $\mathbf{y}$ has Hamming weight of at most $2\beta \leq \delta$. Finally, since the pair $(\mathbf{x},\mathbf{x}')$ forms a collision, it holds that $\mathbf{M} \cdot \mathsf{Expand}(\mathbf{x}) = \mathbf{M} \cdot \mathsf{Expand}(\mathbf{x}')$ and therefore (3) follows as well. ◀

In the following we show that one can construct (b, β) expanding algorithm with constant input and output locality (and therefore also with constant degree and linear circuit size). The first part of the lemma optimizes the parameters b and β (and achieves large locality parameters) and the second part optimizes locality (at the expense of a looser relation between b and β).

▶ **Lemma 13.** *For every constant $\beta \in (0, 1/2)$ (weight upper-bound) the following holds.*

1. *For every $b > 1/H_2(\beta)$ there exists an efficiently computable mapping $\mathsf{Expand} : \{0,1\}^k \to \{0,1\}^{n(k)}$ which is (b, β)-expanding for all sufficiently large k's and has constant input locality c and constant output locality d where c and d depend on β and b.*
2. *If β is a power of $1/2$ then there exists an efficiently computable $(b = \frac{1}{\beta \log(1/\beta)}, \beta)$-expanding mapping $\mathsf{Expand}' : \{0,1\}^k \to \{0,1\}^{n(k)}$ with output locality of $\log(1/\beta)$ and input locality of $1/\beta$.*

Note that $b > 1/H_2(\beta)$ is a necessary requirement (otherwise by Eq. (2.1) the image of the mapping contains less than 2^k strings and so it cannot be injective). Therefore, the first part of the lemma achieves an optimal dependency between b and β.

Proof. (1) Without the locality constraint, the algorithm $\mathsf{Expand}_{\beta,b}$ can be easily implemented. Indeed, given an input $x \in \{0,1\}^k$ interpreted as an integer in $[1, 2^k]$, we can output the lexicographically x-th n-bit string of weight w efficiently by computing the output $y \in \{0,1\}^n$ in a bit-by-bit manner. (E.g., compute the number $T = \binom{n-1}{w}$ of n-bit word of weight w that begin with zero, set y_1 to zero if $x < T$ and to 1 otherwise, and continue recursively with the other bits.) Setting $n = \lfloor kb \rfloor$ and $w = \lfloor \beta n \rfloor$, and recalling that, by Eq. (2.1), for $b > 1/H_2(\beta)$ and sufficiently large k, there are more than 2^k strings of length n and weight w, we conclude that the mapping is injective.

To get low locality choose sufficiently large constants c and d such that $1/H_2(\beta) < c/d < b$ and such that $\mathsf{Expand}_{\beta,c/d}$ is injective for inputs of length d. Now partition your k-bit input into k/d-blocks of size d each. Apply $\mathsf{Expand}_{\beta,c/d}$ to each such block of inputs and generate an output block of length at most c. Output the concatenation of all k/d output blocks. By definition, the mapping has the desired expansion and locality. The (b, β)-expansion property is inherited from the original $\mathsf{Expand}_{\beta,c/d}$ algorithm.

(2) The procedure Expand' works as follows: It splits the k input bits into blocks of size $\log(1/\beta)$ bits. For each block $\mathbf{z} \in \{0,1\}^{\log(1/\beta)}$, compute a block $\mathbf{z}' \in \{0,1\}^{1/\beta}$ which is 1 in exactly the $\mathbf{z}^{th}$ location. It is easy to check that the output length n is $\frac{k}{\beta \log(1/\beta)}$ and that its Hamming weight is $\frac{k}{\log(1/\beta)} = \beta n$, as required. It is also clearly injective and can be computed with output locality of $\log(1/\beta)$ and input locality of $1/\beta$. ◀

4.2 Degree-3 CRH

Based on Lemmas 12 and 13, we prove the following theorem.

▶ **Theorem 14.** *Suppose that there exist constants $\delta \in (0, 1/4), \alpha \in (0, 1)$ with $\delta > 2H_2^{-1}(\alpha)$ and an efficient matrix sampler $\mathcal{M}$ which samples some (α, δ)-bSVP hard distribution. Then, there exists a linearly shrinking CRH with constant degree.*

Proof. Fix δ and α and take $\beta = \delta/2$ and $b \in (1/H_2(\beta), 1/\alpha)$ (the interval is non-empty due to the requirement $\delta > 2H_2^{-1}(\alpha)$). Instantiate Construction 11 with the matrix sampler $\mathcal{M}$ and the (b, β)-expanding mapping Expand promised in item 1 of Lemma 13. Then, by Lemma 12, we derive a linearly-shrinking CRH with constant degree. ◀

Our next goal is to turn the above construction into a degree-3 CRH with linear shrinkage. To this end, we show that the CRH constructed in Theorem 14 admits a degree-3 perfect randomized encoding that uses only linear amount ($O(k)$) of random bits.

▶ **Lemma 15.** *Let $h(\mathbf{x})$ be a function of the form $\mathbf{M} \cdot g(\mathbf{x})$ where $g : \mathbb{Z}_2^k \to \mathbb{Z}_2^n$ is an NC^0 function and $\mathbf{M}$ is an $m \times n$ matrix of full rank with $m < n$. Then, h can be perfectly encoded by a degree-3 function with randomness complexity of $O(n)$.*

Recall that any function can be perfectly encoded by a degree-3 encoding (Proposition 4), however the randomness complexity of the best known general transformations grows polynomially with the total size of the formulas (or branching programs) that compute the output bits of the encoded function. Such a blowup will give us only sub-linear shrinkage. The lemma bypasses this problem by introducing a new randomness-efficient degree-3 encoding which is tailored to the structure of the CRH constructed in Theorem 14.

Proof. Let $\ell = n - m$ and take $\mathbf{L} \in \mathbb{Z}_2^{n \times \ell}$ to be a matrix which spans the kernel of $\mathbf{M}$. We begin by observing that the function h is perfectly encoded by the function

$$\hat{h}(\mathbf{x}; \mathbf{r}) = g(\mathbf{x}) + \mathbf{L}\mathbf{r},$$

where $\mathbf{r} \in \mathbb{Z}_2^\ell$. Indeed, given $\mathbf{z} = \hat{h}(\mathbf{x}; \mathbf{r})$ we can decode $h(\mathbf{x})$ by computing $\mathbf{M} \cdot \mathbf{z}$. On the other direction, given $\mathbf{y} = h(\mathbf{x})$ we can perfectly simulate $\mathbf{z} = \hat{h}(\mathbf{x}; \mathbf{r})$ by sampling a random preimage of $\mathbf{y}$ under $\mathbf{M}$. Since $\mathbf{M}$ has full rank, the resulting simulator is balanced. Finally, the encoding is stretch preserving since the output-input difference $n - (k + \ell)$ of $\hat{h}$ equals to $m - k$, the output-input difference of h.

Next consider the NC^0 function $f(\mathbf{x}, \mathbf{y})$ which takes $\mathbf{x} \in \mathbb{Z}_2^k$ and $\mathbf{y} \in \mathbb{Z}_2^n$ and outputs $g(\mathbf{x}) + \mathbf{y}$. By Proposition 4, f can be perfectly encoded by a degree-3 encoding $\hat{f}(\mathbf{x}, \mathbf{y}; r')$ with randomness complexity of $O(ns^2) = O(n)$.

Finally, observe that the function $\hat{h}(\mathbf{x}; \mathbf{r})$ can be written as $f(\mathbf{x}, \mathbf{L}\mathbf{r})$. Therefore, by the substitution lemma (Lemma 6), the function $e(\mathbf{x}, \mathbf{r}; r') \triangleq \hat{f}(\mathbf{x}, \mathbf{L}\mathbf{r}; r')$ perfectly encodes the function $\hat{h}(\mathbf{x}, \mathbf{r})$. Hence, by the composition lemma (Lemma 5), the function $e(\mathbf{x}; \mathbf{r}, r')$ perfectly encodes h. Noting that e has degree 3 and randomness complexity of $O(n+\ell) = O(n)$, the lemma follows. ◀

Recall that we always assume that a hard-bSVP-distribution puts all but a negligible fraction of its mass on matrices whose columns are linearly independent. Hence, we can apply Lemma 15 to the CRH constructed in Theorem 14, and derive, by Lemma 3, the following improved version of Theorem 14.

▶ **Theorem 16.** *Under the hypothesis of Theorem 14, there exists a linearly shrinking CRH with degree 3.*

Instantiating bSVP with the random linear code ensemble, we derive the following corollary.

▶ **Corollary 17.** *Suppose that there exist constants $\delta \in (0, 1/4), \alpha \in (0, 1)$ which satisfy $\delta > 2H_2^{-1}(\alpha)$ for which $(\alpha, \delta) - \mathsf{bSVP}$ holds. Then, there exists a degree-3 linearly-shrinking CRH.*

Corollary 17 serves as a feasibility result for the existence of degree-3 CRH with linear shrinkage. This statement attempts to optimize the parameters of the underlying intractability assumption (making it as plausible as possible) and the degree, but yields a poor (constant) shrinkage factor. By iterating the CRH a sufficiently large (constant) number of times, we

can reduce the shrinkage factor to an arbitrary constant ϵ at the expense of increasing the degree to a large constant $d = d(\epsilon)$. Alternatively, we can get a better tradeoff between the degree and the shrinkage factor by strengthening the assumption as follows.

▶ **Proposition 18.** Suppose that $(\alpha, \delta)-\mathsf{bSVP}$ holds for every constants $\delta \in (0, 1/4), \alpha \in (0, 1)$ which satisfy $\delta < \alpha/2$. Then, for every constants $d > 4$ and $\gamma > 4/d$ there exists a degree-d CRH with shrinkage factor of γ.

For example, we can get a degree 5 CRH with shrinkage-factor of 0.81 or degree-8 CRH with shrinkage factor of 0.51.

Proof. Let $\beta = 2^{-d}$ and recall that item 2 of Lemma 13 provides a (b, β)-expanding mapping Expand' with $b = \frac{1}{\beta \log(1/\beta)} = 2^d/d$ and output locality (and therefore also degree) of $\log(1/\beta) = d$. Let $\delta = 2\beta = 2^{-d+1}$ and $\alpha = \gamma/b$. Since $\gamma > 4/d$, it follows that $\delta < \alpha/2$, which, according to our assumption, implies that $(\alpha, \delta) - \mathsf{bSVP}$ holds. By plugging Expand' and the matrix-sampler that samples uniform $\alpha n \times n$ matrices into Construction 11, we get, by Lemma 12, a degree-d CRH with shrinkage factor of γ. The proposition follows. ◀

▶ Remark. Recall that we measure the degree of a collection of functions $H = \{h_z\}$ as the maximal degree of each function in the collection and ignore the degree of the evaluation algorithm H which maps the collection key z and the input x to $h_z(x)$. (See Remark 2.) Nevertheless, it is not hard to see that all the constructions of this section admit an evaluation algorithm of constant degree. (In fact, the degree is $d + 1$ where d is the degree of h_z).

4.3 Locally-Computable CRH

Our next goal is to construct CRH's with constant output and input locality. To this end, we instantiate bSVP with the LDPC ensemble.

▶ **Theorem 19.** *Suppose that there exist constants $\delta \in (0, 1/4), \alpha \in (0, 1)$ with $\delta > 2H_2^{-1}(\alpha)$ and a constant $d \in \mathbb{N}$ for which $(d, \alpha, \delta) - \mathsf{bSVP}$ holds. Then, there exists a linearly-shrinking CRH with constant input locality and constant output locality. Moreover, one can reduce the output locality to 4 (while keeping the shrinkage linear and the input locality constant).*

Proof. Fix δ and α and take $\beta = \delta/2$ and $b \in (1/H_2(\beta), 1/\alpha)$. Let Expand be the (b, β)-expanding mapping promised in item 1 of Lemma 13 which has input locality of c' and output locality d'. Instantiate Construction 11 with Expand and with the LDPC matrix sampler $\mathcal{M}$ which samples a uniformly chosen $\alpha \cdot n \times n$ matrix subject to the constraint that each column contains exactly $c = \alpha d$ ones and each row contains exactly d ones. Then, by Lemma 12, we derive CRH $\mathcal{H} = \{h_{\mathbf{M}}\}$ with linear shrinkage, output locality of $D = d \cdot d'$ and input locality of $C = c \cdot c'$. This proves the first part of the theorem.

For the second part, take the CRH $\mathcal{H} = \left\{h_z : \{0,1\}^k \to \{0,1\}^m\right\}$ constructed in the first part of the theorem, and apply the 4-local perfect encoding promised in Proposition 4. The resulting collection $\hat{\mathcal{H}}$ has the required syntactic properties, and, by Lemma 3, it forms a CRH. ◀

Since any NC^0 function can be computed by a circuit of linear size, Theorem 14 yields a linear-time computable CRH with linear-shrinkage. Such a function can be turned into a linear-time computable CRH with arbitrary polynomial-stretch (using a hash-tree), we therefore derive the following corollary.

▶ **Corollary 20.** *Under the assumption of Theorem 19, for every constant $c < 1$ there exists a CRH $\mathcal{H} = \left\{h_z : \{0,1\}^k \to \{0,1\}^{k^c}\right\}$ which can be computed by a circuit of size $O(k)$.*

5 Degree-2 Hash Functions

In Section 5.1, we construct a universal one-way hash function family under the MQ assumption (see Definition 10 for the definition of the $\mathcal{D}_{n,m,p}$-MQ assumption). We then turn our attention to collision-resistance. In Section 5.2, we show that a natural family of uniformly random quadratic functions is *not* collision-resistant, by showing an explicit polynomial-time attack. An intriguing question left open by our work is the existence of a degree-2 CRH family. In Section 5.3, we show how this question (and a related question on statistically hiding commitments) relates to a long-standing question on constructing degree-2 randomized encodings.

5.1 Universal One-way Hash Function

▶ **Construction 21.** Let λ be the security parameter, and let $n = n(\lambda)$, $m = m(\lambda)$, $p = p(\lambda)$ (with $m < n$) be the MQ parameters. Let the MQ distribution $\mathcal{D} = \mathcal{D}_{n,m,p}$ be the uniform distribution that outputs a set of m uniformly random upper-triangular matrices $\mathbf{Q}_i$ and m vectors $\mathbf{L}_i$.

Define the family of hash functions $\mathcal{H}_{n,m,p} = \{h_{\vec{\mathbf{Q}},\vec{\mathbf{L}}} : \mathbb{Z}_p^n \to \mathbb{Z}_p^m \ : \ \vec{\mathbf{Q}} \in (\mathbb{Z}_p^{n\times n})^m,\ \vec{\mathbf{L}} \in (\mathbb{Z}_p^n)^m\}$ as follows:

$$h_{\vec{\mathbf{Q}},\vec{\mathbf{L}}}(\mathbf{x}) = \left(\mathbf{x}^T\mathbf{Q}_i\mathbf{x} + \mathbf{L}_i^T\mathbf{x}\right)_{i=1}^{m}$$

We now show that under the MQ assumption, this family is universal one-way.

▶ **Theorem 22.** *Let $n = n(\lambda)$, $m = m(\lambda)$, $p = p(\lambda)$ and $\mathcal{D}_{n,m,p}$ be such that (a) $m < n$ and (b) $\mathcal{D}_{n,m,p}$ is the uniform distribution. Then, under the $\mathcal{D}_{n,m,p}$-MQ assumption, the family $\mathcal{H}_{n,m,p}$ is universal one-way.*

The construction and proof immediately generalize to other families of distributions where the distribution of $\mathbf{Q}_i$ is arbitrary but $\mathbf{L}_i$ is still uniformly random. In this exposition, we choose to present the simpler version where both $\mathbf{Q}_i$ and $\mathbf{L}_i$ are uniformly random.

Proof. First, since $m < n$, $\mathcal{H}_{n,m,p}$ is a compressing family of functions.

We now show that it is universally one-way. Assume that there is a PPT UOWHF-breaker algorithm $(\mathsf{Adv}_1, \mathsf{Adv}_2)$. We will construct an algorithm $\mathcal{B}$ that breaks the $\mathcal{D}$-MQ assumption. $\mathcal{B}$ gets as input an MQ challenge $(\mathbf{Q}_i, \mathbf{L}_i)_{i=1}^m$ and does the following.

- Run Adv_1 to get a target input $\mathbf{x}$ and state information r.
- Define the UOWHF family using the matrices $\mathbf{Q}_i^*$ and $\mathbf{L}_i^*$ where:

$$\mathbf{Q}_i^* = \mathbf{Q}_i \text{ and } \mathbf{L}_i^* = \mathbf{L}_i - (\mathbf{Q}_i^* + (\mathbf{Q}_i^*)^T)\mathbf{x} \tag{5.1}$$

- Feed $\vec{\mathbf{Q}} := (\mathbf{Q}_1^*, \ldots, \mathbf{Q}_m^*)$ and $\vec{\mathbf{L}} := (\mathbf{L}_1^*, \ldots, \mathbf{L}_m^*)$ to Adv_2 together with the state information r. Get back a colliding input $\mathbf{y}$, output $\mathbf{y} - \mathbf{x}$ and halt.

First note that the distribution of $\mathbf{Q}_i$ and $\mathbf{L}_i$ from equation 5.1 are uniformly random and hence, the adversary $\mathsf{Adv} = (\mathsf{Adv}_1, \mathsf{Adv}_2)$ will find a colliding input $\mathbf{y}$ with non-negligible probability $1/q(\lambda)$.

Let $\Delta := \mathbf{y} - \mathbf{x}$. Since $\mathbf{x}$ and $\mathbf{y}$ are colliding inputs, we have

$$(\mathbf{x}+\Delta)^T\mathbf{Q}_i^*(\mathbf{x}+\Delta) + (\mathbf{L}_i^*)^T(\mathbf{x}+\Delta) = \mathbf{x}^T\mathbf{Q}_i^*\mathbf{x} + (\mathbf{L}_i^*)^T\mathbf{x}$$

for all $i \in [m]$. A quick calculation then tells us that

$$\Delta^T\mathbf{Q}_i\Delta + \Delta^T\mathbf{Q}_i\mathbf{x} + \mathbf{x}^T\mathbf{Q}_i\Delta + (\mathbf{L}_i^*)^T\Delta = \Delta^T\mathbf{Q}_i\Delta + \left(\mathbf{x}^T\mathbf{Q}_i^T + \mathbf{x}^T\mathbf{Q}_i + (\mathbf{L}_i^*)^T\right)\Delta = 0$$

which in turn gives us

$$\Delta^T\mathbf{Q}_i\Delta + \mathbf{L}_i^T\Delta = 0 \ ,$$

by our definition of $\mathbf{L}_i := \mathbf{L}_i^* + (\mathbf{Q}_i^* + (\mathbf{Q}^*)^T)\mathbf{x}$. Thus, $\mathcal{B}$ outputs a solution to the challenge MQ instance with probability $1/p(\lambda)$ as well, which shows that $\mathcal{H}_{n,m,p}$ is a universal one-way hash family. ◀

Generalizing to Other MQ Distributions

Our proof readily generalizes to distributions for the MQ problem which output an arbitrary distribution of the quadratic forms $\mathbf{Q}_i$ and a uniformly random distribution of the linear forms $\mathbf{L}_i$.

Generalizing to Larger Degrees

Our construction and proof also generalize to the setting where the hash function has degree d and can be based on the hardness of solving random degree-d polynomial equations, a generalization of the MQ assumption. The reason for considering this generalization is to achieve better shrinkage. The MQ construction can shrink n bits to no less than $m = \sqrt{n}$ bits, since the MQ assumption is false for smaller m. Since we do not know attacks against the degree-d assumption with shrinkage $m = n^{\Omega(1/d)}$, this variant will give us larger shrinkage at the expense of larger degree (and a different assumption).

5.2 Finding Collisions in Random Degree-2 Functions

We now show that the hash function family $\mathcal{H}_{n,m,p}$ is *not* collision-resistant. We remind the reader that $\mathcal{H}_{n,m,p}$ refers to the function where $\mathbf{Q}_i$ are uniformly random upper-triangular matrices and $\mathbf{L}_i$ are uniformly random vectors. The attack we describe below was discovered by Ding and Yang [30] but without a proof of correctness.

▶ **Theorem 23.** *For every $n, m < n$ and p, there is a* $\mathsf{poly}(n, m, \log p)$*-time algorithm* ColFinder *such that*

$$\Pr_{h \leftarrow \mathcal{H}_{n,m,p}}[\mathsf{ColFinder}(h) = (\mathbf{x}, \mathbf{y}) : \ h(\mathbf{x}) = h(\mathbf{y}) \wedge \mathbf{x} \neq \mathbf{y}] = \Omega(1)$$

In other words, the family $\mathcal{H}_{n,m,p}$ is not collision-resistant.

Proof. The strategy of ColFinder is simple. It chooses a uniformly random $\Delta \in \mathbb{Z}_p^n$ and solves the system of equations

$$\left\{ \ (\mathbf{x}+\Delta)^T\mathbf{Q}_i(\mathbf{x}+\Delta) + \mathbf{L}_i^T(\mathbf{x}+\Delta) = \mathbf{x}^T\mathbf{Q}_i\mathbf{x} + \mathbf{L}_i^T\mathbf{x} \ \right\}_{i\in[m]}$$

This is in fact a linear system of equations in the unknown $\mathbf{x}$:

$$\left\{ \ \mathcal{L}_i : \mathbf{x}^T(\mathbf{Q}_i^T + \mathbf{Q}_i)\Delta + \mathbf{L}_i^T\Delta = 0 \ \right\}_{i\in[m]}$$

where all computations are done mod p. Any solution $\mathbf{x}$ to this system of linear equations gives us a collision $(\mathbf{x}, \mathbf{x} + \Delta)$. Conversely, if there exists a collision with difference Δ, ColFinder will find such a collision.

It remains to show that for uniformly random upper-triangular matrices $\mathbf{Q}_i$ (and possibly uniformly random Δ and $\mathbf{L}_i$), this system has a solution with high probability. We show a stronger statement: namely, that the n-by-m matrix $\widetilde{\mathbf{Q}}$ defined as

$$\widetilde{\mathbf{Q}} = \begin{bmatrix} | & \vdots & | \\ (\mathbf{Q}_1^T + \mathbf{Q}_1)\Delta & \vdots & (\mathbf{Q}_m^T + \mathbf{Q}_m)\Delta \\ | & \vdots & | \end{bmatrix}$$

has full rank, namely rank m a constant probability. This in turn implies that the equations $\mathcal{L}_i$ are guaranteed to have a solution with constant probability.

Let us now bound the probability that $\widetilde{\mathbf{Q}}$ has rank less than m. To do so, let us understand the distribution of $\widetilde{\mathbf{Q}}$ using the following observations.

- Fix an $i \in [m]$ be such that $\Delta_i \neq 0$. Such an i is guaranteed to exist as $\Delta \neq \mathbf{0}$.
  We now claim that for each $j \in [m]$, the entries of $(\mathbf{Q}_j + \mathbf{Q}_j^T)\Delta$ are uniformly random except possibly for the i-th entry. This follows from the fact that the i-th column of $(\mathbf{Q}_j + \mathbf{Q}_j^T)$ is uniformly random (except for its i-th entry) and uncorrelated to the rest of the matrix except the i-th row (which is identical to the i-th column by symmetry).
- This implies, in turn, that $\widetilde{\mathbf{Q}}$ has a uniformly random $(n-1)$-by-m submatrix. The probability that this is full-rank, namely rank $\mathsf{min}(n-1, m) = m$, is a constant (see, e.g., [17]).

Put together, we see that ColFinder succeeds with constant probability in finding a collision. We remark that this argument did not use the randomness of $\mathbf{L}_i$ or Δ, but rather only the fact that the $\mathbf{Q}_i$ are uniformly random upper-triangular matrices. ◀

5.3 Degree-2 CRH via Randomized Encoding?

An intriguing question left open by our work is the existence of a degree-2 CRH. The same question is open also for the related primitive of non-interactive statistically hiding commitments (SHC), which can be easily constructed from a CRH (see Appendix A). We relate these questions to questions about the existence of degree-2 statistically private randomized encodings that were left open by [51].

We start by defining a relaxation of the perfect notion of randomized encoding from Definition 2 that allows for statistical privacy error and eliminates the balanced simulation and length requirements.

▶ **Definition 24** (Statistically-Private, Perfectly Correct Randomized Encoding)**.** Let $f : \{0,1\}^n \to \{0,1\}^m$ be a function. We say that a function $\hat{f} : \{0,1\}^n \times \{0,1\}^\rho \to \{0,1\}^s$ is an *ϵ-private, perfectly correct randomized encoding* (ϵ-RE) of f if there exists a deterministic decoding algorithm C and a randomized simulator S which satisfy the following:

- (Perfect correctness.) For every input $x \in \{0,1\}^n$ and $r \in \{0,1\}^\rho$, it holds that $C(\hat{f}(x;r)) = f(x)$.
- (ϵ-privacy) For every $x \in \{0,1\}^n$, the distribution $\hat{f}(x;r)$, induced by a uniform choice of $r \xleftarrow{R} \{0,1\}^\rho$, satisfies $\mathsf{SD}(\hat{f}(x;r), S(f(x))) \leq \epsilon$, where SD denotes statistical distance.

For the dual notion of ϵ-correct, perfectly-private RE, it is shown in [51] that only very special functions admit such an encoding with a degree-2 $\hat{f}$ (in the Boolean case, this class

of functions includes only degree-2 polynomials in the input and functions that test whether the input is in an affine subspace of $\{0,1\}^n$). It is open whether the same holds for the above notion of ϵ-RE.

▶ **Question 25.** Does every finite $f : \{0,1\}^n \to \{0,1\}$ admit a family of degree-2, ϵ_t-private, perfectly correct randomized encodings $\hat{f}_t : \{0,1\}^n \times \{0,1\}^{\rho_t} \to \{0,1\}^{s_t}$ with $\epsilon_t = \text{neg}(t)$ and $\rho_t, s_t = \text{poly}(t)$?

This question is open even for the specific function $f : \{0,1\}^4 \to \{0,1\}$ defined by $f(a,b,c,d) = abc \oplus d$ and even with fixed ϵ (say $\epsilon = 1/3$). In fact, it follows from [1] that the latter function is complete in the sense that an affirmative answer to Question 25 for this function implies an affirmative answer for all functions.

We show that an affirmative answer to Question 25 together with standard cryptographic assumptions would imply the existence of a degree-2 SHC. Thus, ruling out such an SHC would effectively require settling Question 25 in the negative.

A (non-interactive) SHC is defined by a collection $C_z(x,\sigma)$, which given a public random string z (that can be reused for many commitments) maps an input x and secret randomness σ to a commitment c. The commitment c should statistically hide x. It should also be *computationally binding* in the sense that given z it is infeasible to find a pair (x,σ) and (x',σ') which are consistent with the same c, where $x \neq x'$. See Appendix A for a formal definition.

▶ **Theorem 26.** *Suppose there is a CRH or SHC in* NC^1*. Moreover, suppose that the answer to Question 25 is affirmative. Then there is a degree-2 SHC.*

Proof. Using Theorem 37, a CRH in NC^1 implies an SHC in NC^1, which in turn implies an SHC $C_z(x,\sigma)$ in NC^0 [1]. Since every output bit of $C_z(x,\sigma)$ depends on a constant number of input bits, we can apply the degree-2 encoding implied by an affirmative answer to Question 25, independently to every output bit of C_z and with $t = |x|$, viewing it as a deterministic function of (x,σ). This yields a polynomial-size degree-2 function $\hat{C}_z(x,\sigma;\tau)$ which is an ϵ-RE of C_z with ϵ negligible in $k = |x|$. We view $\hat{C}_z$ as a commitment scheme with input x and secret randomness (σ,τ). The perfect correctness requirement of the ϵ-RE implies that $\hat{C}_z$ is computationally binding (since if $(x,(\sigma,\tau))$ and $(x',(\sigma',\tau'))$ violate the binding of $\hat{C}_z$ then (x,σ) and (x',σ') violate the binding of C_z). The statistical hiding property is implied by the fact that the error ϵ of the ϵ-RE is negligible in the input length. Indeed, for every $x \neq x'$ we have

$$\hat{C}_z(x;\sigma,\tau) \approx S_z(C_z(x;\sigma)) \approx S_z(C_z(x';\sigma)) \approx \hat{C}_z(x';\sigma,\tau),$$

where σ,τ are uniformly distributed, $\approx$ denotes statistical indistinguishability, and S_z is the simulator of the encoding. ◀

For the case of CRH, even an affirmative answer to Question 25 does not seem to suffice for a degree-2 construction, since an ϵ-RE of a CRH may lose the shrinking property. Instead, we formulate an ad-hoc variant of randomized encoding that captures a minimal set of requirements needed for respecting the CRH properties.

▶ **Definition 27** (CRH-Respecting Randomized Encoding)**.** Let $f : \{0,1\}^n \to \{0,1\}^m$ be a function with $m < n$. We say that a function $\hat{f} : \{0,1\}^n \times \{0,1\}^\rho \to \{0,1\}^s$ is a *CRH-respecting randomized encoding* of f if the following hold:

- (Perfect correctness.) There exists a deterministic decoding algorithm C such that for every input $x \in \{0,1\}^n$ and $r \in \{0,1\}^\rho$, it holds that $C(\hat{f}(x;r)) = f(x)$.

- (Injective randomness) For any fixed x, the function $\hat{f}(x;\cdot)$ is injective; namely for any $r \neq r'$ we have $\hat{f}(x;r) \neq \hat{f}(x;r')$.
- (Shrinkage) The encoding $\hat{f}(x;r)$ is shrinking, namely $s < n + \rho$.

Note that given the perfect correctness and injective randomness requirements, the best one can hope for is to match the shrinkage of f, namely the shortest possible encoding output is of size $s = \rho + m$. If the shrinkage requirement of Definition 27 is strengthened to require this optimal shrinkage, the definition becomes equivalent to the notion of PRE from Definition 2 [1]. In particular, perfect privacy is implied by the perfect correctness, injective randomness, and optimal shrinkage.

On the other hand, even the relaxed requirements of Definition 27 *do* imply some weak form of "average-case privacy." Indeed, if the input x could always be recovered from $\hat{f}(x,r)$, then injective randomness guarantees that r can also be recovered, and since $s < n + \rho$ we get a contradiction. Thus, the notion of CRH-respecting randomized encoding crudely has the same flavor of perfect correctness and partial privacy as the notion of ϵ-RE from Definition 24.

We now show that applying a CRH-respecting randomized encoding to a CRH indeed yields a CRH. (We use concrete function notation instead of infinite collections of functions for simplicity.)

▶ **Claim 1.** *Suppose $h_z : \{0,1\}^n \to \{0,1\}^m$ is a CRH and $\hat{h}_z : \{0,1\}^n \times \{0,1\}^\rho \to \{0,1\}^s$ is an efficient, CRH-respecting randomized encoding of h_z. Then the function $\hat{h}_z$, viewed as a mapping from $n + \rho$ input bits to s output bits, is a CRH.*

Proof. First, the shrinkage requirement directly guarantees that $\hat{h}$ is shrinking its input (x,r). We show that $\hat{h}$ inherits the collision resistance of h. Suppose that $\mathsf{Adv}(z)$, given a random z, finds a collision $(x,r),(x,r')$ for $\hat{h}_z$, where $(x,r) \neq (x',r')$. By the injective randomness requirement we must have $x \neq x'$ and by perfect correctness we must have $h(x) = h(x')$. Hence, Adv can be used to find a collision (x,x') for h with the same success probability. ◀

Finally, we pose a concrete question about the existence of CRH-respecting randomized encodings which is related to the existence of degree-2 CRH.

▶ **Question 28.** Does every $f : \{0,1\}^n \to \{0,1\}^{\lfloor n/10 \rfloor}$ in NC^0 admit (an efficiently computable) degree-2 CRH-respecting randomized encoding?

Under the assumptions of Theorem 19, ruling out a degree-2 CRH would require proving a negative answer to Question 28.

6 Win-Win Results

In this section we prove that a failure of our constructions leads to interesting algorithmic consequences. Both of our results are based on the following observation.

▶ **Lemma 29.** *Suppose that there exists an algorithm Adv with complexity T for which*

$$\Pr_{\mathbf{M} \xleftarrow{R} \mathbb{Z}_2^{m \times n}} [\mathsf{Adv}(\mathbf{M}) = \mathbf{x} \text{ such that } \mathbf{x} \neq \mathbf{0}, \mathbf{M}\mathbf{x} = \mathbf{0} \text{ and } \Delta(\mathbf{x}) \leq \delta] \geq \epsilon.$$

Then there exists an algorithm Adv' with complexity $T' = T + \mathrm{poly}(m)$ such that for every $\mathbf{y} \in \mathbb{Z}_2^m$ it holds

$$\Pr_{\mathbf{M} \xleftarrow{R} \mathbb{Z}_2^{m \times n}} [\mathsf{Adv}'(\mathbf{M}, \mathbf{y}) = \mathbf{x} \text{ such that } \mathbf{M}\mathbf{x} = \mathbf{y} \text{ and } \Delta(\mathbf{x}) \leq \delta] \geq \epsilon/2.$$

That is, an algorithm Adv that finds a small subset of the columns of $\mathbf{M}$ that spans the all-zero vector, can be transformed into an algorithm Adv′ that finds a small subset of the columns that spans *any* given target vector $\mathbf{y}$.

Proof. The algorithm Adv′ is given a random matrix $\mathbf{M} \stackrel{R}{\leftarrow} \mathbb{Z}_2^{m\times n}$ and an arbitrary target vector $\mathbf{y} \in \mathbb{Z}_2^m$. It samples a vector $\mathbf{u} \stackrel{R}{\leftarrow} \mathbb{Z}_2^n$ and calls Adv with the input $\mathbf{M}' = \mathbf{M} + \mathbf{y} \cdot \mathbf{u}^T$ (note that this is an outer-product). Note that if the output $\mathbf{x}$ of Adv is (1) a valid solution (i.e., it is a non-zero vector of weight at most δn and is in the Kernel of $\mathbf{M}$); and (2) is non-orthogonal to $\mathbf{u}$ (i.e., $\langle \mathbf{x}, \mathbf{u}\rangle = 1$), then $\mathbf{Mx} = \mathbf{Mx} + (\mathbf{y} \cdot \mathbf{u}^T)\mathbf{x} = \mathbf{y}$ and so Adv′ succeeds.

To analyze the success probability, note that the joint distribution of $(\mathbf{M}, \mathbf{u})$ is uniform and therefore (1) happens with probability ϵ, by assumption. Moreover, conditioned on (1), the probability of (2) is exactly $\frac{1}{2}$. The lemma follows. ◀

6.1 bSVP and Distributed Parity-Learning

In this section we show that if the bSVP assumption (as phrased in Corollary 17) does not hold, one can learn parities in a distributed setting with non-trivial memory/communication tradeoffs. The influence of memory and communication restrictions on learning in distributed environments has been studied recently by several works (cf. [6, 68, 70, 67] and references therein). We consider here another variant of this question.

Let us first recall the standard notion of PAC-learning parity functions over uniformly sampled examples. For a secret parity function f_s (s is an m-bit vector), the learner is given random (non-noisy) labeled samples of the form (r_i, b_i) where $r_i \stackrel{R}{\leftarrow} \mathbb{Z}_2^m$ is a random example and $b_i = f_s(r_i) = \langle r_i, s\rangle$ is a binary label. The goal is to predict f_s on a random vector $r^* \stackrel{R}{\leftarrow} \mathbb{Z}_2^m$ with probability, say, 2/3. We consider the case where the learner is composed of two parties: a measurement device W that collects the samples and has only limited memory of S bits and no computational power, and an analyst A who runs in polynomial-time and, given r^*, attempts to predict $f_s(r^*)$. We assume that A sees the vectors r_i's but can access a bit b_i only by reading it from W's memory.[6] Our goal is to minimize the number of bit probes that A makes (subject to the given memory bound S).

In the following we think of a memory-bound of $S = cm$ for some $c > 1$. In this case, W can store cm labels $(b_1, \ldots, b_S)$ and A can trivially achieve a communication of m bits by finding an m-size subset $R' \subset R \stackrel{\Delta}{=} \{r_1, \ldots, r_m\}$ of linearly-independent examples and ask for the corresponding labels. At this point A can recover s and compute $f_s(r^*)$. In fact, A can reduce the communication to $m/2$: first write r^* as a linear combination $\sum v_i R'_i$ of the vectors in R', then ask only for the b_i for which $v_i \neq 0$, and finally compute $f_s(r^*)$ by $\sum v_i b_i$. It is not hard to show (similarly to Observation 8) that the expected communication is $m/2$. More generally, the analyst A can achieve a communication of w bits if she can write the challenge vector r^* as a w-weight linear combination of the example vectors R. As shown in Lemma 29, this problem reduces to the bSVP problem. In particular, we prove the following lemma.

[6] This captures a scenario where the inputs r_i are public (e.g., generated by some environment) but only the measurement device gets to see how the function reacts to it and measure $f_s(r_i)$. We mention that the results of this section carry over (with minor adaptations) to a setting where the r_i's are only given to W.

▶ **Lemma 30.** *Given an efficient algorithm B that solves the $(\alpha, \delta) - \mathsf{bSVP}$ problem with probability $2/3$ there exists an efficient algorithm that solves the distributed parity-learning problem with memory limitation of m/α and with $m(\delta/\alpha)$ bit probes.*

Proof. The analyst A is given a random matrix of examples $R \xleftarrow{R} \mathbb{Z}_2^{m \times S}$, where $S = m/\alpha$, and a random challenge $r^* \xleftarrow{R} \mathbb{Z}_2^m$. It calls the algorithm B' promised in Lemma 29 with input R and target vector r^*. If the algorithm succeeds (which happens with probability $1/3$), the analyst gets a vector v of weight δS for which $Rv = r^*$, and can predict $f_s(r^*)$ using $\delta S = m(\delta/\alpha)$ bit probes. Otherwise, the analysis outputs a random bit. The overall success probability is $\geq 1/3 + 2/3 \cdot (1/2) = 2/3$, as required. ◀

Recall that in Corollary 17 we showed that if there exist constants $\delta \in (0, 1/4), \alpha \in (0, 1)$ with $\delta > 2H_2^{-1}(\alpha)$ for which $(\alpha, \delta) - \mathsf{bSVP}$ holds, then degree-3 linearly-shrinking CRH exist. Using standard amplification techniques, one can prove a similar result even under the assumption that $(\alpha, \delta) - \mathsf{bSVP}$ cannot be solved in polynomial time with probability better than $2/3$.[7] Overall, by combining this with Lemma 30 and the approximation of the inverse entropy function from Eq. (2.2), we conclude the following "win-win" result.

▶ **Corollary 31.** *At least one of the following holds:*

- *There exists a degree-3 linearly-shrinking CRH.*
- *For any constant $c > 1$ and any $\gamma > (2/\log c)$, the distributed parity problem can be solved efficiently with memory-bound of cm and γm bit probes for infinitely many m.*

Note that the bit probe rate γ tends to zero when c grows – we are not aware of any efficient solution which achieves such a dependency.

6.2 Speeding-up the BKW algorithm

We move on to the more traditional setting of *learning parity with noise* (LPN) [18]. Recall that in this setting the learner is given random noisy labeled samples of the form (r_i, b_i) where $r_i \xleftarrow{R} \mathbb{Z}_2^m$ is a random example and $b_i = f_s(r_i) + \chi_i$ is a binary label where f_s is a parity function (specified by a secret $s \in \{0,1\}^m$) and χ_i is a random variable which takes the value 1 with probability τ for some noise parameter $\tau \in (0, \frac{1}{2})$. The learner should be able to recover s with, say, probability $2/3$ while minimizing the running time and the sample complexity.[8]

The best known algorithm for solving the LPN problem (i.e., to recover s), due to Blum, Kalai and Wasserman [19], runs in time (and sample) complexity of $2^{O(m/\log m)}$. We show that either the complexity can be reduced to $2^{cm/\log m}$ for arbitrary small constant $c > 0$, or linearly-shrinking CRH of logarithmic degree exist. To this end, we consider the bSVP assumption (for random linear codes) in the polynomial regime, i.e., when the number of columns n is polynomially larger than the number of rows m.

---

[7] Indeed, by plugging the weaker assumption in our construction, we get a linearly-shrinking degree-3 "weak"-CRH in which the probability of finding collisions (as defined in Eq. (2.3)) is at most $2/3$ as opposed to negligible. Such a CRH can be amplified into standard CRH while preserving the degree and the linear-shrinkage by expanding the k-bit input x into an $O(k)$-bit vector y via a linear (fixed) error correcting code and then shrinking y down to $(1-\epsilon)k$-long vector, by applying independent copies of the weak CRH to distinct blocks of size $\sqrt{k}$, see [25] for further details. (In fact, one can even get a locality-preserving transformation [3, Lemma 5.7].)

[8] Again, we could define the goal as predicting the value $f_s(r^*)$ for random r^* with non-trivial success probability. However, in this setting the two goals reduces to each other with polynomial overhead.

▶ **Assumption 32.** There exists a positive constant $a > 1$ for which (α, δ)-bSVP holds for $\alpha = 1/n^{1/a}$ and $\delta = 8\alpha/(\log(1/\alpha))$.

The constant 8 in the above is somewhat arbitrary and any constant larger than 2 suffices. It will be useful to state the above assumption in terms of the parameter m (and not n as usual). That is, the assumption asserts that, given a random $m \times (n = m^a)$ binary matrix $\mathbf{M}$, it is hard to find a vector of weight $w = \delta n = \frac{8m}{(a-1)\log m}$ in the kernel of M. Note that, unlike in the previous sections, now the dimensions of the matrix are polynomially related (and not linear) and correspondingly we can ask for a kernel vector of sub-linear weight.

▶ **Lemma 33.** *Suppose that Assumption 32 does not hold. Then, for every constant $c > 0$ and constant noise rate $\tau \in (0, \frac{1}{2})$ there exists an algorithm that for infinitely many m's, solves the m-dimensional LPN problem with noise rate τ (i.e., recovers the secret s) in time (and sample complexity) of $N = poly(m) \cdot 2^{cm/\log m}$.*

Proof. We describe an algorithm that in time N computes s_1, the first bit of s, with probability 2/3. Using standard amplification, and by exploiting the symmetry of the LPN problem, such an algorithm can be converted to an algorithm that recovers s with, say, probability 2/3 at the expense of increasing the time and sample complexity by a factor of $q(m)$ for some fixed (universal) polynomial $q(\cdot)$. (First reduce the error below $1/3m$ via repetition and majority vote, and then apply the amplified algorithm m times where in each iteration we recover the i-bit of s by rotating the examples $i-1$ coordinates to the left.)

Let $a > 1$ be a constant whose value will be determined later, and let $w = \frac{8m}{(a-1)\log m}$. Since Assumption 32 does not hold, there exists, by Lemma 29, a polynomial-time algorithm Adv_a such that for infinitely many m's, for all $\mathbf{y} \in \mathbb{Z}_2^m$

$$\Pr_{\mathbf{M} \xleftarrow{R} \mathbb{Z}_2^{m \times m^a}} [\mathsf{Adv}_a(\mathbf{M}, \mathbf{y}) = \mathbf{x} \text{ such that } \mathbf{Mx} = \mathbf{y} \text{ and } \mathbf{x} \text{ has Hamming weight of at most } w],$$

is larger than some inverse polynomial $\epsilon(m)$.

Let $n = m^a$, $\mu = 1 - 2\tau$, $t = O(\mu^{2w})$ and $t' = O(t/\epsilon)$. The algorithm asks for nt' labeled examples and partitions them into t' sets T_i each of n examples. For each set T_i, let S_i denote the set of examples without their noisy labels. We apply Adv_a to S_i and set the target vector $\mathbf{y}$ to be the first unit vector $\mathbf{e}_1$. If Adv_a succeeds (i.e., returns a subset $S_i' \subseteq S_i$ of size $\frac{bm}{\log m}$ whose sum is $\mathbf{e}_1$) then we XOR together the labels that correspond to the vectors in S_i' and record the result as a vote v_j (which serves as a guess for s_1). If the algorithm fails, we do not record the vote. Finally, we output the majority of all recorded votes v_j.

Analysis: First we claim that each recorded vote is correct (equals to s_1) independently with probability $1/2 + \mu^w$. Indeed, each vote is of the form $s_1 + \sum_{i=1}^{w} \chi_i$ where the χ_i's are independent Bernoulli variables each with expectation τ. It is well known (e.g., [19, Lemma 4]) that $\chi = \sum_{i=1}^{w} \chi_i$ is a Bernoulli random variable with expectation of $(1 - \mu^w)/2$ for $\mu = 1 - 2\tau$.

Next, we argue that, except with probability 1/10, there is a large number of votes. Indeed, each invocation of Adv_a succeeds with at least ϵ probability hence, by Markov's inequality, the probability that there are less than t successful invocations out of, say $t' = 10t/\epsilon$ attempts, is at most 1/10.

Finally, conditioned on having t votes, by a Chernoff bound, the probability that the final outcome is wrong is 1/10. The claim follows by a union bound.

Overall, the time complexity of the algorithm is

$$O(nt') = O(m^a \cdot (1-2\tau)^{\frac{20m}{(a-1)\log m}}) = O(m^a \cdot e^{\frac{8m}{\tau(a-1)\log m}}),$$

where e is the natural exponent. Hence, we get the desired running time by taking $a = a(\tau, c)$ to be a sufficiently large constant. ◀

Next we show that if Assumption 32 holds then we get CRH of logarithmic degree.

▶ **Lemma 34.** *Under Assumption 32, there exists a linearly-shrinking CRH with logarithmic degree.*

Proof. Let $a > 1$ be the constant promised by Assumption 32 and let $\alpha = \frac{1}{n^{1/a}}$, $\delta = \frac{8\alpha}{\log(1/\alpha)}$. Also, let

$$d = \log(2/\delta) = \log(n^{1/a}) + \log\log(n^{1/a}) - 2, \quad \beta = 2^{-d},$$

$$b = \frac{2^d}{d} = \frac{n^{1/a}\log(n^{1/a})}{4(\log(n^{1/a}) + \log\log(n^{1/a}) - 2)}.$$

We instantiate Construction 11 with the (α, δ)-bSVP sampler and with the (b, β)-expanding mapping promised in the second item of Lemma 13. (This part of the lemma holds for non-constant β as well.) Since $\beta \leq \delta/2$ and $b\alpha < 1/4$, we get, by Lemma 12, a linearly shrinking CRH with degree of $d = O(\log n)$. The lemma follows. ◀

We conclude the following corollary.

▶ **Corollary 35.** *At least one of the following holds:*

- *There exists a linearly-shrinking CRH with logarithmic degree.*
- *For any constant $c > 0$ and any constant noise rate $\tau \in (0, \frac{1}{2})$ there exists an algorithm that, for infinitely many m, solves the m-dimensional LPN problem with noise rate τ in time and sample complexity of $poly(m) \cdot 2^{cm/\log m}$.*

7 Conclusions and Open Questions

Under plausible intractability assumptions, we establish the existence of low-complexity cryptographic hash functions that compress the input by (at least) a constant factor. In particular, we construct CRH with linear circuit size, constant locality, or algebraic degree 3 over $\mathbb{Z}_2$ under different flavors of the newly introduced binary SVP (bSVP) assumption. We also establish connections with other problems that either support our assumptions or indicate that further progress may be difficult.

While we provide some evidence supporting the validity of the flavors of bSVP we rely on, including a weak connection with the LPN problem, it is left open to obtain a better understanding of the relation between bSVP and LPN or other well studied cryptographic assumptions. It would also be interesting to obtain similar positive results under better or incomparable assumptions, such as the MQ assumption (that we use to construct degree-2 UOWHFs) or the one-wayness of random local functions (used in [3] for constructing local UOWHFs).

Our work leaves open several other natural questions. One such question is the existence of CRH (or even 2-message statistically hiding commitments) with degree 2 or output locality 3. Another is the maximal achievable compression of a degree-d CRH: The bSVP-based security analysis of our construction can only support a constant compression factor, which seems unlikely to be optimal. (In contrast, for *linear-size* CRH we can provide an arbitrary polynomial compression.) A final question is to understand the collision resistance properties of *random* degree-d mappings. While we rule out collision resistance for $d = 2$ with any non-trivial compression, the question is wide open for $d \geq 3$. It would be interesting to study the maximal compression (if any) for which a random degree-d mapping can be a CRH.

Acknowledgement. We thank Zvika Brakerski for participating in an earlier stage of this project. We also thank David Burstein, Simon Litsyn, Ronny Roth, Ohad Shamir, and David Woodruff for helpful discussions.

A Statistically Hiding Commitments

In this section we define a non-interactive notion of *statistically hiding commitments* (SHC), which can be viewed as a randomized version of CRH that achieves an input hiding property. We then show that positive results for CRH apply also to the case of SHC.

Similarly to a CRH, an SHC is defined by a public random string z (which can be reused for many commitments). The string z defines a mapping from an input x and secret randomness σ to a commitment string c. The commitment c should statistically hide x. It should also be *computationally binding* in the sense that given z it is infeasible to find a pair (x, σ) and (x', σ') which are consistent with the same c, where $x \neq x'$. We formalize these requirements below.

▶ **Definition 36** (Statistically Hiding Commitment)**.** A collection of functions

$$\mathcal{C} = \left\{ C_z : \{0,1\}^k \times \{0,1\}^{\rho(k)} \to \{0,1\}^{m(k)} \right\}_{z \in \{0,1\}^{s(k)}}$$

is a (non-interactive) *statistically hiding commitment* (SHC) if the following hold:

- (Efficient evaluation and sampling) There exists a pair of efficient algorithms: (a) a *commitment algorithm* C which given $(z \in \{0,1\}^s, x \in \{0,1\}^k, \sigma \in \{0,1\}^\rho)$ outputs $C_z(x, \sigma)$; and (b) a key-sampling algorithm $\mathcal{K}$ which given 1^k samples a index $z \in \{0,1\}^{s(z)}$.
- (Statistical hiding) For every pair of inputs $x, x' \in \{0,1\}^k$ we have

  $$\mathsf{SD}((z, C_z(x, \sigma)), (z, C_z(x', \sigma))) \leq \mathrm{neg}(k),$$

  where SD denotes statistical distance, z is picked by $\mathcal{K}(1^k)$, and σ is picked uniformly from $\{0,1\}^{\rho(k)}$.
- (Computational binding) For every probabilistic polynomial-time adversary Adv it holds that

  $$\Pr_{z \xleftarrow{R} \mathcal{K}(1^k)} [\mathsf{Adv}(z) = ((x, \sigma), (x', \sigma')) \text{ s.t. } x' \neq x \text{ and } C_z(x, \sigma) = C_z(x', \sigma')] \leq \mathrm{neg}(k).$$

As in the case of CRH, we consider the efficiency of SHC for any fixed public challenge z, namely z defines a function of x and s. This is justified by the fact that the same z can reused.

We now show a simple transformation of a CRH into an SHC using a randomness extractor [29, 47]. The high level idea is to apply a CRH to a secret random input α, and then mask the SHC input with randomness extracted from α. Since the CRH shrinks the input, there is residual entropy in α even when conditioned on the output of the CRH.

▶ **Theorem 37.** *Suppose* $\mathcal{H} = \left\{ h_z : \{0,1\}^k \to \{0,1\}^{m(k)} \right\}_{z \in \{0,1\}^{s(k)}}$ *is a CRH, where* $m(k) = \lfloor (1-c)k \rfloor$ *for some constant* $0 < c < 1$. *Let* $\mathsf{Ext}_k : \{0,1\}^k \times \{0,1\}^d \to \{0,1\}^{\lfloor ck/3 \rfloor}$ *be a strong* $(ck/2, \epsilon)$ *randomness extractor with error* $\epsilon(k) = \mathrm{neg}(k)$.
Then $\mathcal{C} = \left\{ C_z : \{0,1\}^{k'} \times \{0,1\}^{k+d} \to \{0,1\}^{m(k)} \right\}_{z \in \{0,1\}^{s(k)}}$, *where* $k(k')$ *is chosen such that* $\lfloor ck/3 \rfloor = k'$ *and* $C_z(x', (\alpha, \beta)) = (h_z(\alpha), \beta, x' \oplus \mathsf{Ext}_k(\alpha, \beta))$ *for* $\alpha \in \{0,1\}^k$ *and* $\beta \in \{0,1\}^d$, *is an SHC.*

Implementing Ext by a random linear function, the SHC obtained in Theorem 37 has the same algebraic degree as the underlying CRH. Moreover, if Ext is implemented by the linear-size pairwise independent hash function from [52], the SHC additionally maintains

the asymptotic circuit size of the CRH. Thus, we get a linear-size (degree-3) SHC under the assumptions of Theorem 19.

Unlike the case of CRH, there is no shrinkage requirement for SHC, hence a degree-3 SHC with locality 4 is implied by the existence of any SHC or CRH in NC^1, which is in turn implied by most standard cryptographic assumptions [1]. However, the existence of degree-2 SHC is left open. Using Theorem 37, a degree-2 SHC would be implied by the existence of a degree-2 CRH, which is one of the main questions left open by this work.

Hierarchical Functional Encryption*†

Abstract

Functional encryption provides fine-grained access control for encrypted data, allowing each user to learn only specific functions of the encrypted data. We study the notion of *hierarchical* functional encryption, which augments functional encryption with *delegation* capabilities, offering significantly more expressive access control.

We present a *generic transformation* that converts any general-purpose public-key functional encryption scheme into a hierarchical one without relying on any additional assumptions. This significantly refines our understanding of the power of functional encryption, showing that the existence of functional encryption is equivalent to that of its hierarchical generalization.

Instantiating our transformation with the existing functional encryption schemes yields a variety of hierarchical schemes offering various trade-offs between their delegation capabilities (i.e., the depth and width of their hierarchical structures) and underlying assumptions. When starting with a scheme secure against an unbounded number of collusions, we can support *arbitrary* hierarchical structures. In addition, even when starting with schemes that are secure against a bounded number of collusions (which are known to exist under rather minimal assumptions such as the existence of public-key encryption and shallow pseudorandom generators), we can support hierarchical structures of bounded depth and width.

1 Introduction

The rapidly evolving vision of functional encryption [49, 15, 48] offers tremendous flexibility when accessing encrypted data. Specifically, functional encryption schemes support restricted decryption keys that allow users to learn specific functions of the encrypted data and nothing else. Motivated by the early examples of functional encryption schemes for specific functionalities (such as identity-based encryption [51, 13, 27]), extensive research has recently been devoted to the study of functional encryption (see, for example, [49, 15, 48, 38, 3, 9, 19, 30, 37, 5, 53, 32, 7, 22, 42, 21] and the references therein).

In a functional encryption scheme, a trusted authority holds a master secret key known only to the authority. When the authority is given the description of some function f as input, it uses its master secret key to generate a functional key sk_f associated with the function f. Now, anyone holding the functional key sk_f and an encryption of any message x, can compute $f(x)$ but cannot learn any additional information about the message x. Such fine-grained access to encrypted data is extremely useful for a wide variety of applications, including expressive access control, spam filtering, mining encrypted databases, and more (we refer the reader to the survey by Boneh, Sahai and Waters [16] for an in-depth discussion of these applications).

Hierarchical functional encryption. Motivated by the applicability of functional encryption to expressive access-control systems, in this paper we study the notion of *hierarchical* functional encryption, which was introduced by Ananth, Boneh, Garg, Sahai and Zhandry [4]. The hierarchical notion augments standard functional encryption with delegation capabilities, enabling significantly more expressive access control.

Specifically, recall that in a functional encryption scheme, the holder of the master secret key msk can generate a functional key sk_f corresponding to any given function f. In a hierarchical functional encryption scheme, the holder of any such functional key sk_f can in turn generate a functional key $\mathsf{sk}_{g\circ f}$ corresponding to the function $g \circ f$ for any given function g. Now, anyone holding the delegated functional key $\mathsf{sk}_{g\circ f}$ and an encryption of any message x, can compute $(g \circ f)(x) = g(f(x))$ but cannot learn any additional information about the message x. Such expressive delegation capabilities give rise to *hierarchical* access control, which is a sought-after ingredient in modern access control systems. In particular, the notion of hierarchical functional encryption generalizes those of hierarchical attribute-based encryption, hierarchical identity-based encryption and more (see the discussion at the end of Section 3 on the delegation capabilities of functional encryption).

Ananth et al. formalized a notion of security for hierarchical functional encryption schemes, and sketched how the functional encryption scheme of Garg et al. [30] can be transformed into a hierarchical one by using a general-purpose indistinguishability obfuscator [8, 30].[1] Their approach, however, is both tailored to the specific functional encryption scheme of Garg et al. [30], and can only support hierarchical structures of *constant* depth (i.e., can only support a constant number of successive delegations).[2]

[1] It was recently shown by Ananth and Jain [6] and by Bitansky and Vaikuntanathan [10] that indistinguishability obfuscation can be constructed from some flavors of functional encryption. Specifically, from *succinct* functional encryption with *sub-exponential security*. Our approach is both more direct and requires no such properties.

[2] In the hierarchical scheme of Ananth et al. [4], a delegated functional key $\mathsf{sk}_{g\circ f}$ for the function $g \circ f$ is

1.1 Our Contributions

We present a *generic transformation* that converts any general-purpose public-key functional encryption scheme into a hierarchical one without relying on any additional assumptions (and, in particular, without relying on indistinguishability obfuscation). Our transformation allows instantiations based both on unbounded-collusion functional encryption schemes and on bounded-collusion ones. This level of generality yields a variety of hierarchical schemes based on various assumptions in the standard model. These include strong assumptions such as indistinguishability obfuscation [30, 53] or multilinear maps [32], and much milder assumptions such as learning with errors [37], and even the existence of any public-key encryption scheme and low-depth pseudorandom generator [38].

We stress that our result stands even if it turns out that indistinguishability obfuscation is impossible to achieve or requires strong computational assumptions. One could view it as evidence that the hierarchical properties do not stem from the "obfuscation-like" features of functional encryption, but rather from the more rudimentary properties that are achievable under minimal assumptions.

Security and efficiency. In terms of security, the schemes resulting from our transformation guarantee semi-adaptive security. Moreover, by assuming that the underlying functional encryption scheme is sub-exponentially secure, we obtain adaptive security via a standard complexity leveraging argument. In terms of efficiency, our approach results in keys and ciphertexts with a rather low overhead compared to the efficiency of the underlying functional encryption scheme. A ciphertext in our scheme is essentially a ciphertext of the underlying scheme. A delegated functional key for $g \circ f$ contains two functional keys for functions that essentially compute f and g, respectively, in addition to some basic cryptographic computation (an evaluation of a PRF, and an encryption of a ciphertext of the underlying scheme). We refer the reader to the overview below for more details on the security and efficiency of the schemes resulting from our approach.

Instantiations. The variety of schemes resulting from our transformation offer different trade-offs between their underlying assumptions and their delegation capabilities (i.e., the depth and width of the hierarchical structures that they support). For example, instantiating our transformation with the schemes of Garg et al. [30] and Waters [53] results in hierarchical schemes that support hierarchical structures of any polynomial depth and any polynomial width (where these polynomials do not have to be specified in advance). In addition, instantiating our transformation with the schemes of Goldwasser et al. [37] or Gorbunov et al. [38] results in hierarchical schemes that support hierarchical structures of any constant depth and any pre-determined polynomial width. This should be compared to the hierarchical scheme of Ananth et al. [4] that is constructed from the specific functional encryption scheme of Garg et al. [30], and can only support hierarchical structures of *constant* depth, and to the alternative hierarchical scheme in this work (see Section 1.3) that is constructed based on even stronger assumptions and still requires an a-priori bound on the depth of the support hierarchical structures. We refer the reader to Table 1 for a comparison of the assumptions underlying the known hierarchical functional encryption schemes and of their supported hierarchical structures.

computed from sk_f by applying the obfuscator to a program that contains sk_f as part of its description. Thus, since sk_f itself consists of such an obfuscated program, this allows for only a constant number of successive delegations.

Table 1 A comparison of the assumptions underlying the known hierarchical functional encryption schemes and of their supported hierarchical structures. We note that indistinguishability obfuscation ($i\mathcal{O}$) is known to imply unbounded-collusion functional encryption [53], which in turn clearly implies bounded-collusion functional encryption. In addition, bounded-collusion functional encryption is implied by much milder assumptions such as learning with errors [37], and even the existence of any public-key encryption scheme and low-depth pseudorandom generator [38].

Assumption	**Hierarchical Structure**	
	Depth	**Width**
$i\mathcal{O}$ [4]	Constant	Unbounded
Sub-exponentially-secure $i\mathcal{O}$ and sub-exponentially-secure HIBE (this work [25])	Any fixed polynomial	Unbounded
Unbounded-collusion FE (this work [23])	Unbounded	Unbounded
Bounded-collusion FE (this work [23])	Constant	Any fixed polynomial

1.2 Overview of Our Approach

Formally, a hierarchical FE scheme contains the standard $(\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ algorithms, in addition to a new *delegation* algorithm $\mathsf{Delegate}$. The delegation algorithm $\mathsf{Delegate}(\mathsf{hsk}_f, g)$ is identical in syntax to the KG algorithm, except that it takes a functional key hsk_f (which can itself be the output of a previous delegation) instead of the master secret key msk. Its output is a key $\mathsf{hsk}_{g\circ f}$ corresponding to the composed function $g \circ f$.

Indeed, the way we implement this functionality is by associating a unique master secret key with any delegable functional key. Namely, a delegable key hsk_f (with respect to the master key pair $(\mathsf{msk}, \mathsf{mpk})$) will contain a fresh master secret key msk' in addition to a "standard" functional key for a re-encryption function $\mathsf{sk}_{\mathsf{ReEnc}_{f,\mathsf{mpk}'}}$ (the key pair $(\mathsf{msk}', \mathsf{mpk}')$ is generated using the standard setup procedure). The function $\mathsf{ReEnc}_{f,\mathsf{mpk}'}(x)$, intuitively, takes an input x and outputs a *functional encryption* of $f(x)$ under the new key mpk'. It is obvious that since msk' is a part of hsk_f, then the owner of $\mathsf{hsk}_f = (\mathsf{sk}_{\mathsf{ReEnc}_{f,\mathsf{mpk}'}}, \mathsf{msk}')$ can derive $f(x)$ itself if it so desires. The beauty of this procedure is that it can then be repeated. If hsk_f needs to be delegated via $\mathsf{Delegate}(\mathsf{hsk}_f, g)$, then one only needs to generate a new pair $(\mathsf{msk}'', \mathsf{mpk}'')$, use msk' to obtain $\mathsf{sk}'_{\mathsf{ReEnc}_{g,\mathsf{mpk}''}}$ and output $\mathsf{hsk}_{g\circ f} = (\mathsf{sk}_{\mathsf{ReEnc}_{f,\mathsf{mpk}'}}, \mathsf{sk}'_{\mathsf{ReEnc}_{g,\mathsf{mpk}''}}, \mathsf{msk}'')$. In the decryption process, we start with some $\mathsf{ct} = \mathsf{FE.Enc}_{\mathsf{mpk}}(x)$, use the first component of the key to obtain $\mathsf{ct}' = \mathsf{FE.Enc}_{\mathsf{mpk}'}(f(x))$, and then using the second component to obtain $\mathsf{ct}'' = \mathsf{FE.Enc}_{\mathsf{mpk}''}(g(f(x)))$. Finally, msk'' is used to decrypt ct'' and thus learn the value $g(f(x))$.

Care needs to be taken in order to securely realize the above intuition. In particular, one has to come up with a source of randomness for the re-encryption process. This is done by slightly modifying the encryption algorithm of the hierarchical scheme such that $\mathsf{Enc}(\mathsf{mpk}, x) = \mathsf{FE.Enc}(\mathsf{mpk}, (x, K, \perp))$, where K is a key to a puncturable pseudorandom function PRF, and $\perp$ is a placeholder that will only be used in the proof. Similarly, we will generate functional keys of the form $\mathsf{sk}_{\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}}$, where t is a random tag and c is a random string that will be used in the proof. The function $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}(x, K, \perp)$ will compute $f(x)$ and encrypt the tuple $(f(x), K', \perp)$ under msk' using randomness r'. The randomness for the generation of K' and r' is produced by evaluating $\mathsf{PRF}_K(t)$.

For the sake of our security proof, one last addition is made to the description of $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}$. If its input is of the form $(\cdot,\cdot,\mathsf{k})$, where k is a key for a symmetric encryption scheme, then the first two arguments are ignored and $\mathsf{SKE.Dec}_{\mathsf{k}}(c)$ is output. Thus we implement a "trapdoor circuit" (or a "Trojan") as per [29, 5].

Security notion. The notions of security that we consider in this work are those formalized by Ananth et al. [4]. Specifically, we consider adversaries that obtain functional keys for various functions of their choice by issuing key-generation queries and delegation queries. We require that such adversaries have only a negligible advantage in distinguishing the encryptions of two challenge messages, x_0^* and x_1^*, of their choice as long as for any function f for which they obtain a functional key it holds that $f(x_0^*) = f(x_1^*)$, where such a key may be produced either as a result of a key-generation query or a delegation query (we refer the reader to Section 3 for more details).

We prove that if the underlying scheme $\mathcal{FE}$ is selectively secure then the resulting hierarchical scheme is selectively secure, and if $\mathcal{FE}$ is semi-adaptively secure then the resulting hierarchical scheme is semi-adaptively secure.[3] We leave it as an intriguing open problem to design a hierarchical functional encryption scheme that guarantees adaptive security. We note that already in the less-expressive setting of identity-based encryption, designing adaptively-secure hierarchical schemes is extremely challenging. In particular, Lewko and Waters [46] recently showed why known proof methods fall short of proving adaptive security even for adaptively-secure hierarchical identity-based encryption (which is a special case of hierarchical FE) without degrading exponentially with the number of delegation levels.

Proof overview. Let us focus on the case of selective security, semi-adaptive security follows by a practically identical argument. In the selective security game, the adversary first specifies challenge messages x_0^* and x_1^*, receives mpk, and then makes a sequence of key-generation and delegation queries. One could visualize the structure that is generated by these queries as a tree, whose root is $(\mathsf{msk},\mathsf{mpk})$ and whose nodes are the key pairs that are generated upon each call to KG or $\mathsf{Delegate}$. Each such call generates a new child for one of the nodes in the tree, as per the adversary's choice. Each node is associated with a function f which was input to $\mathsf{KG}/\mathsf{Delegate}$ in its creation, and also with a function $\tilde{f}$, which is the composition of all functions from the root to that node. If $\tilde{f}(x_0^*) = \tilde{f}(x_1^*)$ then we say that the node is *observable*, since the adversary is allowed to see the functional key $\mathsf{hsk}_{\tilde{f}}$ associated with that node. We can assume w.l.o.g that all the leaves of the tree are observable.

The high-level intuition of the proof is the following. Let us pretend that ReEnc is actually capable of outputting a re-encrypted ciphertext which is encrypted with true randomness, rather than with pseudorandomness. Now, consider an unobservable node i (i.e., a node corresponding to f_i and $\tilde{f}_i$ for which $\tilde{f}_i(x_0^*) \neq \tilde{f}_i(x_1^*)$) that only has observable children. This means that all functions $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}$ that are generated relative to this node's msk_i will output the same value whether the challenge ciphertext is an encryption of x_0^* or of x_1^*. The security of the underlying scheme will guarantee that the re-encrypted ciphertext cannot be used to distinguish x_0^* from x_1^*. Let us take another leap of faith and pretend that

[3] We briefly remind the reader the differences between selective, semi-adaptive, and adaptive security. *Selective* security considers adversaries that specify their challenge messages before seeing the public parameters or making any key queries. *Semi-adaptive* security, as recently defined by Chen and Wee [26], considers adversaries that specify their challenge messages after seeing the public parameters but before making any key queries. Finally, *adaptive* security considers adversaries that specify their challenge messages even after seeing the public parameters and making key queries.

not only the re-encrypted ciphertext cannot distinguish x_0^* from x_1^* but it is in fact identical in both cases. Then the above process can propagate towards the root of the tree, where at every step we increase the number of nodes whose output is the same regardless of whether the challenge ciphertext encrypts x_0^* or x_1^*. Once this process gets all the way to the root and applied to the challenge ciphertext itself, the proof is complete.

This intuition is implemented using the mechanisms of punctured programming [50] and "trapdoor circuits" [29] (or "Trojans" [5]). We will replace the c values in $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}$ with symmetric encryptions of our "fantasy ciphertexts" (ones that are encrypted with true randomness), and append the challenge ciphertext with the appropriate symmetric decryption key (in fact, multiple symmetric keys will be needed, one for every level of the hierarchy, and one has to carefully control their propagation along the tree). Puncturable PRFs will be used to argue that the use of fantasy ciphertexts is indistinguishable from the actual output of $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}$, which will allow the proof idea from above to go through. This requires a careful and delicate argument since we can only puncture a PRF key that had been generated with fresh randomness, hence one has to also consider fantasy PRF keys and propagate them along the tree as well together with the fantasy ciphertexts. The formal proof thus contains many fine points and a large number of steps, and is provided in Section 4.

1.3 The Multi-Authority Setting and an Alternative Hierarchical Scheme

While above, we have focused on the question of delegating functional keys to other parties, a closely related problem is that of achieving functional encryption in the context of multiple key-issuing authorities. In Multi-Authority Functional Encryption (MAFE), we allow n authorities to "independently" generate their private and public keys. An encryptor should be able to encrypt a message m along with a policy F over the various authorities. Any authority i, should be able to generate a token for a user with identity UID and property U_i. A user with identity UID with tokens for U_i from authority $i \in [n]$, should be able to decrypt the ciphertext to recover $F(U_1, .., U_n, m)$. We require that colluding users, say UID_1 and UID_2, (possibly, in collusion with some corrupt authorities) should not jointly learn anything more from the ciphertext than what they are authorized to.

Our main construction idea is natural – we view a ciphertext as an obfuscated program and functional keys as signatures generated with respect to each authority's unique public key. To elucidate this main idea, let us first analyze the problem in a single authority scenario. The starting point of our construction is a construction of a functional encryption scheme due to [19] based on *differing-inputs obfuscation* (diO). In their construction, a ciphertext is an obfuscated circuit that checks the signature for a function f and computes f if the signature is valid. The security proof relied on the fact that if the adversary distinguishes the ciphertext (or rather an obfuscated circuit) encrypting m_0 from that of m_1, then one must be able to extract a signature on a function g such that $g(m_0) \neq g(m_1)$ thereby producing a forgery. This construction is easily scalable to the multi-authority setting. However, given the implausibility of differing-inputs obfuscation [31], our objective is a construction based on indistinguishability obfuscation (iO). While it was observed in [19] that iO behaves like diO for the setting where the circuits in question differ only on a polynomially bounded number of points, unfortunately, there are simply too many points on which these functions would differ for this strategy to yield a construction from iO.

Constructing MAFE based on indistinguishability obfuscation. Our first idea is to use signatures that are *unique*, in the sense, that for every message there exists only one signature that verifies. In order to instantiate unique signatures, we use puncturable PRF's, indistinguishability obfuscation and an injective one way function following the punctured programming technique from [50]. The main idea of the security proof is that we can build exponentially many hybrids corresponding to the function space. We index each hybrid with a function x. In hybrid x, the ciphertext takes as input f with a signature σ and checks if $f < x$. If that is the case, it outputs $f(m_0)$ otherwise $f(m_1)$. We argue indistinguishability between hybrids x and $x+1$ by intermediate hybrids where we puncture the PRF at x and replace the PRF evaluations with a random sample. Then we further note that if the adversary now distinguishes these hybrids, then it can be used to invert an injective one way function in sub-exponential time. In order to handle key corruptions, we now let the signing key be an obfuscation of a circuit that evaluates a PRF on the input. This allows us to "program" the secret keys using puncturing techniques [50] and the techniques described above so that the proof can be made to go through.

Constructing MAFE based on LWE. Since MAFE for arbitrary policies imply obfuscation it is unlikely to construct them from simpler assumptions. We also study a very natural policy referred to as the $n - out - of - n$ threshold policy. In this policy for any function f the decryptor must get tokens from all the authorities to learn $f(m)$. We describe our construction at a very high level below. Our starting point is the recent construction of threshold homomorphic encryption (TFHE) by [47]. In a TFHE scheme the secret key can be shared among n parties and any (evaluated) ciphertext can be partially decrypted using each of the n key shares. The partial decryptions can be finally added to yield the output. The security guarantee is two fold: First, given at most $n-1$ key shares the semantic security of the encryption holds. Second, partial decryption of any ciphertext using any key share can be statistically simulated using the remaining $n-1$ shares and the output of the decryption. The (simplified) scheme can be described as follows. Each authority runs an FE setup. To encrypt a message m, the encryptor runs a fresh setup of a TFHE system. He encrypts m as ct and outputs n FE ciphertexts, one corresponding to each authority. For authority i he encrypts $(\mathsf{ct}, \mathsf{sk}_i, *)$ where $*$ represents some additional strings (for example, PRF keys, e.t.c used for programming the proof) and sk_i is i^{th} partial TFHE decryption key. The key for a function f is now simply an FE key for a function that takes as input a TFHE ciphertext ct and evaluates it for function f and then computes a partial decryption using sk_i.

The solution described above suffers from one key flaw. The problem is that the scheme is not *user-collusion-resistant*. One user uid_1 can query tokens for f from say k authorities, while another user uid_2 can query them from other $n-k$ authorities and later collude to recover $f(m)$. We prevent this by relying on Pseudo-Random Zero-Sharing (PRSS) [28]. Using this primitive one can secret share 0 pseudorandomly and deterministically using initially distributed shares $(\beta_1, .., \beta_n)$ and any common input. Concretely there exists a publicly known function g such that for any index x, $\{g(\beta_i, x)\}_{i\in[n]}$ forms a pseudorandom secret sharing of 0. We now modify the existing scheme as follows: FE ciphertext for each authority i now also consists β_i and the FE key now produces TFHE partial decryptions masked by $g(\beta_i, uid, f)$. This masking prevents the adversary to collude in the manner described above.

Applications. We also show that MAFE immediately implies multi-authority attribute based encryption and this yields the first decentralised ABE scheme without setup and without the use of random oracles.

Alternate construction of Hierarchical FE. An application of the unique signature idea described above is that it can be extended to allow for delegation of function keys. In what we described above, if the signature scheme is delegatable (i.e. if it allows us to compute a signature on $f||g$ for any g given a signature on f) then it allows us to compute keys for $g \cdot f$ given a key for f, where $g \cdot f$ denotes the composition of functions f and g and on input x computes $g(f(x))$. In order to construct this primitive, we make use of the exponential hybrid approach and make interesting use of hierarchical identity based encryption (HIBE). The main idea behind this construction is as follows: to encrypt a message m, we let the ciphertext be an obfuscated program that takes as input a "function" f. On input f, the obfuscated program will compute a HIBE encryption of $f(m)$ on identity f using randomness generated from a PRF applied on f. Any decryptor can then decrypt this ciphertext using a HIBE key for identity f or its prefix. Here too, the security proof goes input by input over the space of all circuits. Our construction supports delegation up to any (a-priori bounded) polynomial number of times, in contrast to prior schemes which allowed delegation only up to $O(1)$ number of times [4].

A detailed description of the MAFE construction as well as the alternate construction for HFE can be found in [25].

1.4 Related Work

Hierarchical encryption schemes. Encryption schemes supporting a hierarchical structure have been extensively studied in the setting of identity-based encryption, and have been recently studied in the more general setting of attribute-based encryption and functional encryption.

The line of research on hierarchical identity-based encryption has been extremely successful, starting with schemes in the random oracle model, evolving through selectively-secure schemes in the standard model and graduating to adaptively secure schemes for polynomially many levels. It is far beyond the scope of this paper to provide an extensive overview of this line of research, and we refer the reader to [34, 40, 11, 12, 18, 33, 52, 1, 2, 43, 44, 45, 24, 46] and the references therein.

Recently, Boneh et al. [14] constructed an attribute-based encryption scheme that supports delegation of keys. This scheme enables anyone holding a key sk_P corresponding to a predicate P to generate a key $\mathsf{sk}_{P \wedge Q}$ corresponding to the predicate $P \wedge Q$ for any given predicate Q. Now, given the key $\mathsf{sk}_{P \wedge Q}$ and an encryption of any pair (x, m), one can recover m if and only if $(P \wedge Q)(x) = 1$. Although the setting of attribute-based encryption is significantly more expressive than the identity-base one, it does not seem to come close to the general setting of functional encryption that we consider in this paper.

Finally, as discussed above, Ananth et al. [4] sketched how the functional encryption scheme of Garg et al. [30] can be transformed into a hierarchical one by using a general-purpose indistinguishability obfuscator. When compared to their scheme our approach offers two main advantages. First, whereas Ananth et al. rely on a specific scheme and on indistinguishability obfuscation, we can rely on any underlying general-purpose scheme. This enables us to rely on a variety of underlying assumptions, including learning with errors and even the existence of any public-key encryption scheme and low-depth pseudorandom

generators, as discussed in Section 1.1. Furthermore, as new functional encryption schemes are presented, they can immediately be plugged in to our construction. Second, the schemes resulting from our transformation guarantee semi-adaptive security, whereas the scheme of Ananth et al. guarantees only the somewhat less realistic notion of selective security.

Encapsulation techniques in functional encryption. Key encapsulation is a very useful approach for improving both the efficiency and the security of encryption schemes. Specifically, key encapsulation typically means that instead of encrypting a message x under a fixed key sk, one can instead sample a fresh key k, encrypt x under k, and then encrypt k under sk. Recently, Ananth et al. [5], followed by Brakerski et al. [21], showed that key encapsulation is useful also for functional encryption, and can be used for generically enhancing the functionality and the security of such schemes. Their approaches suggest that encapsulation techniques may in fact be a general tool that is useful in the design of functional encryption schemes. As discussed in Section 1.2, our construction relies on encapsulation techniques as a key ingredient, significantly extending the initial ideas of Ananth et al. and Brakerski et al. from encapsulating keys to realizing a re-encryption mechanism that generates a hierarchical structure.

1.5 Paper Organization

The remainder of this paper is organized as follows. In Section 2 we provide an overview of the notation, definitions, and tools underlying our constructions. In Section 3 we present the notion of a hierarchical functional encryption scheme and define its security. In Section 4 we present our generic construction of a hierarchical functional encryption scheme.

The details of the results described in Section 1.3 are deferred from this extended abstract and can be found in [25].

2 Preliminaries

In this section we present the notation and basic definitions that are used in this work. For a distribution X we denote by $x \leftarrow X$ the process of sampling a value x from the distribution X. Similarly, for a set $\mathcal{X}$ we denote by $x \leftarrow \mathcal{X}$ the process of sampling a value x from the uniform distribution over $\mathcal{X}$. For an integer $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1, \ldots, n\}$. Throughout the paper, we denote by λ the security parameter. A function $\mathsf{neg} : \mathbb{N} \to \mathbb{R}$ is *negligible* if for every constant $c > 0$ there exists an integer N_c such that $\mathsf{neg}(\lambda) < \lambda^{-c}$ for all $\lambda > N_c$. Two sequences of random variables $X = \{X_\lambda\}_{\lambda \in \mathbb{N}}$ and $Y = \{Y_\lambda\}_{\lambda \in \mathbb{N}}$ are *computationally indistinguishable* if for any probabilistic polynomial-time algorithm $\mathcal{A}$ there exists a negligible function $\mathsf{neg}(\cdot)$ such that $\left|\Pr[\mathcal{A}(1^\lambda, X_\lambda) = 1] - \Pr[\mathcal{A}(1^\lambda, Y_\lambda) = 1]\right| \leq \mathsf{neg}(\lambda)$ for all sufficiently large $\lambda \in \mathbb{N}$.

2.1 Pseudorandom Functions

Let $\{\mathcal{K}_\lambda, \mathcal{X}_\lambda, \mathcal{Y}_\lambda\}_{\lambda \in \mathbb{N}}$ be a sequence of sets and let $\mathcal{PRF} = (\mathsf{PRF.Gen}, \mathsf{PRF.Eval})$ be a function family with the following syntax:

- $\mathsf{PRF.Gen}$ is a probabilistic polynomial-time algorithm that takes as input the unary representation of the security parameter λ, and outputs a key $K \in \mathcal{K}_\lambda$.
- $\mathsf{PRF.Eval}$ is a deterministic polynomial-time algorithm that takes as input a key $K \in \mathcal{K}_\lambda$ and a value $x \in \mathcal{X}_\lambda$, and outputs a value $y \in \mathcal{Y}_\lambda$.

The sets $\mathcal{K}_\lambda$, $\mathcal{X}_\lambda$, and $\mathcal{Y}_\lambda$ are referred to as the *key space*, *domain*, and *range* of the function family, respectively. For $K \in \mathcal{K}_\lambda$, we use the notation $\mathsf{PRF.Eval}(K,\cdot)$, $\mathsf{PRF.Eval}_K(\cdot)$ and $\mathcal{PRF}_K(\cdot)$ interchangeably.

The following is the standard definition of a pseudorandom function family.

▶ **Definition 2.1** (Pseudorandomness)**.** A function family $\mathcal{PRF} = (\mathsf{PRF.Gen}, \mathsf{PRF.Eval})$ is *pseudorandom* if for every probabilistic polynomial-time algorithm $\mathcal{A}$ there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\begin{aligned}\mathsf{Adv}_{\mathcal{PRF},\mathcal{A}}(\lambda) &\stackrel{\mathsf{def}}{=} \left| \Pr_{K\leftarrow\mathsf{PRF.Gen}(1^\lambda)}\left[\mathcal{A}^{\mathsf{PRF.Eval}_K(\cdot)}(1^\lambda)=1\right] - \Pr_{f\leftarrow F_\lambda}\left[\mathcal{A}^{f(\cdot)}(1^\lambda)=1\right]\right| \\ &\leq \mathsf{neg}(\lambda),\end{aligned}$$

for all sufficiently large $\lambda \in \mathbb{N}$, where F_λ is the set of all functions that map $\mathcal{X}_\lambda$ into $\mathcal{Y}_\lambda$.

In addition to the standard notion of a pseudorandom function family, we rely on the seemingly stronger (yet existentially equivalent) notion of a *puncturable* pseudorandom function family [41, 17, 50, 20]. In terms of syntax, this notion asks for an additional probabilistic polynomial-time algorithm, $\mathsf{PRF.Punc}$, that takes as input a key $K \in \mathcal{K}_\lambda$ and a set $S \subseteq \mathcal{X}_\lambda$ and outputs a "punctured" key K_S. The properties required by such a puncturing algorithm are captured by the following definition.

▶ **Definition 2.2** (Puncturable PRF)**.** A pseudorandom function family $\mathcal{PRF} = (\mathsf{PRF.Gen}, \mathsf{PRF.Eval}, \mathsf{PRF.Punc})$ is *puncturable* if the following properties are satisfied:

1. **Functionality:** For all sufficiently large $\lambda \in \mathbb{N}$, for every set $S \subseteq \mathcal{X}_\lambda$, and for every $x \in \mathcal{X}_\lambda \setminus S$ it holds that

$$\Pr_{\substack{K\leftarrow\mathsf{PRF.Gen}(1^\lambda);\\ K_S\leftarrow\mathsf{PRF.Punc}(K,S)}}[\mathsf{PRF.Eval}_K(x) = \mathsf{PRF.Eval}_{K_S}(x)] = 1.$$

2. **Pseudorandomness at punctured points:** Let $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ be any probabilistic polynomial-time algorithm such that $\mathcal{A}_1(1^\lambda)$ outputs a set $S \subseteq \mathcal{X}_\lambda$, a value $x \in S$, and state information state. Then, for any such $\mathcal{A}$ there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\begin{aligned}\mathsf{Adv}_{\mathcal{PRF},\mathcal{A}}(\lambda) &\stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathcal{A}_2(K_S, \mathsf{PRF.Eval}_K(x), \mathsf{state})=1\right] - \Pr\left[\mathcal{A}_2(K_S, y, \mathsf{state})=1\right]\right| \\ &\leq \mathsf{neg}(\lambda)\end{aligned}$$

for all sufficiently large $\lambda \in \mathbb{N}$, where $K \leftarrow \mathsf{PRF.Gen}(1^\lambda)$, $(S, x, \mathsf{state}) \leftarrow \mathcal{A}_1(1^\lambda)$, $K_S = \mathsf{PRF.Punc}(K, S)$, and $y \leftarrow \mathcal{Y}_\lambda$.

For our constructions we rely on pseudorandom functions that need to be punctured only at a single point (i.e., in both parts of Definition 2.2 it holds that $S = \{x^*\}$ for some $x^* \in \mathcal{X}_\lambda$). As observed by [41, 17, 50, 20] the GGM construction [36] of PRFs from any one-way function can be easily altered to yield such a puncturable pseudorandom function family.

Augmented evaluation. When dealing with pseudorandom functions that need to be punctured only at a single point, we find it natural to consider an "augmented" evaluation algorithm that outputs a pre-determined value y^* at the punctured point. That is, we extend the functionality of $\mathsf{PRF.Eval}$ such that given an augmented key of the form $(K_{x^*}, (x^*, y^*))$, it holds that

$$\mathsf{PRF.Eval}_{(K_{x^*},(x^*,y^*))}(x) = \begin{cases} y^*, & \text{if } x = x^* \\ \mathsf{PRF.Eval}_{K_{x^*}}(x), & \text{if } x \neq x^* \end{cases}.$$

2.2 Private-Key Encryption with Pseudorandom Ciphertexts

A private-key encryption scheme over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ is a triplet $\Pi = (\mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ of probabilistic polynomial-time algorithms. The key-generation algorithm KG takes as input the unary representation 1^λ of the security parameter $\lambda \in \mathbb{N}$ and outputs a secret key k. The encryption algorithm Enc takes as input a secret key k and a message $x \in \mathcal{X}_\lambda$, and outputs a ciphertext c. The decryption algorithm Dec takes as input a secret key k and a ciphertext c, and outputs a message $x \in \mathcal{X}_\lambda$ or the dedicated symbol $\perp$. In terms of correctness we require that for any key k that is produced by $\mathsf{KG}(1^\lambda)$ and for every message $x \in \mathcal{X}_\lambda$ it holds that $\mathsf{Dec}(\mathsf{k}, \mathsf{Enc}(\mathsf{k}, x)) = x$ with probability 1 over the internal randomness of the algorithms Enc and Dec. We also require that a uniformly distributed string does not decrypt to a valid message with overwhelming probability, i.e. $\mathsf{Dec}(\mathsf{k}, \rho) = \perp$ with probability $(1 - \mathsf{neg}(\lambda))$ over the randomness of the key k and a uniformly distributed string ρ of the same length as the ciphertext[4]. In terms of security, we rely on the following standard notion of pseudorandom ciphertexts which can be based on any one-way function (see, for example, [35]).

▶ **Definition 2.3** (Pseudorandom ciphertexts)**.** A private-key encryption scheme $\Pi = (\mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ has *pseudorandom ciphertexts* if for any probabilistic polynomial-time adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$, there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\mathsf{Adv}^{\mathsf{PC}}_{\Pi,\mathcal{A}}(\lambda) \stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathsf{Exp}^{\mathsf{PC}}_{\Pi,\mathcal{A}}(\lambda) = 1\right] - \frac{1}{2}\right| \leq \mathsf{neg}(\lambda),$$

for all sufficiently large $\lambda \in \mathbb{N}$, where the random variable $\mathsf{Exp}^{\mathsf{PC}}_{\Pi,\mathcal{A}}(\lambda)$ is defined via the following experiment:

1. $\mathsf{k} \leftarrow \mathsf{KG}(1^\lambda)$, $b \leftarrow \{0,1\}$.
2. $(x^*, \mathsf{state}) \leftarrow \mathcal{A}_1^{\mathsf{Enc}(\mathsf{k},\cdot)}(1^\lambda)$, where $x^* \in \mathcal{X}_\lambda$.
3. $c_0^* \leftarrow \mathsf{Enc}(\mathsf{k}, x^*)$, $c_1^* \leftarrow \{0,1\}^{|c_0^*|}$.
4. $b' \leftarrow \mathcal{A}_2^{\mathsf{Enc}(\mathsf{k},\cdot)}(c_b^*, \mathsf{state})$.
5. If $b' = b$ then output 1, and otherwise output 0.

2.3 Public-Key Functional Encryption

A public-key functional encryption scheme over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ and a function space $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{N}}$ is a quadruple $\Pi = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ of probabilistic polynomial-time algorithms. The setup algorithm Setup takes as input the unary representation 1^λ of the security parameter $\lambda \in \mathbb{N}$ and outputs a master-secret key msk and a master-public key mpk. The key-generation algorithm KG takes as input a master-secret key msk and a function $f \in \mathcal{F}_\lambda$, and outputs a functional key sk_f. The encryption algorithm Enc takes as input a master-public key mpk and a message $x \in \mathcal{X}_\lambda$, and outputs a ciphertext ct. In terms of correctness we require that for all sufficiently large $\lambda \in \mathbb{N}$, for every function $f \in \mathcal{F}_\lambda$ and message $x \in \mathcal{X}_\lambda$ it holds that $\mathsf{Dec}(\mathsf{KG}(\mathsf{msk}, f), \mathsf{Enc}(\mathsf{mpk}, x)) = f(x)$ with all but a negligible probability over the internal randomness of the algorithms Setup, KG, and Enc.

We rely on the standard indistinguishability-based notion of adaptive security for public-key functional encryption (see, for example, [15, 48, 9, 5]), asking that encryptions of any

[4] More accurately, since the ciphertext length may (in general) not be a fixed function of the security parameter, the uniform string ρ is sampled as follows: Given the key k, encrypt a fixed message (say, the message 0) to obtain a ciphertext c, and then uniformly sample $\rho \leftarrow \{0,1\}^{|c|}$, where $|c|$ denotes the bit-length of c.

two messages, x_0 and x_1, are computationally indistinguishable given access to functional keys for any function f such that $f(x_0) = f(x_1)$.

▶ **Definition 2.4** (Adaptive security)**.** A functional encryption scheme $\Pi = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ and a function space $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{N}}$ is *adaptively secure* if for any probabilistic polynomial-time adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\mathsf{Adv}^{\mathsf{FE}}_{\Pi,\mathcal{A}}(\lambda) \stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathsf{Exp}^{\mathsf{FE}}_{\Pi,\mathcal{A}}(\lambda) = 1\right] - \frac{1}{2}\right| \leq \mathsf{neg}(\lambda),$$

for all sufficiently large $\lambda \in \mathbb{N}$, where the random variable $\mathsf{Exp}^{\mathsf{FE}}_{\Pi,\mathcal{A}}(\lambda)$ is defined via the following experiment:

1. $(\mathsf{msk}, \mathsf{mpk}) \leftarrow \mathsf{Setup}(1^\lambda)$, $b \leftarrow \{0,1\}$.
2. $(x_0^*, x_1^*, \mathsf{state}) \leftarrow \mathcal{A}_1^{\mathsf{KG}(\mathsf{msk},\cdot)}(1^\lambda, \mathsf{mpk})$, where $x_0^*, x_1^* \in \mathcal{X}_\lambda$, and for each function $f \in \mathcal{F}_\lambda$ with which $\mathcal{A}_1$ queries $\mathsf{KG}(\mathsf{msk}, \cdot)$ it holds that $f(x_0^*) = f(x_1^*)$.
3. $\mathsf{ct}^* \leftarrow \mathsf{Enc}(\mathsf{mpk}, x_b^*)$.
4. $b' \leftarrow \mathcal{A}_2^{\mathsf{KG}(\mathsf{msk},\cdot)}(\mathsf{ct}^*, \mathsf{state})$, where for each function $f \in \mathcal{F}_\lambda$ with which $\mathcal{A}_2$ queries $\mathsf{KG}(\mathsf{msk}, \cdot)$ it holds that $f(x_0^*) = f(x_1^*)$.
5. If $b' = b$ then output 1, and otherwise output 0.

In addition to the above notion of adaptive security we consider two natural relaxations: semi-adaptive security, and selective security. Semi-adaptive security is defined via an experiment $\mathsf{Exp}^{\mathsf{semiFE}}_{\Pi,\mathcal{A}}(\lambda)$ that is obtained from the experiment $\mathsf{Exp}^{\mathsf{FE}}_{\Pi,\mathcal{A}}(\lambda)$ by asking the adversary to determine the challenge messages before making any key-generation queries (but *after* receiving the public key). Selective security is defined via an experiment $\mathsf{Exp}^{\mathsf{selFE}}_{\Pi,\mathcal{A}}(\lambda)$ that is obtained from the experiment $\mathsf{Exp}^{\mathsf{FE}}_{\Pi,\mathcal{A}}(\lambda)$ by asking the adversary to determine the challenge messages in advance (i.e., *before* receiving the public key).

Known constructions. General-purpose functional encryption schemes that satisfy the above notion of adaptive security are known to exist based on a variety of assumptions. Ananth et al. [5] gave a generic transformation from selective security to adaptive security, implying that schemes that are adaptively secure for any number of key-generation queries can be based on indistinguishability obfuscation [30, 53], differing-input obfuscation [19, 4], and multilinear maps [32]. In addition, schemes that are adaptively secure for a bounded number $B = B(\lambda)$ of key-generation queries can be based on the Learning with Errors (LWE) assumption (where the length of ciphertexts grows with B and with a bound on the depth of allowed functions) [37], based on any public-key encryption scheme and pseudorandom generators computable by small-depth circuits (where the length of ciphertexts grows with B and with an upper bound on the circuit size of the functions) [38], and even based on any public-key encryption scheme (for $B = 1$) [38].

3 Hierarchical Functional Encryption

In this section we define the notion of a hierarchical functional encryption scheme and formalize several notions of security for such schemes (based on [4]). A hierarchical functional encryption scheme is a functional encryption scheme that supports delegation of functional keys: Given a functional key sk_f corresponding to a function f, and given a function g, it is possible to efficiently compute a functional key $\mathsf{sk}_{g\circ f}$ corresponding to the function $g \circ f$

(i.e., the function that first applies f and then applies g). This capability is provided via a delegation algorithm denote $\mathsf{Delegate}$.

Formally, a hierarchical functional encryption scheme over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ and a function space $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{N}}$ is a tuple $\Pi = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Delegate})$ of probabilistic polynomial-time algorithms, where $(\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec})$ is a functional encryption scheme (see Section 2.3), and $\mathsf{Delegate}$ is a delegation algorithm that operates as follows: It takes as input a functional key sk_f (which had been produced either by the key-generation algorithm or by the delegation algorithm itself) corresponding to a function $f \in \mathcal{F}_\lambda$, and a function $g \in \mathcal{F}_\lambda$, and outputs a functional key $\mathsf{sk}_{g\circ f}$.

Correctness. In terms of correctness we require that for every $\lambda \in \mathbb{N}$, for every polynomial $\ell = \ell(\lambda)$, for every sequence of functions $f_1, \ldots, f_\ell \in \mathcal{F}_\lambda$, and for every message $x \in \mathcal{X}_\lambda$, it holds that

$$\mathsf{Dec}(\mathsf{sk}_{f_\ell\circ\cdots\circ f_1}, \mathsf{Enc}(\mathsf{mpk}, x)) = (f_\ell \circ \cdots \circ f_1)(x)$$

with all but a negligible probability over the internal randomness of the algorithms Setup, KG, Enc and $\mathsf{Delegate}$, where $\mathsf{sk}_{f_1} \leftarrow \mathsf{KG}(\mathsf{msk}, f_1)$ and $\mathsf{sk}_{f_{i+1}\circ\cdots\circ f_1} \leftarrow \mathsf{Delegate}(\mathsf{sk}_{f_i\circ\cdots\circ f_1}, f_{i+1})$ for every $i \in [\ell - 1]$. One can also consider schemes that support ℓ delegation levels for some *fixed* polynomial $\ell = \ell(\lambda)$, although we note that our scheme in this paper supports *any* polynomial number of delegation levels.

Security. As in the work of Ananth et al. [4, Appendix E] we consider the natural extensions of the existing indistinguishability-based definitions of functional encryption [15, 48] to the hierarchical setting. Specifically, we consider adversaries that obtain functional keys for various functions of their choice by issuing key-generation queries and delegation queries. We require that such adversaries have only a negligible advantage in distinguishing the encryptions of two challenge messages, x_0^* and x_1^*, of their choice as long as for any function f for which they obtain a functional key it holds that $f(x_0^*) = f(x_1^*)$.

The experiment $\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda)$. Let $\Pi = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Delegate})$ be a hierarchical public-key functional encryption scheme over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ and a function space $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{N}}$, and let $\mathcal{A}$ be a probabilistic polynomial-time adversary. For each $\lambda \in \mathbb{N}$ we denote by $\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda)$ the random variable that is defined via the following experiment involving the scheme Π, the adversary $\mathcal{A}$, and a challenger:

1. **Setup phase:** The challenger samples $(\mathsf{msk}, \mathsf{mpk}) \leftarrow \mathsf{Setup}(1^\lambda)$ and $b \leftarrow \{0, 1\}$.
2. **Pre-challenge phase:** $\mathcal{A}$ on input $(1^\lambda, \mathsf{mpk})$ adaptively issues queries of the form $(f, \mathsf{parent}, \mathsf{mode})$, where $f \in \mathcal{F}_\lambda$, $\mathsf{parent} \in \mathbb{N} \cup \{0\}$ and $\mathsf{mode} \in \{\mathsf{OutputKey}, \mathsf{StoreKey}\}$. The ith query $(f_i, \mathsf{parent}_i, \mathsf{mode}_i)$ is answered by the challenger as follows:
   - **a.** If $\mathsf{parent} = 0$ then the challenger generates $\mathsf{hsk}_i \leftarrow \mathsf{KG}(\mathsf{msk}, f)$.
   - **b.** Else, if $\mathsf{hsk}_{\mathsf{parent}_i}$ had already been generated (and is not $\perp$), then the challenger generates $\mathsf{hsk}_i \leftarrow \mathsf{Delegate}(\mathsf{hsk}_{\mathsf{parent}_i}, f)$. Otherwise set $\mathsf{hsk}_i = \perp$.
   - **c.** Finally, if $\mathsf{mode}_i = \mathsf{OutputKey}$ then the challenger outputs hsk_i, and if $\mathsf{mode} = \mathsf{StoreKey}$ then the challenger outputs $\perp$.
3. **Challenge phase:** $\mathcal{A}$ outputs $(x_0^*, x_1^*) \in \mathcal{X}_\lambda \times \mathcal{X}_\lambda$, and then the challenger computes $\mathsf{ct}^* \leftarrow \mathsf{Enc}(\mathsf{mpk}, x_b^*)$ and sends it to $\mathcal{A}$.
4. **Post-challenge phase:** $\mathcal{A}$ adaptively issues queries as in the pre-challenge phase.
5. **Output phase:** $\mathcal{A}$ outputs b', and the output of the experiment is 1 if and only if $b' = b$.

Valid adversaries. As standard in functional encryption, we rule out adversaries that can easily distinguish between the two challenge messages, x_0^* and x_1^*, using their queries. Specifically, we say that an adversary is *valid* if for any query $(f_i, \mathsf{parent}_i, \mathsf{mode}_i)$ where $\mathsf{mode}_i = \mathsf{OutputKey}$, it holds that $\tilde{f}_i(x_0^*) = \tilde{f}_i(x_1^*)$, where $\tilde{f}$ is defined recursively by $\tilde{f}_i = f_i \circ \tilde{f}_{\mathsf{parent}_i}$ and $f_0(x) = x$ (if any of these values is not well defined then $\tilde{f}_i(x) \equiv \perp$ for all x).

Having defined the experiment $\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda)$ and the notion of a valid adversary, we are now ready to present our notion of adaptive security for hierarchical functional encryption schemes.

▶ **Definition 3.1.** A hierarchical functional encryption scheme $\Pi = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Delegate})$ over a message space $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}$ and a function space $\mathcal{F} = \{\mathcal{F}_\lambda\}_{\lambda\in\mathbb{N}}$ is *adaptively secure* if for any probabilistic polynomial-time valid adversary $\mathcal{A}$ there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\mathsf{Adv}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda) \stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda) = 1\right] - \frac{1}{2}\right| \leq \mathsf{neg}(\lambda),$$

for all sufficiently large $\lambda \in \mathbb{N}$.

In addition to our notion of adaptive security we consider two natural relaxations: semi-adaptive security, and selective security. Semi-adaptive security is defined via an experiment $\mathsf{Exp}^{\mathsf{semiHFE}}_{\Pi,\mathcal{A}}(\lambda)$ that is obtained from the experiment $\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda)$ by eliminating the pre-challenge query phase (note that the adversary determines the challenge messages *after* receiving the public key). Selective security is defined via an experiment $\mathsf{Exp}^{\mathsf{selHFE}}_{\Pi,\mathcal{A}}(\lambda)$ that is obtained from the experiment $\mathsf{Exp}^{\mathsf{HFE}}_{\Pi,\mathcal{A}}(\lambda)$ by asking the adversary to determine the challenge messages in advance (i.e., *before* receiving the public key).

Discussion: The delegation capabilities of functional encryption. It is important to point out that given a functional key sk_f, one cannot hope to delegate anything beyond the set of functions $g \circ f$ while maintaining the security properties of functional encryption. To see this, assume towards contradiction that there exists a function h such that h cannot be expressed as $g \circ f$, but sk_h can be derived from sk_f. Since the value of $h(x)$ cannot be inferred just by examining the value of $f(x)$, there must exist two inputs, x_0 and x_1 such that $f(x_0) = f(x_1)$ but $h(x_0) \neq h(x_1)$. Given sk_f, therefore, one should not be able to distinguish encryptions of x_0 and x_1, but by delegating to sk_h, this becomes possible, hence the contradiction.

The above optimality claim may seem a little confusing when we think about special cases such as attribute-based encryption (ABE) or even identity-based encryption (IBE). In ABE for example, each ciphertext contains an attribute x and a message m, and sk_f reveals m if and only if $f(x) = 1$. In hierarchical ABE (HABE) [39, 14], given sk_f, one should be able to derive $\mathsf{sk}_{f\wedge f'}$ for all f'. At first glance, this seems to not be covered by our definition since $f \wedge f'$ cannot be expressed as $g \circ f$. However, we notice that in fact when thinking about HABE as a special case of functional encryption, it must be the case that what we call sk_f, is in fact a functional key for the function $f^+(x, m) = ((f(x) = 1)?(x, m) : \perp)$ (i.e., the function that takes (x, m) as input, and if $f(x) = 1$ it returns (x, m) and otherwise it returns $\perp$). This is because if $f(x) = 1$ then x can always be recovered by considering delegated keys that fix the value of each bit of x to 0 or 1, and check if decryption still works. It is clear from this viewpoint that $(f \wedge f')^+$ can be seen as $g \circ f^+$ for an appropriate g. Therefore, our definition and construction are fully compatible also with the more restricted settings of HABE and HIBE.

4 Our Generic Transformation

In this section we show how to transform any general-purpose public-key functional encryption scheme into a hierarchical one. Our construction relies on the following building blocks:

1. A general-purpose public-key functional encryption scheme $\mathcal{FE} = (\mathsf{FE.Setup}, \mathsf{FE.KG}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$.
2. A private-key encryption scheme $\mathcal{SKE} = (\mathsf{SKE.KG}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$.
3. A puncturable pseudorandom function family $\mathcal{PRF} = (\mathsf{PRF.Gen}, \mathsf{PRF.Eval}, \mathsf{PRF.Punc})$.

Our hierarchical scheme $\mathcal{HFE} = (\mathsf{Setup}, \mathsf{KG}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Delegate})$ is defined as follows.

- **The setup algorithm.** On input the security parameter 1^λ the setup algorithm samples and outputs $(\mathsf{msk}, \mathsf{mpk}) \leftarrow \mathsf{FE.Setup}(1^\lambda)$.
- **The encryption algorithm.** On input the public key mpk and a message x, the encryption algorithm first samples a PRF key $K \leftarrow \mathsf{PRF.Gen}(1^\lambda)$. Then, it computes and outputs $\mathsf{ct} \leftarrow \mathsf{FE.Enc}(\mathsf{mpk}, (x, K, \bot))$. (Note that the message space of the resulting scheme is thus smaller than that of the original scheme.)
- **The key-generation algorithm.** On input the master secret key msk and a function f, the key-generation algorithm first generates a fresh key pair $(\mathsf{msk}', \mathsf{mpk}') \leftarrow \mathsf{FE.Setup}(1^\lambda)$ and uniformly samples a tag $t \leftarrow \{0,1\}^\lambda$. Then, it uniformly samples $c \leftarrow \{0,1\}^\ell$ where $\ell = \ell(\lambda)$ is the length of an $\mathcal{SKE}$ encryption of an $\mathcal{FE}$ ciphertext.[5] Finally, it computes $\mathsf{sk}_f \leftarrow \mathsf{FE.KG}(\mathsf{msk}, \mathsf{ReEnc}_{f,t,\mathsf{mpk}',c})$, where ReEnc is defined in Figure 1, and outputs $\mathsf{hsk}_f = (\mathsf{sk}_f, \mathsf{msk}')$.
- **The delegation algorithm.** On input a (possibly delegated) functional key of the form $\mathsf{hsk}_{f_i \circ \cdots \circ f_1} = (\mathsf{sk}_{f_1}, \ldots, \mathsf{sk}_{f_i}, \mathsf{msk}')$ for some integer $i \geq 1$, and a function f_{i+1}, the delegation algorithm uses the key-generation algorithm described above to compute $(\mathsf{sk}_{f_{i+1}}, \mathsf{msk}'') \leftarrow \mathcal{HFE}.\mathsf{KG}(\mathsf{msk}', f_{i+1})$, and outputs $\mathsf{hsk}_{f_{i+1} \circ \cdots \circ f_1} = (\mathsf{sk}_{f_1}, \ldots, \mathsf{sk}_{f_i}, \mathsf{sk}_{f_{i+1}}, \mathsf{msk}'')$.
- **The decryption algorithm.** On input a functional key $\mathsf{hsk}_{f_i \circ \cdots \circ f_1} = (\mathsf{sk}_{f_1}, \ldots, \mathsf{sk}_{f_i}, \mathsf{msk}')$ for some integer $i \geq 1$, and a ciphertext ct, the decryption algorithm first sets $\mathsf{ct}_0 = \mathsf{ct}$ and computes $\mathsf{ct}_j \leftarrow \mathsf{FE.Dec}(\mathsf{sk}_{f_j}, \mathsf{ct}_{j-1})$ for $j = 1, \ldots, i$. Then, ct_i is decrypted by using msk' for generating a functional key for the identity function $\mathsf{ID} \in \mathcal{F}$:

  $$w \leftarrow \mathsf{FE.Dec}(\mathsf{FE.KG}(\mathsf{msk}', \mathsf{ID}), \mathsf{ct}_i).$$

  Finally, w is parsed as a triplet $w = (y, \cdot, \cdot)$, of which the first element y is returned as output.

In what follows we first discuss the correctness of our resulting scheme, then discuss its parameters and overhead, and then state and prove its security based on that of its underlying building blocks.

[5] To be accurate, ℓ is also a function of the message space of the scheme and of the specific properties of the master secret key. We refrain from mentioning these implicit parameters to avoid cluttering of notation. We note however that this imposes an a-priori bound on the length of the ciphertext and thus also on the message space of our resulting scheme. Lifting this restriction is an interesting research direction.

$\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}(x, K, \mathsf{k})$

1. Compute $\mathsf{ct} \leftarrow \mathsf{SKE.Dec}(\mathsf{k}, c)$, $(s, r) = \mathsf{PRF.Eval}(K, t)$, and $K' = \mathsf{PRF.Gen}\left(1^\lambda; s\right)$.
2. If $\mathsf{ct} \neq \bot$ then output ct, and otherwise output $\mathsf{FE.Enc}\left(\mathsf{mpk}', (f(x), K', \bot); r\right)$.

1 The function $\mathsf{ReEnc}_{f,t,\mathsf{mpk}',c}$.

Correctness. The correctness of our scheme follows easily by induction on the delegation depth i. Let $(\mathsf{msk}, \mathsf{mpk}) \leftarrow \mathsf{Setup}(1^\lambda)$, and fix a message $x \in \mathcal{X}_\lambda$ and a sequence of functions $f_1, \ldots, f_i \in \mathcal{F}_\lambda$.

For $i = 1$ the correctness of decrypting a ciphertext $\mathsf{ct}_0 \leftarrow \mathsf{FE.Enc}(\mathsf{mpk}, (x, K_0, \bot))$ using a key $\mathsf{hsk}_{f_1} = (\mathsf{sk}_{f_1}, \mathsf{msk}_1) \leftarrow \mathsf{KG}(\mathsf{msk}, f_1)$ follows from that of the underlying scheme $\mathcal{FE}$. Specifically, the decryption algorithm first computes $\mathsf{ct}_1 \leftarrow \mathsf{FE.Dec}(\mathsf{sk}_{f_1}, \mathsf{ct}_0)$, and by the correctness of $\mathcal{FE}$ with an overwhelming probability it holds that $\mathsf{ct}_1 = \mathsf{FE.Enc}(\mathsf{mpk}_1, (f_1(x), K_1, \bot); r_1)$, where $(s_1, r_1) = \mathsf{PRF.Eval}(K_0, t)$ for some t chosen during the key generation, $K_1 = \mathsf{PRF.Gen}\left(1^\lambda; s_1\right)$, and mpk_1 is a master public key that is sampled together with msk_1. Next, the decryption algorithm decrypts ct_1 with msk_1, and noting that r_1 is pseudorandom given the triplet $(\mathsf{mpk}_1, f_1(x), K_1)$ we can once again rely on the correctness of the underlying scheme $\mathcal{FE}$ and argue that the decryption algorithm outputs $f_1(x)$ with an overwhelming probability.[6]

Assume that the scheme is correct for up to $i-1$ levels of delegation, and consider decrypting a ciphertext $\mathsf{ct}_0 \leftarrow \mathsf{FE.Enc}(\mathsf{mpk}, (x, K_0, \bot))$ using a key $\mathsf{hsk}_{f_i \circ \cdots \circ f_1} = (\mathsf{sk}_{f_1}, \ldots, \mathsf{sk}_{f_i}, \mathsf{msk}_i) \leftarrow \mathsf{Delegate}(\mathsf{hsk}_{f_{i-1}}, f_i)$ that is generated using i levels of delegation. Then, the correctness for up to $i-1$ levels guarantees that by repeatedly applying the keys $\mathsf{sk}_{f_1}, \ldots, \mathsf{sk}_{f_{i-1}}$ starting with the initial ciphertext ct_0 as prescribed by the decryption algorithm, we obtain with an overwhelming probability a ciphertext $\mathsf{ct}_{i-1} = \mathsf{FE.Enc}(\mathsf{mpk}_{i-1}, ((f_{i-1} \circ \cdots \circ f_1)(x), K_{i-1}, \bot); r_{i-1})$ for some mpk_{i-1}, K_{i-1} and r_{i-1}, where r_{i-1} is pseudorandom given the triplet $(\mathsf{mpk}_{i-1}, (f_{i-1} \circ \cdots \circ f_1)(x), K_{i-1})$. Next, the decryption algorithm computes $\mathsf{ct}_i \leftarrow \mathsf{FE.Dec}(\mathsf{sk}_{f_i}, \mathsf{ct}_{i-1})$, and by the correctness of $\mathcal{FE}$ with an overwhelming probability it holds that $\mathsf{ct}_i = \mathsf{FE.Enc}(\mathsf{mpk}_i, ((f_i \circ \cdots \circ f_1)(x), K_i, \bot); r')$, where $(s_i, r_i) = \mathsf{PRF.Eval}(K_{i-1}, t)$ for some t chosen during the key generation, $K_i = \mathsf{PRF.Gen}\left(1^\lambda; s_{i-1}\right)$, and mpk_i is a master public key that is sampled together with msk_i. Note that again r_i is pseudorandom given the triplet $(\mathsf{mpk}_i, (f_i \circ \cdots \circ f_1)(x), K_i)$. Therefore, when the decryption algorithm decrypts ct_i with msk_i, it outputs $(f_i \circ \cdots \circ f_1)(x)$ with an overwhelming probability.

Parameters and overhead. We now discuss the parameters that govern the properties that are required of the underlying scheme and thus the overhead of our construction. We address two parameters of the hierarchy: The *width* which is the maximal number of delegated keys that are derived from each key at the previous level, and the *depth* which is the maximal number of successive derivations.[7] The functionality and security of our scheme hold for arbitrary and a-priori unbounded width and depth. However, if the underlying scheme is

[6] If we further assume that either the underlying functional encryption scheme is perfectly correct, or that the underlying pseudorandom function produces outputs whose marginal distribution is uniform, the argument significantly simplifies and there is no need to argue that r_1 is pseudorandom given the triplet $(\mathsf{mpk}_1, f_1(x), K_1)$.

[7] One could consider a more fine-grained view of the parameters, e.g. that the maximal width itself depends on the depth of the key. Such analyses follow the same principles presented here.

restricted in some way, then this restriction could propagate through our reduction. For example, if the underlying scheme only supports bounded collusion, then the maximal width will be restricted. Furthermore, since the ReEnc function produces a functional ciphertext with respect to the next level of the hierarchy, certain instantiations could produce a cascading effect that will increase the overhead. We analyze these restrictions below and show that in some cases they can be overcome completely and in others they can be managed.

Define the *compactness parameter* of a (standard) FE scheme, denoted $C(\lambda, S)$, as the computational complexity of encrypting a message of length λ (or some other fixed length which does not depend on S), while allowing to produce functional keys for size S functions. Note that C is also a bound on the length of the ciphertext, and in the currently-known schemes it also governs the complexity of key generation (see Section 2.3 for the currently-known schemes). Then in our construction, the ciphertext encryption complexity at depth i, which we denote by C_i is at most $C_i \leq C(\lambda, C_{i+1} \cdot \mathrm{poly}(\lambda))$. This relation follows immediately from the description of the scheme.

For a scheme which only allows bounded collusion, the compactness is $C(\lambda, S, B)$, where B is the bound on the number of collusions. In this case, the width factors in as well such that for a scheme with width w it holds that $C_i \leq C(\lambda, C_{i+1} \cdot \mathrm{poly}(\lambda), w)$.

In particular, in the known schemes with unbounded collusion [30, 53, 32], the encryption complexity is independent of S and therefore instantiating our construction with such a scheme will support arbitrary polynomial depth and width while keeping the encryption complexity polynomial. In fact, one can show, via a little modification of [5], that any scheme that supports unbounded collusions can be modified using randomized encodings to one where the compactness is independent of S.

For known schemes with bounded collusion, such as those based on public-key encryption [38] or on LWE [37], the compactness is $C(\lambda, S, B) \leq \mathrm{poly}(\lambda) \cdot S \cdot B$, which implies that C_i is bounded by $C_{i+1} \cdot \mathrm{poly}(\lambda) \cdot w$. If we intend to support a total depth d, then unfolding the reduction, the bound we have is $C_0 \leq w^d \cdot \lambda^{O(d)}$. This means that if we wish to keep the encryption complexity polynomial in λ, we can only allow $d = O(1)$ and $w = \mathrm{poly}(\lambda)$. Furthermore, we must know w ahead of time in order to instantiate the parameters of the scheme.

Security. The following theorem captures the security of our resulting scheme. We note that the assumptions stated in the theorem are all known to be implied by the existence of any (selectively-secure) general-purpose public-key functional encryption scheme (see Section 2 for formal descriptions of our building blocks and their known instantiations).

▶ **Theorem 4.1.** *Assuming that (1) $\mathcal{FE}$ is semi-adaptively (resp., selectively) secure (2) $\mathcal{SKE}$ has pseudorandom ciphertexts, and (3) $\mathcal{PRF}$ is a puncturable pseudorandom function family, then $\mathcal{HFE}$ is a semi-adaptively-secure (resp., selectively-secure) hierarchical functional encryption scheme.*

Proof. For ease of exposition we focus here on the case where the underlying scheme $\mathcal{FE}$ is semi-adaptively secure. The proof for the case where $\mathcal{FE}$ is only selectively secure is identical, except for requiring the adversary to provide the challenge messages prior to receiving the public parameters. Let $\mathcal{A}$ be a valid probabilistic polynomial-time adversary (as defined in Section 3). We present a sequence of experiments and upper bound $\mathcal{A}$'s advantage in distinguishing each two consecutive experiments. The first experiment is the experiment $\mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda)$ and the last experiment is completely independent of the bit b. This enables

us to prove that there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\mathsf{Adv}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda) \stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda)=1\right]-\frac{1}{2}\right| \leq \mathsf{neg}(\lambda)$$

for all sufficiently large $\lambda \in \mathbb{N}$.

How to read this proof. To read our proof, one starts from the first hybrid and proceeds in order to the next, each adjacent hybrid is shown to be computationally indistinguishable from its predecessor. When a loop is encountered, this means that a sequence of hybrids is now being defined, one hybrid for each "iteration" of the loop. The hybrid defined in the first iteration needs to be indistinguishable from the last hybrid before the loop, and all hybrids except the first need to be indistinguishable from the hybrid of the previous iteration. In a *nested loop*, each iteration of the external loop represents a generation of many hybrids, as many as the internal loop generates. In such case, in the first iteration of the external loop, and the first iteration of the internal loop, the hybrid being defined needs to be indistinguishable from the one preceding the loop. However, in the next execution of the external loop, the first iteration of the internal needs to be indistinguishable with the *last* iteration of the internal loop that have been carried out in the previous iteration of the external loop. For example, say that the external loop iterates for $i = 1, \ldots, S$ and the internal loop iterates for $j = 1, \ldots, T$. Then what we prove for $\mathcal{H}^{(i,j)}$ is that: $\mathcal{H}^{(1,1)}$ is indistinguishable from the last hybrid before the loop, $\mathcal{H}^{(i,1)}$ for $i > 1$ is indistinguishable from $\mathcal{H}^{(i-1,T)}$, and for $i, j > 1$ that $\mathcal{H}^{(i,j)}$ is indistinguishable from $\mathcal{H}^{(i,j-1)}$.

In order to explain the purpose of the different steps in the proof, we also include *invariants* which are properties of the distribution of the current experiment. The invariant holds *only* at that point in the proof where it appears and does not necessarily hold in following hybrids. An invariant inside a loop holds whenever the flow of the proof reaches that point in the loop. Namely, going back to our nested loop example from above, an invariant that appears after the "for $i = 1, \ldots, S$" statement, holds for the experiment immediately preceding the loop, and for all hybrids $\mathcal{H}^{(i,T)}$, except $\mathcal{H}^{(S,T)}$. An invariant that appears after the "for $j = 1, \ldots, T$" statement, should hold for the hybrid immediately preceding the loop, as well as for all $\mathcal{H}^{(i,T)}$, except $\mathcal{H}^{(S,T)}$.

We advise the reader to read our proof as if it was an execution of a computer program. We believe that while this proof writing method is still not very widely used, it is quite beneficial in writing complicated proofs, and will find additional uses. In what follows we first describe the notation used throughout the proof, and then describe the experiments.

Notation. Let $Q = Q(\lambda)$ denote a polynomial upper bound on the number of queries that are made by $\mathcal{A}$ in the experiment $\mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda)$. We denote these queries by $\{(f_i, \mathsf{parent}_i, \mathsf{mode}_i)\}_{i\in[Q]}$ and we also consider an implicit "zeroth" query which generates the master key pair $(\mathsf{msk}, \mathsf{mpk})$ of the scheme. This allows us to define the *depth* of the ith query, denoted $\mathsf{d}(i)$, s.t. $\mathsf{d}(0) = 0$ and $\mathsf{d}(i) = \mathsf{d}(\mathsf{p}(i)) + 1$ for $i > 0$, where we use $\mathsf{p}(i)$ as shorthand for parent_i. Thus we can view $\mathcal{A}$'s queries as a tree rooted by the zeroth query, where each query $(f_i, \mathsf{parent}_i, \mathsf{mode}_i)$ is the child of the query $\mathsf{p}(i)$ and has depth $\mathsf{d}(i)$ in the tree.

For any query $i \in \{0, \ldots, Q\}$, we define a function $\tilde{f}_i$ as follows: $\tilde{f}_0$ is the identity function, and for all $i > 0$ we define $\tilde{f}_i = f_i \circ \tilde{f}_{\mathsf{p}(i)}$. In other words, the ith query $(f_i, \mathsf{parent}_i, \mathsf{mode}_i)$ generates a delegated key that allows to compute the function $\tilde{f}_i(x)$ given an encryption of x. We say that the ith query is *observable* if $\tilde{f}_i(x^*_0) = \tilde{f}_i(x^*_1)$, and *unobservable* otherwise. We note that if the ith query is unobservable then necessarily $\mathsf{mode}_i = \mathsf{StoreKey}$.

We let $(\mathsf{msk}_i, \mathsf{mpk}_i)$ denote the key pair generated by the challenger while answering the ith query, and let $(\mathsf{msk}_0, \mathsf{mpk}_0)$ be the master key pair $(\mathsf{msk}, \mathsf{mpk})$ that is generated by the setup algorithm. Similarly, we let t_i denote the tag that is sampled while answering the ith query.

We denote by x_0^* and x_1^* the challenge messages that are chosen by $\mathcal{A}$, and by K^* the PRF key that is used for computing the challenge ciphertext. We further define $K_0^* = K^*$, and for all $i > 0$ we define K_i^*, s_i^*, and r_i^* as follows: $(s_i^*, r_i^*) = \mathsf{PRF.Eval}(K^*_{\mathsf{p}(i)}, t_i)$, and $K_i^* = \mathsf{PRF.Gen}(1^\lambda; s_i^*)$. Note that these are exactly the values that are computed by the ReEnc function produced in the ith query, when evaluated on the challenge ciphertext.

Finally, throughout the proof we find it convenient to denote by $\$$ a fresh value that is sampled uniformly and independently of all other existing values.

Experiment $\mathcal{H}_0$. This is the experiment $\mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda)$ (see Section 3).

Experiment $\mathcal{H}_1$. This experiment is obtained from the experiment $\mathcal{H}_0$ by having the challenger sample in advance the tags and the key pairs that are used for replying to $\mathcal{A}$'s queries. In fact, we will sample these values in a redundant manner so that we prepare several such triplets for each query, and the choice of which triplet to use is determined by the depth of the query. We thus have the following claim:

Specifically, at the beginning of the experiment, for all $i, d \in [Q]$ the challenger samples $t^{(\mathrm{o})}_{i,d}, t^{(\mathrm{u})}_{i,d} \leftarrow \{0,1\}^\lambda$ and $(\mathsf{msk}_{i,d}, \mathsf{mpk}_{i,d}) \leftarrow \mathsf{FE.Setup}(1^\lambda)$. Then, the experiment proceeds exactly as in $\mathcal{H}_1$, and whenever the challenger needs to sample t_i and $(\mathsf{msk}_i, \mathsf{mpk}_i)$ for replying to the ith query, it will use $t_i = t^{(\mathrm{o})}_{i,\mathsf{d}(i)}$ if i is an observable query, and $t_i = t^{(\mathrm{u})}_{i,\mathsf{d}(i)}$ otherwise. It will further use $(\mathsf{msk}_i, \mathsf{mpk}_i) = (\mathsf{msk}_{i,\mathsf{d}(i)}, \mathsf{mpk}_{i,\mathsf{d}(i)})$.

looking ahead, this experiment allows the challenger to know in advance, for every possible depth, a polynomial superset of the tags and key pairs that will be produced for replying to queries of this depth. The view of the adversary in this experiment is distributed identically to its view in the experiment $\mathcal{H}_0$, yielding the following observation:

▶ **Observation 4.2.** *For all $\lambda \in \mathbb{N}$ it holds that*

$$\Pr[\mathcal{H}_0(\lambda) = 1] = \Pr[\mathcal{H}_1(\lambda) = 1]\,.$$

Experiment $\mathcal{H}_2$. This experiment is obtained from the experiment $\mathcal{H}_1$ as follows. After the generation of the tags $t^{(\mathrm{o})}_{i,d}$ and $t^{(\mathrm{u})}_{i,d}$, and before interacting with the adversary, the challenger checks if any of the values $t^{(\mathrm{o})}_{i,d}$ or $t^{(\mathrm{u})}_{i,d}$ for some $(i,d) \in [Q]^2$ appears more than once. In such case the output of the experiment is defined as $\perp$, and otherwise the experiment is identical to the experiment $\mathcal{H}_1$. A standard union bound implies that the experiments $\mathcal{H}_1$ and $\mathcal{H}_2$ differ with probability at most $2(Q+1)^4 \cdot 2^{-\lambda} = \mathsf{neg}(\lambda)$, yielding the following observation:

▶ **Observation 4.3.** *For all $\lambda \in \mathbb{N}$ it holds that*

$$|\Pr[\mathcal{H}_1(\lambda) = 1] - \Pr[\mathcal{H}_2(\lambda) = 1]| \leq \frac{2(Q+1)^4}{2^\lambda}.$$

Experiment $\mathcal{H}_3$. This experiment is obtained from the experiment $\mathcal{H}_2$ by sampling a sequence $\mathsf{k}_0, \ldots, \mathsf{k}_{Q-1} \leftarrow \mathsf{SKE.KG}(1^\lambda)$ of symmetric keys (one for each possible depth – recall that Q is always an upper bound on the maximal depth), and modifying the symmetric ciphertext c that is generated by the key-generation algorithm when replying to each query as

follows: When replying to the ith query $(f_i, \mathsf{parent}_i, \mathsf{mode}_i)$, instead of sampling c uniformly, the key-generation algorithm computes

$$\boxed{c_i = \mathsf{SKE.Enc}\left(\mathsf{k}_{\mathsf{d}(i)-1}, \mathsf{ct}_i; \$\right)}$$

where $\mathsf{ct}_i = \mathsf{FE.Enc}(\mathsf{mpk}_i, (\tilde{f}_i(x_b^*), K_i^*, \bot); r_i^*)$ (recall that throughout the proof we find it convenient to denote by $\$$ a fresh value that is sampled uniformly and independently of all other existing values).

Note that ct_i is exactly the same as the "ct_i" value that is computed in the process of decrypting the challenge ciphertext using the ith functional key (and is also computed as an intermediate value when decrypting the challenge ciphertext with any descendant of the ith key). See the decryption algorithm above.

It thus makes sense to extend our notation and denote the challenge ciphertext by ct_0 (as in the decryption algorithm). Note that while ct_0 is encrypted with true randomness and includes a properly generated PRF key, all other ct_i's are encrypted using pseudorandomness and contain PRF keys that were generated pseudorandomly. We further say that ct_i is observable if the ith query is an observable query and unobservable otherwise.

To see why the adversary's view in $\mathcal{H}_3$ is indistinguishable from $\mathcal{H}_2$, we note that in $\mathcal{H}_3$, the symmetric keys $\mathsf{k}_0, \ldots, \mathsf{k}_{Q-1}$ are used only for generating the c_i's. In other words, this experiment can be carried out given only access to an encryption oracle $\mathsf{SKE.Enc}(\mathsf{k}_d, \cdot)$ for each $d \in \{0, \ldots, Q-1\}$ (instead of explicit access to the actual keys $\mathsf{k}_0, \ldots, \mathsf{k}_{Q-1}$). This enables us to use the ciphertext pseudorandomness of $\mathcal{SKE}$ to prove computational indistinguishability from $\mathcal{H}_2$, yielding the following claim in a rather straightforward manner:

▶ **Claim 4.4.** *Assuming that $\mathcal{SKE}$ has pseudorandom ciphertexts, there exists a negligible function $\mathsf{neg}(\cdot)$ such that*

$$|\Pr[\mathcal{H}_2(\lambda) = 1] - \Pr[\mathcal{H}_3(\lambda) = 1]| \leq \mathsf{neg}(\lambda)$$

for all sufficiently large $\lambda \in \mathbb{N}$.

For $d = 0, \ldots, Q$:

▶ **Invariant 4.5.** *In the previous experiment, it should hold that all ciphertexts ct_i that correspond to* unobservable *queries (i.e., queries for which $\tilde{f}_i(x_0^*) \neq \tilde{f}_i(x_1^*)$) such that $\mathsf{d}(i) < d$ are of the form $\mathsf{FE.Enc}(\mathsf{mpk}_i, (\bot, K_i^*, \mathsf{k}_{\mathsf{d}(i)}); \$)$, and all such ciphertext such that $\mathsf{d}(i) = d$ are of the form $\mathsf{ct}_i = \mathsf{FE.Enc}(\mathsf{mpk}_i, (\tilde{f}_i(x_b^*), K_i^*, \bot); \$)$. Further, if $\mathsf{d}(i) \leq d$ then $K_i^* = \mathsf{PRF.Gen}(1^\lambda; \$)$. More specifically:*

- *If i is such that $\mathsf{d}(i) < d$ and $\tilde{f}_i(x_0^*) \neq \tilde{f}_i(x_1^*)$, then it holds that*

  $$\mathsf{ct}_i = \mathsf{FE.Enc}\left(\mathsf{mpk}_i, \left(\bot, K_i^*, \mathsf{k}_{\mathsf{d}(i)}\right); \$\right)$$

  and $K_i^* = \mathsf{PRF.Gen}(1^\lambda; \$)$.
- *If i is such that $\mathsf{d}(i) = d$ and $\tilde{f}_i(x_0^*) \neq \tilde{f}_i(x_1^*)$, then it holds that*

  $$\mathsf{ct}_i = \mathsf{FE.Enc}\left(\mathsf{mpk}_i, \left(\tilde{f}_i(x_b^*), K_i^*, \bot\right); \$\right)$$

  and $K_i^* = \mathsf{PRF.Gen}(1^\lambda; \$)$.
- *If i is such that $\mathsf{d}(i) > d$ or $\tilde{f}_i(x_0^*) = \tilde{f}_i(x_1^*)$, then it holds that*

  $$\mathsf{ct}_i = \mathsf{FE.Enc}\left(\mathsf{mpk}_i, \left(\tilde{f}_i(x_b^*), K_i^*, \bot\right); r_i^*\right)$$

  and $K_i^* = \mathsf{PRF.Gen}(1^\lambda; s_i^*)$.

We note that this indeed holds for $d = 0$ in experiment $\mathcal{H}_3$.

For $i = 0, \ldots, Q$:

Experiment $\mathcal{H}_4^{(i,d)}$. In this experiment, the challenger changes the way ct_i is computed as follows. Before generating ct_i, the challenger checks if both $\mathsf{d}(i) = d$ and ct_i is unobservable ($\tilde{f}_i(x_0^*) \neq \tilde{f}_i(x_1^*)$). If both conditions hold then it sets

$$\mathsf{ct}_i = \mathsf{FE.Enc}(\mathsf{mpk}_i, (\bot, K_i^*, \mathsf{k}_d); \$) \ .$$

Otherwise ct_i is computed as in the previous experiment.

To see why the adversary's view in this experiment is indistinguishable from the previous hybrid, we note that for any child of i, i.e., j such that $\mathsf{p}(j) = i$,

$$\mathsf{ReEnc}_{f_j,t_j,\mathsf{mpk}_j,c_j}(\tilde{f}_i(x_b^*), K_i^*, \bot) = \mathsf{ReEnc}_{f_j,t_j,\mathsf{mpk}_j,c_j}(\bot, K_i^*, \mathsf{k}_d) = \mathsf{ct}_j \ .$$

This is because necessarily $\mathsf{d}(j) = d + 1 > d$ and due to Invariant 4.5. Thus, the security of the $(\mathsf{msk}_{i,d}, \mathsf{mpk}_{i,d})$ key pair guarantees that this hybrid is indistinguishable from the previous one: Since ct_i is unobservable, then necessarily the adversary cannot access $\mathsf{msk}_{i,d}$ directly, but rather only via further delegation (i.e., via functional keys to $\mathsf{ReEnc}_{f_j,t_j,\mathsf{mpk}_j,c_j}$). This yields the following claim in rather straightforward manner:

▶ **Claim 4.6.** *Assuming that $\mathcal{FE}$ is semi-adaptively secure, there exists a negligible function* $\mathsf{neg}(\cdot)$ *such that*

$$\left|\Pr\left[\mathcal{H}_4^{(0,0)}(\lambda) = 1\right] - \Pr[\mathcal{H}_3(\lambda) = 1]\right| \leq \mathsf{neg}(\lambda)$$

and

$$\left|\Pr\left[\mathcal{H}_4^{(i,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_4^{(i-1,d)}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d \in \{0, \ldots, Q\}$ and $i \in \{1, \ldots, Q\}$, and for all sufficiently large $\lambda \in \mathbb{N}$.

End For i.

▶ **Invariant 4.7.** *In the previous experiment, it should hold that all ciphertexts ct_i corresponding to unobservable queries such that $\mathsf{d}(i) \leq d$ are of the form $\mathsf{FE.Enc}(\mathsf{mpk}_i, (\bot, K_i^*, \mathsf{k}_{\mathsf{d}(i)}); \$)$ and further $K_i^* = \mathsf{PRF.Gen}(1^\lambda, \$)$.*

Recall that our goal is to restore Invariant 4.5 for value $(d + 1)$. To this end, we next need to replace r_j^* and s_j^* for all j such that $\mathsf{d}(j) = d + 1$, with random values (rather than values that are generated from $K_{\mathsf{p}(j)}^*$).

For $j = 0, \ldots, Q$:

▶ **Invariant 4.8.** *This is similar to Invariant 4.7, but for all ciphertexts $\mathsf{ct}_{j'}$ corresponding to unobservable queries such that $j' < j$ and $\mathsf{d}(j') = d + 1$ it holds that $r_{j'}^*$ and $s_{j'}^*$ had already been replaced with random.*

For $i = 0, \ldots, Q$:

Experiment $\mathcal{H}_5^{(i,j,d)}$. In this hybrid, we again change ct_i as follows. If ct_i is unobservable and $\mathsf{d}(i) = d$, then define $K_i^* = \mathsf{PRF.Gen}(1^\lambda, \$)$ (as before), $K_i^{\circledast} = \mathsf{PRF.Punc}(K_i^*, t_{j,d+1}^{(\mathrm{u})})$, $y_{i,j,d+1} = \mathsf{PRF.Eval}(K_i^*, t_{j,d+1}^{(\mathrm{u})})$. We now set:

$$\mathsf{ct}_i = \mathsf{FE.Enc}\left(\mathsf{mpk}_i, \left(\bot, \left(K_i^{\circledast}, (t_{j,d+1}^{(\mathrm{u})}, y_{i,j,d+1})\right), \mathsf{k}_{\mathsf{d}(i)}\right); \$\right) .$$

Namely, we replace the PRF key with a punctured key at the point $t_{j,d+1}^{(\mathrm{u})}$, and supply the value at that point[8]. We note that the functionality of $\mathsf{PRF.Eval}((K_i^{\circledast}, (t_{j,d+1}^{(\mathrm{u})}, y_{i,j,d+1})), \cdot)$ is identical to $\mathsf{PRF.Eval}(K_i^*, \cdot)$. The security of the key pair $(\mathsf{msk}_{i,d}, \mathsf{mpk}_{i,d})$ guarantees the indistinguishability of this hybrid (again relying on ct_i being unobservable and thus $\mathsf{msk}_{i,d}$ is not given to the adversary). This yields the following claim in rather straightforward manner:

▶ **Claim 4.9.** *Assuming that $\mathcal{FE}$ is semi-adaptively secure, there exists a negligible function $\mathsf{neg}(\cdot)$ such that*

$$\left|\Pr\left[\mathcal{H}_5^{(0,0,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_4^{Q,d}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d \in \{0, \ldots, Q\}$, and

$$\left|\Pr\left[\mathcal{H}_5^{(i,j,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_5^{(i-1,j,d)}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d, j \in \{0, \ldots, Q\}$ and $i \in \{1, \ldots, Q\}$, and for all sufficiently large $\lambda \in \mathbb{N}$.

End For i.

▶ **Invariant 4.10.** *In the current experiment, it holds that the PRF key for all depth-d ciphertexts which are unobservable had been punctured at point $t_{j,d+1}^{(u)}$, namely at the point on which it will be evaluated if indeed ct_j is of level $d+1$.*

For $i = 0, \ldots, Q$:

Experiment $\mathcal{H}_6^{(i,j,d)}$. In this hybrid, we again change ct_i in the case where ct_i is unobservable and $\mathsf{d}(i) = d$. The change from the previous experiment is only that now $y_{i,j,d+1} \leftarrow \$$, namely sampled randomly. We notice that already in the previous hybrid we never use K^* for unobservable queries, only the respective $K^{\circledast}$ and y values. Therefore swapping the y value to a completely random will be indistinguishable to the adversary by the punctured PRF property. This yields the following claim in rather straightforward manner:

▶ **Claim 4.11.** *Assuming that $\mathcal{PRF}$ is a puncturable pseudorandom function, there exists a negligible function $\mathsf{neg}(\cdot)$ such that*

$$\left|\Pr\left[\mathcal{H}_6^{(0,j,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_5^{Q,j,d}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

[8] As discussed in Section 2.1, we find it natural to consider an "augmented" evaluation algorithm that outputs a pre-determined value at the punctured point. That is, the augmented evaluation algorithm is given an augmented key $(K_i^{\circledast}, (t_{j,d+1}^{(\mathrm{u})}, y_{i,j,d+1}))$, where $K_i^{\circledast}$ is punctured at $t_{j,d+1}^{(\mathrm{u})}$, and given an input t it outputs $\mathsf{PRF.Eval}_{K_i^{\circledast}}(t)$ if $t \neq t_{j,d+1}^{(\mathrm{u})}$, and it outputs $y_{i,j,d+1}$ if $t = t_{j,d+1}^{(\mathrm{u})}$.

and

$$\left|\Pr\left[\mathcal{H}_6^{(i,j,d)}(\lambda)=1\right]-\Pr\left[\mathcal{H}_6^{(i-1,j,d)}(\lambda)=1\right]\right|\leq \mathsf{neg}(\lambda)$$

for all $d,j\in\{0,\ldots,Q\}$ *and* $i\in\{1,\ldots,Q\}$*, and for all sufficiently large* $\lambda\in\mathbb{N}$*.*

End For i.

▶ **Invariant 4.12.** *In the current experiment, it holds that the PRF key for all depth-d ciphertexts which are unobservable had been punctured at point* $t_{j,d+1}$*, and further that the punctured value had been substituted with random.*

Experiment $\mathcal{H}_7^{(j,d)}$. In this hybrid, we (finally) change the way ct_j is generated in the case where ct_j is unobservable and $\mathsf{d}(j)=d+1$ (if these conditions don't hold then we proceed as in the previous experiment). In particular, we change the way the randomness for ct_j and K_j^* is generated. Note that if ct_j is unobservable then it must be the case that $\mathsf{ct}_{\mathsf{p}(j)}$ is also unobservable (since $\tilde{f}_j=f_j\circ\tilde{f}_{\mathsf{p}(j)}$). In the previous experiment, we had

$$(s_j^*,r_j^*)=\mathsf{PRF.Eval}\left(\left(K^{\circledast}_{\mathsf{p}(j)},(t^{(\mathrm{u})}_{j,d+1},y_{\mathsf{p}(j),j,d+1})\right),t^{(\mathrm{u})}_{j,d+1}\right)\ .$$

We now define instead $(s'_j,r'_j)=y_{\mathsf{p}(j),j,d+1}$. We set $K_j^*=\mathsf{PRF.Gen}(1^\lambda,s'_j)$ and

$$\mathsf{ct}_j=\mathsf{FE.Enc}\left(\mathsf{mpk}_j,\left(\tilde{f}_j(x_b^*),K_j^*,\bot\right);r'_j\right)\ .$$

The view of the adversary here remains exactly the same, since $(s'_j,r'_j)=(s_j^*,r_j^*)$. However, conceptually this means that (s_j^*,r_j^*) are detached from the value that is embedded in $\mathsf{ct}_{\mathsf{p}(i)}$. As we will see in the next experiment, we will remove $y_{i,j,d+1}$ from ct_i, but (s'_j,r'_j) will still be well defined. This yields the following observation:

▶ **Observation 4.13.** *For all* $\lambda\in\mathbb{N}$ *it holds that*

$$\Pr\left[\mathcal{H}_7^{(j,d)}(\lambda)=1\right]=\Pr\left[\mathcal{H}_6^{Q,j,d}(\lambda)=1\right]$$

for all $d,j\in\{0,\ldots,Q\}$*.*

For $i=0,\ldots,Q$:

Experiment $\mathcal{H}_8^{(i,j,d)}$. In this hybrid, we again change ct_i in the case where ct_i is unobservable and $\mathsf{d}(i)=d$. We will now undo the puncturing of the PRF keys.

$$\mathsf{ct}_i=\mathsf{FE.Enc}\left(\mathsf{mpk}_i,\left(\bot,K_i^*,\mathsf{k}_{\mathsf{d}(i)}\right);\$\right)\ .$$

Indistinguishability holds since in all positions except $t^{(\mathrm{u})}_{j,d+1}$ the new and old keys, K_i^* and $\left(K^{\circledast}_i,(t_{j,d+1},y_{i,j,d+1})\right)$ are functionally equivalent. Furthermore, the function $\mathsf{PRF.Eval}$ is never evaluated at $t^{(\mathrm{u})}_{j,d+1}$ (since if ct_j is unobservable then (r'_j,s'_j) are used instead of (r_j^*,s_j^*)). The functional encryption security of $(\mathsf{msk}_{i,d},\mathsf{mpk}_{i,d})$ therefore implies indistinguishability. This yields the following claim in rather straightforward manner:

▶ **Claim 4.14.** *Assuming that* $\mathcal{FE}$ *is semi-adaptively secure, there exists a negligible function* $\mathsf{neg}(\cdot)$ *such that*

$$\left|\Pr\left[\mathcal{H}_8^{(0,j,d)}(\lambda)=1\right]-\Pr\left[\mathcal{H}_7^{j,d}(\lambda)=1\right]\right|\leq \mathsf{neg}(\lambda)$$

for all $d, j \in \{0, \ldots, Q\}$*, and*

$$\left|\Pr\left[\mathcal{H}_8^{(i,j,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_8^{(i-1,j,d)}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d, j \in \{0, \ldots, Q\}$ *and* $i \in \{1, \ldots, Q\}$*, and for all sufficiently large* $\lambda \in \mathbb{N}$*.*

End For i.

The proof of the following claim is almost identical to that of Claim 4.9 and is therefore omitted:

▶ **Claim 4.15.** *Assuming that* $\mathcal{FE}$ *is semi-adaptively secure, there exists a negligible function* $\mathsf{neg}(\cdot)$ *such that*

$$\left|\Pr\left[\mathcal{H}_8^{(Q,j,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_5^{(0,j+1,d)}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d \in \{0, \ldots, Q\}$ *and* $j \in \{0, \ldots, Q-1\}$*, and for all sufficiently large* $\lambda \in \mathbb{N}$*.*

End For j.

The proof of the following claim is almost identical to that of Claim 4.6 and is therefore omitted:

▶ **Claim 4.16.** *Assuming that* $\mathcal{FE}$ *is semi-adaptively secure, there exists a negligible function* $\mathsf{neg}(\cdot)$ *such that*

$$\left|\Pr\left[\mathcal{H}_8^{(Q,Q,d)}(\lambda) = 1\right] - \Pr\left[\mathcal{H}_4^{(0,d+1)}(\lambda) = 1\right]\right| \leq \mathsf{neg}(\lambda)$$

for all $d \in \{0, \ldots, Q-1\}$*, and for all sufficiently large* $\lambda \in \mathbb{N}$*.*

End For d.

We now notice that the proof is practically finished, since the last hybrid $\mathcal{H}_8^{(Q,Q,Q)}$ is completely independent of the bit b. To see this, note that the only values that depend on b in the experiment are the values $\tilde{f}_i(x_b^*)$ that appear inside the ciphertexts ct_i (in particular inside the challenge ciphertext $\mathsf{ct}^* = \mathsf{ct}_0$). We first point out that the value $\tilde{f}_i(x_b^*)$ is in fact *independent* of b in observable ciphertexts, since by definition $\tilde{f}_i(x_0^*) = \tilde{f}_i(x_1^*)$. As for unobservable ciphertexts, in $\mathcal{H}_8^{(Q,Q,Q)}$ none of them contains $\tilde{f}_i(x_b^*)$ at all, as this value had been replaced by $\perp$. This yields the following observation:

▶ **Observation 4.17.** *For all* $\lambda \in \mathbb{N}$ *it holds that*

$$\Pr\left[\mathcal{H}_8^{(Q,Q,Q)}(\lambda) = 1\right] = \frac{1}{2}\ .$$

We presented a sequence of polynomially-many experiments starting with the experiment $\mathcal{H}_0 = \mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}$ and ending with the experiment $\mathcal{H}_8^{(Q,Q,Q)}$ which is completely independent of the bit b. We showed that the output distributions of each two consecutive experiments are negligibly close, which implies that there exists a negligible function $\mathsf{neg}(\cdot)$ such that

$$\begin{aligned}
\mathsf{Adv}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda) &\stackrel{\mathsf{def}}{=} \left|\Pr\left[\mathsf{Exp}^{\mathsf{semiHFE}}_{\mathcal{HFE},\mathcal{A}}(\lambda) = 1\right] - \frac{1}{2}\right| \\
&= \left|\Pr\left[\mathcal{H}_0(\lambda) = 1\right] - \Pr\left[\mathcal{H}_8^{(Q,Q,Q)}(\lambda) = 1\right]\right| \\
&\leq \mathsf{neg}(\lambda)
\end{aligned}$$

for all sufficiently large $\lambda \in \mathbb{N}$, as required. ◀

1 Summary of the paper

Differential privacy [3, 4] has become the dominant theoretical framework for quantifying privacy loss, and has begun to make its way into policy and legal frameworks as a potential means for such a quantification. Running a differentially private mechanism on a dataset produces an outcome whose distribution is insensitive to removing one individual's data from the dataset or modifying her data. Consequently, differential privacy guards an individual against the possibility that observers of the mechanism's outcome will make strong inferences about her participation or non-participation (or, contingent on participation, inferences about her data).

Even without an individual's participation in a dataset, probabilistic inferences about her private data may be possible due to its correlation with the data of other individuals present in the dataset. In some cases, but not all, it may be desirable to protect individuals from such inferences. This paper aims to quantify the extent to which differentially private mechanisms guarantee such "inferential privacy protection", as a function of the prior belief (or set of potential priors) held by observers prior to the release of the mechanism's outcome.

We can illustrate the issues at play here using the oft-cited example of a study showing that smoking causes cancer [5]. If the data underlying the study were analyzed in a differentially private manner, readers of the study should not significantly update their beliefs about a given individual's participation in the dataset. However, if the individual were a known smoker, they should significantly revise their beliefs about her probability of developing cancer. Such belief revisions, in this circumstance, are generally not construed as a violation of privacy, because they merely reflect improved knowledge of an aggregate property of the population, not any knowledge specific to the individual. On the other hand, suppose that the hypothetical study focused on the more fine-grained question of how the likelihood of developing smoking-related cancers varies as a function of factors such as age, diet, lifestyle, and family history, and that the supplementary material accompanying the article included a

machine learning model (e.g., a random forest regressor) trained to predict these likelihoods. Even if the input-output behavior of the regressor were not construed as violating privacy, the regressor itself could be a highly complex object (e.g., a collection of more than a thousand decision trees) and its contents might reflect private information in the training data. If the training algorithm were differentially private, would it ensure that participants in the study were protected from "inferential privacy violations"? This paper abstracts away the specifics of the example and asks the basic question: when does a differential privacy guarantee for an algorithm imply an inferential privacy guarantee?

In the paper, we formally define the inferential privacy parameter of a mechanism with respect to a set of prior distributions. Informally, it measures the maximum amount by which an adversary might multiplicatively update his belief in the likelihood that a particular individual's entry in the database assumes a particular value, given that the adversary starts with one of the specified prior distributions and performs a Bayesian update on the mechanism's outcome. An easy application of Bayes' Law confirms the fact (known to many prior authors, e.g. [7]) that when individuals' private data are mutually independent, the differential privacy parameter of a mechanism equals its inferential privacy parameter. On the other hand, we have seen that when the adversary's prior incorporates uncertainty about certain aggregate statistics of the population (e.g., the frequency of cancer among smokers) the inferential privacy parameter of a mechanism may be much greater than its differential privacy parameter. Interpolating between these two extremes, one might guess that differentially private mechanisms are guaranteed to have a relatively small inferential privacy parameter when correlations between individuals are either weak or localized, i.e. when each individual has only a few others with whom her data correlates strongly.

Our work makes this intuition precise and confirms it rigorously. To do so, we identify a surprisingly tight relationship between our questions about privacy and inference and a corresponding set of questions in mathematical physics regarding the magnitude of the change in a Gibbs measure when an external field is applied to the system. While it may initially seem surprising that the two fields are connected in this way, one can see the first intimations of the connection in the discussion about weak, localized correlations at the end of the preceding paragraph—this is none other than the *correlation decay* property that is the hallmark of statistical mechanical systems at high temperature.

Our first main theorem pertains to cases in which the data are binary-valued and the adversary's prior distribution satisfies *positive affiliation*, meaning that conditioning on all but two entries in the database, the remaining two entries can never be negatively correlated. This assumption is satisfied by the priors commonly ascribed to biological data—where heredity and contagion lead to positive correlations among individuals' attributes, but never or rarely lead to negative correlations—and to social data, where positive correlations result from homophily and social contagion. (If one interprets the adversary's prior as a Gibbs measure, the positive affiliation property says that the system is *ferromagnetic*.) Our theorem gives a precise formula for the worst-case inferential privacy parameter of ϵ-differentially private mechanisms in terms of the magnetization of the corresponding ferromagnetic system in an external field of strength $\frac{\epsilon}{2}$. The proof of the theorem shows that the mechanism attaining this worst-case bound is not a contrived mechanism; in fact it is one of the most commonly occurring differentially private mechanisms: adding Laplace noise to the sum of the values in the database! Thus, when data are positively affiliated, any inferential privacy guarantee that one can prove for the Laplace mechanism *automatically* carries over to arbitrary differentially private mechanisms.

Because our theorem provides an exact formula for worst-case inferential privacy in terms of magnetization (and not merely an upper bound) it allows us to translate results about the physics of magnets directly into results about inferential privacy. In particular, existing results about phase transitions in Ising models (e.g., for the infinite d-regular tree [1]) imply that inferential privacy parameters can be surprisingly sensitive to variations in other parameters of the model. For example, if we vary the differential privacy parameter of the Laplace mechanism, starting at $\epsilon = 0$ and increasing from there, the mechanism's inferential privacy parameter increases gradually until ϵ crosses a critical value, at which point it can increase very precipitously, approaching a step discontinuity as the number of individuals tends to infinity. In other words, tiny variations in the differential privacy parameter of a mechanism can potentially lead to enormous variations in inferential privacy, a privacy-theoretic manifestation of the physical phenomenon of phase transitions in spin systems.

Our second main result applies when the data are not binary-valued, or when the prior violates positive affiliation. It shows that the inferential privacy parameter of a mechanism is bounded above by a function of the mechanism's differential privacy parameter and the spectral norm of an *influence matrix* encoding the strength of pairwise correlations between individuals. The theorem again manifests the relationship between inferential privacy and statistical mechanics; its statement and proof constitute an adaptation of the Dobrushin Comparison Theorem [2, 6, 8] from the traditional setting of additive approximation to multiplicative approximation.

Abstract

An interesting challenge for the cryptography community is to design authentication protocols that are so simple that a human can execute them without relying on a fully trusted computer. We propose several candidate authentication protocols for a setting in which the human user can only receive assistance from a semi-trusted computer – a computer that stores information and performs computations correctly but does not provide confidentiality. Our schemes use a semi-trusted computer to store and display public challenges $C_i \in [n]^k$. The human user memorizes a random secret mapping $\sigma : [n] \to \mathbb{Z}_d$ and authenticates by computing responses $f(\sigma(C_i))$ to a sequence of public challenges where $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ is a function that is easy for the human to evaluate. We prove that any statistical adversary needs to sample $m = \tilde{\Omega}\left(n^{s(f)}\right)$ challenge-response pairs to recover σ, for a security parameter $s(f)$ that depends on two key properties of f. Our lower bound generalizes recent results of Feldman et al. [26] who proved analogous results for the special case $d = 2$. To obtain our results, we apply the general hypercontractivity theorem [45] to lower bound the *statistical dimension* of the distribution over challenge-response pairs induced by f and σ. Our *statistical dimension* lower bounds apply to arbitrary functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ (not just to functions that are easy for a human to evaluate). As an application, we propose a family of human computable password functions f_{k_1,k_2} in which the user needs to perform $2k_1 + 2k_2 + 1$ primitive operations (e.g., adding two digits or remembering a secret value $\sigma(i)$), and we show that $s(f) = \min\{k_1 + 1, (k_2 + 1)/2\}$. For these schemes, we prove that forging passwords is equivalent to recovering the secret mapping. Thus, our human computable password schemes can maintain strong security guarantees even after an adversary has observed the user login to many different accounts.

1 Introduction

A typical computer user has many different online accounts which require some form of authentication. While passwords are still the dominant form of authentication, users struggle to remember their passwords. As a result users often adopt insecure password practices (e.g., reuse, weak passwords) [28, 21, 39, 18] or end up having to frequently reset their passwords. Recent large-scale password breaches highlight the importance of this problem [1, 21, 11, 2, 50, 3, 4, 5, 6, 7, 8, 9]. An important research goal is to develop usable and secure password management scheme – a systematic strategy to help users create and remember multiple passwords. Blocki et al. [13] and Blum and Vempala [17] recently proposed password management schemes that maintain some security guarantees after a small constant number of breaches (e.g., an adversary who sees three of the user's passwords still has some uncertainty about the user's remaining passwords).

In this work we focus on the goal of developing human computable password management schemes in which security guarantees are strongly maintained after *many* breaches (e.g., an adversary who sees one-hundred of the user's passwords still has high uncertainty about the user's remaining passwords). In a human computable password management scheme the user reconstructs each of his passwords by *computing* the response to a public challenge.

Our human computable password schemes admittedly require more human effort than the password management schemes of Blocki et al. [13] and Blum and Vempala [17], and, unlike Blocki et al. [13], our scheme requires users to do simple mental arithmetic (e.g., add two single-digit numbers) in their head. However, our proposed schemes are still human usable in the sense that a motivated, security-conscious user would be able to learn to use the scheme and memorize all associated secrets in a few hours. In particular, the human computation in our schemes only involves a few very simple operations (e.g., addition modulo 10) over secret values (digits) that the user has memorized. More specifically, in our candidate human computable password schemes the user learns to compute a simple function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$,[1] and memorizes a secret mapping $\sigma : [n] \to \mathbb{Z}_d$. The user authenticates by responding to a sequence of single digit challenges, i.e., a challenge-response pair $(C, f(\sigma(C)))$ is a challenge $C \in X_k \subseteq [n]^k$ and the corresponding response.

One of our candidate human computable password schemes involves the function

$$f(x_0, x_1, x_2, x_3, x_4, x_5, \ldots, x_{13}) = x_{13} + x_{12} + x_{(x_{10}+x_{11} \mod 10)} \mod 10 .$$

If the user memorizes a secret mapping σ from n images to digits then each challenge $C = (I_0, \ldots, I_{13})$ would correspond to an ordered subset of 14 of these images and the response to the challenge is $f\big(\sigma(I_0), \ldots, \sigma(I_{13})\big)$. We observe that a human would only need to perform three addition operations modulo 10 to evaluate this function. The user would respond by (1) adding the secret digits associated with challenge images I_{10} and I_{11} to get a secret index $0 \le i \le 9$, (2) finding image I_i, (3) adding the secret digits associated with images I_i, I_{12} and I_{13} to produce the final response. To amplify security the user may respond to $\lambda \ge 1$ single-digit challenges $C_1, \ldots, C_\lambda$ to obtain a λ digit password $f(\sigma(C_1)), \ldots, f(\sigma(C_\lambda))$. We note that the challenge C does not need to be kept secret and thus the images can be arranged on the screen in helpful manner for the human user – see Figure 1 for an example and see Appendix A for more discussion of the user interface.

[1] In our security analysis we consider arbitrary bases d. However, our specific schemes use the base $d = 10$ that is most familiar to human users.

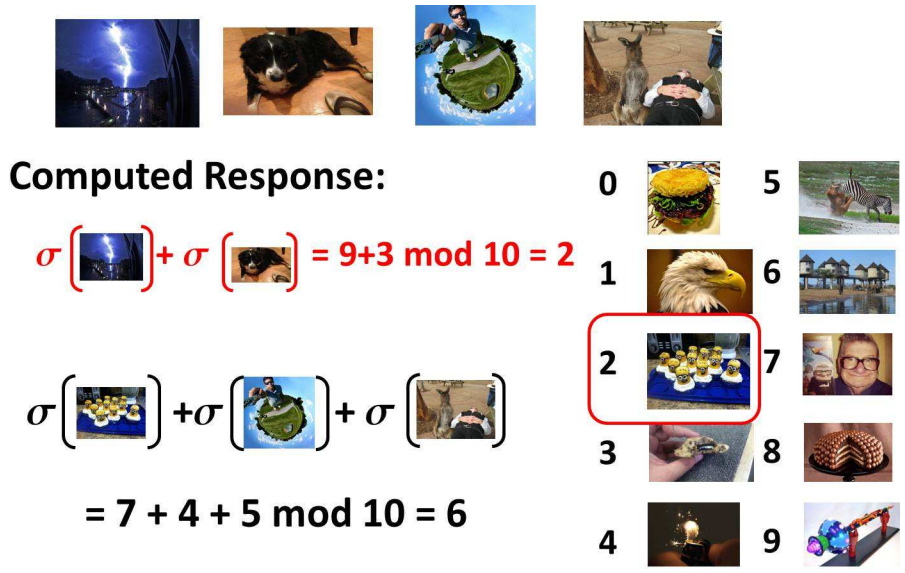

Figure 1 Computing the response $f(\sigma(C)) = 6$ to a single digit challenge C.

We present a natural conjecture which implies that a polynomial time attacker will need to see the responses to $\tilde{\Omega}\left(n^{s(f)}\right)$ random challenges before he can forge the user's passwords (accurately predict the responses to randomly selected challenges)[2]. Here, $s(f)$ is a security parameter that depends on two key properties of the function f (in our above example $s(f) = 3/2$). Furthermore, we provide strong evidence for our conjecture by ruling out a broad class of algorithmic techniques that the adversary might use to attack our scheme.

Following Blocki et al. [13] we consider a setting where a user has two types of memory: *persistent memory* (e.g., a sticky note or a text file on his computer) and *associative memory* (e.g., his own human memory). We assume that persistent memory is reliable and convenient but not private (i.e., an adversary can view all challenges stored in persistent memory, but he cannot tamper with them). In contrast, a user's associative memory is private but lossy – if the user does not rehearse a memory it may be forgotten. Thus, the user can store a password challenge $C \in X_k$ in persistent memory, but the mapping σ must be stored in associative memory (e.g., memorized and rehearsed). We allow the user to receive assistance from a semi-trusted computer. A semi-trusted computer will perform computations accurately (e.g., it can be trusted to show the user the correct challenge), but it will not ensure privacy of its inputs or outputs. This means that a human computable password management scheme should be based on a function f that the user can compute entirely in his head.

Contributions

We provide precise notions of security and usability for a human computable password management scheme (Section 2). We introduce the notion of UF-RCA security (Unforgeability under Random Challenge Attacks). Informally, a human computable password scheme is

[2] We stress that, unlike [13, 17], our security guarantees are not information theoretic. In fact, a computationally unbounded adversary would need to see at most $O(n)$ challenge-response pairs to break the human computable password management scheme.

UF-RCA secure if an adversary cannot forge passwords after seeing many example challenge-response pairs.

We present the design of a candidate family of human computable password management schemes f_{k_1,k_2}, and analyze the usability and security of these schemes (Section 3). Our usability analysis indicates that to compute $f_{k_1,k_2}(\sigma(C))$ the user needs to execute $2k_1+2k_2+1$ simple operations (e.g., addition of single digits modulo 10). The main technical result of this section (Theorem 10) states that our scheme is UF-RCA secure given a plausible conjecture about the hardness of random planted constraint satisfiability problems (*RP-CSP*). Our conjecture is that any polynomial time adversary needs to see at least $m = n^{\min\{r(f)/2, g(f)+1-\epsilon\}}$ challenge-response pairs $(C, f(\sigma(C)))$ to recover the secret mapping σ. Here, $s(f) = \min\{r(f)/2, g(f)+1\}$ is a composite security parameter involving $g(f)$ (how many inputs to f need to be fixed to make f linear?) and $r(f)$ (what is the largest value of r such that the distribution over challenge-response pairs are $(r-1)$-wise independent?). We prove that $g(f_{k_1,k_2}) = k_1$ and $r(f_{k_1,k_2}) = (k_2+1)$.

Next we prove that any statistical adversary needs at least $\tilde{\Omega}\left(n^{r(f)/2}\right)$ challenge-response pairs $(C, f(\sigma(C)))$ to find a secret mapping σ' that is ϵ-correlated with σ (Section 4). This result may be interpreted as strong evidence in favor of the *RP-CSP* hardness assumption as most natural algorithmic techniques have statistical analogues (see discussion in Section 4). While Gaussian Elimination is a notable exception, our composite security parameter accounts for attacks based on Gaussian Elimination – an adversary needs to see $m = \tilde{\Omega}\left(n^{1+g(f)}\right)$ challenge-response pairs to recover σ using Gaussian Elimination. Moving beyond asymptotic analysis we also provide empirical evidence that our human computable password management scheme is hard to crack. In particular, we used a CSP solver to try to recover $\sigma \in \mathbb{Z}_{10}^n$ given m challenge-response pairs using the functions $f_{1,3}$ and $f_{2,2}$. Our CSP solver failed to find the secret mapping $\sigma \in \mathbb{Z}_{10}^{50}$ given $m = 1000$ random challenge-response pairs with both functions $f_{1,3}$ and $f_{2,2}$. Additionally, we constructed public challenges for cryptographers to break our human computable password management schemes under various parameters (e.g., $n = 100$, $m = 1000$).

Our lower bound for statistical adversaries is based on the *statistical dimension* of the distribution over challenge-response pairs induced by f and σ. We stress that our analysis of the statistical dimension applies to arbitrary functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$, not just to functions that are easy for humans to compute. Our analysis of the statistical dimension generalizes recent results of Feldman et al. [26] for binary predicates and may be of independent interest. While the analysis is similar at a high level, we stress that our proofs do require some new ideas. Because our function f is not a binary predicate we cannot use the Walsh basis functions to express the Fourier decomposition of f and analyze the statistical dimension of our distribution over challenge-response pairs as Feldman et al. [26] do. Instead, we use a generalized set of Fourier basis functions to take the Fourier decomposition of f, and we apply the general hypercontractivity theorem [45] to obtain our bounds on the statistical dimension.

We complete the proof of Theorem 10 in Section 5 by proving that forging passwords and approximately recovering the secret mapping are equivalent problems for a broad class of human computable password schemes, including our candidate family f_{k_1,k_2}. This result implies that any adversary who can predict the response $f(C)$ to a random challenge C with better accuracy than random guessing can be used as a blackbox to approximately recover the secret mapping.

2 Definitions

2.1 Notation

Given two strings $\alpha_1, \alpha_2 \in \mathbb{Z}_d^n$ we use $H(\alpha_1, \alpha_2) \doteq |\{i \in [n] \mid \alpha_1[i] \neq \alpha_2[i]\}|$ to denote the Hamming distance between them. We will also use $H(\alpha_1) \doteq H(\alpha_1, \vec{0})$ to denote the Hamming weight of α_1. We use $\sigma : [n] \to \mathbb{Z}_d$ to denote a secret random mapping that the user will memorize. We will sometimes abuse notation and think of $\sigma \in \mathbb{Z}_d^n$ as a string which encodes the mapping, and we will use $\sigma \sim \mathbb{Z}_d^n$ to denote a random mapping chosen from $\mathbb{Z}_d^n$ uniformly at random. Given a distribution $\mathcal{D}$ we will use $x \sim \mathcal{D}$ to denote a random sample from this distribution. We also use $x \sim S$ to denote an element chosen uniformly at random from a finite set S.

▶ **Definition 1.** We say that two mappings $\sigma_1, \sigma_2 \in \mathbb{Z}_d^n$ are ϵ-correlated if $\frac{H(\sigma_1,\sigma_2)}{n} \leq \frac{d-1}{d} - \epsilon$, and we say that a mapping $\sigma \in \mathbb{Z}_d^n$ is δ-balanced if $\max_{i \in \{0,\ldots,d-1\}} \left| \frac{H(\sigma,\vec{i})}{n} - \frac{d-1}{d} \right| \leq \delta$.

Note that for a random mapping σ_2 we expect σ_1 and σ_2 to differ at $\mathbb{E}_{\sigma_2 \sim \mathbb{Z}_d^n}[H(\sigma_1, \sigma_2)] = n\left(\frac{d-1}{d}\right)$ locations, and for a random mapping σ and $i \sim \{0, \ldots, d-1\}$ we expect σ to differ from $\vec{i}$ at $\mathbb{E}_{i \sim \mathbb{Z}_d, \sigma \sim \mathbb{Z}_d^n}\left[H\left(\sigma, \vec{i}\right)\right] = n\left(\frac{d-1}{d}\right)$ locations. Thus, with probability $1 - o(1)$ a random mapping σ_2 will not be ϵ-correlated with σ_1, but a random mapping σ will be δ-balanced with probability $1 - o(1)$.

We let $X_k \subseteq [n]^k$ denote the space of ordered clauses of k variables without repetition. We use $C \sim X_k$ to denote a clause C chosen uniformly at random from X_k and we use $\sigma(C) \in \mathbb{Z}_d^k$ to denote the values of the corresponding variables in C. For example, if $d = 10$, $C = (3, 10, 59)$ and $\sigma(i) = (i + 1 \mod 10)$ then $\sigma(C) = (4, 1, 0)$.

We view each clause $C \in X_k$ as a *single-digit challenge*. The user responds to a challenge C by computing $f(\sigma(C))$, where $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ is a *human computable* function (see discussion below) and $\sigma : [n] \to \mathbb{Z}_d$ is the secret mapping that the user has memorized. For example, if $d = 10$, $C = (3, 10, 59)$, $\sigma(i) = (i + 1 \mod 10)$ and $f(x, y, z) = (x - y + z \mod 10)$ then $f(\sigma(C)) = (4 - 1 + 0 \mod 10) = 3$. A length-$\lambda$ password challenge $\vec{C} = \langle C_1, \ldots, C_\lambda \rangle \in (X_k)^\lambda$ is a sequence of t single digit challenges, and $f(\sigma(\vec{c})) = \langle f(\sigma(C_1)), \ldots, f(\sigma(C_\lambda)) \rangle \in \mathbb{Z}_d^\lambda$ denotes the corresponding response (e.g., a password).

Let's suppose that the user has m accounts $A_1, \ldots, A_m$. In a human computable password management scheme we will generate m length-λ password challenges $\vec{C}_1, \ldots, \vec{C}_m \in (X_k)^\lambda$. These challenges will be stored in persistent memory so they are always accessible to the user as well as the adversary. When our user needs to authenticate to account A_i he will be shown the length-t password challenge $\vec{C}_i = \langle C_1^i, \ldots, C_\lambda^i \rangle$. The user will respond by computing his password $p_i = \langle f(\sigma(C_1^i)), \ldots, f(\sigma(C_\lambda^i)) \rangle \in \mathbb{Z}_d^\lambda$.

2.2 Requirements for a Human Computable Function

In our setting we require that the composite function $f \circ \sigma : X_k \to \mathbb{Z}_d$ is human computable. Informally, we say that a function f is *human-computable* if a human user can evaluate f *quickly* in his head.

▶ **Requirement 2.** *A function f is $\hat{t}$-*human computable *for a human user H if H can reliably evaluate f in his head in $\hat{t}$ seconds.*

We argue that a function f will be *human-computable* whenever there is a fast streaming algorithm [10] to compute f using only very simple primitive operations. A streaming

algorithm is an algorithm for processing a data stream in which the input (e.g., the challenge C) is presented as a sequence of items that can only be examined once. In our context the streaming algorithm must have a very low memory footprint because a typical person can only keep 7 ± 2 'chunks' of information in working memory [41] at any given time. Our streaming algorithm can only involve primitive operations that a person could execute quickly in his head (e.g., adding two digits modulo 10, recalling a value $\sigma(i)$ from memory).

▶ **Definition 3.** Let P be a set of primitive operations. We say that a function f is $(P, \tilde{t}, \hat{m})$-computable if there is a space $\hat{m}$ streaming algorithm $\mathcal{A}$ to compute f using only $\tilde{t}$ operations from P.

In this paper we consider the following primitive operations P: **Add**, **Recall** and **TableLookup**. **Add** : $\mathbb{Z}_{10} \times \mathbb{Z}_{10} \to \mathbb{Z}_{10}$ takes two digits x_1 and x_2 and returns $x_1 + x_2$ mod 10. **Recall** : $[n] \to \mathbb{Z}_{10}$ takes an index i and returns the secret value $\sigma(i)$ that the user has memorized. **TableLookup** : $\mathbb{Z}_{10} \times [n]^{10} \to [n]$ takes a digit x_1 and finds the x_1'th value from a table of 10 indices. We take the view that no human computable function should require users to store intermediate values in long-term memory because the memorization process would necessarily slow down computation. Therefore, we restrict our attention to space $\hat{m}$ streaming algorithms and do not include any primitive operation like **MemorizeValue**.

▶ **Example.** The function $f \circ \sigma(i_1, \ldots, i_5) = \sigma(i_1) + \ldots + \sigma(i_5)$ requires 9 primitive operations (five **Recall** operations and four **Add** operations) and requires space $\hat{m} = 3$ (e.g., we need one slot to store the current total, one slot to store the next value from the data stream and one free slot to execute a primitive operation).

Similar primitive operations have been studied by cognitive physchologists (e.g., [51]). The time γ_H it takes a human user H to execute one primitive operation will typically improve with practice (e.g., [33]). We note that we allow this computation speed constant γ_H to vary from user to user in the same way that two computers might operate at slightly different speeds. We conjecture that, after training, a human user H with a moderate mathematical background will be able to evaluate a $(P, \tilde{t}, 3)$-computable function in $\hat{t} \leq \tilde{t}$ seconds – the first author of this paper found that (after some practice) he could evaluate $(P, 9, 3)$-computable functions in 7.5-seconds ($\gamma_H \leq 1$).

▶ **Conjecture 4.** *Let $P = \{\mathbf{Add}, \mathbf{Recall}, \mathbf{TableLookup}\}$. For each human user H there is a small constant $\gamma_H > 0$ such that any $(P, \tilde{t}, 3)$-computable function f will be $\hat{t}$-human computable for H with $\hat{t} = \gamma_H \tilde{t}$.*

2.3 Password Unforgeability

In the password forgeability game the adversary attempts to guess the user's password for a randomly selected account after he has seen the user's passwords at m/λ other randomly selected accounts. We say that a scheme is UF-RCA (Unforgeability against Random Challenge Attacks) secure if any probabilistic polynomial time adversary fails to guess the user's password with high probability. In the password forgeability game we select the secret mapping $\sigma : [n] \to \mathbb{Z}_d$ uniformly at random along with challenges $C_1, \ldots, C_{m+\lambda} \sim X_k$. The adversary is given the function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ and is shown the challenges $C_1, \ldots, C_{m+\lambda}$ as well as the values $f(\sigma(C_i))$ for $i \in \{1, \ldots, m\}$. The game ends when the adversary $\mathcal{A}$ outputs a guess $\langle q_1, \ldots, q_\lambda \rangle \in \mathbb{Z}_d^\lambda$ for the value of $\langle f(\sigma(C_{m+1})), \ldots, f(\sigma(C_{m+\lambda})) \rangle$. We say that the adversary wins if he correctly guesses the responses to all of the challenges $C_{m+1}, \ldots, C_{m+\lambda}$, and we use $\mathbf{Wins}(\mathcal{A}, n, m, \lambda)$ to denote the event that the adversary wins the game (e.g.,

$\forall i \in \{1,\ldots,\lambda\}.q_i = f\left(\sigma\left(C_{m+i}\right)\right)$). We are interested in understanding how many example single digit challenge-response pairs the adversary needs to see before he can start breaking the user's passwords.

▶ **Definition 5** (Security)**.** We say that a function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ is $\mathbf{UF-RCA}\left(n, m, \lambda, \delta\right)$ – *secure* if for every probabilistic polynomial time (in n, m) adversary $\mathcal{A}$ we have

$$\Pr\left[\mathbf{Wins}\left(\mathcal{A}, n, m, \lambda\right)\right] \leq \delta \ ,$$

where the randomness is taken over the selection of the secret mapping $\sigma \sim \mathbb{Z}_d^n$, the challenges $C_1, \ldots, C_{m+\lambda}$ as well as the adversary's coins.

Discussion

Our security model is different from the security model of Blocki et al. [13] in which the adversary gets to adaptively select which accounts to compromise and which account to attack. While our security model may seem weaker at first glance because the adversary does not get to select which account to compromise/attack, we observe that the password management schemes of Blocki et al. [13] are only secure against one to three adaptive breaches. By contrast, our goal is to design human computable password schemes that satisfy $\mathbf{UF-RCA}$ security for large values of m (e.g. 1000), which means that it is reasonable to believe that the user has at most m/λ password protected accounts. If the user has at most m/λ accounts then union bounds imply that an adaptive adversary – who gets to compromise all but one account – will not be able to forge the password at any remaining account with probability greater than $m\delta/\lambda$ (typically, $m \ll \lambda/\delta$)[3].

2.4 Security Parameters of f

Given a function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ we define the function $Q^f : \mathbb{Z}_d^{k+1} \to \{\pm 1\}$ s.t. $Q^f\left(x, i\right) = 1$ if $f(x) = i$; otherwise $Q^f\left(x, i\right) = -1$. We use Q_σ^f to define a distribution over $X_k \times \mathbb{Z}_d$ (challenge-response pairs) as follows: $\Pr_{Q_\sigma^f}\left[C, i\right] \doteq \frac{Q^f(\sigma(C), i)+1}{2|X_k|}$. Intuitively, Q_σ^f is the uniform distribution over challenge response pairs (C, j) s.t. $f\left(\sigma\left(C\right)\right) = j$. We also use $Q^{f,j} : \mathbb{Z}_d^k \to \{\pm 1\}$ $\left(Q^{f,j}\left(x\right) = Q^f\left(x, j\right)\right)$ to define a distribution over X_k. $\Pr_{Q_\sigma^{f,j}}[C] = \frac{Q^{f,j}(f(\sigma(C)))+1}{2|\{C' \in X_k : f(\sigma(C'))=j|} = \Pr_{Q_\sigma^f}\left[(C, i) \mid i = j\right]$. We write the Fourier decomposition of a function $Q : \mathbb{Z}_d^k \to \{\pm 1\}$ as follows

$$Q(x) = \sum_{\alpha \in \mathbb{Z}_d^k} \hat{Q}_\alpha \cdot \chi_\alpha\left(x\right) \ \text{, where the basis functions are } \ \chi_\alpha\left(x\right) \doteq \exp\left(\frac{-2\pi\sqrt{-1}\left(x \cdot \alpha\right)}{d}\right) .$$

We say that a function Q has degree ℓ if $\ell = \max\left\{H\left(\alpha\right) \;\middle|\; \alpha \in \mathbb{Z}_d^k \wedge \hat{Q}_\alpha \neq 0\right\}$ – equivalently if $Q(x) = \sum_i Q_i(x)$ can be expressed as a sum of functions where each function $Q_i : \mathbb{Z}_d^k \to \mathbb{R}$ depends on at most ℓ variables.

▶ **Definition 6.** We use $r(Q) \doteq \min\left\{H\left(\alpha\right) \;\middle|\; \exists \alpha \in \mathbb{Z}_d^k . \hat{Q}_\alpha \neq 0 \wedge \alpha \neq \vec{0}\right\}$ to denote the distributional complexity of Q, and we use $r(f) = \min\left\{r\left(Q^{f,j}\right) \mid j \in \mathbb{Z}_d\right\}$ to denote the distributional complexity of f. We use $g(f) \doteq$

$$\min\left\{\ell \in \mathbb{N} \cup \{0\} \;\middle|\; \exists \alpha \in \mathbb{Z}_d^\ell, S \subseteq [k], \hat{d} \in \mathbb{Z}_d . \text{s.t } |S| = \ell \ \&\ f_{|S,\alpha} \text{ is a linear function mod } \hat{d}\right\} \ ,$$

[3] We assume in our analysis that the adversary does not get to pick the challenges C that the user will solve.

to denote the minimum number of variables that must be fixed to make f a linear function. Here, $f_{|S,\alpha} : \mathbb{Z}_d^{k-\ell} \to \mathbb{Z}_d$ denotes the function f after fixing the variables at the indices specified by S to α. Finally, we use $s(f) \doteq \min\{r(f)/2, g(f)+1\}$ as our composite security measure.

We conjecture that a polynomial time adversary will need to see $m = n^{s(f)}$ challenge-response pairs before he can approximately recover the secret mapping σ. We call this conjecture about the hardness of random planted constraint satisfiability problems RP-CSP (Conjecture 7). In support of RP-CSP we prove that any statistical algorithm needs to see at least $m = \tilde{\Omega}\left(n^{r(f)/2}\right)$ challenge response pairs to (approximately) recover the secret mapping σ and we observe that a polynomial time adversary would need to see $m = O\left(n^{g(f)+1}\right)$ challenge-response pairs to recover σ using Gaussian Elimination. In Section 5 we show that the human computable password scheme will be UF-RCA secure provided that RP-CSP holds and that f satisfies a few moderate properties (e.g., the output of f is evenly distributed).

▶ **Conjecture 7** (RP-CSP). *For every probabilistic polynomial time adversary $\mathcal{A}$ and every $\epsilon, \epsilon' > 0$ there is an integer N s.t. for all $n > N$, $m \leq n^{\min\left\{r(f)/2, g(f)+1-\epsilon'\right\}}$ we have* $\Pr\left[\textbf{Success}\left(\mathcal{A}, n, m, \epsilon\right)\right] \leq \mu(n)$, *where* $\textbf{Success}\left(\mathcal{A}, n, m, \epsilon\right)$ *denotes the event that $\mathcal{A}$ finds a mapping σ' that is ϵ-correlated with σ given m randomly selected challenge response pairs* $\left(C_1, f\left(\sigma\left(C_1\right)\right)\right), \ldots, \left(C_m, f\left(\sigma\left(C_m\right)\right)\right)$ *and $\mu(n)$ is a negligible function. The probability is over the selection of the random mapping σ, the challenges $C_1, \ldots, C_m$ and the random coins of the adversary.*

3 Candidate Secure Human Computable Functions

In this section we present a family of candidate human computable functions. We consider the usability of these human computable password schemes in Section 3.1, and we analyze the security of our schemes in Section 3.2.

We first introduce our family of candidate human computable functions (for all of our candidate human computable functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ we fix $d = 10$ because most humans are used to performing arithmetic operations on digits). Given integers $k_1 > 0$ and $k_2 > 0$ we define the function $f_{k_1,k_2} : \mathbb{Z}_{10}^{10+k_1+k_2}$ as follows

$$f_{k_1,k_2}\left(x_0, \ldots, x_{9+k_1+k_2}\right) = x_j + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10, \quad \text{where} \quad j = \left(\sum_{i=10}^{9+k_1} x_i\right) \mod 10\ .$$

Authentication Process

We briefly overview the authentication process – see Algorithms 2 and 3 in Appendix A for a more formal presentation of the authentication process. We assume that the mapping $\sigma : \{1, ..., n\} \to \mathbb{Z}_{10}$ is generated by the user's local computer in secret. The user may be shown mnemonic helpers (see discussion below) to help memorize σ, but these mnemonic helpers are discarded immediately afterward. After the user has memorized σ he can create a password pw_i for an account A_i as follows: the user's local computer generates λ random single-digit challenges $C_1^i, \ldots, C_\lambda^i \in X_\lambda$ and the user computes $pw_i = f\left(\sigma\left(C_1\right)\right), \ldots, f\left(\sigma\left(C_\lambda\right)\right)$. The authentication server for account A_i stores the cryptographic hash of pw_i, while the challenges $C_1^i, \ldots, C_\lambda^i \in X_\lambda$ are stored in public memory (e.g., on the user's local computer), which means that they can be viewed by the adversary as well as the legitimate user. To authenticate the user retrieves the public challenges $C_1^i, \ldots, C_\lambda^i$ for account A_i and computes pw_i. The server for A_i verifies that the cryptographic hash of pw_i matches its records. To protect users from offline attacks in the event of a server breach, the password pw_i should be stored using a slow cryptographic hash function $\mathbf{H}$ like BCRYPT [47].

3.1 Usability

In our discussion of usability we focus on the time it would take a human user to compute a password once he has memorized the secret mapping σ. Other important considerations include the challenge of memorizing and rehearsing the secret mapping σ to ensure that the user remembers the secret mapping σ over time.

3.1.1 Computation Time

Given a challenge $C = (c_0, \ldots, c_{9+k_1+k_2}) \in X_{10+k_1+k_2}$ we can compute $f_{k_1,k_2}(\sigma(C))$ we compute $j = \sum_{i=10}^{9+k_1} \sigma(c_i) \mod 10$ using $k_1 - 1$ **Add** operations and k_1 **Recall** operations. We then execute **TableLookup**$(j, c_0, \ldots, c_9)$ to obtain c_j. Now we need k_2 **Add** operations and $k_2 + 1$ **Recall** operations to compute the final response $\sigma(c_j) + \sigma(c_{10+k_1}) + \ldots + \sigma(c_{9+k_1+k_2})$.

▶ **Fact 8.** *Let* $P = \{\textbf{Add}, \textbf{Recall}, \textbf{TableLookup}\}$ *then* $f_{k_1,k_2} \circ \sigma$ *is* $(P, 2k_1 + 2k_2 + 1, 3)$*-computable.*

Fact 8 and Conjecture 4 would imply that $f_{1,3}$ and $f_{2,2}$ are $\hat{t}$-human computable with $\hat{t} = 9$ seconds for humans H with computation constant $\gamma_H \leq 1$. The functions $f_{1,3}$ and $f_{2,2}$ were both $\hat{t}$-human computable with $\hat{t} = 7.5$ seconds for the main author of this paper. While the value of γ_H might be larger for many human users who are less comfortable with mental arithmentic, we note we may have $\gamma_H \ll 1$ for many human users after training (e.g., see `https://youtu.be/_-2L6ZxFacg` for a particularly impressive demonstration of mental arithmetic by young children.).

3.1.2 Memorizing and Rehearsing σ

Memorizing the secret mapping might be the most difficult part of our schemes. In practice, we envision that the user memorizes a mapping from n objects (e.g., images) to digits. For example, if $n = 26$ and $d = 10$ then the user might memorize a random mapping from characters to digits. The first author of this paper was able to memorize a mapping from $n = 100$ images to digits in about 2 hours. We conjecture that the process could be further expedited using mnemonic helpers – see discussion in the appendix.

After the user memorizes σ he may need to rehearse parts of the mapping periodically to ensure that he does not forget it. One of the benefits of our human computable password schemes is that the user will get lots of practice rehearsing the secret mapping each time he computes a password. In fact users who authenticate frequently enough will not need to spend any extra time rehearsing the secret mapping as they will get sufficient natural practice to remember σ.

3.2 Security Analysis

Claim 9 demonstrates that $s(f_{k_1,k_2}) = \min\{(k_2+1)/2, k_1+1\}$. Intuitively, the security of our human computable password management scheme will increase with k_1 and k_2. However, the work that the user needs to do to respond to each single-digit challenge is proportional to $2k_1 + 2k_2 + 1$ (See Fact 8).

▶ **Claim 9.** *Let* $0 \leq k_1$ *and* $k_2 > 0$ *be given and let* $f = f_{k_1,k_2}$ *we have* $g(f) = \min\{k_1, 10\}$, $r(f) = k_2 + 1$ *and* $s(f) = \min\left\{\frac{k_2+1}{2}, k_1 + 1, 11\right\}$.

An intuitive way to see that $r(f_{k_1,k_2}) > k_2$ is to observe that we cannot bias the output of f_{k_1,k_2} by fixing k_2 variables. Fix the value of *any* k_2 variables and draw the values for the other $k_1 + 10$ variables uniformly at random from $\mathbb{Z}_{10}$. One of the $k_2 + 1$ variables in the sum $x_j + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10$ will not be fixed. Thus, the probability that the final output of $f_{k_1,k_2}(x_0, \ldots, x_{9+k_1+k_2})$ will be r is exactly $1/10$ for each digit $r \in \mathbb{Z}_{10}$. Similarly, an intuitive way to see that $r(f_{k_1,k_2}) \leq k_2 + 1$ is to observe that we can bias the value of $f_{k_1,k_2}(x_0, \ldots, x_{9+k_1+k_2})$ by fixing the value of $k_2 + 1$ variables. In particular if we fix the variables $x_0, x_{10+k_1}, \ldots, x_{9+k_1+k_2}$ so that $0 = x_0 + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10$ then the output of $f_{k_1,k_2}(x_0, \ldots, x_{9+k_1+k_2})$ is more likely to be 0 than any other digit. The full proof of Claim 9 can be found in Appendix F.

Theorem 10 states that our human computable password management scheme is UF-RCA secure as long as RP-CSP (Conjecture 7) holds. In Section 4 we provide strong evidence in support of RP-CSP. In particular, no statistical algorithm can approximately recover the secret mapping given $m = \tilde{O}\left(n^{r(f)/2}\right)$ challenge-response pairs. To prove Theorem 10 we need to show that an adversary that breaks UF-RCA security for f_{k_1,k_2} can be used to approximately recover the secret mapping σ. We prove a more general result in Section 5.

▶ **Theorem 10.** *Let $\epsilon, \epsilon' > 0, \lambda \geq 1$ be given. Under the RP-CSP conjecture (Conjecture 7) the human computable password scheme defined by f_{k_1,k_2} is $\mathbf{UF-RCA}(n, m, \lambda, \delta)$ − secure for any $m \leq n^{\min\{(k_2+1)/2, k_1+1-\epsilon'\}} - \lambda$ and $\delta > \left(\frac{1}{10} + \epsilon\right)^{\lambda}$.*

▶ Remark. In the Appendix we demonstrate that our security bounds are asymptotically tight. In particular, there is a statistical algorithm to break our human computable password schemes (f_{k_1,k_2}) which requires $m = \tilde{O}\left(n^{(k_2+1)/2}\right)$ to 1-MSTAT to recover σ (See Theorem 27 in Section G). We also demonstrate that there is a attack based on Gaussian Elimination that uses $m = \tilde{O}\left(n^{k_1+1}\right)$ challenge-response pairs to recover σ.

3.2.1 Exact Security Bounds

We used the Constraint Satisfaction Problem solver from the Microsoft Solver Foundations library to attack our human computable password scheme[4]. In each instance we generated a random mapping $\sigma : [n] \to \mathbb{Z}_{10}$ and m random challenge response pairs $(C, f(\sigma(C)))$ using the functions $f_{2,2}$ and $f_{1,3}$. We gave the CSP solver 2.5 days to find σ on a computer with a 2.83 GHz Intel Core2 Quad CPU and 4 GB of RAM. The full results of our experiments are in Appendix C. Briefly, the solver failed to find the random mapping in the following instances with $f = f_{2,2}$ and $f = f_{1,3}$: (1) $n = 30$ and $m = 100$, (2) $n = 50$ and $m = 1,000$ and (3) $n = 100$ and $m = 10,000$.

▶ Remark. While the theoretical security parameter for $f_{1,3}$ ($s(f_{1,3}) = 2$) is slightly better than the security parameter for $f_{2,2}$ ($s(f_{2,2}) = 1.5$), we conjecture that $f_{2,2}$ may be more secure for small values of n (e.g., $n \leq 100$) because it is less vulnerable to attacks based on Gaussian Elimination. In particular, there is a polynomial time attack on $f_{1,3}$ based on Gaussian Elimination that requires at most n^2 examples to recover σ, while the same attack would require n^3 examples with $f_{2,2}$. Our CSP solver was not able to crack $\sigma \in \mathbb{Z}_{10}^{100}$ given $10,000 = 100^2$ challenge response pairs with $f_{2,2}$.

[4] Thanks to David Wagner for suggesting the use of SAT solvers.

Human Computable Password Challenge.

We are challenging the security and cryptography community to break our human computable password scheme for instances that our CSP solver failed to crack (see Appendix B for more details about the challenge). Briefly, for each challenge we selected a random secret mapping $\sigma \in \mathbb{Z}_{10}^n$, and published (1) m single digit challenge-response pairs $(C_1, f(\sigma(C_1))),\ldots,$ $(C_m, f(\sigma(C_m)))$, where each clause C_i is chosen uniformly at random from X_k, and (2) 20 length–$\lambda = 10$ password challenges $\vec{C}_1, \ldots, \vec{C}_{20} \in (X_k)^{10}$. The goal of each challenge is to correctly guess one of the secret passwords $p_i = f\left(\sigma\left(\vec{C}_i\right)\right)$ for some $i \in [20]$. The challenges can be found at `http://www.cs.cmu.edu/~jblocki/HumanComputablePasswordsChallenge/challenge.htm`. There is a \$20 prize associated with each individual challenge (total: \$360). We remark that these challenges remain unsolved even after they were presented during the rump sessions at a cryptography conference and a security conference[12].

4 Statistical Adversaries and Lower Bounds

Our main technical result (Theorem 14) is a lower bound on the number of single digit challenge-response pairs that a statistical algorithm needs to see to (approximately) recover the secret mapping σ. Our results are quite general and may be of independent interest. Given *any* function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ we prove that *any* statistical algorithm needs $\tilde{\Omega}\left(n^{r(f)/2}\right)$ examples before it can find a secret mapping $\sigma' \in \mathbb{Z}_d^n$ such that σ' is ϵ-correlated with σ. We first introduce statistical algorithms in Section 4.1 before stating our main lower bound for statistical algorithms in Section 4.2. We also provide a high level overview of our proof in Section 4.2.

4.1 Statistical Algorithms

A statistical algorithm is an algorithm that solves a distributional search problem $\mathcal{Z}$. In our case the distributional search problem $\mathcal{Z}_{\epsilon,f}$ is to find a mapping τ that is ϵ-correlated with the secret mapping σ given access to m samples from Q_σ^f – the distribution over challenge response pairs induced by σ and f. A statistical algorithm can access the input distribution Q_σ^f by querying the 1-MSTAT oracle or by querying the VSTAT oracle (Definition 11).

▶ **Definition 11.** [26] [1-MSTAT(L) oracle and VSTAT oracle] Let D be the input distribution over the domain X. Given any function $h : X \to \{0, 1, \ldots, L-1\}$, 1-MSTAT($L$) takes a random sample x from D and returns $h(x)$. For an integer parameter $T > 0$ and any query function $h : X \to \{0, 1\}$, VSTAT (T) returns a value $v \in [p - \tau, p + \tau]$ where $p = \mathbb{E}_{x\sim D}[h(x)]$ and $\tau = \max\left\{\frac{1}{T}, \sqrt{\frac{p(1-p)}{T}}\right\}$.

In our context the domain $X = X_k \times \mathbb{Z}_d$ is the set of all challenge response pairs and the distribution $D = Q_\sigma^f$ is the uniform distribution over challenge-response pairs induced by σ and f. Feldman et al. [26] used the notion of statistical dimension (Definition 12) to lower bound the number of oracle queries necessary to solve a distributional search problem (Theorem 13). Before we can present the definition of statistical dimension we need to introduce the *discrimination norm*. Intuitively, if the discrimination norm is small then a statistical algorithm will (whp) not be able to distinguish between honest samples $(C, f(\sigma(C))$ and samples from reference distribution T over $X_k \times \mathbb{Z}_d$ which is completely

independent of σ [5]. We define our reference distribution as follows:

$$\Pr_T[(C,i)] = \frac{\Pr_{x\sim\mathbb{Z}_d^k}[f(x)=i]}{|X_k|} \ .$$

Now given a set $\mathcal{D}' \subseteq \mathbb{Z}_d^n$ of secret mappings the discrimination norm of $\mathcal{D}'$ is denoted by $\kappa_2(\mathcal{D}')$ and defined as follows:

$$\kappa_2(\mathcal{D}') \doteq \max_{h,\|h\|=1} \left\{\mathbb{E}_{\sigma\sim\mathcal{D}'}\left[\left|\Delta\left(h,\sigma\right)\right|\right]\right\} \ ,$$

where $h : X_k \times \mathbb{Z}_d \to \mathbb{R}$, $\|h\| \doteq \sqrt{\mathbb{E}_{(C,i)\sim X_k\times\mathbb{Z}_d}\left[h^2\left(C,i\right)\right]}$ and

$$\Delta\left(h,\sigma\right) \doteq \mathbb{E}_{C\sim X_k}\left[h\left(C, f\left(\sigma\left(C\right)\right)\right)\right] - \mathbb{E}_{(C,i)\sim T}\left[h\left(C,i\right)\right] \ .$$

▶ **Definition 12.** [26][6]. For $\kappa > 0$, $\eta > 0$, $\epsilon > 0$, let d' be the largest integer such that for any mapping $\sigma \in \mathbb{Z}_d^n$ the set $\mathcal{D}_\sigma = \mathbb{Z}_d^n \setminus \{\sigma' \in \mathbb{Z}_d^n \mid \sigma' \text{ is } \epsilon\text{-correlated with } \sigma\}$ has size at least $(1-\eta)\cdot|\mathbb{Z}_d^n|$ and for any subset $\mathcal{D}' \subseteq \mathcal{D}_\sigma$ where $|\mathcal{D}'| \geq |\mathcal{D}_\sigma|/d'$, we have $\kappa_2(\mathcal{D}') \leq \kappa$. The **statistical dimension** with discrimination norm κ and error parameter η is d' and denoted by $\mathrm{SDN}(\mathcal{Z}_{\epsilon,f}, \kappa, \eta)$.

Feldman et al. [26] proved the following lower bound on the number of 1-MSTAT and VSTAT queries needed to solve a distributional search problem. Intuitively, Theorem 13 implies that many queries are needed to solve a distributional search problem with high statistical dimension. In Section 4.2 we argue that the statistical dimension our distributional search problem (finding σ' that is ϵ-correlated with the secret mapping σ given m samples from the distribution Q_σ^f) is high.

▶ **Theorem 13.** *[26, Theorems 10 and 12] For $\kappa > 0$ and $\eta \in (0,1)$ let $d' = \mathrm{SDN}(\mathcal{Z}_{\epsilon,f}, \kappa, \eta)$ be the statistical dimension of the distributional search problem $\mathcal{Z}_{\epsilon,f}$. Any randomized statistical algorithm that, given access to a VSTAT$\left(\frac{1}{3\kappa^2}\right)$ oracle (resp. 1-MSTAT(L)) for the distribution Q_σ^f for a secret mapping σ chosen randomly and uniformly from $\mathbb{Z}_d^n$, succeeds in finding a mapping $\tau \in \mathbb{Z}_d^n$ that is ϵ-correlated with σ with probability $\Lambda > \eta$ over the choice of distribution and internal randomness requires at least $\frac{\Lambda-\eta}{1-\eta}d'$ (resp. $\Omega\left(\frac{1}{L}\min\left\{\frac{d'(\Lambda-\eta)}{1-\eta}, \frac{(\Lambda-\eta)^2}{\kappa^2}\right\}\right)$) calls to the oracle.*

As Feldman et al. [26] observe, almost all known algorithmic techniques can be modeled within the statistical query framework. In particular, techniques like Expectation Maximization[25], local search, MCMC optimization[30], first and second order methods for convex optimization, PCA, ICA, k-means can be modeled as a statistical algorithm even with $L = 2$ – see [16] and [22] for proofs. One issue is that a statistical simulation might need polynomially more samples. However, for $L > 2$ we can think of our queries to 1-MSTAT(L) as evaluating L disjoint functions on a random sample. Indeed, Feldman et al. [26] demonstrate that there is a statistical algorithm for binary planted satisfiability problems using $\tilde{O}\left(n^{r(f)/2}\right)$ calls to 1-MSTAT $\left(n^{\lceil r(f)/2\rceil}\right)$.

---

[5] Observe that this implies that a statistical algorithm cannot find the secret σ. In particular, because the distribution T is independent of the secret mapping σ samples from T will not leak any information about σ.

[6] For the sake of simplicity we define the discrimination norm and the statistical dimension using our particular distributional search problem $\mathcal{Z}_{\epsilon,f}$. Our definition is equivalent to the definition in [26] once we fix the reference distribution T.

▶ Remark. We can also use the statistical dimension to lower bound the number of queries that an algorithm would need to make to other types of statistical oracles to solve a distributional search problem. For example, we could also consider an oracle MVSTAT(L,T) that takes a query $h : X \to \{0,\ldots,L-1\}$ and a set $\mathcal{S}$ of subsets of $\{0,\ldots,L-1\}$ and returns a vector $v \in \mathbb{R}^L$ s.t for every $Z \in \mathcal{S}$

$$\left|\sum_{i\in Z} v[i] - p_Z\right| \leq \max\left\{\frac{1}{T}, \sqrt{\frac{p_Z\left(1-p_Z\right)}{T}}\right\},$$

where $p_Z = \Pr_{x\sim D}\left[h(x) \in Z\right]$ and the cost of the query is $|\mathcal{S}|$. Feldman et al. [26, Theorem 7] proved lower bounds similar to Theorem 13 for the MVSTAT oracle. In this paper we focus on the 1-MSTAT and VSTAT oracles for simplicity of presentation.

4.2 Statistical Dimension Lower Bounds

We are now ready to state our main technical result[7].

▶ **Theorem 14.** *Let $\sigma \in \mathbb{Z}_d^n$ denote a secret mapping chosen uniformly at random, let Q_σ^f be the distribution over $X_k \times \mathbb{Z}_d$ induced by a function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ with distributional complexity $r = r(f)$. Any randomized statistical algorithm that finds an assignment τ such that τ is $\left(\sqrt{\frac{-2\ln(\eta/2)}{n}}\right)$-correlated with σ with probability at least $\Lambda > \eta$ over the choice of σ and the internal randomness of the algorithm needs at least m calls to the 1-MSTAT(L) oracle (resp. VSTAT$\left(\frac{n^r}{2(\log n)^{2r}}\right)$ oracle) with $m \cdot L \geq c_1\left(\frac{n}{\log n}\right)^r$ (resp. $m \geq n^{c_1 \log n}$) for a constant $c_1 = \Omega_{k,1/(\Lambda-\eta)}(1)$ which depends only on the values k and $\Lambda-\eta$. In particular if we set $L = \left(\frac{n}{\log n}\right)^{r/2}$ then our algorithms needs at least $m \geq c_1\left(\frac{n}{\log n}\right)^{r/2}$ calls to 1-MSTAT(L).*

The proof of Theorem 14 follows from Theorems 16 and 13. Theorems 14 and 16 generalize results of Feldman et al. [26] which only apply for binary predicates $f : \{0,1\}^k \to \{0,1\}$. An interested reader can find our proofs in Appendix D. At a high level our proof proceeds as follows: Given any function $h : X_k \times \mathbb{Z}_d \to \mathbb{R}$ we show that $\Delta\left(\sigma,h\right)$ can be expressed in the following form: $\Delta\left(\sigma,h\right) = \sum_{\ell=r(f)}^{k} \frac{1}{|X_\ell|} b_\ell\left(\sigma\right)$, where $|X_\ell| = \Theta\left(n^\ell\right)$ and each function b_ℓ has degree ℓ (Lemma 21). We then use the general hypercontractivity theorem [45, Theorem 10.23] to obtain the following concentration bound.

▶ **Lemma 15.** *Let $b : \mathbb{Z}_d^n \to \mathbb{R}$ be any function with degree at most ℓ, and let $\mathcal{D}' \subseteq \mathbb{Z}_d^n$ be a set of assignments for which $d' = d^n/\left|\mathcal{D}'\right| \geq e^\ell$. Then $\mathbb{E}_{\sigma\sim\mathcal{D}'}\left[\left|b\left(\sigma\right)\right|\right] \leq 2(\ln d'/c_0)^{\ell/2}\|b\|_2$, where $c_0 = \ell\left(\frac{1}{2ed}\right)$ and $\|b\|_2 = \sqrt{\mathbb{E}_{x\sim\mathbb{Z}_d^n}\left[b\left(x\right)^2\right]}$.*

We then use Lemma 15 to bound $\mathbf{E}_{\sigma\sim\mathcal{D}'}\left[\Delta\left(\sigma,h\right)\right]$ for any set $\mathcal{D}' \subseteq \mathbb{Z}_d^n$ such that $\left|\mathcal{D}'\right| = \left|\mathbb{Z}_d^k\right|/d'$ (Lemma 25). This leads to the following bound on $\kappa_2(\mathcal{D}') = O_k\left(\left(\ln d'/n\right)^{r(f)/2}\right)$.

[7] We remark that for our particular family of human computable functions f_{k_1,k_2} we could get a theorem similar to Theorem 14 by selecting $\sigma \sim \{0,5\}^n$ and appealing directly to results of Feldman et al. [26]. However, this theorem would be weaker than Theorem 14 as it would only imply that a statistical algorithm cannot find an assignment σ' that is $\frac{1}{2} - \frac{1}{10} + \epsilon$-correlated with σ for $\epsilon > 0$. In contrast, our theorem implies that we cannot find σ' that is ϵ-correlated.

▶ **Theorem 16.** *There exists a constant $c_Q > 0$ such that for any $\epsilon > 1/\sqrt{n}$ and $q \geq n$ we have*

$$\mathrm{SDN}\left(\mathcal{Z}_{\epsilon,f}, \frac{c_Q\,(\log q)^{r/2}}{n^{r/2}}, 2e^{-n\cdot\epsilon^2/2}\right) \geq q\ ,$$

where $r = r(f)$ is the distributional complexity of f.

Discussion

We view Theorem 14 as strong evidence for RP-CSP (Conjecture 7) because almost all known algorithmic techniques can be modeled within the statistical query framework[16, 22]. Thus, Theorem 14 rules out most known attacks that an adversary might mount. It also implies that many popular heuristic based SAT solvers (e.g., DPLL[24]) will not be able to recover σ in polynomial time. While Theorem 14 does not rule our attacks based on Gaussian Elimination we consider this class of attacks separately. We need $m = \tilde{O}\left(n^{g(f)+1}\right)$ examples to extract $O(n)$ linear constraints and solve for σ (see Appendix G.2). However, our composite security parameter $s(f) \geq g(f) + 1$ accounts for attacks based on Gaussian Elimination.

5 Security Analysis

In the last section we presented evidence in support of RP-CSP (Conjecture 7) by showing that any statistical adversary needs $m = \tilde{\Omega}\left(n^{r(f)/2}\right)$ examples to (approximately) recover σ. However, RP-CSP only says that it is hard to (approximately) recover the secret mapping σ, not that it is hard to forge passwords. As an example consider the following NP-hard problem from learning theory: find a 2-term DNF that is consistent with the labels in a given dataset. Just because 2-DNF is hard to learn in the *proper* learning model does not mean that it is NP-hard to learn a good classifier for 2-DNF. Indeed, if we allow our learning algorithm to output a linear classifier instead of a 2-term DNF then 2-DNF is easy to learn [37]. Could an adversary win our password security game without properly learning the secret mapping?

Theorem 18, our main result in this section, implies that the answer is no. Informally, Theorem 18 states that any adversary that breaks UF-RCA security of our human computable password scheme f_{k_1,k_2} can also (approximately) recover the secret mapping σ. This implies that our human computable password scheme is UF-RCA secure as long as RP-CSP holds. Of course, for some functions it is very easy to predict challenge-response pairs without learning σ. For example, if f is the constant function – or any function highly correlated with the constant function – then it is easy to predict the value of $f\left(\sigma\left(C\right)\right)$. However, any function that is highly correlated with a constant function is a poor choice for a human computable passwords scheme. We argue that any adversary that can win the password game can be converted into an adversary that properly learns σ provided that the output of function f is evenly distributed (Definition 17).

▶ **Definition 17.** We say that the output of a function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ is *evenly distributed* if there exists a function $g : \mathbf{Z}_d^{k-1} \to \mathbb{Z}_d$ such that $f\left(x_1, \ldots, x_k\right) = g\left(x_1, \ldots, x_{k-1}\right) + x_k \mod d$.

Clearly, our family f_{k_1,k_2} has evenly distributed output. To see this we simply set $g = f_{k_1,k_2-1}$. We are now ready to state our main result from this section.

▶ **Theorem 18.** *Suppose that f has evenly distributed output, but that f is not* **UF − RCA** (n, m, λ, δ) *− secure for* $\delta > \left(\frac{1}{d} + \epsilon\right)^{\lambda}$. *Then there is a probabilistic polynomial time algorithm (in n, m, λ and $1/\epsilon$) that extracts a string $\sigma' \in \mathbb{Z}_d^n$ that is $\epsilon/8$-correlated with σ with probability at least $\frac{\epsilon^3}{(8d)^2}$ after seeing $m + \lambda$ example challenge response pairs.*

The proof of Theorem 18 is in Appendix E. We overview the proof here. The proof of Theorem 18 uses Theorem 19 as a subroutine. Theorem 19 shows that we can, with reasonable probability, find a mapping σ' that is correlated with σ given predictions of $f(\sigma(C))$ for each clause as long as the probability that each prediction is accurate is slightly better than a random guess (e.g., $\frac{1}{d} + \delta$). The proof of Theorem 19 is in Appendix E.

▶ **Theorem 19.** *Let f be a function with evenly distributed output (Definition 17), let $\sigma \sim \mathbb{Z}_d^n$ denote the secret mapping, let $\epsilon > 0$ be any constant and suppose that for every $C \in X_k$ we are given labels $\ell_C \in \mathbb{Z}_d$ s.t.* $\Pr_{C \sim X_k}[f(\sigma(C)) = \ell_C] \geq \frac{1}{d} + \epsilon$. *There is a polynomial time algorithm (in n, m,$1/\epsilon$) that finds a mapping $\sigma' \in \mathbb{Z}_d^n$ such that σ' is $\epsilon/2$-correlated with σ with probability at least $\frac{\epsilon}{2d^2}$*

The remaining challenge in the proof of Theorem 18 is to show that there is an efficient algorithm to extract predictions of $f(\sigma(C))$ given blackbox access to an adversary $\mathcal{A}$ that breaks UF-RCA security. However, just because the adversary $\mathcal{A}$ gives the correct response to an entire password challenge $C_1, \ldots, C_\lambda$ with probability greater than $\left(\frac{1}{d} + \epsilon\right)^{\lambda}$ it does not mean that the response to each individual challenge C is correct with probability $\frac{1}{d} + \epsilon$. To obtain our predictions for individual clauses C we draw λ extra example challenge response pairs $(C'_1, f(\sigma(C'_1))), \ldots, (C'_\lambda, f(\sigma(C'_\lambda)))$, which we use to check the adversary. To obtain the label for a clause C we select a random index $i \in [\lambda]$ and give $\mathcal{A}$ the password challenge $C'_1, \ldots, C'_\lambda$, replacing C'_i with C. If for some $j < i$ the label for clause C'_j is not correct (e.g., $\neq f(\sigma(C'_j))$) then we discard the label and try again. Claim 26 in Appendix E shows that this process will give us predictions for individual clauses that are accurate with probability at least $\frac{1}{d} + \epsilon$.

6 Related Work

The literature on passwords has grown rapidly over the past decade (e.g., see [40, 46, 18, 19, 38, 15].) Perhaps most related to our paper is the work of Blocki et al. [13, 14] and Blum and Vempala [17] on developing usable and secure password management schemes. While the password management schemes proposed in these works are easier to use (e.g., involve less memorization and/or computation) than our human computable password scheme, these schemes only remain secure up to their information theoretic limit – after a very small (e.g., 1–6) number of breaches security guarantees start to break down. By contrast, our schemes remain secure after a large (e.g., 100) number or breaches.

In contrast to our work, password management software (e.g., PwdHash [49] or KeePass [48]) relies strong trust assumptions about the user's computational devices. The recent breach at LastPass[8] highlights the potential danger of such strong assumptions.

Hopper and Blum [34] designed a Human Identification Protocol based on noisy parity, a learning problem that is believed to be hard[9]. We emphasize a few fundamental differences

[8] See `https://blog.lastpass.com/2015/06/lastpass-security-notice.html/` (Retrieved 9/1/2015).
[9] Subsequent work [35, 31, 20, 36] has explored the use of the Hopper-Blum protocol for authentication on pervasive devices like smartcards.

between our work and the work of Hopper and Blum. First, a single digit challenge in their protocol consists of an n-digit vector $x \in \mathbb{Z}_{10}^n$ and the user responds with the $\mod 10$ sum of the digits at $\ell \leq n$ secret locations (occasionally the user is supposed to respond with a random digit instead of the correct response so that the adversary cannot simply use Gaussian Elimination to find the secret locations). By contrast, a single digit challenge in our protocol consists of an ordered clause of length $k \ll n$. Second, their protocols allow for an $O\left(n^{\ell/2}\right)$-time attack called Meet-In-The-Middle [34] after the adversary has seen $\tilde{O}(\log \binom{n}{\ell})$ challenge-response pairs. Thus, it is critically important to select ℓ sufficiently large (e.g., $\ell = \Omega(\log(n))$) in the Hopper-Blum protocol to defend against this Meet-In-The-Middle attack. By contrast, we focus on computation of *very simple* functions over a *constant* number of variables so that a human can compute the response to each challenge quickly. In particular, we provide strong evidence that our scheme is secure against any polynomial time attacker even if the adversary has seen up to $O\left(n^{c \cdot k}\right)$ challenge-response pairs for some constant $c \geq 1$. Finally, computations in our protocols are deterministic. This is significant because humans are not good at consciously generating random numbers [53, 27, 42] (e.g., noisy parity could be easy to learn when humans are providing source of noise)[10].

Naor and Pinkas[43] proposed using visual cryptography[44] to address a related problem: how can a human verify that a message he received from a trusted server has not been tampered with by an adversary? Their protocol requires the human to carry a visual transparency (a shared secret between the human and the trusted server in the visual cryptography scheme), which he will use to verify that messages from the trusted server have not been altered.

A related goal in cryptography, constructing pseudorandom generators in NC^0, was proposed by Goldreich [32] and by Cryan and Miltersen [23]. In Goldreich's construction we fix $C_1, \ldots, C_m \in [n]^k$ once and for all, and a binary predicate $P : \{0,1\}^k \to \{0,1\}$. The pseudorandom generator is a function $G : \{0,1\}^n \to \{0,1\}^m$, whose i'th bit $G(x)[i]$ is given by P applied to the bits of x specified by C_i. O'Donnel and Witmer gave evidence that the "Tri-Sum-And" predicate $(TSA\,(x_1, \ldots, x_5) = x_1 + x_2 + x_3 + x_4 x_5 \mod 2)$ provides near-optimal stretch. In particular, they showed that for $m = n^{1.5-\epsilon}$ Goldreich's construction with the TSA predicate is secure against subexponential-time attacks using SDP hierarchies. Our candidate human-computable password schemes use functions $f : \mathbb{Z}_{10}^k \to \mathbb{Z}_{10}$ instead of binary predicates. While our candidate functions are contained in NC^0, we note that an arbitrary function in NC^0 is not necessarily human computable.

On a technical level our statistical dimension lower bounds extend work of Feldman et al. [26], who considered the problem of finding a planted solution in a random *binary* planted constraint satisfiability problem. We extend their analysis to handle non-binary planted constraint satisfiability problems, and argue that our candidate human computable password schemes are secure. We will discuss this work in more detail later in the paper.

7 Discussion

7.1 Improving Response Time

The easiest way to improve response time is to decrease λ –the number of single-digit challenges that the user needs to solve. However, if the user wants to ensure that each of his passwords are strong enough to resist offline dictionary attacks then he would need

[10] Hopper and Blum also proposed a deterministic variant of their protocol called sum of k-mins, but this variant is *much* less secure. See additional discussion in the appendix.

to select a larger value of λ (e.g., $\lambda \geq 10$). Fortunately, there is a natural way to circumvent this problem. The user could save time by memorizing a mapping $w : \mathbb{Z}_{10} \rightarrow \{x \mid x \text{ is one of 10,000 most common english words}\}$ and responding to each challenge C with $w\left(f\left(\sigma\left(C\right)\right)\right)$ – the word corresponding to the digit $f\left(\sigma\left(C\right)\right)$. Now the user can create passwords strong enough to resist offline dictionary attacks by responding to just 3–5 challenges. Even if the adversary learns the words in the user's set he won't be able to mount online attacks. Predicting $w\left(f\left(\sigma\left(C\right)\right)\right)$ is at least as hard as predicting $f\left(\sigma\left(C\right)\right)$ even if the adversary knows the exact mapping w[11].

7.2 One-Time Challenges

Malware

Consider the following scenario: the adversary infects the user's computer with a keylogger which is never detected over the user's lifetime. We claim that it is possible to protect the user in this extreme scenario using our scheme by generating multiple (e.g., 10^6) one-time passwords for each of the user's accounts. When we initially generate the secret mapping $\sigma \sim \mathbb{Z}_d^n$ we could also generate cryptographic hashes for millions of one-time passwords $\mathbf{H}\left(\vec{C}, f_{k_1,k_2}\left(\sigma\left(\vec{C}\right)\right)\right)$. While usability concerns make this approach infeasible in a traditional password scheme (it would be far too difficult for the user to memorize a million one-time passwords for each of his accounts), it may be feasible to do this using a human computable password scheme. In our human computable password scheme we could select k_1 and k_2 large enough that $s\left(f_{k_1,k_2}\right) = \min\{k_1 + 1, (k_2 + 1)/2\} \geq 6$. Assuming that the user authenticates fewer than 10^6 times over his lifetime a polynomial time adversary would never obtain enough challenge-response examples to learn σ. The drawback is that f_{k_1,k_2} will take longer for a user to execute in his head.

Secure Cryptography in a Panoptic World

Standard cryptographic algorithms could be easily broken in a panoptic world where the user only has access to a semi-trusted computer (e.g., if a user asks a semi-trusted computer to sign a message m using a secret key sk stored on the hard drive then the computer will respond with the correct value $Sign\left(sk, m\right)$, but the adversary will learn the values m and sk). Our human computable password schemes could also be used to secure some cryptographic operations (e.g., signatures) in a panoptic world by leveraging recent breakthroughs in program obfuscation [29]. The basic idea is to obfuscate a "password locked" circuit $P_{\sigma,sk,r}$ that can sign messages under a secret key sk – we need a trusted setup phase for this step. The circuit $P_{\sigma,sk,r}$ will only sign a message m if the user provides the correct response to a unique (pseudorandomly generated) challenge for m.

7.3 Open Questions

Eliminating the Semi-Trusted Computer

Our current scheme relies on a semi-trusted computer to generate and store random public challenges. An adversary with full control over the user's computer might be able to extract the user's secret if he is able to see the user's responses to $O(n)$ adaptively selected password challenges. Can we eliminate the need for a semi-trusted computer?

[11] In fact, it is quite likely that it is much harder for the adversary to predict $w\left(f\left(\sigma\left(C\right)\right)\right)$ because the adversary will not see which word corresponds with each digit.

Exact Security Bounds

While we provided asymptotic security proofs for our human computable password schemes, it is still important to understand how much effort an adversary would need to expend to crack the secret mapping for specific values of n and m. Our attacks with a SAT solver (see Appendix C) indicate that the value $n = 26$ is too small to provide UF-RCA security even with small values of m (e.g., $m = 50$). As n increases the problem rapidly gets harder for our SAT solver (e.g., with $n = 50$ and $m = 1000$ the solver failed to find σ). We also present a public challenge with specific values of n and m to encourage cryptography and security researchers to find other techniques to attack our scheme.

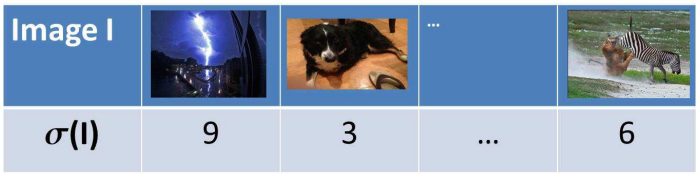

Figure 2 A Random Mapping from Images to Digits.

A Authentication Process

In this section of the appendix we illustrate our human computable password schemes graphically. In our examples, we use the function $f = f_{2,2}$. To compute the response $f(\sigma(C))$ to a challenge $C = \{x_0, \ldots, x_{13}\}$ the user computes $f(\sigma(C)) = \sigma\left(x_{\sigma(x_{10})+\sigma(x_{11}) \mod 10}\right) + \sigma(x_{12}) + \sigma(x_{13}) \mod 10$

Memorizing a Random Mapping

To begin using our human computable password schemes the user begins by memorizing a secret random mapping $\sigma : [n] \to \{0, \ldots, 9\}$ from n objects (e.g., letters, pictures) to digits. See Figure 2 for an example.

The computer can provide the user with mnemonics to help memorize the secret mapping σ – see Figures 3b and 3c. For example, if we wanted to help the user remember that $\sigma(eagle) = 2$ we would show the user Figure 3b. We observe that a $10 \times n$ table of mnemonic images would be sufficient to help the user memorize *any* random mapping σ. We stress that the computer will only save the original image (e.g., Figure 3a). The mnemonic image (e.g., Figure 3b or 3c) would be discarded after the user memorizes $\sigma(eagle)$.

Single-Digit Challenges

In our scheme the user computes each of his passwords by responding to a sequence of single-digit challenges. For $f = f_{2,2}$ a single-digit challenge is a tuple $C \in [n]^{14}$ of fourteen objects. See Figure 6 for an example. To compute the response $f(\sigma(C))$ to a challenge $C = \{x_0, \ldots, x_{13}\}$ the user computes $f(\sigma(C)) = \sigma\left(x_{\sigma(x_{10})+\sigma(x_{11}) \mod 10}\right) + \sigma(x_{12}) + \sigma(x_{13}) \mod 10$. Observe that this computation involves just three addition operations modulo ten. See Figure 1 for an example. In this example the response to the challenge $C = \{x_0 = \text{burger}, x_1 = \text{eagle}, \ldots, x_{10} = \text{lightning}, x_{11} = \text{dog}, x_{12} = \text{man standing on world}, x_{13} = \text{kangaroo}\}$ is

$$\begin{aligned}
f(\sigma(C)) &= \sigma\left(x_{\sigma(x_{10})+\sigma(x_{11}) \mod 10}\right) + \sigma(x_{12}) + \sigma(x_{13}) \mod 10 \\
&= \sigma\left(x_{\sigma(\text{lightning})+\sigma(\text{dog}) \mod 10}\right) \\
&\quad + \sigma(\text{man standing on world}) + \sigma(\text{kangaroo}) \mod 10 \\
&= \sigma(x_{9+3 \mod 10}) + \sigma(\text{man standing on world}) + \sigma(\text{kangaroo}) \mod 10 \\
&= \sigma(\text{minions}) + \sigma(\text{man standing on world}) + \sigma(\text{kangaroo}) \mod 10 \\
&= 7 + 4 + 5 \mod 10 = 6\,.
\end{aligned}$$

We stress that this computation is done entirely in the user's head. It takes the main author 7.5 seconds on average to compute each response.

Figure 5 Table of Mnemonic Helpers to Help Learn Any Secret Mapping

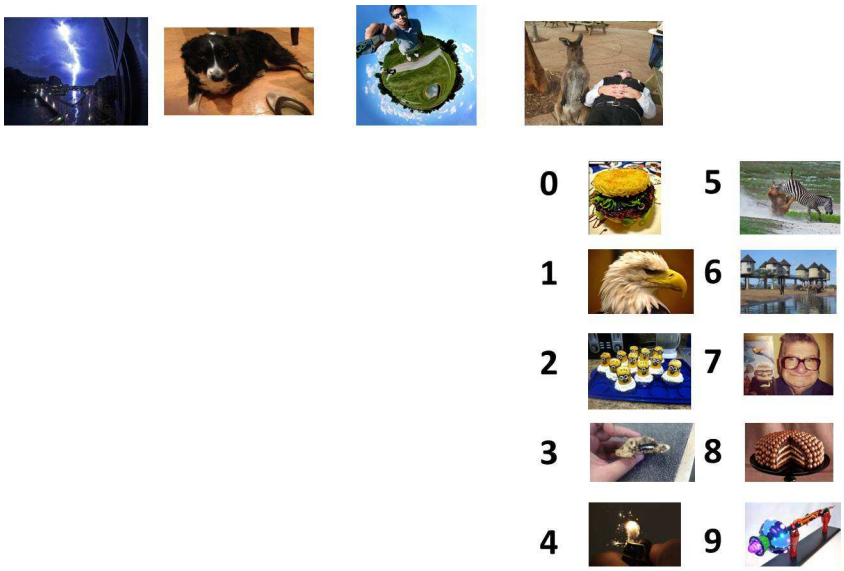

Figure 6 A single-digit challenge.

Creating an Account

To help the user create an account the computer would first pick a sequence of single-digit challenges $C_1, \ldots, C_\lambda$, where the security parameter is typically $\lambda = 10$, and would display the first challenge C_1 to the user – see Figure 7 for an example. To compute the first digit of his password the user would compute $f(\sigma(C_1))$. After the user types in the first digit $f(\sigma(C_1))$ of his password the computer will display the second challenge C_2 to the user – see Figure 8. After the user creates his account the computer will store the challenges $C_1, \ldots, C_{10}$ in public memory. The password $pw = f(\sigma(C_1)) \ldots f(\sigma(C_\lambda))$ will not be stored on the user's local computer (the authentication server may store the cryptographic hash of pw).

Authentication

Authenticating is very similar to creating an account. To help the user recompute his password for an account the computer first looks up the challenges $C_1, \ldots, C_\lambda$ which were stored in public memory, and the user authenticates by computing his password $pw = f(\sigma(C_1)) \ldots f(\sigma(C_\lambda))$. We stress that the single-digit challenges the user sees during authentication will be the same single-digit challenges that the user saw when he created the account. The authentication server verifies that the cryptographic hash of pw matches its record.

Helping the user remember his secret mapping

The computer keeps track of when the user rehearses each value of his secret mapping (e.g., $(i, \sigma(i))$ for each $i \in [n]$), and reminds the user to rehearse any part of his secret mapping that he hasn't used in a long time. One advantage of our human computable password scheme (compared with the Shared Cues scheme of Blocki et al.[13]) is that most users will use each part of their secret mapping often enough that they will not need to be reminded to rehearse – see discussion in Section A.2. The disadvantage is that we require the user to spend extra effort computing his passwords each time he authenticates.

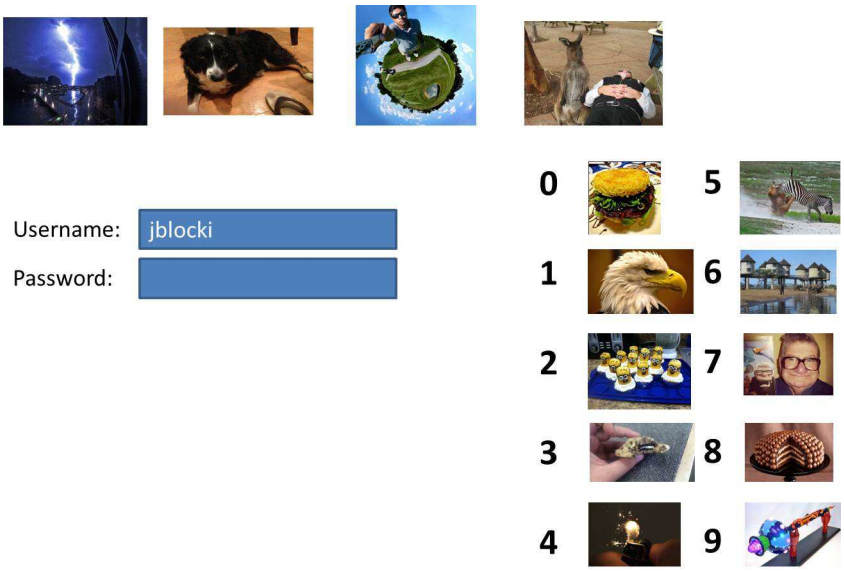

Figure 7 Login Screen

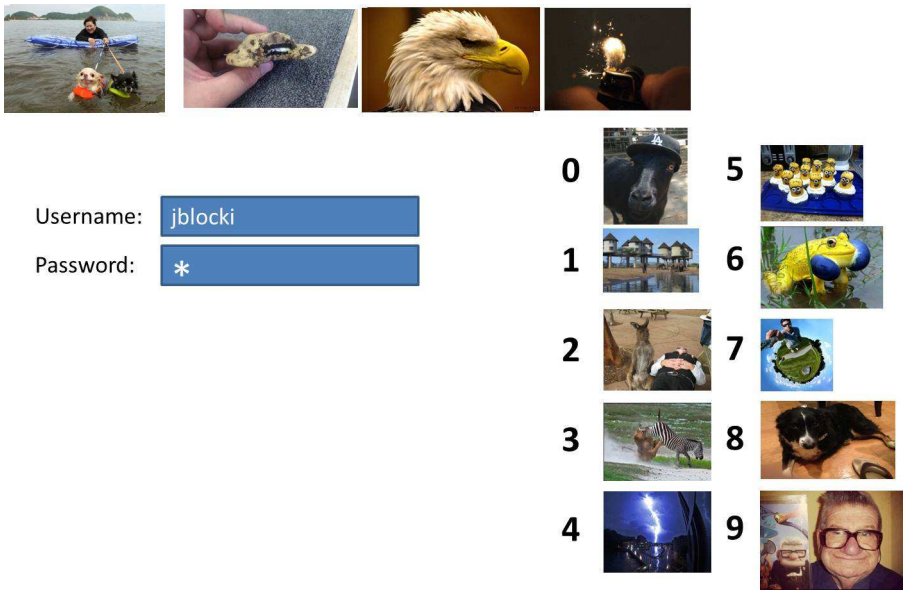

Figure 8 Login Screen after the user responds to the first single-digit challenge

Algorithm 1: MemorizeMapping

input : $I_1, ..., I_n$, d, b and $M_{i,j}$ for $i \in [n], j \in \{0, \ldots, d-1\}$.
Given $j \in \{0, \ldots, d-1\}$ and $i \in \{1, \ldots, n\}$ $M_{i,j}$ is a mnemonic to help the user associate image I_i with the number j. d is whatever base the user is familiar with (typically $d = 10$), and the value b contains random bits which are used to select the secret mapping σ. ;

Generate and Memorize Secret Mapping;

  `// Using random bits b`
  $\sigma(i) \sim \{0, \ldots, d-1\}$;
  $M_i \leftarrow M_{i,\sigma(i)}$;
  (User) Using M_i memorizes the association $(I_i, \sigma(i))$ for $i \in [n]$. ;
end

A.1 Formal View

We now present a formal overview of the authentication process. Algorithm 1 outlines the initialization process in which the user memorizes a secret random mapping σ generated by the user's computer, and Algorithm 2 outlines the account creation process. In Algorithm 2 the user generates the password for an account i by computing the response to a sequence of random challenges C generated by the user's computer. The sequence of challenges are stored in public memory. We assume that all steps in algorithms 1, 2 and 3 are executed on the user's local computer unless otherwise indicated. We also assume that the initialization phase (Algorithms 1 and 2) is carried out in secret (e.g., we assume that the secret mapping is chosen in secret), but we do not assume that the challenges are kept secret. We use **(User)** to denote a step completed by the human user and we use **(Server)** to denote a step completed by a third-party server. Algorithm 3 illustrates the authentication process.

A.2 Memorizing and Rehearsing σ

After the user memorizes σ he may need to rehearse parts of the mapping periodically to ensure that he does not forget it. How much effort does this require? Blocki et al.[13] introduced a usability model to estimate how much extra effort that a user would need to spend rehearsing the mapping σ. We used this model to obtain the predictions in Table 1.

Imagine that we had a program keep track of how often the user rehearsed each association $(i, \sigma(i))$ and predict how much longer the user will safely remember the association $(i, \sigma(i))$ without rehearsing again – updating this prediction after each rehearsal. The user rehearses the association $(i, \sigma(i))$ *naturally* whenever he needs to recall the value of $\sigma(i)$ while computing the password for any of his password protected accounts. If the user is in danger of forgetting the value $\sigma(i)$ then the program sends the user a reminder to rehearse (Blocki et al.[13] call this an *extra rehearsal*). Table 1 shows the value of $\mathbb{E}[ER_{365}]$, the expected number of extra rehearsals that the user will be required to do to remember the secret mapping σ during the first year. This value will depend on how often the user rehearses σ naturally. We consider four types of users: Active, Typical, Occasional and Infrequent. An Active user visits his accounts more frequently than a Infrequent user. See Appendix H for specific details about how Table 1 was computed.

Algorithm 2: CreateChallenge

input : n, i, λ, d, b and $I_1, ..., I_n$.

Generate Password Challenge for account A_i. t is a security parameter which specifies how many digits the password will contain.;

for $j = 1 \to \lambda$ **do**

  $C_j^i \sim X_k$;

	50	N/A	50	N/A

Discussion

One of the advantages of our human computable passwords schemes is that memorization is essentially a one time cost for our Very Active, Typical and Occasional users. Once the user has memorized the mapping $\sigma : \{1, ..., n\} \to \mathbb{Z}_d$ he will get sufficient natural rehearsal to maintain this memory. In fact, our schemes require the user to expend *less* extra effort rehearsing his secret mapping than the Shared Cues password management scheme of Blocki et al. [13] (with the exception of SC-0 – the least secure Shared Cues scheme). Intuitively, this is because human computable password schemes require to recall $\sigma(i)$ for multiple different values of i to respond to each single-digit challenge C. To compute $f_{2,2}(\sigma(\{0, \ldots, 13\}))$ the user would need to recall the values of $\sigma(10), \sigma(11), \sigma(12), \sigma(13)$ and $\sigma(j)$, where $j = \sigma(10) + \sigma(11) \mod 10$. If the user has 10 digit passwords then he will naturally rehearse the value of $\sigma(i)$ for up to fifty different values of i each time he computes one of his passwords. While the user needs to spend extra time computing his password each time he authenticates in our human computable password scheme, this extra computation time gives the user more opportunities to rehearse his secret mapping.

B Human Computable Passwords Challenge

While we provided asymptotic security bounds for our human computable password schemes in our context it is particularly important to understand the constant factors. In our context, it may be reasonable to assume that $n \leq 100$ (e.g., the user may be unwilling to memorize longer mappings). In this case it would be feasible for the adversary to execute an attack that takes time proportional to $10^{\sqrt{n}} \leq 10^{10}$. We conjecture that in practice scheme 2 ($f_{1,3}$) is slightly weaker than scheme 1 ($f_{2,2}$) when $n \leq 100$ despite the fact that $s(f_{2,2}) < s(f_{1,3})$

because of the attack described in Remark G.2. This attack requires $\tilde{O}\left(n^{1+g(f)/2}\right)$ examples, and the running time $O\left(10^{\sqrt{n}}n^3\right)$ may be feasible for $n \leq 100$. To better understand the exact security bounds we created several public challenges for researchers to break our human computable password schemes under different parameters (see Table 3). At this time these challenges remain unsolved even after they were presented during the rump sessions at a cryptography conference and a security conference[12]. The challenges can be found at `http://www.cs.cmu.edu/~jblocki/HumanComputablePasswordsChallenge/challenge.htm`. For each challenge we selected a random secret mapping $\sigma \in \mathbb{Z}_{10}^n$, and published (1) m single digit challenge-response pairs $(C_1, f(\sigma(C_1))), \ldots, (C_m, f(\sigma(C_m)))$, where each clause C_i is chosen uniformly at random from X_k, and (2) 20 length – 10 password challenges $\vec{C}_1, \ldots, \vec{C}_{20} \in (X_k)^{10}$. The goal is to guess one of the secret passwords $p_i = f\left(\sigma\left(\vec{C}_i\right)\right)$ for some $i \in [20]$.

C CSP Solver Attacks

Theorems 14 and 18 provide asymptotic security bounds (e.g., an adversary needs to see $m = \tilde{\Omega}\left(n^{s(f)}\right)$ challenge-response pairs to forge passwords). However, in our context n is somewhat small (e.g., $n \leq 100$). Thus, it is also important to address the following question: how many challenge-response pairs does the adversary need to see before it becomes feasible for the adversary to recover the secret on a modern computer? To better understand the exact security bounds of our human computable password schemes we used a Constraint Satisfaction Problem (CSP) solver to attack our scheme. We also created several public challenges to break our candidate human computable password schemes (see Table 3).

CSP Solver

Our computations were performed on a computer with a 2.83 GHz Intel Core2 Quad CPU and 4 GB of RAM. In each instance we generated a random mapping $\sigma : [n] \to \mathbb{Z}_{10}$ and m random challenge response pairs $(C, f(\sigma(C)))$ using the functions $f_{2,2}$ and $f_{1,3}$. We used the Constraint Satisfaction Problem solver from the Microsoft Solver Foundations library to try to solve for σ[12]. The results of this attack are shown in Tables 4 and 5. Due to limited computational resources we terminated each instance if the solver failed to find the secret mapping within 2.5 days, and if our solver failed to find σ in 2.5 days on and instance (n, m) we did not run the solver on strictly harder instances (e.g., (n', m') with $n' \geq n$ and $m' \leq m$). We remark that our empirical results are consistent with the hypothesis that the time/space resources consumed by the CSP solver increase exponentially in n (e.g., when we decrease n from 30 to 26 with $m = 100$ examples the CSP solver can solve for $\sigma \in \mathbb{Z}_{10}^{26}$ in 40 minutes, while the solver failed to find $\sigma \in \mathbb{Z}_{10}^{30}$ in 2.5 days and we observe similar threshold behavior in other columns of the table.).

D Statistical Dimension

At a high level our statistical dimension lower bounds closely mirror the lower bounds from [26] for binary predicates. For example, Lemmas 21, 22, 15, 23 and 25 are similar to Lemmas 2, 4, 5, 6 and 7 from [26] respectively.

[12] http://blogs.msdn.com/b/solverfoundation/ (Retrieved 9/15/2014).

Table 4 CSP Solver Attack on $f_{2,2}$
Key: UNSOLVED – Solver failed to find solution in 2.5 days; HARD – Instance is harder than an unsolved instance;

	$m = 50$	$m = 100$	$m = 300$	$m = 500$	$m = 1000$	$m = 10000$
$n = 26$	23.5 hr	40 min	4.5 hr	29 min	10 min	2 min
$n = 30$	HARD	UNSOLVED	2.33 hr	35.5 min	10 min	20 s
$n = 50$	HARD	HARD	HARD	HARD	UNSOLVED	7 hr
$n = 100$	HARD	HARD	HARD	HARD	HARD	UNSOLVED

Table 5 CSP Solver Attack on $f_{1,3}$
Key: UNSOLVED – Solver failed to find solution in 2.5 days; HARD – Instance is harder than an unsolved instance;

	$m = 50$	$m = 100$	$m = 300$	$m = 500$	$m = 1000$	$m = 10000$
$n = 26$	8.7 hr	53 min	1.33 hr	13.5 min	6.3min	2 min
$n = 30$	HARD	UNSOLVED	1 hr	41 min	2 min	15 s
$n = 50$	HARD	HARD	HARD	HARD	UNSOLVED	6.5 hr
$n = 100$	HARD	HARD	HARD	HARD	HARD	UNSOLVED

While the high level proof strategy is very similar, we stress that our lower bounds do requires new ideas because we are working with planted solutions $\sigma \in \mathbb{Z}_d^n$ instead of $\sigma \in \mathbb{Z}_d^n$. We use the basis functions χ_α where for $\alpha \in \mathbb{Z}_d^n$ is

$$\chi_\alpha(x) = \exp\left(\frac{-2\pi\sqrt{-1}\,(x \cdot \alpha)}{d}\right) .$$

Note that if $d > 2$ then the Fourier coefficients $\hat{b}_\alpha$ of a function $b : \mathbb{Z}_d^k \to \mathbb{R}$ might include complex numbers. While we need to take care to deal with the possibility that a Fourier coefficients might be complex, we are still able to apply powerful tools from Fourier analysis. For example, Parseval's identity

$$\sum_{\alpha \in \mathbb{Z}_d^k} \left|\hat{b}_\alpha\right|^2 = \mathbb{E}_{x \sim \mathbb{Z}_d^k}\left[b(x)^2\right] ,$$

still applies and there are versions of the hypercontractivity theorem [45, Chapter 10] that still apply even when Fourier coefficients are complex.

Another difference is that the reference distribution is defined over clauses and outputs $X_k \times \mathbb{Z}_d$ (instead of just clauses X_k) because we are working with a function $f : \mathbb{Z}_d^n \to \mathbb{Z}_d$ with non-binary outputs. Some care is needed in finding the right reference distribution. Unlike [26] we cannot just use the uniform distribution over $X_k \times \mathbb{Z}_d$ as a reference distribution – instead the reference distribution inherently depends on the function f (Of course it is must still be independent of σ).

The following definition will be useful in our proofs.

▶ **Definition 20.** Given a clause $C \in X_k$ and $S \subseteq [k]$ of size ℓ, we let $C_{|S} \in X_\ell$ denote the clause of variables of C at the positions with indices in S (e.g., if $C = (1, \ldots, k)$ and $S = \{1, 5, k-2\}$ then $C_{|S} = (1, 5, k-2) \in X_3$). Given a function $h : X_k \times \mathbb{Z}_d \to \mathbb{R}$, a clause $C_\ell \in X_\ell$ and $i \in \mathbb{Z}_d$ and a set $S \subseteq [k]$ of size $|S| = \ell$ we define

$$h_S^i(C_\ell) = \frac{|X_\ell|}{|X_k|} \sum_{C \in X_k, C_{|S} = C_\ell} h(C, i) .$$

We first show that $\Delta(\sigma, h)$ can be expressed in terms of the Fourier coefficients of $\hat{Q}$ as well as the functions h_ℓ. In particular, given a function $h : X_k \times \mathbb{Z}_d \to \mathbb{R}$ we define the degree ℓ function $b_\ell : \mathbb{Z}_d^n \to \mathbb{C}$ as follows

$$b_\ell(\sigma) \doteq \frac{1}{2} \sum_{\alpha \in \mathbb{Z}_d^\ell : H(\alpha) = \ell} \binom{k}{\ell} \sum_{i=0}^{d-1} \hat{Q}_\alpha^{f,i} \sum_{C \in X_\ell} \chi_\alpha(\sigma(C)) h_\ell^i(C) \ .$$

Lemma 21 states that

$$\Delta(\sigma, h) = \sum_{\ell=1}^{k} \frac{1}{|X_\ell|} b_\ell(\sigma) \ .$$

This observation will be important later because we can use hypercontractivity to bound the expected value of $|b_\ell(\sigma)|$. Notice that if Q has distributional complexity r and $\ell \leq r$ then $b_\ell(\sigma) = 0$ because $\hat{Q}_\alpha^{f,i} = 0$ for all $i \in \mathbb{Z}_d$ and $\alpha \in \mathbb{Z}_d^k$ s.t. $1 \leq H(\alpha) \leq r$. This means that first r terms of the sum in Lemma 21 will be zero.

▶ **Lemma 21.** *For every $\sigma \in \mathbb{Z}_d^k$, $j \in \mathbb{Z}_d$ and $h : X_k \to \mathbb{R}$ we have $\Delta(\sigma, h) = \sum_{\ell=1}^{k} \frac{1}{|X_\ell|} b_\ell(\sigma)$.*

Proof of Lemma 21. Before calculating we first observe that for any $j \in \mathbb{Z}_d$ we have

$$\hat{Q}_{\vec{0}}^{f,j} = \mathbb{E}_{x \sim \mathbb{Z}_d^k}\left[Q^{f,j}(x) \chi_\alpha(x)\right] = \mathbb{E}_{x \sim \mathbb{Z}_d^k}\left[Q^{f,j}(x)\right] = \sum_{x \in \mathbb{Z}_d^k} \frac{Q^{f,j}(x)}{d^k} = \frac{2-d}{d} \ .$$

Given $\alpha \in \mathbb{Z}_d^k$ we also define $S_\alpha \subset [k]$ to be the set of indices i s.t. $\alpha_i \neq 0$ – $|S_\alpha| = H(\alpha)$.

Now we note that

$$\begin{aligned}
\Delta(\sigma,h) &= \mathbb{E}_{C\sim X_k}\left[h\left(C,f\left(\sigma\left(C\right)\right)\right)\right]-\mathbb{E}_{(C,i)\sim T}\left[h\left(C,i\right)\right]\\
&= \sum_{C\in X_k}\left(\frac{h\big(C,f(\sigma(C))\big)}{|X_k|}-\sum_{i=0}^{d-1}\Pr_T[(C,i)]h(C,i)\right)\\
&= \sum_{C\in X_k}\left(\frac{h\big(C,f(\sigma(C))\big)}{|X_k|}-\sum_{i=0}^{d-1}\frac{\Pr_{x\sim\mathbb{Z}_d^k}[f(x)=i]}{|X_k|}h(C,i)\right)\\
&= \sum_{C\in X_k}\sum_{i=0}^{d-1}\left(\frac{h(C,i)\left(\frac{Q_\sigma^{f,i}(C)+1}{2}-\Pr_{x\sim\mathbb{Z}_d^k}[f(x)=i]\right)}{|X_k|}\right)\\
&= \sum_{C\in X_k}\sum_{i=0}^{d-1}\left(\frac{h(C,i)}{|X_k|}\left(\frac{1}{2}-\Pr_{x\sim\mathbb{Z}_d^k}[f(x)=i]+\sum_{\alpha\in\mathbb{Z}_d^k}\frac{\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)}{2}\right)\right)\\
&= \sum_{C\in X_k}\sum_{i=0}^{d-1}\left(\frac{h(C,i)}{|X_k|}\left(\frac{1}{d}-\Pr_{x\sim\mathbb{Z}_d^k}[f(x)=i]+\sum_{\alpha\in\mathbb{Z}_d^k:\alpha\neq\vec{0}}\frac{\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)}{2}\right)\right)\\
&= \sum_{C\in X_k}\sum_{i=0}^{d-1}\left(\frac{h(C,i)}{|X_k|}\left(\sum_{\alpha\in\mathbb{Z}_d^k:\alpha\neq\vec{0}}\frac{\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)}{2}\right)\right)\\
&= \sum_{C\in X_k}\sum_{i=0}^{d-1}\left(\frac{h(C,i)}{|X_k|}\left(\sum_{\ell=1}^{k}\sum_{\alpha\in\mathbb{Z}_d^k:H(\alpha)=\ell}\frac{\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)}{2}\right)\right)\\
&= \frac{1}{2\left|X_k\right|}\sum_{\ell=1}^{k}\sum_{C\in X_k}\sum_{i=0}^{d-1}\left(h(C,i)\left(\sum_{\alpha\in\mathbb{Z}_d^k:H(\alpha)=\ell}\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)\right)\right)\\
&= \frac{1}{2\left|X_k\right|}\sum_{\ell=1}^{k}\sum_{\alpha\in\mathbb{Z}_d^k:H(\alpha)=\ell}\sum_{C\in X_k}\sum_{i=0}^{d-1}\left(h(C,i)\left(\hat{Q}_\alpha^{f,i}\chi_\alpha\left(\sigma\left(C\right)\right)\right)\right)\\
&= \frac{1}{2\left|X_k\right|}\sum_{\ell=1}^{k}\sum_{\alpha\in\mathbb{Z}_d^k:H(\alpha)=\ell}\sum_{i=0}^{d-1}\hat{Q}_\alpha^{f,i}\sum_{C_\ell\in X_\ell}\sum_{C\in X_k,C_{|S_\alpha}=C_\ell}\chi_\alpha\left(\sigma\left(C\right)\right)h^i(C)\\
&= \frac{1}{2\left|X_k\right|}\sum_{\ell=1}^{k}\sum_{\alpha\in\mathbb{Z}_d^\ell:H(\alpha)=\ell}\binom{k}{\ell}\sum_{i=0}^{d-1}\hat{Q}_\alpha^{f,i}\sum_{C_\ell\in X_\ell}\sum_{C\in X_k,C_{|S_\alpha}=C_\ell}\chi_\alpha\left(\sigma\left(C_\ell\right)\right)h(C,i)\\
&= \sum_{\ell=1}^{k}\frac{1}{2\left|X_\ell\right|}\sum_{\alpha\in\mathbb{Z}_d^\ell:H(\alpha)=\ell}\binom{k}{\ell}\sum_{i=0}^{d-1}\hat{Q}_\alpha^{f,i}\sum_{C_\ell\in X_\ell}\chi_\alpha\left(\sigma\left(C_\ell\right)\right)h_{S_\alpha}^i(C)\\
&= \sum_{\ell=1}^{k}\frac{1}{|X_\ell|}b_\ell(\sigma)\ .
\end{aligned}$$

◀

The following lemma is similar to Lemma 4 from [26]. Lemma 22 is based on the general hypercontractivity theorem [45, Chapter 10] and applies to more general (non-boolean) functions.

▶ **Lemma 22.** *[45, Theorem 10.23] If $b : \mathbb{Z}_d^n \to \mathbb{R}$ has degree at most ℓ then for any $t \geq \left(\sqrt{2ed}\right)^\ell$,*

$$\Pr_{x\sim\mathbb{Z}_d^n}\left[|b(x)| \geq t\|b\|_2\right] \leq \frac{1}{d^\ell}\exp\left(-\frac{\ell}{2ed}t^{2/\ell}\right) ,$$

where $\|b\|_2 = \sqrt{\mathbb{E}_{x\sim\mathbb{Z}_d^n}\left[b\left(x\right)^2\right]}$

Lemma 15 and its proof are almost identical to Lemma 5 in [26]. We simply replace their concentration bounds with the concentration bounds in Lemma 22. We include the proof for completeness.

▶ **Lemma 15** (restated). *Let $b : \mathbb{Z}_d^n \to \mathbb{R}$ be any function with degree at most ℓ, and let $\mathcal{D}' \subseteq \mathbb{Z}_d^n$ be a set of assignments for which $d' = d^n/|\mathcal{D}'| \geq e^\ell$. Then $\mathbb{E}_{\sigma\sim\mathcal{D}'}\left[|b\left(\sigma\right)|\right] \leq 2(\ln d'/c_0)^{\ell/2}\|b\|_2$, where $c_0 = \ell\left(\frac{1}{2ed}\right)$ and $\|b\|_2 = \sqrt{\mathbb{E}_{x\sim\mathbb{Z}_d^n}\left[b\left(x\right)^2\right]}$.*

Proof of Lemma 15. The set $\mathcal{D}'$ contains $1/d'$ fraction of points in $\mathbb{Z}_d^n$. Therefore,

$$\Pr_{x\sim\mathcal{D}'}\left[|b(x)| \geq t\|b\|_2\right] \leq \frac{d'}{d^\ell}\exp\left(-\frac{\ell}{2ed}t^{2/\ell}\right) ,$$

for any $t \geq \left(\sqrt{2ed}\right)^\ell$. For any random variable Y and value $a \in \mathbb{R}$,

$$\mathbb{E}[Y] \leq a + \int_a^\infty \Pr[Y \geq t]\, dt .$$

We set $Y = |b\left(\sigma\right)|/\|b\|_2$ and $a = \left(\frac{\ln d'}{c_0}\right)^{\ell/2}$. Assuming that $a > \left(\sqrt{2ed}\right)^\ell$ we get

$$\begin{aligned}\frac{\mathbb{E}_{\sigma\sim\mathcal{D}'}[|b(\sigma)|]}{\|b\|_2} &\leq \left(\frac{\ln d'}{c_0}\right)^{\ell/2} + \int_{(\ln d'/c_0)^{\ell/2}}^\infty \frac{d'}{d^\ell}\cdot e^{-c_0 t^{2/\ell}} dt \\ &= (\ln d'/c_0)^{\ell/2} + \frac{\ell\cdot d'}{2d^\ell\cdot c_0^{\ell/2}}\cdot\int_{\ln d'}^\infty e^{-z} z^{\ell/2-1} dz .\end{aligned}$$

Let $u(i) \doteq \int_{\ln d'}^\infty e^{-z} z^{\ell/2-i} dz$. Applying integration by parts we have

$$\begin{aligned}u(i) \doteq \int_{\ln d'}^\infty e^{-z} z^{\ell/2-i} dz &= \left(e^{-z} z^{\ell/2-i+1}\right)\Big|_{\ln d'}^\infty + \int_{\ln d'}^\infty e^{-z} z^{\ell/2-i+1} dz - \left(\frac{\ell}{2}-i\right)\int_{\ln d'}^\infty e^{-z} z^{\ell/2-i} dz \\ &= \left(e^{-z} z^{\ell/2-i+1}\right)\Big|_{\ln d'}^\infty + u(i-1) - \left(\frac{\ell}{2}-i\right)u(i) .\end{aligned}$$

Thus,

$$u(i-1) = \left(\frac{\ell}{2}-i+1\right)u(i) - \left(e^{-z} z^{\ell/2-i+1}\right)\Big|_{\ln d'}^\infty = \left(\frac{\ell}{2}-i+1\right)u(i) + \frac{(\ln d')^{\frac{\ell}{2}-i+1}}{d'} .$$

Unrolling the recurrence for $T \geq 1$ we get

$$u(1) = \frac{(\ln d')^{\frac{\ell}{2}}}{d'} + \sum_{i=1}^{T-1}\frac{(\ln d')^{\frac{\ell}{2}-i}}{d'}\prod_{j=1}^{i}\left(\frac{\ell}{2}-j+1\right) + u\left(T+1\right)\prod_{j=1}^{T}\left(\frac{\ell}{2}-j+1\right) .$$

We also note that for $T = \lceil \frac{\ell}{2} + 1 \rceil$ we have $u(T+1)\prod_{j=1}^{T}\left(\frac{\ell}{2} - j + 1\right) \leq 0$. This follows because $u(T+1) \geq 0$ for any integer $T \geq 0$ and $\prod_{j=1}^{T}\left(\frac{\ell}{2} - j + 1\right) \leq 0$. It follows that

$$u(1) \leq \frac{(\ln d')^{\frac{\ell}{2}}}{d'} + \sum_{i=1}^{\lceil \frac{\ell}{2}+1 \rceil} \frac{(\ln d')^{\frac{\ell}{2}-i}}{d'} \prod_{j=1}^{i}\left(\frac{\ell}{2} - j + 1\right) \leq \frac{(\ln d')^{\frac{\ell}{2}}}{d'}\left(1 + \sum_{i=1}^{\lceil \frac{\ell}{2}+1 \rceil} \ell^{-i}\left(\frac{\ell}{2}\right)^{i}\right) \leq \frac{2\,(\ln d')^{\frac{\ell}{2}}}{d'}$$

where we used the condition $d' \geq e^{\ell}$ to obtain the second to last inequality. Now we have

$$\begin{aligned}
\frac{\mathbb{E}_{\sigma\sim\mathcal{D}'}[|b(\sigma)|]}{\|b\|_2} &\leq (\ln d'/c_0)^{\ell/2} + \frac{\ell \cdot d'}{2d^{\ell} \cdot c_0^{\ell/2}} \cdot u(1) \\
&\leq (\ln d'/c_0)^{\ell/2} + \frac{\ell \cdot d'}{2d^{\ell} \cdot c_0^{\ell/2}} \cdot \left(\frac{2\,(\ln d')^{\frac{\ell}{2}}}{d'}\right) \\
&\leq 2(\ln d'/c_0)^{\ell/2} \,.
\end{aligned}$$

◀

▶ **Lemma 23.** *Let $\mathcal{D}' \subseteq \{0,\ldots,d-1\}^n$ be a set of assignments for which $d' = d^n/|\mathcal{D}'|$. Then*

$$\mathbb{E}_{\sigma\sim\mathcal{D}'}\left[\left|\frac{1}{|X_\ell|} b_\ell(\sigma)\right|\right] \leq 2\left(\binom{k}{\ell}\sqrt{\ell! d}\right)(\ln d'/c_0)^{\ell/2} \max_{\alpha\in\mathbb{Z}_d^\ell} \sum_{i=0}^{d-1} \frac{\|h_{S_\alpha}(\sigma)\|_2}{\sqrt{|X_\ell|}} \,.$$

Proof. For simplicity of notation we set $b = b_\ell$. Our first goal will be to find the Fourier coefficients of

$$b(\sigma) = \frac{1}{2} \sum_{\alpha\in\mathbb{Z}_d^\ell : H(\alpha)=\ell} \binom{k}{\ell} \sum_{i=0}^{d-1} \hat{Q}_\alpha^{f,i} \sum_{C\in X_\ell} \chi_\alpha(\sigma(C))\, h_{S_\alpha}^i(C) \,.$$

Given $\alpha = (\alpha_1,\ldots,\alpha_\ell) \in \mathbb{Z}_d^\ell$ with $H(\alpha) = \ell$ and a clause $C = (c_1,\ldots,c_\ell) \in X_\ell$ we define the projection $\alpha^C \in \mathbb{Z}_d^\ell$ of α onto C to be the unique vector s.t. $\alpha^C_{c_i} = \alpha_i$ for each $i \leq \ell$ and $\alpha_j = 0$ for each $j \notin \{c_1,\ldots,c_\ell\}$ – note that $H(\alpha^C) = \ell$.

Given $\alpha, \alpha' \in \mathbb{Z}_d^k$ with $H(\alpha) = H(\alpha') = \ell$ and $C, C \in X_\ell$ we say that the pairs (α, C_ℓ) and (α', C'_ℓ) are equivalent if and only if their projections are equal $\alpha^C = \alpha'^{C'}$[13]. We can partition the set $\{\alpha \in \mathbb{Z}_d^k : H(\alpha) = \ell\} \times X_\ell$ into equivalence classes $E_1,\ldots,E_t$. If the pairs (α, C_ℓ) and (α', C'_ℓ) are equivalent then we observe that the clauses C and C' must contain the same variables though perhaps in a different order. Furthermore, given an equivalence class E_j such that $(\alpha, C) \in E_j$ we have $(\alpha', C) \notin E_j$ for any $\alpha' \neq \alpha \in \mathbb{Z}_d^k$. Thus each equivalence class has size $\ell!$ because there are $\ell!$ ways to reorder the ℓ variables in a clause C. We can rewrite $b(\sigma)$ as

$$b(\sigma) = \frac{\binom{k}{\ell}}{2} \sum_{j=1}^{t} \sum_{(\alpha,C)\in E_j} \sum_{i=0}^{d-1} \hat{Q}_\alpha^{f,i} h_{S_\alpha}^i(C) \chi_\alpha(\sigma(C))$$

Let $(\alpha, C) \in E_j$ then the Fourier coefficient of α^C is

$$\hat{b}_j = \hat{b}_{\alpha^C} = \frac{\binom{k}{\ell}}{2} \sum_{(\alpha',C')\in E_j} \sum_{i=0}^{d-1} \hat{Q}_\alpha^{f,i} h_\ell^i(C') \,.$$

[13] For example, if $C = (1,2,5)$, $C = (1,5,2)$ and $\alpha = (4,5,6)$ and $\alpha' = (4,6,5)$ then the pairs (α, C_ℓ) and $\left(\alpha', C'_\ell\right)$ are equivalent.

We also note that $t = \frac{|X_\ell|(d-1)^k}{\ell!}$.

Now we can apply Parseval's identity along with the Cauchy-Schwarz inequality to obtain

$$\begin{aligned}
\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[b(\sigma)\overline{b(\sigma)}\right] &= \mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[|b(\sigma)|^2\right] \\
&= \mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[\sum_{j=1}^{t}\left|\hat{b}_j\right|^2\right] \\
&= \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[\sum_{j=1}^{t}\left|\sum_{(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\hat{Q}_\alpha^{f,i}h_{S_\alpha}^i(C)\right|^2\right] \\
&\le \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[\sum_{j=1}^{t}\left(\sum_{(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\left(\sum_{(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|h_{S_\alpha}^i(C)\right|^2\right)\right] \\
&\le \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n} \\
&\quad\left[\sum_{j=1}^{t}\left(\ell!\max_{j\le t,(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\left(\sum_{(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|h_{S_\alpha}^i(C)\right|^2\right)\right] \\
&\le \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n} \\
&\quad\left[\left(\ell!\max_{j\le t,(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\left(\sum_{j=1}^{t}\sum_{(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|h_{S_\alpha}^i(C)\right|^2\right)\right] \\
&\le \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n} \\
&\quad\left[\left(\ell!\max_{j\le t,(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\left(\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{C\in X_\ell}\sum_{i=0}^{d-1}\left|h_{S_\alpha}^i(C)\right|^2\right)\right] \\
&\le \frac{\binom{k}{\ell}^2}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n} \\
&\quad\left[\left(\ell!\max_{j\le t,(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\left(|X_\ell|\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d-1}\mathbb{E}_{C\sim X_\ell}\left[h_{S_\alpha}^i(C)^2\right]\right)\right] \\
&\le \frac{\binom{k}{\ell}^2 d\ell!\,|X_\ell|}{4}\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[\left(\max_{j\le t,(C,\alpha)\in E_j}\sum_{i=0}^{d-1}\left|\hat{Q}_\alpha^{f,i}\right|^2\right)\right]\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d-1}\|h_{S_\alpha}^i\|_2^2 \\
&\le \frac{\binom{k}{\ell}^2 d\ell!\,|X_\ell|}{4}\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d-1}\|h_{S_\alpha}^i\|_2^2 \,.
\end{aligned}$$

Before we can apply Lemma 15 we must address a technicality. The range of $b = b_\ell$ might include complex numbers, but Lemma 15 only applies to functions b with range $\mathbb{R}$. For $c, d \in \mathbb{R}$ we adopt the notation $Im\left(c + d\sqrt{-1}\right) = d$ and $Re\left(c + d\sqrt{-1}\right) = c$. We observe that

$$\begin{aligned}
\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[b(\sigma)\overline{b(\sigma)}\right] &= \mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[Re(b(\sigma))^2 + Im(b(\sigma))^2\right] \\
&= \|Re(b)\|_2^2 + \|Im(b)\|_2^2 \,.
\end{aligned}$$

We first observe that $Re(b)$ and $Im(b)$ are both degree ℓ functions because b is a degree ℓ function.

Now we can apply Lemma 15 to get

$$\begin{aligned}\mathbf{E}_{\sigma\sim\mathcal{D}'}\left[\left|Re\left(b\left(\sigma\right)\right)\right|\right] &\leq \frac{2\left(\ln d'/c_0\right)^{\ell/2}}{d^\ell}\|Re(b)\|_2 \\ &\leq \frac{2\left(\ln d'/c_0\right)^{\ell/2}}{d^\ell}\sqrt{\mathbb{E}_{\sigma\sim\mathbb{Z}_d^n}\left[b\left(\sigma\right)\overline{b\left(\sigma\right)}\right]} \\ &\leq \left(\binom{k}{\ell}\sqrt{\ell!d}\right)\left(\ln d'/c_0\right)^{\ell/2}\sqrt{|X_\ell|}\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d}\|h_{S_\alpha}\left(\sigma\right)\|_2 \ .\end{aligned}$$

A symmetric argument can be used to bound $\mathbf{E}_{\sigma\sim\mathcal{D}'}\left[Im\left(b\left(\sigma\right)\right)\right]$. Now because

$$\left|b\left(\sigma\right)\right| \leq \left|Re\left(b\left(\sigma\right)\right)\right| + \left|Im\left(b\left(\sigma\right)\right)\right| \ ,$$

it follows that

$$\begin{aligned}\mathbf{E}_{\sigma\sim\mathcal{D}'}\left[\left|\frac{1}{|X_\ell|}b\left(\sigma\right)\right|\right] &\leq 2\left(\binom{k}{\ell}\sqrt{\ell!d}\right)\left(\frac{1}{|X_\ell|}\right)\left(\left(\ln d'/c_0\right)^{\ell/2}\right)\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d-1}\|h_{S_\alpha}\left(\sigma\right)\|_2\sqrt{|X_\ell|} \\ &\leq 2\left(\binom{k}{\ell}\sqrt{\ell!d}\right)\left(\ln d'/c_0\right)^{\ell/2}\max_{\alpha\in\mathbb{Z}_d^\ell}\sum_{i=0}^{d-1}\frac{\|h_{S_\alpha}\left(\sigma\right)\|_2}{\sqrt{|X_\ell|}} \ .\end{aligned}$$

◀

We will use Fact 24 to prove Lemma 25. The proof of Fact 24 is found in [26, Lemma 7]. We include it here for completeness.

▶ **Fact 24.** *[26] If $h : X_k \times \mathbb{Z}_d \to \mathbb{R}$ satisfies $\|h\|_2^2 = 1$ then for any $i \in \mathbb{Z}_d$, $0 \leq \ell \leq k$ and $S \subseteq [k]$ of size $|S| = \ell$ we have $\sum_{i=0}^{d-1}\|h_S^i\|_2^2 \leq d$.*

Proof. First notice that for any C_ℓ, $S \subseteq [k]$ s.t $|S| = \ell$

$$\left|\{C \in X_k \,|\, C_{|S} = C_\ell\}\right| = \frac{|X_k|}{|X_\ell|} \ .$$

By applying the definition of h_ℓ along with the Cauchy-Schwartz inequality

$$\begin{aligned}\sum_{i=0}^{d-1}\|h_S^i\|_2^2 &= \sum_{i=0}^{d-1}\mathbb{E}_{C_\ell\sim X_\ell}\left[h_S^i\left(C_\ell\right)^2\right] \\ &= \left(\frac{|X_\ell|}{|X_k|}\right)^2\sum_{i=0}^{d-1}\mathbb{E}_{C_\ell\sim X_\ell}\left[\left(\sum_{C\in X_k, C_{|S}=C_\ell}h\left(C,i\right)\right)^2\right] \\ &\leq \left(\frac{|X_\ell|}{|X_k|}\right)^2\sum_{i=0}^{d-1}\mathbb{E}_{C_\ell\sim X_\ell}\left[\frac{|X_k|}{|X_\ell|}\left(\sum_{C\in X_k, C_{|S}=C_\ell}h\left(C,i\right)^2\right)\right] \\ &\leq \left(\frac{|X_\ell|}{|X_k|}\right)d\mathbb{E}_{C_\ell\sim X_\ell, i\sim\mathbb{Z}_d}\left[\left(\sum_{C\in X_k, C_{|S}=C_\ell}h\left(C,i\right)^2\right)\right] \\ &= d\mathbb{E}_{C\sim U_k}\left[h\left(C\right)^2\right] = d\|h\|_2^2 = d \ .\end{aligned}$$

◀

▶ **Lemma 25.** *Let $r = r(f)$, let $\mathcal{D}' \subseteq \{0,\ldots,d-1\}^n$ be a set of secret mappings and let $d' = d^n/|\mathcal{D}'|$. Then $\kappa_2(\mathcal{D}') = O_k\left(\left(\ln d'/n\right)^{r/2}\right)$*

Proof. Let $h : X_k \to \mathbb{R}$ be any function such that $\mathbb{E}_{U_k}\left[h^2\right] = 1$. Using Lemma 21 and the definition of r,

$$\begin{aligned} |\Delta(\sigma, h)| &= \left| \sum_{\ell=r}^{k} \frac{1}{|X_\ell|} b_\ell(\sigma) \right| \\ &\leq \sum_{\ell=r}^{k} \left| \frac{1}{|X_\ell|} b_\ell(\sigma) \right| . \end{aligned}$$

We apply Lemma 23 and Fact 24 to get

$$\begin{aligned} \mathbb{E}_{\sigma\sim\mathcal{D}'}\left[|\Delta(\sigma, h)|\right] &\leq 2\sum_{\ell=r}^{k} \binom{k}{\ell} \sqrt{\ell! d} \left(\ln d'/c_0\right)^{\ell/2} \max_{\alpha\in\mathbb{Z}_d} \sum_{i=0}^{d-1} \frac{\|h^i_{S_\alpha}(\sigma)\|_2}{\sqrt{|X_\ell|}} \\ &\leq \sum_{\ell=r}^{k} \left(\binom{k}{\ell} d\sqrt{\ell!} \right) \left(\frac{2\left(\ln d'/c_0\right)^{\ell/2}}{\sqrt{|X_\ell|}} \right) \\ &\leq O_k\left(\frac{\left(\ln d'\right)^{\ell/2}}{n^{r/2}} \right) . \end{aligned}$$

◀

▶ **Theorem 16** (restated). *There exists a constant $c_Q > 0$ such that for any $\epsilon > 1/\sqrt{n}$ and $q \geq n$ we have*

$$\mathrm{SDN}\left(\mathcal{Z}_{\epsilon,f}, \frac{c_Q \left(\log q\right)^{r/2}}{n^{r/2}}, 2e^{-n\cdot\epsilon^2/2} \right) \geq q ,$$

where $r = r(f)$ is the distributional complexity of f.

Proof of Theorem 16. First note that, by Chernoff bounds, for any solution $\tau \in \mathbb{Z}_d^n$ the fraction of assignments $\sigma \in \mathbb{Z}_d^n$ such that τ and σ are ϵ-correlated (e.g., $H(\sigma,\tau) \leq \frac{n(d-1)}{d} - \epsilon\cdot n$) is at most $e^{-2n\cdot\epsilon^2}$. In other words $|\mathcal{D}_\sigma| \geq \left(1 - e^{-2n\cdot\epsilon^2}\right)|\mathbb{Z}_d^n|$, where $\mathcal{D}_\sigma = \mathbb{Z}_d^n \setminus \left\{ \sigma' \,\middle|\, H(\sigma,\sigma') \leq \frac{n(d-1)}{d} - \epsilon\cdot n \right\}$ Let $\mathcal{D}' \subseteq \mathcal{D}_\sigma$ be a set of distributions of size $|\mathcal{D}_\sigma|/q$. Then for $d' = d^n/|\mathcal{D}'| = q\cdot d^n/|\mathcal{D}_\sigma|$, by Lemma 25 we get

$$\kappa_2(\mathcal{D}') = O_k\left(\frac{\left(\ln d'\right)^{r/2}}{n^{r/2}} \right) \tag{1}$$

$$= O_k\left(\frac{\left(\ln q\right)^{r/2}}{n^{r/2}} \right) , \tag{2}$$

where the last line follows by Sterling's Approximation

$$q = d'|\mathcal{D}_\sigma|/d^n = d'|\mathcal{D}_\sigma|/d^n \approx d'c'\sqrt{\frac{d}{n}}$$

for a constant c'. The claim now follows from the definition of SDN. ◀

The proof of Theorem 14 follows from Theorem 16 and the following result of Feldman et al. [26].

▶ **Theorem 13** (restated). *[26, Theorems 10 and 12] For $\kappa > 0$ and $\eta \in (0,1)$ let $d' = \mathrm{SDN}(\mathcal{Z}_{\epsilon,f}, \kappa, \eta)$ be the statistical dimension of the distributional search problem $\mathcal{Z}_{\epsilon,f}$. Any randomized statistical algorithm that, given access to a VSTAT$\left(\frac{1}{3\kappa^2}\right)$ oracle (resp. 1-MSTAT(L)) for the distribution Q^f_σ for a secret mapping σ chosen randomly and uniformly from $\mathbb{Z}_d^n$, succeeds in finding a mapping $\tau \in \mathbb{Z}_d^n$ that is ϵ-correlated with σ with probability $\Lambda > \eta$ over the choice of distribution and internal randomness requires at least $\frac{\Lambda-\eta}{1-\eta}d'$ (resp. $\Omega\left(\frac{1}{L}\min\left\{\frac{d'(\Lambda-\eta)}{1-\eta}, \frac{(\Lambda-\eta)^2}{\kappa^2}\right\}\right)$) calls to the oracle.*

▶ **Theorem 14** (restated). *Let $\sigma \in \mathbb{Z}_d^n$ denote a secret mapping chosen uniformly at random, let Q^f_σ be the distribution over $X_k \times \mathbb{Z}_d$ induced by a function $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ with distributional complexity $r = r(f)$. Any randomized statistical algorithm that finds an assignment τ such that τ is $\left(\sqrt{\frac{-2\ln(\eta/2)}{n}}\right)$-correlated with σ with probability at least $\Lambda > \eta$ over the choice of σ and the internal randomness of the algorithm needs at least m calls to the 1-MSTAT(L) oracle (resp. VSTAT$\left(\frac{n^r}{2(\log n)^{2r}}\right)$ oracle) with $m \cdot L \geq c_1\left(\frac{n}{\log n}\right)^r$ (resp. $m \geq n^{c_1 \log n}$) for a constant $c_1 = \Omega_{k,1/(\Lambda-\eta)}(1)$ which depends only on the values k and $\Lambda - \eta$. In particular if we set $L = \left(\frac{n}{\log n}\right)^{r/2}$ then our algorithms needs at least $m \geq c_1\left(\frac{n}{\log n}\right)^{r/2}$ calls to 1-MSTAT(L).*

E Security Proofs

▶ **Theorem 19** (restated). *Let f be a function with evenly distributed output (Definition 17), let $\sigma \sim \mathbb{Z}_d^n$ denote the secret mapping, let $\epsilon > 0$ be any constant and suppose that for every $C \in X_k$ we are given labels $\ell_C \in \mathbb{Z}_d$ s.t. $\Pr_{C\sim X_k}[f(\sigma(C)) = \ell_C] \geq \frac{1}{d} + \epsilon$. There is a polynomial time algorithm (in n, m,$1/\epsilon$) that finds a mapping $\sigma' \in \mathbb{Z}_d^n$ such that σ' is $\epsilon/2$-correlated with σ with probability at least $\frac{\epsilon}{2d^2}$*

Proof of Theorem 19. Let $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ be a function with evenly distributed output. We select fix $C^{-1} \sim X_{k-1}$ and $i \sim [n] \setminus C^{-1}$. Given $j \in [n] \setminus C^{-1}$ we let $C_j = (C^{-1}, j) \in X_k$ denote the corresponding clause. Now we generate the mapping σ' by selecting $\sigma'(i)$ at random, and setting $\sigma'(j) = \sigma'(i) + \ell_{C_j} - \ell_{C_i} \mod d$ for $j \in [n] \setminus C_i$. For $j \in C^{-1}$ we select $\sigma'(j)$ at random. We let $\mathbf{GOOD}\left(C^{-1}, i, \sigma'\right)$ denote the event that

$$\Pr_{j\sim[n]\setminus C^{-1}}\left[\ell_{C_j} = f\left(\sigma\left(C_j\right)\right)\right] \geq \frac{1}{d} + \epsilon/2 \ ,$$

$\sigma'(i) = \sigma(i)$ and $\ell_{C_i} = f(\sigma(C_i))$. Assume that the event $\mathbf{GOOD}\left(C^{-1}, i\right)$ occurs, in this case for each j s.t. $\ell_{C_j} = f(\sigma(C_j))$ we have

$$\begin{aligned}
\sigma'(j) - \sigma(j) &\equiv \left(\sigma'(i) + \ell_{C_j} - \ell_{C_i}\right) - \sigma(j) \mod d \\
&\equiv \left(\ell_{C_j} - \ell_{C_i}\right) + \sigma(i) - \sigma(j) \mod d \\
&\equiv g\left(\sigma\left(C^{-1}\right)\right) + \sigma(j) - \left(g\left(\sigma\left(C^{-1}\right)\right) + \sigma(i)\right) + \sigma(i) - \sigma(j) \mod d \\
&\equiv 0 \mod d \ .
\end{aligned}$$

Therefore, we have

$$\frac{n - H(\sigma, \sigma')}{n} \geq \frac{1}{d} + \epsilon/2 - \frac{k-1}{n} \ .$$

We note that by Markov's inequality the probability of success is at least

$$\Pr_{C^{-1}\sim X_{k-1}}\left[\mathbf{GOOD}\left(C^{-1}\right)\right] \geq \frac{\epsilon}{2d^2} \ . \qquad \blacktriangleleft$$

Before proving Theorem 18 we introduce some notation and prove an important claim. We use $\mathcal{A}_{C_1,\ldots,C_m} : (X_k)^\lambda \to \mathbb{Z}_d^\lambda$ to denote an adversary who sees the challenges $C_1,\ldots,C_m \in X_k$ and the corresponding responses $f(\sigma(C_1)),\ldots,f(\sigma(C_m))$. $\mathcal{A}_{C_1,\ldots,C_m}(C'_1,\ldots,C'_\lambda) \in \mathbb{Z}_d^\lambda$ denotes the adversaries prediction of $f(\sigma(C'_1)),\ldots,f(\sigma(C'_\lambda))$. Given a function $b : (X_k)^\lambda \to \mathbb{Z}_d^\lambda$, challenges $C'_1,\ldots,C'_\lambda \in X_k$ and responses $f(\sigma(C'_1)),\ldots,f(\sigma(C'_\lambda))$ we use $\mathcal{P}_{b,i,C'_1,\ldots,C'_m} : X_k \times [t] \to \mathbb{Z}_d \cup \{\perp\}$ to predict the value of a clause $C \in X_k$

$$\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) = \begin{cases} b\left(\hat{C}_1,\ldots,\hat{C}_\lambda\right)[i], & \text{if } f\left(\sigma\left(\hat{C}_j\right)\right) = b\left(\hat{C}_1,\ldots,\hat{C}_\lambda\right)[j] \ \ \forall j < i \\ \perp, & \text{otherwise} \end{cases}$$

where $\hat{C}_i = C$ and $\hat{C}_j = C'_j$ for $j \neq i$. We allow our predictor $\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i)$ to output $\perp$ when it is unsure. Informally, Claim 26 says that for $b = \mathcal{A}_{C_1,\ldots,C_m}$ our predictor $\mathcal{P}_{b,i,C'_1,\ldots,C'_m}$ is reasonably accurate whenever it is not unsure. Briefly, Claim 26 follows because for $b = \mathcal{A}_{C_1,\ldots,C_m}$ we have

$$\Pr[\mathbf{Wins}(\mathcal{A},n,m,\lambda)] = \prod_{i=1}^{d} \Pr_{\substack{C\sim X_k \\ C_1,\ldots,C_m\sim X_k \\ C'_1,\ldots,C'_\lambda\sim X_k}} \left[\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) = f(\sigma(C)) \;\middle|\; \mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) \neq \perp\right] .$$

▶ **Claim 26.** *Let $\mathcal{A}$ be an adversary s.t $\Pr[\mathbf{Wins}(\mathcal{A},n,m,\lambda)] > \left(\frac{1}{d}+\epsilon\right)^\lambda$ and let $b = \mathcal{A}_{C_1,\ldots,C_m}$ then*

$$\Pr_{\substack{i\sim[\lambda],C\sim X_k \\ C_1,\ldots,C_m\sim X_k \\ C'_1,\ldots,C'_\lambda\sim X_k}} \left[\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) = f(\sigma(C)) \;\middle|\; \mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) \neq \perp\right] \geq \left(\frac{1}{d}+\epsilon\right) .$$

Proof of Claim 26. We draw examples $(C_1, f(\sigma(C_1))),\ldots,(C_m, f(\sigma(C_m)))$ to construct $b = \mathcal{A}_{C_1,\ldots,C_m}$. Given a random length-$\lambda$ password challenge $(C'_1,\ldots,C'_\lambda) \in (X_k)^t$ we let

$$p_j = \Pr_{C,C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda\sim X_k} \left[\mathcal{P}_{b,j,C'_1,\ldots,C'_t}(C) = f(\sigma(C)) \;\middle|\; \mathcal{P}_{b,j,C'_1,\ldots,C'_\lambda}(C) \neq \perp\right]$$

denote the probability that the adversary correctly guesses the response to the j'th challenge conditioned on the event that the adversary correctly guesses all of the earlier challenges. Observe that

$$\Pr_{C,C_1,\ldots,C_m,C'_1,\ldots,C'_{\lambda-1}\sim X_k,i\sim[t]} \left[\mathcal{P}_{b,i,C'_1,\ldots,C'_\lambda}(C,i) = f(\sigma(C))\right] = \sum_{i=1}^{\lambda} p_i/\lambda ,$$

so it suffices to show that $\sum_{i=1}^{\lambda} p_i/\lambda \geq \frac{1}{d}+\epsilon$. We obtain the following constraint

$$\begin{aligned} \prod_{i=1}^{\lambda} p_i &= \prod_{i=1}^{\lambda} \Pr_{C,C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda\sim X_k} \left[\mathcal{P}_{b,j,C'_1,\ldots,C'_\lambda}(C) = f(\sigma(C)) \;\middle|\; \mathcal{P}_{b,j,C'_1,\ldots,C'_\lambda}(C) \neq \perp\right] \\ &= \prod_{i=1}^{\lambda} \Pr_{C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda\sim X_k} \\ &\quad \left[\mathcal{A}_{C_1,\ldots,C_m}\left(C'_1,\ldots,C'_\lambda\right)[i] = f\left(\sigma\left(C'_i\right)\right) \;\middle|\; \forall j < i.\ \mathcal{A}_{C_1,\ldots,C_m}\left(C'_1,\ldots,C'_\lambda\right)[j] = f\left(\sigma\left(C'_j\right)\right)\right] \\ &= \Pr_{C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda\sim X_k} \left[\mathcal{A}_{C_1,\ldots,C_m}\left(C'_1,\ldots,C'_\lambda\right) = \left(f\left(\sigma\left(C'_1\right)\right),\ldots,f\left(\sigma\left(C'_\lambda\right)\right)\right)\right] \\ &\geq \left(\frac{1}{d}+\epsilon\right)^\lambda . \end{aligned}$$

If we minimize $\sum_{i=1}^{t} p_i/\lambda$ subject to the constraint $\prod_{i=1}^{\lambda} p_i \geq \left(\frac{1}{d}+\epsilon\right)^{\lambda}$ then we obtain the desired upper bound $\sum_{i=1}^{\lambda} p_i/\lambda \geq \frac{1}{d}+\epsilon$. ◀

▶ **Theorem 18** (restated). *Suppose that f has evenly distributed output, but that f is not $\mathbf{UF-RCA}(n,m,\lambda,\delta)$ − secure for $\delta > \left(\frac{1}{d}+\epsilon\right)^{\lambda}$. Then there is a probabilistic polynomial time algorithm (in n, m, λ and $1/\epsilon$) that extracts a string $\sigma' \in \mathbb{Z}_d^n$ that is $\epsilon/8$-correlated with σ with probability at least $\frac{\epsilon^3}{(8d)^2}$ after seeing $m+\lambda$ example challenge response pairs.*

Proof of Theorem 18. Given random clauses $C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda \sim X_k$ we let $\mathbf{Good}(C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda)$ denote the event that

$$\Pr_{i\sim[t],C\sim X_k}\left[\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) = f(\sigma(C)) \;\middle|\; \mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) \neq \perp\right] \geq \left(\frac{1}{d}+\frac{\epsilon}{2}\right).$$

By Markov's Inequality and Claim 26 we have $\Pr[\mathbf{Good}(C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda)] \geq \frac{\epsilon}{2}$. Here, $b = \mathcal{A}_{C_1,\ldots,C_m}$ and

$$\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,i) = \begin{cases} b\left(\hat{C}_1,\ldots,\hat{C}_\lambda\right)[i], & \text{if } f\left(\sigma\left(\hat{C}_j\right)\right) = b\left(\hat{C}_1,\ldots,\hat{C}_\lambda\right)[j] \;\; \forall j<i \\ \perp, & \text{otherwise} \end{cases}$$

Assuming that the event $\mathbf{Good}(C_1,\ldots,C_m,C'_1,\ldots,C'_\lambda)$ occurs we obtain labels for each clause $C \in X_k$ by selecting a random permutation $\pi:[\lambda]\to[\lambda]$, setting $i=1$ and setting $\ell_C = \mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,\pi(i))$ – if $\ell_C \neq \perp$ then we increment i and repeat. Note that we will always find a label $\ell_C \neq \perp$ within t attempts because $\mathcal{P}_{b,C'_1,\ldots,C'_\lambda}(C,1) \neq \perp$. Let **GoodLabels** denote the event that

$$\Pr_{C\sim X_k}[G_C] \geq \frac{1}{d}+\frac{\epsilon}{4},$$

where G_C is the indicator random variable for the event $\ell_C = f(\sigma(C))$. We have

$$\mathbb{E}\left[\frac{1}{|X_k|}\sum_{C\in X_k} G_C\right] \geq \frac{1}{d}+\frac{\epsilon}{2},$$

so we can invoke Markov's inequality again to argue that $\Pr[\mathbf{GoodLabels} \mid \mathbf{Good}] \geq \frac{\epsilon}{4}$. If the event **GoodLabels** occurs then we can invoke Theorem 19 to obtain σ' that is $\epsilon/8$-correlated with σ with probability at least $\frac{\epsilon}{8d^2}$. Our overall probability of success is

$$\frac{\epsilon}{8d^2}\times\frac{\epsilon}{4}\times\frac{\epsilon}{2} = \frac{\epsilon^3}{(8d)^2}.$$ ◀

F Security Parameters of f_{k_1,k_2}

▶ **Claim 9** (restated). *Let $0 \leq k_1$ and $k_2 > 0$ be given and let $f = f_{k_1,k_2}$ we have $g(f) = \min\{k_1,10\}$, $r(f) = k_2+1$ and $s(f) = \min\left\{\frac{k_2+1}{2}, k_1+1, 11\right\}$.*

Proof of Claim 9. Let $f(x) = f_{k_1,k_2}(x) = x_{\left(\sum_{i=10}^{9+k_1} x_i \mod 10\right)} + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10$. We first observe that if we fix the values of $x_{10},\ldots,x_{9+k_1} \in \mathbb{Z}_{10}$ and let $i' = \sum_{i=10}^{9+k_1} x_i \mod 10$ then $f'(x_0,\ldots,x_9,x_{10+k_1},\ldots,x_{9+k_1+k_2}) = x_{i'} + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10$ is a linear function. Similarly, if we fix the values of $x_0 = \ldots = x_9 = c$ then the resulting function

$f'(x_{10},\ldots,x_{9+k_1+k_2}) = c + \sum_{i=10+k_1}^{9+k_1+k_2} x_i \mod 10$ is linear. Thus, $g(f) \leq \min\{10,k_1\}$. Now suppose that we don't fix all of the values $x_{10},\ldots,x_{9+k_1} \in \mathbb{Z}_{10}$ and at least one of the variables $x_0,\ldots,x_9$ is not fixed. In this case the resulting function will not be linear. Thus, $g(f) \geq \min\{k_1,10\}$. We also note that for any $\alpha \in \mathbb{Z}_{10}^{10+k_1+k_2}$ s.t. $H(\alpha) \leq k_2$ and $i,t \in \mathbb{Z}_{10}$ that

$$\Pr_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}[f(x)=t \mid \alpha\cdot x \equiv i \mod 10] = \Pr_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}[f(x)=t] = \frac{1}{10}\ .$$

Therefore,

$$\begin{aligned}
\hat{Q}_\alpha^{f,t} &= \mathbb{E}_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[Q^{f,t}(x)\,\chi_\alpha(x)\right] \\
&= \sum_{i=0}^{9} \Pr[\alpha\cdot x \equiv i \mod 10]\,\mathbb{E}_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[Q^{f,t}(x)\,\chi_\alpha(x)\;\middle|\;\alpha\cdot x\equiv i \mod 10\right] \\
&= \sum_{i=0}^{9} \exp\left(\frac{-2\pi i\sqrt{-1}}{10}\right)\Pr[\alpha\cdot x \equiv i \mod 10]\,\mathbb{E}_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[Q^{f,t}(x)\;\middle|\;\alpha\cdot x\equiv i \mod 10\right] \\
&= \frac{1}{10}\sum_{i=0}^{9} \exp\left(\frac{-2\pi i\sqrt{-1}}{10}\right)\mathbb{E}_{x\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[Q^{f,t}(x)\;\middle|\;\alpha\cdot x\equiv i \mod 10\right] \\
&= 0\ ,
\end{aligned}$$

which implies that $r(f) \geq k_2+1$. Similarly, if we set $\alpha = (\alpha_0,\ldots,\alpha_{9+k_1+k_2})$ such that $\alpha_0 = 1$ and $\alpha_{10+k_1} = \ldots = \alpha_{9+k_1+k_2} = 1$ so that α has hamming weight k_2+1 then we can verify that $\hat{Q}_\alpha^{f,t} \neq 0$. ◀

G Security Upper Bounds

G.1 Statistical Algorithms

Theorem 27 demonstrates that our lower bound for statistical algorithms are asymptotically tight for our human computable password schemes f_{k_1,k_2}. In particular, we demonstrate that $m = \tilde{O}\left(n^{(k_2+1)/2}\right)$ queries to 1-MSTAT are sufficient for a statistical algorithm to recover σ.

▶ **Theorem 27.** *For $f = f_{k_1,k_2}$ there is a randomized algorithm that makes $O\left(n^{\max\{1,(k_2+1)/2\}}\log^2 n\right)$ calls to the 1-MSTAT$\left(n^{\lceil r(f_i)/2\rceil}\right)$ oracle and returns σ with probability $1-o(1)$.*

For binary functions $f' : \{0,1\}^k \to \{0,1\}$, Feldman et al. [26] gave a randomized statistical algorithm to find $\sigma' \in \{0,1\}^n$ using just $O\left(n^{r(f)/2}\log^2 n\right)$ calls to the 1-MSTAT $\left(n^{\lceil r(f)/2\rceil}\right)$ oracle. Their main technique is a discrete spectral iteration procedure to find the eigenvector (singular vector) with the largest eigenvalue (singular value) of a matrix M sampled from a distribution $M_{\sigma',p}$ over $\left|X_{\lfloor r(f)/2\rfloor}\right| \times \left|X_{\lceil r(f)/2\rceil}\right|$ matrices. With probability $1-o(1)$ this eigenvector will encode the value $\sum_{i\in C}\sigma'(i) \mod 2$ for each clause $C \in X_{r(f)/2}$. We show that the discrete spectral iteration algorithm of Feldman et al [26] can be extended to recover $\sigma \in \mathbb{Z}_{10}$ when f_{k_1,k_2} is one of our candidate human computable functions.

Discussion

We note that Theorem 27 cannot be extended to arbitrary functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$. Consider for example the unique function $f : \mathbb{Z}_{10}^6 \to \mathbb{Z}_{10}$ s.t. $f(x_1,\ldots,x_6) \equiv f'(x_1 \mod 2,\ldots,x_6 \mod 2) \mod 2$ and $f(x_1,\ldots,x_6) \equiv f''(x_1 \mod 5,\ldots,x_6 \mod 5) \mod 5$, where $f' : \mathbb{Z}_2^6 \to \mathbb{Z}_2$ and

$f'' : \mathbb{Z}_5^6 \to \mathbb{Z}_5$. By the Chinese Remainder Theorem instead of picking a secret mapping $\sigma \in \mathbb{Z}_{10}^n$ we could equivalently pick the unique secret mappings $\sigma_1 \in \mathbb{Z}_2^n$ and $\sigma_2 \in \mathbb{Z}_5^n$ s.t $\sigma \equiv \sigma_1 \mod 2$ and $\sigma \equiv \sigma_2 \mod 5$. Now drawing challenge response pairs from the distributions Q_σ^f is equivalent to drawing challenge-response pairs from the distributions $Q_{\sigma_1}^{f'}$ and $Q_{\sigma_2}^{f''}$. Suppose that $f'(x_1, \ldots, x_6) = x_1x_2 + x_3 + x_4 + x_5 + x_6 \mod 2$, and $f''(x_1, \ldots, x_6) = x_1$. Then we have $r(f) = \min(r(f'), r(f'')) = r(f'') = 1$, but $r(f') = 4$. We can find σ_2 using $O\left(n \log^2 n\right)$ calls to 1-MSTAT(n), but to find σ we must also recover σ_1. This provably requires at least $\tilde{\Omega}\left(n^{r(f')/2}\right) = \tilde{\Omega}\left(n^2\right)$ calls to 1-MSTAT$\left(n^2\right)$.

Background

The proof of Theorem 27 relies on the discrete spectral iteration algorithm of [26]. We begin by providing a brief overview of their algorithm. In their setting the secret mapping σ is defined over the binary alphabet $\mathbb{Z}_2^n$. Let $c_1 = \lceil \frac{r(f)}{2} \rceil, c_2 = \lfloor \frac{r(f)}{2} \rfloor$ and let $\delta \in [0, 2] \backslash \{1\}$. They use σ to define a distribution over $|X_{c_1}| \times |X_{c_2}|$ matrices $M_{\sigma,\delta,p} = \hat{M}\left(Q_{\sigma,\delta,p}\right) - Jp$, where J denotes the all ones matrix. For $(C_1) \in X_{c_1}$, $(C_2) \in X_{c_2}$ such that $C_1 \bigcap C_2 = \emptyset$ we have

$$\hat{M}\left(Q_{\sigma,\delta,p}\right)[(C_1), (C_2)] = \begin{cases} 1, & \text{with probability } (p(2-\delta)) \text{ if } \sum_{j \in C_1 \cup C_2} \sigma(j) \equiv 0 \mod 2 \\ 1, & \text{with probability } (p\delta) \text{ if } \sum_{j \in C_1 \cup C_2} \sigma(j) \not\equiv 0 \mod 2 \\ 0, & \text{otherwise} \end{cases}.$$

Given a vector $x \in \{\pm 1\}^{|X_{c_2}|}$ (resp. $y \in \{\pm 1\}^{|X_{c_1}|}$) $M_{\sigma,\delta,p}x$ defines a distribution over vectors in $\mathbb{R}^{|X_{c_1}|}$ (resp. $M_{\sigma,p}^T y$ defines a distribution over vectors in $\mathbb{R}^{|X_{c_1}|}$).

If $r(f)$ is even then the largest eigenvalue of $\mathbb{E}[M_{\sigma,\delta,p}]$ has a corresponding eigenvector $x^* \in \{\pm 1\}^{X_{r(f)/2}}$, where for $C_i \in X_{r(f)/2}$ we have $x^*[C_i] = 1$ if $\sum_{j \in C_i} \sigma(j) \equiv 1 \mod 2$; otherwise $x^*[C_i] = -1$ (if $r(f)$ is odd then we consider the top singular value instead). Feldman et al [26] use discrete spectral iteration to find x^* (or $-x^*$). Given x^* it is easy to find σ using Gaussian Elimination.
The discrete spectral iteration algorithm of Feldman et al [26] starts with a random vector $x^0 \in \{0,1\}^{|X_{c_2}|}$. They then sample $x^{i+1} \sim M_{\sigma,p}x^i$ and execute a normalization step to ensure that $x^{i+1} \in \{0,1\}^{|X_{k_2}|}$. When $r(f)$ is odd, power iteration has two steps: draw a sample $y^i \sim M_{\sigma,\delta,p}x^i$ and sample from the distribution $x^{i+1} = M_{\sigma,\delta,p}^T y^i$. They showed that $O\left(\log |X_{r(f)}|\right)$ iterations suffice to recover σ whenever $p = \frac{K \log |X_{r(f)}|}{(\delta-1)^2 \sqrt{|X_{r(f)}|}}$, and that for a vector $x \in \{0,1\}^{|X_{k_2}|}$ (resp. $y \in \{\pm 1\}^{|X_{k_1}|}$) it is possible to sample from $M_{\sigma,\delta,p}x$ (resp. $M_{\sigma,\delta,p}^T y$) using $O(1/p)$ queries to 1-MSTAT$(|X_{c_1}|)$.

Our Reduction

The proof of Theorem 27 uses a reduction to the algorithm of Feldman et al[26].

Proof of Theorem 27 (sketch). Given a mapping $\sigma \in \mathbb{Z}_d^n$ and a number $i \in \mathbb{Z}_d$ we define a mapping $\sigma_i \in \mathbb{Z}_2^n$ where

$$\sigma_i(j) = \begin{cases} 1, & \textbf{if} \sigma(j) = i \\ 0, & \text{otherwise} \end{cases}.$$

Clearly, to recover σ it is sufficient to recover σ_i for each $i \in \mathbb{Z}_d$. Therefore, to prove Theorem 27 it suffices to show that given $x \in \{\pm 1\}^{|X_{k_2}|}$ (resp. $y \in \{\pm 1\}^{|X_{k_1}|}$) we can sample from

the distribution $M_{\sigma_i,\delta,p}x$ (resp. $M^T_{\sigma_i,\delta,p}y$) using $O(1/p)$ queries to 1-MSTAT $\left(\left|X_{\lceil r(f)/2\rceil}\right|\right)$ for each $i \in \{0,\ldots,d-1\}$, where 1-MSTAT uses the distribution Q^f_σ. In general, this will not possible for arbitrary functions f. However, Lemma 28 shows that for our candidate human computable functions $f_{1,3}, f_{2,2}$ we can sample from the distributions $M_{\sigma_i,\delta,p}x$ (resp. $M^T_{\sigma_i,\delta,p}y$). The proof of Lemma 28 is similar to the proof of [26, Lemma 10]. ◀

▶ **Lemma 28.** *Given vectors $\vec{x} \in \{\pm 1\}^{|X_{c_1}|}, \vec{y} \in \{\pm 1\}^{|X_{c_2}|}$ we can sample from $M_{\sigma_i,\delta,p}x$ and $M^T_{\sigma,\delta,p}y$ using $O\left(n^{(k_2+1)/2}\log^2 n\right)$ calls to the 1-MSTAT$\left(n^{\lceil r(f)/2\rceil}\right)$ oracle for $f = f_{k_1,k_2}$.*

The proof of Lemma 28 relies on Fact 29.

▶ **Fact 29.** *For each $j,t \in \mathbb{Z}_{10}$ we have*

$$\Pr_{(x_0,\ldots,x_{9+k_1+k_2})\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[x_t + \sum_{i=10+k_1}^{10+k_1+k_2} x_i \equiv j \;\middle|\; f_{k_1,k_2}(x_0,\ldots,x_{9+k_1+k_2}) \equiv j \mod 10\right] = \frac{\left(\frac{9}{10}\left(\frac{1}{10}\right)+\frac{1}{10}\right)\left(\frac{1}{10}\right)}{\left(\frac{1}{10}\right)} = \frac{19}{100}\ ,$$

and

$$\Pr_{(x_0,\ldots,x_{9+k_1+k_2})\sim\mathbb{Z}_{10}^{10+k_1+k_2}}\left[x_t + \sum_{i=10+k_1}^{10+k_1+k_2} x_i \equiv j \;\middle|\; f_{k_1,k_2}(\sigma(x_0,\ldots,x_{9+k_1+k_2})) \not\equiv j \mod 10\right] = \frac{\left(\frac{9}{10}\left(\frac{1}{10}\right)+\frac{1}{10}(0)\right)\left(\frac{1}{10}\right)}{\left(\frac{1}{10}\right)} = \frac{9}{100}\ .$$

Proof of Lemma 28. Given a value $j \in \mathbb{Z}_{10}$ and a value $i \in \mathbb{Z}_{10}$ we let $x^i_j \in \{0,1\}$ be the indicator variable for the event $x_j = i$. By Fact 29 it follows that

$$\begin{aligned}
&\Pr_{(x_0,\ldots,x_{k_1+k_2+9})\sim\mathbb{Z}_{10}^{k_1+k_2+10}}\left[x^i_0 + x^i_{9+k_1} + \ldots + x^i_{7+k_1+c_1} \equiv 1 \mod 2 \;\middle|\; f_{k_1,k_2}(\sigma(x_0,\ldots,x_{9+k_1+k_2})) \equiv ic_1 \mod 10\right] \\
\neq\ &\Pr_{(x_0,\ldots,x_{k_1+k_2+9})\sim\mathbb{Z}_{10}^{k_1+k_2+10}}\left[x^i_0 + x^i_{9+k_1} + \ldots + x^i_{7+k_1+c_1} \equiv 1 \mod 2 \;\middle|\; f_{k_1,k_2}(\sigma(x_0,\ldots,x_{9+k_1+k_2})) \not\equiv ic_1 \mod 10\right]\ .
\end{aligned}$$

Now for f_{k_1,k_2} we define the function $h^{i,+} : X_{k_1+k_2+10} \times \mathbb{Z}_{10} \to X_{c_1} \cup \{\perp\}$ as follows

$$h^{i,+}(x_0,\ldots,x_{9+k_1+k_2}, f_{k_1,k_2}(\sigma(x_0,\ldots,x_{9+k_1+k_2}))) = \begin{cases} (x_0, x_{9+k_1},\ldots,x_{7+k_1+c_1}) & \text{if} f_{k_1,k_2}(\sigma(x_0,\ldots,x_{13})) \equiv ic_1 \mod 10 \\ \perp & \text{otherwise.} \end{cases}.$$

Intuitively, given a clause $C_1 \in X_{c_1}$ the probability that $h^{i,+}$ returns C_1 is greater if $\sum_{j\in C_1}\sigma_i(j) \equiv 1 \mod 2$.

Given a vector $x \in \{\pm 1\}^{|X_{c_1}|}$ we query our 1-MSTAT $(|X_{c_1}|+1)$ oracle $\lceil 10/p\rceil$ times with the function $h^{i,+}$ to sample from $M_{\sigma_i,\delta,p}x$. Let $q_1,\ldots,q_{\lceil 10/p\rceil} \in X_{c_1}$ denote the responses and let $x[q_j]$ denote the value of the vector x at index q_j. We observe that for some $\delta \neq 1$ we have

$$M_{\sigma_i,\delta,p}x[C] \sim \sum_{\substack{j\in\lceil 10/p\rceil \\ q_j\neq\perp}} x[q_j] - p\sum_{C'\in X_{c_1}} x[C']\ ,$$

for every $C \in X_{c_2}$. ◀

Open Question

Can we precisely characterize the functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$ for which we can efficiently recover σ after seeing $\tilde{O}\left(n^{r(f)/2}\right)$ challenge-response pairs? Feldman et al. [26] gave a statistical algorithm that recovers the secret mapping whenever $d = 2$ after making $\tilde{O}\left(n^{r(f)/2}\right)$ queries to 1-MSTAT $\left(n^{r(f)/2}\right)$. While we show that the same algorithm can be used to recover σ after making $\tilde{O}\left(n^{r(f)/2}\right)$ queries to 1-MSTAT $\left(n^{r(f)/2}\right)$ in our candidate human computable password schemes with $d = 10$, we also showed that these results do not extend to all functions $f : \mathbb{Z}_d^k \to \mathbb{Z}_d$.

G.2 Gaussian Elimination

Most known algorithmic techniques can be modeled within the statistical query framework. Gaussian Elimination is a notable exception. As an example consider the function $f(x_1, \ldots, x_7) = x_1 + \ldots + x_7 \mod 10$ (in this example $r(f) = 7$ and $g(f) = 0$). Our previous results imply that any statistical algorithm would need to see at least $m = \tilde{\Omega}\left(n^{7/2}\right)$ challenge response pairs $(C, f(\sigma(C)))$ to recover σ. However, it is trivial to recover σ from $O(n)$ random challenge response pairs using Gaussian Elimination. In general, consider the following attacker shown in algorithm 4, which uses Gaussian Elimination. Algorithm 4 relies on the subroutine $\mathbf{TryExtract}(C, f(\sigma(C)), S, \alpha)$, which attempts to extract a linear constraint from $(C, f(\sigma(C)))$ under the assumption that $\sigma(S) = \alpha$. We assume $\mathbf{TryExtract}(C, f(\sigma(C)), S, \alpha)$ returns $\emptyset$ if it cannot extract a linear constraint. For example, if we assume that $\sigma(1) = 4$ and $\sigma(2) = 8$ and let $C = (i_0, i_1, ..., i_9, 1, 2, i_{10}, i_{11})$ (with $i_j \in [n] \setminus \{1, 2\}$) then we have $f_{2,2}(\sigma(C)) = \sigma(i_{4+8 \mod 10}) + \sigma(i_{10}) + \sigma(i_{11}) \mod 10$. In this case, $\mathbf{TryExtract}(C, f(\sigma(C)), \{1, 2\}, \{4, 8\})$ would return the constraint $f(\sigma(C)) = \sigma(i_2) + \sigma(i_{10}) + \sigma(i_{11}) \mod 10$. However, $\mathbf{TryExtract}(C, f(\sigma(C)), \{i_0, 2\}, \{4, 8\})$ would return $\emptyset$.

Fact 30 says that an attacker needs at least $m = \tilde{\Omega}\left(n^{1+g(f)}\right)$ challenge-response pairs to recover σ using Gaussian Elimination. This is because the probability that $\mathbf{TryExtract}(C, f(\sigma(C)) S, \alpha)$ extracts a linear constraint is at most $O\left(\left(\frac{|S|}{n}\right)^{-g(f)}\right)$, which is $O\left(n^{-g(f)}\right)$ for $|S|$ constant. The adversary needs $O(n)$ linearly independent constraints

to run Gaussian Elimination. If the adversary can see at most $\tilde{O}\left(n^{s(f)}\right)$ examples neither approach (Statistical Algorithms or Gaussian Elimination) can be used to recover σ.

▶ **Fact 30.** *Algorithm 4 needs to see at least* $m = \tilde{\Omega}\left(n^{1+g(f)}\right)$ *challenge-response pairs to recover* σ*.*

Remark G.2 explores the tradeoff between the adversary's running time and the number of challenge-response pairs that an adversary would need to see to recover σ using Gaussian elimination. In particular the adversary can recover σ from $\tilde{O}\left(n^{1+g(f)/2}\right)$ challenge-response pairs if he is willing to increase his running time by a factor of $d^{\sqrt{n}}$. In practice, this attack may be reasonable for $n \leq 100$ and $d = 10$, which means that it may be beneficial to look for candidate human computable functions f that maximize $\min\{r(f)/2, 1 + g(f)/2\}$ instead of $s(f)$ whenever $n \leq 100$.

▶ Remark. If the adversary correctly guesses value of $\sigma(S)$ for $|S| = n^{\epsilon}$ then he may be able to extract a linear constraint from a random example with probability $\Omega(1/n^{(1-\epsilon)g(f)})$. The adversary would only need $\tilde{O}\left(n^{1+(1-\epsilon)g(f)}\right)$ examples to solve for σ, but his running time would be proportional to $d^{\epsilon n}$ – the expected number of guesses before he is correct.

H Rehearsal Model

In this section we review the usability model of Blocki et al. [13]. Their usability model estimates the 'extra effort' that a user needs to expend to memorize and rehearse all of his secrets for a password management scheme. In this section we use $(\hat{c}, \hat{a})$ to denote a cue-association pair, and we use the variable t to denote time (days). In our context $(\hat{c}, \hat{a})$ might denote the association between a letter (e.g., 'e') and the secret digit associated with that letter (e.g., $\sigma(e)$). If the user does not rehearse an association $(\hat{c}, \hat{a})$ frequently enough then the user might forget it. Their are two main components to their usability model: rehearsal requirements and visitation schedules. Rehearsal requirements specify how frequently a cue-association pair must be used for a user to remember the association. Visitation schedules specify how frequently the user authenticates to each of his accounts and rehearses any cue-association pairs that are linked with the account.

H.1 Rehearsal Requirements

Blocki et al. [13] introduce a rehearsal schedule to ensure that the user remembers each cue-association pair.

▶ **Definition 31.** [13] A rehearsal schedule for a cue-association pair $(\hat{c}, \hat{a})$ is a sequence of times $t_0^{\hat{c}} < t_1^{\hat{c}} < ....$ For each $i \geq 0$ we have a *rehearsal requirement*, the cue-association pair must be rehearsed at least once during the time window $\left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right) = \{x \in \mathbb{R} \,\middle|\, t_i^{\hat{c}} \leq x < t_{i+1}^{\hat{c}}\}$.

A rehearsal schedule is *sufficient* if a user can maintain the association $(\hat{c}, \hat{a})$ by following the rehearsal schedule. The length of each interval $\left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)$ may depend on the strength of the mnemonic techniques used to memorize and rehearse a cue-association pair $(\hat{c}, \hat{a})$ as well as i – the number of prior rehearsals [54, 52].

Expanding Rehearsal Assumption [13]: The rehearsal schedule given by $t_i^{\hat{c}} = 2^{i\mathbf{s}}$ is sufficient to maintain the association $(\hat{c}, \hat{a})$, where $\mathbf{s} > 0$ is a constant.

Table 6 Visitation Schedules - number of accounts visited with frequency λ (visits/days)

Schedule | λ	$\frac{1}{1}$	$\frac{1}{3}$	$\frac{1}{7}$	$\frac{1}{31}$	$\frac{1}{365}$
Very Active	10	10	10	10	35
Typical	5	10	10	10	40
Occasional	2	10	20	20	23
Infrequent	0	2	5	10	58

H.2 Visitation Schedules

Suppose that the user has m accounts $A_1, \ldots, A_m$. A visitation schedule for an account A_i is a sequence of real numbers $\tau_0^i < \tau_1^i < \ldots$, which represent the times when the account A_i is visited by the user. Blocki et al. [13] do not assume that the exact visitation schedules are known a priori. Instead they model visitation schedules using a random process with a known parameter λ_i based on $E\left[\tau_{j+1}^i - \tau_j^i\right]$ – the average time between consecutive visits to account A_i.

A rehearsal requirement $\left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)$ can be satisfied naturally if the user visits a site A_j that uses the cue $\hat{c}$ ($\hat{c} \in c_j$) during the given time window. Here, c_j denote the set of cue-association pairs that the user must remember when logging into account A_j. Formally,

▶ **Definition 32.** [13] We say that a rehearsal requirement $\left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)$ is *naturally satisfied* by a visitation schedule $\tau_0^i < \tau_1^i < \ldots$ if $\exists j \in [m], k \in \mathbb{N}$ s.t $\hat{c} \in c_j$ and $\tau_k^j \in \left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)$. We use

$$ER_{t,\hat{c}} = \left|\left\{i \;\middle|\; t_{i+1}^{\hat{c}} \leq t \wedge \forall j, k.\left(\hat{c} \notin c_j \vee \tau_k^j \notin \left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)\right)\right\}\right| ,$$

to denote the number of rehearsal requirements that are not naturally satisfied by the visitation schedule during the time interval $[0, t]$.

▶ **Example.** Consider the human computable function $f_{2,2}$ from section 3, and suppose that the user has to compute $f_{2,2}(\sigma(C_i))$ to authenticate at account A_j, where $C_i = (x_0, \ldots, x_{13})$. When the user computes $f_{2,2}$ he must rehearse the associations $(x_{10}, \sigma(x_{10}))$, $(x_{11}, \sigma(x_{11}))$, $(x_{12}, \sigma(x_{12}))$, $(x_{13}, \sigma(x_{13}))$ and $(x_i, \sigma(x_i))$ where $i = (\sigma(x_{10}) + \sigma(x_{11}) \mod 10)$. Thus $c_j \supset \{x_i, x_{10}, x_{11}, x_{12}, x_{13}\}$. When user authenticates he naturally rehearses each of these associations in c_j.

If a cue-association pair $(\hat{c}, \hat{a})$ is not rehearsed naturally during the interval $\left[t_i^{\hat{c}}, t_{i+1}^{\hat{c}}\right)$ then the user needs to perform an extra rehearsal to maintain the association. Intuitively, $ER_{t,\hat{c}}$ denotes the total number of extra rehearsals of the cue-association pair $(\hat{c}, \hat{a})$ during the time interval $[0, t]$, and $ER_t = \sum_{\hat{c} \in C} ER_{t,\hat{c}}$ denotes the total number of extra rehearsals during the time interval $[0, t]$ to maintain all of the cue-association pairs. Thus, a smaller value of $E[ER_t]$ indicates that the user needs to do less extra work to rehearse his secret mapping.

Poisson Arrival Process

The visitation schedule for each account A_j is given by a Poisson arrival process with parameter λ_j, where $1/\lambda_j = E\left[\tau_{j+1}^i - \tau_j^i\right]$ denotes the average time between consecutive visits to account A_j.

Table 7 $\mathbb{E}[ER_{365}]$: Extra Rehearsals over the first year to remember $\sigma : \{1, \ldots, n\} \to \mathbb{Z}_{10}$ in our scheme with $f_{2,2}$ or $f_{1,3}$. Compared with Shared Cues schemes SC-0,SC-1 and SC-2[13].

Evaluating Usability

Blocki et al. [13] prove the following theorem. Given a sufficient rehearsal schedule and a visitation schedule, Theorem 33 predicts the value of ER_t, the total number of extra rehearsals that a user will need to do to remember all of the cue-association pairs required to reconstruct all of his passwords.

▶ **Theorem 33.** *[13] Let* $i_{\hat{c}}* = \left(\arg\max_x t_x^{\hat{c}} < t\right) - 1$ *then*

$$E[ER_t] = \sum_{\hat{c} \in C} \sum_{i=0}^{i_{\hat{c}}*} \exp\left(- \left(\sum_{\substack{j \ s.t. \\ \hat{c} \in c_j}} \lambda_j \right) \left(t_{i+1}^{\hat{c}} - t_i^{\hat{c}} \right) \right)$$

We use the formula from Theorem 33 to obtain the usability results in Table 7. To evaluate this formula we need to be given the rehearsal requirements, a visitation schedule (λ_i) for each account A_i and a set of public challenges $\vec{C}_i \in (X_{14})^{10}$ for each account A_i. The rehearsal requirements are given by the Expanding Rehearsal Assumption [13] (we use the same association strength parameter $\mathbf{s} = 1$ as Blocki et al. [13]), and the visitation schedules for each user are given in Table 6. We assume that each password is 10 digits long and that the challenges $\vec{C}_i \in (X_{14})^{10}$ are chosen at random by Algorithm 2. Notice that each time the user responds to a single digit challenge he rehearses the secret mapping at five locations (see discussion in Section 3.1). Because the value of $\mathbb{E}[ER_{365}]$ depends on the particular password challenges that we generated for each account, we ran Algorithm 2 and computed the resulting value $\mathbb{E}[ER_{365}]$ one-hundred times. The values in Table 7 represent the mean value of $\mathbb{E}[ER_{365}]$ across all hundred instances.

I Sum of k-Mins

In the basic Hopper-Blum [34] Human Identification Protocol the user memorizes a subset $S \subseteq [n]$ of $k = |S|$ secret indices. A single digit challenge consisted of a vector $x \in \mathbb{Z}_{10}^n$ of n digits and the user responded by with the $\mod 10$ sum of the digits at $k \leq n$ secret locations plus an error term e

$$\sum_{i \in S} x_i \mod 10 + e \ .$$

Typically, the user will set $e = 0$, but occasionally the user is supposed to respond with a completely random digit instead of the correct response (e.g., so that the adversary cannot simply use Gaussian Elimination to find S). Thus, the human user must occasionally generate random numbers in his head to execute the Hopper-Blum protocol. This is potentially problematic because humans are not good at consciously generating random numbers [53, 27, 42]. In fact, hard learning problems like noisy parity might even be easy to learn when humans are providing the source of noise.

Hopper and Blum [34] also proposed a deterministic human identification protocol call sum of k-mins. In this protocol the user memorized k secret pairs (i, j) of indices $S \subseteq [n]^2$. As before a single digit challenge consists of a vector $x \in \mathbb{Z}_{10}^n$ of n digits. However, now the response to the challenge is deterministic

$$\sum_{(i,j) \in S} \min\{x_i x_j\} \mod 10 \ .$$

We observe that for any constant k the protocol is not secure against polynomial time attackers who have seen $O\big(k \cdot \log n\big)$ examples. The adversary can simply enumerate all possible sets S of k pairs and cross out the ones that are inconsistent with the challenge-response pairs he has already seen. Even for larger k (e.g., greater human work) Hopper and Blum [34] observed that the protocol was not secure against an adversary who has seen $O(n^2)$ examples. To see this observe that we can create an indicator variable $y_{i,j}$ for each pair (i, j). Each challenge response pair (x, r) yields a linear constraint

$$\sum_{(i,j)} y_{i,j} \min\{x_i, x_j\} = r \mod 10 \ .$$

Towards Hardness of Approximation for Polynomial Time Problems*

Abstract

Proving hardness of approximation is a major challenge in the field of fine-grained complexity and conditional lower bounds in P. How well can the Longest Common Subsequence (LCS) or the Edit Distance be approximated by an algorithm that runs in near-linear time? In this paper, we make progress towards answering these questions. We introduce a framework that exhibits barriers for truly subquadratic and *deterministic* algorithms with good approximation guarantees. Our framework highlights a novel connection between deterministic *approximation algorithms* for natural problems in P and *circuit lower bounds*.

In particular, we discover a curious connection of the following form: if there exists a $\delta > 0$ such that for all $\varepsilon > 0$ there is a deterministic $(1+\varepsilon)$-approximation algorithm for LCS on two sequences of length n over an alphabet of size $n^{o(1)}$ that runs in $O(n^{2-\delta})$ time, then a certain plausible hypothesis is refuted, and the class E^{NP} does not have non-uniform linear size Valiant Series-Parallel circuits. Thus, designing a "truly subquadratic PTAS" for LCS is as hard as resolving an old open question in complexity theory.

1 Introduction

Canonical examples of problems that are in P due to natural dynamic programming solutions are Edit Distance and Longest Common Subsequence (LCS) [44, 54]. Given two strings x, y of length n, the LCS problem asks for the length of the longest sequence that appears in both x and y as a (not necessarily contiguous) subsequence, and Edit Distance asks to compute the minimum number of operations (insertion, deletion, or substitution) that is required to transform x into y. Despite decades of attempts, it is not known how to speed up the dynamic programming solution beyond the $O(n^2/\log^2 n)$ bound of Masek and Paterson [66] via the "four Russians" technique. Recent research on the exact complexity of polynomial time problems proved that faster algorithms do not exist [19, 2, 32], not even by polylog factors [5], unless SAT can be solved faster than brute force. A natural question arises: How well can we approximate LCS and Edit Distance in truly subquadratic (or near linear) time? And more generally, can we speed up dynamic programming algorithms without paying too much in the optimality of the solution?

Various generalizations of LCS and Edit Distance, like the Local Alignment problem [75, 8], are fundamental in computational biology and genomics. In such applications, the input size is a few billions, quadratic time algorithms are prohibitive and are rarely run in practice. To analyze the genome, researchers often use various heuristics, like BLAST [13], that run in near linear time but have no optimality guarantees. Despite BLAST's impact, as witnessed by its more than fifty thousand citations, the bioinformatics community is in an everlasting search of "better" algorithms that are able to reveal new phenomena in the massive amounts of biological data that we currently have (see [77, 63, 49]). The theory community ought to provide guidance: is there hope for fast algorithms with strong guarantees? Is there evidence against a $(1+\varepsilon)$-approximation algorithm that runs in near-linear time, even for the more basic LCS and Edit Distance problems?

We say that an algorithm c-approximates the Edit Distance $ED(S,T)$ of two given sequences S,T if it outputs a value x that is $ED(S,T) \leq x \leq c \cdot ED(S,T)$. Since the Edit Distance is at most n, an n-approximation is trivial. A linear time $\sqrt{n}$-approximation follows from the exact algorithm that computes the Edit Distance in time $O(n+d^2)$ where $d = ED(S,T)$ [65]. Subsequently, this approximation factor has been improved to $n^{3/7}$ by Bar-Yossef et al. [21], then to $n^{1/3+o(1)}$ by Batu et al. [22]. Building on the breakthrough embedding of Edit Distance by Ostrovsky and Rabani [69], Andoni and Onak obtained the first near-linear time algorithm with a *subpolynomial* approximation factor of $2^{\tilde{O}(\sqrt{\log n})}$. Most recently, in FOCS'10, Andoni, Krauthgamer, and Onak [15] significantly improved the approximation to polylogarithmic obtaining an algorithm that runs in time $n^{1+\varepsilon}$ and gives $(\log n)^{O(1/\varepsilon)}$ approximation for every fixed $\varepsilon > 0$. There are many works on approximate Edit Distance in various computational models, see e.g. [68, 15, 38] and the references therein.

While LCS and Edit Distance are closely related, they behave quite differently with respect to approximations, and these clever approximation algorithms for Edit Distance are not known to lead to any nontrivial result for LCS. We say that an algorithm c-approximates the LCS of two given sequences S,T if it outputs a value x that is $\frac{LCS(S,T)}{c} \leq x \leq LCS(S,T)$. A cute observation shows that the LCS of binary sequences can be approximated to a factor of 2 in linear time: the longest common subsequence that is all-zero or all-one is at least half from optimal. Note that a 2 approximation for Edit Distance on binary sequences would be a breakthrough. In general, for an alphabet of size $|\Sigma| = s$, it is easy to get an s-approximation for the LCS and it is a longstanding open question to design an $(s-\delta)$-approximation in near-linear time or even strongly subquadratic time for any constant integer $s \geq 2$ and constant $\delta > 0$. Even though many ideas and heuristics for LCS were designed [43, 27, 48, 45] (see also [68, 28] for surveys), none has proven sufficient to compute an $(s-\delta)$-approximation in strongly subquadratic time. A general tool for speeding up dynamic programming algorithms through a controlled relaxation of the optimality constraint could have great impact for algorithm design. Recently, encouraging positive results along these lines were obtained by Saha [72, 73] for problems related to parsing context-free languages. However, we are still far from understanding, more generally, when and how such speedups are possible.

Proving lower bounds for problems in P, under popular conjectures like the Strong Exponential Time Hypothesis (SETH) [57, 35], is a recent and very active line of work [2, 4, 6, 7, 8, 9, 14, 19, 32, 33, 31, 30, 42, 70, 71, 79, 1, 18, 20, 47, 41, 40]. The known results for LCS and Edit Distance [19, 2, 32, 5] do not imply any non-trivial hardness of approximation, i.e. they only rule out (roughly) $(1+1/n)$-approximations in subquadratic time. Achieving strong hardness of approximations results is often highlighted as an important open question for this line of research, and the general sense of the community is that new ideas that deviate significantly from current techniques might be required.

Our Work

In this paper, we make progress towards the important goal of proving inapproximability results for such fundamental problems in P. We introduce a framework that exhibits barriers for subquadratic and *deterministic* algorithms with good approximation guarantees. Admittedly, the "lower bounds" we obtain for problems like LCS are quite weak and are still far from the upper bounds. Still, they are *much* higher than what we knew before: e.g. instead of the trivial $(1 + 1/n)$-approximation hardness, we can show evidence against $(1 + 1/\text{poly} \log n)$ or even $(1 + o(1))$ approximations. Perhaps more interesting than the statements is the framework itself, which highlights a novel connection between deterministic *approximation algorithms* for natural problems in P and *circuit lower bounds*.

We prove a curious connection of the following form: if there is a truly subquadratic deterministic $(1 + \varepsilon)$-approximation algorithm for LCS on two sequences of length n over an alphabet of size $n^{o(1)}$, then the complexity class E^{NP} does not have non-uniform linear size series parallel circuits[1]. This consequence (explained in more detail below) is widely believed to be true. However, proving it unconditionally would be a breakthrough in complexity theory and the study of non-uniform circuit lower bounds. As stated, this is merely a "difficulty" or a "no-pass" result for LCS, not "hardness". It only shows a "circuit lower bounds" barrier for designing a fast $(1 + o(1))$-approximation algorithm for LCS: it is at least as difficult as resolving a longstanding (and considered to be difficult) open question in circuit complexity. However, we prove a stronger result (Theorem 5 below), which we think should be regarded as a "hardness" result as well, giving evidence that such algorithms for LCS might not exist.

We contribute to the growing body of surprising connections between algorithm design and circuit lower bounds (see the recent survey [85]) [62, 56, 83, 86, 61, 50, 37, 16, 59, 60, 64]. A notable tight connection between faster algorithms for Circuit-SAT and circuit lower bounds was shown by Williams [83, 86]: faster-than-trivial Circuit-SAT algorithms for many circuit classes $\mathcal{C}$ imply interesting new lower bounds against that class. For example, via this connection, Jahanjou, Miles, and Viola [60] show that refuting SETH leads to proving the same lower bound against series-parallel circuits stated above. Abboud et al. [5] go a step further and show that slightly faster algorithms for natural and well-studied problems in P (as opposed to Circuit-SAT) are enough to prove lower bounds against large classes like non-uniform NC. A related intriguing connection is between *derandomization* (of algorithms and circuits) and circuit lower bounds [56, 61, 84, 74, 26, 12]. A derandomization algorithm for a circuit class $\mathcal{C}$ is a deterministic algorithm that is able to distinguish, given a circuit from $\mathcal{C}$, whether it is unsatisfiable (zero satisfying assignments) or "very satisfiable" (at least $2^n \cdot (1 - o(1))$ satisfying assignments). Note that a derandomization algorithm can be obtained from an algorithm that approximates the number of satisfying assignments to circuits from $\mathcal{C}$ (known as CAPP - Circuit Acceptance Probability Problem). Combining the framework of Williams [83] with a "Succinct PCP" [67, 26] shows that to prove a lower bound against a class $\mathcal{C}$ it is enough to obtain a nontrivial *derandomization* algorithm for a class $\mathcal{C}'$ (that could be slightly larger than $\mathcal{C}$) [83, 74, 26]. Our work connects circuit lower bounds, via circuit derandomization tasks, to designing approximation algorithms for natural optimization problems in P like LCS, as opposed to CAPP or algebraic problems like polynomial identity testing (Williams [87] recently showed that derandomizing a quadratic time algorithm for a variant of this problem implies interesting circuit lower bounds).

[1] The class E^{NP} or $\mathsf{TIME}[2^{O(n)}]^{\mathsf{NP}}$ is the class of problems solvable in exponential time with access to an NP oracle.

1.1 Our Results

We will now give a more detailed overview of our results, and then in Section 3 we present the technical details of our framework. Section 1.3 will discuss how our approach could lead to further hardness of approximation results for problems in P. The complete proofs are given in the subsequent sections.

The Gap Block Disjointness Hypothesis

Our result for LCS will be based on the presumed difficulty of solving the following Gap Block Disjointness (GBD) problem in subquadratic time.

▶ **Definition 1** (Gap Block Disjointness)**.** Given two lists of Boolean matrices $A, B \subseteq \{0,1\}^{K \times D}$ of size $|A| = |B| = N$, we say that a pair $A_i \in A, B_j \in B$ is a "good pair" if there exists a $k \in [K]$ such that the rows $A_i(k, \cdot)$ and $B_j(k, \cdot)$ are disjoint, i.e.

$$\vee_{k \in [K]}(\wedge_{h \in [D]}(\neg A_i(k,h) \vee \neg B_j(k,h))) = 0.$$

The Gap Block Disjointness problem is to decide whether we are in case 1 or in case 2 (and if we are in neither, the output can be arbitrary):

1. (zero "good" pairs) none of the pairs $A_i \in A, B_j \in B$ are good.

$$\Pr_{i,j \in [N]}\left[\ \vee_{k \in [K]}(\wedge_{h \in [D]}(\neg A_i(k,h) \vee \neg B_j(k,h))) = 0\ \right] = 0$$

2. (many "good" pairs) at least $N^2 \cdot (1 - 1/\log_2^{10} N)$ pairs $A_i \in A, B_j \in B$ are good.

$$\Pr_{i,j \in [N]}\left[\ \vee_{k \in [K]}(\wedge_{h \in [D]}(\neg A_i(k,h) \vee \neg B_j(k,h))) = 1\ \right] \geq (1 - 1/\log_2^{10} N)$$

A trivial algorithm solves this problem in quadratic time, by going over all pairs of matrices, but can we do better? Note that if we ask whether at least one "good pair" exists (without the above gap-promise) then the problem requires $N^{2-o(1)}$ under SETH (which is conjectured to hold even for randomized algorithms), even when $K = 1$ and $D = \Omega(\log N)$, since this is the Orthogonal Vectors problem [82, 10, 39]. We introduce the hypothesis that this *gap* version, with $D = \Omega(\log N)$ and $K = N^{o(1)}$, cannot be solved by a deterministic algorithm in truly subquadratic time.

▶ **Hypothesis 2.** *There is no $\varepsilon > 0$ and $\alpha > 0$ such that for all constant d we can solve the Gap Block Disjointness problem on binary matrices in $n^\alpha \times d \log n$ in deterministic $O(n^{2-\varepsilon})$ time.*

Interestingly, unlike all previous hardness conjectures in the "Hardness in P" research [52, 70, 79, 6, 9, 55, 3, 11], ours does not remain plausible when faced against randomized algorithms. A near-linear time randomized algorithm that samples a few pairs can easily solve this problem, with high probability. But can a *deterministic* algorithm do anything clever enough to solve the problem in truly subquadratic time? Such an algorithm is not known, and in fact, Lemma 3 below suggests that it would be a breakthrough.

Series-parallel circuits [78, 34, 81, 46] (or VSP circuits) are special kind of circuits that can be obtained by combining circuits either in series or in parallel (defined formally in Section 2). In 1977, Valiant introduced these circuits and argued that most known computer programs fit under this restriction. His hope was that understanding these circuits would be easier than the general case. Four decades later, we still do not know how to resolve basic challenges proposed in his paper, like showing an explicit function that does not have *linear*

size series parallel circuits. It is still conceivable that the large class E^{NP} can be computed by such circuits, and proving otherwise would be a major achievement. Our first lemma states that refuting Hypothesis 2 is at least as difficult as showing these results.

▶ **Lemma 3.** *If Hypothesis 2 is false, then the class* E^{NP} *does not have non-uniform linear size* VSP *circuits.*

A reader familiar with previous SETH lower bounds might wonder why we need this GBD problem, as opposed to simply considering the $K = 1$ case, i.e. the gap version of Orthogonal Vectors. Without going into the details, we remark that, as far as we can show, a faster deterministic algorithm for that case would not imply any new circuit lower bound. Intuitively, this is because the $K = 1$ case can only encode CNF formulas, which is an extremely weak computational model, for which the corresponding circuit lower bounds are easy to prove unconditionally.

We stress that this circuit lower bound consequence is only meant to show that the hypothesis is hard to *refute*. As evidence that the hypothesis is *plausible*, we remark that none of the current (e.g. [39, 53]) or conjectured-to-exist derandomization techniques (e.g. if $\mathsf{P} = \mathsf{BPP}$) are enough to refute it. While a common belief is that randomized algorithms cannot outperform deterministic ones by more than a polynomial factor, it is plausible that randomization can give, say, a linear $\Omega(n)$ speedup.

Reduction to Approximate LCS

The simplicity of the GBD problem makes Hypothesis 2 an appealing starting point for proving barriers. Our main technical lemma shows how GBD can be reduced to LCS while creating a multiplicative gap, giving the first nontrivial hardness of approximation result for LCS.

▶ **Lemma 4.** *If for some* $\delta > 0$*, there is a deterministic algorithm that can approximate the LCS of two given sequences of length* n *over an alphabet of size* $n^{o(1)}$ *to within a* $(1 + \varepsilon)$ *factor, for all* $\varepsilon > 0$*, in* $O(n^{2-\delta})$ *time, then Hypothesis 2 is false.*

Together, these two lemmas imply our main theorem:

▶ **Theorem 5.** *If for some* $\delta > 0$ *there is a deterministic* $(1 + o(1))$*-approximation algorithm for LCS on two sequences of length* n *over an alphabet of size* $n^{o(1)}$ *in* $O(n^{2-\delta})$ *time, then Hypothesis 2 is false and the class* E^{NP} *does not have non-uniform linear size* VSP *circuits.*

We remark that our hardness for approximate LCS immediately transfers to nontrivial results for other problems. For example, we get that the RNA Folding problem which is central in computational biology [2, 17, 51, 76, 80] cannot be approximated to within in a $(1 + o(1))$ factor in truly subquadratic time.

A simple application of our framework, gives a weaker lower bound for Edit Distance and LCS on *binary* sequences. In Section 4.1, we show that a deterministic $(1 + 1/\mathrm{poly}\log n)$-approximation for these problems in truly subquadratic time implies that E^{NP} does not have log-depth (NC^1) circuits.

It is likely that more efficient reductions from GBD to LCS (and Edit Distance) can be devised, and if certain gadgets in our proof can be implemented more efficiently, a *tight* conditional lower bound against $(2 - \delta)$-approximations for LCS on binary sequences could follow. Moreover, better gadgetry would be able to boost the consequence from a VSP circuit lower bound through GBD to a stronger circuit lower bound as in [5]. On a different

note, we believe that a further tightening of the connections between nontrivial circuit derandomization and approximation algorithm for extensively studied problems like LCS and Edit Distance could be a promising direction for *proving* new circuit lower bounds. Perhaps, via stronger connections, one would be able to use highly involved algorithms like Andoni et al.'s approximation for Edit Distance [15] to prove new breakthroughs in complexity theory.

1.2 Technical Overview

To motivate our framework, we give a short exposition of the known constructions for hardness of sequence alignment problems, and why they fail to give any nontrivial consequences of approximation algorithms.

For concreteness, consider the reductions from CNF-SAT to LCS used to prove that LCS requires $n^{2-o(1)}$ time under SETH [2, 32]. In these reductions, we take a CNF formula on n variables and m clauses, say $m = O(n)$, and produce two sequence of length $N \cdot \operatorname{poly}\log N$ where $N = 2^{n/2}$, so that the LCS of the two sequences is large iff the formula is satisfiable. Each sequence is composed of $O(N)$ segments of length $O(\log N)$ called *assignment gadgets*, representing all $2^{n/2}$ partial assignments to half of the variables (each half of the variables is represented in the gadgets in one of the two sequences). When two assignment gadgets are "matched" in an LCS alignment, the contribution to the total score is X_{sat} if the two corresponding partial assignments make up a satisfying assignment to our CNF formula and X_{unsat} otherwise, where $X_{sat} > X_{unsat}$. Due to the way these gadgets are composed, the optimal LCS will be achieved by matching roughly $N = 2^{n/2}$ pairs and therefore gaining a score that is at most $N \cdot X_{unsat}$ if the formula is unsatisfiable, and at least $(N-1) \cdot X_{unsat} + X_{sat}$ if it is satisfiable. Now, notice that X_{sat} cannot be more than $O(\log N)$, since it is upper bounded by the length of the assignment gadgets, while X_{unsat} is at least 1, since otherwise the gadgets do not encode enough information. This implies that the multiplicative gap between the two cases is no more than $(1 + 1/N)$.

A natural attempt to increase this gap is by using a PCP theorem on the initial CNF formula before reducing it to LCS. For instance, this approach has been used in many ETH based lower bounds [29] [2]. Even if an ultra efficient PCP theorem existed, where the number of variables remains $(1 + o(1)) \cdot n$ and the gap increases arbitrarily, this approach does not give any interesting hardness for approximate LCS: The PCP will only affect the gap between X_{sat} and X_{unsat}, which only affects the low order terms in the total score: it is always upper bounded by the length of the gadgets $X_{sat}/X_{unsat} = N^{o(1)}$, and so the multiplicative gap remains $(1 + N^{o(1)}/N)$. The problem with this approach is that the dominant factor is *not* how many clauses our best assignment satisfies, but it is how many *assignments* satisfy all clauses. Standard PCP approaches make unsatisfying assignments less satisfying, but they do not affect the *number of satisfying assignments*.

This leads to another natural attempt: can we find a different kind of gap amplification result that reduces a formula f to another formula f' so that f' has *many* satisfying assignments iff f is satisfiable? To get interesting hardness results for LCS, we will need the gap between the two cases to be quite large, e.g. zero satisfying assignments vs. at least $2^n/10$ satisfying assignments. We would like to do this while keeping the number of variables $(1 + o(1)) \cdot n$. Unfortunately, this kind of gap amplification for CNF's and circuits is unlikely as it would lead to a randomized polynomial time algorithm for CNF-SAT ($\mathsf{BPP} = \mathsf{NP}$): perform the reduction then sample $O(n)$ assignments and check if they satisfy f'.

[2] ETH states that 3-SAT cannot be solved in $2^{o(n)}$ time. Obtaining tight lower bounds for problems in P under ETH is a major open question.

While it is easy for a randomized algorithm to distinguish between unsatisfiable formulas (or circuits) and almost-completely satisfiable ones, the main observation at the base of our framework is that this task might not be so easy for *deterministic* algorithms. Given a circuit on n variables that has $2^n - 2^n/n^{10}$ satisfying assignment, how can a deterministic algorithm find one of its satisfying assignments? If the algorithm treats the circuit as a black-box and blindly queries it with assignments until it outputs 1, the runtime will not be $O(2^{(1-\varepsilon)n})$. Otherwise, the algorithm could try to analyze the circuit and understand its satisfiability properties in order to achieve faster deterministic runtime. The central insight in the connections between algorithms and lower bounds [85] is that our ability to design algorithms for analyzing circuits (from a certain class $\mathcal{C}$) is closely related to our ability to show limitations of circuits (lower bounds against the class $\mathcal{C}$). In fact, there are formal and quite tight connections showing that a faster-than-trivial deterministic algorithm for the "circuit-derandomization" problem above, on certain classes of circuits, implies new circuit lower bounds.

Our framework takes this route in order to get evidence for difficulty and hardness of designing approximation algorithms. Depending on the target problem (in P) for which we seek a "lower bound", one might want to start from a different derandomization problem concerning a different class of circuits so that it embeds as efficiently as possible into the problem. In this paper, we instantiate the framework with the class of linear size series parallel circuits and prove that they embed nicely into approximate LCS (via the GBD problem).

We remark that all our results for consequences of *deterministic* algorithms remain valid for (appropriately defined) *co-nondeterministic* algorithms (see [36] for interesting results on this notion). It is difficult to approximate LCS even with nondeterminism.

Derandomization implies Circuit Lower Bounds

The connection between derandomizing circuits and lower bounds originates in the works of Impagliazzo, Kabanets, and Wigderson [56] and has been optimized significantly by the work of Williams [83], Santhanam and Williams [74], and more recently by Ben-Sasson and Viola [26]. These connections rely on "Succinct PCP" theorems [24, 67, 25, 23, 26], and the recent optimized construction of Ben-Sasson and Viola [26] is crucial to our main result.

Our starting point is the following theorem (Theorem 1.4 in [26]), which we will state more formally later in the paper: Let F_n be a set of functions from $\{0,1\}^n$ to $\{0,1\}$ that satisfies some minor requirements (e.g. functions that can be computed by linear size circuits from some class $\mathcal{C}$). If the acceptance probability of a function of the form

- AND of fan-in $n^{O(1)}$
- of OR's of fan-in 3
- of functions from $F_{n+O(\log n)}$

can be distinguished from being $= 1$ or $\leq 1/n^{10}$ in $2^n/n^{\omega(1)}$ deterministic time, then there is a function f in E^{NP} on n variables such that $f \notin F_n$ (and therefore cannot be computed by linear size circuits from $\mathcal{C}$, and E^{NP} is not contained in non-uniform $\mathcal{C}$).

The optimization of the Succinct PCP by Ben-Sasson and Viola makes the overhead in this connection quite small: we only need two additional levels to the original circuit class (the AND and OR), one of which has fan-in 3. When instantiating this theorem with linear size VSP circuits, this minor overhead allows us to still obtain a simple enough class of circuits that allows for an efficient reduction to our GBD problem (and then to approximate LCS).

Next, we show a reduction from the derandomization task above of AND-OR-VSP circuits to the GBD problem. This reduction is obtained via a series of transformations to the circuit, so that we end up with an OR-AND-OR circuit of the following form, for some constants ℓ, c, μ, which embeds nicely into GBD:

- OR of fan-in $n^{O(1)} \cdot 2^{n/\ell} \cdot 2^{\varepsilon n}$,
- of AND of fan-in $f(\varepsilon, k) \cdot n$ where $k = 2^{2^{\mu c \ell}}$,
- of OR of fan-in k of literals.

To get this form, we use the classical depth reduction of Valiant [78] which is especially powerful for VSP circuits, as well as the sparsification lemma for CNF formulas [57, 58]. The details of Valiant's depth reduction theorem were clarified by Calabro [34] and Viola [81] (cf. Cygan et al. [46]). To reduce the derandomization problem of such AND-OR-AND circuits to GBD we follow the split-and-list technique, similarly to the reduction from CNF-SAT to Orthogonal Vectors [82]. Choosing all the parameters carefully, we get Lemma 3.

Reducing to Approximate LCS

The reduction from GBD to approximate LCS has two main components: an *inner construction*, in which we encode each of the matrices separately into (short) "matrix" or "inner" gadgets, and an *outer construction* that combines the inner gadgets into two final (long) sequences. This outer and inner outline is not different from previous reductions to LCS and Edit Distance, except that now will we have to make sure that our constructions preserve multiplicative gaps. Getting a gap in either of these constructions was beyond previous techniques, and our work contributes to both: The gap in the outer construction will follow, for the most part, from our starting point (GBD and the derandomization problems as opposed to SAT). For the inner construction, however, we need to design new gadgetry that could be of interest even beyond our "difficulty via derandomization" framework. We explain the main ideas below.

The inner construction: In the inner construction we map each one of our input matrices $A_i \in A$ into a sequence a_i and each of our $B_j \in B$ into a sequence b_j so that there is a value X_{bad} and a constant $\varepsilon > 0$ for which: $LCS(a_i, b_j) \leq X_{bad}$ if A_i, B_j is not a good pair, while if A_i, B_j is a good pair then the LCS is much larger $LCS(a_i, b_j) \geq (1 + \varepsilon) \cdot X_{bad}$.

Constructions from previous work [2, 32, 5] easily give such "matrix" gadgets, except the gap between the two cases would be too small: X_{bad} vs $X_{bad} \cdot (1 + 1/n^{\alpha})$. Instead, we introduce some new ideas that lead to a $(1 + \varepsilon)$ gap at the cost of less efficiency in terms of the length of the gadgets and the alphabet size.

We will first construct "disjointness" gadgets that encode each row of each of our matrices. For this discussion, fix a pair of matrices $A_i \in A, B_j \in B$. We will first encode each of A_i's rows $A_i(k, \cdot)$ with a sequence $a_{i,k}$ and each of B_j's rows $B_j(k, \cdot)$ with a sequence $b_{j,k}$ (these are the disjointness gadgets). Our goal will be to have $LCS(a_{i,k}, b_{j,k})$ be $X_{intersect}$ if the two rows intersect, and at least $(1+\varepsilon) \cdot X_{intersect}$ if the rows are disjoint. To achieve this, we use a new encoding that is specifically tailored towards LCS on large alphabets. The idea of our encoding is to chop each of our rows of length $d \log n$ into ℓ pieces of length $d \log n / \ell$ each, and then think of each piece as a separate letter from an alphabet of size $2^{d \log n/\ell} = n^{o(1)}$. Then, we let $a_{i,k}$ be the concatenation of ℓ such symbols, corresponding to the ℓ pieces that appear in the row $A_i(k, \cdot)$. Meanwhile, $b_{j,k}$ will be defined differently: for each piece x, we will enumerate all possible letters σ that correspond to pieces y that are disjoint from x, and write them in a dedicated segment in $b_{j,k}$. By doing this, the LCS of $a_{i,k}$ and $b_{j,k}$ will be exactly ℓ if the two rows are disjoint (since all pieces will be disjoint and contribute a letter

to the LCS), while if the rows intersect the LCS will be at most $\ell - 1$. Since we can afford to pick ℓ to be a (large enough) constant, we obtain a multiplication gap of $(1 + \varepsilon)$ where $\varepsilon = 1/(\ell - 1)$ is a constant.

Next, we need to combine these "disjointness" gadgets into "matrix gadgets" with an OR: we want the score to be large iff *there exists* a $k \in [K]$ for which the rows are disjoint. Previously known OR gadgets are not sufficient: the total score would contain a sum over all $k \in [K]$ of the score of the k^{th} disjointness gadget, which would decrease the gap back to $(1 + 1/K) = (1 + 1/n^{\alpha})$. To overcome this, we use a different OR gadget that heavily abuses the alphabet in order to keep the multiplicative gap *unchanged*. The idea is simple: let us designate a separate alphabet Σ_k for the k^{th} disjointness gadget $a_{i,k}$ or $b_{j,k}$ (representing the k^{th} row of A_i or B_j), so that for $k \neq k'$ the alphabets are disjoint $\Sigma_k \cap \Sigma_{k'} = \emptyset$. And now our matrix gadgets, which are an OR of our disjointness gadgets, are defined as follows:

$$a_i := a_{i,1}\ a_{i,2}\ \cdots\ a_{i,k}$$

$$b_j := a_{j,k}\ b_{j,k-1}\ \cdots\ b_{j,1}$$

The extremely useful property of this construction is that the LCS is the *maximum* over k of the LCS of $a_{i,k}$ and $b_{j,k}$, as opposed to any expression with a summation over all k. To see this, first note that only letters from gadgets with the same index k can be matched, and now imagine we pick at least one matching for some k, say for $k = 1$ so that we matched some letter between $a_{i,1}$ and $b_{j,1}$, and notice that now we can no longer match any letters from gadgets with a different index $k' \neq k$ without creating a crossing. Therefore, we get that the score of these matrix gadgets is *exactly the same* as the score of the best disjointness gadget across all rows $k \in [K]$, and so if A_i, B_j is a bad pair the score cannot be more than $X_{bad} = X_{intersect}$, while if the pair is good the score is $X_{good} = X_{disjoint} \geq (1+\varepsilon) \cdot X_{intersect}$, where ε is the same constant defined above.

For the outer construction, we use a similar "alignment gadget" to the one used in previous works [2, 32], but we need to analyze it more carefully in order to argue that it generates a gap when working with a gap problem like GBD. We show that if we are in case 2, then there is a matching that contains a large number of pairs A_i, B_j each contributing $(1 + \varepsilon) \cdot X_{bad}$, while in case 1 all pairs in all optimal matchings will contribute only X_{bad}. While previous work used padding of size that is linear in the size of the inner gadgets, we will have to work with much smaller paddings of size that is linear only in the LCS between the inner gadgets. By a careful choice of the parameters we show that this is a $(1 + \varepsilon')$ gap, for some $\varepsilon' > 0$.

1.3 Discussion

Fundamentally, our approach is based on the following intuition. If there is a search problem that we do not expect any (deterministic or randomized) algorithm to be able to solve much faster than brute force, like the problem of finding a pair of vectors that satisfy some function (as in GBD and Orthogonal Vectors), then we might expect the *gap* version of the problem to be hard for deterministic algorithms: maybe we cannot even distinguish the case in which no "good solutions" exist in the search space from the case that almost any solution is "good".

In the context of circuit lower bound consequences from circuit analysis algorithms, this intuition is more or less formal: most lower bound consequences we can get from SAT algorithm follow also from such a distinguisher.

Does the same hold with respect to the other conjectures used in "Hardness in P" research? Consider the 3-SUM problem which asks if a set of n numbers contains three that sum to zero, and is conjectured to require $n^{2-o(1)}$ time. If we believe the 3-SUM conjecture, should

we also believe that we cannot deterministically distinguish an input with many triples that sum to zero from an instance with few? Would this "Gap 3-SUM Conjecture" have interesting consequences? We believe that this is an intriguing avenue for future research and expect it to be fruitful, either in terms of conditional lower bounds, or in terms of a better understanding of our conjectured-to-be-hard problems.

2 Valiant series-parallel circuits

▶ **Definition 6** (Valiant series-parallel graphs [78, 34, 81, 46]). A *multidag* $G = (V, E)$ is a directed acyclic multigraph. Let input(G) be the set of vertices of G with in-degree 0. Let output(G) be the set of vertices of G with out-degree 0. We say that the multidag G is a Valiant series parallel (VSP) graph if there exists a *labelling* $l : V \to \mathbb{Z}$ of G with the following properties:

- For all directed edges $(u, v) \in E$ we have that $l(u) < l(v)$.
- There exists an integer $d \in \mathbb{Z}$ such that for all $v \in$ input(G), $l(v) = d$. The definition from [34] asks that $d = 0$. It is not hard to verify that our definition is equivalent to theirs.
- There exists an integer $d' \in \mathbb{Z}$ such that for all $v \in$ output(G), $l(v) = d'$.
- There is *no* pair of directed edges $(u, v), (u', v') \in E$ such that the inequality $l(u) < l(u') < l(v) < l(v')$ holds.

▶ **Definition 7** (Valiant series-parallel circuits [78, 34, 81, 46]). A circuit is a Valiant series-parallel circuit if the underlying multidag is a VSP graph and the fan-in of every gate is at most 2.

▶ **Definition 8** (Size of a circuit). The size of a circuit on n input variables is equal to the number of gates in it. We do not count the $n + 2$ input nodes, i.e. the input variables and the two constant values 0 and 1 (which are assumed to be given as the last two input nodes to a circuit).

▶ **Definition 9** (VSP_c). We define class VSP_c to be the set of languages recognizable by VSP circuits of size at most $\leq cn$ where n is the number of input variables. The set of allowed gates is the set of *all* gates of fan-in at most 2.

Below we show properties of the class VSP_c that we will use later in the paper.
We need the following definition from [26].

▶ **Definition 10** ([26]). Let F_n be a set of functions from $\{0,1\}^n$ to $\{0,1\}$. We say that F_n is *efficiently closed under projections* if functions in F_n have a poly(n)-size description and given (the description of) a function $f \in F_n$, indexes $i, j \leq n$, and a bit b, we can compute in time poly(n) the functions $\neg f$, $f(x_1, \ldots, x_{i-1}, b \text{ XOR } x_j, x_{i+1}, \ldots, x_n)$, and $f(x_1, \ldots, x_{i-1}, b, x_{i+1}, \ldots, x_n)$, all of which are in F_n.

▶ **Lemma 11.** *The class* VSP_c *is efficiently closed under projections for any constant* $c > 1$.

Proof. From Definition 9 it follows that the class VSP_c has poly(n) description: the circuit itself. Consider a function f on n input variables from VSP_c that has a VSP circuit of size at most $\leq cn$. We show that the three functions from the statement of Definition 10 can be computed in poly(n) time and that all of them are in VSP_c.

Function $\neg f$

Consider the output. If it is one of the inputs, we add a NOT gate and remove all the other gates. If the output is not one of the inputs, it must be some gate g. We replace it with gate $\neg g$. Since allow *all* gates of fan-in at most 2, we can do this. The number of gates did not increase and the function $\neg f$ is now in VSP_c. Clearly, the transformation can be done in poly(n) time.

Function $f(x_1, \ldots, x_{i-1}, b \text{ XOR } x_j, x_{i+1}, \ldots, x_n)$

If $b = 0$, we rewire all gates that used input x_i to use input x_j. If $b = 1$, we rewire all gates to use NOT x_j. Since we have all gates of fan in at most 2, we don't need to introduce the NOT gate. Instead, we replace the gate by another gate that negates the corresponding input. Similarly as before, the transformation can be done in poly(n) time and we did not increase the number of gates. Thus, the resulting function is in VSP_c.

Function $f(x_1, \ldots, x_{i-1}, b, x_{i+1}, \ldots, x_n)$

The transformation is similar as in the previous case. Instead of rewiring to x_j, we rewire to the constant function 0 which is among the inputs. ◀

▶ **Lemma 12.** *Let $f_1, f_2, f_3 \in \mathsf{VSP}_c$ be three functions on n variables from the class VSP_c. Then the function*

$$f := \neg(f_1 \ OR \ f_2 \ OR \ f_3)$$

on the same n variables belongs to VSP_{4c} if $c \geq 4$ and $n \geq 10$.

Proof. For every $i = 1, 2, 3$, let C_i be the VSP circuit of size $\leq cn$ corresponding to the function f_i, and let G_i be the underlying VSP multidag of C_i. Let the multidag $G := P(G_1, G_2, G_3)$ be the *disjoint* union of the underlying VSP multidags G_1, G_2, G_3, and let $\text{input}(G_i) = \{u_i^1, \ldots, u_i^n, u_i^{n+1}, u_i^{n+2}\}$ be the $n + 2$ input nodes for C_i, $i = 1, 2, 3$ (see Definition 8), where the first n nodes $u_i^1, \ldots, u_i^n$ correspond to the n input variables, and u_i^{n+1} and u_i^{n+2} correspond to the two constant functions 0 and 1, respectively. We have that $\text{input}(G) = \text{input}(G_1) \cup \text{input}(G_2) \cup \text{input}(G_3)$. Moreover, since $|\text{input}(G_i)| = n + 2$, $|\text{input}(G)| = 3n + 6$. Each C_i has only one output gate. Thus, $\text{output}(G_i) = \{o_i\}$ for some node o_i. Therefore, $|\text{output}(G)| = 3$.

A disjoint union of two VSP multidags is a multidag (see the proof of Lemma 3 in [34]). Therefore, the multidag G is a VSP multidag. Let, then, l be the labeling of G according to Definition 6 of VSP graphs. We construct a circuit C for the function f as follows. First, we let C be the disjoint union of C_1, C_2, C_3 (each C_i has its own $n + 2$ input nodes). Therefore, the underlying graph of C is G. Next, whenever we add a node or an edge to G, we do the same for C, and the other way around. As the circuits C_1, C_2, C_3 do not share their inputs, we add $n + 2$ input nodes $u^1, \ldots, u^n, u^{n+1}, u^{n+2}$ to C (and to G). The first n input nodes $u^1, \ldots, u^n$ correspond to the n input variables, and the 2 input nodes u^{n+1} and u^{n+2} correspond to the two constant function 0 and 1, respectively. We connect the n input nodes $u^1, \ldots, u^n$ in pairs to the first n input nodes of C_i (for every $i = 1, 2, 3$). That is, for every $j = 1, \ldots, n$ and $i = 1, 2, 3$, we connect u^j to u_i^j. In addition, for every $j = n + 1, n + 2$ and $i = 1, 2, 3$, we connect u^j to u_i^j.

For every newly added input node u^j, $j = 1, \ldots, n+2$, we update the labeling: $l(u^j) = d-1$. As a result, the multidag G has $\text{input}(G) = \{u^1, \ldots, u^n, u^{n+1}, u^{n+2}\}$ and all weights of these

nodes are equal to $d-1$. It remain to verify the fourth property of VSP graphs. Since for every u^j, if (u^j, v) is an edge in G, then $l(v) = d$, the fourth property also holds. Thus G is VSP graph.

Now we have three functions f_1, f_2, f_3 on the same set of $n+2$ inputs. To get the function $f = \neg(f_1 \text{ OR } f_2 \text{ OR } f_3)$, we add two more gates u_1, u_2 to the circuit C. We set the labeling: $l(u_1) = d' + 1$ and $l(u_2) = d' + 2$. u_1 is an OR gate, and it computes the OR of o_1 and o_2 (the outputs of the functions f_1 and f_2). The gate u_2 is a $\neg$OR gate, and it computes the negation of the OR of u_1 (the OR of f_1 and f_2) and o_3 (the output of the function f_3). Since all gates of fan-in at most two are allowed, we can implement a $\neg$OR gate. We can check that C computes f (the negation of the OR of f_1, f_2, f_3). The size of the circuit C is at most $3cn + |\text{input}(G)| + 2 = 3cn + 3n + 8 \leq 4cn$ as required. It is not hard to verify that the resulting labeling of u_1, u_2 and the rest of the multigraph G satisfies the properties from Definition 6. Thus, we conclude that the resulting underlying multidag G is a VSP graph and that C is a VSP_{4cn} circuit. ◀

3 VSP Circuits and Block Disjointness

Circuit Lower Bounds from Derandomization

The connection between derandomizing circuits and lower bounds originates in the works of Impagliazzo, Kabanets, and Wigderson [56] and has been optimized significantly by the work of Williams [83], Santhanam and Williams [74], and more recently by Ben-Sasson and Viola [26]. These connections rely on "Succinct PCP" theorems [67, 26], and the recent optimized construction of Ben-Sasson and Viola [26] is crucial to our main result. Our starting point is the following theorem.

▶ **Theorem 13** (Theorem 1.4 in [26]). *Let F_n be a set of function from $\{0,1\}^n$ to $\{0,1\}$ that are efficiently closed under projections (see Definition 10).*

If the acceptance probability of a function of the form

- *AND of fan-in $n^{O(1)}$ of*
- *OR's of fan-in 3 of*
- *functions from $F_{n+O(\log n)}$*

can be distinguished from being $= 1$ or $\leq 1/n^{10}$ in TIME$(2^n/n^{\omega(1)})$, then there is a function f in E^{NP} on n variables such that $f \notin F_n$.

The optimization of the Succinct PCP by Ben-Sasson and Viola makes the overhead in this connection quite small: only two additional levels to the circuit, one of which has fan-in 3. Next, we instantiate this theorem with VSP circuits and then do simple tricks to the circuits in order to simplify the derandomization task as much as possible.

▶ **Lemma 14.** *To prove that E^{NP} does not have non-uniform Valiant series parallel* (VSP) *circuits of size cn on n input variables, it is enough to show a deterministic algorithm for the following Derand-VSP problem that runs in $2^n/n^{\omega(1)}$ time. Given a circuit over n input variables of the form:*

- *OR of fan-in $n^{O(1)}$ of*
- *negations of OR's of fan-in 3 of*
- VSP *circuits of size cn,*

distinguish between the case where no assignments satisfy it, versus the case in which at least a $\geq 1 - 1/n^{10}$ fraction of the assignments satisfy it.

Lemma 14 follows from Theorem 13 almost directly: By Lemma 11, the class VSP_c (of functions recognizable by VSP circuits of size $\leq cn$) is efficiently closed under projections. Therefore, we can instantiate Theorem 13 on VSP_c. Since distinguishing the acceptance probability from being $= 1$ or $\leq 1/n^{10}$ is equivalent to distinguishing the *rejection* probability from being $= 0$ or $\geq 1 - 1/n^{10}$, we get Lemma 14 by *negating* the function which is AND of OR of $F_{n+O(\log n)}$ and using De Morgan's law on the AND. W.l.o.g. we replace the number of inputs $n + O(\log n)$ by n.

From Derandomizing VSP Circuits to Gap Block Disjointness

Let C be the circuit on n variables given as an input to the Derand-VSP problem described in Lemma 14. We use known results in complexity theory to convert this circuit into a simpler form that will be easier to work with when reducing to other problems. By Lemma 12, the circuit C can be interpreted as:

- OR of fan-in $n^{O(1)}$ of
- VSP circuits of size $\leq 4cn$,

where the $n^{O(1)}$ VSP circuits use the same set of n inputs.

Next, we use the following classical theorem of Valiant to convert each of these VSP circuits into an OR of CNF's on our n inputs. The ideas in the proof are due to Valiant [78], but the details were shown by Calabro [34] and Viola [81] (cf. Cygan et al. [46]).

▶ **Theorem 15** (Depth reduction [78]). *For all $\ell \geq 1$, we can convert any VSP of size $4cn$ on n variables into an equivalent formula which is OR of $2^{n/\ell}$ k-CNF's on the same n variables, where $k = 2^{2^{\mu c \ell}}$ for some absolute constant $\mu > 0$. The reduction runs in $2^{n/\ell} \cdot n^{O(1)}$ time for any constants c and l.*

▶ Remark. Let $\varepsilon > 0$ an arbitrary constant. Given a circuit on n variables with fan-in 2 gates, of size $O(n)$ and $O(\log n)$ depth, we can transform it into an equivalent formula which is *OR* of $2^{O(\frac{\log n}{\log \log n})}$ CNFs with clause size $\leq n^{\epsilon}$ [78]. However, we can't use this result for our purposes because it will be crucial for us that the clause size in the statement of Theorem 15 is upper bounded by a *constant*.

We will also need to apply the sparsification lemma [57, 58].

▶ **Lemma 16.** *For all $k \geq 3$ and $\varepsilon > 0$ we can convert a k-CNF formula on n variables into an equivalent OR of $2^{\varepsilon n}$ k-CNF formulas on the same variables where each CNF has $f(\varepsilon, k) \cdot n$ clauses, where $f(\varepsilon, k) = (k/\varepsilon)^{O(k)}$.*

Combining all these transformations allows us to focus on circuits of the following OR-AND-OR form. By the following claim, to solve the Derand-VSP problem it is enough to distinguish between the case in which no assignments satisfy a formula of the above OR-AND-OR form and the case in which at least $2^n - 2^n/n^{10}$ assignments do satisfy it.

▶ **Claim 17.** *Let C be an input circuit to the Derand-VSP problem (as described in Lemma 14). For all $\ell \geq 1$ and $\varepsilon > 0$, we can convert C into an* equivalent *formula C' on the same set of n inputs of the following form:*

- *OR of fan-in $n^{O(1)} \cdot 2^{n/\ell} \cdot 2^{\varepsilon n}$, of*
- *AND of fan-in $f(\varepsilon, k) \cdot n$ where $k = 2^{2^{\mu c \ell}}$, of*
- *OR of fan-in k of literals.*

Proof. Recall that an input circuit to the Derand-VSP problem has the form of an OR of fan-in $n^{O(1)}$ of series parallel circuits of size $\leq 4cn$. We want to decide if C is unsatisfiable or at least a $1 - 1/n^{10}$ fraction of the assignments satisfy it. First, we apply Theorem 15 on

every VSP circuit of size $\leq 4cn$. This produces a formula which is an OR of $2^{n/l}$ k-CNFs. Then, we apply the sparsification of Lemma 16 on every k-CNF to obtain a circuit as in the statement of the claim. ◀

This OR-AND-OR form motivates the definition of our Gap Block Disjointness problem (see Definition 1 in Section 1.1). Recall that our GBD Hypothesis (Hypothesis 2 in Section 1.1) states that GBD cannot be solved in truly subquadratic time with a deterministic algorithm. We are now ready to prove that refuting our hypothesis implies a circuit lower bound against linear size VSP circuits, thus establishing a "circuit lower bounds barrier" for refuting our hypothesis. The following claim implies Lemma 3 from Section 1.1.

▶ **Claim 18.** *For all $c \geq 1$ and $\alpha > 0$, there exists a constant $d \geq 1$ such that if there is a deterministic algorithm that solves the Gap Block Disjointness problem on two lists of size N of binary $N^\alpha \times d \log N$ matrices in $N^2/\log^{\omega(1)} N$ time, then E^{NP} does not have non-uniform VSP circuits of size cm (m is the number of input variables). The constant d can be upper bounded by*

$$d \leq 2^{2^{2^{O(c/\alpha)}}}.$$

Proof. By Theorem 13, to show that E^{NP} does not have non-uniform VSP circuits of size cm, it suffices to solve the Derand-VSP problem on a circuit C with $n = m + O(\log m)$ variables in time $2^n/n^{\omega(1)}$.

First, by Claim 17, we can transform the circuit C into an equivalent formula C' of form OR-AND-OR (as described in the statement). Then, we show a reduction from the Derand-VSP problem on the formula C' to the Block Disjoint Pairs problem with the required parameters, as follows. Let $N := 2^{n/2}$. We apply the transformation from Claim 17 to C, with parameters $\varepsilon := \frac{\alpha}{6}$, $l := \frac{6}{\alpha}$, and $d := 2f(\varepsilon, k) \leq (k/\varepsilon)^{O(k)}$, and get an equivalent formula C' of the following form:

- OR of fan-in $n^{O(1)} \cdot 2^{n/\ell} \cdot 2^{\varepsilon n} \leq 2^{\alpha n/2} = N^\alpha$, of
- AND of fan-in $f(\varepsilon, k) \cdot n = d \cdot \log N \leq (k/\alpha)^{O(k)} \cdot n$ where $k = 2^{2^{\mu c \ell}} \leq 2^{2^{O(c/\alpha)}}$, of
- OR of fan-in k of literals.

We think of the formula C' as a disjunction of CNF's with clause size k.

Let us now transform C' to an instance of the Block Disjoint Pairs problem. C' has n binary input variables $x_1, \ldots, x_n$. We split these variables into two parts: $x_1, \ldots, x_{n/2}$ and $x_{1+(n/2)}, \ldots, x_n$, and construct two sets A and B of matrices for the Block Disjoint Pairs problem.

Set of matrices A

Consider all the $N = 2^{n/2}$ partial assignments of the first half $x_1, \ldots, x_{n/2}$ of the variables. We will construct a matrix A_i, $i = 1, \ldots N$, for each partial assignment p_i of $x_1, \ldots, x_{n/2}$ as follows. For every k-CNF in C' we have a corresponding row in A_i, such that every clause of the k-CNF has a corresponding column. Thus, for $r = 1, \ldots, N^\alpha$, the r-th row of the matrix A_i corresponds to the r-th k-CNF in C', and every clause of the r-th k-CNF has a corresponding column in the r-th row such that the t-th clause corresponds to the t-th column in the r-th row of A_i. We set $A_i[r, t]$ to 0 if p_i satisfies the t-th clause of the r-th k-CNF, and to 1 otherwise. A clause is satisfied by a *partial* assignment iff it is satisfied independently of the assignment of the rest of the variables. We assume that the number of k-CNFs is N^α and the number of clauses in each k-CNF is $d \cdot \log N$. If this is not the case, then we can add dummy k-CNFs that are not satisfiable, or clauses that are satisfied by any partial assignment.

Set of matrices B

The second set of matrices B is constructed like the set A but with the second half of variables $x_{1+(n/2)}, \ldots, x_n$.

Our construction satisfies all the parameters of the Block Disjoint Pairs problem. In particular, $d \leq (k/\varepsilon)^{O(k)} \leq 2^{2^{2^{O(c/\alpha)}}}$.

Correctness of the reduction

To prove the correctness of our reduction, it suffices to show that the fraction of pairs of matrices that form a satisfying assignment (the first condition in Definition 1), is the same as the fraction of assignments that satisfy the circuit C'. We show that the i-th partial assignment of $x_1, \ldots, x_{n/2}$ and the j-th partial assignment of $x_{1+(n/2)}, \ldots, x_n$ satisfy C' iff the matrices A_i and B_j form a satisfying assignment too. If C' is satisfied, then at least one of the k-CNFs in C' is satisfied. Assume, then, without loss of generality, that the r-th k-CNF is satisfied. Our goal is to show that $\wedge_{h \in [d \log N]}(\neg A_i(r,h) \vee \neg B_j(r,h)) = True$. Or, equivalently, that $A_i(r,h) \cdot B_j(r,h) = 0$, for every $h \in [d \log N]$. In fact, this follows from the fact that the r-th k-CNF is satisfied and from the construction of A_i and B_j. If, on the other hand, $\vee_{k \in [N^\alpha]}(\wedge_{h \in [d \log N]}(\neg A_i(k,h) \vee \neg B_j(k,h))) = False$, then the i-th partial assignment of $x_1, \ldots, x_{n/2}$ and the j-th partial assignment of $x_{1+(n/2)}, \ldots, x_n$ do not satisfy C'. This follows from the construction of A_i and B_j and the fact that *no* k-CNF is satisfied in this case.

Therefore, $1 - 1/\log_2^{10} N = 1 - 2^{10}/n^{10} \leq 1 - 1/n^{10}$, concluding the proof. ◀

4 The Reduction to Approximate LCS

Our main technical contribution is a reduction from Gap Block Disjointness to $(1+\varepsilon)$ approximate LCS. Lemma 4 from Section 1.1 follows from the following claim, and the rest of this section is dedicated to its proof. For a high level intuition of the reduction see the introduction.

▶ **Claim 19** (Main). *If for some $\delta > 0$, there is a deterministic algorithm that can approximate the LCS of two given sequences of length n over an alphabet of size $n^{o(1)}$ to within a $(1+\varepsilon)$ factor, for all $\varepsilon > 0$, in $O(n^{2-\delta})$ time, then Hypothesis 2 is false.*

Weighted LCS

A natural generalization of LCS that will be useful in our proof is the *weighted longest common subsequence* (WLCS), where each symbol s has a positive integer weight $w(s)$. The weight of a subsequence is the total weight of the symbols it contains, and the WLCS score is the maximum total weight that we can obtain if we range over all common subsequences. As long as the weights are not too large, WLCS and LCS are computationally equivalent due the following lemma.

▶ **Lemma 20** (Lemma 2 in [2]). *Given two weighted sequences x and y, $WLCS(x,y) = LCS(x',y')$, where $|x'| = \sum_{i=1}^{|x|} w(x_i)$ and $|y'| = \sum_{i=1}^{|y|} w(y_i)$. The construction time of x', y' is $O(\max(|x'|,|y'|))$. $|z|$ denotes the length of the sequence z.*

Below, we will use the terms LCS and WLCS interchangeably, and if we do not specify the weight of a symbol s, then it is assumed that $w(s) = 1$.

The parameters of the reduction

We will show the following statement which implies what we need.

If we have a deterministic algorithm for the LCS problem that runs in $O(n^{2-\varepsilon})$ time and that gives $(1+(\delta/10^5))$ approximation, then we can solve the Block Disjoint Pairs problem in $O(N^{2-(\varepsilon/2)})$ time on binary matrices of size $N^\alpha \times d \log N$ for $\alpha := \varepsilon/10$ and $d := \alpha(1+\delta)/\delta$. Choosing $\delta = o(1)$ implies $d = \omega(1)$ and proves the theorem. W.l.o.g. we assume that $\delta \geq 1/\log n$ and $\varepsilon \leq 1/100$.

We will show the statement by providing a deterministic reduction from the Block Disjoint Pairs problem to the LCS problem. We will take the first set of N matrices $A = \{A_1, \ldots, A_N\}$ (each matrix is of size $N^\alpha \times d \log N$) and produce a sequence x of symbols. The sequence x is of length $|x| \leq O(N^{1+2\alpha}d/\alpha) =: n$. Similarly, we will take the second set of N matrices $B = \{B_1, \ldots, B_N\}$ and produce a sequence y of symbols, $|y| \leq O(N^{1+2\alpha}d/\alpha) = n$. The sequences x and y have the property that $LCS(x,y) \leq T$ if we are in Case 1 of Block Disjoint Pairs problem on sets of matrices A and B (see Definition 1) and $LCS(x,y) \geq (1+(\delta/10^5))T$ if we are in Case 2. T is some fixed value. We run the deterministic approximation algorithm for the LCS problem and decide in which case we are. Since the reduction is deterministic, this gives a deterministic algorithm for the Block Disjoint Pairs problem that runs in time

$$O(n^{2-\varepsilon}) \leq O\left(\left(N^{1+2\alpha}d/\alpha\right)^{2-\varepsilon}\right) \leq O\left(\left(N^{1+(\varepsilon/5)}/\delta\right)^{2-\varepsilon}\right),$$

where we use the fact that $\alpha = \varepsilon/10$ and $d = \alpha(1+\delta)/\delta$. Since $\delta \geq 1/\log n$ and $\varepsilon \leq 1/100$, we get that the runtime is upper bounded by $O(N^{(1+(\varepsilon/5))(2-\varepsilon)} \log^2 N) \leq O\left(N^{2-(\varepsilon/2)}\right)$ as required.

Construction of *inner gadgets*

To construct sequences x and y, we need *inner gadgets* $IG(A_i)$, $IG(B_j)$ for every set $A_i \in A$ and $B_j \in B$. We want that $IG(A_i)$ and $IG(B_j)$ satisfy the property that $LCS(IG(A_i), IG(B_j)) = T'$ if the pair A_i, B_j is not satisfying and $LCS(IG(A_i), IG(B_j)) = (1+\delta)T'$ if the pair A_i, B_j is satisfying. Below we will construct such inner gadgets with $|IG(A_i)|, |IG(B_j)| \leq O(N^{2\alpha}d/\alpha)$. After that we will construct the final sequences x and y with the required properties by putting together inner gadgets for all matrices in A and B.

We construct the inner gadgets $IG(A_i)$, $IG(B_j)$ by constructing *disjointness gadgets* $DG(A_i(k,\cdot))$, $DG(B_j(k,\cdot))$ for every row $k \in [K]$ of matrices A_i and B_j.

Properties of the disjointness gadgets

The disjointness gadgets will satisfy the following properties

- For every $k \in [K]$, $|DG(A_i(k,\cdot))|, |DG(B_j(k,\cdot))| \leq O(N^\alpha d/\alpha)$.
- If $\wedge_{h\in[D]}(\neg A_i(k,h) \vee \neg B_j(k,h)) = False$, then $LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) = T'$. Otherwise, $LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) = (1+\delta)T'$.
- For every $k \in [K]$, $DG(A_i(k,\cdot)), DG(B_j(k,\cdot)) \in \Sigma_k^*$. $\Sigma_k \cap \Sigma_{k'} = \emptyset$ for $k \neq k'$.

Given such disjointness gadgets, we construct inner gadgets $IG(A_i)$, $IG(B_j)$ as follows:

$$IG(A_i) := \bigcirc_{k=1}^{K} DG(A_i(k,\cdot)) = A_i(1,\cdot) \circ A_i(2,\cdot) \circ A_i(3,\cdot) \circ \ldots \circ A_i(k,\cdot),$$

$$IG(B_j) := \bigcirc_{k=1}^{K} DG(B_j(K+1-k,\cdot)) = B_j(k,\cdot) \circ B_j(k-1,\cdot) \circ B_j(k-2,\cdot) \circ \ldots \circ B_j(1,\cdot).$$

Since $\Sigma_k \cap \Sigma_{k'} = \emptyset$ for $k \neq k'$, the only way to get $LCS(IG(A_i), IG(B_j)) > 0$ is by matching symbols in $A_i(k,\cdot)$ and $B_j(k,\cdot)$. By the construction of $IG(A_i)$ and $IG(B_j)$, if we match

symbols between $A_i(k,\cdot)$ and $B_j(k,\cdot)$, then we can't match symbols between $A_i(k',\cdot)$ and $B_j(k',\cdot)$ if $k' \neq k$. This means that

$$LCS(IG(A_i), IG(B_j)) = \max_{k=1}^{K} LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))).$$

From the properties of disjointness gadgets, we get the required properties of the inner gadgets.

Construction of the disjointness gadgets

Now we will construct the disjointness gadgets $DG(A_i(k,\cdot)), DG(B_j(k,\cdot))$. $A_i(k,\cdot)$ is a binary vector of length $d \log N$. We split it into d/α binary vectors $v_t \in \{0,1\}^{\alpha \log N}$ each of length $|v_t| = \alpha \log N$: $A_i(k,\cdot) = v_1 \dots v_{d/\alpha}$. We define

$$DG(A_i(k,\cdot)) := c_k \circ \bigcirc_{t=1}^{d/\alpha} s_{k,t,v_t},$$

where we set $w(c_k) := (d/\alpha) - 1$. s_{k,t,v_t} are symbols indexed by rows k, indices of vectors t and vectors v_t. We have that

$$DG(A_i(k,\cdot)) \in \Sigma_k^* := \{c_k\} \cup \{s_{k,t,v} \mid v \in \{0,1\}^{\alpha \log N} \text{ and } t \in [d/\alpha]\}.$$

Similarly we split the binary vector $B_j(k,\cdot)$ of length $d \log N$ into d/α binary vectors $w_t \in \{0,1\}^{\alpha \log N}$ each of length $|w_t| = \alpha \log N$: $B_j(k,\cdot) = w_1 \dots w_{d/\alpha}$. We define

$$DG(B_j(k,\cdot)) := \left(\bigcirc_{t=1}^{d/\alpha} \bigcirc_{v \,:\, v \cdot w_t = 0} s_{k,t,v} \right) \circ c_k,$$

where we do the inner product $v \cdot w_t$ over the integers (not modulo 2). Notice that $|DG(A_i(k,\cdot))| \leq O(d/\alpha)$ and $|DG(B_j(k,\cdot))| \leq O(N^\alpha d/\alpha)$ as required.

We claim that if $\wedge_{h \in [D]}(\neg A_i(k,h) \vee \neg B_j(k,h)) = False$, then

$$LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) = (d/\alpha) - 1$$

and $LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) = d/\alpha$ otherwise. Since $d = \alpha(1+\delta)/\delta$, we have that $T' = (d/\alpha) - 1$ satisfies the second property of the disjointness gadgets. We now show the claim.

Clearly, $LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) \geq (d/\alpha) - 1$ because we can match the symbols c_k. Also, we have the equality if we match the symbols c_k in the optimal alignment. Suppose that we don't match c_k. Then it's not hard to check that $LCS(DG(A_i(k,\cdot)), DG(B_j(k,\cdot))) = d/\alpha$ if $\wedge_{h \in [D]}(\neg A_i(k,h) \vee \neg B_j(k,h)) = True$ and $\leq (d/\alpha) - 1$ otherwise. Since we have to take maximum between the cases when we match the symbols c_k and when we don't match c_k, we get the required equalities.

The outer construction

In the remainder of the proof we construct the final sequences x and y with the promised properties. The sequence x is a concatenation of the inner gadgets $IG(A_i)$ with some additional symbols. The sequence y is a concatenation of the inner gadgets $IG(B_j)$ with some additional symbols. Each inner gadget $IG(B_j)$ appears twice in the sequence y.

We define integer values $v_0 < v_1 < v_2 < v_3$ as follows. We set $v_0 := T'$ (see the definition of the inner gadgets for T'), $v_1 := (1+\delta)T'$, $v_2 := 10v_1$, $v_3 := 100v_1$. For the simplicity of the notation, we will write A_i instead of $IG(A_i)$ and B_j instead of $IG(B_j)$. It will be clear

from the context whether we refer to A_i (B_j, resp.) or to $IG(A_i)$ ($IG(B_j)$, resp.). We define the sequence x:

$$x := \left(\bigcirc_{i=1}^{3n} 2\right) \circ \left(\bigcirc_{i=1}^{n} (0\ A_i\ 1)\right) \circ \left(\bigcirc_{i=1}^{3n} 2\right).$$

We define the sequence y:

$$y := \left(\bigcirc_{j=1}^{n} (2\ 0\ B_j\ 1)\right) \circ \left(\bigcirc_{j=1}^{n} (2\ 0\ B_j\ 1)\right) \circ 2.$$

We set the weight of symbols 0, 1 and 2 as follows: $w(2) := v_2$ and $w(0) = w(1) := v_3$.

We have two goals. First, we want to show that if there are many satisfying assignments (each assignment is a pair of A_i and B_j), then the LCS score between x and y is large: $LCS(x, y) \geq (1 + (\delta/10^5))T$. T is some fixed value that we will define later. Second, if there are no satisfying assignments, then the LCS score is small: $LCS(x, y) \leq T$. We achieve these two goals via the next two lemmas.

▶ **Lemma 21.** *If there are many satisfying assignment (see Definition 1), then*

$$LCS(x, y) \geq (n + 2)v_2 + 2nv_3 + 0.99nv_1 + 0.01nv_0 =: T''.$$

Proof. We will exhibit n different alignments between x and y and we will show that at least one of them achieves the LCS score T''. This gives the lower bound on $LCS(x, y)$.

For $k = 1, \ldots, n$ we write

$$y = \left(\bigcirc_{j=1}^{k-1} (2\ 0\ B_j\ 1)\right) \circ 2 \circ s_k \circ \left(\bigcirc_{j=k}^{n} (2\ 0\ B_j\ 1)\right) \circ 2,$$

where

$$s_k := (0\ B_k\ 1) \circ \left(\bigcirc_{j=k+1}^{n} (2\ 0\ B_j\ 1)\right) \circ \left(\bigcirc_{j=1}^{k-1} (2\ 0\ B_j\ 1)\right).$$

Clearly,

$$\begin{aligned} LCS(x, y) \geq & LCS\left(\bigcirc_{i=1}^{3n} 2, \left(\bigcirc_{j=1}^{k-1} (2\ 0\ B_j\ 1)\right) \circ 2\right) \\ & + LCS\left(\bigcirc_{i=1}^{n} (0\ A_i\ 1), s_k\right) \\ & + LCS\left(\bigcirc_{i=1}^{3n} 2, \left(\bigcirc_{j=k}^{n} (2\ 0\ B_j\ 1)\right) \circ 2\right). \end{aligned}$$

The total contribution of the first and the third term on the r.h.s. is $(n + 2)v_2$ because only symbols 2 can contribute to the LCS score and there are $n + 2$ symbols 2. For the middle term we align inner gadgets in pairs and match all symbols 0 and 1. We get the lower bound

$$LCS(x, y) \geq (n + 2)v_2 + 2nv_3 + \sum_{i=1}^{n} LCS(A_i, B_{j_k(i)}),$$

$$where j_k(i) := \begin{cases} i + k - 1 & \text{if } i \leq n + 1 - k, \\ i + k - 1 - n & \text{otherwise.} \end{cases}$$

By averaging the r.h.s. over all $k = 1, \ldots, n$, we get

$$\begin{aligned} LCS(x, y) &\geq \frac{1}{n} \sum_{k=1}^{n} \left((n + 2)v_2 + 2nv_3 + \sum_{i=1}^{n} LCS(A_i, B_{j_k(i)}) \right) \\ &= (n + 2)v_2 + 2nv_3 + \frac{1}{n} \sum_{i,k=1}^{n} LCS(A_i, B_{j_k(i)}) \\ &= (n + 2)v_2 + 2nv_3 + \frac{1}{n} \sum_{i,j=1}^{n} LCS(A_i, B_j) \\ &\geq (n + 2)v_2 + 2nv_3 + 0.99nv_1 + 0.01nv_0, \end{aligned}$$

where in the last inequality we use the fact that there are many satisfying assignments. This finishes the proof of the lemma. ◀

▶ **Lemma 22.** *If there are no satisfying assignments, then*

$$LCS(x,y) \leq (n+2)v_2 + 2nv_3 + nv_0 =: T.$$

Proof. We start with the intuition behind the analysis.

Intuition

We saw in the proof of Lemma 21 that there is an alignment that achieves a large LCS score. In the alignment we match the n inner gadgets from the first sequence x with an n consecutive inner gadgets from the second sequence y in pairs. We want to claim that in an optimal alignment, we will do the same: map the n inner gadgets from the first sequence with an n consecutive inner gadgets from the second sequence in pairs. Intuitively, this is because of the following three reasons:

- We don't want to choose less than n inner gadgets from the second sequence because otherwise we can't match all symbols 0 and 1 from the first sequence with their counterparts (symbols 0 and 1 have the largest weight - we loose a lot by not matching them).
- We don't want to choose more than n inner gadgets from the second sequence because otherwise we have fewer symbols 2 from the second sequence to be matched with their counterparts. Symbols 2 have smaller weight than symbols 0 and 1 but still we loose a lot by not matching them.
- Finally, if we choose n inner gadgets from the second sequence we want to match them in pairs. If we don't do that, we can't match all symbols 0 and 1 which is again expensive.

We proceed to formalize the intuition.

Sequence x starts with $3n$ copies of symbol 2. Suppose that some of those symbols are matched. W.l.o.g. the matched symbols from a suffix of $\bigcirc_{i=1}^{3n} 2$. W.l.o.g. the last symbol of $\bigcirc_{i=1}^{3n} 2$ is matched. If this is not the case we can match it with the first symbol of y and this can only increase LCS. Consider the symbol 2 from y that is matched to the last symbol 2 from $\bigcirc_{i=1}^{3n} 2$. Consider the symbol to the right of the symbol 2 in y. It is 0. Let s be its position in y. W.l.o.g. this symbol 0 is matched to the first symbol 0 from x. If this is not so, we can make this match and this can't decrease the LCS score. Analogously we can argue that the last symbol 1 from x is matched to a symbol 1 in y. Let t be the location of the symbol 1 in y. Let x' be the substring of x that is to the right of the first symbol 0 in x and to the left of the last symbol 1 in x. Let y' be the substring of y that is to the right of the symbol 0 at location s in y and to the left of the symbol 1 at location t in y. We write $x = x_1 x' x_2$ and $y = y_1 y' y_2$. We can upper bound LCS if we range over all such partitions of x and y:

$$LCS(x,y) \leq \max_{\substack{x=x_1x'x_2 \\ y=y_1y'y_2}} LCS(x_1,y_1) + LCS(x',y') + LCS(x_2,y_2). \tag{1}$$

Let $m \geq 1$ denote the number of inner gadgets in y'.

▶ **Claim 23.**

$$LCS(x_1,y_1) + LCS(x_2,y_2) \leq 2v_3 + (2n+1-(m-1))v_2.$$

Proof. The total number of symbols 2 in y_1 and y_2 is $2n+1-(m-1)$. The total contribution from all symbols 2 is upper bounded by $(2n+1-(m-1))v_2$. We can also match symbol 0 in x_1 and symbol 1 in x_2. This upper bounds the total contribution from symbols 0 and 1 by $2v_3$. There are no other symbols that we can match. The claim follows. ◀

It remains to give an upper bound on $LCS(x', y')$. Consider any symbol 0 in x'. Its *neighbour* is the symbol 1 to the left of it. Similarly, for any symbol 1 in x' the neighbour is the symbol 0 to the right of it. For any symbol 0 in y' the neighbour is the first symbol 1 to the left of it. For any symbol 1 in y' the neighbour is the first symbol 0 to the right of it. For any two symbols 0 that are matched between x' and y', their neighbours (symbols 1) form a match too. If this does not true, we match the symbols 1 and this can only increase the LCS score. Similarly, for any two symbols 1 that are matched, their neighbours form a match too. Let $M \geq 0$ denote the number of pairs of matched symbols 0 and 1. This allows us to upper bound the total contribution from symbols 0 and 1 to $LCS(x', y')$ by $S := 2Mv_2$. The M pairs of matched symbols split the sequence x into $M+1$ maximal substrings $r_1, \ldots, r_{M+1}$. In each one of the $M+1$ substrings s_i does not contain a symbol 0 or 1 that is matched. Similarly, we split y' into $M+1$ maximal substrings $p_1, \ldots, p_{M+1}$ so that each p_i does not contain a symbol 0 or 1 that is matched. Symbols in r_i can only be matched to symbols in p_i. The only symbols that can be matched from r_i with symbols from p_i come from the inner gadgets by the definition of r_i and p_i. Let $d_i \geq 1$ denote the number of the inner gadgets in r_i and $l_i \geq 1$ denote the number of the inner gadgets in p_i. Clearly, $\sum_{i=1}^{M+1} d_i = n$ and $\sum_{i=1}^{M+1} l_i = m$. We claim that $LCS(r_i, p_i) \leq (d_i + l_i - 1)v_0$. Since the pairs of matched symbols can't cross, we can easily check that the total number of pairs of inner gadgets that can have a match is upper bounded by $d_i + l_i - 1$. Because there are no satisfying assignments, the upper bound $LCS(r_i, p_i) \leq (d_i + l_i - 1)v_0$ follows. From all this we have

$$LCS(x', y') \leq S + \sum_{i=1}^{M+1} LCS(r_i, p_i) \leq 2Mv_2 + \sum_{i=1}^{M+1} (d_i + l_i - 1)v_0.$$

We combine this with the equalities $\sum_{i=1}^{M+1} d_i = n$ and $\sum_{i=1}^{M+1} l_i = m$ and get the following Claim.

▶ **Claim 24.**

$$LCS(x', y') \leq 2Mv_3 + (n+m)v_0 - (M+1)v_0.$$

We combine (1) with Claims 23 and 24 and get the following upper bound:

$$\begin{aligned} LCS(x, y) \leq & 2v_2 + n(2v_2 + v_0) \\ & + (M+1)(2v_3 - v_0) - m(v_2 - v_0). \end{aligned}$$

From $\sum_{i=1}^{M+1} d_i = n$ and $\sum_{i=1}^{M+1} l_i = m$ we get that $M \leq \min(n, m) - 1$. As we increase M, the r.h.s. of the upper bound only increases. We choose $M = \min(n, m) - 1$. Consider two cases.

- $m \geq n$. We have $M = n - 1$ and $LCS(x, y) \leq v_2(2n+2) + 2nv_3 - m(v_2 - v_0) \leq T$.
- $m \leq n$. We have $M = m - 1$ and $LCS(x, y) \leq v_2(2n+2) + nv_0 + m(2v_3 - v_2) \leq T$. ◀

From the above Lemmas 21 and 22 we have that $LCS(x, y) \geq T''$ if there are many satisfying assignment and $LCS(x, y) \leq T$ if there are no satisfying assignments. From the definition of values v_0, v_1, v_2, v_3 (in particular, $v_1 = (1+\delta)v_0$), we can easily conclude that $T'' \geq (1 + (\delta/10^5))T$ which gives the properties of x and y that we need.

Harder variants of the Block Disjoint Pairs problem

In the paragraph "Construction of the disjointness gadgets", we do the following construction. Given two vectors $z^k := A_i(k,\cdot), w^k := B_j(k,\cdot) \in \{0,1\}^{d \log N}$, we construct sequences $DG(z^k)$ and $DG(w^k)$ such that LCS between them is $LCS(z^k, w^k) = d/\alpha$ if the vectors are orthogonal and $LCS(z^k, w^k) = (d/\alpha) - 1$ otherwise. We split the vector z^k into d/α shorter vectors $z^k_1, \ldots, z^k_{d/\alpha} \in \{0,1\}^{\alpha \log N}$. Similarly, we split the vector w^k into d/α shorter vectors $w^k_1, \ldots, z^k_{d/\alpha} \in \{0,1\}^{\alpha \log N}$. We construct $DG(z^k)$ by replacing each shorter vector z^k_t by a symbol corresponding to it (indexed by the $\alpha \log N$ binary values) and its position. We construct $DG(w^k)$ by replacing each shorter vector w^k_t by a sequence of symbols corresponding to all vectors that are orthogonal to w^k_t. This implies that we have a large LCS score if there are many orthogonal pairs z^k_t, w^k_t of short vectors. Instead of replacing w^k_t by a sequence of symbols corresponding to all orthogonal vectors, we can take an arbitrary function $f^k_t : \{0,1\}^{2\alpha \log N} \to \{0,1\}$ and replace w^k_t by a sequence of symbols corresponding to all vectors $u \in \{0,1\}^{\alpha \log N}$ such that $f^k_t(u, w^k_t) = 1$. We recover the orthogonality constraint by choosing functions f^k_t that evaluates to 1 iff the two vectors are orthogonal. For arbitrary functions $f^k_1, \ldots, f^k_{d/\alpha} : \{0,1\}^{2\alpha \log N} \to \{0,1\}$, we get that $LCS(z^k, w^k) = d/\alpha$ if $f^k_1(z^k_1, w^k_1) = \ldots = f^k_{d/\alpha}(z^k_{d/\alpha}, w^k_{d/\alpha}) = 1$ and $LCS(z^k, w^k) = (d/\alpha) - 1$ otherwise. Clearly, the new version of Block Disjoint Pairs problem is harder to solve than the one restricted to the orthogonality constraints.

To further increase the hardness of the Block Disjoint Pairs problem we can define functions $g^k : \{0,1\}^{d/\alpha} \to \{0,1\}$ and require that $LCS(z^k, w^k) = q$ if

$$g^k(f^k_1(z^k_1, w^k_1), \ldots, f^k_{d/\alpha}(z^k_{d/\alpha}, w^k_{d/\alpha})) = 1$$

and $LCS(z^k, w^k) = q' < q$ otherwise (for some constants q and q'). Notice that previously all functions g^k are AND functions. This modification requires that the gap $(q/q') - 1$ is at least a constant (we have a constant gap for the AND function) and that the functions g^k can be efficiently simulated with LCS.

4.1 Hardness for Approximate Binary LCS and Edit Distance

The results in this section follow from simple observations over [5] that are easy to make with our framework in mind.

We refer the reader to [5] for the definition and background on Branching Programs.

▶ **Theorem 25** (Theorem 2 in [5]). *There is a reduction from SAT on nondeterministic branching programs on m variables, length T, and width W, to an instance of Edit-Distance or LCS on two binary sequences x and y of length $n = 2^{m/2} \cdot T^{O(\log W)}$, and the reduction runs in $O(n)$ time.*

We need additional properties of the reduction from Theorem 25.

▶ **Claim 26.** *Let P be the Branching Program that we want to reduce.*

If we reduce Branching Program P to LCS problem then we have the following two properties:

- *If P is not satisfiable, then $LCS(x,y) \leq C$ for some integer constant $C = C(m,T,W) \leq n$.*
- *If at least half of the assignments satisfy the Branching Program P, then $LCS(x,y) \geq C + (2^{m/2}/2)$.*

If we reduce Branching Program P to Edit-Distance problem then we have the following two properties:

- *If P is not satisfiable, then $Edit(x,y) \geq C$ for some integer constant $C = C(m,T,W) \leq n$.*

- *If at least half of the assignments satisfy the Branching Program P, then $Edit(x, y) \leq C - (2^{m/2}/2)$.*

Proof. The proof follows from the proof of Claim 9 in [5].

Consider the case when P is not satisfiable. The proof does not change - we show that LCS is upper bounded and Edit-Distance is lower bounded by some fixed quantity C.

Consider the case when P is satisfied by at least half of the assignments. In the proof of Claim 9 the authors choose an integer Δ such that the corresponding alignment pairs up two gadgets that form a satisfying assignment to the Branching Program P. When there are many satisfying assignments (at least half), we can show that there is an integer such in the corresponding alignment at least half of the assignments are satisfying. By the properties of the gadgets constructed in [5], we get the required lower bound on LCS and the required upper bound on Edit-Distance. ◀

Theorem 25 and Claim 26 combined give the following theorem.

▶ **Theorem 27.** *Suppose we have a $(1 + \delta)$ approximation algorithm for Edit-Distance or LCS with $\delta = o(1/T^{O(\log W)})$ that runs in $f(n) = f(2^{m/2} \cdot T^{O(\log W)})$ deterministic time for some function f. Then in time $f(2^{m/2} \cdot T^{O(\log W)})$ we can decide if a Branching program on m variables, length T and width W is not satisfiable or at last half of the assignments are satisfying.*

From the discussion in [5] on the connection between BPs and NC circuits, a lower bound for NC^1 follows. Namely, $1 + 1/\text{poly} \log n$ approximation algorithm implies that there exists $f \in \mathsf{E}^{\mathsf{NP}}$ such that $f \notin NC^1$.

Abstract

We investigate the parameters in terms of which the complexity of sublinear-time algorithms should be expressed. Our goal is to find input parameters that are tailored to the combinatorics of the specific problem being studied and design algorithms that run faster when these parameters are small. This direction enables us to surpass the (worst-case) lower bounds, expressed in terms of the input size, for several problems. Our aim is to develop a similar level of understanding of the complexity of sublinear-time algorithms to the one that was enabled by research in parameterized complexity for classical algorithms.

Specifically, we focus on testing properties of functions. By parameterizing the query complexity in terms of the size r of the image of the input function, we obtain testers for monotonicity and convexity of functions of the form $f : [n] \to \mathbb{R}$ with query complexity $O(\log r)$, with no dependence on n. The result for monotonicity circumvents the $\Omega(\log n)$ lower bound by Fischer (Inf. Comput., 2004) for this problem. We present several other parameterized testers, providing compelling evidence that expressing the query complexity of property testers in terms of the input size is not always the best choice.

1 Introduction

In this paper, we set out to investigate the parameters in terms of which the complexity of sublinear-time algorithms should be expressed. Our goal is to find input parameters that are tailored to the combinatorics of the specific problem being studied and design algorithms that run faster when these parameters are small. This direction could enable one to surpass the (worst-case) lower bounds on the problem complexity that are usually expressed in terms of the input size. The spirit of our study is similar to that in the field of parameterized complexity. In parameterized complexity, the focus is on expressing the complexity of problems as a function of one or more input parameters in order to obtain a fine-grained complexity classification, for example, of NP-hard problems. Our aim is to

develop a similar level of understanding of the complexity of sublinear-time algorithms to the one that was enabled by research in parameterized complexity for classical algorithms.

We focus our study on the framework of property testing, introduced by Goldreich et al. [28] and Rubinfeld and Sudan [40]. In property testing, an algorithm (an ε-tester) for property $\mathcal{P}$, where $\mathcal{P}$ is viewed as a class of functions, is given a parameter $\varepsilon \in (0,1)$ as input and has oracle access to a function f. The tester has to accept with probability at least $2/3$ if f belongs to the class $\mathcal{P}$, and reject with probability at least $2/3$ if f is *ε-far* from $\mathcal{P}$, that is, differs from every function in $\mathcal{P}$ on at least an ε fraction of function values. In the context of property testing of functions, the query complexity of a tester is usually expressed in terms of ε and the size of the domain of the input function. This works well for properties whose query complexity depends only on the proximity parameter ε. However, for other properties, it is not clear whether the domain size is the right parameter to express their testing complexity.

Consider, for example, the widely studied problem of testing monotonicity of real-valued functions (see, e.g., [27, 22, 23, 36, 26, 24, 31, 1, 32, 2, 11, 10, 13, 16, 12, 9, 17, 18, 15, 20, 19, 35, 4, 5, 21], and recent surveys [38, 14]). For functions over a discrete domain $[n]$ (also called the line), monotonicity testing is equivalent to testing sortedness of arrays. Algorithms for sortedness testing have found use, for instance, in determining the "state of sortedness" of relational databases [6], where the testing step is performed to decide on the sorting algorithms to be run on the database. The complexity of sortedness testing (for constant ε) is $\Theta(\sqrt{n})$ if the tester is only allowed to make independent and uniformly random queries [26]; it is $\Theta(\log n)$ if the tester is allowed to make arbitrary queries [23, 24].

From the above discussion, it might appear that one cannot make any more improvements to the complexity of monotonicity testing over $[n]$. However, we argue that this is the case only when the complexity of the problem is parameterized in terms of n, the domain size.

In this work, we ask whether better monotonicity testers can be designed by parameterizing the query complexity in terms of the size of the image of the input function. The starting point for our investigation is the folklore result that, for ε-testing monotonicity of Boolean functions over $[n]$, only $O(1/\varepsilon)$ queries suffice. A slightly more general corollary of this result is that monotonicity of functions over $[n]$ with image size at most 2 can be ε-tested with only $O(1/\varepsilon)$ queries. The only bound for monotonicity testing (over $[n]$) that is expressed in terms of the image size r of the input function is the bound of $\Omega(\log r)$ for nonadaptive[1] testers due to Blais et al. [12]. We design an ε-tester for monotonicity of functions over $[n]$ with query complexity $O((\log r)/\varepsilon)$, where r is an upper bound on the size of the image of the input function. This result circumvents Fischer's lower bound of $\Omega(\log n)$ for this problem by focusing on a different parameter for measuring query complexity.

The size of the image is one of the natural parameters in terms of which one can express the complexity of property testing algorithms. In this work, we show that there are several testing problems for which parameterizing the complexity in terms of the image size works well. Another example where parameterization has helped in the design of efficient testers is the work of Jha and Raskhodnikova [34] on Lipschitz testing, even though they do not view their results from this angle. The complexity of their testers is expressed in terms of the *image diameter*. The *image diameter* of a function $f : \mathcal{D} \mapsto \mathbb{R}$ is $\max_{x,y\in\mathcal{D}} |f(x) - f(y)|$. In many situations, the image diameter is much smaller than the domain size. We believe that all this evidence is compelling enough to make one rethink the way in which the complexity

[1] Testers whose queries do not depend on the answers to previous queries are called *nonadaptive*; general testers that do not satisfy this requirement are *adaptive*.

of sublinear-time algorithms is expressed. Our paper is a first step towards formalizing this notion and finding what we think are the right parameters to express the complexity of some central problems in sublinear-time algorithms.

1.1 Parameters and Properties Studied in this Work

We study the dependence of complexity of monotonicity and convexity testers on the image size of the input functions. The image of a function is defined as follows.

▶ **Definition 1.1** (Image of a function)**.** Let f be a function defined over a finite, discrete domain $\mathcal{D}$. The image of f, denoted $\mathrm{Im}(f)$, is the set $\{f(x) : x \in \mathcal{D}\}$ or, in other words, the set of all values taken by f on points in $\mathcal{D}$.

For the special case, when $\mathcal{D}$ is $[n]$, a function $f : [n] \mapsto \mathbb{R}$ can also be viewed as a real-valued array of length n. Here, $\mathrm{Im}(f)$ is equal to the set of distinct values in the array.

We restrict our attention to real-valued functions defined over the following domains. These are domains for which testing monotonicity and convexity have been studied extensively.

▶ **Definition 1.2** (Hypergrid, Hypercube, Line)**.** For $x \in [n]^d$, let x_i denote the i^{th} coordinate of x. A *hypergrid* is a partial order $([n]^d, \preceq)$ where $x \preceq y$ means that $x_i \leq y_i$ for all $x, y \in [n]^d$ and $i \in [d]$. The partial order $([2]^d, \preceq)$ is called a *hypercube* and the total order $([n], \preceq)$ is called a *line*.

Next, we summarize some of the previous work on testing monotonicity and convexity of real-valued functions.

Monotonicity. A function $f : \mathcal{D} \mapsto \mathbb{R}$ defined over a partial order $(\mathcal{D}, \preceq)$ is *monotone* if $f(x) \leq f(y)$ for all $x, y \in \mathcal{D}$ satisfying $x \preceq y$. Monotonicity is one of the most widely studied properties in the field of property testing [27, 22, 23, 36, 26, 24, 31, 1, 32, 2, 11, 10, 13, 16, 12, 9, 17, 18, 15, 20, 19, 35, 4, 5, 21]. The complexity of ε-testing monotonicity of functions of the form $f : [n]^d \mapsto \mathbb{R}$ is $\Theta\left(\frac{d \log n}{\varepsilon}\right)$ [16, 17]. For the special case of the line, the testing complexity is $\Theta\left(\frac{\log n}{\varepsilon}\right)$ [23, 24]. For functions defined over general poset domains $\mathcal{D}$, the complexity of monotonicity testing is $O\left(\sqrt{|\mathcal{D}|/\varepsilon}\right)$ [26].

Convexity. For a convex set $\mathcal{D}$, a function $f : \mathcal{D} \mapsto \mathbb{R}$ is convex if $\forall x, y \in \mathcal{D}$ and $t \in [0, 1]$, $f(tx + (1-t)y) \leq tf(x) + (1-t)f(y)$. For real-valued functions over $[n]$, convexity can be ε-tested using $O(\frac{\log n}{\varepsilon})$ queries [37]. This bound is tight (for constant ε) for nonadaptive testers [12].

1.2 Our Results

In this section, we describe the key technical contributions of our work. We design efficient testers for monotonicity over various hypergrid domains and convexity over the line. For monotonicity of functions over the line $[n]$, which is equivalent to the property of sortedness of arrays of length n, we design efficient testers under two different models of input access: (i) query access and (ii) uniform samples. Our testers are given an upper bound r on the image size of the input function, and their complexity is parameterized in terms of r.

Sortedness testing. We present our tester for sortedness of n-element arrays (monotonicity over the line $[n]$) in Section 3. The complexity of our tester is independent of n. Our tester has 1-sided error, that is, it always accepts a function with the property. (In contrast, the general tester is said to have 2-sided error.) We prove the following theorem.

▶ **Theorem 1.3.** *There exists a 1-sided error ε-tester making $O\left(\frac{\log r}{\varepsilon}\right)$ queries to test sortedness of arrays with at most r distinct values.*

An important ingredient in our sortedness tester is a nearly optimal nonadaptive tester for this task, presented in Section 2. Its performance is summarized in the next theorem.

▶ **Theorem 1.4.** *There exists a nonadaptive, 1-sided error ε-tester making $O\left(\frac{1}{\varepsilon}\log\frac{r}{\varepsilon}\right)$ queries to test sortedness of arrays with at most r distinct values.*

The query complexity of our nonadaptive tester matches (for constant ε) the $\Omega(\log r)$ lower bound for nonadaptive sortedness testers in [12]. Note that for $r \geq 1/\varepsilon$, the complexity of the nonadaptive tester is $O\left(\frac{\log r}{\varepsilon}\right)$. The tester that we design to prove Theorem 1.3 runs the nonadaptive tester for $r \geq 1/\varepsilon$ and a different (adaptive) tester, presented in Section 3, for $r < 1/\varepsilon$.

Uniform sortedness testing. The work that defined property testing [28], in addition to the model with oracle access to the input, also considered testers that are allowed access to function values only at points sampled uniformly and independently at random from the domain. This model of property testing, known as *uniform* or *sample-based* testing, was further studied by Goldreich and Ron [30], Fischer et al. [25], Berman et al. [8] and Berman et al. [7]. The query complexity of ε-testing sortedness of n-element arrays (for constant ε) using only uniformly and independently drawn samples is $\Theta(\sqrt{n})$ [26]. We design optimal (up to the dependence on ε) uniform testers whose query complexity is parameterized in terms of the number or distinct elements in the input arrays. These results can be found in Sections 5 and 6.

▶ **Theorem 1.5.** *There exists a 1-sided error ε-tester that makes $O(\sqrt{r}/\varepsilon)$ uniform and independent queries to test sortedness of arrays with at most r distinct values.*

▶ **Theorem 1.6.** *Testing sortedness of arrays with values in $[r]$ requires $\Omega(\sqrt{r})$ uniform queries, even with 2-sided error.*

Monotonicity testing over hypergrids. We present our tester for monotonicity of real-valued functions over hypergrid domains in Section 4 and prove the following theorem.

▶ **Theorem 1.7.** *There exists a 1-sided error ε-tester that makes $O\left(\frac{d}{\varepsilon}\log\frac{d}{\varepsilon}\log r\right)$ queries to test monotonicity of real-valued functions $f : [n]^d \mapsto \mathbb{R}$ over the hypergrid domain, where $|Im(f)| \leq r$.*

Note that our tester has a better complexity (up to log factors) than the optimal tester for monotonicity of real-valued functions over the hypergrid domains that makes $O\left(\frac{d\log n}{\varepsilon}\right)$ queries [16] for small r. Parameterizing the complexity of testing in terms of the image size of the functions being tested is what enables us to bypass the $\Omega\left(\frac{d\log n}{\varepsilon}\right)$ lower bound for monotonicity testing of functions over hypergrid domains in [17].

Convexity testing over the line. Finally, in Section 7, we give a nonadaptive convexity tester for real-valued functions over the line and prove the following theorem.

▶ **Theorem 1.8.** *There exists a nonadaptive, 1-sided error ε-tester for convexity of functions $f : [n] \mapsto \mathbb{R}$ that takes an integer $r \geq |Im(f)|$ as input and makes $O(1/\varepsilon)$ queries when $r < \varepsilon n/3$ and $O\left(\frac{\log(r/\varepsilon)}{\varepsilon}\right)$ queries otherwise.*

Recall that for real-valued functions over $[n]$, the complexity of (nonadaptively) ε-testing convexity (for constant ε) is $\Theta(\log n)$. Contrary to this, our tester makes only a constant number of queries when the image size of the function is small.

1.3 Related Work

A related concept of parameterized testability of graph properties was studied by Iwama and Yoshida [33]. The focus of their work was to design efficient algorithms for the property testing variants of several NP-hard decision problems on graphs, by expressing their complexity in terms of parameters that have been successfully used in the literature on parameterized algorithms. In most of the cases, the parameters that they used are NP-hard to compute. In contrast, our goal is to determine the right input parameters in terms of which to express the complexity of property testers and, more generally, sublinear-time algorithms. The parameters we use are often easy to compute or estimate and, in many situations, can be assumed to be given to the algorithm. We also believe that the parameters that we use are tied to the intrinsic combinatorial structure of the properties and give insights into complexity of testing them.

2 The Nonadaptive Sortedness Tester

In this section, we describe a nonadaptive, 1-sided error ε-tester for sortedness of arrays containing at most r distinct values and prove Theorem 1.4. Our tester (Algorithm 1) uses a proximity oblivious tester (POT) for sortedness as a subroutine.

▶ **Definition 2.1** (POT, Goldreich and Ron [29])**.** A *proximity oblivious tester* for a property $\mathcal{P}$ is an algorithm that has oracle access to a function f and

1. always accepts if $f \in \mathcal{P}$;
2. rejects with probability at least $\text{dist}(f, \mathcal{P})$ if $f \notin \mathcal{P}$, where $\text{dist}(f, \mathcal{P})$ is the minimum fraction of values in f that needs to be changed, so that $f \in \mathcal{P}$.

Observe that a POT for $\mathcal{P}$ can be repeated $O(1/\varepsilon)$ times to obtain a 1-sided error ε-tester for $\mathcal{P}$. We note that Definition 2.1 is a special case of the definition of POT in [29]. Specifically, Goldreich and Ron [29] allow the rejection probability of a POT to be a non-decreasing function of $\text{dist}(f, \mathcal{P})$. However, the special case in Definition 2.1 is sufficient for our purposes.

We now give an overview of Algorithm 1. It runs for $O(1/\varepsilon)$ iterations. In each iteration, it first runs a POT for sortedness on a subarray B of the input array A consisting of $1 + 2r/\varepsilon$ (nearly) equally spaced indices. Next, it picks an index $i \in [n]$ uniformly at random. It compares $A[i]$ with the array values of the indices closest to i that were included in B. Algorithm 1 rejects if either of these steps finds elements out of order.

At least three distinct POTs for sortedness of arrays with $O(\log n)$ query complexity are known [23, 10, 16]. We can use any of them in Algorithm 1. Note that Algorithm 1 is not proximity oblivious itself, as it uses the proximity parameter ε to determine its queries. For simplicity, we assume throughout that $2r/\varepsilon$ is an integer that divides n.

Algorithm 1: The Nonadaptive Sortedness Tester

input: query access to an array A of size n, an upper bound r on the number of distinct values in A, and a distance parameter $\varepsilon \in (0,1)$.

1 Let B be the subarray of A consisting of the indices $1, \frac{\varepsilon n}{2r}, \frac{2\varepsilon n}{2r}, \ldots, \left(\frac{2r}{\varepsilon}-1\right)\frac{\varepsilon n}{2r}, n$.
`// No need to explicitly construct` B.
2 **repeat** $\left\lceil \frac{8}{\varepsilon} \right\rceil$ **times**
3 Run a POT for sortedness of arrays (e.g., from [23], [10] or [16]) on B and **reject** if it rejects.
4 Query an index i from A uniformly at random.
5 Set $k = \left\lfloor \frac{2ri}{\varepsilon n} \right\rfloor + 1$. `// Note that` $B[k] = A\left[\frac{(k-1)\varepsilon n}{2r}\right]$ `and` $B[k+1] = A\left[\frac{k\varepsilon n}{2r}\right]$.
6 Query $B[k]$ and $B[k+1]$.
7 **Reject** if $(B[k], A[i], B[k+1])$ is not in sorted order.
8 **Accept**.

Proof of Theorem 1.4. We prove that Algorithm 1 is a nonadaptive, 1-sided error ε-tester making $O\left(\frac{1}{\varepsilon}\log\frac{r}{\varepsilon}\right)$ queries to test sortedness of arrays with at most r distinct values. Algorithm 1 is nonadaptive, since its queries can be chosen in advance. It has 1-sided error as it always accepts sorted arrays. Lemmas 2.2 and 2.3 complete the proof of Theorem 1.4. ◀

▶ **Lemma 2.2.** *Algorithm 1 makes $O\left(\frac{1}{\varepsilon}\log\frac{r}{\varepsilon}\right)$ queries.*

Proof. The query complexity of Step 3 is $O(\log|B|) = O(\log(r/\varepsilon))$. Steps 4-7 make a constant number of queries. Steps 3-7 are executed $O(1/\varepsilon)$ times. Hence, the overall query complexity of the tester is $O\left(\frac{1}{\varepsilon}\log\frac{r}{\varepsilon}\right)$. ◀

Recall that an array is *ε-far* from sorted if at least an ε fraction of elements need to be modified to make it sorted; otherwise, it is *ε-close* to sorted.

▶ **Lemma 2.3.** *Algorithm 1, with probability at least $2/3$, rejects every array that has at most r distinct values and is ε-far from sorted.*

Proof. Consider an array A that has at most r distinct values and is ε-far from sorted. Let B be the subarray of A as defined in Step 1 of Algorithm 1. If B is $\frac{\varepsilon}{7}$-far from sorted, then by the definition of POT for sortedness, Step 3 of our tester rejects with probability at least $\frac{\varepsilon}{7}$ in each iteration. In the rest of the proof, we consider the case when B is $\frac{\varepsilon}{7}$-close to sorted.

▶ **Claim 2.4.** If B is $\frac{\varepsilon}{7}$-close to sorted, then Steps 4-7 reject with probability at least $\frac{\varepsilon}{7}$ in each iteration.

Proof. The subarray B consists of $1 + 2r/\varepsilon$ (nearly) equally spaced indices, which partition A into $2r/\varepsilon$ intervals of nearly the same size. Let $\mathcal{I} = \{I_1, I_2, \ldots, I_{2r/\varepsilon}\}$ denote the set of these intervals. Here, I_1 denotes the interval[2] $\left[2..\frac{\varepsilon n}{2r}-1\right]$ and, for $k > 1$, the interval $\left[\frac{(k-1)\varepsilon n}{2r}+1..\frac{k\varepsilon n}{2r}-1\right]$ is denoted by I_k. Note that, by definition, $B[k]$ and $B[k+1]$ denote the values of the elements in A present immediately to the left and right of I_k, respectively.

An interval I_k is *nearly-constant* if $B[k] = B[k+1]$. Let $\mathcal{C}_t$ be the set of arrays with all their values equal to t. Let $A[I_k]$ denote the subarray of A on the indices in I_k. Let $d(I_k)$

[2] We use $[a..b]$ to denote $\{a, a+1, \ldots, b-1, b\}$ for $a, b \in \mathbb{Z}, a < b$.

and $D(I_k)$ denote the fractional and absolute Hamming distance of $A[I_k]$ from the property $\mathcal{C}_{B[k]}$. Note that $d(I_k) = D(I_k)/|I_k|$.

We now prove Claim 2.4 as follows in two steps. First, we show that $\sum_{I_k \in \mathcal{I}'} D(I_k) > \varepsilon n/7$, where $\mathcal{I}' = \{I_k \in \mathcal{I} : I_k \text{ is nearly-constant}\}$. Second, we show that Steps 4-7 of Algorithm 1 reject with probability at least $\sum_{k \in \mathcal{I}'} D(I_k)/n$ in each iteration.

Since B is $\frac{\varepsilon}{7}$-close to sorted, there exists a set S of at most $\varepsilon|B|/7$ indices in B whose values can be changed to make B sorted. Note that, for $r \geq 3$, we have $|S| < r/3$ since $|B| = 1 + 2r/\varepsilon$. Consider the set of intervals E_1 in $\mathcal{I}$ adjacent to at least one index from S. As each index in S is adjacent to at most two intervals, $|E_1| < 2r/3$.

Let E_2 denote the set of intervals in $\mathcal{I} \setminus E_1$ that are not nearly-constant. For all k such that $I_k \in E_2$, we have $B[k] < B[k+1]$. This is so because, if $B[k] > B[k+1]$, then $I_k \in E_1$ and if $B[k] = B[k+1]$, then I_k is nearly-constant. The total number of distinct values taken by the elements belonging to intervals in E_2 is at least $|E_2|$. But A has at most r distinct values, and hence, $|E_2| \leq r$. Consequently, $|E_1 \cup E_2| < \frac{2r}{3} + r = \frac{5r}{3}$.

Consider the subarray A'' of A induced by the indices in the intervals in $\mathcal{I} \setminus (E_1 \cup E_2)$. Let $D_{\mathcal{S}}(A)$ denote the absolute Hamming distance of the array A to the sortedness property. As $D_{\mathcal{S}}(A) \geq \varepsilon n$, we get $D_{\mathcal{S}}(A'') > \varepsilon n - \frac{5r}{3} \cdot \frac{\varepsilon n}{2r} = \frac{\varepsilon n}{6}$. Note that all the intervals in A'' are nearly-constant. Hence, $(\mathcal{I} \setminus (E_1 \cup E_2)) \subseteq \mathcal{I}'$ and, consequently,

$$\sum_{I_k \in \mathcal{I}'} D(I_k) \geq D_{\mathcal{S}}(A'') > \frac{\varepsilon n}{6} > \frac{\varepsilon n}{7}.$$

This completes the first step of the proof.

Consider a nearly-constant interval $I_k \in \mathcal{I}'$ such that $D(I_k) > 0$. As $B[k] = B[k+1]$, there exists $D(I_k)$ elements in I_k whose values are not $B[k]$, i.e.,

$$|\{x \in I_k : A[x] \neq B[k]\}| = D(I_k).$$

Algorithm 1 rejects if it samples an index $x \in I_k$ in Step 4 such that $B[k] = B[k+1]$ (i.e., $I_k \in \mathcal{I}'$) and $A[x] \neq B[k]$. As there are $\sum_{I_k \in \mathcal{I}'} D(I_k)$ such indices in A, Steps 4-7 of Algorithm 1 reject A with probability at least $\sum_{I_k \in \mathcal{I}'} D(I_k)/n$. Since $\sum_{I_k \in \mathcal{I}'} D(I_k) > \varepsilon n/7$, the proof of Claim 2.4 is complete. ◀

Hence, the probability that Steps 3-7 reject in each iteration is at least $\varepsilon/7$. The probability that Algorithm 1 accepts after $\lceil 8/\varepsilon \rceil$ iterations is at most $(1 - \varepsilon/7)^{8/\varepsilon} \leq e^{-8/7} < 1/3$. This completes the proof of Lemma 2.3. ◀

3 The Sortedness Tester with $O\left(\frac{\log r}{\varepsilon}\right)$ Query Complexity

In this section, we describe a 1-sided error ε-tester for sortedness of arrays containing at most r distinct values and prove Theorem 1.3. The tester, described in Algorithm 2, runs the nonadaptive tester (Algorithm 1) described in Section 2 when $r \geq 1/\varepsilon$, and a different procedure, which is described in Algorithm 2, otherwise.

Proof of Theorem 1.3. We prove that Algorithm 2 is a 1-sided error ε-tester making $O\left(\frac{\log r}{\varepsilon}\right)$ queries to test sortedness of arrays with at most r distinct values. When $r \geq 1/\varepsilon$, Algorithm 2 runs Algorithm 1 and outputs its answer. By Theorem 1.4, Algorithm 1 is a 1-sided error ε-tester with query complexity $O\left(\frac{1}{\varepsilon} \log \frac{r}{\varepsilon}\right)$ which is equal to $O\left(\frac{\log r}{\varepsilon}\right)$ as $r \geq 1/\varepsilon$. When $r < 1/\varepsilon$, Algorithm 2 only rejects if it finds array elements out of order, and so, it has 1-sided error. Lemmas 3.1 and 3.2 complete the proof of Theorem 1.3. ◀

Algorithm 2: The Sortedness Tester

input: query access to an array A of size n, an upper bound r on the number of distinct values in A, and distance parameter $\varepsilon \in (0, 1)$.

1 If $r \geq 1/\varepsilon$, run **Algorithm 1** and **return** its answer.
2 If $A[1] > A[n]$, **reject**.
3 Initialize a balanced binary search tree T to contain keys 1 and n.
`// Define` $\mathsf{successor}(i) = \min\{j \in T : j > i\}$; $\mathsf{predecessor}(i) = \max\{j \in T : j < i\}$.
4 **while** $\exists i, j \in T$ *such that* $j = \mathsf{successor}(i)$ *and* $|i - j| > \frac{\varepsilon n}{2r}$ *and* $A[i] < A[j]$ **do**
5 Set $m = \left\lfloor \frac{i+j}{2} \right\rfloor$ and query $A[m]$.
6 **if** $A[i] \leq A[m] \leq A[j]$ **then** insert m into T **else reject**.
7 **if** $i > 1$ *and* $A[\mathsf{predecessor}(i)] = A[i] = A[m]$ **then**
8 Delete i from T.
9 **if** $j < n$ *and* $A[m] = A[j] = A[\mathsf{successor}(j)]$ **then**
10 Delete j from T.
11 **repeat** $\left\lceil \frac{2 \ln 3}{\varepsilon} \right\rceil$ **times**
12 Sample an index x from $[n]$ uniformly at random and query $A[x]$.
13 **if** $(A[\mathsf{predecessor}(x)], A[x], A[\mathsf{successor}(x)])$ is not in sorted order **then reject**.
14 **Accept**.

▶ **Lemma 3.1.** *For $r < 1/\varepsilon$, Algorithm 2 makes $O\left(\frac{\log r}{\varepsilon}\right)$ queries.*

Proof. We first bound the query complexity of Steps 4-10. Let w be the number of times Steps 4-10 are run by Algorithm 2. For $k \in [0..w]$, let T_k be the snapshot of the binary search tree T of array indices (initialized in Step 3) at the end of iteration k. Note that $T_0 = \{1, n\}$ and T_w is the tree at the end of the algorithm. Let $V_k = \{v : v = A[i] \text{ for some } i \in T_k\}$ be the set of all array values of indices in T_k. Observe that once a value v is in V_k, it remains in $V_{k'}$ for all $k' > k$. For $v \in V_k$, define $\mathsf{successor\text{-}distance}(v, T_k) = |i - \mathsf{successor}(i)|$ such that $A[i] = v$ and $A[\mathsf{successor}(i)] \neq v$, where $\mathsf{successor}$ is defined with respect to the tree T_k (for $v = A[n]$, define $\mathsf{successor\text{-}distance}(v, T_k) = 0$). Consider the k^{th} iteration of Steps 4-10 where $k \in [w]$. In Step 4 of k^{th} iteration, an index $i \in T$ is chosen such that $\mathsf{successor\text{-}distance}(A[i], T_{k-1}) > \varepsilon n/2r$. At the end of the iteration, $\mathsf{successor\text{-}distance}(A[i], T_k) = \mathsf{successor\text{-}distance}(A[i], T_{k-1})/2$ ignoring the errors due to rounding. Generalizing this argument, for each iteration $k \in [w]$, there exists some $v_k \in V_{k-1} \setminus \{A[n]\}$, such that $\mathsf{successor\text{-}distance}(v_k, T_k) = \mathsf{successor\text{-}distance}(v_k, T_{k-1})/2$.

Fix $v^* \in V_w \setminus \{A[n]\}$. Let $k_1, k_2, \ldots, k_q \in [w]$, where $k_1 < k_2 < \ldots < k_q$, be the iterations where the choice of i in Step 4 satisfies $A[i] = v^*$. From the description of the tester, for any $i \in [2..q]$, we have $\mathsf{successor\text{-}distance}(v^*, T_{k_i}) = \mathsf{successor\text{-}distance}(v^*, T_{k_{i-1}})/2$. By extending this relation, we get $\mathsf{successor\text{-}distance}(v^*, T_{k_q}) = \mathsf{successor\text{-}distance}(v^*, T_{k_1})/2^{q-1}$. But $\mathsf{successor\text{-}distance}(v^*, T_{k_1}) < n$ and $\frac{\varepsilon n}{4r} < \mathsf{successor\text{-}distance}(v^*, T_{k_q}) \leq \frac{\varepsilon n}{2r}$. Solving for q, we get

$$2^{q-1} = \frac{\mathsf{successor\text{-}distance}(v^*, T_{k_1})}{\mathsf{successor\text{-}distance}(v^*, T_{k_q})} < \frac{n}{\varepsilon n/4r} = \frac{4r}{\varepsilon};$$

$$q < \log \frac{8r}{\varepsilon}.$$

Hence, the tester runs at most $\log(8r/\varepsilon)$ iterations where $\mathsf{successor\text{-}distance}(v^*, \cdot)$ is halved.

Accounting for all the iterations for each value in $V_w \setminus \{A[n]\}$, we get

$$w < |V_w| \cdot \log(8r/\varepsilon) \leq r \log(8r/\varepsilon),$$

since $|V_w| \leq r$. In each iteration, the tester makes a constant number of queries. So, the overall query complexity of Steps 4-10 is $O\left(r \log \frac{r}{\varepsilon}\right)$. The query complexity of Steps 11-13 is $O(1/\varepsilon)$. Hence, the overall query complexity of the tester is $O\left(\frac{1}{\varepsilon} + r \log \frac{r}{\varepsilon}\right)$.

Now, we prove that $O\left(r \log \frac{r}{\varepsilon}\right) = O\left(\frac{\log r}{\varepsilon}\right)$ for $r < 1/\varepsilon$. We have $O\left(r \log \frac{r}{\varepsilon}\right) = O\left(r \log \frac{1}{\varepsilon}\right)$ as $r < 1/\varepsilon$. Note that the function $g(x) = \frac{x}{\log x}$ is increasing for $x \geq 3$. Hence, for $r < 1/\varepsilon$, we have $\frac{r}{\log r} < \frac{1/\varepsilon}{\log(1/\varepsilon)}$, and hence $r \log \frac{1}{\varepsilon} < \frac{\log r}{\varepsilon}$. Therefore, the query complexity of Algorithm 2 is $O\left(\frac{\log r}{\varepsilon}\right)$. ◀

▶ **Lemma 3.2.** *Steps 2-14 of Algorithm 2, with probability at least 2/3, reject every array that has at most r distinct values and is ε-far from sorted, when $r < 1/\varepsilon$.*

Proof. Consider an array A that has at most r distinct values and is ε-far from sorted, where $r < 1/\varepsilon$. Algorithm 2 rejects whenever it finds elements out of order. We show that Steps 11-13 reject with probability at least 2/3, if Steps 2-10 do not find array elements out of order.

Consider the indices in the tree T at the end of the while loop. Let $E = \{j \in T : A[j] < A[\mathsf{successor}(j)]\}$ be the indices in T whose array values differ from that of their respective successor in T. As A has at most r distinct values, by Pigeonhole principle, $|E| < r$. Each $i \in E$ satisfies $|i - \mathsf{successor}(i)| \leq \varepsilon n/2r$. Define $E' = \{k \in [n] : i < k < \mathsf{successor}(i), i \in E\}$. Clearly, $|E'| \leq \frac{\varepsilon n}{2r} \cdot |E| < \frac{\varepsilon n}{2}$. Consider the subarray of A indexed by $[n] \setminus E'$. This subarray is $\frac{\varepsilon}{2}$-far from sorted as A is ε-far from sorted. Also, all $k \in [n] \setminus E'$ satisfy $\mathsf{predecessor}(k) < k < \mathsf{successor}(k)$ and $A[\mathsf{predecessor}(k)] = A[\mathsf{successor}(k)]$ (note that the definitions of $\mathsf{predecessor}$ and $\mathsf{successor}$ are applicable to all elements in $[n]$). That is, for all such indices k, we know what the element $A[k]$ should be if A is sorted. Recall that if $A[i] = A[j]$, then $[i..j]$ constitutes a *nearly-constant* interval, as defined in Section 2. By the proof method used in Lemma 2.3, there exists at least $\varepsilon n/2$ indices of the form $k \in [n]$ such that $A[\mathsf{predecessor}(k)] = A[\mathsf{successor}(k)]$ and $A[k] \neq A[\mathsf{successor}(k)]$. The probability that Steps 12 and 13 fail to capture such an index in any of its $\left\lceil \frac{2 \ln 3}{\varepsilon} \right\rceil$ iterations is at most

$$(1 - \varepsilon/2)^{\frac{2 \ln 3}{\varepsilon}} \leq 1/3.$$ ◀

4 The Monotonicity Tester over Hypergrids

In this section, we describe a monotonicity tester for functions over hypergrid domains and prove Theorem 1.7. We prove the correctness of this tester using the correctness of the sortedness tester described in Section 3, a dimension reduction theorem by Chakrabarty et al. [15] and the work investment strategy by Berman et al. [9].

An axis-parallel line ℓ of the hypergrid $[n]^d$ is a set of n points that agree on all but one coordinate. Let $f|_\ell$ denote the restriction of a function f to ℓ. Note that $f|_\ell$ can be thought of as a real-valued function over $[n]$.

The tester iteratively samples uniformly random axis-parallel lines, runs Algorithm 2 on each of them, and rejects if any run of Algorithm 2 rejects. We now analyze the tester and prove Theorem 1.7.

Proof of Theorem 1.7. We prove that Algorithm 3 is a 1-sided error ε-tester that makes $O\left(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon} \log r\right)$ queries to test monotonicity of real-valued functions $f : [n]^d \mapsto \mathbb{R}$ over the

Algorithm 3: The Monotonicity Tester over Hypergrids

input: query access to $f : [n]^d \mapsto \mathbb{R}$, an upper bound r on $|\mathrm{Im}(f)|$, and a distance parameter $\varepsilon \in (0, 1)$.

1 **for** $i = 1$ *to* $\left\lceil 3 \log \frac{4d}{\varepsilon} \right\rceil$ **do**
2 **repeat** $\left\lceil \frac{16d \ln 4}{2^i \varepsilon} \right\rceil$ **times**
3 Sample a uniformly random axis-parallel line ℓ.
4 Repeat twice: run Algorithm 2 on the array induced by $f|_\ell$, with the distance parameter set to 2^{-i} and the upper bound on the number of distinct elements set to r; **reject** if it rejects at least once.
5 **Accept**.

hypergrid domain, where $|\mathrm{Im}(f)| \leq r$. Algorithm 3 has 1-sided error because Algorithm 2, which it runs as a subroutine, has 1-sided error. Lemmas 4.1 and 4.2 complete the proof of Theorem 1.7. ◀

▶ **Lemma 4.1.** *Algorithm 3 makes* $O\left(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon} \log r\right)$ *queries.*

Proof. The query complexity of a single execution of Step 4 during the i^{th} iteration of the outermost loop (Step 1) is $O(2^i \log r)$. As Step 4 is repeated $O\left(\frac{d}{2^i \varepsilon}\right)$ times in the i^{th} iteration, the overall query complexity of the i^{th} iteration of the tester is $O\left(\frac{d}{\varepsilon} \log r\right)$. The outermost loop is executed $O(\log \frac{d}{\varepsilon})$ times, and hence the query complexity of the tester is $O\left(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon} \log r\right)$. ◀

▶ **Lemma 4.2.** *Algorithm 3, with probability at least* $2/3$*, rejects every function over the hypergrid domain which is* ε*-far from sorted and has image size is at most* r*.*

Proof. Let $f : [n]^d \mapsto \mathbb{R}$ be ε-far from monotone, with $|Im(f)| \leq r$. Let $\mathcal{L}_{n,d}$ denote the set of all axis-parallel lines in $[n]^d$ and $d_{\mathcal{M}}(f)$ denote the relative distance of f to monotonicity. We also use $d_{\mathcal{M}}(f|_\ell)$ to denote the relative distance to monotonicity of the function $f|_\ell$. We have $|\mathrm{Im}(f|_\ell)| \leq r$ since $|\mathrm{Im}(f)| \leq r$. We use the following dimension reduction theorem proved by Chakrabarty et al. [15].

▶ **Theorem 4.3** (Chakrabarty et al. [15])**.**

$$\mathbb{E}_{\ell \leftarrow \mathcal{L}_{n,d}}[d_{\mathcal{M}}(f|_\ell)] \geq \frac{d_{\mathcal{M}}(f)}{4d}.$$

We note that Theorem 4.3 is a special case of the dimension reduction theorem proved in [15]. Clearly, if $d_{\mathcal{M}}(f) \geq \varepsilon$, then, $\mathbb{E}_{\ell \leftarrow \mathcal{L}_{n,d}}[d_{\mathcal{M}}(f|_\ell)] \geq \varepsilon/4d$. We use the work investment strategy due to Berman et al. [9] to extend the monotonicity tester on the line domain to the hypergrid domain.

▶ **Theorem 4.4** (Berman et al. [9])**.** *For a random variable* $X \in [0, 1]$ *with* $\mathbb{E}[X] \geq \mu$ *for* $\mu < 1/2$*, let* $p_i = \Pr[X \geq \frac{1}{2^i}]$ *and* $\delta \in (0, 1)$ *be the desired probability of error. Let* $k_i = \frac{4 \ln 1/\delta}{2^i \mu}$*. Then,*

$$\prod_{i=1}^{\lceil 3 \log(1/\mu) \rceil} (1 - p_i)^{k_i} \leq \delta.$$

Algorithm 4: The Uniform Sortedness Tester

input: query access to an array A of size n, an upper bound r on the number of distinct values in A, and a distance parameter $\varepsilon \in (0,1)$.

1 Sample $\left\lceil \frac{24\sqrt{r}}{\epsilon} \right\rceil$ indices from A uniformly and independently at random.

2 **Reject** if the array restricted to the sampled indices is not sorted; otherwise, **accept**.

Consider running Algorithm 3 on f. Let $X = d_{\mathcal{M}}(f|_\ell)$, where ℓ is sampled uniformly at random from $\mathcal{L}_{n,d}$. We apply the work investment strategy (Theorem 4.4) on X with error probability $\delta = 1/4$. By Theorem 4.3, $\mathbb{E}[X] \geq \varepsilon/4d$. Thus, in Theorem 4.4, we set $\mu = \varepsilon/4d$ and $k_i = \frac{16d \ln 4}{2^i \varepsilon}$ for all $i \in \left[\left\lceil 3 \log \frac{4d}{\varepsilon} \right\rceil\right]$. By Theorem 4.4, with probability at least 3/4, for some $i \in \left[\left\lceil 3 \log \frac{4d}{\varepsilon} \right\rceil\right]$, we sample a line ℓ such that $d_{\mathcal{M}}(f|_\ell) \geq 2^{-i}$ in Step 3. Conditioned on sampling such a line, Step 4 rejects ℓ with probability at least 8/9. Thus, given a function f that is ε-far from sorted, Algorithm 3 rejects f with probability at least $\frac{3}{4} \cdot \frac{8}{9} = \frac{2}{3}$, as required. This completes the proof of Lemma 4.2. ◀

Note on a nonadaptive tester for hypergrids. We can get a nonadaptive, 1-sided error ε-tester for monotonicity over hypergrids by using Algorithm 1 instead of Algorithm 2 in Step 4 of Algorithm 3. The same analysis goes through for this case and the overall query complexity of the tester is $O\left(\frac{d}{\varepsilon} \log \frac{d}{\varepsilon} \log \frac{rd}{\varepsilon}\right)$.

5 The Uniform Tester for Sortedness

In this section, we describe a nonadaptive ε-tester that makes $O(\sqrt{r}/\varepsilon)$ uniform and independent queries to test sortedness of arrays containing at most r distinct values and prove Theorem 1.5.

Our tester is Algorithm 4. The bound on the query complexity of the tester follows directly from its description. The tester has 1-sided error as it always accepts sorted arrays. In the rest of the section, we show that, with high probability, the tester rejects arrays that are ε-far from sorted.

▶ **Lemma 5.1.** *Algorithm 4, with probability at least 2/3, rejects every array that has at most r distinct elements and is ε-far from sorted.*

Proof. Consider an array A that has at most r distinct values and is ε-far from sorted. Recall that a pair of indices (x, y), where $x, y \in [n]$ and $x < y$, is *violated* in an array A if $A(x) > A(y)$. Consider the undirected *violation graph* $G = ([n], E)$ of A, where an edge $\{u, v\} \in E$ if (u, v) is a violated pair. Dodis et al. [22, Lemma 7] show that if A is ε-far from sorted then G has a matching M of size at least $\varepsilon n/2$.

For a pair $(x, y) \in [n] \times [n]$ such that $x < y$, we refer to x as its lower endpoint and y as its higher endpoint. We first partition the pairs in M into r classes as follows. Let $v_1 < v_2 < \cdots < v_r$ be the values in the range. A pair $(x, y) \in M$ such that $x < y$ belongs to the i^{th} class C_i, if $A(x) = v_i$. Note that C_1 is empty. For each $i \in [r]$, let C_i^{L} and C_i^{H} denote the set of lower and higher endpoints of pairs in C_i, respectively. Note that $|C_i| = |C_i^{\text{L}}| = |C_i^{\text{H}}|$. For each $i \in [r]$, define the i^{th} lower bucket B_i^{L} to consist of the smallest $\lceil |C_i|/2 \rceil$ indices in C_i^{L} and the i^{th} higher bucket B_i^{H} to consist of the largest $\lceil |C_i|/2 \rceil$ indices in C_i^{H}. Note that $\left|\bigcup_{i \in [r]} B_i^{\text{L}}\right| = \left|\bigcup_{i \in [r]} B_i^{\text{H}}\right| \geq \varepsilon n/4$. It is easy to see that for each $i \in [r]$,

every pair in $B_i^{\mathrm{L}} \times B_i^{\mathrm{H}}$ is a violated pair. Therefore, if an algorithm samples indices from both B_i^{L} and B_i^{H}, for some $i \in [r]$, it rejects. To bound the probability of this event from below, we use the following generalization of the Birthday Paradox proved by Goldreich et al. [27, Lemma 19].

▶ **Claim 5.2** ([27, Lemma 19]). Let $S_1, S_2 \ldots, S_r, T_1, T_2 \ldots, T_r$ be disjoint subsets of a universe U. For each $i \in [r]$, let $p_i = |S_i|/|U|$ and $q_i = |T_i|/|U|$. Let $\rho = \sum_i \min\{p_i, q_i\}$. Then, if we uniformly sample $6\sqrt{r}/\rho$ elements from U, with probability at least $2/3$, for some $i \in [r]$, the sample will contain at least one element from both S_i and T_i.

If we set $S_i = B_i^{\mathrm{L}}$ and $T_i = B_i^{\mathrm{H}}$ for each $i \in [r]$ in Claim 5.2, we have $\rho \geq \varepsilon/4$. Therefore, a uniform sample of $24\sqrt{r}/\varepsilon$ points from $[n]$, with probability at least $2/3$, will have, for some $i \in [r]$, an index from B_i^{L} and B_i^{H}, and the algorithm will reject. This completes the proof of the lemma. ◀

6 A Lower Bound for the Uniform Sortedness Tester

In this section, we prove that $\Omega(\sqrt{r})$ uniform queries are required to test sortedness of an array with at most r distinct values, even when one allows for 2-sided error, and prove Theorem 1.6. The proof uses Yao's principle [41], the version with two distributions (see, e.g., Raskhodnikova and Smith [39]). We first define two hard distributions $\mathcal{P}$ and $\widehat{\mathcal{N}}$ on arrays with r distinct values such that every array drawn from $\mathcal{P}$ is in sorted order and every array drawn from $\widehat{\mathcal{N}}$ is $\frac{1}{8}$-far from sorted. We then show that, for any tester that uses $o(\sqrt{r})$ uniform queries, the statistical difference between tester's views of the two distributions is small, and hence, with high probability, it cannot distinguish between the distributions.

The statistical distance between two distributions $\mathcal{D}_1$ and $\mathcal{D}_2$, denoted by $\mathrm{SD}(\mathcal{D}_1, \mathcal{D}_2)$, is defined as

$$\mathrm{SD}(\mathcal{D}_1, \mathcal{D}_2) = \max_{S \subseteq (\mathrm{support}(\mathcal{D}_1) \cup \mathrm{support}(\mathcal{D}_2))} \left(\left| \Pr_{x \leftarrow \mathcal{D}_1}[x \in S] - \Pr_{x \leftarrow \mathcal{D}_2}[x \in S] \right| \right).$$

We write $\mathcal{D}_1 \approx_\delta \mathcal{D}_2$ to denote $\mathrm{SD}(\mathcal{D}_1, \mathcal{D}_2) \leq \delta$.

Proof of Theorem 1.6. First, we define distributions $\mathcal{P}$ and $\mathcal{N}$ on arrays of size n taking values in the set $[r]$, where $n \geq 16r \ln 8r$. Without loss of generality, we assume that r is an even number that divides n.

The distribution $\mathcal{P}$ is constructed as follows. Partition an n-element array into $r/2$ blocks, each of length $2n/r$. For $i \in [r/2]$, set the values in the i^{th} block of the array to $((2i-1), 2i, 2i, \ldots, 2i)$ with probability $1/2$ and $((2i-1), (2i-1), \ldots, (2i-1), 2i)$ with probability $1/2$, independent of the other blocks.

The distribution $\mathcal{N}$ is constructed as follows. As before, partition an n-element array into $r/2$ blocks, each of length $2n/r$. For $i \in [r/2]$, set the first value in the i^{th} block to $(2i-1)$ and the last value to $2i$. The values at all other indices in that block are set to either $(2i-1)$ or $2i$ uniformly and independently at random.

Note that every array drawn from $\mathcal{P}$ is in sorted order. We will show that, with high probability, an array drawn from $\mathcal{N}$ is $\frac{1}{8}$-far from sorted.

▶ **Lemma 6.1.** *Let E denote the event that an array chosen according to $\mathcal{N}$ is $\frac{1}{8}$-far from sorted. Then,*

$$\Pr[E] > \frac{5}{6}.$$

Proof. Consider an array A chosen according to $\mathcal{N}$. Consider the i^{th} block of A for some $i \in [r/2]$. Let Y_{2i} denote the number of elements with value $2i$ in the first half of this block and Y_{2i-1} denote the number of elements with value $(2i-1)$ in the second half of the block. As the size of each half of the block is n/r, and the value at each index (except for the first and the last index) is assigned either $(2i-1)$ or $2i$ uniformly and independently at random,

$$\mathbb{E}[Y_{2i}] = \mathbb{E}[Y_{2i-1}] = \frac{n}{2r} - \frac{1}{2}.$$

By a Chernoff bound, for all $i \in \left[\frac{r}{2}\right]$,

$$\begin{aligned}\Pr\left[Y_{2i} \le \frac{n}{4r}\right] = \Pr\left[Y_{2i-1} \le \frac{n}{4r}\right] &= \Pr\left[Y_{2i-1} \le \left(1 - \frac{n-2r}{2(n-r)}\right)\left(\frac{n}{2r} - \frac{1}{2}\right)\right] \\ &\le \exp\left(-\frac{n}{16r} \cdot \frac{(n-2r)^2}{n(n-r)}\right) \\ &< \frac{1}{6r}.\end{aligned}$$

If $Y_{2i} > n/4r$ and $Y_{2i-1} > n/4r$, then at least $n/4r$ elements in i^{th} block need to be changed to make it sorted, as all the indices with value $2i$ in the first half or all the indices with value $2i-1$ in the last half need to be changed. By the union bound,

$$\Pr\left[\bigvee_{j=1}^{r}\left(Y_j \le \frac{n}{4r}\right)\right] \le r \cdot \Pr\left[Y_1 \le \frac{n}{4r}\right] < \frac{1}{6}.$$

With probability at least $5/6$, we have $Y_{2i} > n/4r$ and $Y_{2i-1} > n/4r$ for all $i \in [r/2]$. This implies that at least $n/4r$ elements need to be changed in each of the $r/2$ blocks to make it sorted. Hence, with probability at least $5/6$, the array A is $\frac{1}{8}$-far from sorted. ◀

Denote the conditional distribution $\mathcal{N}|_E$ by $\widehat{\mathcal{N}}$. Any instance sampled according to $\widehat{\mathcal{N}}$ is $\frac{1}{8}$-far from sorted. The statistical distance $\mathrm{SD}(\mathcal{N}, \widehat{\mathcal{N}})$ can be bounded using the following lemma proven by Raskhodnikova and Smith [39].

▶ **Lemma 6.2** ([39, Claim 4]). *Let E be an event that happens with probability at least $1-\delta$ under the distribution $\mathcal{D}$. Then, $\mathcal{D} \approx_{\delta'} \mathcal{D}|_E$, where $\delta' = \frac{1}{1-\delta} - 1$.*

Applying Lemma 6.2 to $\mathcal{N}$ and $\widehat{\mathcal{N}}$, we get $\mathcal{N} \approx_{1/5} \widehat{\mathcal{N}}$.

Consider any $\frac{1}{8}$-tester for sortedness that makes q queries where $q \le \sqrt{r}/5$. Define $\mathcal{P}$-view to be the distribution of values at the q locations queried by the tester in an array sampled according to $\mathcal{P}$. Similarly, define $\mathcal{N}$-view and $\widehat{\mathcal{N}}$-view. Next, we show that it is hard to distinguish $\mathcal{P}$-view from $\widehat{\mathcal{N}}$-view.

▶ **Lemma 6.3.**

$$SD(\mathcal{P}\text{-view}, \widehat{\mathcal{N}}\text{-view}) < \frac{1}{3}.$$

Proof. Let F denote the event that at least 2 out of the tester's q uniform samples from an array A are from the same block. An upper bound on the probability of this event can be obtained using the following lemma.

▶ **Lemma 6.4** (Bellare and Rogaway [3]). *Consider q balls and N bins, where each ball is assigned uniformly and independently at random to one of the bins. The probability that there exists a pair of balls assigned to the same bin is at most $\frac{q(q-1)}{2N}$.*

Algorithm 5: The Convexity Tester

input: query access to $f : [n] \mapsto \mathbb{R}$, an upper bound r on $|\mathrm{Im}(f)|$, and a distance parameter $\varepsilon \in (0, 1)$.

if $r \geq \frac{\varepsilon n}{3}$ **then**

1 Run the ε-tester for convexity by Parnas et al. [37] on f and **reject** if it rejects.

else

2 Let $M \leftarrow [r + 1, \ldots, n - r]$.

3 Sample $\lceil \frac{4}{\varepsilon} \rceil$ indices from M uniformly and independently at random.

4 **Reject** if f restricted to those indices is not constant.

5 **Accept**.

By Lemma 6.4, we get $\Pr[F] \leq \frac{q(q-1)}{2 \cdot r/2} < \frac{q^2}{r} = \frac{1}{25}$. Then, by Lemma 6.2,

$$\mathcal{P}\text{-view} \approx_{1/24} \mathcal{P}\text{-view}|_{\overline{F}}; \tag{1}$$

$$\mathcal{N}\text{-view} \approx_{1/24} \mathcal{N}\text{-view}|_{\overline{F}}. \tag{2}$$

Since $\mathcal{N} \approx_{1/5} \widehat{\mathcal{N}}$, the definition of statistical difference implies that

$$\mathcal{N}\text{-view} \approx_{1/5} \widehat{\mathcal{N}}\text{-view}. \tag{3}$$

It remains to show that $\mathcal{P}\text{-view}|_{\overline{F}} = \mathcal{N}\text{-view}|_{\overline{F}}$. Let x be an index in the i^{th} block, for some $i \in [r/2]$. If x is neither the first nor the last index of i^{th} block, then $\Pr[A[x] = (2i-1)] = \Pr[A[x] = 2i] = 1/2$ irrespective of whether $A \leftarrow \mathcal{P}$ or $A \leftarrow \mathcal{N}$. If x is the first or the last index of the i^{th} block, then $A[x]$ is fixed to the same value under both $\mathcal{P}$ and $\mathcal{N}$. If $\overline{F}$ holds, then at most 1 index from each block is sampled by the tester. By the definition of $\mathcal{P}$ and $\mathcal{N}$, for any two indices from different blocks, the values assigned to them are independent of each other. Hence, $\mathcal{P}\text{-view}|_{\overline{F}} = \mathcal{N}\text{-view}|_{\overline{F}}$. By (1)-(3),

$$\mathrm{SD}(\mathcal{P}\text{-view}, \widehat{\mathcal{N}}\text{-view}) \leq \frac{1}{24} + \frac{1}{24} + \frac{1}{5} < \frac{1}{3}.$$

This completes the proof of Lemma 6.3. ◀

By Yao's principle [41], as stated in [39, Claim 5], for $q \leq \sqrt{r}/5$, it is hard for any $\frac{1}{8}$-tester using q uniform queries to distinguish $\mathcal{P}$ from $\widehat{\mathcal{N}}$. Thus, uniform testers for sortedness of arrays with values in $[r]$ require $\Omega(\sqrt{r})$ queries. This completes the proof of Theorem 1.6. ◀

7 Testing Convexity

In this section, we describe a nonadaptive tester for convexity of functions $f : [n] \mapsto \mathbb{R}$ and prove Theorem 1.8. Recall that a function $f : [n] \mapsto \mathbb{R}$ is convex if $f(i)-f(i-1) \leq f(i+1)-f(i)$ for $1 < i \leq n$. Our convexity tester is Algorithm 5. It uses the nonadaptive convexity tester of Parnas et al. [37] as a black box.

The query complexity of our tester is $O(1/\varepsilon)$ when $r < \varepsilon n/3$, as is evident from its description. In the other case, $n \leq 3r/\varepsilon$, our tester runs the tester of [37], which makes $O(\log n/\varepsilon)$ queries. Substituting the upper bound on n, we get the query complexity bound claimed in Theorem 1.8.

Given a function $f : [n] \mapsto \mathbb{R}$ and a set $S \subseteq [n]$, let f_S denote the restriction of f to the indices in S whenever $S \neq \emptyset$. To prove the correctness of our tester, we first prove the following characterization of convex functions with image size at most r.

▶ **Claim 7.1.** If $f : [n] \mapsto \mathbb{R}$ is convex and $|\text{Im}(f)| \leq r$, then f_M for $M = [r+1..n-r]$ is a constant function.

Proof. We can assume that $r < n/2$, for otherwise, $M = \emptyset$. Assume for the sake of contradiction that there exists points $x, x+1 \in M$ such that $f_M(x) \neq f_M(x+1)$. If $f_M(x) < f_M(x+1)$, then f has to be monotonically increasing on the domain restricted to $[x+1, \ldots, n]$, which has more than r elements in it as $x < n - r + 1$. By the pigeonhole principle, this results in a contradiction, as $|\text{Im}(f)| \leq r$. If $f_M(x) > f_M(x+1)$, then f has to be monotonically decreasing on the set $[1, \ldots, x+1]$, which has more than r elements in it since $x \geq r$. By the pigeonhole principle, this also leads to a contradiction, as $|\text{Im}(f)| \leq r$. Hence, f can take only one value on M and therefore, f_M is a constant function. ◀

We will now show that the tester accepts every function that is convex and rejects with probability at least 2/3, every function that is ε-far from convex.

▶ **Lemma 7.2.** *Consider a function $f : [n] \mapsto \mathbb{R}$. Algorithm 5, on input $r \geq |Im(f)|$ and ε, accepts if f is convex and rejects, with probability at least 2/3, if f is ε-far from convex.*

Proof. If $r \geq \frac{\varepsilon n}{3}$, Algorithm 5 runs the tester for convexity by [37], and so the correctness follows from their analysis.

Consider the case where $r < \varepsilon n/3$. It follows from Claim 7.1 that Algorithm 5 accepts f if it is convex. Now assume that f is ε-far from convex. It remains to prove that f_M is $\varepsilon/3$-far from being a constant function, where $M = [r+1, \ldots, n-r]$. Assume for the sake of contradiction that f_M is $\varepsilon/3$-close to constant. We will construct a convex function $g : [n] \mapsto \mathbb{R}$ such that g is ε-close to f and satisfies $|\text{Im}(g)| \leq r$. This will give us the required contradiction. Let the constant function closest to f_M be h, where $h(x) = c$ for every $x \in M$. The function g is then defined as a constant function taking the value c on all points in $[n]$. Since the Hamming distance of f_M from h is at most $\varepsilon n/3$, the total Hamming distance of f from g is at most $\varepsilon n/3 + 2r < \varepsilon n$. This contradicts the fact that f is ε-far from convex. Hence, f_M is $\frac{\varepsilon}{3}$-far from being a constant function. The probability that $4/\varepsilon$ samples fail to detect that f_M is $\varepsilon/3$-far from constant is at most $(1 - \varepsilon/3)^{4/\varepsilon} \leq \exp(-4/3) < 1/3$. ◀

Abstract

Instances of computational problems do not exist in isolation. Rather, multiple and correlated instances of the same problem arise naturally in the real world. The challenge is how to gain computationally from correlations when they can be found. [DGH, ITCS 2015] showed that significant computational gains can be made by having access to auxiliary instances which are correlated to the primary problem instance *via the solution space*. They demonstrate this for constraint satisfaction problems, which are *NP-hard* in the general worst case form.

Here, we set out to study the impact of having access to correlated instances on the complexity of *polynomial time problems*. Namely, for a problem P that is conjectured to require time n^c for $c > 0$, we ask whether access to a few instances of P that are correlated in some natural way can be used to solve P on one of them (the designated "primary instance") faster than the conjectured lower bound of n^c.

We focus our attention on a number of problems: the Longest Common Subsequence (LCS), the minimum Edit Distance between sequences, and Dynamic Time Warping Distance (DTWD) of curves, for all of which the best known algorithms achieve $\tilde{O}(n^2)$ runtime via dynamic programming. These problems form an interesting case in point to study, as it has been shown that a $O(n^{2-\epsilon})$ time algorithm for a worst-case instance would imply improved algorithms for a host of other problems as well as disprove complexity hypotheses such as the *Strong Exponential Time Hypothesis*.

We show how to use access to a logarithmic number of auxiliary correlated instances, to design novel $o(n^2)$ time algorithms for LCS, EDIT, DTWD, and more generally improved algorithms for *computing any tuple-based similarity measure* - a generalization which we define within on strings. For the multiple sequence alignment problem on k strings, this yields an $O(nk \log n)$ algorithm contrasting with classical $O(n^k)$ dynamic programming.

Our results hold for several correlation models between the primary and the auxiliary instances. In the most general correlation model we address, we assume that the primary instance is a worst-case instance and the auxiliary instances are chosen with uniform distribution subject to the constraint that their allignments are ϵ-correlated with the optimal allignment of the primary instance. We emphasize that optimal solutions for the auxiliary instances will not generally coincide withan optimal solutions for the worst case primary instance.

We view our work as pointing out a new avenue for looking for significant improvements for sequence alignment problems and computing similarity measures, by taking advantage of access to sequences which are correlated through natural generating processes. In this first work we show how to take advantage of mathematically inspired simple clean models of correlation – the intriguing question, looking forward, is to find correlation models which coincide with evolutionary models and other relationships and for which our approach to multiple sequence alignment gives provable guarantees.

1 Introduction

A recent work of Dinur, Goldwasser, and Lin [6] which appeared in ITCS 2015 puts forth the following thesis: "Instances of computational problems of interest rarely exist in isolation, rather, multiple and correlated instances of the same problem arise naturally in the real world. The challenge is not to find settings which present correlated instances, but how to take advantage of correlations when they exist." Obvious examples are in biology where learning genotype to phenotype mappings of an organism can draw on data from multiple specimens with highly correlated DNA; or when multiple files are stored on (or transmitted over) the same error-prone medium, then error patterns in one file may be correlated to error patterns in other files which can be useful for error detection and recovery.

Indeed [DGH, ITCS 2015] show that significant computational gains can be made in solving instances of intractable combinatorial problems, when additional auxiliary instances are available which are *correlated to the primary instance via the solution space*. In particular, they show for several correlation models on the auxiliary instances polynomial time algorithms for constraint satisfaction problems which are NP-hard in the traditional worst case single-instance setting. Similarly, the work of Heninger et al [8] provides examples of number-theoretic problems where correlated cryptographic keys for the RSA function chosen due to poorly designed pseudorandom number generators enable efficient factorization of the RSA moduli involved. The works of [6] and [8] show that access to a polynomial number of auxiliary (but correlated) instances can enable us to find a polynomial time solution to an otherwise **intractable problem**.

In this paper, we set out to study the impact of having access to correlated instances on the complexity of **tractable problems**. Namely, for a polynomial time problem P, we ask whether we can use access to multiple instances of P that are correlated in some natural way, to solve P on one of them – the designated "primary instance" of size n– faster than the conjectured lower bound of n^c.

The question of which polynomial time problems to study is non-obvious. To draw meaningful conclusions from an algorithmic improvement to a polynomial time problem, one should choose problems which are at the same time classical and well-studied and for which there is hopefully some formal evidence to the complexity barrier they face, possibly in the form of a conditional lower bound. An approach for showing conditional lower bounds on a problem P which has gained significant prominence in the last few years and dates back to 1995[7], is to assume a lower bound on the complexity of one long standing open problem Q such as 3SUM or orthogonal-vectors and show a fine-grained reduction of Q to P which implies that any significant algorithmic improvement to P will imply an algorithmic improvement to Q. Another approach has been to show exact polynomial time lower bounds on P under complexity conjectures such as the Strong Exponential Time Hypothesis(SETH) which was introduced by Impagliazzo and Paturi[10] and asserts that solving satisfiability cannot be done significantly faster than exhaustive search.

This "conditional lower bound approach" has been successfully applied, as we detail below, [4, 1, 5] to various problems which compute similarity measures between strings, sequences

and curves, including computing the Longest Common Subsequence (LCS) between pairs and k-tuples of strings (kLCS), computing the minimal Edit Distance (EDIT) between pairs of strings and the dynamic time warping distance (DTWD) between curves. All these problems are currently addressed by dynamic programming algorithms which run in *quadratic time*.

These particular problems are not only the focus of intense theoretical study in the last few years, but arise in natural real-world settings according to some natural generating processes which is suggestive of the availability of multiple correlated instances. For example, the LCS and EDIT sequence alignment problems are often used in identifying conserved sequence regions across a group of sequences of DNA, RNA or proteins hypothesized to be evolutionarily related, or as aid in establishing evolutionary relationships by constructing phylogenetic trees. The dynamic time warping distance applied to signals over time can compare temporal data such as video and audio to detect whether an audio or video sequence is a sped up version of another audio or video sequence. Finally, we remark that to the best of our knowledge there are no known sub-quadratic algorithms for solving LCS, EDIT or DTWD on uniform (vs. worst case) input distributions nor are conditional lower bounds known, although this fascinating challenge has been raised in a multitude of works.

Looking ahead, in this work we will study and demonstrate how the availability of a logarithmic number of auxiliary instances which are correlated to primary instances of the LCS, EDIT and DTWD problems for several natural correlation modes enables us to overcome the quadratic complexity barrier.

But which correlation model over auxiliary instances should be assumed? In this first work we show how to take advantage of mathematically inspired simple and yet natural and clean models of correlation. The intriguing question, looking forward, is to find correlation models which coincide with evolutionary models and other relationships and for which our approach to multiple sequence alignment gives provable guarantees. We view our work as pointing out a novel direction to look for significant improvements, by taking advantage of access to sequences which are correlated through natural processes.

Our algorithmic approach departs from the dynamic programming approaches. It builds on the primary and auxiliary instances to construct new instances over a slightly larger alphabet for which solving the LCS (EDIT and DTWD respectively) can be done in sub-quadratic time and from which the optimal answer for the primary instance can be extracted. Rather than develop a different algorithm for each problem, we define a general notion of a tuple-based similarity measure which captures the LCS, EDIT and DTWD similarity measures on strings as special cases. We will show an algorithm for computing any tuple-based similarity measure over strings as long as access to correlated instances is available.

2 The New Results

We set out to study the impact of access to correlated instances on the complexity of polynomial time problems. The immediate questions which comes to mind is which problems and for which correlations

2.1 The problems: Any tuple-based Similarity Measure

We address the following problems.

- *Longest Common Subsequence* (LCS): Given two strings x and y over an alphabet Σ, find the maximum length of not necessarily consecutive substring common to both.
- *Minimum Edit Distance* (EDIT): Given two strings x and y over alphabet Σ, find the minimum number of insert character, delete character and replace character by another

character operations to apply to x to obtain y.

- *Dynamic Time Warping Distance (DTWD)*: Given two input strings x and y over an alphabet Σ compute the minimal cost of any allowed traversal of the two strings from first character to last where at each traversal step, one advances forward on at least x or y, and the cost is the sum over all time steps of the distance between the current entries. Namely, the sum of the distances between each pair of the traversal When the distances are restricted to $\{0,1\}$ we refer to the problem as $DTWD_{0,1}$
- *k-Longest Common Subsequence* (k-LCS) : Given k strings over alphabet Σ, find the maximum length not necessarily consecutive substring common to all k strings

Each of the above problems computes a different measure of similarity between pairs (or tuples) of strings, but all share a common feature which makes them amenable to speedups using correlated instances. Namely, the value of each of these similarity measures is the optimum over a set of values which only depend on the locations of the alignment. When this is the case, we will show that we can use a correlation model where the alignment stays the same (or with higher probability than uniform stays the same) in the correlated instances, to give a faster algorithm for finding this optimal alignment.

Formally, we define *tuple based similarity measure* which generalizes of all of the above and design an algorithm for any tuple based similarity measure, instead of treating each problem separately.

Main Definition: Let Σ denote an alphabet and let $f : \Sigma^{m_1} \times \Sigma^{m_2} \times, ..., \times \Sigma^{m_k} \to \mathbb{R}$ be a real valued function over k strings of lengths $m_1, ..., m_k$ whose output we informally think of as a measure of similarity between the strings. We say that f is a **tuple-based similarity measure** if there exists:

- a set of allowable k-tuples $\mathcal{S} \subseteq \bigcup_{m_1,m_2,...,m_k} \mathcal{P}([m_1] \times [m_2] \times ... \times [m_k])$ where $\mathcal{P}$ denotes the power set, (these can be viewed as the set of allowable "pseudo-alignments" where multiple positions in one string can match to the same position in another string) and
- a cost function $\mathcal{C}$ defined on pseudo-alignments $S \in \mathcal{S}$ s.t. $\mathcal{C}(S)$ is computable in time $\tilde{O}(|S|)$ and $f(x_1, x_2, ..., x_k) = \max\{\mathcal{C}(S)\text{: } S \in \mathcal{S} \text{ s.t. } \forall (i_1, i_2, ..., i_k) \in S, x_1[i_1] = x_2[i_2] = ... = x_k[i_k]\}$
  (or $f(x_1, x_2, ..., x_k) = \min\{\mathcal{C}(S)\text{: } S \in \mathcal{S} \text{ s.t. } \forall (i_1, i_2, ..., i_k) \in S, x_1[i_1] = x_2[i_2] = ... = x_k[i_k]\}$)

We note that this definition provides a generalization of the alignment gadget of [5] (where $k = 2$) which captures what is needed to have an improved algorithm given correlated instances. Bringmann and Kunnemann [5] introduce the notion of an alignment gadget, and show that any problem with an alignment gadget cannot be solved in strongly subquadratic time. Our definition is more general than theirs in that we do not restrict ourselves to looking at alignments: multiple positions in one string can match to the same position in another string. On the other hand, we only look at measures where the function is determined by the positions of the matches, whereas the gadgets of [5] speak of general measures.

It is easy to see that LCS is a pair-based similarity measure when we take $\mathcal{C}(S) = |S|$; the allowed sets of tuples are all possible alignments, and the maximum over all sets of alignments of $\mathcal{C}(S)$ is precisely the length of the longest common subsequence. In section 3, we prove that computing EDIT and DTWD are each a special case of a pair-based similarity measure.

2.2 The Models of Correlation Models over Auxiliary: Exact and Relaxed

The choices of which auxiliary instances (and which correlations) to consider for the LCS, k-LCS, $EDIT$, and $DTWD$ problems are tailor-made to the problems themselves. Indeed, one may argue that this will likely always be the case, as our hope is to consider correlations which would come up via *natural* generating processes of problem instances.

For example, in bioinformatics, sequence alignment is a way of arranging the sequences of DNA, RNA, or proteins to identify regions of similarity that may be a consequence of functional, structural, or evolutionary relationships between the sequences. Although we expect that only certain parts of the genome will be in common between multiple organisms, these parts will have a much higher rate of matching than random chance. Thus, which correlations between genomic sequences one may expect are dictated by evolutionary process which would be highly problem specific.

To describe distributions over the auxiliary instances, we use the framework of generating processes suggested by [6] to describe distributions over instances where correlations are defined between the *solutions* of the primary and auxiliary instance. A generating process $G_{Pri,Aux,t}$ for a problem P proceeds as follows: initialize the process with primary instance I of P drawn from primary distribution Pri. Let S be an underlying solution to I. Then choose t auxiliary instances $\{I_j\}_{j=1,...,t}$ from a distribution Aux conditioned on S in some fashion. The algorithm designer is given the tuple of $t+1$ instances $I, I_1, ..., I_t$ and is tasked with finding a solution to I.

We consider two generating models, which apply for any tuple-based similarity measure, but are easiest to first illustrate for the LCS problem.

Let Pri denote a distribution over pairs of strings of lengths m over alphabet Σ.

Exact LCS Correlation Model GenLCS$_{Pri}(m,t)$: Draw a pair of strings (x,y) from Pri. Let the longest common sub-sequence of (x,y) be at locations $\vec{a} = (a_1, ...a_n)$ in x and locations $\vec{b} = (b_1, ..., b_n)$ in y. Then choose auxiliary instances (x^1, y^1),...,(x^t, x^t) uniformly in $\Sigma^{m_1} \times \Sigma^{m_2}$ subject to the condition that each pair (x^j, y^j) contains a common sub-sequence at locations $\vec{a}$ and $\vec{b}$. Namely, $x^j_{a_i} = y^j_{b_i}$ for all j, for $1 \leq i \leq n$.

We next relax the restriction that each of the auxiliary instance pairs (x^j, y^j) contain a common (although not the longest) subsequence at the locations $\vec{a}$ and $\vec{b}$ of the longest common subsequence of the primary instance (x,y). Instead, we require that in each of the locations in (x^j, y^j) which coincide with locations of the longest common subsequence of x and y, the strings x^j and y^j agree with probability slightly higher than $\frac{1}{2}$.

Let Pri denote a distribution over pairs of strings of lengths m over alphabet Σ.

Relaxed LCS Correlation Model GenLCS2$_{Pri}(m,t,\epsilon)$: Draw a pair of strings (x,y) of length m each from Pri. Let the longest common sub-sequence of (x,y) be at locations $\vec{a} = (a_1, ...a_n)$ in x and locations $\vec{b} = (b_1, ..., b_n)$ in y. Then choose auxiliary instances (x^1, y^1),...,(x^t, x^t) uniformly in $\Sigma^m \times \Sigma^m$. Next, for each pair (x^j, y^j) and for each $1 \leq i \leq n$,set $x^j[a_i] := y^j[b_i]$ with probability ϵ and leave unchanged with probability $1-\epsilon$.

Correlations Models for General Tuple Based Similarity Measures

We are now ready to describe the models stated in terms of *any tuple-based similarity measure on strings*. We again consider two generating processes, an exact and a relaxed one.

The first generating process draws primary instances from a primary distribution, and auxiliary instances from the auxiliary distribution conditioned on the optimal set of tuples for the primary instances matching in each auxiliary instance. The second generating process will be similar to the first generating process, but instead of making the contents of the locations indicated by the optimum tuple always match in the auxiliary instances, there will only be a higher probability of matching in these locations.

Let f be a tuple-based similarity measure with allowed sets of tuples $\mathcal{S}$ and cost function $\mathcal{C}$.

Exact General Generating Model $Gen_{Pri,Aux}(f,k,\vec{m},t)$**:** First draw from the primary distribution Pri strings $x_1,x_2,...,x_k$ of lengths $\vec{m}=m_1,m_2,...,m_k$ where location tuples $S=\{(a_{11},a_{21},...,a_{k1}),...,(a_{1n},a_{2m},...,a_{kn})\}=\arg\min\{\mathcal{C}(S):S\in\mathcal{S}$ s.t. $\forall(i_1,i_2,...,i_k)\in S,x_1[i_1]=x_2[i_2]=...=x_k[i_k]\}$. Next, draw t auxiliary tuples $(x_1^{(i)},x_2^{(i)},...,x_k^{(i)})$ from distribution Aux conditioned on $\forall(j_1,j_2,...,j_k)\in S,x_1^{(i)}[j_1]=x_2^{(i)}[j_2]=...:=x_k^{(i)}[j_k]$ $\forall 1\leq i\leq t$ and output the primary and auxiliary instances drawn.

The main restriction in the above correlation model is that the optimal set of tuple locations must also induce a matching set of tuples for every auxiliary instance. Let us now relax this restriction to give faster algorithms when the optimal set of tuples only has a higher probability of inducing a matching set of tuples in the auxiliary instances.

Relaxed Generating Model $Gen_{Pri,Aux}(f,k,\vec{m},t,\epsilon)$**:** First draw from the primary distribution Pri strings $x_1,x_2,...,x_k$ of lengths
$\vec{m}=m_1,m_2,...,m_k$ where location tuples $S=\{(a_{11},a_{21},...,a_{k1}),...,(a_{1n},a_{2m},...,a_{kn})\}=\arg\min\{\mathcal{C}(S):S\in\mathcal{S}$ s.t. $\forall(i_1,i_2,...,i_k)\in S,x_1[i_1]=x_2[i_2]=...=x_k[i_k]\}$. Next, draws t auxiliary tuples $(x_1^{(i)},x_2^{(i)},...,x_k^{(i)})$ from distribution Aux Finally, set $x_1^{(i)}[j_1]=x_2^{(i)}[j_2]=...:=x_k^{(i)}[j_k]$ with probability ϵ for all tuples $(j_1,j_2,...,j_k)\in S$ and output the primary and auxiliary instances drawn.

Important Discussion on on Correlation Models: A word of caution is in order. One should be careful not to consider correlations which trivialize the problem.

- An example of such trivializations would be access to "too many" auxiliary instances. Whereas in [6] "too many" would correspond to more than a polynomial number of instances, in the current work it would be more than a linear number of auxiliary instances. Indeed, a logarithmic number of additional instances suffice to get a marked improvement.
- Another forbidden trivialization would be access to auxiliary "easy" instances for which the correlation enables trivial extraction of the answer for the primary instance. This is avoided in the exact correlation model as follows. Recall that the primary instance (x,y) can be selected in a worst case manner, whereas the auxiliary instances are selected at random subject to the condition that in each auxiliary pair x^j and y^j share a common subsequence at the same locations that primary x and y contain the *longest* common subsequence. However, we emphasize that the longest common subsequence for any of the auxiliary pairs, does not generally coincide with the longest common subsequence for the primary pair (x,y) . Therefore, we can not extract the solution to the LCS of (x,y) from a solution to one of the auxiliary pairs (x^j,y^j). Indeed, our solutions need $l=O(logn)$ auxiliary instances to be able to compute the solution to the primary instance and does not solve the LCS on auxiliary pairs (x^j,y^j). We also emphasize that the actual substring at the $\vec{a}$ locations of x^j does not agree with the substring at the $\vec{a}$ locations of the primary instance x, nor does the substring at the $\vec{b}$ locations of y^j match the substrings at the $\vec{b}$

locations of y, only the substring at locations $\vec{a}$ of x^j is required to match the substring at locations $\vec{b}$ of y^j.[1]

2.3 The New Algorithms in Exact and Relaxed Correlation Models

We start by describing our results for the LCS generating processeses.

Theorem 1 (LCS with exact correlation model) There exists an algorithm which on input $((x,y),(x^1,y^1),...,(x^t,y^t)$ generated according to the exact correlation model $GenLCS_{Pri}(m,t)$ defined above for Pri being a worst case distribution solves the LCS problem on string pair $(x,\ y\ )$ and runs in expected time $O(m\log m)$ for $t=O(\log m)$ where the expectation is taken over the choices of auxiliary inputs in $GenLCS_{Pri}(m,t)$.

The key technical insight for the aforementioned theorem is that it is now possible to construct a new instance of the LCS problem over an extended alphabet where each character corresponds to a vector in Σ^{l+1} and which now has enough structure (as opposed to the primary worst case instance) to be solved in sub-quadratic time. Essentially, each character in a position of the new LCS instance is determined by the characters in the original primary and auxiliary instances at the same position. When the number of auxiliary instances is large enough and the distribution is uniform, it will mean that the probability of any two non-matching positions having the same values for each of the auxiliary instances is small. This means that any positions that match on every auxiliary instance belong to the longest common subsequence with high probability. It is then possible to use hashing on the extended alphabet symbols to find the positions of the longest common subsequence.

The LCS results described are a special case of a general algorithm applied to any tuple-based similarity measure.

Main Theorem 2 (tuple-based similarity measures with exact correlation model) Let f be a tuple-based similarity measure on k strings of lengths $\vec{m}=m_1,...,m_k$ over alphabet Σ with no overlapping tuples. There exists an algorithm that finds $f(x_1,x_2,...,x_k)$ in time $\tilde{O}(kn\log n+|S|)$ where $|S|$ is the size of the largest allowed set of tuples on a primary instance $x_1,x_2,...,x_k$ and auxiliary instances $(x_1^{(1)},x_2^{(1)}...,x_k^{(1)}),...,(x_1^{(t)},...,x_k^{(t)})$ with $t=O(\log n)$ drawn from $Gen_{Pri,Aux}(f,k,\vec{m},t)$ with Pri worst-case and Aux uniform.
Note that in all of the similarity measures of interest, $|S|$ is of linear size in the input length.

Main Corollary 3

- On a primary instance $x_1,...,x_k$ of lengths $\vec{m}$ and $O(\log n)$, where $n=\max m_1,...,m_k$, auxiliary instances of k-LCS drawn from $Gen_{Pri,Aux}(LCS,k,\vec{m},O(\log n))$ with Pri worst-case and Aux uniform, we can find the longest common subsequence of the primary instance in time $\tilde{O}(nk)$.

[1] Interestingly, as we mentioned above, the induced distribution over the auxiliary instances produced by the exact correlation model, coincides with the semi-random model proposed by [3] in their work on the smooth complexity analysis of the EDIT problem. Recall, that they consider perturbing a worst case pair of strings (x,y) to (x',y') by randomly and independently choosing each of the characters of x' and y' in locations which were not part of the longest common subsequence of x and y; whereas for locations of x and y which are part of the longest common subsequence, x' and y' are forced to contain the same randomly chosen character. The existence of a linear time approximation algorithm for longest common subsequence for the (x',y') distribution, as shown by [3], does not seem to be useful directly for finding an approximate (nor exact) solution for LCS on (x,y) .

- On a primary instance x_1, x_2 of lengths m and n and $O(\log \max m, n)$ auxiliary instances of EDIT drawn from $Gen_{Pri,Aux}(EDIT, 2, \{m, n\}, O(\log \max m, n))$, we can find the minimum edit distance between the primary sequences in time $\tilde{O}(m + n)$.
- On a primary instance of x_1, x_2 of lengths m and n and $O(\log \max m, n)$ auxiliary instances of 0-1 DTWD drawn from $Gen_{Pri,Aux}(DTWD_{0,1}, 2, \{m, n\}, O(\log \max m, n))$ with Pri worst-case and Aux uniform, we can find the dynamic time warping distance of the primary instance in time $\tilde{O}(m + n)$.

Using considerably more complex algorithms and in particular techniques to find Hamming nearest neighbors, we extend the techniques to show the following for the relaxed correlation model.

Theorem 4 (LCS with relaxed correlation model) Let $\epsilon \in [0, \frac{1}{2}]$. There exists an algorithm which on a tuple of input instances $(x, y), (x^1, y^1), ..., (x^t, y^t)$ drawn from $GenLCS2_{Pri}(m, t, \epsilon)$ solves the LCS on string pair (x, y) with probability at least $2/3$ for $t = \Omega(\log m)$ and runs in expected time $O(tn^{1+d})$ for $d < 1$ (i.e sub quadratic time). (where the probability and runtime expectation is taken over the choices of auxiliary inputs in$GenLCS2_{Pri}(m, t, \epsilon)$.

Stating the general theorem for similarity measures.

Main Theorem 5 (tuple-based similarity measure with relaxed correlation model) Let f be a tuple-based similarity measure on k strings of lengths $\vec{m} = m_1, ..., m_k$ over alphabet Σ with no overlapping tuples. There exists an algorithm that finds $f(x_1, x_2, ..., x_k)$ in time $O(|S| + n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$ where $|S|$ is the size of the largest allowed set of tuples on a primary instance $(x_1, x_2, ..., x_k)$ and auxiliary instances $(x_1^{(1)}, x_2^{(1)} ..., x_k^{(1)}), ..., (x_1^{(t)}, ..., x_k^{(t)})$ drawn from $Gen_{Pri,Aux}(f, k, \vec{m}, t, \epsilon)$ with $t = O(\log n)$,Pri worst-case and Aux uniform.

Main Corollary 6

- On a primary instance $x_1, ..., x_k$ of lengths $\vec{m}$ and $O(\log n)$, where $n = \max m_1, ..., m_k$, auxiliary instances of k-LCS drawn from $Gen_{Pri,Aux}(LCS, k, \vec{m}, O(\log n), \epsilon)$ with Pri worst-case and Aux uniform, we can find the longest common subsequence of the primary instance in time $O(n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.
- On a primary instance x_1, x_2 of lengths m and n and $O(\log \max m, n)$ auxiliary instances of EDIT drawn from
  $Gen_{Pri,Aux}(EDIT, 2, \{m, n\}, O(\log \max m, n), \epsilon)$, we can find the minimum edit distance between the primary sequences in time $O((m + n)^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.
- On a primary instance of x_1, x_2 of lengths m and n and $O(\log \max m, n)$ auxiliary instances of 0-1 DTWD drawn from $Gen_{Pri,Aux}(DTWD_{0,1}, 2, \{m, n\}, O(\log \max m, n), \epsilon)$ with Pri worst-case and Aux uniform, we can find the dynamic time warping distance of the primary instance in time $O((m + n)^{\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.

2.4 Another correlation model and results for EDIT

In addition to the correlation model implied for computing the min edit distance (EDIT), we consider another model which may be more natural to consider and show an efficient algoritme for EDIT in this model.

Consider the following generating process. Let $\pi_1, \pi_2, ..., \pi_k$ be the minimum sequence of edits needed to transform x to y. The auxiliary instances are random pairs of n-bit strings whose minimum edit sequence are the same as for the primary instance. Namely,

for auxiliary pair $x^{(1)}, y^{(1)}$, $y^{(1)}$ is obtained from $x^{(1)}$ using the same edit sequence which transformed x to y. Somewhat more generally, consider a worst case instance (x, y) and auxiliary instances $(x^{(1)}, y^{(1)}), (x^{(2)}, y^{(2)}), ...$, with $x^{(i)} = x$ with each character changed with probability $\epsilon \in [0, 1]$ and $y^{(i)} = \pi_k(\pi_{k-1}(...(\pi_1(x^{(i)}))...))$. This is the distribution on which our algorithms perform.

Theorem 7(Solve EDIT exactly with $O(\log n)$ instances) There exists an algorithm A which on inputs generated as above solves the $EDIT(x, y)$ for a worst case primary instance and auxiliary instances as above such that on $O(\log n)$ auxiliary instances , the algorithm computes $EDIT(x, y)$ with high probability and runs in expected time $O(n \log n)$.

2.5 Overview of Techniques

The main idea of this paper is a new algorithm for solving similarity measure problems with correlated instances. This algorithm is significantly different than the dynamic programming algorithms that are used in the absence of correlated instances.

Given a tuple-based similarity measure, our goal is to find the set of tuples of locations which form the optimal (e.g. longest in LCS) solution to the primary instance $(x_1, ..., x_k)$. With correlated instances, consider a tuple of locations (e.g. $(i_1, ..., i_k)$ in $(x_1, ..., x_k)$), then in our exact correlation model, if these locations are not part of optimal solution these will be detected by comparing them across all instances, primary and auxiliary. This is the case as the correlation model makes it unlikely that even a pair of locations (i_u, i_v), which are not part of a matching tuple in the primary instance, would have the same value in the primary instances and all auxiliary instances.

Thus, algorithmically we can look at pairs of positions and determine whether they are in the same tuple by comparing them across all instances, primary and auxiliary. We do not need to do this for all pairs; we can use hashing to map pairs to each other, using the fact that similar pairs will be in the same tuple, and thereby find the tuples that determine the value of the similarity measure. The use of hashing proceeds as follows. First, we construct vectors out of the same position for the primary instance and each auxiliary instance for all of the strings. Then, we construct a hash table out of the vectors for the first string, and use the hash function to determine which vectors in the other strings are the same as vectors in the first string.

This idea works as is for the exact correlation model where pairs of locations in tuple of the optimal solution are guaranteed to contain the same value in all auxiliary instances, but fails when we relax this to the model where contents of such location pairs only have a higher probability of being the same.

In this case, if two locations were part of the same tuple, when we consider the vectors obtained from the auxiliary instances at those locations, they will be closer to each other than vectors obtained from positions which are not part of the same tuple. As a result, the nearest neighbors of the vector corresponding to a position are the vectors corresponding to the positions in the same tuple. Then, we can use algorithms that find nearest neighbors faster than brute-force search to find the tuples. Thus we can solve instances generated by the relaxed correlation model not in nearly linear time like the exact correlation model, but still significantly faster than the best known algorithms for the problem without correlated instances.

2.6 Related Works

We review the relevant results known in the literature for the EDIT,LCS, and DTWD problems.

Backurs and Indyk [4] have shown that if EDIT – the minimum number of insertions, deletions, and substitutions needs to transform one string into another – can be computed in time $O(n^{2-\delta})$ for some constant $\delta > 0$, then the satisfiability of CNF formulas with n variables and m clauses can be solved orm one string into anothertime $poly(m)2^{\epsilon n}$ for a constant $\epsilon > 0$. This would violate the Strong Exponential Time Hypothesis (SETH). A $O(n^{2-\delta})$ algorithm for EDIT would also imply a sub-quadratic algorithm for the orthogonal vector problem and a host of others.

Abboud, Backurs and Williams [1] addresses (among other problems) the LCS problem. They show that an $O(n^{2-\epsilon})$ algorithm for the LCS of two sequences of length n over a constant size alphabet would refute SETH and show a sub-quadratic algorithm for the orthogonal vectors problem and a host of others. For finding the longest subsequence common to k input sequences, it is similarly argued that achieving $O(n^{k-\epsilon})$ for any $\epsilon > 0$ is unlikely in [1].

Bringmann and Kunnermann [5] provide a lower bound for dynamic time warping distance, the minimum cost of a traversal of two strings where at each step, at least one of the strings moves forward, and the cost is the sum of the distances at each step. This problem is also solvable using dynamic programming, and [5] show that an $O(n^{2-\epsilon})$ that finds the dynamic time warping distance would refute SETH. Their proof uses the concept of an alignment gadget, which we will generalize with our notion of pair-based similarity measures.

We also mention work on the smoothed complexity of the EDIT distance problem. Recall, that the smoothed complexity of an algorithm by Spielmann and Teng [12], analyzes for an input x the expected behavior of the algorithm on correlated inputs which are the result of subjecting x to perturbations (e.g. flip its bits with a certain probability).

Andoni and Krauthgamer [3] study of the smoothed complexity of EDIT in the following perturbation model. Given two adversarially chosen binary input strings with common longest subsequence A , eacn character of the input strings is replaced independely (with some fixed probability p) with one restriction: the same perturbation is applied in both strings to the charcters in locations of the common longest subsequence A. They then show a constant factor approximation algorithms for EDIT which runs in nearly linear time for such perturbed instances.The existence of a linear time approximation algorithm for the LCS of (x', y') distribution, as shown by [3], does not seem to be useful directly for finding an approximate (nor exact) solution for the LCS of (x, y). Looking ahead, the stringest dostributions which we consider (which we call "exact correlation model") over auxiliary instances to a primary instance x essentially coincides with the [3] perturbation model applied to x.

We remark that the approach of smoothed analysis in general and the work of [3] in particuar, differs from our study and results in several aspects. First, in contrast to smoothed analysis our goal is not an analysis of when the problem becomes easier (or harder) but rather the development of algorithms which take advantage of (and when) extra correlated information is available in addition to an original input. Second, we solve the exact version of the min-EDIT distance problem on the primary worst case input pair itself with high probability (over the perturbed instances) whereas they approximate the min-EDIT distance on a perturbed instance.

Having said that, there is an interesting interplay between the explorations of smoothed analysis and improving algorithmics by access to correlated instances . That is, one may consider any distribution induced by semi-random models over problem instances both as

distributions for which smoothed complexity can be studied, or as distributions over the auxiliary correlated instances which are available for improving algorithms on a primary worst case instance.

Finally, we note that the idea of using larger alphabets to make the longest common subsequence problem easier is related to work of Hunt and Szymanski [9]. In this paper, they show that if r is the number of pairs of locations that are the same in the two sequences, there is an algorithm to compute the longest common subsequence of two strings of length n in time $O((r+n)\log n)$. Thus, if the number of matching pairs is small, the longest common subsequence can be computed easily. This idea is present in our work as well; when we consider correlated instances to make a new pair of sequences over a larger alphabet, the matching pairs will just be the pairs that are part of the longest common subsequence of the primary instance. Although the algorithm we use to find the longest common subsequence is different, the fundamental concept is the same.

2.7 Roadmap to The paper

The rest of the paper will proceed as follows. In Section 2, we will give the definition of a tuple-based similarity measure. We will also introduce the definitions of longest common subsequence, edit distance, and dynamic time warping distance and then show that LCS, EDIT, and a restricted version of DTWD are all tuple-based similarity measures. In Section 3, we define the correlation models used in the rest of the paper. We are then able to proceed to the results in Section 4. Section 4.1 covers the exact correlation model and Section 4.2 covers the relaxed correlation model. We leave the discussion of the other model for edit distance to the appendix.

3 A generalization of similarity measures

The longest common subsequence problem, edit distance problem, and dynamic time warping distance problem all have similar features which make them amenable to speedups using correlated instances. The feature that we will be looking at is the fact that the value of each of these similarity measures is the optimum over a set of values which only depend on the locations of the alignment. If this is the case, we will show that we can use a correlation model where the alignment stays the same to give a faster algorithm for finding this optimal alignment. The following definition provides a criterion which ensures that a similarity measure will have a good algorithm given correlated instances.

▶ **Definition 1.** *Let f be a function that takes k strings and outputs a number, which we think of as a measure of similarity between the strings. f is a tuple-based similarity measure on strings $x_1, ..., x_k$ if there exist $\mathcal{S} \subseteq \bigcup_{m_1,m_2,...,m_k} \mathcal{P}([m_1] \times [m_2] \times ... \times [m_k])$ of allowed sets of tuples, where $m_1, ..., m_k$ correspond to the length of each string, along with a function $c(S)$ computable in time $\tilde{O}(|S|)$ such that*
$f(x_1, x_2, ..., x_k) = \max_{S \in \mathcal{S}, \forall (i_1,i_2,...,i_k) \in S x_1[i_1]=x_2[i_2]=...=x_k[i_k]} c(S)$ *or*
$f(x_1, x_2, ..., x_k) = \min_{S \in \mathcal{S}, \forall (i_1,i_2,...,i_k) \in S x_1[i_1]=x_2[i_2]=...=x_k[i_k]} c(S)$.

▶ **Definition 2.** *A pair-based similarity measure is a tuple-based similarity measure for tuples of size 2.*

The motivation for this definition is to provide a generalization of the alignment gadget of [5] that captures the property we need to achieve faster algorithms given correlated instances. In [5], they introduce the notion of an alignment gadget, and show that any problem with an

alignment gadget cannot be solved in strongly subquadratic time. Our definition is more general than theirs in that we do not restrict ourselves to looking at alignments; multiple positions in one string can match to the same position in another string. However, we only look at measures where the function is determined by the positions of the matching pairs; this is for reasons related to the correlation model that will become apparent.

We denote the ith character of a string x over an alphabet Σ by $x[i]$.

▶ **Definition 3.** *A longest common subsequence of two strings $x, y \in \Sigma^*$ ($LCS(x, y)$) of length m is a largest set of pairs $(a_1, b_1), ..., (a_m, b_m)$ such that $1 \leq a_1 < a_2 < ... < a_m \leq n$, $1 \leq b_1 < b_2 < ... < b_m \leq n$, and $x[a_i] = y[b_i]$ for $i \in \{1, ..., m\}$.*

▶ **Definition 4.** *A longest common subsequence of k strings ($LCS(x[1], x[2], ..., x[k])$) of strings $x[1], x[2], x[3], ..., x[k]$ is a largest set of tuples $(a_1[1], a_2[1], ..., a_k[1]), ..., (a_1[m], a_2[m], ..., a_k[m])$ with $1 \leq a_j[1] < a_j[2] < ... < a_j[m] \leq n$ for all $j \in \{1, ..., k\}$ and $x_1[a_1[i]] = x_2[a_2[i]] = ... = x_k[a_k[i]]$ for all $i \in \{1, ..., m\}$*

It is easy to see that LCS is a tuple-based similarity measure when we take $c(S) = |S|$; the allowed sets of tuples are all possible alignments, and the maximum over all sets of alignments of $c(S)$ is precisely the length of the longest common subsequence.

▶ **Definition 5.** *The edit distance ($EDIT$) between two strings x, y is the minimum number of insertions, deletions, and character substitutions it takes to get from x to y. $EDIT(x, y) = LEV_{x,y}(|x|, |y|)$, where*

$$LEV_{x,y}(i,j) = \begin{cases} \max i, j & \text{if } \min i, j = 0 \\ \min \begin{cases} LEV_{x,y}(i, j-1) \\ LEV_{x,y}(i-1, j) \\ LEV_{x,y}(i-1, j-1) + \mathbb{1}_{a_i \neq b_j} \end{cases} \end{cases}$$

$$\text{and } \mathbb{1}_{a_i \neq b_j} = \begin{cases} 1 & \text{if } a_i \neq b_j \\ 0 & \text{if } a_i = b_j \end{cases}.$$

▶ **Proposition 1.** *$EDIT$ is a pair-based similarity measure.*

Proof. We observe that if every alignment has a unique minimum sequence edit associated with it, then the proposition follows as the set of pairs corresponding to a location unchanged by the minimum sequence of edits in the first string and the location where it moved to in the second string is an alignment, and thus taking the minimum over all alignments of the edit distance that preserves the alignment gives us the minimum edit distance. Thus it suffices to show that this is the case. Suppose that $(a_1, b_1), ..., (a_k, b_k)$ is the set of pairs that are unchanged when the edit operation is applied. We claim that the minimum number of edits leaving these pairs unchanged is equal to $\sum_{i=0}^{k} \max(a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$ if this is true. To see this, the edit takes $x[a_i]$ to $y[b_i]$, and thus everything between $x[a_i]$ and $x[a_{i+1}]$ must be matched to things between $y[b_i]$ and $y[b_{i+1}]$. This edit distance is equal to $\max(a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$. Thus, the minimum number of edits leaving this set of pairs unchanged is $\sum \max(a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$. Therefore the minimum edit distance is the minimum of this function over all sets of matching pairs that satisfy the constraint that for any i, j, either $a_i < a_j$ and $b_i < b_j$ or $a_i > a_j$ and $b_i > b_j$. ◀

▶ **Definition 6.** *A traversal of two sequences x, y of length m, n respectively is a list of pairs $(a_1, b_1), ..., (a_t, b_t)$ such that $(a_1, b_1) = (1, 1)$, $(a_t, b_t) = (m, n)$, and (a_{i+1}, b_{i+1}) is either $(a_i + 1, b_i), (a_i, b_i + 1)$, or $(a_i + 1, b_i + 1)$.*

▶ **Definition 7.** *The dynamic time warping distance (DTWD) between two strings x, y is the minimum cost of a traversal of the two strings. The cost of a traversal is the sum of the distances between each pair of the traversal.*

▶ **Proposition 2.** *DTWD when the distances are 0 and 1 ($DTWD_{0,1}$) is a pair-based similarity measure.*

Proof. Let $(a_1, b_1), ..., (a_k, b_k)$ be the set of pairs with $x[a_i] = y[b_i]$ in order in the traversal with the minimum cost. Similarly to the edit distance situation, the traversal must match everything between $x[a_i]$ and $x[a_{i+1}]$ and $y[b_i]$ and $y[b_{i+1}]$, and the dynamic time warping distance here is $\sum_{i=1}^{k-1} \max b_{i+1} - b_i - 1, a_{i+1} - a_i - 1$ because none of these were included in matching pairs because of the definition of a traversal. Then, determining the minimum dynamic time warping distance is equivalent to determining the minimum of this quantity over all subsets of traversals. This means that $DTWD_{0,1}$ is a pair-based similarity measure. ◀

4 Correlation models for tuple-based similarity measures

In this section we will define the way primary and auxiliary instances are generated by our generating processes. The first generating process draws primary instances from the primary distribution, and auxiliary instances from the auxiliary distribution conditioned on the optimal set of tuples for the primary instances matching for each auxiliary instance. This does not mean that the values at the locations specified by each tuple are the same between the primary and auxiliary instances; it indicates that the contents of the strings in an auxiliary instance at the locations indicated by the tuple will be the same. The second generating process will be similar to the first generating process, but instead of making the locations always match, there will be a higher probability of matching locations being the same.

▶ **Definition 8.** *Suppose that f is a tuple-based similarity measure with allowed sets of tuples $\mathcal{S}$ and cost function c. Let l be the number of correlated instances, k be the number of strings that f is a measure on, and let $m_1, ..., m_k$ be the length of each string.*

The generating process $Gen_{Pri,Aux}(f, k, \vec{m}, l)$ draws $x_1, x_2, ..., x_k$ of length $m_1, m_2, ..., m_k$ respectively from Pri with the allowed set of tuples $S = \{(a_{11}, a_{21}, ..., a_{k1}), ..., (a_{1m}, a_{2m}, ..., a_{km})\} = \arg\min_{S \in \mathcal{S} | \forall (i_1, i_2, ..., i_k) \in S, x_1[i_1] = x_2[i_2] = ... = x_k[i_k]} c(S)$. Then, it outputs l tuples $(x_1^{(i)}, x_2^{(i)}, ..., x_k^{(i)})$ drawn from $Aux^{\otimes n}$ conditioned on $\forall (j_1, j_2, ..., j_k) \in S, x_1^{(i)}[j_1] = x_2^{(i)}[j_2] = ... = x_k^{(i)}[j_k]$.

▶ **Definition 9.** *Suppose that f is a tuple-based similarity measure with allowed sets of tuples $\mathcal{S}$ and cost function c. Let l be the number of correlated instances, k be the number of strings that f is a measure on, ϵ be the probability that a given tuple is matching for an auxiliary instance, and let $m_1, ..., m_k$ be the length of each string.*

The generating process $Gen_{Pri,Aux}(f, k, \vec{m}, l, \epsilon)$ draws $x_1, x_2, ..., x_k$ of length $m_1, m_2, ..., m_k$ from Pri with the allowed set of tuples $S = \{(a_{11}, a_{21}, ..., a_{k1}), ..., (a_{1m}, a_{2m}, ..., a_{km})\} = \arg\min_{S \in \mathcal{S} | \forall (i_1, i_2, ..., i_k) \in S, x_1[i_1] = x_2[i_2] = ... = x_k[i_k]} c(S)$. Then, it outputs l tuples $(x_1^{(i)}, x_2^{(i)}, ..., x_k^{(i)})$ drawn from $Aux^{\otimes n}$ and then we make $x_1^{(i)}[j_1] = x_2^{(i)}[j_2] = ... = x_k^{(i)}[j_k]$ with probability ϵ for all tuples $(j_1, j_2, ..., j_k) \in S$.

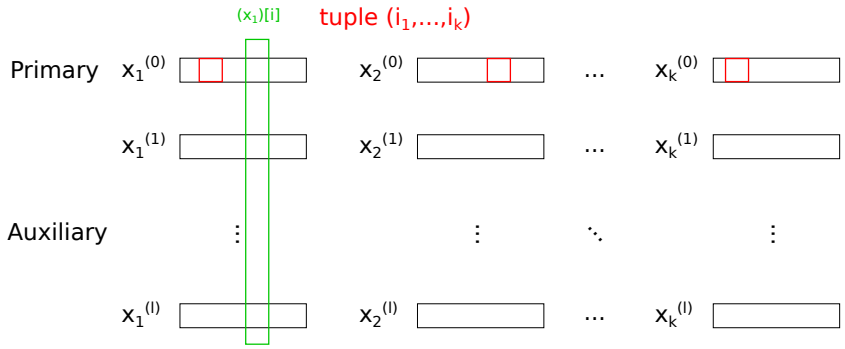

Figure 1 This shows the structure of the primary and auxiliary instances. The instance column is delineated in green, and a tuple in the primary instance is shown in red.

5 Results

5.1 Exact correlation model

What correlations should we expect to provide advantages? For tuple-based similarity measures, we should expect information about what the optimal set of tuples is to give us a speedup. In the model that we are considering, each location tuple in the optimal set of tuples of our primary instance will also be a set of locations with the same value in each auxiliary instance. For example, consider the two sequences 1010010 and 1101100. The longest common subsequence between the two sequences is 10110, so we can expect auxiliary instances to look like $abc^{**}de$ and $^{*}abcde^{*}$, where a, b, c, d, e have the same value and * is a wildcard.

This correlation model is not just solving a random instance of the problem. The goal is to find the optimal set of tuples for the primary instance. There are no guarantees on the distribution for the primary instance; the primary instance is worst-case. As a result, the problem is not equivalent to finding the optimal set of tuples for an auxiliary instance, and thus finding the correlations is not the same as solving a random instance of the original problem.

▶ **Definition 10.** *The instance column $(x)[i]$ is defined as follows. Suppose we have strings $(x_1, x_2, ..., x_k)$ which are primary instances, which we will refer to $(x_1^{(0)}, x_2^{(0)}, ..., x_k^{(0)})$, and auxiliary instances $(x_1^{(1)}, x_2^{(1)}, ..., x_k^{(1)})..., (x_1^{(l)}, x_2^{(l)}, ..., x_k^{(l)})$. Then, we denote $(x_j^{(0)}[i], x_j^{(1)}[i], ..., x_j^{(n)}[i]) = (x_j)[i]$ for any $j \in \{1, ..., k\}$.*

Given the correlation model, we know that two characters in each auxiliary instance will be equal with probability 1 if they belong to a tuple in the optimal set of tuples and with probability less than 1 otherwise. This suggests the following algorithm which runs in $O(kn \log n)$ time, or $O(n \log n)$ if k is constant. If we are given auxiliary instances from $Gen_{Pri,Aux}(f, k, \vec{m}, l)$ with Pri a worst-case distribution and Aux the uniform distribution, we can construct buckets indexed by elements of Σ_{l+1} and the entries of each bucket are the indices of the columns that have the same value as the bucket's index. Then, it looks up the columns of string 1 to see where the matches are. FIND proceeds in three steps; first, for the last $k-1$ strings, it puts each column of the string in the corresponding bucket in the set of buckets for that string. Next, it checks the columns of string 1 against the columns of string

2 to see which positions in string 1 are part of tuples. Then, we construct the set of tuples by looking up the positions in strings 2 through k that match to positions in string 1.

In FIND, the H_j are arrays of buckets where $((x_j)[i], i)$ is stored for $j = 2, ..., n$, and A is the array of k-tuples in the longest common subsequence. $H_j[s]$ denotes the contents of the bucket for the jth string, and is filled iff there exists i such that $(x_j)[i] = s$. $A_{i,j}$ is the index in the jth string of the ith entry of the longest common subsequence.

▶ **Theorem 1.** *Suppose we have a pair-based similarity measure or a k-tuple-based similarity measure with no overlapping tuples. If we are given a primary instance $x_1, x_2, ..., x_k$ and auxiliary instances $x_1^{(1)}, x_2^{(1)} ..., x_k^{(1)}, ..., x_1^{(l)}, ..., x_k^{(l)}$ with $l = O(\log n)$ drawn from $Gen_{Pri,Aux}(f, k, \vec{m}, l)$ with Pri worst-case and Aux uniform, FIND finds $f(x_1, x_2, ..., x_k)$ in time $\tilde{O}(kn \log n + |S|)$, where S is the largest set of tuples in $\mathcal{S}$ and $n = \max m_1, ..., m_k$.*

Proof. If A is the optimal set S^* from the primary instance, we can compute $f(x_1, x_2, ..., x_k) = c(A)$ in $\tilde{O}(|S^*|)$. Then, we will show that given the primary and auxiliary instances, the algorithm finds find the optimal set of tuples for the primary instance. Let $(i_1, ..., i_k) \in S^*$. By the definition of the correlation model, we will have that $(x_1)[i_1] = (x_2)[i_2] = ... = (x_k)[i_k]$ because the tuple is one of the optimal tuples in the primary instance which means that this is a matching tuple in both the primary and auxiliary instances. Suppose that we have a tuple $(i_1, i_2, ..., i_k)$ not in S^*. Then, the probability that $x_1^{(j)}[i_1] = x_2^{(j)}[i_2]$ for a given i is $1/2$, so then the probability of equality for all j is $\frac{1}{2^{O(\log n)}} < \frac{1}{3n^2}$. Taking a union bound over all pairs, we see that the probability of any tuple not in S^* having $(x_1)[i_1] = (x_2)[i_2]$ is at most $1/3$, so therefore with probability at least $2/3$, every tuple with $(x_1)[i_1] = (x_2)[i_2] = ... = (x_k)[i_k]$ will be be in S^*. Thus, with probability at least $2/3$, every hash collision corresponds to a tuple, and therefore A is the optimal set tuples for the primary instance. ◀

Algorithm 1: FIND$(f, x_1, x_2, ..., x_k, x_1^{(1)}, ..., x_k^{(1)}, ..., x_1^{(l)}, ..., x_k^{(l)})$

```
    Put columns into buckets
1   For j = 2, ..., k
2       Construct the array H_j with elements linked lists.
3       For i = 1, ...., n
4           Add ((x_j)[i], i) to H_j[(x_j)[i])].
5   Make the n × k array A.
6   m = 1
    Check which positions in string 1 are part of tuples in S*
7   For i = 1, ..., n
8       For (v, j) in H_2[(x_1)[i]]
9           If (x_1)[i] = v
10              A_{m,1} = i
11              A_{m,2} = j
12              m = m + 1
    Match positions in strings 2 through k to positions in string 1
13  For s = 3, ..., k
14      For l = 1, ..., m
15          i = A_{l,1}
16          If H_s[(x_1)[i]] is empty
17              Remove A_l and skip to the next l
18          For (v, j) in H_s[(x_1)[i]]
19              If (x_1)[i] = v
20                  A_{m,s} = j
21  Output c(A).
```

▶ **Corollary 1.** *If we are given a primary and $O(\log n)$, where $n = \max m_1, ..., m_k$, auxiliary instances of k-LCS drawn from $Gen_{Pri,Aux}(LCS, k, \vec{m}, O(k \log n))$ with Pri worst-case and Aux uniform, we can find the longest common subsequence of the primary instance in time $\tilde{O}(nk)$.*

▶ **Corollary 2.** *If we are given a primary and $O(\log \max m, n)$ auxiliary instance of EDIT drawn from $Gen_{Pri,Aux}(EDIT, 2, \{m, n\}, O(\log \max m, n))$, we can find the minimum edit distance between the primary sequences in time $\tilde{O}(m + n)$.*

▶ **Corollary 3.** *If we are given a primary and $O(\log \max m, n)$ auxiliary instances of $DTWD_{01}$ drawn from*
$Gen_{Pri,Aux}(DTWD_{0,1}, 2, \{m, n\}, O(\log \max m, n))$ with Pri worst-case and Aux uniform, we can find the dynamic time warping distance of the primary instance in time $\tilde{O}(m + n)$.

5.2 Relaxed correlation models

In the preceding section, we established that under a strict correlation model, we are able to find the solution to problems such as longest common subsequence and edit distance much faster than current lower bounds suggest if we did not have auxiliary instances. The main restriction is that the optimal set of tuples must also be a matching set of tuples for every auxiliary instance. When we talk about a matching tuple, we are referring to a tuple such that the characters at the locations specified by the tuple are the same. In this section, we will show how to relax this condition to give faster algorithms when a tuple in the optimal set of tuples only has a higher probability of being a matching tuple.

The main difficulty here is identifying the correct tuples. In the previous case, this was easy, because we could use the fact that every member of a correct tuple would be the same for each auxiliary instance. Then it sufficed to look at locations where the values matched up for each auxiliary instance, and we could use hashing to find these matching locations. In this case, we do not have this guarantee; we only have the guarantee that locations which are in the same tuple will have a higher probability of being the same in an auxiliary instance. This guarantee still allows us to find the elements of a tuple given its first element, as now the Hamming distance between two columns in the same tuple will be less than if they are not in the same tuple with high probability, and then we use faster algorithms for Hamming nearest neighbors such as the one in [2].

The following lemma will guarantee that the nearest neighbors of the column corresponding to the values of a position on the primary instance and auxiliary instances are the columns corresponding to the positions that are part of a tuple in the optimal set of tuples for the primary instance and has the first position in it also. As a result, this means that if we run a Hamming nearest neighbors algorithm on the columns, we will be able to find which tuples were the optimal tuples for the primary instance and thus compute the optimal value of the function for the primary instance.

▶ **Definition 11.** *$\mathbb{1}_{a=b}$ is 1 if $a = b$ and 0 otherwise.*

▶ **Lemma 1.** *Suppose we have x_1, x_2, ..., x_k and $x_1^{(1)}, x_2^{(1)}, ...x_k^{(1)}, ..., x_1^{(l)}, x_2^{(l)}, ..., x_k^{(l)}$ drawn from $Gen_{Pri,Aux}(f, k, \vec{m}, l\epsilon)$ with Pri worst-case and Aux uniform. Let $j \in \{2, ..., k\}, a \in \{1, ..., m_1\}$ and $b \in \{1, ..., m_j\}$. Then, for any δ such that $0 < \delta < 1/2 + \varepsilon$, if $a = i_1$ and $b = i_j$ for some $(i_1, ..., i_k) \in S^*$, the optimal set of tuples for the primary instance,*

$$\Pr[\mathbb{E}_m[\mathbb{1}_{x_1^{(m)}[a]=x_j^{(m)}[b]}] \leq 1/2 + \varepsilon - \delta] \leq e^{-\frac{(\delta/(1/2+\varepsilon))^2 l}{2}}$$

and otherwise

$$\Pr[\mathbb{E}_m[\mathbb{1}_{x_1^{(m)}[a]=x_j^{(m)}[b]}] \geq 1/2+\delta] \leq e^{-4\delta^2 l/3}$$

Proof. We use the form of the Chernoff bound given in [11]: for X a sum of independent random variables $X_1, ..., X_n$ taking values $\{0,1\}$ with expectation μ, we have that $\Pr[X \leq (1-\delta)\mu] \leq e^{-\delta^2\mu/2}$ and $\Pr[X \geq (1+\delta)\mu] \leq e^{-\delta^2\mu/3}$ for $0 < \delta < 1$. The first inequality is proven by plugging in $\mu = (1/2+\varepsilon) * l$ into the first Chernoff bound and noting that the expectation is the sum of the indicator random variables divided by l, and the second inequality follows similarly. ◀

Given this result, we can now use an algorithm to find Hamming nearest neighbors to find the optimal set of tuples. The best algorithm is the one of [2], which runs in time $n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))}$ to find the approximate nearest neighbors. What follows is the algorithm, treating finding the Hamming nearest neighbors as a black box.

FIND-RELAXED$(f, x_1, x_2, ..., x_k, x_1^{(1)}, ..., x_k^{(1)}, ..., x_1^{(l)}, ..., x_k^{(l)}, \epsilon)$

1 Make an $n \times k$ array A.
2 For $i = 1, ..., m_1$
3 For $j = 2, ..., k$ and $t = 1, ..., m_k$, find all vectors $(x_j)[t]$ that are less than $(1/2 - \epsilon/2) * l$ away from $(x_1)[i]$ in Hamming distance using the algorithm for approximate nearest neighbors
4 Add the tuple of all these vectors to A
5 Compute $c(A)$.

▶ **Theorem 2.** *Suppose we have a pair-based similarity measure or a k-tuple-based similarity measure with no overlapping tuples f. Let $l = 1000 \log n$. With probability at least $2/3 - o(1)$, the preceding algorithm computes $f(x_1, ..., x_k)$ given correlated instances from $Gen_{Pri,Aux}(f, k, \vec{m}, l, \epsilon)$ with Pri worst-case and Aux uniform in time $O(|S| + n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$, where S is the largest set of tuples in $\mathcal{S}$ and $n = \max m_1, ..., m_k$.*

Proof. Given $1000 \log n$ instances, we can use the lemma to say that for any two columns, with probability $1/n^3$ they do not correspond to a tuple and have Hamming distance less than $1/2 - \epsilon/4$ or they do correspond to a tuple and have Hamming distance more than $1/2 - 3\epsilon/4$. Taking a union bound gets us that the probability that this holds for any pair of columns is less than k/n. This means that the nearest neighbors of every column are the columns that it shares a tuple with, with probability $1 - o(1)$. Then in time $O(n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$ using the algorithm of [2] we can find the optimal set of tuples S^* with probability $2/3$. Then in time $|S|$ we can compute $c(S^*) = f(x_1, ..., x_k)$. ◀

▶ **Corollary 4.** *If we are given a primary and $O(\log n)$, where $n = \max m_1, ..., m_k$, auxiliary instances of k-LCS drawn from $Gen_{Pri,Aux}(LCS, k, \vec{m}, O(k \log n), \epsilon)$ with Pri worst-case and Aux uniform, we can find the longest common subsequence of the primary instance in time $O(n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.*

▶ **Corollary 5.** *If we are given a primary and $O(\log \max m, n)$ auxiliary instance of EDIT drawn from $Gen_{Pri,Aux}(EDIT, \{m, n\}, 2, O(\log \max m, n), \epsilon)$, we can find the minimum edit distance between the primary sequences in time $O(n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.*

▶ **Corollary 6.** *If we are given a primary and $O(\log \max m, n)$ auxiliary instances of $DTWD_{01}$ drawn from $Gen_{Pri,Aux}(DTWD_{01}, \{m, n\}, 2, O(\log \max m, n), \epsilon)$ with Pri worst-case and Aux uniform, we can find the dynamic time warping distance of the primary instance in time $O(n^{2-\Omega(\epsilon^{1/3}/\log(1/\epsilon))})$.*

6 Another correlation model for edit distance

▶ **Definition 12.** *The generating process* $Genedit_{Pri,Aux,\epsilon}(n,l)$ *draws* x, y *of length* n *and a sequence of character insertions, deletions, and substitutions* $\pi_1, \pi_2, ..., \pi_k$ *that is the minimum sequence of edits needed to transform* x *to* y *from* Pri*. The output is* $x, y, x^{(1)}, y^{(1)}, x^{(2)}, y^{(2)}, ..., x^{(l)}, y^{(l)}$*, with* $x^{(i)}$ *being* x *with each character changed with probability* ϵ *and* $y^{(i)} = \pi_k(\pi_{k-1}(...(\pi_1(x^{(i)}))...))$.

Suppose that we have two strings x, y for which we want to compute the minimum edit distance. If our auxiliary instances have the same sequence of edit operations, then with $3 \log n$ auxiliary instances the probability that $(x)_i = (y)_j$ and x_i did not to y_j during the sequence of inserts, deletes, and changes is less than $1/n^3$. This means that we can find the parts of the original string that are preserved under the edit and their new positions. Our algorithm works as follows. First, we get $O(\log n)$ auxiliary instances from $Genedit_{Pri,Aux,\epsilon}$, where Pri is worst-case, and then put the $(y)_j$ in buckets and check which $(x)_i$ have $(x)_i = (y)_j$. Then, with the pairs $(a_1, b_1), ..., (a_k, b_k)$, the edit distance is $\sum_{i=0}^{k} \max a_{i+1} - a_i - 1, b_{i+1} - b_i - 1$ with high probability. This algorithm obviously runs in $O(n \log n)$ time.

In FIND-EDIT, the array H of buckets is used to store $(y)_i$, and $COMMONPAIRS$ holds the i, j such that $(x)_i = (y)_j$.

Algorithm 2: FIND-EDIT$(x, y, x^{(1)}, y^{(1)}, ..., x^{(l)}, y^{(l)})$

```
1  Initialize an n × 2 array COMMONPAIRS.
2  Construct an array H of size n of linked lists.
3  For j = 1, ..., n
4        Add ((y)_j, j) to H[(y)_j].
5  For i = 1, ..., n
6        For (v, j) in H[(x)_i]
7              If (x)_i = v add (i, j) to COMMONPAIRS.
8  Output Σ_{i=0}^{k} max (a_{i+1} − a_i − 1, b_{i+1} − b_i − 1),
   where ((a_1, b_1), (a_2, b_2), ..., (a_k, b_k)) = COMMONPAIRS.
```

▶ **Claim 1.** *The algorithm* FIND-EDIT *on* $O(\log n)$ *instances generated by* $Genedit_{Pri,Aux,\epsilon}(n,l)$ *with* Pri *worst-case and* Aux *uniform works and runs in time* $O(n \log n)$ *with probability at least 7/8.* [2]

Proof. Suppose that x_i did not move to y_j by the original sequence of edits. Then, the probability that $x_i^{(k)} = y_j^{(k)}$ is $1/2$ because they were drawn independently uniformly at random. Suppose we have $2 \log n + 3$ auxiliary instances. This means that the probability that $(x)_i = (y)_j$ is at most $1/8n^2$ because each auxiliary instance is independent. Taking a union bound means that the probability that there is a pair x_i, y_j where x_i does not correspond to y_j and $(x)_i = (y)_j$ is at most '/8. Thus, the hashing finds the pairs $(a_1, b_1), ..., (a_k, b_k)$ with probability at least 7/8 in expected time $O(n \log n)$. We claim that the edit distance is equal to $\sum_{i=0}^{k} \max (a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$ if this is true. To see this, the original edit takes x_{a_i} to y_{b_i}, and thus everything between x_{a_i} and $x_{a_{i+1}}$ must be matched to things between y_{b_i} and $y_{b_{i+1}}$. This edit distance is equal to $\max (a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$. Suppose that the edit distance was less. Then there must be a coordinate x_c or y_d that was in the original string.

[2] Recall that $Genedit_{Pri,Aux,\epsilon}$ outputs auxiliary instances where the first string is a perturbation of the original string and the second string is obtained by applying the same edits to the first string.

But then, we could extend this to a smaller edit for the entire string than the original edit, which is a contradiction. Thus, the edit distance is at least $\max(a_{i+1} - a_i - 1, b_{i+1} - b_i - 1)$, and this is achieved by the original edit, because none of them are preserved. The running time is $O(n \log n)$ because each loop takes time $O(n \log n)$. ◀

Multi-Clique-Width*

Martin Fürer†

The Pennsylvania State University, University Park, USA
furer@cse.psu.edu

Abstract

Multi-clique-width is obtained by a simple modification in the definition of clique-width. It has the advantage of providing a natural extension of tree-width. Unlike clique-width, it does not explode exponentially compared to tree-width. Efficient algorithms based on multi-clique-width are still possible for interesting tasks like computing the independent set polynomial or testing c-colorability. In particular, c-colorability can be tested in time linear in n and singly exponential in c and the width k of a given multi-k-expression. For these tasks, the running time as a function of the multi-clique-width is the same as the running time of the fastest known algorithm as a function of the clique-width. This results in an exponential speed-up for some graphs, if the corresponding graph generating expressions are given. The reason is that the multi-clique-width is never bigger, but is exponentially smaller than the clique-width for many graphs. This gap shows up when the tree-width is basically equal to the multi-clique width as well as when the tree-width is not bounded by any function of the clique-width.

1 Introduction

Tree-width is the first and by far the most important width parameter. It is motivated by the fact that almost all interesting problems that are hard for general graphs allow efficient algorithms when restricted to trees. Furthermore such algorithms are often quite trivial. The promise of the notion of tree-width is to extend such efficient algorithms to much larger classes of tree-like graphs. Graphs of bounded tree-width have one shortcoming though. They are all sparse.

Clique-width [8] is the second most important width parameter. It has been defined by Courcelle and Olariu [12] based on previously used operations [8]. It is intended to compensate for the main shortcoming of the class of graphs of bounded tree-width. The idea is that many graphs are not sparse, but are still constructed in a somewhat simple and uniform way. One would expect to find efficient algorithms for such graphs too. The most extreme example is the clique. It's hard to find a natural problem that is difficult for a clique.

It turns out that graphs of bounded tree-width actually also have bounded clique-width [12, 6], and many efficient algorithms extend to the larger class. Indeed, every graph property expressible in $\mathcal{MS}_1$, the monadic second order logic with set quantifiers for vertices only,

is decidable in linear time (linear in $|V| + |E|$) for graphs of bounded clique-width [10]. On the other hand, graph properties expressible in $\mathcal{MS}_2$, the monadic second order logic with set quantifiers for vertices and edges, is decidable in linear time for graphs of bounded tree-width [7], but not for graphs of bounded clique-width [10] under suitable complexity assumptions.

Recently the split-matching-width (sm-width), a new width parameter has been defined [25] to handle some of the $\mathcal{MS}_2$ expressible problems for unbounded tree-width. The strength of sm-width is strictly between tree-width and clique-width. We will not discuss it, because we focus on parameters that are at least as strong as clique-width.

We are concerned with the fact that the containment of the bounded tree-width graphs in bounded clique-width graphs is not obvious. Furthermore, the generalization from bounded tree-width to bounded clique-width does not come cheap. The width can blow up exponentially, with a potential for a significant loss of efficiency for many algorithms.

This creates a cumbersome situation for the many problems that have efficient solutions in terms of tree-width as well as in terms of clique-width, assuming the corresponding decompositions are known. One would like to run the algorithm based on clique-width to cover a much larger class of graphs, but that would mean an exponential sacrifice in running time for some graphs with small tree-width. Arguably, there should be a notion of a width parameter that bridges this gap more graciously.

Naturally, this aesthetic goal is not the whole story. One could run a tree-width and a clique-width based algorithm and take the result from the one that finishes first. Maybe the following argument is more important. If every clique-width based algorithm is exponentially slower than a tree-width based algorithm for a typical graph of small tree-width, then this seems to indicate some deficiency of the notion of clique-width. Therefore, what we really want, and what we will achieve, is finding a natural notion of width, such that for many important computational problems, algorithms based on this width have all of the following desirable properties.

- The algorithms based on this width are at least as fast as algorithms based on tree-width.
- The algorithms based on this width are at least as fast as algorithms based on clique-width.
- The algorithms based on this width are exponentially faster than algorithms based on clique-width, not only for graphs of small tree-width, but for many graphs of arbitrary large tree-width.

The current author has searched for some time for a parameter naturally generalizing tree-width and clique-width. Ideally, there should be no exponential blow-up in the parameter value. The second objective has been obtained with the notion of fusion-width [18]. It has been shown before that the fusion operation does not produce unbounded clique-width graphs from bounded clique-width graphs [9]. Indeed, there is a much tighter relationship. Graphs of tree-width k have fusion-width at most $k + 2$ [18], while in the worst case, they have clique-width exponential in k [6].

This is a very desirable property of fusion width. The drawback is that attaching a fusion operation is somewhat unnatural. It is an artificial push of the tree-width concept into a clique-width-like environment. Here, we investigate a far more natural width parameter that achieves this goal in a more direct way. We call it *multi-clique-width*, it is obtained by a simple modification in the notion of clique-width, namely by allowing every vertex to have multiple labels. Furthermore, it seems that the multi-clique-width might often be exponentially smaller than the fusion-width. On the other hand, it can be shown that multi-clique-width is never more than twice the fusion-width.

In this paper, we propose multi-clique-width as a serious contender of clique-width. This powerful parameter has some very desirable properties. Its definition is equally simple and natural as that of clique-width. The multi-clique-width is never bigger than the clique-width, but often exponentially smaller [13]. And most importantly, there is no explosion of the width when moving from tree-width to multi-clique-width. Furthermore, there are interesting algorithms where the dependence of the running time on the (potentially much smaller) multi-clique-width is about the same as the dependence on the clique width for a similar algorithm working with clique-width. Thus, multi-clique-width allows some tasks to be solved much more efficiently than previously known.

There are other important width parameter, the rank-width [22] and the boolean-width [5], that share some significant properties with the multi-clique-width. They too are never bigger than the clique-width and can be exponentially smaller. So why do we want to investigate yet another similar parameter?

Rank-width, boolean-width, clique-width, and multi-clique-width are all equivalent in the sense that the exact same problems are solvable in polynomial time for bounded width. If one of these parameters is bounded (by a constant), then so are the others. Rank-width has been introduced with this equivalence in mind [22]. Before, the graphs of bounded clique-width could not be identified computationally. Therefore, graphs of bounded clique-width could only be handled efficiently, when a corresponding k-expression had been given. Now the rank-width $\mathrm{rw}(G)$ can be approximated by a constant factor, and a $2^{3\mathrm{rw}(G)+2}-1$-expression can be computed in time $O(f(k)\,n^9 \log n)$ for some function f [22]. The later algorithm [20] to compute the rank-width exactly with a similar running time has not much effect on the approximability of clique-width. In theoretical investigations, the exponential bound on the clique-width has not often been viewed as a major concern, because the main goal has been to handle bounded clique-width graphs in polynomial time, not to speed them up, even when the rank-width is much smaller than the clique-width.

There are algorithms based directly on rank-width [19]. Still, for many application algorithms, clique-width based algorithms are more natural and easier to design.

We will show that for some computational tasks multi-clique-width can be used with the same ease as clique-width, but with an exponential speed-up for many graphs. These are exponential speed-ups in the parameter, meaning that the class of graphs with bounded parameter value would not change, just the computations get much faster.

Many questions are not yet answered for multi-clique-width. We conjecture multi-clique-width to be NP-hard. Nevertheless it might be that multi-clique-width could be approximated by a constant factor in polynomial time. We don't yet know. These are open problems for clique-width and boolean-width too.

In comparison with boolean-width or rank-width, when the corresponding decompositions are given, we notice that the known efficient algorithms for NP-complete problems are quadratic in n for bounded width, while for $\mathcal{MS}_1$ expressible graph properties, we have linear time algorithms [10] for bounded clique-width or multi-clique-width. Furthermore, we will illustrate that such algorithms can be quite simple and efficient as a function of the multi-clique-width.

Naturally, one could argue that this is an unfair comparison. The linear time is a result of the structural information that is given by the expression defining a graph with a bound on the clique-width or multi-clique-width. Boolean-width or rank-width on the other hand are defined with existential properties that constantly require some search in the graph. There are no concise boolean expressions or rank expressions defining these graphs. There is truth in this argument, but at the same time, one could claim that this is still an advantage of clique-width and multi-clique width. Maybe, some nice classes of graphs have

nice expressions describing them. If such expressions are known or can easily be found, they certainly should be used for efficient algorithms.

2 Definitions and Preliminaries

We use the standard notions of tree decomposition, tree-width, k-expression, and clique-width.

▶ **Definition 1.** A *tree decomposition* of a graph $G = (V, E)$ is a pair $(\{B_i : i \in I\}, T)$, where $T = (I, F)$ is a tree and each node $i \in I$ has a subset $B_i \subseteq V$ of vertices (called the bag of i) associated to it with the following properties.

1. $\bigcup_{i \in I} B_i = V$, i.e., each vertex belongs to at least one bag.
2. For all edges $e = \{p, q\} \in E$, there is at least one $i \in I$ with $\{p, q\} \subseteq B_i$, i.e., each edge is represented by at least one bag.
3. For every vertex $v \in V$, the set of indices i of bags containing v induces a subtree of T (i.e., a connected subgraph of T).

▶ **Definition 2.** The *width of a tree decomposition* is 1 less than its largest bag size. The *tree-width* $\mathrm{tw}(G)$ [24] of a graph G is the width of a minimal width tree decomposition of G.

It is NP-complete to decide whether the tree-width of a graph is at most k (if k is part of the input) [1]. For every fixed k, there is a linear time algorithm deciding whether the tree-width is at most k, and if that is the case, producing a corresponding tree decomposition [2]. For arbitrary k, this task can still be approximated. A tree decomposition of width $O(k \log n)$ can be found in polynomial time [4], and in time $O(c^k n)$ almost a 5-approximation [3] can be found (a tree of width at most $5k + 4$ to be precise). Furthermore, a tree decomposition of width $O(k^2)$ can be found in time $O(k^7 n \log n)$ [17].

It is often convenient to view T as a rooted tree, where an arbitrary fixed node has been chosen as the root.

▶ **Definition 3.** A *semi-smooth tree decomposition* of width k is a rooted tree decomposition where the bag B_i of every node i contains exactly 1 vertex that is not in the bag of the parent node $p(i)$. For rooted trees T with $v \in B_i \setminus B_{p(i)}$, we say that *node i is the* home *of vertex v*.

In other words, the home of a vertex v is the highest node whose bag contains v. The bag B_r of the root r of a semi-smooth tree decomposition contains just one vertex.

▶ **Proposition 4.** *Every graph $G = (V, E)$ has a semi-smooth tree decomposition of width $k = \mathrm{tw}(G)$ with $|I| = |V|$. Any tree decomposition of bounded width can be transformed into a semi-smooth tree decomposition in linear time.*

Proof. Do a depth-first search of the tree and omit nodes whose bag is contained in the bag of the parent. Insert intermediate nodes if more than one vertex has the same home. ◀

We use the standard notation of k-expression to define clique-width.

▶ **Definition 5.** A *k-expression* is an expression formed from the atoms $i(v)$, the two unary operations $\eta_{i,j}$ and $\rho_{i \to j}$, and one binary operation $\oplus$ as follows.

- $i(v)$ creates a vertex v with label i, where i is from the set $\{1, \ldots, k\}$.
- $\eta_{i,j}$ creates an edge between every vertex with label i and every vertex with label j for $i \neq j$ (with $i, j \in \{1, \ldots, k\}$).
- $\rho_{i \to j}$ changes all labels i to j (with $i, j \in \{1, \ldots, k\}$).
- $\oplus$ (join-operation) does a disjoint union of the generated labeled graphs.

Finally, the *generated graph* is obtained by deleting the labels.

We also allow multi-way join-operations, as $\oplus$ is associative.

▶ **Definition 6.** The *clique-width* $\mathrm{cw}(G)$ of a graph is the smallest k such that the graph can be defined by a k-expression [12].

Computing the clique-width is NP-hard [15]. Thus, one usually assumes that a graph is given together with a k-expression.

Theoretically, this is not necessary, because for constant k, the clique-width can be approximated in polynomial time [22, 21]. But the approximation ratio is exponential in k.

Now we define multi-clique-width in a similar way as clique-width. The essential difference is that every vertex can have any set of labels (including singleton sets and the empty set). There is a new operation ϵ_i to delete a label. The creation of multiple vertices with the same set of labels by one command is an unessential convenience.

▶ **Definition 7.** A *multi-k-expression* is an expression formed from the atoms $m\langle i_1, \ldots, i_\ell\rangle$, the three unary operations $\eta_{i,j}$, $\rho_{i\to S}$, and ϵ_i, as well as the binary operation $\oplus$ as follows. Assume $i, j \in \{1, \ldots, k\}$, $\ell \in \{0, \ldots, k\}$ and $\emptyset \subseteq S, \{i_1, \ldots, i_\ell\} \subseteq \{1, \ldots, k\}$).

- $m\langle i_1, \ldots, i_\ell\rangle$ with m a positive integer and $i_1 < \cdots < i_\ell \leq k$, creates m vertices, each with label set $\{i_1, \ldots, i_\ell\}$.
- $\eta_{i,j}$ creates an edge between every vertex u with label i and every vertex v with label j. This operation is only allowed when there are no vertices with label i and j simultaneously, in particular $i \neq j$.
- $\rho_{i\to S}$ replaces label i by the set of labels S, i.e., if a vertex v had label set S' with $i \in S'$ before this operation, then v has label set $(S' \setminus i) \cup S$ after the operation.
- ϵ_i deletes the label i from all vertices.
- $\oplus$ (join-operation) does a disjoint union of the generated labeled graphs.

Finally, the *generated graph* is obtained by deleting the labels.

S and $\{i_1, \ldots, i_\ell\}$ are allowed to be empty, even though the latter is not very interesting, as it only creates isolated vertices. Note that ϵ_i is just the special case of $\rho_{i\to S}$ with $S = \emptyset$. We list it separately, because one might want to consider the *strict multi-k-expressions* without $\rho_{i\to S}$. In Theorem 13 below, $\rho_{i\to S}$ is not used. Alternatively, one might restrict $\rho_{i\to S}$ to the classical case with S being a singleton. The relative power of these 3 versions might be worth studying.

▶ **Definition 8.** The *multi-clique-width* $\mathrm{mcw}(G)$ of a graph is the smallest k such that the graph can be defined by a multi-k-expression.

It turns out that multiply labeled graphs have been used before [12] in a more auxiliary role, and a variant of the multi-clique-width has actually appeared in the literature under the name m-clique-width [13] in the context of preprocessing for shortest path routing computations.

Here we list the standard definition of boolean-width in order to compare it with multi-clique-width.

▶ **Definition 9.** A *decomposition tree* of a graph $G = (V, E)$ is a tree T where V is the set of leaves and where all internal nodes have degree 3.
Every edge e of T defines a partition of V into X and $\overline{X}$ consisting of the leaves of the two trees obtained from T by removing e.
The *set of unions of neighborhoods* of X across the cut $\{X, \overline{X}\}$ is the set

$$U(X) = \{S' \subseteq \overline{X} \mid \exists S \subseteq X \;\; S' = N(S) \cap \overline{X}\}.$$

X defines bool-dim$(X) = \log_2 |U(X)|$.
The *boolean-width* of G is the minimum over all trees T of the maximum over all cuts $\{X, \overline{X}\}$ defined by an edge e of T of bool-dim$(X) = \log_2 |U(X)|$.

3 Relationship between Different Width Parameters

Multi-clique-width extends the notions of tree-width and of clique-width in a natural way.

▶ **Proposition 10.** *For every graph G,* $\mathrm{mcw}(G) \leq \mathrm{cw}(G) \leq 2^{\mathrm{mcw}(G)}$.

Proof. The first inequality directly follows from the definitions. For the second inequality, just use a label for every set of labels. ◀

▶ **Corollary 11.** *A class of graphs has bounded clique-width if and only if it has bounded multi-clique-width.*

▶ **Corollary 12.** *Properties of graphs expressible in $\mathcal{MS}_1$ (monadic second order logic without quantifiers over sets of edges) are linear time decidable for graphs of bounded multi-clique-width.*

Proof. This follows from Corollary 11 and the corresponding meta-theorem for clique-width [10]. ◀

▶ **Theorem 13.** *If a tree-decomposition of width k of a graph $G = (V, E)$ is given, then a multi-$(k+2)$-expression for G can be found in polynomial time.*

Proof. Assume, G is given with a tree decomposition of width $k = \mathrm{tw}(G)$. In linear time, the tree decomposition is transformed into a semi-smooth tree decomposition $(\{B_i : i \in I\}, T)$. Now we assign an identifier $\iota(v)$ from $\{1, 2, \ldots, k+1\}$ to each vertex v top-down, i.e., starting at the root of T. When identifiers have been assigned to the vertices whose homes are above the home of vertex v, we assign to vertex v the smallest identifier not assigned to the other vertices in the bag of the home of v.

Next, we define a multi-$(k+2)$-expression whose parse tree T' is basically isomorphic to the tree T of the tree decomposition. The difference it that in T' every internal node has an additional child that is a leaf. We call it an auxiliary leaf. Furthermore, above each internal node i, we introduce three auxiliary nodes obtained by subdividing the edge to the parent of i.

The main idea is that every vertex v is created at its home, or more precisely, in the auxiliary node below its home. Then the edges from v to neighbors of v with a home further down the tree are added. The upper neighbors of v, i.e., those that have their home higher up the tree, are not yet created. Vertex v remembers to attach to these neighbors later by taking the set of identifiers of these neighbors as its labels. All upper neighbors of v are together with v in the bag B_i of the home i of v in T. The vertex v needs at most k labels for this purpose. We give v an additional label, $k+2$, to allow the lower neighbors of v to connect to v. Node i of T' is a multi-way join operation of all its children, including the new auxiliary child. The purpose of the three nodes inserted above node i is to add the edges between v and its neighbors in the subtree of i, and to delete the two labels ($k+2$, and $\iota(v)$, the identifier of v) that have been used to create these new edges. The multi-$(k+2)$-expression is built bottom-up.

Now we define the multi-$(k+2)$-expression exactly by assigning atoms to the leaves and operations to the internal nodes as follows.

Regular leaf: Let the leaf i be the home of some vertex v. Let $v_1, \ldots, v_\ell$ be the neighbors of v with identifiers $i_1, \ldots, i_\ell$. Clearly, $\{v, v_1, \ldots, v_\ell\} \subseteq B_i$. Then the expression $1\langle i_1, \ldots, i_\ell\rangle$ creates v in leaf i.

Auxiliary leaf: Let the internal node i be the home of some vertex v. Let $v_1, \ldots, v_\ell$ be the upper neighbors of v with identifiers $i_1, \ldots, i_\ell$. Let $c_0(i)$ be the child of i which is an auxiliary leaf. Then the expression for $c_0(i)$ is $1\langle k+2, i_1, \ldots, i_\ell\rangle$.

Internal node: Let i be the home of some vertex v, and let $c_1(i), \ldots, c_q(i)$ be the children of i in T. Let $c_0(i)$ be the auxiliary leaf child of i in T'. Furthermore, let $\iota(v)$ be the identifier of v. Assume, for child $c_j(i)$ we already have the expression E_j. Then the multi-$(k+2)$-expression for node i, or more precisely of the third auxiliary node above it, is

$$\epsilon_{k+2}(\epsilon_{\iota(v)}(\eta_{\iota(v),k+2}(E_0 \oplus E_1 \oplus \cdots \oplus E_q))).$$

Now the following is easily proved by induction on the height of node i.

▶ **Claim 14.** *The multi-$(k+2)$-expression for node i generates the labeled graph $G_i = (V_i, E_i)$ induced by the vertices whose home is in the subtree of i. Furthermore, the set of labels of every vertex $v \in V_i$ is equal to the set of identifiers of the neighbors of v in $V \setminus V_i$.*

By the inductive hypothesis of the claim, all vertices V' in the subtree of node i that are adjacent to v in G have a label $\iota(v)$. The vertex v has a label $k+2$, but no label $\iota(v)$. Thus the operation $\eta_{\iota(v),k+2}$ creates exactly the edges between v and V'. Now, the labels $\iota(v)$ and $k+2$ can be deleted, because both have served their purpose. From every vertex labeled $\iota(v)$, the edge to v is now already constructed, and the label $k+2$ only had to mark the vertex v for the construction of these edges.

The claim for the root implies the theorem. ◀

A weaker form of Theorem 13 is the implied inequality between multi-clique-width and tree-width.

▶ **Corollary 15.** *For every graph G,* $\mathrm{mcw}(G) \leq \mathrm{tw}(G) + 2$.

As an immediate corollary, we obtain $cw(G) \leq 2^{\mathrm{tw}(G)+2}$. The tighter bound of $cw(G) \leq 2^{\mathrm{tw}(G)+1} + 1$ [12] is obtained by noticing that one could use the label $k+2$ strictly as a singleton label. Instead of deleting it with an ϵ_{k+2} operation, one could change it to the set of other labels we wanted to assign to that vertex using a $\rho_{i\to S}$ operation. The even tighter bound $cw \leq 1.5 \cdot 2^{\mathrm{tw}(G)}$ [6] is obtained by handling higher degree join nodes more efficiently. Following every binary join, the necessary edges could be inserted, allowing the number of labels to be decreased. This saves one fourth of the labels.

▶ **Corollary 16.** *There are graphs G with* $\mathrm{cw}(G) \geq 2^{\lfloor \mathrm{mcw}(G)/2 \rfloor - 2}$.

Proof. There are graphs G with $\mathrm{tw}(G) = k$ and clique-width $\mathrm{cw}(G) \geq 2^{\lfloor k/2 \rfloor - 1}$ [6]. Such graphs have multi-clique-width $\mathrm{mcw}(G) \leq k+2$ by Corollary 15. ◀

Naturally, it is easy to find graph classes with unbounded tree-width that still exhibit this exponential discrepancy between clique-width and multi-clique-width. One way is just to add a large clique, but there are many not so obvious ways.

We want to compare multi-clique-width with boolean-width.

▶ **Theorem 17.** *For every graph G,* $\mathrm{boolw}(G) \leq \mathrm{mcw}(G) \leq 2^{\mathrm{boolw}(G)}$.

Proof. boolw$(G) \leq$ mcw(G): Assuming mcw$(G) = k$, we start with a multi-k-expression for G. W.l.o.g., assume that each vertex v is created as a single vertex by the operation $m\langle i_1, \ldots, i_j\rangle$ with $m = 1$. Then, there is a bijection between the vertices V and the leaves of the parse tree T. Viewed as a graph, the other nodes of T have degrees 2 or 3. We replace all maximal paths with internal nodes of degree 2 by single edges to obtain a tree T'.

Consider any edge $e = (u, v)$ of T', where v is a descendant of u in T. Let $X \subseteq V$ be the set of vertices of the subtree T_v. For every subset $S \subseteq X$, the set $N(S) \cap \overline{X}$ of neighbors of S outside of X only depends on the union of the set of labels of the vertices of S. There are at most 2^k such subsets of labels, and thus at most 2^k such neighborhoods. The binary logarithm of the largest such number of neighborhoods over all edges of T' is an upper bound on boolw(G), i.e., boolw$(G) \leq k$.

mcw$(G) \leq 2^{\text{boolw}(G)}$: By Proposition 10, mcw$(G) \leq$ cw(G), and the inequality cw$(G) \leq 2^{\text{boolw}(G)}$ [5] is known. ◀

Even though, boolean-width has the desirable property boolw$(G) \leq$ mcw(G), sometimes more efficient algorithms are possible in terms of mcw(G) than in terms of boolw(G). Indeed, every graph property expressible in $\mathcal{MS}_1$, is decidable in linear time for graphs of bounded clique-width [10], while for arbitrary graphs of bounded boolean-width, at least quadratic time is required. Naturally, this can also be viewed as an indication of the strength of the boolean-width parameter. Even graphs without a simple structure can have small boolean-width. In the next section, we will see that for specific problems the (exponential) dependance of the running time on the multi-clique-width can be quite good.

4 Algorithms based on Multi-Clique-Width

The algorithmic purpose of clique-width and other width parameters is to put problems into FPT, i.e., making them fixed parameter tractable (see [14]). This means achieving a running time of $O(f(k)n^{O(1)})$ for an arbitrary computable function f. In reality things are not so bad. Algorithms based on clique-width often have a running time of $O(c^k n^e)$ or $O(c^{k \log k} n^e)$ with $k =$ cw(G), $n = |V|$, and c and e being small constants.

Assume that we are given a multi-k-expression for G and we have an algorithm with similar running time when k is the multi-clique-width. Then we have an exponential time speed-up when choosing the multi-clique based algorithm with running time $2^{O(k)}n^e$, instead of the clique-width based algorithm with clique-width $2^{\Omega(k)}$ and running time $2^{2^{\Omega(k)}}n^e$ for infinitely many graphs.

Indeed, we want to illustrate here that this scenario is occurring quite frequently. Let us see that there are many graphs with unbounded tree-width, multi-clique-width k, and clique-width exponential in k. Without changing the notion of multi-clique-width, we could extend the multi-k-expressions to allow arbitrary $k/2$-labeled graphs of tree-width at most $k/2 - 2$ as atoms instead of just isolated vertices. It is not had to see that such graphs could be produced by proper multi-k-expressions. $k/2$ labels are sufficient to simulate the tree-width construction, and the remaining $k/2$ labels could be placed in any possible way.

But if at least one of the tree-width $k/2-2$ components are complicated, then the clique-width is exponential in k [6]. And if the graph contains a large clique of size ℓ (which could be $\Omega(n)$), then the tree-width is at least ℓ. Thus, we have a huge class of graphs where the multi-clique-width is exponentially better than the clique-width.

Now we exhibit the ease of use of the parameter mcw(G) for Independent Set. The running time as a function of the width is roughly the same for clique-width k as for multi-clique-width k. Hence, we gain an exponential speed-up in the width parameter for all the many instances were the clique-width is exponentially bigger than the multi-clique-width.

Instead of only finding a maximum independent set, or even just computing its size, we solve the more involved problem of computing the independent set polynomial, i.e., computing the numbers of independent sets of all sizes. This is not much more difficult, and one can easily simplify the algorithm if only a maximum independent set is needed. Then the dependence of the running time on the size n goes down to linear from polynomial, while the dependence on the width k stays singly exponential. In particular, we have an FPT algorithm to compute the independent set polynomial. We refer to [11, 16] for more discussions of the fixed parameter tractability of counting problems.

It is worth mentioning that the very same problem of computing the number of independent sets of all sizes has been studied by Bui-Xuan et al. [5]. They achieve a running time of $O(\alpha^2 n^2 k 2^{2k})$ for graphs with boolean-width k and maximum independent set size α. Note that α could be as large as $\Omega(n)$. We will not elaborate on our running time, but just remark that using FFTs, $O(\alpha \log \alpha\, nk2^k)$ is sufficient for multi-clique-width k.

▶ **Definition 18.** The independent set polynomial of a graph G is

$$I(x) = \sum_{i=1}^{n} a_i x^i$$

where a_i is the number of independent sets of size i in G.

The independent set polynomial is not strong enough to describe the involvement of the different labels in the independent sets. We need to do a more detailed counting to allow recurrence equations to govern the definition of the polynomials as the labeled graph is assembled by a multi-k-expression.

▶ **Definition 19.** Let $[k] = \{1, \ldots, k\}$ be the set of vertex labels. The $[k]$-labeled independent set polynomial of a $[k]$-labeled graph G (each vertex can have multiple labels from $[k]$) is

$$P(x, x_1, \ldots, x_k) = \sum_{i=1}^{n} \sum_{(n_1,\ldots,n_k)\in\{0,1\}^k} a_{i;n_1,\ldots,n_k}\, x^i \prod_{j=1}^{k} x_j^{n_j}$$

where $n_j \in \{0, 1\}$ and $a_{i;n_1,\ldots,n_k}$ is the number of independent sets of size i in G which contain some vertices with label j if and only if $n_j = 1$.

The $[k]$-labeled independent set polynomial is used in the inductive construction. At the end, the independent set polynomial $I(x)$ is easily obtained from $[k]$-labeled independent set polynomial.

▶ **Theorem 20.** *Given a graph G with n vertices, and a multi-k-expression generating G with multi-clique-width k, the independent set polynomial $I(x)$ of G can be computed in time $O(2^k(kn)^{O(1)})$.*

Proof. Using dynamic programming, we compute the $[k]$-labeled independent set polynomial of the $[k]$-labeled graphs generated by subexpressions of the given multi-k-expression. The computation is done bottom-up in the parse tree of the given multi-k-expression.

For any atomic expression $m\langle i_1, \ldots, i_j\rangle$ creating m vertices with labels $i_1, \ldots, i_j$, we have the $[k]$-labeled independent set polynomial

$$1 + \sum_{\ell=1}^{m} \binom{m}{\ell} x^\ell x_{i_1} \cdots x_{i_j} = 1 + ((1+x)^m - 1) x_{i_1} \cdots x_{i_j}.$$

In $O(m)$ arithmetic operations, we can compute all coefficients using the recurrence $\binom{m}{\ell+1} = \binom{m}{\ell}(m-\ell)/(\ell+1)$. Thus all atomic expressions for the $n = |V|$ vertices can be computed in time $O(n)$.

If the expression E has the polynomial $\tilde{P}(x, x_1, \ldots, x_k)$, then $\eta_{i,j}(E)$ has the polynomial

$$P(x, x_1, \ldots, x_k) = \tilde{P}(x, x_1, \ldots, x_k) \mod x_i x_j,$$

i.e., terms containing x_i and x_j are deleted. This is correct, because a set of vertices is independent after the introduction of the edges between labels i and j, if and only if it was an independent set before and does not contain both labels i and j.

If the expression E has the polynomial $\tilde{P}(x, x_1, \ldots, x_k)$, then $\rho_{i\to S}(E)$ has the polynomial

$$\begin{aligned} P(x, x_1, \ldots, x_k) = \tilde{P}(x, x_1, \ldots, x_{i-1}, x_{i_1} \cdots x_{i_j}, x_{i+1}, \ldots, x_k) \\ \mod (x_{i_1}^2 - x_{i_1}) \cdots \mod (x_{i_j}^2 - x_{i_j}) \end{aligned} \tag{1}$$

for $S = \{i_1, \ldots, i_j\}$, i.e., first x_i is replaced by the product $x_{i_1} \ldots x_{i_j}$. Then squares of indeterminates are replaced by their first powers. This is correct, because we still count all independent sets. They just occur in different categories as they involve different labels.

If the expression E has the polynomial $\tilde{P}(x, x_1, \ldots, x_k)$, then $\epsilon_i(E)$ has the polynomial

$$P(x, x_1, \ldots, x_k) = \tilde{P}(x, x_1, \ldots x_{i-1}, 1, x_{i+1}, \ldots, x_k),$$

i.e., the indeterminate x_i is replaced by 1. This is correct, because it is just a special case $\rho_{i\to S}(E)$.

If the expression E_ℓ ($\ell \in \{1, 2\}$) has the polynomial $\tilde{P}_\ell(x, x_1, \ldots, x_k)$, then the expression $E_1 \oplus E_2$ has the polynomial

$$\begin{aligned} P(x, x_1, \ldots, x_k) = \tilde{P}_1(x, x_1, \ldots, x_k)\, \tilde{P}_2(x, x_1, \ldots, x_k) \\ \mod (x_1^2 - x_1) \cdots \mod (x_k^2 - x_k), \end{aligned} \tag{2}$$

i.e., in the product of the polynomials, every x_i^2 is replaced by x_i, as we only care about the occurrence of a label and not about the multiplicity of such an occurrence. This is correct, because every independent set of G_1 can be combined with every independent set of G_2 to form an independent set of the join graph G, and every independent set of G can be formed in this way.

Finally,

$$I(x) = \sum_{i=1}^{n} a_i x^i = \sum_{i=1}^{n} \sum_{(n_1,\ldots,n_k)\in\{0,1\}^k} a_{i,n_1,\ldots,n_k} x^i = P(x, 1, \ldots, 1),$$

because
$a_i = \sum_{(n_1,\ldots,n_k)\in\{0,1\}^k} a_{i,n_1,\ldots,n_k}$.

To bound the running time, one should notice that the polynomial $P(x, x_1, \ldots, x_k)$ has $2^k(n+1)$ coefficients.

The polynomial $\tilde{P}(x, x_1, \ldots, x_{i-1}, x_{i_1} \cdots x_{i_j}, x_{i+1}, \ldots, x_k)$ in Eq. (1) has at most $2^k(n+1)$ non-zero coefficients, not $3^k(n+1)$, because the substitution does not increase the number of monomials. If the product in Eq. (2) is computed by school multiplication, then the running time is $O(4^k(kn)^{O(1)})$. But with a fast Fourier transform (evaluating the polynomial for $x_i = 0$ and $x_1 = 1$ for all i), the time is only $O(2^k(kn)^{O(1)})$. ◀

The easier problem of just finding the size of a maximum independent set (rather than computing the numbers of independent sets of all sizes) is now trivial. At each stage, for all exponents $n_1, \ldots, n_k$, the coefficient $a_{i;n_1,\ldots n_k}$ is only stored for the largest i with $a_{i;n_1,\ldots,n_k} \neq 0$.

▶ **Corollary 21.** *A maximum independent set can be found in time $O(2^k k^{O(1)} n)$ in graphs with multi-clique-width k.*

Proof. If during the dynamic programming algorithm to compute the size of a maximum independent set, one always stores where the largest exponent i came from, then at the end, one can easily backtrace to actually find a maximum independent set. ◀

As an additional example, we consider the NP-complete decision problem c-coloring, asking whether the input graph G can be colored with c colors for a constant integer $c \geq 3$, such that no adjacent vertices have the same color.

▶ **Theorem 22.** *For graphs G of multi-clique-width k with a given multi-k-expression for G, and any positive integer constant c, the c-coloring problem can be solved in time $2^{O(ck)} n$.*

Proof. We present a dynamic programming algorithm based on the parse tree structure of the multi-k-expression. We classify the colorings of the graphs generated by sub-expressions according to the labels used for the vertices of each color. Let Q with $|Q| = c$ be the set of colors and L with $|L| = k$ be the set of labels. Let $B_1, \ldots, B_r$ with $r = 2^{ck}$ be the sequence (say in lexicographic order) of all bipartite graphs with the left vertex set Q and the right vertex set L. Let E_p be the set of edges in B_p. For every subexpression F, we define $F(B_p)$ to be true, if and only if the following holds. The graph generated by F can be colored with Q such that some vertex colored with $q \in Q$ is labeled with a set of labels containing $i \in L$, if and only if (q, i) is an edge in B_p.

We now show that $F(B_p)$ can easily be computed from all the $F'(B_{p'})$ where F' is a subexpression of F and $p' \in \{1, \ldots, r\}$. We analyze according to the structure of F.

If F is an atomic expression $m\langle i_1, \ldots, i_j\rangle$ creating m vertices with labels $i_1, \ldots, i_j$, then $F(B_p)$ is true, if and only if $E_p = \{(q, i) \mid q \in Q' \text{ and } i \in \{i_1, \ldots, i_j\}\}$ for some Q' with $\emptyset \neq Q' \subseteq Q$.

If $F = \eta_{i,j}(F')$, then $F(B_p)$ is true, if and only if $F'(B_p)$ is true and for no color $q \in Q$ there are both edges (q, i) and (q, j) present in B_p. In other words, a previous coloring is still valid, if and only if no color appears at both endpoints of newly added edges.

If $F = \rho_{i\to S}(F')$, then $F(B_p)$ is true, if and only if $F'(B_{p'})$ is true for some p' with

$$E_p = \{(q, \ell) \mid (q, \ell) \in E_{p'} \text{ and } \ell \neq i\} \cup \{(q, j) \mid (q, i) \in E_{p'} \text{ and } j \in S\}.$$

If $F = F' \oplus F''$, then $F(B_p)$ is true, if and only if $F'(B_{p'})$ is true and $F''(B_{p''})$ is true for some p', p'' with $E_p = E_{p'} \cup E_{p''}$.

Given this simple characterization of $F(B_p)$ in terms of $F'(B_{p'})$ for some p' and the immediate sub-expressions F', it should be immediately clear how the value of $F(B_p)$ can be computed, when the values of the $F'(B_{p'})$ are known.

Furthermore, it is a simple proof by induction on the structure of an expression F that $F(B_p)$ is true, if and only if the graph generated by F can be colored with Q such that some vertex colored with $q \in Q$ is labeled with a set of labels containing $i \in L$, if and only if (q, i) is an edge in B_p.

Naturally, at the end, the graph generated by F is k-colorable, if and only if $F(B_p)$ is true for some B_p.

The running time is linear in n, because there are $O(n)$ nodes to process and the time spent in every node only depends on the number c of colors and the number k of labels. In every node, an array of 2^{ck} boolean values (one for each bipartite graph on the vertex sets Q and L) has to be processed in a simple fashion. The resulting running time is $2^{O(ck)}n$.

There is quite some waste of time involved in handling all the bipartite graphs on the vertex sets Q and L, because the truth value for a graph B_j does not change, when the set of colors Q and the set of labels L are permuted in an arbitrary way. This does not mean that the running time can be divided by $c!k!$, because typically many such permutations are automorphisms not creating new bipartite graphs. The exact number of isomorphism types of such bipartite graphs can be computed with the Redfield-Pólya enumeration theorem (see [23]), but that does not result in a nicer upper bound. Clearly, any practical implementation would do the computation for just one bipartite graph for every isomorphism type. ◀

5 Conclusions and Open Problems

We have proposed a powerful parameter multi-clique-width. It allows us to achieve faster running times for natural classes of graphs and interesting algorithmic tasks. Assume, we are given the input graph by a multi-k-expression. Then we have very efficient algorithms for this class of graphs, as illustrated by the independent set polynomial and the coloring problem. On the other hand, for any algorithm based on clique-width, we could only get exponentially slower (in k) algorithms for the same problems and the same collection of graphs. Also, equally efficient algorithms are not known based on rank-width or boolean-width, when the corresponding decompositions are given.

Most questions related to the new multi-clique-width are still open. Is it difficult to compute or approximate? We expect it to be NP-hard, like clique-width. We also conjecture it to be in FPT (fixed parameter tractable) and to be constant factor approximable in time singly exponential in the multi-clique-width and linear in the length like tree-width. But obviously this is very difficult, as it is also open for clique-width.

A main question is whether most algorithms for clique-width k, can be extended to work with similar efficiency for multi-clique-width k. We have illustrated that this is the case for some interesting counting and decision problems. On the other hand, there is the question of identifying the problems where this is not the case.

Abstract

We initiate a line of investigation into biological neural networks from an algorithmic perspective. We develop a simplified but biologically plausible model for distributed computation in *stochastic spiking neural networks* and study tradeoffs between computation time and network complexity in this model. Our aim is to abstract real neural networks in a way that, while not capturing all interesting features, preserves high-level behavior and allows us to make biologically relevant conclusions.

In this paper, we focus on the important 'winner-take-all' (WTA) problem, which is analogous to a neural leader election unit: a network consisting of n input neurons and n corresponding output neurons must converge to a state in which a single output corresponding to a firing input (the 'winner') fires, while all other outputs remain silent. Neural circuits for WTA rely on inhibitory neurons, which suppress the activity of competing outputs and drive the network towards a converged state with a single firing winner. We attempt to understand how the number of inhibitors used affects network convergence time.

We show that it is possible to significantly outperform naive WTA constructions through a more refined use of inhibition, solving the problem in $O(\theta)$ rounds in expectation with just $O(\log^{1/\theta} n)$ inhibitors for any θ. An alternative construction gives convergence in $O(\log^{1/\theta} n)$ rounds with $O(\theta)$ inhibitors. We complement these upper bounds with our main technical contribution, a nearly matching lower bound for networks using $\geq \log\log n$ inhibitors. Our lower bound uses familiar indistinguishability and locality arguments from distributed computing theory applied to the neural setting. It lets us derive a number of interesting conclusions about the structure of any network solving WTA with good probability, and the use of randomness and inhibition within such a network.

1 Introduction

In this paper, we study biological neural networks from an algorithmic perspective, focusing on understanding tradeoffs between computation time and network complexity. We use a biologically plausible yet simplified neural computational model. Our goal is to abstract real neural networks in a way that, while not capturing all interesting features, preserves high-level behavior and allows us to make biologically relevant conclusions.

1.1 Model and Problem Statement

Model

We work with *spiking neural networks* (SNNs) [26, 27, 12, 18, 15], in which neurons fire in discrete pulses, in response to a sufficiently high membrane potential. This potential is induced by spikes from neighboring neurons, which can have either an excitatory or inhibitory effect (increasing or decreasing the potential). Our model is *stochastic* – each neuron functions as a probabilistic threshold unit, spiking with probability given by applying a sigmoid function to its membrane potential. In this respect, our networks are similar to the popular Boltzmann machine [1], with the important distinction that synaptic weights are not required to be symmetric and, as observed in nature, neurons are either strictly inhibitory (all outgoing edge weights are negative) or excitatory. While a rich literature focuses on deterministic threshold circuits [31, 16] we employ a stochastic model as it is widely accepted that neural computation is inherently stochastic [3, 42, 10], and that while this can lead to a number of challenges, it also affords significant computational advantages [30].

The WTA Problem

We focus on the Winner-Take-All (WTA) problem, which is one of the most studied problems in computational neuroscience. A WTA network has n input neurons, n corresponding outputs, and a set of auxiliary neurons that facilitate computation. The goal is to pick a 'winning' input – that is, the network should produce a single firing output which corresponds to a firing input. Often the winning input is the one with the highest firing rate, in which case WTA serves as a neural max function. We focus on the case when all inputs have the same or similar firing rates, in which case WTA serves as a leader election unit.

WTA is widely applicable, including in circuits that implement visual attention via WTA competition between groups of neurons that process different input classes [21, 23, 17]. It is also the foundation of competitive learning [32, 20, 14], in which classifiers compete to respond to specific input types. More broadly, WTA is known to be a powerful computational primitive [28, 29] – a network equipped with WTA units can perform some tasks significantly more efficiently than with just linear threshold neurons (McCulloch-Pitts neurons or perceptrons).

Related Work

Due to its importance, there has been significant work on WTA, including in biologically plausible spiking networks [22, 48, 43, 7, 47, 34, 33, 2]. This work is extremely diverse – while mathematical analysis is typically given, different papers show different guarantees and apply varying levels of rigor. To the best of our knowledge, no asymptotic time bounds (e.g., as a function of the number of inputs n) for solving WTA in spiking neural networks have been

established.[1] Additionally, previous analysis often requires a specific initial network state to show convergence and does not show that the network is self-stabilizing and converges from an arbitrary starting state, as is necessary in a biological system.

Within theoretical computer science, our work is most inspired by: (1) work on the computational power of spiking neural networks, including the power of WTA as a black-box primitive, most notably by Maass et al. [27, 28, 29] (2) the pioneering work of Les Valiant on the neuroidal model [44, 45, 46] and (3) self-stabilization algorithms in distributed networks [8, 25]. We survey this literature in more depth in Appendix A.1.

Basic WTA Networks

We restrict our attention to a simple network structure that can implement WTA efficiently using a small number of auxiliary neurons. A network consists of three layers: n input neurons X, n output neurons Y, and α auxiliary neurons Z. We usually assume all auxiliary neurons are inhibitory, however in Appendix C give extensions to the more general case where we allow auxiliary neurons to also be excitatory. Similar to well-known feedforward networks, all synaptic connections are between layers[2] with the exception of an excitatory self-loop from each output y_i to itself. This basic structure is biologically plausible; in particular self-loops and reciprocal excitatory-inhibitory connections (as implemented in our networks) are used in many biological models of WTA computation [48, 7, 38].

It is well known that inhibition is crucial for solving WTA – outputs compete for activation via *lateral inhibition* or *recurrent inhibition* [7, 38]. In our network, outputs fire in response to stimulation by their corresponding inputs, thereby stimulating inhibitors which suppress the activity of other outputs. Once a single winner is selected, it must remain distinguished from the remainder of the outputs. This is achieved via positive feedback – a consistently firing output will tend to continue firing due to its excitatory self-loop.

1.2 Our Contribution

Computational Tradeoffs

We explore the tradeoff between the number of inhibitors α used in a WTA network (i.e., the complexity of the network) and the time required to select a winning output (to converge to a WTA state). In artificial neural networks, inhibitory and excitatory connections are often treated equally, as connections with either positive or negative weights. However, in reality, neurons themselves are either inhibitory or excitatory and do not have outgoing connections of both types. There are many fewer inhibitors (around 15% of the neural population [39, 13]), and they typically have restricted connectivity structures, often inhibiting just neurons in their local vicinity [29]. This gives natural motivation to understanding how the number of inhibitors used in a network affects its computational power. We give two main results:

▶ **Theorem 1** (Upper bound). *(1) For any $\alpha \geq 2$ there exists a basic WTA network with α inhibitors that, from any* arbitrary *starting configuration, converges to a valid WTA state in $O(\alpha \log^{1/\alpha} n)$ expected time. (2) For any $\theta \geq 1$ there exists a basic WTA network with $\alpha = O(\theta \log^{1/\theta} n)$ inhibitors that converges in $O(\theta)$ expected time.*

[1] Aside from immediate bounds for deterministic circuits using many ($\Omega(n)$) auxiliary neurons [22, 29].
[2] Although, due to recurrent connections the network convergence time is not synonymous with the number of layers.

For $\alpha \geq \log\log n$ the above gives runtime $\tilde{O}\left(\frac{\log\log n}{\log \alpha}\right)$. We give a near matching lower bound in this case, which holds even if we allow both excitatory and inhibitory auxiliary neurons.

▶ **Theorem 2** (Lower bound). *Any basic WTA network with α inhibitors requires $\Omega(\log\log n/\log\alpha)$ rounds to solve WTA in expectation.*

Upper Bound Techniques

Our upper bounds are based on random competition between outputs that fire in response to stimulation from their firing inputs. One "stability" inhibitor is responsible for maintaining a WTA steady-state: as soon as just a single output fires in a round it becomes the winner of the network. Its positive feedback self-loop allows it to keep firing in subsequent rounds, while all other outputs do not fire due to inhibition from the stability inhibitor.

In order to reach a round in which just a single output fires, we employ a number of "convergence inhibitors". Ideally, if k competing outputs fire in a round, each would fire in the next round with probability $1/k$ and we would have just a single firing output with constant probability. We can approximate this behavior using $\lfloor \log n \rfloor$ convergence inhibitors, each of which acts as a threshold circuit and fires whenever $\geq 2^i$ outputs fire for $i \in 1, ..., \lfloor \log n \rfloor$. Thus when k outputs fire, approximately $\log(k)$ inhibitors fire, the inhibition causes outputs to continue firing with probability $\Theta(1/k)$, and convergence is achieved in constant rounds in expectation. This technique implicitly splits the possible number of firing outputs into $\log n$ *density classes* and uses one inhibitor to ensure fast convergence from each class. To obtain more general runtime tradeoffs, we will use density classes of increasing coarseness, with the inhibitors assigned to each density classes ensuring that the number of firing outputs decreases in few rounds until it falls into a finer density class, and eventually until just a single output fires.

Lower Bound Techniques

Our lower bound shows that *any* network which solves WTA must have a similar structure to the network described above. The inhibitory neurons can always be roughly be divided into two classes: stability and convergence inhibitors. Further, while randomness is important in breaking symmetry between competing inputs, we show that in any efficient network, the inhibitors behave in a *nearly deterministic* manner, matching behavior seen in our upper bounds. After significantly constraining inhibitor behavior, we are able to analyze how any network which solves WTA behaves on inputs with varying numbers of firing neurons. Specifically, we consider $\Theta(\log n)$ different inputs configurations, with geometrically increasing numbers of firing input neurons, ranging from $O(1)$ to $O(n)$. We show that, after t rounds, with good probability, the network *does not distinguish between* (i.e. behaves identically for) $\Theta(\log n/\alpha^t)$ inputs.

As long as $\log n/\alpha^t > 2$, after t rounds, there are at least two inputs not distinguished by the network, and so on which the network cannot achieve WTA with good probability. This yields our lower bound of $t = \Omega(\log\log n/\log\alpha)$ rounds in expectation. Our argument uses techniques familiar in distributed computing theory [24], showing that limited local information prevents outputs from behaving in distinct manners for a large number of density classes in each round.

We obtain a corresponding lower bound for the number of rounds required to solve WTA *with high probability* by showing that in general, the high probability runtime is $\Omega(\log n/\log\log\log n)$ times the expected runtime. This nearly matches the $O(\log n)$ gap which can be achieved by noting that in $O(\log n)$ runs, any network will converge within its

Table 1 Expected Time vs. Number of Inhibitors Tradeoff in Basic WTA Networks.

Inhibitors	Lower Bound (Expected Time)	Upper Bound (Expected Time)
Unbounded	$\Omega(1)$ ($\Omega(\log n)$ high probability time)	$O(1)$ with $\alpha = \Theta(\log^{1/c} n)$
1	$\Omega(n^c)$	$O(n^c)$
2	$\Omega(\log n / \log\log n)$	$O(\log n)$
α	$\Omega(\log\log n / \log \alpha)$	$O(\alpha \cdot \log^{1/\alpha} n)$, for $\alpha = O(\log\log n)$ $\tilde{O}\left(\frac{\log\log n}{\log \alpha}\right)$, for $\alpha = \Omega(\log\log n)$

expected runtime at least once with high probability. Our conversion result shows that, in our setting, expected runtime is a more natural metric – it is controlled by the number of inhibitors used, whereas the high probability runtime is just a function of expected runtime, independent of the number of inhibitors

1.3 Biological Insights in Our Results

Previous work has conjectured that widespread use of simple WTA implementations in the brain may explain how complex computation is possible even when inhibition is relatively limited and localized [29]. Our work shows that WTA can be achieved and maintained efficiently using very few inhibitors and with a very simple connectivity structure.

Our upper and lower bound constructions have a common take home message that may shed some light into the biological implementations of WTA networks. For instance, the division of inhibitors into "task preservers" (stability inhibitors) and "task solvers" (convergence inhibitors) seems fundamental. Further, while randomness is crucial as it allows for symmetry breaking amongst competing outputs, it appears (both in the upper bounds and the corresponding lower bound) that in optimal networks the inhibitors behave almost as deterministic threshold circuits, firing with high probability whenever the number of firing outputs is above a certain level. This presents an interesting dichotomy – while randomness is necessary computationally, it also has a cost in leading to unpredictable behavior amongst the inhibitors which 'control' the network.

1.4 Road Map

In Sec. 2 we describe our spiking neural network model and specify the WTA problem. In Sec. 3 we give two warm up examples of WTA networks to illustrate the tradeoff between convergence time and network size. The first has two inhibitors and converges to the WTA state within $O(\log n)$ rounds in expectation. The second has $O(\log n)$ inhibitors and $O(1)$ expected runtime. In Sec. 4.1, we provide more delicate constructions for any number of inhibitors α. Our key technical result appears in Sec. 4.2 where we provide a runtime lower bound (both for expected and high probability time) for circuits using α inhibitors, for any α. Our lower bound nearly matches our upper bounds for $\alpha = \Omega(\log\log n)$. Missing proofs are deferred to the Appendix.

2 Neural Network Model

A *Spiking Neural Network* (SNN) $\mathrm{N} = \langle \mathrm{X}, \mathrm{Y}, \mathrm{Z}, w, b \rangle$ consists of n input neurons $\mathrm{X} = \{x_1, \ldots, x_n\}$, n output neurons $\mathrm{Y} = \{y_1, \ldots, y_n\}$, and α auxiliary neurons $\mathrm{Z} = \{z_1, ..., z_\alpha\}$. The directed, weighted synaptic connections between X, Y, and Z are described by the weight function $w : [\mathrm{X} \cup \mathrm{Y} \cup \mathrm{Z}] \times [\mathrm{X} \cup \mathrm{Y} \cup \mathrm{Z}] \to \mathbb{R}$. The in-degree of every input neuron x_i is zero.

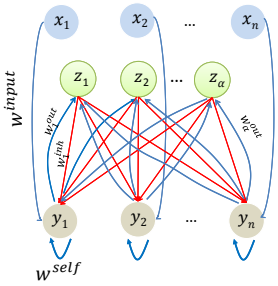

Figure 1 Basic WTA Network structure.

Each neuron is either inhibitory or excitatory: if v is inhibitory, then $w(v,u) \leq 0$ for every u, and if v is excitatory, then $w(v,u) \geq 0$ for every u. Finally, for any neuron v, $b(v) \in \mathbb{R}_{\geq 0}$ is the activation bias – as we will see, roughly, v's membrane potential must reach $b(v)$ for a spike to occur with good probability.

The Basic WTA Network and its Dynamics:

We focus on a restricted class of *basic SNNs*, in which all auxiliary neurons are inhibitory, inputs connect only to their corresponding outputs, and there are no connections within the inhibitory or output layers, aside from an excitatory self-loop from each output to itself. All outputs have identical parameters, i.e., bias values and edge weights.

We introduce some more concise notation to describe basic SNNs. Let $\mathrm{w}^{\mathrm{input}} > 0$ be the synaptic weight from each input x_j to its corresponding output y_j. Let $\mathrm{w}^{\mathrm{self}} > 0$ be the weight of the excitatory self-loop from output y_j to itself. Let $\mathrm{w}^{\mathrm{inh}}{}_j \leq 0$ be the weight of each inhibitory synapse from inhibitor z_j to an output neuron. Conversely, let $\mathrm{w}^{\mathrm{out}}{}_j \geq 0$ be the weight of each excitatory synapse from an output in Y to inhibitor z_j. Finally, let $\mathrm{b}^{\mathrm{out}}$ be the bias value for each output neuron. For an diagram of the basic architecture, see Fig. 1.

The network evolves in discrete, synchronous *rounds* as a Markov chain, with an alternating dynamic between the neurons in X, Y and Z. We give in-depth biological motivation in Appendix A.2. Each round t consists of three sub-rounds denoted by $(t,1),(t,2)$ and $(t,3)$ where the three layers inputs, outputs and inhibitors are scheduled to fire: In the first sub-round $(t,1)$ of each round t, the input layer fires. We consider static inputs so each x_i either fires in every round or does not fire in any round. After that, in sub-round $(t,2)$ the output neurons in Y spike with probabilities dependent on their membrane potentials. Finally, in sub-round $(t,3)$ the inhibitors in Z spike in response to their potentials. The firing probability of every neuron depends on the firing status of its neighboring neurons in the preceding three sub-rounds (i.e., a length of one round). This probabilistic firing is modeled using a standard sigmoid function. For each neuron u, and each round $t \geq 1$, let $u^{(t,k)} = 1$ if u fires (i.e., generates a spike) in sub-round (t,k) for $k \in \{1,2,3\}$. Let $u^{0,k}$ denote the initial firing state of the neuron – we will discuss how this is determined below.

Since each neuron is always scheduled to fire in one of $(t,1)$, $(t,2)$ or $(t,3)$ depending on whether it is in layer X, Y, or Z, for convenience we will often omit the sub-round notation, writing $u^t = 1$ if u fires in *one* of the sub-rounds (t,k). We call u^t, the *firing state* of u in round t. Informally, we say that u *fires in round* t if $u^t = 1$. For each output $y_j \in \mathrm{Y}$ and every $t \geq 1$, let $pot(y_j,t)$ denote the membrane potential at sub-round $(t,2)$ and $p(y_j,t)$

denote the corresponding firing probability. These values are calculated as:

$$pot(y_j,t) = (x_j^{(t,1)}\, \mathrm{w}^{\mathrm{input}}) + (y_j^{(t-1,2)} \cdot \mathrm{w}^{\mathrm{self}}) + \left[\sum_{z_i \in \mathrm{Z}} z_i^{(t-1,3)} \cdot \mathrm{w}^{\mathrm{inh}}{}_i\right] - \mathrm{b}^{\mathrm{out}}$$
$$\text{and } p(y_j,t) = \frac{1}{1+e^{-pot(y_j,t)/\lambda}} \tag{1}$$

where $\lambda > 0$ is a *temperature parameter*, which determines the steepness of the sigmoid. Note that (1) incorporates excitatory and inhibitory effects from any spikes occurring within the three sub-rounds before the outputs spike in sub-round $(t,2)$. Specifically, this includes input spikes in sub-round $(t,1)$ along with output and inhibitory spikes in sub-rounds $(t-1,2),(t-1,3)$ respectively. Also note that when $t=1$, the firing probability depends on the initial firing states $x_j^{(0,1)}$, $y_j^{(0,2)}$ and $z_i^{(0,3)}$. We will discuss how these are determined below. Applying the same rules, in sub-round $(t,3)$, each inhibitor in Z fires with probability $p(z_j,t)$ calculated as:

$$pot(z_j,t) = \left[\sum_{y_i \in \mathrm{Y}} y_i^{(t,2)} \cdot \mathrm{w}^{\mathrm{out}}{}_j\right] - b(z_j) \text{ and } p(z_j,t) = \frac{1}{1+e^{-pot(z_j,t)/\lambda}}. \tag{2}$$

Again (2) incorporates effects from relevant spikes within three sub-rounds $(t-1,3),(t,1)$ and $(t,2)$. However, since inhibitors are connected only to outputs, the only sub-round that affects them is $(t,2)$. After the inhibitors fire, we proceed to round $t+1$, beginning with the firing of the inputs.

We finally specify how the initial firing states are determined. As inputs are static, $x_j^{(0,1)}$ is 1 for firing inputs and 0 for non-firing inputs. $y_j^{(0,2)}$ is arbitrary, while $z_i^{(0,3)}$ is determined as in any regular round according to (2) below with $t=0$ (and so depends on each $y_j^{(0,2)}$). It is not hard to see that is equivalent to just allowing all initial firing states to be arbitrary. This would lead to arbitrary $y_i^{(1,2)}$ and $z_i^{(1,3)}$ determined according to equation (2), which matches our model if we relabel the states in round 1 to be the initial states.

Temperature and Background Noise

It is clear that the temperature λ does not affect the computational power of the network as we can simply adjust all synapse weights and neuron biases by a factor of λ/λ' to simulate a network with temperature λ'. Hence, we can fix λ to make exposition easier. In our proofs we will always set $\lambda = 1/\Theta(\log n)$. We assume that neurons in Z, Y have bias $b(v) = \Omega(\lambda \log n)$, so they do not fire with probability $1 - 1/(1+e^{-c\cdot\log n}) = 1 - 1/n^c$ when they receive no external stimulation. We call this the *no-background noise* assumption: the network is quiet when no input is introduced. This assumption is used only for technical reasons in our general α inhibitor lower bound. We are hopeful that it could be removed.

System Configuration

For any $t \geq 1$, the configuration $\mathcal{C}^t = (\mathrm{X}^t, \mathrm{Y}^t, \mathrm{Z}^t)$ in round t is defined by the firing states[3] of the corresponding neurons in round t where $\mathrm{X}^t = [x_1^t, ..., x_n^t]$ and Y^t and Z^t are defined analogously. Recall that $x_i^t = 1, y_i^t = 1, z_i^t = 1$ if the input x_i (output y_i, inhibitor z_i) fires in

[3] The firing state of a neuron is a binary number indicating if it is firing or not.

sub-round $(t, 1)$ (resp., $(t, 2), (t, 3)$). We consider a static input setting where $\mathrm{X}^t = \mathrm{X}$ for all t.[4] We abuse notation slightly, thinking of X as a vector of binary input values where $x_j = 1$ indicates that x_j fires in every round ($x_j^t = 1$ for all t) and $x_j = 0$ implies that x_j never fires ($x_j^t = 0$ for all t). We denote the the initial configuration $\mathcal{C}^0$. As discussed we have $\mathrm{X}^0 = \mathrm{X}$, Y^0 arbitrary, and Z^0 determined as in any round according to equation (2).

The WTA Problem

A binary winner-take-all network given n inputs should converge to having a single firing output corresponding to a firing input (the 'winner'), if one exists. Formally, given $\mathrm{X} \in \{0,1\}^n$, let $f(\mathrm{X}) = \{\mathrm{Y} \in \{0,1\}^n \mid y_i \leq x_i \ \forall i \text{ and } \| \mathrm{Y} \|_1 = \min(1, \| \mathrm{X} \|_1)\}$ where $\| \cdot \|_1$ is the standard 1-norm, used to denote the number of firing neurons in a set.

We say N *satisfies WTA* in round t if $\mathrm{Y}^t \in f(\mathrm{X})$. We say N *converges to WTA* in t rounds with probability $1 - \delta$ if for every input $\mathrm{X} \in \{0,1\}^n$ and every initial output configuration Y^0, with probability at least $1 - \delta$, $\mathrm{Y}^t \in f(x)$ and $\mathrm{Y}^{t'} = \mathrm{Y}^t$ for all $t' \in [t+1, t+n^c]$ where c is a positive constant.[5] That is, the network satisfies WTA in round t and maintains the satisfying configuration for polynomial in n subsequent rounds. As our neurons are inherently probabilistic, our definition of convergence is as well – we will never be able to avoid occasional random deviations from a correct output state and so just demand that the state is maintained a large number of rounds.

We let $\mathcal{ET}(\mathrm{N})$ denote the maximum expected time required to converge to WTA, taken over all possible inputs X and initial output configurations Y^0. In the same manner, $\mathcal{HT}(\mathrm{N})$ denotes the maximum time required for convergence to WTA with high probability.[6]

3 Warm Up: Two Simple Networks for WTA

We begin by presenting two WTA networks that represent two extremes of the inhibitor-time tradeoff. They also illustrate the rough intuition that will appear in our later network constructions and lower bound strategies.

WTA with Two Inhibitors

In our two inhibitor network we have $\mathrm{Z} = \{z_s, z_c\}$. The neuron z_s is a *stability* inhibitor that maintains the WTA state once it has been reached. It fires w.h.p. in sub-round $(t, 3)$ whenever at least one output fires in sub-round $(t, 2)$. The neuron z_c is a *convergence* inhibitor that fires w.h.p. whenever WTA has not yet been reached – i.e. whenever ≥ 2 outputs fire in sub-round $(t, 2)$.

We set the weights connecting z_s and z_c to the outputs such that when both fire in round t, any output that fired in round t will fire with probability $1/2$ in round $t+1$. Any output that *did not fire* in round t will not fire in round $t+1$ w.h.p. as it will not have an active excitatory self-loop and so its membrane potential will be too low to overcome the inhibition.

---

[4] Note however that our model can easily handle non-static inputs. All algorithms given will converge from an arbitrary initial configuration and so will converge if X changes.

[5] Formally, a family if networks $\mathcal{N} = \{N(n)\}$ for all integers $n \geq 1$ converges to WTA in $t(n)$ rounds with probability $1 - \delta$ if there exists $c > 0$ such that for all n, for all $X \in \{0,1\}^n$ and for all $Y^0 \in \{0,1\}^n$, with probability at least $1 - \delta$, $N(n)$ satisfies WTA in rounds $[t(n), ..., t(n) + n^c]$.

[6] Throughout, *with high probability* (w.h.p.) refers to events occuring with probability $\geq 1 - 1/n^c$ for constant c. Formally, a family of events $\mathcal{E} = \{E(n)\}$ for all integers $n \geq 1$ occurs w.h.p. if there exists $c > 0$ such that for all n, $\Pr[E(n)] \geq 1 - 1/n^c]$.

In this way, as long as ≥ 2 outputs fire in round t, both inhibitors fire w.h.p. and the high level of inhibition causes outputs to 'drop out of contention' for the winning position with probability $1/2$. After $O(\log n)$ rounds, nearly all the outputs stop firing and with constant probability there is a round in which exactly 1 output fires. Once this round occurs, z_c ceases firing w.h.p. and just z_s fires. This decreased level of inhibition allows the winner to keep firing, as it is offset by the winner's excitatory self-loop. However, it prevents any other output, whose excitatory self-loop is inactive, from firing w.h.p. See Fig. 2 in Appendix B.1 for illustration of the network with its edge weights. We analyze the network in depth in B.1, showing convergence given any input X and initial output configuration Y^0, and yielding:

▶ **Theorem 3.** *There exists a basic WTA network* N *with* $\alpha = 2$ *inhibitors and* $\mathcal{ET}(\mathrm{N}) = O(\log n)$ *and* $\mathcal{HT}(\mathrm{N}) = O(\log^2 n)$.

In Appendix B.1, we show that the network is optimal up to a $\log \log n$ factor and in Appendix B.2 we show that it represents a critical point in the inhibitor-time tradeoff: any network with just one inhibitor requires $\Omega(n^c)$ rounds to solve WTA. Essentially, it is not possible for a single inhibitor to implement the two opposing tasks of stability and convergence.

WTA with $O(\log n)$ Inhibitors

Our second network represents another extreme point of the inhibitor-time tradeoff, using $\alpha = O(\log n)$ inhibitors to achieve $O(1)$ expected convergence time.

The idea is to approximate the ideal behavior in which outputs fire with probability $1/k_t$ in round $t+1$ if k_t outputs fired in round t. As in our two inhibitor algorithm, we have a single stability inhibitor z_s that fires w.h.p. whenever at least one output fires and insures that as soon as a single output fires in a round, the network converges to WTA. We then have $\lceil \log n \rceil - 1$ convergence inhibitors $z_1, ..., z_{\alpha-1}$. We set the bias of the z_i to $b(z_i) = 2^i - .5$ and set $\mathrm{w^{out}}_i = 1$ for all i. In this way, z_i fires w.h.p. in round t whenever $\geq 2^i$ outputs fire. We set the inhibitor to output weights to $\mathrm{w^{inh}}_i = \Theta(\lambda)$ for all i. Thus, when $k_t \in [2^i, 2^{i+1})$, w.h.p. inhibitors $z_1, ..., z_i$ all fire (while $z_{i+1}, ..., z_{\alpha-1}$ do not). The total inhibition from the inhibitors is thus $\Theta(i\lambda)$ and hence each of the k_t outputs fire with probability $1/(1 + e^{\Theta(i)}) \approx 1/2^i \approx 1/k_t$ in round $t+1$. In expectation (and with constant probability) there will be exactly one firing output, giving an expected runtime of just $O(1)$ rounds to reach WTA. In Appendix B.3, we give a full analysis, yielding:

▶ **Theorem 4.** *There exists a basic WTA network* N *with* $\alpha = O(\log n)$ *inhibitors,* $\mathcal{ET}(\mathrm{N}) = O(1)$ *and* $\mathcal{HT}(\mathrm{N}) = O(\log n)$.

Vacuously, no network can beat this expected runtime. We also show in Appendix B.3 that no network can do better with high probability: even with an unlimited number of inhibitors, $\Theta(\log n)$ rounds are requires to solve WTA w.h.p. Intuitively, as long as WTA has not yet been reached in round t, there is no single distinguished output. All outputs have identical connections to X, Z so each active output fires with the *same* probability p in round $t+1$.[7]. Hence the probability that a single output becomes distinguished (is the only one to fire) is $k_t \cdot p(1-p)^{k_t - 1}$, which is bounded by a constant for all k_t, p. Thus, converging to the WTA state w.h.p. takes at least $\Omega(\log n)$ rounds.

[7] By the monotonicity property, it is sufficient to consider in round t only the outputs that fire in round $t-2$, all these outputs have the same firing probability p.

4 WTA with $\alpha \geq 2$ Inhibitors

The above results give a rough outline of the tradeoff between the number of inhibitors and the runtime for WTA. We now explore this tradeoff in more depth for general $\alpha \in (2, \log n]$

4.1 Upper Bound Networks

We first show that both our two inhibitor and $\lceil \log n \rceil$ inhibitor networks can be improved significantly with modest increases in the number of inhibitors or runtime used. We can (up to constant factors) match the runtime of the $\lceil \log n \rceil$ inhibitor network with just $O(\log^{1/c} n)$ inhibitors for any c. Additionally, for any $\alpha \geq \log \log n$ we can achieve expected runtime $O\left(\frac{\log \log n \log \log \log n}{\log \alpha}\right)$, nearly matching our main lower bound of Section 4.2.

▶ **Theorem 5.** *For any integer θ, there is a basic WTA network* N *with $\alpha = O(\theta \log^{1/\theta} n)$ inhibitors, $\mathcal{ET}(\mathrm{N}) = O(\theta)$, and $\mathcal{HT}(\mathrm{N}) = O(\theta \log n)$.*

For $\alpha \geq \log \log n$, writing $\alpha = \log \log^x n$ for $x \geq 1$ if we set $\theta = \frac{c_1 \log \log n \log \log \log n}{\log \alpha} = \frac{c_1 \log \log n}{x}$ then the number of inhibitors required is: $\frac{c_1 \log \log n}{x} \cdot e^{x/c_1} \leq \log \log^x n \leq \alpha$ for small enough c_1.

Proof Sketch. To see the high level idea, consider the case of $\theta = 2$. We will $2\sqrt{\log n}$ inhibitors which are divided into two classes: $\sqrt{\log n}$ coarse inhibitors and $\sqrt{\log n}$ fine inhibitors. The edges from the fine inhibitors to outputs have weight -1 and the edges from coarse inhibitors to outputs have weight $-\sqrt{\log n}$. All the edges from the outputs to the inhibitors have weight 1. We set the bias values of the inhibitors such that: (1) the i^{th} coarse inhibitor fires if the number of active outputs is at least $2^i\sqrt{\log n}$ and (2) the i^{th} fine inhibitor fires if the number of active outputs is at least 2^i. Consider any output density 2^d and let $d' = \lfloor d/\sqrt{\log n} \rfloor$. When 2^d outputs fire in round t, this will excite the first d' coarse inhibitors. As a result, the firing probability for the outputs in round $t+1$ will be approximately $2^{-d' \cdot \sqrt{logn}}$ (ignoring negligible effects from the fine inhibitors). In other words, within a single round the density will be reduced from 2^d to $2^{d-d'\sqrt{\log n}}$ which is a new density in the range $1, 2, 4, ..., 2^{\sqrt{\log n}}$. After this initial round, since at most $2^{\sqrt{\log n}}$ outputs fire, the circuit converges in constant rounds in expectation as the $\sqrt{\log n}$ fine inhibitors can induce probabilities roughly equal to $1/k_t$ just as is done in the $O(\log n)$ inhibitor circuit.

Generalization to larger θ is by repeating the above construction: we have θ levels of increasing coarseness: $[1, 2^{\log^{1/\theta} n}], [2^{\log^{1/\theta} n}, 2^{\log^{2/\theta} n}], ..., [2^{\log^{(\theta-1)/\theta} n}, 2^{\log n}]$. The $\log^{1/\theta} n$ inhibitors at each level ensure that if the number of firing outputs is at level i in round t, it is reduced to level $i-1$ in round $t+1$, yielding $O(\theta)$ expected runtime. We give a full analysis in Appendix B.4. ◀

Our second construction uses similar techniques, but uses just one convergence inhibitor per density class, balancing the time required to move through each density class and the number of classes used. It significantly improves on our two inhibitor algorithm, achieving runtime $O(\log^{1/c} n)$ for any constant c with $O(1)$ inhibitors and $O(\log \log n)$ runtime with $O(\log \log n)$ inhibitors.

▶ **Theorem 6.** *For any $\alpha \geq 2$, there is a basic WTA network* N *with α inhibitors, $\mathcal{ET}(\mathrm{N}) = O\left(\alpha \log^{1/(\alpha-1)} n\right)$ and $\mathcal{HT}(\mathrm{N}) = O\left(\alpha \log^{1+1/(\alpha-1)} n\right)$.*

Proof Sketch. Consider $\alpha = 3$. We have 2 convergence inhibitors: a fine inhibitor z_f and a coarse inhibitor z_c. The inhibitor z_c fires whenever the number of active outputs is at least $2^{\sqrt{\log n}}$, and induces outputs to fire with probability $1/2^{\sqrt{\log n}}$ in the next round. In this way, starting with any density of firing inputs $k_t \in [2^{\sqrt{\log n}}, n]$, within $\sqrt{\log n}$ rounds the density will be reduced to $\leq 2^{\sqrt{\log n}}$. The inhibitor z_f fires whenever at least 2 outputs fire, and induces outputs to fire with probability $1/2$ in the next round. So, within $\sqrt{\log n}$ additional rounds, with constant probability just a single output will remain firing. Again, a full network description for general α and proof is given in Appendix B.4. ◀

4.2 Lower Bound: The Tradeoff Between Inhibitors and Time

We now present our main lower bound which matches Theorem 5 up to $\log\log\log n$ factors.

▶ **Theorem 7.** *For any basic WTA network* N *with* α *inhibitors,* $\mathcal{ET}(\mathrm{N}) = \Omega\left(\frac{\log n \log n}{\log \alpha}\right)$ *and* $\mathcal{HT}(\mathrm{N}) = \Omega\left(\frac{\log\log n}{\log \alpha} \cdot \frac{\log n}{\log\log\log n}\right)$.

Lower Bound Overview

We focus on initial output configuration $Y^0 = \vec{0}$ (i.e., no output fires in the sub-round $(0, 2)$) which we call the *reset configuration*. We show that for any network N with α inhibitors there exists at least one input X for which the expected time to reach WTA starting from the reset configuration is $\Omega(\log\log n/\log\alpha)$. If suffices to consider the case where $\alpha = O(\log^{1/c} n)$ for some constant c since for $\alpha = \Theta(\log^{1/c} n)$, the expected runtime is $O(1)$. Throughout this section, we say an event happens with *good probability* if its probability is at least $1 - O(\log^4 n)$.

Our argument contains two main parts. First, we show that the inhibitors fire in a *nearly* deterministic manner and hence we can treat them (up to some slack) as *threshold circuits*. Equipped with this property, we then consider $\Theta(\log n)$ *density classes* each covering a constant multiplicative range of firing outputs. The predictable behavior of the inhibitors is used to show that even after $\Omega(\log n \log n/\log\alpha)$ rounds, the network cannot distinguish between at least two different density classes, which yields our claim as it does not converge to WTA for at least one class.

(1) Inhibitor classification: inhibitors are nearly deterministic for most density classes

To address the first challenge (i.e., showing that inhibitors are predictable), we divide the set of inhibitors Z into three classes and show the predictability property for each class separately. The "stability" class (or "WTA preservers") S contains inhibitors whose *goal* is to maintain the WTA steady state. The "convergence" class (or "progress inhibitors") C contains the inhibitors that are responsible for driving fast convergence to a WTA state. Finally, the third class R contains the remaining inhibitors whose contribution to both stability and convergence is negligible.

Formally, for any inhibitor $z_i \in \mathrm{Z}$ and $j \in [1, n]$ let $pot_j(z) = j \cdot \mathrm{w^{out}}_i - b(z_i)$ be the potential of z_i when exactly j outputs fire (I.e., if in sub-round $(t, 2)$ the number of firing outputs is j, then the potential of z_i in sub-round $(t, 3)$ is $pot_j(z)$ and it fires in sub-round $(t, 3)$ with probability $1/(1 + e^{-pot_j(z)})$). The set S contains all inhibitors that fire in steady state (i.e., when exactly one output is firing) with reasonably high probability. Fixing some constant $c \geq 1$, $S = \{z_i \in \mathrm{Z} \mid 1/(1 + e^{-pot_1(z_i)}) \geq 1/\log^{3c} n\}$. The set C is comprised of

all inhibitors $z_i \notin S$ whose firing probability is least $1/\log^c n$ when all n outputs fire in the previous sub-round: $C = \{z_i \in \mathrm{Z} \mid z_i \notin S \text{ and } 1/(1+e^{-pot_n(z_i)}) \geq 1/\log^c n\}$[8]. Finally, R contains all remaining inhibitors not in S or C.

We show that the firing states of the inhibitors can *in certain cases* be predicated with good probability. The argument for each of the three classes S, C and R is different and is presented in Appendix B.5.1. Since the inhibitors in S fire with good probability when just one output fires, we can show that they fire w.h.p. when at least two outputs fire:

▶ **Lemma 8** (S is predictable). *Let $(t,2)$ be a sub-round in which at least two outputs fire, then sub-round $(t,3)$, all inhibitors of S fire with probability at least $1-1/n$.*

Since the firing probability of the R inhibitors is small compared to the $O(\log\log n/\log\alpha)$ execution length that we care about, we have:

▶ **Lemma 9** (R is predictable). *Given any input* X *and any initial configuration, with probability at least $1-1/\log^{c-3} n$, none of the inhibitors in R fire in $O(\log^2 n)$ rounds of execution of* N.

Perhaps the most surprising claim concerns the predictability of the convergence inhibitors:

▶ **Lemma 10** (C is almost predictable). *For every $z \in C$, there exists an integer $k(z) \in [1,n]$, such that for $c \geq 4$:*

(1) Low Density: *When there are at most $k(z)/2$ firing outputs in sub-round $(t,2)$, the probability that z fires in sub-round $(t,3)$ is at most $1/\log^c n$ (i.e., with good probability, z does not fire);*

(2) High Density: *When there are at least $2k(z)$ firing outputs in sub-round $(t,2)$, the probability that z fires in sub-round $(t,3)$ is at least $1-1/\log^c n$ (i.e., with good probability, z fires).*

Overall, except for the case where the number of firing outputs in sub-round $(t,2)$ is in the density class $K(z) = [k(z)/2, k(z)]$, z behaves in sub-round $(t,3)$ in an almost deterministic manner. Roughly speaking, this is shown by exploiting the *gap* in the firing probabilities of these inhibitors between the steady state rounds (when they fire with probability $\leq 1/\log^{3c} n$) and the rounds in which there are sufficiently many firing outputs (where they fire with probability $\geq 1/\log^c n$). The proof of Lemma 10 shows that this gap implies that the sigmoid function which converts the number of firing inputs to z's firing probability must be steep enough such that z has predictable behavior outside a small range around $k(z)$.

(2) Network prediction for nearly deterministic inhibitors

Using the predictable nature of the inhibitors, we now show that there is at least one *density class* of competing inputs for which we can predict (with good probability) the behavior of N for $\Omega(\log\log n/\log\alpha)$ rounds, at the end of which the WTA state has not been reached. We consider a set of $\ell = \lfloor \log n \rfloor$ inputs $\mathcal{X} = \{\mathrm{X}_1, ..., \mathrm{X}_\ell\}$ where X_i contains exactly 2^i firing inputs (i.e. $\|\mathrm{X}_i\|_1 = 2^i$). Thus, $\mathcal{X}$ contains a representative input from each density class of input vectors whose number of firing inputs is within a factor two of each other.

For any $\mathrm{X} \in \mathcal{X}$ let $\widehat{R}_t(\mathrm{X}) \in \{1,\ldots,n\}$ be the random variable indicting the number of firing outputs in sub-round $(t,2)$ starting from the initial configuration $Y_0 = \vec{0}$. Let $\widehat{F}_t(\mathrm{X}) \in \{0,1\}^\alpha$ be the random variable indicating the firing status of the inhibitors in

[8] The difference between $1/\log^{3c} n$ when defining the threshold for the inhibitors in S and $1/\log^c n$ when defining the threshold for the inhibitors C, is crucial in the analysis.

sub-round $(t, 3)$. For each $\mathrm{X} \in \mathcal{X}$ we will attempt to maintain a *predicted* range $R_t(\mathrm{X})$ of the number of firing outputs in sub-round $(t, 2)$ along with a *predicted* inhibitor configuration in sub-round $(t, 3)$, $F_t(\mathrm{X})$. We will let $\mathcal{X}_t \subseteq \mathcal{X}$ denote the subset of inputs whose behavior we can predict well in (all sub-rounds of) round t – specifically, for which we know $\widehat{R}_t(\mathrm{X}) \in R_t(\mathrm{X})$ and $\widehat{F}_t(\mathrm{X}) = F_t(\mathrm{X})$ with good probability (at least $1 - 1/\log n$).

For any inhibitor $z \in C$, we call the range $K(z) = [k(z)/2, 2k(z)]$– the *critical range* of z (see Lemma 10 for the definition of $k(z)$). If the number of firing outputs enters this range, we will not be able to predict the behavior of z in the next sub-round with good probability. On the other hand, as long as the number of firing outputs in sub-round $(t, 2)$ is not in the critical range of any $z \in C$, then the firing behavior of the inhibitors in sub-round $(t, 3)$ can be predicted with good probability.

We will progress through rounds, predicting the behavior of N in round t for each input in $\mathcal{X}_{t-1}$ based off the predictions in round $t - 1$. We will ensure that in any round, not too may inputs have predicted ranges overlapping critical regions by ensuring that these predicted ranges remain separated by constant factors and hence, at most $|C|$ of them can overlap $K(z)$ for some $z \in C$.

Predicting the number of firing outputs given inhibitor states

We now describe how to predict the range $R_t(X)$ given the prediction $F_{t-1}(X)$. Our main goal is to preserve the separation between the predicted ranges $R_t(\mathrm{X})$ for sufficiently many inputs $\mathrm{X} \in \mathcal{X}_{t-1}$.

To maintain the separation, we consider only the largest subset $\mathcal{X}_t^{same} \subseteq \mathcal{X}_{t-1}$ of inputs whose predicted firing configuration for the inhibitors in the previous sub-round $(t - 1, 3)$ is exactly the *same* (i.e., inputs X with the same $F_{t-1}(\mathrm{X})$ vector). By doing this, we guarantee that the firing probabilities of all the outputs in sub-round $(t, 2)$ is the same. Letting this probability be p, the expected number of firing outputs in sub-round $(t, 2)$ is in the range $p \cdot R_{t-1}(\mathrm{X})$ for each $\mathrm{X} \in \mathcal{X}_t^{same}$ and the separation between these ranges is preserved in expectation. To show that the ranges are also separated with good probability, we omit from $\mathcal{X}_t^{same}$ at most $\Theta(\log \log n)$ inputs with ranges $R_t(\mathrm{X})$ containing values $\leq \log^c n$ for some constant c. They remaining inputs thus have output ranges concentrated around their expectation. The key point to observe is that because the inhibitors behave almost as threshold circuits, the number of different firing configurations in sub-round $(t - 1, 3)$ is at most α (i.e., there are at most α different $F_{t-1}(\mathrm{X})$ vectors for $\mathrm{X} \in \mathcal{X}_{t-1}$) and hence the cardinality of the set $\mathcal{X}_t^{same}$ for which we predict the range of firing outputs in sub-round $(t, 2)$ is at least $|\mathcal{X}_{t-1}|/\alpha$.

Predicting the inhibitor states given the number of firing outputs

We next describe how to predict the inhibitor firings $F_t(\mathrm{X})$ given the prediction $R_t(\mathrm{X})$. Since the convergence inhibitors are predictable when the number of firing outputs is not in any critical range $K(z)$, we first omit from $\mathcal{X}_t^{same}$ all inputs X whose predicted range $R_t(\mathrm{X})$ intersects the critical range of some $z \in C$ (i.e. $R_t(\mathrm{X}) \cap K(z) \neq \emptyset$ for some z). We call the resulting set $\mathcal{X}_t$. Since the ranges of $\mathcal{X}_t^{same}$ are separated by some constant, we do not discard more than $|C| = O(\alpha)$ inputs.

Overall, we predict the circuit behavior in sub-rounds $(t, 2), (t, 3)$ with good probability for all inputs $\mathrm{X} \in \mathcal{X}_t$ where $|\mathcal{X}_t| \geq |\mathcal{X}_{t-1}|/\alpha - \alpha$. Since $\alpha = O(\log^{1/c} n)$, we get that after t rounds, there are $|\mathcal{X}_t| = \Omega(\log n/\alpha^t)$ inputs for which the network behaves *exactly* the same in each of the t rounds with good probability. This argument proceeds as long as

$\log n/\alpha^t \geq 2$, leading to the lower bound of expected time $\Omega(\log\log n/\log\alpha)$ since we can show if two inputs are not distinguished, at least one will not have reached WTA. In Appendix B.5.2, we describe the prediction process in detail and complete the proof of Theorem 7.

High Probability Lower Bound

Finally, we show that our lower bound for expected runtime extends to a lower bound on the high probability runtime. Our lower bound implies that "repeating" the execution of a network that converges with constant probability $\Theta(\log n)$ times to achieve a high probability guarantee is essentially the best one can do (up to a $\log\log\log n$ factor).

▶ **Lemma 11.** *For any basic WTA network* N *with* α *inhibitors* $\mathcal{HT}(\mathrm{N}) = \Omega(\frac{\log n\cdot\log\log n}{\log\alpha\log\log\log n})$.

Proof Sketch. Let $DC = \Theta\left(\frac{\log\log n}{\log\alpha}\right)$ and $DH = DC\cdot\left(\frac{\log n}{\log\log\log n}\right)$. Fix a network N with α inhibitors and let X be the input for which, by Theorem 7, N requires at least DC rounds in expectation starting from initial configuration $\mathcal{C}_0$ with input X and $\mathrm{Y}^0 = \vec{0}$. In the following proof, we will actually exploit the fact that the lower bound in Theorem 7 applies to the time it takes to reach a WTA state with *constant probability* (a stronger time measure than expected time).

We work with the *execution tree* T which includes all possible DH round executions of N starting from $\mathcal{C}_0$. The tree T has depth DH where each layer corresponds to the configuration of the network in each round t. Each node u at level t is labeled by an $(n+\alpha)$-length binary vector $Q(u)$ describing the firing states of the outputs and inhibitors in round t, i.e., the firing states of the outputs in sub-round $(t,2)$ and the firing states of the inhibitors in sub-round $(t,3)$. Node u has $2^{n+\alpha}$ children, with the edge to each child labeled with the transition probability between the configuration in u to the child configuration. The root node r is labeled with $\mathcal{C}_0$. The mass of node u is given by the product of edge weights on its path to r. It is the probability of reaching u's configuration through that execution path. We call a node u a *reset* node (resp., *WTA* node), if in the configuration $Q(u)$ no output fires (resp., exactly one output with active input fires).

To lower bound $\mathcal{HT}(\mathrm{N})$ we will show that the probability to reach a non-WTA leaf node when starting from the root r is at least $1/n^2$, and thus the probability to reach a WTA leaf node is at most $1-1/n^2 < 1-1/n^c$, contradicting a w.h.p. runtime of $\leq DH$ rounds.

Our strategy is based on traversing the tree in an asynchronous manner from the root to (sufficiently many) non-WTA leaf nodes with sufficiently high total probability mass. For a given node u in layer t, we may move to a subset of its *non-WTA* children nodes in layer $t+1$. We call this move a *small jump*. Alternatively, we may make a *large jump*, moving DC steps from u and proceeding the traversal from a subset of *non-WTA* leaf nodes of $T_{DC}(u)$ (the height DC subtree rooted at u). With each jump starting at u, we loose some probability mass – the idea is to show that we do not loose it too quickly.

In more detail, in each step of our traversal, we maintain a collection of non-WTA nodes. When arriving a node u in the traversal, we consider its configuration $Q(u)$ and look at the probability that the next round is a *reset* round (with 0 firing outputs) given $Q(u)$. We show that if the probability of having at most 1 firing outputs in the next round is $\geq 1/\log\log n$, the probability of having a reset (no firing outputs) is large – i.e., $\geq 1/(\log\log n)^3$.

In this case we continue traversal only from the children of u that are reset nodes. For each of these children v, let $T_{DC}(v)$ be the execution tree of depth DC rooted at v. By the lower bound in Theorem 7, the probability to reach a non-WTA leaf node in $T_{DC}(v)$ starting from $Q(v)$ is at least a constant. So from each reset-node v, we make a large jump to the leaves of

$T_{DC}(v)$. Overall, we maintain a $\Theta(1/(\log\log n)^3)$ fraction of the probability mass of u in making this large jump. Since such a jump can occur at most $DH/DC = \log n/\log\log\log n$ times, we maintain at least a $1/(\log\log n)^{3DH/DC} \geq 1/n^2$ fraction of the probability mass throughout the traversal.

On the other hand, when arriving a node u for which the probability of having at most 1 firing output in the next round is less than $1/\log\log n$, we make a small jump to the children of u in which the number of firing outputs is at least 2 (and hence which are non-WTA nodes). This jump maintains $1 - 1/\log\log n$ of the probability mass and since such a jump can happen at most DH times, we again maintain $(1-1/\log\log n)^{DH} \geq 1/n^2$ of the original probability. Overall, through making both large and small jumps, at the end of the traversal, we reach a set of non-WTA nodes containing at least a $1/n^2$ fraction of the probability mass in the DH level execution tree. This gives us our high probability time lower bound. See Appendix B.6 for a complete analysis and Fig. 3 for an illustration of the execution tree. ◀

In Appendix C, we extend our lower bounds (for both expected and high probability time) to the case where the α auxiliary neurons can be both excitatory and inhibitory neurons. The more general bound holds under the restriction that outputs with no active input are not allowed to fire during the execution. Only competing outputs (that have a positive signal from their inputs) ever fire.

5 Discussion

We hope that this paper is a starting point for further investigation into stochastic spiking networks from an algorithmic perspective, which investigates fundamental tradeoffs between biological resources and identifies basic building blocks and principles for algorithm design in neural settings.

We focus on a restricted class of three layer networks, in which auxiliary neurons are not interconnected. This models the generally restricted connectivity structure that inhibitory neurons appear to have in biological networks and lets us give both very strong upper bounds and matching lower bounds. Still, it would be interesting to understand the effect of connections between auxiliary neurons. We have preliminary work showing that some speedups are possible in these more general networks, however obtaining any non-trivial lower bounds would be very interesting.

Studying other important primitives aside from the binary version of WTA that we focus on would also be interesting. We again have preliminary work on *non-binary WTA* in which the network must choose the input with the highest, or near highest firing rate as the winner. There are many other problems to consider.

Our model attempts to be biologically plausible enough to capture high level behavior, yet not be overly complex. However, many modeling assumptions are possible, and we hope that future work explores if changes to the model can lead to significant differences in computational power or algorithmic techniques. As an example, for simplicity we considered a synchronous model, however, asynchrony seems to be an important part of neural computation which would be valuable to study.

Finally, we note that significant theoretical work attempts to understand how neural networks can *learn* through the modification of synapse weights as their endpoints fire more or less frequently [46, 36]. The most common model for how synapse weights evolve is the *hebbian learning* rule, which is itself the focus of a vast literature. Merging the view of neural networks as executing algorithms given predetermined network parameters with understanding of learning would be very interesting. Can a WTA network 'evolve' naturally

via simple learning rules? How do fixed network motifs such as WTA circuits interact with more flexible 'learning' networks?

Acknowledgments. We are grateful to Mohsen Ghaffari for noting the general upper bound network construction and for many helpful discussions on the lower bound proof. We would also like to thank Nir Shavit, Rati Gelashvili, and Sergio Rajsbaum for insightful discussions.

A Additional Discussion

A.1 Related Work

Spiking Neural Networks

A vast literature studies computation in stochastic spiking neural networks. Work includes detailed models aimed at matching biological observations [12, 18], large scale simulation in hardware and software [5, 37], attempts to understand general properties of computation in these networks [6], the design of specific algorithms [4, 41], and theoretical investigation of computational power [26, 15]. For instance, it has been shown that deterministic spiking networks can simulate Turing machines and that stochastic spiking networks can implement MCMC sampling [6]. As is popular in the biologically-inspired algorithms literature, spiking networks have been used as heuristic 'stochastic search' solvers for NP-hard constraint satisfaction problems, such as Sudoku and TSP [19].

Our model can be seen as a discrete version of the continuous model discussed in by Maass in [30] or as a noisy version of the deterministic model in [27]. In addition to being stochastic, in comparison to the model of [27], our response latency Δ is constant for all connections in the network. Additionally, we have just a single round memory – each neuron's membrane potential is affected just by spikes of neighboring neurons in the same or immediately preceding round of computation. We note that if connections are allowed between auxiliary neurons, a longer memory can be easily be implemented within our general model.

Self-Stabilization in Distributed Computing

The notion of self-stabilization goes back to Dijkstra in 1973. A self-stabilizing system can automatically recover following the occurrence of transient faults. The goal in this area is to design systems that converge to a desired behavior from any arbitrary starting point [8, 25]. Among the tremendously broad work, perhaps the most relevant to this work is self-stabilizing algorithms for leader election [9, 11].

In a stochastic neural network, self-stabilization is a necessity. Both changes to the given input as well as random deviations of the system from a converged state require the network to re-converge. Hence, we insure that all our networks converge to WTA from any initial network configuration and are self-stabilizing. This property does not hold in many previously studied WTA implementations for spiking networks [33].

Valiant's Neuroidal Model

Valiant considers a model of neural computation in which abstract neurons (which he calls *neuroids*) are connected via a random network of synapses [44]. He discusses how these neurons can learn representations of real world objects whose perception stimulates the network in certain ways. As in our model, neurons fire in response to a membrane potential given by a weighted sum of firing neighbors. Differently, synapse weights evolve in response to increased firing of their end points, which allows *learning* to occur within the network. This learning ability is the primary focus of Valiant's work and of follow up work on the model. For example, recently, [35] extended understanding of how reasonably complex learning and pattern matching tasks can be performed in this model.

Our work deviates is somewhat more 'algorithmic' than the work of Valiant, focusing how basic takes can be computed using a set of neurons with a fixed set of synapses and bias values. We do not consider how, for example, our WTA networks could form within a larger neural circuit through learning of appropriate synapse weights. Following previous work [28] we think of WTA networks as fundamental primitives of neural circuits on top of which high level algorithms, such as learning algorithms, can be built.

A.2 Biological Motivation for Network Dynamics

The timing of neural spikes is determined by two biological parameters, namely, the *refractory period* β and the *response latency*, Δ. The refectory period is the time during which stimulus given to the neuron would not cause a second action potential. The response latency is the delay between the time the action potential reaches the presynaptic terminal of the input neurons and the time the postsynaptic output neuron sends out an action potential (assuming it does). In our setting we consider the case where $\Delta < \beta$ since for connected neurons in close proximity to each other, and inhibitory neurons with primarily local connections, the response delay is a few hundred of micro-seconds whereas the refractory time is several milliseconds [40]. WTA networks are basic, local neural primitives that are not believed to involve long range connections, justifying our assumption.

Every round corresponds to an interval between two pulses of the inputs (hence a round lasts β milliseconds). At the beginning of every round, the input layer spikes (at sub-round $(t, 1)$ in the notation of our discrete model). The spikes generated by the inputs invoke an alternating dynamic between the three layers in the circuit. Specifically, with a delay of δ milliseconds after the input's spike, the outputs spike with probability proportional to their total synaptic strengths (in sub-round $(t, 2)$). As shown in equation (1), this potential incorporates any spikes which occurred within a β millisecond preceding window – the input spikes in sub-round $(t, 1)$ (Δ milliseconds before), the inhibitor spikes in sub-round $(t-1, 3)$ ($\beta - \Delta$ milliseconds before), and the neuron's own self-excitatory output spike in sub-round $(t-1, 2)$, β milliseconds before. Δ milliseconds after the outputs spike, the inhibitors spike in sub-round $(t, 3)$, again incorporating spikes that occurred with a β millisecond window, which due to their limited connectivity structure, just includes the spikes of Y in $(t, 2)$.

B Missing Proofs and Auxiliary Claims

Throughout, we make use of the following Corollary of the Chernoff bound.

▶ **Theorem 12** (Simple Corollary of Chernoff Bound). *Suppose $X_1, X_2, \ldots, X_\ell \in [0, 1]$ are independent random variables. Let $X = \sum_{i=1}^{\ell} X_i$ and $\mu = \mathbb{E}[X]$. If $\mu \geq 5 \log n$, then w.h.p. $X \in \mu \pm \sqrt{5\mu \log n}$, and if $\mu < 5 \log n$, then w.h.p. $X \leq \mu + 5 \log n$.*

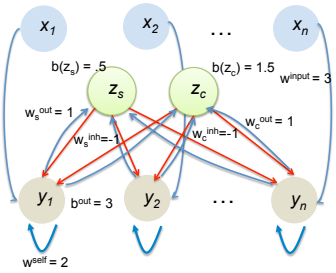

Figure 2 Two Inhibitor WTA Network.

B.1 WTA with Two Inhibitors

Proof of Theorem 3 (Two Inhibitor Upper Bound)

Formally the parameters of the network are set as follows: assume w.l.o.g. that $\lambda = 1/(c_1 \log n)$ for large constant c_1. For both inhibitors, set the excitatory output to inhibitor weights to $\mathrm{w}^{\mathrm{out}}{}_s = \mathrm{w}^{\mathrm{out}}{}_\ell = 1$ and $b(z_s) = .5$, $b(z_c) = 1.5$. Thus, by equation (2) z_s fires w.h.p. in sub-round $(t, 3)$ whenever at least one output fires in sub-round $(t, 2)$, and z_c fires w.h.p. whenever at least two outputs fire.

Set the inhibitor to output weights to $\mathrm{w}^{\mathrm{inh}}{}_s = \mathrm{w}^{\mathrm{inh}}{}_\ell = -1$, the excitatory input to output connection weight to $\mathrm{w}^{\mathrm{input}} = 3$, and the excitatory output to output self-loop to $\mathrm{w}^{\mathrm{self}} = 2$. Finally, set the output bias to $\mathrm{b}^{\mathrm{out}} = 3$.

The above parameters insure that only outputs corresponding to firing inputs ever fire w.h.p. Additionally, if we have not yet reached WTA and both z_s and z_c fire in sub-round $(t, 3)$, any output that fired in sub-round $(t, 2)$ will fire with probability $1/2$ in sub-round $(t + 1, 2)$. If we have reached WTA and just z_s fires, any output (the winner) that fired in round t will fire in round $t + 1$ w.h.p. In either case, any output that did not fire in round t will not fire w.h.p. in round $t + 1$.

We now give a formal proof of the theorem. First note that if the input $\mathrm{X} = \vec{0}$ then in every round, each output has potential $pot(y_j, t) \leq \mathrm{w}^{\mathrm{self}} - \mathrm{b}^{\mathrm{out}} = -1$ and so, recalling that $\lambda = 1/(c_1 \log n)$, fires with probability at most $\frac{1}{1+e^{c_1 \log n}} \leq 1/n^c$ for some large constant c in any round. So w.h.p. no outputs fire in each round, which is the valid output given $X = \vec{0}$ and so N trivially converges to WTA. So for the remainder of the section we focus on the case in which X has at least one firing input. We show that N satisfies the following conditions, which imply Theorem 3:

▶ **Claim 13** (Stability). *If* N *satisfies WTA in round* t *with* $y_j^t = 1$*, then* N *satisfies WTA in round* $t + 1$ *with* $y_j^{t+1} = 1$ *w.h.p.*

▶ **Claim 14** (Convergence). *Letting* $t = c_2 \log n$ *for constant* c_2*, for any input* X *with* $\|X\|_1 \geq 1$ *and any starting configuration* C^0*,* N *satisfies WTA in round* $C^{t'}$ *for some* $t' < t$*, with constant probability.*

Since Claim 14 holds for any starting configuration, we can simply apply it $\Theta(\log n)$ times to show that w.h.p. within $\Theta(\log^2 n)$ rounds, there will be a round in which WTA is satisfied, and hence N will converge to WTA by Claim 13. Additionally, it gives $\mathcal{ET}(\mathrm{N}) = O(\log n)$ as letting c_1 be the constant probability of reaching WTA in $O(\log n)$ rounds, we have:

$$\mathcal{ET}(\mathrm{N}) = O\left(\sum_{i=0}^{\infty}(1 - c_1)^i \cdot c_1 \log n\right) = O(\log n).$$

This gives us Theorem 3.

Proof of Claim 13. N satisfies WTA in round t with output y_j firing, so we have

$$pot(z_s, t) = 1 \cdot \mathrm{w^{out}}_s - b(z_s) = .5 \text{ and } pot(z_c, t) = 1 \cdot \mathrm{w^{out}}_s - b(z_c) = -.5.$$

Thus, recalling that $\lambda = 1/(c_1 \log n)$, in round t z_s fires with probability $\frac{1}{1+e^{-.5c_1 \log n}} \geq 1 - 1/n^c$ for large c and z_c fires with probability $\frac{1}{1+e^{.5c_1 \log n}} \leq 1/n^c$ for large c. So w.h.p. just z_s fires in round t. This gives that w.h.p.

$$pot(y_j, t+1) = (1 \cdot \mathrm{w^{inh}}_s) + (0 \cdot \mathrm{w^{inh}}_\ell) + (1 \cdot \mathrm{w^{self}}) + \mathrm{w^{input}} - \mathrm{b^{out}} = -1 + 2 + 3 - 3 = 1.$$

So y_j fires with probability $\frac{1}{1+e^{c_1 \log n}} \geq 1 - 1/n^c$ in round $t+1$. In contrast, for any $j' \neq j$, $y_{j'}$ does not fire in round t so we have w.h.p.

$$pot(y_{j'}, t+1) \leq (1 \cdot \mathrm{w^{inh}}_s) + (0 \cdot \mathrm{w^{inh}}_\ell) + (0 \cdot \mathrm{w^{self}}) + \mathrm{w^{input}} - \mathrm{b^{out}} = -1 + 3 - 3 = -1.$$

Therefore y'_j fires with probability $\leq 1/n^c$ in round $t+1$ so WTA is satisfied with output y_j firing in round $t+1$ w.h.p. ◀

Proof of Claim 14. Recall that we only consider $\|X\|_1 \geq 1$ as convergence to WTA is trivial when $X = \vec{0}$. We analyze three simple cases depending the initial configuration C^0:

Case 0: No output y_j with $x_j = 1$ fires in $\mathbf{Y^0}$

We first consider the subcase that no output (regardless of the value of x_j) fires in Y^0. In this case, $pot(z_s, 0) = -b(z_s) = -.5$ and $pot(z_c, 0) = -b(z_c) = -1$ so neither inhibitor fires w.h.p. in round 0. So w.h.p. all outputs with firing inputs have $pot(y_j, 1) \geq \mathrm{w^{input}} - \mathrm{b^{out}} = 0$ and so fire with probability $\geq 1/2$ in round 1. Since, $\mathrm{X} \neq \vec{0}$, with constant probability at least one of these outputs fires in round 1, in which case we appeal to Cases 1 and 2 below (where we re-label C^2 as the initial configuration C^0.).

Next consider the case when at least one output fires in Y^0, but all firing outputs correspond to non-firing inputs. In this case, we have $pot(z_s, 0) \geq 1 \cdot \mathrm{w^{out}} - b(z_s) \geq .5$ and so z_s fires w.h.p. in round 0. As noted, in any round, any output y_j with $x_j = 0$ has $pot(y_j, t) \leq \mathrm{w^{self}} - \mathrm{b^{out}} = -1$ and so does not fire w.h.p. Additionally, since every output with $x_j = 1$ has $y_j^0 = 1$, these outputs have $pot(y_j, 1) = \mathrm{w^{inh}}_s + \mathrm{w^{input}} - \mathrm{b^{out}} = -1 + 3 - 3 = -1$ and so do not fire w.h.p. in round 1. So w.h.p. in round 1 no outputs fire and we are in the first case above.

Case 1: Exactly one output y_j with $x_j = 1$ fires in $\mathbf{Y^0}$

By Claim 13 and the fact that outputs with $x_j = 0$ do fire w.h.p. in any round, N satisfies WTA in round 1 and so immediately converges to WTA.

Case 2: More than one output y_j with $x_j = 1$ fires in $\mathbf{Y^0}$

Let k_t be the number of *active* outputs in round t – that is outputs corresponding to firing inputs that fire in round t. For any round with $k_t \geq 2$, we have $pot(z_s, t) \geq 2\,\mathrm{w^{out}} - b(z_s) = 1.5$ and $pot(z_c, t) \geq 2\,\mathrm{w^{out}} - b(z_c) = 1$. So both inhibitors fire in round t w.h.p. Conditioning on this event, all active outputs have:

$$pot(y_j, t+1) = (1 \cdot \mathrm{w^{inh}}_s) + (1 \cdot \mathrm{w^{inh}}_\ell) + (1 \cdot \mathrm{w^{self}}) + \mathrm{w^{input}} - \mathrm{b^{out}} = -1 - 1 + 2 + 3 - 3 = 0$$

and so fire with probability $1/2$ in round $t+1$. All inactive outputs, which did not fire in round t, do not have an active self loop and hence have $pot(y_j, t) = -2$ and don't fire in round $t+1$ w.h.p. (as discussed, all outputs with $x_j = 0$ also do not fire w.h.p.)

Conditioning on this event, with probability $1/2$, $k_{t+1} \leq k_t/2$. Further,

$$\Pr[k_{t+1} = 0] = 1/2^{k_t} \text{ and } \Pr[k_{t+1} = 1] = k_t \cdot (1/2^{k_t}) \geq \Pr[k_{t+1} = 0].$$

So the probability of reaching $k_{t+1} = 1$ and hence N converging to WTA is at least as high as the probability of overshooting WTA and having no outputs firing in round $t+1$.

Conditioning on the fact that z_s and z_c fire in every round in which $k_t \geq 2$ and that no output which was inactive in round t fires in round $t+1$, whenever $k_t \geq 2$ it decreases by a factor of $1/2$ in round $t+1$ with good probability. So w.h.p. within $O(\log(k_0)) = O(\log n)$ rounds there is a round t with either $k_t = 1$ or $k_t = 0$. $k_t = 1$ is at least as likely as $k_t = 0$ so with constant probability, N converges to WTA within $O(\log n)$ rounds. ◀

Two Inhibitor Lower Bound

▶ **Theorem 15.** *For any basic WTA network* N *with* $\alpha = 2$ *inhibitors,* $\mathcal{ET}(\mathrm{N}) = \Omega(\log n / \log\log n)$ *and* $\mathcal{HT}(\mathrm{N}) = \Omega(\log^2 n / \log\log^2 n)$.

The key idea is that the use of a stability inhibitor z_s and a convergence inhibitor z_c in the algorithm is not just a design choice, but is required for *any* near-optimal two inhibitor WTA network.

▶ **Claim 16.** *For any basic WTA network* N *with* $\alpha = 2$ *inhibitors and* $\mathcal{ET}(\mathrm{N}) = O(\log^3 n)$*, one inhibitor* z_s *fires w.h.p. in sub-round* $(t, 3)$ *if at least one output fires in sub-round* $(t, 2)$*. The second inhibitor* z_c*, does not fire w.h.p. in* $(t, 3)$ *if just a single output fires in* $(t, 2)$*.*

Proof. Assume for contradiction that both inhibitors fire with probability $\omega(1/n^c)$ in sub-round $(t, 3)$ after just a single output fires in sub-round $(t, 2)$. Then, after a round t in which $z_s^t = z_c^t = 1$, any output y_j with $x_j = 1$ and $y_j^t = 1$ must fire w.h.p. in round $t+1$. This is because once N converges to WTA, when the single winning output fires in sub-round $(t, 2)$, by our assumption, with relatively high $\omega(1/n^3)$ probability, both z_s and z_c fire in sub-round $(t, 3)$. Even if this event occurs, the winning output must fire w.h.p. in round $t+1$ to maintain WTA w.h.p.

However, if we let $\mathrm{X} = \vec{1}$ and $\mathrm{Y}^0 = \vec{1}$, then for some constant c_1, all outputs will continue firing for $\omega(n^{c_1})$ rounds w.h.p. even if both z_s and z_c fire in every round. This contradicts our assumed $O(\log^3 n)$ runtime. Hence we have that at least one of the inhibitors, which we label z_c, fires with probability $O(1/n^c)$ in sub-round $(t, 3)$ if just a single output fires in sub-round $(t, 2)$.

Similarly, assume for contradiction that z_s *does not fire* with probability $\omega(1/n^c)$ in sub-round $(t, 3)$ if a single output fires in sub-round $(t, 2)$. Then, it must be that even if neither inhibitor fires in sub-round $(t, 3)$, any output y_j that did not fire in sub-round $(t, 2)$ (i.e. $y^t = 0$), must also not fire w.h.p. in sub-round $(t+1, 2)$. This is because, by our assumption, after WTA is reached, with probability $(1 - O(n^c)) \cdot \omega(1/n^c) = \omega(1/n^c)$ neither inhibitor will fire in sub-round $(t, 3)$ when just the single winning output fires in sub-round $(t, 2)$. Still, all non-winning outputs must continue not firing in round $t+1$ to maintain WTA w.h.p.

However, if we let $\mathrm{X} = \vec{1}$ and $\mathrm{Y}^0 = \vec{0}$, since even when neither inhibitor fires in round t, each output does not fire in round $t+1$ w.h.p. if it did not fire in round t, it will take $\omega(n^{c_1})$ rounds (for some constant c_1) before even a single output fires w.h.p. contradicting our assumed $O(\log^3 n)$ runtime. ◀

The above claim allows us to strongly constrain the behavior of the network based on the action of the inhibitors z_s and z_c. Let p_0 be the probability that an output y_j fires in round $t+1$ given that $y^t = 0$, $x^t = 1$ and $z_s^t = z_c^t = 0$.

▶ **Claim 17.** *For any basic WTA network* N *with* $\alpha = 2$ *inhibitors and* $\mathcal{ET}(\mathrm{N}) = o(\log^2 n)$, $p_0 = \omega(1/\log^2 n)$.

Proof. Consider X with just two firing inputs $x_1 = 1$ and $x_2 = 1$. For any round t in which $y_1^t = y_2^t = 0$, the probability that y_1 or y_2 fires in round $t+1$ is *at most* p_0 – since the firing of z_s or z_c can only decrease the probability of the outputs firing. Assuming by way of contradiction that a $p_0 \leq c_1/\log^2 n$ for some constant c_1, starting from $\mathrm{Y}^0 = \vec{0}$, with constant probability, neither output will fire for $\Omega(\log^2 n)$ consecutive rounds, and so N cannot converge to WTA in expected $o(\log^2 n)$ rounds. ◀

Let p_{out} be the probability that output y_j fires in round $t+1$ given $y^t = 1$, $x^t = 1$ and $z_s^t = z_c^t = 1$.

▶ **Claim 18.** *For any basic WTA network* N *with* $\alpha = 2$ *inhibitors and* $\mathcal{ET}(\mathrm{N}) = o(\log^2 n)$, $p_{out} = \omega(1/\log^6 n)$.

Proof. Consider X with $\Theta(\log^4 n)$ firing inputs and initial configuration Y^0 where $y_j = 1$ for all j with $x_j = 1$. Consider some round t in which at least two outputs (corresponding to firing inputs) have fired in all rounds $t' \leq t$. If either (or both) of z_s or z_c do not fire in round t, then since they face at most as much inhibition as when the network has converged to WTA, all outputs with firing inputs that fired in round t fire w.h.p. in round $t+1$. However, if both z_s and z_c do fire in round t, if $p_{out} = O(1/\log^6 n)$ then with probability $\leq (1-p_{out})^{\Theta(\log^4 n)} = 1 - \Theta(1/\log^2 n)$ *no* output corresponding to a firing input fires in round $t+1$. Since by Claim 16 a single inhibitor firing is enough to maintain convergence to WTA, once these outputs do not fire in some round t, they do not fire again w.h.p. until a round in which neither z_s or z_c fire. Then by Claim 17 and a Chernoff bound (Theorem 12) $\omega(\log^2 n)$ of them fire w.h.p.

So overall, we alternate between having many (between $\omega(\log^2 n)$ and $\Theta(\log^4 n)$) outputs corresponding to firing inputs and 0 outputs with firing inputs. Each time we have many firing outputs, with probability at least $1 - \Theta(\log^2 n)$ we have no firing outputs in the next round. So it takes at least $\Omega(\log^2 n)$ rounds before we have a round with exactly one valid firing output with constant probability, contradicting our assumed runtime of $\mathcal{ET}(\mathrm{N}) = o(\log^2 n)$. ◀

With the above claims in place, we are ready to prove Theorem 15. Consider $\mathrm{X} = \vec{1}$ and initial configuration with $\mathrm{Y}^0 = \vec{1}$. Let $k_t = \|Y^t\|_1$ be the number of outputs that fire in round t. Now, if y_j fires in round t, then it fires with probability *at least* p_{out} in round $t+1$, since p_{out} is the firing probability with maximum inhibition. Let $d = c_1 \log n/p_{out}$ for some constant c_1. By Claim 18, $d = O(\log^7 n)$ and since $p_{out} \leq 1$, trivially $d = \Omega(\log n)$. Starting from Y^0 with all outputs firing, for $t = c_2 \frac{\log(d/n)}{\log p_{out}}$ for sufficiently small c_2 we have that any output fires in all rounds up to t with probability $\theta\left(p_{out}^t\right) = \omega\left(\frac{d}{n}\right)$. So by a Chernoff bound (Theorem 12) w.h.p. $\omega(d)$ outputs fire in all rounds $t' \leq t$.

Let t_f represent the first round in which $\leq d$ outputs fire. By our argument above, w.h.p.

$$t_f = \Theta(\log(n/d)/\log(1/p_{out})) = \Theta(\log n/\log(1/p_{out})) = \Omega(\log n/\log\log n) \tag{3}$$

by Claim 18. This gives us $\mathcal{ET}(\mathrm{N}) = \Omega(\log n/\log\log n)$. So it just remains to show our lower bound on $\mathcal{HT}(\mathrm{N})$.

Since $> d$ outputs fire in round $t_f - 1$, again by a Chernoff bound, w.h.p. $k_{t_f} \geq d \cdot p_{out} = \Omega(\log n)$. Consider any round $t > t_f$ in which $k_{t'} > 1$ for all $t' \leq t$. If either of z_s of z_c do not fire in round t, then $k_{t+1} = k_t > 1$ w.h.p. Otherwise, $\Pr[k_{t+1} = 1] = k_t \cdot p_{out}(1 - p_{out})^{k_t - 1}$ and:

$$\Pr[k_{t+1} = 0] = (1 - p_{out})^{k_t} = \Pr[k_{t+1} = 1]] \cdot \frac{1 - p_{out}}{k_t p_{out}} \geq \Pr[k_{t+1} = 1]] \cdot \frac{1}{\log^8 n}$$

where we use the fact that $k_t \leq d = O(\log^7 n)$ and $1 - p_{out} \geq \log n$ or else by (3) we would already not reach WTA w.h.p. in $O(\log^2 n)$ rounds.

So, the probability that $k_{t+1} = 0$ is high (within a polylog n) factor of the probability that $k_{t+1} = 1$. So, with probability at least $\Omega(1/\log^8 n)$, t_f is followed by a reset round in 0 outputs fire before a round in which a single output fires. Further, once such a reset round occurs, then no output will fire until z_s and z_c don't fire in a round (and hence inhibition is lower than it is after convergence to WTA) in which case by Claim 17 $\omega(n/\log^2 n)$ outputs will fire. So w.h.p. there will be $\Omega(\log n/\log\log n)$ rounds before another round in which ≤ 1 outputs fire.

Overall, in order to have a round in which exactly 1 output fires w.h.p. requires $\Omega(\log n/\log(\log^8 n)) = \Omega(\log n/\log\log n)$ resets, each taking $\Omega(\log n/\log\log n)$ rounds, and giving our final lower bound of $\Omega(\log^2 n/\log\log^2 n)$.

B.2 WTA with One Inhibitor

One Inhibitor Lower Bound

▶ **Theorem 19.** *For any basic WTA network* N *with* $\alpha = 1$ *inhibitors,* $\mathcal{ET}(\mathrm{N}) = \Omega(n^c)$.

We fix any constant c and assume by way of contradiction that there is a network N which converges to WTA in $O(n^c)$ rounds in expectation. Let z denote the single inhibitor in N. We first argue that N must be at least somewhat active – given no firing activity from the outputs Y and the inhibitor z, each output connected to an active input should fire with reasonably high probability.

▶ **Claim 20** (Sufficiently Active Network)**.** *If* $z^t = 0$ *then each output* y_j *with* $x_j = 1$ *and* $y_j^t = 0$ *fires in round* $t + 1$ *with probability* $\Omega(1/n^c)$.

Proof. Let X be an input in which exactly one input x_j fires and let $Y^0 = \vec{0}$. The time for N to converge to WTA is lower bounded by the time required for y_j to fire at least once.

Let p_0 be the probability that y_j fires in round $t + 1$ if $y_j^t = 0$ and $z^t = 0$ and let p_1 be the probability that y_j fires in round $t + 1$ if $y_j^t = 0$ and $z^t = 1$. $p_1 \leq p_0$, so as long as y_j does not fire in round t, it fires with probability at most p_0 in round $t + 1$. If $p_0 \leq c_1/n^c$ for some constant c_1 then starting from C_0, with constant probability, y_j will not fire for $\Omega(n^c)$ consecutive rounds. By our assumption that N converges to WTA in $O(n^c)$ rounds in expectation, we have $p_0 = \Omega(1/n^c)$. ◀

We next show that the inhibitor z must fire in round t w.h.p. whenever at least one output fires, in order to maintain stability once WTA has been reached.

▶ **Claim 21** (Stability)**.** *For any configuration* $\mathcal{C}^t$ *of* N*, if at least one output neuron fires in round* t *(i.e.* $\| \mathrm{Y}^t \|_1 \geq 1$*), z fires in round* t *w.h.p.*

Proof. Consider input $X = \vec{1}$. Let t be a round in which WTA is satisfied (exactly one output y_j fires while no other outputs fire). Using the notation of Claim 20, the probability that a non-firing output fires in round $t+1$ is:

$$\Pr[z^t = 1 | Y^t] \cdot p_1 + \Pr[z^t = 0 | Y^t] \cdot p_0.$$

By Claim 20 we have $p_0 \geq c_1/n^c$ for some constant c_1. Since N converges to WTA it must be that w.h.p. in round $t+1$, y_j continues firing and no other output fires. So we have, for some large constant c_2:

$$\begin{aligned} \Pr[z^t = 1 | Y^t] \cdot p_1 + \Pr[z^t = 0 | Y^t] \cdot p_0 &\leq 1/n^{c_2} \\ \Pr[z^t = 0 | Y^t] \cdot c_1/n^c &\leq 1/n^{c_2} \\ \Pr[z^t = 0 | Y^t] &= O(1/n^{c_2 - c}) \end{aligned}$$

which gives the claim as long as $c < c_2$ since exactly one output fires in Y^t. The probability that z fires when > 1 output fires is at least as large due to the excitatory nature of the outputs. ◀

Finally, by way of contradiction, we show that when z fires, any output must stop firing with reasonably high probability. Otherwise, starting with multiple firing outputs, it will take too long to converge to WTA. As we will see this convergence requirement conflicts with the stability requirement of Claim 21 since it means that the winning output will stop firing with reasonably high probability after convergence to WTA.

▶ **Claim 22** (Convergence). *If $z^t = 1$ then y_j with $y_j^t = 1$ and $x_j = 1$ does not fire in round $t+1$ with probability $\Omega(1/n^c)$.*

Proof. Let p denote the probability that an output which corresponds to a firing input and which fires in round t does not fire in round $t+1$ given that $z^t = 1$. We want to show that $p = \Omega(1/n^c)$.

Let $X = \vec{1}$ and let t be any round in which at least two outputs fire. By Claim 21, $z^t = 1$ w.h.p. and at least two outputs fire in round 1 with probability $(1-p)^2 \geq 1 - 2p$. If we start from $Y^0 = \vec{1}$, then w.h.p. at least two outputs will fire in $\Theta\left(\frac{1}{p}\right)$ consecutive rounds. By assumption N converges to WTA within $O(n^c)$ rounds in expectation so we must have $p = \Omega(1/n^c)$. ◀

Putting it all together, consider an execution that satisfies WTA in round t with exactly one output y_j firing. Then, by Claim 21, z fires in round t w.h.p. Thus, by Claim 22, y_j stops firing in round $t+1$ with probability $\Omega(1/n^c)$, in contradiction to the fact that the network must eventually converge to WTA and have y_j fire for n^{c_1} consecutive rounds for some large constant c_1. We briefly note that the above lower bound can be matched with a trivial single inhibitor algorithm.

▶ **Observation 23.** *There is basic network N with $\alpha = 1$ inhibitors with $\mathcal{ET}(N) = O(n^c)$.*

Proof. The single inhibitor z simply fires w.h.p. in round t whenever ≥ 1 outputs fire in round t. The weights are set such that when $z^t = 1$ and $y_j^t = 1$, y_j fires in round $t+1$ with probability $1/n^{c+1}$. If z does not fire, any y_j with $x_j = 1$ fires w.h.p.

It is not hard to see that starting with any input, we will reach a round satisfying WTA within $O(n^c)$ rounds in expectation and after this round is reached, WTA will be maintained for $O(n^{c-1})$ additional rounds in expectation (and so $O(n^{c-2})$ w.h.p.). ◀

B.3 WTA with $O(\log n)$ Inhibitors

Proof of Theorem 4 ($O(\log n)$ Inhibitor Upper Bound). Recall that we assume w.l.o.g. $1/\lambda = c_1 \log n$ for some constant c_1. We set $\mathrm{w}^{\mathrm{input}} = 3$, $\mathrm{w}^{\mathrm{self}} = 2$, and $\mathrm{b}^{\mathrm{out}} = 3$. In this way, exactly as in the two inhibitor network analyzed in Section B.1, any output y_j with $x_j = 0$ will have $pot(y_j, t) \leq \mathrm{w}^{\mathrm{self}} - \mathrm{b}^{\mathrm{out}} = -1$ in every round t and so will not fire w.h.p. in any round.

Our network has $\alpha = \lceil \log n \rceil$ inhibitors. The first is a stability inhibitor z_s, which behaves exactly as the stability inhibitor in the two inhibitor network analyzed in Section B.1. ${\mathrm{w}^{\mathrm{out}}}_s = 1$, $b(z_s) = 0.5$ and ${\mathrm{w}^{\mathrm{inh}}}_s = -1$. z_s fires w.h.p. in sub-round $(t, 3)$ if ≥ 1 output fires in sub-round $(t, 2)$ and does not fire w.h.p. if no output fires. We also have $\alpha - 1$ convergence inhibitors $z_1, ..., z_{\alpha-1}$. For each z_i, $b(z_i) = 2^i - .5$ and ${\mathrm{w}^{\mathrm{out}}}_i = 1$. Therefore, z_i fires w.h.p. in round t whenever $\geq 2^i$ outputs fire in the round. It does not fire w.h.p. if $< 2^i$ outputs fire. We set the inhibitor weight from z_1 to each output to be ${\mathrm{w}^{\mathrm{inh}}}_1 = -1$. For each $i \in 2, ..., \alpha - 1$ we set ${\mathrm{w}^{\mathrm{inh}}}_i = -\lambda \cdot \log_2(e)$.

We can see that the stability Claim 13 holds just as it does in the two inhibitor network analyzed in Section B.1. Specifically, if just a single output y_j with $x_j = 1$ fires in some round t, w.h.p. z_s will fire while the convergence inhibitors will all not fire. So we will have:

$$pot(y_j, t+1) = {\mathrm{w}^{\mathrm{inh}}}_s + \mathrm{w}^{\mathrm{input}} + 1 \cdot \mathrm{w}^{\mathrm{self}} - \mathrm{b}^{\mathrm{out}} = -1 + 3 + 2 - 3 = 1$$

so y_j fires w.h.p. in round t+1. At the same time for $j' \neq j$, since $y_{j'}$ does not fire in round t:

$$pot(y_{j'}, t+1) = {\mathrm{w}^{\mathrm{inh}}}_s + \mathrm{w}^{\mathrm{input}} + 0 \cdot \mathrm{w}^{\mathrm{self}} - \mathrm{b}^{\mathrm{out}} = -1 + 3 + 0 - 3 = -1$$

so $y_{j'}$ will not fire in round $t+1$. So, once a single y_j with $x_j = 1$ fires in some round t, N will converge to WTA w.h.p. We now show that N reaches such a round in $O(1)$ expected time.

Consider any round $t > 0$ in which $k_t \geq 2$ outputs fire. We can assume that all these outputs corresponding to firing inputs since as discussed, outputs corresponding to non-firing inputs do not fire w.h.p. in any round. For some i we have $k_t \in [2^i, 2^{i+1})$ and so w.h.p. in round t, $z_s, z_1, ..., z_i$ fire while all other inhibitors do not fire (note that $\alpha - 1 = \lceil \log n \rceil - 1$ and so even if n outputs fire, all inhibitors fire). We thus have, w.h.p. for any active output y_j with $y_j^t = 1$ and $x_j = 1$:

$$\begin{aligned} pot(y_j, t+1) &= \mathrm{w}^{\mathrm{self}} + \mathrm{w}^{\mathrm{input}} - \mathrm{b}^{\mathrm{out}} + {\mathrm{w}^{\mathrm{inh}}}_s + {\mathrm{w}^{\mathrm{inh}}}_1 + \sum_{j=2}^{i} {\mathrm{w}^{\mathrm{inh}}}_j \\ &= 2 + 3 - 3 - 1 - 1 - (i-1)\lambda = (i-1)\lambda \cdot \log_2(e). \end{aligned}$$

So y_j fires in round $t+1$ with probability:

$$p(y_j, t+1) = \frac{1}{1 + e^{(i-1)\lambda \log_2(e)/\lambda}} = \frac{1}{1 + 2^{i-1}}$$

Since $k_t \in [2^i, 2^{i+1})$, we have $1 \leq \frac{k_t}{1+2^{i-1}} \leq 4$ and so can bound the probability that exactly one output that was active in round t fires in round $t+1$ as:

$$\begin{aligned} k_t \cdot \frac{1}{1+2^{i-1}} \cdot \left(1 - \frac{1}{1+2^{i-1}}\right)^{k_t - 1} &\geq \left(1 - \frac{1}{1+2^{i-1}}\right)^{k_t - 1} \\ &\geq \left(1 - \frac{1}{1+2^{i-1}}\right)^{4(1+2^{i-1})} \\ &\geq \frac{1}{4^4}. \end{aligned}$$

So, with constant probability exactly one output that fired in round t also fires in round $t+1$. Any output that did not fire in round t has potential $\leq \mathrm{w}^{\mathrm{input}} - \mathrm{b}^{\mathrm{out}} + \mathrm{w}^{\mathrm{inh}}{}_s + \mathrm{w}^{\mathrm{inh}}{}_\ell = -2$ and so does not fire with high probability. So, with constant probability, exactly one output y_j with $x_j = 1$ fires, and so N converges to WTA.

We conclude by noting that, by the arguments of Claim 14 for our two inhibitor network, with constant probability, starting with any Y^0 we in fact have a round with $k_t \geq 1$ firing outputs all with active inputs within constant rounds. So from any starting configuration, we converge to WTA with constant probability in $O(1)$ rounds. Repeating this constant probability argument gives both $\mathcal{ET}(\mathrm{N}) = O(1)$ and $\mathcal{HT}(\mathrm{N}) = O(\log n)$. ◀

$\Omega(\log n)$ High Probability Runtime Lower Bound

▶ **Theorem 24.** *Any basic WTA network* N*, with any number of inhibitors, has* $\mathcal{HT}(\mathrm{N}) = \Omega(\log n)$*.*

Proof. We show that any network N requires $\Omega(\log n)$ rounds before a round t in which WTA is satisfied w.h.p. This immediately gives our lower bound on convergence time.

Consider input $X = \vec{1}$ (so any output is a valid winner) and any round t such that WTA has not been satisfied for any $t' < t$. That is, in no round t' does exactly one output y_j fire. Let W_t be the event that in round t exactly one output fires and hence WTA is satisfied. We claim that $\Pr[W_t = 1 \mid C^{t-1}] \leq c$ for any configuration C^{t-1} of N in round $t-1$ and some universal constant c. That is, no matter the network configuration in round $t-1$, WTA will only be achieved with constant probability in the next round. Hence, as long as the initial output configuration Y^0 is one in which WTA is not satisfied, for $t = O(\log n)$, with probability at least $(1-c)^t = \Omega(1/n^{c'})$, for some constant c', WTA will not be satisfied in any even round up to t. This gives that $\mathcal{HT}(\mathrm{N}) = \Omega(\log n)$. There are two cases:

Network Reset

$Y^{t-1} = \vec{0}$. In this case, no output fired in round $t-1$. Since all outputs are identical w.r.t their edge weights and bias values, conditioned on the behavior Z^{t-1} of the inhibitors in round $t-1$, all outputs will fire independently with some fixed probability p in round t. For any p and any $n \geq 2$, the probability that exactly 1 will fire in round t is:

$$\Pr[W_t = 1 \mid C^{t-1}] = n \cdot p(1-p)^{n-1} \leq \frac{1}{2}.$$

No Reset

$\|Y^{t-1}\|_1 \geq 2$ – i.e. there are at least 2 firing outputs in round $t-1$. Let O_1 be the set of firing outputs in round $t-1$ and O_0 be the set of non-firing outputs. Conditioned on Z^{t-1}, any output in O_1 fires independently with some probability p_1 in round t and any output in O_0 fires with some probability p_0. Further, $p_0 \leq p_1$ since the only difference in membrane potential between the neurons in O_0 and O_1 will be whether their excitatory self loop is active.

For $a \in \{0,1\}$ let V_a be the event that exactly 1 output from O_a fires in round t. Clearly, $W_t \subseteq V_1 \cup V_0$. For any p_1, $\Pr[V_1 \mid C^{t-1}] = |O_1| \cdot p_1(1-p_1)^{|O_1|-1} \leq 1/2$ since we have not reached WTA and so $|O_1| \geq 2$. If $|O_0| = 0$, then vacuously, $\Pr[V_0 \mid C^{t-1}] = 0$ and hence $\Pr[W_t \mid C^{t-1}] \leq 1/2$. Alternatively, If $|O_0| \geq 2$ then we also have $\Pr[V_0 \mid C^{t-1}] \leq 1/2$ and, since all outputs fire independently conditioned on C^{t-1},

$$\Pr[W_t \mid C^{t-1}] \leq 1 - \Pr[\neg(V_1 \cup V_0)] \leq 1 - (1-1/2)^2 = 3/4.$$

Finally, if $|O_0| = 1$ either $p_0 \leq 1/2$, in which case $\Pr[V_0 \mid C^{t-1}] \leq 1/2$ and we again have $\Pr[W_t \mid C^{t-1}] \leq 3/4$ or $p_0 \geq 1/2$ in which case $p_1 \geq p_0 \geq 1/2$, and the probability that at least two outputs from O_1 fire is at least $1/4$ and hence WTA is achieved with probability at most $3/4$. ◀

B.4 WTA with $\alpha \geq 2$ Inhibitors

Proof of Theorem 5. We first describe the network construction in detail. As in our previous networks, we have a stability inhibitor z_s that fires w.h.p. whenever ≥ 1 outputs fire in round t. This inhibitor ensures that in round $t+1$ w.h.p. only outputs that fired in round t (and hence have an active self loop) will fire in round $t+1$.

We set the excitatory input to output connection weight to $\mathrm{w}^{\mathrm{input}} = 3$, the excitatory output self-loop to $\mathrm{w}^{\mathrm{self}} = 2$, and the output bias to $\mathrm{b}^{\mathrm{out}} = 3$. For the stability inhibitor we set the excitatory output to inhibitor weight ${\mathrm{w}^{\mathrm{out}}}_s 1$, $b(z_s) = .5$, and ${\mathrm{w}^{\mathrm{inh}}}_s = -1$ just as we did in the two inhibitor algorithm.

We have θ groups each containing $\lceil (\log n)^{1/\theta} \rceil$ convergence inhibitors, $Z_1, Z_2, ..., Z_\theta$ where we denote $Z_i = \{z_{i,1}, z_{i,2}, ..., z_{i,\lceil (\log n)^{1/\theta} \rceil}\}$. We set ${\mathrm{w}^{\mathrm{out}}}_i = 1$ for all $i \in Z_1, Z_2, ..., Z_\theta$ and $b(z_{i,j}) = 2^{jd_i} - .5$. In this way, when $k_t \in \left[2^{jd_i}, 2^{(j+1)d_i}\right)$ w.h.p. $z_s, Z_1, ..., Z_{i-1}, z_{i,1}, ..., z_{i,j}$ all fire while the remaining inhibitors do not. We set ${\mathrm{w}^{\mathrm{inh}}}_{i,j}$ such that

$$pot_{i,j} = \mathrm{w}^{\mathrm{input}} + \mathrm{w}^{\mathrm{self}} + {\mathrm{w}^{\mathrm{inh}}}_s - \mathrm{b}^{\mathrm{out}} + \sum_{\{(k,l) | k<i \text{ or } l \leq j\}} {\mathrm{w}^{\mathrm{inh}}}_{k,l}$$

satisfies:

$$p_{i,j} = \frac{1}{1 + e^{-pot_{i,j}/\lambda}} = \frac{c_1}{2^{jd_i}}$$

for some small constant c_1. For simplicity of presentation, we do not explicitly calculate out these weights. However, it is clear that choosing correct weights $p_{i,j}$ decreases as most inhibitors fire and the sigmoid function is continuous and decreases monotonically as pot_i decreases. We are now ready to analyze the network behavior in detail.

No Firing Inputs

As in the two inhibitor network, any y_j with $x_j = 0$, has maximum potential is $\mathrm{w}^{\mathrm{self}} - \mathrm{b}^{\mathrm{out}} = -1$ (even when no inhibitors fire) so and will not fire w.h.p. outside of the initial configuration Y^0. ($p(y_j, t) \leq \frac{1}{1+e^{1/\lambda}} \leq 1/n^c$ for any t since $\lambda = 1/c_1 \log n$). If $\mathrm{X} = \vec{0}$, this implies that a valid WTA state in which no outputs fire will be converged to w.h.p. trivially. We now focus on the case when $\| \mathrm{X} \|_1 \geq 1$.

Maintaining WTA (Stability)

If just a single output y_j corresponding to an active input ($x_j = 1$) fires in round t then w.h.p. by Claim 13 in Appendix B.1, N converges to WTA. This is because w.h.p. just z_s will fire in round t and y_j has potential

$$pot(y_j, t+1) = (1 \cdot {\mathrm{w}^{\mathrm{inh}}}_s) + (0 \cdot {\mathrm{w}^{\mathrm{inh}}}_\ell) + (1 \cdot \mathrm{w}^{\mathrm{self}}) + \mathrm{w}^{\mathrm{input}} - \mathrm{b}^{\mathrm{out}} = -1 + 2 + 3 - 3 = 1.$$

So y_j fires with probability $\frac{1}{1+e^{c_1 \log n}} \geq 1 - 1/n^c$ in round $t+1$. In contrast, for any $j' \neq j$, $y_{j'}$ does not fire in round t so has

$$pot(y_{j'}, t+1) \leq (1 \cdot {\mathrm{w}^{\mathrm{inh}}}_s) + (0 \cdot {\mathrm{w}^{\mathrm{inh}}}_\ell) + (0 \cdot \mathrm{w}^{\mathrm{self}}) + \mathrm{w}^{\mathrm{input}} - \mathrm{b}^{\mathrm{out}} = -1 + 3 - 3 = -1.$$

Therefore y'_j fires with probability $\leq 1/n^c$ in round $t+1$ so WTA is satisfied with output y_j firing in round $t+1$ w.h.p.

Converging to WTA

It now just remains to show that with constant probability, within $O(\theta)$ rounds, there is at least one round in which exactly one output y_j with $x_j^t = 1$ fires. By the stability argument above once such a round occurs, N will converge to WTA w.h.p.

By the arguments of the convergence Claim 14 for the two inhibitor network, with constant probability, starting with any Y^0 we in fact have a round with $k_t \geq 1$ firing outputs all with active inputs within constant rounds. If $k_t = 1$ then N converges to WTA and we are done. So it suffices to consider the case when $k_t \geq 2$.

If $k_t \in \left[2^{jd_i}, 2^{(j+1)d_i}\right)$ then w.h.p. $z_s, Z_1, ..., Z_{i-1}, z_{i,1}, ..., z_{i,j}$ fire while the other inhibitors do not and so in round $t+1$ any active output that fired in round t fires with probability $p_{i,j}$. So we have $E[k_{t+1}] \in [1, c_1 2^{d_i})$, and, so with at least constant probability by a Markov bound $k_{t+1} < 2^{d_i}$ if we set c_1 to a small constant.

Additionally, in any round with $k_t \geq 2$ conditioning on the high probability event that the correct inhibitors fire,

$$\Pr[k_{t+1} = 1] = k_t \cdot p_{i,j}(1 - p_{i,j})^{k_t - 1}$$

and:

$$\begin{aligned}
\Pr[k_{t+1} = 0] = (1 - p_{i,j})^{k_t} &= \Pr[k_{t+1} = 1] \cdot \frac{(1 - p_{i,j})}{k_t p_{i,j}} \\
&\leq \Pr[k_{t+1} = 1] \cdot \frac{1}{2^{jd_i} \cdot c1/2^{jd_i}} \\
&\leq \frac{1}{c_1} \Pr[k_{t+1} = 1].
\end{aligned}$$

So, the probability of having exactly one output fire and hence converging to WTA is within a constant factor of the probability or having 0 outputs fire and 'reseting' the network. So overall with constant probability, we reach such a round with $k_t = 1$ within just $O(\theta)$ rounds. Iterating this argument gives the expected and high probability runtime bounds of Theorem 5. ◀

Proof of Theorem 6. Again we have a stability inhibitor z_s that fires w.h.p. in sub-round $(t, 3)$ whenever ≥ 1 outputs fire in sub-round $(t, 2)$. We also have a 'base level' convergence inhibitor that fires w.h.p. whenever ≥ 2 outputs fire. When just z_s and z_ℓ fire in round t, any output (with an active input) that fired in round t fires with probability $1/2$ in round $t+1$.

We then employ $\alpha - 2$ additional convergence inhibitors $z_1, ...z_{\alpha-2}$. For $i \in 1, ..., \alpha - 2$ let

$$d_i = (\log n)^{i/(\alpha-1)}.$$

Letting k_t be the number of outputs that fire in round t, z_i fires w.h.p. in round t whenever $k_t \geq 2^{d_i}$. The synapse weights from the inhibitors to the outputs are chosen such that, when $k_t \in \left[2^{d_i}, 2^{d_{i+1}}\right)$, and hence $z_1, ..., z_i$ each active output (i.e. each y_j with $y_j^t = 1$ and $x_j = 1$) fires with probability:

$$p_i = \frac{c \log n}{d_i} = \frac{c \log n}{(\log n)^{i/(\alpha-1)}}$$

in round $t+1$. This probability is enough to ensure that within few rounds, we will have $< 2^{d_i}$ active outputs. Specifically, since $k_t \in \left[2^{d_i}, 2^{d_{i+1}}\right)$, for

$$r = \frac{\log k_t}{\log 1/p_i} \leq \frac{(\log n)^{(i+1)/(\alpha-1)}}{(\log n)^{i/(\alpha-1)} - \log(c \log n)} = O\left((\log n)^{1/(\alpha-1)}\right)$$

with high probability, there will be a round $r' = O(r)$ with $k_{t+r'} \leq 2^{d_i}$. At the same time, p_i is large enough that w.h.p. we will not overshoot WTA and have 0 firing outputs in round $t + r'$. Even if $k_t = 2^{d_i}$ then we have $k_t \cdot p_i = c \log n$ and so, for large enough c, with high probability, by a Chernoff bound (Theorem 12) at least $O(\log n)$ outputs fire in round $t+1$.

Overall, within $O\left((\alpha-2)(\log n)^{1/(\alpha-1)}\right)$ rounds, the number of active outputs falls within $[2, 2^{d_1}]$ w.h.p. Once k_t is in this range, just z_s and z_1 fire w.h.p. so our network is essentially identical to the two inhibitor network described in the previous section and analyzed in detail in Appendix B.1. We thus reach WTA with constant probability in $\Theta(\log 2^{d_1}) = \Theta\left((\log n)^{1/(\alpha-1)}\right)$ additional rounds, giving our final runtime bound of $O\left(\alpha(\log n)^{1/(\alpha-1)}\right)$.

We now formalize the above arguments. Following our earlier constructions, we set the excitatory input to output connection weight to $\mathrm{w}^{\mathrm{input}} = 3$, the excitatory output self-loop to $\mathrm{w}^{\mathrm{self}} = 2$, and the output bias to $\mathrm{b}^{\mathrm{out}} = 3$. Set the excitatory output to inhibitor weights ${\mathrm{w}^{\mathrm{out}}}_s = {\mathrm{w}^{\mathrm{out}}}_\ell = 1$, $b(z_s) = .5$, $b(z_\ell) = 1.5$, and ${\mathrm{w}^{\mathrm{inh}}}_\ell = {\mathrm{w}^{\mathrm{inh}}}_s = -1$ just as we did in the two inhibitor algorithm.

For the additional convergence inhibitors, set ${\mathrm{w}^{\mathrm{out}}}_i = 1$ for all $i \in 1, ..., \alpha - 2$ and $b(z_i) = 2^{d_i} - .5$. In this way, when $k_t < 2^{d_1}$, w.h.p. just z_s and z_1 fire, and each active output in round t has potential

$$pot(y_j, t+1) = \mathrm{w}^{\mathrm{input}} + \mathrm{w}^{\mathrm{self}} + {\mathrm{w}^{\mathrm{inh}}}_s + {\mathrm{w}^{\mathrm{inh}}}_\ell - \mathrm{b}^{\mathrm{out}} = 3 + 2 - 1 - 1 - 3 = 0$$

and so fires with probability $p_1 = 1/2$ in round $t+1$. We set ${\mathrm{w}^{\mathrm{inh}}}_i$ such that

$$pot_i = \mathrm{w}^{\mathrm{input}} + \mathrm{w}^{\mathrm{self}} + {\mathrm{w}^{\mathrm{inh}}}_s + {\mathrm{w}^{\mathrm{inh}}}_\ell - \mathrm{b}^{\mathrm{out}} + \sum_{j=1}^{i} {\mathrm{w}^{\mathrm{inh}}}_j$$

satisfies:

$$p_i = \frac{1}{1 + e^{-pot_i/\lambda}} = \frac{c \log n}{2^{d_i}}.$$

As in the proof of Theorem 5, we do not explicitly calculate out these weights. Roughly, ${\mathrm{w}^{\mathrm{inh}}}_i \approx \Theta(\frac{\lambda \log\log n}{\alpha - 1})$ such that when i inhibitors fire $p_i \approx \frac{1}{e^{-\Theta(\frac{i\lambda \log\log n}{\alpha-1})}} \approx \frac{c \log n}{2^{d_i}}$. It is clear that choosing correct weights is possible as $1/2 > p_1 > ... > p_{\alpha-1}$ and the sigmoid function is continuous and decreases monotonically as pot_i decreases.

By identical arguments to those in the proof of Theorem 5, we converge to WTA in constant rounds w.h.p. if there are no firing inputs or if a single output with a firing input fires in a round. Hence it just remains to show that with constant probability, within $O(\alpha(\log n)^{1/(\alpha-1)})$ rounds, there is at least one round in which exactly one output y_j with $x_j^t = 1$ fires.

Again, by the arguments of the convergence Claim 14 for the two inhibitor network, with constant probability, starting with any Y^0 we in fact have a round with $k_t \geq 1$ firing outputs all with active inputs within constant rounds. If $k_t = 1$ then N converges to WTA and we are done. So it suffices to consider the case when $k_t \geq 2$. In this case, as discussed if $k_t \in \left[2, 2^{d_1}\right)$ then w.h.p. just z_s and z_ℓ fire, and so each active output has potential

$$pot(y_j, t+1) = (1 \cdot {\mathrm{w}^{\mathrm{inh}}}_s) + (1 \cdot {\mathrm{w}^{\mathrm{inh}}}_\ell) + (1 \cdot \mathrm{w}^{\mathrm{self}}) + \mathrm{w}^{\mathrm{input}} - \mathrm{b}^{\mathrm{out}} = -1 - 1 + 2 + 3 - 3 = 0$$

and fires with probability $1/2$ in round $t+1$. All inactive outputs, which did not fire in round t, do not have an active self loop and hence have $pot(y_j,t) = -2$ and don't fire in round $t+1$ w.h.p. (as discussed, all outputs with $x_j = 0$ also do not fire w.h.p.)

Conditioning on this event, with probability $1/2$, $k_{t+1} \leq k_t/2$ and by the arguments in Claim 14, we converge to WTA with constant probability within $O(k_t) = O(d_1) = O\left((\log n)^{1/(\alpha-1)}\right)$ rounds.

If $k_t \in \left[2^{d_i}, 2^{d_{i+1}}\right)$ for some $i \in 1, ..., \alpha-2$ then as discussed, w.h.p. $z_s, z_\ell, z_1, ..., z_i$ all fire in round t while all other inhibitors do not fire. We thus have

$$\mathrm{E}[k_{t+1}] \geq 2^{d_i} \cdot p_i = \frac{2^{(\log n)^{i/(\alpha-1)}} \cdot c \log n}{2^{(\log n)^{i/(\alpha-1)}}} = c \log n$$

By a Chernoff bound (Theorem 12), w.h.p. k_{t+1} falls within a constant multiplicative factor of its expection. Thus, w.h.p. we still have $k_{t+1} \geq 2$. At the same time, w.h.p. $k_{t+1} \leq c_1 k_t \cdot p_i$ for some constant c_1. So overall, within $r = \frac{\log k_t}{\log 1/p_i} = O\left((\log n)^{1/(\alpha-1)}\right)$ rounds, w.h.p. $k_{t+r} < 2^{d_i}$. Within $\alpha-2$ epochs of $O\left((\log n)^{1/(\alpha-1)}\right)$ rounds we thus have $k_t \in \left[2, 2^{d_1}\right)$ w.h.p. and then reach WTA withing $O\left((\log n)^{1/(\alpha-1)}\right)$ additional rounds with constant probability.

Iterating this constant proability argument gives the expected and high probability runtime bounds of Theorem 6. ◀

B.5 Missing Proofs for Main Lower Bound (Theorem 7)

B.5.1 Inhibitors are Nearly Deterministic for Most Density Classes

Proof of Lemma 8. By the definition of the set S, for $z \in S$ it holds that z fires in sub-round $(t,3)$ with probability $1/(1+e^{-pot_1(z)}) \geq 1/\log^{3c} n$ and hence $\mathrm{w^{out}}_z - b(z) \geq -3c \log\log n$. By our no-background noise assumption that neurons do not fire w.h.p. with no external input, we can assume $b(z) \geq 3\log n$ and hence have $pot_2(z) = 2\,\mathrm{w^{out}}_z - b(z) \geq 2\log n$. Thus, z fires with probability at least $1 - 1/n^2$ in sub-round $(t,3)$. Overall, all the $|S| \leq O(\log n)$ inhibitors fire in sub-round $(t,3)$, with probability at least $1-1/n$ as required. ◀

Proof of Lemma 9. In any round t, even if all n outputs fire in sub-round $(t,2)$, the firing probability of each inhibitor in R in sub-round $(t,3)$ is at most $1/\log^c n$ (or else the inhibitor would fall in C). Union bounding over the first $O(\log\log n)$ rounds of execution and the at most $O(\log n)$ inhibitors in R, we get that with probability at least $1 - 1/\log^{c-3} n$, none of these inhibitors fires in these rounds. ◀

Proof of Lemma 10. Let $k(z)$ be the smallest integer in $[1,n]$ such that z fires in sub-round $(t,3)$ with probability at least $1/\log^c n$ when $k(z)$ outputs fire in sub-round $(t,2)$. By the definition of C, when n outputs fire, z fires in the next sub-round with probability at least $1/\log^c n$, and hence $k(z)$ is well defined. In addition, since $z \notin S$, $k(z) \geq 2$.

Part (1) of the claim follows immediately by the definition of $k(z)$. To prove part (b), the key idea is to exploit the following gap in the behavior of $z \in C$: since z is not in S, the firing probability of z in steady state (with exactly one firing output) is *at most* $1/\log^{3c} n$. On the other hand, when there are at least $k(z) \geq 2$ active outputs, the firing probability of z is *at least* $1/\log^c n$. This implies that the sigmoid function which converts the number of firing inputs to z's firing probability must be steep enough such that z fires with good probability when $\geq 2k(z)$ outputs fire. By the fact that $z \notin S$, $pot_1(z) = \mathrm{w^{out}}_z - b(z) \leq -3c \cdot \log\log n$

and so $\mathrm{w^{out}}_z \leq b(z) - 3c\log\log n$. On the other hand, by the definition of $k(z)$, $\mathrm{w^{out}}_z$ cannot be too small since $pot_{k(z)}(z) = k(z)\cdot \mathrm{w^{out}} - b(z) \geq -c\cdot\log\log n$ so

$$k(z)\cdot \mathrm{w^{out}}_z \geq b(z) - c\log\log n. \tag{4}$$

Combining this we get: $k(z)b(z) - 3k(z)\cdot c\log\log n \geq b(z) - c\log\log n$ and so $b(z) \geq 3c\log\log n$. Using that and Eq. (4), we get: $pot_{2k(z)}(z) = 2k(z)\cdot \mathrm{w^{out}} - b(z) \geq 2b(z) - 2c\log\log n - b(z) = b(z) - 2c\log\log n \geq c\log\log n$. Hence, $1/(1+e^{-pot_{2k(z)}(z)}) \geq 1 - 1/(\log^c n)$ as required. ◀

B.5.2 Detailed Description of the Prediction Process

In this section we describe the prediction process in more detail.

Inductive Assumptions

For each round t, in showing that we are able to predict the behavior of N for a large number of inputs in round t, we make several inductive assumptions:

For two ranges of positive numbers $R_1 = [r_1, r_2]$ and $R_2 = [r_3, r_4]$ such that $r_1 \leq r_2 \leq r_3 \leq r_4$, and a positive number a, the ranges are called a-separated if $r_3/r_2 \geq a$. The *value* of the range $R_1 = [r_1, r_2]$ is taken to be r_1. We assume that for $\mathrm{X} \in \mathcal{X}_{t-1} \subset \mathcal{X}$ the ranges $R_{t-1}(\mathrm{X})$ are all a separated for some constant a and have minimum value $\Theta(\log^7 n)$. We also assume that our earlier predictions are accurate: for each $X \in \mathcal{X}_{t-1}$, $\widehat{R}_{t-1}(\mathrm{X}) \in R_{t-1}(\mathrm{X})$ and $\widehat{F}_{t-1}(\mathrm{X}) = F_{t-1}(\mathrm{X})$ with probability at least $1 - \Theta(1/\log n)$. We first show that these assumptions hold for round one:

Predicting the number of firing outputs in sub-round $(1,2)$

Since we consider the initial reset configuration $Y^0 = \vec{0}$ we have $\widehat{R}_0(\mathrm{X}_i) = 0$ for all X_i. Trivially we can set $\mathcal{X}_0 = \mathcal{X}$ – we deterministically know the behavior of all outputs in round 0. By our no-background noise assumption, for every $z \in \mathrm{Z}$, $b(z) = c\log n$, and so w.h.p. $\widehat{F}_0(\mathrm{X}_i) = 0$ for all X_i (no inhibitor fires in the initialization round). Let $\mathcal{X}_1^{large} = \{\mathrm{X}_i \mid 2^i \geq \log^9 n\}$ (note that $|\mathrm{X}_1^{large}| = \Theta(\log n)$). Let p_0 be the probability that an output fires in sub-round $(t+1,2)$ given that no inhibitor and no output fires in round t (i.e, no output has an active self-loop). Since there are 2^i active *input neurons* in X_i, conditioned on the high probability event that $\widehat{R}_0(\mathrm{X}_i) = 0$ and $\widehat{F}_0(\mathrm{X}_i) = \vec{0}$, the expected number of firing outputs in sub-round $(1,2)$ is $p_0 \cdot \mathrm{X}_i$. It is not hard to show that $p_0 = \Omega(1/\log^2 n)$ and by combining this fact with a Chernoff bound we have:

▶ **Claim 25.** *For every $\mathrm{X}_i \in \mathcal{X}_1^{large}$, w.h.p. the number of firing outputs in sub-round $(1,2)$, $\widehat{R}_1(\mathrm{X}_i)$ is in the range $R_1(\mathrm{X}_i) = [(1 - 1/\log^3 n)\cdot p_0 2^i, (1 + 1/\log^3 n)\cdot p_0 2^i]$. Hence, the predicted output ranges for the inputs in $\mathcal{X}_1^{large}$ are $2(1 - 1/\log n)$ separated. Additionally each has minimum value $\Omega(\log^7 n)$.*

Proof. Let X_1 be a vector with exactly one firing input and let y_i be its corresponding output. Starting from $Y^0 = \vec{0}$, w.h.p., no inhibitor fires in round 0. If $p_0 < 1/\log^2 n$ then since p_0 rate is the maximum firing probability for y_j in sub-round $(t+1,2)$ given that it didn't fire in sub-round $(t,2)$, the network requires $\Omega(\log^2 n)$ rounds until y_j fires with constant probability and so at least that long to converge to WTA. So we can work in the case where $p_0 \geq 1/\log^2 n$.

For $\mathrm{X}_i \in \mathcal{X}^{large}$ we thus have the expected number of firing outputs in sub-round $(1,1)$ is $p_0 \cdot 2^i \geq 1/\log^2 n \cdot \log^9 n = \log^7 n$. Since the random firings of the outputs are independent

given the firing behavior of the inhibitors and since no inhibitors fire in sub-round $(0,3)$ w.h.p. by a Chernoff bound (Theorem 12), we have that w.h.p. the number of firing outputs $\widehat{R}_1(\mathrm{X}_i)$ is in the range $(1 \pm 1/\log^3 n) \cdot p_0 \cdot 2^i$ for all $\mathrm{X}_i \in \mathcal{X}^{large}$. ◀

The above shows that the predicted ranges for all $\mathrm{X} \in \mathcal{X}_1^{large}$ are well separated, accurate, and have high value. We can now set $\mathcal{X}_1$ to include any $\mathrm{X} \in \mathcal{X}_1^{large}$ except possibly $|C| \leq \alpha$ inputs where $R_1(\mathrm{X})$ overlaps a critical region $K(z)$ for some $z \in C$. Since the remaining ranges do not overlap any critical regions, by Lemmas 8, 9, and 10 we are able to predict $\widehat{F}_1(\mathrm{X})$ with good probability, and so have all our inductive assumptions in round 1.

Predicting the number of firing outputs for $t \geq 2$

We first define a subset of inputs $\mathcal{X}_t^{large} \subseteq \mathcal{X}_{t-1}$ for which we can predict the behavior of the outputs in N in sub-round $(t,2)$. Let $\mathcal{X}_t^{same} \subseteq \mathcal{X}_{t-1}$ be the largest subset of inputs whose predicted firing vector $F_{t-1}(\mathrm{X})$ for the inhibitors in sub-round $(t-1,3)$ is the *same*, and denote this common firing vector by F_{t-1}^*. Let $\mathcal{X}_t^{large}$ be the set of inputs in $\mathcal{X}_t^{same}$ after omitting $\Theta(\log\log n)$ inputs with the smallest range value in sub-round $(t-1,2)$.

Eventually we will show that $\mathcal{X}_t^{large}$ is a reasonably large set of inputs compared to $\mathcal{X}_{t-1}$, and hence we can continue predicting behavior for at least some inputs for a large number of rounds. But first we show how to predict $R_t(\mathrm{X})$ for every input $\mathrm{X} \in \mathcal{X}_t^{large}$.

Let p be the probability that an active output (one with $y_j^{(t-1,2)} = 1$) fires in sub-round $(t,2)$ given that the inhibitors fired in sub-round $(t-1,3)$ according to F_{t-1}^*. Since all inputs in $\mathcal{X}_t^{same}$ have the same predicted firing vector F_{t-1}^*, in each of them, an active output fires in sub-round $(t,2)$ with probability p. In addition, by induction for every $\mathrm{X} \in \mathcal{X}_t^{same} \subseteq \mathcal{X}_{t-1}$, $R_{t-1}(\mathrm{X})$ has a minimum of $\Theta(\log^7 n)$ predicted firing outputs. So inhibition in sub-round $(t-1,3)$ w.h.p. must be at least as high as it is once we have converged to WTA and just a single output is firing. Thus, any output that did not fire in sub-round $(t-1,2)$ must not fire w.h.p. in sub-round $(t,2)$, since non-firing outputs continue not to fire once WTA is converged to.

So just focusing on active outputs that fire in sub-round $(t,2)$, for every $\mathrm{X}_i \in \mathcal{X}_t^{same}$, let $R_{t-1}(\mathrm{X}_i) = [\ell_i, m_i]$ be the predicated range of firing outputs in sub-round $(t-1,2)$. Then the expected number of firing outputs in sub-round $(t,2)$ is in the range $[p \cdot \ell_i \ , \ p \cdot m_i]$. For every $\mathrm{X}_i \in \mathcal{X}_t^{same}$, let $R_t(\mathrm{X}_i) = [(1 - 1/\log^3 n) \cdot p\ell_i \ , \ (1 + 1/\log^3 n) \cdot pm_i]$.

We now observe that if the expected number of firing outputs is too small for even one of the inputs in $\mathcal{X}_t^{same}$, then it implies a lower bound of $\Omega(\log n)$ for $\mathcal{ET}(\mathrm{N})$. Essentially this is because if this is the case, with good probability, 0 outputs will fire in round t, and a reset configuration identical to Y^0 will occur. This will keep occurring, causing the network to have large runtime.

▶ **Observation 26.** *For every $t \geq 1$, if there exists $\mathrm{X} \in \mathcal{X}_t^{same}$, such that the smallest value of $R_t(\mathrm{X}_i)$ is less then $1/\log^4 n$, then $\mathcal{ET}(\mathrm{N}) = \Omega(\log n)$.*

Proof. Let $\mathrm{X} \in \mathcal{X}_t^{same}$ be such that $R_t(\mathrm{X})$ is less then $1/\log^4 n$. Then, given that the inhibitors fire according to the prediction F_{t-1}^* in sub-round $(t-1,3)$, by Markov inequality, the probability that the number of firing outputs in sub-round $(t,2)$ is at least 1 is less then $1/\log^4 n$. In other words, the conditional probability (where we condition on the prediction for round $t-1$) that a reset where 0 outputs fire happens in sub-round $(t,2)$ is at least $1 - 1/\log^4 n$. However, by our inductive assumption $\widehat{F}(\mathrm{X}) = F_{t-1}^*$ must be correct with probability at least $1 - 1/\log n$. Hence, with probability at least $1 - \Theta(\log n)$ $Y^t = \vec{0}$ and a reset round occurs. With constant probability this occurs $\Omega(\log n)$ times before WTA is ever reached. The observation follows. ◀

Hence, from now on, we assume the complementary case that the number of predicted firing outputs in sub-round $(t, 2)$ is at least $1/\log^4 n$ for every $\mathrm{X} \in \mathcal{X}_t^{same}$. This allows us to show:

▶ **Claim 27.** *For every* $\mathrm{X} \in \mathcal{X}_t^{large}$

(1) *Given that the inhibitors fire according to* F_{t-1}^* *in sub-round* $(t-1, 3)$*, then with probability* $1 - 1/n$*, the number of firing outputs in sub-round* $(t, 2)$ *is in the range* $R_t(\mathrm{X})$*.*

(2) *The set of ranges* $R_t(\mathrm{X})$ *for* $\mathrm{X} \in \mathcal{X}_t^{large}$ *are all* a*-separated for some constant* a*.*

(3) $R_t(\mathrm{X})$ *has value at least* $\Omega(\log^7 n)$ *for every* $\mathrm{X} \in \mathcal{X}_t^{large}$*.*

Proof. Since for any $\mathrm{X} \in \mathcal{X}_t^{same}$ the predicted number of firing outputs is $\Omega(1/\log^4 n)$, and since the ranges are constant separated by our inductive assumption that the ranges $R_{t-1}(\mathrm{X})$ for $\mathrm{X} \in \mathcal{X}_{t-1}$ are separated, by omitting $\Theta(\log\log n)$ inputs from $\mathcal{X}_t^{same}$, the minimum number of firing outputs in the predicted ranges for the remaining set of inputs, namely, $\mathcal{X}_t^{large}$ is $\Omega(\log^7 n)$. Hence the true number of firing outputs is well concentrated around this expectation and so we have (1) by a Chernoff bound (Theorem 12).

Further, since we increase the width of the predicted range $R_t(\mathrm{X})$ by factor of at most $(1 + 1/\log^3 n)$ compared to the range $R_{t-1}(\mathrm{X})$, over all $O(\log\log n)$ rounds of prediction, the range is increased by at most a factor of $(1 + 1/\log^3 n)^{O(\log\log n)} \leq 1 + O(1/\log^2 n)$. Since the ranges have separation 2 in the initialization round, they remain constant separated in round t, giving (2). ◀

Predicting $\widehat{F}_t(\mathrm{X})$ given the predicted range $R_t(\mathrm{X})$

We first define the final subset $\mathcal{X}_t \subseteq \mathcal{X}_t^{large}$ of inputs for which round t is fully predicted (i.e., both the number of firing outputs in sub-round $(t, 2)$ and the states of the inhibitors in sub-round $(t, 3)$). The set $\mathcal{X}_t$ contains any $\mathrm{X} \in \mathcal{X}_t^{large}$ unless $R_t(\mathrm{X})$ intersects the critical range $K(z)$ for some convergence inhibitor $z \in C$. By Lemma 10, the firing state of each inhibitor $z \in C$ can be predicted with good probability as long as the number of firing outputs in previous sub-round is not in the critical range $K(z) = [k(z)/2, 2k(z)]$. In particular, if the range $R_t(\mathrm{X})$ falls below $k(z)/2$, then we predict that z does not fire in sub-round $(t, 3)$. On the other hand, if the range $R_t(\mathrm{X})$ falls above $2k(z)$, then we predict that z fires in sub-round $(t, 3)$. Regardless of the exact number of firing outputs in sub-round $(t, 2)$, since $R_t(\mathrm{X})$ does not intersect the critical ranges of the inhibitors of C, we can predict with good probability the firing states of C in sub-round $(t, 3)$ by Lemma 10. By Lemma 8, with probability at least $1 - 1/n$, all the stability inhibitors S fire in sub-round $(t, 3)$ and by Lemma 9, with good probability, no inhibitor in R fires. So overall we can predict all inhibitor behavior with good probability. With the above in place we are finally have that our inductive assumptions hold in round t. We summarize:

▶ **Lemma 28.** *For every* $t \geq 1$ *it holds that:*

(Q1) *For every* $\mathrm{X} \in \mathcal{X}_t$*, the predicted range of firing outputs* $R_t(\mathrm{X})$ *satisfies:*

$$\Pr[\widehat{R}_t(\mathrm{X}) \in R_t(\mathrm{X}) \;\mid\; \widehat{F}_{t-1}(\mathrm{X}) = F_{t-1}(\mathrm{X})] \geq 1 - 1/n \;. \tag{5}$$

(Q2) *The collection of predicted ranges* $R_t(\mathrm{X})$ *for* $\mathrm{X} \in \mathcal{X}_t$ *are all* a*-separated for some constant* a *and all have value at least* $\Omega(\log^7 n)$*.*

(Q3) *For every* $\mathrm{X} \in \mathcal{X}_t$*, the predicted firing pattern for the inhibitors satisfies*

$$\Pr[\widehat{F}_t(\mathrm{X}) = F_t(\mathrm{X}) \;\mid\; \widehat{R}_t(\mathrm{X}) \in R_t(\mathrm{X})] \geq 1 - 1/\log^3 n \;. \tag{6}$$

The final step before giving our expected time lower bound is to show that $\mathcal{X}_t$ is reasonably large, so we are able to keep predicting the behavior of N for a number of outputs round after round. This follows from a few simple observations:

▶ **Observation 29.** $|\mathcal{X}_t^{same}| \geq |\mathcal{X}_{t-1}|/\alpha$.

Recall that $\mathcal{X}_t^{same}$ consists of the largest subset of $\mathcal{X}_{t-1}$ with the *same* predicted inhibitor behavior F_{t-1}^* in round $t-1$. Naively, there are 2^α possible predictions for F_{t-1}^* which gives that $|\mathcal{X}_t^{same}| \geq |\mathcal{X}_{t-1}|/2^\alpha$. In order to obtain the much stronger bound above, we again use Lemma 10 which shows that, as long as $\widehat{R}_{t-1}(\mathrm{X})$ does not intersect the critical region of any $z \in C$, the inhibitors behave with good probability as linear threshold circuits and so there are only α possible predictions $F_{t-1}(\mathrm{X})$.

Proof. Since by Lemma 10 each inhibitor $z \in C$ behaves with probability $1 - \log^c n$ as a threshold network in sub-round $(t, 3)$ (so long that the number of firing outputs in sub-round $(t, 2)$ is not in the critical range $K(z)$), the total number of different inhibitor firing state configurations (different $F_{t-1}(\mathrm{X})$ vectors predicted in the previous step) is bounded by $|C|$. To see this, since conditioning on the prediction $R_t(\mathrm{X})$ being correct, there is at least one firing output in sub-round $(t-1, 2)$, the inhibitors of S will fire w.h.p. Further the inhibitors R never fire with good probability, so the only varying part in $F_{j-1}(\mathrm{X})$ is the prediction for C and as discussed there are only $|C| \leq \alpha$ such possible predictions. ◀

▶ **Observation 30.** $|\mathcal{X}_t^{large}| \geq |\mathcal{X}_t^{same}| - O(\log\log n)$.

This is immediate as $\mathcal{X}_t^{large}$ was derived by removing $\Theta(\log\log n)$ of the inputs with the smallest predicted range values from $\mathcal{X}_t^{same}$.

▶ **Observation 31.** $|\mathcal{X}_t| \geq |\mathcal{X}_t^{large}| - O(\alpha)$.

This follows as $\mathcal{X}_t$ is derived by removing all inputs from $\mathcal{X}_t^{large}$ where $R_t(\mathrm{X})$ overlaps the critical region of some $z \in C$. By (Q2) the $R_t(\mathrm{X})$ are all constant separated so there can be at most $|C| = O(\alpha)$ which overlap critical regions. We are now ready to show:

▶ **Lemma 32.** $\mathcal{ET}(\mathrm{N}) = \Omega(\log\log n/\log\alpha)$.

Proof. We can continue predicting the behavior of N up to round t until we have $|\mathcal{X}_t| = \Theta(\log\log n)$ (at which point $\mathcal{X}_t^{large}$ may be empty and so we will have to stop simulation). Further, as long as we can predict for t rounds, by Lemma 28 we will know with good probability that at least $\Omega(\log^7 n)$ outputs are still firing for all $\mathrm{X} \in \mathcal{X}_t$. So with good probability WTA is not reached for those inputs, giving a lower bound of $\Omega(t)$ rounds in expectation to solve WTA.

Set $t = c_1 \log\log n/\log\alpha$ for small enough constant c_1 and recall that we can assume $\alpha = O(\log^{c_2} n)$ for small constant c_2 since otherwise our runtime bound is $\Omega(1)$ and so holds vacuously. By Observations 29, 30, and 31 after t rounds we have:

$$\begin{aligned}|\mathcal{X}_t| &\geq \frac{|\mathcal{X}_0|}{\alpha^t} - t\cdot\alpha - t\cdot O(\log\log n)\\ &\geq \frac{\log n}{\log^{c_1} n} - \log\log n\cdot\log^{c_2} n - (\log\log n)^2 = \Omega(\log^{1-c_1} n)\end{aligned}$$

and hence can predict for at least t rounds. This completes the proof. ◀

Monotonicity property of basic WTA networks.

We show that the WTA dynamic is monotone so long as there is at least one firing output. Intuitively, we show that all basic WTA networks pick a single winner by monotonically decreasing the number of firing outputs until just a single output is firing. The number of firing outputs only ever increases if the network 'overshoots' the WTA state and has a round in which no outputs fire.

▶ **Lemma 33.** *For any basic WTA network* N*, as long as the number of firing outputs is more than one, their number is monotone non-increasing. In particular, if at least one output fires in round* t*, w.h.p. , an output that did not fire in that round, will not fire again in round* $t+1$*.*

Proof. Given input X with at least one firing input neuron, the network N must eventually converge so that in every round exactly 1 output fires w.h.p. Consider a round t in this *steady state period*. Since all outputs have the same parameters (e.g., edge weights and bias values) and since the weight of the self-loop is positive, if output y_i fires in round t, it is at least as likely to fire in round $t+1$ as output y_j for any $j \neq i$. Additionally, conditioned on the configuration of the inhibitors in time t, the probability that each output fires in round $t+1$ is independent. Hence, it must be that w.h.p., if y_i fired in round t, it continues to fire in round $t+1$ and each y_j, which did not fire in round t does not fire in round $t+1$ with high probability.

Further, consider any round t with at least one firing output. Since all connections from the output layer are excitatory, the probability that any inhibitor in Z fires at the end of round t is at least as large as it is in the steady state of the network, and hence any output that does not fire in round t does not fire in round $t+1$ w.h.p. ◀

B.6 Complete Proof for High Probability Lower Bound (Lemma 11)

Let $Q_Y \subseteq \{0,1\}^n, Q_Z \subseteq \{0,1\}^\alpha$ be the vectors describing the firing states of the outputs and inhibitors in a given round. Let $Q = Q_Y \circ Q_Z \subseteq \{0,1\}^{n+\alpha}$ be a vector describing the firing states of the inhibitors and outputs. Let $P_{1,j}(Q)$ be the probability to achieve the WTA state in round j given Q, that is the probability that exactly one output fires in sub-round $(j,2)$ given that the firing states of the outputs (resp., inhibitors) in sub-round $(j-1,2)$ (resp., $(j-1,3)$) is Q_Y (resp., Q_Z). Similarly, let $P_{0,j}(Q)$ be the probability that *no output* fires in sub-round $(j,2)$ given Q, that is the probability that a reset event happens. Finally, let $P_{01,j}(Q)$ be the probability that a reset event or a WTA event happens in round j given that configuration in round $j-1$ is Q, hence $P_{01,j}(Q) = P_{1,j}(Q) + P_{0,j}(Q)$. We begin by claiming the following.

▶ **Claim 34.** *For every round* j *and for every vector* $Q \in \{0,1\}^{n+\alpha}$ *in which there are at least two firing outputs (i.e.,* Q *is neither a WTA state nor a reset state), and such that* $P_{01,j}(Q) \geq \Theta(1/\log\log n)$*, it holds that* $P_{0,j}(Q) \geq \Theta(1/(\log\log n)^3)$*.*

Proof. Since $P_{01,j}(Q) = P_{0,j}(Q) + P_{1,j}(Q)$, if $P_{0,j}(Q) \geq P_{01,j}(Q)/2$, then we are done. Hence, we can assume from now on that $P_{1,j}(Q) = \Theta(1/\log\log n)$. We will show that $P_{0,j}(Q) \geq P_{1,j}(Q)/(\log\log n)^2$, which will establish our claim.

Let p be the firing probability of an active output[9] in sub-round $(j,2)$ given Q and let $k \geq 2$ be the number of outputs that fire in round $j-1$ as specified by Q. Since Q has at

[9] Recall that an output is active in round j if it fires in sub-round $(j-1,2)$.

least two firing outputs, w.h.p., only active outputs (those that fire in the previous round) can fire in the next round. The probability that the WTA state is achieved in round j is $P_{1,j}(Q) = k \cdot p \cdot (1-p)^{k-1}$ and the probability that a reset is achieved in round j is $P_{0,j}(Q) = (1-p)^k$.

We consider two cases depending whether the firing probability p is large or small. First, assume that $p \geq 0.1$ and set $r = c/\log\log n$. Since $P_{1,j}(Q) \geq r$, we have that $1 - p \geq r/k$. We also have:

$$k(9/10)^{k-1} \geq k \cdot p \cdot (1-p)^{k-1} \geq r,$$

and hence $k \leq \Theta(\log\log n)$. Overall, $P_{0,j}(Q)/P_{1,j}(Q) = (1-p)/(kp) \geq (1-p)/k \geq r/k^2 \geq c/(\log\log n)^2$. Next, consider the complementary case where $p < 0.1$. Letting $y = kp/2$,

$$y \cdot e^{-y} \geq (kp/2)(1-p)^{k/2} \geq (k/2)p(1-p)^{k-1} \geq r/2,$$

hence $y \leq 2\log 1/r = \Theta(\log\log\log n)$. Overall,

$$P_{0,j}(Q)/P_{1,j}(Q) = (1-p)/kp \geq \Theta(1/\log\log\log n).$$ ◀

The Execution Tree

A key tool used in this section is the notion *execution tree* that captures all possible transcripts that can evolve in a window of DH rounds when starting with the initial configuration C_0. The execution tree T is a tree of depth DH where each layer j corresponds to round j when running the network on the initial configuration C_0. Each node in T is labeled by an $(n+\alpha)$-length binary vector describing the firing configurations (or states) of the outputs and the inhibitors in a given round, and the edges are labelled by the transition probabilities. Hence, this tree describes all the possible firing states in a span of DH rounds when starting from the initial configuration C_0 (for which the time it takes to achieve WTA with constant probability is at least DC). The root r is labeled by the zero vector (since in round 0, no output fires and hence w.h.p also no inhibitor fires). For every $j \geq 2$, every node u in layer j is labeled by a vector $Q(u) = Q_Y(u) + Q_Z(u) \in \{0,1\}^{n+\alpha}$ describing the firing status of the outputs and the inhibitors in round j. Hence, each node has $2^{n+\alpha}$ children in the configuration tree. Every edge $e = (\pi(u), u)$ connecting u to its parent $\pi(u)$ in T is labeled by a probability $p(e)$ that the firing configuration in round j is $Q(u)$ given that the configuration in round $j-1$ is $Q(\pi(u))$.

Let $T_d(u)$ be the subtree of depth d rooted at u. When d is omitted $T(u)$ is simply the entire subtree of u in T.

For a leaf node $\ell \in T$, let $\mathcal{P}(\ell) = [r = u_0, u_1, \ldots, u_{DH}]$ be the path connecting ℓ to the root r in T. Let $p_{leaf}(u)$ be the probability that starting from r the firing configuration in each round $j \in \{0, \ldots, DH\}$ is $Q(u_j)$. Since there is an independence between the coin flips in every round j given the configuration in round $j-1$, we get that

$$\begin{aligned}
&p_{leaf}(u) = \\
&\prod_{j=0}^{DH} \Pr[Q_Y(u_j) \text{ in round } (j,2) \mid Q_Y(u_{j-1}), Q_Z(u_{j-1}) \text{ in rounds } (j-1,2),(j-1,3)] \\
&\cdot \Pr[Q_Z(u_j) \text{ in sub-round } (j,3) \mid Q_Y(u_j) \text{ in sub-round } (j,2)] \\
&= \prod_{j=1}^{DH} p(e_j) \quad \text{where} \quad e_j = (u_j, u_{j+1}).
\end{aligned}$$

For a node $u \in T$, let $Leaf(u)$ be the set of leaves in $T(u)$ and define

$$p_{node}(u) = \sum_{\ell \in Leaf(u)} p_{leaf}(u) \ ,$$

and for a subset of nodes U, let $p_{node}(U) = \sum_{u \in U} p_{node}(u)$. It is convenient to view $p_{node}(u)$ as the *weight* of tree $T(u)$. Hence, the weight of T is 1. In the same spirit, for a given subset of nodes U_i whose subtrees in T are vertex disjoint, we view $\sum_{u \in U_i} p_{node}(u)$ as the weight of the forest $\bigcup_{u \in U_i} T(u)$. We would like to show that:

$$\sum_{u \in Leaf(r)} \{p_{leaf}(u) \mid u \text{ is a WTA node } \} < 1 - 1/n^c \ , \tag{7}$$

In the next paragraphs, we will find a collection of non-WTA leaf nodes of large weight, i.e. of weight at least $1/n^2$ which will establish Eq. (7) for $c > 2$. To do that, we iteratively traverse the tree T from root to leaves, omitting undesired subtrees (and hence also leaf nodes) through the journey. This traversal is done in an asynchronous manner in the following sense: there are times that for a given node u in layer j, we move to a subset of its children in layer $j+1$, we call this move a *small jump* in the tree. In contrast, there are cases in which from a given node u in layer t, we jump DC layers in the subtree $T(u)$ and proceed the traversal from a subset of leaf nodes in the tree $T_{DC}(u)$ of depth DC, we call such a move a *large jump*. In the analysis part we will claim that by eliminating nodes in the tree T, we do not loose much weight, to deal with the fact that there are two types of jumps: small and large, we will employ an amortization claim that will enable us to bound the loss of weight layer by layer. See Fig. 3, for an illustration of the Execution Tree.

In each iteration $j \in \{1, \ldots, DH\}$, we maintain a collection of *non-WTA* nodes U_j whose subtrees in T are vertex disjoint. The final set U_{DH} will be a set of non-WTA leaf nodes for which we will show that their weight is at least $1/n^2$. Starting with $U_0 = \{r\}$, in every iteration $j \in \{1, \ldots, DH\}$, we have a set of nodes U_j that satisfy the following:

(A1) The subtrees $T(u)$, $u \in U_j$, are vertex-disjoint.
(A2) The distance of each node $u \in U_j$ from r is at least j.
(A3) No node in U_j is a WTA node.

In the high level, the nodes U_{j+1} are the leaf nodes of subtrees rooted at the nodes $u \in U_j$. Particularly, from each node $u \in U_j$, when constructing U_{j+1}, we omit part of the subtree $T(u) \subseteq T$ and replace u by a subset of nodes $V(u)$ in the subtree of u in T. The nodes $V(u)$ are subset of the leaf nodes of the subtree $T_{d(u)}(u)$ of depth $d(u)$ rooted at u. The value of the depth $d(u)$ is set to be either 1 or DC [10] depending on the configuration stored at node u. That is, either the nodes $V(u)$ are a subset of the children of u or that they are subset of the leaf nodes of the DC-depth tree rooted at u.

In the first case where $d(u) = 1$, we will show that we loose only $\Theta(1/\log\log n)$ of the weight of the tree $T(u)$, hence we keep $1 - \Theta(1/\log\log n)$ fraction of the weight. In the second case, we will show that we keep $\Theta(1/\log\log n)$ fraction of the weight of $T(u)$. The key observation here is to note that this cannot happen more than DH/DC times in a given branch, since the depth of the sub-tree of u is DC. In other words, on average, we maintain $\Theta(1/\log\log n)^{1/DC}$ of the weight per layer of the subtree $T_{DC}(u)$, and hence overall, after DH iterations, we maintain $1/n^2$ fraction of the total weight.

We first eliminate from the tree T all nodes u such that $Q_Y(u) = \vec{0}$ but $Q_Z(u) \neq \vec{0}$. Since the bias value of the inhibitors in $\Omega(\log n)$, we know that if no output fires in round j, then

[10] To be more precise it is either 1 or $\min\{DC, DH - dist(r, u, T)\}$.

w.h.p. no inhibitor fires in that round. Let T' be the resulting tree. We first observe that by that step, we eliminate only $1/n^c$ of the total weight of the tree T.

▶ **Observation 35.** *The total weight of r in T' is at least $1 - 1/n^c$.*

From now on, we consider the tree T' and describe the iterative construction of the set U_j in details. Let $U_0 = \{r\}$. For $j \geq 1$ given U_j, the set U_{j+1} is obtained by defining for each node $u \in U_j$, a subset of non-WTA nodes $V(u)$ as described next.

Case 1: u is a reset node. Set the depth of the subtree to be $d(u) = \min\{DH - dist(u, r, T), DC\}$ and let $V(u)$ be the non-WTA nodes in the leaf nodes of $T_{d(u)}(u)$.

Since u is not a WTA node, it remains to consider the case where the number of active outputs in $Q(u)$ is at least 2. Recall that $P_{01,j}(Q(u))$ be the probability of achieving WTA or reset in round $t+1$ given the configuration in round t is $Q(u)$. We distinguish between two cases depending on the value of $P_{01,j}(Q(u))$.

Case 2.1: $P_{01,j}(Q(u)) \geq \Theta(1/\log\log n)$. Let $V'(u)$ be the children of u in T that are reset-nodes. For each reset-node $w \in V'(u)$, let $V(w)$ be the non-WTA nodes in the leaf nodes of $T_{d(u)-1}(w)$ and let $V(u) = \bigcup V(w)$.

Case 2.2: $P_{01,j}(Q(u)) < \Theta(1/\log\log n)$. Let $V(u)$ be the children of u that have at least 2 active outputs in $Q(v)$ (hence $d(u) = 1$). This completes the definition of U_{j+1}.

To bound the weight of U_{DH}, we make use of the following claims that show that we do not loose too much weight in this traversal. Consider a node u and let $NW_{DC}(u)$ be the set of non-WTA leaves of the tree $T_{DC}(u)$.

▶ **Claim 36.** *If u is a reset node, then $p_{node}(NW_{DC}(u)) \geq c' \cdot p_{node}(u)$, for some constant c'.*

Proof. Let j be the layer of node u. Then by the selection of the initial configuration C_0, we know that the time it takes to achieve WTA with constant probability c when starting from C_0 is strictly larger than DC. Since a reset node is labelled with this same initial configuration, we get that $p_{node}(NW_{DC}(u)) \geq c' \cdot p_{node}(u)$ for $c' = 1 - c$. ◀

▶ **Claim 37.** *Let u be a node in layer j that satisfies Case (1) or Case (2.1), then $p_{node}(V(u)) \geq \Theta((1/\log\log n)^3) \cdot p_{node}(u)$.*

Proof. If u satisfies Case (1), the claim follows immediately by Cl. 36. We now consider the case where u satisfies Case (2.1). Recall that in this case the number of active outputs in $Q(u)$ is at least 2. Let A_0, A_1 be the set of children of u that are reset nodes, WTA nodes respectively. Let $A_{0,1} = A_0 \cup A_1$.

Then, since u satisfies Case (2.1), $p_{node}(A_{0,1}) \geq \Theta(1/\log\log n) \cdot p_{node}(u)$. In addition, since in $Q(u)$ there are at least two firing outputs, we can safely apply Cl. 34, to have that $p_{node}(A_0) \geq \Theta(1/(\log\log n)^2) \cdot p_{node}(A_1)$. Combining these two inequalities, we get that

$$p_{node}(A_0) \geq \Theta(1/(\log\log n)^3) \cdot p_{node}(u).$$

Next, by using Cl. 36, for every node $v \in A_0$ (which is a reset node), we have that $p_{node}(NW_{DC-1}(v)) \geq c' \cdot p_{node}(v)$. All together, we get that

$$\begin{aligned} p_{node}(NW_{DC}(u)) &\geq \sum_{v \in A_0} p_{node}(NW_{DC-1}(v)) \\ &\geq c' \cdot p_{node}(A_0) \geq \Theta(1/(\log\log n)^3) \cdot p_{node}(u) \ . \end{aligned}$$

Since $V(u) = A_0$, the claim follows. ◀

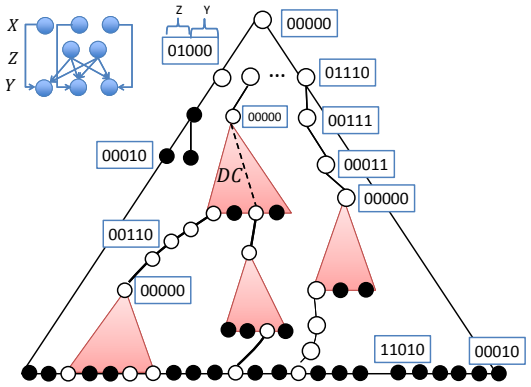

Figure 3 The Execution Tree. Shown is a schematic illustration of the Execution Tree for a small network with two inhibitors and three outputs. Every node u in layer j is labeled by a vector of length 5 describing an optional firing state for the inhibitors and outputs in round j. Each node has 2^5 children – covering all possible firing behaviors in round $j+1$. The weight nodes are non WTA nodes and the black nodes are the WTA nodes. When arriving a reset node u, a large jump is made by considering the leaf nodes of $T(u)$. When arriving a non-WR node, a small jump is made by considering subset of its children.

▶ **Claim 38.** *Let u be a node that satisfies Case (2.2), then* $\sum_{w\in V(u)} p_{node}(w) \geq 1 - \Theta(1/\log\log n)\cdot p_{node}(u)$.

Proof. By the definition of u, $P_{01,j}(Q(u)) < \Theta(1/\log\log n)$. Hence, letting $V(u)$ be the children of u that have at least 2 active outputs in $Q(v)$ (hence $d(u)=1$), we have that $\sum_{w\in V(u)} \geq 1 - \Theta(1/\log\log n)\cdot p_{node}(u)$. ◀

Starting from a tree of weight 1, we would like to show that at the end of the process after at most DH iterations, the total weight of the leaf nodes U_{DH} is at least $1/n^2$. We now use Cl. 37 and 38 to prove the lower bound. By Cl. 37, when we consider $u \in U_j$ that satisfies either case (1) or case (2.1), we keep $\Theta(1/(\log\log n)^3)$ fraction of the weight but enjoy a large jump of DC layers in the sub-tree $T(u)$. Hence, on average, we keep $\Theta(1/(\log\log n)^3)^{1/DC}$ fraction of the weight of $T(u)$ per layer. By Cl. 38, in type (2), we keep at least $1-\Theta(1/\log\log n)$ fraction of the weight of $T(u)$ when moving from a node u in layer i to a subset of its children $V(u)$ in layer $i+1$. Hence, on average in every iteration, we keep at least

$$\max\{(c/(\log\log n)^3)^{1/DC}, 1 - c/\log\log n\}$$

fraction of the weight of the current forest. Hence, after $DH = DC\cdot\Theta(\log n/\log\log\log n)$ iterations, our total weight of the leaf set U_{DH} is at least

$$(\max\{(c/(\log\log n)^3)^{1/DC}, 1 - c/\log\log n\})^{DH} \geq 1/n^2.$$

C Extension to Excitatory Auxiliary Neurons

In this section, we consider the more general case where the auxiliary neurons can be either excitatory or inhibitory. Let α denote their number. We assume that outputs with no active input are not allowed to fire. Hence, in a given sub-round $(t,2)$, we consider two types of outputs that might fire: *active* outputs – those that fire in the previous round and hence

have a positive feedback via the self-loop; and *inactive* outputs – those that did not fire in the previous round. Whereas in the inhibitory case, we could show that the dynamic is monotonic – hence incative outputs do not fire with high probability, here it is not the case. Specifically, it might be the case that the level of inhibition during the process to achieve the WTA state is *lower* than that in steady-state and hence inactive outputs (outputs that did not fire in the previous rounds) join the game in later rounds. In our lower bound proofs, we heavily used the monotonicity property as it allowed us focus only on the active outputs (those that fired in the previous rounds) and totally neglect the inactive ones. In this section, we revise the claims that are based on the monotonicity lemma and adapt the proof to the general case of excitatory and inhibitory neurons.

C.1 Extensions for the Lower Bound for Expected Time

We classify the auxiliary neurons as before into three classes S, C and R. Note that all the proofs that concern the predictability of the inhibitors, i.e., Lemmas 8,9,10 depend only on the potential functions of the inhibitors and not on their effect on the outputs. Since the excitatory auxiliary neurons have exactly the same potential functions, the proofs follow immediately.

The main adaptation is in the second part where we use the predictability of the auxiliary neurons to predict the network for at least one input configuration. We proceed by bounding the gap in potentials between active outputs and inactive outputs by showing that the weight of the self-loop is large.

▶ **Observation 39.** $\mathrm{w}^{\mathrm{self}} \geq 2c \cdot \log n$.

Proof. In the steady state situation, there exists one leader u that fires in each round w.h.p. $1 - 1/n^c$ for polynomially many rounds. On the other hand, all other outputs v that do not have the positive feedback from the self-loop fire with probability $1/n^c$. Hence for such a round t in steady state, we have: $pot_t(u) \geq c \log n$ and $pot_t(v) \leq -c \log n$. We get that $\mathrm{w}^{\mathrm{self}} = pot_t(u) - pot(v) \geq 2c \log n$. The observation follows. ◀

An immediate corollary of that is the following:

▶ **Corollary 40.** *Consider a sub-round $(t, 2)$ and let F_{t-1} be the firing configuration of the auxiliary neurons in sub-round $(t-1, 3)$. If the firing probability of an inactive output v (output that did not fire in the previous sub-round $(t-1, 2)$) in sub-round $(t, 2)$ is at least $1/n^c$, then the firing probability of an active output u in sub-round $(t, 2)$ is $\geq 1 - 1/n^c$.*

Proof. Since all outputs have the same connections to the auxiliary neurons, only difference in the potential of an inactive output and an active output is the weight of the self-loop. Hence, $pot_t(u) = pot_t(v) + \mathrm{w}^{\mathrm{self}} \geq -c \log n + 2c \log n \geq c \log n$, where the first inequality follows by plugging Obs. 39 and using the fact that the firing probability of v is $1/(1+e^{-pot_t(v)}) \geq 1/n^c$. Thus, u fires with probability $1/(1 + e^{-c \log n}) = 1 - 1/n^c$. ◀

We now consider the second part of the lower bound where we predict $\Omega(\log \log n / \log \alpha)$ rounds of the network for at least one density input class. Since in the zero round no-output fires and w.h.p. also no auxiliary neuron is firing (since their bias value is $\omega(\log n)$), predicting the number of firing outputs in round 1 is exactly the same as in the only-inhibitor case.

Predicting the number of firing outputs in round $t \geq 2$

We first define a subset of inputs $\mathcal{X}_t^{large} \subseteq \mathcal{X}_{t-1}$ for which we can predict the behavior of the outputs in the network N in round t. Let $\mathcal{X}_t^{same} \subseteq \mathcal{X}_{t-1}$ be the largest subset of inputs whose predicted firing vector $F_{t-1}(\mathrm{X})$ for the auxiliary neurons in round $t-1$ is the *same*, and denote this common firing vector by F_{t-1}^*. Let $\mathcal{X}_t^{large}$ be the set of inputs in $\mathcal{X}_t^{same}$ after omitting $\Theta(\log\log n)$ inputs with the smallest range value in round $t-1$. Eventually we will show that $\mathcal{X}_t^{large}$ is a reasonably large set of inputs compared to $\mathcal{X}_{t-1}$, and hence we can continue predicting behavior for at least some inputs for a large number of rounds. But first we show how to predict $R_t(\mathrm{X})$ for every input $\mathrm{X} \in \mathcal{X}_t^{large}$.

Let p' be the firing probability that an inactive output (one with $y_j^{t-1} = 0$) fires in sub-round $(t,2)$ given that the inhibitors fired in sub-round $(t-1,3)$ according to F_{t-1}^*. Since all inputs in $\mathcal{X}_t^{same}$ have the same predicted firing vector F_{t-1}^*, in each of them, an inactive output fires in sub-round $(t,2)$ with probability p'. Let p be the corresponding firing probability of an active output. We now consider two cases depending on the value of p'. If $p' < 1/n^c$, we predict that no inactive output fires in that round. Note that this prediction holds with probability $\geq 1 - 1/n^{c-1}$. In such a case we only predict the range for the active outputs in the exact same manner as before. Note that when we predicted the range of firing active outputs in the previous section, we did not use the fact that the auxiliary neurons are inhibitory, only that all competing outputs whose cardinality is to be estimated fire with the same probability in that round.

Next, we consider the more interesting case where $p' \geq 1/n^c$, that is the inactive outputs have a fair chance of firing in sub-round $(t,2)$. Here, we make use of Lemma 40 that says that with probability at least $1 - 1/n^{c-1}$, all active outputs (i.e., that fired in round $t-1$) fire in sub-round $(t,2)$ as well. Let $k = 2^i$ be the number of active inputs in the vector X. Let $E_{t-1} = E(\widehat{R}_{t-1}(\mathrm{X}) \mid F_{t-2}(X))$ be the expected number of firing outputs in sub-round $(t-1,2)$ given the predicted firing vector $F_{t-2}(X)$. Then, the expected number of firing outputs in sub-round $(t,2)$ is

$$E(\widehat{R}_t(\mathrm{X}) \mid F_{t-1}(X)) = E_{t-1} + p' \cdot (k - E_{t-1}) = (1-p') \cdot E_{t-1} + p' \cdot k.$$

▶ **Claim 41.** *Let* $\mathrm{X}_1, \mathrm{X}_2 \in \mathcal{X}_t$ *be such that* $||\,\mathrm{X}_1\,||_1 \geq 2||\,\mathrm{X}_2\,||_1$. *Then*

$$E(\widehat{R}_t(\mathrm{X}_1) \mid F_{t-1}(\mathrm{X}_1)) \geq 2E(\widehat{R}_t(\mathrm{X}_2) \mid F_{t-1}(\mathrm{X}_2)).$$

Proof. We will prove by induction on the number of rounds t. Let $k_j = ||\,\mathrm{X}_j\,||_1$ and $E_{j,t} = E(\widehat{R}_t(\mathrm{X}_j) \mid F_{t-1}(\mathrm{X}_j))$ for $j \in \{1,2\}$.

Since $\mathrm{X}_1, \mathrm{X}_2 \in \mathcal{X}_t$, it holds that $\mathrm{X}_1, \mathrm{X}_2 \in \mathcal{X}_\ell$ for every $\ell \in \{1,\ldots,t\}$ hence $F_\ell(\mathrm{X}_1) = F_\ell(\mathrm{X}_2)$ for every $\ell \in \{1,\ldots,t\}$. For the base of the induction of round $t = 1$, this clearly holds since $E_{0,t} = p_0 \cdot k_j$, $j \in \{1,2\}$, where p_0 is the firing probability of an output where in the previous round no one fired. Assume the claim holds up to round $t-1$. We have that $E_{j,t} = E_{j,t-1} + p' \cdot (k_j - E_{j,t-1}) = (1-p')E_{j,t-1} + p'k_j$, for $j \in \{1,2\}$. By the induction assumption for $t-1$, we get $E_{1,t-1} \geq 2 \cdot E_{2,t-1}$ and by definition $k_1 \geq 2 \cdot k_2$, overall $E_{1,t} \geq 2E_{2,t}$ as required. ◀

We get that the expected number of firing outputs (conditioned on the predictions) are 2-separated. Now, we can claim exactly as before that all these expected values should be $\Omega(1/\log^4 n)$ as otherwise there is at least one input configuration for which there is a reset (i.e., in the next round no output fires) for $\Omega(\log n)$ times (see Obs. 26).

Since all expected predictions for the number of firing outputs are $\Omega(1/\log^4 n)$, by removing the $\Theta(\log\log n)$ inputs from $\mathcal{X}^{same}$ (i.e., as given by set $\mathcal{X}^{large}$), we get that all

expected numbers of firing outputs are $\Omega(\log^7 n)$ and hence the random variables $\widehat{R}_t(\mathrm{X})$ are well concentrated around their expectation. The remaining proof goes exactly the same as in the inhibitory-case.

C.2 Extensions for the Lower Bound for High Probability Time

We define the *weak* WTA state to be state in which exactly one active output is firing (but possibly many inactive firing outputs). Whenever we use the notion of WTA nodes in the proof of Lemma 11, we now use the notion of weak WTA nodes instead. The definition of a reset node remains as is, i.e., a node u such that in its configuration $Q(u)$ no output (of any type) fires.

Note that the lower bound proof for the expected time implies that there is an input X_0 such that with a good probability after $t = \Omega(\log\log n/\log\alpha)$ rounds there are still $\Omega(\log n)$ competing outputs. After $t+1$ rounds, either we can assume w.h.p. that no inactive output fires or that all the $\Omega(\log n)$ active outputs fire. Hence, the lower bound implies that after $t+1$ rounds, with good probability, the number of firing active outputs is $\Omega(\log n)$, implying that the network is in a *weak* WTA state. Let $P_{1,j}(Q)$ be the probability that exactly one *active* output fires in sub-round $(j,2)$ given that the auxiliary neurons fire in round $j-1$ according to Q. Similarly, let $P_{0,j}(Q)$ be the probability that *no active output* fires in sub-round $(j,2)$ given Q. Finally, let $P_{01,j}(Q)$ be the probability that at most one active output fires in round $(j,2)$ given that configuration in round $j-1$ is Q, hence, $P_{01,j}(Q) = P_{1,j}(Q) + P_{0,j}(Q)$. Since we consider only the active outputs, Cl. 34 follows as is. We now claim the following.

▶ **Corollary 42.** *For every round j and for every vector $Q \in \{0,1\}^{n+\alpha}$ in which there are at least two active firing outputs and such that $P_{01,j}(Q) \geq \Theta(1/\log\log n)$, it holds that there is a (total) reset in round j (i.e., no output fires) with probability at least $\Theta(1/(\log\log n)^3)$.*

Proof. Since in Q there are at least two firing *active* outputs, by Cl. 34, $P_{0,j}(Q) \geq \Theta(1/(\log\log n)^3)$. Hence the probability that no active output fires is at least $\Theta(1/(\log\log n)^3)$. We now claim that the probability that also no inactive output fires is at least $1-1/n^{c-1}$. Hence, by the independence between the output decisions (given the firing states of the inhibitors), we get that the probability that no output fires is at least $\Theta(1/(\log\log n)^3)$ as required.

Assume towards contradiction that inactive output fires with probability $\geq 1/n^c$. By Cor. 40, we get that an active output fires with probability at least $1-1/n^c$. Since in the previous round there are at least two firing *active* outputs, we get that with probability $\geq 1-1/n^c$ there are at least two firing outputs in sub-round $(j,2)$, contradiction to the assumption that $P_{01,j}(Q) \geq \Theta(1/\log\log n)$.

Thus we get that each inactive output fires with probability $< 1/n^c$, and with probability $\geq 1-1/n^c$ no inactive output fires. The claim follows. ◀

Equipped with Cor. 42 and the lower bound for expected time, we can now use the execution tree to show that the weight of non weak-WTA nodes is at least $1/n^2$. The same idea generally holds up to few adaptations. Recall that in our execution tree traversal, at step j we obtain a collection of non weak WTA nodes. That is nodes u with configuration $Q(u)$ which either there are at least two active outputs that are firing. For $j \geq 1$ given U_j, the set U_{j+1} is obtained by defining for each node $u \in U_j$, a subset of non weak WTA nodes $V(u)$ as described next.

Case 1: u is a reset node. Set the subtree depth $d(u) = \min\{DH - dist(u, r, T), DC\}$ and let $V(u)$ be the non weak WTA nodes in the leaf nodes of $T_{d(u)}(u)$. By the lower bound proof, the set $V(u)$ captures $1 - 1/\log n$ of the probability mass in $T(u)$.

Since u is a non weak WTA node, it remains to consider the case where the number of active firing outputs in $Q(u)$ is at least 2. Recall that $P_{0,1}(Q(u))$ is the probability that in sub-round $(j, 2)$ at most one active output fires given that the configuration in round $j-1$ is $Q(u)$.

Case 2.1: $P_{0,1}(Q(u)) \geq \Theta(1/\log\log n)$. Let $V'(u)$ be the children of u in T that are reset-nodes. For each reset-node $w \in V'(u)$, let $V(w)$ be the non-WTA nodes in the leaf nodes of $T_{d(u)-1}(w)$ and let $V(u) = \bigcup V(w)$.
By Cl. 42, since the number of firing active outputs in $Q(u)$ is at least 2 and since $P_{0,1}(Q(u)) \geq \Theta(1/\log\log n)$, the probability for a (total) reset in the next round is at least $\Theta(1/(\log\log n)^3)$ and hence $V'(u)$ captures $\Theta(1/(\log\log n)^3)$ of the probability mass in $T(u)$. This will allow us to follow the same argument as before when following the case 2.1.

Case 2.2: $P_{0,1}(Q(u)) < \Theta(1/\log\log n)$. Let $V(u)$ be the children of u that have at least 2 *active* outputs in $Q(v)$ (hence $d(u) = 1$). Since $P_{0,1}(u) \leq \Theta(1/\log\log n)$, we capture $1 - \Theta(1/\log\log n)$ of the weight of the tree $T(u)$. This completes the definition of U_{j+1}. The argument that uses this case follows now the exact same line. In sum, either we capture only $\Theta(1/\log\log n)$ of the probability mass in such a case we have a large jump in the tree or that we capture $1 - \Theta(1/\log\log n)$ of the probability mass. As before using the amortization argument, overall the number of non weak WTA nodes can be bounded by $\geq 1/n^2$. The completes the extension to excitatory auxiliary neurons.

Mutation, Sexual Reproduction and Survival in Dynamic Environments

Abstract

A new approach to understanding evolution [34], namely viewing it through the lens of computation, has already started yielding new insights, e.g., natural selection under sexual reproduction can be interpreted as the *Multiplicative Weight Update* (MWU) Algorithm in coordination games played among genes [8]. Using this machinery, we study the role of mutation in changing environments in the presence of sexual reproduction. Following [35], we model changing environments via a Markov chain, with the states representing environments, each with its own fitness matrix. In this setting, we show that in the absence of mutation, the population goes extinct, but in the presence of mutation, the population survives with positive probability.

On the way to proving the above theorem, we need to establish some facts about dynamics in games. We provide the first, to our knowledge, polynomial convergence bound for noisy MWU in a coordination game. Finally, we also show that in static environments, sexual evolution with mutation converges, for any level of mutation.

1 Introduction

Evolution has been the subject of intensive scientific investigation since the early 19th century, yet many of its critical elements still remain under debate. A new, potent approach to studying evolution was initiated by Valiant [34], namely viewing it through the lens of computation. This viewpoint has already started yielding concrete insights by translating qualitative hypotheses in biological systems to provable computational properties of Markov chains and other dynamical systems [18, 8, 22, 24, 30, 31], which are standard hallmarks of TCS research. We build on this direction whilst focusing on the challenge of evolving environments.

Recent work due to Chastain, Livnat, Papadimitriou and Vazirani [8] linked natural selection under sexual reproduction (*sexual evolution*) to a tangential field, namely dynamics in games. Building on the work of Nagylaki [26], they showed that this process can be interpreted as the *Multiplicative Weight Update* (MWU) Algorithm [3], which we call discrete replicator dynamics, in coordination games played among genes. This connection opens up doors for applying tools from game theory and dynamical systems to understanding these fundamental processes. Another important question is the role of mutation, especially in the presence of changes to the environment. In the case of asexual reproduction, this was studied by Wolf, Vazirani, and Arkin [35]. They modeled a changing environment via a Markov chain and described a model in which in the absence of mutation, the population goes extinct, but in the presence of mutation, the population survives with positive probability.

In this paper we study the next natural question, namely the role of mutation in the presence of sexual reproduction. The Chastain et al. result shows that MWU (sex) tries to maximize fitness as well as entropy via the process of recombination in genes. The question arises whether this is enough to safeguard against extinction in a changing environment, or is mutation still needed.

As in Chastain et al. [8], we will consider a haploid organism with two genes. Each gene can be viewed as a player in a game and the alleles of each gene represent strategies of that player. Once an allele is decided for each gene, an individual is defined, and its fitness is the payoff to each of the players, i.e., both players have the same payoff matrix, and therefore it is a coordination/partnership game. Each state of the Markov chain represents an environment and has its own fitness matrix. We show the following under this model, where mutations are captured through a standard model appeared in [13]:

Informal Theorem 1. For a class of Markov chains (satisfying somewhat necessary conditions, see Section B), a haploid species under *sexual evolution*[1] without mutation dies out with probability one. In contrast, under sexual evolution with mutation the probability of long term survival is strictly positive.

For each gene, if we think of its allele frequencies in a given population as defining a mixed strategy, then after reproduction, the frequencies change as per MWU [8]. Furthermore, in the presence of mutation [13], every allele mutates to another allele of the corresponding gene in a small fraction of offsprings. As it turns out, in every generation the population size (of the species) changes by a multiplicative factor of the current expected payoff (mean fitness). Hence, in order to prove Theorem 1, we need to analyze MWU (and its variant which captures mutations) in a time-evolving coordination game whose matrix is changing as per a Markov chain.

The idea behind the first part of the theorem is as follows: It is known that MWU converges, in the limit, to a pure equilibrium in coordination games [22]. This implies that in a static environment, in the limit the population will be rendered monomorphic. Showing such a convergence in a stochastically changing environment is not straightforward. We first show that such an equilibrium can be reached fast enough in a static environment. We then appeal to the Borel-Cantelli theorem to argue that with probability one, the Markov chain will visit infinitely often and remain sufficiently long in one environment at some point and hence the population will eventually become monomorphic. An assumption in our theorem is that for each individual, there are bad environments, i.e., one in which it will go extinct.

[1] We refer to 'evolution by natural selection under sexual reproduction' by *sexual evolution* for brevity.

Eventually the monomorphic population will reach such an unfavorable environment and will die out.

Polynomial time convergence in static environment: For such a reasoning to be applicable we need a fast convergence result, which does not hold in the worst case, since by choosing initial conditions sufficiently close to the stable manifold of an unstable equilibrium, we are bound to spend super-polynomial time near such unstable states. To circumvent this we take a typical approach of introducing a small noise into the dynamics [32, 12, 14], and provide the first, to our knowledge, polynomial convergence bound for noisy MWU in coordination games; this result is of independent interest. We note that pure MWU captures frequency changes of alleles in case of infinite population, and the small noise can also be thought of as sampling error due to finiteness of the population. In the following theorem, dependence on all identified system parameters is necessary (see discussion in Section B).

Informal Theorem 2. In static environments under small random noise ($||.||_\infty = \delta$), sexual evolution (without mutation) converges with probability $1-\epsilon$ to a monomorphic fixed point in time $O\left(\frac{n \log \frac{n}{\epsilon}}{\gamma^4 \delta^6}\right)$, where n is the number of alleles, and γ the minimum fitness difference between two genotypes.

Although mutations seem to hurt mean population fitness in the short run in static environments, they are critical for survival in dynamic environments, as shown in the second part of Theorem 1; it is proved as follows. The random exploration done by mutations and aided by the selection process, which rapidly boosts the frequency of alleles with good mean fitness, helps the population survive. Essentially we couple the random variable capturing population size with a biased random walk, with a slight bias towards increase. The result then follows using a well-known lemma on biased random walks.

Robustness to mutations: Finally we show that the convergence of MWU (without mutation) in static environments [21, 19, 22] can be extended to the case where mutations are also present. The former result critically hinges on the fact that mean fitness strictly increases under MWU in coordination games, and thereby acts as a potential function. This is no more the case. However, using an inequality due to Baum and Eagon [4] we manage to obtain a new potential function which is the product of mean fitness and a term capturing diversity of the allele distribution. The latter term is essentially the product of allele frequencies.

Informal Theorem 3. In static environments, sexual evolution with mutation converges, for any level of mutation. Specifically, if we are not at equilibrium, at the next time generation at least one of mean population fitness or product of allele frequencies will increase.

Besides adding computational insights to biologically inspired themes, which to some extent may never be fully settled, we believe that our work is of interest even from a purely computational perspective. The nonlinear dynamical systems arising from these models are gradient-like systems of non-convex optimization problems. Their importance and the need to develop a theoretical understanding beyond worst case analysis has been pinpointed as a key challenge for numerous computational disciplines, e.g., from [2]:

> *"Many procedures in statistics, machine learning and nature at large – Bayesian inference, deep learning, protein folding – successfully solve non-convex problems ... Can we develop a theory to resolve this mismatch between reality and the predictions of worst-case analysis?"*

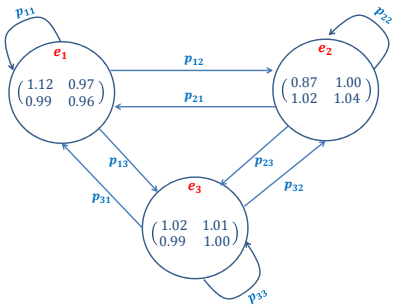

Figure 1 An example of a Markov Chain model of fitness landscape evolution.

Our theorems and techniques share this flavor. Theorem 1 expresses time-average efficiency guarantees for gradient-like heuristics in the case of time-evolving optimization problems, Theorem 2 argues about speedup effects by adding noise to escape out of saddle points, whereas Theorem 3 is a step towards arguing about robustness to implementation details. We make this methodological similarities more precise by pointing them out in more detail in the related work section (see discussion in Section 2).

Organization of the paper. The rest of the paper is organized as follows. In the next section we discuss the relevant literature. In Section 3 we provide formal description of the model we analyze. In Section 4, we provide an overview of the proofs of our main theorems. The proofs of main Theorems 1, 2, 3 and their formal statements appear in Section 6, 5 and 7 respectively. The omitted proofs can be found in the Appendix, along with explanation of the biological terms.

2 Related Work

In the last few years we have witnessed a rapid cascade of theoretical results on the intersection of computer science and evolution. Livnat et al. [17] introduced the notion of mixability, the ability of an allele to combine itself successfully with others. In [8] connections were established between sexual evolution and dynamics in coordination games. Meir and Parkes [24] has provided a more detailed examination of these connections. These dynamics are close variants of the standard (discrete) replicator dynamics [13]. Replicator dynamics is closely connected to the multiplicative weights update algorithm [14, 28]. In [22] Mehta et al. established that these systems converge for almost all initial conditions to monomorphic states. It is also possible to introduce connections between satisfiability and evolution [18] as well as understand the complexity of predicting the survival of diversity in complex species [23]. In [30] Panageas et al. shed light on the speed of asexual evolution (see also [31]). Wolf, Vazirani, and Arkin [35] analyzed models of mutation and survival of diversity also for asexual populations but the dynamical systems in this case are linear and the involved methodologies are rather different.

Introducing noise in non-linear dynamics have been shown to be able to simplify the analysis of nonlinear dynamical systems by "destroying" Turing-completeness of classes of dynamical systems and thus making the system's long-term behavior computationally

predictable [6]. Those techniques focus on establishing invariant measures for the systems of interest and computing their statistical characteristics. In our case, our unperturbed dynamical systems have exponentially many saddle points and numerous stable fixed points and species survival is critically dependent on the the amount of time that trajectories spend in the vicinity of these points thus much stronger topological characterizations are necessary. Adding noise to game theoretic dynamics [14, 1, 9] to speed up convergence to approximate equilibria in potential games is a commonly used approach in algorithmic game theory, however, the respective proof techniques and notions of approximation are typically sensitive to the underlying dynamic, the nature of noise added as well as the details of the class of games.

In the last year there has been a stream of work on understanding how gradient (and more generally gradient-like) systems escape out of the saddle fixed points fast [12, 15]. This is critically important for a number of computer science applications, including speeding up the training of deep learning networks. The approach pursued by these papers is similar to our own, including past papers in the line of TCS and biology/game theory literature [14, 28, 22]. For example, in [28, 22] it has been established that in non-convex optimization settings gradient-like systems (e.g., variants of Multiplicative Weights Updates Algorithm) converge for all but a zero measure of initial conditions to local minima of the fitness landscape (instead of saddle points even in the presence of exponentially many saddle points). Moreover, as shown in [14] noisy dynamics diverge fast from the set of saddle points whose Jacobian has eigenvalues with large positive real parts. Similar techniques and arguments can be applied to argue generic convergence to local minima of numerous other dynamics (including noisy/deterministic versions of gradient dynamics). Finally, using techniques developed in [28], one can argue that gradient dynamics converge to local minima with probability one in non-convex optimization problems even in the presence of continuums of saddle points [29], answering an open question in [15]. We similarly hope that techniques developed here about fast and robust convergence can also be extended to other classes of gradient(-like) dynamics in non-convex optimization settings.

Finite population evolutionary models over time evolving fitness landscapes are typically studied via simulations (e.g., [16] and references therein). These models have also inspired evolutionary models of computation, e.g., genetic algorithms, whose study under dynamic fitness environments is a well established area with many applications (e.g., [36] and references therein) but with little theoretical understanding and even theoretical papers on the subject typically rely on combinations of analytical and experimental results [5].

3 Preliminaries

Notation. All vectors are in bold-face letters, and are considered as column vectors. To denote a row vector we use $\mathbf{x}^\top$. The i-th coordinate of $\mathbf{x}$ is denoted by x_i. Let $\Delta_n = \{\mathbf{x} \in \mathbb{R}^n \mid \mathbf{x} \geq 0,\ \sum_{i=1}^n x_i = 1\}$ be the set of probability distributions on n coordinates. For given matrix A define $A_{\max}, A_{\min}$ the largest, smallest entry in matrix A respectively and $(A\mathbf{x})_i := \sum_j A_{ij}x_j$. Define $\mathrm{Supp}(\mathbf{x}) = \{i \mid x_i \neq 0\}$.

3.1 Dynamics: Discrete Replicator Dynamics with/without Mutation

For a haploid species[2] (one with single set of chromosomes, unlike diploids such as humans who have chromosome pairs) with two genes (coordinates), let S_1 and S_2 be the set of possible alleles (types) for the first and second gene respectively. Then, an individual of such a species can be represented by an ordered pair $(i, j) \in S_1 \times S_2$. Let W_{ij} be the fitness of such an individual capturing its ability to reproduce during a mating. Thus, fitness landscape of such a species can be represented by matrix W of dimension $n \times n$, where we assume that $n = |S_1| = |S_2|$.

Sexual Model without mutation. In every generation, each individual (i, j) mates with another individual (i', j') picked uniformly at random from the population (can pick itself). The offspring can have any of the four possible combinations, namely (i, j), (i, j'), (i', j), (i', j'), with equal probability. Let x_i be a random variable that denotes the proportion of the population with allele i in the first coordinate, and similarly y_j be the frequency of the population with allele j in the second coordinate. After one generation, the expected number of offsprings with allele i in first coordinate is proportional to $x_i \cdot x_i \cdot (W\mathbf{y})_i + 2\frac{1}{2}(1 - x_i)x_i \cdot (W\mathbf{y})_i = x_i(W\mathbf{y})_i$ (x_i^2 stands for the probability both individuals have allele i in the first coordinate - which the offspring will inherit - and $2\frac{1}{2}(1 - x_i)x_i$ stands for the probability that exactly one of the individuals has allele i in the first coordinate and the offspring will inherit). Similarly the expected number of offsprings with allele j for the second coordinate is $y_j(W^\top \mathbf{x})_j$. Hence, if $\mathbf{x}', \mathbf{y}'$ denote the frequencies of the alleles in the population in the next generation (random variables)

$$E[x_i'|\mathbf{x}, \mathbf{y}] = \frac{x_i(W\mathbf{y})_i}{\mathbf{x}^\top W\mathbf{y}} \text{ and } E[y_j'|\mathbf{x}, \mathbf{y}] = \frac{y_j(W^\top \mathbf{x})_j}{\mathbf{x}^\top W\mathbf{y}}.$$

We are interested in analyzing a *deterministic* version of the equations above, which essentially captures an infinite population model. Thus if frequencies at time t are denoted by $(\mathbf{x}(t), \mathbf{y}(t))$, they obey the following dynamics governed by the function $g : \Delta \to \Delta$, where $\Delta = \Delta_n \times \Delta_n$:

$$\text{Let } (\mathbf{x}(t+1), \mathbf{y}(t+1)) = g(\mathbf{x}(t), \mathbf{y}(t)), \text{ where } \begin{array}{l} \forall i \in S_1,\ x_i(t+1) = x_i(t)\frac{(W\mathbf{y}(t))_i}{\mathbf{x}^\top(t)W\mathbf{y}(t)} \\ \forall j \in S_2,\ y_j(t+1) = y_j(t)\frac{(W^\top\mathbf{x}(t))_j}{\mathbf{x}^\top(t)W\mathbf{y}(t)}. \end{array} \quad (1)$$

It is easy to see that g is well-defined when W is a positive matrix. Chastain et al. [8] gave a game theoretic interpretation of the deterministic equations (1). It can be seen as a repeated two player coordination game (each gene is a player), the possible alleles for a gene are its pure strategies and both players play according to dynamics (1). A modification of these dynamics has also appeared in models of grammar acquisition [27], and can be seen as the discrete analogue of continuous replicator dynamics [19]. Furthermore, Mehta et al. [22] showed that dynamics with equations (1) converges point-wise to a pure fixed point, i.e., where exactly one coordinate is non-zero in both $\mathbf{x}$ and $\mathbf{y}$, for all but measure zero of initial conditions in Δ, when W has distinct entries.

Sexual Model with mutation. Next we extend the dynamics of (1) to incorporate mutation. The mutation model which appears in Hofbauer's book [13], is a two step process. The first step is governed by (1), and after that in each individual, and for each of its gene,

[2] See Section A in the appendix for a short discussion of all relevant biological terms.

corresponding allele, say k, mutates to another allele of the same gene, say k', with probability $\tau > 0$ for all $k' \neq k$. After a simple calculation (see C.8 for calculations) the resulting dynamics turns out to be as follows, where f is a $\Delta \to \Delta$ function:

$$\text{Let } (\mathbf{x}(t+1), \mathbf{y}(t+1)) = f(\mathbf{x}(t), \mathbf{y}(t)), \text{ then } \begin{array}{l} x_i(t+1) = (1-n\tau)x_i(t)\frac{(W\mathbf{y}(t))_i}{\mathbf{x}(t)^\top W\mathbf{y}(t)} + \tau, \\ y_j(t+1) = (1-n\tau)y_j(t)\frac{(\mathbf{x}(t)^\top W)_j}{\mathbf{x}(t)^\top W\mathbf{y}(t)} + \tau. \end{array} \tag{2}$$

3.2 Our model

In this paper we will analyze a noisy version of (1), (2). Essentially we add small random noise to non-zero coordinates of $(\mathbf{x}(t), \mathbf{y}(t))$ [3].

▶ **Definition 1.** Given $\mathbf{z} \in \Delta$ and a small $0 < \delta$ (δ is $o_n(\tau)$), define $\Delta(\mathbf{z}, \delta)$ to be a set of vectors $\{\mathbf{z} + \delta \in \Delta \mid \text{Supp}(\delta) = \text{Supp}(\mathbf{z});\ \delta_i \in \{-\delta, +\delta\},\ \forall i\}$.[4]

Note that if $\mathbf{z}$ is pure (has support size one), then δ is all zero vector[5]. Define noisy versions of both g from (1) and f from (2) as follows: Given $(\mathbf{x}(t), \mathbf{y}(t))$ pick $\delta_\mathbf{x} \in \Delta(\mathbf{x}(t), \delta)$ and $\delta_\mathbf{y} \in \Delta(\mathbf{y}(t), \delta)$ uniformly at random. Set with probability half $\delta_\mathbf{x}$ to zero, and with the other half set $\delta_\mathbf{y}$ to zero. Then redefine dynamics g of (1) as follows:

$$(\mathbf{x}(t+1), \mathbf{y}(t+1)) = g_\delta(\mathbf{x}(t), \mathbf{y}(t)) = g(\mathbf{x}(t), \mathbf{y}(t)) + (\delta_\mathbf{x}, \delta_\mathbf{y}). \tag{3}$$

And redefine dynamics f of (12) capturing sexual evolution with mutation as follows.

$$(\mathbf{x}(t+1), \mathbf{y}(t+1)) = f_\delta(\mathbf{x}(t), \mathbf{y}(t)) = f(\mathbf{x}(t), \mathbf{y}(t)) + (\delta_\mathbf{x}, \delta_\mathbf{y}). \tag{4}$$

Furthermore, we will have that if any x_i, y_j goes below δ, we set it to zero. This is crucial for our theorems because otherwise the dynamics with equations (1) and (2) (or even (3) and (4)) can converge to a fixed point at $t \to \infty$, but never reach a point in a finite amount of time. This is true in the result of [22], the dynamics converge almost surely to pure fixed points as $t \to \infty$ but do not reach fixation in a finite time. So x_i, y_j reaches fixation (set it to zero) if $x_i, y_j < \delta$. We need to re-normalize after this step.

$$\begin{array}{l} \forall i \in S_1, \text{ if } x_i(t) < \delta \text{ then set } x_i(t) = 0. \text{ Re-normalize } \mathbf{x}(t). \\ \forall j \in S_1, \text{ if } y_j(t) < \delta \text{ then set } y_j(t) = 0. \text{ Re-normalize } \mathbf{y}(t). \end{array} \tag{5}$$

▶ **Definition 2.** We call a vector $\mathbf{v}$ *negligible* if there exists an i s.t $v_i < \delta$.

Tracking population size. Suppose the size of the initial population is N^0, and let population at time t be N^t. In every time period N^t gets multiplied by average fitness of the current population, namely $\mathbf{x}(t)^T W(t)\mathbf{y}(t)$, where $(\mathbf{x}(t), \mathbf{y}(t))$ denote the frequencies of alleles at generation t and $W(t)$ the matrix fitness/environment at time (see discussion below about changing of environments).

$$\text{Let average fitness } \Phi^t = \mathbf{x}(t)^\top W(t)\mathbf{y}(t) \quad \text{then } \mathbb{E}[N^{t+1} | \mathbf{x}(t), \mathbf{y}(t), N^t] = N^t\Phi^{t+1} \tag{6}$$

We will consider $N^{t+1} = N^t\Phi^{t+1}$ (this is not necessarily an integer at every step; it captures the average population size, see also [33]). Based on the value of N^t, we give the definition of survival and extinction.

[3] This is different from diffusion approximation, noise helps to avoid saddle points essentially.
[4] In case the size of the support of $\mathbf{z}$ is odd, there will be a zero entry in δ, so $|\text{Supp}(\delta)| = |\text{Supp}(\mathbf{z})| - 1$
[5] There are no sampling errors in monomorphic population

▶ **Definition 3.** We say the population *goes extinct* if for initial population size N^0, there exists a time t so that $N^t < 1$. On the other hand, we say that population *survives* if for all times $t \in \mathbb{N}$ we have that $N^t \geq 1$. Another definition one can have is that the population goes extinct if $\liminf_{t\to\infty} N^t = 0$, and survives if $\liminf_{t\to\infty} N^t > 0$. For the rest of the paper we use the former definition, but our results and arguments work for the latter definition as well.

3.2.1 Model of environment change

Following the work of Wolf et al. [35], we consider a Markov chain based model of changing environment. Let $\mathcal{E}$ be the set of different possible environments, and W^e be the fitness matrix in environment $e \in \mathcal{E}$. E denotes the set of (e, e') pairs if there is a non-zero probability $p_{e,e'} \in (0, 1)$ to go from environment e to e'. See Figure 1 for an example. For a parameter $p < 1$ we assume that $\sum_{e':(e,e')\in E} p_{e,e'} \leq p,\ \forall e \in \mathcal{E}$. That is, after every generation of the dynamics (3) or (4), the environment changes to one of its neighboring environment with probability at most $p < 1$, and remains unchanged with probability at least $(1 - p)$. The graph formed by edges in $\mathcal{E}$ is assumed to be connected, thus the resulting Markov chain eventually will stabilize to a stationary distribution π_e (is ergodic).

Even though fitness matrices W^e can be arbitrary, it is generally assumed that W^e has distinct positive entries [7, 22]. Furthermore, no individual can survive all the environments on average. Mathematically, if π_e is the stationary distribution of this Markov chain then, $\forall i, j, \quad \prod_{e\in\mathcal{E}} (W^e_{ij})^{\pi_e} < 1$. Furthermore, we assume that every environment has alleles of good type as well as bad type. An allele i of good type has uniform fitness (i.e., $\frac{\sum_j W_{ij}}{n}$) of at least $(1 + \beta)$ for some $\beta > 0$, and alleles of bad type are dominated by a good type allele point-wise.[6] Finally, the number of bad alleles are $o(n)$ (sublinear in n). Let the set of bad alleles for genes $i = 1, 2$ in environment e be denoted by B^e_i.

Putting all of the above together, the Markov chain for environment change is defined by set $\mathcal{E}$ of environments and its adjacency graph, fitness matrices W^e, $\forall e \in \mathcal{E}$, probability $1 - p$ with which dynamics remains in current environment, sets $B^e_i \subset S_i,\ i = 1, 2$ of bad alleles in environment e, and $\beta > 0$ to lower-bound average fitness of good type alleles. See also Section B.2 for discussion on the assumptions where we claim that most of them are necessary for our theorems. In the next sections we will analyze the dynamics with equations (3, 4) in terms of convergence and population size for fixed and dynamic environments.

4 Overview of proofs

The dynamical systems that we analyze, namely (3) and (4), under the evolving environment model of Section 3.2.1 are (stochastically perturbed) nonlinear replicator-like dynamical systems whose parameters evolve according to a (possibly slow mixing) Markov chain. We reduce the analysis of this complex setting to a series of smaller, modular arguments that combine as set-pieces to produce our main theorems.

Convergence rate for evolution without mutation in static environment. Our starting point is [22] where it was shown that in the case of noise-free sexual dynamics governed by (1) the average population fitness increases in each step and the system converges to equilibria, and moreover that for almost all initial conditions the resulting fixed point corresponds to a

[6] Think of bad type alleles akin to a terminal genetic illness. Such assumptions are typical in the biological literature (e.g., [16]).

Table 1 List of parameters.

Symbol	Interpretation
W^e	fitness matrix at environment e
$W(t), W^{e(t)}$	fitness matrix at time t
γ^e	minimum difference between entries in fitness matrix W^e
$\mathbf{x}, \mathbf{y}$	frequencies of (alleles) strategies
δ	noise/perturbation
Φ	potential/average fitness $\mathbf{x}^\top W \mathbf{y}$
β	If allele i is of good type in environment e then it satisfies $\frac{\sum_j W^e_{ij}}{n} \geq 1+\beta$
τ	probability that an individual with allele k mutates to k' (of the same gene)

monomorphic population (pure/not mixed equilibrium). Conceptually, the first step in our analysis tries to capitalize on this stronger characterization by showing that convergence to such states happens fast. This is critical because while there are only linearly many pure equilibria, there are (generically) exponentially many isolated, mixed ones [7], which are impossible to meaningfully characterize. By establishing the predictive power of pure states, we radically reduce our uncertainty about system behavior and produce a building block for future arguments.

Without noise we cannot hope to prove fast convergence to pure states since by choosing initial conditions sufficiently close to the stable manifold of an unstable equilibrium, we are bound to spend super-polynomial time near such unstable states. In finite population models, however, the system state (proportions of different alleles) is always subject to small stochastic shocks (akin to sampling errors). These small shocks suffice to argue fast convergence by combining an inductive argument and a potential/Lyapunov function argument.

To bound the convergence time to a pure fixed point starting at an arbitrary mixed strategy (maybe with full support), it suffices to bound the time it takes to reduce the size of the support by one, because once a strategy x_i becomes zero it remains zero under (3), i.e., an extinct allele can never come back in absence of mutations (and then use induction). For the inductive step, we need two non trivial arguments. First we need a lower bound on the rate of increase of the mean population fitness when the dynamics is not at approximate fixed points[7], shown in Lemma 4. This requires a quantitative strengthening of potential/(nonlinear dynamical system) arguments in [22]. Secondly, we show that the noise suffices to escape fast (with high probability) from the influence of fixed points that are not monomorphic (these are like saddle points). We used a combination of stochastic techniques including origin returning random walks, Azuma type inequalities for submartingales, and arguing about the increase in expected mean fitness $\mathbf{x}(t)^\top W(t)\mathbf{y}(t)$ in a few steps (Lemmas 7-11), where $\mathbf{x}$ and $\mathbf{y}$ capture allele frequencies at time step t. As a result we show polynomial-time convergence of (3) to pure equilibrium under static environment in Theorem 12. This result may be of independent interest since fast convergence of nonlinear dynamics to equilibrium is not typical [25].

Survival, extinction under dynamic environments. As described in Section 3.2.1, we consider a Markov chain based model of environmental changes, where after every selection step, the fitness matrix changes with probability at most p. Suppose the starting population

[7] We call these states α-close points.

size is $N^0 > 0$ and let N^t denote the size at time t then in every step N^t gets multiplied by the mean fitness $\mathbf{x}(t)^\top W(t)\mathbf{y}(t)$ of the current population (see (6)). We say that population goes extinct if for some t, $N^t < 1$, and it survives if $N^t \geq 1$, for all t.

We assume that there do not exist "all-weather" phenotypes. We encode this by having the monomorphic population of any genotype decrease when matched to an environment chosen according to the stationary distribution of the Markov chain.[8] In other words, an allele may be both "good" and "bad" as environment changes, sometimes leading to growth, and other times to decrease in population.

Case a) sexual evolution without mutation. If the population becomes monomorphic then this single phenotype can not survive in all environments, and will eventually wither as its population will be in exponential decline once the Markov chain mixes. The question is whether monomorphism is achieved under changing environment; the above analysis is not applicable directly as the fitness matrix is not fixed any more. Our first theorem (Theorem 12) upper bounds the amount of time T needed to "wait" in a single environment so as the probability of convergence to a monomorphic state is at least some constant (e.g., $\frac{1}{2}$). Breaking up the time history in consecutive chunks of size T and applying Borel-Cantelli theorem implies that the population will become monomorphic with probability one (Theorem 14). This is the strongest possible result without explicit knowledge of the specifics of the Markov chain (e.g., mixing time).

Case b) sexual evolution with mutation. As described in Section 3.1, we consider a well-established model of mutation [13], where after every selection step, each allele mutates to another with probability τ. The resulting dynamics is governed by (2), and we analyze its noisy counterpart (4). This ensures that in each period the proportion of every allele is at least τ. We show that this helps the population survive.

Unlike the *no mutation* case [22], the average fitness $\mathbf{x}(t)^\top W\mathbf{y}(t)$ is no more increasing in every step, even in absence of noise. Instead we derive another potential function that is a combination of average fitness and entropy. Due to mutations forcing exploration, natural selection weeds out the bad alleles fast (Lemma 15). Thus there may be initial decrease in fitness, however the decrease is upper bounded. Furthermore, we show that the fitness is bound to increase significantly within a short time horizon due to increase in population of good alleles (Lemma 16). Since population size gets multiplied by average fitness in each iteration, this defines a biased random walk on logarithm of the population size. Using upper and lower bounds on decrease and increase respectively, we show that the probability of extinction stochastically dominates a simpler to analyze random variable pertaining to biased random walks on the real line (Lemma 17). Thus, the probability of long term survival is strictly positive (Theorem 18). This completes the proof of informal Theorem 1.

Deterministic convergence despite mutation in static environments. Finally, as an independent result for the case of noise free dynamics (infinite population) with mutation governed by (2), we show convergence to fixed points in the limit, by defining a novel potential function which is the product of mean fitness $\mathbf{x}^\top W\mathbf{y}$ and a term capturing diversity of the allele distribution (Theorem 20). The latter term is essentially the product of allele

[8] If, for any genotype, the population increased in expectation over the randomly chosen environment, then once monomorphic population consisting of only such a genotype is reached, the population would blow up exponentially (and forever) as soon as the Markov chain reached its mixing time.

frequencies ($\prod_i x_i \prod_i y_i$). Such convergence results are not typical in dynamical systems literature [25], and therefore this potential function may be useful to understand limit points of this and similar dynamics (the continuous time analogue can be found here [13]). One way to interpret this result is a homotopy method for computing equilibria in coordination games, where the algorithm always converges to fixed points, and as mutation goes to zero the stable fixed points correspond to the pure Nash equilibria [7].

5 Rate of Convergence: Dynamics without Mutation in Fixed Environments

In this section we show a polynomial bound on the convergence time of dynamics (3), governing sexual evolution under natural selection with noise, in a static environment. In addition, we show that the fixed points reached by the dynamics are pure.

Consider a fixed environment e and we use W to denote its fitness matrix W^e. It is known that average fitness $\mathbf{x}^\top W\mathbf{y}$ increases under the non-noisy counterpart (1) [22]. In the next lemma we obtain a lower bound on this increase.

▶ **Lemma 4.** *Let $(\hat{\mathbf{x}},\hat{\mathbf{y}}) = g(\mathbf{x},\mathbf{y})$ where $(\mathbf{x},\mathbf{y}) \in \Delta$ and g is from equation (1). Then,*

$$\hat{\mathbf{x}}^\top W\hat{\mathbf{y}} - \mathbf{x}^\top W\mathbf{y} \geq C\left(\sum_i x_i\left((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y}\right)^2 + \sum_i y_i\left((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y}\right)^2\right)$$

for $C = \frac{3}{8\cdot\max_{i,j} W_{ij}}$.

For the rest of the section, C denotes $\frac{3}{8\cdot W_{\max}}$ where $W_{\max} = \max_{ij} W_{ij}$ and $W_{\min} = \min_{ij} W_{ij}$. Note that the lower bound obtained in Lemma 4 is strictly positive unless $(\mathbf{x},\mathbf{y})$ is a fixed point of (1). This gives an alternate proof of the fact that, under dynamics (1), average fitness is a potential function, i.e., increases in every step. On the other hand, the lower bound can be arbitrarily small at some points, and therefore it does not suffice to bound the convergence time. Next, we define points where this lower-bound is relatively small.

▶ **Definition 5.** We call a point $(\mathbf{x},\mathbf{y})$ α-close for an $\alpha > 0$, if for all $\mathbf{x}',\mathbf{y}' \in \Delta$ such that $\mathrm{Supp}(\mathbf{x}') \subseteq \mathrm{Supp}(\mathbf{x})$ and $\mathrm{Supp}(\mathbf{y}') \subseteq \mathrm{Supp}(\mathbf{y})$ we have $|\mathbf{x}^\top W\mathbf{y} - \mathbf{x}'^\top W\mathbf{y}| \leq \alpha$ and $|\mathbf{x}^\top W\mathbf{y} - \mathbf{x}^\top W\mathbf{y}'| \leq \alpha$.

α-close points, are a specific class of *"approximate" stationary points*, where the progress in average fitness is not significant (see Figure 3, the big circles contain these points). From now on, think α as a small parameter that will be determined in the end of this section. If a given point $(\mathbf{x},\mathbf{y})$ is not α-close and not *negligible* (see Definition 2) then using Lemma 4 it follows that the increase in potential is at least $C\delta\alpha^2$. Formally:

▶ **Corollary 6.** *If $(\mathbf{x},\mathbf{y}) \in \Delta$ is neither α-close nor negligible, and $(\hat{\mathbf{x}},\hat{\mathbf{y}}) = g(\mathbf{x},\mathbf{y})$, then*

$$\hat{\mathbf{x}}^\top W\hat{\mathbf{y}} \geq \mathbf{x}^\top W\mathbf{y} + C\delta\alpha^2.$$

Proof. Since the vector $(\mathbf{x},\mathbf{y})$ is neither α-close nor negligible, it follows that there exists an index i such that $|(W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y}| > \alpha$ and $x_i \geq \delta$ and hence $x_i((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y})^2 > \delta\alpha^2$, or $|(W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y}| > \alpha$ and $y_i \geq \delta$ and hence $y_i((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y})^2 > \delta\alpha^2$. Therefore in Lemma 4, the r.h.s is at least $C\delta\alpha^2$ and thus we get that $\hat{\mathbf{x}}^\top W\hat{\mathbf{y}} - \mathbf{x}^\top W\mathbf{y} \geq C\delta\alpha^2$. ◀

In the analysis above we considered non-noisy dynamics governed by (1). Our goal is to analyze finite population dynamics, which introduces noise and the resulting dynamics is (3). This changes how the fitness increases/decreases. The next lemma shows that in expectation the average fitness remains unchanged after the introduction of noise.

▶ **Lemma 7.** *Let $\delta = (\delta_{\mathbf{x}}, \delta_{\mathbf{y}})$ be the noise vector. It holds that $\mathbb{E}_\delta[(\mathbf{x}+\delta_{\mathbf{x}})^\top W(\mathbf{y}+\delta_{\mathbf{y}})] = \mathbf{x}^\top W\mathbf{y}$.*

Next, we show how random noise can help the dynamic escape from a polytope of α-close points. We first analyze how adding noise may help increase fitness with high enough probability. A simple application of Catalan numbers shows that:

▶ **Lemma 8.** *The probability of a (unbiased) random walk on the integers that consist of $2m$ steps of unit length, beginning at the origin and ending at the origin, that never becomes negative is $\frac{1}{m+1}$.*

We define $\gamma = \min_{(i,j)\neq(i',j')} |W_{ij} - W_{i'j'}|$. The following lemma is essentially a corollary of Lemma 8.

▶ **Lemma 9.** *Let $\delta_{\mathbf{y}}$ be a random noise with support size m. For all i in the support of $\mathbf{x}$ we have that $(W\delta_{\mathbf{y}})_i \geq \frac{\gamma\delta m}{2}$ with probability at least $\frac{1}{1+m/2}$ (same is true for $\delta_{\mathbf{x}}$ and $\mathbf{y}$).*

We will also need the following theorem due to Azuma [10] on submartingales.

▶ **Theorem 10** (Azuma [10])**.** *. Suppose $\{X_k, k = 0, 1, 2, ..., N\}$ is a submartingale and also $|X_k - X_{k-1}| < c$ almost surely then for all positive integers N and all $t > 0$ we have that*

$$\mathbb{P}[X_N - X_0 \leq -t] \leq e^{-\frac{t^2}{2Nc^2}}$$

Towards our main goal of showing polynomial time convergence of the noisy dynamics (3) (shown in Theorem 12), we need to show that the fitness increases within a few iterations of the dynamic with high probability. It suffices to show that the average fitness under some transformation is a submartingale, and then the result will follow using Azuma's inequality.

▶ **Lemma 11.** *Let Φ^t be the random variable which corresponds to the average fitness at time t. Assume that for the time interval $t = 0, ..., 2T$ the trajectory $(\mathbf{x}(t), \mathbf{y}(t))$ has the same support. Let $m = \max\{|Supp(\mathbf{x}(t))|, |Supp(\mathbf{y}(t))|\}$, and the non-zero entries of $(\mathbf{x}(t), \mathbf{y}(t))$ be at least δ. If $\frac{1}{(m+2)}(\frac{\gamma\delta m}{2} - 2\alpha)^2 \geq \delta\alpha^2$ then we have that*

$$E[\Phi^{2t+2}|\Phi^{2t}, ..., \Phi^0] \geq \Phi^{2t} + C\delta\alpha^2.$$

In other words, the sequence $Z^t \equiv \Phi^{2t} - t \cdot C\delta\alpha^2$ for $t = 1, ..., T$ is a submartingale and also $|Z^{t+1} - Z^t| \leq W_{\max} - W_{\min}$.

Using all the above analysis and Azuma's inequality (Theorem 10), we establish our first main result on convergence time of the noisy dynamics governed by (3) for sexual evolution under natural selection and without mutation.

▶ **Theorem 12** (Main 2)**.** *For all initial conditions $(\mathbf{x}(0), \mathbf{y}(0)) \in \Delta$, the dynamics governed by (3) in an environment represented by fitness matrix W reaches a pure fixed point with probability $1 - \epsilon$ after $O\left(\frac{(W_{\max})^4 n \ln(\frac{2n}{\epsilon})}{\delta^6\gamma^4}\right)$ iterations.*

Proof. It suffices to show that support size of the $\mathbf{x}$ or $\mathbf{y}$ reduces by one in a bounded number of iterations with at least $1 - \frac{\epsilon}{2n}$ probability.

Using Lemma 11 we have that the random variable $\Phi^{2t} - t \cdot C\delta\alpha^2$ is a submartingale and since $W_{\min} \leq \Phi^t \leq W_{\max}$ we use Azuma's inequality 10 and we get that

$$\mathbb{P}[\Phi^{2t} - t \cdot C\delta\alpha^2 \leq \Phi^0 - \lambda] \leq e^{-\frac{\lambda^2}{2tW_{max}^2}},$$

hence for $\lambda = \sqrt{2tW_{max}^2 \ln(\frac{2n}{\epsilon})}$ we get that the average fitness after $2t$ steps will be at least $\Phi^0 - \sqrt{2tW_{max}^2 \ln(\frac{2n}{\epsilon})} + t \cdot C\delta\alpha^2$ with probability at least $1 - \frac{\epsilon}{2n}$. By setting $t \geq \frac{8W_{\max}^2}{C^2\delta^2\alpha^4} \ln\left(\frac{2n}{\epsilon}\right)$ we have that the average fitness at time $2t$ will be greater than $W_{\max}$ with probability $1 - \frac{\epsilon}{2n}$, but since the potential is at most $W_{\max}$ for all vectors in the simplex, it follows that at some point the frequency vector become *negligible*, i.e., a coordinate of $\mathbf{x}$ or $\mathbf{y}$ became less than δ. Hence, the probability that the support size decreased during the process is at least $1 - \frac{\epsilon}{2n}$.

By union bound (the initial support size is at most $2n$) we conclude that dynamics (3) reaches a pure fixed point with probability $1 - \epsilon$ after t iterations with $t = 2n\frac{8W_{\max}^2}{C^2\delta^2\alpha^4} \ln\left(\frac{2n}{\epsilon}\right)$. Finally, for assumption $\frac{1}{(m+2)}(\frac{\gamma\delta m}{2} - 2\alpha)^2 \geq \delta\alpha^2$ used in Lemma 11 to hold for $2 \leq m \leq n$, we set α to be such that $\alpha \leq \frac{\gamma\delta}{4}$ where we have $\frac{4(m-1)^2}{(m+2)} \geq 1 > \delta$. Using such an α it follows that dynamics (3) reaches a pure fixed point with probability $1 - \epsilon$ after $\frac{2^{18}}{9} \times \frac{nW_{\max}^4}{\delta^6\gamma^4} \ln\left(\frac{2n}{\epsilon}\right)$ iterations. ◀

6 Changing Environment: Survival or Extinction?

In this section we analyze how evolutionary pressures under changing environment may lead to survival/extinction depending on the underlying mutation level. Motivated from Wolf et al. work [35], we use Markov chain based model to capture the changing environment, where every state captures a particular environment (see Section 3.2.1 for details).

6.1 Extinction without mutation

We show that the population goes extinct with probability one, if the evolution is governed by (3), i.e., natural selection *without* mutations under sexual reproduction. The proof of this result critically relies on polynomial-time convergence to monomorphic population shown in Theorem 12 in case of fixed environment.

As discussed in Section 3.2.1, we have assume that the Markov chain is such that no individual can be fit to survive in all environments. Formally,

$$\forall i, j, \quad \prod_{e \in \mathcal{E}} (W_{ij}^e)^{\pi_e} < 1. \tag{7}$$

Thus, if we can show convergence to monomorphic population under evolving environments as well then the extinction is guaranteed using (7) and the fact that population size N^t gets multiplied by current average fitness (see (6)). However, showing convergence in stochastically changing environment is tricky because environment can change in any step with some probability and then the argument described in the previous section breaks down. To circumvent this we will make use of Borel-Cantelli theorem where we say that *an event happens* if environment remains unchanged for a large but fixed number of steps.

▶ **Theorem 13** (Second Borel-Cantelli [11]). *Let $E_1, E_2, \ldots$ be a sequence of events. If the events E_n are independent and the sum of the probabilities of the E_n diverges to infinity, then the probability that infinitely many of them occur is 1.*

Using the above theorem with appropriate *event* definition, we prove the first part of the main result stated in Theorem 1.

▶ **Theorem 14** (Main 1a). *Regardless of the initial distributions $(\mathbf{x}(0), \mathbf{y}(0)) \in \Delta$, the population goes extinct with probability one under dynamics governed by (3), capturing sexual evolution without mutation under natural selection.*

Proof. Let T^e be the number of iterations the dynamics (3) need to reach a pure fixed point with probability $\frac{1}{2}$. Theorem 12 implies $T^e = O\left(\frac{nW_{\max}^{e\,4}}{\delta^6\gamma^{e\,4}}\ln 4n\right)$. Let $T = \max_e T^e$. We consider the time intervals $1, ..., T,\ T+1, ..., 2T, ...$ which are multiples of T. The probability that Markov chain will remain at a specific environment e in the time interval $kT+1, ..., (k+1)T$ is $\rho_k = (1-p)^T$. We define the sequence of events $E_1, E_2, ...$, where E_i corresponds to the fact that the chain remains in the same environment from time $(i-1)T+1, ..., iT$. It is clear that E_i's are independent and also $\sum_{i=1}^{\infty}\mathbb{P}[E_i] = \sum_{i=1}^{\infty}\rho_i = \infty$. From Borel-Cantelli Theorem 13 it follows that E_i's happen infinitely often with probability 1. When E_i happens there is a time interval of length T that the chain remains in the same environment and therefore with probability $\frac{1}{2}$ the dynamics will reach a pure fixed point. After E_i happen for k times, the probability to reach a pure fixed point is at least $1-\frac{1}{2^k}$. Hence with probability one (letting $k\to\infty$), the dynamics (3) will eventually reach a pure fixed point.

To finish the proof, let T_{pure} be a random variable that captures the time when a pure fixed point, say (i,j), is reached. The population will have size at most $N^0V^{T_{pure}}$ where $V = \max_e W_{\max}^e$. Under the assumption on the entries (see inequality (7)) it follows that at any time T' sufficiently large we get that the population at time $T'+T_{pure}$ will be roughly at most

$$N^0V^{T_{pure}}\prod_e (W_{ij}^e)^{T'\pi_e} = N^0V^{T_{pure}}\left(\prod_e (W_{ij}^e)^{\pi_e}\right)^{T'}.$$

By choosing $T' \geq \frac{\ln(N^0V^{T_{pure}})}{-\ln\left((W_{ij}^e)^{\pi_e}\right)}$ (and also satisfying the constraint that is much greater than the mixing time) it follows that $N^{T'+T_{pure}} < 1$ and hence the population dies. So, the population goes extinct with probability one in the dynamics without mutation. ◀

6.2 Survival with mutation

In this section we consider evolutionary dynamics governed by (4) capturing sexual evolution *with* mutation under natural selection. Contrary to the case where there are no mutations we show that population survives with positive probability. Furthermore, this result turns out to be robust in the sense that it holds even when every environment has some (few) very bad type alleles. Also, the result is independent of the starting distribution of the population.

The main intuition behind proving this result is that, as for the mutation model in [13], every allele is carried by at least τ fraction of the population in every generation. Therefore even if a"good" allele becomes "bad" as the environment changes, as far as the new environment has a few fit alleles, there will be some individuals carrying those who will then procreate fast, spreading their alleles further and leading to overall survival. However, unlike in the no mutation case [22], average fitness is no more a potential function even for non-noisy dynamics, i.e., it may decrease, and therefore showing such an improvement is tricky.

First we show that if some small amount of time is spent in an environment then the frequencies of the bad alleles become small and their effect is negligible, independent of the population distribution at the time when this environment was entered. Recall the assumption on good/bad type alleles (Section 3.2.1). Formally, let B_i^e be the set of bad type alleles for $i = 1, 2$ in environment e,

$$\begin{aligned} &\forall i \in S_1 \setminus B_1^e,\ \frac{\sum_j W_{ij}^e}{n} \geq 1+\beta, \quad \text{and} \quad \forall i \in S_1 \setminus B_1^e, \forall k \in B_1^e, W_{ij}^e \geq W_{kj}^e,\ \forall j \\ &\forall j \in S_2 \setminus B_2^e,\ \frac{\sum_i W_{ij}^e}{n} \geq 1+\beta, \quad \text{and} \quad \forall j \in S_2 \setminus B_2^e, \forall k \in B_2^e, W_{ij}^e \geq W_{ik}^e,\ \forall i \end{aligned} \tag{8}$$

▶ **Lemma 15.** *Suppose that the environment e is static for time at least $t \geq \frac{\ln(2n)}{n\tau}$. For any $(\mathbf{x}(0), \mathbf{y}(0)) \in \Delta$, we have that $\sum_{i \in B_1^e} x_i(t) + \sum_{j \in B_2^e} y_i(t) \leq \frac{2(|B_1^e|+|B_2^e|)}{n} = \frac{2|B^e|}{n}$ with $B^e = B_1^e \cup B_2^e$.*

Using the fact that number of individuals with bad type alleles decreases very fast, established in Lemma 15, we can prove that within an environment while there may be decrease in average fitness initially, this decrease is lower bounded. Moreover, it will later increase fast enough so that the initial decrease is compensated.

▶ **Lemma 16.** *Suppose that the environment e is static for time t and also $\tau \leq \frac{\beta}{16n}$, $|B^e| \ll n\beta$ then there exists a threshold time T_{thr} such that for any given initial distributions of the alleles $(\mathbf{x}(0), \mathbf{y}(0)) \in \Delta$, if $t < T_{thr}$ then the population size will experience a loss factor of at most $\frac{1}{d}$, otherwise it will experience a gain factor of at least d for some $d > 1$, where $T_{thr} = \frac{6\ln(2n)}{n\tau\beta W_{\min}}$ and $W_{\min} = \min_e W_{\min}^e$.*

To show the second part of Theorem 1 (main result), we will couple the random variable corresponding to the number of individuals at every iteration with a biased random walk on the real line. This can be done since in Lemma 16 we established that the decrease and increase in average fitness is upper and lower bounded, respectively. We will apply the following well-known lemma about the biased random walks.

▶ **Lemma 17** (Biased random walk)**.** *Assume we perform a random walk on the real line, starting from point $k \in \mathbb{N}$ and going right (+1) with probability $q > \frac{1}{2}$ and left (-1) with probability $1 - q$. The probability that we will eventually reach 0 is $\left(\frac{1-q}{q}\right)^k$.*

Using Lemma 16 together with the biased random walk Lemma 17, we show our next main result on survival of population under mutation in the following theorem.

▶ **Theorem 18** (Main 1b)**.** *If $p < \frac{1}{2T_{thr}}$ where $T_{thr} = \frac{6\ln(2n)}{n\tau\beta W_{\min}}$ then the probability of survival is at least $1 - \left(\frac{pT_{thr}}{1-pT_{thr}}\right)^{c \ln N^0}$ for some c independent of N^0, $c = \left(\frac{n\tau W_{\min}}{\ln(2n)}\right)$.*

Proof. The probability that the chain remains at a specific environment for least T_{thr} iterations is $(1-p)^{T_{thr}} > 1 - pT_{thr}$ (from the moment it enters the environment until it departs) and hence the probability that the chain stays at an environment for time less that T_{thr} is at most pT_{thr}. Let $N^t = N^0 \prod_{j=1}^t \mathbf{x}(j)^\top W^{e(j)} \mathbf{y}(j)$ (see (6) where here $e(j)$ corresponds to the environment at time j) the number of individuals at time t and Z^i be the position of the biased random walk at time i as defined in Lemma 17 with $q = 1 - pT_{thr}$ and assume that $Z^0 = \lfloor \log_d N^0 \rfloor$ (d is from lemma 16). Let $t_1, t_2, \ldots$ be the sequence of times where there is a change of environment (with $t_0 = 0$) and consider the trivial coupling where when the chain changes environment then a move is made on the real line. If the chain remained in the environment for time less than T_{thr} then the walk goes left, otherwise it goes right. It is clear by Lemma 16 that random variable $\log_d N^{t_i}$ dominates Z^i. Hence, the probability that the population survives is at least the probability that Z^i never reaches zero ($Z^i > 0$ for all $i \in \mathbb{N}$). By Lemma 17 this is at most $(\frac{pT_{thr}}{1-pT_{thr}})^{\lfloor \log_d N^0 \rfloor}$ and thus the probability of survival is at least $1 - \left(\frac{pT_{thr}}{1-pT_{thr}}\right)^{c \ln N^0}$ where $c = \left(\frac{n\tau W_{\min}}{\ln(2n)}\right)$ depends on n, τ and fitness matrices W^e (the minimum $W_{\min} = \min_e W_{\min}^e$, and also from Lemma 16 we have that $\ln d \approx \frac{\ln 2n}{W_{\min} n\tau}$). ◀

7 Convergence of Discrete Replicator Dynamics with Mutation in Fixed Environments

In this section we extend the convergence result of Mehta et al. [22] for dynamics (1) in static environment to dynamics governed by (12) where mutations are also present. The former result critically hinges on the fact that mean fitness strictly increases unless the system is at a fixed-point, and thereby acts as a potential function. Despite the fact that this is no longer the case when mutations are introduced, we manage to show that the system still converges and follows an intuitively clear behavior. Namely, in every step of the dynamic, either the average fitness $\mathbf{x}^\top W\mathbf{y}$ or the product of the proportions of all different alleles $\prod_i x_i \prod_i y_i$ (or both) will increase. This latter quantity is, in some sense, a measure of how mixed/diverse the population is. To argue this we apply the following inequality due to Baum and Eagon:

▶ **Theorem 19** (Baum and Eagon Inequality [4]). *Let $P(\mathbf{x}) = P(\{x_{ij}\})$ be a polynomial with nonnegative coefficients homogeneous of degree d in its variables $\{x_{ij}\}$. Let $\mathbf{x} = \{x_{ij}\}$ be any point of the domain $D : x_{ij} \geq 0, \sum_{j=1}^{q_i} x_{ij} = 1, i = l, \ldots, p, j = l, \ldots, q_i$. For $\mathbf{x} = \{x_{ij}\} \in D$, let $\Xi(\mathbf{x}) = \Xi\{x_{ij}\}$ denote the point of D whose i, j coordinate is*

$$\Xi(\mathbf{x})_{ij} = \left(x_{ij} \frac{\partial P}{\partial x_{ij}}\bigg|_{(\mathbf{x})} \right) \cdot \left(\sum_{j=1}^{q_i} x_{ij} \frac{\partial P}{\partial x_{ij}}\bigg|_{(\mathbf{x})} \right)^{-1}.$$

Then $P(\Xi(\mathbf{x})) > P(\mathbf{x})$ unless $\Xi(\mathbf{x}) = \mathbf{x}$.

We will establish a potential function P that for the dynamics governed by (12), capturing sexual evolution with mutation. This will imply convergence for the dynamics. Note that feasible values of τ are in $[0, \frac{1}{n}]$, since τ represents fraction of allele i mutating to allele i' of the same gene implying $n * \tau \leq 1$.

▶ **Theorem 20** (Main 3). *Given a static environment W, dynamics governed by (12) with mutation parameter $\tau \leq \frac{1}{n}$ has a potential function $P(\mathbf{x}, \mathbf{y}) = (\mathbf{x}^\top W\mathbf{y})^{1-n\tau} \prod_i x_i^\tau \prod_i y_i^\tau$ that strictly increases unless an equilibrium (fixed-point) is reached. Thus, the system converges to equilibria, in the limit. Equilibria are exactly the set of points $(\mathbf{p}^*, \mathbf{q}^*)$ that satisfy for all $i, i' \in S_1$, $j, j' \in S_2$:*

$$\frac{(W\mathbf{q}^*)_i}{1 - \frac{\tau}{p_i^*}} = \frac{(W\mathbf{q}^*)_{i'}}{1 - \frac{\tau}{p_{i'}^*}} = \frac{\mathbf{p}^{*T} W\mathbf{q}^*}{1 - n\tau} = \frac{(W^\top\mathbf{p}^*)_j}{1 - \frac{\tau}{q_j^*}} = \frac{(W^\top\mathbf{p}^*)_{j'}}{1 - \frac{\tau}{q_{j'}^*}}.$$

As a consequence of the above theorem we get the following:

▶ **Corollary 21.** *Along every nontrivial trajectory of dynamics governed by (12) at least one of average population fitness $\mathbf{x}^\top W\mathbf{y}$ or product of allele frequencies $\prod_i x_i \prod_i y_i$ strictly increases at each step.*

8 Conclusion and Open problems

In this paper we study various aspects of discrete replicator-like/MWUA dynamics and show three results: Two for dynamics with fixed parameters, and one where the parameters evolve over time as per a Markov chain. Theorem 12 establishes that a noisy version of discrete replicator dynamics converges *polynomially fast* to pure fixed points in coordination games. Due to the connections established by Chastain et al. [8], this implies that evolution

under sexual reproduction in haploids converges fast to a monomorphic population if the environment is static (fitness/payoff matrix is fixed). Introducing mutations to this model, as in [13], augments the replicator dynamics, and our second result shows convergence for this augmented replicator in coordination games. The proof is via a novel potential function, which is a combination of mean payoff and entropy, which may be of independent interest.

Finally, for the replicator dynamics with noise, capturing finite populations, we show that assuming some conditions (see Section B for discussion on the assumptions), the population size will eventually become zero with probability one (extinction) under (standard) replicator, while under augmented replicator (with mutations) it will never whither out (survival) with a non-trivial probability.

A host of novel questions arise from this model and there is much space for future work.

- For the fast convergence result (first result above), we assumed that the random noise δ lies in a subset of hypercube of length δ, i.e., every entry δ_i is ± 1 times magnitude δ and $\sum_i \delta_i = 0$. Can the result be generalized for a different class of random noise, where the noise also depends on the distribution of the alleles at every step and or population size?
- The second result talks about convergence to fixed points, which happens at the limit (time $t \to \infty$). Therefore, an interesting question would be to settle the speed of convergence. Additionally, for the *no mutations* case the result of [22] shows that all the stable fixed points are pure. It would be interesting to perform stability analysis for the *replicator with mutations* as well.
- Mutation can be modeled in an alternative way, where an individual can mutate to a completely new allele that is not part of some in advance fixed set of alleles. It will be interesting to define and analyze dynamics where the number of different alleles in nature is not known a priori. Finally, what happens if environment changes are not completely independent but are instead affected by population size?

A Terms Used From Biology

We provide brief non-technical definitions of a few biological terms useful for this paper.

Gene. A unit that determines some characteristic of the organism, and passes traits to offsprings. All organisms have genes corresponding to various biological traits, some of which are instantly visible, such as eye color or number of limbs, and some of which are not, such as blood type.

Allele. Allele is one of a number of alternative forms of the same gene, found at the same place on a chromosome, Different alleles can result in different observable traits, such as different pigmentation.

Genotype. The genetic constitution of an individual organism.

Phenotype. The set of observable characteristics of an individual resulting from the interaction of its genotype with the environment.

Diploid. Diploid means having two copies of each chromosome. Almost all of the cells in the human body are diploid.

Haploid. A cell or nucleus having a single set of unpaired chromosomes. Our sex cells (sperm and eggs) are haploid cells that are produced by meiosis. When sex cells unite during fertilization, the haploid cells become a diploid cell.

B Discussion on the Assumptions and Examples

In this section, we will discuss why our assumptions are necessary and their significance.

B.1 On the parameters $\gamma, \delta, \beta, \tau$

The effective range of δ is $o\left(\frac{1}{n}\right)$, where $||\delta||_\infty = \delta$, whereas for γ is $O\left(\frac{1}{n^2}\right)$. For example, if we consider the entries of fitness matrices W^e to be uniform from interval $(1-\sigma, 1+\sigma)$ for some positive $\sigma > 0$ then γ is of $\Theta(\frac{1}{n^2})$ order. If the entries of the matrix are constants (in weak selection scenario they lie in the interval $(1-\sigma, 1+\sigma)$) then the convergence time of dynamics 3 is polynomial w.r.t n (size of fitness matrices W^e is $n \times n$). We note that the main result of [22] for dynamics (1) has been derived under the assumption that the entries of the fitness matrix are all distinct. It is proven that this assumption is necessary by giving examples where the dynamic doesn't converge to pure fixed points if the fitness matrix has some entries that are equal (the trivial example is when W has all entries equal, then every frequency vector in Δ is a fixed point). This is an indication that γ is needed to analyse the running time and is not artificial. The noise vector δ has coordinates $\pm\delta$, so it is uniformly chosen from hypercube, but there is no dependence on the current frequency vector (δ is independent of current $(\mathbf{x}, \mathbf{y})$). Finally, β should be thought of as a small constant number (like in weak selection) independent of n, and τ to be $O(\frac{1}{n})$ ($1 - n\tau \geq 0$ must hold so that the dynamics with mutation are meaningful and from Lemma 16, it must hold that $\tau \leq \frac{\beta}{16n}$).

B.2 On the environments

We analyze a finite population model where N^t is the population size at time t. It is natural to define survival if $N^t \geq 1$ for all $t \in \mathbb{N}$ (number of people is at least 1 at all times) and extinction if $N^t < 1$ for some t (if the number of people is less than one at some point then the population goes extinct). As described in preliminaries, $N^t = N^{t-1} \cdot \Phi^t$ where $\Phi^t = x(t)^\top W^{e(t)} y(t)$ is the average fitness at time t and $W^{e(t)}$ is the fitness matrix of environment $e(t)$ (at time t).

Fix a fitness matrix W (i.e., fix an environment). If $W_{ij} > 1 + \epsilon$ for all (i, j) then $\mathbf{x}^\top W \mathbf{y} \geq 1$ for all $(\mathbf{x}, \mathbf{y}) \in \Delta$ and thus the number of individuals is increasing along the generations by a factor of $1 + \epsilon$ (the population survives). On the other hand, if $W_{ij} < 1 - \epsilon$ for all (i, j) then $\mathbf{x}^\top W \mathbf{y} < 1 - \epsilon$ for all $(\mathbf{x}, \mathbf{y}) \in \Delta$, so it is clear that the number of individuals is decreasing with a factor of $1 - \epsilon$ (thus population goes extinct). So either extreme makes the problem irrelevant.

Finally, it is natural to assume that complete diversity should favor survival, i.e., if the population is uniform along the alleles/types then the population size must not decrease in the next generation. Therefore, we assume that the average fitness under uniform frequencies is $\geq 1 + \beta$ (for all but few number of bad alleles that can be seen as deleterious). The alleles that are good should dominate entry-wise the bad alleles. Example Figure 2 in the appendix C shows that this assumption is necessary. In Figure 2, $\tau = 0.03$ and $W^e = \begin{pmatrix} 0.99 & 0.37 \\ 0.56 & 2.09 \end{pmatrix}$. If we start from any vector $(\mathbf{x}, \mathbf{y})$ in the shaded area, the dynamics converges to the stable fixed point B. The average fitness $\mathbf{x}^\top W \mathbf{y}$ at B is less than the maximum at the corner which is $W^e_{1,1} = 0.99 < 1$. So if the size of population is Q when entering e, after t generations on the environment e, the population size will be at most $Q \cdot 0.99^t$ (which decreases exponentially). In that case Theorem 18 doesn't hold, even though $\frac{0.99+0.37+0.56+2.09}{4} = 1.0025 > 1$ and $\beta = 0.0025$ (qualitatively we would have the same picture for any $\tau \in [0, 0.03]$ and W^e).

The assumption defined in (7) is necessary as well for the following reason: Assume there is a combination of alleles (i,j) so that $\prod_e (W^e_{ij})^{\pi_e} \geq 1$ (*). In that case we can have one of the environments so that $x_i = 1, y_j = 1$ is a stable fixed point and hence there are initial frequencies so that the dynamics (3) converge to it. After that, it is easy to argue that this monomorphic population survives on average because of (*), so the probability of survival in that case is non zero.

B.3 Explanation of Figure 1

Figure 1 shows the adjacency graph of a Markov chain. There are 3 environments with fitness matrices, say $W^{e_1}, W^{e_2}, W^{e_3}$, and the entries of every matrix are distinct. Take $p_{ii} = 1-p$ and $p_{ij} = \frac{p}{2}$ so that the stationary distribution is $(1/3, 1/3, 1/3)$. Observe that $W^{e_1}_{1,1} \cdot W^{e_2}_{1,1} \cdot W^{e_3}_{1,1} = 1.12 \cdot 1.02 \cdot 0.87 < 0.994 < 1$. The same is true for entries (1,2),(2,1),(2,2). So the assumption defined in (7) is satisfied.

Moreover, observe that if we choose $\beta = 0.005$ and hence $\tau = \frac{0.005}{32}$ it follows that the assumptions defined in (8) are satisfied (also the bad alleles are dominated entry-wise by the good alleles). Hence, in case of no mutation, from theorem 14 the population dies out with probability 1 for all initial population sizes N^0 and all initial frequency vectors in Δ. In case of mutation, and for sufficiently large initial population size N^0, for all initial frequency vectors in Δ the probability of survival is positive (Theorem 18).

C Missing proofs

C.1 Proof of Lemma 4

Proof. From the definition of g (equation 1) we get,

$$
\begin{aligned}
&2\left(\hat{\mathbf{x}}^\top W \hat{\mathbf{y}}\right)\left(\mathbf{x}^\top W \mathbf{y}\right)^2 = 2\sum_{ij} W_{ij}\hat{x}_i\hat{y}_j\left(\mathbf{x}^\top W\mathbf{y}\right)^2 \\
&= 2\sum_{ij} W_{ij}x_iy_j \frac{(W\mathbf{y})_i}{\mathbf{x}^\top W\mathbf{y}} \frac{(W^\top\mathbf{x})_j}{\mathbf{x}^\top W\mathbf{y}}\left(\mathbf{x}^\top W\mathbf{y}\right)^2 \\
&= 2\sum_{i,j} W_{ij}x_iy_j(W\mathbf{y})_i(W^\top\mathbf{x})_j \\
&= \sum_{i,j,k} W_{ij}W_{ik}x_iy_jy_k(W^\top\mathbf{x})_j + \sum_{i,j,k} W_{ij}W^\top_{jk}x_ix_ky_j(W\mathbf{y})_i \\
&= \sum_{i,j,k} W_{ij}W_{ik}x_iy_jy_k\frac{1}{2}((W^\top\mathbf{x})_j + (W^\top\mathbf{x})_k) + \sum_{i,j,k} W_{ij}W_{kj}x_ix_ky_j\frac{1}{2}((W\mathbf{y})_i + (W\mathbf{y})_k) \\
&\geq \sum_{i,j,k} W_{ij}W_{ik}x_iy_jy_k\sqrt{(W^\top\mathbf{x})_j(W^\top\mathbf{x})_k} + \sum_{i,j,k} W_{ij}W_{kj}x_ix_ky_j\sqrt{(W\mathbf{y})_i(W\mathbf{y})_k} \\
&= \sum_i x_i\left(\sum_j y_jW_{ij}\sqrt{(W^\top\mathbf{x})_j}\right)^2 + \sum_j y_j\left(\sum_i x_iW_{ij}\sqrt{(W\mathbf{y})_i}\right)^2 \\
&\geq \left(\sum_{i,j} x_iy_jW_{ij}\sqrt{(W^\top\mathbf{x})_j}\right)^2 + \left(\sum_{j,i} y_jx_iW_{ij}\sqrt{(W\mathbf{y})_i}\right)^2 \quad \text{from convexity of } f(z)=z^2 \\
&= \left(\sum_j y_j(W^\top\mathbf{x})_j^{3/2}\right)^2 + \left(\sum_i x_i(W\mathbf{y})_i^{3/2}\right)^2. \qquad (0)
\end{aligned}
$$

Let ξ be a random variable that takes value $(W\mathbf{y})_i$ with probability x_i. Then $\mathbb{E}[\xi] = \mathbf{x}^\top W\mathbf{y}$, $\mathbb{V}[\xi] = \sum_i x_i((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y})^2$ and ξ takes values in the interval $[0,\mu]$ with $\mu = \max_{ij} W_{ij}$. Consider the function $f(z) = z^{3/2}$ on the interval $[0,\mu]$ and observe that $f''(z) \geq \frac{3}{4}\frac{1}{\sqrt{\mu}}$ on $[0,\mu]$ since $\mu \geq \mathbf{p}^\top W\mathbf{q} \geq 0$ for all $(\mathbf{p},\mathbf{q}) \in \Delta$. Observe also that $f(\mathbb{E}[\xi]) = (\mathbf{x}^\top W\mathbf{y})^{3/2}$ and $\mathbb{E}[f(\xi)] = \sum_i x_i (W\mathbf{y})_i^{3/2}$.

▶ **Claim 22.** *$\mathbb{E}[f(\xi)] \geq f(\mathbb{E}[\xi]) + \frac{A}{2}\mathbb{V}[\xi]$, where $A = \frac{3}{4\sqrt{\mu}}$.*

Proof. By Taylor expansion we get that (we expand w.r.t $\mathbb{E}[\xi]$)

$$f(z) \geq f(\mathbb{E}[\xi]) + f'(\mathbb{E}[\xi])(z - \mathbb{E}[\xi]) + \frac{A}{2}(z - \mathbb{E}[\xi])^2$$

and hence we have that:

$$\begin{aligned} f(z) \geq f(\mathbb{E}[\xi]) + f'(\mathbb{E}[\xi])(z - \mathbb{E}[\xi]) + \frac{A}{2}(z - \mathbb{E}[\xi])^2 &\overset{\text{taking expectation}}{\Rightarrow} \\ \mathbb{E}[f(\xi)] \geq \mathbb{E}[f(\mathbb{E}[\xi])] + f'(\mathbb{E}[\xi])(\mathbb{E}[\xi] - \mathbb{E}[\xi]) + \frac{A}{2}\mathbb{V}[\xi] & \\ = f(\mathbb{E}[\xi]) + \frac{A}{2}\mathbb{V}[\xi]. & \end{aligned}$$

◀

Using the above claim it follows that:

$$\sum_i x_i (W\mathbf{y})_i^{3/2} \geq (\mathbf{x}^\top W\mathbf{y})^{3/2} + \frac{3}{8\sqrt{\mu}} \sum_i x_i ((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y})^2.$$

Squaring both sides and omitting one square from the r.h.s we get

$$\left(\sum_i x_i (W\mathbf{y})_i^{3/2}\right)^2 \geq (\mathbf{x}^\top W\mathbf{y})^3 + \frac{3}{4\sqrt{\mu}} (\mathbf{x}^\top W\mathbf{y})^{3/2} \sum_i x_i ((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y})^2. \tag{9}$$

We do the same by setting ξ to be $(W^\top\mathbf{x})_i$ with probability y_i and using similar argument we get

$$\left(\sum_i y_i (W^\top\mathbf{x})_i^{3/2}\right)^2 \geq (\mathbf{x}^\top W\mathbf{y})^3 + \frac{3}{4\sqrt{\mu}} (\mathbf{x}^\top W\mathbf{y})^{3/2} \sum_i y_i ((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y})^2. \tag{10}$$

Therefore it follows that

$$\begin{aligned} 2(\hat{\mathbf{x}}^\top W\hat{\mathbf{y}})(\mathbf{x}^\top W\mathbf{y})^2 &\geq \left(\sum_j y_j (W^\top\mathbf{x})_j^{3/2}\right)^2 + \left(\sum_i x_i (W\mathbf{y})_i^{3/2}\right)^2 \text{ by inequality (0)} \\ &\overset{(9)+(10)}{\geq} 2(\mathbf{x}^\top W\mathbf{y})^3 + \frac{3}{4\sqrt{\mu}} (\mathbf{x}^\top W\mathbf{y})^{3/2} \Big(\sum_i x_i \left((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y}\right)^2 \\ &\quad + \sum_i y_i \left((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y}\right)^2\Big) \end{aligned}$$

Finally we devide both sides by $2(\mathbf{x}^\top W\mathbf{y})^2$ and we get that

$$\begin{aligned}(\hat{\mathbf{x}}^\top W\hat{\mathbf{y}}) &\geq (\mathbf{x}^\top W\mathbf{y}) + \frac{3}{8\sqrt{\mu(\mathbf{x}^\top W\mathbf{y})}}\Big(\sum_i x_i\left((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y}\right)^2 \\ &\quad + \sum_i y_i\left((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y}\right)^2\Big) \\ &\geq (\mathbf{x}^\top W\mathbf{y}) + \frac{3}{8\mu}\left(\sum_i x_i\left((W\mathbf{y})_i - \mathbf{x}^\top W\mathbf{y}\right)^2 + \sum_i y_i\left((W^\top\mathbf{x})_i - \mathbf{x}^\top W\mathbf{y}\right)^2\right)\end{aligned}$$

with $\frac{3}{8\sqrt{\mu\Phi(\mathbf{x},\mathbf{y})}} \geq \frac{3}{8\mu}$ since $\mu \geq \mathbf{x}^\top W\mathbf{y}$. This inequality and the proof techniques can be seen as a generalization of an inequality and proof techniques in [20]. ◀

C.2 Proof of Lemma 7

Proof. Vectors $(\delta_\mathbf{x}, \delta_\mathbf{y}), (-\delta_\mathbf{x}, \delta_\mathbf{y}), (\delta_\mathbf{x}, -\delta_\mathbf{y}), (-\delta_\mathbf{x}, -\delta_\mathbf{y})$ appear with the same probability, and observe that

$$\begin{aligned}&(\mathbf{x}+\delta_\mathbf{x})^\top W(\mathbf{y}+\delta_\mathbf{y}) + (\mathbf{x}-\delta_\mathbf{x})^\top W(\mathbf{y}+\delta_\mathbf{y}) + (\mathbf{x}+\delta_\mathbf{x})^\top W(\mathbf{y}-\delta_\mathbf{y}) \\ &+ (\mathbf{x}-\delta_\mathbf{x})^\top W(\mathbf{y}-\delta_\mathbf{y}) = 4\mathbf{x}^\top W\mathbf{y},\end{aligned}$$

and the claim follows. ◀

C.3 Proof of Lemma 9

Proof. Assume w.l.o.g that we have $W_{i1} \geq W_{i2} \geq ...$ (otherwise we permute them so that are in decreasing order). Consider the case where the signs are revealed one at a time, in the order of indices of the sorted row. The probability that $+$ signs dominate $-$ signs through the process is $\frac{1}{m/2+1}$ (ballot theorem/Catalan numbers) (see 8). It is clear that when the $+$ signs dominate the $-$ signs then

$$(W\delta_\mathbf{y})_i = \sum_j^m W_{ij}\delta_j \quad \geq \quad \sum_{j=1}^{m/2}(W_{i(2j-1)} - W_{i(2j)})\delta \quad \geq \quad \gamma\delta\frac{m}{2}.$$ ◀

C.4 Proof of Lemma 11

Proof. First of all, since the average fitness is increasing in every generation (before adding noise) and by Lemma 7 we get that for all $t \in \{0, ..., 2T\}$

$$\mathbb{E}[\Phi^{t+1}|\Phi^t] \geq \Phi^t$$

namely the average fitness is a submartingale (0).

Let $(\mathbf{x}^t, \mathbf{y}^t) := (\mathbf{x}(t), \mathbf{y}(t))$ be the frequency vector at time t which has average fitness $\Phi^t \equiv \Phi(\mathbf{x}^t, \mathbf{y}^t) = \mathbf{x}^{t\top} W\mathbf{y}^t$ (abusing notation we use $\Phi(\mathbf{x}, \mathbf{y})$ for function $\mathbf{x}^\top W\mathbf{y}$ and Φ^t for the value of average fitness at time t), also we denote $(\hat{\mathbf{x}}^t, \hat{\mathbf{y}}^t) = g(\mathbf{x}^t, \mathbf{y}^t)$ and recall that $(\mathbf{x}^{t+1}, \mathbf{y}^{t+1}) = (\hat{\mathbf{x}}^t + \delta^t_\mathbf{x}, \hat{\mathbf{y}}^t + \delta^t_\mathbf{y})$. Assume that in the next generation $(\hat{\mathbf{x}}^{2t}, \hat{\mathbf{y}}^{2t}) = g(\mathbf{x}^{2t}, \mathbf{y}^{2t})$ the average fitness before the noise, namely $\hat{\mathbf{x}}^{2t\,T} W\hat{\mathbf{y}}^{2t}$ will be at least $\Phi^{2t} + C\delta\alpha^2$. Hence by

Lemma 7 we get that $\mathbb{E}[\Phi^{2t+1}|\Phi^{2t}] = \hat{\mathbf{x}}^{2t\,T} W \hat{\mathbf{y}}^{2t} \geq \Phi^{2t} + C\delta\alpha^2$ (1). Therefore we have that

$$\begin{aligned}
\mathbb{E}[\Phi^{2t+2}|\Phi^{2t}] &= \mathbb{E}_{\delta^{2t+1},\delta^{2t}}[(\hat{\mathbf{x}}^{2t+1} + \delta_{\mathbf{x}}^{2t+1})^\top W(\hat{\mathbf{y}}^{2t+1} + \delta_{\mathbf{y}}^{2t+1})|\Phi^{2t}] \\
&= \mathbb{E}_{\delta^{2t}}[\left(\hat{\mathbf{x}}^{2t+1}\right)^\top W \hat{\mathbf{y}}^{2t+1}|\Phi^{2t}] \\
&\geq \mathbb{E}_{\delta^{2t}}[\left(\mathbf{x}^{2t+1}\right)^\top W \mathbf{y}^{2t+1}|\Phi^{2t}] \\
&= \mathbb{E}[\Phi^{2t+1}|\Phi^{2t}] \\
&\geq \Phi^{2t} + C\delta\alpha^2
\end{aligned}$$

where the second inequality is claim (1) and the first inequality comes from inequality 4 (since the r.h.s of inequality 4 is non-negative). The first, third equality comes from model definition and second equality comes from Lemma 7.

Assume now that in the next generation $(\hat{\mathbf{x}}^{2t}, \hat{\mathbf{y}}^{2t}) = g(\mathbf{x}^{2t}, \mathbf{y}^{2t})$ the average fitness before the noise, namely $\hat{\mathbf{x}}^{2t\,T} W \hat{\mathbf{y}}^{2t}$ will be less than $\Phi^{2t} + C\delta\alpha^2$. This means that the vector $(\mathbf{x}^{2t}, \mathbf{y}^{2t})$ is α-close by corollary 6, so after adding the noise by the definition of α-close we get that $\hat{\mathbf{x}}^{2t\,T} W \hat{\mathbf{y}}^{2t} + \alpha \geq \Phi^{2t+1} \geq \hat{\mathbf{x}}^{2t\,T} W \hat{\mathbf{y}}^{2t} - \alpha$ (2). From Lemma 9 we will have with probability at least $\frac{1}{2}\frac{1}{m/2+1}$ that $(W\mathbf{y}^{2t+1})_i \geq (W\hat{\mathbf{y}}^{2t})_i + \frac{\gamma\delta m}{2}$ for all i in the support of vector $\mathbf{x}^t$ (we multiplied the probability by $\frac{1}{2}$ since you perturb $\mathbf{y}$ with probability half) (3). The same argument works if we purturb $\mathbf{x}$, so w.l.o.g we work with purturbed vector $\mathbf{y}$ which has support of size at least 2. Essentially by inequality 4 we get the following inequalities:

$$\begin{aligned}
\mathbb{E}[\Phi^{2t+2}|\Phi^{2t}] &= \mathbb{E}_{\delta^{2t+1},\delta^{2t}}[(\hat{\mathbf{x}}^{2t+1} + \delta_{\mathbf{x}}^{2t+1})^\top W(\hat{\mathbf{y}}^{2t+1} + \delta_{\mathbf{y}}^{2t+1})|\Phi^{2t}] \\
&= \mathbb{E}_{\delta^{2t}}[\left(\hat{\mathbf{x}}^{2t+1}\right)^\top W \hat{\mathbf{y}}^{2t+1}|\Phi^{2t}] \\
&\overbrace{\geq}^{4} \mathbb{E}_{\delta^{2t}}[\left(\mathbf{x}^{2t+1}\right)^\top W \mathbf{y}^{2t+1}|\Phi^{2t}] + \\
&+ C \cdot \mathbb{E}_{\delta^{2t}}\left[\sum_i x_i^{2t+1} \cdot \left((W\mathbf{y}^{2t+1})_i - \left(\mathbf{x}^{2t+1}\right)^\top W \mathbf{y}^{2t+1}\right)^2 \middle| \Phi^{2t}\right] \\
&\geq \Phi^{2t} + \frac{C}{m+2}\left(\frac{\gamma\delta m}{2} - 2\alpha\right)^2 \\
&\geq \Phi^{2t} + C\delta\alpha^2
\end{aligned}$$

where last inequality comes from the assumption and the second comes from claim (0), (2), (3). Hence by induction we get that

$$\mathbb{E}[\Phi^{2t+2} - (t+1)\cdot C\delta\alpha^2|\Phi^{2t}] \geq \Phi^{2t} - t \cdot C\delta\alpha^2.$$

It is easy to see that $W_{\max} \geq \Phi^t \geq W_{\min}$ for all t. ◀

C.5 Proof of Lemma 15

Proof. Consider one step of the dynamics that starts at $(\mathbf{x}, \mathbf{y})$ and has frequency vector $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$ in the next step before adding the noise. Let $i*$ be the bad allele that has the greatest

fitness at it, namely $(W^e\mathbf{y})_{i*} \geq (W^e\mathbf{y})_i$ for all $i \in B_1^e$. It holds that

$$\begin{aligned}
\sum_{i\in B_1^e} \tilde{x}_i &= (1-n\tau)\sum_{i\in B_1^e} x_i \frac{(W^e\mathbf{y})_i}{\mathbf{x}^\top W^e\mathbf{y}} + \tau|B_1^e| \\
&= (1-n\tau)\frac{\sum_{i\in B_1^e} x_i(W^e\mathbf{y})_i}{\sum_{i\in G_1\setminus B_1^e} x_i(W^e\mathbf{y})_i + \sum_{i\in B_1^e} x_i(W^e\mathbf{y})_i} + \tau|B_1^e| \\
&\leq (1-n\tau)\frac{\sum_{i\in B_1^e} x_i(W^e\mathbf{y})_{i*}}{\sum_{i\in G_1\setminus B_1^e} x_i(W^e\mathbf{y})_i + \sum_{i\in B_1^e} x_i(W^e\mathbf{y})_{i*}} + \tau|B_1^e| \qquad (*) \\
&\leq (1-n\tau)\frac{\sum_{i\in B_1^e} x_i(W^e\mathbf{y})_{i*}}{\sum_{i\in G_1\setminus B_1^e} x_i(W^e\mathbf{y})_{i*} + \sum_{i\in B_1^e} x_i(W^e\mathbf{y})_{i*}} + \tau|B_1^e| \\
&= (1-n\tau)\frac{(W^e\mathbf{y})_{i*}\sum_{i\in B_1^e} x_i}{(W^e\mathbf{y})_{i*}\sum_i x_i} + \tau|B_1^e| \\
&= (1-n\tau)\sum_{i\in B_1^e} x_i + \tau|B_1^e|
\end{aligned}$$

where inequality (*) is true because if $\frac{a}{b} < 1$ then $\frac{a}{b} < \frac{a+c}{b+c}$ for all a, b, c positive. Hence after we add noise δ with $||\delta||_\infty = \delta$, the resulting vector $(\mathbf{x}', \mathbf{y}')$ (which is the next generation frequency vector) will satisfy $\sum_{i\in B_1^e} x_i' \leq (1-n\tau)\sum_{i\in B_1^e} x_i + \tau|B_1^e| + \delta|B_1^e|$. By setting $S_t = \sum_{i\in B_1^e} x_i(t)$ it follows that $S_{t+1} \leq (1-n\tau)S_t + (\tau+\delta)|B_1^e|$ and also $S_0 \leq 1$. Therefore $S_t \leq (\tau+\delta)|B_1^e|\frac{1-(1-n\tau)^t}{n\tau} + (1-n\tau)^t$. By choosing $t = -\frac{\ln(2n)}{\ln(1-n\tau)} \approx \frac{\ln(2n)}{n\tau}$ it follows that $\sum_{i\in B_1^e} x_i(t) \leq \frac{(1+o(1))|B_1^e|+1/2}{n} \leq \frac{2|B_1^e|}{n}$ where we used the assumption that $\delta = o_n(\tau)$. The same argument holds for B_2^e. ◀

C.6 Proof of Lemma 16

Proof. By Lemma 15 after $\frac{\ln(2n)}{n\tau}$ generations it follows that

$$\sum_{i\in B_1^e} x_i(t) + \sum_{j\in B_2^e} y_i(t) \leq \frac{2|B^e|}{n}. \tag{11}$$

We consider the average fitness function $\mathbf{x}^\top W^e\mathbf{y}$ which is not increasing (as has already been mentioned). Let $\tau = \tau\cdot(1,...,1)^\top$, $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) = f(\mathbf{x}, \mathbf{y})$ and $(\hat{\mathbf{x}}, \hat{\mathbf{y}}) = g(\mathbf{x}, \mathbf{y})$ with fitness matrix W^e and also denote by $(\mathbf{x}', \mathbf{y}')$ the resulting vector after noise δ is added. It is easy to observe that

$$\tilde{\mathbf{x}}^\top W^e\tilde{\mathbf{y}} = (1-n\tau)^2\hat{\mathbf{x}}^\top W^e\hat{\mathbf{y}} + (1-n\tau)\hat{\mathbf{x}}^\top W^e\tau + (1-n\tau)\tau^\top W^e\hat{\mathbf{y}} + \tau^\top W^e\tau,$$

and also that

$$\mathbf{x}'^\top W^e\mathbf{y}' \geq \tilde{x}^\top W^e\tilde{y} - 2n\delta W^e_{\max} \geq \tilde{x}^\top W^e\tilde{y}\left(1 - O\left(2n\delta\frac{W_{max}}{W_{min}}\right)\right) = (1-o_{n\tau}(1))\tilde{x}^\top W\tilde{y},$$

where $W_{\max} = \max_e W^e_{\max}$. Under the assumption 8 we have the following upper bounds:

- $\hat{\mathbf{x}}^\top W^e\tau \geq (1+\beta)n\tau\left(1 - \frac{2|B_1^e|}{n}\right)$ and $\hat{\tau}^\top W^e\hat{\mathbf{y}} \geq (1+\beta)n\tau\left(1 - \frac{2|B_2^e|}{n}\right)$.
- $\tau^\top W^e\tau \geq (n\tau)^2(1+\beta)\left(1 - \frac{|B^e|}{n}\right) \geq (1+\beta)\left(1 - \frac{2|B^e|}{n}\right)^2 n^2\tau^2$.

First assume that $\mathbf{x}^\top W^e \mathbf{y} \leq 1 + \frac{\beta}{2}$. We get the following system of inequalities:

$$\begin{aligned}
\frac{\mathbf{x}'^\top W^e \mathbf{y}'}{\mathbf{x}^\top W^e \mathbf{y}} &\geq (1 - o_{n\tau}(1)) \frac{\tilde{\mathbf{x}}^\top W^e \tilde{\mathbf{y}}}{\mathbf{x}^\top W^e \mathbf{y}} \\
&\geq (1 - o_{n\tau}(1))((1-n\tau)^2 \frac{\hat{\mathbf{x}}^\top W^e \hat{\mathbf{y}}}{\mathbf{x}^\top W^e \mathbf{y}} + 2(1-n\tau)n\tau \left(1 - \frac{2|B^e|}{n}\right) \frac{(1+\beta)}{\mathbf{x}^\top W^e \mathbf{y}} + \\
&\qquad + \frac{(1+\beta)}{\mathbf{x}^\top W^e \mathbf{y}} \left(1 - \frac{2|B^e|}{n}\right)^2 n^2\tau^2) \\
&\geq (1 - o_{n\tau}(1))((1-n\tau)^2 + 2(1-n\tau)n\tau \left(1 - \frac{2|B^e|}{n}\right)\left(1 + \frac{\beta}{2+\beta}\right) + \\
&\qquad + \left(1 + \frac{\beta}{2+\beta}\right)\left(1 - \frac{2|B^e|}{n}\right)^2 n^2\tau^2) \\
&\geq (1 - o_{n\tau}(1)) \left(1 + n\tau \left(\frac{2\beta}{2+\beta} - \frac{6|B^e|}{n} - \frac{2\beta}{2+\beta} n\tau\right)\right) \\
&\geq 1 + n\tau \left(\frac{\beta}{2+\beta}\right)
\end{aligned}$$

The second inequality comes from the fact that $\hat{\mathbf{x}}^\top W^e \hat{\mathbf{y}} \geq \mathbf{x}^\top W^e \mathbf{y}$ (the average fitness is increasing for the no mutation setting) and also since $\mathbf{x}^\top W^e \mathbf{y} \leq 1 + \frac{\beta}{2}$. The third and the fourth inequality use the fact that $|B^e| \ll n\beta$ and $\tau \leq \frac{\beta}{16n}$. Therefore, the fitness increases in the next generation for the mutation setting as long as the current fitness $\mathbf{x}^\top W^e \mathbf{y} \leq 1 + \frac{\beta}{2}$ with a factor of $1 + n\tau\frac{\beta}{2+\beta}$ (i). Hence the time we need to reach the value of 1 for the average fitness is $\frac{2\ln\frac{1}{h}}{n\tau\frac{\beta}{2+\beta}}$ which is dominated by $t_1 = \frac{\ln(2n)}{n\tau}$. Therefore the total loss factor is at most $\frac{1}{d} = h^{t_1}$, namely $d = \left(\frac{1}{h}\right)^{t_1}$. Let t_2 be the time for the average fitness to reach $1 + \frac{\beta}{4}$ (as long as it has already reached 1), thus $t_2 = \frac{2}{n\tau}$ which is dominated by t_1. By similar argument, let's now assume that $\mathbf{x}^\top W^e \mathbf{y} \geq 1 + \frac{\beta}{2}$ then

$$\begin{aligned}
\frac{\mathbf{x}'^\top W^e \mathbf{y}'}{\mathbf{x}^\top W^e \mathbf{y}} &\geq (1 - o_{n\tau}(1)) \left(\frac{\tilde{\mathbf{x}}^\top W^e \tilde{\mathbf{y}}}{\mathbf{x}^\top W^e \mathbf{y}}\right) \\
&\geq (1 - o_{n\tau}(1))((1-n\tau)^2 \frac{\hat{\mathbf{x}}^\top W^e \hat{\mathbf{y}}}{\mathbf{x}^\top W^e \mathbf{y}} + 2(1-n\tau)n\tau \left(1 - \frac{2|B^e|}{n}\right) \frac{(1+\beta)}{\mathbf{x}^\top W^e \mathbf{y}} \\
&+ \frac{(1+\beta)}{\mathbf{x}^\top W^e \mathbf{y}} \left(1 - \frac{2|B^e|}{n}\right)^2 n^2\tau^2) \\
&\geq 1 - 2n\tau
\end{aligned}$$

Hence $\mathbf{x}'^\top W^e \mathbf{y}' \geq (1 - 2n\tau)(1 + \frac{\beta}{2})$, namely $\mathbf{x}'^\top W^e \mathbf{y}' \geq 1 + \frac{\beta}{4}$ (ii) for $\tau < \frac{\beta}{16n}$. Therefore as long as the fitness surpasses $1 + \frac{\beta}{4}$, it never goes below $1 + \frac{\beta}{4}$ (conditioned on the fact you remain at the same environment). This is true from claims (i), (ii). When the fitness is at most $1 + \frac{\beta}{2}$, it increases in the next generation and when it is greater than $1 + \frac{\beta}{2}$, it remains at least $1 + \frac{\beta}{4}$ in the next generation. To finish the proof we compute the times. The time t_3 to have a total gain factor of at least d, will be such that $(1 + \frac{\beta}{4})^{t_3} = \frac{1}{h^{t_1}}$. Hence $t_3 = t_1 \frac{2\ln\frac{1}{h}}{\beta}$. By setting $T_{thr} = \frac{6\ln(2n)}{n\tau\beta W_{\min}} > \frac{6\ln\frac{1}{h}\ln(2n)}{n\tau\beta} > 3t_3 > t_1 + t_2 + t_3$ the proof finishes. ◀

C.7 Proof of Theorem 20

Proof. We first prove the results for rational τ; let $\tau = \frac{\kappa}{\lambda}$. We use the theorem of Baum and Eagon [4]. Let

$$L(\mathbf{x}, \mathbf{y}) = (\mathbf{x}^\top W \mathbf{y})^{\lambda - m\kappa} \prod_i x_i^\kappa \prod_i y_i^\kappa.$$

Then

$$x_i \frac{\partial L}{\partial x_i} = 2\kappa L + \frac{2x_i (W\mathbf{y})_i (\lambda - m\kappa) L}{\mathbf{x}^\top W \mathbf{y}}.$$

It follows that

$$\begin{aligned} \frac{x_i \frac{\partial L}{\partial x_i}}{\sum_i x_i \frac{\partial L}{\partial x_i}} &= \frac{2\kappa L + \frac{2x_i (W\mathbf{y})_i (\lambda - m\kappa) L}{\mathbf{x}^\top W \mathbf{y}}}{2m\kappa L + 2(\lambda - m\kappa) L} \\ &= \frac{2\kappa L}{2\lambda L} + \frac{2L(\lambda - m\kappa) x_i (W\mathbf{y})_i}{2\lambda L \mathbf{x}^\top W \mathbf{y}} \\ &= (1 - n\tau) x_i \frac{(W\mathbf{y})_i}{\mathbf{x}^\top W \mathbf{y}} + \tau \end{aligned}$$

where the first equality comes from the fact that $\sum_{i=1}^n x_i (W\mathbf{y})_i = \mathbf{x}^\top W \mathbf{y}$. The same is true for $y_i \frac{\partial L}{\partial y_i}$. Since L is a homogeneous polynomial of degree 2λ, from Theorem 19 we get that L is strictly increasing along the trajectories, namely

$$L(f(\mathbf{x}, \mathbf{y})) > L(\mathbf{x}, \mathbf{y})$$

unless $(\mathbf{x}, \mathbf{y})$ is a fixed point (f is the update rule of the dynamics, see also 2). So $P(\mathbf{x}, \mathbf{y}) = L^{\frac{1}{\kappa}}(\mathbf{x}, \mathbf{y})$ is a potential function for the dynamics.

To prove the result for irrational τ, we just have to see that the proof of [4] holds for all homogeneous polynomials with degree d, even irrational.

To finish the proof let $\Omega \subset \Delta$ be the set of limit points of an orbit $\mathbf{z}(t) = (\mathbf{x}(t), \mathbf{y}(t))$ (frequencies at time t for $t \in \mathbb{N}$). $P(\mathbf{z}(t))$ is increasing with respect to time t by above and so, because P is bounded on Δ, $P(\mathbf{z}(t))$ converges as $t \to \infty$ to $P^* = \sup_t \{P(\mathbf{z}(t))\}$. By continuity of P we get that $P(\mathbf{v}) = \lim_{t\to\infty} P(\mathbf{z}(t)) = P^*$ for all $\mathbf{v} \in \Omega$. So P is constant on Ω. Also $\mathbf{v}(t) = \lim_{k\to\infty} \mathbf{z}(t_k + t)$ as $k \to \infty$ for some sequence of times $\{t_i\}$ and so $\mathbf{v}(t)$ lies in Ω, i.e. Ω is invariant. Thus, if $\mathbf{v} \equiv \mathbf{v}(0) \in \Omega$ the orbit $\mathbf{v}(t)$ lies in Ω and so $P(\mathbf{v}(t)) = P^*$ on the orbit. But P is strictly increasing except on equilibrium orbits and so Ω consists entirely of fixed points. ◀

C.8 Calculations for mutation

Let $(\hat{\mathbf{x}}, \hat{\mathbf{y}}) = g(\mathbf{x}, \mathbf{y})$. If in every generation allele $i \in S_1$ mutates to allele $k \in S_1$ with probability μ_{ik}, where $\sum_k \mu_{ik} = 1$, $\forall i$, then the final proportion (after reproduction, mutation) of allele $i \in S_1$ in the population will be

$$x_i' = \sum_{k \in S_1} \mu_{ki} \hat{x}_k.$$

Similarly, if $j \in S_2$ mutates to $k \in S_2$ with probability δ_{jk}, then proportion of allele $j \in S_2$ will be

$$y_j' = \sum_{k \in S_2} \delta_{ki} \hat{y}_k.$$

If mutation happens after every selection (mating), then we get the following dynamics with update rule $f' : \Delta \to \Delta$ governing the evolution (update rule contains selection+mutation).

$$\text{Let } (\mathbf{x}', \mathbf{y}') = f'(\mathbf{x}, \mathbf{y}), \text{ then } \begin{array}{rcl} x'_i & = & \sum_{k \in S_1} \mu_{ki} x_k \frac{(W\mathbf{y})_k}{\mathbf{x}^\top W \mathbf{y}}, \ \forall i \in S_1 \\ y'_j & = & \sum_{k \in S_2} \delta_{kj} y_k \frac{(\mathbf{x}^\top W)_k}{\mathbf{x}^\top W \mathbf{y}}, \ \forall j \leq S_2 \end{array} \tag{12}$$

Suppose $\forall k,\ \forall i \neq k$ and $\forall j \neq k$, we have $\mu_{ik} = \delta_{jk} = \tau$, where $\tau \leq \frac{1}{n}$. Since $\sum_k \mu_{ik} = \sum_k \delta_{jk} = 1$, we have $\mu_{ii} = \delta_{jj} = 1 - (n-1)\tau = 1 + \tau - n\tau$. Hence

$$\begin{aligned} x'_i &= \sum_{k \in S_1} \mu_{ki} x_k \frac{(W\mathbf{y})_k}{\mathbf{x}^\top W \mathbf{y}} \\ &= (1 + \tau - n\tau) x_i \frac{(W\mathbf{y})_i}{\mathbf{x}^\top W \mathbf{y}} + \tau \sum_{k \neq i} x_k \frac{(W\mathbf{y})_k}{\mathbf{x}^\top W \mathbf{y}} \\ &= (1 - n\tau) x_i \frac{(W\mathbf{y})_i}{\mathbf{x}^\top W \mathbf{y}} + \tau \sum_{k} x_k \frac{(W\mathbf{y})_k}{\mathbf{x}^\top W \mathbf{y}} \\ &= (1 - n\tau) x_i \frac{(W\mathbf{y})_i}{\mathbf{x}^\top W \mathbf{y}} + \tau. \end{aligned}$$

The same is true for vector $\mathbf{y}'$. The dynamics of (12) where $\mu_{ik} = \delta_{ik} = \tau$ for all $k \neq i$ simplifies to the equations 2 as appear in the preliminaries.

D Figures

To draw the phase portrait of a discrete time system $f : \Delta \to \Delta$, we draw vector $f(\mathbf{x}) - \mathbf{x}$ at point $\mathbf{x}$.

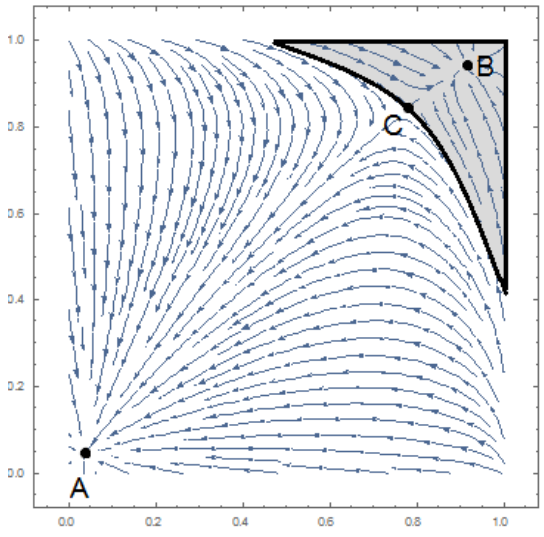

Figure 2 Example where population goes extinct in environment e for some initial frequency vectors $(\mathbf{x}, \mathbf{y})$ that are close to stable point B (inside the shaded area). Mutation probability is $\tau = 0.03$ and the fitness matrix of environment e is $W^e_{1,1} = 0.99, W^e_{2,2} = 2.09, W^e_{1,2} = 0.37, W^e_{2,1} = 0.56$.

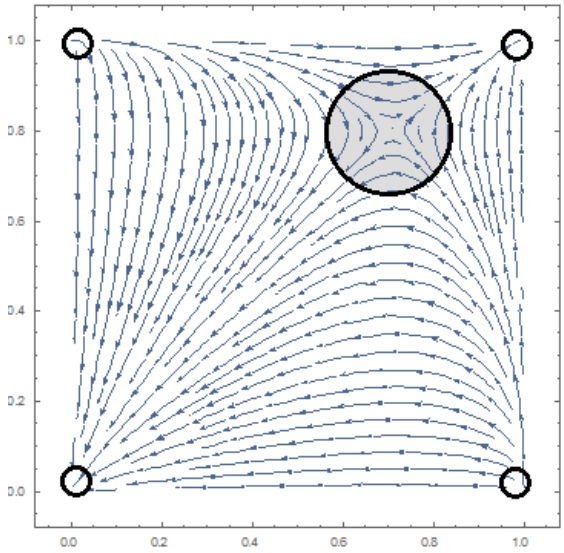

Figure 3 Example of dynamics without mutation in specific environment $W^e_{1,1} = 0.99, W^e_{2,2} = 2.09, W^e_{1,2} = 0.37, W^e_{2,1} = 0.56$. The circles qualitatively show all the points that slow down the increase in the average fitness $\mathbf{x}^T W^e \mathbf{y}$, i.e α-close points or negligible.

Self-Sustaining Iterated Learning*

Abstract

An important result from psycholinguistics (Griffiths & Kalish, 2005) states that no language can be learned iteratively by rational agents in a self-sustaining manner. We show how to modify the learning process slightly in order to achieve self-sustainability. Our work is in two parts. First, we characterize iterated learnability in geometric terms and show how a slight, steady increase in the lengths of the training sessions ensures self-sustainability for any discrete language class. In the second part, we tackle the nondiscrete case and investigate self-sustainability for iterated linear regression. We discuss the implications of our findings to issues of non-equilibrium dynamics in natural algorithms.

1 Introduction

Consider this hypothetical scenario: A native speaker of Quenya[1] sets out to teach the language to an English speaker; after a year of teaching, the learner considers herself fluent enough to teach Quenya to some other English speaker, who a year later does the same. In this form of *iterated learning*, agents teach each other in sequence: X teaches Y, who then teaches Z, who then teaches...[2, 8, 7, 15, 12, 9, 14, 16, 18, 11]. By a classic result of Griffiths and Kalish [7], Quenya will vanish after a finite number of iterations, at which point the agents, assumed to be rational, will be "teaching" each other plain English. In other words, after a while, learners will be taught nothing they don't already know: iterated learning is not self-sustaining.

Such findings are hard to validate empirically but variants of it are within the reach of experimental psychology. As early as 1932, in fact, the English psychologist Frederic Bartlett used iterated learning to expose hidden biases among humans. He presented a picture of an owl to a person for given period of time and then asked her to draw it from memory. Her picture was then shown to the next learner for the same amount of time, who then proceeded to draw it back from memory. After 20 iterations of this process, to Bartlett's surprise, what was being drawn was no longer an owl but, quite clearly, a cat! The challenge was to explain why humans would exhibit a pro-feline bias without falling into the trap of just-so stories.

Griffiths et al. [11] repeated the same experiment ten years ago, this time trading owls for lines. The goal was to see if linear regression could be iterated: the answer was a resounding No. Skipping over logistical details, the experiment presents the first learner with a cloud of 20 points drawn randomly, with noise, from the line $Y = 1 - X$. The cloud vanishes and the learner is then asked to reconstruct it from memory. She then becomes the teacher by passing on her own cloud to the next learner, who likewise, looks at it for a while, and then tries to reconstruct it from memory, etc. Surprisingly, iterating this process a mere nine times leads the last learner in the sequence to draw a cloud that regresses to the line $Y = X$; in other words, teaching about descending lines iteratively has precisely the opposite effect! In fact the initial picture is essentially is irrelevant. A random cloud of points will also lead to $Y = X$.

Unlike the Quenya scenario, where the bias toward English is not unexpected, the cat and line experiments both reveal a hidden prior among the participants. Humans seem to love cats and possess a strong positive correlation bias; it is easy to speculate why.[2] It is noteworthy that the prior should prevail even in the absence of any sort of priming. Indeed, this experiment fails miserably if you try it yourself by playing the role of all the agents in sequence. The use of different learners ensures that the training does not acquire long-term memory. Similar laboratory experiments with human subjects (well, undergraduates) have confirmed the unstainability of iterated learning [11, 2, 19, 1, 9].

In our first example, Quenya gets “washed out" by English in a way reminiscent of the fixation of an allele through genetic drift. Indeed, the original impetus for studying iterated learning in psycholinguistics was to look for a parallel to Kimura’s neutral theory of molecular evolution in the area of cultural transmission. People learn their native tongue from speakers who themselves learned it from others. This process introduces variation along the way, some of which is retained durably. The selectionist view seeks to explain this process by fitness considerations at the population level. Iterated learning suggests a different explanation. Language acquisition suffers from a well-documented information bottleneck (the notorious “poverty of stimulus"), so one might expect languages to evolve so as to be easy to learn: could complexity theory be the key? This push for simplicit would then trigger the emergence of linguistic universals (eg, compositionality) that one finds present in all languages [8]. This view complements – some will argue, contradict – Chomsky’s interpretation of universals as the product of constraints imposed by an innate genetic endowment.

Following Chomsky and Lasnik’s theory of “Principles and Parameters," Rafferty et al. [15] model languages by means of a handful of parameters: think of a few knobs whose settings specify any given language. Language evolution thus entails the trans-generational update of a probability distribution over that parameter space. Assuming that the learners are rational Bayesian agents, iterated learning acts as a Gibbs sampler for a joint probability distribution over languages and their sentences. By converging to a stationary distribution, iterated learning proves incapable of sustaining itself past the mixing time. In that model, languages evolve to reflect the priors of the learners while losing all trace of the ancestor language. While this phenomenon is of central relevance in the study of universal grammars, it leaves open the possibility that changes in the sampling algorithm might make iterated learning self-sustaining. Of course, it is easy to think of situations where this feature would be highly desirable (eg, school teaching, social transmission of norms, legends, jokes, etc.) We show how keeping the length of the training sessions growing slightly allows iterated

[2] Our favorite piece of anecdotal evidence in support of the positive slope bias is that no road sign in the US features an aircraft on a descending path.

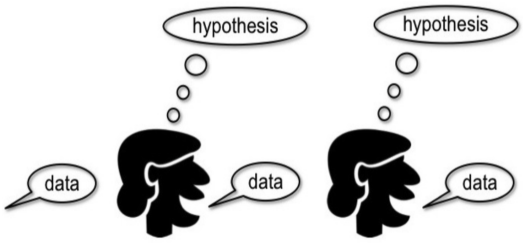

Figure 1 Chained iterated learning.

learning to be sustained in perpetuity.

In the first part of the paper, we characterize iterated learnability in geometric terms and show how a slight, steady increase in the lengths of the learning sessions ensures self-sustainability for any discrete language class. In the second part, we tackle the nondiscrete case and investigate self-sustainability for iterated Bayesian linear regression. In all cases, self-sustainability requires making the underlying Markov process time-inhomogeneous in order to stay out of equilibrium. This gives us an opportunity to offer a few thoughts on the growing importance of non-equilibrium in natural algorithms.

Background

Following [2, 8, 7, 15, 12, 9, 14, 16, 18, 11], we begin with *chained iterated learning*: a learner's prior is modeled by a distribution over a hypothesis space $\mathcal{H}$, which is itself equipped with a likelihood function: $\mathbb{P}[d|h]$ indicates the probability of generating data $d \in \mathcal{D}$ given the hypothesis $h \in \mathcal{H}$. The first learner samples m_1 items *iid* from the initial hypothesis $\boldsymbol{h}_{\texttt{init}}$: these items provide the training data $\mathbf{d}_1 = (d_{1,1}, \ldots, d_{1,m_1})$ with which the first learner Bayes-updates its prior. Its posterior is given by setting $t = 1$ in this formula:

$$\mathbb{P}[h|\mathbf{d}_t] = \mathbb{P}[\mathbf{d}_t|h]\,\mathbb{P}[h]/\mathbb{P}[\mathbf{d}_t], \quad \text{with } \mathbb{P}[\mathbf{d}_t] = \sum_{h\in\mathcal{H}} \mathbb{P}[\mathbf{d}_t|h]\,\mathbb{P}[h]. \tag{1}$$

From that point on, each successive learner updates its prior from their predecessor. For any $t > 1$, learner t receives m_t items sampled from the posterior of agent $t-1$ to form the training set $\mathbf{d}_t$. To do that, she picks a random hypothesis h from $\mathcal{H}$ with probability $\mathbb{P}[h|\mathbf{d}_{t-1}]$ (the posterior of learner $t-1$) and then samples m_t items *iid* from h to form $\mathbf{d}_t \in \mathcal{D}^{m_t}$. The posterior $\mathbb{P}[h|\mathbf{d}_t]$ is derived according to (1). Note that learner t has no direct access to the posterior of learner $t-1$ but only to data drawn from a hypothesis sampled from the posterior. Our formulation assumes a discrete space $\mathcal{H}$ but extends to continuous settings, as we show in §3.

In the case of linguistic transmission, each hypothesis $h \in \mathcal{H}$ is a "knob" whose setting is given by a number between 0 and 1, specifically the prior probability $\mathbb{P}[h]$. All learners share the same prior. Picking some h from that prior specifies a *language* (also denoted h for convenience). In this case, a language is defined as a probability distribution over $\mathcal{D}$, interpreted here as a set of *sentences*. In this way, the prior can be viewed as a mixture over $\mathcal{H}$: by abuse of terminology, we call it a *mixed* hypothesis, which we distinguish from a *pure* hypothesis of the form $h \in \mathcal{H}$ (corresponding to a single-point distribution). Access to language h is achieved by random sampling: the sentence $d \in \mathcal{D}$ is picked with probability $\mathbb{P}[d|h]$.

Iterated learning proceeds as follows. After selecting language h with probability $\mathbb{P}[h|\mathbf{d}_{t-1}]$, learner t collects m_t independent samples from h. Thus, given a tuple $\mathbf{d}_t = (d_1, \ldots, d_{m_t})$ of sentences from $\mathcal{D}$, the likelihood $\mathbb{P}[\mathbf{d}_t|h]$ is equal to $\prod_{1\le k\le m_t} \mathbb{P}[d_k|h]$. The learner is now

ready to Bayes-update its prior. Of course, the first one ($t = 1$) samples directly from the language $\boldsymbol{h}_{\texttt{init}}$ chosen for iterated learning. The notation is boldfaced to indicate that $\boldsymbol{h}_{\texttt{init}}$ may be a mixed hypothesis or, in other words, a distribution over hypotheses.

Suppose that $\mathcal{D} = \{d_1, \ldots, d_s\}$ and $\mathcal{H} = \{h_1, \ldots, h_n\}$ are both finite. While sampling from the posterior of learner $t-1$, if learner t winds up choosing h_i then, by Bayesian updating, the probability $P_{ij}^{|t}$ that its posterior picks h_j is given by:

$$P_{ij}^{|t} = \sum_{\mathbf{d} \in \mathcal{D}^{m_t}} \mathbb{P}[h_j|\mathbf{d}]\, \mathbb{P}[\mathbf{d}|h_i] = \sum_{\mathbf{d} \in \mathcal{D}^{m_t}} \frac{\mathbb{P}[\mathbf{d}|h_i]\, \mathbb{P}[\mathbf{d}|h_j]\, \mathbb{P}[h_j]}{\sum_{k=1}^{n} \mathbb{P}[\mathbf{d}|h_k]\, \mathbb{P}[h_k]}\,. \tag{2}$$

To our knowledge, the entire literature on the topic assumes a common, fixed sample size for all the learners: $m_t = m$. Equation (2) can be then interpreted as marginalizing a Gibbs sampler over the data space, which creates a Markov chain over the hypothesis space $\mathcal{H}$: if $\boldsymbol{h}^t$ denotes the row vector formed by the n probabilities $\mathbb{P}[h_k \,|\, \mathbf{d}_t]$, then $\boldsymbol{h}^t = \boldsymbol{h}^{t-1} P^t$, where $\boldsymbol{h}^0 = \boldsymbol{h}_{\texttt{init}}$. Assuming ergodicity (in this case, a fairly inconsequential technical assumption), the chain can be shown to converge to a unique stationary distribution $\boldsymbol{h}$. It can be easily checked that it coincides with the prior: $\boldsymbol{h} = (\mathbb{P}[h_1], \ldots, \mathbb{P}[h_n])$ [7, 13]; see [15, 16] for an analysis of the mixing time in specific linguistic scenarios. This convergence reveals the long-term unsustainability of iterated learning. We show how diversifying the sample sizes m_t, hence making the Markov chain time-inhomogeneous, can overcome this weakness.

Our results

In §2, we show how to achieve self-sustainability in the discrete setting [8, 7], using only a logarithmically increasing sample size; specifically, the new hypothesis to be learned is acquired by all the (infinitely many) learners with probability at least $1 - \varepsilon$ using a sample size of $O(\log \frac{t}{\varepsilon})$ for the t-th learner. The constant factor depends on the geometry of the hypothesis space. By relaxing the objective and allowing learners to settle on an arbitrarily close approximation of the hypothesis to be learned, we can remove all dependency on the geometry of the hypothesis space.

In §3, we extend the iterated learning model to a Gaussian setting for an infinite hypothesis space and show that a sample size of $O(t)^{1+o(1)}$ is sufficient to ensure self-sustainability. We also show that allowing learners to pick their teachers at random cuts down the sample size to $O(\log t)^{1+o(1)}$. The arguments used for the discrete case bump into singularities so we use a different approach, which allows us to exploit various "stability" properties of the Gaussian setting.

In §4, we turn our attention to the iterated version of Bayesian linear regression and prove a high-probability statement about self-sustainability. This requires spectral arguments from random matrix theory and, in particular, bounds on the lowest singular value of Wishart matrices.

Discussion

Before moving to the technical part of this work, we add a few thoughts about its larger context and relevance. For a dynamicist, the loss of Quenya is a byproduct of the memory-erasing ergodicity implied by mixing. For a physicist, the loss is due to the Second Law of thermodynamics and the bounded supply of free energy available to each agent: together these two constraints make it impossible to keep the system out of equilibrium. For a biologist, this entropic pull toward equilibrium is the hallmark of a dying system. Evolution is nature's attempt to optimize the absorption of free energy into work while maximizing

the production of entropy. The first requirement is keeping the system out of equilibrium over timescales well in excess of the metabolic rate (here, the teaching rate). From that perspective, our work can be seen as an effort to find out the minimum conditions necessary to keep a target dynamics active in perpetuity. There are several approaches to this question and the two we follow are among the simplest: (i) increasing the supply of free energy (eg, lengthening the training sessions) and (ii) mixing timescales (eg, rewiring the communication network).

Most of the work on Markov chains in theoretical computer science regards mixing as a blessing: large spectral gaps are good while small ones are to be avoided. In biology, however, mixing often means death. In fact, much of life can be seen as nature's attempt to keep mixing at bay. This paper explores what can be done to prevent a Markov chain from reaching equilibrium. We expect this theme to gain prominence in future work on natural algorithms.

2 Self-Sustainability

We show how to make iterated learning self-sustaining in the presence of a finite hypothesis space $\mathcal{H} = \{h_1, \ldots, h_n\}$. This involves specifying a sequence of training session lengths $m_1, m_2, \ldots$ so that the posterior of any learner ends up differing from $\boldsymbol{h}_{\texttt{init}}$ by an arbitrarily small amount. Formally, given any $\delta, \varepsilon \geq 0$, we say that iterated learning is (δ, ε)-*self-sustaining* if, with probability at least $1 - \varepsilon$, a random $h \in \mathcal{H}$ picked from any learner's posterior distribution differs from $\boldsymbol{h}_{\texttt{init}}$ in total variation by at most δ. We recall a few facts: the hypothesis h denotes a language modeled as a probability distribution over $\mathcal{D}$; the total variation distance is half the ℓ_1-norm; and the posterior of learner t after the t-th iteration is defined by marginalizing $\mathbb{P}[h|\mathbf{d}_t]$ over all samples $\mathbf{d}_t$ drawn from a random h picked from the posterior of learner $t-1$ (or $\boldsymbol{h}_{\texttt{init}}$ if $t = 1$). As a shorthand, we speak of ε-self-sustainability to refer to the case $\delta = 0$.

The parameters δ and ε allow us to distinguish between two metrics: the distance between two languages over $\mathcal{D}$ and the distance between two mixtures over $\mathcal{H}$. The two notions could differ widely. For example, if all of $\mathcal{H}$ corresponds to languages very close to $\boldsymbol{h}_{\texttt{init}}$, to achieve (δ, ε)-self-sustainability might be easy for a tiny $\delta > 0$ but hopelessly difficult for $\delta = 0$. The complexity of iterated learning depends on the geometry of the languages formed by the pure hypotheses. This is best captured by introducing a metric that, though more specialized than the total variation (it works only on the simplex of probability vectors) brings all sorts of technical benefits: the *root-sine distance* between two probability distributions $\boldsymbol{a} = (a_1, \ldots, a_s)$ and $\boldsymbol{b} = (b_1, \ldots, b_s)$ over $\mathcal{D}$ is defined as

$$d_{RS}(\boldsymbol{a}, \boldsymbol{b}) = \sqrt{\frac{1}{2} \sum_{i,j=1}^{s} \left(\sqrt{a_i b_j} - \sqrt{a_j b_i} \right)^2} = \sqrt{1 - \left(\sum_{i=1}^{s} \sqrt{a_i b_i} \right)^2}. \tag{3}$$

It would be surprising if this distance had not been used before, but we could not find a reference. We prove that it is indeed a metric in the Appendix and also explain its name. We show that it is related to the Hellinger, Bhattacharyya and total variation distances, d_H, d_B, d_{TV} by the following relations:

$$\begin{cases} d_H = \sqrt{1 - \sqrt{1 - d_{RS}^2}}\,; \\ d_B = -\frac{1}{2} \ln(1 - d_{RS}^2)\,; \\ d_{TV} \leq \sqrt{2s}\, d_{RS}. \end{cases} \tag{4}$$

2.1 The results

We focus on the "pure" case $\boldsymbol{h}_{\texttt{init}} \in \mathcal{H}$, and later briefly discuss how to generalize the method to mixed hypotheses. Using the shorthand $\mathtt{d}_{ij}$ for $d_{RS}(\mathbb{P}[\cdot|h_i], \mathbb{P}[\cdot|h_j])$, we define $\mathtt{d}_i := \min_{j:j\neq i} \mathtt{d}_{ij}$. Let $\boldsymbol{p} = (p_1, p_2, \ldots, p_n)$ be the prior distribution over $\mathcal{H}$, where $p_i := \mathbb{P}[h_i]$. We can obviously assume that each p_i is positive and that all the pure hypotheses are distinct, hence $\mathtt{d}_i > 0$. The two theorems below assume that $\boldsymbol{h}_{\texttt{init}} = h_1$.

▶ **Theorem 1.**. *For any positive $\varepsilon < 1$, the following sample size sequence makes iterated learning ε-self-sustaining:*

$$m_t = \frac{4}{\mathtt{d}_1^2} \ln \frac{nt}{\varepsilon\, p_1} = \frac{4}{\mathtt{d}_1^2}\Big(\log \frac{t}{\varepsilon} + C\Big),$$

for some $C > 0$ independent of $t, \varepsilon, \mathtt{d}_1$.

The factor 4 can be reduced to $2^{1+o(1)}$ if we adjust the constant C. It is to be expected that the lengths of the training sessions should grow to infinity as p_1 tends to zero, as the vanishing prior makes it increasingly difficult for the posteriors to "attach" to h_1. The session lengths are sensitive to the minimum distance between the languages specified by $\mathcal{H}$ and the target language h_1. Settling for (δ, ε)-self-sustainability allows us to remove this dependency.

▶ **Theorem 2.**. *For any positive $\delta, \varepsilon < 1$, the following sample size sequence makes iterated learning (δ, ε)-self-sustaining:*

$$m_t = \frac{8sn^2}{\delta^2}\Big(\ln \frac{t}{\varepsilon} + C\Big).$$

for some $C > 0$ independent of t, δ, ε.

2.2 The proofs

To establish Theorem 1, we estimate the probability P^* that each leaner ends up picking h_1. Recall that $\boldsymbol{h}^t$ is the posterior distribution of learner t, by the Markovian property of the system,

$$P^* = \mathbb{P}[\boldsymbol{h}^0 = h_1] \prod_{t\geq 0} \mathbb{P}[\boldsymbol{h}^{t+1} = h_1 | \boldsymbol{h}^t = h_1] = \prod_{t\geq 1} P_{11}^{|t}. \tag{5}$$

Since the matrix $P^{|t}$ is the transition matrix of a Markov chain, we proceed by bounding its off-diagonal elements $P_{ij}^{|t}$ for $i \neq j$. By (2) and Young's inequality,

$$\begin{aligned}
P_{ij}^{|t} &\leq \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \frac{\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]p_j}{\mathbb{P}[\mathbf{d}|h_i]p_i + \mathbb{P}[\mathbf{d}|h_j]p_j} = \frac{p_j}{p_i} \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \frac{\big(\frac{p_i}{p_j}\big)\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]}{\big(\frac{p_i}{p_j}\big)\mathbb{P}[\mathbf{d}|h_i] + \mathbb{P}[\mathbf{d}|h_j]} \\
&\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \sum_{\mathbf{d}\in\mathcal{D}^{m_t}} \sqrt{\mathbb{P}[\mathbf{d}|h_i]\,\mathbb{P}[\mathbf{d}|h_j]} = \frac{1}{2}\sqrt{\frac{p_j}{p_i}}\Big(\sum_{d\in\mathcal{D}} \sqrt{\mathbb{P}[d|h_i]\,\mathbb{P}[d|h_j]}\Big)^{m_t} \\
&\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \exp\left\{\frac{m_t}{2}\Big(\Big(\sum_{d\in\mathcal{D}} \sqrt{\mathbb{P}[d|h_i]\,\mathbb{P}[d|h_j]}\Big)^2 - 1\Big)\right\}.
\end{aligned}$$

By definition of the root-sine distance, we have

$$P_{ij}^{|t} \leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} e^{-\frac{1}{2}\mathtt{d}_{ij}^2 m_t} \quad (i \neq j). \tag{6}$$

Setting $i = 1$ in (6) and summing over $2 \le j \le n$, it follows by Cauchy-Schwarz that

$$\sum_{j=2}^{n} P_{1j}^{|t} \le \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}}\, e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}. \tag{7}$$

Combining (5) and (7) yields

$$P^* \ge \prod_{t\ge 1}\left(1 - \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}}\, e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}\right) \ge 1 - \frac{1}{2}\sqrt{\frac{n(1-p_1)}{p_1}}\sum_{t\ge 1} e^{-\frac{1}{2}\mathtt{d}_1^2 m_t}. \tag{8}$$

Given $0 < \varepsilon < 1$, we constrain the sequence (m_t) to satisfy:

$$\sum_{t\ge 1} e^{-\frac{1}{2}\mathtt{d}_1^2 m_t} < \varepsilon\sqrt{\frac{4p_1}{n(1-p_1)}}. \tag{9}$$

For example, we can pick the sequence

$$m_t = \frac{1}{\mathtt{d}_1^2}\ln\frac{n(1-p_1)t^4}{\varepsilon^2 p_1},$$

which completes the proof. A closer look at the calculation shows that the factor t^4 can be reduced to $C_\alpha t^{2+\alpha}$ for any small $\alpha > 0$ and a suitable constant $C_\alpha > 0$, which makes the dependency on t arbitrarily close to $(2/\mathtt{d}_1^2)\ln t$. ◀

To prove Theorem 2, we set a target distance $\rho := \delta/(n\sqrt{2s})$ and find a subset $A \subseteq \mathcal{H}$ such that (i) $\mathtt{d}_{1j} \le \rho n$ for $j \in A$ and (ii) $\mathtt{d}_{ij} \ge \rho$ for $i \in A$ and $j \notin A$. To see why such a subset must exist, consider spheres centered at $\boldsymbol{h}_{\mathtt{init}} = h_1$ of radius $k\rho$, for $k = 1, \ldots, n+1$ (with respect to d_{RS}). These define $n+1$ disjoint (open) regions and, by the pigeonhole principle, at least one of them must be empty. We set A to include all the points in the regions preceding the empty one; note that $h_1 \in A$. The claim follows from the triangular inequality. We begin with a straightforward generalization of (7): for any $i \in A$,

$$\sum_{j\notin A} P_{ij}^{|t} \le \frac{1}{2}\sqrt{\frac{n(1-p_A)}{p_A}}\, e^{-\frac{1}{2}\rho^2 m_t}, \tag{10}$$

where $p_A := \min_{i\in A} p_i$. Now let P^* be the probability that $\boldsymbol{h}^t \in A$ for each t, then (5) and (8) are generalized to

$$P^* \ge \prod_{t\ge 1}\left(1 - \max_{i\in A}\sum_{j\notin A} P_{ij}^{|t}\right) \ge 1 - \frac{1}{2}\sqrt{\frac{n(1-p_A)}{p_A}}\sum_{t\ge 1} e^{-\frac{1}{2}\rho^2 m_t}. \tag{11}$$

Setting

$$m_t = \frac{1}{\rho^2}\ln\frac{n(1-p_A)t^4}{\varepsilon^2 p_A} \tag{12}$$

ensures that $P^* > 1-\varepsilon$. The root-sine distance between the languages denoted by h_1 and any $h \in A$ is at most ρn, so that, by (4), the total variation distance is bounded by $\sqrt{2s}\rho n = \delta$, which concludes the proof of Theorem 2. ◀

So far, we have analyzed only the "pure" case $\boldsymbol{h}_{\mathtt{init}} \in \mathcal{H}$. The idea of the training is to prevent the prior to "drag" the posterior mixture all across $\mathcal{H}$. It should be clear that a

similar result obtains if $\boldsymbol{h}_{\texttt{init}} \in \Delta\mathcal{H}$ is concentrated on a subset A of $\mathcal{H}$. The proof follows the path charted in Theorem 2 and need not be repeated here. It is crucial to note, however, that this result is to be understood in a coarse-graining sense: iterated learning cannot ensure that the original weights in the mixture $\boldsymbol{h}_{\texttt{init}}$ are retained but only that A contributes most of the mass in the posteriors. To retain the weights would require changing the stationary distribution to conform with $\boldsymbol{h}_{\texttt{init}}$, as the process unfolds, something that straightforward Bayesian learning seems unable to do. Learning pure hypotheses bypasses that difficulty.

2.3 Applications

We briefly discuss a direct application of our results to a well-known model of language acquisition via iterated learning and we mention some natural extensions of the techniques.

Language evolution

Rafferty et al. [15] show how iterated learning fails rapidly in a simple model of language evolution. Given n hypotheses, iterated learning with fixed-length training sessions ceases to learn anything new after only $O(\log n \log\log n)$ rounds. The previous theorems show how to turn this around and achieve self-sustainality. In the model, $\mathcal{H} = \{h_1, \ldots, h_n\}$, where $n = 2^k$ and h_i denotes the language whose sentences are words in $\{0, 1, ?\}^k$ with exactly m question marks and $0, 1$ matching the binary decomposition of $i-1$ outside the question marks. For example, if $k = 4$ and $m = 2$, then h_3 denotes the language

$$\{\, 00??, 0?1?, ?01?, 0??0, ?0?0, ??10 \,\}.$$

We can assume that m is much smaller than k. Each language has the same length $\binom{k}{m}$ and the total number of sentences is $s = \binom{k}{m}2^{k-m}$. The prior is given by $\mathbb{P}[h_i] = p_i = 1/n$. Given a hypothesis h_i, $\mathbb{P}[d|h_i] = 1/\binom{k}{m}$ if d has m question marks and match the bits of $i-1$ elsewhere; else it is 0 (and d, h are called incompatible). Given $h \in \mathcal{H}$,

$$\begin{cases} \mathbb{P}[d] = \sum_{h\in\mathcal{H}} \mathbb{P}[d|h]\mathbb{P}[h] = 2^{m-k}/\binom{k}{m}\,; \\ \mathbb{P}[h|d] = \mathbb{P}[d|h]\mathbb{P}[h]/\mathbb{P}[d] = 2^{-m} \quad \text{(or 0 if } d, h \text{ are incompatible).} \end{cases}$$

We easily check that $\mathtt{d}_1^2 = 1 - \left(\sum_{i=1}^s \sqrt{a_i b_i}\right)^2 \geq 1 - \left(\frac{m}{k}\right)^2 > \frac{1}{2}$; hence, by Theorem 1, session lengths m_t no larger than $O(\log \frac{t}{\varepsilon})$ are sufficient to maintain ε-self-sustainability.

Meanings and utterances

In the use of iterated learning for studying language evolution [7, 14], it is common to model the data $\mathbf{d}$ as a joint distribution $(\boldsymbol{x}, \boldsymbol{y})$ over a product space $\mathcal{X}^{m_t} \times \mathcal{Y}^{m_t}$. The idea is to distinguish between "meanings" $\boldsymbol{x}$ and "utterances" $\boldsymbol{y}$. In this setting, $\mathbb{P}[\mathbf{d}|h] = \mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h]\mu(\boldsymbol{x})$, where $\mu(\boldsymbol{x})$ is the probability of generating $\boldsymbol{x}$. The transition matrix of the Markov chain thus becomes

$$\begin{aligned} P_{ij}^{|t} &= \sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}} \sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}} \mathbb{P}[h_j|\boldsymbol{x}, \boldsymbol{y}]\, \mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\mu(\boldsymbol{x}) \\ &= \sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}} \sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}} \frac{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\, \mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]\, \mathbb{P}[h_j]}{\sum_{k=1}^m \mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_k]\, \mathbb{P}[h_k]} \mu(\boldsymbol{x})\,. \end{aligned} \tag{13}$$

Since the output $\boldsymbol{y}$ now depends on both the hypothesis and the input data, we redefine $\mathtt{d}_{ij}$ as the root-sine distance between the two distributions $\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\mu(\boldsymbol{x})$ and $\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]\mu(\boldsymbol{x})$:

$$\mathtt{d}'_{ij} := 1 - \left(\sum_{\boldsymbol{x}\in\mathcal{X}} \sum_{\boldsymbol{y}\in\mathcal{Y}} \sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]}\,\mu(\boldsymbol{x}) \right)^2 \tag{14}$$

and we define $\mathtt{d}'_i := \min_{j:j\neq i} \mathtt{d}'_{ij}$. Given any $i \neq j$,

$$\begin{aligned}
P_{ij}^{|t} &\leq \sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}} \sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}} \frac{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]\,p_j}{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\,p_i + \mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]\,p_j}\mu(\boldsymbol{x}) \\
&\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \sum_{\boldsymbol{x}\in\mathcal{X}^{m_t}} \sum_{\boldsymbol{y}\in\mathcal{Y}^{m_t}} \sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\,\mathbb{P}[\mathbf{y}|\boldsymbol{x}, h_j]}\,\mu(\boldsymbol{x}) \\
&\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \Big(\sum_{\boldsymbol{x}\in\mathcal{X}} \sum_{\boldsymbol{y}\in\mathcal{Y}} \sqrt{\mathbb{P}[\boldsymbol{y}|h_i]\,\mathbb{P}[\boldsymbol{y}|h_j]}\,\mu(\boldsymbol{x}) \Big)^{m_t} \\
&\leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} \exp\left\{ \frac{m_t}{2} \Big(\Big(\sum_{\boldsymbol{x}\in\mathcal{X}} \sum_{\boldsymbol{y}\in\mathcal{Y}} \sqrt{\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_i]\,\mathbb{P}[\boldsymbol{y}|\boldsymbol{x}, h_j]}\,\mu(\boldsymbol{x}) \Big)^2 - 1 \Big) \right\}.
\end{aligned}$$

This gives us this new version of inequality (6), which we can use as the basis for a repeat of the argument of the previous section:

$$P_{ij}^{|t} \leq \frac{1}{2}\sqrt{\frac{p_j}{p_i}} e^{-\frac{1}{2}\mathtt{d}'^2_{ij} m_t} \qquad (i \neq j). \tag{15}$$

3 Iterated Learning in Continuous Spaces

When iterated learning operates over a hypothesis space $\mathcal{H}$ parametrized continuously, say, in $\mathbb{R}$, the minimum root-sine distance usually vanishes and the previous arguments run into singularities and collapse. A new approach is needed. To make our discussion concrete, we assume that the prior distribution of each learner is a Gaussian $\mathbb{P}[h] \sim N(\bar{\mu}, \bar{\sigma}^2)$ and that the likelihood of producing data d given hypothesis h is also normal: $\mathbb{P}[d|h] = N(h, \sigma^2)$. The likelihood can also be understood as a noisy measurement of h: $d = h + \phi$, where the noise $\phi \sim N(0, \sigma^2)$. We assume that the data received by the first learner comes from $N(\mu_0, \sigma_0^2)$. This is the simplest instance of a continuous setting in which the root-sine distance argument fails. We discuss it in some detail, considering both chained learning and its generalizations; and then we use the results to treat the case of iterated Bayesian linear regression.

During its training session, the t-th learner receives data $\mathbf{d}_t = (d_{t,1}, \ldots, d_{t,m_t})$ from its predecessor: it is obtained by first picking a random hypothesis h from the posterior of learner $t-1$ and then collecting m_t independent random samples from $N(h, \sigma^2)$. For the case $t = 1$, we can treat the original teacher as learner 0 with its posterior equal to $N(\mu_0, \sigma_0^2)$. Learner t Bayes-updates its posterior as follows:

$$\mathbb{P}[h|\mathbf{d}_t] \propto \mathbb{P}[\mathbf{d}_t|h]\mathbb{P}[h] \propto \exp\Big(-\frac{1}{2\sigma^2}\sum_{i=1}^{m_t}(d_{t,i} - h)^2\Big) \exp\Big(-\frac{1}{2\bar{\sigma}^2}(h - \bar{\mu})^2\Big),$$

which is still Gaussian, with mean and variance denoted by μ_t and σ_t^2, respectively. Carrying out the usual square completion gives up these update rules: for $t > 0$,

$$\begin{cases} \mu_t = \frac{1}{\bar{\tau}+m_t\tau}\left(\bar{\tau}\bar{\mu} + \tau(d_{t,1} + d_{t,2} + \cdots + d_{t,m_t})\right) \\ \tau_t \;= \bar{\tau} + m_t\tau, \end{cases} \tag{16}$$

where we define the precisions $\tau = 1/\sigma^2$, $\bar{\tau} = 1/\bar{\sigma}^2$, and $\tau_t = 1/\sigma_t^2$. We say that iterated learning is *ε-self-sustaining* if $|\mathbb{E}\,\mu_t - \mu_0| \le \varepsilon$ and $\sigma_t^2 + \operatorname{var}\mu_t$ remains bounded for all t. If $\sigma_t^2 + \operatorname{var}\mu_t \to 0$ as $t \to \infty$, we say that iterated learning is *strongly ε-self-sustaining*. We consider successively the case of chained iterated learning and the more challenging "hopping" scenario in which a new learner picks a random teacher from the past (instead of the previous one).

3.1 Chained learning

In chained iterated learning, the data $d_{t,i}$ is a noisy message drawn from the posterior of the $(t-1)$-th learner; hence $d_{t,i} \sim N(\mu_{t-1}, \sigma_{t-1}^2 + \sigma^2)$. In view of (16), μ_t is itself Gaussian. By taking the expectation and variance of equation (16), we find the following recursive relations for $\mathbb{E}\,\mu_t$ and $\operatorname{var}\mu_t$: for $t > 0$,

$$\begin{cases} \mathbb{E}\,\mu_t = \frac{1}{\bar{\tau}+m_t\tau}\big(\bar{\tau}\bar{\mu} + m_t\tau\,\mathbb{E}\,\mu_{t-1}\big); \\ \operatorname{var}\mu_t = \frac{m_t\tau^2}{(\bar{\tau}+m_t\tau)^2}\big(\operatorname{var}\,\mu_{t-1} + \sigma_{t-1}^2 + \sigma^2\big). \end{cases} \tag{17}$$

If we define $\beta_t := m_t\tau/(\bar{\tau} + m_t\tau)$, then (17) becomes $\mathbb{E}\,\mu_t = \beta_t\,\mathbb{E}\,\mu_{t-1} + (1-\beta_t)\bar{\mu}$. If $m_t = m$ is a constant, then so is β_t, and the recursive relation (17) becomes

$$\mathbb{E}\,\mu_t - \bar{\mu} = \beta_1^t(\mu_0 - \bar{\mu}),$$

which shows that $\mathbb{E}\,\mu_t$ converges to $\bar{\mu}$ exponentially fast. As in the discrete case, iterated learning is not self-sustainable with constant-length training sessions. By letting m_t increase as $O(t^{1+o(1)})$ order, however, we can achieve self-sustainability:

▶ **Theorem 3.** *For any $0 < \varepsilon < 1$, the following sample size sequence makes chained iterated learning strongly ε-self-sustaining:*

$$m_t = \frac{|\mu_0 - \bar{\mu}|}{\varepsilon}\Big(1 + \frac{1}{c}\Big)\Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 t^{1+c},$$

for an arbitrarily small constant $c > 0$.

Proof. We observe that $\mathbb{E}\,\mu_t$ is a convex combination of $\bar{\mu}$ and $\mathbb{E}\,\mu_s$ $(s < t)$; specifically,

$$\mathbb{E}\,\mu_t = \prod_{s=1}^{t}\beta_s\mu_0 + \Big(1 - \prod_{s=1}^{t}\beta_s\Big)\bar{\mu}. \tag{18}$$

Because $\sum_{s>0}(1/s)^{1+c} < 1 + \int_1^\infty x^{-1-c}\,dx = 1 + 1/c$, we have

$$\begin{aligned} 1 \;&\ge\; \prod_{s=1}^{t}\beta_s = \prod_{s=1}^{t}\Big(1 - \frac{\bar{\tau}}{m_s\tau + \bar{\tau}}\Big) \ge 1 - \sum_{s=1}^{t}\frac{\bar{\tau}}{m_s\tau + \bar{\tau}} \\ &\ge\; 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}\Big(\frac{c}{c+1}\Big)\sum_{s=1}^{\infty}\frac{1}{s^{1+c}} > 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}\,. \end{aligned}$$

This shows that

$$|\mathbb{E}\,\mu_t - \mu_0| = \Big(1 - \prod_{s=1}^{t}\beta_s\Big)|\bar{\mu} - \mu_0| \le \varepsilon.$$

By (16), $\sigma_t^2 = 1/\tau_t < 1/m_t\tau \to 0$. Since $\sigma_{t-1}^2 \le \bar{\sigma}^2$ for $t > 1$, it follows from (17) that $\operatorname{var}\mu_t \le (\operatorname{var}\mu_{t-1} + \sigma^2 + \bar{\sigma}^2)/m_t$ for $t > 1$, and $\operatorname{var}\mu_1 \le (\sigma_0^2 + \sigma^2)/m_1$. Writing $M_t := m_t m_{t-1} \dots m_1$, we have

$$\begin{aligned} M_t \operatorname{var}\mu_t &\le M_{t-1}\operatorname{var}\mu_{t-1} + M_{t-1}(\sigma^2 + \bar{\sigma}^2) \\ &\le tM_{t-1}(\sigma_0^2 + \sigma^2 + \bar{\sigma}^2), \end{aligned}$$

and thus $\operatorname{var}\mu_t \le (\sigma_0^2 + \sigma^2 + \bar{\sigma}^2)t/m_t \to 0$ since $m_t = \Omega(t^{1+c})$. ◀

3.2 Hopped learning

We consider the "hopped learning" scenario in which learner t hops back to pick a teacher from $\{0, 1, \dots, t-1\}$ at random, and then samples m_t bits of data from her posterior. The recursive relation for μ_t becomes

$$\mu_t = \frac{\beta_t}{m_t} \sum_{s=0}^{t-1} \chi_{t,s} \sum_{i=1}^{m_t} d_{t,s,i} + (1 - \beta_t)\bar{\mu}, \tag{19}$$

where, given t, the random variable $\chi_{t,s}$ is 1 for a value of s picked at random between 0 and $s-1$, and is zero elsewhere; recall that $\beta_t := m_t\tau/(\bar{\tau} + m_t\tau)$. Hopped iterated learning provides access to earlier data, so one would expect the lengths of the training sessions to grow more slowly than in chained learning. The change is indeed quite dramatic:

▶ **Theorem 4.** *For any positive $\varepsilon < |\mu_0 - \bar{\mu}|$, the following sample size sequence makes hopped iterating learning ε-self-sustaining:*

$$m_t = B_c \frac{|\mu_0 - \bar{\mu}|}{\varepsilon} \left(\frac{\sigma}{\bar{\sigma}}\right)^2 (1 + \log t)^{1+c},$$

for an arbitrarily small $c > 0$ and a constant B_c that depends only on c.

Proof. By taking expectation on both sides of (19), for any $t > 0$,

$$\mathbb{E}\,\mu_t = \frac{\beta_t}{t} \sum_{s=0}^{t-1} \mathbb{E}\,\mu_s + (1 - \beta_t)\bar{\mu},$$

We define $\gamma_1 = \beta_1$ and, for $t > 1$,

$$\gamma_t := (1 + \beta_1)\left(1 + \frac{\beta_2}{2}\right) \cdots \left(1 + \frac{\beta_{t-1}}{t-1}\right) \frac{\beta_t}{t}.$$

We verify easily that $\mathbb{E}\,\mu_t = \gamma_t\mu_0 + (1 - \gamma_t)\bar{\mu}$, for $t > 0$; therefore, the first part in establishing ε-self-sustainability consists of proving that

$$1 \ge \gamma_t \ge 1 - \frac{\varepsilon}{|\mu_0 - \bar{\mu}|}, \tag{20}$$

which will show that $|\mathbb{E}\,\mu_t - \mu_0| \le \varepsilon$. Note that

$$\gamma_t \le \frac{1}{t} \prod_{s=1}^{t-1} \left(1 + \frac{1}{s}\right) = 1.$$

Now define

$$\alpha_s = \frac{\varepsilon}{B_c |\mu_0 - \bar{\mu}| s (1 + \log s)^{1+c}}.$$

for $s > 0$. We pick a constant B_c large enough so that α_s is small enough to carry out first-order Taylor approximations around $1 + \alpha_s$. We find that

$$1 + \frac{\beta_s}{s} = 1 + \frac{1}{s}\Big(1 - \frac{1}{1 + m_t\tau/\bar\tau}\Big) \ge \Big(1 + \frac{1}{s}\Big)\Big(1 - \frac{1}{(s+1)m_t\tau/\bar\tau}\Big)$$
$$\ge \Big(1 + \frac{1}{s}\Big)\Big(1 - \frac{s\alpha_s}{s+1}\Big) \ge \Big(1 + \frac{1}{s}\Big)(1 - \alpha_s) \ge \Big(1 + \frac{1}{s}\Big)e^{-2\alpha_s}.$$

Thus,

$$\gamma_t \ge \frac{\beta_t}{t}\prod_{s=1}^{t-1}\Big(1 + \frac{1}{s}\Big)e^{-2\sum_{s=1}^{t-1}\alpha_s} = \beta_t e^{-2\sum_{s=1}^{t-1}\alpha_s} \ge 1 - \frac{\varepsilon}{|\mu_0 - \bar\mu|},$$

which establishes (20). Our derivation relies on the fact that

$$\beta_t \ge 1 - \frac{\varepsilon}{B_c|\mu_0 - \bar\mu|(1 + \log t)^{1+c}} \ge 1 - \frac{\varepsilon}{2|\mu_0 - \bar\mu|}$$

and

$$\sum_{s=1}^{t-1}\frac{1}{s(1+\log s)^{1+c}} \le 1 + \frac{1}{(\log e)^{1+c}}\int_2^{t-1}\frac{1}{x(\ln x)^{1+c}}\,dx = O\Big(\frac{1}{c}\Big);$$

hence,

$$e^{-2\sum_{s=1}^{t-1}\alpha_s} \ge e^{-O(\varepsilon/(cB_c|\mu_0-\bar\mu|))} \ge 1 - \frac{\varepsilon}{2|\mu_0 - \bar\mu|}.$$

Having shown that $|\mathbb{E}\,\mu_t - \mu_0| \le \varepsilon$ for all t, it now suffices to prove that $\sigma_t^2 + \operatorname{var}\mu_t$ remains bounded. We note that $\tau_t > m_t\tau \to \infty$, hence $\sigma_t^2 = 1/\tau_t \to 0$, so the remainder of the proof needs to establish that the variance of μ_t stays bounded. Writing $D_{t,s} := d_{t,s,1} + \cdots + d_{t,s,m_t}$, we have $\operatorname{var} D_{t,s} = m_t \operatorname{var} d_{t,s,1} = m_t(\sigma_s^2 + \sigma^2 + \operatorname{var}\mu_s)$; hence

$$\mathbb{E}\,D_{t,s}^2 = \operatorname{var} D_{t,s} + (\mathbb{E}\,D_{t,s})^2 = m_t(\sigma_s^2 + \sigma^2 + \operatorname{var}\mu_s) + m_t^2(\mathbb{E}\,\mu_s)^2.$$

In (19), the variables $\chi_{t,s}$ and $D_{t,s}$ are independent, for $0 \le s \le t-1$; furthermore, $\mathbb{E}\,\chi_{t,s} = \mathbb{E}\,\chi_{t,s}^2 = 1/t$, and $\mathbb{E}\,\chi_{t,s_1}\chi_{t,s_2} = 0$ if $s_1 \ne s_2$; therefore,

$$\operatorname{var}[\chi_{t,s}D_{t,s}] = \mathbb{E}\,\chi_{t,s}^2\,\mathbb{E}\,D_{t,s}^2 - (\mathbb{E}\,\chi_{t,s})^2(\mathbb{E}\,D_{t,s})^2 = \frac{\mathbb{E}\,D_{t,s}^2}{t} - \frac{(\mathbb{E}\,D_{t,s})^2}{t^2}$$
$$= \Big(\frac{m_t}{t}\Big)\big(\sigma_s^2 + \sigma^2 + \operatorname{var}\mu_s + m_t(\mathbb{E}\,\mu_s)^2\big) - \Big(\frac{m_t}{t}\Big)^2(\mathbb{E}\,\mu_s)^2 \tag{21}$$

and, for $s_1 \ne s_2$,

$$\begin{aligned}\operatorname{cov}[\chi_{t,s_1}D_{t,s_1}, \chi_{t,s_2}D_{t,s_2}] &= \mathbb{E}[\chi_{t,s_1}\chi_{t,s_2}D_{t,s_1}, D_{t,s_2}] - \mathbb{E}[\chi_{t,s_1}D_{t,s_1}]\mathbb{E}[\chi_{t,s_2}D_{t,s_2}]\\ &= \mathbb{E}[\chi_{t,s_1}\chi_{t,s_2}]\mathbb{E}[D_{t,s_1}D_{t,s_2}] - \mathbb{E}\,\chi_{t,s_1}\mathbb{E}\,D_{t,s_1}\mathbb{E}\,\chi_{t,s_2}\mathbb{E}\,D_{t,s_2}\\ &= -\frac{1}{t^2}\mathbb{E}\,D_{t,s_1}\mathbb{E}\,D_{t,s_2} = -\Big(\frac{m_t}{t}\Big)^2\mathbb{E}\,\mu_{s_1}\mathbb{E}\,\mu_{s_2}.\end{aligned} \tag{22}$$

Then, by taking the variance on both sides of (19), we have

$$\begin{aligned}
\operatorname{var}\mu_t &= \Big(\frac{\beta_t}{m_t}\Big)^2 \operatorname{var}\sum_{s=0}^{t-1}\chi_{t,s}D_{t,s}\\
&= \Big(\frac{\beta_t}{m_t}\Big)^2\Big(\sum_{s=0}^{t-1}\operatorname{var}\left[\chi_{t,s}D_{t,s}\right] + \sum_{0\le s_1\ne s_2\le t-1}\operatorname{cov}\left[\chi_{t,s_1}D_{t,s_1},\chi_{t,s_2}D_{t,s_2}\right]\Big)\\
&= \Big(\frac{\beta_t}{m_t}\Big)^2\Big(\sum_{s=0}^{t-1}\Big(\frac{m_t}{t}\Big)\big(\sigma_s^2+\sigma^2+\operatorname{var}\mu_s+m_t(\mathbb{E}\,\mu_s)^2\big) - \Big(\frac{m_t}{t}\Big)^2\Big(\sum_{s=0}^{t-1}\mathbb{E}\,\mu_s\Big)^2\Big)\\
&\le \frac{1}{tm_t}\sum_{s=0}^{t-1}\big(\sigma_s^2+\sigma^2+\operatorname{var}\mu_s+m_t(\mathbb{E}\,\mu_s)^2\big).
\end{aligned}$$

Notice that $\sigma_s^2\to 0$ and $(\mathbb{E}\,\mu_s)^2$ is bounded since $|\mathbb{E}\,\mu_t-\mu_0|\le\varepsilon$. We conclude that $\sigma_t^2+\operatorname{var}\mu_t$ remains bounded for all t. ◀

4 Iterated Bayesian Linear Regression

The iterated version of Bayesian linear regression has been the subject of extensive study in the field of psychology [11, 2, 19, 1, 9]. The work has involved experimentation with human subjects but little in the way of theoretical analysis. This section is a first step toward filling this void. The task at hand is to estimate a hypothesis $h\in\mathcal{H}:=\mathbb{R}^d$ given a noisy measurements on the hyperplane $y=h^Tx$, where $x\in\mathbb{R}^d$. In the Bayesian setting, we assume a Gaussian prior on the hypothesis space: $\mathbb{P}[h]\sim N(\bar\mu,\bar\sigma^2 I_d)$. The data is given by (x,y), where $x\sim N(0,I_d)$ and $y=h^Tx+\phi$, for $\phi\sim N(0,\sigma^2)$ (with x,ϕ independent). Since we typically make several measurements, we write this (likelihood) relation in matrix form: $y=Xh+\phi$, where $y\in\mathbb{R}^m$ (with m the number of measurements); $\phi\sim N(0,\sigma^2 I_m)$; and X is an m-by-d matrix each of whose rows denotes a random vector $x\sim N(0,I_d)$. This means that the matrix X is random (a fact of key importance in our discussion below). We have:

$$\begin{cases}
\mathbb{P}[\phi]\sim \exp\{-\frac{1}{2\sigma^2}\|\phi\|_2^2\} & \texttt{(noise)}\\
\mathbb{P}[h]\sim \exp\{-\frac{1}{2\bar\sigma^2}\|h-\bar\mu\|_2^2\} & \texttt{(prior)}\\
\mathbb{P}[y|X,h]\sim \exp\{-\frac{1}{2\sigma^2}\|y-Xh\|_2^2\} & \texttt{(likelihood)}
\end{cases}$$

In iterated Bayesian linear regression, the t-th learner receives her data from learner $t-1$. Here, learner 0 is treated just like any other agent, except that his prior $\mathbb{P}[h]\sim N(\mu_0,\bar\sigma^2 I_d)$ is the distribution to be learned iteratively. Since sampling from the prior is independent of X, Bayesian updating gives the posterior $N(\mu_t,\Sigma_t)$, where

$$\mathbb{P}[h|X,y]=\mathbb{P}[h]\,\mathbb{P}[y|X,h]/\mathbb{P}[y|X]\sim\exp\Big\{-\frac{1}{2\bar\sigma^2}\|h-\bar\mu\|_2^2-\frac{1}{2\sigma^2}\|y-Xh\|_2^2\Big\}.$$

Completing the square in the usual fashion shows that the posterior of learner t is given by:

$$\begin{cases}
\Sigma_t=\left(\bar\sigma^{-2}I_d+\sigma^{-2}X_t^TX_t\right)^{-1};\\
\mu_t=\Sigma_t\left(\bar\sigma^{-2}\bar\mu+\sigma^{-2}X_t^Ty_t\right),
\end{cases}\tag{23}$$

where (X_t,y_t) is the data gathered by learner t from her predecessor: specifically, $y_t=X_th+\phi_t$, where h is collected from the $(t-1)$-th learner by sampling his posterior distribution $N(\mu_{t-1},\Sigma_{t-1})$.

▶ **Theorem 5.** *Given any small enough $\delta, \varepsilon > 0$, the following sample size sequence for iterated Bayesian linear regression ensures that $\|\mathbb{E}\mu_t - \mu_0\|_2 \leq \delta$ with probability greater than $1 - \varepsilon$:*

$$m_t = D_c \frac{\|\mu_0 - \bar{\mu}\|_2}{\delta} \left(\frac{\sigma}{\bar{\sigma}}\right)^2 t^{1+c} + D_c\, d \log \frac{t+1}{\varepsilon},$$

for an arbitrarily small $c > 0$ and a constant D_c that depends only on c.

Proof. We proceed in two steps: first, we show that to keep $\mathbb{E}\mu_t$ arbitrarily close to μ_0 for all t hinges on spectral properties of certain random matrices; second, we call on known facts about the singular values of random Gaussian matrices to translate the spectral condition into a high-probability event. The proof unfolds as a series of simple relations, which we state first and then demonstrate. The first one follows directly from (23):

$$\mathbb{E}\mu_t = (I_d + M_t)^{-1} (\bar{\mu} + M_t\, \mathbb{E}\mu_{t-1}), \quad \text{where} \quad M_t := \left(\frac{\bar{\sigma}}{\sigma}\right)^2 X_t^T X_t. \tag{24}$$

Note that (24) is a randomized recursive relation since the data points $X_1, X_2, \ldots$ are themselves random. We note that all the matrices whose inverses are taken are positive definite, hence nonsingular. To move on to our second relation, we define the matrix

$$Q_t := (I_d + M_t)^{-1} M_t (I_d + M_{t-1})^{-1} M_{t-1} \cdots (I_d + M_1)^{-1} M_1,$$

for $t > 0$, with $Q_0 = I_d$, and prove by induction that

$$\mathbb{E}\,\mu_t = Q_t \mu_0 + (I_d - Q_t)\bar{\mu}. \tag{25}$$

The base case is obvious so we assume that $t > 0$: by (24),

$$\begin{aligned}
\mathbb{E}\,\mu_t &= (I_d + M_t)^{-1}(\bar{\mu} + M_t\, \mathbb{E}\,\mu_{t-1}) \\
&= (I_d + M_t)^{-1}(\bar{\mu} + M_t Q_{t-1}\mu_0 + M_t(I_d - Q_{t-1})\bar{\mu}) \\
&= (I_d + M_t)^{-1} M_t Q_{t-1}\mu_0 + (I_d + M_t)^{-1}(I_d + M_t(I_d - Q_{t-1}))\bar{\mu} \\
&= Q_t\, \mu_0 + (I_d - (I_d + M_t)^{-1} M_t Q_{t-1})\bar{\mu},
\end{aligned}$$

which proves (25). Our next goal is to bound the information decay $\|\mathbb{E}\,\mu_t - \mu_0\|_2$. To do that, we investigate the spectral norm of the matrix $I_d - Q_t$, which leads to our third relation. We prove by induction that, for $t > 0$,

$$\|I_d - Q_t\|_2 \leq \sum_{s=1}^{t} \|A_s\|_2, \tag{26}$$

where $A_s := (I_d + M_s)^{-1}$. For $t = 1$, $Q_1 = (I_d + M_1)^{-1} M_1 = I_d - (I_d + M_1)^{-1}$ and the claim follows. If $t > 1$, then

$$\begin{aligned}
\|I_d - Q_t\|_2 &= \|(I_d - Q_{t-1}) + (Q_{t-1} - Q_t)\|_2 \\
&\leq \|I_d - Q_{t-1}\|_2 + \|Q_t - Q_{t-1}\|_2 \leq \sum_{s=1}^{t-1} \|A_s\|_2 + \|\Psi\|_2,
\end{aligned}$$

where $\Psi := (A_t M_t - I_d) Q_{t-1}$. Since $A_t(I_d + M_t) = I_d$, we have $\Psi = -A_t Q_{t-1}$. Each matrix M_s is positive semidefinite, so the eigenvalues of $(I_d + M_s)^{-1} M_s$ are of the form $\lambda/(1+\lambda)$, where $\lambda \geq 0$. This shows that all the eigenvalues of Q_s are between 0 and 1;

therefore $\|Q_s\|_2 \le 1$. The eigenvalues of $I_d - A_t M_t$ are the same as those of A_t; hence, by submultiplicativity, $\|\Psi\|_2 \le \|A_t\|_2 \|Q_{t-1}\|_2 \le \|A_t\|_2$, which establishes (26).

We are now ready to express the information decay in spectral terms. Pick an arbitrarily small constant $c > 0$ and assume that

$$\|A_s\|_2 \le \frac{\delta}{\|\bar{\mu} - \mu_0\|_2} \Big(\frac{c}{1+c}\Big) \Big(\frac{1}{s}\Big)^{1+c}. \tag{27}$$

By (25), $\mathbb{E}\,\mu_t - \mu_0 = (I_d - Q_t)(\bar{\mu} - \mu_0)$; therefore, by (26),

$$\begin{aligned} \|\mathbb{E}\,\mu_t - \mu_0\|_2 &\le \|\bar{\mu} - \mu_0\|_2 \sum_{s=1}^{t} \|A_s\|_2 \le \frac{\delta c}{1+c} \sum_{s=1}^{t} s^{-1-c} \\ &\le \frac{\delta c}{1+c} \Big(1 + \int_1^{\infty} x^{-1-c}\, dx\Big) = \delta, \end{aligned} \tag{28}$$

The relation says that, on average, the means of any of the agents' posteriors can be brought as close to the original mean to be learned as we want. We can turn this into a high-probability event by using some basic random matrix theory. Recall that $\mathbb{E}\,\mu_t$ is itself a random variable whose stochasticity comes from the matrices X_s, which are all drawn from Gaussians. Because M_s is positive semidefinite,

$$\|A_s\|_2 \le \|M_s^{-1}\|_2 \le \frac{(\sigma/\bar{\sigma})^2}{\lambda_{\min}(X_t^T X_t)} \le \Big(\frac{\sigma/\bar{\sigma}}{\sigma_1(X_t)}\Big)^2, \tag{29}$$

which gives us a relation between the spectral norm of $(I_s + M_s)^{-1}$ and the smallest singular value $\sigma_1(X_t)$ of an m_t-by-d matrix X_t whose elements are drawn *iid* from $N(0,1)$. The asymptotic behavior of $\sigma_1(X_t)$ for large values of m_t has been extensively studied within the field of random matrix theory [5, 6, 17]. Following Theorem II.13 in (Davidson & Szarek [5]), for any $\gamma_t > 0$,

$$\mathbb{P}[\sigma_1(X_t) < \sqrt{m_t} - \sqrt{d} - \gamma_t] \le e^{-\gamma_t^2/2}.$$

We use C below as a generic constant large enough to satisfy the inequalities where it appears. Setting $\gamma_t = C\sqrt{\log((t+1)/\varepsilon)}$ ensures that $\sum_{t>0} e^{-\gamma_t^2/2} < \varepsilon$, hence that $\sigma_1(X_t) < \sqrt{m_t} - \sqrt{d} - \gamma_t$ holds for all t with probability less than ε. With our setting of m_t, this means that, for all $t > 0$,

$$\mathbb{P}\Big[\,\sigma_1(X_t) \ge \frac{\sqrt{m_t}}{2}\,\Big] > 1 - \varepsilon. \tag{30}$$

Assuming the event in (30), it follows from (29) and our setting of m_t that

$$\|A_t\|_2 \le \frac{4}{m_t} \Big(\frac{\sigma}{\bar{\sigma}}\Big)^2 \le \frac{\delta}{\|\bar{\mu} - \mu_0\|_2} \Big(\frac{4}{D_c}\Big) \Big(\frac{1}{t}\Big)^{1+c};$$

hence (27) for D_c large enough. By (28, 30), this proves that, with probability greater than $1 - \varepsilon$, $\|\mathbb{E}\,\mu_t - \mu_0\|_2 \le \delta$ for all $t > 0$, which completes the proof. ◀

A Appendix

The two forms of the function d_{RS} in (3) make it clear that $0 \leq d_{RS}(\boldsymbol{a}, \boldsymbol{b}) \leq 1$ and $d_{RS}(\boldsymbol{a}, \boldsymbol{b}) = 0$ if and only if $\boldsymbol{a}$ and $\boldsymbol{b}$ are identical. We easily check that d_{RS} makes the simplex $\mathcal{S}$ of distributions over $\mathcal{D}$ into a metric space. Indeed, $d_{RS}(\cdot, \cdot)$ is obviously symmetric, and $d_{RS}(\boldsymbol{a}, \boldsymbol{b}) = 0$ implies that $\boldsymbol{a} = \boldsymbol{b}$. To check the triangular inequality, notice that

$$d_{RS}(\boldsymbol{a}, \boldsymbol{b}) = \sqrt{1 - \Big(\sum_{i=1}^{s} \sqrt{a_i b_i}\Big)^2} = \sin\langle \sqrt{\boldsymbol{a}}, \sqrt{\boldsymbol{b}} \rangle, \tag{31}$$

where $\langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,\rangle$ is the angle between the unit vectors $\sqrt{\boldsymbol{a}}$ and $\sqrt{\boldsymbol{b}}$, using the notation $\sqrt{\boldsymbol{v}} = (\sqrt{v_1},\ldots,\sqrt{v_s})$. To prove that $d_{RS}(\boldsymbol{a},\boldsymbol{b}) + d_{RS}(\boldsymbol{b},\boldsymbol{c}) \geq d_{RS}(\boldsymbol{a},\boldsymbol{c})$ for any $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c} \in \mathcal{S}$, we denote by α,β,γ the corresponding angles in that order, ie, $\alpha = \langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,\rangle$, etc. The coordinates in $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c}$ are nonnegative; therefore $0 \leq \alpha,\beta,\gamma \leq \pi/2$. These form the three angles at the origin of a tetrahedron with a vertex at the origin; therefore, by the triangular inequality in spherical geometry, $\alpha+\beta \geq \gamma$. If $\alpha+\beta \leq \frac{\pi}{2}$, then $\sin\alpha+\sin\beta \geq \sin\alpha\cos\beta+\cos\alpha\sin\beta = \sin(\alpha+\beta) \geq \sin\gamma$. On the other hand, if $\alpha+\beta > \pi/2$, then $\sin\alpha+\sin\beta = 2\sin\frac{\alpha+\beta}{2}\cos\frac{\alpha-\beta}{2} \geq 2\sin\frac{\pi}{4}\cos\frac{\pi}{4} = 1 \geq \sin\gamma$, which establishes the triangular inequality.

Relation to the Euclidean distance

Shrinking the simplex $\mathcal{S}$ by a tiny amount, we define $\mathcal{S}_\varepsilon := \{\boldsymbol{a} \in \mathcal{S} : \varepsilon \leq a_i \leq 1-\varepsilon\}$ and note that

$$d_E(\boldsymbol{a},\boldsymbol{b}) := \|\boldsymbol{a}-\boldsymbol{b}\|_2 = \sqrt{\sum_{i=1}^{s}(\sqrt{a_i}-\sqrt{b_i})^2(\sqrt{a_i}+\sqrt{b_i})^2}.$$

It follows that, for $\boldsymbol{a},\boldsymbol{b} \in \mathcal{S}_\varepsilon$,

$$\frac{1}{2}d_E(\boldsymbol{a},\boldsymbol{b}) \leq d_E(\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,) \leq \frac{1}{2\sqrt{\varepsilon}}\,d_E(\boldsymbol{a},\boldsymbol{b}). \tag{32}$$

On the other hand, $\|\sqrt{\boldsymbol{a}}\|_2 = \|\sqrt{\boldsymbol{b}}\|_2 = 1$, so the vectors $\sqrt{\boldsymbol{a}}$ and $\sqrt{\boldsymbol{b}}$ form an isosceles triangle; hence

$$d_E(\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,) = 2\sin\frac{1}{2}\langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\rangle = \frac{\sin\langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\rangle}{\cos\frac{1}{2}\langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\rangle} = \frac{d_{RS}(\boldsymbol{a},\boldsymbol{b})}{\cos\frac{1}{2}\langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\rangle}\,.$$

Since $0 \leq \langle\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,\rangle \leq \frac{\pi}{2}$,

$$d_{RS}(\boldsymbol{a},\boldsymbol{b}) \leq d_E(\sqrt{\boldsymbol{a}},\sqrt{\boldsymbol{b}}\,) \leq \sqrt{2}\,d_{RS}(\boldsymbol{a},\boldsymbol{b}).$$

Together with (32) this shows that, for any $\boldsymbol{a},\boldsymbol{b} \in \mathcal{S}_\varepsilon$,

$$\frac{1}{2\sqrt{2}}\,d_E(\boldsymbol{a},\boldsymbol{b}) \leq d_{RS}(\boldsymbol{a},\boldsymbol{b}) \leq \frac{1}{2\sqrt{\varepsilon}}\,d_E(\boldsymbol{a},\boldsymbol{b}), \tag{33}$$

which shows that the Euclidean distance and the metric d_{RS} are equivalent in $\mathcal{S}_\varepsilon$.

Relation to other distances

The metric d_{RS} is related to the Hellinger and Bhattacharyya distances. Writing $C(\boldsymbol{a},\boldsymbol{b}) = \sum_{i=1}^{s}\sqrt{a_ib_i}$ [4], then $d_{RS}(\boldsymbol{a},\boldsymbol{b}) = \sqrt{1-C(\boldsymbol{a},\boldsymbol{b})^2}$. The Hellinger distance is defined as $d_H(\boldsymbol{a},\boldsymbol{b}) = \sqrt{1-C(\boldsymbol{a},\boldsymbol{b})}$ [10], while the Bhattacharyya distance is defined as $d_B(\boldsymbol{a},\boldsymbol{b}) = -\ln C(\boldsymbol{a},\boldsymbol{b})$ [3]. The total variation distance d_{TV} is half the ℓ_1-norm; therefore $d_{TV}(\boldsymbol{a},\boldsymbol{b}) \leq \frac{1}{2}\sqrt{s}\,d_E(\boldsymbol{a},\boldsymbol{b})$. Combining these observations with (33) establishes (4):

$$\begin{cases} d_H = \sqrt{1-\sqrt{1-d_{RS}^2}}\,; \\ d_B = -\frac{1}{2}\ln(1-d_{RS}^2)\,; \\ d_{TV} \leq \sqrt{2s}\,d_{RS}. \end{cases}$$

Coding in Undirected Graphs Is Either Very Helpful or Not Helpful at All

Abstract

While it is known that using network coding can significantly improve the throughput of directed networks, it is a notorious open problem whether coding yields *any* advantage over the multicommodity flow (MCF) rate in undirected networks. It was conjectured in [11] that the answer is 'no'. In this paper we show that even a small advantage over MCF can be amplified to yield a near-maximum possible gap.

We prove that any undirected network with k source-sink pairs that exhibits a $(1+\varepsilon)$ gap between its MCF rate and its network coding rate can be used to construct a family of graphs G' whose gap is $\log(|G'|)^c$ for some constant $c < 1$. The resulting gap is close to the best currently known upper bound, $\log(|G'|)$, which follows from the connection between MCF and sparsest cuts.

Our construction relies on a gap-amplifying graph tensor product that, given two graphs G_1, G_2 with small gaps, creates another graph G with a gap that is equal to the product of the previous two, at the cost of increasing the size of the graph. We iterate this process to obtain a gap of $\log(|G'|)^c$ from any initial gap.

1 Introduction

The area of network coding addresses the following basic problem: in a distributed communication scenario, can one use coding to outperform packet routing-based solutions? While the problem of communicating information over a network can be viewed as the process of moving information packets between terminals, a key distinction between moving packets and moving commodities is that information packets can be re-encoded by intermediate nodes. For example, a node which receives packets P_1 and P_2 can calculate and transmit the bitwise XOR packet $P_1 \oplus P_2$ to its neighbor. This operation has no analogue in multicommodity flow scenarios.

Whether (and to what extent) this ability confers any benefits over the simple routing-based solution, depends on the specific goal of the communication at hand. Such goals may include uni-cast and multi-cast throughput, error-resilience and security, to name a few. These questions have been the subject of active study in the recent past. A summary of major directions can be found in the books [14, 13], and surveys [5, 15].

In this paper we focus on noiseless unicast communication. The network is a capacitated graph G with k source-sink terminal pairs (s_i, t_i). Each source vertex s_i wants to transmit an information stream to t_i. The network coding rate $\mathrm{NC}(G)$ is the maximum rate at which transmission between all pairs can happen simultaneously, given the capacity constraints [2].

If we forbid coding, and restrict nodes to forwarding information packets that they receive, the problem becomes equivalent to multicommodity flow over G — the very well-studied problem of maximizing the rate $\mathrm{MCF}(G)$ at which commodities are moved from sources to sinks subject to the capacity constraints (see e.g. [3] for background). Clearly, the multicommodity rate can always be achieved — but can it be beaten using "bit tricks"?

If the graph G is directed, there are well-known examples which show that coding can improve throughput in a very dramatic way [7, 1]. There is a family of examples G, where the gap between the multicommodity flow rate and network coding throughput is as large as $O(|G|)$. Despite substantial effort, it is not clear whether coding confers *any* benefit over routing in undirected networks. Li and Li [11] conjectured that the answer is 'no'. This conjecture is currently open.

It is known that the Li and Li conjecture holds in some special cases. Naturally, it holds whenever the sparsity of the graph matches the multicommodity flow rate. For cases where these quantities are not equal, [8] and [9] show that the conjecture is true for the Okamura-Seymour graph and [8, 1] show it for an infinite family of bipartite graphs. Empirical evidence also suggests that the conjecture is true [12].

One simple case where coding rate cannot exceed capacity is the case when the channel is a single edge: two parties cannot be sending messages to each other at a total rate exceeding the channel's capacity. This is a simple consequence of Shannon's Noiseless Coding Theorem. As a simple corollary, the sparsest cut in G provides an upper bound for the network coding rate $\mathrm{NC}(G)$. The sparsity of a cut $(U, V \setminus U)$ is defined as

$$\mathrm{Sparsity}(U, V \setminus U) := \frac{\mathrm{Capacity}(U, V \setminus U)}{\mathrm{Demand}(U, V \setminus U)} \tag{1}$$

If we merge the vertices on either side of the cut, the network coding rate becomes $\mathrm{Sparsity}(U, V \setminus U)$. Merging nodes can only increase network coding rate, and thus we have $\mathrm{NC}(G) \leq \mathrm{Sparsity}(U, V \setminus U)$. Since the sparsity of G is defined as the minimum of (1) over all cuts, we have $\mathrm{NC}(G) \leq \mathrm{Sparsity}(G)$.

As discussed below, the multicommodity flow problem is very well-studied. In the one commodity case, the Max-Flow Min-Cut Theorem asserts that sparsity is equal to the flow rate. In the multicommodity case, the sparsity is still an upper bound on the multicommodity flow rate $\mathrm{MCF}(G)$, but it might be loose by a factor of $\log |G|$:

$$\mathrm{Sparsity}(G)/O(\log |G|) \leq \mathrm{MCF}(G) \leq \mathrm{Sparsity}(G). \tag{2}$$

Thus the advantage one can gain for network coding over undirected graphs is at most $O(\log |G|)$:

$$\mathrm{NC}(G)/O(\log |G|) \leq \mathrm{Sparsity}(G)/O(\log |G|) \leq \mathrm{MCF}(G) \leq \mathrm{NC}(G). \tag{3}$$

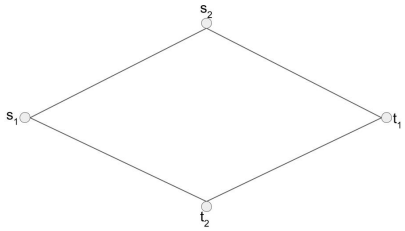

Figure 1 Graph G_1 and G_2.

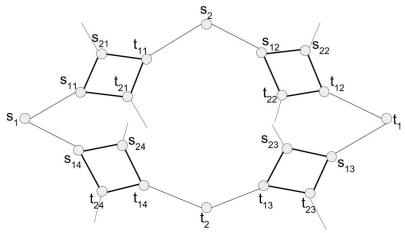

Figure 2 Basic gadget that embeds a copy of G_2 into each edge of G_1. The edges coming out of the copies will be used to connect to other copies of the outer graph (G_1). Labelled source-sink pairs of G_2 are just for reference. The thin edges are just an artifact and their respective end points represent a single vertex.

The Li and Li conjecture asserts that the rightmost '$\leq$' is indeed an equality. Our main result is that either the conjecture is true, or it must be nearly 'completely false': the gap between $\mathrm{NC}(G)$ and $\mathrm{MCF}(G)$ can be as high as poly-logarithmic in $|G|$.

▶ **Theorem 1.** *Given a graph G that achieves a gap of $1+\epsilon$ between the multicommodity flow rate and the network coding rate, we can construct an infinite family of graphs $\widetilde{G}$ that achieve a gap of $O\left(\log|\widetilde{G}|\right)^c$ for some constant $c<1$ that depends on the original graph G.*

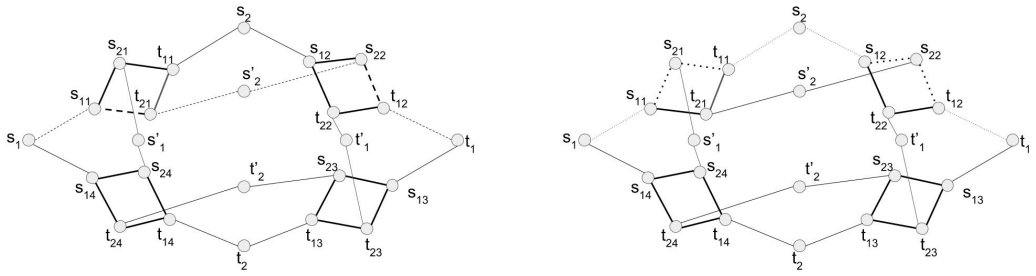
In order to prove Theorem 1, we will show a simpler construction that can be applied repeatedly.

▶ **Theorem 2.** *Given a graph G of size n with a gap of $1+\epsilon$ between the multicommodity flow rate and the network coding rate, we can create another graph G' of size n^{c^2} and a gap of $(1+\epsilon)^2$, where c depends on the diameter of the graph G.*

The idea of gap-amplification in the context of network coding has been studied before. In [4] the authors combine linear programming techniques with hypergraph product operations to prove general gap amplification results between linear and non-linear network coding for directed graphs.

Proof outline

The main part of the construction is to define a *graph tensor* on graphs G_1 and G_2 that have gaps of $1+\epsilon_1$ and $1+\epsilon_2$ respectively, between the multicommodity flow rate and the network coding rate, which gives a new graph G with a gap of $(1+\epsilon_1)(1+\epsilon_2)$ while keeping a check on the size of G. We can then take a graph with a small gap and tensor it with itself to produce a graph with an even larger gap. Repeatedly tensoring the output of the previous iteration with itself will give us Theorem 1.



(a) A cheating path is highlighted with dashed edges.

(b) An honest path is highlighted with dotted edges.

Figure 3 Two copies of G_1 (with source-sink pairs $s_1 - t_1, s_2 - t_2$ and $s'_1 - t'_1, s'_2 - t'_2$, respectively) have 8 edges. These edges are replaced with 4 copies of G_2, each copy having two source-sink pairs. All edges in the first copy of G_1 are replaced with s_{1X}-t_{1X} source-sink pairs of G_2; edges in the second copy of G_2 are replaced with s_{2X}-t_{2X} source-sink pairs of G_2

In G_2, network coding allows us to send more information from every source to its corresponding sink than what simple flows allow. We construct a gadget for the graph tensor exploiting this fact as in Figure 2. We replace each edge of G_1 by a copy of G_2 with endpoints at a deterministic source-sink pair. We keep the source-sink pairs of G_1 and edges of G_2.

For simplicity, assume that each edge in Figure 1 has capacity 1. The effective capacity at each edge seen by G_1 under network coding is more than that under flows. Intuitively, replacing each edge with a source-sink pair of G_2 should give network coding a "capacity advantage" of $(1 + \epsilon_2)$ over multicommodity flow. Since the information transferred grows linearly with the capacity, the new information exchanged between source-sink pairs in the gadget under network coding should be $(1 + \epsilon_1)(1 + \epsilon_2)$ times the information exchanged under flows.

We need to be careful because G_2 exhibits a gap only when we need to send information from all sources simultaneously. We address this by adding more copies of G_1 to the graph tensor and replacing its edges with other source-sink pairs of the copies of G_2 as in Figure 3. In each copy of G_1, we replace all edges with the same source-sink pair of G_2. At the same time, each copy of G_2 serves to replace the same edge in all copies of G_1. This is done to facilitate the proof of the upper bound on the MCF rate in the resulting graph.

Our work is not done here. It is easy to get a lower bound on the network coding rate on the final graph G by just showing a network coding solution. For this, informally, we just compose the network coding solutions for G_1 and G_2. The hard part is to get an upper bound on the multicommodity flow rate. Since MCF is a linear program, we can upper bound the value of multicommodity flows by looking at the dual solution of its relaxed linear program. This dual, described in Section 2, involves computing shortest distances between source-sink pairs under some metric. This metric readily tensorizes: we can take the length of an edge in a copy of G_2 to be the product of the length of that edge in G_2 times the length of the edge(s) in G_1 this particular copy of G_2 is replacing. The problem is to get the lengths of *whole paths* to tensorize.

What could go wrong? Consider Figure 3. We would ideally want the dotted paths as in Figure 3b to be the shortest path between $S1$ and $T1$ in G', since its length is the length of the shortest $s_1 - t_1$ path in G_1 times the length of the shortest $s_{1X} - t_{1X}$ path in G_2. Unfortunately, during the tensoring operation we inadvertently introduce additional $s_1 - t_1$ paths that do not correspond to "products" of paths from G_1 and G_2. For example, the dashed path in Figure 3a is a "cheating" path which can make the distance between s_1 and t_1 shorter than expected. We deter the use of "cheating" paths by increasing the number of

hops between different copies of G_1 that a path has to take before it reaches the same copy again. The technical ingredient which prevents such cheating is in the design of the bipartite graph which tells which copy of G_1 should use which copies of G_2 (and how to connect them). To prevent cheating, the bipartite graph will need to be of high girth. The crucial part of the construction is thus constructing high girth bipartite graphs while still keeping check on the size so as to get a $O(\log(\text{size})^c)$ $(c < 1)$ gap when the tensor is applied repeatedly.

Discussion

A natural question arises: Can we have a tensor construction that starts with a graph G having some gap between the multicommodity flow rate and the network coding rate and outputs a graph G' with gap $\omega(\log(|G'|))$, thus contradicting (3) and proving the Li and Li conjecture? We address this question with respect to our construction in Section 4. We show that the MCF vs. Sparsest Cut gap tensorizes for our construction, and thus the tensorization process on its own cannot cause the gap to exceed $O(\log |G'|)$.

At the same time, if one's goal is to prove the conjecture, it might be easier to reach a contradiction to the gap being $(\log |G|)^c$ than to a constant gap.

2 Preliminaries

In this section we introduce the problems that we will be interested in studying and any relevant notation. Where appropriate, we use the same notation and definitions as [1, 7].

When $G = (V, E)$ is a graph, we specify vertex set of G with $V(G)$ when the underlying graph G is not clear from the context. Similarly $E(G)$ represents the edge set for graph G. The set $\{1, 2, ..., n\}$ is represented by $[n]$. $I(G)$ denotes the set of k source-sink pairs $(s_i, t_i), i \in [k], s_i, t_i \in V$. Given a bipartite graph $B = (V_1, V_2, E)$, we denote the left side of the graph by $V_1(B)$ and the right by $V_2(B)$. A bipartite graph is (r, s) bi-regular when each vertex on the left side has degree r whereas each vertex on right side has degree s.

2.1 Network coding

▶ **Definition 3.** An instance of the k-pairs communication problem consists of

- a graph $G = (V, E)$,
- a capacity function $c : E \to \mathbb{R}^+$,
- a set I of commodities of size k, each of which can be described by a triplet of values (s_i, t_i, d_i) corresponding to the source node, the sink node and the demand of commodity i.

In line with [1], for undirected graphs we consider each edge e as two directed edges $\vec{e}, \overleftarrow{e}$, whose capacities will be defined later. It will also be convenient to think of source and sink nodes as edges. Therefore, for every source and sink pair (s_i, t_i), we create new nodes S_i, T_i and connect them via single edges to s_i, t_i respectively. These edges are of unbounded capacity and we will refer to these as the source and sink edges respectively. Every source S_i wants to communicate a message to its sink.

We give the formal definition of a network coding solution in Appendix A. Let M_i be the set of messages the i-th source-sink pair wants to communicate, and $M = \prod_i M_i$. Let $\Delta(e)$ be the alphabet of characters available at edge e. Informally, the solution to a network coding problem must specify for each edge e a function $f_e : M \to \Delta(e)$, which dictates the character transmitted on that edge. The function f_e must be computable from the characters on the incoming edges at the sender end point. The message at the source and sink edges of any commodity must agree.

The network coding rate (henceforth known as coding rate) is the largest value r such that for each source-sink pair at least $r \cdot d_i$ information is transmitted while preserving the capacity constraint on all edges.

2.2 Multicommodity flow problems and sparsity cuts

A flow problem consists of a graph $G = (V, E)$ with k commodities together with k pairs of nodes (s_i, t_i) and quantities d_i. The goal is to transmit d_i units of commodity i from s_i to t_i while keeping the total sum of commodities that go through a given edge e below its capacity $c(e)$. There are many optimization problems surrounding this problem. We will focus on the following one: what is the largest λ such that at least λ fraction of each commodity's demand is routed? This is justified by assuming that no commodity is prioritized over another and that all resources are shared. We refer to this quantity as the flow rate of the graph. There are well-known linear programming formulations for these problems (see LP 5 in Section B in the appendix). Since we will be interested in providing provable upper bounds to the flow rate, it will suffice to look at the dual of this problem. In particular, we use the variables on the following dual LP to provide upper bounds on the flow rate of the sequence of graphs we create. We will refer to the $w_{(u,v)}$ as the weight of edge (u, v) in the dual solution.

$$\begin{aligned} \text{minimize} \sum_{u,v} w_{(u,v)} c(u,v) & \\ \text{subject to} \sum_{(s_i,t_i)} l(s_i,t_i) d_i \geq 1 & \qquad \text{(Distance Constraint)} \\ \sum_{(u,v)\in p} w_{(u,v)} \geq l(s_i,t_i) & \qquad \forall i \in [k], p \in P_i \\ w_{(u,v)} \geq 0 & \qquad \forall (u,v) \in E \wedge \forall (u,v) = (s_i,t_i) \end{aligned} \tag{4}$$

This LP introduces a semi-metric on the graph which assigns weights to the edges. $l(s_i, t_i)$ is the shortest distance between $i-$th source-sink pair w.r.t. this metric. The goal is to minimize the weighted length of the edges of the graph while maintaining a certain separation between the source-sink pairs. Zero weight edges can be problematic for our graph tensor since they may reduce the weighted girth of the graph in ways we cannot account for. Our tensor, however, does not produce new zero weight edges. Therefore it suffices for our purposes to show that we can get rid of them at the beginning of the construction.

▶ **Lemma 4.** *If G is a graph such that the gap between the flow rate and the coding rate is $(1 + \epsilon)$, a new graph G' can be constructed such that the gap does not decrease and all the edge weights in LP (4) are non-zero.*

Proof. We defer the proof of this lemma to Section B of the appendix. ◀

Interestingly, this lemma is not true for directed graphs.

3 Construction

In this section we present the construction of our graph tensor and prove our main results, Theorems 1 and 2. The construction takes two graphs with small gaps and tensors them in such a way that the resulting graph has a gap equal to the product of the previous gaps. Iteratively tensoring a graph with a small gap with itself will yield our main results.

Throughout this section, when referring to a graph $G_i = (V_i, E_i), i \in [2]$, k_i is the number of source-sink pair, v_i the number of vertices and m_i the number of edges. The capacity of edge $e \in E_i$ will be denoted by c_{ie}.

3.1 Overview

As mentioned in Section 1, we need a bijection between the graph tensor on G_1 and G_2 and bipartite graphs. We represent the copies of G_1 by numbered nodes on the left side of the bipartite graph (say B) and copies of G_2 by nodes on the right side of B. We add an edge (i, j) in B when an edge in the i-th copy of G_1 got replaced by the j-th copy of G_2 aligned at a specific source-sink pair. But this definition of bipartite graph B loses information about which specific edge was replaced with which specific source-sink pair. Thus, we consider a variant of bipartite graphs: *colored bipartite graphs*, which have two colors associated with each edge. We will use the first color to represent the edge that got replaced in a copy of G_1 and the other to represent the source-sink pair of G_2 that replaced that edge. Thus, edges of B get colored from the set $[m_1] \times [k_2]$. Note that each vertex on the left side has degree m_1 and that on right hand side has degree k_2. The formal description of colored bipartite graphs and *graph tensor* based on this idea is given in Subsection 3.2.

As discussed in Section 1, we can avoid "cheating" paths by increasing the number of hops that a dashed path (Figure 3) needs to take to come back to the same copy of G_1. Our first requirement would be for the colored bipartite graph B to have high girth. Lemma 19 states the existence of nearly optimal sized high girth bipartite graphs and Subsection 3.2.2 shows how to construct specific colored bipartite graphs (as in Subsection 3.2) of high girth.

Is having a high girth B sufficient for the number of hops to be large? No. When G_2 has two sources at the same vertex, the end points (on source side) of the edges in copies of G_1 that these two source-sink pairs replaced will collapse on the same vertex implying that we can move between these copies of G_1 instantly without traveling along any edge in the tensored graph. But, we would have travelled two consecutive edges in B. To remedy this, we condition on the graph G_2 to have all sources and sinks lying on distinct vertices. Note that the length of the cheating paths is defined with respect to the weights of edges in a dual solution. Thus, we cannot just transfer the source/sinks to leaves at the corresponding vertex through infinite capacity edges as they would always get weight 0 in the dual. In Subsection 3.2.1, we present a way to modify graph G_2 to satisfy the above condition.

The multicommodity flow rate for the tensored graph is upper bounded by constructing a dual solution for it based on dual solutions for graphs G_1 and G_2. In Subsection 3.2.3, we show the dual construction and prove that the gap of the tensored graph is the product of the previous gaps given appropriate girth.

The last subsection of this section contains the details of repeated tensoring to get Theorem 1.

3.2 Graph Tensor

▶ **Definition 5. Colored Bipartite Graph:** We define $\mathcal{B}_{n_1,n_2,d_1,d_2,g,q_1,q_2}$ to be the set of bipartite graphs (V_1, V_2, E) with girth g, $|V_1| = n_1, |V_2| = n_2$, such that degree of each vertex in V_1 and V_2 is d_1 and d_2 respectively and each edge is given a color l_e in $[q_1] \times [q_2]$. Note that $n_1 d_1 = n_2 d_2$.

▶ **Definition 6.** $\boldsymbol{T(G_1, G_2, B)}$ is defined to be the graph tensor on directed graphs G_1 and G_2 based on the colored bipartite graph B.

For $T(G_1, G_2, B)$ to be defined, we need B to satisfy the following properties:

1. $B \in \mathcal{B}_{n_1,n_2,m_1,k_2,g,m_1,k_2}$ for some $n_1, g \in \{1, 2, ...\}$.
   - G_1 has m_1 edges and G_2 has k_2 source-sink pairs. Therefore the degrees of each node on the left and right sides should be m_1 and k_2, respectively.
   - As mentioned in Subsection 3.1, edges must be colored in the set $[m_1] \times [k_2]$.
2. $\forall v \in V_2$, the set $B_v = \{b_e \mid e \text{ is incident to } v \text{ and } l_e = (a_e, b_e)\}$ is the complete set $[k_2]$. We want each source-sink pair of a copy of G_2 to replace some edge in a copy of G_1.
3. $\forall u \in V_1$, the set $A_u = \{a_e \mid e \text{ is incident to } u \text{ and } l_e = (a_e, b_e)\}$ is the complete set $[m_1]$. This ensures that each edge in a copy of G_1 is replaced.
4. $\forall v \in V_2$, the set $A_v = \{a_e \mid e \text{ is incident to } v \text{ and } l_e = (a_e, b_e)\}$ has cardinality 1. To define capacities in the new tensored graph naturally, we want that each source-sink pair in a copy of G_2 replaces some unique edge in its corresponding copy of G_1.
5. $\forall u \in V_1$, the set $B_u = \{b_e \mid e \text{ is incident to } u \text{ and } l_e = (a_e, b_e)\}$ has cardinality 1. This ensures that each edges in a copy of G_1 is replaced by the same source-sink pair in different copies of G_2.

We construct the graph $T(G_1, G_2, B)$ as follows:

- Enumerate the n_1 nodes in $V_1(B)$ and n_2 nodes in $V_2(B)$: $u^{(1)}, u^{(2)}, ..., u^{(n_1)}$ and $v^{(1)}, .., v^{(n_2)}$ respectively.
- Enumerate all the edges in G_1: $e^{(1)}_{G_1}, e^{(2)}_{G_1}, ..., e^{(m_1)}_{G_1}$.
- Create n_1 copies of G_1 (vertices and source-sink pairs) and n_2 copies of G_2 (vertices and edges). Represent the x^{th} copy of graph $G_y, y \in \{1, 2\}$ by $G^{(x)}_y$. Let $u^{(i)} \in V_1(B)$ represent the i-th copy of G_1 and $v^{(j)} \in V_2(B)$ represent the j-th copy of G_2.
- For every edge $e = (u^{(i)}, v^{(j)})$ colored (p, k), merge the vertices $a_{G^{(i)}_1}$ and $s_{kG^{(j)}_2}$, and $t_{kG^{(j)}_2}$ and $b_{G^{(i)}_1}$ in $T(G_1, G_2, B)$. Here, $e^{(p)}_{G^{(i)}_1} = (a_{G^{(i)}_1}, b_{G^{(i)}_1})$ is the p^{th} edge in the i-th copy of G_1 and $(s_{kG^{(j)}_2}, t_{kG^{(j)}_2})$ is the k^{th} source-sink pair of the j^{th} copy of G_2. Informally, we are replacing each edge in a copy of G_1 by a copy of G_2 with end points aligned with the k^{th} source-sink pair. Set the capacity of every edge e' in this j^{th} copy of G_2 to be $c_{1e^{(p)}_{G_1}} c_{2e'}$. This can be done consistently due to Property (4).
- Make all the edges undirected.

We define a tensor on directed graphs to allow for composition of network coding solutions of G_1 and G_2. The direction of an edge in G_1 tells us how to align the source-sink pair of G_2 on that edge. An example of a tensor is the graph in Figure 3.

3.2.1 Standard Forms and Graph Extensions

Without loss of generality, we assume that for the graph G, all the demands $d_i, i \in [|I(G)|]$ are equal. Otherwise, we can just divide the demands into small demands of size x such that x divides all the initial rational demands. As discussed in Subsection 3.1, we want all sources and sinks to lie on distinct vertices. For all the dual solutions D that we mention, we assume that D does not contain any zero weight edges. This is justified by Lemma 4 and the fact that new duals constructed while tensoring, which will be defined later, don't create zero weight edges. We say a graph-dual pair (G, D) is in *standard form* when all the assumptions above are satisfied.

We now present a construction whose goal is to make all $s_i, t_i, i \in [k]$ lie on distinct vertices.

▶ **Definition 7.** Given a graph $G = (V, E)$ with all demands being equal to d, and a dual solution D with $\frac{NC_G}{z(D)} \geq 1 + \varepsilon$, $\forall \alpha, 0 < \alpha < \varepsilon$, construct a new graph G_α such that all

$s_i, t_i, i \in [k]$ lie on distinct vertices and G_α has a dual solution $D_\alpha(G)$ with $\frac{NC_{G_\alpha}}{z(D_\alpha(G))}$ being at least $\frac{1+\varepsilon}{1+\alpha}$. G_α is defined as the **α-Extension of G given D**. $z(D)$ is the objective value of dual solution D.

Here, we just move the sources/sinks at a vertex to the leaves of the new edges added at this vertex while keeping edge capacities and dual weights in check. The detailed description of G_α and $D_\alpha(G)$ is given in Section C of the Appendix.

3.2.2 Colored Bipartite Graph Construction

We need small, colored bipartite graphs for every degree and girth to define the graph tensor on any two graphs with gaps. We construct such graphs using biregular bipartite graphs with high girth. The following lemma states the existence of nearly-optimal sized colored bipartite graphs.

▶ **Lemma 8.** *$\forall r, s, g \geq 3$, there exists a colored bipartite graph $C_{rsg} \in \mathcal{B}_{n_1,n_2,r,s,2g,r,s}$ with $n_1, n_2 \leq (9rs)^{g+3}$.*

Proof. We defer the detailed construction and proof of the next lemma to Section D of the Appendix. ◀

3.2.3 Gap Amplification

We are given G_1 and G_2 in standard form with G_y, $y \in [2]$ having gap $(1 + \varepsilon_y)$. Let N_y be the optimal network coding solution for $G_y, y \in [2]$. Construct a directed graph G'_1 from G_1 by replacing each (undirected) edge $e = (u, v) \in E(G_1)$ of capacity c_{1e} with 2 directed edges (u, v) and (v, u) of capacities c_{1eu} and c_{1ev} respectively. Here, c_{1eu} and c_{1ev} are the capacities of edge e used by N_1 in the defined directions. Note that $c_{1eu} + c_{1ev} \leq c_{1e}$. Without loss of generality, assume $c_{1eu} + c_{1ev} = c_{1e}$, as we can always increase one of the capacities without changing the network coding solution to get the equality. Similarly, construct G'_2 from G_2 based on N_2. G'_1 and G'_2 has $m'_1 = 2m_1$ and $m'_2 = 2m_2$ edges respectively.

▶ **Definition 9. Tensor(G_1, G_2, D_1, D_2)** is defined as $T(G'_1, G'_2, B')$, where $B' = C_{m'_1 k_2 g}$, $2g = \frac{2l_1 l_2}{w_1 w_2}$. Here, l_1 and l_2 are the maximum dual distances between any source-sink pair in the dual solutions D_1 of G_1 and D_2 of G_2 respectively. $w_1 > 0$ and $w_2 > 0$ are the minimum edge weights in the dual D_1 and D_2 respectively.

Define **Dual(G_1, G_2, D_1, D_2)** to be the specific dual solution for Tensor(G_1, G_2, D_1, D_2) that would be constructed in proof of Lemma 12.

All the demands in the graph Tensor(G_1, G_2, D_1, D_2) are equal to $\frac{d_1 d_2}{q}$ where $q = \frac{V_1(B')}{k_2} = \frac{V_2(B')}{m_1}$. Here, d_y is the demand of each commodity in graph $G_y, y \in [2]$. We use such a scaling to have a simple description of Dual(G_1, G_2, D_1, D_2) in terms of D_1 and D_2.

We prove the gap amplification part of Theorem 2 next. The details of how size grows are in the next subsection.

▶ **Theorem 10.** *Given graphs G_1 and G_2 in standard form and dual solutions D_1 and D_2 respectively, such that $\frac{NC_{G_y}}{z(D_y)} \geq 1 + \varepsilon_y, y \in [2]$, $G =$ Tensor(G_1, G_2, D_1, D_2) has a dual solution $D =$ Dual(G_1, G_2, D_1, D_2) such that $\frac{NC_G}{z(D)} \geq (1 + \varepsilon_1)(1 + \varepsilon_2)$.*

In the next two lemmas, we lower bound the network coding rate and upper bound the multicommodity flow rate of G.

▶ **Lemma 11.** *The coding rate for G is at least $r_1 r_2 (1+\varepsilon_1)(1+\varepsilon_2)q$ where r_1 and r_2 are objective values of dual solutions D_1 and D_2 respectively.*

Proof Sketch. The proof follows from composing the optimal network coding solutions of G_1 and G_2. The details are given in Section E of the Appendix. ◀

▶ **Lemma 12.** *D has objective value at most $r_1 r_2 q$ where r_1 and r_2 are the objective values of dual solutions D_1 and D_2 respectively.*

Proof Sketch. $G = T(G_1', G_2', B')$ where variables are as defined in Definition 9. For every edge $e \in E(G)$, e is the undirected version of an edge in a copy of G_2' (of say e_2 in G_2') and this copy of G_2' must have replaced a unique edge (say $e_1 \in E(G_1')$) in different copies of G_1'. Edges e_1 and e_2 are directed edges but have undirected counterparts in G_1 and G_2. Let w_{1e_1} and w_{2e_2} be the weights given to the counterpart edges of e_1 and e_2 in dual solutions D_1 and D_2 respectively. Give weight $w_e = w_{1e_1} w_{2e_2}$ to edge e in D. Note that $\forall e, w_e > 0$ if $w_{1e_1}, w_{2e_2} > 0 \forall e_1, e_2$. Thus, non-zero dual solutions D_1 and D_2 give a non-zero dual solution D to graph G. We still need to show that D is a valid dual solution for G. Since B' has girth at least $\frac{2l_2 l_1}{w_1 w_2}$ and G_2 is in standard form, the dotted paths (as in Figure 3) are the shortest paths with respect to dual D. We can then write the distances between source-sink pairs in G in terms of the distance of this source-sink pair in G_1 w.r.t. D_1 and the distance of the source-sink pair in G_2 that replaced edges in this copy of G_1 w.r.t. D_2. This allows us to easily show the satisfiability of the distance constraint for D when demands are as specified in Definition 9.

The detailed proof is continued in Section E of the Appendix. There we also show $z(D) = \frac{n_1}{k_2} z(D_1) z(D_2) = q r_1 r_2$. ◀

Proof of Theorem 10. It follows from just dividing the lower bound on the network coding rate of G and the upper bound on the objective value of D obtained in Lemma 11 and Lemma 12. ◀

In the next subsection, we show how to repeatedly apply this construction. Note that, we can only apply the tensor construction on graphs in *standard form*. The following lemma allows us to tensor the new graph obtained with itself.

▶ **Lemma 13.** *Given G_1 and G_2 in standard form, Tensor(G_1, G_2, D_1, D_2) is also in standard form.*

Proof. We defer the proof of this lemma to Section E of the Appendix. ◀

3.2.4 Iterative Tensoring

In the next two statements size refers to the number of vertices in the graph A_i. The calculation of the size involves calculating the required girth at each iteration and the size of the colored bipartite graph used to tensor at each iteration.

▶ **Theorem 14.** *Given a graph $A = (V, E)$ with gap $(1+\varepsilon)$, we can construct a sequence of graphs $A_i = (V_i, E_i)$ with gap at least $(1+\frac{\varepsilon}{2})^{2^i}$, size at most $(3c_m)^{(4c_1)^{2^{i+1}}}$ where c_m and c_1 are absolute constants.*

Proof. We defer the proof to Section F of the Appendix. Let $\alpha = \frac{1+\varepsilon}{1+\varepsilon/2} - 1$. The proof first considers the α-Extension of A to start the recursion with a graph in standard form, then recursively defines pairs of tensored graphs and duals (A_i, D_i) such that the gap increases geometrically. ◀

Proof of Theorem 1. Now, we calculate an expression for the gap in terms of size. $\frac{\log(\text{gap})}{\log(1+\varepsilon/2)} \geq 2^i \geq \frac{\log\log(\text{size}) - \log\log 3c_m}{\log(16c_1^2)}$. Thus, we get a sequence of graphs with gap at least $\Omega((\log(\text{size}))^{c_2})$ where c_2 is an absolute positive constant less than 1 equal to $\frac{\log(1+\varepsilon/2)}{\log(16c_1^2)}$. ◀

4 Limits of the Construction

In this section, we show that the construction we present can not be used "as is" to prove the Li and Li conjecture. The requirement for the underlying bipartite graph to have a high girth seems to heavily contribute to the size of the graph in the next iteration. Can we do better in terms of size to yield a gap of $\omega(\log|G|)$ by choosing a smaller bipartite graph at every iteration while still having a clever upper bound on the multicommodity flow in the new graph? The answer is no. Theorem 15 states that for every colored bipartite graph B, the tensor of G_1 and G_2 with B as basis has sparsity of at least the product of the sparsities of G_1 and G_2 when the demands are all 1 in all the graphs. With the appropriate demands, this means that the sparsity grows exactly like the coding rate as in Lemma 11. Thus, for any iterative tensoring procedure that starts with a graph G with NC/MCF gap and repeatedly tensors the graph at the ith iteration (G_i) with itself or with G based on a colored bipartite graph B_i will end up with a graph G' with $\omega(\log|G'|)$ gap. Hence we can start with a graph H with a gap between the flow rate and the sparsity and apply this procedure to get a graph H' with $\omega(\log|H'|)$ gap between the flow rate and the sparsity, contradicting the bounds from [10]. This means that through iterative tensoring, if we were able to prove the conjecture, we would also prove the statement that there exists no graphs with sparsity-multicommodity flow rate gap which is clearly false.

▶ **Theorem 15.** *For any G_1, G_2, B for which $G = T(G_1', G_2', B)$ is defined (G_1' and G_2' are directed graphs obtained from G_1 and G_2 by directing each edge arbitrary in two directions such that new capacities add up to the previous),*

$$\textit{Sparsity}(G) \geq \textit{Sparsity}(G_1) \cdot \textit{Sparsity}(G_2).$$

when the demands of G_1, G_2 and G are all scaled to 1.

Proof. We defer the proof to Section G in the Appendix. ◀

Note that this gives an identical theorem as Theorem 10 for sparsity vs multicommodity flow rate for the corresponding demands.

A Definition of Network Coding

Let $M(i)$ be the set of all messages s_i wants to send, and let $M = \Pi_i M(i)$. For every $v \in V$, let $\text{In}(v) \subseteq E$ denote the set of edges incident to e.

▶ **Definition 16.** A *network coding solution* for a graph G specifies for each directed edge $e \in E$ an alphabet $\Gamma(e)$ and a function $f_e : M \to \Gamma(e)$ mapping the symbol transmitted on edge e. This must satisfy the following two conditions:

- Correctness: each sink node receives the message from its corresponding source, i.e. $f_{T(i)} = f_{S(i)}$.
- Causality: every message transmitted on edge e is computable from information received at its tail vertex at a time prior to the message's transmission.

▶ **Definition 17.** A *causal computation* of a network consists of

- A sequence of edges $e_1, ..., e_T$ where each edge can appear multiple times,
- A sequence of alphabets $\Lambda_1, ..., \Lambda_T$, and
- A sequence of coding functions $\rho_1, ..., \rho_T$, which in turn satisfy:
  1. For each function ρ_t such that $e_t = (u, v)$ is not a source edge, the value of ρ_t is uniquely determined by the values of the functions in the set $\{\rho_x : x < t, e_x \in \text{In}(u)\}$.
  2. For each edge e, the Cartesian product of the alphabets in the set $\{\Lambda_i : e_i = e\}$ is equal to $\Gamma(e)$.
  3. For each edge e, the set of coding functions $\{\rho_i : e_i = e\}$ together define the coding function f_e specified by the network coding solution.

At this point we are equipped with the tools needed to define the network coding rate, the information-theoretic equivalent of the flow rate.

▶ **Definition 18.** A *network coding solution* for a graph G achieves a rate r if there exists a constant $b \geq 0$ such that

- $H(S(i)) \geq r \cdot d_i \cdot b$ for each commodity i,
- for each edge $e \in E$, $H(\vec{e}) + H(\overleftarrow{e}) \leq c(e) \cdot b$,

where by $H(\vec{e})$ we denote the entropy of edge $\vec{e}$. The coding rate is defined to be the supremum of the rates of all network coding solutions.

B Multicommodity Flows

The standard LP formulation for concurrent multicommodity flow problems is written below. It has a variable for every path $p \in P_i$, where P_i is the set of all paths between s_i and t_i. We want to find the largest rate λ that can be concurrently sent between all source-sink pairs subject to the path variables being non-negative and not exceeding the capacity of any edge over all commodities.

$$\begin{aligned} \text{maximize} \quad & \lambda \\ \text{subject to} \quad & \sum_{p \in P_i} f(p) \geq \lambda d_i \quad \forall i \in [k] \\ & \sum_{p : e \in p} f(p) \leq c(e) \quad \forall e \in E \\ & f(p) \geq 0 \qquad \forall p \\ & \lambda \geq 0 \end{aligned} \tag{5}$$

Proof of Lemma 4. We contract all the edges with zero weight in the dual. We need to show that the gap does not decrease. Removing a zero dual variable from a multicommodity solution cannot improve the flow rate, since the distances and the dual objective remains the same. We can use the same coding solution for the new graph with the exception that we now compose the encoding on the edges that were contracted. This shows that the flow rate does not increase and the coding rate does not decrease, proving that their ratio does not decrease. ◀

C Standard Form

This section gives the detailed description of G_α and $D_\alpha(G)$. Let k_v be the number of sources and sinks at vertex $v \in V(G)$. In the graph G_α, add k_v edges (leaves) at v with capacity $z(D)d(1+\varepsilon)$ and shift all the sources or sinks at v to the unique endpoints of these leaves. As each source sends $\geq z(D)d(1+\varepsilon)$ amount of information in an optimal network coding solution and can still send $z(D)d(1+\varepsilon)$, the network coding rate doesn't decrease below $z(D)(1+\varepsilon)$. We construct $D_\alpha(G)$ as follows:

1. For each edge originally in G, assign the same weights as in D.
2. Give weight $\frac{\alpha}{kd(1+\varepsilon)}$ to the new edges.

Distances in the dual don't decrease, so $D_\alpha(G)$ is a valid solution. Since we added k new edges, $z(D_\alpha(G)) = kz(D)d(1+\varepsilon)\frac{\alpha}{kd(1+\varepsilon)} + z(D) = z(D)(1+\alpha)$. Thus, $\frac{NC_G}{z(D\alpha(G))} \geq \frac{1+\varepsilon}{1+\alpha}$.

D Colored Bipartite Graph Construction

In this section, we give a construction for a colored bipartite graph C_B in $\mathcal{B}_{n_1,n_2,r,s,2g,r,s}$ $\forall r, s, g \geq 3$ with $n_1, n_2 \leq rs(9rs)^{g+2}$. We start with a (r, s)-biregular bipartite graph with girth at least $2g$.

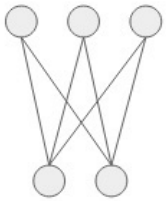

Figure 4 (2,3) biregular bipartite graph with girth 4.

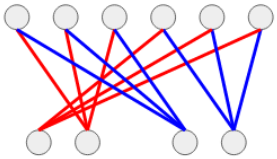

Figure 5 Intermediate graph when one set of colors hasf been assigned.

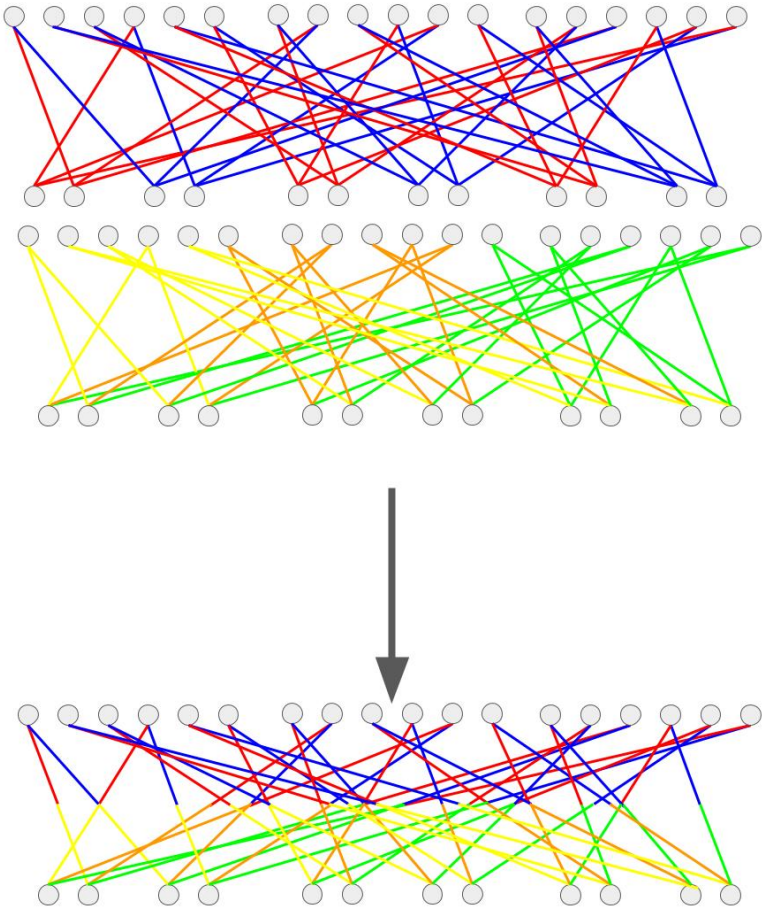

Figure 6 Final colored bipartite graph with girth 4.

▶ **Lemma 19.** *[6] For all $r, s, g \geq 3$, there exists a (r, s)-biregular bipartite graph with girth at least $2g$ and having at most $n = (9rs)^{g+2}$ vertices.*

This lemma follows from Theorem E in [6].

Proof of Lemma 8. Let $B(r, s, g)$ be a graph satisfying the above property. For simplicity, denote $B(r, s, g)$ by just $B = (V_1, V_2, E)$. Denote the coloring for every edge e by (a_e, b_e). First we construct an intermediate graph H in $\mathcal{B}_{n'_1,n'_2,r,s,2g,1,s}$ $(n'_1 = s|V_1|, n'_2 = s|V_2|)$ as follows:

1. Enumerate all the edges incident to a vertex $v \in V_2$ as $e_v^{(1)}, ..., e_v^{(s)}$.
2. Add s copies of V to graph H. Enumerate these copies as $(V_1^{(1)}, V_2^{(1)}), ..., (V_1^{(s)}, V_2^{(s)})$.
3. $\forall v^j \in V_2^{(j)}, j \in [s]$, $\forall i \in [s]$, corresponding to edge $e_v^{(i)} = (u, v) \in E(B)$, add an edge e from v^j to $u^{(((j+i-2) \bmod s)+1)} \in V_1^{(((j+i-2) \bmod s)+1)}$ (copy of u in $(((j + i - 2) \bmod s) + 1)$-th copy of V_1). Set $b_e = ((j + i - 2) \bmod s) + 1$. Therefore, $\forall u^j \in V_1^{(j)}$, edges e' incident at u^j have $b_{e'} = j$ (same color).

For a vertex $v \in V_2^{(j)}$, the edge corresponding to $e_v^{(i)}$ comes from a vertex in $V_1^{(((j+i-2) \bmod s)+1)}$. Thus, all edges incident to v have distinct colors.

We still need to show that the girth of H is at least $2g$. For this, we show that a cycle C of length c in H implies a cycle of length $\leq c$ in B. As all the edges incident to a vertex in H correspond to different edges in B, when we project back C to a cycle C' in B, no two consecutive edges in C' are the same implying C' has no cycle of length 2. Thus, C' must have a cycle of length $3 \leq c' \leq c$. B has girth at least $2g$, so the girth of H cannot be smaller.

Now, we repeat the process for $H = (H_1, H_2)$ to get graph C_B with H_1 playing the role of V_2 and H_2 playing the role of V_1 in the above algorithm. This time we assign $a_e \in [r]$ and make r copies of H. We can see that as was the case for b_e, each vertex in a copy of H_1 gets r distinct a_e values and each vertex in a copy of H_2 gets the same a_e depending on which copy it belongs to. The girth doesn't decrease on going from H to C_B giving us the result we claim. ◀

An example of a colored bipartite graph in $\mathcal{B}_{12,18,3,2,4,3,2}$ is given in Figure 6. We start with $K_{2,3}$ as in Figure 4 with girth 4. Then, we construct the intermediate graph in $\mathcal{B}_{4,6,3,2,4,1,2}$ as shown in Figure 5. The color of the edge depends on the copy it is incident to on the lower side. For a vertex on the upper side, we send edges to correct vertices in distinct copies cyclically.

E Gap Amplification Proofs

Proof of Lemma 11. Graph G_1 has a network coding rate of at least $r_1(1 + \varepsilon_1)$ and hence each source sends $r_1(1 + \varepsilon_1)d_1$ amount of information to its corresponding sink, and similarly for G_2. This is true even for the directed graphs G'_1 and G'_2 by definition. While constructing $T(G'_1, G'_2, B')$, we aligned the source-sink pair in the same direction as the directed edge. This allows us to compose the network coding solutions (N_2 over N_1) to get the information sent from each source in G to be at least $r_1r_2(1+\varepsilon_1)(1+\varepsilon_2)d_1d_2$. This is due to the fact that as we are replacing edges in G'_1 by a source-sink pair of a copy of G'_2, the effective capacity seen by the replaced edge (e) with capacity c_{1e} is now $c_{1e}r_2(1 + \varepsilon_2)d_2$. Thus, the coding rate for graph G is at least $\frac{r_1r_2(1+\varepsilon_1)(1+\varepsilon_2)d_1d_2}{(\text{demand in graph } G)} = \frac{r_1r_2(1+\varepsilon_1)(1+\varepsilon_2)d_1d_2q}{d_1d_2} = r_1r_2(1+\varepsilon_1)(1+\varepsilon_2)q.$ ◀

Proof of Lemma 12. Here, we prove that D is indeed a valid dual solution. B' has $n_1 = k_2q$ nodes on the left side. Let $l_1(s_i, t_i)$ denote the shortest distance between i-th source-sink pair

with respect to dual D_1. Let $l_2(s_i, t_i)$ denote the shortest distance between i-th source-sink pair with respect to dual D_2.

Let $G_1'^u$ and $G_2'^u$ be the undirected version of the graphs G_1' and G_2' respectively. $G_1'^u$ and $G_2'^u$ are graphs G_1 and G_2 where each edge is divided into 2 edges with capacities adding up to the previous one. Construct dual solutions D_1' and D_2' for $G_1'^u$ and $G_2'^u$ such that each divided edge still gets the same weight as in dual solutions D_1 and D_2. The distances between source-sink pairs remain the same. In G, calculate the shortest distance, i.e. $l(s_i^{(y)}, t_i^{(y)})$ between source-sink pair $(s_i^{(y)}, t_i^{(y)})$ which corresponds to the i-th source-sink pair (s_i, t_i) in the y-th copy of $G_1'^u$ (finally, we make the graph undirected). In this copy of $G_1'^u$, assume that we replaced each edge with the j_y-th source-sink pair of $G_2'^u$ (this is unique due to Property (2) in Definition 6). Therefore, according to D, $l(s_i^{(y)}, t_i^{(y)}) \leq l_1(s_i, t_i) l_2(s_{j_y}, t_{j_y})$ (these correspond to dotted paths). Any other path from $s_i^{(y)}$ to $t_i^{(y)}$ involves traversing to another copy of $G_1'^u$ through a copy of $G_2'^u$ that replaced edges in this copy of $G_1'^u$. This transition from a copy of $G_1'^u$ to another copy of $G_1'^u$ in G corresponds to two consecutive edges in the bipartite graph B'. Any such path in G having no loops would thus have to make at least g of these transitions to revert back to the original copy of $G_1'^u$ containing the source. Here, the girth of graph B' is at least $2g$. Each transition involves crossing at least one edge (in a copy of G_2') with weight at least $w_1 w_2$ in D because G_2, being in standard form, has all sources and sinks lying on distinct vertices and vertices of a copy of G_1' connect only to the vertices of a copy of G_2' carrying a unique source or sink. Thus, such a path would have distance at least $g w_1 w_2 = \frac{l_2 l_1}{w_1 w_2} w_1 w_2 \geq l_1 l_2$ using l_1, l_2, w_1, w_2 from Definition 9. The cheating paths have distance at least $l_1 l_2$ implying $l(s_i^{(y)}, t_i^{(y)}) = l_1(s_i, t_i) l_2(s_{j_y}, t_{j_y})$. The left hand side of the distance constraint in LP 4 becomes $\sum_{i=1,y=1}^{k_1,n_1} \frac{d_1 d_2}{q} l(s_i^{(y)}, t_i^{(y)}) \geq 1$, where the first expression in the summand is the demand of source-sink pairs in G. Now, we are going to show that the constraint is true:

$$\sum_{i=1,y=1}^{k_1,n_1} \frac{d_1 d_2}{q} l(s_i^{(y)}, t_i^{(y)}) = \sum_{i=1,y=1}^{k_1,n_1} \frac{d_1 d_2}{q} l_1(s_i, t_i) l_2(s_{j_y}, t_{j_y}) = \frac{d_1 d_2}{q} \sum_{y=1}^{n_1} l_2(s_{j_y}, t_{j_y}) \sum_{i=1}^{k_1} l_1(s_i, t_i)$$

$$= \frac{1}{q} \cdot \frac{n_1}{k_2} \left(\sum_{j=1}^{k_2} d_2 l_2(s_j, t_j) \right) \left(\sum_{i=1}^{k_1} d_1 l_1(s_i, t_i) \right) \geq \frac{n_1}{q k_2} = 1$$

The second to last equality follows from the fact that there are total n_1 copies of G_1', j_y is fixed for fixed y-th copy of G_1' and each $l_2(s_j, t_j)$ ($j \in [k_2]$) is thus counted $\frac{n_1}{k_2}$ time. The last inequality follows from D_1' and D_2' being valid dual solutions of $G_1'^u$ and $G_2'^u$ respectively (distance constraints). This proves that D is a valid dual solution.

The value of $z(D_1')$ for graph $G_1'^u$ is r_1. D_1' assigns the same dual weights as that of D_1 for the divided edges and is a valid dual solution for G_1', and similarly for D_2'. We can see from the construction of D and the edge capacities that $z(D) = \frac{n_1}{k_2} z(D_1') z(D_2') = q r_1 r_2$. D is a function of G_1, G_2, D_1, D_2. ◀

Proof of Lemma 13. Demands are equal for all source-sink pairs in $G = \text{Tensor}(G_1, G_2, D_1, D_2)$ by definition. We need to prove that all sources and sinks in G still lie on distinct vertices. We don't add any new source-sink pairs and thus, each source-sink pair lies on distinct vertices on a copy of G_1'. While constructing $T(G_1', G_2', B')$, we merge a vertex v in a copy of G_1' with a source or a sink vertex of a copy of G_2' and since each vertex contains a unique source or sink of G_2', no two vertices from different copies of G_1' are merged together. This implies that all sources and sinks still lie on distinct vertices of G. ◀

F Proof of Theorem 14

Proof. Using Lemma 4, we can assume that graph A has an optimal dual solution D with all dual variables being non-zero. It is without loss of generality that A has equal demands for all source-sink pairs. Define A^* to be the α-Extension of A given D and $D^* = D_\alpha(A)$ $(1+\alpha = \frac{1+\varepsilon}{1+\varepsilon/2})$. Let A^* have c_n vertices, c_m edges and c_k source-sink pairs having c_d demand each. Without loss of generality we can assume that $c_m \geq c_k, c_n$ as otherwise we can just divide some edges into multiple edges with reduced capacities. Let l be the largest distance between any source-sink pair in the dual D^* and $w > 0$ be the minimum weight of an edge in dual D^*. We also know that $\frac{NC_{A^*}}{z(D^*)} \geq \frac{1+\varepsilon}{1+\alpha} = 1 + \frac{\varepsilon}{2}$. As the objective value of any dual solution is at least the flow rate, we get that A^* has a gap of at least $(1 + \frac{\varepsilon}{2})$. A^* is in standard form. A_i is defined iteratively as follows:

$A_0 = A^*, D_0 = D^*, \varepsilon_0 = \frac{\varepsilon}{2}$.
For $i \geq 1$:
ε_i is such that $(1 + \varepsilon_i) = (1 + \varepsilon_{i-1})^2$.
A_i =Tensor$(A_{i-1}, A_{i-1}, D_{i-1}, D_{i-1})$.
D_i =Dual$(A_{i-1}, A_{i-1}, D_{i-1}, D_{i-1})$.

Note that $\forall i, A_i$ is in standard form using Lemma 13 and thus iterative tensoring is valid. Through Theorem 10, we know that if $\frac{NC_{A_{i-1}}}{z(D_{i-1})} \geq (1+\varepsilon_{i-1})$, then $\frac{NC_{A_i}}{z(D_i)} \geq (1+\varepsilon_{i-1})^2 = 1+\varepsilon_i$. As $\frac{NC_{A^*}}{z(D^*)} = 1 + \frac{\varepsilon}{2}$, we get $\frac{NC_{A_i}}{z(D_i)} \geq 1 + \varepsilon_i = (1 + \varepsilon/2)^{2^i} \forall i$ by induction. The objective value of any dual solution is at least the flow rate implying that the gap between coding and flow rate for A_i is at least $(1 + \frac{\varepsilon}{2})^{2^i}$.

To see how the size of A_i grows, we first calculate the required girth $(2g_i)$ at each iteration. From the construction of $D_i = \text{Dual}(A_{i-1}, A_{i-1}, D_{i-1}, D_{i-1})$ in the proof of Lemma 12 we see that $w_i = w_{i-1}^2, l_i \leq l_{i-1}^2$. By induction, we have that for all i, $w_i = w^{2^i}$ and $l_i \leq l^{2^i}$. From Definition 9, we have that $g_i = \frac{l_{i-1}^2}{w_{i-1}^2} \leq \frac{(l^{2^{i-1}})^2}{(w^{2^{i-1}})^2} = (\frac{l}{w})^{2^i}$. Therefore, $g_i \leq (\frac{l}{w})^{2^i} \forall i \geq 1$. Let $c = \frac{l}{w} \geq 1$.

Now, we establish an upper bound on the size of the graph. Recall A_i is the $T(A'_{i-1}, A'_{i-1}, B_i)$ where $B_i = C_{m'_{i-1} k_{i-1} g_i}$ and $m'_{i-1} = 2m_{i-1}$. A'_{i-1} is the directed graph constructed according to the optimal network coding solution of A_{i-1}. Let $n_{1i} = |V_i(B_i)|, n_{2i} = |V_2(B_i)|$. From Lemma 8, $n_{1i} \leq (9m_{i-1}k_{i-1})^{g_i+3} \leq (9m_{i-1}k_{i-1})^{c^{2^i}+3}$.

Note that $m_i = \frac{n_{1i}}{k_{i-1}} m_{A'_{i-1}} m_{A'_{i-1}} = \frac{n_{1i}}{k_{i-1}} (4m_{i-1}^2)$ and $k_i = n_{1i}k_{i-1}$. Each edge in A'_{i-1} is replaced by a copy of A'_{i-1} and each copy is counted k_{i-1} times implying $v_i \leq 2m_{i-1}v_{i-1}\frac{n_{1i}}{k_{i-1}}$.

Moreover, $\frac{m_i}{k_i} = 4(\frac{m_{i-1}}{k_{i-1}})^2$. By induction, $k_i \leq m_i$ as $c_k \leq c_m$. Likewise, we get that $\frac{m_i}{v_i} = 2\frac{m_{i-1}}{v_{i-1}} \geq 1 \forall i$. The upper bound on m_i (the number of edges in A_i) is as follows:

$m_i \leq 4n_{1i}(m_{i-1}^2) \leq 4m_{i-1}^2(9m_{i-1}k_{i-1})^{g_i+3} \leq (9m_{i-1}^2)^{g_i+4} = (3m_{i-1})^{2c^{2^i}+8} \leq (3m_{i-1})^{2(c+1)^{2^i}+8} \leq (3m_{i-1})^{4(c+1)^{2^i}} \forall i \geq 1$ $(c \geq 1)$.

Let $c_1 = c + 1$.

▶ **Claim 20.** $m_i \leq (3c_m)^{(4c_1)^{2^{i+1}}}$.

Proof. For $i = 0$, the right hand side evaluates to $(3c_m)^{(4c_1)^2} \geq c_m$, which is equal to the left hand side. Now we assume that the statement is true for $i - 1$ and prove for i where $i \geq 1$. $m_i \leq (3m_{i-1})^{4c_1^{2^i}} \leq (3(3c_m)^{(4c_1)^{2^i}})^{4c_1^{2^i}} = 3^{(4c_1)^{2^i} 4c_1^{2^i} + 4c_1^{2^i}} c_m^{(4c_1)^{2^i} 4c_1^{2^i}} \leq (3c_m)^{(4c_1)^{2^{i+1}}}$ as $4^{2^i+1} + 4 \leq 4^{2^{i+1}} \forall i \geq 1$.

We have $v_i \leq m_i$. Thus, the size of graph A_i is at most $(3c_m)^{(4c_1)^{2^{i+1}}}$. ◀

◀

G Proof of Theorem 15

Proof. Think of G_1 and G_2 as undirected G_1' and G_2'; their sparsity remains the same. Let H be the set of edges on the cut that achieves the sparsest cut on G separating n source-sink pairs. Consider partitioning this set into sets $H_i = \{e_{1i}, e_{2i}, ..., e_{h_i i}\}$ according to which copy of G_2 (or equivalently G_2'), the edge belongs to in G. H_i denotes the edges belonging to the i-th copy of G_2, $|H_i| = h_i$. Note that $|H| = \sum_i h_i$. Let $n_i^{(2)}$ be the number of source and sink pairs that H_i separates in the i-th copy of G_2. These cuts have capacity $\sum_{e\in H_i} c_{2e}$ in G_2. By construction, each of these source-sink pairs would have replaced an edge in some copy of G_1 (or equivalently undirected G_1'). Assume the k-th ($k \in [n_i^{(2)}]$) source-sink pair replaced edge e_i in the j_{ik}-th copy of G_1 (All source-sink pairs replace the same edge). Mark this edge in the j_{ik}-th copy of G_1 (which has now been replaced in G). The i-th copy of G_2 makes $n_i^{(2)}$ marks. Let F_j be the set of all such marked edges in the j-th copy of G_1. Let F_j cut $n_j^{(1)}$ source-sink pairs in G_1. Any source-sink pair that gets cut in G by H must be cut in G_1 under F_j by construction. Therefore, $\sum_j n_j^{(1)} \geq n$. It is not an equality because there could be a source-sink pair that gets cut by F_j but not by H in G, due to paths that travel from the source to other copies of G_1 through connecting copies of G_2 and come back at the sink. The theorem follows from the following inequalities:

$$\begin{aligned}
\sum_{e\in H} c_e &= \sum_i c_{1e_i} \sum_{e\in H_i} c_{2e} = \sum_i n_i^{(2)} c_{1e_i} \frac{\sum_{e\in H_i} c_{2e}}{n_i^{(2)}} \\
&\geq \sum_i n_i^{(2)} c_{1e_i} \text{Sparsity}(G_2) = \text{Sparsity}(G_2) \left(\sum_i n_i^{(2)} c_{1e_i} \right) \\
&= \text{Sparsity}(G_2) \left(\sum_j \sum_{e\in F_j} c_{1e} \right) = \text{Sparsity}(G_2) \left(\sum_j n_j^{(1)} \frac{\sum_{e\in F_j} c_{1e}}{n_j^{(1)}} \right) \\
&\geq \text{Sparsity}(G_2) \left(\sum_j n_j^{(1)} \right) \text{Sparsity}(G_1) \geq n \left(\text{Sparsity}(G_1) \cdot \text{Sparsity}(G_2) \right)
\end{aligned} \tag{6}$$

The first equality follows from the definition of edge capacities in G in terms of edge capacities in G_1 and G_2. Since H_i cuts $n_i^{(2)}$ source-sink pairs in a copy of G_2, the first inequality follows from the Sparsity(G_2) being the smallest ratio for all the cuts. The first equality on the third line follows from the fact that an edge belongs to F_j only when the corresponding source-sink pair that replaced this edge in G_1 is cut by the cut corresponding to that copy of G_2 and i-th copy of G_2 result in exactly $n_i^{(2)}$ such edges distributed amongst F_js. Therefore, $\frac{\sum_{e\in H} c_e}{n} \geq \text{Sparsity}(G_1) \cdot \text{Sparsity}(G_2) \implies \text{Sparsity}(G) \geq \text{Sparsity}(G_1) \cdot \text{Sparsity}(G_2)$. Here, we assumed that all the demands are 1 in graphs G_1, G_2 and G. ◀

Compression in a Distributed Setting

Abstract

Motivated by an attempt to understand the formation and development of (human) language, we introduce a "distributed compression" problem. In our problem a sequence of pairs of players from a set of K players are chosen and tasked to communicate messages drawn from an unknown distribution Q. Arguably languages are created and evolve to compress frequently occurring messages, and we focus on this aspect. The only knowledge that players have about the distribution Q is from previously drawn samples, but these samples differ from player to player. The only *common* knowledge between the players is restricted to a common prior distribution P and some constant number of bits of information (such as a learning algorithm). Letting T_ϵ denote the number of iterations it would take for a typical player to obtain an ϵ-approximation to Q in total variation distance, we ask whether T_ϵ iterations suffice to compress the messages down roughly to their entropy and give a partial positive answer.

We show that a natural uniform algorithm can compress the communication down to an average cost per message of $O(H(Q) + \log(D(P||Q)))$ in $\tilde{O}(T_\epsilon)$ iterations while allowing for $O(\epsilon)$-error, where $D(\cdot||\cdot)$ denotes the KL-divergence between distributions. For large divergences this compares favorably with the static algorithm that ignores all samples and compresses down to $H(Q) + D(P||Q)$ bits, while not requiring $T_\epsilon \cdot K$ iterations that it would take players to develop optimal but separate compressions for each pair of players. Along the way we introduce a "data-structural" view of the task of communicating with a natural language and show that our natural algorithm can also be implemented by an efficient data structure, whose storage is comparable to the storage requirements of Q and whose query complexity is comparable to the lengths of the message to be compressed. Our results give a plausible mathematical analogy to the mechanisms by which human languages get created and evolve, and in particular highlights the possibility of coordination towards a joint task (agreeing on a language) while engaging in distributed learning.

1 Introduction

Motivated by the goal of understanding human communication and in particular phenomena associated with the formation and development of language, we introduce a distributed compression problem and study it. We start with a description of the compression problem first, and then give our motivation.

1.1 Model

The Basic Model

We consider a distributed setting where K players, with a complete network of point-to-point connections, are exchanging a sequence of messages drawn from an, apriori unknown, distribution Q. In our model the set of possible messages is a countable set, and we use $\mathbb{N}$, the set of natural numbers to denote this set without loss of generality. The communication proceeds in rounds: In round t, a message m is chosen from $\mathbb{N}$ according to Q independent of the past. Simultaneously an ordered pair of players $i, j \in [K] \stackrel{\text{def}}{=} \{1, \ldots, K\}$ with $i \neq j$ is chosen uniformly from all such pairs. The goal is for player i to encode the message m into a sequence of bits and send it to player j. Player j receives this sequence of bits and decodes it to a message $\hat{m}$. (Note that the encoding, and decoding, may depend on the history of interactions involving the sender, respectively receiver.) The round t is said to have an error if $m \neq \hat{m}$. The goal is to design encoding and decoding schemes that satisfy the condition that for every round t, the probability of error, over the history of random choices, is at most ε and the measure of performance is the expected length of communication averaged over the rounds up to t, studied as a function of t.

Efficiency Issues

A second measure of performance of the encoding and decoding algorithms is their "computational efficiency". We define this notion using a "data-structural" perspective. Note that any encoder or decoder essentially needs to learn and store (approximations to) the distribution Q in order to perform moderately well. Thus, such an encoder or decoder needs to work with the amount of space that it might take to remember Q. At the same time, encoding or decoding a single message should not, and need not, take time linear in the storage. We thus measure the efficiency of the encoding and decoding algorithms in terms of its *space* requirement, and its *processing time* to compute the encoding of a message m including the time it takes to update its memory to incorporate this new message in its history.

Setup Assumptions

Finally, we parameterize one commonality in the initialization of the different players. Note that to initialize any communication the players must have some way of exchanging messages. One may consider the natural binary description of messages as one such possibility. Other possibilities may go via Kolmogorov complexity, i.e., by letting the players share a common universal machine and then representing a message via the encoding of machine that outputs the binary representation of the message and halts. Rather than choosing any one of these representations, we parametrize the setup by the exact initial representation. More precisely, we consider a distribution P on $\mathbb{N}$ for which a given initial representation is optimal and

assume that all players share P at the outset[1]. Thus the encoding and decoding algorithms may depend on this prior distribution, but otherwise the algorithms must be completely uniform and may not rely on any other shared information. Note that Q is chosen adversarially and has no relationship to P, however we will allow our performance, i.e., the expected length of the compression to depend on the gap (distance or divergence) between P and Q.

1.2 Motivation: Language Formation and Development

Our motivation to study this distributed compression problem is to give a fresh perspective on phenomena associated with the formation and evolution of human languages. We note that the study of languages is a central quest in linguistics, cognitive science and philosophy and much is known about it based on empirical studies. Our hope is to add some mathematical flavors to this.

For our purpose, we may view language as providing a map that describes how to convert a message in an individual's brain into a sequence of utterances. Yet no language has a short description of this map. Part of the challenge seems to be that language is constantly evolving and if one were to fix any bound, language seems to evolve to a point where the description length exceeds this bound. The reason for this evolution may be viewed as some form of compression. While the ultimate goal may not be the time it takes to convey a message, language certainly evolves by creating shortcuts for currently frequent messages[2]. This motivates our use of the compression capability of the message-to-utterance map as a crude measure of performance. It is not the unique goal, but it is well-aligned with the goals of language.

A second feature about languages is that no two individuals probably have identical descriptions of the map. Attempts to give a unified description of the language (say, as in a dictionary) end up with many different dictionaries and each one capturing some segment of the population. Yet, language is robust to this variation and for the most part, communication manages to work despite the lack of agreement on the dictionary. Our view of this diversity is to consider the process of language acquisition. Individuals (children) learn from examples and indeed there is major diversity in the set of examples one encounters depending on one's own circumstances, but even if one were to factor out this diversity (e.g., by considering identical twins), their experiences are still different. This inspires our setting: individuals are all born identical and get samples from the same distribution. (Furthermore there are no network effects - the underlying graph is a complete graph and the message distribution is independent of the edge distribution. We will discuss this shortly.) Yet their samples are not identical and even this minor discrepancy seems to foil simple algorithms to coordinate on a compression map and introduces either diversity in the map, or complexity in the coordination process. Thus, the distributed compression problem already gives a potential reason for the diversity in language.

We emphasize that our choice of a simple graph (the complete graph) and the independence between the messages and the graph are not restrictions of the "model". It is quite easy to extend our model to the setting where the graphs are complex, the distributions on edges are weighted and to allow the distribution of the messages to depend on the edge. While

[1] Intuitively, we can think of P as being a primitive "gesturing language" that is understandable to all people.

[2] For instance, a language could evolve to use the word "Ix" to denote "a boy who is not able to satisfactorily explain what a Hrung is, nor why it should choose to collapse on Betelgeuse Seven" [1].

such richness is permitted by the model, we restrict to the simple setting to allow simpler contrasts between basic options (and our more sophisticated one).

Finally, one intriguing aspect of language is the amount of influence that different players have on its development. For the most part, language evolution seems to be a decentralized process, but this does not imply equal influence for all players. The role of books, especially those on grammar or dictionaries, of the media, and popular figures definitely assigns disproportionate influence to different players. A question that might be asked is whether language could manage to gain coherence across the population in the absence of such highly influential figures. Our model offers a way to study such questions (in our simplified setting of compression).

1.3 Context and Main Benchmarks

Our main result is a distributed compression algorithm with "decent" performance. To set the stage for this algorithm, we first describe some basic benchmarks and then some basic compression schemes.

In what follows, we use $Q(m)$ to denote the probability of a message m being drawn according to distribution Q. We let $H(Q) = \sum_{m\in\mathbb{N}} Q(m)\log_2(1/Q(m))$ denote the binary entropy of Q and we let $D(Q||P) = \sum_{m\in\mathbb{N}} Q(m)\log_2(Q(m)/P(m))$ denote the KL-divergence between Q and P. The best possible compression scheme would need at least $H(Q)$ bits per message in expectation – this is true in the 2-person case and we will discuss below whether this is achievable in the distributed setting.

We refer to $\tau = 2t/K$ as the *local time*, which roughly measures the number of messages any one player has seen (either as sender or receiver) at time t. We use T_ε to denote the local time by when a fixed player can obtain a ε-close approximation to Q, with probability at least $1-\varepsilon$. Note that T_ε can be upper bounded by $O(2^{H(Q)/\varepsilon})$ (and so in particular T_ε is finite for distributions with finite entropy). Intuitively, T_ε is a reasonable measure of local time by which one may expect to be able to compress well according to Q (even in the simple 2-player setting) and this will be a benchmark time for our compression algorithms also.

Finally, a natural upper bound on the space complexity of storing (an ε-approximation to) Q is again $2^{H(Q)/\varepsilon}$. We will compare the storage needs of the various solutions below to this benchmark. Natural measures of update times would be polylogarithmic in space and we will ask for that. (In what follows, we assume messages are given as black boxes that can be stored in unit time and space and that basic operations such as comparison of messages (is $m_1 \le m_2$?) take unit time.)

We now turn to some basic schemes for compression.

Near Ideal Compression: We first point out the (obvious?) flaw with the most natural hope one may have: Players could try to learn Q and get ε-close to the right distribution moderately fast (in local time T_ε) and then use the optimal (Huffman) coding applied to such a distribution. Unfortunately, they can not agree on this naive distribution and so no naive variation of the 2-player compression mechanism seems to be implementable.

Static Compression: Players simply encode and decode according to the Huffman code for distribution P. The error probability is zero and the expected length of the compression will be at most $H(Q) + D(Q||P) + O(1)$. The good news with this scheme is that the performance does not depend on K, but the bad news is that players do not learn to speak more effectively from examples. This is captured by the fact that the gap from optimal compression is $D(Q||P)$ and we think of this as a large quantity.

Point-to-Point Compression: For every ordered pair (i, j), player i uses the Lempel-Ziv (or any universal) compression algorithm restricted to the sequence of messages that were directed from i to j and player j decodes according to the same history. This scheme converges to a compression length of $H(Q)$ but it takes a relatively long time - a local time of $K \times T_\varepsilon$. We view dependence on K in the local time as too high. This scheme also involves memory requirement which is K times larger than the space needed for a 2-player solution.

Dictatorial Compression: Here one player (the dictator) is singled out and tasked with the compression task. He learns a distribution close to Q and then communicates the resulting encoding/decoding scheme to all other players. The compression achieved by this scheme is near-optimal (converges to $H(Q)$); and the space requirement is also near-optimal. The main quantitative weakness we see is a mild dependence on K in the time it takes for this scheme to converge: Specifically it takes about T_ε local time for the dictator to learn the distribution (which is perfectly fine), but then it needs to spread the information out to all K players and this takes $T_\varepsilon + \Theta(\log K)$ additional local time (using any reasonable gossip algorithm with proper pipelining of messages). The main "criticism" of the scheme may be that it is centralized. While centralized mechanisms do plausibly play a role in the development of languages, they do not seem to be the only mechanism, and so we seek a truly distributed solution below.

1.4 Results

We now state our main theorem.

▶ **Theorem 1** (Main Theorem). *Let $\varepsilon > 0$ be a sufficiently small positive absolute constant. For all K and P, there exists a deterministic distributed compression protocol Π, such that for any distribution Q over $\mathbb{N}$ when run for T iterations,*

- *the amortized communication cost of Π over T iterations approaches $O(H(Q)+\log D(Q||P)+\log(1/\epsilon))$ as T gets large. More formally, the amortized communication cost is*

$$O\left(H(Q)+\log D(Q||P)+\log(1/\epsilon)+\frac{2^{\Theta(H(Q)+D(Q||P))/\varepsilon}\cdot K}{T}\cdot D(Q||P)+1\right)$$

- *in each round, the transmitter and receiver run in time linear in their input and output sizes.*
- *the space usage is exponential in $(H(Q)+D(Q||P))/\epsilon$.*

Our scheme is obtained with each player mixing the static scheme (used initially) with a switch to a more complex scheme once a sufficiently good approximation to Q has been learned (by the player). A central ingredient in our scheme is a solution to the "Uncertain Compression" problem studied by Juba et al. [6] and Haramaty and Sudan [4]. In the uncertain compression problem, two players attempt to compress a single message drawn from a distribution Q, but only the sender knows P and the receiver only knows some distribution Q' which is close to Q. The uncertain compression problem seems to arise naturally in our setting (neither the sender nor the receiver know Q in our case, but both are close and this mild difference can simply be ignored). [6] give a "randomized" solution to this problem which compresses messages roughly down to $H(Q)+O(1)$ bits. Adapting this solution to our setting, essentially as a black box, achieves similar effects in our setting (compression down to $H(Q)+\delta\cdot D(Q||P)$ bits in time $\delta^{-1}\cdot T_\varepsilon$ local time), but a flaw with this scheme is that it requires the players to share a large random string in the setup phase.

Instead we turn to the solution of [4] which does not need any randomness, but their solution assumes that Q is supported on a finite set (of size N) and their compression length is $O(H(Q) + \log\log N)$. Since our distributions are not supported on finite sets, we need to modify their scheme and a careful modification followed by a relatively straightforward analysis leads to our eventual scheme and analysis. In the process, we are also able to build a small data structure implementing the encoding and decoding with efficient processing time. We point out that if one does not care about computational efficiency, then we can remove the additive $\log(1/\epsilon)$ term from the communication cost in Theorem 1 above while also replacing the multiplicative $2^{\Theta(H(Q)+D(Q||P))/\varepsilon}$ factor by $2^{\Theta(H(Q))/\varepsilon}$ (for more details, see Section 3.6).

1.5 Previous Work on Language Evolution

There have been many works on language evolution (to the best of our knowledge all from outside the theoretical computer science community). Without trying to be exhaustive, we briefly mention some of them. In the lingustics field, significant work has been done in the last decades on trying to understand language evolution, including [2, 3]. Several papers also study language from the landscape of evolutionary game theory and evolutionary biology, e.g., [14, 12, 13, 9, 10, 11, 5, 7, 8], and neuroscience, e.g., [16]. There has also been some previous attempts to connect language evolution to the framework of information theory (e.g., [15]), but their focus is on word formation in the "two-player" case, unlike our setup where we consider language as the outcome of the interaction between several players. To the best of our knowledge, the distributed compression perspective developed in this paper has not been considered before.

1.6 Conclusions

We believe that the model raised is an extremely interesting one and is quite pertinent to the analyses of collective distributed phenomena where distributed entities are trying to come together to form joint actions. We believe the process and notation permit a much richer study, especially when one starts to allow correlations between the messages generated and the sender-receiver pairs. The ability to study the encoding and decoding functions – are they really functions, are they inverses of each other, how do they evolve? – are all intriguing questions that can now be subject to analyses. While our results do not address all these aspects, we do hope it will be the subject of future work.

In terms of the constructions and results, one interesting aspect of the compression protocol we use is that it mimics some of the curious features shown in human language. For every message m, player i and round t, the encoding function describes a specific word which is player i's encoding of m, i.e., it gives a (encoding) dictionary. The same player also possesses at the same round a decoding dictionary which we may view as saying, for every message m, which words this player would decode to m. Unlike in the basic schemes described, in our scheme the encoding dictionary is not identical to the decoding dictionary. While the encoding dictionary is a function mapping messages to words, the decoding dictionary is not: It is more conservative and lists many words for any given message. This phenomenon is definitely visible in human languages and our work suggests a plausible reason for the occurence of this phenomenon.

We now mention some important questions that arise from this work. On the conceptual side, it would be very interesting to further use the formalism and ideas developed in theoretical computer science over the last decades in order to capture the phenomena

exhibited by human languages. In particular, it would be interesting to extend our model to take into account other objectives along with compression. It would also be very interesting to consider the case where Q and the set of interacting players vary (slightly) with time, in the hope of modelling cultural changes that take place from one generation to another.

On the more technical side, we sticked in this work to the complete graph representing the interactions between various players. It would be worthwile to investigate other graph structures that favor the creation of communities, and study the properties of the language(s) that evolve in this case. Moreover, while we have considered in this work generic distributions Q, it would be nice to explore the data-structural aspects in the case where Q comes from a well-structured family of distributions (e.g, a Markov Chain). Finally, a concrete question is to determine whether the $O(\log(D(P||Q)))$ additive term in Theorem 3 is actually needed, which seems to be related to some intriguing questions about the chromatic number of certain families of graphs (see [4]).

Outline of the Rest of the Paper

In Section 2, we formally define our distributed compression model. In Section 3, we describe our main protocol along with its computationally efficient implementation (Section 3.1, Section 3.2, Section 3.3, Section 3.4 and Section 3.5). In Section 3.6, we describe a computationally inefficient variant of our protocol that requires smaller communication.

2 Formal Definitions

Throughout this paper, we denote by $H(Q) \triangleq \sum_x Q(x)\log(1/Q(x))$ the Shannon entropy of a probability distribution Q, and by $D(Q||P) \triangleq \sum_x Q(x)\log(Q(x)/P(x))$ the KL divergence between probability distributions Q and P. For any set S of elements, we write $u \in_R S$ to mean that u is sampled uniformly at random from the set S. We also denote by $\mathbb{N}$ the set of all natural numbers.

We now formally define our setup.

▶ **Definition 2** (Distributed Compression)**.** A *distributed compression protocol* Π is parametrized by a tuple (K, P, ε) where

- K is the number of players.
- P is a prior distribution over $\mathbb{N}$, which the players all agree on.
- ε is an error parameter.

The protocol is run on an instance parametrized by a pair (Q, T) where Q is the "true" distribution over $\mathbb{N}$, and T is the total number of iterations for which the protocol is run. Both Q and T are unknown to the players. In any iteration $t \in [T]$,

- Two distinct players i and j are chosen uniformly at random from $[K]$.
- A message m is sampled from distribution Q, and is given to player i.
- Player i attempts to communicate m to player j by sending a single message comprising of C_t bits.
- Player j outputs a message $\widehat{m}$.

The protocol is required to be such that, for any Q, and in any iteration t, it holds that $\Pr[\widehat{m} \neq m] \leq \varepsilon$, where the the probability is over the randomness of the messages and players chosen in the history of the protocol. The amortized communication cost of Π is defined to be $\sum_{t\in[T]} C_t/T$.

During the description of the protocol and the analysis, we will use t to denote the current iteration. Also, we will use t_i to denote the 'local time' of player i. That is, t_i is the number of times player i was picked as the sender. Note that $t = \sum_{i \in [K]} t_i$.

3 A Distributed Compression Protocol

In this section, we prove the following theorem, which is the same as Theorem 1 but "without the computational efficiency" part. The proof of the computational efficiency part of Theorem 1 appears in Section 3.5.

▶ **Theorem 3.** *Let $\varepsilon > 0$ be a sufficiently small positive absolute constant. For all K and P, there exists a deterministic distributed compression protocol Π, such that for any distribution Q over $\mathbb{N}$ when run for T iterations, the amortized communication cost of Π over T iterations approaches $O(H(Q) + \log D(Q||P) + \log(1/\epsilon))$ as T gets large.*

More formally, for $T \geq 8 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \cdot K$, the amortized communication cost is

$$O\left(H(Q) + \log D(Q||P) + \log(1/\epsilon) + \frac{2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \cdot K}{T} \cdot D(Q||P) + 1\right).$$

In the rest of this section, we describe the protocol behind the proof of Theorem 3.

3.1 Overview of the Protocol

We begin by giving a brief overview of the protocol. In any iteration, the chosen players will use one of two protocols that we call Static protocol (Section 3.2) and Uncertain protocol (Section 3.3).

On a high level, the Static protocol communicates messages with zero error, but it uses $H(Q) + D(Q||P) + O(1)$ bits of communication in expectation. On the other hand, the Uncertain protocol communicates $O(H(Q) + \log(D(Q||P)))$ bits in expectation, but it makes errors with some probability.

Suppose during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled from the unknown distribution Q. In this case, player i will decide to communicate using either the Static protocol or the Uncertain protocol. Intuitively, in the initial few rounds in which player i is the sender, she will use the Static protocol as she does not want to risk incurring large error by using the Uncertain protocol. But, once player i has seen enough messages, she will switch to using the Uncertain protocol. The final bound on the amortized communication cost comes about by showing that the protocol ends up using the Uncertain protocol much more often than the Static protocol.

In Section 3.4, we describe exactly how the players switch between the two protocols and prove Theorem 3.

3.2 The Static Protocol

In the Static protocol, player i uses the Huffman codebook for distribution P in order to communicate the message m. The expected communication cost of doing so is $H(Q) + D(Q||P) + O(1)$. The good aspects of this protocol are that the error probability is zero, and the players do not require any knowledge about the unknown distribution Q. However, the downside is that the communication cost is quite high in terms of the dependence on $D(Q||P)$.

We summarize the Static protocol in the following straightforward lemma.

▶ **Lemma 4** (STATIC Protocol). *Suppose that during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. Then, player i can communicate m to player j with zero error, such that the expected communication length is upper bounded by*

$$H(Q) + D(Q||P) + 1.$$

3.3 The Uncertain Protocol

The UNCERTAIN protocol is suitable when the players have individually learnt good estimates of the distribution Q. However, since the players do not exactly agree on their learned estimates, we need an approach for the players to communicate when their estimates of Q are *close* but may not be exactly identical. Our approach is inspired from [4], and we obtain a protocol that in expectation communicates roughly $O(H(Q) + \log D(Q||P)) + O(1)$ bits. We summarize the UNCERTAIN protocol in the following lemma,

▶ **Lemma 5** (UNCERTAIN Protocol). *Suppose that during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. Then, player i can communicate m to player j, such that the expected communication length is upper bounded by*

$$O\left(H(Q) + \log D(Q||P) + \log(1/\epsilon) + 1\right).$$

Moreover, the error probability is at most

$$2 \cdot e^{-\frac{1}{8}\frac{Q(m)}{K}t} + \frac{\epsilon}{4},$$

where the randomness is over all past messages and players chosen in the previous iterations.

Isolating Hash Families

In order to describe the UNCERTAIN protocol achieving Lemma 5, we will need the following notion of an *isolating hash family* which generalizes that of [4].

▶ **Definition 6** (Isolating Hash Families). Let N, R and ℓ be positive integers and $\varepsilon \in (0, 1]$. Then, a collection $\mathcal{H} = \{h_1, h_2, \ldots, h_M : [N] \to [R]\}$ is said to be (N, ℓ, ϵ)-isolating if for every subset $S \subseteq [N]$ with $|S| \leq 2^{\ell-1}$ and every $m \in [N] \setminus S$, we have that $\Pr_{h\in\mathcal{H}}[h(m) \in h(S)] < \varepsilon$. We call M the *size* and R the *range-size* of the isolating hash family $\mathcal{H}$. The family $\mathcal{H}$ is said to be *efficiently computable* if there is an algorithm that takes as input $i \in [M]$ and $j \in [N]$ and computes $h_i(j)$ in time polynomial in $\log M$, $\log N$ and $\log R$.

We note that the family used in [4] corresponds to setting $\epsilon = 1$ in Definition 6. The next lemma shows the existence of an *explicit* and *efficiently computable* (N, ℓ, ϵ)-isolating hash family of relatively small size and small range-size.

▶ **Lemma 7.** *For every positive integers N and ℓ and every $\varepsilon \in (0, 1]$, there exists an* explicit *and* efficiently computable *(N, ℓ, ε)-isolating hash family $\mathcal{H}_{(N,\ell,\varepsilon)}$ of size and range-size at most $2^\ell \cdot \frac{\log N}{\varepsilon}$.*

Proof. Let $q = 2^{\ell+\lceil \log n + \log \frac{1}{\varepsilon}\rceil}$. For each $x \in \mathbb{F}_q$, define the function h_x to be the evaluation of the polynomial defined by m on x, i.e.,

$$h_x(m_0, ..., m_{n-1}) \triangleq \sum_{i=0}^{n-1} m_i x^i.$$

By the fundamental theorem of algebra, for every $m' \neq m$, we have that $\Pr_x[h_x(m) = h_x(m')] \leq \frac{n}{q} \leq 2^{-\ell - \log \frac{1}{\varepsilon}}$. Thus, by the union bound, for every set S of size at most $2^{\ell-1}$, we have $\Pr[f(m) \in f(S)] \leq \varepsilon$, as required. ◀

Pre-Processing Step

As stated earlier, all the players come in with a prior distribution P. In addition, as part of the pre-processing, they compute and store the following:

- Divide the input space $\mathbb{N}$ into a countable number of buckets indexed by $r \in \mathbb{N}_{>0}$, given by $A_r = \left\{m : 2^{-r} < P(m) \leq 2^{-r+1}\right\}$. Clearly, for any r, it holds that $|A_r| \leq 2^r$. In addition, define the function $r(m) := \lceil \log(1/P(m)) \rceil$ for every $m \in \mathbb{N}$, that is, $r(m)$ is the index of the bucket to which m belongs.
- For every r, fix an (arbitrary) choice of isolating hash families $\mathcal{H}_{(N,\ell,\epsilon/4)}$, for $N = |A_r|$ and every choice of $\ell \in \{1, 2, \cdots, \lceil \log N \rceil\}$.

Suppose during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. Define Q_t^i to be the empirical distribution of the samples seen by player i up to iteration t (which includes the iteration t, where the message seen is m). Similarly, define Q_t^j to be the empirical distribution of the samples seen by player j up to iteration t (this includes iteration t, but by definition player j does not see any message in this iteration). The players use the encoding and decoding strategies described next.

Encoding

Upon receiving message m, player i does the following,

(i) let $A \stackrel{\text{def}}{=} A_{r(m)}$ and $N \stackrel{\text{def}}{=} |A|$.
(ii) let $\ell = \left\lceil \log(4/Q_t^i(m)) \right\rceil$.
(iii) let $u \in_R [\mathcal{H}_{(N,\ell,\epsilon/4)}]$.
(iv) Send the tuple $(r, \ell, u, h_u(m))$ to player j.

The intuition for this encoding is as follows: upon receiving r, player j understands that $m \in A_r$, upon receiving ℓ, she understands which hash family to use, upon receiving u, she knows which hash function to use, and hopefully with $h_u(m)$, she will be able to recover m correctly.

Decoding

Upon receiving the tuple (r, ℓ, u, h_*), player j does the following:

(i) Set $A = A_r$ and $N \stackrel{\text{def}}{=} |A|$.
(ii) Identify $h_u \in \mathcal{H}_{(N,\ell,\epsilon/4)}$.
(iii) Output $\arg\max_{m' \in A : h_u(m') = h_*} Q_t^j(m')$.

3.3.1 Analysis

We now analyze the operation of the above protocol.

Communication Cost

Suppose the message m is chosen to be sent by player i to player j. The communication cost of sending the tuple $(r, \ell, u, h_u(m))$ is as follows:

(i) $\log \lceil \log(1/P(m)) \rceil$ bits to send r.

(ii) $\log(\log(1/Q_t^i(m)) + 3)$ bits to send ℓ, since $\ell \le \log|S| + 1 \le \log(4/Q_t^i(m)) + 1$.
(iii) $\log(1/Q_t^i(m)) + \log\lceil\log(1/P(m))\rceil + \log(1/\epsilon) + 5$ bits to send u (it takes $\ell + \log\log N + \log(4/\epsilon)$ bits).
(iv) $\log(1/Q_t^i(m)) + \log\lceil\log(1/P(m))\rceil + \log(1/\epsilon) + 5$ bits to send $h_u(m)$.
Thus, the total communication is given by,

$$2\underbrace{\log(1/Q_t^i(m))}_{(I)} + 3\underbrace{\log\lceil\log(1/P(m))\rceil}_{(II)} + \underbrace{\log(\log(1/Q_t^i(m)) + 3) + 10}_{(III)} + 2\log(1/\epsilon)$$

We wish to prove guarantees on the expected communication cost, when m is drawn from Q. The terms in (III) are lesser order terms, which are smaller than (I), thus we can ignore them. Term (II) in expectation is,

$$\mathop{\mathbb{E}}_{m\sim Q}\left[\log\left(\left\lceil\log\frac{1}{P(m)}\right\rceil\right)\right] \le \log\left(\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{1}{P(m)}\right]\right) \le \log(H(Q) + D(Q||P) + 1)$$

Term (I) is slightly more tricky to bound in expectation. Note that the empirical distribution changes on receiving message m (this turns out to be critical in bounding the communication!). That is, $Q_t^i(m) = \frac{1+(t-1)Q_{(t-1)}^i(m)}{t}$. Also let $\mathcal{M}_t^i$ be the multi-set of all messages that player i has seen up to time t. Thus, Term (I) in expectation is as follows,

$$\mathop{\mathbb{E}}_{\mathcal{M}_{(t-1)}^i}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{1}{Q_t^i(m)}\right] = H(Q) + \mathop{\mathbb{E}}_{\mathcal{M}_{(t-1)}^i}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{Q(m)}{\frac{1}{t_i} + \frac{(t_i-1)Q_{(t-1)}^i(m)}{t_i}}\right]$$

In order to bound the second term above, we consider two cases, (i) $Q_{(t-1)}^i(m) \ge Q(m)/2$ or (ii) $Q_{(t-1)}^i(m) < Q(m)/2$. After fixing t_i and m, by Chernoff bound over the randomness of $\mathcal{M}_{(t-1)}^i$ we have that case (i) happens with probability at least $1 - \exp(-t\cdot Q(m)/8)$.

$$\text{Case (i) } Q_{(t-1)}^i(m) \ge Q(m)/2 \implies \log\left(\frac{Q(m)}{\frac{1}{t_i} + \frac{(t-1)Q_{(t)}^i(m)}{t_i}}\right) \le 1$$

$$\text{Case (ii) } Q_{(t-1)}^i(m) < Q(m)/2 \implies \log\left(\frac{Q(m)}{\frac{1}{t_i} + \frac{(t_i-1)Q_{(t-1)}^i(m)}{t_i}}\right) \le \log(t_i\cdot Q(m))$$

Using these upper bounds we get that,

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathcal{M}_{(t-1)}^i}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{Q(m)}{\frac{1}{t} + \frac{(t_i-1)Q_{(t-1)}^i(m)}{t_i}}\right] &\le \mathop{\mathbb{E}}_{m\sim Q}\left[1\cdot\left(1 - e^{-t_i\cdot Q(m)/8}\right) + \log(t_i\cdot Q(m))\cdot e^{-t_i\cdot Q(m)/8}\right] \\ &\le 1 + \mathop{\mathbb{E}}_{m\sim Q}\left[\log(t_i\cdot Q(m))\cdot e^{-t_i\cdot Q(m)/8}\right] \\ &\le 2\,,\end{aligned}$$

where the last inequality just follows from the fact that $\log(x)\cdot e^{-x/8} \le 1$ for all x.
Thus the overall communication is bounded by

$$(2 + o(1))\,H(Q) + 3\log D(Q||P) + 2\log(1/\epsilon) + O(1)\,.$$

Error Guarantee

We now show that the error probability in iteration t, denoted by p_t^{err} of the protocol is upper bounded by $2\cdot e^{-\frac{1}{8}\frac{Q(m)}{K}t} + \epsilon/4$, where m is fixed to be the message sent in round t.

Since player i has communicated (r, ℓ, u), player j knows the correct bucket of messages A_r to which m belongs. Knowing ℓ and u, player j also knows which hash function is being used, which is chosen to ensure that for every set S of size $\leq 2^\ell$, with probability $1 - \varepsilon/4$, for all $m' \in S \setminus \{m\}$, $h_u(m) \neq h_u(m')$.

Thus, if $\ell \leq \log(1/Q_t^j(m))$ then the j-th player will distinguish m from the set $S = \{m' \in A \mid Q_t^j(m') \geq Q_t^j(m)\}$ with probability $1 - \varepsilon/4$. We will bound the probability that this does not happen.

$$\begin{aligned} p_t^{\text{err}} &\leq \Pr\left[\ell > \log(1/Q_t^j(m))\right] + \frac{\epsilon}{4} \\ &\leq \Pr\left[4 \cdot Q_t^i(m) \geq Q_t^j(m)\right] + \frac{\epsilon}{4} \\ &\leq \Pr\left[Q_t^i(m) \geq 2 \cdot Q(m)\right] + \Pr\left[Q_t^j(m) \leq \frac{1}{2}Q(m)\right] + \frac{\epsilon}{4} \\ &\leq e^{-\frac{1}{3}\frac{Q(m)}{K}t} + e^{-\frac{1}{8}\frac{Q(m)}{K}t} + \frac{\epsilon}{4}\,, \end{aligned}$$

where the last equality follows by Chernoff bound and the fact that Q_t^i, Q_t^j are binomial distributions with parameters t and $\frac{Q(m)}{K}$.

3.4 Final Protocol

We are now ready to present the protocol desired in Theorem 3. As before, suppose that during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. As defined in Section 3.3, define Q_t^i to be the empirical distribution of the samples seen by player i up to iteration t (which includes the iteration t, where the message seen is m). Similarly define Q_t^j to be the empirical distribution of the samples seen by player j up to iteration t (this includes iteration t, but by definition player j does not see any message in this iteration).

For ease of presentation, we will first assume that the players know the entropy of the distribution Q. This is not a natural assumption, and indeed we do get around it in Section 3.4.2. However, we will describe the main protocol with this assumption to make the analysis more intuitive.

Encoding

Upon receiving message m, player i does the following:

- If $t_i < 80 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon)$,
  - send the bit $b = 0$
  - use the Static protocol (Lemma 4) to send message m.
- Else,
  - send the bit $b = 1$
  - use the Uncertain protocol (Lemma 5) to send message m.

(where the bit b indicates whether player i is using the Static protocol or the Uncertain protocol).

Decoding

Depending on the value of the received bit b, player j uses either the Static protocol or the Uncertain protocol to decode and output $\widehat{m}$.

3.4.1 Analysis

We now upper-bound the amortized communication cost and the error probability in any iteration of the above protocol.

Communication Cost

By the design of the final protocol, each player uses the STATIC protocol at most $80 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon)$ times, and hence overall, the STATIC protocol is used at most $O(2^{2H(Q)/\varepsilon} \cdot \log(1/\varepsilon) \cdot K)$ times. Thus, if the total number of iterations is T, then the total communication cost in expectation is at most,

$$\underbrace{O\left(2^{2H(Q)/\varepsilon} \cdot \log(1/\varepsilon) \cdot K\right) \cdot (H(Q) + D(Q||P) + 1)}_{\text{STATIC}} + \underbrace{T \cdot O\Big(H(Q) + \log D(Q||P) + O(1)\Big)}_{\text{UNCERTAIN}} .$$

And hence, the expected amortized communication cost is at most

$$O\left(H(Q) + \log D(Q||P) + \frac{2^{2H(Q)/\varepsilon} \cdot \log(1/\varepsilon) \cdot K}{T} \cdot D(Q||P) + 1\right).$$

Error Guarantee

We first show the following lemma, which is an easy consequence of Markov's inequality.

▶ **Lemma 8.** *For any distribution Q over $\mathbb{N}$, it holds that,*

$$\Pr_{m \sim Q}\left[Q(m) \geq 2^{-H(Q)/\varepsilon}\right] \geq 1 - \varepsilon.$$

Proof. By the definition of the entropy $H(Q)$, we have that $\mathbb{E}_{m \sim Q}\left[\log \frac{1}{Q(m)}\right] = H(Q)$. Thus, the following application of Markov's inequality immediately implies the lemma:

$$\Pr_{m \sim Q}\left[\log \frac{1}{Q(m)} \geq \frac{H(Q)}{\varepsilon}\right] \leq \varepsilon.$$ ◀

We will show that in any iteration t, the error probability is at most ε, where the randomness is over all the past and current messages and chosen players. We distinguish two cases:

Case 1. If $t < 8 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \cdot K$:
Using the Chernoff bound, it is easy to see that

$$\Pr\left[t_i > 80 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \;\middle|\; t < 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \cdot K\right] \leq \exp\left[-\Omega\left(2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon)\right)\right] \ll \varepsilon.$$

Thus, it follows that with probability $\geq 1 - \varepsilon$, player i uses the STATIC protocol in which case there is zero error. Thus, the probability of error is at most ε.

Case 2. If $t \geq 8 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon) \cdot K$:
Section 8 implies that when a message m is sampled from Q, with probability at least $1 - \varepsilon/2$ it holds that $Q(m) \geq 2^{-2H(Q)/\varepsilon}$. In this situation, player i may choose to use either the STATIC or the UNCERTAIN protocol. In the former case, the protocol makes no error. In the latter case, by Lemma 5, the protocol makes error with probability at most

$$2 \cdot e^{-\frac{1}{8} K \frac{t}{Q(m)}} + \frac{\epsilon}{4} \leq 2 \cdot e^{-\frac{1}{8} 2^{-2H(Q)/\varepsilon} 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon)} + \frac{\epsilon}{4},$$

which is at most $\varepsilon/2$ if $Q(m) \geq 2^{-2H(Q)/\varepsilon}$. Hence, the total error probability is at most ε.

3.4.2 Getting around the entropy assumption

We let $\varepsilon > 0$ be a sufficiently small positive absolute constant. We now informally describe how to construct a protocol that does not assume that the players know the entropy of the distribution Q. We note that the main reason for the "switching" criterion $t_i < 80 \cdot 2^{2H(Q)/\varepsilon} \cdot \log(8/\varepsilon)$ was to ensure that when we are using the UNCERTAIN protocol and we encounter a message m with $Q(m) \geq 2^{-2H(Q)/\varepsilon}$ (which happens with probability at least $1 - \varepsilon/2$), it holds that $t_i \cdot Q(m) \gg \log(1/\varepsilon)$.

Thus, the protocol guarantees will still hold as long as the players switch to the UNCERTAIN protocol after a sufficiently "large" time t_i. Indeed, we show that it is possible to switch to the UNCERTAIN protocol after time t_i such that $\Pr_{m\sim Q}\left[t_i \cdot Q(m) \gg \log(1/\varepsilon)\right] \geq 1 - \frac{\varepsilon}{4}$.

We now describe the "switching" criterion. In what follows, we prove that for every player, the switching criterion is not met too early, nor is it met too late. Lemma 10 shows that the probability that the switching criterion is met "too early" (i.e., before the time T_0 defined below) is very small. Moreover, it turns out that the probability that the switching criterion is met "too late" (i.e., after time $2^{O\left(\frac{H(Q)}{\epsilon}\right)} \cdot K$) is also very small (see Lemma 9 below). Together, these two properties allow individual players to switch from the STATIC protocol to the UNCERTAIN protocol based on their observed history of messages. In turn, this allows us to carry out an analysis of the communication cost and the error probability without knowledge of the entropy of Q.

We say that at player i, the switching criterion is met at iteration t_i if

$$t_i \geq \varepsilon^{-3} \quad \text{and} \quad \sum_{m:Q_t^i(m) > t_i^{-\frac{1}{2}}} Q_t^i(m) \geq 1 - \frac{\epsilon}{2}.$$

We first show that, with high probability, the switching criterion is met in time $2^{O\left(\frac{H(Q)}{\epsilon}\right)} \cdot K$

▶ **Lemma 9.** *For every player i, the probability that the switching criterion is met before time $t > 4 \cdot 2^{\frac{16H(Q)}{\epsilon}} K$ is at least $1 - \exp\left(-\frac{1}{64}\epsilon^2 2^{-\frac{4H(Q)}{\epsilon}} \frac{t}{K}\right)$.*

Proof. Let m be such that $Q(m) \geq 2^{-\frac{4H(Q)}{\epsilon}}$. By the Chernoff bound,

$$\Pr\left[Q_t^i(m) \leq (1 - \frac{\epsilon}{4})Q(m)\right] \leq \exp\left(-\frac{1}{32}\epsilon^2 \frac{Q(m)}{K} t\right).$$

Moreover, by the Chernoff bound, we have that $\Pr[t_i \leq \frac{t}{2K}] \leq \exp\left(-\frac{t}{8K}\right)$. We define the event

$$E = \left[t_i \leq \frac{t}{2K} \vee \exists m : Q(m) \geq 2^{-\frac{4H(Q)}{\epsilon}} \wedge Q_t^i(m) \leq (1 - \frac{\epsilon}{4})Q(m)\right].$$

By the union bound, we get that

$$\begin{aligned}
\Pr[E] &\leq \exp\left(-\frac{t}{8K}\right) + \exp\left(\frac{4H(Q)}{\epsilon} - \frac{1}{32}\epsilon^2 \frac{2^{-\frac{4H(Q)}{\epsilon}}}{K} t\right) \\
&\leq \exp\left(-\frac{1}{64}\epsilon^2 2^{-\frac{4H(Q)}{\epsilon}} \frac{t}{K}\right).
\end{aligned}$$

If the event E does not hold, then for every m that satisfies $Q(m) > 2^{-\frac{4H(Q)}{\epsilon}}$ we get that

$$Q_t^i(m) > (1 - \frac{\epsilon}{4})Q(m) > (1 - \frac{\epsilon}{4})2^{-\frac{4H(Q)}{\epsilon}} > \left(\frac{t}{2K}\right)^{-\frac{1}{2}} > t_i^{-\frac{1}{2}}.$$

Thus,

$$\begin{aligned}
\sum_{m:Q_t^i(m)>t_i^{-\frac{1}{2}}} Q_t^i(m) &\geq \sum_{m:Q(m)>2^{-\frac{4H(Q)}{\epsilon}}} Q_t^i(m) \\
&\geq (1-\frac{\epsilon}{4})\cdot \sum_{m:Q(m)>2^{-\frac{4H(Q)}{\epsilon}}} Q(m) \\
&= (1-\frac{\epsilon}{4})\cdot \Pr_{m\sim Q}\left[Q(m)>2^{-\frac{4H(Q)}{\epsilon}}\right] \\
&= (1-\frac{\epsilon}{4})\cdot \Pr_{m\sim Q}\left[\log\frac{1}{Q(m)}<\frac{4H(Q)}{\epsilon}\right] \\
&\geq (1-\frac{\epsilon}{4})\cdot(1-\frac{\epsilon}{4}) \\
&\geq 1-\frac{\epsilon}{2}.
\end{aligned}$$

Moreover, $t_i > \frac{t}{2K} > \varepsilon^{-3}$. Hence, in this case, the switching criterion is met. ◀

Let T_0 be the smallest $t > \frac{1}{\varepsilon^3 K}$ that satisfies $\Pr_{m\sim Q}\left[Q(m) \geq \frac{1}{4}\sqrt{\frac{K}{t}}\right] > 1-\frac{3}{4}\epsilon$. First, we will observe that after time T_0, it is indeed safe to switch to the UNCERTAIN protocol.

▶ **Observation 3.1.** *For every time $t \geq T_0$, the* UNCERTAIN *protocol succeeds with probability at least $1-\varepsilon$.*

Proof. By Lemma 5, with probability at least $1-\frac{3}{4}\varepsilon$, the protocol succeeds with probability at least $1-\frac{\varepsilon}{4}$. ◀

It remains to show that with high probability, we will not use the Uncertain protocol before T_0.

▶ **Lemma 10.** *The probability that player i meet the switching criterion before time T_0 is at most ε.*

Proof. We will show that for any fixed $t_i \leq \frac{2T_0}{K}$, we have that the probability that for player i, the switching criterion is met in local time t_i, is at most $2\cdot\exp\left(-\frac{1}{12}\sqrt{t_i}\right)$. By the union bound, we will get that the probability that for player i, the switching criterion is met before local time $\frac{2T_0}{K}$ is bounded by

$$\sum_{t_i=\epsilon^{-3}+1}^{\infty} 2\cdot\exp\left(-\frac{1}{12}\sqrt{t_i}\right) \leq \int_{\epsilon^{-3}}^{\infty} 2\cdot\exp\left(-\frac{1}{12}\sqrt{t_i}\right)dt_i = 24\cdot(\sqrt{\epsilon^{-3}}+12)\cdot\exp\left(-\frac{1}{12}\sqrt{\epsilon^{-3}}\right) \leq \frac{\epsilon}{2}.$$

Moreover, by the Chernoff bound, we have that the probability that the local time of player i in (global) time T_0 exceeds $\frac{2T_0}{K}$ is at most $\exp(-\frac{T_0}{3K})$. Thus, the probability that for player i the switching criterion is met before time T_0 is at most $\frac{\varepsilon}{2}+\exp(-\frac{T_0}{3K}) \leq \epsilon$, as required.

Fix t_i and let $M = \left\{m\in\mathbb{N} \mid Q(m) \geq \frac{1}{2\sqrt{t_i}}\right\}$. Since $t_i < \frac{2T_0}{K}$, we have that

$$\Pr_{m\sim Q}[m\in M] = \Pr_{m\sim Q}\left[Q(m)\geq\frac{1}{2\sqrt{t_i}}\right] \leq \Pr_{m\sim Q}\left[Q(m)\geq\frac{\sqrt{K}}{2\sqrt{2T_0}}\right] \leq \Pr_{m\sim Q}\left[Q(m)\geq\frac{\sqrt{K}}{4\sqrt{T_0}}\right] \leq 1-\frac{3}{4}\epsilon\,.$$

Thus, by the Chernoff bound,

$$\Pr\left[\sum_{m\in M} Q_t^i(m) \geq 1-\frac{\varepsilon}{2}\right] \leq \exp\left(-\frac{\epsilon\cdot t_i}{25}\right) \tag{1}$$

Now we upper bound $\Pr\left[\exists m \notin M : Q_t^i(m) > \frac{1}{2}\sqrt{\frac{K}{t}}\right]$. To prove this bound, we can assume without lost of generality that for all m except one, we have that $Q(m) > \frac{1}{5\sqrt{t_i}}$: if there exist two elements of such a small probability, we can merge them together to a single element and only increase the probability $\Pr\left[\exists m \notin M : Q_t^i(m) > \frac{1}{2}\sqrt{\frac{K}{t}}\right]$. So we will assume that there are at most $5\sqrt{t_i}+1$ such elements. By the Chernoff bound, we have that for each $m \notin M$, $\Pr\left[Q_t^i(m) > \frac{1}{\sqrt{t_i}}\right] \leq \exp\left(-\frac{1}{6}\sqrt{t_i}\right)$ and by a union bound we can get that

$$\Pr\left[\exists m \notin M : Q_t^i(m) > \frac{1}{\sqrt{t_i}}\right] \leq (5\sqrt{t_i}+1)\cdot\exp\left(-\frac{1}{6}\sqrt{t_i}\right) \leq \exp\left(-\frac{1}{12}\sqrt{t_i}\right). \tag{2}$$

By Combining Equations 1 and 2 , assuming $t_i \geq \varepsilon^{-3}$, we get

$$\Pr\left[\sum_{m:Q_t^i(m)>\frac{1}{\sqrt{t_i}}} Q_t^i(m)\right] \leq \Pr\left[\sum_{m\in M} Q_t^i(m) \geq 1-\frac{\epsilon}{2} \vee \exists m \notin M : Q_t^i(m) > \frac{1}{\sqrt{t_i}}\right] \leq 2\cdot\exp\left(-\frac{1}{12}\sqrt{t_i}\right).$$

This gives an upper bound of $2\cdot\exp\left(-\frac{1}{12}\sqrt{t_i}\right)$ on the probability that at player i, the switching criterion is met in local time t_i, as needed. ◀

3.5 Efficient Implementation

We briefly sketch how to *efficiently* implement the encoding and decoding strategies of Section 3. The details are deferred to the full version. The overall update time will be linear in $(H(Q)+D(Q||P))/\epsilon$, and the used memory will be proportional to the dictionary-size which is exponential in $(H(Q)+D(Q||P))/\epsilon$. The key question of interest is how to compute the uncertain compression function efficiently. Note that while we would like a fast "processing time" per update, the model naturally allows us to amortize the cost over many operations. In particular, the switch from the STATIC protocol to the UNCERTAIN one does not have to be carried out in an instant. We will exploit this feature strongly. The corresponding efficient algorithm will have three phases:

1. A phase where we simply use the STATIC protocol while updating the empirical distributions.
2. A phase where the encoding and decoding dictionaries are being built, but where we still use the STATIC protocol.
3. A phase where we use the UNCERTAIN protocol.

In what follows, we assume that the messages m and the prior distribution P are presented jointly so that the message m given to player i in round t is $E_P(m)$, namely the STATIC (Huffman) encoding of m under P. This is a natural assumption about P – after all P is meant to represent a simple and natural, though unoptimized, distribution over the message space. We now recall the statement of Theorem 1.

▶ **Theorem 1.** *Let $\varepsilon > 0$ be a sufficiently small positive absolute constant. For all K and P, there exists a deterministic distributed compression protocol Π, such that for any distribution Q over $\mathbb{N}$ when run for T iterations,*

- *the amortized communication cost of Π over T iterations approaches $O(H(Q)+\log D(Q||P)+\log(1/\epsilon))$ as T gets large. More formally, the amortized communication cost is*

$$O\left(H(Q)+\log D(Q||P)+\log(1/\epsilon)+\frac{2^{\Theta(H(Q)+D(Q||P))/\varepsilon}\cdot K}{T}\cdot D(Q||P)+1\right)$$

- *in each round, the transmitter and receiver run in time linear in their input and output sizes.*
- *the space usage is exponential in* $(H(Q) + D(Q||P))/\epsilon$.

Note that in Theorem 1, the input to the transmitter is $E_P(m)$ and the input to the receiver is the message that she gets from the transmitter.

Proof Sketch. Let $T_\epsilon = 2^{\Theta(H(Q)+D(Q||P))/\epsilon}$ denote the local time at which our inefficient transmitter and receiver – described in the previous section – should switch from the STATIC protocol to the UNCERTAIN one. In the efficient protocol, during the execution of the STATIC protocol for the first T_ϵ units of local time, each player will also maintain a count of the number of times she has seen each message using a simple binary tree indexed by $E_P(m)$. At local time T_ϵ, player i updates his empirical distribution $Q^i_{T_\epsilon}$. Note that we can amortize this update time over several rounds. After round T_ϵ, the efficient protocol will start building an encoding and decoding table for the uncertain compression algorithm, but will take $T' = \mathsf{poly}(T_\epsilon)$ rounds to do so (as we will explain below), and in the meanwhile, it will continue using the STATIC protocol for these T' rounds. At round $T_\epsilon + T'$, it will then switch to the UNCERTAIN protocol, and at this stage it will have a complete table (for all relevant messages) for the encoding and decoding functions, and so it can encode and decode by a simple table lookup.

We also note that the upper bound on the amortized communication cost follows from a similar argument as in the proof of Theorem 3 in Section 3.

So it suffices to show that the encoding and decoding tables can be computed in time $\mathsf{poly}(T_\epsilon)$. A straightforward implementation of the algorithm used in the proof of Theorem 3 essentially works, with a few additional observations. First, we note that we do not need to encode messages m with $P(m) \leq 2^{-\Theta(H(Q)+D(Q||P))/\epsilon}$ since by Markov's inequality such messages occur with probability less than ϵ. This makes sure that the hash families that we need work with a value of N which is at most $2^{(H(Q)+D(Q||P))/\epsilon}$ and the $\log N$ factor in the size of these hash families is equal to $(H(Q) + D(Q||P))/\epsilon$, which is affordable. Next, we use the efficiently computable hash functions which are given by Lemma 7. We apply these hash functions to $E_P(m)$ rather than m in order to make sure that their domain is also small. The upper bound on the encoding time now follows.

For the decoding time, we note that filling in one entry of the decoding table takes time linear in N which is exponentially larger than the budget in the statement of Theorem 1. However, we can divide this task over N rounds while performing $O(1)$ computations per round. The upper bound on the decoding time now follows.

Finally, the space usage is proportional to the size of the encoding and decoding lookup tables which is exponential in $(H(Q) + D(Q||P))/\epsilon$. ◀

3.6 A Computationally Inefficient Protocol with Smaller Communication

In this section, we show that if one does not care about computational efficiency, then we can remove the additive $\log(1/\epsilon)$ term from the communication cost in Theorem 1 while also replacing the multiplicative $2^{\Theta(H(Q)+D(Q||P))/\varepsilon}$ factor by $2^{\Theta(H(Q))/\varepsilon}$. The details are deferred to the full version.

The general structure of the protocol is similar to the one in Section 3 except that for the description and analysis of the UNCERTAIN protocol (Section 3.3). We now describe a computationally inefficient variant of the UNCERTAIN protocol which has smaller communication. The performance of this variant is summarized in the following lemma.

▶ **Lemma 11** (Uncertain Protocol). *Suppose that during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. Then, player i can communicate m to player j, such that the expected communication length is upper bounded by*

$$O\left(H(Q) + \log D(Q||P)\right) + O(1).$$

Morever, the error probability is at most

$$\frac{1}{Q(m)} \cdot \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right),$$

where the randomness is over all past messages and players chosen in the previous iterations.

We now describe the corresponding encoding and decoding procedures (along with the pre-processing step). Recall Definition 6 of an (N, ℓ, ϵ)-isolating hash family. We now define an (N, ℓ)-isolating hash family to be an $(N, \ell, 1)$-isolating hash family.

Pre-Processing Step

As stated earlier, all the players come in with a prior distribution P. In addition, as part of the pre-processing, they compute and store the following:

- Divide the input space $\mathbb{N}$ into a countable number of buckets indexed by $r \in \mathbb{N}_{>0}$, given by $A_r = \left\{m : 2^{-r} < P(m) \leq 2^{-r+1}\right\}$. Clearly, for any r, it holds that $|A_r| \leq 2^r$. In addition, define the function $r(m) := \lceil \log(1/P(m)) \rceil$ for every $m \in \mathbb{N}$, that is, $r(m)$ is the index of the bucket to which m belongs.
- For every r, fix an (arbitrary) choice of isolating hash families $\mathcal{H}_{(N,\ell)}$, for $N = |A_r|$ and every choice of $\ell \in \{1, 2, \cdots, \lceil \log N \rceil\}$.

Suppose during iteration t, a message m is chosen to be sent by player i to player j, where m is sampled according to the unknown distribution Q. Define Q_t^i to be the empirical distribution of the samples seen by player i up to iteration t (which includes the iteration t, where the message seen is m). Similarly, define Q_t^j to be the empirical distribution of the samples seen by player j up to iteration t (this includes iteration t, but by definition player j does not see any message in this iteration). The players use the encoding and decoding strategies described next.

Encoding

Upon receiving message m, player i does the following,

(i) let $A \stackrel{\text{def}}{=} A_{r(m)}$ and $N \stackrel{\text{def}}{=} |A|$.
(ii) let $S \stackrel{\text{def}}{=} \left\{m' \in A \setminus \{m\} : Q_t^i(m') \geq \frac{1}{16} Q_t^i(m)\right\}$.
(iii) let $\ell = \lceil \log |S| \rceil$.
(iv) let $u \in [|\mathcal{H}_{(N,\ell)}|]$ and $h_u \in \mathcal{H}_{(N,\ell)}$ such that $h_u(m) \notin h_u(S)$.
(v) Send the tuple $(r, \ell, u, h_u(m))$ to player j.

Note that the property of isolating hash families (see Definition 6) guarantees the existence of $h_u \in \mathcal{H}_{(N,\ell)}$ as desired in (iv).

The intuition for this encoding is as follows: upon receiving r, player j understands that $m \in A_r$, upon receiving ℓ, she understands which hash family to use, upon receiving u, she knows which hash function to use, and hopefully with $h_u(m)$, she will be able to recover m correctly.

Decoding

Upon receiving the tuple (r, ℓ, u, h_*), player j does the following:

(i) Set $A = A_r$ and $N \stackrel{\text{def}}{=} |A|$.
(ii) Identify $h_u \in \mathcal{H}_{(N,\ell)}$.
(iii) Output $\arg\max_{m' \in A : h_u(m') = h_*} Q_t^j(m')$.

The analysis of the communication cost and the error guarantee appears in Appendix A, where Lemma 11 is proved.

A Analysis of Computationally Inefficient Protocol

We now analyze the operation of the protocol described in Section 3.6.

Communication Cost

Suppose the message m is chosen to be sent by player i to player j. The communication cost of sending the tuple $(r, \ell, u, h_u(m))$ is as follows:

(i) $\log\lceil\log(1/P(m))\rceil$ bits to send r.
(ii) $\log(\log(1/Q^i_t(m)) + 5)$ bits to send ℓ, since $\ell \le \log|S| + 1 \le \log(16/Q^i_t(m)) + 1$.
(iii) $\log(1/Q^i_t(m)) + \log\lceil\log(1/P(m))\rceil + 5$ bits to send u (it takes $\ell + \log N$ bits).
(iv) $\log(1/Q^i_t(m)) + 5$ bits to send $h_u(m)$.

Thus, the total communication is given by,

$$\underbrace{2\log(1/Q^i_t(m))}_{(I)} + \underbrace{2\log\lceil\log(1/P(m))\rceil}_{(II)} + \underbrace{\log(\log(1/Q^i_t(m)) + 5) + 10}_{(III)}$$

We wish to prove guarantees on the expected communication cost, when m is drawn from Q. The terms in (III) are lesser order terms, which are smaller than (I), thus we choose to ignore them. Term (II) in expectation is,

$$\mathop{\mathbb{E}}_{m\sim Q}\left[\log\left(\left\lceil\log\frac{1}{P(m)}\right\rceil\right)\right] \le \log\left(\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{1}{P(m)}\right]\right) \le \log(H(Q) + D(Q||P) + 1)$$

Term (I) is slightly more tricky to bound in expectation. Note that the empirical distribution changes on receiving message m (this turns out to be critical in bounding the communication!). That is, $Q^i_t(m) = \frac{1+(t-1)Q^i_{(t-1)}(m)}{t}$. Also let $\mathcal{M}^i_t$ be the multi-set of all messages that player i has seen up to time t. Thus, Term (I) in expectation is as follows,

$$\mathop{\mathbb{E}}_{\mathcal{M}^i_{(t-1)}}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{1}{Q^i_t(m)}\right] = H(Q) + \mathop{\mathbb{E}}_{\mathcal{M}^i_{(t-1)}}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{Q(m)}{\frac{1}{t_i} + \frac{(t_i-1)Q^i_{(t-1)}(m)}{t_i}}\right]$$

In order to bound the second term above, we consider two cases, (i) $Q^i_{(t-1)}(m) \ge Q(m)/2$ or (ii) $Q^i_{(t-1)}(m) < Q(m)/2$. After fixing t_i and m, by Chernoff bound over the randomness of $\mathcal{M}^i_{(t-1)}$ we have that case (i) happens with probability at least $1 - \exp(-t\cdot Q(m)/8)$.

$$\text{Case (i) } Q^i_{(t-1)}(m) \ge Q(m)/2 \implies \log\left(\frac{Q(m)}{\frac{1}{t_i} + \frac{(t-1)Q^i_{(t)}(m)}{t_i}}\right) \le 1$$

$$\text{Case (ii) } Q^i_{(t-1)}(m) < Q(m)/2 \implies \log\left(\frac{Q(m)}{\frac{1}{t_i} + \frac{(t_i-1)Q^i_{(t-1)}(m)}{t_i}}\right) \le \log(t_i\cdot Q(m))$$

Using these upper bounds we get that,

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathcal{M}^i_{(t-1)}}\mathop{\mathbb{E}}_{m\sim Q}\left[\log\frac{Q(m)}{\frac{1}{t} + \frac{(t_i-1)Q^i_{(t-1)}(m)}{t_i}}\right] &\le \mathop{\mathbb{E}}_{m\sim Q}\left[1\cdot\left(1 - e^{-t_i\cdot Q(m)/8}\right) + \log(t_i\cdot Q(m))\cdot e^{-t_i\cdot Q(m)/8}\right] \\ &\le 1 + \mathop{\mathbb{E}}_{m\sim Q}\left[\log(t_i\cdot Q(m))\cdot e^{-t_i\cdot Q(m)/8}\right] \\ &\le 2\,,\end{aligned}$$

where the last inequality just follows from the fact that $\log(x)\cdot e^{-x/8} \le 1$ for all x.
Thus the overall communication is bounded by

$$(2 + o(1))\,H(Q) + 2\log D(Q||P) + O(1)\,.$$

Error Guarantee

We now show that the error probability in iteration t, denoted by p_t^{err} of the protocol is upper bounded by $\frac{1}{Q(m)} \cdot 2^{-\Omega\left(\frac{t \cdot Q(m)}{K}\right)}$, where m is fixed to be the message sent in round t.

We first give an intuitive explanation for the error bound. Since player i has communicated (r, ℓ, u), player j knows the correct bucket of messages A_r to which m belongs. Knowing ℓ and u, player j also knows which hash function is being used, which is chosen to ensure that for every $m' \in S \setminus \{m\}$, $h_u(m) \neq h_u(m')$. Thus, the only way in which an error can happen is that there exists some $m' \notin S$ such that $h_u(m) = h_u(m')$ and $Q_t^j(m') > Q_t^j(m)$.

Since $m' \notin S$, it implies by definition of S that $Q_t^i(m') \leq Q_t^i(m)/16$, which means that player i has seen the message m' significantly fewer times compared to the message m. On the other hand, we also have that $Q_t^j(m') > Q_t^j(m)$, which means that player j has seen the message m' at least as many times as message m. For "large" t, it is very unlikely that players i and j have seen m and m' in such disproportionate manner.

To make the arguments go through, we need to union bound over all $m' \in A_r \setminus S$. However, a naive union bound is too lossy because we do not have any reasonable upper bound on the number of m's. To get around this issue, we do a simple bucketing argument.

The formal upper bound on p_t^{err} is shown as follows,

$$
\begin{aligned}
p_t^{\text{err}} &= \Pr[\exists m' \in A :\ h_u(m') = h_u(m) \text{ and } Q_t^j(m') > Q_t^j(m)] \\
&\leq \Pr\left[\exists m' \in A :\ Q_t^i(m') < \frac{1}{16} Q_t^i(m) \text{ and } Q_t^j(m') > Q_t^j(m)\right] \\
&\leq \Pr\left[\exists m' \in A :\ Q(m') > \frac{1}{4} Q(m) \text{ and } Q_t^i(m') < \frac{1}{16} Q_t^i(m)\right] \\
&\quad + \Pr\left[\exists m' \in A :\ Q(m') \leq \frac{1}{4} Q(m) \text{ and } Q_t^j(m') > Q_t^j(m)\right] \\
&\leq \Pr\left[\exists m' \in A :\ Q(m') > \frac{1}{4} Q(m) \text{ and } Q_{t-1}^i(m') < \frac{1}{16}\left(Q_{t-1}^i(m) + \frac{1}{t_i - 1}\right)\right] \\
&\quad + \Pr\left[\exists m' \in A :\ Q(m') \leq \frac{1}{4} Q(m) \text{ and } Q_t^j(m') > Q_t^j(m)\right] \\
&\leq \underbrace{\Pr\left[\exists m' \in A :\ Q(m') > \frac{1}{4} Q(m) \text{ and } Q_{t-1}^i(m') < \frac{1}{8} Q(m)\right]}_{(I)} \\
&\quad + \underbrace{\Pr\left[Q_{t-1}^i(m) + \frac{1}{t_i - 1} > 2 \cdot Q(m) \;\middle|\; t_i \geq \frac{t}{2K}\right]}_{(II)} + \underbrace{\Pr\left[t_i \leq \frac{t}{2K}\right]}_{(III)} \\
&\quad + \underbrace{\Pr\left[\exists m' \in A :\ Q(m') \leq \frac{1}{4} Q(m) \text{ and } Q_t^j(m') > \frac{1}{2} Q(m)\right]}_{(IV)} \\
&\quad + \underbrace{\Pr\left[Q_t^j(m) < \frac{1}{2} Q(m)\right]}_{(V)} .
\end{aligned}
$$

We bound each term individually. Firstly, since $\left\{Q_{t-1}^i(m) | t_i\right\}$ (i.e., $Q_{t-1}^i(m)$ conditioned on a fixed t_i), t_i and $Q_t^j(m)$ are binomial random variables with probabilities $Q(m)$, $\frac{1}{K}$ and $\frac{Q(m)}{K}$ respectively, the terms (II), (III) and (V) are easily upper bounded using the Chernoff

bound. In particular,

$$\begin{aligned}\Pr\left[Q^i_{t-1}(m) + \frac{1}{t_i - 1} > 2 \cdot Q(m) \;\middle|\; t_i \geq \frac{t}{2K}\right] &\leq \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right) \\ \Pr\left[t_i \leq \frac{t}{2K}\right] &\leq \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right) \\ \Pr\left[Q^j_t(m) < \frac{1}{2}Q(m)\right] &\leq \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right) .\end{aligned}$$

Term (I) is also upper bounded by Chernoff bound and a union bound over m', since the number of m' satisfying $Q(m') > \frac{1}{4}Q(m)$ is at most $4/Q(m)$. Thus,

$$\Pr\left[\exists m' \in A :\; Q(m') > \frac{1}{4}Q(m) \text{ and } Q^i_t(m') < \frac{1}{8}Q(m)\right] \leq \frac{4}{Q(m)} \cdot \exp(-\Omega(t_i \cdot Q(m))).$$

To bound term (IV), we can assume without loss of generality that there is at most one $m' \in A$, such that, $Q(m') \leq \frac{1}{8}Q(m)$. This is because, if there were to exist $m'_1, m'_2 \in A$, such that, $Q(m'_1), Q(m'_2) \leq \frac{1}{8}Q(m)$, then we can identify m'_1 and m'_2 as the same message m'_0. Note that we can do this because we will still have that $\Pr[Q(m'_0) \leq \frac{1}{4}Q(m)]$ and

$$\Pr\left[Q^j_t(m'_1) > \frac{1}{2}Q(m) \text{ or } Q^j_t(m'_2) > \frac{1}{2}Q(m)\right] \leq \Pr\left[Q^j_t(m'_0) > \frac{1}{2}Q(m)\right]$$

Thus, to bound term (IV), we can again use a Chernoff bound and a union bound over m', since the number of m' such that $Q(m') > \frac{1}{8}Q(m)$ is at most $8/Q(m)$. Thus, we get that,

$$\Pr\left[\exists m' \in A :\; Q(m') \leq \frac{1}{4}Q(m) \text{ and } Q^j_t(m') > \frac{1}{2}Q(m)\right] \leq \frac{1}{Q(m)} \cdot \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right)$$

Thus, overall in any individual round, we have that,

$$p^{\text{err}}_t \leq \frac{1}{Q(m)} \cdot \exp\left(-\Omega\left(\frac{t \cdot Q(m)}{K}\right)\right).$$

This concludes the proof of Lemma 5.

Outlaw Distributions and Locally Decodable Codes

Abstract

Locally decodable codes (LDCs) are error correcting codes that allow for decoding of a single message bit using a small number of queries to a corrupted encoding. Despite decades of study, the optimal trade-off between query complexity and codeword length is far from understood. In this work, we give a new characterization of LDCs using distributions over Boolean functions whose expectation is hard to approximate (in L_∞ norm) with a small number of samples. We coin the term 'outlaw distributions' for such distributions since they 'defy' the Law of Large Numbers. We show that the existence of outlaw distributions over sufficiently 'smooth' functions implies the existence of constant query LDCs and vice versa. We give several candidates for outlaw distributions over smooth functions coming from finite field incidence geometry and from hypergraph (non)expanders.

We also prove a useful lemma showing that (smooth) LDCs which are only required to work on average over a random message and a random message index can be turned into true LDCs at the cost of only constant factors in the parameters.

1 Introduction

Error correcting codes (ECCs) solve the basic problem of communication over noisy channels. They encode a message into a codeword from which, even if the channel partially corrupts it, the message can later be retrieved. With one of the earliest applications of the *probabilistic method*, formally introduced by Erdős in 1947, pioneering work of Shannon [25] showed the existence of optimal (capacity-achieving) ECCs. The problem of explicitly constructing such codes has fueled the development of coding theory ever since. Similarly, the exploration of many other fascinating structures, such as Ramsey graphs, expander graphs, two source

extractors, etc., began with a striking existence proof via the probabilistic method, only to be followed by decades of catch-up work on explicit constructions. Locally decodable codes (LDCs) are a special class of error correcting codes whose development has not followed this line. The defining feature of LDCs is that they allow for ultra fast decoding of single message bits, a property that typical ECCs lack, as their decoders must read an entire (possibly corrupted) codeword to achieve the same. They were first formally defined in the context of channel coding in [18], although they (and the closely related locally correctable codes) implicitly appeared in several previous works in other settings, such as program checking [5], probabilistically checkable proofs [4, 3] and private information retrieval schemes (PIRs) [9]. More recently, LDCs have even found applications in Banach-space geometry [7] and LDC-inspired objects called local reconstruction codes found applications in fault tolerant distributed storage systems [15]. See [34] for a survey of LDCs and some of the applications.

Despite their many applications, our knowledge of LDCs is very limited; the best-known constructions are far from what is currently known about their limits. Although standard random (linear) ECCs do allow for some weak local-decodability, they are outperformed by even the earliest explicit constructions [19]. All the known constructions of LDCs were obtained by explicitly designing such codes using some algebraic objects like low-degree polynomials or matching vectors [34].

In this paper, we give a characterization of LDCs in probabilistic and geometric terms, making them amenable to probabilistic constructions. On the flip side, these characterizations might also be easier to work with for the purpose of showing lower bounds. We will make this precise in the next section. Let us first give the formal definition of an LDC.

▶ **Definition 1** (Locally decodable code)**.** For positive integers k, n, q and $\eta, \delta \in (0, 1/2]$, a map $C : \{0,1\}^k \to \{0,1\}^n$ is a (q, δ, η)-*locally decodable code* if, for every $i \in [k]$, there exists a randomized *decoder* (a probabilistic algorithm) $\mathcal{A}_i$ such that:

- For every message $x \in \{0,1\}^k$ and string $y \in \{0,1\}^n$ that differs from the codeword $C(x)$ in at most δn coordinates,

$$\Pr[\mathcal{A}_i(y) = x_i] \geq \frac{1}{2} + \eta. \tag{1}$$

- The decoder $\mathcal{A}_i$ (non-adaptively) queries at most q coordinates of y.[1]

Known results

The main parameters of LDCs are the number of queries q and the length of the encoding n as a function of k and q, typically the parameters δ, η are some fixed constants. The simplest example is the Hadamard code, which is a 2-query LDC with $n = 2^k$. The 2-query regime is the only nontrivial case where optimal lower bounds are known: it was shown in [20, 14] that exponential length is necessary. In general, Reed-Muller codes of degree $q - 1$ are q-query LDCs of length $n = \exp(O(k^{1/q-1}))$. For a long time, these were the best constructions for constant q, until in a breakthrough work by [33, 13], 3-query LDCs were constructed with subexponential length $n = \exp(\exp(O(\sqrt{\log k})))$. More generally they constructed 2^r-query LDCs with length $n = \exp(\exp(O(\log^{1/r} k)))$. For $q \geq 3$, the best-known lower bounds leave huge gaps, giving only polynomial bounds. Any 3-query

[1] We can assume that on input $y \in \{0,1\}^n$, the decoder $\mathcal{A}_i$ first samples a set $S \subseteq [n]$ of at most q coordinates according to a probability distribution depending on i only and then returns a random bit depending only on i, S and the values of y at S.

LDC must have length $n \geq \tilde{\Omega}(k^2)$ [32], and more generally any q-query LDC must have length $n \geq \tilde{\Omega}(k^{1+1/(\lceil q/2 \rceil - 1)})$[18, 31]. LDCs where the codewords are over a large alphabet are also studied because of their relation to private information retrieval schemes [9, 18]. In [12], 2-query LDCs of length $n = \exp(k^{o(1)})$ over an alphabet of size $\exp(k^{o(1)})$ were constructed. There is also some exciting recent work on LDCs when the number of queries can also grow with k, in which case there are explicit constructions with constant-rate (that is, $n = O(k)$) and query complexity $q = \exp(O(\sqrt{\log n}))$; in fact we can even achieve the optimal rate-distance tradeoff of traditional error correcting codes [23, 22, 16]. We cannot yet rule out the exciting possibility that constant rate LDCs with polylogarithmic query complexity exist.

1.1 LDCs from distributions over smooth Boolean functions

Our main result shows that LDCs can be obtained from "outlaw" distributions over "smooth" functions. The term outlaw refers to the Law of Large Numbers, which says that the average of independent samples tends to the expectation of the distribution from which they are drawn. Roughly speaking, a probability distribution is an outlaw if many samples are needed for a good estimation of the expectation and a smooth function over the n-dimensional Boolean hypercube is one that has no influential variables. Paradoxically, while many instances of the probabilistic method use the fact that sample means of a small number of independent random variables tend to concentrate around the true mean, as captured for example by the Chernoff bound, our main result requires precisely the opposite. We show that if *at least* k samples from a distribution over smooth functions are needed to approximate the mean, then there exists an $O(1)$-query LDC sending $\{0,1\}^{\Omega(k)}$ to $\{0,1\}^n$, where the hidden constants depend only the smoothness and mean-estimation parameters.

To make this precise, we now formally define smooth functions and outlaw distributions. Given a function $f : \{-1,1\}^n \to \mathbb{R}$, its *spectral norm* (also known as the algebra norm or Wiener norm) is defined as

$$\|f\|_{\mathrm{sp}} = \sum_{S \subset [n]} |\widehat{f}(S)|,$$

where $\widehat{f}(S)$ are the Fourier coefficients of f (see Section 2 for some preliminaries in Fourier analysis). We also consider the supremum norm, $\|f\|_{L_\infty} = \sup\{|f(x)| : x \in \{-1,1\}^n\}$. It follows from the Fourier inversion formula that $\|f\|_{L_\infty} \leq \|f\|_{\mathrm{sp}}$. The *ith discrete derivative* of f is the function $(D_i f)(x) = (f(x) - f(x^i))/2$, where x^i is the point that differs from x on the ith coordinate. Smooth functions are functions whose discrete derivatives have small spectral norms.

▶ **Definition 2** (σ-smooth functions)**.** For $\sigma > 0$, a function $f : \{-1,1\}^n \to \mathbb{R}$ is σ-smooth, if for every $i \in [n]$, we have $\|D_i f\|_{\mathrm{sp}} \leq \sigma/n$.

Intuition for the above definition may be gained from the fact that smooth functions have no influential variables. The influence of the ith variable, $(\mathbb{E}_{x \in \{-1,1\}^n}[(D_i f)(x)^2])^{1/2}$, measures the extent to which changing the ith coordinate of a randomly chosen point changes the value of f. Since $\|D_i f\|_{L_\infty} \leq \|D_i f\|_{\mathrm{sp}}$, the directional derivatives of σ-smooth functions are uniformly bounded by σ/n, which is a much stronger condition than saying that the derivatives are small on average. Outlaws are defined as follows.

▶ **Definition 3** (Outlaw)**.** Let n be a positive integer and μ be a probability distribution over real-valued functions on $\{-1,1\}^n$. For a positive integer k and $\varepsilon > 0$, say that μ is a

(k, ε)-*outlaw* if for independent random μ-distributed functions $f_1, \ldots, f_k$ and $\bar{f} = \mathbb{E}_\mu[f]$,

$$\mathbb{E}\left[\left\|\frac{1}{k}\sum_{i=1}^{k}(f_i - \bar{f})\right\|_{L_\infty}\right] \geq \varepsilon.$$

Denote by $\kappa_\mu(\epsilon)$ the largest integer k such that μ is a (k, ε)-outlaw.

To approximate the true mean of an outlaw μ to within ε on average in the L_∞-distance, one thus needs $\kappa_\mu(\varepsilon)+1$ samples. Note that if μ is a distribution over σ-smooth functions, then the distribution $\tilde{\mu}$ obtained by scaling functions in the support of μ by $1/\sigma$ is a distribution over 1-smooth functions and $\kappa_{\tilde{\mu}}(\varepsilon/\sigma) = \kappa_\mu(\varepsilon)$.

Our main result is then as follows.

▶ **Theorem 4** (Main theorem)**.** *Let n be a positive integer and $\varepsilon > 0$. Let μ be a probability distribution over 1-smooth functions on $\{-1, 1\}^n$ and $k = \kappa_\mu(\varepsilon)$. Then, there exists a (q, δ, η)-LDC sending $\{0, 1\}^l$ to $\{0, 1\}^n$ where $l = \Omega(\varepsilon^2 k/\log(1/\varepsilon))$, $q = O(1/\varepsilon)$, $\delta = \Omega(\varepsilon)$ and $\eta = \Omega(\varepsilon)$. Additionally, if μ is supported by degree-d functions, then we can take $q = d$.*

Note that the smoothness requirement is essential. For example the uniform distribution over the n dictator functions $f_i(x) = x_i$ for $i \in [n]$ is an $(n/2, 1)$-outlaw, but it cannot imply constant rate, constant query LDCs which we know do not exist. In fact we establish a converse to Theorem 4, showing that its hypothesis is essentially equivalent to the existence of LDCs in the small query complexity regime.

▶ **Theorem 5.** *If $C : \{0, 1\}^k \to \{0, 1\}^n$ is a (q, δ, η)-LDC, then there exists a probability distribution μ over 1-smooth degree-q functions on $\{-1, 1\}^n$ such that*

$$\kappa_\mu(\varepsilon) \geq \eta k$$

where $\varepsilon = \eta\delta/(q2^{q/2})$.

Let us remark in passing that Theorem 5 can in turn convert the problem of proving lower bounds on the length of LDCs to a problem on Banach space geometry. In particular, it can be shown that for a distribution μ over 1-smooth degree-q functions on $\{0, 1\}^n$, one can upper bound $\kappa_\mu(\varepsilon)$ in terms of type constants of the space of q-linear forms on ℓ_q^{n+1} [6].

Candidate outlaws

One scenario in which outlaw distributions can be obtained is using incidence geometry in finite fields. In particular, the following result can be derived from our main theorem (stated a bit informally here, see Section 6.1 for the formal version).

▶ **Corollary 6.** *Let $p > 2$ be a fixed prime. Suppose that for every set of directions $D \subset \mathbb{F}_p^n$ of size $|D| \leq k$, there exists a set $B \subset \mathbb{F}_p^n$ of size $|B| \geq \Omega(p^n)$ which does not contain any lines with direction in D. Then, there exists a p-query LDC sending $\{0, 1\}^{\Omega(k)}$ to $\{0, 1\}^{p^n}$.*

Another setting in which our approach leads to interesting open problems is in relation to expansion in hypergraphs. Consider a partition of the complete bipartite graph $K_{n,n}$ into n perfect matchings. It is known that picking $k = O(\log(n))$ of these matchings at random will give us an expander graph (of degree k). For some particular partitions (e.g., given by an Abelian group) this bound is tight. The questions arising from our approach can be briefly summarized as follows: Can one find an n-vertex hypergraph H (say three uniform to be precise) and a partition of H into matchings so that, to get an expander (defined appropriately) one needs at least k random matchings. This would give a code sending k bit messages with encoding length n and so, becomes interesting when k is super poly-logarithmic in n. We elaborate on this in Section 6.2

1.2 Techniques

Our proof of Theorem 4 proceeds in two steps. The first step consists of turning an outlaw over smooth functions into a seemingly crude type of LDC that is only required to work on average over a uniformly distributed message and a uniformly distributed message index. We call such codes *average-case smooth codes* (see below). The second step consists of showing that such codes are in fact not much weaker than honest LDCs.

From outlaws to average-case smooth codes

The key ingredient for the first step is *symmetrization*, a basic technique from high-dimensional probability. We briefly sketch how this is used (we refer to Section 3 for the full proof). Suppose that $f_1, \ldots, f_k$ are independent smooth functions distributed according to a (k, ε)-outlaw with expectation $\bar{f}$. We introduce an independent copy[2] f_i' of f_i for each $i \in [k]$ and consider the symmetrically distributed random functions $f_i - f_i'$. Since $\bar{f} = \mathbb{E}[f_i']$ for each $i \in [k]$, Jensen's inequality and Definition 3 imply that

$$\mathbb{E}\big[\|(f_1 - f_1') + \cdots + (f_k - f_k')\|_{L_\infty}\big] \geq \mathbb{E}\big[\|(f_1 - \mathbb{E}[f_1']) + \cdots + (f_k - \mathbb{E}[f_k')\|_{L_\infty}\big] \geq \varepsilon k.$$

Since the random functions $f_i - f_i'$ are independent and symmetric, we get that for independent uniformly random signs $x_1, \ldots, x_k \in \{-1, 1\}$, the above left-hand side equals

$$\mathbb{E}\big[\|x_1(f_1 - f_1') + \cdots + x_k(f_k - f_k')\|_{L_\infty}\big].$$

The triangle inequality and the Averaging Principle then give that there exist *fixed* smooth functions $f_1^\star, \ldots, f_k^\star$ such that on average over the random signs, we have

$$\mathbb{E}\big[\|x_1 f_1^\star + \cdots + x_k f_k^\star\|_{L_\infty}\big] \geq \varepsilon k/2. \tag{2}$$

To get an average-case smooth code out of this, we view each sequence $x = (x_1, \ldots, x_k)$ as a k-bit message and choose an arbitrary n-bit string for which the L_∞-norm in (2) is achieved to be the its encoding, $C(x)$. This gives a map $C : \{-1, 1\}^k \to \{0, 1\}^n$ satisfying

$$\mathbb{E}\big[x_1 f_1^\star(C(x)) + \cdots x_k f_k^\star(C(x))\big] \geq \varepsilon k/2.$$

Equivalently, for uniform x and i, we have $\Pr[f_i^\star(C(x)) = x_i] \geq \frac{1}{2} + \frac{\varepsilon}{4}$. Finally, we use the smoothness property to transform the $f_i^\star$ into decoders with the desired properties. This is done in Section 3. Let us point out that it is in the application of the Averaging Principle where the probabilistic method appears in our construction of LDCs.

Average-case smooth codes are LDCs

Katz and Trevisan [18] observed that LDC decoders must have the property that they select their queries according to distributions that do not favor any particular coordinate. The intuition for this is that if they did favor a certain coordinate, then corrupting that coordinate would cause the decoder to err with too high a probability. If instead, queries are sampled according to a "smooth" distribution, they will all fall on uncorrupted coordinates with good probability provided the fraction of corrupted coordinates δ and query complexity q aren't too large. The following definition allows us to make this intuition precise.

[2] in this context sometimes referred to as a "ghost copy" as it will later disappear again

▶ **Definition 7** (Smooth code)**.** For positive integers k, n, q and parameters $\eta \in (0, 1/2]$ and $c > 0$, a map $C : \{0,1\}^k \to \{0,1\}^n$ is a (q, c, η)-*smooth code* if, for every $i \in [k]$, there exists a randomized decoder $\mathcal{A}_i : \{0,1\}^n \to \{0,1\}$ such that

- For every $x \in \{0,1\}^k$,

$$\Pr\big[x_i = \mathcal{A}_i\big(C(x)\big)\big] \geq \frac{1}{2} + \eta. \tag{3}$$

- The decoder $\mathcal{A}_i$ (non-adaptively) queries at most q coordinates of $C(x)$.
- For each $j \in [n]$, the probability that $\mathcal{A}_i$ queries the coordinate $j \in [n]$ is at most c/n.

The formal version of Katz and Trevisan's observation is as follows.

▶ **Theorem 8** (Katz–Trevisan)**.** *If $C : \{0,1\}^k \to \{0,1\}^n$ is a (q, δ, η)-LDC, then C is also a $(q, q/\delta, \eta)$-smooth code. Conversely, if $C : \{0,1\}^k \to \{0,1\}^n$ is a (q, c, η)-smooth code, then C is also a $(q, \eta/2c, \eta/2)$-LDC.*

Our second step in the proof of Theorem 4 is a stronger form of the converse part of Theorem 8. We show that even smooth codes that are only required to work *on average* can be turned into LDCs, losing only a constant factor in the rate and success probability.

▶ **Definition 9** (Average-case smooth code)**.** A code as in Definition 7 is a (q, c, η)-*average-case* smooth code if instead of the first item, (3) is required to hold only on average over uniformly distributed $x \in \{0,1\}^k$ and uniformly distributed $i \in [k]$, which is to say that

$$\Pr\big[x_i = \mathcal{A}_i\big(C(x)\big)\big] \geq \frac{1}{2} + \eta,$$

where the probability is taken over x, i and the randomness used by $\mathcal{A}_i$.

▶ **Lemma 10.** *Let $C : \{0,1\}^k \to \{0,1\}^n$ be a (q, c, η)-average-case smooth code. Then, there exists an $(q, \Omega(\eta/c), \Omega(\eta))$-LDC sending $\{0,1\}^l$ to $\{0,1\}^n$ where $l = \Omega(\eta^2 k/\log(1/\eta))$.*

The idea behind the proof of Lemma 10 is as follows. We first switch the message and codeword alphabets to $\{-1, 1\}$ and let $f_i : \{-1,1\}^n \to [-1,1]$ be the expected decoding function $f_i(z) = \mathbb{E}[\mathcal{A}_i(z)]$. The properties of C then easily imply that the set $T \subseteq [-1,1]^k$ given by $T = \{(f_1(z), \ldots, f_k(z)) : z \in \{-1,1\}^n\}$ has large *Gaussian width*, in particular it holds that for a standard k-dimensional Gaussian vector g, we have $\mathbb{E}[\sup_{t \in T} \langle g, t\rangle] \gtrsim \varepsilon k$.[3] Next, we employ a powerful result of [24] showing that T contains an l-dimensional hypercube-like structure with edge length some absolute constant $c \in (0, 1]$, for $l \gtrsim k$. Roughly speaking, this implies that C is a smooth code on $\{-1,1\}^l$ whose decoding probability depends on ε and c. Finally, we obtain an LDC via an application of Theorem 8. The full proof is given in Section 4.

1.3 Organization

Section 2 contains some preliminaries in Fourier analysis over the Boolean cube. In Section 3, we prove our main theorem (Theorem 4) by first showing that outlaw distributions over smooth functions imply existence of average-case smooth codes and using Lemma 10 to convert them to LDCs. In Section 4, we prove Lemma 10 showing how to convert average-case

[3] We write $A \gtrsim B$ and $A = \Omega(B)$ interchangeably to mean that $A \geq cB$ for some absoulte constant $c > 0$ independent of all parameters involved.

smooth-codes to LDCs. In Section 5, we show the converse to our main theorem (Theorem 5) showing how to get outlaw distributions over smooth functions from LDCs. Finally in Section 6, we give some candidate constructions of outlaw distributions over smooth functions using incidence geometry and Cayley hypergraphs.

2 Preliminaries

We recall a few basic definitions and facts from analysis over the n-dimensional Boolean hypercube $\{-1,1\}^n$. Equipped with the coordinate-wise multiplication operation, the hypercube forms an Abelian group whose group of characters is formed by the functions $\chi_S(x) = \prod_{i\in S} x_i$ for all $S \subseteq [n]$. The characters form a complete orthonormal basis for the space of real-valued functions on $\{-1,1\}^n$ endowed with the inner product $\langle f, g\rangle = \mathbb{E}_{x\in\{-1,1\}^n}[f(x)g(x)]$, where we use the notation $\mathbb{E}_{a\in S}$ to denote the expectation with respect to a uniformly distributed element a over a set S. The *Fourier transform* of a function $f : \{-1,1\}^n \to \mathbb{R}$ is the function $\widehat{f} : 2^{[n]} \to \mathbb{R}$ defined by $\widehat{f}(S) = \langle f, \chi_S\rangle$. The Fourier inversion formula (which follows from orthonormality of the character functions) asserts that

$$f = \sum_{S\subseteq[n]} \widehat{f}(S)\chi_S.$$

Parseval's Identity relates the L_2-norms of f and its Fourier transform by

$$\left(\mathbb{E}_{x\in\{-1,1\}^n}[f(x)^2]\right)^{1/2} = \Big(\sum_{S\subseteq[n]} |\widehat{f}(S)|^2\Big)^{1/2}.$$

A function f has *degree* q if $\widehat{f}(S) = 0$ when $|S| > q$ and the *degree-q truncation* of f, denoted $f^{\leq q}$, is the degree-q function defined by

$$f^{\leq q} = \sum_{|S|\leq q} \widehat{f}(S)\chi_S.$$

A function f is a *q-junta* if it depends only on a subset of q of its variables, or equivalently, if there exists a subset $T \subseteq [n]$ of size $|T| \leq q$ such that $\widehat{f}(S) = 0$ for every $S \not\subseteq T$. The *ith discrete derivative* $D_i f$ is the function $(D_i f)(x) = (f(x) - f(x^i))/2$, where x^i is the point that differs from x on the ith coordinate. It is easy to show that the ith discrete derivative in of a function f is given by

$$D_i f = \sum_{S\ni i} \widehat{f}(S)\chi_S.$$

Hence, it follows that $\|D_i f\|_{\mathrm{Spec}} = \sum_{S\ni i} |\widehat{f}(S)|$.

3 From outlaws to LDCs

In this section we prove Theorem 4. For convenience, in the remainder of this paper, we switch the message and codeword alphabets of all codes from $\{0,1\}^n$ to $\{-1,1\}^n$. We begin by showing that outlaw distributions over degree-q functions give q-query average-case smooth codes. Combined with Lemma 10, this implies the second part of Theorem 4.

▶ **Theorem 11.** *Let μ be a probability distribution on 1-smooth degree-q functions on $\{-1,1\}^n$, let $\varepsilon \in (0,1]$ and let $k = \kappa_\mu(\varepsilon)$. Then, there exists a $(q, 1, \varepsilon/4)$-average-case smooth code sending $\{-1,1\}^k$ to $\{-1,1\}^n$.*

Proof. The proof uses a symmetrization argument. Let $\mathcal{F} = (f_1, \ldots, f_k), \mathcal{F}' = (f'_1, \ldots, f'_k)$ be two k-tuples of independent μ-distributed random variables and let $\bar{f} = \mathbb{E}_\mu[f]$. Then, by definition of $\kappa_\mu(\varepsilon)$ and Jensen's inequality,

$$\begin{aligned}
\varepsilon &\leq \mathbb{E}_{\mathcal{F}}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}(f_i - \bar{f})\Big\|_{L_\infty}\Big] \\
&= \mathbb{E}_{\mathcal{F}}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}\big(f_i - \mathbb{E}_{\mathcal{F}'}[f'_i]\big)\Big\|_{L_\infty}\Big] \\
&\leq \mathbb{E}_{\mathcal{F},\mathcal{F}'}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}(f_i - f'_i)\Big\|_{L_\infty}\Big].
\end{aligned}$$

The random variables $f_i - f'_i$ are symmetrically distributed, which is to say that they have the same distribution as their negations $f'_i - f_i$. Since they are independent, it follows that for every $x \in \{-1,1\}^k$, the random variable $x_1(f_1 - f'_1) + \cdots + x_k(f_k - f'_k)$ has the same distribution as $(f_1 - f'_1) + \cdots + (f_k - f'_k)$. Therefore,

$$\begin{aligned}
\mathbb{E}_{\mathcal{F},\mathcal{F}'}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}(f_i - f'_i)\Big\|_{L_\infty}\Big] &= \mathbb{E}_{x\in\{-1,1\}^k}\Big[\mathbb{E}_{\mathcal{F},\mathcal{F}'}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}x_i(f_i - f'_i)\Big\|_{L_\infty}\Big]\Big] \\
&\leq 2\mathbb{E}_{\mathcal{F}}\Big[\mathbb{E}_{x\in\{-1,1\}^k}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}x_i f_i\Big\|_{L_\infty}\Big]\Big].
\end{aligned}$$

Applying the Averaging Principle to the outer expectation, we find that there exist 1-smooth degree-q functions $f_1^\star, \ldots, f_k^\star : \{-1,1\}^n \to \mathbb{R}$ such that

$$\mathbb{E}_{x\in\{-1,1\}^k}\Big[\Big\|\frac{1}{k}\sum_{i=1}^{k}x_i f_i^\star\Big\|_{L_\infty}\Big] \geq \frac{\varepsilon}{2}. \tag{4}$$

Define the code $C : \{-1,1\}^k \to \{-1,1\}^n$ such that for each $x \in \{-1,1\}^k$, we have

$$\frac{1}{k}\sum_{i=1}^{k}x_i f_i^\star(C(x)) = \Big\|\frac{1}{k}\sum_{i=1}^{k}x_i f_i^\star\Big\|_{L_\infty}. \tag{5}$$

For each $i \in [k]$, define the decoder $\mathcal{A}_i$ as follows. Let $\nu_i : 2^{[n]} \to [0,1]$ be the probability distribution defined by $\nu_i(S) = |\widehat{f_i^\star}(S)|/\|\widehat{f_i^\star}\|_{\mathrm{sp}}$. Given a string $z \in \{-1,1\}^n$, with probability $1 - \|\widehat{f_i^\star}\|_{\mathrm{sp}}$, the decoder $\mathcal{A}_i$ returns a uniformly random sign, and with probability $\|\widehat{f_i^\star}\|_{\mathrm{sp}}$, it samples a set $S \subseteq [n]$ according to ν_i and returns $\chi_S(z)$. This is a valid probability distribution since for any 1-smooth function f, we have

$$\|f\|_{\mathrm{sp}} = \sum_{S\subset[n]}|\widehat{f}(S)| \leq \sum_{S\subset[n]}|S||\widehat{f}(S)| = \sum_{i=1}^{n}\sum_{S\ni i}|\widehat{f}(S)| \leq n\cdot\frac{1}{n} = 1.$$

Then, $\mathcal{A}_i$ queries at most q coordinates of z and since $f_i^\star$ is 1-smooth, the probability that it queries any coordinate $j \in [n]$ is at most $\|D_j f_i^\star\|_{\mathrm{sp}} \leq 1/n$.

We also have $\mathbb{E}[\mathcal{A}_i(z)] = f_i^\star(z)$. Therefore, by (4) and (5), we have

$$\begin{aligned}\mathbb{E}_{x\in\{-1,1\}^k, i\in[k]}\left[\Pr[x_i = \mathcal{A}_i(C(x))]\right] &= \frac{1}{2} + \frac{1}{2}\mathbb{E}_{x\in\{-1,1\}^k, i\in[k]}\left[x_i\mathbb{E}[\mathcal{A}_i(C(x))]\right] \\ &= \frac{1}{2} + \frac{1}{2}\mathbb{E}_{x\in\{-1,1\}^k, i\in[k]}\left[x_i f_i^\star(C(x))\right] \\ &= \frac{1}{2} + \frac{1}{2}\mathbb{E}_{x\in\{-1,1\}^k}\left[\left\|\frac{1}{k}\sum_{i=1}^k x_i f_i^\star\right\|_{L_\infty}\right] \\ &\geq \frac{1}{2} + \frac{\varepsilon}{4}.\end{aligned}$$

Hence, C is a $(q, 1, \varepsilon/4)$-average-case smooth code. ◀

The final step before the proof of Theorem 4 is to show that for any distribution μ over smooth functions, there exists a distribution $\tilde{\mu}$ over smooth functions of bounded degree that is not much more concentrated than μ.

▶ **Lemma 12.** *Let μ be a probability distribution over 1-smooth functions on $\{-1,1\}^n$ and let $\varepsilon > 0$. Then, there exists a probability distribution $\tilde{\mu}$ over 1-smooth functions of degree $q = 4/\epsilon$ such that $\kappa_{\tilde{\mu}}(\epsilon/2) \geq \kappa_\mu(\epsilon)$.*

Proof. We first establish that smooth functions have low-degree approximations in the supremum norm. If $f : \{-1,1\}^n \to \mathbb{R}$ is 1-smooth, then

$$q\sum_{|S|>q}|\widehat{f}(S)| \leq \sum_{S\subset[n]}|S||\widehat{f}(S)| = \sum_{i=1}^n\sum_{S\ni i}|\widehat{f}(S)| = \sum_{i=1}^n\|D_i f\|_{\mathrm{sp}} \leq 1.$$

It follows that the degree-q truncation $f^{\leq q}$ satisfies

$$\left\|f - f^{\leq q}\right\|_{L_\infty} \leq \sum_{|S|>q}|\widehat{f}(S)| \leq \frac{1}{q} = \frac{\epsilon}{4}. \tag{6}$$

Define $\tilde{\mu}$ as follows: sample f according to μ and output $f^{\leq q}$. Clearly, $\tilde{\mu}$ is also a distribution over 1-smooth functions. For $k = \kappa_\mu(\varepsilon)$, we have

$$\mathbb{E}_{f_1,\ldots,f_k\sim\mu}\left[\left\|\frac{1}{k}\sum_{i=1}^k\left(f_i - \mathbb{E}[f_i]\right)\right\|_{L_\infty}\right] \geq \varepsilon.$$

Hence, by the triangle inequality and (6), we have

$$\mathbb{E}_{f_1,\ldots,f_k\sim\tilde{\mu}}\left[\left\|\frac{1}{k}\sum_{i=1}^k\left(f_i - \mathbb{E}[f_i]\right)\right\|_{L_\infty}\right] \geq \frac{\epsilon}{2},$$

giving the claim. ◀

Proof of Theorem 4. By applying Lemma 12 to μ, we get a distribution $\tilde{\mu}$ over 1-smooth degree $q = O(1/\epsilon)$ functions with $k' = \kappa_{\tilde{\mu}}(\epsilon/2) \geq \kappa_\mu(\epsilon) = k$. By Theorem 11, we get a $(q, 1, \Omega(\epsilon))$-average-case smooth code $C' : \{-1,1\}^{k'} \to \{-1,1\}^n$. Finally we use Lemma 10 to convert C' to a $(q, \Omega(\epsilon), \Omega(\epsilon))$-LDC $C : \{-1,1\}^\ell \to \{-1,1\}^n$ where $\ell = \Omega(\epsilon^2 k'/\log(1/\epsilon))$. For the last part of the theorem we can simply apply Theorem 11 directly. ◀

4 From average-case smooth codes to LDCs

In this section, we prove Lemma 10. For this, we need the notion of the Vapnik–Chervonenkis dimension (VC-dimension).

▶ **Definition 13** (VC-dimension)**.** For $T \subset [-1,1]^k$ and $w > 0$, $\mathrm{vc}(T,w)$ is defined as the size of the largest subset $\sigma \subset [k]$ such that there exists a shift $s \in [-1,1]^k$ satisfying the following: for every $x \in \{-1,1\}^\sigma$, there exists $t \in T$ such that for every $i \in \sigma$, $(t_i - s_i)x_i \geq w/2$.

Observe that if T is convex, then $\mathrm{vc}(T,w)$ is the maximum dimension of a shifted hypercube with edge lengths at least w contained in T .

▶ **Definition 14** (Gaussian width)**.** Let g be a k-dimensional standard Gaussian vector, with independent standard normal distributed entries. The *Gaussian width* of a set $T \subseteq \mathbb{R}^k$ is defined as

$$E(T) = \mathbb{E}_g[\sup_{t\in T}\langle g,t\rangle].$$

It is easy to see that a large VC-dimension implies a large Gaussian width. The following theorem shows the converse: containing a hypercube-like structure is the only way to have large Gaussian width.

▶ **Theorem 15** ([24])**.** *Let $T \subset [-1,1]^k$. Then, the Gaussian width of T is bounded as*

$$E(T) \lesssim \sqrt{k}\int_{\alpha E(T)/k}^{1} \sqrt{\mathrm{vc}(T,w)\log(1/w)}dw$$

for some absolute constant $\alpha > 0$.

Finally, we use that fact that, as for LDCs, we can assume that on input $y \in \{0,1\}^n$, the decoder $\mathcal{A}_i$ of a smooth code first samples a set $S \subseteq [n]$ of at most q coordinates according to a probability distribution that depends on i only and then returns a random sign depending only on i, S and the values of y at S.

Proof of Lemma 10. The proof works by showing that the average-case smooth code property implies that the image of the (average) decoding functions should have large Gaussian width. We then use Theorem 15 to find a hypercube like structure inside the image, which we use to construct a smooth code. Finally we use Theorem 8 to convert the smooth code to an LDC.

Recall the switch of the message and codeword alphabets to $\{-1,1\}$. For each $i \in [k]$, let $f_i : \{-1,1\}^n \to [-1,1]$ be the expected decoding function $f_i(z) = \mathbb{E}[\mathcal{A}_i(z)]$. Let g be a standard k-dimensional Gaussian vector and $T = \{(f_1(z),\ldots,f_k(z)) : z \in \{-1,1\}^n\}$. By the definition of average-case smooth code we have

$$2\eta k \leq \mathbb{E}_{x\in\{-1,1\}^k}\left[\sum_{i=1}^{k} x_i f_i(C(x))\right] \leq \mathbb{E}_{x\in\{-1,1\}^k}\left[\sup_{t\in T}\langle x,t\rangle\right] \lesssim \mathbb{E}_g\left[\sup_{t\in T}\langle g,t\rangle\right].$$

(See for instance [26, Lemma 3.2.10] for the last inequality.) By Theorem 15, for some constant $\alpha > 0$, we have

$$\eta k \lesssim \sqrt{k}\int_{\alpha\eta}^{1}\sqrt{\mathrm{vc}(T,w)\log(1/w)}dt \leq \sqrt{k}\cdot\sqrt{\mathrm{vc}(T,\alpha\eta)\log(1/\alpha\eta)}$$

where we used the fact that $\mathrm{vc}(T, w)$ is decreasing in w. So for $\tau = \alpha\eta$, we have $\mathrm{vc}(T, \tau) \gtrsim \eta^2 k/\log(1/\eta)$. By the definition of VC-dimension, there exists a subset $\sigma \subset [k]$ of size $|\sigma| \geq \mathrm{vc}(T, \tau)$ and a shift $s \in [-1, 1]^k$ such that for every $x \in \{-1, 1\}^\sigma$ there exists $t \in T$ such that $(t_i - s_i)x_i \geq \tau/2$ for every $i \in \sigma$.

Now we will define the code $C' : \{-1, 1\}^\sigma \to \{-1, 1\}^n$. Given $x \in \{-1, 1\}^\sigma$, there exists $t(x) \in T$ such that $(t(x)_i - s_i)x_i \geq \tau/2$ for every $i \in \sigma$. Define $C'(x) \in \{-1, 1\}^n$ to be one of the preimages of $t(x)$ under f, that is,

$$(f_1(C'(x)), \ldots, f_k(C'(x))) = t(x).$$

Let W_p denote a $\{-1, 1\}$-valued random variable with mean p. The decoding algorithms $\mathcal{A}'_i(y)$ run $\mathcal{A}_i(y)$ internally and give their output as follows:

$$\mathcal{A}'_i(y) = \begin{cases} \text{Output } W_{(1-s_i)/2} & \text{if } \mathcal{A}_i(y) \text{ returns } 1 \\ \text{Output } -W_{(1+s_i)/2} & \text{if } \mathcal{A}_i(y) \text{ returns } -1 \end{cases}$$

Therefore, for every $x \in \{-1, 1\}^\sigma$ and for every $i \in \sigma$,

$$\begin{aligned} x_i \mathbb{E}[\mathcal{A}'_i(C'(x))] &= x_i \mathbb{E}\left[\frac{(1 + \mathcal{A}_i(C'(x)))}{2} W_{(1-s_i)/2} - \frac{(1 - \mathcal{A}_i(C'(x)))}{2} W_{(1+s_i)/2}\right] \\ &= \frac{x_i}{2} \mathbb{E}\left[\mathcal{A}_i(C'(x)) - s_i\right] \\ &= \frac{x_i}{2}(f_i(C'(x)) - s_i) \\ &= \frac{x_i}{2}(t(x)_i - s_i) \\ &\geq \frac{\tau}{4} \gtrsim \eta. \end{aligned}$$

Since the probability that $\mathcal{A}'_i(C'(x))$ queries any particular location of $C'(x)$ is still at most c/n, it follows that C' is a $(q, c, \Omega(\eta))$-smooth code. By Theorem 8, C' is also a $(q, \Omega(\eta/c), \Omega(\eta))$-LDC. ◀

5 From LDCs to outlaws

In this section we prove Theorem 5, the converse of our main result.

Proof of Theorem 5. By Theorem 8, $C : \{-1, 1\}^k \to \{-1, 1\}^n$ is also a $(q, q/\delta, \eta)$-smooth code. For each $i \in [k]$, let $\mathcal{B}_i$ be its decoder for the ith index. Let $\nu_i : 2^{[n]} \to [0, 1]$ be the probability distribution used by $\mathcal{B}_i$ to sample a set $S \subseteq [n]$ of at most q coordinates and let $f_{i,S} : \{-1, 1\}^n \to [-1, 1]$ be function whose value at $y \in \{-1, 1\}^n$ is the expectation of the random sign returned by $\mathcal{B}_i(y)$ conditioned on the event that it samples S. Since this value depends only on the coordinates in S, the function $f_{i,S}$ is a q-junta.

Fix an $i \in [k]$ and let $f_i : \{-1, 1\}^n \to [-1, 1]$ be the function given by $f_i = \mathbb{E}_{S \sim \nu_i}[f_{i,S}]$. Then, since a q-junta has degree at most q, so does f_i. We claim that f_i is $\delta/(q2^{q/2})$-smooth. Since the functions $f_{i,S} : \{-1, 1\}^n \to \{-1, 1\}$ are q-juntas, it follows from Parseval's identity that they have spectral norm at most $2^{q/2}$. Moreover, for each $j \in [n]$, we have $\Pr_{S \sim \nu_i}[j \in S] \leq q/(\delta n)$. Hence, since $f_{i,S}$ depends only on the coordinates in S, we have

$$\|D_j f_i\|_{\mathrm{sp}} \leq \sum_{S \ni j} \nu_i(S) \|f_{i,S}\|_{\mathrm{sp}} \leq \frac{q2^{q/2}}{\delta n},$$

which gives the claim. By (3), it holds for every $x \in \{-1,1\}^k$ and every $i \in [k]$ that

$$x_i f_i\big(C'(x)\big) \geq 2\eta. \tag{7}$$

Define the distribution μ to correspond to the process of sampling $i \in [k]$ uniformly at random and returning f_i. Let $\bar{g} = (f_1 + \cdots + f_k)/k$ be the mean of μ. We show that $\kappa_\mu(\eta) \geq \eta k$. To this end, let $l = \eta k$, let $\sigma : [l] \to [k]$ be an arbitrary map and define the functions $g_1, \ldots, g_l$ by $g_i = f_{\sigma(i)}$. Let $x \in \{-1,1\}^k$ be such that for each $i \in [l]$, we have $x_{\sigma(i)} = 1$ and $x_j = -1$ elsewhere. It follows from (7) that $f_{\sigma(i)}\big(C(x)\big) \in [2\eta, 1]$ for every $i \in [l]$ and that $f_i\big(C(x)\big) \leq 0$ for every other $i \in [k]$. Hence,

$$\begin{aligned}\Big\|\frac{1}{l}\sum_{i=1}^{l}(g_i - \bar{g})\Big\|_{L_\infty} &\geq \Big(\frac{1}{l}\sum_{i=1}^{l}(g_i - \bar{g})\Big)\big(C(x)\big) \\ &= \frac{1}{l}\sum_{i=1}^{l} f_{\sigma(i)}\big(C(x)\big) - \frac{1}{k}\sum_{i=1}^{k} f_i\big(C(x)\big) \\ &\geq 2\eta - \frac{l}{k} = \eta.\end{aligned}$$

If σ maps each element in $[l]$ to a uniformly random element in $[k]$, then $g_1, \ldots, g_l$ are independent, μ-distributed and satisfy

$$\mathbb{E}\left[\Big\|\frac{1}{l}\sum_{i=1}^{l}(g_i - \bar{g})\Big\|_{L_\infty}\right] \geq \eta,$$

which shows that $\kappa_\mu(\eta) \geq l$. Finally we can scale all the functions in μ to make them 1-smooth, and get a distribution $\tilde{\mu}$ over 1-smooth functions with $\kappa_{\tilde{\mu}}(\eta\delta/(q2^{q/2})) \geq \eta k$. ◀

6 Candidate outlaws

In this section we elaborate on the candidate outlaws mentioned in the introduction.

6.1 Incidence geometry

We begin by describing a variant of Corollary 6 based on a slightly different assumption and show conditions under which this assumption holds. Let p be an odd prime, let $\mathbb{F}_p$ be a finite field with p elements and let n be a positive integer. For $x, y \in \mathbb{F}_p^n$, the *line* with origin x in direction y, denoted $\ell_{x,y}$, is the sequence $(x + \lambda y)_{\lambda \in \mathbb{F}_p}$. A line is nontrivial if $y \neq 0$.

▶ **Corollary 16.** *For every odd prime p and $\varepsilon \in (0,1]$, there exist a positive integer $n_1(p,\varepsilon)$ and a $c = c(p,\varepsilon) \in (0, 1/2]$ such that the following holds. Let $n \geq n_1(p,\varepsilon)$ and k be positive integers. Assume that for every set $A \subseteq \mathbb{F}_p^n$ of size $|A| \leq k$, there exists a set $B \subseteq \mathbb{F}_p^n$ of size εp^n such that every nontrivial line through A contains at most $p-2$ points of B. Then, there exists a $(p-1, c, c)$-LDC sending $\{0,1\}^l$ to $\{0,1\}^{p^n}$, where $l = \Omega(c^2 k/\log(1/c))$.*

The proof uses the following version of Szemerédi's Theorem [28, Theorem 1.5.4] and its standard "Varnavides-type" corollary (see for example [30, Exercise 10.1.9]).

▶ **Theorem 17** (Szemerédi's theorem)**.** *For every odd prime p and any $\varepsilon \in (0,1]$, there exists a positive integer $n_0(p,\varepsilon)$ such that the following holds. Let $n \geq n_0(p,\varepsilon)$ and let $S \subseteq \mathbb{F}_p^n$ be a set of size $|S| \geq \varepsilon p^n$. Then, S contains a nontrivial line.*

▶ **Corollary 18.** *For every odd prime p and any $\varepsilon \in (0,1]$, there exists a positive integer $n_1(p,\varepsilon)$ and a $c(p,\varepsilon) \in (0,1]$ such that the following holds. Let $n \geq n_1(p,\varepsilon)$ and let $S \subseteq \mathbb{F}_p^n$ be a set of size $|S| \geq \varepsilon p^n$. Then, S contains at least $c(p,\varepsilon)p^{2n}$ nontrivial lines, that is,*

$$\Pr_{x\in\mathbb{F}_p^n, y\in\mathbb{F}_p^n\setminus\{0\}}\left[\{(x+\lambda y)_{\lambda=0}^{p-1}\} \subset S\right] \geq c(p,\epsilon).$$

Proof of Corollary 16. With some abuse of notation, we identify functions $f : \mathbb{F}_p^n \to \{-1,1\}$ with vectors in $\{-1,1\}^{\mathbb{F}_p^n}$. Let $\phi : \{-1,1\} \to \{0,1\}$ be the invertible map $\phi(\alpha) = (\alpha+1)/2$. For a function $f : \mathbb{F}_p^n \to \{-1,1\}$, let $\phi(f) : \mathbb{F}_p^n \to \{0,1\}$ be the function $\phi(f)(x) = \phi(f(x))$ and for $f : \mathbb{F}_p^n \to \{0,1\}$, define $\phi^{-1}(f) : \mathbb{F}_p^n \to \{-1,1\}$ analogously.

For every $x \in \mathbb{F}_p^n$, let $F_x : \{-1,1\}^{\mathbb{F}_p^n} \to \mathbb{R}$ be the degree-$(p-1)$ function

$$F_x(f) = \mathbb{E}_{y\in\mathbb{F}_p^n\setminus\{0\}}\left[\prod_{\lambda\in\mathbb{F}_p^*}\phi(f)(x+\lambda y)\right]. \tag{8}$$

Then, for a set $B \subseteq \mathbb{F}_p^n$, the value $F_x(\phi^{-1}(1_B))$ equals the fraction of all nontrivial lines $\ell_{x,y}$ through x of which B contains the $p-1$ points $\{x+\lambda y : \lambda \in \mathbb{F}_p^*\}$. If B has size at least εp^n, it thus follows from Corollary 18 that $\mathbb{E}_{x\in\mathbb{F}_p^n}[F_x(\phi^{-1}(1_B))] \geq c(p,\varepsilon)$. Moreover, since the monomials in the expectation of (8) involve disjoint sets of variables and can be expanded as

$$\prod_{\lambda\in\mathbb{F}_p^*}\phi(f)(x+\lambda y) = \frac{1}{2^q}\sum_{S\subseteq\mathbb{F}_p^*}\prod_{\lambda\in S} f(x+\lambda y),$$

it follows that each F_x is $2(1-p^{-n})$-smooth.

Let μ be the uniform probability distribution over all F_x. We claim that $\kappa_\mu(c(p,\varepsilon)) \geq k$, which implies the result by Theorem 4 since μ is supported by degree $(p-1)$-functions. For every set $A \subseteq \mathbb{F}_p^n$ of size $|A| \leq k$, let $B \subseteq \mathbb{F}_p^n$ be an arbitrary set as in the assumption of the corollary and let $f_A = \phi^{-1}(1_B)$. Let z be a uniformly distributed random variable over $\mathbb{F}_p^n$, let $z_1,\ldots,z_k$ be independent copies of z and let $A = \{z_1,\ldots,z_k\}$. Then, $F_{z_1},\ldots,F_{z_k}$ are independent μ-distributed random functions and since every nontrivial line through A meets B in at most $p-2$ points, we have $F_{z_i}(f_A) = 0$ for every $i \in [k]$. Hence,

$$\mathbb{E}\Big[\Big\|\frac{1}{k}\sum_{i=1}^k\big(F_{z_i}-\mathbb{E}[F_z]\big)\Big\|_{L_\infty}\Big] \geq \mathbb{E}\Big[\Big|\frac{1}{k}\Big(\sum_{i=1}^k\big(F_{z_i}-\mathbb{E}[F_z]\big)\Big)(f_A)\Big|\Big] \geq c(p,\varepsilon),$$

which gives the claim. ◀

The proof of the formal version of Corollary 6 (given below) is similar to that of Corollary 16, so we omit it. In the following, $\mathbb{PF}_p^{n-1}$ is the projective space of dimension $n-1$, which is the space of directions in $\mathbb{F}_p^n$. The formal version of Corollary 6 is then as follows.

▶ **Corollary 19.** *For every odd prime p and $\varepsilon \in (0,1]$, there exist a positive integer $n_1(p,\varepsilon)$ and a $c = c(p,\varepsilon) \in (0,1/2]$ such that the following holds. Let $n \geq n_1(p,\varepsilon)$ and k be positive integers. Suppose that for every set of directions $D \subset \mathbb{PF}_p^{n-1}$ of size $|D| \leq k$, there exists a set $B \subset \mathbb{F}_p^n$ of size $|B| \geq \varepsilon p^n$ which does not contain any lines with direction in D. Then, there exists a (p,c,c)-LDC sending $\{0,1\}^l$ to $\{0,1\}^{p^n}$, where $l = \Omega(c^2k/\log(1/c))$.*

Feasible parameters for Corollary 16

Proving lower bounds on k for which the assumption of Corollary 16 holds true thus allows one to infer the existence of $(p-1)$-query LDCs with rate $\Omega(k/N)$ for $N = p^n$, provided p and ε are constant with respect to n. We establish the following bounds, which imply the (well-known) existence of $(p-1)$-query LDCs with message length $k = \Omega((\log N)^{p-2})$.

▶ **Theorem 20.** *For every odd prime p there exists an $\varepsilon(p) \in (0,1]$ such that the following holds. For every set $A \subseteq \mathbb{F}_p^n$ of size $|A| \leq \binom{n+p-3}{p-2} - 1$, there exists a set $B \subseteq \mathbb{F}_p^n$ of size $\varepsilon(p)p^n$ such that every line through A contains at most $p-2$ points of B.*

The proof uses some basic properties of polynomials over finite fields. For an n-variate polynomial $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ denote $Z(f) = \{x \in \mathbb{F}_p^n : f(x) = 0\}$. The starting point of the proof is the following standard result (see for example [29]), showing that small sets can be 'captured' by zero-sets of nonzero, homogeneous polynomials of low degree.

▶ **Lemma 21** (Homogeneous Interpolation)**.** *For every $A \subseteq \mathbb{F}_p^n$ of size $|A| \leq \binom{n+d-1}{d} - 1$, there exists a nonzero homogeneous polynomial $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ of degree d such that $A \subseteq Z(f)$.*

The next two lemmas show that if f is nonzero, homogeneous and degree d, and if $a \in \mathbb{F}_p^*$ is such that $f^{-1}(a)$ is nonempty, then lines through $Z(f)$ meet $f^{-1}(a)$ in at most d points.

▶ **Lemma 22.** *Let $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ be a nonzero homogeneous polynomial of degree d. Let $a \in \mathbb{F}_p^*$ be such that the set $f^{-1}(a)$ is nonempty. Then, every line that meets $f^{-1}(a)$ in $d+1$ points must have direction in $Z(f)$.*

Proof. The univariate polynomial $g(\lambda) = f(x + \lambda y)$ formed by the restriction of f to a line $\ell_{x,y}$ has degree at most d. By the Factor Theorem, such a polynomial must be the constant polynomial $g(\lambda) = a$ to assume the value a for $d+1$ values of λ. Since f is homogeneous, the coefficient of λ^d, which must be zero, equals $f(y)$, giving the result. ◀

The following lemma is essentially contained in [8].

▶ **Lemma 23** (Briët–Rao)**.** *Let $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ be a nonzero homogeneous polynomial of degree d. Let $a \in \mathbb{F}_p^*$ be such that $f^{-1}(a)$ is nonempty. Then, there exists no line that intersects $Z(f)$, meets $f^{-1}(a)$ in at least d points and has direction in $Z(f)$.*

Proof. For a contradiction, suppose there exists a line $\ell_{x,y}$ through $Z(f)$ that meets $f^{-1}(a)$ in d points and has direction $y \in Z(f)$. Observe that for every $\lambda \in \mathbb{F}_p$, the shifted line $\ell_{x+\lambda y,y}$ also meets $f^{-1}(a)$ in d points. Hence, without loss of generality we may assume that the line starts in $Z(f)$, that is $x \in Z(f)$. Let $g(\lambda) = a_0 + a_1\lambda + \cdots + a_d\lambda^d = f(x + \lambda y) \in \mathbb{F}_p[\lambda]$ be the restriction of f to $\ell_{x,y}$. It follows that $a_0 = g(0) = f(x) = 0$ and, since f is homogeneous, that $a_d = f(y) = 0$. Moreover, there exist distinct elements $\lambda_1, \ldots, \lambda_d \in \mathbb{F}_p^*$ such that $g(\lambda_i) = f(x + \lambda_i y) = a$ for every $i \in [d]$. Then $g(\lambda) - a$ is a degree $d-1$ polynomial with d distinct roots. But it cannot be the zero polynomial since it takes value $-a$ when $\lambda = 0$. ◀

The final ingredient for the proof of Theorem 20 is the DeMillo–Lipton–Schwartz–Zippel Lemma as it appears in [10].

▶ **Lemma 24** (DeMillo–Lipton–Schwartz–Zippel)**.** *Let $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ be a nonzero polynomial of degree d and denote $r = |\mathbb{F}_p|$. Then,*

$$|Z(f)| \leq \Big(1 - \frac{1}{r^{d/(r-1)}}\Big) r^n.$$

Proof of Theorem 20. Let $A \subseteq \mathbb{F}_p^n$ be a set of size $|A| \leq \binom{n+p-3}{p-2} - 1$. Let $f \in \mathbb{F}_p[x_1, \ldots, x_n]$ be a nonzero degree-$(p-2)$ homogeneous polynomial such that $A \subseteq Z(f)$, as promised to exist by Lemma 21. By Lemma 24, there exists an $a \in \mathbb{F}_p^*$ such that the set $B = f^{-1}(a)$ has size at least $|B| \geq p^n / p^{(2p-3)/(p-1)}$. By Lemma 22, every line that meets B in $p-1$ points must have direction in $Z(f)$, but by Lemma 23 no such line can pass through $Z(f)$. Hence, every line through A meets B in at most $p-2$ points. ◀

6.2 Uniformity of random Cayley hypergraphs

A second candidate for constructing outlaws comes from quasirandom properties of Cayley graphs and hypergraphs.

Random Cayley graphs and 2-query LDCs

For graphs, an important quasirandom property is spectral expansion. If for a regular graph G, we let $1 = \lambda_1(G) \geq \lambda_2(G) \geq \cdots \geq \lambda_n(G) \geq -1$ denote the eigenvalues of the normalized adjacency matrix, then the second eigenvalue is defined as $\lambda(G) = \max_{i\in\{2,\ldots,n\}} |\lambda_i(G)|$. The importance of this parameter stems from the fact that if it is small, then every large subset of vertices is connected to its complement by a large number of edges [27, 1], a property that sparse random graphs have with high probability (we refer to [17] for a survey on expander graphs).

A famous result of Alon and Roichman [2] asserts that random Cayley graphs require relatively low degree to be spectral expanders with good probability. For a finite group Γ and an element $g \in \Gamma$, the Cayley graph $\mathrm{Cay}(\Gamma, \{g\})$ is the 2-regular graph with vertex set Γ and edge set $\{\{u, gu\} : u \in \Gamma\}$, where in case $g^2 = 1$, all edges are doubled (parallel edges are thus allowed). For a multiset $S = \{g_1, \ldots, g_k\} \subseteq \Gamma$, the Cayley graph $\mathrm{Cay}(\Gamma, S)$ is the $2k$-regular graph formed by the disjoint union of the graphs $\mathrm{Cay}(\Gamma, \{g_1\}), \ldots, \mathrm{Cay}(\Gamma, \{g_k\})$.

▶ **Theorem 25** (Alon–Roichman Theorem). *For any $\varepsilon \in (0, 1)$ there exists a $c(\varepsilon) \in (0, \infty)$ such that the following holds. Let Γ be a finite group of cardinality n. Let $k \geq c(\varepsilon) \log n$ be an integer and let $g_1, \ldots, g_k$ be independent uniformly distributed elements from Γ. Then, with probability at least $1/2$, the Cayley graph $G = \mathrm{Cay}(\Gamma, \{g_1, \ldots, g_k\})$ satisfies $\lambda(G) \leq \varepsilon$.*

The link with Theorem 4 follows from the fact that the above result can equivalently be phrased as saying that the normalized adjacency matrix A_G of the random graph G as in Theorem 25 *concentrates* around its expectation. The normalized adjacency matrix of $\mathrm{Cay}(\Gamma, \{g_i\})$, denoted A_i, has expectation J/n, where J is the all-ones matrix, and A_G is the average $(A_1 + \cdots + A_k)/k$. The Schatten-∞ norm (also known as the spectral norm or operator norm) of a matrix B is given by $\|B\|_{S_\infty} = \sup\{x^{\mathsf{T}} B y : \|x\|_{\ell_2} \leq 1, \|y\|_{\ell_2} \leq 1\}$. Due to the characterization $\lambda(G) = \|A_G - J/n\|_{S_\infty}$, Theorem 25 says that the value

$$\Big\| \frac{1}{k} \sum_{i=1}^{k} (A_i - J/n) \Big\|_{S_\infty}$$

is small with good probability provided k is large enough. Good concentration is thus good for expansion. Our Theorem 4 implies that *poor* concentration is good for LDCs!

▶ **Corollary 26.** *Let Γ be a finite group of cardinality n and let $\varepsilon \in (0, 1)$. Let k be the largest positive integer such that with probability at least $1/2$, for independent uniformly distributed elements $g_1, \ldots, g_k \in \Gamma$, the graph $G = \mathrm{Cay}(\Gamma, \{g_1, \ldots, g_k\})$ satisfies $\lambda(G) > \varepsilon$. Then, there exists a $(2, 1, \Omega(\varepsilon))$-LDC sending $\{0,1\}^l$ to $\{0,1\}^n$, where $l = \Omega(\varepsilon^2 k / \log(1/\varepsilon))$.*

It is not hard to show that if Γ is Abelian, then any Cayley graph $G = \mathrm{Cay}(\Gamma, S)$ generated by $|S| \leq (\log|\Gamma|)/3$ group elements satisfies $\lambda(G) \geq 1/2$ [17, Proposition 11.5]. Together with Corollary 26, this fact implies the existence of 2-query LDCs of exponential length; arguably the most round-about way to prove this!

Below, we prove a more general version of Corollary 26, giving the existence of q-query LDCs from lower bounds on the required degree for uniformity of random q-uniform Cayley hypergraphs. For this, we gather the following definitions.

Regular hypergraphs and uniformity

A q-uniform hypergraph $H = (V, E)$ with vertex set V has as edge set E a family of unordered q-element multisets with possible parallel edges. For $u_1, \dots, u_q \in V$ let $e_H(u_1, \dots, u_q)$ denote the number of edges equal to $\{u_1, \dots, u_q\}$.[4] The *adjacency form* of H is the q-linear form $\overline{A}_H : \mathbb{R}^V \times \cdots \times \mathbb{R}^V \to \mathbb{R}$ given by $\overline{A}_H(1_{\{u_1\}}, \dots, 1_{\{u_q\}}) = e_H(u_1, \dots, u_q)$. The degree of a vertex $v \in V$ is defined by $\overline{A}_H(1_{\{v\}}, 1_V, \dots, 1_V)$ and H is k-regular if every vertex has degree exactly k, in which case its normalized adjacency form is $A_H = \overline{A}_H/k$. Observe that we obtain the usual definition of a regular graph for the case $q = 2$.

Given a regular hypergraph $H = (V, E)$ and a regular sub-hypergraph $J = (V, E')$ of H based on a multiset $E' \subseteq E$, we define the *uniformity of J relative to H* by

$$\Delta_H(J) = \max_{T_1,\dots,T_q \subseteq V} \frac{1}{|V|} \Big| A_J(1_{T_1}, \dots, 1_{T_q}) - A_H(1_{T_1}, \dots, 1_{T_q}) \Big|. \tag{9}$$

Observe that we get the usual notion of uniformity for graphs if H is the complete graph with all self-loops. We say that J *is ε-uniform relative to H* if $\Delta_H(J) \le \varepsilon$.

Cayley hypergraphs

A Cayley hypergraph over a finite group Γ is a disjoint union of hypergraphs with edge sets of the form $\{\pi_1(v), \dots, \pi_q(v)\}$, $v \in \Gamma$, where $\pi_1, \dots, \pi_q$ are permutations on Γ, and where the edge multiplicities are set such that

$$e_H(u_1, \dots, u_q) = \sum_{\sigma \in S_q} \sum_{v \in \Gamma} 1_{\{u_1\}}\big(\pi_{\sigma(1)}(v)\big) \cdots 1_{\{u_q\}}\big(\pi_{\sigma(q)}(v)\big). \tag{10}$$

This choice of multiplicities ensures that we always get a $(q!)$-regular hypergraph regardless of the choice of permutations. The permutations defining Cayley hypergraphs are given in terms of an integer vector $r \in (\mathbb{Z} \setminus \{0\})^q$ such that Γ has no elements of order r_j for every $j \in [q]$, so that for every $g \in \Gamma$ and $j \in [q]$, the map $u \mapsto u^{r_j} g$ is a permutation. For a q-tuple $\mathbf{g} = (g[1], \dots, g[q]) \in \Gamma^q$, we then define $\mathrm{Cay}^{(q)}(\Gamma, r, \mathbf{g})$ to be the hypergraph as above with $\pi_j(u) = u^{r_j} g[j]$. For a multiset $S = \{\mathbf{g}_1, \dots, \mathbf{g}_k\} \subseteq \Gamma^q$, we let $\mathrm{Cay}^{(q)}(\Gamma, r, S)$ be the $(q!)k$-regular hypergraph given by the disjoint union of $\mathrm{Cay}^{(q)}(\Gamma, r, \{\mathbf{g}_i\})$ for $i \in [k]$.

Examples

Notice that $\mathrm{Cay}^{(2)}(\Gamma, (1,1), (g,h))$ is the 2-regular Cayley graph generated by the element $g^{-1}h$. If $\Gamma = \mathbb{F}_p^n$ for some odd prime p, if $\mathbf{1} \in \mathbb{Z}^p$ is the all-ones vector and if $S = \{(0, y, 2y, \dots, (p-1)y) : y \in \mathbb{F}_p^n\}$, then the edges of $H = \mathrm{Cay}^{(p)}(\Gamma, \mathbf{1}, S)$ are all the affine lines in $\mathbb{F}_p^n$. Moreover, if $D \subseteq \mathbb{F}_p^n$ and $S' = \{(0, y, 2y, \dots, (p-1)y) : y \in D\}$, then the edges $J = \mathrm{Cay}^{(p)}(\Gamma, \mathbf{1}, S')$ are all the affine lines whose direction lies in D. Finally, if $\Delta_H(J) \le \varepsilon$, then for every set $T \subseteq \mathbb{F}_p^n$, the fraction of lines in T with direction in D is within ε of the fraction of all lines in T. In [8] it is shown that if $n \ge p^2$, then there is an absolute constant $c(p) \in (0,1)$ depending on p only such that if H and J are as above, then $\Delta_H(J) < c(p)$ implies that $|D| \ge \Omega(n^{p-1})$.[5]

[4] Curly brackets delimit *multisets*: unordered lists that may contain repeated elements.

[5] Their proof, however, does not show that the assumption of Corollary 19 holds for $|D| \ge \Omega(n^{p-1})$, as it relies on the construction of a combinatorial rectangle $T_1 \times \cdots \times T_p$ consisting of different sets.

Random q-uniform Cayley hypergraphs and q-query LDCs

Theorem 4 implies the following link between LDCs and random Cayley hypergraphs.

▶ **Corollary 27.** *Let Γ be a finite group of cardinality n and let $H = \mathrm{Cay}^{(q)}(\Gamma, r, S)$ be a q-uniform Cayley hypergraph. Let k be the largest positive integer such that with probability at least 1/2, if $\mathbf{g}_1, \ldots, \mathbf{g}_k$ are independent uniformly distributed random elements over S, the random Cayley hypergraph $J = \mathrm{Cay}^{(q)}(\Gamma, r, \{\mathbf{g}_1, \ldots, \mathbf{g}_k\})$ satisfies $\Delta_H(J) \geq \varepsilon$. Then, there exists a $(q, 1, \Omega(\varepsilon))$-LDC sending $\{0,1\}^l$ to $\{0,1\}^n$, where $l = \Omega(\varepsilon^2 k / \log(1/\varepsilon))$.*

Proof. Associate with every q-linear form $A : \mathbb{R}^\Gamma \times \cdots \times \mathbb{R}^\Gamma \to \mathbb{R}$ a homogeneous $q|\Gamma|$-variate degree-q function $f : \{-1,1\}^{q|\Gamma|} \to \mathbb{R}$ in the obvious way. It follows from (10) and the normalization of the adjacency forms that for every fixed $g \in \Gamma$, the functions f_g associated with the adjacency form of the hypergraph $\mathrm{Cay}^{(q)}(\Gamma, r, \{g\})$ are 1-smooth.

Moreover, for any q-linear form A on $\mathbb{R}^n$, it holds that

$$\frac{\max\left\{|A(x[1], \ldots, x[q])| : x[1], \ldots, x[q] \in \{-1,1\}^n\right\}}{\max\left\{|A(1_{T_1}, \ldots, 1_{T_q})| : T_1, \ldots, T_q \subseteq [n]\right\}} \geq 1.$$

The form A_J is the average of k independent identically distributed adjacency forms $A_1, \ldots, A_k$ that have expectation A_H. Letting $f_1, \ldots, f_k$ and $\bar{f}$ be the functions associated with $A_1, \ldots, A_k$ and A_H, respectively, it follows that

$$\begin{aligned}\mathbb{E}\left[\left\|\frac{1}{k}\sum_{i-1}^{k}(f_i - \bar{f})\right\|_{L_\infty}\right] &= \mathbb{E}\left[\max\left\{|(A_J - A_H)(x[1], \ldots, x[q])| : x[1], \ldots, x[q] \in \{-1,1\}^\Gamma\right\}\right] \\ &\geq \mathbb{E}[\Delta_H(J)] \\ &\geq \frac{\varepsilon}{2},\end{aligned}$$

where the last line follows from the fact that uniformity is nonnegative. The result now follows from Theorem 4. ◀

Spectral expansion and uniformity

For regular *graphs*, the famous Expander Mixing Lemma [17] shows that $\Delta(G) \leq \lambda(G)$ holds in general. Whereas the reverse inequality does not hold in general [11], the reason why Corollary 26 could be stated in terms of the second eigenvalue is that for Cayley graphs, a near-reverse inequality does hold: for some absolute constant $c \in (0, \infty)$, we have $\Delta(G) \geq c\lambda(G)$ [21, 11]. A second eigenvalue for hypergraphs, analogous to uniformity for hypergraphs, was defined and studied in [8], where first steps to generalize the Alon–Roichman Theorem were taken. While the Expander Mixing Lemma easily generalizes, it is unknown whether the analogue of [21, 11] holds for Cayley hypergraphs.

Constant-Rate Interactive Coding Is Impossible, Even In Constant-Degree Networks

Abstract

Multiparty interactive coding allows a network of n parties to perform distributed computations when the communication channels suffer from noise. Previous results (Rajagopalan and Schulman, STOC '94) obtained a multiparty interactive coding protocol, resilient to random noise, with a blowup of $O(\log(\Delta+1))$ for networks whose topology has a maximal degree Δ. Vitally, the communication model in their work forces all the parties to send one message at every round of the protocol, even if they have nothing to send.

We re-examine the question of multiparty interactive coding, lifting the requirement that forces all the parties to communicate at each and every round. We use the recently developed information-theoretic machinery of Braverman et al. (STOC '16) to show that if the network's topology is a cycle, then there is a specific "cycle task" for which any coding scheme has a communication blowup of $\Omega(\log n)$. This is quite surprising since the cycle has a maximal degree of $\Delta = 2$, implying a coding with a *constant blowup* when all parties are forced to speak at all rounds.

We complement our lower bound with a matching coding scheme for the "cycle task" that has a communication blowup of $\Theta(\log n)$. This makes our lower bound for the cycle task tight.

1 Introduction

In multiparty interactive communication, n parties, connected via some arbitrary network $G = (V, E)$, try to compute some function f of their private inputs by communicating messages over the network. *Coding for interactive communication* asks for coding schemes that succeed to compute any such function even when the communication may be noisy. A fundamental question in this field is finding the maximal *rate* such coding schemes can achieve[1], that is, what is the minimal amount of redundancy coding schemes must add in order to successfully compute any function f despite the noise.

* Part of this work was done while the author was at Princeton University. Supported in part by NSF grant CCF-1149888.

[1] The rate of a coding scheme is the ratio between the communication of a protocol that performs over a noiseless network, to the communication of the coding scheme for the same task, over the noisy network.

The work of Rajagopalan and Schulman [13] gave an initial answer to this question, assuming stochastic noise (e.g., when each bit is being flipped independently with some fixed probability $\varepsilon < 1/2$): Let Δ be the maximal degree in G, then any (noiseless) protocol χ can be simulated with high probability over the noisy network by a protocol χ' with communication complexity $\mathsf{CC}(\chi') = \mathsf{CC}(\chi) \cdot O(\log(\Delta + 1))$. That is, for constant-degree networks such as the line or the cycle, the rate, $\mathsf{CC}(\chi)/\mathsf{CC}(\chi')$, is a constant bounded away from 0 while for highly-connected graphs such as the star or the complete graph, the rate goes to zero when n tends to infinity, i.e., the rate is $\Theta(1/\log n)$. The work of Alon et al. [2] shows that coding schemes with constant (non-zero) rate also exist for the complete graph, and other highly-connected graphs, hinting that it may be possible to achieve a constant rate coding scheme for any network G. This hope was terminated by Braverman et al. [3], showing that a rate of $\Theta(\log\log n/\log n)$ is maximal for a specific task over the star network.

All the above works assume that the communication over the network is performed in rounds, where at every round *all the parties speak*, that is, $2|E|$ symbols are being communicated—one symbol over each channel of the network. A natural question to ask is: Why is such an assumption justifiable? One interpretation is that these previous works try to optimize the *round complexity*, as opposed to the communication complexity, and hence the assumption that all parties send a message to all other connected parties in each round.

In this work, our goal is to optimize the *communication complexity* (as opposed to round complexity), and we ask whether similar bounds on the rate follow if we don't force all parties to speak at every round.

Surprisingly, we show that the rate of coding schemes when G is a cycle (assuming channels with large alphabets) is at most $O(1/\log n)$. This corresponds to a lower bound of $\Omega(\log n)$ on the communication blowup. Informally, our main theorem is the following:

▶ **Theorem 1** (main, informal)**.** *Let G be the cycle graph with n parties. Then, for any constant $\varepsilon < 1/2$ there exists a task whose communication complexity over the noiseless G is d while any coding scheme over any noisy graph G' (with noise parameter ε) that succeeds with high probability has communication complexity $\Omega(d \log n)$.*

The above theorem is quite surprising in light of the result of Rajagopalan and Schulman [13]: the maximal degree in the cycle graph is $\Delta = 2$, therefore the coding scheme of [13] (in the "everybody speaks" model) has a rate of $\Theta(1)$, regardless of the size of the network! In hindsight, the reason for this discrepancy is simple: the fact that everybody speaks in the model of [13] implies an inherent blowup in the communication of $O(n)$, which allows the parties to overcome errors. Indeed, assume that the "relevant" information for computing the function f progresses along the cycle: first p_1 sends a message to p_2 (while all the other parties have nothing to send in the meantime), only then p_2 has a message to send to p_3 and so on. While the "relevant" information is limited to a single edge on the network at any round, the fact that all the parties *must* speak at every round multiplies the effective communication by n both for the noiseless and noisy protocols, hence, it cancels out in the rate. On the other hand, this superfluous redundancy gives the parties the opportunity to correct previous errors in rounds where they are supposed to be idling if we weren't to force all the parties to speak at every round, and charge the parties according to the communication that actually happened.

For our lower bound we don't restrict the topology G' of the noisy graph, and allow any party to communicate with any other party (since anyways we count the actual communication, allowing the coding scheme to utilize any underlying graph just makes our lower bound stronger). Our lower bound actually works when the noise erases symbols instead of corrupting symbols (again, making the result stronger). The only "restrictive" assumption we have on the coding scheme is a fixed speaking order, independent of the inputs and the noise; see the "Communication Model" subsection below for a discussion regarding this assumption.

1.1 The Cycle Task

The noiseless task we use for Theorem 1 is an analog of the "pointer jumping" task over a cycle (see formal description in Section 2.5). Every party begins with a 2^n-ary tree of depth d, where each edge is labeled by a single bit. Each party begins at the root of its own tree, and the goal is to travel down the tree until it reaches a leaf.

It is most convenient to describe this task via the protocol that solves it. The parties are activated in a cyclic order (first p_1, then p_2, etc.). When p_i is activated, it receives a message of the form $(b_1, \ldots, b_n)$ from p_{i-1}, corresponding to the labels of the edges traversed by the parties in the previous n rounds (padding with zeros as necessary in the first $n-1$ rounds). Upon receiving this message $\ell = (b_1, \ldots, b_n)$ from p_{i-1}, p_i moves down from its current node to its ℓ-th child. Denoting by b the label of the edge it just took, p_i communicates to p_{i+1} the string $(b_2, \ldots, b_n, b)$. This process continues until all parties reach a leaf at depth d in their input tree. The output is the path each party took along its tree.

In addition to the lower bound on the communication blowup, we show a coding scheme that successfully computes the cycle task over a noisy network with rate $\Theta(1/\log n)$, matching the rate of our lower bound for the cycle task (up to a constant).

▶ **Theorem 2** (upper bound, informal). *For any constant $\varepsilon < 1/2$, there exists a coding scheme that solves the cycle task of depth d over noisy channels with large alphabet and error parameter ε. The coding scheme obtains a rate of $\Theta(1/\log n)$ and a success probability of $1 - 2^{-\Omega(d \log n)}$.*

1.2 Communication Model

For our communication model, we assume that protocols have a *fixed* order of speaking. That is, we can assume that the protocol works in rounds so that the party that speaks at round i is determined in advance, independently of inputs and noise. This assumption is not without loss of generality, but we claim here that lifting this assumptions trivializes the model.

A completely unrestricted model would let the parties determine, at any round, whether they speak or not (cf. adaptive protocols for the two party case [1]; see also [8]). Such a model trivializes coding in the multiparty scenario, as parties can "encode" information via the path that the message is sent through: say p_1 wants to send a single bit to p_2. If the bit is 0, then p_1 sends the message directly. If it is 1, he can send the bit through p_n (who will relay it to p_2). Now, even if noise occurs[2], p_2 can figure out the bit in certainty by the identity of the sender.

Another model, which is not completely unrestricted but still trivializes coding in our scenario, is described in [11]. There, parties are allowed to decide whether to send a message or not (and to whom) according to the transcript so far. On its surface, this restriction avoids the "path encoding" described above, as parties are not allowed to change the delivery path according to their inputs. Nevertheless, such a model still enables error correction via "path selection", since the transcript still depends on the inputs. To give a simple example, assume a noiseless protocol in which the parties speak in order (p_1 sends a bit to p_2, then p_2 sends a bit to p_3, and so on). Such a protocol can be easily simulated over a noisy network in the [11] model: After p_i sends a bit to p_{i+1} the latter sends the bit back either directly (if it was a 0), or through p_{i-1} (if it was a 1); note that this decision is made as a function of the observed (possibly noisy) transcript, and thus it is allowed in that model. Now p_1 knows if its

[2] As long as we do not allow a stronger type of noise, i.e., insertions and deletions, see [4].

original bit reached p_{i+1} correctly or not and either retransmits the bit, or sends a message to p_{i+2} (who forwards it to p_{i+1}) to indicate that the bit was transferred correctly, and the simulation can move on to simulating the next bit of the noiseless protocol. In other words, this model reduces bit flips into erasures, and performing error correction from erasures with rate $1-\varepsilon$ is fairly simple if the model allows changing the order of the speaking according to the observed noise.

To conclude, we show that there is a strong relation between the order of speaking and the obtained coding rate. On one hand, allowing the order of speaking to change adaptively, allows trivial coding schemes. On the other hand, fixing the order of speaking allows us to show an $\Omega(\log n)$ lower bound on the blowup for the cycle task. It is however possible that worse rates are possible for other tasks. In fact, we conjecture that the blowup can get as high as $\Omega(n)$ in specific situations, as a function of the "mismatch" between the order of speaking in the noiseless protocol and the coding scheme.

▶ **Conjecture 3.** *There exists a topology G and a noiseless protocol χ with a fixed order of speaking for which any coding scheme χ' with fixed order of speaking has rate at most $O(1/n)$.*

Our findings are reminiscent of the two-party case: if the simulation has a fixed order, the order of speaking in the original scheme determines the maximal rate of the coding; specifically, it is conjectured that there exists a protocol whose simulation has rate bounded away from 1. On the other hand, if the simulation is allowed to be adaptive, better rates (that approach 1) can be achieved. See discussion in [12, 9].

1.3 On Binary vs. Large Alphabet

While our main result (Theorem 1) assumes that the parties communicate symbols from a large alphabet, we also obtain a lower-bound for the case where the parties communicate bits, i.e., use a binary alphabet. Typically, constructing coding schemes over the binary alphabet is harder than constructing such schemes over a large alphabet. However, our result is a lower-bound rather than a coding scheme, and it is not necessarily so that the binary-case is stronger (nor is more difficult to obtain).

Nevertheless, the setting of binary channels and the setting of large-alphabet channels seem *incomparable*, since the alphabet applies both to the original (noiseless) protocol and to the coded (noisy) protocol. We elaborate on this in Section 5.

We extend our lower bound result also to the case where the noiseless protocol and the coding scheme are binary. Specifically, we show a lower bound of $\tilde{\Omega}(\log n)$ on the blowup of the communication for binary coding scheme over the star network (where the $\tilde{\Omega}$ notation means neglecting $\log\log n$ terms). Informally, the theorem is the following.

▶ **Theorem 4** (binary case, informal)**.** *Let G be the star graph with n parties. Then, for any constant $\varepsilon < 1/2$ there exists a task whose communication complexity over the noiseless G is d while any coding scheme (with fixed order) over any noisy graph G' (with noise parameter ε) that succeeds with high probability has communication complexity $\tilde{\Omega}(d \log n)$.*

We stress that the above theorem is incomparable to the result of [3]: in our model parties may speak in an arbitrary (but fixed) order and are not forced to speak at every round. The task in consideration is the generalized jumping pointer described in [3]. The proof of Theorem 4 follows by combining the techniques developed in this paper for the cycle task with the techniques of [3] in quite a straightforward way, and we omit the details here.

1.4 Overview of our Techniques

The proof of our lower bound uses techniques from [3] for bounding the progress of a coding scheme χ' in simulating a noiseless protocol χ. As in [3], we use the notion of *cutoff* (Definition 11) that measures for any partial transcript of χ', how many cycles of the noiseless protocol χ are still not-simulated: when the cutoff is k, then the last $d-k$ cycles of χ are not simulated by the given transcript. More accurately (but still very informally) the transcript gives very little of information about the labels $\{b_i\}$ of the last $d-k$ cycles.

We show that any coding scheme that solves the cycle task with high probability must produce transcripts whose cutoff is $\approx d$, in expectation. Then, we show that for any segment in which the coding scheme communicates $O(n \log n)$ symbols, the cutoff advances by at most $O(1)$ cycles in expectation. Namely, let π be some fixed previous communication (including erasures), and let Π^{new} be the random variable describing the next $O(n \log n)$ symbols communicated by the coding scheme χ' (including erasures), then

$$\mathbb{E}[\mathsf{cutoff}(\pi \circ \Pi^{new}) \mid \mathsf{cutoff}(\pi) = k] \leq k + O(1).$$

In order for χ' to achieve an expected cutoff of $\approx d$, which is crucial for being correct with high probability, the coding scheme must communicate at least $\Omega(dn \log n)$ symbols, yielding a rate of $O(1/\log n)$.

The reason for the restricted progress in the cutoff is that many parties do not send any useful information in the segment Π^{new}, and that the next "move" (in the input tree) of each party depends on the moves of *all* the parties in the previous cycle. This means that most parties are missing a lot of crucial information in order to advance more than a constant number of levels in their input tree. Bounding the exact information sent by the parties (and thus the expected increase in the cutoff) is performed via the machinery of [3].

Showing that many parties give no information in any segment of $O(n \log n)$ rounds in our setting is a main technical difference from [3]. In the model of [3] all parties speak at every round, thus when the coding scheme communicates $O(n \log n)$ symbols we know that this communication is evenly spread—every party communicates exactly $O(\log n)$ symbols. In our setting, it is possible that the communication is evenly spread, but it is also possible that all $O(n \log n)$ symbols are communicated by a single party (or any other pattern in between). In the latter case, even if the noise targets the single party that speaks, that party could still convey $O(n \log n)$ bits of information by encoding its message via a standard error-correction code. Nevertheless, we show that there is a large set of parties that do not communicate any information in the new segment: either they don't speak at all, or they speak very little and their entire communication is completely erased by the noise. Furthermore, previous communication of these parties contains very little information on their labels in the last $d-k$ cycles to begin with.

The existence of this set of "erased" parties implies that the non-erased parties in this segment don't know how to proceed in their input tree, and their communication in that segment is "irrelevant" to the progress of the protocol, even if it is not erased by the noise. Indeed, assume a party's current node in its input tree is given, and assume that the party doesn't know which of its children it should go to next. The best that a party can do is to send all the labels below its current node. However, due to the fact that each node has 2^n children, that party cannot communicate more than $O(1)$ levels below its current node even if it gets to speak all the $O(n \log n)$ symbols in the next segment.

Naturally, the actual proof is more complex, since the party has some prior information about the children it should go (due to communication in previous rounds). This means that the children are not equiprobable and the party can communicate more information about

(the labels of) more probable children. Still, since the arity of the input tree is so large and since the information on the next children it should take is rather little, the party will be able to communicate information on the labels of only $O(1)$ levels below its current node (in expectation).

1.5 Other Related Work

The field of coding for interactive communication was initiated by Schulman [14, 15] who formalized the question for the two-party case and developed basic techniques used for solving this task, either when the noise is stochastic (where each bit is flipped with some constant probability) or adversarial (where any subset of up to ε-fraction of the bits can be flipped). Later works in the two-party setting improve on the computational efficiency, success probability, and achievable rate of coding schemes. We refer the reader to [6] for a survey on interactive coding.

As mentioned above, the interactive coding in the multiparty case was initiated by Rajagopalan and Schulman [13] for the random noise case. Efficiency for this setting is obtained by Gelles, Moitra and Sahai [7]. The works of Alon et al. [2] and of Braverman et al. [3] identify the maximal rate obtainable over the complete graph and the star (and provide efficient schemes that obtain such a rate). The case of adversarial noise is considered by Jain, Kalai and Lewko [11] providing a scheme for topologies that have a star as a subgraph, that withstands $O(1/n)$-fraction of adversarial noise and blows up the communication by only a constant. The work of Hoza and Schulman [10] provides a coding scheme for any topology $G = (V, E)$ that withstands $O(1/n)$-fraction of noise and obtains a rate of $\Theta(n/|E| \log n)$.

2 Preliminaries: Notations, Model, Coding Schemes

2.1 Notations and Basic Properties

For $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1, 2, \ldots, n\}$. The log() function is taken to base 2.

▶ **Definition 5.** The Hamming distance $\Delta(\sigma, \sigma')$ of two strings $\sigma = \sigma_1 \ldots \sigma_m$ and $\sigma' = \sigma'_1 \ldots \sigma'_m$ of length m over an alphabet S, is the number of positions i such that $\sigma_i \neq \sigma'_i$.

Given any tree $\mathcal{T}$ of depth N, we denote its first k levels by $\mathcal{T}^{\leq k}$ and its $N - k$ last levels by $\mathcal{T}^{>k}$. Given a path $z = (e_1, e_2, \ldots)$, we denote by $\mathcal{T}[z]$ the subtree of $\mathcal{T}$ rooted at the end of the path that begins at the root of $\mathcal{T}$ and follows the edge-sequence z. The above notation composes for sets of trees, e.g., if $\vec{\mathcal{T}} = (\mathcal{T}_1, \mathcal{T}_2, ...)$ is an array of trees and $\vec{z} = (z_1, z_2, \ldots)$ is an array of paths, then we let $\vec{\mathcal{T}}^{\leq k}$ denote the array $(\mathcal{T}_1^{\leq k}, \mathcal{T}_2^{\leq k}, ...)$ and $\vec{\mathcal{T}}[\vec{z}]$ the array $(\mathcal{T}_1[z_1], \mathcal{T}_2[z_2], ...)$, etc.

As a rule, we use small letters to denote specific values (e.g., the input x_i given to party i), and capital letters to denote the corresponding random variables (i.e., X_i for the random variable describing the input of the i-th party, when the inputs are drawn from some given distribution).

2.2 Multiparty Interactive Communication and Protocols

We assume an undirected network $G = (V, E)$ of $n = |V|$ parties, $p_1, \ldots, p_n$, where p_i is connected to p_j if and only if $(i, j) \in E$. Each party is given an input x_i, and is assumed to output $f_i(x_1, \ldots, x_n)$ at the end of the protocol.

A *protocol* dictates to each party what is the next symbol to send and over which channel, given the party's input, the round number, and all the symbols that the party has received

so far. After a fixed and predetermined number of rounds, the protocol terminates and each party outputs a value as a function of its input and observed transcript. We assume that the order of speaking is *fixed* and is independent of the party's inputs and the noise. That is, it is determined in advance which channel is utilized at each round.

2.3 Noisy and Noiseless Networks

For the noiseless network, we focus on the *cycle network*. In the cycle, each party p_i is connected to p_{i-1} and p_{i+1} (all indices are modulo n).

For showing lower bounds over the noisy network we allow the parties to utilize the complete graph, avoiding any limitation on the protocol (since limiting the connectivity may harm the rate artificially). For our upper bound (coding scheme) the underlying topology is still the complete graph, however, the specific scheme we show does not need to communicate over all possible links—it communicates only over the cycle subgraph.

In a noisy network, each channel is assumed to suffer from random noise. For our lower bound we will assume each channel is a large-alphabet *erasure channel* EC_ε with erasure probability ε.

▶ **Definition 6.** For $\varepsilon \in [0,1]$ and a finite set Σ, the erasure channel over alphabet Σ is a random function $\mathsf{EC}_\varepsilon : \Sigma \to \Sigma \cup \{\perp\}$ which turns each input symbol into an erasure mark $\perp$ with probability ε, or otherwise keeps the symbol intact. When a channel is accessed multiple times, each instance is independent.

When considering upper bounds (coding schemes), channels with random noise are too weak (i.e., they can be reduced to erasure channels with high probability). Therefore, for our scheme we will assume a stronger type of noise we name semi-adversarial. Here, the transmissions that will be corrupted are determined in a random manner, however the received symbol of a corrupted transmission is determined *adversarially*; see discussion in Section 3.

▶ **Definition 7.** For $\varepsilon \in [0,1]$ and a finite set Σ, the semi-adversarial noisy channel over alphabet Σ is a random function $\mathsf{SAC}_\varepsilon : \Sigma \to \Sigma$ which corrupts any input symbol with probability ε, independently per instance. Once a symbol is corrupted, it may turn into any symbol in Σ, determined adversarially by the channel (possibly, all the corrupted symbols are chosen in a dependent manner).

2.4 Communication Complexity

For any protocol χ communicating symbols from an alphabet Σ, denote by $|\chi|$ the maximum number of symbols communicated by any execution of χ. Since we assume the order of speaking is fixed regardless of the inputs (and noise), each execution of χ has exactly $|\chi|$ number of symbols communicated. The communication complexity of χ is given by $\mathsf{CC}(\chi) = |\chi| \cdot \log|\Sigma|$.

2.5 The Cycle Task

In this section we define the cycle task and discuss a simple protocol that solves it over the noiseless cycle network.

Recall we have n parties $\{p_1, \ldots, p_n\}$ where each p_i receives the input x_i. We assume each input x_i is a labeled $|\Sigma|$-ary tree of depth d, where $\Sigma = \{0,1\}^n$ and each edge in the tree is labeled by a single bit.

The output of p_i is a simple root-to-leaf path (of length d) denoted by path_i, and the complete task output is denoted by $\mathsf{path} = (\mathsf{path}_1, \ldots, \mathsf{path}_n)$. We define the output in an inductive manner. For $i \in [n]$ and $j \in [d]$, let $\mathsf{path}_i(j) \in \{0,1\}^n$ denote the (index of the) j-th edge of path_i. Moreover, let $b_i(j) \in \{0,1\}$ denote the label of the edge that corresponds to $\mathsf{path}_i(j)$. For the induction basis, assume $b_i(j) = 0$ for all $i \in [n]$ and $j \leq 0$.

For $j \geq 1$, and for $i \in [n]$ we define $\mathsf{path}_i(j)$ as a function of $\{\mathsf{path}_{i'}(j')\}_{(j',i')<(j,i)}$, where $(x,y) < (u,v)$ holds if $x < u$ or if both $x = u$ and $y < v$; note that this implies a total order on pairs (j,i). The value of $\mathsf{path}_i(j)$ is given by the labels $b_{i'}(j')$ for the $n-1$ pairs (j',i') preceding (j,i) according to the total order we defined. Namely,

$$\mathsf{path}_i(j) = (b_{i+1}(j-1), b_{i+2}(j-1) \ldots, b_n(j-1), b_1(j), \ldots, b_{i-2}(j), b_{i-1}(j)).$$

Note that the cycle task can be solved by a simple protocol as described in Section 1. The protocol works in "cycles" where each such cycle means repeating the following process for $p_1, p_2, \ldots, p_n$ in order. During the j-th cycle p_i sends to p_{i+1} the value of $\mathsf{path}_i(j)$ along with the label $b_i(j)$ of the edge it just took. Now p_{i+1} can infer the value of $\mathsf{path}_{i+1}(j)$, and obtain the bit $b_{i+1}(j)$ labeling that edge in its input x_{i+1}. It follows that after d such "cycles" all parties reach a leaf at level d in their input, and can output path_i. Assuming the parties communicate symbols from Σ, the protocol communicates dn symbols[3] and has a communication complexity of dn^2 bits. It can be verified that the communication complexity of solving the cycle task is $\Theta(dn^2)$.

For our lower bound, we assume the inputs $X = (X_1, \ldots, X_n)$ are sampled so that each label is uniform in $\{0,1\}$. We are looking for coding schemes that solve the above task with high probability over the inputs X, the noise and the randomness of the coding scheme.

3 Upper Bound: A Coding Scheme For The Cycle Task With Blowup $\Theta(\log n)$

Before showing a lower bound of $\Omega(\log n)$ on the communication blowup of the cycle task over noisy networks, let us provide a sketch for a coding scheme that achieves a communication blowup of $\Theta(\log n)$, rendering our lower bound tight for the cycle task. The key idea is that repeating each symbol for $\Theta(\log n)$ times reduces the error probability to polynomially small in the number of parties. Then, the event of an error is so rare that standard coding techniques (that recover from small amount of errors) succeed with overwhelming probability.

When considering random noise over large alphabet, notice that the analog of the binary-symmetric-channel—a channel that uniformly picks the corrupted symbol—is too weak. Indeed, the parties could use only a small fraction of the symbol space in order to "catch" errors with high probability, thus essentially reducing the noise model into the case of erasures, while keeping the asymptotic rate the same up to a constant (see, for instance, the blueberry code technique in [5]).

Hence, our upper bound is defined in the somewhat stronger noise-model, which we call *semi-adversarial*, formally defined in Definition 7. In this noise model, each symbol is corrupted with probability ε, independently across different symbols. However, once a symbol is corrupted, the output symbol of the channel is chosen *adversarially*, in a worst case manner.

[3] In fact, it is enough to use $\Sigma = \{0,1\}^{n-1}$. We will neglect this issue as it doesn't change the asymptotic behaviour of the communication complexity, nor the asymptotic rate of related coding schemes.

3.1 Coding Scheme For The Cycle Task

The construction of our coding utilizes a primitive known as tree codes (see [15]; also see [6]).

▶ **Definition 8.** A β-ary tree code of depth γ, distance α and alphabet σ is a prefix code $TC : [\beta]^{\leq\gamma} \to \sigma^{\leq\gamma}$ that satisfies the following. For any two strings $x, y \in [\beta]^{\ell}$ of the same length $\ell \leq \gamma$ whose first difference is at the i-th coordinate,

$$\Delta(TC(x), TC(y)) \geq \alpha(\ell - i + 1),$$

where $\Delta(\cdot,\cdot)$ is the Hamming distance.

Schulman [15] showed that infinite-depth tree codes exist, and described the tradeoff between their distance and arity to their alphabet size.

▶ **Lemma 9** ([15]). *For any fixed $\beta \in \mathbb{N}$ and $\alpha \in (0,1)$, there exists a finite alphabet σ of size $|\sigma| = \beta^{O(1/(1-\alpha))}$ which suffices to construct a β-ary tree code with distance α and any depth.*

Our coding scheme, denoted by χ', uses tools from [13], and adapts them to our communication-model in which the parties are not forced to speak at every round. Let χ be the noiseless protocol for the cycle task described in Section 2.5. Our coding scheme χ' simulates χ step by step, sending each symbol that χ sends using two levels of coding (tree code and repetition code). While the decoding cannot guarantee that a party correctly decodes *all* the symbols sent to him so far, the symbols that were sent earlier in the protocol will be decoded correctly with an increasing probability. The party can then verify that the symbols he has already sent during previous rounds are consistent with his current understanding of the decoded incoming transmissions. In case they are not, the party will transmit a special $\mathcal{B}$ symbol whose meaning at the recipient is to "delete" the last (non-$\mathcal{B}$) symbol it has received. By sending multiple $\mathcal{B}$ symbols, the party can delete any incorrect suffix of his outgoing transmissions, until they become consistent with his (current view of his) incoming transmissions.

In the coding scheme χ' the parties communicate over channels with alphabet of size $(|\Sigma| + 1)$ that corresponds to all the symbols of χ and the additional "back" symbol $\mathcal{B}$. We assume a tree code with input alphabet $O(\Sigma)$ (specifically, a $(|\Sigma| + 1)$-ary tree), distance $\alpha > \varepsilon$, and output alphabet of size $|\Sigma'| = |\Sigma|^{O_\varepsilon(1)}$. Such a tree code exists due to Lemma 9. The coding scheme is described in Figure 1.

▶ Remark. In Figure 1, "sending a symbol" means sending $k = O_\varepsilon(\log n)$ repetitions of the same symbol using a repetition code with failure probability at most n^{-10}.

▶ **Theorem 10.** *For any $\epsilon < 1/2$, the coding scheme χ' has rate $\Theta_\varepsilon\left(\frac{1}{\log n}\right)$ and success probability $\geq 1 - 2^{-\Omega_\varepsilon(d \log n)}$, assuming the communication is over a SAC_ε network.*

4 The Lower Bound

In this section we give an outline of the proof of our lower bound. The complete description as well as detailed proofs are deferred to the full paper. Following [3], we define the notion of *cutoff* which measures the progress in simulating the cycle task. We show that the cutoff of a simulation is correlated with the length of the correct simulated output, in the sense that if the cutoff is k, it is improbable that the simulation gives an output whose correct prefix is of length more than k. Hence, if a simulation is correct with high probability, the implied cutoff must be high (i.e., around d).

The coding scheme χ'.

1. Repeat the following for $d' = 100d$ times.
2. For $i = 1$ to n, perform the following for p_i:
   - **a.** Let $y \in (\Sigma')^{\leq d'}$ be all the received communication from p_{i-1} in all the previous rounds.
     - **i.** Decode y via the tree code to obtain $x \in (\Sigma \cup \{\mathcal{B}\})^{\leq d'}$, i.e., set $x = TC^{-1}(y)$.
     - **ii.** Parse x to obtain $x' = \mathsf{Parse}(x)$.
       The function $\mathsf{Parse}(x)$ is defined in the following manner: Process x symbol-by-symbol in order. When processing a symbol from Σ, copy it to the output register. When processing a $\mathcal{B}$ symbol, delete the last non-deleted symbol in the output register. For instance, the string '$abd\mathcal{B}ccc\mathcal{B}d\mathcal{B}\mathcal{B}d$' is parsed to the string '$abcd$'.
   - **b.** Let $z \in (\Sigma \cup \{\mathcal{B}\})^{\leq d'}$ be all the symbols communicated by p_i so far during the protocol (before the tree-code encoding); let $z' = \mathsf{Parse}(z)$. p_i checks the consistency of its parsed incoming string x' and its parsed outgoing transmissions z'. The consistency is checked according to what p_i should have communicated over the noiseless χ, given the communication x'.
     If all its (parsed) outgoing messages z' are consistent with the (parsed) incoming messages, the next symbol to be sent, σ, is determined according to χ (if χ has already terminated, set $\sigma = 0$).
     If p_i finds an inconsistency, the next symbol to be sent is $\sigma = \mathcal{B}$.
   - **c.** p_i encodes the next symbol using the tree code, that is, it sends to p_{i+1} the last symbol of $TC(z \circ \sigma)$.

Figure 1 The coding scheme χ' for the Cycle Task.

Recall that x_i is the input of the i-th party, and X_i is the random variable describing it; similarly, π is used to describe a specific (observed) transcript while Π is the corresponding random variable. Also recall that the output of the i-th party is path_i describing the root-to-leaf path that the party traversed along x_i. Finally, recall that we denote by $\mathsf{path}_i(k)$ the first k edges in path_i and by $x_i[\mathsf{path}_i(k)]$ the subtree of x_i rooted at the end of $\mathsf{path}_i(k)$.

▶ **Definition 11** (Cutoff)**.** For any transcript π, and any input $x = (x_1, \ldots, x_n)$, the *cutoff of the protocol*, denoted by $\mathsf{cutoff}(\pi, x)$, is the minimal number k, such that

$$\sum_{i=1}^{n} I(X_i[\mathsf{path}_i(k)] \mid \Pi = \pi, \mathsf{PATH}(k) = \mathsf{path}(k)) \leq 0.01n. \tag{1}$$

We note that if $\mathsf{cutoff}(\pi, x) = k$ then for any x' such that $x'^{\leq k} = x^{\leq k}$, it holds that $\mathsf{cutoff}(\pi, x') = k$. Furthermore, the cutoff is only a function of the path up to level k, that is, if $\mathsf{cutoff}(\pi, x) = k$ then for any input x' that has the same $\mathsf{path}(k)$ it holds that $\mathsf{cutoff}(\pi, x') = k$; This property allows us to abuse notation and write $\mathsf{cutoff}(\pi, \mathsf{path}(k)) = k$, when the path is fixed but we do not care about the specific input.

The following proposition shows that in order for a protocol to output the correct value with high probability, the cutoff (given the complete transcript) must be $\approx d$. Hence, protocols that succeed with high probability must produce transcripts whose cutoff is large in expectation.

▶ **Proposition 12.** *Fix a protocol that solves the cycle task of depth d over a network with n parties (with large enough n), that succeeds with probability at least $1/5$ on average, i.e., a protocol for which $\Pr_{X,\Pi}[\textit{correct output}] \geq 1/5$. Then,*

$$\mathbb{E}_{X,\Pi}[\mathsf{cutoff}(\Pi, X)] \geq \frac{d}{10}.$$

Our main theorem shows that in order to obtain a coding with such a high cutoff (which is required for high success probability) a communication blowup of $\Omega(\log n)$ is necessary.

▶ **Theorem 13.** *For any $\varepsilon \in (0,1)$ there exists a constant $c = c(\varepsilon)$ such that for large enough n, any protocol that solves the cycle task of depth d over a network with n parties communicating less than $cd \cdot n \log n$ symbols assuming each communication channel is an EC_ε, has a success probability at most $1/5$.*

The main idea is to show that $O(n \log n)$ symbols sent by the simulation can increase the cutoff by at most $O(1)$, in expectation. That is, $O(\log n)$ cycles of the simulation are required in order to advance $O(1)$ cycles of the original protocol, giving a rate of $O(1/\log n)$.

Assume that given the (partial) observed transcript π and some path $\mathsf{path}(\ell)$, the cutoff of the coding scheme is ℓ, that is, $\mathsf{cutoff}(\pi, \mathsf{path}(\ell)) = \ell$. Then, assume we let the coding scheme communicate another $\delta \cdot n \log n$ symbols for some parameter $\delta = \delta(\varepsilon)$ we set later. We denote these new observed (potentially erased) symbols by Π^{new}; This is a random variable that depends on the noise and the randomness of the protocol. The claim is that the new cutoff (i.e., with respect to $\pi \circ \Pi^{new}$), is bounded by $\ell + O(1)$ in expectation.

▶ **Proposition 14.** *For any $\ell \leq d$, any $\mathsf{path}(\ell)$ and any transcript π,*

$$\mathbb{E}[\mathsf{cutoff}(\pi \circ \Pi^{new}, X) \mid \Pi = \pi, \mathsf{PATH}(\ell) = \mathsf{path}(\ell), \mathsf{cutoff}(\pi, \mathsf{path}(\ell)) = \ell] \leq \ell + 500.$$

With the above proposition, the proof of the main theorem is immediate.

Proof of Theorem 13. Assume χ is a coding scheme that succeeds with probability at least $1/5$. Proposition 12 claims that the expected cutoff at the end of the protocol χ is at least $d/10$.

On the other hand, assume toward contradiction that χ communicates less than $c \cdot d \cdot n \log n$ symbols. Split χ's transcript into segments of $\delta \cdot n \log n$ transmissions each. Using Proposition 14, the cutoff at the end of χ is bounded in expectation by

$$cd \cdot n \log n \cdot \frac{1}{\delta n \log n} \cdot 500 \leq \frac{500c}{\delta} d.$$

By choosing, say, $c < \delta/5000$, we get that the expected cutoff at the end of χ is strictly less than $d/10$, contradicting Proposition 12. ◀

The proof of Proposition 14 is rather involved and the details are deferred to the full version of this work.

5 Discussion: On the Rate vs. the Channel's Alphabet

In this section we discuss the effect of the channel's alphabet size on the obtainable rate. We can consider four independent settings: binary/large alphabet at the original (noiseless) scheme vs. binary/large alphabet at the coding scheme. For any $n \in \mathbb{N}$ and for $orig, code \in \{b, l\}$ let $c_{orig,code}(n)$ be the infimum over all possible n-party functions f of the maximal rate

Table 1 The relations between maximal rates of coding schemes with {binary, large}-alphabet, given the noiseless protocol uses {binary, large}-alphabet.

Noiseless Scheme χ	Coding Scheme χ': binary alphabet	Coding Scheme χ': large alphabet
binary alphabet	c_{bb}	$c_{bl} \geq \frac{c_{bb}}{\log \lvert\Sigma\rvert}$
large alphabet	$\Omega(c_{ll}) \leq c_{lb}$ $c_{bb} \leq c_{lb}$	$c_{ll} \geq c_{bl}$ $c_{ll} \geq \frac{c_{lb}}{\log \lvert\Sigma\rvert}$

obtainable when the original protocol χ for f is binary ($orig = b$) or with a large alphabet ($orig = l$) and the coding schemes χ' for f is binary or with a large alphabet ($code = b$ or $code = l$, respectively),

$$c_{orig,code}(n) = \inf_f \frac{\min_\chi \mathsf{CC}(\chi)}{\min_{\chi'} \mathsf{CC}(\chi')}.$$

The capacity of each setting—the maximal achievable rate in each setting—is defined to be the limit inferior of the above quantities when n tends to infinity,

$$c_{orig,code} = \liminf_{n\to\infty} c_{orig,code}(n).$$

We now explore relations between the four capacities. See Table 1 for a summary of the relations between the capacities of the different settings.

Any binary coding can be simulated by a large-alphabet coding by incurring a blowup of $\log|\Sigma|$, thus trivial relations are $c_{bl} \geq c_{bb}/\log|\Sigma|$ and $c_{ll} \geq c_{lb}/\log|\Sigma|$.

When the original protocol uses large alphabet, a large-alphabet coding can be reduced to a binary one by translating each symbol to a sequence of bits encoded with a standard error-correction code (so that the probability for the entire sequence to be decoded incorrectly is below ε; this can be done with a constant overhead). Thus $\Omega(c_{ll}) \leq c_{lb}$.

To see that $c_{lb} \geq c_{bb}$, note that we can convert the original large-alphabet protocol (that determines c_{lb}) into a binary one with the same communication complexity; this converted protocol may not be the hardest one for coding with a binary simulation, thus the rate we can achieve when coding it may be larger than the rate for the "worst" binary protocol, which determines c_{bb}. A similar reasoning yields $c_{ll} \geq c_{bl}$.

The above relations still allow c_{bb} to be either larger or smaller than c_{ll}, and their specific relation (as well as their feasibility with respect to a given underlying topology) remains an interesting open question.

Abstract

In a recent work, Moshkovitz [FOCS '14] presented a transformation on two-player games called "fortification", and gave an elementary proof of an (exponential decay) parallel repetition theorem for fortified two-player projection games. In this paper, we give an *analytic reformulation* of Moshkovitz's fortification framework, which was originally cast in combinatorial terms. This reformulation allows us to expand the scope of the fortification method to new settings.

First, we show *any* game (not just projection games) can be fortified, and give a simple proof of parallel repetition for general fortified games. Then, we prove parallel repetition and fortification theorems for games with players sharing quantum entanglement, as well as games with more than two players. This gives a new gap amplification method for general games in the quantum and multiplayer settings, which has recently received much interest.

An important component of our work is a variant of the fortification transformation, called "ordered fortification", that preserves the entangled value of a game. The original fortification of Moshkovitz does not in general preserve the entangled value of a game, and this was a barrier to extending the fortification framework to the quantum setting.

1 Introduction

A central concept in theoretical computer science and quantum information is that of a *two-player one-round game*. A two-player game G is specified by question sets X and Y, answer sets A and B, a distribution μ over pairs of questions, and a verification predicate $V : A \times B \times X \times Y \to \{0, 1\}$. The game is played between two cooperating (but non-communicating) players and a referee. The referee samples $(x, y) \in X \times Y$ according to μ

and sends x and y to each player, who provide answers $a \in A$ and $b \in B$ respectively. The players win the game if their answers satisfy the predicate $V(a, b, x, y)$.

Games arise naturally in settings ranging from hardness of approximation [21] and interactive proof systems [5, 20] to the study of Bell inequalities and non-locality in quantum physics [12, 13]. Depending on the context it is natural to consider players with access to different resources. In particular, in this work we distinguish between the *classical value* $\textsc{Val}(G)$ of a game, defined as the maximum winning probability of players allowed to produce their answers using private and shared randomness, and the *entangled value* $\textsc{Val}^*(G)$, for which the players may use shared entanglement as well .

An important operation on games and the main focus of this work is that of *repeated tensor product* or *parallel repetition*. This operation takes a game G and a parameter m and outputs a new game $G^{\otimes m}$ in which m independent instances of G are simultaneously played with the two players: the referee samples m independent questions $\{(x_i, y_i)\}_{i=1}^m$ from G, sends $(x_1, \ldots, x_m)$ to the first and $(y_1, \ldots, y_m)$ to the second player, and checks their corresponding answers $(a_1, \ldots, a_m)$ and $(b_1, \ldots, b_m)$ using the predicate $V = \prod_{i=1}^m V(a_i, b_i, x_i, y_i)$. Parallel repetition is often used in complexity theory in order to perform some form of *amplification*, such as amplifying the completeness-soundness gap of a proof system. A fundamental question that arises in this context is how the value of a repeated game $G^{\otimes m}$ relates to the value of the original game G and the number of repetitions m.

The behavior of the game value under parallel repetition can in general be quite subtle [19, 18, 31]. In a celebrated paper, Raz showed that if $\textsc{Val}(G) < 1$, then $\textsc{Val}(G^{\otimes m})$ goes to 0 exponentially fast in m [30]. Even with later simplifications and improvements to the proof (e.g. [22, 29, 8]), Raz's parallel repetition theorem remains a substantial technical result.

Recently, Moshkovitz [28] introduced a simple yet powerful framework for parallel repetition, called *parallel repetition via fortification*. In this framework, a game G is transformed through an operation called "fortification" to a new game G'. This new game G' is equivalent to G in that $\textsc{Val}(G) = \textsc{Val}(G')$, but then Moshkovitz shows that behavior of the value of *fortified* games under parallel repetition is much simpler than the general case, and avoids many of the subtleties encountered in the general case. The main benefits of fortified games are two-fold: first, their behavior under parallel repetition is much simpler than the general case, and second, all games can be easily fortified. Thus for nearly all intents and purposes, it suffices to focus on the parallel repetition of fortified games.

Despite its attractive features, the fortification framework [28] has some limitations; for instance it is only applicable to the restricted (though very important) setting of classical two-player projection games. In this work, we continue the study of the fortification approach to parallel repetition and try to expand its scope to wider classes of games.

Previously, an attempt to address the limitation of fortification to projection games was made in [6, Lemma 1.9], but this was only partially successful.[1] Here, using a slightly modified form of the framework (see the discussion of our analytic formulation below), we are able to extend fortification to all *classical games* (i.e. games that are not projection games, and involve any number of players), as well as the challenging setting of *entangled games*.

More precisely, the following is a summary of our main contributions:

[1] The difficulty there was that fortification increases the alphabet size of the game considerably, which in turn increased the additive error of the parallel repetition to the extent that for general two-prover games the whole approach seemed to entirely break down. We get around this difficulty by showing that for the kinds of games (concatenated games) that arise from the fortification procedure it is possible to establish a parallel repetition theorem where the additive error only depends on the alphabet size of the original, rather than the fortified game. See Subsection 1.1 for more on this.

- **Analytic formulation of fortification.** The framework of parallel repetition by fortification was originally cast in combinatorial terms; Moshkovitz's definition of fortified games, which we describe below in detail, involves a guarantee on the value of every sufficiently large rectangular subgame of a game. In our analytic reformulation, fortified games are defined in terms of *substrategies*, which one can think of as randomized strategies for the game where the probability that the players output an answer may be less than 1. This definition behaves much more "smoothly", allowing us to generalize them to the entangled and multiplayer settings.
- **Fortification of general classical games and games with more than two players.** Next, we show how to fortify a general k-player game G, for any $k \geq 2$. We show that for any two fortified general classical games G' and H', $\textsc{Val}(G' \otimes H') \approx \textsc{Val}(G') \cdot \textsc{Val}(H')$. Together this implies new gap amplification results for general (as opposed to projection) two-player and multiplayer classical games.
- **An entangled-value preserving variant of concatenation.** A major obstacle in extending the fortification framework to the quantum setting is that concatenation, the main ingredient of the original fortification results, does not in general preserve the entangled value. That is, if G' is the fortification of G, it doesn't generally hold that $\textsc{Val}^*(G') = \textsc{Val}^*(G)$ (even though $\textsc{Val}(G') = \textsc{Val}(G)$). This is problematic for obtaining gap amplification results: if $\textsc{Val}^*(G) = 1$, then $\textsc{Val}^*(G^{\otimes n}) = 1$, but $\textsc{Val}^*(G'^{\otimes n})$ could be exponentially small!
  To resolve this issue, we augment the ordinary concatenation procedure of [28] by giving the players some auxiliary advice input (see Definition 4) which helps in keeping the entangled value unchanged. Using this, we define a variant of the fortification transformation which we call *ordered fortification*. As desired, in addition to preserving the classical value, this transformation also preserves the entangled value, which is essential for the completeness of our gap amplification result.
- **Fortification of games with entangled players.** We show that for a general two-player game G, its ordered-fortification G_{OF} is a two-player game such that $\textsc{Val}^*(G_{OF}) = \textsc{Val}^*(G)$, and is also quantumly fortified. We then prove that for any two quantumly fortified games G' and H', $\textsc{Val}^*(G' \otimes H') \approx \textsc{Val}^*(G') \cdot \textsc{Val}^*(H')$. Together this implies a new general gap amplification method for entangled two-player games. This (see Theorem 3) is the most technically challenging component of this work.

Let us note that our extensions of the fortification approach, as described in the last three items above, are ultimately enabled by the analytic viewpoint described in point 1. In order to describe the main ideas behind these results, we first briefly recall the combinatorial framework from [28].

The combinatorial framework

Let G be a two-player game with question sets X, Y and acceptance predicate V. For $S \subseteq X$ and $T \subseteq Y$, the *subgame* $G_{S\times T}$ is defined as the game where the referee selects $(x, y) \in X \times Y$ according to μ conditioned on $x \in S, y \in T$ and checks the players' answers according to the same predicate V (the referee accepts automatically if $\mu(S \times T) = 0$). A game G is said to be (ε, δ)-*combinatorially fortified*[2] if

$$\textsc{Val}(G_{S\times T}) \leq \textsc{Val}(G) + \varepsilon, \qquad \forall\, S \subseteq X,\, T \subseteq Y,\ \text{s.t. } \mu(S \times T) \geq \delta. \tag{1}$$

[2] We shall refer to this notion as combinatorial fortification to distinguish it from the distinct (though closely related) notion of *analytic fortification* we primarily use throughout the paper; see Definition 19.

The main insight underlying [28] is that games satisfying (1) also satisfy a strong form of parallel repetition (up to some number of rounds depending on ε, δ, and the alphabet size of G). This motivates the following approach to parallel repetition: Given a game G, Moshkovitz transforms the game $G \to G'$ such that $\textsc{Val}(G') \approx \textsc{Val}(G)$ and G' is (ε, δ)-combinatorially fortified for an appropriate choice of (ε, δ). Since fortified games satisfy a strong form of parallel repetition, one expects

$$\textsc{Val}(G'^{\otimes m}) \approx \textsc{Val}(G')^m \approx \textsc{Val}(G)^m. \tag{2}$$

Indeed, by appropriately choosing the parameters (ε, δ), [28] can show that the full procedure

$$G \longrightarrow G' \longrightarrow G'^{\otimes m} \tag{3}$$

amounts to a size-efficient method of *gap amplification*. That is, we have

$$\begin{array}{lcl} \textsc{Val}(G) \geq c & \Rightarrow & \textsc{Val}(G'^{\otimes m}) \gtrsim c^m \\ \textsc{Val}(G) \leq s & \Rightarrow & \textsc{Val}(G'^{\otimes m}) \lesssim s^m \end{array}, \tag{4}$$

where we refer to the first condition as completeness and the second as soundness. The gap amplification procedure of Moshkovitz $G \to G' \to G'^{\otimes m}$ from (3) has three components: (i) a preprocessing step (biregularization), (ii) fortification, (iii) parallel repetition for fortified games.

The goal of the preprocessing step – the simplest step of the three – is to make the game *biregular* (a game G is called biregular if the marginals of questions on both Alice and Bob sides are uniform), since it is typically easier to analyze the fortification procedure for such games. The second step is *fortification*, which is the main technical ingredient of the whole approach. It is achieved by "concatenating" the game (see Section 1.1 below) with appropriate bipartite pseudorandom graphs. The third step $G' \to G'^{\otimes m}$ is the parallel repetition of fortified games, which as observed by [28] is considerably simpler to analyze than the general (non-fortified) games.

1.1 Results and techniques

The main result of our work is the extension of the fortification framework to general classical games (with any number of players) and two-player entangled games. On the way to these results we prove new results on all three components of the fortification framework: (i) biregularization, (ii) fortification, and (iii) parallel repetition. In this subsection, we discuss some of these results in detail.

Parallel repetition

A main contribution of [28] was the realization that the two-player projection fortified games satisfy a strong form of parallel repetition, up to an additive error. This additive error depended on the parameters of fortification as well as the alphabet size of the fortified game. In this work, we prove an improved parallel repetition theorem (Theorem 22) which has the same dependance in the parameters of fortification, but instead of the alphabet size of the resulting fortified game, it only depends on the alphabet size of the original game (which has exponentially smaller alphabet size). This new parallel repetition theorem is crucial for extending the fortification framework to the setting of general (as opposed to projection) two-player games.

Let us remark that the reason why alphabet blow-up of fortification does not cause an issue for projection games is because for projection games it suffices to only fortify one side of the game (by working with so-called "square projection" version of the game). As a result there is no alphabet blow-up for the "unfortified" side, which allows the arguments of [28, 6] to go through. This one-sided fortification does not work for general games, which is why we need Theorem 22.

Fortification

We start with a definition. Let $G = (X \times Y, A \times B, \mu, V)$ be a game, and M and P two bipartite graphs over vertex sets (X', X) and (Y', Y) respectively. For each $x \in X$ or $x' \in X'$ let $N(x) \subseteq X'$ and $N(x') \subseteq X$ denote the set of neighbors of x and x', respectively (similarly for any y, y').

▶ **Definition 1** (Concatenated game [28])**.** In the concatenated game $G' = (M \circ G \circ P)$, the referee selects questions (x, y) according to μ, and independently selects a random neighbor x' for x using M, and y' for y using P. The players receive questions x' and y' and respond with assignments $a' : N(x') \to A$ and $b' : N(y') \to B$ respectively. The players win if $V(a'(x), b'(y), x, y) = 1$.

Our first two main results show how, both in the classical and quantum settings, any game can be fortified by concatenating it with bipartite graphs M and P with sufficiently good spectral expansion.[3] (See Section 2.4 for the definition of spectral expanders, and Section 3.1 for the notion of weak fortification.)

▶ **Theorem 2** (Main-classical)**.** *Let G be a biregular game and M and P two bipartite λ-spectral expanders. If $\lambda \leq \frac{\varepsilon}{2}\sqrt{\frac{\delta}{2}}$, then the concatenated game $G' = (M \circ G \circ P)$ is (ε, δ)-weakly fortified against classical substrategies.*

▶ **Theorem 3** (Main-quantum)**.** *Let G be a biregular game and M and P two bipartite λ-spectral expanders. If $\lambda \leq \frac{\varepsilon^2\delta}{56}$, then the concatenated game $G' = (M \circ G \circ P)$ is (ε, δ)-weakly fortified against entangled strategies.*

We stress that both in the quantum and classical settings the procedure used to fortify a game is precisely the same, i.e. concatenation with spectral expanders, and the only difference is in the resulting parameters. Despite the similarities, the proof of Theorem 3 is significantly more involved, requiring several new ideas and substantial matrix analytic arguements.

Next we discuss a distinctively quantum phenomenon which makes the construction of a full quantum gap amplification theorem – quantum analogue of (4) – considerably more difficult. As it turns out, even though Theorem 3 is sufficient to prove the soundness case of the gap amplification theorem, the concatenation procedure used in the process can undermine the completeness condition (i.e. $\textsc{Val}^*(G'^{\otimes m}) \gtrsim \textsc{Val}^*(G)^m$ in general fails to hold).

The issue is as follows: let G be a game and $G' = (M \circ G \circ P)$ be a concatenated version of G. Classically we have $\textsc{Val}(G') = \textsc{Val}(G)$. Quantumly, even though we still have $\textsc{Val}^*(G') \leq \textsc{Val}^*(G)$ the other direction in general fails: we would have liked to argue that the players in G' are able to utilize the strategy in G to achieve the same success probability

[3] Even though explaining these results in full requires the definition of analytically fortified games, which we introduce only later in Section 3.1, the analogy with the notion of combinatorially fortified games from (1) should still be sufficient to understand the basic ideas.

in the concatenated game, but this seems impossible: having received $x' \in X'$ and $y' \in Y'$, the players have access to lists $N(x') \subseteq X$ and $N(y') \subseteq Y$ that they know contain the true questions of the referee, i.e. $x^* \in N(x')$, $y^* \in N(y')$. The players would like to apply their optimal strategy in G to each and every $(x, y) \in N(x') \times N(y')$ simultaneously, but this is in general impossible in the quantum setting.[4]

Note that the same issue does not arises classically because the optimal strategy in G can be taken to be a deterministic one, and the players in G' can use the same labeling suggested by the optimal strategy in G to give labels to all of $N(x')$ and $N(y')$ simultaneously. This strategy however relies on the fact that classically different questions have a simultaneous labeling, a fact which certainly has no quantum analogue.

We resolve the above issue using a novel entangled value-preserving variant of fortification which we call *ordered fortification*. The basic idea for ordered fortification is to give the players some extra advice information which helps in preserving the entangled value.

Let G be a game and $G' = (M \circ G \circ P)$ be a concatenated version of G. There is an extra parameter l in the construction defined as $l = \max\{\max_{x' \in X'} |N(x')|, \max_{y' \in Y'} |N(y')|\}$.

▶ **Definition 4** (Ordered concatenation)**.** Let G and G' be as above. In G'_{OF}, the referee samples (x, y) according to G and picks random neighbors $x' \sim N(x)$ and $y' \sim N(y)$ independently. She then also picks two random injective maps $r_{x'} : N(x') \to [l]$ and $s_{y'} : N(y') \to [l]$ conditioned on $s_{x'}(x) = r_{y'}(y)$. The referee sends x' and $r_{x'}$ to the first player, and y' and $s_{y'}$ to the second and accepts if the players' answers $a' : N(x') \to A$ and $b' : N(y') \to B$ satisfy $V(a'(x), b'(y), x, y) = 1$.

Here the crucial point is that $r_{x'}$ and $s_{y'}$ are correlated. They give matching labels to true questions x and y. To achieve the same winning probability as in G, the players in G'_{OF} will share l copies of the state $|\psi\rangle$ from the optimal strategy in G. For each $x^* \in N(x')$ with label $i = r_{x'}(x^*)$, the first player will apply the optimal G-strategy for x to the i^{th} copy of $|\psi\rangle$ (similarly for the second player). The fact that $r_{x'}(x) = s_{y'}(y)$ ensures that for the true questions x and y the players apply the optimal G strategies to the same copy of $|\psi\rangle$, and hence are able to win with exactly the same winning probability as in G.

Of course, the crucial part here is that even though the auxiliary information in $r_{x'}$ and $s_{y'}$ is helpful to the players for replicating the winning probability of G, it should not be "too helpful". In particular, we need to still be able to prove that G'_{OF} is fortified with appropriate parameters. This point is established by the following theorem.

▶ **Theorem 5** (Main-ordered fortification)**.** *Let G be a game and M and P be two bipartite graphs as above. Let G'_{OF} be constructed from G and $G' = (M \circ G \circ P)$ as in Definition 4. Then, we have*

$$\textsc{Val}^*(G'_{OF}) = \textsc{Val}^*(G).$$

Furthermore if M and P are λ-spectral expanders and $\lambda \leq \frac{\varepsilon^2\delta}{56}$, then G'_{OF} is also (ε, δ) weakly fortified.

We prove Theorem 5 in Section 6 using a spectral argument that reduces it to Theorem 3. Beside the above, we also prove a simple multiplayer fortification in Section 5 for classical

[4] This is because the measurement operators of different questions do not in general commute which prevents Alice (say) to obtain simultaneous answers for all questions in $N(x')$. As a further illustration of this issue, see Section 2.2 for an example of a game where $\textsc{Val}^*(G') < \textsc{Val}^*(G)$.

games. It may be possible to adapt the proofs of Theorem 3 and Theorem 28 to obtain a *multiplayer fortification theorem* for entangled games. Although plausible, some further technical issues arise in this case which we do not pursue here.

Biregularization

As already mentioned, biregularization is a minor (but necessary) step in the fortification framework. Our biregularization lemmas are presented in Subsection 2.3 and are proved in Appendix A. In terms of final statement, our biregularization lemmas are incomparable with those of [28, 6]. For example, in the case of graphical games, we prove a biregularization lemma which preserves the value exactly but has a cubic blow-up in the number of questions, whereas the biregularization lemmas from [6, 28] had a nearly linear blow-up but only preserved value up to an additive error. Moreover, in this work we prove biregularization for all games whereas [6, 28] only considered graphical games. (See Subsection 2.3 for definitions.)

1.2 Related work

The main result underlying the present work is Moshkovitz [28], where the framework of parallel repetition via fortification was first introduced. Some simplifications and corrections to the work of Moshkovitz appeared in Bhangale et al. [6]. In particular, an important contribution of [6] was the clarification of the best bounds possible in classical fortification theorems [6, Appendix C]. Going back, the general idea of modifying the game in order to facilitate its analysis under parallel repetition originates from the work of Feige and Kilian [17] who introduced the confuse/miss-match style repetition of games. The Feige-Kilian type parallel repetition was later extended by Kempe and Vidick [25] to the quantum setting allowing them to obtain the first general parallel repetition theorem for quantum games.[5]

Another important set of ideas underlying our work is related to the analytic approach to parallel repetition pioneered by Dinur and Steurer [15], further extended by Dinur et al. [16]. Our analytic reformulation of fortification framework is very much inspired by the ideas in these works.

Yet another different stream of work (more distantly related to the present work) follows the original ideas of Raz and Holenstein [30, 22] by taking a more information theoretic approach to quantum parallel repetition. The first results in this direction were obtained by Chailloux and Scarpa [10] and Jain et al. [24] who prove exponential-decay parallel repetition results for free two-player games. Their analysis, as well as the follow-up work of Chung et al. [11], provided the basis for the recent work of the authors [4] who obtained hardness amplification method in great generality by introducing and analyzing the parallel repetition of a class of games called *anchored games*. The final hardness amplification results obtained here through fortification are incomparable to that of [4]: fortification allows for a somewhat faster rate of decay in some regimes,[6] yet it suffers from a much larger blow-up in terms of alphabet size.

[5] Their transformation did not preserve the entangled value, and hence did not lead to a fully general hardness amplification method for entangled games (being restricted to the case where the completeness holds with classical strategies). Our Theorem 3, without the improvement of Theorem 5, is applicable to a similar setting.

[6] For example, for general two-player games the fortification approach gives a nearly perfect decay in terms of number of repetitions and question size blow-up, whereas [4] and other information theoretic results have a $(1-\varepsilon^2)^{\Omega(m)}$ type behavior which is weaker than fortification when $m \ll \varepsilon^{-1}$.

Turning to the multiplayer setting, very little was known prior to the present work and [4]. It is folklore that free games with any number of players satisfy a parallel repetition theorem, and this was explicitly proved in both classical and quantum settings in [11]. Multiplayer parallel repetition has been studied in the setting of *non-signaling strategies*, a superset of entangled strategies which allows the players to generate any correlations that do not imply communication. Buhrman et al. [9] show that the non-signaling value of a game G with any number of players decays exponentially under parallel repetition, with a rate of decay that depends on the entire description of the game G. Arnon-Friedman et al. [1] and Lancien and Winter [27] achieve similar results using a different technique based on "de Finetti reductions". An interesting fact about the latter work [27] is the use of a notion of sub-no-signalling strategies which seems related to our notion of quantum/classical substrategies.

1.3 Organization

In Section 2, we introduce some basic definitions and notation including the notion of substrategies, induced strategies, and some other basic results and definitions that are used throughout the paper. In Section 3, we complete the presentation of our main results (which was started in the introduction), discuss the parameters of the final gap amplification results, and present the formal definition of analytically fortified games.

The remaining sections contain proof of the main theorems. Our parallel repetition theorem is proved in Section 4. Theorems 2 and 3 are proved in Sections 5 and 7, respectively. The reduction from Theorem 5 to Theorem 3 is given in Section 6. The biregularization lemmas are proved in Appendix A. We conclude by some open problems in Section 8.

2 Preliminaries

Given a distribution μ, by $z \sim \mu$ we mean that the random variable z is distributed according to μ. For a set S, by $z \sim S$ we mean $z \sim U_S$ where U_S is the uniform distribution over S. For Hermitian matrices A, B we write $A \geq B$ if and only if $A - B$ is positive semidefinite.

Given two games G_1 and G_2, we define the tensor product game $G_1 \otimes G_2$ as the game where the referee selects two pairs of questions (x_1, y_1) and (x_2, y_2) independently according to G_1 and G_2, sends (x_1, x_2) and (y_1, y_2) to Alice and Bob respectively, and checks their answers (a_1, a_2) and (b_1, b_2) according to the product predicate $\prod_{i=1}^{2} V(a_i, b_i, x_i, y_i)$.

2.1 Game value and strategies

The main goal of this section is to introduce the notion of classical and quantum *substrategies* which replace the notion of *subgames* from [28, 6]. As subgames were central in the *combinatorial* framework of [28], substrategies are similarly central to our analytic framework.

Let G be a game with question sets X, Y, answer sets A, B, predicate V, and question distribution μ on $X \times Y$.

▶ **Definition 6** (Classical substrategies)**.** Let $G = (X \times Y, A \times B, \mu, V)$ be a two-player game. A *classical substrategy* is given by (f, g) where $f : X \times A \to [0, 1], g : Y \times B \to [0, 1]$ satisfy

$$\forall x \in X,\ f(x) := \sum_a f(x, a) \leq 1, \qquad \forall y \in Y,\ g(y) := \sum_b g(y, b) \leq 1.$$

We call (f, g) a *"complete strategy"* (sometimes simply *strategy*) if equality holds in all above inequalities, i.e. $f(x) = g(y) = 1$ for all x, y.

▶ **Definition 7.** Given a substrategy (f, g), the value of G with respect to (f, g) is given by

$$\textsc{Val}(G, f, g) := \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{a\in A, b\in B} V(a, b, x, y)\, f(x, a) \cdot g(y, b). \tag{5}$$

The *classical value* of G is

$$\textsc{Val}(G) := \sup_{f,g} \textsc{Val}(G, f, g), \tag{6}$$

where the supremum is taken over all complete strategies f, g.

We note that the definition given by (6) can be easily seen to be equivalent to the more traditional definition of the classical value, i.e.

$$\textsc{Val}(G) := \max_{\substack{p:X\to A\\ q:Y\to B}} \mathop{\mathbb{E}}_{(x,y)\sim\mu} V(p(x), q(y), x, y), \tag{7}$$

because any strategy $f : X \times A \to [0, 1], g : Y \times B \to [0, 1]$ can be written as convex combination of a collection of strategies of $\{0, 1\}$ valued strategies; on the other hand, taking supremum over f, g which are $\{0, 1\}$ valued is precisely equivalent to (7).

Next, we extend the above notions to the quantum setting.

▶ **Definition 8** (Quantum substrategies)**.** Let $G = (X \times Y, A \times B, \mu, V)$ be a two-player game. A *quantum* (or *entangled*) *substrategy* for G is a tuple $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$ defined by an integer $d \in \mathbb{N}$, a unit vector $|\psi\rangle \in \mathbb{C}^{d\times d}$ and sets of positive semi-definite matrices $\{A_x^a\}_{x\in X, a\in A}, \{B_y^b\}_{y\in Y, b\in B}$ over $\mathbb{C}^d$ satisfying

$$\forall x \in X,\ A_x := \sum_a A_x^a \le \mathrm{Id}, \qquad \forall y \in Y,\ B_y := \sum_b B_y^b \le \mathrm{Id}\,. \tag{8}$$

If $A_x = B_y = \mathrm{Id}$ for every x, y the quantum substrategy is called a *"complete strategy"* (sometimes simply *strategy*).

▶ **Definition 9.** Given a quantum substrategy $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$, the value of G with respect to $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$ is given by

$$\textsc{Val}^*(G, |\psi\rangle, \{A_x^a\}, \{B_y^b\}) = \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{a,b} V(a, b, x, y) \langle\psi| A_x^a \otimes B_y^b |\psi\rangle.$$

The *entangled value* of G is defined as

$$\textsc{Val}^*(G) = \sup_{|\psi\rangle, \{A_x^a\}, \{B_y^b\}} \textsc{Val}^*(G, |\psi\rangle, \{A_x^a\}, \{B_y^b\}), \tag{9}$$

where the supremum is taken over all complete strategies $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$.

2.2 Concatenated games

Let $G = (X \times Y, A \times B, \mu, V)$ be a game, and M and P two bipartite graphs over vertex sets (X', X) and (Y', Y) respectively. For each $x \in X$ or $x' \in X'$ let $N(x) \subseteq X'$ and $N(x') \subseteq X$ denote the set of neighbors of x and x', respectively (similarly for any y, y'). Recall the definition of Concatenated Games from the introduction.

▶ **Definition 10** (Definition 1 restated)**.** In the concatenated game $G' = (M \circ G \circ P)$, the referee selects questions (x, y) according to μ, and independently selects a random neighbor x' for x using M, and y' for y using P. The players receive questions x' and y' and respond by assignments $a' : N(x') \to A$ and $b' : N(y') \to B$ respectively. The players win if $V(a'(x), b'(y), x, y) = 1$.

For a concatenated game $G' = (M \circ G \circ P)$, we refer to G' as the *outer game* and to G as the *inner game*.

Let $G' = (M \circ G \circ P)$ be a concatenated game. Let $d_{X'} = \max_{x' \in X'} |N(x')|$, $d_{Y'} = \max_{y' \in B'} |N(y')|$. Then, the alphabet of the concatenated game is given by $A' = A^{d_{X'}}$, $B' = B^{d_{Y'}}$. Similarly, it is easy to see that the distribution μ' of questions in G' is given by $\mu'(x', y') = \mathbb{E}_{(x,y)\sim\mu} \frac{1_{x' \in N(x)}}{|N(x)|} \cdot \frac{1_{y' \in N(y)}}{|N(y)|}$.

▶ **Definition 11.** Let $G' = (M \circ G \circ P)$ be a concatenated game. To any pair of substrategies (f, g) for G' we associate the *induced substrategy*[7]

$$f(x, a) := \mathop{\mathbb{E}}_{x' \sim N(x)} \sum_{a' : a'(x) = a} f(x', a'), \qquad g(y, b) := \mathop{\mathbb{E}}_{y' \sim N(y)} \sum_{b' : b'(y) = b} f(y', b'). \tag{10}$$

Similarly, given an entangled substrategy $(|\psi\rangle, \{A^{a'}_{x'}\}, \{B^{b'}_{y'}\})$ for G', we define the *induced substrategy* as

$$A^a_x := \mathop{\mathbb{E}}_{x' \sim N(x)} \sum_{a'(x) = a} A^{a'}_{x'}, \qquad B^b_y := \mathop{\mathbb{E}}_{y' \sim N(y)} \sum_{b'(y) = b} B^{b'}_{y'}. \tag{11}$$

Intuitively, an induced strategy is a strategy for the inner game in which the players proceed as follows: given question $x \in X$, $y \in Y$ and a strategy (f, g) for the outer game, the players select two random neighbors of their questions $x' \in N(x), y' \in N(y)$ independently, and play according to the labeling of x, y suggested by (f, g) at x' and y'.

The following simple proposition will play an important role throughout the paper.

▶ **Proposition 12.** *Let $G' = (M \circ G \circ P)$ be a concatenated game. The value of any classical strategy (f, g) (resp. quantum strategy $(|\psi\rangle, \{A^{a'}_{x'}\}, \{B^{b'}_{y'}\})$) in the outer game G' is equal to the value of the induced strategy in the inner game G:*

$$\textsc{Val}(G', f, g) = \textsc{Val}(G, f, g) \tag{12}$$

$$\textsc{Val}^*(G', |\psi\rangle, \{A^{a'}_{x'}\}, \{B^{b'}_{y'}\}) = \textsc{Val}^*(G, |\psi\rangle, \{A^a_x\}, \{B^b_y\}). \tag{13}$$

As a consequence,

$$\textsc{Val}(G') \leq \textsc{Val}(G), \qquad \textit{and} \qquad \textsc{Val}^*(G') \leq \textsc{Val}^*(G). \tag{14}$$

Furthermore,

$$\textsc{Val}(G') = \textsc{Val}(G). \tag{15}$$

[7] Note the slight (but convenient) abuse of notation due to the use of the same letter to represent a substrategy and the corresponding induced substrategy. The more accurate but more cumbersome way of denoting the induced strategies in in [15]'s language would have been Mf and Pg.

Proof. The first equality in (12) follows from linearity of expectation and the definition of induced strategies as

$$\begin{aligned}\textsc{Val}(G', f, g) &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathop{\mathbb{E}}_{x'\sim N(x)} \mathop{\mathbb{E}}_{y'\sim N(y)} \sum_{a'\in A', b'\in B'} V(a'(x), b'(y), x, y)\, f(x', a') \cdot g(y', b') \\ &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{a\in A, b\in B} V(a, b, x, y)\, f(x, a) \cdot g(y, b) \\ &= \textsc{Val}(G, f, g).\end{aligned}$$

The second equality is proved similarly. The two inequalities (14) follow directly from (12). To show (15) it remains to show that $\textsc{Val}(G') \geq \textsc{Val}(G)$. Consider an optimal deterministic strategy for G given by $p : X \to A$ and $q : Y \to B$. For any $x' \in X'$, $y' \in Y'$ define $a' : N(x') \to A$ according to p and $b' : N(y') \to B$ according to q. It is easy to see that this achieves the same value in G' as (p, q) did in G. ◀

As mentioned in the introduction, the quantum analogue of (15) does not hold in general. For example, consider the case that M and P are complete bipartite graphs. In this case, the players playing $G' = (M \circ G \circ P)$ need to provide a labeling to all vertices in X and Y simultaneously. But this is essentially just a classical strategy as the labelings for X, Y are now fixed. Hence, $\textsc{Val}^*(G') = \textsc{Val}(G)$, the classical value, which in many cases could be much smaller than $\textsc{Val}^*(G)$.

2.3 Biregularization

As in [28, 6] we prove our fortification theorems for the special class of *biregular games*.

▶ **Definition 13.** A two-prover game $G = (X \times Y, A \times B, \mu, V)$ is called biregular if the marginals of μ on X and Y are both uniform.

The following lemma justifies that for our purposes we may always assume a game is biregular.

▶ **Lemma 14** (Biregularization lemma)**.** *Let $G = (X \times Y, A \times B, \mu, V)$ be a two-prover game and $\tau \in (0, 1)$ a fixed constant. There exists an efficient algorithm that given G produces a biregular game G_{int} with question sets X_{int} and Y_{int} of cardinality at most*

$$|X_{int}| \leq \frac{8|X|^2|Y|}{\tau}, \qquad |Y_{int}| \leq \frac{8|X||Y|^2}{\tau}, \tag{16}$$

the same answer alphabet size as G, and value satisfying

$$\textsc{Val}(G) \leq \textsc{Val}(G_{int}) \leq \textsc{Val}(G) + \tau, \qquad \textsc{Val}^*(G) \leq \textsc{Val}^*(G_{int}) \leq \textsc{Val}^*(G) + \tau. \tag{17}$$

Note that (17) implies that applying the Biregularization Lemma to a game never decreases its value, and hence the procedure is completeness preserving.

A widely used class of games in applications are so-called *graphical games*, for which we can get an improved biregularization result that does not require any approximation factor τ.

▶ **Definition 15.** A graphical game G is a game where the questions are given by choosing an edge of a bipartite graph uniformly at random (i.e. $E \subseteq X \times Y$ and $\mu(x, y) = \frac{1}{|E|}$ if $(x, y) \in E$ and $\mu(x, y) = 0$ otherwise). The predicate and the answers do not have any restrictions.

▶ **Lemma 16** (Biregularization lemma, graphical case)**.** *Suppose G is two-prover graphical game with E edges between (X, Y). There exists an efficient algorithm that given G produces a biregular game G_{int} with question sets X_{int} and Y_{int} bounded by*

$$|X_{int}| \leq |E| \cdot |X| \leq |X|^2|Y|, \qquad |Y_{int}| \leq |E| \cdot |Y| \leq |X||Y|^2, \tag{18}$$

the same answer alphabet size as G, and the value satisfying

$$\textsc{Val}(G) = \textsc{Val}(G_{int}) \qquad \textsc{Val}^*(G) = \textsc{Val}^*(G_{int}). \tag{19}$$

▶ Remark. In the above, we can allow for multiple edges across vertices of G. In this case E must be taken as a multi-set and the bound $|E| \leq |X||Y|$ used in (18) must be suitably modified.

Interestingly, our technique for proving the biregularization lemmas is concatenation itself! This is done in Appendix A.

2.4 Expanders

The method used in [28, 6] for fortifying a game is concatenation with sufficient pseudorandom bipartite graphs. This is done using extractors in [28] whereas expanders are employed in [6].[8] Here we follow the latter approach and use expanders.

Let $M = (X' \times X, E)$ be a bipartite graph. For $x \in X$ let $N(x) \subseteq X'$ denote the set of neighbors of x and similarly for $x' \in X'$. We shall work with graphs that are X-regular, i.e. $d = |N(x)|$ for all $x \in X$. Define distributions μ and μ' on X and X' via

$$\mu(x) = \frac{1}{|X|}, \qquad \mu'(x') = \frac{|N(x')|}{d}.$$

for all $x \in X$ and $x' \in X'$. Note that $\mu'(x')$ is the probability of obtaining x' by sampling $x \sim \mu$ and taking a random neighbor of (according M) x . Let $\mathcal{M}$ be the following normalized adjacency matrix of M

$$\mathcal{M}(x, x') = \begin{cases} \frac{1}{d} \cdot \sqrt{\frac{\mu(x)}{\mu'(x')}} & \text{if } x' \in N(x) \\ 0 & \text{otherwise} \end{cases}$$

We usually view $\mathcal{M}$ as an operator from $\ell_2(X')$ to $\ell_2(X)$. Note that when M is a biregular expander we get the simpler definition $\mathcal{M}(x, x') = \frac{1}{d}\sqrt{\frac{|X'|}{|X|}}$ for $x' \in N(x)$, and 0 otherwise.

▶ **Definition 17.** A bipartite graph M is called a λ-*spectral expander* if the second-largest singular value of $\mathcal{M}$ is at most λ.

A simple useful proposition for us is the following:

▶ **Proposition 18.** *Let $M = (X' \times X, E)$ be a bipartite λ-spectral expander. For $f : X' \to \mathbb{R}$ and $x \in X$ let $f(x) = \mathbb{E}_{x' \sim N(x)} f(x')$, and $\bar{f} = \mathbb{E}_{x' \sim \mu'} f(x') = \mathbb{E}_{x \sim \mu} f(x)$. Then*

$$\mathop{\mathbb{E}}_{x \sim \mu} (f(x) - \bar{f})^2 \leq \lambda^2 \mathop{\mathbb{E}}_{x' \sim \mu'} (f(x') - \bar{f})^2. \tag{20}$$

[8] The two approaches however lead to essentially to similar parameters (e.g. $\lambda = O(\varepsilon\sqrt{\delta})$ to get (ε, δ)-fortified graph where λ is the second largest singular value of normalized adjacency matrix of the concatenating graph.); moreover, in the classical setting the approaches are in fact are more or less equivalent. See [6] for more.

Proof. Let $p_\mu \in \mathbb{R}^X, p_{\mu'} \in \mathbb{R}^{X'}$ to unit vectors defined as $p_\mu(x) := \sqrt{\mu(x)}$ and $p_{\mu'}(x') := \sqrt{\mu(x')}$. Let$q_X(x) := \sqrt{\mu(x)}\, f(x)$, $q_{X'}(x') := \sqrt{\mu(x')}\, f(x')$.

First, observe that $\mathcal{M}\, p_{\mu'} = p_\mu$ and $\mathcal{M}^t\, p_{\mu'} = p_\mu$. It follows that $(p_\mu, p_{\mu'})$ form a pair of singular vectors of $\mathcal{M}$. Moreover, it is easy to see[9] that these are top singular vectors which shows that $\|\mathcal{M}\|_{op} = 1$. Now notice that

$$\mathop{\mathbb{E}}_{x' \leftarrow \mu'} (f(x') - \bar{f})^2 = \sum_{x'} (\sqrt{\mu(x')} f(x') - \bar{f}\sqrt{\mu(x')})^2 = \|q_{X'} - \bar{f} p_{\mu'}\|_2^2, \tag{21}$$

Second, observe

$$\mathcal{M}\, q_{X'} = q_X. \tag{22}$$

As such, (20) precisely corresponds to

$$\|q_X - \bar{f}\, p_\mu\|_2^2 = \|\mathcal{M}\,(q_{X'} - \bar{f}\, p_{\mu'})\|_2^2 \le \lambda^2 \cdot \|q_{X'} - \bar{f}\, p_{\mu'}\|_2^2. \tag{23}$$

The claim follows by noting the orthogonality property

$$\langle q_{X'} - \bar{f}\, p_{\mu'}, p_{\mu'} \rangle = \sum_{x'} \mu(x') f(x') - \bar{f} = 0. \tag{24}$$

◀

3 Fortification Framework

This section introduces the fortification framework. We define the notion of analytically fortified games and recall our main parallel repetition and fortification theorems. We end by a discussion of the parameters of the resulting gap amplification results.

3.1 Analytical fortification

We distinguish between two variants of the notion of fortified games which we call *weakly fortified games* and *strongly fortified games*. Although the difference between the two may seem minor, this difference is in fact quite important in the quantum case.

▶ **Definition 19** (Fortified games)**.** Let $\varepsilon, \delta \in [0,1]$. A concatenated game $G' = (M \circ G \circ P)$ is called weakly (ε, δ)- fortified against classical substragies if for any substrategy f, g we have

$$\textsc{Val}(G', f, g) \le (\textsc{Val}(G) + \varepsilon) \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mu} f(x)\, g(y) + \delta. \tag{25}$$

Similarly, we define G' to be weakly (ε, δ)-fortified against entangled substrategies if for any substrategy $\{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}$ we have

$$\textsc{Val}^*(G', \{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}) \le (\textsc{Val}^*(G) + \varepsilon) \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mu} \langle \psi | A_x \otimes B_y | \psi \rangle + \delta. \tag{26}$$

If furthermore $\textsc{Val}(G)$ (resp. $\textsc{Val}^*(G)$) can be replaced by $\textsc{Val}(G')$, (resp. $\textsc{Val}^*(G')$) in the above then the game is called "strongly fortified" against classical (resp. quantum) substrategies.

[9] e.g. by appealing to the Perron-Frobenius theorem.

Note that our main results, Theorems 2 and 3, show how any game can be (weakly) fortified by concatenating it with good-enough spectral expanders.

Two remarks regarding the above definition are in order:

- Using (14), we see that strong fortification implies weak fortification, as expected from the terminaology.
- From (15) it follows that the two notions in fact coincide in the case of classical fortification, but this is no longer the case for quantum fortification.

Our notion of fortified games and that of [28, 6] are closely related. Essentially, in Definition 19 we have replaced the the condition for all δ-large rectangles in (1) with a smoother condition. In terms of a precise relation, we can show the following.

▶ **Claim 20.** *Every $(\varepsilon, \varepsilon\delta)$ strongly fortified game is also $(2\varepsilon, \delta)$ combinatorially fortified.*

Proof. Consider a subgame given by $S \subseteq X, T \subseteq Y$ in G. To every strategy (p, q) for $G_{S\times T}$, i.e., $p : S \to A$, $q : T \to B$, we can associate a natural substrategy (f, g) by

$$f(x,a) = \begin{cases} 1 & \text{if } x \in S \wedge p(x) = a, \\ 0 & \text{otherwise} \end{cases}, \qquad g(y,b) = \begin{cases} 1 & \text{if } y \in T \wedge q(y) = b, \\ 0 & \text{otherwise} \end{cases}. \tag{27}$$

Then one can easily see

$$\textsc{Val}(G, f, g) = \textsc{Val}(G_{S\times T}, p, q) \cdot \mu(S \times T).^{10} \tag{28}$$

Now assuming that rectangle $S \times T$ is δ-large, i.e. $\mu(S \times T) \geq \delta$, and since G is fortified against classical substrategies, we have

$$\begin{aligned} \textsc{Val}(G_{S\times T}, p, q) &= \frac{\textsc{Val}(G, f, g)}{\mu(S \times T)} && (29)\\ &\leq (\textsc{Val}(G) + \varepsilon) \cdot \frac{\mathbb{E}_{(x,y)\sim\mu} f(x)g(y)}{\mu(S \times T)} + \frac{\delta\varepsilon}{\mu(S \times T)} && (30)\\ &\leq \textsc{Val}(G) + 2\varepsilon && (31) \end{aligned}$$

where in the second inequality we used $\mu(S \times T) = \mathbb{E}_{(x,y)\sim\mu} f(x)g(y)$. ◀

We note that in Lemma 20, the reverse implication does not hold and the notion of analytically fortified game is strictly stronger. In what follows, in the rare occasion when we call a game fortified (without specifying weak or strong) we mean strongly fortified.

3.2 Parallel repetition of fortified games

Using the definition of fortified games, it is straightforward to prove the following parallel repetition theorem.

▶ **Theorem 21** (Basic parallel repetition)**.** *Let G'_2 be a (ε, δ)-fortified game against classical substrategies. Then for any game G'_1 we have*

$$\textsc{Val}(G'_1 \otimes G'_2) \leq (\textsc{Val}(G'_2) + \varepsilon) \cdot \textsc{Val}(G'_1) + \delta \cdot |\Sigma_{G'_1}|, \tag{32}$$

where $\Sigma_{G'_1}$ is the total answer alphabet size (i.e. the product of Alice and Bob's alphabets) of G'_1.

[10] The term $\mu(S \times T) = \mathbb{E}_{(x,y)\sim\mu} f(x)g(y)$ is a natural scaling parameter playing an important role in our discussion as a measure of the "largeness" of a subgame or a substrategy.

We prove this theorem in Section 4 by adapting the proof of the analogous theorems in [28, 6] to the analytic setting. Unfortunately, while this theorem exemplifies the main idea behind our results, it is not directly useful for applications. The reason for this is that the fortification procedure $G \to G'$ via concatenation induces a large blow-up in the alphabet size, $|\Sigma_{G'}| \approx |\Sigma_G|^D$, where $D = \frac{1}{\varepsilon\sqrt{\delta}}$ is the degree of the expander graph chosen. As one iterates the repetition procedure m times, the blow-up due to the additive term in (32) will be of order $\delta|\Sigma_{G'}|^{m-1}$. But typically $|\Sigma_{G'}|^{m-1} \gg |\Sigma_G|^{(m-1)/\sqrt{\delta}}$, leading to a term larger than 1 and rendering the theorem useless.

We resolve this problem by proving an improved repetition theorem which exploits the fact that G' takes the form of a concatenated game, whose inner game G has a much smaller alphabet.

▶ **Theorem 22.** *Let G' be a concatenated game, with inner game G, that is (ε, δ)-weakly fortified against classical substrategies. If $\delta \cdot (m-1) \cdot |\Sigma_G|^{m-1} \leq \eta$ then*

$$\textsc{Val}(G'^{\otimes m}) \leq (\textsc{Val}(G) + \varepsilon)^m + \eta. \tag{33}$$

Similarly, if G' is (ε, δ) weakly-fortified against entangled substrategies and $\delta \cdot (m-1) \cdot |\Sigma_G|^{m-1} \leq \eta$ then

$$\textsc{Val}^*(G'^{\otimes m}) \leq (\textsc{Val}^*(G) + \varepsilon)^m + \eta. \tag{34}$$

The main advantage of Theorem 22 compared to Theorem 21 is in the additive error, which is now is in terms $|\Sigma_G|$ rather than $|\Sigma_{G'}|$. What is important here is that the size of $|\Sigma_G|$ is independent of the fortification parameters (ε, δ) whereas $|\Sigma_{G'}|$ grows exponentially as δ decreases. Let us also note that Theorem 22 is quite general, and in particular applies to the multiplayer case.

3.3 Gap amplification

Having stated our main parallel repetition, fortification, and biregularization theorems, all the main components of gap amplification are finally in place. Indeed, using $\textsc{Val}(G) = \textsc{Val}(G')$ Theorem 22 implies our final gap amplification for the classical value. This matches the parameters of main results of [28, 6] and extends it to more general settings.

Since quantumly we could have $\textsc{Val}^*(G') < \textsc{Val}^*(G)$, from (34) we cannot obtain

$$\textsc{Val}^*(G'^{\otimes m}) \leq (\textsc{Val}^*(G') + \varepsilon)^m + \eta. \tag{35}$$

However, Theorem 3 and Theorem 22 are still sufficient to prove a gap amplification theorem for the case where the completeness holds against classical players and the soundness against the quantum ones.[11] To obtain a fully quantum gap amplification however, we need to appeal to the notion of *ordered fortification* which, as we discussed, is a entangled-value preserving variant of the ordinary fortification.

▶ **Theorem 23** (Theorem 5 restated)**.** *Let G be a game and M and P be two bipartite graphs as above. Let G'_{OF} be constructed from G and $G' = (M \circ G \circ P)$ as in Definition 4. Then, we have*

$$\textsc{Val}^*(G'_{OF}) = \textsc{Val}^*(G).$$

Furthermore if M and P are λ-spectral expanders and $\lambda \leq \frac{\varepsilon^2\delta}{56}$, then G'_{OF} is also (ε, δ) weakly fortified.

[11] E.g. as was the case in [23, 32].

We stress that G'_{OF} constructed above is itself a concatenated game with the inner game $G^{\oplus l}$, disjoint union of $l = \mathrm{poly}(\frac{1}{\varepsilon^2\delta})$ copies of G. This means the inner alphabet size of G'_{OF} is precisely the same as G's, and therefore there is fortunately no issue in terms of alphabet blow-up for applying Theorem 22 to G'_{OF}. So using G'_{OF} instead of G' in Theorem 22, we can finally prove the analogue of (35) for G'_{OF}.

Parameters of gap amplification

We can now discuss the parameters of the gap amplification corollaries. As in [28, 6], the parameters are typically very good in terms of question sizes but much worse in terms of alphabet size. Here, we mostly focus our discussion to gap amplification in the classical setting as the calculations in the quantum setting are similar.

To understand the parameters, we need to only consider the soundness case. Suppose we are given a game G with guarantee $\textsc{Val}(G) \le 1-\tau$ and a target soundness value β. We choose $\varepsilon = \tau/2$ and m such that $(\textsc{Val}(G)+\varepsilon)^m \le \beta/2$. Hence, we have $m = \frac{\log(2/\beta)}{\log(1-\tau/2)} \le \frac{2\log(2/\beta)}{\tau}$. We want

$$\textsc{Val}(G'^{\otimes m}) \le (\textsc{Val}(G)+\varepsilon)^m + \delta\cdot(m-1)|\Sigma_G|^{m-1} \le \beta. \tag{36}$$

Hence, we just need to ensure $\delta\cdot|\Sigma_G|^{m-1} \le \beta/2$. So we have $\delta = \frac{\beta}{(m-1)\cdot|\Sigma_G|^{m-1}}$.

So what does the above mean in terms of the size of the final output of gap amplification $G'^{\otimes m}$. The question size is $|X|^m$ and $|Y|^m$ (since we have $|X'| = |X|$ and $|Y'| = |Y|$). Note that m is essentially as small as we can hope for because even given a perfect parallel repetition theorem, we had to take $m \approx \frac{\log(1/\beta)}{\tau}$. Hence, the construction is essentially optimal in terms of question sizes.

For the alphabet size, the situation is much worse. We have $|\Sigma_{G'}| = |\Sigma_G|^D$ where $D = O(\frac{\mathrm{poly}\log(1/\varepsilon^2\delta)}{\varepsilon^2\delta})$. This means (up to dominant factors) that $|\Sigma_{G'^{\otimes m}}| = |\Sigma_G|^{\frac{m^2|\Sigma_G|^{m-1}}{\beta}}$ which means that the alphabet is exponentially worse than basic parallel repetition which results in $|\Sigma_G|^m$. Note that however in typical settings where $|\Sigma_G|$ is constant and β a small constant (or inverse logarithmic in size of G), this exponentially worse behavior of alphabet size does not cause a significant problem.

Next, let us consider the setting where the completeness holds for classical players and soundness against entangled players. In this case, we can just use Theorem 3 instead of Theorem 2, and hence all the calculations are precisely the same with ε and δ replaced with their squares.

Lastly, in the fully quantum case we need to use Theorem 5. In this case, m, ε, δ are chosen in precisely the same way. Alphabet size is also exactly the same as G'_{OF} has the same alphabet size as G'. The only difference is that the question sizes in G'_{OF} are slightly larger than G': we have $|X'| = |X|\cdot\mathrm{poly}(\frac{|\Sigma_G|^m}{\beta})$ and $|Y'| = |Y|\cdot\mathrm{poly}(\frac{|\Sigma_G|^m}{\beta})$. This is however arguably a minor blow-up since we typically expect that $|\Sigma_G|/\beta$ to be much smaller than $\mathit{size}(G) = |X|\cdot|Y|$.

4 Parallel Repetition Theorems

In this section we prove our main parallel repetition theorem.

▶ **Theorem 24** (Theorem 22 restated). *Let G' be a concatenated game (ε,δ)-weakly fortified against classical substrategies with inner game G. If $\delta\cdot(m-1)\cdot|\Sigma_G|^{m-1} \le \eta$ then*

$$\textsc{Val}(G'^{\otimes m}) \le (\textsc{Val}(G)+\varepsilon)^m + \eta. \tag{37}$$

Similarly, if G' is (ε, δ) weakly-fortified against entangled substrategies and $\delta \cdot (m-1) \cdot |\Sigma_G|^{m-1} \leq \eta$ then

$$\textsc{Val}^*(G'^{\otimes m}) \leq (\textsc{Val}^*(G) + \varepsilon)^m + \eta. \tag{38}$$

The proof follows directly from the following proposition.

▶ **Proposition 25.** *Let $\{G'_i\}_{i=1}^t$ be a collection of concatenated games with inner games $\{G_i\}_{i=1}^t$. Suppose that G'_t is (ε, δ) weakly fortified against classical substrategies. Then,*

$$\textsc{Val}(G'_1 \otimes G'_2 \otimes \ldots \otimes G'_t) \leq (\textsc{Val}(G_t) + \varepsilon) \cdot \textsc{Val}(G'_1 \otimes G'_2 \otimes \ldots \otimes G'_{t-1}) + \delta \cdot \prod_{i=1}^{t-1} |\Sigma_{G_i}|. \tag{39}$$

Similarly, if G'_t is (ε, δ) weakly fortified against quantum substrategies, then

$$\textsc{Val}^*(G'_1 \otimes G'_2 \otimes \ldots \otimes G'_t) \leq (\textsc{Val}^*(G_t) + \varepsilon) \cdot \textsc{Val}^*(G'_1 \otimes G'_2 \otimes \ldots \otimes G'_{t-1}) + \delta \cdot \prod_{i=1}^{t-1} |\Sigma_{G_i}|. \tag{40}$$

The key to proving Proposition 25 is to work with the induced strategies. This allows us to get an additive error depending just on the alphabet size of the inner game. In the proof, we use the usual notation where a strategy missing an (answer) argument indicates summation over that variable. For example,

$$f(x_1, a_1, \ldots, x_{t-1}, a_{t-1}, x_t) = \sum_{a_t} f(x_1, a_1, \ldots, x_{t-1}, a_{t-1}, x_t, a_t).$$

Proof. We only prove (39) as the proof of (40) follows the same structure. Also for simplicity, we focus on the case of two-player games as the proof of the multiplayer case is a straightforward extension.

Consider any strategies $f : X'_1 \times A'_1 \times \ldots \times X'_t \times A'_t \to [0,1]$, $g : Y'_1 \times B'_1 \times \ldots \times Y'_t \times B'_t \to [0,1]$. To clarify notation we will denote tuples $(z_1, \ldots, z_{t-1})$ as $\mathbf{z}_{<t}$. With this notation, $\textsc{Val}(G'_1 \otimes \ldots \otimes G'_t, f, g)$ is precisely

$$\mathop{\mathbb{E}}_{(\mathbf{x}_{\leq t}, \mathbf{y}_{\leq t})} \mathop{\mathbb{E}}_{\mathbf{x'}_{\leq t}} \mathop{\mathbb{E}}_{\mathbf{y'}_{\leq t}} \sum_{\mathbf{a'}_{\leq t}, \mathbf{b'}_{\leq t}} \prod_{i=1}^{t} V(a'_i(x_i), b'_i(y_i), x_i, y_i)\, f(\mathbf{x'}_{\leq t}, \mathbf{a'}_{\leq t}) \cdot g(\mathbf{y'}_{\leq t}, \mathbf{b'}_{\leq t}), \tag{41}$$

where the expectations are according to $(x_i, y_i) \sim \mu_i$ and $x'_i \sim N(x_i)$ and $y'_i \sim N(y_i)$ for all $i = 1, \ldots, t$. As usual let

$$f(\mathbf{x}_{<t}, \mathbf{a}_{<t}, x'_t, a'_t) = \mathop{\mathbb{E}}_{\mathbf{x'}_{<t} \sim N(\mathbf{x}_{<t})} \sum_{a'_i(x_i) = a_i,\, i<t} f(\mathbf{x'}_{<t}, \mathbf{a'}_{<t}, x'_t, a'_t). \tag{42}$$

Using this notation, we can rewrite (41) as

$$\mathop{\mathbb{E}}_{(\mathbf{x}_{<t}, \mathbf{y}_{<t})} \sum_{\mathbf{a}_{<t}, \mathbf{b}_{<t}} \prod_{i=1}^{t-1} V(a_i, b_i, x_i, y_i)\, S(\mathbf{x}_{<t}, \mathbf{y}_{<t}, \mathbf{a}_{<t}, \mathbf{b}_{<t}), \tag{43}$$

where $S(\mathbf{x}_{<t}, \mathbf{y}_{<t}, \mathbf{a}_{<t}, \mathbf{b}_{<t})$ is given by

$$\mathop{\mathbb{E}}_{(x_t, y_t)} \mathop{\mathbb{E}}_{x'_t} \mathop{\mathbb{E}}_{y'_t} \sum_{a'_t, b'_t} V(a'_t(x_t), b'_t(y_t), x_t, y_t)\, f(\mathbf{x}_{<t}, \mathbf{a}_{<t}, x'_t, a'_t) \cdot g(\mathbf{y}_{<t}, \mathbf{b}_{<t}, y'_t, b'_t). \tag{44}$$

Consider the following substrategy G'_t: fix the first $2(t-1)$ arguments of f to $(\mathbf{x}_{<t}, \mathbf{a}_{<t})$ and the first $2(t-1)$ arguments of g to $(\mathbf{y}_{<t}, \mathbf{b}_{<t})$. Then (44) is precisely the value of this substrategy in G'_t. Since G'_t is (ε, δ) weakly fortified, it follows that

$$(44) \leq (\textsc{Val}(G_t) + \varepsilon) \cdot \mathop{\mathbb{E}}_{(x_t, y_t)} f(\mathbf{x}_{<t}, \mathbf{a}_{<t}, x_t) \cdot g(\mathbf{y}_{<t}, \mathbf{b}_{<t}, y_t) + \delta. \tag{45}$$

Plugging this expression back into (43), $\textsc{Val}(G'_1 \otimes \ldots \otimes G'_t, f, g)$ is bounded by

$$(\textsc{Val}(G_t) + \varepsilon) \mathop{\mathbb{E}}_{(\mathbf{x}_{\leq t}, \mathbf{y}_{\leq t})} \sum_{\mathbf{a}_{<t}, \mathbf{b}_{<t}} \prod_{i=1}^{t-1} V(a_i, b_i, x_i, y_i) f(\mathbf{x}_{<t}, \mathbf{a}_{<t}, x_t) g(\mathbf{y}_{<t}, \mathbf{b}_{<t}, y_t) + \delta \prod_{i=1}^{t-1} |\Sigma_{G_i}|.$$

To conclude we observe that

$$\mathop{\mathbb{E}}_{(\mathbf{x}_{\leq t}, \mathbf{y}_{\leq t})} \sum_{\mathbf{a}_{<t}, \mathbf{b}_{<t}} \prod_{i=1}^{t-1} V(a_i, b_i, x_i, y_i)\, f(\mathbf{x}_{<t}, \mathbf{a}_{<t}, x_t) \cdot g(\mathbf{y}_{<t}, \mathbf{b}_{<t}, y_t) \tag{46}$$

is at most $\textsc{Val}(G'_1 \otimes \ldots \otimes G'_{t-1})$, as for any fixed (x_t, y_t) the functions $f(\cdot, x_t) : X'_1 \times A'_1 \times \ldots \times X'_{t-1} \times A'_{t-1} \to [0,1]$ and $g(\cdot, y_t) : Y'_1 \times B'_1 \times \ldots \times Y'_{t-1} \times B'_{t-1} \to [0,1]$ are valid strategies in $G'_1 \otimes \ldots \otimes G'_{t-1}$. ◀

▶ Remark. Theorem 21 immediately follows from Proposition 25 by taking $t = 2$ and considering the trivial concatenation $G'_1 = G_1$, $G'_2 = G_2$.

Theorem 22 follows easily.

Proof of Theorem 22. We prove (37) as the proof of (38) is similar.

The proof is by induction on m. The case $m = 1$ is clear. By the induction hypothesis we have

$$\textsc{Val}(G'^{\otimes(m-1)}) \leq (\textsc{Val}(G) + \varepsilon)^{m-1} + \delta \cdot (m-2)|\Sigma_G|^{m-2}.$$

Note that we can assume $\textsc{Val}(G) + \varepsilon < 1$ otherwise (37) holds trivially. Applying Proposition 25 we see that

$$\begin{aligned}
\textsc{Val}(G'^{\otimes m}) &\leq (\textsc{Val}(G) + \varepsilon) \cdot \textsc{Val}(G'^{\otimes(m-1)}) + \delta \cdot |\Sigma_G|^{m-1} \\
&\leq (\textsc{Val}(G) + \varepsilon)^m + \delta \cdot (\textsc{Val}(G) + \varepsilon) \cdot (m-2)|\Sigma_G|^{m-2} + \delta \cdot |\Sigma_G|^{m-1} \\
&\leq (\textsc{Val}(G) + \varepsilon)^m + \delta \cdot (m-1) \cdot |\Sigma_G|^{m-1}.
\end{aligned}$$ ◀

5 Classical Fortification

In this section we prove our main theorem regarding the fortification of classical games. Beside providing a short and self-contained treatment of the main result of [28, 6], it serves as preparation for the analysis of Section 7.

▶ **Theorem 26** (Theorem 2 restated). *Let G be a biregular game, M and P two bipartite λ-spectral expanders. If $\lambda \leq \frac{\varepsilon}{2}\sqrt{\frac{\delta}{2}}$, then the concatenated game $G' = (M \circ G \circ P)$ is (ε, δ) weakly fortified against classical substrategies.*

We note that it follows from [6, Appendix C] that the dependence λ and δ in Theorem 2 is up to constant factors optimal. On the other hand, the tightness of dependence of ε and δ does not seem to follow from [6] lower bound (however, δ is by far the more significant of the two parameters).

5.1 Proof of Theorem 2

We start with a simple claim whose proof we will defer to the end of the subsection.

▶ **Claim 27.** *Let $M = (X' \times X, E)$ and $N = (Y' \times Y, F)$ be two biregular bipartite graphs that are λ-spectral expanders. Let μ be a distribution on $X \times Y$ such that both marginals of μ are uniform. Let $f : X' \to \mathbb{R}$ and $g : Y' \to R$ be any functions, and denote $f : X \to \mathbb{R}$ and $g : Y \to \mathbb{R}$ the functions $f : x \mapsto \mathbb{E}_{x' \sim N(x)} f(x)$, $g : y \mapsto \mathbb{E}_{y' \sim N(y)} g(y)$ respectively. Then*

$$\mathop{\mathbb{E}}_{(x_1,y_1)\sim\mu} \Big| f(x_1)g(y_1) - \mathop{\mathbb{E}}_{(x_2,y_2)\sim\mu} f(x_2)g(y_2) \Big| \le 2\sqrt{2}\lambda \Big(\mathop{\mathbb{E}}_{x'\sim X'} |f(x')|^2 \Big)^{1/2} \Big(\mathop{\mathbb{E}}_{y'\sim Y'} |g(y')|^2 \Big)^{1/2}$$

and

$$\Big| \mathop{\mathbb{E}}_{x_1\sim X} f(x) \mathop{\mathbb{E}}_{y_1\sim Y} g(y_1) - \mathop{\mathbb{E}}_{(x_2,y_2)\sim\mu} f(x_2)g(y_2) \Big| \le 2\lambda^2 \Big(\mathop{\mathbb{E}}_{x'\sim X'} |f(x')|^2 \Big)^{1/2} \Big(\mathop{\mathbb{E}}_{y'\sim Y'} |g(y')|^2 \Big)^{1/2}.$$

We prove a slightly stronger statement which implies Theorem 2. Let f, g be any substrategies for G, and let $\gamma = \mathbb{E}_{(x,y)\sim\mu} f(x)g(y)$. We claim that

$$\textsc{Val}(G', f, g) \le \textsc{Val}(G)\gamma + 2\sqrt{2}\,\lambda\sqrt{\gamma} + 4\,\lambda^2. \tag{47}$$

To deduce the bound claimed in Theorem 2 from (47) we distinguish two cases. Either $\gamma \le \delta$, in which case using the trivial estimate $\textsc{Val}(G', f, g) \le \gamma$ the bound immediately follows. Or $\gamma > \delta$, in which case

$$\begin{aligned} \textsc{Val}(G)\gamma + 2\sqrt{2}\lambda\sqrt{\gamma} + 4\lambda^2 &\le \gamma(\textsc{Val}(G) + 2\sqrt{2}\lambda\delta^{-1/2}) + 4\lambda^2 \\ &\le \gamma(\textsc{Val}(G) + \varepsilon) + \delta \end{aligned}$$

given the relation between ε, δ and λ expressed in the theorem.

It remains to prove (47). Fix substrategies f and g. We have

$$\begin{aligned} \textsc{Val}(G', f, g) &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=1} f(x,a) \cdot g(y,b) \\ &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} f(x)g(y) \sum_{V(a,b,x,y)=1} \frac{f(x,a)}{f(x)} \cdot \frac{g(y,b)}{g(y)}, \end{aligned}$$

where we adopt the convention that $0/0 = 0$. Using the triangle inequality,

$$\begin{aligned} \textsc{Val}(G', f, g) &\le \gamma \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=1} \frac{f(x,a)}{f(x)} \cdot \frac{g(y,b)}{g(y)} + \mathop{\mathbb{E}}_{(x,y)\sim\mu} \big| f(x)g(y) - \gamma \big| \\ &\le \gamma\, \textsc{Val}(G) + \mathop{\mathbb{E}}_{(x,y)\sim\mu} \big| f(x)g(y) - \gamma \big|, \end{aligned} \tag{48}$$

where the second inequality follows since $(x, a) \mapsto f(x, a)/f(x)$ and $(y, b) \mapsto g(y, b)/g(y)$ form a valid pair of strategies for G. It remains to estimate the second term above. Applying the first inequality in Claim 27,

$$\begin{aligned} \mathop{\mathbb{E}}_{(x,y)\sim\mu} \big| f(x)g(y) - \gamma \big| &\le 2\sqrt{2}\lambda \Big(\mathop{\mathbb{E}}_{x'\sim X'} |f(x')|^2 \Big)^{1/2} \Big(\mathop{\mathbb{E}}_{y'\sim Y'} |g(y')|^2 \Big)^{1/2} \\ &\le 2\sqrt{2}\lambda \Big(\mathop{\mathbb{E}}_{x'\sim X'} f(x') \mathop{\mathbb{E}}_{y'\sim Y'} g(y') \Big)^{1/2} \\ &\le 2\sqrt{2}\lambda \sqrt{\gamma + 2\lambda^2} \\ &\le 2\sqrt{2}\lambda (\sqrt{\gamma} + \sqrt{2}\lambda) \\ &= 2\sqrt{2}\lambda\sqrt{\gamma} + 4\lambda^2, \end{aligned}$$

where in the second inequality we used $0 \le f(x'), g(y') \le 1$ for all x', y' and the third uses the second inequality in Claim 27. Together with (48) this proves (47).

Finally, we prove Claim 27.

Proof of Claim 27. For the first inequality, write

$$\begin{aligned}
&\mathop{\mathbb{E}}_{(x_1,y_1)\sim\mu}\big|f(x_1)g(y_1) - \mathop{\mathbb{E}}_{(x_2,y_2)\sim\mu} f(x_2)g(y_2)\big| \\
&\qquad\le \mathop{\mathbb{E}}_{(x_1,y_1),(x_2,y_2)\sim\mu}\big(|f(x_1)-f(x_2)||g(y_1)| + |f(x_2)||g(y_1)-g(y_2)|\big) \\
&\qquad\le \Big(\mathop{\mathbb{E}}_{x_1,x_2\sim X}|f(x_1)-f(x_2)|^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1\sim Y}|g(y_1)|^2\Big)^{1/2} \\
&\qquad\qquad\qquad + \Big(\mathop{\mathbb{E}}_{x_2\sim X}|f(x_2)|^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1,y_2\sim Y}|g(y_1)-g(y_2)|^2\Big)^{1/2} \\
&\qquad\le \lambda\Big(\mathop{\mathbb{E}}_{x_1',x_2'\sim X'}|f(x_1')-f(x_2')|^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1'\sim Y'}|g(y_1')|^2\Big)^{1/2} \\
&\qquad\qquad\qquad + \lambda\Big(\mathop{\mathbb{E}}_{x_2'\sim X'}|f(x_2')|^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1',y_2'\sim Y'}|g(y_1')-g(y_2')|^2\Big)^{1/2},
\end{aligned}$$

where the last inequality uses Proposition 18. Now note that $\mathbb{E}_{x_1',x_2'\sim X'}|f(x_1')-f(x_2')|^2 \le 2\,\mathbb{E}_{x'\sim X'}|f(x')|^2$. Applying a similar bound for g gives us the first inequality. For the second, write

$$\begin{aligned}
&\Big|\mathop{\mathbb{E}}_{(x_2,y_2)\sim\mu} f(x_2)g(y_2)\mathop{\mathbb{E}}_{x_1\sim X} f(x)\mathop{\mathbb{E}}_{y_1\sim Y} g(y_1)\Big| \\
&\qquad= \Big|\mathop{\mathbb{E}}_{(x_2,y_2)\sim\mu,x_1\sim X,y_1\sim Y}(f(x_1)-f(x_2))(g(y_1)-g(y_2))\Big| \\
&\qquad\le \Big(\mathop{\mathbb{E}}_{x_1,x_2\sim X}(f(x_1)-f(x_2))^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1,y_2\sim Y}(g(y_1)-g(y_2))^2\Big)^{1/2} \\
&\qquad\le \lambda^2\Big(\mathop{\mathbb{E}}_{x_1',x_2'\sim X'}(f(x_1)-f(x_2))^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y_1',y_2'\sim Y'}(g(y_1')-g(y_2'))^2\Big)^{1/2} \\
&\qquad\le 2\lambda^2\Big(\mathop{\mathbb{E}}_{x'\sim X'}|f(x')|^2\Big)^{1/2}\Big(\mathop{\mathbb{E}}_{y'\sim Y'}|g(y')|^2\Big)^{1/2}.
\end{aligned}$$

◀

5.2 A simple multiplayer fortification

The following is a simple fortification theorem for k-player games. Since Theorem 22 applies equally well to the multiplayer setting, we get a hardness amplification result for classical multiplayer games.

▶ **Theorem 28.** *Let G be a k-player game. Suppose G' is given by composing each of the k sides of G by a λ-spectral expander where $\lambda \le 2\delta/k$. Then G' is a $(0,\delta)$ fortified game.*[12]

Proof. Consider a classical substrategy for G' given by $f_i : X_i' \times A_i' \to \mathbb{R}^+$ for $i = 1, 2, \ldots, k$. As usual, denote $f_i : X_i \times A_i \to \mathbb{R}^+$ the projection of f_i to the inner game G. By definition,

$$\textsc{Val}(G, \{f_i\}_{i=1}^k) = \mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \sum_{a_1,a_2,\ldots,a_k} V(a_1,\ldots,a_k,x_1,\ldots,x_k)\prod_{j=1}^k f_j(x_j,a_j).$$

[12] Although there is no ε dependence in the above, when applied to 2-player games the theorem is still weaker than Theorem 2 because of the worse dependence on δ – which is the more crucial parameter than ε.

We can rewrite the above as

$$\mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \prod_{i=1}^{k} f_i(x_i) \sum_{a_1,\ldots,a_k} V(a_1,\ldots,a_k,x_1,\ldots,x_k) \cdot \frac{f_1(x_1,a_1)\cdot f_x(x_2,a_2)\ldots f_k(x_k,a_k)}{f(x_1)\cdot f(x_2)\cdot\ldots\cdot f(x_k)}.$$

Let $\gamma = \mathbb{E}_{(x_1,\ldots,x_k)} \prod_{i=1}^{k} f_i(x_i)$. Applying the triangle inequality,

$$\textsc{Val}(G,\{f_i\}_{i=1}^k) \leq \gamma \cdot \textsc{Val}(G) + \mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} |\prod_{i=1}^{k} f_i(x_i) - \gamma|.$$

To conclude it will suffice to show the second term above is at most δ. Let $\overline{f_i} = \mathbb{E}_{x_i} f(x_i)$. Then

$$\begin{aligned}
\mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \left|\prod_{i=1}^{k} f_i(x_i) - \gamma\right| &\leq \mathop{\mathbb{E}}_{x_1,\ldots,x_k} \left|\prod_{i=1}^{k} f_i(x_i) - \prod_{i=1}^{k} \overline{f_i}\right| + \mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \left|\prod_{i=1}^{k} \overline{f_i} - \gamma\right| \\
&= \mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \left|\prod_{i=1}^{k} f_i(x_i) - \prod_{i=1}^{k} \overline{f_i}\right| + \left|\prod_{i=1}^{k} \overline{f_i} - \mathop{\mathbb{E}}_{x_1,\ldots,x_k} \prod_{i=1}^{k} f_i(x_i)\right| \\
&\leq 2 \cdot \mathop{\mathbb{E}}_{(x_1,\ldots,x_k)} \left|\prod_{i=1}^{k} f_i(x_i) - \prod_{i=1}^{k} \overline{f_i}\right| \\
&\leq 2 \sum_{i=1}^{k} \mathop{\mathbb{E}}_{x_i} |f_i(x_i) - \overline{f_i}|,
\end{aligned}$$

where the first equality is by definition of γ, the second inequality by convexity of $|\cdot|$, and the last follows from

$$\begin{aligned}
&|f_1(x_1)f_2(x_2)\ldots f_k(x_k) - \overline{f_1 f_2}\ldots\overline{f_k}| \\
&\leq \sum_{\ell=1}^{k} \left|\prod_{i=1}^{\ell-1} f_i(x_i)\cdot \prod_{i=\ell}^{k} \overline{f_i} - \prod_{i=1}^{\ell} f_i(x_i)\cdot \prod_{i=\ell+1}^{k} \overline{f_i}\right| \\
&\leq \sum_{i=1}^{k} \mathop{\mathbb{E}}_{x_i} |f_i(x_i) - \overline{f_i}|.
\end{aligned}$$

Hence,

$$\mathop{\mathbb{E}}_{x_1,\ldots,x_k} \left|\prod_{i=1}^{k} f_i(x_i) - \gamma\right| \leq 2\sum_{i=1}^{k} \left(\mathop{\mathbb{E}}_{x_i}(f_i(x_i) - \overline{f_i})^2\right)^{1/2} \leq 2\lambda \sum_{i=1}^{k} \left(\mathop{\mathbb{E}}_{x_i'}(f_i(x_i') - \overline{f_i})^2\right)^{1/2} \leq 2\lambda k.$$

The desired result follows. ◀

6 Reducing Strong to Weak Fortification for Entangled Games

In this section, we start working toward the problem of fortifying games in the entangled case. In particular, we show how Theorem 5 follows from Theorem 3. Let $G = (X \times Y, A \times B, \mu, V)$ be a two-player game.

▶ **Definition 29.** For a game G and integer $l \in \mathbb{N}$ let $G^{\oplus l}$ denote the disjoint union of l copies of G.

Suppose that M and P are regular bipartite graphs over $X' \times X$ and $Y' \times Y$, respectively. Suppose further that M and P are balanced, i.e. $|X'| = |X|$ and $|Y'| = |Y|$. Let d_M and d_N denote the degree of vertices M and P, respectively. (Note that since the graphs are balanced and regular, the left and right degrees are the same.)

Following [6], we assume that M and P are explicit bipartite almost-Ramanujan expanders, as provided e.g. by [7], for which the second-largest singular values λ_M and λ_P of A_M and A_P (the normalized adjacency matrices) respectively satisfy

$$\lambda_M = O\left(\frac{\mathrm{poly}(\log d_M)}{\sqrt{d_M}}\right), \qquad \lambda_P = O\left(\frac{\mathrm{poly}(\log d_P)}{\sqrt{d_P}}\right). \tag{49}$$

Note that if $d_M, d_P = \widetilde{\Omega}(\frac{1}{\varepsilon^2\delta})$ then Theorem 3 implies that $G' = (M \circ G \circ P)$ is (ε, δ) weakly-fortified. Next we recall the definition of G'_{OF} from the introduction.

Ordered fortification

Let G, M, P and $G' = (M \circ G \circ P)$ be as above. let $l = \max\{d_M, d_P\}$. In G'_{OF_l} (or simply G'_{OF} where $l = \max\{d_M, d_P\}$) the referee samples questions (x, y) as in G and selects two random neighbors $x' \in X'$ and $y' \in Y'$ of x and y in M and P respectively. Then the referee selects two random injective maps $r_{x'} : N(x') \to [l]$ and $s_{y'} : N(y') \to [l]$ under the condition $r_{x'}(x) = s_{y'}(y)$. Alice's question then is the pair $(x', r_{x'})$ and Bob's is the pair $(y', s_{y'})$. Alice outputs an answer tuple $a' : N(x') \to A$ and Bob $b' : N(y') \to B$. The players win if $V(a'(x), b'(y), x, y) = 1$.

▶ Remark. Note that G'_{OF} has exactly the same answer alphabet size as G', the question sizes $|X'_{OF}|$ and $|Y'_{OF}|$ are larger than in G'. This blow-up can be mitigated as follows. It turns out that in Definition 30 the use of the complete set $S_{(d,l)}$ is unnecessary. More precisely, from the proof of the main claim of this section, Claim 33 below, it will be clear that the only condition required is that the permutations be chosen from a pairwise independent subset of $S_{(d,l)}$. Selecting the smallest possible such subset lets us reduce the blow-up in the size of the question sets from a multiplicative $D!$ down to $\mathrm{poly}(D) = \mathrm{poly}(\frac{1}{\varepsilon^2\delta})$. We omit the details.

Although it may not be immediately apparent, it is possible to view G'_{OF} as a concatenated game. Let $G^{\oplus l}$ be as in Definition 29. Note that $G^{\oplus l}$ has exactly the same classical and entangled value as G. Let $S_{(d_M,l)}$ denote the set of all injective maps from $[d_M] \to [l]$. Fix maps $u_{x'} : N(x') \to [d_M]$ and $v_{y'} : N(y') \to [d_M]$ ordering the neighborhoods of each x', y' in an arbitrary way.

▶ **Definition 30.** Let M be a regular bipartite graph over $X' \times X$ as above . We define $\widetilde{M}$ as a bipartite graph over $X'_{OF} := X' \times S_{(d_M,l)}$ and $X_{OF} := X \times [l]$ where

$$(x', \pi) \sim_{\widetilde{M}} (x, i) \qquad \Longleftrightarrow \qquad \pi(u_{x'}(x)) = i.$$

We define $\widetilde{P}$ from P in a similar way.

Note that here $\pi \circ u_{x'}$ exactly corresponds to $r_{x'} : N(x') \to [l]$ map from the original definition of G'_{OF}. Hence, we obtain the following alternative characterization of G'_{OF}.

▶ **Proposition 31.** *The game G'_{OF} constructed above is a concatenated game given by*

$$G'_{OF} = (\widetilde{M} \circ G^{\oplus l} \circ \widetilde{P}).$$

Next, we show that ordered fortification preserves the entangled value (the classical value is also preserved but that is not important here).

▶ **Proposition 32.** *We have* $\textsc{Val}^*(G'_{OF}) = \textsc{Val}^*(G)$.

Proof. In one direction we have $\textsc{Val}^*(G'_{OF}) \leq \textsc{Val}^*(G^{\oplus l}) = \textsc{Val}^*(G)$ where we used Propositions 12 and 31. For the other direction, consider any entangled strategy $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$ for G. We construct a strategy for $G'_{\oplus}$ that achieves the same value. The provers share l copies of the state $|\psi\rangle$, and each copy is assigned a unique label $i \in [l]$. Alice and Bob receive questions $(x', r_{x'})$ and $(y', s_{y'})$, respectively. For each $x \in N(x')$, Alice applies $\{A_x^a\}$ to the $r_{x'}(x)$-th copy of $|\psi\rangle$. Bob applies a similar strategy.

Since by construction the "true questions" x^* and y^* are given the same label, the distribution of answers obtained for x^* and y^* is identical to the distribution of answers obtained while playing G using $(|\psi\rangle, \{A_x^a\}, \{B_y^b\})$, hence achieving the same winning probability. ◀

The main technical step in reducing Theorem 5 to Theorem 3 is an analysis of the singular values of $\widetilde{M}, \widetilde{N}$ in terms of the singular values of M and N. We prove the following.

▶ **Claim 33.** *Let M be a bipartite graph over $X' \times X$ as above and let λ_M denote the second largest singular value of M. Let $\tilde{M}$ be as in Definition 30. Then,*

$$\lambda_{\tilde{M}} \leq \max\left\{\lambda_M, \frac{1}{\sqrt{d_M - 1}}\right\}.$$

Since in our case $\lambda_M = O\left(\mathrm{poly}(\log d_M)/d_M\right)$, Claim 33 implies that $\lambda_{\tilde{M}}$ satisfies the same bound. Also note that a similar statement of course applies to $\tilde{P}$ and $\lambda_{\tilde{P}}$. So we see that Theorem 3, Propositions 32 and 31, and Claim 33 together imply Theorem 5; it remains to prove the latter.

Proof of Claim 33. Recall that by assumption M is a regular balanced bipartite graph. Let $d := d_M$ the degree of vertices in M. The normalized adjacency matrix of $\tilde{M}$ is given by

$$A_{\tilde{M}}((x', \pi), (x, i)) = \begin{cases} \frac{1}{d} \cdot \sqrt{\frac{(l-d)!}{(l-1)!}} & (x', \pi) \sim_{\tilde{M}} (x, i) \\ 0 & (x', \pi) \not\sim_{\tilde{M}} (x, i) \end{cases}. \tag{50}$$

We relate the second largest singular value λ_M of A_M and the second largest singular value $\lambda_{\tilde{M}}$ of $\tilde{M}$ by relating the eigenvalues of $B = A_M^\top A_M$ and $C = A_{\tilde{M}}^\top A_{\tilde{M}}$. We can explicitly compute the entries of B and C. For B,

$$B(x_1, x_2) = \frac{|\{x' \in X' : \{x_1, x_2\} \subset N(x')\}|}{d^2}, \tag{51}$$

and in particular $B(x, x) = \frac{1}{d}$ for all $x \in X$. To compute entries of C, first note that when $x_1 \neq x_2$ and $i \neq j$ we have

$$C((x_1, i), (x_2, j)) = \frac{|\{x' \in X' : \{x_1, x_2\} \subset N(x')\}| \cdot (l-d)!}{d^2 (l-1)!} \cdot \frac{(l-2)!}{(l-d)!} = \frac{B(x_1, x_2)}{l-1}. \tag{52}$$

Finally, observe the following special cases:

- $C((x, i), (x, i)) = \frac{1}{d}$.
- $C((x_1, i), (x_2, i)) = 0$ if $x_1 \neq x_2$.
- $C((x, i), (x, j)) = 0$ when $i \neq j$.

Let $\widetilde{B} = B - \frac{1}{d}\,\mathrm{Id}$ and $\widetilde{C} = C - \frac{1}{d}\,\mathrm{Id}$. Let $\widetilde{J} = \frac{1}{l-1}(J - \mathrm{Id})$ be the $l \times l$ matrix that is $(l-1)^{-1}$ in the off-diagonal entries, and 0 along the diagonal. Then it is easy to see that

$$\widetilde{C} = \widetilde{B} \otimes \widetilde{J}. \tag{53}$$

The matrix $\widetilde{J}$ has a single eigenvalue equal to 1 and $l-1$ eigenvalues equal to $-\frac{1}{l-1}$, and $\widetilde{B}$ has a single eigenvalue equal to $1-1/d$ and the remaining are in the range $[-\frac{1}{d}, \lambda_M^2 - \frac{1}{d}]$. It follows that the top eigenvalue of $C = \widetilde{C} + \frac{1}{d}\,\mathrm{Id}$ is 1 (as expected) and the next one satisfies

$$\lambda_{\tilde{M}} \leq \max\left\{\lambda_M, \sqrt{\frac{1}{d(l-1)} + \frac{1}{d}}\right\},$$

which is bounded by $\max\left\{\lambda_M, \frac{1}{\sqrt{d-1}}\right\}$ since $l \geq d$. ◀

7 Weak Fortification of Entangled Games

Our goal in this section is to prove the following.

▶ **Theorem 34** (Theorem 3 restated). *Let $G' = (M \circ G \circ P)$ be a concatenated game obtained by concatenating two sides of a game G with some λ-spectral expanders M and P. If $\lambda \leq \frac{\varepsilon^2\delta}{56}$, then G' is (ε, δ) weakly-fortified against entangled substrategies.*

We need some basic matrix analytic facts.

7.1 Basic lemmas

Choi-Jamiolkowski isomorphism

We make use of the correspondence between bipartite states $|\psi\rangle \in \mathcal{H}_1 \otimes \mathcal{H}_2$ and linear operators $L : \mathcal{H}_2^* \to \mathcal{H}_1$ given by the Choi-Jamiolkowski isomorphism. Explicitly, let $|\psi\rangle \in \mathbb{C}^d \otimes \mathbb{C}^d$ be a quantum state and consider a Schmidt basis for $|\psi\rangle$ so we have $|\psi\rangle = \sum_{i=1}^d \sqrt{\lambda_i}|i\rangle|i\rangle$ where $\lambda_i \in \mathbb{R}^{\geq 0}$, up to a local change of basis. Set

$$\rho := \sum_{i=1}^d \lambda_i |i\rangle\langle i|. \tag{54}$$

▶ **Proposition 35.** *Let Z, W be two linear operators acting on $\mathbb{C}^d$ and let $|\psi\rangle$ and ρ be as above. Then,*

$$\langle\psi|Z \otimes W|\psi\rangle = \mathrm{Tr}(Z\rho^{1/2}W^T\rho^{1/2}).$$

Proof. Both expressions evaluate to $\sum_{i,j=1}^d \sqrt{\lambda_i\lambda_j}\, Z_{ij} \cdot W_{ij}$. ◀

For a density matrix ρ and a matrix A for convenience we sometimes denote $\mathrm{Tr}(A\rho)$ by $\mathrm{Tr}_\rho(A)$.

Matrix norms and inequalities

The Frobenius norm of a matrix $A \in \mathbb{C}^{n\times m}$ is defined as $\|A\|_F = \sqrt{\mathrm{Tr}(AA^\dagger)}$. The trace norm is defined as $\|A\|_{tr} = \mathrm{Tr}\sqrt{AA^\dagger}$. The following analogue of Proposition 18 will be used repeatedly in our argument.

▶ **Claim 36.** *Let M be a bipartite λ-spectral expander on vertex set $X' \cup X$. Let $\{A_{x'}\}_{x'\in X'}$ and ρ be positive semidefinite matrices. For all $x \in X$, define $A_x = \mathbb{E}_{x'\sim N(x)} A_{x'}$ and define $A = \mathbb{E}_{x\sim\mu} A_x$. Then*

$$\mathop{\mathbb{E}}_{x\sim\mu} \mathrm{Tr}_\rho((A_x - A)^2) \leq 2\lambda^2 \cdot \mathop{\mathbb{E}}_{x'\sim\mu'} \mathrm{Tr}_\rho(A_{x'}^2). \tag{55}$$

Proof. Define $S_{x'} = \rho^{1/2} A_{x'}$, $S_x = \rho^{1/2} A_x$, and $S = \mathbb{E}_x S_x = \rho^{1/2} A$. Using that M is a bipartite λ-spectral expander, for any fixed entry (i,j)

$$\mathop{\mathbb{E}}_{x} |(S_x)_{ij} - S_{ij}|^2 \leq \lambda^2 \cdot \mathop{\mathbb{E}}_{x'} |(S_{x'})_{ij} - S_{ij}|^2 \leq 2\lambda^2 \cdot \mathop{\mathbb{E}}_{x'} |(S_{x'})_{ij}|^2 \tag{56}$$

Summing over all entries,

$$\mathop{\mathbb{E}}_{x} \sum_{i,j} |(S_x)_{ij} - S_{ij}|^2 = \mathop{\mathbb{E}}_{x} \|S_x - S\|_F^2 \leq 2\lambda^2 \mathop{\mathbb{E}}_{x'} \sum_{i,j} |(S_{x'})_{ij}|^2 = 2\lambda^2 \mathop{\mathbb{E}}_{x'} \|S_{x'}\|_F^2. \tag{57}$$

Observing that $\mathrm{Tr}_\rho((A_x - A)^2) = \|S_x - S\|_F^2$ and $\|S_{x'}\|_F^2 = \mathrm{Tr}_\rho(A_{x'}^2)$, we obtain the desired result. ◀

If A has singular value decomposition $A = UJV^\dagger$ its pseudo-inverse is $A^{-1} = VJ^{-1}U^\dagger$, where J^{-1} is obtained from J by taking the reciprocal of non-zero diagonal entries. A simple consequence of the singular value decomposition is the following:

▶ **Fact 37.** *Let A be an $n \times n$ matrix. Then there exists a unitary matrix $\mathcal{U}$ such that $\mathcal{U}A$ is positive semi-definite.*

Proof. Write the SVD as $A = UJV^\dagger$, and choose $\mathcal{U} = VU^\dagger$. ◀

We make frequent use of the matrix Cauchy-Schwarz inequality.

▶ **Proposition 38.** *For any two matrices S, T we have*

$$\mathrm{Tr}(ST^\dagger) \leq \mathrm{Tr}(SS^\dagger)^{1/2} \cdot \mathrm{Tr}(TT^\dagger)^{1/2} = \|S\|_F \|T\|_F.$$

If S and T are Hermitian,

$$\mathrm{Tr}(STST) \leq \mathrm{Tr}(S^2T^2).$$

Finally, we need a variant of Powers-Størmer inequality due to Kittaneh [26]. This also played a role in the analysis of [16].

▶ **Lemma 39** ([26])**.** *Let X, Y be positive semidefinite matrices. Then*

$$\mathrm{Tr}\left((X-Y)^4\right) \leq \mathrm{Tr}\left((X^2 - Y^2)^2\right).$$

7.2 Proof of Theorem 3

At a high level, the proof of Theorem 3 follows the same outline as the classical proof of Section 5.

Consider a substrategy $\{A_{x'}^{a'}\}_{(x',a') \in X' \times A'}$, $\{B_{y'}^{b'}\}_{(y',b') \in Y' \times B'}$ for G'. Define $A_x = \mathbb{E}_{x' \sim N(x')} A_{x'}$ and $B_y = \mathbb{E}_{y' \sim N(y')} B_{y'}$.[13] Define $A = \mathbb{E}_{x \sim \mu_X} A_x$ and $B = \mathbb{E}_{y \sim \mu_Y} B_y$. To prove Theorem 3 we must analyze the following expression:

$$\begin{aligned}
\textsc{Val}^*(G', \{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}) &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathop{\mathbb{E}}_{\substack{x' \sim N(x) \\ y' \sim N(y)}} \sum_{a',b'} V(a'_{x'}(x), b'_{y'}(y), x, y) \cdot \mathrm{Tr}(A_{x'}^{a'} \rho^{1/2} B_{y'}^{b'} \rho^{1/2}) \\
&= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{a,b} V(a,b,x,y) \cdot \mathrm{Tr}(A_x^a \rho^{1/2} B_y^b \rho^{1/2}) \\
&= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}) \cdot \sum_{V(a,b,x,y)=1} \frac{\mathrm{Tr}(A_x^a \rho^{1/2} B_y^b \rho^{1/2})}{\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2})},
\end{aligned}$$

[13] In what follows, we assume without loss of generality that all $A_{x'}$ and $B_{y'}$ are invertible. Note that proving Theorem 3 for this subset of substrategies suffices. This follows by a limiting argument because of the continuity of (26) in $A_{x'}$ and $B_{y'}$.

where A_x^a and B_y^b are defined as in (11), and we use the convention that $0/0 = 0$. Our analysis splits into two cases. First let us consider the *small case*. This is handled by the following proposition.

▶ **Proposition 40.** *Suppose* $\mathrm{Tr}(\rho^{1/2}A\rho^{1/2}B) < \delta/2$. *Then* $\textsc{Val}^*(G', \{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}) < \delta$.

Proof. First of all we have

$$\textsc{Val}^*(G', \{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}) = \mathop{\mathbb{E}}_{x,y} \sum_{V(a,b,x,y)=1} \mathrm{Tr}(A_x^a \rho^{1/2} B_y^b \rho^{1/2}) \leq \mathop{\mathbb{E}}_{x,y} \mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}).$$

Subtracting $\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2})$,

$$\mathop{\mathbb{E}}_{x,y} \mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}) - \mathrm{Tr}(A\rho^{1/2}B\rho^{1/2}) = \mathop{\mathbb{E}}_{x,y} \mathrm{Tr}((A_x - A)\rho^{1/2}(B_y - B)\rho^{1/2}).$$

By applying Cauchy-Schwarz to the latter expression and using Claim 36 it follows that

$$\textsc{Val}^*(G', \{A_{x'}^{a'}\}, \{B_{y'}^{b'}\}) \leq \delta/2 + \lambda^2;$$

this is smaller than δ by the choice of λ. ◀

The large case.

In this case, the hypothesis of Proposition 40 is not satisfied and without loss of generality we assume that

$$\min\left\{ \mathrm{Tr}_\rho(A), \mathrm{Tr}_\rho(B) \right\} \geq \mathrm{Tr}(A\rho^{1/2}B\rho^{1/2}) \geq \delta/2. \tag{58}$$

Let

$$\gamma := \mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}). \tag{59}$$

By the triangle inequality,

$$\textsc{Val}^*(G', A_{x'}, B_{y'}) \leq \mathop{\mathbb{E}}_{(x,y)\sim\mu} |\,\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}) - \gamma| \tag{60}$$

$$+ \gamma \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=1} \frac{\mathrm{Tr}(A_x^a \rho^{1/2} B_y^b \rho^{1/2})}{\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2})}. \tag{61}$$

To bound the first term, we use the triangle inequality to get

$$|\,\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2}) - \gamma| \leq |\,\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2} - A\rho^{1/2}B\rho^{1/2})| + |\,\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2}) - \gamma|. \tag{62}$$

The first term on the right-hand side of (62) can be bounded as

$$\begin{aligned}
&\mathop{\mathbb{E}}_{(x,y)\sim\mu} |\,\mathrm{Tr}(A_x \rho^{1/2} B_y \rho^{1/2} - A\rho^{1/2}B\rho^{1/2})| \\
&\leq \mathop{\mathbb{E}}_{(x,y)\sim\mu} |\,\mathrm{Tr}(A_x \rho^{1/2} (B_y - B)\rho^{1/2})| + \mathop{\mathbb{E}}_{x} |\,\mathrm{Tr}((A_x - A)\rho^{1/2}B\rho^{1/2})| \\
&\leq \mathop{\mathbb{E}}_{(x,y)\sim\mu} \left[\mathrm{Tr}_\rho(A_x^2)^{1/2} \cdot \mathrm{Tr}_\rho((B_y - B)^2)^{1/2} \right] + \mathop{\mathbb{E}}_{x} \left[\mathrm{Tr}_\rho(B^2)^{1/2} \cdot \mathrm{Tr}_\rho((A_x - A)^2)^{1/2} \right] \\
&\leq \left(\mathop{\mathbb{E}}_{x} \mathrm{Tr}_\rho(A_x^2) \right)^{1/2} \cdot \left(\mathop{\mathbb{E}}_{y} \mathrm{Tr}_\rho((B_y - B)^2) \right)^{1/2} + \mathrm{Tr}_\rho(B^2)^{1/2} \cdot \left(\mathop{\mathbb{E}}_{x} \mathrm{Tr}_\rho((A_x - A)^2) \right)^{1/2} \\
&\leq 4 \cdot \lambda,
\end{aligned} \tag{63}$$

where the first inequality is the triangle inequality, the next two follow from Cauchy-Schwarz, and the last from Claim 36 and the trivial bounds $\mathrm{Tr}_\rho(A_x^2), \mathrm{Tr}_\rho(B^2) \leq \mathrm{Tr}(\rho) = 1$. To bound the second term on the right-hand side of (62) we note that

$$\begin{aligned}|\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2}) - \gamma| &= |\mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathrm{Tr}((A_x - A)\rho^{1/2}(B_y - B)\rho^{1/2})| \\ &\leq (\mathop{\mathbb{E}}_x \mathrm{Tr}_\rho[(A_x - A)^2])^{1/2} \cdot (\mathop{\mathbb{E}}_y \mathrm{Tr}_\rho[(B_y - B)^2])^{1/2},\end{aligned}$$

and the latter is again bounded by 2λ by Claim 36. In total we have

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} |\mathrm{Tr}(A_x\rho^{1/2}B_y\rho^{1/2}) - \gamma| \leq 4\lambda + 2\lambda^2 \leq \delta, \tag{64}$$

which provides an upper bound on the first term in the right-hand side of (60).

To bound the second term term in the right-hand side of (60) we use a strategy inspired in part by the parallel repetition theorem of [16]. Let U_x, V_y, U, V be a family of unitaries such that the operators

$$\Lambda_x = U_x\sqrt{A_x}\rho^{1/4}, \quad \Lambda = U\sqrt{A}\rho^{1/4}, \quad \Gamma_y = V_y\sqrt{B_y}\rho^{1/4}, \quad \Gamma = V\sqrt{B}\rho^{1/4} \tag{65}$$

are all positive semidefinite, which is possible by Fact 37. Note that this in particular implies that $\Lambda_x = \Lambda_x^\dagger$ and hence

$$\Lambda_x^2 = \Lambda_x^\dagger\Lambda_x = \rho^{1/4}\sqrt{A_x}U_x^\dagger U_x\sqrt{A_x}\rho^{1/4} = \rho^{1/4}A_x\rho^{1/4}, \tag{66}$$

and similarly $\Lambda^2 = \rho^{1/4}A\rho^{1/4}$, $\Gamma^2 = \rho^{1/4}B\rho^{1/4}$ and so on.

Define "rescaled" strategies by

$$\widehat{A_x^a} = U_x A_x^{-1/2}A_x^a A_x^{-1/2}U_x^\dagger, \quad \widehat{B_y^b} = V_y B_y^{-1/2}B_y^b B_y^{-1/2}V_y^\dagger, \tag{67}$$

where A_x^{-1}, B_y^{-1}'s are the pseudo-inverses of A_x, B_y. Note that the operators (67) satisfy $\widehat{A_x} = \sum_a \widehat{A_x^a}$, $\widehat{B_y} = \sum_b \widehat{B_y^b} \leq \mathrm{Id}$ as required. Let

$$K_{xy} = \frac{U_x A_x^{1/2}\rho^{1/2}B_y^{1/2}V_y^\dagger}{\sqrt{\mathrm{Tr}(A_x\rho^{1/2}B_y\rho^{1/2})}}, \qquad K = \frac{UA^{1/2}\rho^{1/2}B^{1/2}V^\dagger}{\sqrt{\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2})}}. \tag{68}$$

By definition of $\Lambda_x, \Gamma_y, X, Y$ we see that the above is equivalent to

$$K_{xy} = \frac{\Lambda_x\Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda_x^2\Gamma_y^2)}}, \qquad K = \frac{\Lambda\Gamma}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}}. \tag{69}$$

Now note the following identity

$$\frac{\mathrm{Tr}(A_x^a\rho^{1/2}B_y^b\rho^{1/2})}{\mathrm{Tr}(A_x\rho^{1/2}B_y\rho^{1/2})} = \mathrm{Tr}(\widehat{A_x^a}K_{xy}\widehat{B_y^b}K_{xy}^\dagger). \tag{70}$$

So to finish the argument it suffices to estimate

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=1} \mathrm{Tr}(\widehat{A_x^a}K_{xy}\widehat{B_y^b}K_{xy}^\dagger). \tag{71}$$

To this end note that since $\mathrm{Tr}(KK^\dagger) = 1$ it follows from the definition of $\textsc{Val}^*(G)$ that

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=1} \mathrm{Tr}(K\widehat{A_x^a}K^\dagger\widehat{B_y^b}) \leq \textsc{Val}^*(G). \tag{72}$$

To conclude we use the following proposition.

▶ **Proposition 41.** *Let K_{xy} and K be as above. Then*

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} \|K_{xy} - K\|_F^2 \leq \frac{12\lambda}{\delta}. \tag{73}$$

Before proving the proposition let us see how it implies the desired bound on the second term of (60).

$$\begin{aligned}
&|\operatorname{Tr}(K_{xy}\widehat{A_x^a}K_{xy}^\dagger\widehat{B_y^b}) - \operatorname{Tr}(K\widehat{A_x^a}K^\dagger\widehat{B_y^b})| \\
&\qquad \leq |\operatorname{Tr}((K_{xy}-K)\widehat{A_x^a}K_{xy}^\dagger\widehat{B_y^b})| + |\operatorname{Tr}(K\widehat{A_x^a}(K_{xy}^\dagger - K^\dagger)\widehat{B_y^b})| \\
&\qquad \leq \operatorname{Tr}((K_{xy}-K)\widehat{A_x^a}(K_{xy}-K)^\dagger\widehat{B_y^b})^{1/2}\cdot\operatorname{Tr}(K_{xy}\widehat{A_x^a}K_{xy}^\dagger\widehat{B_y^b})^{1/2} \\
&\qquad\quad + \operatorname{Tr}((K_{xy}-K)\widehat{A_x^a}(K_{xy}-K)^\dagger\widehat{B_y^b})^{1/2}\cdot\operatorname{Tr}(K\widehat{A_x^a}K^\dagger\widehat{B_y^b})^{1/2}.
\end{aligned} \tag{74}$$

Averaging with $\mathbb{E}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}$ and applying Cauchy-Schwarz we see that (74) is bounded by

$$\begin{aligned}
&\Big[\mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\operatorname{Tr}((K_{xy}-K)\widehat{A_x^a}(K_{xy}-K)^\dagger\widehat{B_y^b})\Big]^{1/2}\cdot \\
&\Big[\Big(\mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\operatorname{Tr}(K_{xy}\widehat{A_x^a}K_{xy}^\dagger\widehat{B_y^b})\Big)^{1/2} + \Big(\mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\operatorname{Tr}(K\widehat{A_x^a}K^\dagger\widehat{B_y^b})\Big)^{1/2}\Big].
\end{aligned} \tag{75}$$

We claim that the second term in brackets is at most 2. To see this note that replacing the sum from $\sum_{V(a,b,x,y)=1}$ to a $\sum_{a,b}$ only increase the term, and the claim follows from $\operatorname{Tr}(K_{xy}K_{xy}^\dagger) = \operatorname{Tr}(KK^\dagger) = 1$. To bound the first term in (75), we again relax the summation from $\sum_{V(a,b,x,y)=1}$ to $\sum_{a,b}$. This is valid because all the operators of the form $(K_{xy} - K)\widehat{A_x^a}(K_{xy}-K)^\dagger, B_y \geq 0$ and hence all the additional terms introduced in the sum are nonnegative. The desired result follows because

$$\begin{aligned}
&\mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{a,b}\operatorname{Tr}((K_{xy}-K)\widehat{A_x^a}(K_{xy}-K)^\dagger\widehat{B_y^b}) \\
&\leq \mathop{\mathbb{E}}_{(x,y)\sim\mu}\operatorname{Tr}((K_{x,y}-K)(K_{x,y}-K)^\dagger) \\
&= \mathop{\mathbb{E}}_{x,y}\|K_{x,y}-K\|_F^2,
\end{aligned}$$

which is bounded by Proposition 41. Combining all bounds, from (74) we get

$$\begin{aligned}
\mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\frac{\operatorname{Tr}(A_x^a\rho^{1/2}B_y^b\rho^{1/2})}{\operatorname{Tr}(A_x\rho^{1/2}B_y\rho^{1/2})} &= \mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\operatorname{Tr}(\widehat{A_x^a}K_{xy}\widehat{B_y^b}K_{xy}^\dagger) \\
&\leq \mathop{\mathbb{E}}_{(x,y)\sim\mu}\sum_{V(a,b,x,y)=1}\operatorname{Tr}(\widehat{A_x^a}K\widehat{B_y^b}K^\dagger) \\
&\quad + |\operatorname{Tr}(K_{xy}\widehat{A_x^a}K_{xy}^\dagger\widehat{B_y^b}) - \operatorname{Tr}(K\widehat{A_x^a}K^\dagger\widehat{B_y^b})| \\
&\leq \textsc{Val}^*(G) + 2\cdot\left(\mathop{\mathbb{E}}_{(x,y)\sim\mu}\|K_{xy}-K\|_F^2\right)^{1/2} \\
&\leq \textsc{Val}^*(G) + 2\sqrt{\frac{12\lambda}{\delta}}.
\end{aligned}$$

The latter is bounded by ε by the choice of λ. It only remains to prove Proposition 41.

Proof of Proposition 41. We have

$$\|K_{xy} - K\|_F \leq \left\| \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda_x^2 \Gamma_y^2)}} - \frac{\Lambda\Gamma}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} \right\|_F + \left\| \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} - \frac{\Lambda\Gamma}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} \right\|_F. \quad (76)$$

For the first term,

$$\begin{aligned}
&\mathop{\mathbb{E}}_{(x,y)\sim\mu} \left\| \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda_x^2 \Gamma_y^2)}} - \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} \right\|_F^2 \\
&= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \mathrm{Tr}(\Lambda_x^2\Gamma_y^2) \cdot \left(\frac{1}{\sqrt{\mathrm{Tr}(\Lambda_x^2\Gamma_y^2)}} - \frac{1}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} \right)^2 \\
&= \frac{1}{\mathrm{Tr}(\Lambda^2\Gamma^2)} \mathop{\mathbb{E}}_{(x,y)\sim\mu} \left(\sqrt{\mathrm{Tr}(\Lambda_x^2\Gamma_y^2)} - \sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)} \right)^2 \\
&\leq \frac{1}{\mathrm{Tr}(\Lambda^2\Gamma^2)} \mathop{\mathbb{E}}_{(x,y)\sim\mu} |\mathrm{Tr}(\Lambda_x^2\Gamma_y^2) - \mathrm{Tr}(\Lambda^2\Gamma^2)| \\
&\leq \frac{1}{\mathrm{Tr}(\Lambda^2\Gamma^2)} \mathop{\mathbb{E}}_{(x,y)\sim\mu} |\mathrm{Tr}((\Lambda_x^2 - \Lambda^2)\Gamma_y^2)| + |\mathrm{Tr}(\Lambda^2(\Gamma_y^2 - Y^2))| \\
&\leq \frac{1}{\mathrm{Tr}(\Lambda^2\Gamma^2)} \left| \mathop{\mathbb{E}}_x [\mathrm{Tr}((\Lambda_x^2 - \Lambda^2)^2)] \right|^{1/2} \cdot \left| \mathop{\mathbb{E}}_y [\mathrm{Tr}(\Gamma_y^4)] \right|^{1/2} \quad (77) \\
&+ \frac{1}{\mathrm{Tr}(\Lambda^2\Gamma^2)} \left| \mathop{\mathbb{E}}_x [\mathrm{Tr}((\Gamma_y^2 - \Gamma^2)^2)] \right|^{1/2} \cdot \mathrm{Tr}(\Lambda^4)^{1/2}, \quad (78)
\end{aligned}$$

where the last step follows from two applications of Cauchy-Schwarz. Rewriting the above in terms of A_x, B_y and ρ using (66) and its analogues we see that the term in (77) equals

$$\frac{1}{\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2})} \left| \mathop{\mathbb{E}}_x [\mathrm{Tr}((A_x - A)\rho^{1/2}(A_x - A)\rho^{1/2})] \right|^{1/2} \cdot \left| \mathop{\mathbb{E}}_y [\mathrm{Tr}(B_y\rho^{1/2}B_y\rho^{1/2}) \right|^{1/2} \quad (79)$$

Bounding the last term $\mathrm{Tr}(B_y\rho^{1/2}B_y\rho^{1/2})$ by 1 and the first term by 2λ (which follows by applying Fact 38 and Claim 36) and doing the same analysis for (78) we see that

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} \left\| \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda_x^2 \Gamma_y^2)}} - \frac{\Lambda_x \Gamma_y}{\sqrt{\mathrm{Tr}(\Lambda^2\Gamma^2)}} \right\|_F^2 \leq \frac{8\lambda}{\delta}. \quad (80)$$

To bound the second term in (76) we argue as follows:

$$\begin{aligned}
\|\Lambda_x\Gamma_y - \Lambda\Gamma\|_F^2 &\leq 2 \cdot \|(\Lambda_x - \Lambda)\Gamma_y\|_F^2 + 2 \cdot \|(\Gamma_y - \Gamma)X\|_F^2 \\
&= 2 \cdot \mathrm{Tr}(\Gamma_y^2(\Lambda_x - \Lambda)^2) + 2 \cdot \mathrm{Tr}((\Gamma_y - \Gamma)^2 X^2) \quad (81) \\
&\leq 2 \cdot \mathrm{Tr}(\Gamma_y^4)^{1/2} \cdot \mathrm{Tr}((\Lambda_x - \Lambda)^4)^{1/2} + 2 \cdot \mathrm{Tr}(\Lambda^4)^{1/2} \cdot \mathrm{Tr}((\Gamma_y - \Gamma)^4)^{1/2} \quad (82) \\
&\leq 2 \cdot \mathrm{Tr}(\Gamma_y^4)^{1/2} \cdot \mathrm{Tr}[(\Lambda_x^2 - \Lambda^2)^2]^{1/2} + 2 \cdot \mathrm{Tr}(\Lambda^4)^{1/2} \cdot \mathrm{Tr}[(\Gamma_y^2 - \Gamma^2)^2]^{1/2}, \quad (83)
\end{aligned}$$

where in the last step we used Lemma 39. Using the same bound on the above terms as in the above we see that

$$\mathop{\mathbb{E}}_{(x,y)\sim\mu} \|\Lambda_x\Gamma_y - \Lambda\Gamma\|_F^2 \leq 8\lambda. \quad (84)$$

Since in the large case $\mathrm{Tr}(A\rho^{1/2}B\rho^{1/2}) \geq \frac{\delta}{2}$ the result follows. ◀

8 Discussion and open problems

An obvious open problem is to extend our results to the case of multiplayer entangled games. This is likely to be achievable by combining the ideas of Sections 5.2 and 7. However, some subtleties arise with respect to the use of the Choi-Jamiolkowski isomorphism, and we leave this for future work.

An important (and somewhat surprising) message of our work is that there is a modified form of game concatenation with no adverse effect on the entangled value. This is notable because ordinary concatenation may appear to be not very well-behaved with respect to quantum strategies: we typically do not expect that entangled players would be able to answer a number of questions from a game G simultaneously, while preserving the same question/answer statistics as in G, as players' measurement operators associated with different questions generally do not commute.

The concatenation and composition of games play an important role in the classical setting in the context of PCPs [2, 14] and multiprover interactive proof systems [3]. It remains to be seen whether ideas related to our ordered fortification can be useful in lifting some of these techniques to the quantum world.

A Biregularization

In this section, we prove Lemmas 14 and 16. We start by the second lemma on the graphical games and then derive the general case by reduction.

Graphical games

Suppose G is a graphical game: there is a set of edges $E \subseteq X \times Y$ such that $\mu(x,y) = \frac{1}{|E|}$ for all $(x,y) \in E$. In this case we have

$$\mu(x) = \frac{|N(x)|}{|E|}, \qquad \mu(y) = \frac{|N(y)|}{|E|}, \qquad \forall x \in X,\, y \in Y. \tag{85}$$

Let $d_x := |N(x)|$ denote the degree of x, and set S_x be the set $\{x\} \times [d_x]$. Define

$$X_{int} = \bigcup_{x \sim X} S_x.$$

Note that $|X_{int}| = |E| \leq |X||Y|$. Define $M_{int}((x,i),x) = \frac{1}{d_x}$ for $i \in \{1,\dots,d_x\}$, and 0 otherwise. Construct Y_{int} and P_{int} similarly.

▶ **Proposition 42.** *Let $G_{int} = M_{int} \circ G \circ P_{int}$. Then marginal of μ_{int} induced on X_{int} and Y_{int} is uniform. Moreover, we have*

$$\textsc{Val}(G_{int}) = \textsc{Val}(G), \qquad \textsc{Val}^*(G_{int}) = \textsc{Val}^*(G). \tag{86}$$

Proof. It is easy to see that for all $X_{int} = (x,i) \in X_{int}$ we have $\mu_{int}(x_{int}) = \frac{1}{|E|}$ and similarly for all $y_{int} \in Y_{int}$. The claims $\textsc{Val}(G_{int}) = \textsc{Val}(G)$ and $\textsc{Val}^*(G_{int}) \leq \textsc{Val}^*(G)$ are true for all concatenated games in general. The final claim $\textsc{Val}^*(G_{int}) \geq \textsc{Val}^*(G)$ follows by considering the strategy $A_{(x,i)} = A_x$, $B_{(y,j)} = B_y$ which achieves the same value as (A_x, B_y) in G. ◀

General case

Although graphical games include many games considered in applications, it would nevertheless still be nice to extend the above construction to all games. We do not know how to do this exactly, but we can achieve an approximate variant.

The idea is essentially to approximate a general game by a graphical game. More formally, let $\tau \in (0,1)$ be an error parameter and q an integer such that $\frac{|E|}{\tau} \leq q \leq \frac{2|E|}{\tau}$. We have

$$\frac{\tau}{2|E|} \leq \frac{1}{q} \leq \frac{\tau}{|E|}. \tag{87}$$

We would like to define a game $\tilde{G}$ in which all probabilities in the underlying distribution $\tilde{\mu}(x,y)$ are fractions with denominator q. Let $\tilde{X} = X \cup \{x_{nul}\}$ and $\tilde{Y} = Y \cup \{y_{nul}\}$. For every $(x,y) \in X \times Y$ set

$$\tilde{\mu}(x,y) = \frac{\lfloor q \cdot \mu(x,y) \rfloor}{q}. \tag{88}$$

Finally let $\tilde{\mu}(x_{nul}, y_{nul})$ such that $\tilde{\mu}$ is a proper probability distribution (i.e. by transferring the excess probabilities to (x_{nul}, y_{nul})) and put an arbitrary winnable predicate on (x_{nul}, y_{nul}).

▶ **Proposition 43.** *The game $\tilde{G}$ is a graphical game with q (possibly parallel) edges. Moreover, we have*

$$\textsc{Val}(G) \leq \textsc{Val}(\tilde{G}) \leq \textsc{Val}(G) + \tau, \qquad \textsc{Val}^*(G) \leq \textsc{Val}^*(\tilde{G}) \leq \textsc{Val}^*(G) + \tau. \tag{89}$$

A few remarks are in order: firstly, since the previous construction for graphical games applies equally well in the presence of multiples edges, we can combine it with the above preprocessing to prove Lemma 14. Secondly, note that the operation $G \to \tilde{G}$ is value-increasing and hence preserves perfect completeness. Thirdly, note that the right scale for the error parameter τ is $\frac{c-s}{2}$ where $c - s$ is the completeness-soundness gap.

Proof. By construction all $\tilde{\mu}(x, y)$ are integer multiples of $\frac{1}{q}$. This ensures that the same is true for $\tilde{\mu}(x_{nul}, y_{nul})$. Since $\mu(x, y) \geq \tilde{\mu}(x, y)$ for all (x, y), for any strategy (f, g) for G we have

$$1 - \textsc{Val}(G, f, g) = \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=0} f(x, a) \cdot g(y, b) \geq 1 - \textsc{Val}(\tilde{G}, f, g),$$

which shows that $\textsc{Val}(G) \leq \textsc{Val}(\tilde{G})$. For the other direction, consider an optimal strategy (f, g) for $\tilde{G}$ (which necessarily always wins on (x_{nul}, y_{nul})). We have,

$$\begin{aligned} 1 - \textsc{Val}(G) \leq 1 - \textsc{Val}(G, f, g) &= \mathop{\mathbb{E}}_{(x,y)\sim\mu} \sum_{V(a,b,x,y)=0} f(x, a) \cdot g(y, b) \\ &\leq \sum_{x,y} \tilde{\mu}(x, y) \sum_{V(a,b,x,y)=0} f(x, a) \cdot g(y, b) + \sum_{(x,y)\in E} (\mu(x, y) - \tilde{\mu}(x, y)) \\ &\leq 1 - \textsc{Val}(\tilde{G}) + \tau \end{aligned}$$

The quantum case is similar. ◀

The Classification of Reversible Bit Operations

Abstract

We present a complete classification of all possible sets of classical reversible gates acting on bits, in terms of which reversible transformations they generate, assuming swaps and ancilla bits are available for free. Our classification can be seen as the reversible-computing analogue of *Post's lattice*, a central result in mathematical logic from the 1940s. It is a step toward the ambitious goal of classifying all possible quantum gate sets acting on qubits.

Our theorem implies a linear-time algorithm (which we have implemented), that takes as input the truth tables of reversible gates G and H, and that decides whether G generates H. Previously, this problem was not even known to be decidable (though with effort, one can derive from abstract considerations an algorithm that takes triply-exponential time). The theorem also implies that any n-bit reversible circuit can be "compressed" to an equivalent circuit, over the same gates, that uses at most $2^n \operatorname{poly}(n)$ gates and $O(1)$ ancilla bits; these are the first upper bounds on these quantities known, and are close to optimal. Finally, the theorem implies that every non-degenerate reversible gate can implement either every reversible transformation, or every affine transformation, when restricted to an "encoded subspace."

Briefly, the theorem says that every set of reversible gates generates either all reversible transformations on n-bit strings (as the Toffoli gate does); no transformations; all transformations that preserve Hamming weight (as the Fredkin gate does); all transformations that preserve Hamming weight mod k for some k; all affine transformations (as the Controlled-NOT gate does); all affine transformations that preserve Hamming weight mod 2 or mod 4, inner products mod 2, or a combination thereof; or a previous class augmented by a NOT or NOTNOT gate. Prior to this work, it was not even known that every class was finitely generated. Ruling out the possibility of additional classes, not in the list, requires involved arguments about polynomials, lattices, and Diophantine equations.

Due to the length of the proof, some parts of it have been omitted and may be found in the full version of the paper online.

1 Introduction

The *pervasiveness of universality* – that is, the likelihood that a small number of simple operations already generate all operations in some relevant class – is one of the central phenomena in computer science. It appears, among other places, in the ability of simple logic gates to generate all Boolean functions (and of simple quantum gates to generate all unitary transformations); and in the simplicity of the rule sets that lead to Turing-universality, or to formal systems to which Gödel's theorems apply. Yet precisely because universality is so pervasive, it is often more interesting to understand the ways in which systems can *fail* to be universal.

In 1941, the great logician Emil Post [23] published a complete classification of all the ways in which sets of Boolean logic gates can fail to be universal: for example, by being monotone (like the AND and OR gates) or by being affine over $\mathbb{F}_2$ (like NOT and XOR). In universal algebra, closed classes of functions are known, somewhat opaquely, as *clones*, while the inclusion diagram of all Boolean clones is called *Post's lattice*. Post's lattice is surprisingly complicated, in part because Post did not assume that the constant functions 0 and 1 were available for free.[1]

This paper had its origin in our ambition to find the analogue of Post's lattice for all possible sets of *quantum* gates acting on qubits. We view this as a large, important, and underappreciated goal: something that could be to quantum computing theory almost what the Classification of Finite Simple Groups was to group theory. To provide some context, there are many sets of 1-, 2- and 3-qubit quantum gates that are known to be universal – either in the strong sense that they can be used to approximate any n-qubit unitary transformation to any desired precision, or in the weaker sense that they suffice to perform universal quantum computation (possibly in an encoded subspace). To take two examples, Barenco et al. [6] showed universality for the CNOT gate plus the set of all 1-qubit gates, while Shi [27] showed universality for the Toffoli and Hadamard gates.

There are also sets of quantum gates that are known *not* to be universal: for example, the basis-preserving gates, the 1-qubit gates, and most interestingly, the so-called *stabilizer gates* [12, 3] (that is, the CNOT, Hadamard, and $\pi/4$-Phase gates), as well as the stabilizer gates conjugated by 1-qubit unitary transformations[2]. What is *not* known is whether the preceding list basically exhausts the ways in which quantum gates on qubits can fail to be universal. Are there other elegant discrete structures, analogous to the stabilizer gates, waiting to be discovered? Are there any gate sets, other than conjugated stabilizer gates, that might give rise to intermediate complexity classes, neither contained in P nor equal to BQP?[3] How can we claim to understand quantum circuits – the bread-and-butter of quantum computing textbooks and introductory quantum computing courses – if we do not know the answers to such questions?

---

[1] If one *does* assume constants are free, then Post's lattice dramatically simplifies, with all non-universal gate sets either monotone or affine.

[2] In fact, Grier and Schaeffer [13] have extended our classification to these quantum stabilizer operations under the same model and with a similar proof structure. In the same paper, the authors classify the classical reversible transformations in the quantum regime (i.e., with quantum ancillas), heavily relying on the classification in this paper.

[3] To clarify, there are many restricted models of quantum computing known that are plausibly "intermediate" in that sense, including BosonSampling [1], the one-clean-qubit model [18], and log-depth quantum circuits [9]. However, with the exception of conjugated stabilizer gates, none of those models arises from simply considering which unitary transformations can be generated by some set of k-qubit gates. They all involve non-standard initial states, building blocks other than qubits, or restrictions on how the gates can be composed.

Unfortunately, working out the full "quantum Post's lattice" appears out of reach at present. This might surprise readers, given how much is known about particular quantum gate sets (e.g., those containing CNOT gates), but keep in mind that what is asked for is an accounting of *all* possibilities, no matter how exotic. Indeed, even classifying 1- and 2-qubit quantum gate sets remains wide open (!), and seems, without a new idea, to require studying the irreducible representations of thousands of groups. Recently, Aaronson and Bouland [2] completed a much simpler task, the classification of 2-mode beamsplitters; that was already a complicated undertaking.

Due to its length, this paper has been shortened for these proceedings. Its full version can be found on the arXiv [4].

1.1 Classical Reversible Gates

So one might wonder: can we at least understand all the possible sets of *classical reversible gates* acting on bits, in terms of which reversible transformations they generate? This is an obvious precursor to the quantum case, since every classical reversible gate is also a unitary quantum gate. But beyond that, the classical problem is extremely interesting in its own right, with (as it turns out) a rich algebraic and number-theoretic structure, and with many implications for reversible computing as a whole.

The notion of reversible computing [11, 29, 19, 8, 21, 24] arose from early work on the physics of computation, by such figures as Feynman, Bennett, Benioff, Landauer, Fredkin, Toffoli, and Lloyd. This community was interested in questions like: does universal computation inherently require the generation of entropy (say, in the form of waste heat)? Surprisingly, the theory of reversible computing showed that, in principle, the answer to this question is "no." *Deleting* information unavoidably generates entropy, according to *Landauer's principle* [19], but deleting information is not necessary for universal computation.

Formally, a reversible gate is just a permutation $G : \{0,1\}^k \rightarrow \{0,1\}^k$ of the set of k-bit strings, for some positive integer k. The most famous examples are:

- the 2-bit CNOT (Controlled-NOT) gate, which flips the second bit if and only if the first bit is 1;
- the 3-bit Toffoli gate, which flips the third bit if and only if the first two bits are both 1;
- the 3-bit Fredkin gate, which swaps the second and third bits if and only if the first bit is 1.

These three gates already illustrate some of the concepts that play important roles in this paper. The CNOT gate can be used to copy information in a reversible way, since it maps $x0$ to xx; and also to compute arbitrary affine functions over the finite field $\mathbb{F}_2$. However, because CNOT is *limited* to affine transformations, it is not computationally universal. Indeed, in contrast to the situation with irreversible logic gates, one can show that *no* 2-bit classical reversible gate is computationally universal. The Toffoli gate is computationally universal, because (for example) it maps $x, y, 1$ to $x, y, \overline{xy}$, thereby computing the NAND function. Moreover, Toffoli showed [29] – and we prove for completeness in Section 7.1 – that the Toffoli gate is universal in a stronger sense: it generates all possible reversible transformations $F : \{0,1\}^n \rightarrow \{0,1\}^n$ if one allows the use of ancilla bits, which must be returned to their initial states by the end.

But perhaps the most interesting case is that of the Fredkin gate. Like the Toffoli gate, the Fredkin gate is computationally universal: for example, it maps $x, y, 0$ to $x, \overline{x}y, xy$, thereby computing the AND function. But the Fredkin gate is *not* universal in the stronger sense. The reason is that it is *conservative*: that is, it never changes the total Hamming weight of

the input. Far from being just a technical issue, conservativity was regarded by Fredkin and the other reversible computing pioneers as a sort of discrete analogue of the conservation of energy – and indeed, it plays a central role in certain physical realizations of reversible computing (for example, billiard-ball models, in which the total number of billiard balls must be conserved).

However, all we have seen so far are three specific examples of reversible gates, each leading to a different behavior. To anyone with a mathematical mindset, the question remains: what are all the *possible* behaviors? For example: is Hamming weight the only possible "conserved quantity" in reversible computation? Are there other ways, besides being affine, to fail to be computationally universal? Can one *derive*, from first principles, why the classes of reversible transformations generated by CNOT, Fredkin, etc. are somehow special, rather than just pointing to the sociological fact that these are classes that people in the early 1980s happened to study?

1.2 Ground Rules

In this work, we achieve a complete classification of all possible sets of reversible gates acting on bits, in terms of which reversible transformations $F : \{0,1\}^n \rightarrow \{0,1\}^n$ they generate. Before describing our result, let us carefully explain the ground rules.

First, we assume that swapping bits is free. This simply means that we do not care how the input bits are labeled – or, if we imagine the bits carried by wires, then we can permute the wires in any way we like. The second rule is that an unlimited number of ancilla bits may be used, *provided* the ancilla bits are returned to their initial states by the end of the computation. This second rule might look unfamiliar, but in the context of reversible computing, it is the right choice.

We need to allow ancilla bits because if we do not, then countless transformations are disallowed for trivial reasons. (Restricting a reversible circuit to use *no* ancillas is like restricting a Turing machine to use no memory, besides the n bits that are used to write down the input.) We are forced to say that, although our gates might generate some reversible transformation $F(x,0) = (G(x),0)$, they do not generate the smaller transformation G. The exact value of n then also takes on undeserved importance, as we need to worry about "small-n effects": e.g., that a 3-bit gate cannot be applied to a 2-bit input.

As for the number of ancilla bits: it will *turn out*, because of our classification theorem, that every reversible gate needs only $O(1)$ ancilla bits[4] to generate every n-bit reversible transformation that it can generate at all. However, we do not wish to prejudge this question; if there had been reversible gates that could generate certain transformations, but only by using (say) 2^{2^n} ancilla bits, then that would have been fascinating to know. For the same reason, we do not wish prematurely to restrict the number of ancilla bits that can be 0, or the number that can be 1.

On the other hand, the ancilla bits must be returned to their original states because if they are not, then the computation was not really reversible. One can then learn something about the computation by examining the ancilla bits – if nothing else, then the fact that the computation was done at all. The symmetry between input and output is broken; one cannot then run the computation backwards without setting the ancilla bits differently. This is not just a philosophical problem: if the ancilla bits carry away information about the input

[4] Since it is easy to show that a constant number of ancilla bits are sometimes needed (see Proposition 9), this is the optimal answer, up to the value of the constant (which might depend on the gate set).

x, then *entropy*, or waste heat, has been leaked into the computer's environment. Worse yet, if the reversible computation is a subroutine of a quantum computation, then the leaked entropy will cause *decoherence*, preventing the branches of the quantum superposition with different x values from interfering with each other, as is needed to obtain a quantum speedup. In reversible computing, the technical term for ancilla bits that still depend on x after a computation is complete is *garbage*.[5]

1.3 Our Results

Even after we assume that bit swaps and ancilla bits are free, it remains a significant undertaking to work out the complete list of reversible gate classes, and (especially!) to prove that the list is complete. Doing so is this paper's main technical contribution.

We give a formal statement of the classification theorem in Section 3, and we show the lattice of reversible gate classes in Figure 3. For now, let us simply state the main conclusions informally.

1. **Conserved Quantities.** The following is the complete list of the "global quantities" that reversible gate sets can conserve (if we restrict attention to non-degenerate gate sets, and ignore certain complications caused by linearity and affineness): Hamming weight, Hamming weight mod k for any $k \geq 2$, and inner product mod 2 between pairs of inputs.
2. **Anti-Conservation.** There are gates, such as the NOT gate, that "anti-conserve" the Hamming weight mod 2 (i.e., always change it by a fixed nonzero amount). However, there are no analogues of these for any of the other conserved quantities.
3. **Encoded Universality.** In terms of their "computational power," there are only three kinds of reversible gate sets: degenerate (e.g., NOTs, bit-swaps), non-degenerate but affine (e.g., CNOT), and non-affine (e.g., Toffoli, Fredkin). More interestingly, every non-affine gate set can implement every reversible transformation, and every non-degenerate affine gate set can implement every affine transformation, *if* the input and output bits are encoded by longer strings in a suitable way. For details about "encoded universality," see Section 4.4.
4. **Sporadic Gate Sets.** The conserved quantities interact with linearity and affineness in complicated ways, producing "sporadic" affine gate sets that we have classified. For example, non-degenerate affine gates can preserve Hamming weight mod k, but only if $k = 2$ or $k = 4$. All gates that preserve inner product mod 2 are linear, and all linear gates that preserve Hamming weight mod 4 also preserve inner product mod 2. As a further complication, for an affine transformation $F(x) = Ax + b$, it is possible for A to be orthogonal, mod-2-preserving, or mod-4-preserving without F being orthogonal, mod-2-preserving, or mod-4-preserving, respectively.
5. **Finite Generation.** For each closed class of reversible transformations, there is a single gate that generates the entire class. (*A priori*, it is not even obvious that every class is finitely generated, or that there is "only" a countable infinity of classes!) For more, see Section 4.1.
6. **Symmetry.** Every reversible gate set is symmetric under interchanging the roles of 0 and 1. For more, see Section 4.1.

[5] In Section 2.3, we will discuss a modified rule, which allows a reversible circuit to change the ancilla bits, as long as they change in a way that is independent of the input x. We will show that this "loose ancilla rule" causes only a small change to our classification theorem.

1.4 Algorithmic and Complexity Aspects

Perhaps most relevant to theoretical computer scientists, our classification theorem leads to new algorithms and complexity results about reversible gates and circuits: results that follow easily from the classification, but that we have no idea how to prove otherwise.

Let RevGen (Reversible Generation) be the following problem: we are given as input the truth tables of reversible gates $G_1, \ldots, G_K$, as well as of a target gate H, and wish to decide whether the G_i's generate H. Then we obtain a linear-time algorithm for RevGen. Here, of course, "linear" means linear in the sizes of the truth tables, which is $n2^n$ for an n-bit gate. However, if just a tiny amount of "summary data" about each gate G is provided – namely, the possible values of $|G(x)| - |x|$, where $|\cdot|$ is the Hamming weight, as well as which affine transformation G performs if it is affine – then the algorithm actually runs in $O(n^\omega)$ time, where ω is the matrix multiplication exponent.

We have implemented this algorithm; code is available for download at [25]. For more details see Section 4.2.

Our classification theorem also implies the first general upper bounds (i.e., bounds that hold for all possible gate sets) on the number of gates and ancilla bits needed to implement reversible transformations. In particular, we show (see Section 4.3) that if a set of reversible gates generates an n-bit transformation F at all, then it does so via a circuit with at most $2^n \operatorname{poly}(n)$ gates and $O(1)$ ancilla bits. These bounds are close to optimal.

By contrast, let us consider the situation for these problems without the classification theorem. Suppose, for example, that we want to know whether a reversible transformation $H : \{0,1\}^n \to \{0,1\}^n$ can be synthesized using gates $G_1, \ldots, G_K$. If we knew some upper bound on the number of ancilla bits that might be needed by the generating circuit, then if nothing else, we could of course solve this problem by brute force. The trouble is that, without the classification, it is not obvious how to prove *any* upper bound on the number of ancillas – not even, say, Ackermann(n). This makes it unclear, *a priori*, whether RevGen is even *decidable*, never mind its complexity!

One *can* show on abstract grounds that RevGen is decidable, but with an astronomical running time. To explain this requires a short digression. In universal algebra, there is a body of theory (see e.g. [20]), which grew out of Post's original work [23], about the general problem of classifying closed classes of functions (clones) of various kinds. The upshot is that every clone is characterized by an *invariant* that all functions in the clone preserve: for example, affineness for the NOT and XOR functions, or monotonicity for the AND and OR functions. The clone can then be shown to contain *all* functions that preserve the invariant. (There is a formal definition of "invariant," involving polymorphisms, which makes this statement not a tautology, but we omit it.) Alongside the lattice of clones of functions, there is a dual lattice of *coclones* of invariants, and there is a Galois connection relating the two: as one adds more functions, one preserves fewer invariants, and vice versa.

In response to an inquiry by us, Emil Jeřábek recently showed [15] that the clone/coclone duality can be adapted to the setting of reversible gates. This means that we know, even without a classification theorem, that every closed class of reversible transformations is uniquely determined by the invariants that it preserves.

Unfortunately, this elegant characterization does not give rise to feasible algorithms. The reason is that, for an n-bit gate $G : \{0,1\}^n \to \{0,1\}^n$, the invariants could in principle involve all 2^n inputs, as well arbitrary polymorphisms mapping those inputs into a commutative monoid. Thus the number of polymorphisms one needs to consider grows at least like $2^{2^{2^n}}$. Now, the word problem for commutative monoids is decidable, by reduction to the ideal membership problem (see, e.g., [17, p. 55]). And by putting these facts together, one can

derive an algorithm for RevGen that uses doubly-exponential space and triply-exponential time, as a function of the truth table sizes: in other words, $\exp(\exp(\exp(\exp(n))))$ time, as a function of n. We believe it should also be possible to extract $\exp(\exp(\exp(\exp(n))))$ upper bounds on the number of gates and ancillas from this algorithm, although we have not verified the details.

1.5 Proof Ideas

We hope we have made the case that the classification theorem improves the complexity situation for reversible circuit synthesis! Even so, some people might regard classifying all possible reversible gate sets as a complicated, maybe worthwhile, but fundamentally tedious exercise. Can't such problems be automated via computer search? On the contrary, there are specific aspects of reversible computation that make this classification problem both unusually rich, and unusually hard to reduce to any finite number of cases.

We already discussed the astronomical number of possible invariants that even a tiny reversible gate (say, a 3-bit gate) might satisfy, and the hopelessness of enumerating them by brute force. However, even if we could cut down the number of invariants to something reasonable, there would still be the problem that the size, n, of a reversible gate can be arbitrarily large – and as one considers larger gates, one can discover more and more invariants. Indeed, that is precisely what happens in our case, since the Hamming weight mod k invariant can only be "noticed" by considering gates on k bits or more. There are also "sporadic" affine classes that can only be found by considering 6-bit gates.

Of course, it is not hard just to *guess* a large number of reversible gate classes (affine transformations, parity-preserving and parity-flipping transformations, etc.), prove that these classes are all distinct, and then prove that each one can be generated by a simple set of gates (e.g., CNOT or Fredkin + NOT). Also, once one has a sufficiently powerful gate (say, the CNOT gate), it is often straightforward to classify all the classes *containing* that gate. So for example, it is relatively easy to show that CNOT, together with any non-affine gate, generates all reversible transformations.

As usual with classification problems, the hard part is to rule out exotic additional classes: most of the work, one might say, is not about what is there, but about what isn't there. It is one thing to synthesize some random 1000-bit reversible transformation using only Toffoli gates, but quite another to synthesize a Toffoli gate using only the random 1000-bit transformation!

Thinking about this brings to the fore the central issue: that in reversible computation, it is not enough to output some desired string $F(x)$; one needs to output nothing else *besides* $F(x)$. And hence, for example, it does not suffice to look inside the random 1000-bit reversible gate G, to show that it contains a NAND gate, which is computationally universal. Rather, one needs to deal with *all* of G's outputs, and show that one can eliminate the undesired ones.

The way we do that involves another characteristic property of reversible circuits: that they can have "global conserved quantities," such as Hamming weight. Again and again, we need to prove that if a reversible gate G *fails* to conserve some quantity, such as the Hamming weight mod k, then that fact alone implies that we can use G to implement a desired behavior. This is where elementary algebra and number theory come in.

There are two aspects to the problem. First, we need to understand something about the possible quantities that a reversible gate can conserve. For example, we will need the following three results:

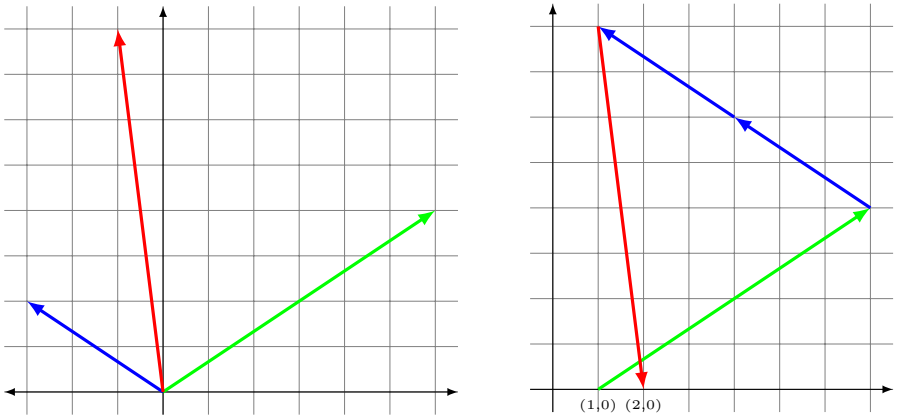

Figure 1 Moving within first quadrant of lattice to construct a COPY gate.

- No reversible gate can change the Hamming weight of some input and also conserve inner products mod k, unless $k = 2$.
- No reversible gate can change Hamming weight mod k by a fixed, nonzero amount, unless $k = 2$.
- No nontrivial linear gate can conserve Hamming weight mod k, unless $k = 2$ or $k = 4$.

We prove each of these statements in Section 6, using arguments based on complex polynomials.

Next, using our knowledge about the possible conserved quantities, we need procedures that take any gate G that fails to conserve some quantity, and that use G to implement a desired behavior (say, making a single copy of a bit, or changing an inner product by exactly 1). We then leverage that behavior to generate a desired gate (say, a Fredkin gate). The two core tasks turn out to be the following:

- Given any non-affine gate, we need to construct a Fredkin gate.
- Given any non-orthogonal linear gate, we need to construct a CNOTNOT gate, a parity-preserving version of CNOT that maps x, y, z to $x, y \oplus x, z \oplus x$.

These proofs are quite lengthy and are included in the full version of our paper [4]. The solution involves 3-dimensional lattices: that is, subsets of $\mathbb{Z}^3$ closed under integer linear combinations. We argue, in essence, that the only possible obstruction to the desired behavior is a "modularity obstruction," but the assumption about the gate G rules out such an obstruction.

We can illustrate this with an example that ends up *not* being needed in the final classification proof, but that we worked out earlier in this research.[6] Let G be any gate that does not conserve (or anti-conserve) the Hamming weight mod k for any $k \geq 2$, and suppose we want to use G to construct a CNOT gate.

[6] In general, after completing the classification proof, we were able to go back and simplify it substantially, by removing results – for example, about the generation of CNOT gates – that were important for working out the lattice in the first place, but which then turned out to be subsumed (or which *could* be subsumed, with modest additional effort) by later parts of the classification. Our current proof reflects these simplifications.

Then we examine how G behaves on restricted inputs: in this case, on inputs that consist entirely of some number of copies of x and $\overline{x}$, where $x \in \{0,1\}$ is a bit, as well as constant 0 and 1 bits. For example, perhaps G can increase the number of copies of x by 5 while decreasing the number of copies of $\overline{x}$ by 7, and can *also* decrease the number of copies of x by 6 without changing the number of copies of $\overline{x}$. Whatever the case, the set of possible behaviors generates some lattice: in this case, a lattice in $\mathbb{Z}^2$ (see Figure 1). We need to argue that the lattice contains a distinguished point encoding the desired "copying" behavior. In the case of the CNOT gate, the point is $(1,0)$, since we want one more copy of x and no more copies of $\overline{x}$. Showing that the lattice contains $(1,0)$, in turn, boils down to arguing that a certain system of Diophantine linear equations must have a solution. One can do this, finally, by using the assumption that G does not conserve or anti-conserve the Hamming weight mod k for any k.

To generate the Fredkin gate, we instead use the Chinese Remainder Theorem to combine gates that change the inner product mod p for various primes p into a gate that changes the inner product between two inputs by exactly 1; while to generate the CNOTNOT gate, we exploit the assumption that our generating gates are linear. In all these cases, it is crucial that we know, from Section 6, that certain quantities *cannot* be conserved by any reversible gate.

There are a few parts of the classification proof that basically *do* come down to enumerating cases, but we hope to have given a sense for the interesting parts.

1.6 Related Work

Surprisingly, the general question of classifying reversible gates such as Toffoli and Fredkin appears never to have been asked, let alone answered, prior to this work.

In the reversible computing literature, there are hundreds of papers on synthesizing reversible circuits (see [24] for a survey), but most of them focus on practical considerations: for example, trying to minimize the number of Toffoli gates or other measures of interest, often using software optimization tools. We found only a tiny amount of work relevant to the classification problem: notably, an unpublished preprint by Lloyd [21], which shows that every non-affine reversible gate is computationally universal, if one does not care what garbage is generated in addition to the desired output. Lloyd's result was subsequently rediscovered by Kerntopf et al. [16] and De Vos and Storme [30].

There is also work by Morita et al. [22] that uses brute-force enumeration to classify certain reversible computing elements with 2, 3, or 4 wires, but the notion of "reversible gate" there is very different from the standard one (the gates are for routing a single "billiard ball" element rather than for transforming bit strings, and they have internal state). Finally, there is work by Strazdins [28], not motivated by reversible computing, which considers classifying reversible Boolean functions, but which imposes a separate requirement on each output bit that it belong to one of the classes from Post's original lattice, and which thereby misses all the reversible gates that conserve "global" quantities, such as the Fredkin gate.[7]

[7] Because of different rules regarding constants, developed with Post's lattice rather than reversible computing in mind, Strazdins also includes classes that we do not (e.g., functions that always map 0^n or 1^n to themselves, but are otherwise arbitrary). To use our notation, his 13-class lattice ends up intersecting our infinite lattice in just five classes: $\langle\varnothing\rangle$, $\langle\text{NOT}\rangle$, $\langle\text{CNOTNOT}, \text{NOT}\rangle$, $\langle\text{CNOT}\rangle$, and $\langle\text{Toffoli}\rangle$.

2 Notation and Definitions

$\mathbb{F}_2$ means the field of 2 elements. $[n]$ means $\{1,\ldots,n\}$. We denote by $e_1,\ldots,e_n$ the standard basis for the vector space $\mathbb{F}_2^n$: that is, $e_1=(1,0,\ldots,0)$, etc.

Let $x=x_1\ldots x_n$ be an n-bit string. Then $\overline{x}$ means x with all n of its bits inverted. Also, $x\oplus y$ means bitwise XOR, x,y or xy means concatenation, x^k means the concatenation of k copies of x, and $|x|$ means the Hamming weight. The *parity* of x is $|x| \bmod 2$. The *inner product* of x and y is the integer $x\cdot y=x_1y_1+\cdots+x_ny_n$. Note that

$$x\cdot(y\oplus z)\equiv x\cdot y+x\cdot z\,(\mathrm{mod}\,2)\,,$$

but the above need not hold if we are not working mod 2.

By $\mathrm{gar}\,(x)$, we mean garbage depending on x: that is, "scratch work" that a reversible computation generates along the way to computing some desired function $f\,(x)$. Typically, the garbage later needs to be *uncomputed*. Uncomputing, a term introduced by Bennett [8], simply means running an entire computation in reverse, after the output $f\,(x)$ has been safely stored.

2.1 Gates

By a *(reversible) gate*, throughout this paper we will mean a reversible transformation G on the set of k-bit strings: that is, a permutation of $\{0,1\}^k$, for some fixed k. Formally, the terms 'gate' and 'reversible transformation' will mean the same thing; 'gate' just connotes a reversible transformation that is particularly small or simple.

A gate is *nontrivial* if it does something other than permute its input bits, and *non-degenerate* if it does something other than permute its input bits and/or apply NOT's to some subset of them.

A gate G is *conservative* if it satisfies $|G\,(x)|=|x|$ for all x. A gate is *mod-k-respecting* if there exists a j such that

$$|G\,(x)|\equiv|x|+j\,(\mathrm{mod}\,k)$$

for all x. It's *mod-k-preserving* if moreover $j=0$. It's *mod-preserving* if it's mod-k-preserving for some $k\geq 2$, and *mod-respecting* if it's mod-k-respecting for some $k\geq 2$.

As special cases, mod-2-respecting gates and mod-2-preserving gates are called is also called *parity-respecting* and *parity-preserving* respectively. A gate G such that

$$|G\,(x)|\not\equiv|x|\,(\mathrm{mod}\,2)$$

for all x is called *parity-flipping*. In Theorem 12, we will prove that parity-flipping gates are the *only* examples of mod-respecting gates that are not mod-preserving.

The *respecting number* of a gate G, denoted $k\,(G)$, is the largest k such that G is mod-k-respecting. (By convention, if G is conservative then $k\,(G)=\infty$, while if G is non-mod-respecting then $k\,(G)=1$.) We have the following fact:

▶ **Proposition 1.** *G is mod-ℓ-respecting if and only if ℓ divides $k\,(G)$.*

Proof. If ℓ divides $k\,(G)$, then certainly G is mod-ℓ-respecting. Now, suppose G is mod-ℓ-respecting but ℓ does not divide $k\,(G)$. Then G is both mod-ℓ-respecting and mod-$k(G)$-respecting. So by the Chinese Remainder Theorem, G is mod-$\mathrm{lcm}\,(\ell,k\,(G))$-respecting. But this contradicts the definition of $k\,(G)$. ◀

A gate G is *affine* if it implements an affine transformation over $\mathbb{F}_2$: that is, if there exists an invertible matrix $A \in \mathbb{F}_2^{k \times k}$, and a vector $b \in \mathbb{F}_2^k$, such that $G(x) = Ax \oplus b$ for all x. A gate is *linear* if moreover $b = 0$. A gate is *orthogonal* if it satisfies

$$G(x) \cdot G(y) \equiv x \cdot y \pmod 2$$

for all x, y. (We will observe, in Lemma 14, that every orthogonal gate is linear.) Also, if $G(x) = Ax \oplus b$ is affine, then the *linear part of* G is the linear transformation $G'(x) = Ax$. We call G orthogonal in its linear part, mod-k-preserving in its linear part, etc. if G' satisfies the corresponding invariant. A gate that is orthogonal in its linear part is also called an *isometry*.

Given two gates G and H, their *tensor product*, $G \otimes H$, is a gate that applies G and H to disjoint sets of bits. We will often use the tensor product to produce a single gate that combines the properties of two previous gates. Also, we denote by $G^{\otimes t}$ the tensor product of t copies of G.

2.2 Gate Classes

Let $S = \{G_1, G_2, \ldots\}$ be a set of gates, possibly on different numbers of bits and possibly infinite. Then $\langle S \rangle = \langle G_1, G_2, \ldots \rangle$, *the class of reversible transformations generated by* S, can be defined as the smallest set of reversible transformations $F : \{0,1\}^n \to \{0,1\}^n$ that satisfies the following closure properties:

1. **Base case.** $\langle S \rangle$ contains S, as well as the identity function $F(x_1 \ldots x_n) = x_1 \ldots x_n$ for all $n \geq 1$.
2. **Composition rule.** If $\langle S \rangle$ contains $F(x_1 \ldots x_n)$ and $G(x_1 \ldots x_n)$, then $\langle S \rangle$ also contains $F(G(x_1 \ldots x_n))$.
3. **Swapping rule.** If $\langle S \rangle$ contains $F(x_1 \ldots x_n)$, then $\langle S \rangle$ also contains all possible functions $\sigma\left(F\left(x_{\tau(1)} \ldots x_{\tau(n)}\right)\right)$ obtained by permuting F's input and output bits.
4. **Extension rule.** If $\langle S \rangle$ contains $F(x_1 \ldots x_n)$, then $\langle S \rangle$ also contains the function

   $$G(x_1 \ldots x_n, b) := (F(x_1 \ldots x_n), b),$$

   in which b occurs as a "dummy" bit.
5. **Ancilla rule.** If $\langle S \rangle$ contains a function F that satisfies

   $$F(x_1 \ldots x_n, a_1 \ldots a_k) = (G(x_1 \ldots x_n), a_1 \ldots a_k) \quad \forall x_1 \ldots x_n \in \{0,1\}^n,$$

   for some smaller function G and fixed "ancilla" string $a_1 \ldots a_k \in \{0,1\}^k$ that does not depend on x, then $\langle S \rangle$ also contains G. (Note that, if the a_i's are set to other values, then F need not have the above form.)

Note that because of reversibility, the set of n-bit transformations in $\langle S \rangle$ (for any n) always forms a group. Indeed, if $\langle S \rangle$ contains F, then clearly $\langle S \rangle$ contains all the iterates $F^2(x) = F(F(x))$, etc. But since there must be some positive integer m such that $F^m(x) = x$, this means that $F^{m-1}(x) = F^{-1}(x)$. Thus, we do not need a separate rule stating that $\langle S \rangle$ is closed under inverses.

We say S *generates* the reversible transformation F if $F \in \langle S \rangle$. We also say that S generates $\langle S \rangle$.

Given an arbitrary set $\mathcal{C}$ of reversible transformations, we call $\mathcal{C}$ a *reversible gate class* (or *class* for short) if $\mathcal{C}$ is closed under rules (1)-(5) above: in other words, if there exists an S such that $\mathcal{C} = \langle S \rangle$.

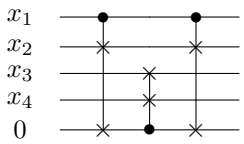

Figure 2 Generating a Controlled-Controlled-Swap gate from Fredkin.

A *reversible circuit* for the function F, over the gate set S, is an explicit procedure for generating F by applying gates in S, and thereby showing that $F \in \langle S \rangle$. An example is shown in Figure 2. Reversible circuit diagrams are read from left to right, with each bit that occurs in the circuit (both input and ancilla bits) represented by a horizontal line, and each gate represented by a vertical line.

If every gate $G \in S$ satisfies some invariant, then we can also describe S and $\langle S \rangle$ as satisfying that invariant. So for example, the set $\{\text{CNOTNOT}, \text{NOT}\}$ is affine and parity-respecting, and so is the class that it generates. Conversely, S violates an invariant if any $G \in S$ violates it.

Just as we defined the respecting number $k(G)$ of a gate, we would like to define the respecting number $k(S)$ of an entire gate set. To do so, we need a proposition about the behavior of $k(G)$ under tensor products.

▶ **Proposition 2.** *For all gates G and H,*

$$k(G \otimes H) = \gcd(k(G), k(H)).$$

Proof. Letting $\gamma = \gcd(k(G), k(H))$, clearly $G \otimes H$ is mod-γ-respecting. To see that $G \otimes H$ is not mod-ℓ-respecting for any $\ell > \gamma$: by definition, ℓ must fail to divide either $k(G)$ or $k(H)$. Suppose it fails to divide $k(G)$ without loss of generality. Then G cannot be mod-ℓ-respecting, by Proposition 1. But if we consider pairs of inputs to $G \otimes H$ that differ only on G's input, then this implies that $G \otimes H$ is not mod-ℓ-respecting either. ◀

If $S = \{G_1, G_2, \ldots\}$, then because of Proposition 2, we can define k on the set S as $\gcd(k(G_1), k(G_2), \ldots)$. For then not only will every transformation in $\langle S \rangle$ be mod-$k(S)$-respecting, but there will exist transformations in $\langle S \rangle$ that are not mod-ℓ-respecting for any $\ell > k(S)$.

We then have that S is mod-k-respecting if and only if k divides $k(S)$, and mod-respecting if and only if S is mod-k-respecting for some $k \geq 2$.

2.3 Alternative Kinds of Generation

We now discuss four alternative notions of what it can mean for a reversible gate set to "generate" a transformation. Besides being interesting in their own right, some of these notions will also be used in the proof of our main classification theorem.

Partial Gates. A *partial reversible gate* is an injective function $H : D \to \{0,1\}^n$, where D is some subset of $\{0,1\}^n$. Such an H is *consistent* with a full reversible gate G if $G(x) = H(x)$ whenever $x \in D$. Also, we say that a reversible gate set S *generates* H if S generates any G with which H is consistent. As an example, COPY is the 2-bit partial reversible gate defined by the following relations:

$$\text{COPY}(00) = 00, \qquad \text{COPY}(10) = 11.$$

If a gate set S can implement the above behavior, using ancilla bits that are returned to their original states by the end, then we say S "generates COPY"; the behavior on inputs 01

and 11 is irrelevant. Note that COPY is consistent with CNOT. One can think of COPY as a bargain-basement CNOT, but one that might be bootstrapped up to a full CNOT with further effort.

Generation With Garbage. Let $D \subseteq \{0,1\}^m$, and $H : D \to \{0,1\}^n$ be some function, which need not be injective or surjective, or even have the same number of input and output bits. Then we say that a reversible gate set S *generates* H *with garbage* if there exists a reversible transformation $G \in \langle S \rangle$, as well as an ancilla string a and a function gar, such that $G(x,a) = (H(x), \text{gar}(x))$ for all $x \in D$. As an example, consider the ordinary 2-bit AND function, from $\{0,1\}^2$ to $\{0,1\}$. Since AND destroys information, clearly no reversible gate can generate it in the usual sense, but many reversible gates can generate AND with garbage: for instance, the Toffoli and Fredkin gates, as we saw in Section 1.1.

Encoded Universality. This is a concept borrowed from quantum computing [5]. In our setting, encoded universality means that there is some way of encoding 0's and 1's by longer strings, such that our gate set can implement any desired transformation on the encoded bits. Note that, while this is a weaker notion of universality than the ability to generate arbitrary permutations of $\{0,1\}^n$, it is stronger than "merely" computational universality, because it still requires a transformation to be performed reversibly, with no garbage left around. Formally, given a reversible gate set S, we say that S *supports encoded universality* if there are k-bit strings $\alpha(0)$ and $\alpha(1)$ such that for every n-bit reversible transformation $F(x_1 \ldots x_n) = y_1 \ldots y_n$, there exists a transformation $G \in \langle S \rangle$ that satisfies

$$G(\alpha(x_1) \ldots \alpha(x_n)) = \alpha(y_1) \ldots \alpha(y_n)$$

for all $x \in \{0,1\}^n$. Also, we say that S *supports affine encoded universality* if this is true for every affine F.

As a well-known example, the Fredkin gate is not universal in the usual sense, because it preserves Hamming weight. But it is easy to see that Fredkin supports encoded universality, using the so-called *dual-rail encoding*, in which every 0 bit is encoded as 01, and every 1 bit is encoded as 10. In Section 4.4, we will show, as a consequence of our classification theorem, that *every* reversible gate set (except for degenerate sets) supports either encoded universality or affine encoded universality.

Loose Generation. Finally, we say that a gate set S *loosely generates* a reversible transformation $F : \{0,1\}^n \to \{0,1\}^n$, if there exists a transformation $G \in \langle S \rangle$, as well as ancilla strings a and b, such that

$$G(x,a) = (F(x), b)$$

for all $x \in \{0,1\}^n$. In other words, G is allowed to change the ancilla bits, so long as they change in a way that is independent of the input x. Under this rule, one could perhaps tell by examining the ancilla bits *that* G was applied, but one could not tell to which input. This suffices for some applications of reversible computing, though not for others.[8]

3 Stating the Classification Theorem

In this section we state our main result, and make a few preliminary remarks about it. First let us define the gates that appear in the classification theorem.

[8] For example, if G were applied to a quantum superposition, then it would still maintain coherence among all the inputs to which it was applied – though perhaps not between those inputs and other inputs in the superposition to which it was *not* applied.

- NOT is the 1-bit gate that maps x to $\overline{x}$.
- NOTNOT, or $\mathrm{NOT}^{\otimes 2}$, is the 2-bit gate that maps x, y to $\overline{x}, \overline{y}$. NOTNOT is a parity-preserving variant of NOT.
- CNOT (Controlled-NOT) is the 2-bit gate that maps x, y to $x, y \oplus x$. CNOT is affine.
- CNOTNOT is the 3-bit gate that maps x, y, z to $x, y \oplus x, z \oplus x$. CNOTNOT is affine and parity-preserving.
- Toffoli (also called Controlled-Controlled-NOT, or CCNOT) is the 3-bit gate that maps x, y, z to $x, y, z \oplus xy$.
- Fredkin (also called Controlled-SWAP, or CSWAP) is the 3-bit gate that maps x, y, z to $x, y \oplus x\,(y \oplus z)\,, z \oplus x\,(y \oplus z)$. In other words, it swaps y with z if $x = 1$, and does nothing if $x = 0$. Fredkin is conservative: it never changes the Hamming weight.
- C_k is a k-bit gate that maps 0^k to 1^k and 1^k to 0^k, and all other k-bit strings to themselves. C_k preserves the Hamming weight mod k. Note that $\mathrm{C}_1 = \mathrm{NOT}$, while C_2 is equivalent to NOTNOT, up to a bit-swap.
- T_k is a k-bit gate (for even k) that maps $x = (x_1, x_2, \ldots, x_k)$ to $\overline{x} = (\overline{x}_1, \overline{x}_2, \ldots, \overline{x}_k)$ if $|x|$ is odd, or to x if $|x|$ is even. A different definition is

  $$\mathrm{T}_k\,(x_1, \ldots, x_k) = (x_1 \oplus b_x, \ldots, x_k \oplus b_x)\,,$$

  where $b_x := x_1 \oplus \cdots \oplus x_k$. This shows that T_k is linear. Indeed, we also have

  $$\mathrm{T}_k\,(x) \cdot \mathrm{T}_k\,(y) \equiv x \cdot y \,(\mathrm{mod}\, 2)\,,$$

  which shows that T_k is orthogonal. Note also that, if $k \equiv 2 \,(\mathrm{mod}\, 4)$, then T_k preserves Hamming weight mod 4: if $|x|$ is even then $|\mathrm{T}_k\,(x)| = |x|$, while if $|x|$ is odd then

  $$|\mathrm{T}_k\,(x)| \equiv k - |x| \equiv 2 - |x| \equiv |x| \,(\mathrm{mod}\, 4)\,.$$

- F_k is a k-bit gate (for even k) that maps x to $\overline{x}$ if $|x|$ is even, or to x if $|x|$ is odd. A different definition is

  $$\mathrm{F}_k\,(x_1 \ldots x_k) = \overline{\mathrm{T}_k\,(x_1 \ldots x_k)} = (x_1 \oplus b_x \oplus 1, \ldots, x_k \oplus b_x \oplus 1)$$

  where b_x is as above. This shows that F_k is affine. Indeed, if k is a multiple of 4, then F_k preserves Hamming weight mod 4: if $|x|$ is odd then $|\mathrm{F}_k\,(x)| = |x|$, while if $|x|$ is even then

  $$|\mathrm{F}_k\,(x)| \equiv k - |x| \equiv |x| \,(\mathrm{mod}\, 4)\,.$$

  Since F_k is equal to T_k in its linear part, F_k is also an isometry.

We can now state the classification theorem.

▶ **Theorem 3** (Main Result). *Every set of reversible gates generates one of the following classes:*

1. *The trivial class (which contains only bit-swaps).*
2. *The class of all transformations (generated by* Toffoli*).*
3. *The class of all conservative transformations (generated by* Fredkin*).*
4. *For each $k \geq 3$, the class of all mod-k-preserving transformations (generated by C_k).*
5. *The class of all affine transformations (generated by* CNOT*).*
6. *The class of all parity-preserving affine transformations (generated by* CNOTNOT*).*
7. *The class of all mod-4-preserving affine transformations (generated by F_4).*

8. *The class of all orthogonal linear transformations (generated by* T_4*).*
9. *The class of all mod-*4*-preserving orthogonal linear transformations (generated by* T_6*).*
10. *Classes 1, 3, 7, 8, or 9 augmented by a* NOTNOT *gate (note: 7 and 8 become equivalent this way).*
11. *Classes 1, 3, 6, 7, 8, or 9 augmented by a* NOT *gate (note: 7 and 8 become equivalent this way).*

Furthermore, all the above classes are distinct except when noted otherwise, and they fit together in the lattice diagram shown in Figure 3.[9]

Let us make some comments about the structure of the lattice. The lattice has a countably infinite number of classes, with the one infinite part given by the mod-k-preserving classes. The mod-k-preserving classes are partially ordered by divisibility, which means, for example, that the lattice is not planar.[10] While there are infinite descending chains in the lattice, there is no infinite ascending chain. This means that, if we start from some reversible gate class and then add new gates that extend its power, we must terminate after finitely many steps with the class of all reversible transformations.

In the full version [4], we prove that if we allow loose generation, then the only change to Theorem 3 is that every class $\mathcal{C}$ containing a NOTNOT gate collapses with $\mathcal{C} + \mathrm{NOT}$.

4 Consequences of the Classification

To illustrate the power of the classification theorem, in this section we use it to prove four general implications for reversible computation. While these implications are easy to prove with the classification in hand, we do not know how to prove any of them without it.

4.1 Nature of the Classes

Here is one immediate (though already non-obvious) corollary of Theorem 3.

▶ **Corollary 4.** *Every reversible gate class* $\mathcal{C}$ *is finitely generated: that is, there exists a finite set* S *such that* $\mathcal{C} = \langle S \rangle$*.*

Indeed, we have something stronger.

▶ **Corollary 5.** *Every reversible gate class* $\mathcal{C}$ *is generated by a single gate* $G \in \mathcal{C}$*.*

Proof. This is immediate for all the classes listed in Theorem 3, except the ones involving NOT or NOTNOT gates. For classes of the form $\mathcal{C} = \langle G, \mathrm{NOT} \rangle$ or $\mathcal{C} = \langle G, \mathrm{NOTNOT} \rangle$, we just need a single gate G' that is clearly generated by $\mathcal{C}$, and clearly *not* generated by a smaller class. We can then appeal to Theorem 3 to assert that G' *must* generate $\mathcal{C}$. For each of the relevant G's – namely, Fredkin, CNOTNOT, F_4, and T_6 – one such G' is the tensor product, $G \otimes \mathrm{NOT}$ or $G \otimes \mathrm{NOTNOT}$. ◀

[9] Let us mention that Fredkin + NOTNOT generates the class of all parity-preserving transformations, while Fredkin + NOT generates the class of all parity-respecting transformations. We could have listed the parity-preserving transformations as a special case of the mod-k-preserving transformations: namely, the case $k = 2$. If we had done so, though, we would have had to include the caveat that C_k only generates all mod-k-preserving transformations when $k \geq 3$ (when $k = 2$, we also need Fredkin in the generating set). And in any case, the parity-respecting class would still need to be listed separately.

[10] For consider the graph with the integers 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 14, 15, 18, 20, 21, 24, and 28 as its vertices, and with an edge between each pair whose ratio is a prime. One can check that this graph contains $K_{3,3}$ as a minor.

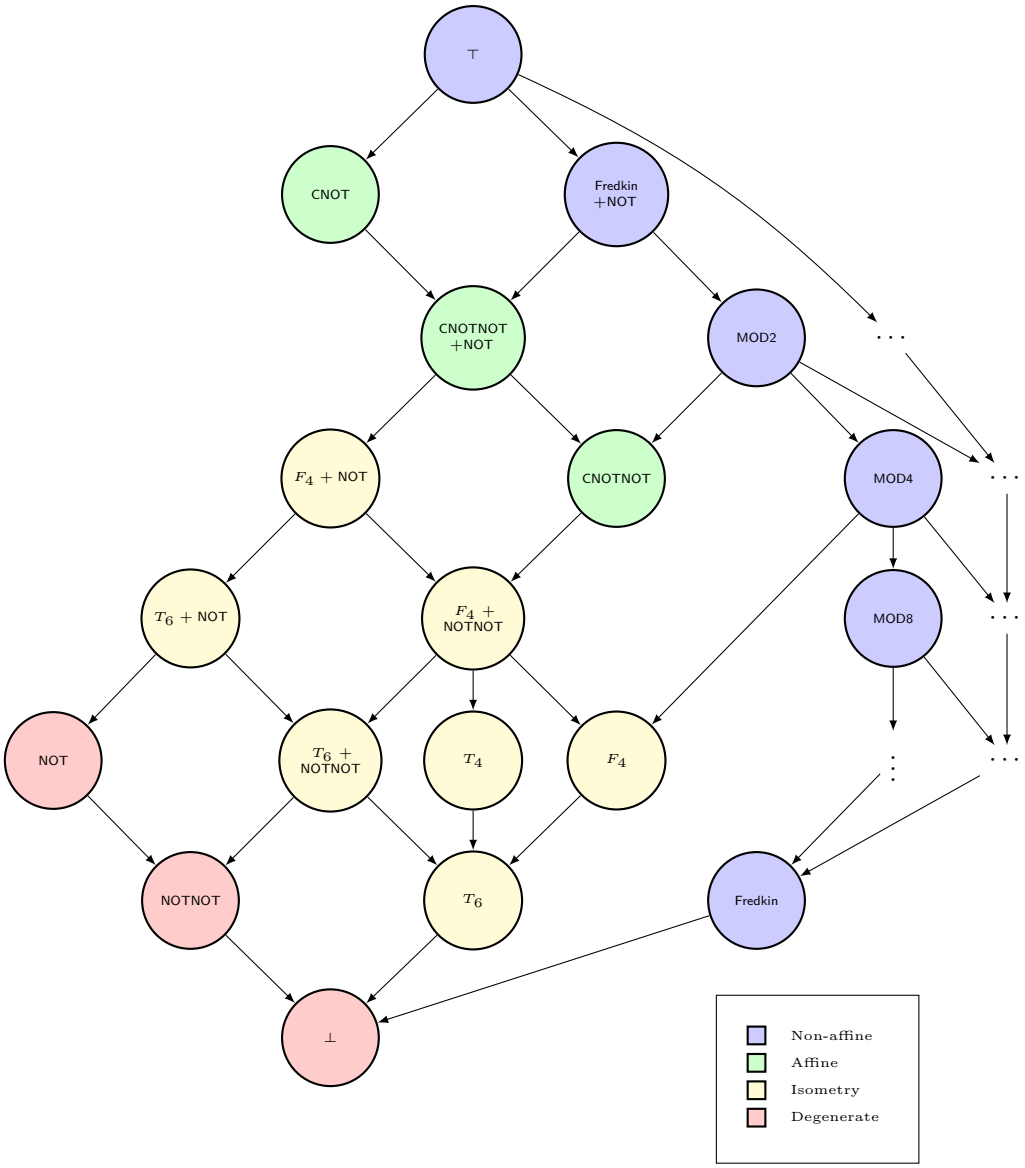

Figure 3 The inclusion lattice of reversible gate classes.

We also wish to point out a non-obvious symmetry property that follows from the classification theorem. Given an n-bit reversible transformation F, let F^*, or the *dual* of F, be $F^*(x_1 \dots x_n) := \overline{F(\overline{x}_1 \dots \overline{x}_n)}$. The dual can be thought of as F with the roles of 0 and 1 interchanged: for example, Toffoli$^*(xyz)$ flips z if and only if $x = y = 0$. Also, call a gate F *self-dual* if $F^* = F$, and call a reversible gate class $\mathcal{C}$ *dual-closed* if $F^* \in \mathcal{C}$ whenever $F \in \mathcal{C}$. Then:

▶ **Corollary 6.** *Every reversible gate class $\mathcal{C}$ is dual-closed.*

Proof. This is obvious for all the classes listed in Theorem 3 that include a NOT or NOTNOT gate. For the others, we simply need to consider the classes one by one: the notions of "conservative," "mod-k-respecting," and "mod-k-preserving" are manifestly the same after we interchange 0 and 1. This is less manifest for the notion of "orthogonal," but one can check that T_k and F_k are self-dual for all even k. ◀

4.2 Linear-Time Algorithm

If one wanted, one could interpret this entire paper as addressing a straightforward *algorithms* problem: namely, the RevGen problem defined in Section 1.4, where we are given as input a set of reversible gates $G_1, \ldots, G_K$, as well as a target reversible transformation H, and we want to know whether the G_i's generate H. From that perspective, our contribution is to reduce the known upper bound on the complexity of RevGen: from recursively-enumerable (!), or triply-exponential time if we use Jeřábek's recent clone/coclone duality for reversible gates [15], all the way down to linear time.

▶ **Theorem 7.** *There is a linear-time algorithm for* RevGen.

Proof. It suffices to give a linear-time algorithm that takes as input the truth table of a single reversible transformation $G : \{0,1\}^n \to \{0,1\}^n$, and that decides which class it generates. For we can then compute $\langle G_1, \ldots, G_K \rangle$ by taking the least upper bound of $\langle G_1 \rangle, \ldots, \langle G_K \rangle$, and can also solve the membership problem by checking whether

$$\langle G_1, \ldots, G_K \rangle = \langle G_1, \ldots, G_K, H \rangle .$$

The algorithm is as follows: first, make a single pass through G's truth table, in order to answer the following two questions.

- Is G affine, and if so, what is its matrix representation, $G(x) = Ax \oplus b$?
- What is $W(G) := \{|G(x)| - |x| : x \in \{0,1\}^n\}$?

In any reasonable RAM model, both questions can easily be answered in $O(n2^n)$ time, which is the number of bits in G's truth table.

If G is non-affine, then Theorem 3 implies that we can determine $\langle G \rangle$ from $W(G)$ alone. If G is affine, then Theorem 3 implies we can determine $\langle G \rangle$ from (A, b) alone, though it is also convenient to use $W(G)$. We need to take the gcd of the numbers in $W(G)$, check whether A is orthogonal, etc., but the time needed for these operations is only $\text{poly}(n)$, which is negligible compared to the input size of $n2^n$. ◀

We have implemented the algorithm described in Theorem 7, and Java code is available for download [25].

4.3 Compression of Reversible Circuits

We now state a "complexity-theoretic" consequence of Theorem 3.

▶ **Theorem 8.** *Let R be a reversible circuit, over any gate set S, that maps $\{0,1\}^n$ to $\{0,1\}^n$, using an unlimited number of gates and ancilla bits. Then there is another reversible circuit, over the same gate set S, that applies the same transformation as R does, and that uses only $2^n \, \text{poly}(n)$ gates and $O(1)$ ancilla bits.*[11]

Proof. If S is one of the gate sets listed in Theorem 3, then this follows immediately by examining the reversible circuit constructions in Section 7, for each class in the classification. Building, in relevant parts, on results by others [26, 7], we will take care in Section 7 to ensure that each non-affine circuit construction uses at most $2^n \, \text{poly}(n)$ gates and $O(1)$ ancilla bits, while each affine construction uses at most $O(n^2)$ gates and $O(1)$ ancilla bits (most actually use no ancilla bits).

[11] Here the big-O's suppress constant factors that depend on the gate set in question.

Now suppose S is *not* one of the sets listed in Theorem 3, but some other set that generates one of the listed classes. So for example, suppose $\langle S \rangle = \langle \text{Fredkin}, \text{NOT} \rangle$. Even then, we know that S *generates* Fredkin and NOT, and the number of gates and ancillas needed to do so is just some constant, independent of n. Furthermore, each time we need a Fredkin or NOT, we can reuse the same ancilla bits, by the assumption that those bits are returned to their original states. So we can simply simulate the appropriate circuit construction from Section 7, using only a constant factor more gates and $O(1)$ more ancilla bits than the original construction. ◀

As we said in Section 1.4, without the classification theorem, it is not obvious how to prove *any upper bound whatsoever* on the number of gates or ancillas, for arbitrary gate sets S. Of course, any circuit that uses T gates also uses at most $O(T)$ ancillas; and conversely, any circuit that uses M ancillas needs at most $\left(2^{n+M}\right)!$ gates, for counting reasons. But the best upper bounds on either quantity that follow from clone theory and the ideal membership problem appear to have the form $\exp(\exp(\exp(\exp(n))))$.

A constant number of ancilla bits *is* sometimes needed, and not only for the trivial reasons that our gates might act on more than n bits, or only (e.g.) be able to map 0^n to 0^n if no ancillas are available.

▶ **Proposition 9** (Toffoli [29]). *If no ancillas are allowed, then there exist reversible transformations of* $\{0,1\}^n$ *that cannot be generated by any sequence of reversible gates on* $n-1$ *bits or fewer.*

Proof. For all $k \geq 1$, any $(n-k)$-bit gate induces an even permutation of $\{0,1\}^n$ – since each cycle is repeated 2^k times, once for every setting of the k bits on which the gate doesn't act. But there are also odd permutations of $\{0,1\}^n$. ◀

It is also easy to show, using a Shannon counting argument, that there exist n-bit reversible transformations that require $\Omega(2^n)$ gates to implement, and n-bit affine transformations that require $\Omega\left(n^2/\log n\right)$ gates. Thus the bounds in Theorem 8 on the number of gates T are, for each class, off from the optimal bounds only by $\text{polylog}\, T$ factors.

4.4 Encoded Universality

If we only care about which Boolean functions $f : \{0,1\}^n \to \{0,1\}$ can be computed, and are completely uninterested in what garbage is output along with f, then it is not hard to see that all reversible gate sets fall into three classes. Namely, non-affine gate sets (such as Toffoli and Fredkin) can compute all Boolean functions;[12] non-degenerate affine gate sets (such as CNOT and CNOTNOT) can compute all affine functions; and degenerate gate sets (such as NOT and NOTNOT) can compute only 1-bit functions. However, the classification theorem lets us make a more interesting statement. Recall the notion of *encoded universality* from Section 2.3, which demands that every reversible transformation (or every affine transformation) be implementable without garbage, once 0 and 1 are "encoded" by longer strings $\alpha(0)$ and $\alpha(1)$ respectively.

▶ **Theorem 10.** *Besides the trivial,* NOT*, and* NOTNOT *classes, every reversible gate class supports encoded universality if non-affine, or affine encoded universality if affine.*

[12] This was proven by Lloyd [21], as well as by Kerntopf et al. [16] and De Vos and Storme [30]; we include a proof for completeness in the full version of this paper [4].

Proof. For $\langle \text{Fredkin} \rangle$, and for all the non-affine classes above $\langle \text{Fredkin} \rangle$, we use the so-called "dual-rail encoding," where 0 is encoded by 01 and 1 is encoded by 10. Given three encoded bits, $x\overline{x}y\overline{y}z\overline{z}$, we can simulate a Fredkin gate by applying one Fredkin to xyz and another to $x\overline{y}\overline{z}$, and can also simulate a CNOT by applying a Fredkin to $xy\overline{y}$. But Fredkin + CNOT generates everything.

The dual-rail encoding also works for simulating all affine transformations using an F_4 gate. For note that

$$\begin{aligned} \mathrm{F}_4\left(xy\overline{y}1\right) &= \left(1, \overline{x \oplus y}, x \oplus y, x\right) \\ &= \left(x, x \oplus y, \overline{x \oplus y}, 1\right), \end{aligned}$$

where we used that we can permute bits for free. So given two encoded bits, $x\overline{x}y\overline{y}$, we can simulate a CNOT from x to y by applying F_4 to x, y, $\overline{y}$, and one ancilla bit initialized to 1.

For $\langle \text{CNOTNOT} \rangle$, we use a repetition encoding, where 0 is encoded by 00 and 1 is encoded by 11. Given two encoded bits, $xxyy$, we can simulate a CNOT from x to y by applying a CNOTNOT from either copy of x to both copies of y. This lets us perform all affine transformations on the encoded subspace.

The repetition encoding also works for $\langle \mathrm{T}_4 \rangle$. For notice that

$$\begin{aligned} \mathrm{T}_4\left(xyy0\right) &= \left(0, x \oplus y, x \oplus y, x\right) \\ &= \left(x, x \oplus y, x \oplus y, 0\right). \end{aligned}$$

Thus, to simulate a CNOT from x to y, we use one copy of x, both copies of y, and one ancilla bit initialized to 0.

Finally, for $\langle \mathrm{T}_6 \rangle$, we encode 0 by 0011 and 1 by 1100. Notice that

$$\begin{aligned} \mathrm{T}_6\left(xyy\overline{y}\overline{y}0\right) &= \left(0, x \oplus y, x \oplus y, \overline{x \oplus y}, \overline{x \oplus y}, x\right) \\ &= \left(x, x \oplus y, x \oplus y, \overline{x \oplus y}, \overline{x \oplus y}, 0\right). \end{aligned}$$

So given two encoded bits, $xx\overline{x}\overline{x}yy\overline{y}\overline{y}$, we can simulate a CNOT from x to y by using one copy of x, all four copies of y and $\overline{y}$, and one ancilla bit initialized to 0. ◀

In the proof of Theorem 10, notice that, every time we simulated Fredkin (xyz) or CNOT (xy), we had to examine only a single bit in the encoding of the control bit x. Thus, Theorem 10 actually yields a stronger consequence: that given an ordinary, unencoded input string $x_1 \ldots x_n$, we can use any non-degenerate reversible gate first to *translate* x into its encoded version $\alpha\left(x_1\right) \ldots \alpha\left(x_n\right)$, and then to perform arbitrary transformations or affine transformations on the encoding.

5 Structure of the Proof

The proof of Theorem 3 naturally divides into four components. First, we need to verify that all the gates mentioned in the theorem really do satisfy the invariants that they are claimed to satisfy – and as a consequence, that any reversible transformation they generate also satisfies the invariants. This is completely routine.

Second, we need to verify that all pairs of classes that Theorem 3 says are distinct, *are* distinct. We handle this in Theorem 11 below (there are only a few non-obvious cases).

Third, we need to verify that the "gate definition" of each class coincides with its "invariant definition"– i.e., that each gate really does generate all reversible transformations that satisfy its associated invariant. For example, we need to show that Fredkin generates all conservative

transformations, that C_k generates all transformations that preserve Hamming weight mod k, and that T_4 generates all orthogonal linear transformations. Many of these results are already known, but for completeness, we prove all of them in Section 7, by giving explicit constructions of reversible circuits.[13]

Finally, we need to show that there are no *additional* reversible gate classes, besides the ones listed in Theorem 3. This is by far the most interesting part, but it appears only in the full version of the paper [4] due to its length. Nevertheless, the organization of the complete proof is as follows:

- In Section 6, we collect numerous results about what reversible transformations can and cannot do to Hamming weights mod k and inner products mod k, in both the affine and the non-affine cases; these results are then drawn on in the rest of the paper. (Some of them are even used for the circuit constructions in Section 7.)
- In the full version, we complete the classification of all non-affine gate sets. We show that the only classes that contain a Fredkin gate (equivalently, the classes above $\langle \text{Fredkin} \rangle$ in the lattice) are $\langle \text{Fredkin} \rangle$ itself, $\langle \text{Fredkin}, \text{NOTNOT} \rangle$, $\langle \text{Fredkin}, \text{NOT} \rangle$, $\langle C_k \rangle$ for $k \geq 3$, and $\langle \text{Toffoli} \rangle$. Next, we show that every nontrivial conservative gate generates Fredkin. We then build on that result to show that every non-affine gate set generates Fredkin.
- The complete classification of all affine gate sets is also contained in the full version. For simplicity, we start with *linear* gate sets only, and show that every nontrivial mod-4-preserving linear gate generates T_6, and that every nontrivial, *non*-mod-4-preserving orthogonal gate generates T_4. Next, we show that every non-orthogonal linear gate generates CNOTNOT. Then, we show that every non-parity-preserving linear gate generates CNOT. Since CNOT generates all linear transformations, this completes the classification of linear gate sets. Finally, we "put back the affine part," showing that it can lead to only 8 additional classes besides the linear classes $\langle \varnothing \rangle$, $\langle T_6 \rangle$, $\langle T_4 \rangle$, $\langle \text{CNOTNOT} \rangle$, and $\langle \text{CNOT} \rangle$.

▶ **Theorem 11.** *All pairs of classes asserted to be distinct by Theorem 3, are distinct.*

Proof. In each case, one just needs to observe that the gate that generates a given class A, satisfies some invariant violated by the gate that generates another class B. (Here we are using the "gate definitions" of the classes, which will be proven equivalent to the invariant definitions in Section 7.) So for example, $\langle \text{Fredkin} \rangle$ cannot contain CNOT because Fredkin is conservative; conversely, $\langle \text{CNOT} \rangle$ cannot contain Fredkin because CNOT is affine.

The only tricky classes are those involving NOT and NOTNOT gates: indeed, these classes *do* sometimes coincide, as noted in Theorem 3. However, in all cases where the classes are distinct, their distinctness is witnessed by the following invariants:

- $\langle \text{Fredkin}, \text{NOT} \rangle$ and $\langle \text{Fredkin}, \text{NOTNOT} \rangle$ are conservative in their linear part.
- $\langle \text{CNOTNOT}, \text{NOT} \rangle$ is parity-preserving in its linear part.
- $\langle F_4, \text{NOT} \rangle = \langle T_4, \text{NOT} \rangle$ and $\langle F_4, \text{NOTNOT} \rangle = \langle T_4, \text{NOTNOT} \rangle$ are orthogonal in their linear part (isometries).
- $\langle T_6, \text{NOT} \rangle$ and $\langle T_6, \text{NOTNOT} \rangle$ are orthogonal and mod-4-preserving in their linear part.

[13] The upshot of the Galois connection for clones [15] is that, if we could prove that a list of invariants for a given gate set S was the *complete* list of invariants satisfied by S, then this second part of the proof would be unnecessary: it would follow automatically that S generates all reversible transformations that satisfy the invariants. But this raises the question: how do we prove that a list of invariants for S is complete? In each case, the easiest way we could find to do this, was just by explicitly describing circuits of S-gates to generate all transformations that satisfy the stated invariants.

As a final remark, even if a reversible transformation is implemented with the help of ancilla bits, as long as the ancilla bits start and end in the same state $a_1 \dots a_k$, they have no effect on any of the invariants discussed above, and for that reason are irrelevant. ◀

6 Hamming Weights and Inner Products

The purpose of this section is to collect various mathematical results about what a reversible transformation $G : \{0,1\}^n \to \{0,1\}^n$ can and cannot do to the Hamming weight of its input, or to the inner product of two inputs. That is, we study the possible relationships that can hold between $|x|$ and $|G(x)|$, or between $x \cdot y$ and $G(x) \cdot G(y)$ (especially modulo various positive integers k). Not only are these results used heavily in the rest of the classification, but some of them might be of independent interest.

6.1 Ruling Out Mod-Shifters

Call a reversible transformation a *mod-shifter* if it always shifts the Hamming weight mod k of its input string by some fixed, nonzero amount. When $k = 2$, clearly mod-shifters exist: indeed, the humble NOT gate satisfies $|\text{NOT}(x)| \equiv |x| + 1 \pmod 2$ for all $x \in \{0,1\}$, and likewise for any other parity-flipping gate. However, we now show that $k = 2$ is the *only* possibility: mod-shifters do not exist for any larger k.

▶ **Theorem 12.** *There are no mod-shifters for $k \geq 3$. In other words: let G be a reversible transformation on n-bit strings, and suppose*

$$|G(x)| \equiv |x| + j \pmod k$$

for all $x \in \{0,1\}^n$. Then either $j = 0$ or $k = 2$.

Proof. Suppose the above equation holds for all x. Then introducing a new complex variable z, we have

$$z^{|G(x)|} \equiv z^{|x|+j} \left(\text{mod } \left(z^k - 1\right)\right)$$

(since working mod $z^k - 1$ is equivalent to setting $z^k = 1$). Since the above is true for all x,

$$\sum_{x \in \{0,1\}^n} z^{|G(x)|} \equiv \sum_{x \in \{0,1\}^n} z^{|x|} z^j \left(\text{mod } \left(z^k - 1\right)\right). \tag{1}$$

By reversibility, we have

$$\sum_{x \in \{0,1\}^n} z^{|G(x)|} = \sum_{x \in \{0,1\}^n} z^{|x|} = (z+1)^n.$$

Therefore equation (1) simplifies to

$$(z+1)^n \left(z^j - 1\right) \equiv 0 \left(\text{mod } \left(z^k - 1\right)\right).$$

Now, since $z^k - 1$ has no repeated roots, it can divide $(z+1)^n \left(z^j - 1\right)$ only if it divides $(z+1)\left(z^j - 1\right)$. For this we need either $j = 0$, causing $z^j - 1 = 0$, or else $j = k - 1$ (from degree considerations). But it is easily checked that the equality

$$z^k - 1 = (z+1)\left(z^{k-1} - 1\right)$$

holds only if $k = 2$. ◀

6.2 Inner Products Mod k

We have seen that there exist *orthogonal* gates (such as the T_k gates), which preserve inner products mod 2. In this section, we first show that no reversible gate that changes Hamming weights can preserve inner products mod k for any $k \geq 3$. We then observe that, if a reversible gate is orthogonal, then it must be linear, and we give necessary and conditions for orthogonality.

▶ **Theorem 13.** *Let G be a non-conservative n-bit reversible gate, and suppose*

$$G(x) \cdot G(y) \equiv x \cdot y \pmod{k}$$

for all $x, y \in \{0,1\}^n$. Then $k = 2$.

Proof. As in the proof of Theorem 12, we promote the congruence to a congruence over complex polynomials:

$$z^{G(x)\cdot G(y)} \equiv z^{x\cdot y} \pmod{z^k - 1}$$

Fix a string $x \in \{0,1\}^n$ such that $|G(x)| > |x|$, which must exist because G is non-conservative. Then sum the congruence over all y:

$$\sum_{y\in\{0,1\}^n} z^{G(x)\cdot G(y)} \equiv \sum_{y\in\{0,1\}^n} z^{x\cdot y} \pmod{z^k - 1}.$$

The summation on the right simplifies as follows.

$$\begin{aligned}\sum_{y\in\{0,1\}^n} z^{x\cdot y} &= \sum_{y\in\{0,1\}^n} \prod_{i=1}^{n} z^{x_i y_i} = \prod_{i=1}^{n} \sum_{y_i\in\{0,1\}} z^{x_i y_i} = \prod_{i=1}^{n} (1 + z^{x_i}) = (1+z)^{|x|}\, 2^{n-|x|}, \\ &= \left(\frac{1+z}{2}\right)^{|x|} 2^n.\end{aligned}$$

Similarly,

$$\sum_{y\in\{0,1\}^n} z^{G(x)\cdot G(y)} = \left(\frac{1+z}{2}\right)^{|G(x)|} 2^n,$$

since summing over all y is the same as summing over all $G(y)$. So we have

$$\begin{aligned}\left(\frac{1+z}{2}\right)^{|G(x)|} 2^n &\equiv \left(\frac{1+z}{2}\right)^{|x|} 2^n \pmod{z^k - 1}, \\ 0 &\equiv (1+z)^{|x|} 2^{-|G(x)|} \left(2^{|G(x)|-|x|} - (1+z)^{|G(x)|-|x|}\right) \pmod{z^k - 1},\end{aligned}$$

or equivalently, letting

$$p(x) := 2^{|G(x)|-|x|} - (1+z)^{|G(x)|-|x|},$$

we find that $z^k - 1$ divides $(1+z)^{|x|} p(x)$ as a polynomial. Now, the roots of $z^k - 1$ lie on the unit circle centered at 0. Meanwhile, the roots of $p(x)$ lie on the circle in the complex plane of radius 2, centered at -1. The only point of intersection of these two circles is $z = 1$, so that is the only root of $z^k - 1$ that can be covered by $p(x)$. On the other hand, clearly $z = -1$ is the only root of $(1+z)^{|x|}$. Hence, the only roots of $z^k - 1$ are 1 and -1, so we conclude that $k = 2$. ◀

We now study reversible transformations that preserve inner products mod 2.

▶ **Lemma 14.** *Every orthogonal gate G is linear.*

Proof. Suppose

$$G(x) \cdot G(y) \equiv x \cdot y \pmod 2.$$

Then for all x, y, z,

$$\begin{aligned} G(x \oplus y) \cdot G(z) &\equiv (x \oplus y) \cdot z \\ &\equiv x \cdot z + y \cdot z \\ &\equiv G(x) \cdot G(z) + G(y) \cdot G(z) \\ &\equiv (G(x) \oplus G(y)) \cdot G(z) \pmod 2. \end{aligned}$$

But if the above holds for all possible z, then

$$G(x \oplus y) \equiv G(x) \oplus G(y) \pmod 2. \quad \blacktriangleleft$$

Theorem 13 and Lemma 14 have the following corollary.

▶ **Corollary 15.** *Let G be any non-conservative, nonlinear gate. Then for all $k \geq 2$, there exist inputs x, y such that*

$$G(x) \cdot G(y) \not\equiv x \cdot y \pmod k.$$

Also:

▶ **Lemma 16.** *A linear transformation $G(x) = Ax$ is orthogonal if and only if $A^T A$ is the identity: that is, if A's column vectors satisfy $|v_i| \equiv 1 \pmod 2$ for all i and $v_i \cdot v_j \equiv 0 \pmod 2$ for all $i \neq j$.*

Proof. This is just the standard characterization of orthogonal matrices; that we are working over $\mathbb{F}_2$ is irrelevant. First, if G preserves inner products mod 2 then for all $i \neq j$,

$$\begin{aligned} 1 &\equiv e_i \cdot e_i \equiv (Ae_i) \cdot (Ae_i) \equiv |v_i| \pmod 2, \\ 0 &\equiv e_i \cdot e_j \equiv (Ae_i) \cdot (Ae_j) \equiv v_i \cdot v_j \pmod 2. \end{aligned}$$

Second, if G satisfies the conditions then

$$Ax \cdot Ay \equiv (Ax)^T Ay \equiv x^T (A^T A) y \equiv x^T y \equiv x \cdot y \pmod 2. \quad \blacktriangleleft$$

6.3 Why Mod 2 and Mod 4 Are Special

Recall that $\wedge$ denotes bitwise AND. We first need an "inclusion/exclusion formula" for the Hamming weight of a bitwise sum of strings.

▶ **Lemma 17.** *For all $v_1, \ldots, v_t \in \{0,1\}^n$, we have*

$$|v_1 \oplus \cdots \oplus v_t| = \sum_{\emptyset \subset S \subseteq [t]} (-2)^{|S|-1} \left| \bigwedge_{i \in S} v_i \right|.$$

Proof. It suffices to prove the lemma for $n = 1$, since in the general case we are just summing over all $i \in [n]$. Thus, assume without loss of generality that $v_1 = \cdots = v_t = 1$. Our problem then reduces to proving the following identity:

$$\sum_{i=1}^{t}(-2)^{i-1}\binom{t}{i} = \begin{cases} 0 & \text{if } t \text{ is even} \\ 1 & \text{if } t \text{ is odd,} \end{cases}$$

which follows straightforwardly from the binomial theorem. ◀

▶ **Lemma 18.** *No nontrivial affine gate G is conservative.*

Proof. Let $G(x) = Ax \oplus b$; then $|G(0^n)| = |0^n| = 0$ implies $b = 0^n$. Likewise, $|G(e_i)| = |e_i| = 1$ for all i implies that A is a permutation matrix. But then G is trivial. ◀

▶ **Theorem 19.** *If G is a nontrivial linear gate that preserves Hamming weight mod k, then either $k = 2$ or $k = 4$.*

Proof. For all x, y, we have

$$\begin{aligned} |x| + |y| - 2(x \cdot y) &\equiv |x \oplus y| \\ &\equiv |G(x \oplus y)| \\ &\equiv |G(x) \oplus G(y)| \\ &\equiv |G(x)| + |G(y)| - 2(G(x) \cdot G(y)) \\ &\equiv |x| + |y| - 2(G(x) \cdot G(y)) \pmod{k}, \end{aligned}$$

where the first and fourth lines used Lemma 17, the second and fifth lines used that G is mod-k-preserving, and the third line used linearity. Hence

$$2(x \cdot y) \equiv 2(G(x) \cdot G(y)) \pmod{k}. \tag{2}$$

If k is odd, then equation (2) implies

$$x \cdot y \equiv G(x) \cdot G(y) \pmod{k}.$$

But since G is nontrivial and linear, Lemma 18 says that G is non-conservative. So by Theorem 13, the above equation cannot be satisfied for any odd $k \geq 3$. Likewise, if k is even, then (2) implies

$$x \cdot y \equiv G(x) \cdot G(y) \left(\mod \frac{k}{2}\right).$$

Again by Theorem 13, the above can be satisfied only if $k = 2$ or $k = 4$. ◀

▶ **Theorem 20.** *Let $\{o_i\}_{i=1}^n$ be an orthonormal basis over $\mathbb{F}_2$. An affine transformation $F(x) = Ax \oplus b$ is mod-4-preserving if and only if $|b| \equiv 0 \pmod 4$, and the vectors $v_i := Ao_i$ satisfy $|v_i| + 2(v_i \cdot b) \equiv |o_i| \pmod 4$ for all i and $v_i \cdot v_j \equiv 0 \pmod 2$ for all $i \neq j$.*

Proof. First, if F is mod-4-preserving, then

$$0 \equiv |F(0^n)| \equiv |A0^n \oplus b| \equiv |b| \pmod 4,$$

and hence

$$|o_i| \equiv |F(o_i)| \equiv |Ao_i \oplus b| \equiv |v_i \oplus b| \equiv |v_i| + |b| - 2(v_i \cdot b) \equiv |v_i| + 2(v_i \cdot b) \pmod 4$$

for all i, and hence

$$\begin{aligned}|o_i + o_j| &\equiv |F(o_i \oplus o_j)| \\ &\equiv |v_i \oplus v_j \oplus b| \\ &\equiv |v_i| + |v_j| + |b| - 2(v_i \cdot v_j) - 2(v_i \cdot b) - 2(v_j \cdot b) + 4|v_i \wedge v_j \wedge b| \\ &\equiv |v_i| + |v_j| + 2(v_i \cdot v_j) + 2(v_i \cdot b) + 2(v_j \cdot b) \pmod 4 \\ &\equiv |o_i| + |o_j| + 2(v_i \cdot v_j) \pmod 4\end{aligned}$$

for all $i \neq j$, from which we conclude that $v_i \cdot v_j \equiv 0 \pmod 2$.

Second, if F satisfies the conditions, then for any $x = \sum_{i \in S} o_i$, we have

$$\begin{aligned}|F(x)| &= \left| b \oplus \sum_{i \in S} v_i \right| \\ &= |b| + \sum_{i \in S} |v_i| - 2\sum_{i \in S} (b \cdot v_i) - 2 \sum_{i \in S \,<\, j \in S} (v_i \cdot v_j) + 4(\cdots) \\ &\equiv \sum_{i \in S} |v_i| - 2(b \cdot v_i) \\ &\equiv \sum_{i \in S} |o_i| \pmod 4,\end{aligned}$$

where the second line follows from Lemma 17. Furthermore, we have that

$$|x| = \left| \sum_{i \in S} o_i \right| = \sum_{i \in S} |o_i| - 2 \sum_{i \in S < j \in S} (o_i \cdot o_j) + 4(\ldots) \equiv \sum_{i \in S} |o_i| \pmod 4,$$

where the last equality follows from the fact that $\{o_i\}_{i=1}^n$ is an orthonormal basis. Therefore, we conclude that $|F(x)| \equiv |x| \pmod 4$. ◀

We note two corollaries of Theorem 20 for later use.

▶ **Corollary 21.** *Any linear transformation $A \in \mathbb{F}_2^{n \times n}$ that preserves Hamming weight mod 4 is also orthogonal.*

▶ **Corollary 22.** *An orthogonal transformation $A \in \mathbb{F}_2^{n \times n}$ preserves Hamming weight mod 4 if and only if all of its columns have Hamming weight 1 mod 4.*

7 Reversible Circuit Constructions

In this section, we show that all the classes of reversible transformations listed in Theorem 3, are indeed generated by the gates that we claimed, by giving explicit synthesis procedures. In order to justify Theorem 8, we also verify that in each case, only $O(1)$ ancilla bits are needed, even though this constraint makes some of the constructions more complicated than otherwise.

Many of our constructions – those for Toffoli and CNOT, for example – have appeared in various forms in the reversible computing literature, and are included here only for completeness. Others – those for C_k and F_4, for example – are new as far as we know, but not hard.

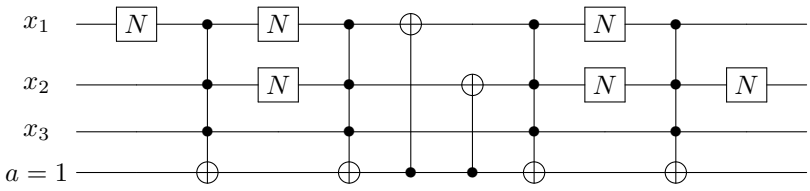

Figure 4 Circuit for the transposition $\sigma_{011,101}$ after simplification.

7.1 Non-Affine Circuits

We start with the non-affine classes: $\langle \text{Toffoli} \rangle$, $\langle \text{Fredkin} \rangle$, $\langle \text{Fredkin}, \text{C}_k \rangle$, and $\langle \text{Fredkin}, \text{NOT} \rangle$.

▶ **Theorem 23** (variants in [29, 26]). Toffoli *generates all reversible transformations on n bits, using only 2 ancilla bits.*[14]

Proof. Any reversible transformation $F : \{0,1\}^n \to \{0,1\}^n$ is a permutation of n-bit strings, and any permutation can be written as a product of transpositions. So it suffices to show how to use Toffoli gates to implement an arbitrary transposition $\sigma_{y,z}$: that is, a mapping that sends $y = y_1 \dots y_n$ to $z = z_1 \dots z_n$ and z to y, and all other n-bit strings to themselves.

Given any n-bit string w, let us define w-CNOT to be the $(n+1)$-bit gate that flips its last bit if its first n bits are equal to w, and that does nothing otherwise. (Thus, the Toffoli gate is 11-CNOT, while CNOT itself is 1-CNOT.) Given y-CNOT and z-CNOT gates, we can implement the transposition $\sigma_{y,z}$ as follows on input x:

1. Initialize an ancilla bit, $a = 1$.
2. Apply y-CNOT (x, a).
3. Apply z-CNOT (x, a).
4. Apply NOT gates to all x_i's such that $y_i \neq z_i$.
5. For each i such that $y_i \neq z_i$, apply CNOT (a, x_i).
6. Apply z-CNOT (x, a).
7. Apply y-CNOT (x, a).

Thus, all that remains is to implement w-CNOT using Toffoli. Observe that we can simulate any w-CNOT using 1^n-CNOT by negating certain input bits (namely, those for which $w_i = 0$) before and after we apply the 1^n-CNOT. An example of the transposition $\sigma_{011,101}$ is given in Figure 4.

So it suffices to implement 1^n-CNOT, with control bits $x_1 \dots x_n$ and target bit y. The base case is $n = 2$, which we implement directly using Toffoli. For $n \geq 3$, we do the following.

- Let a be an ancilla.
- Apply $1^{\lceil n/2 \rceil}$-CNOT $\left(x_1 \dots x_{\lceil n/2 \rceil}, a\right)$.
- Apply $1^{\lfloor n/2 \rfloor + 1}$-CNOT $\left(x_{\lceil n/2 \rceil + 1} \dots x_n, a, y\right)$.
- Apply $1^{\lceil n/2 \rceil}$-CNOT $\left(x_1 \dots x_{\lceil n/2 \rceil}, a\right)$.
- Apply $1^{\lfloor n/2 \rfloor + 1}$-CNOT $\left(x_{\lceil n/2 \rceil + 1} \dots x_n, a, y\right)$.

The crucial point is that this construction works whether the ancilla is initially 0 or 1. In other words, we can use *any* bit which is not one of the inputs, instead of a new ancilla. For instance, we can have one bit dedicated for use in 1^n-CNOT gates, which we use in the

[14] Notice that we need at least 2 so that we can generate CNOT and NOT using Toffoli.

recursive applications of $1^{\lceil n/2 \rceil}$-CNOT and $1^{\lfloor n/2 \rfloor + 1}$-CNOT, and the recursive applications within them, and so on.[15]

Carefully inspecting the above proof shows that $O\left(n^2 2^n\right)$ gates and 2 ancilla bits suffice to generate any transformation. ◀

The particular construction above was inspired by a result of Ben-Or and Cleve [7], in which they compute algebraic formulas in a straight-line computation model using a constant number of registers. We note that Toffoli [29] proved a version of Theorem 23, but with $O(n)$ ancilla bits rather than $O(1)$. More recently, Shende et al. [26] gave a slightly more complicated construction that uses only 1 ancilla bit (assuming that we have CNOT and NOT gates in addition to Toffoli gates), and that also gives explicit bounds on the number of Toffoli gates required based on the number of fixed points of the permutation. Recall that at least 1 ancilla bit is needed by Proposition 9.

Next, let CCSWAP, or Controlled-Controlled-SWAP, be the 4-bit gate that swaps its last two bits if its first two bits are both 1, and otherwise does nothing.

▶ **Proposition 24.** Fredkin *generates* CCSWAP.

Proof. Let a be an ancilla bit initialized to 0. We implement CCSWAP (x, y, z, w) by applying Fredkin (x, y, a), then Fredkin (a, z, w), then again Fredkin (x, y, a). ◀

We can now prove an analogue of Theorem 23 for conservative transformations.

▶ **Theorem 25.** Fredkin *generates all conservative transformations on n bits, using only* 5 *ancilla bits.*

Proof. In this proof, we will use the *dual-rail representation*, in which 0 is encoded as 01 and 1 is encoded as 10. We will also use Proposition 24, that Fredkin generates CCSWAP.

As in Theorem 23, we can decompose any reversible transformation $F : \{0,1\}^n \to \{0,1\}^n$ as a product of transpositions $\sigma_{y,z}$. In this case, each $\sigma_{y,z}$ transposes two n-bit strings $y = y_1 \ldots y_n$ and $z = z_1 \ldots z_n$ of the same Hamming weight.

Given any n-bit string w, let us define w-CSWAP to be the $(n+2)$-bit gate that swaps its last two bits if its first n bits are equal to w, and that does nothing otherwise. (Thus, Fredkin is 1-CSWAP, while CCSWAP is 11-CSWAP.) Then given y-CSWAP and z-CSWAP gates, where $|y| = |z|$, as well as CCSWAP gates, we can implement the transposition $\sigma_{y,z}$ on input x as follows:

1. Initialize two ancilla bits (comprising one dual-rail register) to $a\overline{a} = 01$.
2. Apply y-CSWAP $(x_1 \ldots x_n, a, \overline{a})$.
3. Apply z-CSWAP $(x_1 \ldots x_n, a, \overline{a})$.
4. Pair off the i's such that $y_i = 1$ and $z_i = 0$, with the equally many j's such that $z_j = 1$ and $y_j = 0$. For each such (i, j) pair, apply Fredkin (a, x_i, x_j).
5. Apply z-CSWAP $(x_1 \ldots x_n, a, \overline{a})$.
6. Apply y-CSWAP $(x_1 \ldots x_n, a, \overline{a})$.

[15] The number of Toffoli gates $T(n)$ needed to implement a 1^n-CNOT (which dominates the cost of a transposition) by this recursive scheme, is given by the recurrence

$$T(n) = 2T(1 + \lfloor n/2 \rfloor) + 2T(\lceil n/2 \rceil)$$

which we solve to obtain $T(n) = O\left(n^2\right)$.

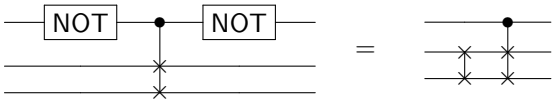

Figure 5 Removing NOT gates from the Fredkin circuit.

The logic here is exactly the same as in the construction of transpositions in Theorem 23; the only difference is that now we need to conserve Hamming weight.

All that remains is to implement w-CSWAP using CCSWAP. First let us show how to implement 1^n-CSWAP using CCSWAP. Once again, we do so using a recursive construction. For the base case, $n = 2$, we just use CCSWAP. For $n \geq 3$, we implement 1^n-CSWAP $(x_1, \ldots, x_n, y, z)$ as follows:

- Initialize two ancilla bits (comprising one dual-rail register) to $a\overline{a} = 01$.
- Apply $1^{\lceil n/2 \rceil}$-CSWAP $\left(x_1 \ldots x_{\lceil n/2 \rceil}, a, \overline{a}\right)$.
- Apply $1^{\lfloor n/2 \rfloor + 1}$-CSWAP $\left(x_{\lceil n/2 \rceil + 1} \ldots x_n, a, y, z\right)$.
- Apply $1^{\lceil n/2 \rceil}$-CSWAP $\left(x_1 \ldots x_{\lceil n/2 \rceil}, a, \overline{a}\right)$.
- Apply $1^{\lfloor n/2 \rfloor + 1}$-CSWAP $\left(x_{\lceil n/2 \rceil + 1} \ldots x_n, a, y, z\right)$.

The logic is the same as in the construction of 1^n-CNOT in Theorem 23 except we now use 2 ancilla bits for the dual-rail representation.

Finally, we need to implement w-CSWAP $(x_1 \ldots x_n, y, z)$, for arbitrary w, using 1^n-CSWAP. We do so by first constructing w-CSWAP from NOT gates and 1^n-CSWAP. Observe that we only use the NOT gate on the control bits of the Fredkin gates used during the construction so the equivalence given in Figure 5 holds (i.e., we can remove the NOT gates).

Hence, we can build a w-CSWAP out of CCSWAPs using only 5 ancilla bits: 1 for CCSWAP, 2 for the 1^n-CSWAP, and 2 for a transposition. ◀

We note that, before the above construction was found by the authors, unpublished and independent work by Siyao Xu and Qian Yu first showed that $O(1)$ ancillas were sufficient and has since been improved to exactly 1 ancilla [31].

In [11], the result that Fredkin generates all conservative transformations is stated without proof, and credited to B. Silver. We do not know how many ancilla bits Silver's construction used.

Next, we prove an analogue of Theorem 23 for the mod-k-respecting transformations, for all $k \geq 2$. First, let CC_k, or Controlled-C_k, be the $(k+1)$-bit gate that applies C_k to the final k bits if the first bit is 1, and does nothing if the first bit is 0.

▶ **Proposition 26.** Fredkin $+ \mathrm{C}_k$ *generates* CC_k*, using* 2 *ancilla bits, for all* $k \geq 2$*.*

Proof. To implement CC_k on input bits $x, y_1 \ldots y_k$, we do the following:

1. Initialize ancilla bits a, b to $0, 1$ respectively.
2. Use Fredkin gates and swaps to swap y_1, y_2 with a, b, conditioned on $x = 0$.[16]
3. Apply C_k to $y_1 \ldots y_k$.
4. Repeat step 2. ◀

Then we have the following.

[16] In more detail, use Fredkin gates to swap y_1, y_2 with a, b, conditioned on $x = 1$. Then swap y_1, y_2 with a, b unconditionally.

▶ **Theorem 27.** Fredkin + CC_k *generates all mod-k-preserving transformations, for* $k \geq 1$*, using only* 5 *ancilla bits.*

Proof. The proof is exactly the same as that of Theorem 25, except for one detail. Namely, let y and z be n-bit strings such that $|y| \equiv |z| \pmod{k}$. Then in the construction of the transposition $\sigma_{y,z}$ from y-CSWAP and z-CSWAP gates, when we are applying step 5, it is possible that $|y| - |z|$ is some nonzero multiple of k, say qk. If so, then we can no longer pair off each i such that $y_i = 1$ and $z_i = 0$ with a unique j such that $z_j = 1$ and $y_j = 0$: after we have done that, there will remain a surplus of '1' bits of size qk, either in y or in z, as well as a matching surplus of '0' bits of size qk in the other string. However, we can get rid of both surpluses using q applications of a CC_k gate (which we have by Proposition 26), with c as the control bit. ◀

As a special case of Theorem 27, note that Fredkin + CC_1 = Fredkin + CNOT generates all mod-1-preserving transformations – or in other words, all transformations.

We just need one additional fact about the C_k gate.

▶ **Proposition 28.** C_k *generates* Fredkin*, using* $k-2$ *ancilla bits, for all* $k \geq 3$*.*

Proof. Let $a_1 \ldots a_{k-2}$ be ancilla bits initially set to 1. Then to implement Fredkin on input bits x, y, z, we apply:

$$\mathrm{C}_k(x, y, a_1 \ldots a_{k-2}), \mathrm{C}_k(x, z, a_1 \ldots a_{k-2}), \mathrm{C}_k(x, y, a_1 \ldots a_{k-2}).$$ ◀

Combining Theorem 27 with Proposition 28 now yields the following.

▶ **Corollary 29.** C_k *generates all mod-k-preserving transformations for* $k \geq 3$*, using only* $k+3$ *ancilla bits.*

Finally, we handle the parity-flipping case.

▶ **Proposition 30.** Fredkin + NOTNOT *(and hence,* Fredkin + NOT*) generates* CC_2*.*

Proof. This follows from Proposition 26, if we recall that C_2 is equivalent to NOTNOT up to an irrelevant bit-swap. ◀

▶ **Theorem 31.** Fredkin + NOT *generates all parity-respecting transformations, using only* 5 *ancilla bits.*

Proof. Let F be any parity-flipping transformation, and let F' be F followed by NOT on one of the output bits. Then F' is parity-preserving. So by Theorem 27, we can implement F' using Fredkin + CC_2 (and we have CC_2 by Proposition 30). We can then apply another NOT gate to get F itself. ◀

One consequence of Theorem 31 is that every parity-flipping transformation can be constructed from parity-preserving gates and exactly one NOT gate.

7.2 Affine Circuits

It is well-known that CNOT is a "universal affine gate":

▶ **Theorem 32.** CNOT *generates all affine transformations, with only* 1 *ancilla bit (or* 0 *for linear transformations).*

Proof. Let $G(x) = Ax \oplus b$ be the affine transformation that we want to implement, for some invertible matrix $A \in \mathbb{F}_2^{n \times n}$. Then given an input $x = x_1 \dots x_n$, we first use CNOT gates (at most $\binom{n}{2}$ of them) to map x to Ax, by reversing the sequence of row-operations that maps A to the identity matrix in Gaussian elimination. Finally, if $b = b_1 \dots b_n$ is nonzero, then for each i such that $b_i = 1$, we apply a CNOT from an ancilla bit that is initialized to 1. ◀

A simple modification of Theorem 32 handles the parity-preserving case.

▶ **Theorem 33.** CNOTNOT *generates all parity-preserving affine transformations with only* 1 *ancilla bit (or* 0 *for linear transformations).*

Proof. Let $G(x) = Ax \oplus b$ be a parity-preserving affine transformation. We first construct the linear part of G using Gaussian elimination. Notice that for G to be parity-preserving, the columns v_i of A must satisfy $|v_i| \equiv 1 \pmod 2$ for all i. For this reason, the row-elimination steps come in pairs, so we can implement them using CNOTNOT. Notice further that since G is parity-preserving, we must have $|b| \equiv 0 \pmod 2$. So we can map Ax to $Ax \oplus b$, by using CNOTNOT gates plus one ancilla bit set to 1 to simulate NOTNOT gates. ◀

Likewise (though, strictly speaking, we will not need this for the proof of Theorem 3):

▶ **Theorem 34.** CNOTNOT + NOT *generates all parity-respecting affine transformations using no ancilla bits.*

Proof. Use Theorem 33 to map x to Ax, and then use NOT gates to map Ax to $Ax \oplus b$. ◀

We now move on to the more complicated cases of $\langle \mathrm{F}_4 \rangle$, $\langle \mathrm{T}_6 \rangle$, and $\langle \mathrm{T}_4 \rangle$.

▶ **Theorem 35.** F_4 *generates all mod-4-preserving affine transformations using no ancilla bits.*

Proof. Let $F(x) = Ax \oplus b$ be an n-bit affine transformation, $n \geq 2$, that preserves Hamming weight mod 4. Using F_4 gates, we will show how to map $F(x) = y_1 \dots y_n$ to $x = x_1 \dots x_n$. Reversing the construction then yields the desired map from x to $F(x)$.

At any point in time, each y_j is some affine function of the x_i's. We say that x_i "occurs in" y_j, if y_j depends on x_i. At a high level, our procedure will consist of the following steps, repeated up to $n - 3$ times:

1. Find an x_i that does not occur in every y_j.
2. Manipulate the y_j's so that x_i occurs in exactly *one* y_j.
3. Argue that no *other* $x_{i'}$ can then occur in that y_j. Therefore, we have recursively reduced our problem to one involving a reversible, mod-4-preserving, affine function on $n - 1$ variables.

It is not hard to see that the only mod-4-preserving affine functions on 3 or fewer variables, are permutations of the bits. So if we can show that the three steps above can always be carried out, then we are done.

First, since A is invertible, it is not the all-1's matrix, which means that there must be an x_i that does not occur in every y_j.

Second, if there are at least three occurrences of x_i, then apply F_4 to three positions in which x_i occurs, plus one position in which x_i does not occur. The result of this is to decrease the number of occurrences of x_i by 2. Repeat until there are at most two occurrences of x_i. Since F_4 is mod-4-preserving and affine, the resulting transformation $F'(x) = A'x + b'$ must still be mod-4-preserving and affine, so it must still satisfy the conditions of Lemma 20. In

particular, no column vector of A' can have even Hamming weight. Since two occurrences of x_i would necessitate such a column vector, we know that x_i must occur only once.

Third, if x_i occurs only once in $F'(x)$, then the corresponding column vector v_i has exactly one nonzero element. Since $|v_i| = 1$, we know by Lemma 20 that $v_i \cdot b \equiv 0 \pmod 2$, which means that b has a 0 in the position where v_i has a 1. Now consider the row of A' that includes the nonzero entry of v_i. If any other column $v_{i'}$ is also nonzero in that row, then $v_i \cdot v_{i'} \equiv 1 \pmod 2$, which once again contradicts the conditions of Lemma 20. Thus, no other $x_{i'}$ occurs in the same y_j that x_i occurs in. Indeed no constant occurs there either, since otherwise F' would no longer be mod-4-preserving. So we have reduced to the $(n-1) \times (n-1)$ case. ◀

The same argument, with slight modifications, handles $\langle \mathrm{T}_4 \rangle$ and $\langle \mathrm{T}_6 \rangle$.

▶ **Theorem 36.** T_4 *generates all orthogonal transformations, using no ancilla bits.*

Proof. The construction is identical to that of Theorem 35, except with T_4 instead of F_4. When reducing the number of occurrences of x_i to at most 2, Lemma 16 assures us that $|v_i| \equiv 1 \pmod 2$. ◀

▶ **Theorem 37.** T_6 *generates all mod-4-preserving linear transformations, using no ancilla bits.*

Proof. The construction is identical to that of Theorem 35, except for the following change. Rather than using F_4 to reduce the number of occurrences of some x_i to at most 2, we now use T_6 to reduce the number of occurrences of x_i to at most 4. (If there are 5 or more occurrences, then T_6 can always decrease the number by 4.) We then appeal to Corollary 22, which says that $|v_i| \equiv 1 \pmod 4$ for each i. This implies that no x_i can occur 2, 3, or 4 times in the output vector. But that can only mean that x_i occurs once. ◀

By Lemma 14 and Corollary 21, an equivalent way to state Theorem 37 is that T_6 generates all affine transformations that are both mod-4-preserving and orthogonal.

All that remains is some "cleanup work" (which, again, is not even needed for the proof of Theorem 3).

▶ **Theorem 38.** $\mathrm{T}_6 + \mathrm{NOT}$ *generates all affine transformations that are mod-4-preserving (and therefore orthogonal) in their linear part.*

$\mathrm{T}_6 + \mathrm{NOTNOT}$ *generates all parity-preserving affine transformations that are mod-4-preserving (and therefore orthogonal) in their linear part.*

$\mathrm{F}_4 + \mathrm{NOT}$ *(or equivalently,* $\mathrm{T}_4 + \mathrm{NOT}$*) generates all isometries.*

$\mathrm{F}_4 + \mathrm{NOTNOT}$ *(or equivalently,* $\mathrm{T}_4 + \mathrm{NOTNOT}$*) generates all parity-preserving isometries.*

NOT *generates all degenerate transformations.*

NOTNOT *generates all parity-preserving degenerate transformations.*

In none of these cases are any ancilla bits needed.

Proof. As in Theorem 34, we simply apply the relevant construction for the linear part (e.g., Theorem 36 or 37), then handle the affine part using NOT or NOTNOT gates. ◀

8 Open Problems

As discussed in Section 1, the central challenge we leave is to give a complete classification of all *quantum* gate sets acting on qubits, in terms of which unitary transformations they can generate or approximate. Here, just like in this paper, one should assume that qubit-swaps are free, and that arbitrary ancillas are allowed as long as they are returned to their initial states.

A possible first step in the direction we want, which would involve Lie algebras, would be to classify all sets of 1- and 2-qubit gates. A second step would be to classify qubit Hamiltonians (i.e., the infinitesimal-time versions of unitary gates), in terms of which n-qubit Hamiltonians they can be used to generate. Here the recent work of Cubitt and Montanaro [10], which classifies qubit Hamiltonians in terms of the complexity of approximating ground state energies, might be relevant. Yet a third possibility would be to classify quantum gates under the assumption that intermediate measurements are allowed. Of course, these simplifications can also be combined.

On the classical side, we have left completely open the problem of classifying reversible gate sets over non-binary alphabets. In the non-reversible setting, it was discovered in the 1950s (see [20]) that Post's lattice becomes dramatically different and more complicated when we consider gates over a 3-element set rather than Boolean gates: for example, there is now an uncountable infinity of clones, rather than "merely" a countable infinity. Does anything similar happen in the reversible case? We know from Gu [14] that for alphabets of size greater than three, there exists a class that is not finitely generated. Recall that for binary alphabets, one gate always suffices to generate a particular class.

Even for reversible gates over (say) $\{0,1,2\}^n$, we cannot currently give an algorithm to decide whether a given gate G generates another gate H any better than the triple-exponential-time algorithm that comes from clone theory, nor can we give reasonable upper bounds on the number of gates or ancillas needed in the generating circuit, nor can we answer basic questions like whether every class is finitely generated.

Finally, can one reduce the number of gates in each of our circuit constructions to the limits imposed by Shannon-style counting arguments? What are the tradeoffs, if any, between the number of gates and the number of ancilla bits?

Acknowledgments. At the very beginning of this project, Emil Jeřábek [15] brought the $\langle \mathrm{C}_k \rangle$ and $\langle \mathrm{T}_6 \rangle$ classes to our attention, and also proved that every reversible gate class is characterized by invariants (i.e., that the "clone-coclone duality" holds for reversible gates). Also, Matthew Cook gave us encouragement, asked pertinent questions, and helped us understand the $\langle \mathrm{T}_4 \rangle$ class. We are grateful to both of them. We also thank Harry Altman, Adam Bouland, Seth Lloyd, Igor Markov, and particularly Siyao Xu for helpful discussions.

Abstract

We study nondeterministic multiparty quantum communication with a quantum generalization of broadcasts. We show that, with number-in-hand classical inputs, the communication complexity of a Boolean function in this communication model equals the logarithm of the *support rank* of the corresponding tensor, whereas the approximation complexity in this model equals the logarithm of the *border support rank*. This characterisation allows us to prove a log-rank conjecture posed by Villagra et al. for nondeterministic multiparty quantum communication with message passing.

The support rank characterization of the communication model connects quantum communication complexity intimately to the theory of asymptotic entanglement transformation and algebraic complexity theory. In this context, we introduce the *graphwise equality problem*. For a cycle graph, the complexity of this communication problem is closely related to the complexity of the computational problem of multiplying matrices, or more precisely, it equals the logarithm of the support rank of the iterated matrix multiplication tensor. We employ Strassen's laser method to show that asymptotically there exist nontrivial protocols for every odd-player cyclic equality problem. We exhibit an efficient protocol for the 5-player problem for small inputs, and we show how Young flattenings yield nontrivial complexity lower bounds.

receives a $y \in Y$ and Charlie receives a $z \in Z$, and each player receives a private random bit string. Then the players communicate in rounds. Each round, one player communicates by broadcasting a bit to the other players. After these rounds of communication, each player has to output a bit, such that if $f(x, y, z) = 1$, then with some nonzero probability all players output 1 and if $f(x, y, z) = 0$, then with probability zero all players output 1. The complexity of such a protocol is the number of broadcasts in the protocol, and we denote the minimum complexity of all such protocols by $\mathrm{N}(f)$.

Now we allow the players to be quantum, as follows. Alice receives an $x \in X$, Bob receives a $y \in Y$ and Charlie receives a $z \in Z$. Then, the players communicate by creating a GHZ state of rank r

$$|\mathrm{GHZ}_r\rangle = \tfrac{1}{\sqrt{r}}(|111\rangle + |222\rangle + \cdots + |rrr\rangle).$$

and sharing this state among each other, a quantum broadcast. Next, the players do local quantum operations. Finally, each player has to output a bit, such that if $f(x, y, z) = 1$, then with some nonzero probability all players output 1 and if $f(x, y, z) = 0$, then with probability zero all players output 1. The quantum complexity of such a quantum protocol is $\log_2 r$, and we denote the minimum complexity of all quantum protocols by $\mathrm{NQ}(f)$. We will make this definition more precise and more general in Section 2. Note that the quantum model can simulate the classical model by a postselection procedure. Also note that, nondeterministically, one quantum broadcast can be used to send a qubit from one player to another by using teleportation (see Theorem 8); the quantum model can thus simulate a message-passing model. The classical and quantum communication model naturally extend to k players.

1.1 Our results

- Our main technical result is that the quantum complexity of a function in the above model equals the logarithm of the so-called *support rank* of the tensor $\sum_{x,y,z} f(x, y, z)\,|x\rangle|y\rangle|z\rangle$ corresponding to f. We prove this in Section 2.
- Modifying the quantum model such that the players can only communicate by message passing and there is no shared $|\mathrm{GHZ}_r\rangle$ at the start – that is, the players now communicate in rounds and in each communication round one player sends a qubit to one other player – increases the complexity by at most a factor $k - 1$ (with k the number of players), and this relationship is tight. However, asymptotically in the input size, the increase is only $k/2$ and this relationship is tight. This solves a *nondeterministic multiplayer quantum log-rank conjecture* in the message-passing model of Villagra et al. [19]. This topic is covered in Section 3.
- We define the k-player *graphwise equality* problem to be the problem in which k players are identified with vertices in a graph G, and each player has to compute the equality function with his neighbours in G. Of particular interest is the cycle graph $G = C_k$ and the corresponding *cyclic equality* problem. For this cyclic equality problem, in the classical broadcast model, the naïve protocol in which every player broadcasts his inputs is the optimal protocol. The same holds in the quantum model when k is even. Interestingly, we show with Strassen's laser method that for all odd $k \geq 3$ there is a nontrivial quantum protocol. Moreover, for all odd $k \geq 3$ we give nontrivial lower bounds on the value of NQ by use of Young flattenings. These results are related to the complexity of matrix multiplication and iterated matrix multiplication. In particular, we improve a lower bound of Ikenmeyer on the border support rank of IMM_n^3 [11, 8.2.17]. A consequence of our work is that finding new protocols for the cyclic equality problem for three players yields new algorithms for matrix multiplication. Section 4 covers the classical case, the even quantum case, an explicit quantum protocol for $k = 5$, and the Young flattening lower bound. Section 5 covers the Strassen laser method.

1.2 Related work

The two-player nondeterministic quantum communication model was introduced by De Wolf [21]. He shows that the communication complexity in this model is characterized by the logarithm of the support rank of the communication matrix. The quantum broadcast channel, a communication model that is very similar to ours, has been studied by e.g. Ambainis et al. [1]. Multiparty nondeterministic quantum communication with message passing has been studied by Villagra et al. [19]. They show that the logarithm of the support rank of the communication tensor is a lower bound for the message-passing complexity and conjecture that this lower bound is polynomially related to the message-passing complexity.

The support rank of 3-tensors has been studied by Cohn and Umans in the context of the complexity of matrix multiplication [9]. They give nontrivial upper bounds on the support rank of the matrix multiplication tensor that do not come from upper bounds on the tensor rank. As an interesting fact, we note that given a matrix A and a number k, deciding whether the support rank of A is at least k is NP-hard [3].

The complexity of matrix multiplication plays a central role in algebraic complexity theory. We refer to [6] for general background information. Connections between algebraic complexity theory and entanglement transformations have been studied before, see for example [7]. The iterated matrix multiplication tensor has been studied in the context of arithmetic circuit complexity and the VP versus VNP problem, see for example [10]. To the knowledge of the authors, the tensor rank or support rank of the iterated matrix multiplication tensor has not been studied before.

Our work has motivated the further investigation of the tensor rank tensors defined by cycle graphs and more general graphs [8], which in turn when used in conjunction with this paper, lead to improved bounds on the non-deterministic quantum communication complexity of the cyclic equality game and more generally equality games played on graphs.

2 Support rank characterization of the quantum broadcast model

We refer to Nielsen and Chuang [15] for background information on the quantum computation model.

Quantum multiparty communication protocol. For any natural number m, denote by $[m]$ the set $\{1, 2, \ldots, m\}$. Let k be a positive integer and let f be a Boolean function on $[2^n]^k = [2^n] \times [2^n] \times \cdots \times [2^n]$,

$$f : [2^n]^k \to \{0, 1\}.$$

We define a *k-player quantum communication protocol* as follows. Each player i has a finite-dimensional Hilbert space H_i. The protocol thus takes place in the space $H_1 \otimes \cdots \otimes H_k$. The space is initialised in the state $|x_1 \cdots x_k\rangle |\mathrm{GHZ}_r^k\rangle$, where

$$|\mathrm{GHZ}_r^k\rangle \coloneqq \sum_{a=1}^{r} |a\rangle|a\rangle \cdots |a\rangle \in (\mathbf{C}^r)^{\otimes k}$$

is the k-party GHZ-state of rank r, shared among the k players, and $x_i \in [2^n]$ is the classical input to player i. (For clarity we will suppress any normalizations in quantum states when possible.) The players now apply local quantum operations. Let R_i be the first qubit of H_i and let $R = R_1 \otimes \cdots \otimes R_k$. We apply a projection onto $|11 \cdots 1\rangle$ in R. If the resulting tensor is 0 then the output of the protocol is 0, otherwise the output of the protocol is 1. The

complexity of the protocol is $\log_2(r)$. We say the protocol *nondeterministically computes* f if the probability that the output equals 1 is nonzero if $f(x_1, \ldots, x_k) = 1$ and the probability that the output equals 0 is one if $f(x_1, \ldots, x_k) = 0$.

▶ **Definition 1.** Let k be a positive integer and let f be a function $[2^n]^k \to \{0, 1\}$. The *k-player nondeterministic quantum communication complexity of f* is the minimal complexity of a k-player quantum communication protocol that nondeterministically computes f, and is denoted by $\mathrm{NQ}(f)$.

Approximating protocols. Let f be a function $[2^n]^k \to \{0, 1\}$. Let $(\Pi_j)_{j \in \mathbf{N}}$ be a sequence of protocols, such that when $f(x_1, \ldots, x_k) = 1$, the probability that Π_j outputs 1 on input x converges to a nonzero number as j goes to infinity, and when $f(x_1, \ldots, x_k) = 0$, the probability that Π_j outputs 0 on input x converges to 1 as j goes to infinity. Then we say that the sequence $(\Pi_j)_{j \in \mathbf{N}}$ *approximately nondeterministically computes* f. The complexity of an approximating sequence is the maximum complexity of any protocol Π_j in the sequence.

▶ **Definition 2.** The *k-player approximate nondeterministic quantum communication complexity of f* is the minimal complexity of a sequence (Π_j) that approximately nondeterministically computes f, and is denoted by $\underline{\mathrm{NQ}}(f)$.

Classical protocol. We define a *k-player classical communication protocol* as follows. Each player receives a classical input and a private random bit string. The protocol proceeds in rounds. Each round we let a single predetermined player communicate by broadcasting a bit to all the other players. After the last communication round, every player presents an output bit. If all the output bits are 1, then the output of the protocol is 1; otherwise the output of the protocol is 0. Again, we say the classical protocol *nondeterministically computes* f if the probability that the output equals 1 is nonzero if $f(x_1, \ldots, x_k) = 1$ and the probability that the output equals 0 is one if $f(x_1, \ldots, x_k) = 0$.

▶ **Definition 3.** The *k-player nondeterministic classical communication complexity of f* is the minimal complexity of a k-player classical communication protocol that nondeterministically computes f, and is denoted by $\mathrm{N}(f)$.

▶ Remark. For simplicity, we have taken the input set for each of the k players to be the same set $[2^n]$. We note that the definitions in this section and most of the results in this paper naturally generalize to the situation where the players get inputs from sets of different sizes.

Support rank and border support rank. Let t be a tensor in $(\mathbf{C}^m)^{\otimes k}$. The *tensor rank* of t is the smallest number r such that t can be written as a sum of r simple tensors, that is, $t = \sum_{i=1}^{r} u_i^1 \otimes u_i^2 \otimes \cdots \otimes u_i^k$ for some vectors $u_i^j \in \mathbf{C}^m$. We denote the tensor rank of t by $\mathrm{R}(t)$. Let $|1\rangle, \ldots, |m\rangle$ be the standard basis for $\mathbf{C}^m$ and define the support of a tensor t in $(\mathbf{C}^m)^{\otimes k}$ to be the set of product basis elements $|i_1\rangle \otimes \cdots \otimes |i_k\rangle$ that occur with nonzero coefficient in t. The *support rank* or *nondeterministic rank* of t is the smallest number r such that there exists a tensor in the space $(\mathbf{C}^m)^{\otimes k}$ with the same support as t and tensor rank r. We denote the support rank of t by $\mathrm{R_s}(t)$. Note that support rank is basis *dependent*.

The *border rank* of t is the smallest number r such that there exists a sequence of tensors $(t_j)_{j \in \mathbf{N}}$ converging to t in the Euclidean topology (or equivalently in the Zariski topology) such that $\mathrm{R}(t_j)$ is at most r for every j. We denote the border rank of t by $\underline{\mathrm{R}}(t)$. The *border support rank* of t is the smallest number r such that there exists a tensor in $(\mathbf{C}^m)^{\otimes k}$ with the same support as t and border rank r. We denote the border support rank of t by $\underline{\mathrm{R}}_{\mathrm{s}}(t)$.

▶ **Theorem 4.** *Let $f : [2^n]^k \to \{0,1\}$ be a function and let t be the tensor in $(\mathbf{C}^{2^n})^{\otimes k}$ with entries given by f, that is, $t = \sum_{i \in [2^n]^k} f(i)\,|i_1\rangle|i_2\rangle \cdots |i_k\rangle$. Then $\mathrm{NQ}(f) = \log_2 \mathrm{R_s}(t)$ and $\underline{\mathrm{NQ}}(f) = \log_2 \underline{\mathrm{R}}_{\mathrm{s}}(t)$.*

▶ **Lemma 5** (Cleanup lemma)**.** *Let $\{|\psi_i\rangle : i \in [q]\} \subseteq (\mathbf{C}^m)^{\otimes k}$ be a set of k-tensors, for some natural number q. Then there exists a k-partite rank-1 linear map $\langle \ell| \coloneqq \langle \ell_1| \otimes \cdots \otimes \langle \ell_k|$ with $\langle \ell_j| \in (\mathbf{C}^m)^*$ such that $\langle \ell|\psi_i\rangle \neq 0$ for every $i \in [q]$.*

Proof. We will give a proof by recursively constructing $\langle \ell|$. Let Id be the identity map on $\mathbf{C}^m$. If $j \leq k$, $\langle a| \in ((\mathbf{C}^m)^*)^{\otimes j}$ and $|b\rangle \in (\mathbf{C}^m)^{\otimes k}$, then we denote by $\langle a|b\rangle$ the contraction of $\langle a|$ and $|b\rangle$, that is, $\langle a|b\rangle = (\langle a| \otimes \mathrm{Id}^{\otimes k-j})\,|b\rangle$.

The base case is $\langle \ell| = 1$. For the recursion, suppose we are given an element $\langle \ell'| \in ((\mathbf{C}^m)^*)^{\otimes j}$ such that $|\phi_i\rangle \coloneqq \langle \ell'|\psi_i\rangle$ is nonzero for every $i \in [q]$. We will construct an element $\langle \ell| \in ((\mathbf{C}^m)^*)^{\otimes j+1}$ such that $\langle \ell|\psi_i\rangle$ is nonzero for every $i \in [q]$. Since $|\phi_i\rangle$ is nonzero for every $i \in [q]$, there is an element $\langle u_i| \in (\mathbf{C}^m)^*$ such that $\langle u_i|\phi_i\rangle$ is nonzero. Consider the the maps $(\langle u_1| + x\,\langle u_2|)\,|\phi_i\rangle$ for $i \in \{1,2\}$, in the variable x. Each map only has a single root. Therefore, there exists a value α_2 for x such that both maps evaluate to a nonzero number. Next, consider the maps $(\langle u_1| + \alpha_2\,\langle u_2| + x\,\langle u_3|)\,|\phi_i\rangle$ for $i \in \{1,2,3\}$, in variable x. Again, each of the three maps has only a single root. Therefore, there exists a value α_3 for x such that all three maps evaluate to a nonzero number. Repeat this construction to obtain an element $\langle u| \in (\mathbf{C}^m)^*$ such that $\langle u|\phi_i\rangle$ is nonzero for every $i \in [q]$. Let $\langle \ell|$ be $\langle \ell'| \otimes \langle u|$. ◀

Proof of Theorem 4. We first show $\mathrm{NQ}(f) \leq \log_2 \mathrm{R_s}(t)$. Let r be the support rank of t. Then there exists a unit vector $\psi \in (\mathbf{C}^{2^n})^{\otimes k}$ with rank r and support equal to the support of f. This means that there are vectors $|u_i^j\rangle \in \mathbf{C}^{2^n}$ such that $\psi = \sum_{i=1}^r |u_i^1\rangle \cdots |u_i^k\rangle$. For every player j define a matrix

$$A_j \coloneqq \alpha_j \sum_{i=1}^{r} |u_i^j\rangle\langle i|$$

where α_j is a nonzero complex number such that $A_j^\dagger A_j$ has eigenvalue at most 1. The matrix $I - A_j^\dagger A_j$ is thus positive semidefinite and hence there exists a matrix A_j' such that ${A_j'}^\dagger A_j' = I - A_j^\dagger A_j$. Define for every player j a quantum operation

$$\mathcal{E}_j : \rho \mapsto A_j \rho A_j^\dagger \otimes |1\rangle\langle 1| + A_j' \rho {A_j'}^\dagger \otimes |0\rangle\langle 0|\,.$$

Note that this operation introduces a new control qubit register which player j can measure to see whether he applied A_j or A_j'.

The protocol for the k players is as follows. Let $x_1, \ldots, x_k$ be the inputs given to the players. The players share a k-party GHZ-state of rank r. Player j applies $\mathcal{E}_j$ to his part of the GHZ-state. If his control qubit is $|0\rangle$ then he sets his output qubit R_i to $|0\rangle$. Otherwise, he measures the rest of the system. If the outcome equals $|x_j\rangle$, then he sets R_j to $|1\rangle$, otherwise he sets R_j to $|0\rangle$.

The above protocol uses a GHZ-state of rank r, so it has complexity $\log_2(r)$. We claim that the protocol nondeterministically computes f. If the players in the first measurement each get outcome $|1\rangle$, then the state of the total system is $|\psi\rangle$. Because $|\psi\rangle$ has norm 1, this happens with nonzero probability $|\alpha_1|^2 \cdots |\alpha_k|^2$. If $f(x_1, \ldots, x_k) = 0$, then $|x_1 \cdots x_k\rangle$ does not occur in the support of ψ, so the probability that the players measure $|x_1\rangle, \ldots, |x_k\rangle$ respectively is zero. Hence in this case the register R is not in state $|11\cdots1\rangle$. On the other hand, if $f(x_1, \ldots, x_k) \neq 0$, then $|x_1 \cdots x_k\rangle$ does occur in the support of ψ, so the probability that the players measure $|x_1\rangle, \ldots, |x_k\rangle$ respectively is nonzero. Hence with nonzero probability the register R is in state $|11\cdots1\rangle$.

We now show $\mathrm{NQ}(f) \geq \log_2 \mathrm{R_s}(t)$. Suppose we have a protocol that nondeterministically computes f with complexity r. This means that the players perform *local* quantum operations that together form a linear map L which transforms, for any $x_1, \ldots, x_k \in [2^n]$, the state

$$|x_1 \cdots x_k\rangle \, |\mathrm{GHZ}_r\rangle$$

to a state of the form

$$|x_1 \cdots x_k\rangle \sum_{a \in \{0,1\}^k} |\psi_x^a\rangle \; |a_1\rangle |a_2\rangle \cdots |a_k\rangle \,,$$

where $|\psi_x^a\rangle$ is some vector representing the state of the work space of the players. By definition of nondeterministic computation, for $a = (1, \ldots, 1)$, if $f(x_1, \ldots, x_k) = 1$, then $|\psi_x^a\rangle$ is nonzero, and if $f(x_1, \ldots, x_k) = 0$, then $|\psi_x^a\rangle$ is zero. Since the map L is linear, it maps the tensor

$$s_1 \coloneqq \sum_{x_1, \ldots, x_k} |x_1 \cdots x_k\rangle \, |\mathrm{GHZ}_r\rangle$$

to the tensor

$$s_2 \coloneqq \sum_{x_1, \ldots, x_k} |x_1 \cdots x_k\rangle \sum_{a \in \{0,1\}^k} |\psi_x^a\rangle \, |a_1 \cdots a_k\rangle \,.$$

The tensor rank of $\sum_x |x_1 \cdots x_k\rangle$ is 1 and hence the tensor rank of s_1 is r. Because L is a local map, the tensor rank of s_2 is at most r. By applying the cleanup lemma (Lemma 5) and projecting on states with $|a_1 \cdots a_k\rangle = |1 \cdots 1\rangle$, we obtain a tensor

$$s_3 \coloneqq \sum_{x_1, \ldots, x_k} |x_1 \cdots x_k\rangle \, c_x$$

where $c_x \in \mathbf{C}$ is zero if $f(x) = 0$ and nonzero if $f(x) = 1$. The rank of the tensor s_3 is at most r. The support of s_3 equals the support of f, so the support rank of f is at most r.

The statement about the approximate complexity of f follows from the definition of border support rank. ◀

▶ **Definition 6** (SLOCC)**.** Let $\phi \in U_1 \otimes \cdots \otimes U_k$ and let $\psi \in V_1 \otimes \cdots \otimes V_k$. We say that ϕ can be converted to ψ by stochastic local operations and classical communication (SLOCC), and write $\phi \xrightarrow{\mathrm{SLOCC}} \psi$, if there exist matrices $A_1, \ldots, A_k$ such that $\psi = (A_1 \otimes \cdots \otimes A_k)\phi$.

▶ Remark. We note that having an NQ-protocol for f of complexity n is the same as having an SLOCC protocol for transforming $\mathrm{GHZ}_{2^n}^k$ to a tensor with the same support as f. We will use the SLOCC paradigm in some parts of the text.

▶ Remark. The NQ-model that we are using is very similar to the following *broadcast channel* model that was studied in [1]. Each player i has a local Hilbert space H_i with a register initialised in the input state $|x_i\rangle$. The players have access to a quantum broadcast channel, which, given a qubit state $\alpha |0\rangle + \beta |1\rangle$, will create the state $\alpha |0\rangle^{\otimes k} + \beta |1\rangle^{\otimes k}$ and distribute this state among the k players. The players proceed in communication rounds; each round a designated player uses the broadcast channel. Let R_i be the first qubit of H_i and let $R = R_1 \otimes \cdots \otimes R_k$. After the communication is finished, we apply a projection onto $|11 \cdots 1\rangle$ in R. If the resulting tensor is 0 then the output of the protocol is 0, otherwise the output of the protocol is 1. The complexity of the protocol is the number of communication rounds. We say the protocol nondeterministically computes f if the probability that the output equals 1 is nonzero if $f(x_1, \ldots, x_k) = 1$ and the probability that the output equals 0 is one if $f(x_1, \ldots, x_k) = 0$.

In particular, let $\mathrm{NQ}'(f)$ denote the complexity of the function f in the broadcast channel model. Then $\mathrm{NQ}'(f) \leq \mathrm{NQ}(f) + 1$. Indeed, consider a protocol in the NQ-model that computes f using $|\mathrm{GHZ}_r^k\rangle$ as a starting state. To simulate this protocol in the NQ'-model, one of the players uses the broadcast channel $\lceil \log_2 r \rceil$ times to create $|\mathrm{GHZ}_r^k\rangle$. Then the players proceed with the local quantum operations to compute f. This finishes the proof. We don't know whether the inequality $\mathrm{NQ}(f) \leq \mathrm{NQ}'(f)$ holds.

3 Nondeterministic log-rank conjecture for message-passing protocols

▶ **Definition 7.** Let $\mathrm{NQ}_0(f)$ be the minimal complexity of a protocol that nondeterministically computes f, without preshared entanglement (that is, the space is initialised in the state $|x_1 \cdots x_k\rangle$ instead of $|x_1 \cdots x_k\rangle |\mathrm{GHZ}_r^k\rangle$) but with the added ability for every player to send a qubit to another player. This communication happens in communication rounds; the protocol specifies per round who communicates to whom, independently of the input. The complexity of such a protocol is the total number rounds.

Villagra et al. [19] show that $\mathrm{NQ}_0(f)$ is at least the logarithm of the support rank of f. They furthermore conjecture that $\mathrm{NQ}_0(f)$ is upper bounded by a polynomial in the logarithm of the support rank. The following theorem proves this conjecture.

▶ **Theorem 8** ("Nondeterministic log-rank conjecture"). *Let $f : [2^n]^k \to \{0,1\}$. Then we have $\mathrm{NQ}(f) \leq \mathrm{NQ}_0(f) \leq (k-1)\,\mathrm{NQ}(f)$.*

Proof. For the first inequality, suppose we have an NQ_0-protocol for f. We replace the communication of a qubit by the nondeterministic teleportation of that qubit. Beforehand, all players agree on the basis in which the teleportation should happen. If any teleportation during the protocol does not happen in this basis, then the player that notices this sets his output register R_i to $|0\rangle$.

For the second inequality, suppose we have an NQ-protocol for f which uses a GHZ-state of rank r. Then we can construct a NQ_0-protocol for f as follows. The players start with no shared entanglement. Player 1 constructs a GHZ-state of rank r locally. In the first $k-1$ communication rounds, player 1 distributes the GHZ-state over the other $k-1$ players. After that, the players perform the NQ-protocol. The resulting NQ_0-protocol has complexity at most $(k-1)\,\mathrm{NQ}(f)$. ◀

To say something about the 'tightness' of Theorem 8 we consider the natural easy function in the NQ-model, namely $f(x_1, \ldots, x_k) = [x_1 = x_2 = \cdots = x_k]$ with $x_i \in [2^n]$.

▶ **Proposition 9** (Single bit inputs). *Let $f : [2]^k \to \{0,1\}$ be the function defined by $f(x_1, \ldots, x_k) = [x_1 = x_2 = \cdots = x_k]$ for $x_i \in [2]$. Then we have $\mathrm{NQ}(f) = 1$ and $\mathrm{NQ}_0(f) = (k-1)\,\mathrm{NQ}(f)$.*

Proof. Note that the tensor of this function is GHZ_2^k, so $\mathrm{NQ}(f) = 1$. Now consider a protocol that nondeterministically computes f without preshared entanglement and r rounds of communication. We may assume, without loss of generality, that the protocol consists of a first phase in which the players communicate and a second phase in which the players only do local quantum operations. After the first phase the players are sharing some state E consisting of EPR-pairs shared among certain pairs of the players. We thus obtain a local linear map which maps $\sum_x |x\rangle\, E$ to a tensor with the same support as GHZ_2^k. However, if $r < k-1$, then, viewing E as a graph, E is disconnected. Therefore there is a grouping of the players into two groups such that there are no EPR-pairs between the groups. Such a state cannot be converted to a GHZ_2^k state by SLOCC. ◀

Asymptotically, we can improve the relationship stated in Theorem 8, as follows.

▶ **Theorem 10** (Asymptotic upper bound). *For any $\varepsilon > 0$, there is an n_0 such that for all $f : [m]^k \to \{0,1\}$, if $\mathrm{NQ}(f) > n_0$, then*

$$\mathrm{NQ}_0(f) \leq \frac{(k+\varepsilon)}{2}\,\mathrm{NQ}(f).$$

To prove Theorem 10 we use the theory of asymptotic SLOCC conversion rates.

▶ **Definition 11.** Given tensors $\psi \in V_1 \otimes \cdots \otimes V_k$ and $\phi \in W_1 \otimes \cdots \otimes W_k$, we say that ψ can be transformed into ϕ via SLOCC operations, if there exist linear transformations $A_i : V_i \to W_i$ such that $\phi = (A_1 \otimes \cdots \otimes A_k)\psi$; and we write $\psi \xrightarrow{\text{SLOCC}} \phi$. Define

$$\omega_n(\psi,\phi) = \frac{1}{n}\inf\{m \in \mathbf{N}_{\geq 1} \mid \psi^{\otimes m} \xrightarrow{\text{SLOCC}} \phi^{\otimes n}\}$$

and

$$\omega(\psi,\phi) = \lim_{n\to\infty} \omega_n(\psi,\phi).$$

▶ **Lemma 12.** *The limit $\omega(\psi,\phi)$ exists and for all n the inequality $\omega_n(\psi,\phi) \geq \omega(\psi,\phi)$ holds; in other words, $\omega_n = \omega + o(1)$.*

▶ **Theorem 13** (Vrana-Christandl [20]). *Let $\mathrm{GHZ}_2^{K_k}$ be the k-party tensor consisting of EPR-pairs between any parties. Then*

$$\omega(\mathrm{GHZ}_2^{K_k}, \mathrm{GHZ}_2^k) = \frac{1}{k-1}.$$

In other words, for any $\varepsilon > 0$, there is an n_0 such that for all $n > n_0$,

$$(\mathrm{GHZ}_2^{K_k})^{\otimes n(\frac{1}{k-1}+\varepsilon)} \xrightarrow{\text{SLOCC}} (\mathrm{GHZ}_2^k)^{\otimes n}.$$

Proof of Theorem 10. Creating $\mathrm{GHZ}_2^{K_k}$ in the NQ_0-model costs $\binom{k}{2}$ messages. Asymptotically, we can transform $1/(k-1)$ copies of $\mathrm{GHZ}_2^{K_k}$ to one copy of GHZ_2^k by SLOCC. More precisely, by Theorem 13, for any $\varepsilon > 0$, there is an n_0 such that for all $n > n_0$,

$$(\mathrm{GHZ}_2^{K_k})^{\otimes \frac{n}{k-1}+\varepsilon n} \xrightarrow{\text{SLOCC}} (\mathrm{GHZ}_2^k)^{\otimes n}.$$

We conclude that, for any $\varepsilon > 0$, there is an n_0 such that for all $n > n_0$, $\binom{k}{2}(\frac{n}{k-1} + \varepsilon n) = ((k+\varepsilon')n)/2$ messages are sufficient to generate $(\mathrm{GHZ}_2^k)^{\otimes n}$ by SLOCC.

To prove the theorem, suppose we have an NQ-protocol for f which uses a GHZ state of rank 2^n and no communication. Consider the following NQ_0-protocol for f. Create a GHZ-state of rank 2^n by sending $\frac{(k+\varepsilon')n}{2}$ messages and then continue with the NQ-protocol. ◀

The following proposition says that the asymptotic relationship of Theorem 10 is tight.

▶ **Proposition 14** (n-bit inputs). *Let $f : [2^n]^k \to \{0,1\}$ be the function defined by $f(x_1,\ldots,x_k) = [x_1 = x_2 = \cdots = x_k]$ for $x_i \in [2^n]$. Then we have $\mathrm{NQ}(f) = n$ and $\mathrm{NQ}_0(f) \geq \frac{k}{2}\,\mathrm{NQ}(f)$.*

Proof. As in the previous proof, note that the tensor corresponding to f is $\mathrm{GHZ}_{2^n}^k$. Suppose there is an NQ_0 protocol using r messages. View the communication pattern of this protocol as an undirected multigraph G (i.e. parallel edges are allowed) on k vertices. Note that G has r edges. Let $E = \mathrm{GHZ}_2^G$ be the tensor that has an EPR pair at every edge in G. The protocol

yields an SLOCC transformation of E to $\mathrm{GHZ}_{2^n}^k$. Let ℓ be the minimal number of edges across any cut of G. Then ℓ is at most the minimal degree d of G. The sum of all degrees in G equals $2r$, so $k\ell \leq kd \leq 2r$, which implies the inequality $r \geq k\ell/2$. The number ℓ is equal to $\min_{S\subseteq[k]} \log_2 \mathrm{rk}_S(E)$, where $\mathrm{rk}_S(E)$ denotes the rank of E after flattening according to the set S. This value cannot increase under any SLOCC transformation. Now note that $\log_2 \mathrm{rk}_{\{i\}}(\mathrm{GHZ}_{2^n}^k) = n$ for any $i \in [k]$, so $\ell \geq n$. We conclude that $r \geq kn/2$. ◀

▶ Remark. Another way to prove Proposition 14 is to first symmetrize the protocol to obtain an SLOCC transformation of a state E with $\log_2 \mathrm{rk}_{\{i\}}(E) = (k-1)!2r$ to the state $\mathrm{GHZ}_{2^{k!n}}^k$. We have $\log_2 \mathrm{rk}_{\{i\}}(\mathrm{GHZ}_{2^{k!n}}^k) = k!\,n$. Since $\log_2 \mathrm{rk}_{\{i\}}$ is an SLOCC-monotone, we obtain the inequality $(k-1)!\,2r \geq k!\,n$ and hence $r \geq kn/2$.

4 Cyclic equality problem

The two-player equality problem EQ_n is the problem of Alice and Bob having to decide whether their n-bit inputs are equal. Since the identity matrix has full support rank, we have $\mathrm{NQ}(\mathrm{EQ}_n) = n$. We generalize EQ_n to multiple players as follows. Let G be an undirected graph. Let EQ_n^G be the problem of $|G|$ players having to solve the n-bit equality problem between players connected by edges. (Note that this definition naturally generalizes to hypergraphs.) If G is a bipartite graph, one easily sees that by grouping the players we can transform the problem into an equality problem on en bits EQ_{en}, where e is the number of edges in the graph. Therefore $\mathrm{NQ}(\mathrm{EQ}_n^G) = en$, that is, the trivial protocol is optimal for bipartite graphs. On the other hand, if G contains an odd cycle, then this argument fails. In the rest of this paper we will focus on the extreme case of G being an odd cycle and investigate the complexity of the corresponding equality problem.

▶ **Definition 15.** The k-player *cyclic equality problem* on n bits $\mathrm{EQ}_n^{C_k}$ is the function

$$\mathrm{EQ}_n^{C_k} : ([2^n]\times[2^n])^k \to \{0,1\} : (a_1b_1,\ldots,a_kb_k) \mapsto \begin{cases} 1 & \text{if } b_1 = a_2,\ b_2 = a_3,\ \ldots,\ b_k = a_1 \\ 0 & \text{otherwise,} \end{cases}$$

that is, the players are arranged in a circle; player i receives two n-bit inputs a_i, b_i and has to decide whether $a_i = b_{i-1}$ and $b_i = a_{i+1}$, where the indices are taken modulo k.

It turns out that the tensor corresponding to this function is a generalisation of the *matrix multiplication tensor*, one of the central objects of study in algebraic complexity theory. This tensor arises as follows in algebraic complexity theory. Consider the bilinear map

$$\mathbf{C}^{m\times m} \times \mathbf{C}^{m\times m} \to \mathbf{C}^{m\times m} : (A,B) \mapsto AB$$

which multiplies two complex $m \times m$ matrices. Any bilinear map $U \times V \to W$ corresponds canonically to a tensor in $U \otimes V \otimes W$. The number of multiplications in the field $\mathbf{C}$ necessary to perform the bilinear map is equal to the tensor rank of the corresponding tensor, up to a factor 2. The tensor corresponding to the matrix multiplication map is

$$\langle m,m,m\rangle \coloneqq \sum_{x\in[m]^3} |x_1x_2\rangle|x_2x_3\rangle|x_3x_1\rangle\,.$$

A natural generalisation of the tensor $\langle m,m,m\rangle$ to a k-party tensor is the so-called *iterated matrix multiplication* tensor

$$\mathrm{IMM}_m^k \coloneqq \sum_{x\in[m]^k} |x_1x_2\rangle|x_2x_3\rangle\cdots|x_kx_1\rangle\,.$$

Clearly, $\mathrm{IMM}_m^3 = \langle m, m, m\rangle$. The tensor IMM_m^k corresponds to the multilinear map

$$(\mathbf{C}^{m\times m})^{\times k} \to \mathbf{C} : (A_1, A_2, \ldots, A_k) \mapsto \mathrm{tr}(A_1 A_2 \cdots A_k)$$

which computes the trace of the product of k matrices. We note that, when viewed as a polynomial in the matrix entries, IMM_m^k plays a special role in the field of arithmetic circuits and geometric complexity theory. Namely, IMM_3^k is complete for the class $\mathrm{VP_e}$ of families of polynomials computable by small formulas [2], and IMM_k^k is complete for the class VQP, for which the determinant is also complete [4]. The following connection between iterated matrix multiplication and cyclic equality is readily observed.

▶ **Proposition 16.** *The tensor corresponding to the cyclic equality function* $\mathrm{EQ}_n^{C_k}$ *on* n *bits is the iterated matrix multiplication tensor* $\mathrm{IMM}_{2^n}^k$ *with* $2^n \times 2^n$ *matrices. Therefore, we have the equalities* $\mathrm{NQ}(\mathrm{EQ}_n^{C_k}) = \log_2 \mathrm{R_s}(\mathrm{IMM}_{2^n}^k)$ *and* $\underline{\mathrm{NQ}}(\mathrm{EQ}_n^{C_k}) = \log_2 \underline{\mathrm{R}}_{\mathrm{s}}(\mathrm{IMM}_{2^n}^k)$

The remainder of this paper is organized as follows. In the following four paragraphs we do the following: (1) we show that in the classical model, the naïve protocol in which every player broadcasts his input is optimal; (2) we show that when k is even the naïve protocol is optimal quantumly; (3) we exhibit nontrivial protocols when $n = 1$ and $k = 3$ or $k = 5$; (4) we show nontrivial lower bounds on the quantum complexity by use of Young flattenings. Finally, in the last section, we show that the Strassen laser method yields nontrivial protocols for all odd $k \geq 3$, asymptotically.

Classical lower bound with the fooling set method. We will show that in the classical situation the trivial protocol is always optimal. To prove a lower bound on the classical complexity of the cyclic equality problem we use the fooling set method. This is a method from the 2-player setting that extends naturally to the k-player setting.

▶ **Theorem 17.** *The classical nondeterministic communication complexity* $\mathrm{N}(\mathrm{EQ}_n^{C_k})$ *of the cyclic equality problem equals* kn*.*

Proof. Let $S \subseteq [2^{2n}]^k$ be the set of 1-inputs of the function $\mathrm{EQ}_n^{C_k}$. This set has size 2^{kn}. Let Π be a classical protocol for $\mathrm{EQ}_n^{C_k}$ and denote by $\Pi_r(x_1, \ldots, x_k)$ the sequence of messages sent by the players in the protocol Π on input $x \in [2^{2n}]^k$ and private randomness $r \in [m]^k$. Suppose there are distinct 1-inputs $x, y \in S$ and private randomnesses $r, s \in [m]^k$ such that $\Pi_r(x_1, \ldots, x_k) = \Pi_s(y_1, \ldots, y_k)$. There is an i such that $x_i \neq y_i$, say $i = 1$. We have $\Pi_r(x_1, \ldots, x_k) = \Pi_{(r_1, s_2, \ldots, s_k)}(x_1, y_2, \ldots, y_k)$, so the protocol outputs 1 on input $x_1, y_2, \ldots, y_k$ with randomness $(r_1, s_2, \ldots, s_k)$. However, $x_1, y_2, \ldots, y_k$ is a 0-input, a contradiction. Therefore, $\Pi_r(x_1, \ldots, x_k) \neq \Pi_s(y_1, \ldots, y_k)$. We conclude that $\mathrm{N}(\mathrm{EQ}_n^{C_k}) \geq \log_2(|S|)$. ◀

An even number of quantum players. When k is even, the cycle graph C_k is bipartite, and, as mentioned above, the best protocol for an equality problem on a bipartite graph is the trivial protocol. We record this statement in terms of border support rank in the following proposition.

▶ **Proposition 18.** *For even* k*,* $m^k \leq \underline{\mathrm{R}}_{\mathrm{s}}(\mathrm{IMM}_m^k)$*. As a consequence, we have the equalities* $\underline{\mathrm{NQ}}(\mathrm{EQ}_n^{C_k}) = \mathrm{NQ}(\mathrm{EQ}_n^{C_k}) = kn$*.*

Proof. Let t be a tensor with the same support as $\mathrm{IMM}_m^k \in (\mathbf{C}^{m^2})^{\otimes k}$. Label the players with the numbers $1, 2, \ldots, k$. Group the *even* players together and group the *odd* players

together and flatten the tensor t accordingly into a matrix A in $(\mathbf{C}^{m^2})^{\otimes k/2} \otimes (\mathbf{C}^{m^2})^{\otimes k/2}$. The matrix A has the same support as the identity matrix in $(\mathbf{C}^{m^2})^{\otimes k/2} \otimes (\mathbf{C}^{m^2})^{\otimes k/2}$ and thus has rank m^k. ◀

Note that for odd k the above proof yields the lower bound $m^{k-1} \leq \underline{\mathrm{R}}_{\mathrm{s}}(\mathrm{IMM}_m^k)$. We will show in Theorem 20 that this lower bound is not tight.

Nontrivial 3-player and 5-player quantum protocols. In the 3-player situation, Strassen's celebrated decomposition of the tensor $\mathrm{IMM}_2^3 = \langle 2,2,2\rangle$ into a sum of 7 simple tensors [17] gives a nontrivial protocol for $\mathrm{EQ}_1^{C_3}$, and thus $\mathrm{NQ}(\mathrm{EQ}_1^{C_3}) \leq \log_2(7)$. We show that for 5 players there also exists a nontrivial protocol for $\mathrm{EQ}_1^{C_5}$, as follows. Recall that we have defined $\mathrm{IMM}_2^5 = \sum_{i\in[2]^5} |i_1i_2\rangle|i_2i_3\rangle|i_3i_4\rangle|i_4i_5\rangle|i_5i_1\rangle$. Observe that an upper bound $\mathrm{R}(\mathrm{IMM}_2^5) \leq r$ implies $\mathrm{R}(\mathrm{IMM}_n^5) \leq \mathcal{O}(n^{\log_2(r)})$ by taking tensor powers of IMM_2^5.

▶ **Theorem 19.** $\mathrm{R}(\mathrm{IMM}_2^5) \leq 31$, *and thus* $\mathrm{NQ}(\mathrm{EQ}_1^{C_5}) \leq \log_2(31)$.

Proof. Let $|-\rangle := |1\rangle - |2\rangle$, $|+\rangle := |1\rangle + |2\rangle$ and $|\Phi^+\rangle = |11\rangle + |22\rangle$. Let $\mathrm{Cyc}_5 := \sum_{\sigma\in C_5} \sigma$ be the cyclic symmetrizer acting on $(\mathbf{C}^4)^{\otimes 5}$ by permuting the 5 parties, and moreover let $\mathrm{Sym}_2 := \sum_{\sigma\in S_2} \sigma$ be a 'local symmetrizer' acting diagonally on $(\mathbf{C}^2)^{\otimes 10}$ by permuting the basis states $|1\rangle$ and $|2\rangle$ of each $\mathbf{C}^2$. Let

$$\begin{aligned} t := &- |-1\rangle\,|11\rangle\,|11\rangle\;|1+\rangle\,|22\rangle \\ &- |-1\rangle\,|12\rangle\,|21\rangle\;|1+\rangle\,|22\rangle \\ &- |\Phi^+\rangle\,|22\rangle\,|-1\rangle|1+\rangle\,|22\rangle. \end{aligned}$$

By direct computation, we see that $\mathrm{IMM}_2^5 = \mathrm{Cyc}_5\big(\mathrm{Sym}_2(t)\big) + |\Phi^+\rangle^{\otimes 5}$. We observe that the right hand side yields a sum of 31 simple tensors. ◀

We have a proof generalizing Theorem 19 to $\mathrm{R}(\mathrm{IMM}_2^k) \leq 2^k - 1$ for all odd k, which will appear in a forthcoming paper [8].

Quantum lower bound with Young flattenings. Let $t \in V_1 \otimes V_2 \otimes V_3$ be some 3-tensor. By grouping V_1 and V_2, the tensor t can be viewed as a matrix $A \in (V_1 \otimes V_2) \otimes V_3$; this is called a *flattening*. The rank of the flattening A is a lower bound for the border rank of t and thus we obtain lower bounds on the border rank of tensors by computing the rank of their flattenings. However, this type of lower bound can never be bigger than the dimension of any local space V_i, and there do exist tensors with border rank larger than the local dimensions, for example the matrix multiplication tensor $\langle 2,2,2\rangle$.

One approach to overcome this 'local dimension limitation' is as follows. We let $\phi : V_2 \to W_1 \otimes W_2$ be a linear map such that $\mathrm{R}(\phi(v)) \leq e$ for all $v \in V_2$. By applying ϕ to the central tensor leg of t, we transform t into a 4-tensor $s \in V_1 \otimes W_1 \otimes W_2 \otimes V_3$. Next, we flatten s to a matrix $A \in (V_1 \otimes W_1) \otimes (W_2 \otimes V_3)$. The rank of A divided by e is a lower bound for the border rank of t. We will be using a specific linear map ϕ which originates from the representation theory of the general linear group. When one takes such representation theoretic maps ϕ to construct a flattening as above one speaks of a *Young flattening* [13]. An early appearance of this type of flattening can be recognized in the work of Strassen [18]. The following lower bound is obtained with a Young flattening.

▶ **Theorem 20.** *For odd* $k \geq 3$, $(2n^2 - n)n^{k-3} \leq \underline{\mathrm{R}}_{\mathrm{s}}(\mathrm{IMM}_n^k)$. *As a consequence, we have the lower bound* $(k-1)n + \log_2(2 - \frac{1}{n}) \leq \underline{\mathrm{NQ}}(\mathrm{EQ}_n^{C_k})$.

Proof. Let $k = 3$. The proof for odd $k > 3$ goes similarly after having grouped the k parties appropriately to 3 parties. For a vector space V, let $\wedge^a V$ be the ath exterior power of V. Define the linear map

$$\begin{aligned}\phi : \mathbf{C}^{2n-1} &\to \wedge^p \mathbf{C}^{2n-1} \otimes \wedge^{p+1} \mathbf{C}^{2n-1} \\ |j\rangle &\mapsto \sum_{j_1<\cdots<j_p} |j_1\rangle\wedge\cdots\wedge|j_p\rangle \otimes |j_1\rangle\wedge\cdots\wedge|j_p\rangle\wedge|j\rangle\,,\end{aligned}$$

and note that the rank of the matrix $\phi(v)$ equals $\binom{2n-2}{p}$ for any $v \in \mathbf{C}^{2n-1}$. We consider the tensor

$$t_1 \coloneqq \sum_i \alpha_{i_1,i_2,i_3} |i_1 i_2\rangle |i_2 i_3\rangle |i_3 i_1\rangle \in \mathbf{C}^{n^2} \otimes \mathbf{C}^{n^2} \otimes \mathbf{C}^{n^2},$$

where i runs over $[n]^3$ and the α_{i_1,i_2,i_3} are nonzero complex numbers. The border rank of t_1 is at least the border rank of

$$t_2 \coloneqq \sum_i \alpha_{i_1,i_2,i_3} |i_1 i_2\rangle |i_2 + i_3 - 1\rangle |i_3 i_1\rangle \in \mathbf{C}^{n^2} \otimes \mathbf{C}^{2n-1} \otimes \mathbf{C}^{n^2}.$$

Apply ϕ to the central tensor leg of t_2 and then flatten to obtain

$$A \coloneqq \sum_i \sum_{j_1<\cdots<j_p} \alpha_{i_1,i_2,i_3} |i_1 i_2\rangle |j_1\rangle\wedge\cdots\wedge|j_p\rangle \otimes |j_1\rangle\wedge\cdots\wedge|j_p\rangle\wedge|i_2 + i_3 - 1\rangle |i_3 i_1\rangle\,.$$

View A as a direct sum of n matrices $A_{i_1} \in (\mathbf{C}^n \otimes \wedge^p \mathbf{C}^{2n-1}) \otimes (\wedge^{p+1}\mathbf{C}^{2n-1} \otimes \mathbf{C}^n)$; the matrix A_{i_1} corresponds to the linear map

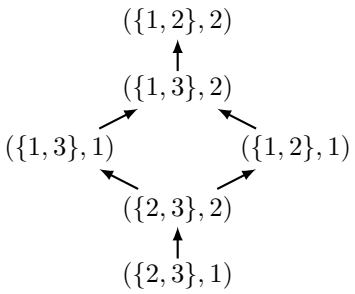
$$f_{i_1} : |i_2\rangle |j_1\rangle\wedge\cdots\wedge|j_p\rangle \mapsto \sum_{i_3} \alpha_{i_1,i_2,i_3} |j_1\rangle\wedge\cdots\wedge|j_p\rangle\wedge|i_2 + i_3 - 1\rangle |i_3\rangle\,.$$

Let $p = n - 1$. We claim that every matrix A_{i_1} is upper triangular with elements α_{i_1,i_2,i_3} on the diagonal, up to permutations of the rows and columns. Assuming the claim is true, we get that $\mathrm{R}(A) = \sum_{i_1} \mathrm{R}(A_{i_1}) = n \dim(\mathbf{C}^n \otimes \wedge^{n-1}\mathbf{C}^{2n-1}) = n^2\binom{2n-1}{n-1}$. This implies the lower bound $\underline{\mathrm{R}}_{\mathrm{s}}(\mathrm{IMM}_n^3) \geq n^2\binom{2n-1}{n-1}/\binom{2n-2}{n-1} = 2n^2 - n$.

To prove this claim we define a partial order on the basis elements $|j_1\rangle \wedge \cdots \wedge |j_n\rangle \otimes |\ell\rangle$ of the target space of A_{i_1}. We will use the same partial order as Landsberg and Michałek [12]. Denote the basis elements of the target space by (P, ℓ) with P an n-subset of $[2n-1]$ and $\ell \in [n]$. Let (P_1, ℓ_1) and (P_2, ℓ_2) be two such basis elements and define $\ell \coloneqq \min(\ell_1, \ell_2)$. We say $(P_1, \ell_1) < (P_2, \ell_2)$

1. if the ordered sequence of the ℓ smallest elements in P_2 is lexicographically smaller than the ordered sequence of the ℓ smallest elements in P_1;
2. or if the sequences of ℓ smallest elements are equal and $\ell_1 < \ell_2$.

One checks that this defines a partial order and that the unique minimal element in this order is $(\{n, \ldots, 2n-1\}, 1)$. For example, with $n = 2$ the partial order has the following Hasse diagram.



We prove the claim by induction on $<$, with the minimal element as a base case. For now let all the α_{i_1,i_2,i_3} be 1. First, under A_{i_1} we have

$$|n\rangle \otimes |n+1\rangle \wedge \cdots \wedge |2n-1\rangle \mapsto |n\rangle \wedge \cdots \wedge |2n-1\rangle \otimes |1\rangle\,,$$

so the minimal element $(\{n,\dots,2n-1\},1)$ is in the image of A_{i_1}. Let (P,ℓ) be in the target space of A_{i_1} and assume that every (P',ℓ') with $(P',\ell') < (P,\ell)$ is in the image. Write $P=(p_1,\dots,p_n)$ with $p_1 \le \cdots \le p_n$. Under A_{i_1} we have,

$$|p_1\rangle \wedge \cdots \widehat{p_\ell} \cdots \wedge |p_n\rangle \otimes |1+p_\ell-\ell\rangle \mapsto \sum_m |p_1\rangle \wedge \cdots \widehat{p_\ell} \cdots \wedge |p_n\rangle \wedge |p_\ell-\ell+m\rangle \otimes |m\rangle\,.$$

Taking $m=\ell$, one sees that the basis element (P,ℓ) is present in the sum. Moreover, for any other (P',m) appearing in the sum we have $(P',m) < (P,\ell)$. Indeed, if $m>\ell$, then $p_\ell-\ell+m > p_\ell$, so the smallest ℓ elements in P' are lexicographically larger than the smallest ℓ elements in P, meaning $(P',m)<(P,\ell)$ by rule 1; if $m<\ell$, then $p_m \le p_\ell-\ell+m < p_\ell$, so the m smallest elements of P' and P are equal, meaning $(P',m)<(P,\ell)$ by rule 2. Therefore, the basis element (P,ℓ) is in the image. This argument shows that A_{i_1} has full rank. Moreover, this argument shows that, up to a permutation of the rows and columns, the matrix A_{i_1} is upper triangular with ones on the diagonal. Repeating this argument with general values for α_{i_1,i_2,i_3} proves the claim. ◀

▶ Remark. The lower bound in Theorem 20 improves a lower bound of Ikenmeyer on the border support rank of IMM_n^3 [11, 8.2.17].

5 Strassen's laser method for iterated matrix multiplication

In this section we show that $\mathrm{NQ}(\mathrm{EQ}_n^{C_k}) < kn$ for odd k. We will prove this result in the language of algebraic complexity theory.

▶ **Definition 21.** Define $\omega_k := \inf\{\alpha \in \mathbf{R} \mid \mathrm{R}(\mathrm{IMM}_n^k) \in \mathcal{O}(n^\alpha)\}$. We call this the *exponent* of iterated matrix multiplication. Define $\omega_{\mathrm{s},k} := \inf\{\alpha \in \mathbf{R} \mid \mathrm{R_s}(\mathrm{IMM}_n^k) \in \mathcal{O}(n^\alpha)\}$. We call this the *support rank exponent* of iterated matrix multiplication.

Asymptotically, we have $\mathrm{NQ}(\mathrm{EQ}_n^{C_k}) \le \omega_{\mathrm{s},k}\, n + \mathcal{O}(1) \le \omega_k\, n + \mathcal{O}(1)$. The exponents ω_3 and $\omega_{\mathrm{s},3}$ are known as ω and ω_{s} in the literature. The support rank exponent of matrix multiplication was first studied by Cohn and Umans [9]. The best upper bound on ω_s comes from the upper bound $\omega \le 2.3728639$ of Le Gall [14]. Interestingly, Cohn and Umans show the relationship

$$\omega \le (3\omega_{\mathrm{s}} - 2)/2.$$

Therefore, one way of finding upper bounds on ω is to construct an efficient quantum communication protocol for the cyclic equality problem $\mathrm{EQ}_n^{C_3}$. On the other hand, this observation indicates that improving the bounds on the quantum communication complexity of $\mathrm{EQ}_n^{C_k}$ is a hard problem.

For any k we have $k-1 \le \omega_k \le k$, and if k is even, then $\omega_k = k$ (Proposition 18). The aim of this section will be to show: if $k \ge 3$ is odd, then

$$\omega_k < k.$$

Schönhage τ-theorem. In this section we will generalize some tools for obtaining upper bounds on the exponent of ω_3 to all exponents ω_k, in particular, we generalize the Schönhage τ-theorem. The proofs in this section are straightforward generalizations of the proofs for $k = 3$ which can be found in [5]. In the next paragraph, we will use Strassen's laser method to show that $\omega_k < k$ for all odd k.

First we recall an important relationship between border rank and rank. We use the following more precise notion of border rank. Let $h \in \mathbf{N}$ and let t be a tensor in $\mathbf{C}^{\otimes m_1} \otimes \cdots \otimes \mathbf{C}^{\otimes m_k}$. Define $\mathrm{R}_h(t)$ to be the minimum number r such that there exist vectors $v_i^j \in (\mathbf{C}[\varepsilon])^{m_j}$ that satisfy $\sum_{i=1}^r v_i^1 \otimes \cdots \otimes v_i^k = \varepsilon^h t + \mathcal{O}(\varepsilon^{h+1})$. A well-known but nontrivial result is that $\underline{\mathrm{R}}(t) = \min_h \mathrm{R}_h(t)$. It is not hard to show that $\mathrm{R}_{h+h'}(t \otimes t') \leq \mathrm{R}_h(t)\,\mathrm{R}_{h'}(t')$. The relationship we are talking about is the following.

▶ **Proposition 22.** *For every $h, k \in \mathbf{N}$, there is a number c_h such that for all tensors $t \in \mathbf{C}^{m_1} \otimes \cdots \otimes \mathbf{C}^{m_k}$, $\mathrm{R}(t) \leq c_h\,\mathrm{R}_h(t)$. The number c_h depends polynomially on h.*

Proof. Let t be a tensor in $\mathbf{C}^{m_1} \otimes \cdots \otimes \mathbf{C}^{m_k}$ with $\mathrm{R}_h(t) = r$. Then there are $v_i^j \in (\mathbf{C}[\varepsilon])^{m_j}$ such that

$$\sum_{i=1}^{r} v_i^1 \otimes \cdots \otimes v_i^k = \varepsilon^h t + \mathcal{O}(\varepsilon^{h+1}).$$

Decomposing every v_i^j into ε-homogeneous components $v_i^j = \sum_{a_j=0}^{h} \varepsilon^{a_j} v_i^j(a_j)$, and collecting powers of ε gives

$$\sum_{i=1}^{r} \sum_{a_1,\ldots,a_k \in [h]} \varepsilon^{a_1+\cdots+a_k}\, v_i^1(a_1) \otimes \cdots \otimes v_i^k(a_k) = \varepsilon^h t + \mathcal{O}(\varepsilon^{h+1}).$$

Taking only the summands such that $a_1 + \cdots + a_k = h$ gives a rank decomposition of t. There are $\binom{h+k-1}{k-1} r$ such summands. ◀

Next, we show that an upper bound on the border rank of 'unbalanced' iterated matrix multiplication tensors yields and upper bound on ω_k. Define the tensor $\langle n_1, n_2, \ldots, n_k \rangle$ to be

$$\sum_{x \in [n_1] \times \cdots \times [n_k]} |x_1 x_2\rangle\, |x_2 x_3\rangle \cdots |x_k x_1\rangle\,.$$

So $\mathrm{IMM}_n^k = \langle n, n, \ldots, n \rangle$ (n occurs k times).

▶ **Proposition 23.** *If $\underline{\mathrm{R}}(\langle n_1, n_2, \ldots, n_k \rangle) \leq r$, then $\omega_k \leq k \log_{n_1 \cdots n_k} r$.*

Proof. Let $N = n_1 \cdots n_k$. There is an h such that $\mathrm{R}_h(\langle n_1, \ldots, n_k \rangle) \leq r$. By taking the tensor product of all cyclic shifts of $\langle n_1, \ldots, n_k \rangle$, we get $\mathrm{R}_{kh}(\langle N, \ldots, N \rangle) \leq r^k$ and thus $\mathrm{R}_{khs}(\langle N^s, \ldots, N^s \rangle) \leq r^{ks}$ for all s. Hence $\mathrm{R}(\langle N^s, \ldots, N^s \rangle) \leq c_{khs} r^{ks}$ for some number c_{khs} which is constant in N. Therefore,

$$\omega \leq \log_{N^s}(c_{khs} r^{ks}) = ks \log_{N^s}(r) + \log_{N^s}(c_{khs}).$$

If s goes to infinity then $\log_{N^s}(c_{khs})$ goes to zero, so $\omega_k \leq k \log_N(r)$. ◀

The real workhorse is the following straightforward generalization of a theorem of Schönhage [16].

▶ **Proposition 24** (k-party Schönhage τ-theorem). *Suppose that $r > p$ and*

$$\underline{\mathrm{R}}\Big(\bigoplus_{i=1}^{p}\langle n_1^i, n_2^i, \ldots, n_k^i\rangle\Big) \leq r.$$

Define τ by $\sum_{i=1}^{p}\big(\prod_{j=1}^{k} n_j^i\big)^{\tau} = r$. Then $\omega_k \leq k\tau$

We follow the proof of [5]. We first prove two lemmas. For tensors $s, t \in \mathbf{C}^{m_1}\otimes\cdots\otimes\mathbf{C}^{m_k}$, let $s \leq t$ denote the existence of an SLOCC transformation mapping t to s. Let $a, b \in \mathbf{N}+1$.

▶ **Lemma 25.** *Let t be a tensor such that $\mathrm{R}(t^{\oplus a}) \leq b$. Then for all s, $\mathrm{R}((t^{\otimes s})^{\oplus a}) \leq \lceil b/a\rceil^s a$.*

Proof. We prove the lemma by induction over s. The base case $s = 1$ follows from the assumption. For the induction step, we have

$$(t^{\otimes s+1})^{\oplus a} = t^{\oplus a}\otimes t^{\otimes s} \leq \mathrm{GHZ}_b \otimes t^{\otimes s} = (t^{\otimes s})^{\oplus b},$$

and thus, by the induction hypothesis,

$$\mathrm{R}((t^{\otimes s+1})^{\oplus a}) \leq \mathrm{R}((t^{\otimes s})^{\oplus b}) \leq \mathrm{R}((t^{\otimes s})^{\oplus(\lceil b/a\rceil a)}) \leq \lceil\tfrac{b}{a}\rceil\lceil\tfrac{b}{a}\rceil^s a \leq \lceil\tfrac{b}{a}\rceil^{s+1} a,$$

proving the lemma. ◀

▶ **Lemma 26.** *If $\mathrm{R}(\langle n_1, n_2, \ldots, n_k\rangle^{\oplus a}) \leq b$, then $\omega_k \leq k\log_{n_1\cdots n_k}\lceil b/a\rceil$.*

Proof. The inequality $\mathrm{R}(\langle n_1, n_2, \ldots, n_k\rangle^{\oplus a}) \leq b$ implies by Theorem 25 the inequality $\mathrm{R}(\langle n_1^s, n_2^s, \ldots, n_k^s\rangle^{\oplus a}) \leq \lceil b/a\rceil^s a$ which by Proposition 23 yields

$$\omega_k \leq k\frac{s\log\lceil\frac{b}{a}\rceil + \log(a)}{s\log(n_1\cdots n_k)},$$

which goes to $k\log\lceil b/a\rceil/\log(n_1\cdots n_k)$ when s goes to infinity. ◀

Proof of Proposition 24. We assume $\underline{\mathrm{R}}\big(\bigoplus_{i=1}^{p}\langle n_1^i, n_2^i, \ldots, n_k^i\rangle\big) \leq r$. This implies that there is an $h \in \mathbf{N}$ such that $\mathrm{R}_h\big(\bigoplus_{i=1}^{p}\langle n_1^i, n_2^i, \ldots, n_k^i\rangle\big) \leq r$. Taking the sth tensor power gives $\mathrm{R}_{hs}\big((\bigoplus_{i=1}^{p}\langle n_1^i, n_2^i, \ldots, n_k^i\rangle)^{\otimes s}\big) \leq r^s$. We expand the tensor power to get

$$\mathrm{R}_{hs}\Big(\bigoplus_{\sigma}\Big(\bigotimes_{i=1}^{p}\langle (n_1^i)^{\sigma_i}, (n_2^i)^{\sigma_i}, \ldots, (n_k^i)^{\sigma_i}\rangle\Big)^{\oplus\binom{s}{\sigma_1,\ldots,\sigma_p}}\Big) \leq r^s,$$

where the first direct sum is over all p-tuples σ of nonnegative integers with sum s. We can also write this inequality as

$$\mathrm{R}_{hs}\Big(\bigoplus_{\sigma}\langle \textstyle\prod_i (n_1^i)^{\sigma_i}, \ldots, \prod_i (n_k^i)^{\sigma_i}\rangle^{\oplus\binom{s}{\sigma_1,\ldots,\sigma_p}}\Big) \leq r^s.$$

There exists a number c_{hs} depending polynomially on h and s such that

$$\mathrm{R}\Big(\bigoplus_{\sigma}\langle \textstyle\prod_i (n_1^i)^{\sigma_i}, \ldots, \prod_i (n_k^i)^{\sigma_i}\rangle^{\oplus\binom{s}{\sigma_1,\ldots,\sigma_p}}\Big) \leq c_{hs}\, r^s.$$

Define τ by $\sum_{i=1}^{p}\big(\prod_{j=1}^{k} n_j^i\big)^{\tau} = r$. Then $\sum_{\sigma}\binom{s}{\sigma_1,\ldots,\sigma_p}\big(\prod_i (n_1^i)^{\sigma_i}\cdots\prod_i (n_k^i)^{\sigma_i}\big)^{\tau} = r^s$. In this sum, consider the maximum summand and fix the corresponding σ. Define the numbers $n_j \coloneqq \prod_i (n_j^i)^{\sigma_i}$. Let $a \coloneqq \binom{s}{\sigma_1,\ldots,\sigma_p}$ and $b \coloneqq r^s c_{hs}$. We apply Theorem 26 to the inequality $\mathrm{R}(\langle n_1, \ldots, n_k\rangle^{\oplus a}) \leq b$ to obtain

$$\omega_k \leq k\tau + \frac{(p-1)\log(s+1) + \log(c_{hs})}{\log(n_1\cdots n_k)},$$

which goes to $k\tau$ when s goes to infinity. (See [5] for more details.) ◀

Strassen's laser method. We will now use Strassen's laser method to prove the main result of this section.

▶ **Theorem 27.** *For any odd k we have $\omega_k < k$.*

We will give a proof for the case $k = 5$, the other cases being similar. Define the 5-tensor $\mathrm{Str}_q^5 = \sum_{i=1}^q |ii000\rangle + |0ii00\rangle$ in $\mathbf{C}^{q+1} \otimes \mathbf{C}^q \otimes \mathbf{C}^{q+1} \otimes \mathbf{C} \otimes \mathbf{C}$.

▶ **Proposition 28.** $\underline{\mathrm{R}}(\mathrm{Str}_q^5) \leq q + 1$.

Proof. Expanding $\sum_{i=1}^q (|0\rangle + \varepsilon\,|i\rangle)\,|i\rangle\,(|0\rangle + \varepsilon\,|i\rangle)\,|0\rangle|0\rangle$ gives

$$\sum_{i=1}^{q} |0i000\rangle + \varepsilon \sum_{i=1}^{q} |ii000\rangle + |0ii00\rangle + \mathcal{O}(\varepsilon^2).$$

Subtracting $|0\rangle\big(\sum_{i=1}^q |i\rangle\big)|000\rangle$ yields $\varepsilon\,\mathrm{Str}_q^5 + \mathcal{O}(\varepsilon^2)$. ◀

▶ **Proposition 29.** $\mathrm{GHZ}_2^5 \leq \langle 2,2,2,2,2\rangle$.

Proof. Let ϕ be the map $|ab\rangle \mapsto \delta_{[a=b]}\,|a\rangle$. Apply $\phi^{\otimes 5}$ to $\langle 2,2,2,2,2\rangle$. This yields one copy of $\mathrm{GHZ}_2^{[5]}$. ◀

▶ Remark. We mention that the subrank result of Proposition 29 can by improved asymptotically in the sense that $\omega(\langle 2,2,2,2,2\rangle, \mathrm{GHZ}^5) = 1/2$ [20]. Using this fact in the proof of Theorem 27 gives the slightly better upper bound $\omega_k \leq \log_q((q+1)^k/4)$.

For the proof of Theorem 27 we have to define the notion of the decomposition of the support of a tensor and the corresponding inner and outer structure of a tensor. Let $I_1, \ldots, I_k$ be finite sets. A *decomposition* $\mathcal{D}$ of $I_1 \times \cdots \times I_k$ is a collection of sets I_i^j such that

$$I_i = \bigsqcup_j I_i^j,$$

meaning that for every i, $\cap_j I_i^j = \emptyset$ and $\cup_j I_i^j = I_i$. Let t be a tensor in $\mathbf{C}^{m_1} \otimes \cdots \otimes \mathbf{C}^{m_k}$ and index the basis elements in this space by elements of $[m_1] \times \cdots \times [m_k]$. Let $\mathcal{D}$ be a decomposition of $[m_1] \times \cdots \times [m_k]$. We view $\mathcal{D}$ as a 'cut' of $[m_1] \times \cdots \times [m_k]$ into smaller product sets and thus as a 'cut' of t into smaller tensors. We define $t|_{I_1^{j_1}, I_2^{j_2}, \ldots, I_k^{j_k}}$ to be the restriction of t to the basis elements in $I_1^{j_1} \times I_2^{j_2} \times \ldots \times I_k^{j_k}$. These smaller tensors we think of as the 'inner structure' of t. We define the 'outer structure' of t with respect to $\mathcal{D}$ to be the tensor $t_{\mathcal{D}}$ indexed by sequences $(j_1, \ldots, j_k)$ such that $t_{\mathcal{D}}$ has a 1 at position $(j_1, \ldots, j_k)$ if t restricted to $I_1^{j_1} \times \cdots \times I_k^{j_k}$ is not the zero tensor, and a 0 otherwise.

Proof of Theorem 27. We will give a proof for the case $k = 5$, the other cases being similar. Define a block decomposition $\mathcal{D}$ of the support $I_1 \times \cdots \times I_5$ of Str_q^5 by

$$I_1 = \{0\} \cup \{1, \ldots, q\}$$
$$I_2 = \{1, \ldots, q\}$$
$$I_3 = \{0\} \cup \{1, \ldots, q\}$$
$$I_4 = \{0\}$$
$$I_5 = \{0\}.$$

We have the outer structure $(\mathrm{Str}_q^5)_{\mathcal{D}} = |11000\rangle + |01100\rangle \cong |10100\rangle + |00000\rangle$. Note that this is just an EPR pair between party 1 and 3. The inner structures are $\sum_{i=1}^q |ii000\rangle$ and

$\sum_{i=1}^{q} |0ii00\rangle$, which are also known as $\langle 1, q, 1, 1, 1\rangle$ and $\langle 1, 1, q, 1, 1\rangle$. Let Cyc_5 be the map $t \mapsto t \otimes \sigma t \otimes \sigma^2 t \otimes \sigma^3 t \otimes \sigma^4 t$ with $\sigma = (12345)$. Let $\hat{\mathcal{D}} = \mathrm{Cyc}_5 \mathcal{D}$ be the naturally corresponding decomposition. Then

$$\langle 2, 2, 2, 2, 2\rangle^{\otimes s} = (\mathrm{Cyc}_5 \operatorname{Str}_q^5)^{\otimes s}_{\hat{\mathcal{D}}^{\otimes s}} \quad \text{and} \quad \underline{\mathrm{R}}\big((\mathrm{Cyc}_5 \operatorname{Str}_q^5)^{\otimes s}\big) \leq (q+1)^{5s}. \tag{1}$$

Note how the first statement relies on 5 being odd.

The inner structure of $(\mathrm{Cyc}_5 \operatorname{Str}_q^5)^{\otimes s}_{\hat{\mathcal{D}}^{\otimes s}}$ consists of tensors from $I \coloneqq \{\langle n_1, n_2, n_3, n_4, n_5\rangle \mid n_1 \cdots n_5 = q^{5s}\}$. Combining equation (1) with Proposition 29 gives that there are 2^s elements $t_1, t_2, \ldots \in I$ such that

$$\underline{\mathrm{R}}(t_1 \oplus t_2 \oplus \cdots) \leq (q+1)^{5s}.$$

Now the τ-theorem says that if we define τ by

$$2^s (q^{5s})^{\tau} = (q+1)^{5s}$$

then $\omega_5 \leq 5\tau$. Therefore,

$$\omega_5 \leq 5\tau \leq \log_q \frac{(q+1)^5}{2}$$

which gives $\omega_5 \leq 4.84438$. In general, one gets $\omega_k \leq \log_q \frac{(q+1)^k}{2}$ which is strictly smaller than k for q large enough. ◀

Quantum Codes from High-Dimensional Manifolds

Matthew B. Hastings

Station Q, Microsoft Research, Santa Barbara and Quantum Architectures and Computation Group, Microsoft Research, Redmond, USA
mahastin@microsoft.com

Abstract

We construct toric codes on various high-dimensional manifolds. Assuming a conjecture in geometry we find families of quantum CSS stabilizer codes on N qubits with logarithmic weight stabilizers and distance $N^{1-\epsilon}$ for any $\epsilon > 0$. The conjecture is that there is a constant $C > 0$ such that for any n-dimensional torus $\mathbb{T}^n = \mathbb{R}^n/\Lambda$, where Λ is a lattice, the least volume unoriented $n/2$-dimensional cycle (using the Euclidean metric) representing nontrivial homology has volume at least C^n times the volume of the least volume $n/2$-dimensional hyperplane representing nontrivial homology; in fact, it would suffice to have this result for Λ an integral lattice with the cycle restricted to faces of a cubulation by unit hypercubes. The main technical result is an estimate of Rankin invariants[24] for certain random lattices, showing that in a certain sense they are optimal. Additionally, we construct codes with square-root distance, logarithmic weight stabilizers, and inverse polylogarithmic soundness factor (considered as quantum locally testable codes[1]). We also provide an short, alternative proof that the shortest vector in the exterior power of a lattice may be non-split[8].

1 Introduction

Quantum CSS stabilizer codes[6] can be understood in terms of homology[18, 13, 4], and different manifolds provide a rich source of different codes. The two-dimensional toric code[18, 13] and four-dimensional toric code[9] are commonly considered examples; they are code families based on families of cellulations of a two and four dimensional tori. Other manifolds[14] provide other interesting properties, such as greater distance, discussed below. In this paper, we consider families of codes based on high dimensional manifolds.

We begin by considering some parameters that quantify a CSS code. The elementary degrees of freedom of a CSS codes are qubits (or, more generally, qudits, for some $d \geq 2$). Let there be N such qudits so that the Hilbert space has dimension d^N. CSS codes can be parametrized by several parameters, which we write as $[[N, K, D, W]]$. Here N is the number of qudits. K is the number of encoded qudits, so that the code has a code space which is a subspace of dimension d^K. D is the "distance" of the code, defined below, while W is the "weight" of the stabilizers, defined also below. Generally speaking, larger K and D is desirable, while smaller W is also desirable (this discussion of desirability of certain values of the parameters ignores other questions like the ability to efficiently decode or encode states, which is a completely separate discussion that we do not consider in this paper).

The best families of quantum codes obtained thus far have significantly worse scaling than the corresponding scaling for classical linear codes. Families of classical codes exist with $K = \Theta(N), D = \Theta(N), W = \mathcal{O}(1)$ (so-called low density parity check codes provide

© Matthew B. Hastings;
licensed under Creative Commons License CC-BY

such an example[15, 20]). If we set $W = \mathcal{O}(1)$, then the largest known distance for a quantum code family is $\Theta(\sqrt{N\log(N)})$as in Ref. [14], while if we want $D = \Theta(N)$, then the lowest known weight is $W = \Theta(\sqrt{N})$ as in Ref. [5]. These parameters refer to stabilizer codes; if one allows subsystem codes[23], then it is possible to achieve $D = \Theta(N^{1-\epsilon}), W = \mathcal{O}(1)$ for $\epsilon = \mathcal{O}(1/\sqrt{\log(N)})$ as in Ref. [3], but now the parameter W does not refer to the weight of a set of commuting stabilizers but rather the to weight of a set of generators of the "gauge group" and these generators need not commute with each other. If one requires that the stabilizer group be generated by local commuting operators, then currently no advantage is known for a subsystem code. Another notable stabilizer code family achieves $K = \Theta(N), D = \Theta(\sqrt{N}), W = \mathcal{O}(1)$ and has efficient an efficient local decoding algorithm[26].

In this paper, we construct code families that, assuming a conjecture in geometry, have almost linear distance and logarithmic weight generators. We review various concepts before giving an overview of the paper.

1.1 Review of CSS Codes and Relation to Homology

The code subspace is the subspace of the d^N-dimensional Hilbert space which is in the $+1$ eigenspace of several "stabilizers". These stabilizers are of two types, called "X-type" and "Z-type". The Z operator on the d-dimensional Hilbert space of a single qudit is the operator

$$Z = \begin{pmatrix} 1 & & & \\ & \exp(\frac{2\pi i}{d}) & & \\ & & \exp(\frac{4\pi i}{d}) & \\ & & & \dots \end{pmatrix}, \tag{1}$$

while the X operator is the operator

$$X = \begin{pmatrix} 0 & 1 & & \\ & 0 & 1 & \\ & & 0 & 1 \\ & & & \dots \\ 1 & 0\dots & & \end{pmatrix}. \tag{2}$$

We write Z_i or X_i to indicate the operator Z or X acting on qudit i, tensored with the identity on all other qudits. Then, a Z-type stabilizer is the tensor product of Z operators on some qubits, possibly raised to integer powers. Such a Z-type stabilizer might be written, for example, $Z_1 Z_3^2$ to indicate that it is the tensor product of Z on qubit 1 with the square of Z on qubit 3. These exponents all can be taken in the range $1, 2, ..., d-1$; if an operator on a given qubit is raised to power 0, we simply do not write it when writing the Z stabilzer. The X-type stabilizers are similar, with Z replaced by X.

We encode the Z-type stabilizers in a matrix that we denote ∂_2. This matrix has N rows and has one column per Z-type stabilizer. The entries of the matrix are over the field $\mathbb{F}_d$. The entry in the i-th row and j-th column indicates which power of Z_i appears in the j-th stabilizer; thus, for example, for the stabilizer $Z_1 Z_3^2$, the first row in the corresponding column would have a 1 and the third row would have a 2 and all other rows would be zero. We encode the X-type stabilizers also in a matrix, denoted by ∂_1. This matrix has N columns and one row per X-type stabilizer, again with the entries over the field $\mathbb{F}_d$. The entry in the i-th row and j-th column indicates which power of X_j appears in the i-th stabilizer

A final requirement on CSS codes is that the stabilizers commute with each other. Any pair of Z-type stabilizers trivially commute, as do any pair of X-type stabilizers. The re-

quirement that the Z-type stabilizer commute with the X-type stabilizers can be simply expressed in terms of ∂_2, ∂_1 as

$$\partial_1 \partial_2 = 0. \tag{3}$$

This requirement is equivalent to saying that there is a chain complex

$$\mathcal{C}_2 \stackrel{\partial_2}{\to} \mathcal{C}_1 \stackrel{\partial_1}{\to} \mathcal{C}_0,$$

where $\mathcal{C}_2, \mathcal{C}_1, \mathcal{C}_0$ are vector spaces over $\mathbb{F}_d$, with basis elements in one-to-one correspondence with Z-type stabilizers, qudits, and X-type stabilizers, respectively. We have $\dim(C_1) = N$.

The number of encoded qudits K is given by the first Betti number, which is equal to $N - \dim(\mathcal{C}_2) - \dim(\mathcal{C}_0)$ assuming that all stabilizers are independent of each other (i.e., that the columns of ∂_2 are linearly independent, as are the rows of ∂_1).

The distance D is defined as follows. Let us say that an operator O is a Z-type logical operator if it is a tensor product of Z operators on qudits which commutes with all X-type stabilizers and which is not itself a product of Z-type stabilizers. In the language of homology, such an operator is a representative of a nontrivial first homology class; write

$$O = \prod_i Z_i^{a_i},$$

where the product ranges over all qudits and a_i are in $\mathbb{F}_d$. Define an N-component vector v with entries a_i, so that the requirement that O commutes with all X-type stabilizers is that $\partial_1 v = 0$, while the requirement that O not be a product of Z-type stabilizers is that v is not in the image of ∂_2. An X-type logical operator is defined similarly, with Z and X integerchanged everywhere in the definition. The weight of a Z-type (or X-type) logical operator O is defined to be the number of qudits i such that Z_i (or X_i)appears in O raised to a nonvanishing power mod d; we say that that Z_i or X_i is in the support of the logical operator. We define D_Z to be the minimum weight of a Z-type logical operator and D_X to be the minimum weight of an X-type logical operator and define the distance D by

$$D = \min(D_X, D_Z). \tag{4}$$

We define the weight W of a code to be the least integer W such that every row and every column of ∂_2 has at most W nonvanishing entries and also every row and every column of ∂_1 has at most W nonvanishing entries. Note that this means that not only does every stabilizer act on at most W different qudits, also every qudit is acted on by at most W different Z-type stabilizers and W different X-type stabilizers.

We define the weight of an operator which is a product of Z and X operators to be the number of qudits on which the operator acts nontrivially; for example, the operator $X_1 X_3$ has weight 2. Thus, every stabilizer has weight at most W.

A vector v in a vector space $\mathcal{C}_k$ is called a k-chain (or simply, a "chain"). If $\partial_k v = 0$, then v is called a k-cycle. The weight of a vector is defined to be the number of nonzero entries in the vector.

1.2 CSS Codes from Manifolds and Systolic Freedom

Conversely, just as one can define a chain complex from a CSS code, one can use a chain complex to define a CSS code. Given any chain complex over some field $\mathbb{F}_d$, one can define a qudit CSS code: choose any vector space in the chain complex to correspond to the qudits,

and then the vector spaces of one higher and one lower dimension correspond to the Z-type and X-type stabilizers. For example, given a triangulation (or cubulation or other discretization) of a four dimensional manifold one can define a chain complex

$$\mathcal{C}_4 \stackrel{\partial_4}{\to} \mathcal{C}_3 \stackrel{\partial_3}{\to} \mathcal{C}_2 \stackrel{\partial_2}{\to} \mathcal{C}_1 \stackrel{\partial_1}{\to} \mathcal{C}_0,$$

where the basis elements of $\mathcal{C}_k$ correspond to k-cells. Then, one can choose any integer q and let the qudits correspond to the q-cells and the Z-type stabilizers correspond to $(q+1)$-cells and the X-type stabilizers correspond to $(q-1)$-cells. The case $q = 2$ is the familiar four-dimensional toric code of Ref. [9], while the cases $q = 0, 4$ are classical repetition codes (Ising models) in the Z or X basis, respectively.

Defining CSS codes from manifolds has several nice advantages. For one, often the distance of the code can be translated into geometric properties of the manifold and (up to some technical details that we discuss below) it can be geometrically interpreted as the least possible volume of a q-dimensional cycle in a nontrivial homology class. Similarly, if the triangulation has a bounded local geometry, then this gives a bound on W.

Naively, it might seem that such constructions will not be able to obtain a better-than-square-root distance, i.e. $D = \Omega(\sqrt{N})$. We now give some intution for this naive belief, and give a more detailed discussion of the relation between volume and number of qudits in one particular example, as it will be useful later. Consider an n-dimensional torus constructed from a hypercube of length ℓ on each side for some integer ℓ by gluing the opposite faces together. Introduce coordinates $(x_1, \ldots, x_n)$. Discretize the torus by hypercubes of unit length in the obvious way, so that the 0-cells are at integer values of the coordinates. In this case, the volume of the torus equals the number of hypercubes in the discretization, which equals ℓ^n. The number of qudits is given by

$$N = \ell^n \binom{n}{q},$$

while

$$D_Z = \ell^q, \quad D_X = \ell^{n-q}.$$

To see that $D_Z \leq \ell^q$, one can pick any q-dimensional plane where q of the coordinates assume arbitrary values and the other coordinates are held fixed at integer values; then, the product of Z over the q-cells in this plane give a logical operator. We omit the proof that this upper bound for D is tight in this case. The value of D_X is given by picking any $(n-q)$-dimensional plane on the dual lattice and then taking the product of X over the the q-cells that intersects this plane also gives a logical operator.

Choosing the optimal value, $q = n/2$ still leads only to $D = \Theta(\sqrt{N})$. Varying the geometry of the torus by changing the aspect ratio (i.e., keeping the sides of the torus orthogonal to each other but changing the relative lengths) does not lead to any improvement.

However, this naive belief is false. "Systolic freedom" is the term for a concept due to Gromov[2], that one may have manifolds for which the product of the q-systole (the least volume cycle representing a nontrivial element of q-th homology) times the $(n-q)$-systole may be arbitrarily larger than the volume of the manifold. This phenomenon was originally observed for integer homology (corresponding to qudit quantum codes with large d), while only later in Ref. [14] was it constructed for $\mathbb{Z}_2$ homology.

1.3 Overview of Paper

In the original construction of systolic freedom[2], the topology of the manifold was held fixed and the metric was varied to obtain a diverging ratio between the product of the q-

systole and the $(n-q)$-systole to the volume of the manifold (for some given pairs $q, n-q$), while in the $\mathbb{Z}_2$ case[14], the topology of the manifold was varied to obtain a diverging ratio. In this paper, we consider instead a family of manifolds with different dimension. Most of the paper is devoted to considering tori $\mathbb{R}^n/\Lambda$ for certain random lattices Λ. In section 2 we make various definitions of the random lattices and define Rankin invariants. In section 3 we give an overview of the construction and present a geometric conjecture 1 and state theorem 5 that, assuming the conjecture, there exist quantum CSS codes with logarithmic weight and almost linear distance. In section 4 we prove lower bounds on the Rankin invariant of certain random lattices, which is the main step in proving theorem 5. In section 5 we discuss some obstacles to proving even a weaker form of conjecture 1 (involving cycles with integer coefficients) and we consider shortest vectors in the exterior product of a lattice. Finally, in section 6 we give some alternative constructions which have only square-root distance but which have inverse polylogarithmic soundness parameters as quantum locally testable codes[1].

To give some motivation to our lattice construction, consider the two-dimensional toric code. On a square lattice with length ℓ on each side, there are $2\ell^2$ qubits and the distance ℓ. Suppose we ignore the details of the cellulation and take an arbitrary torus $\mathbb{R}^2/\Lambda$, pretending that the number of qubits is equal to the area (ℓ^2) and the distance is equal to the shortest vector in the lattice Λ. Then, a slightly better geometry than the square lattice would be to take the hexagonal lattice, as the ratio of the square of the length of the shortest vector to the area of the torus is equal to $2/\sqrt{3}$ rather than 1. This is only a slight constant improvement over the square lattice. However, in higher dimensions, the shortest vector in lattice Λ can be roughly $\sqrt{n}$ longer than the $1/n$ power of the volume of the torus $\mathbb{R}^n/\Lambda$. Further, if we consider least volume cycles representing nontrivial homology for $q > 1$, then larger improvements are possible (at least for cycles which are hyperplanes). This motivates our construction and the consideration of so-called "Rankin invariants"[24].

In this paper, we will consider codes based on cellulations of such tori (in higher dimensions) where the sides of the torus are not orthogonal. These tori will be $\mathbb{R}^n/L$ for some lattice L, where the lattice does not have a basis of orthogonal vectors. However, L will be an integral lattice, so that it is still possible to cellulate $\mathbb{R}^n/L$ by unit hypercubes. This is done by taking the obvious cellulation of $\mathbb{R}^n$ by unit hypercubes (i.e., every unit hypercube whose vertices are at integer points is a cell in the cellulation) and then identifying cells that differ by translation by a lattice vector. Fig. 1 gives a simple example in the case $n = 2$.

2 Random Lattices and Definitions

Consider a so-called LDA lattice[7, 10] as follows. We pick a prime p. We will construct a lattice which is a subset of $\mathbb{Z}^n$ for some even n. We first construct a linear code over field $\mathbb{F}_p^n$. We define this code by a "code generator matrix" G which is an n-by-k matrix such that the *column* vectors are a basis for the codewords. (We explicitly call it a "code generator matrix" rather than just a "generator matrix", as we will also consider lattice generator matrices later.) Usually in coding theory, it is instead conventional to let the *rows* of a code generator matrix be the basis for a code, but to maintain consistency with notation we use later, we instead use the *columns* as the basis. We choose the entries of G independently and uniformly from $\mathbb{F}_p$.

We will be interested in taking n large at fixed ratio $k/n < 1$. With high probability (i.e., with probability tending to 1 as $n \to \infty$ with k/n fixed), G is non-degenerate (see next paragraph). Assuming that G is indeed non-degenerate, one can find a permutation of the

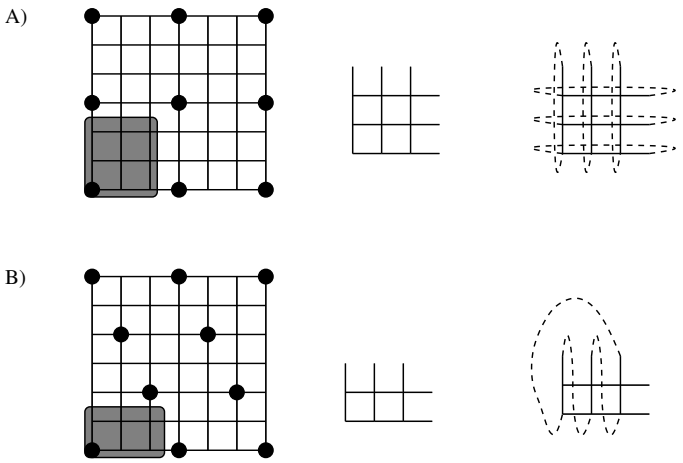

Figure 1 Leftmost part of A) shows part of a cellulation of $\mathbb{R}^2$ by unit squares, as well as showing a lattice L with basis vectors $(3,0)$ and $(0,3)$. Solid circles represent points of L. The shaded region contains a maximal set of points in $\mathbb{Z}^2$ which do not differ by translation by L. Middle part of A) shows 0-cells of the shaded region, as well as 1- and 2-cells attached to them. Rightmost part of A) shows how the 1-cells in the middle part are attached: the dashed lines indicate that the top of a given 1-cell on the top of the figure is attached to a 0-cell at the bottom. Similarly for attaching cells on the right to those on the left. Figure B) is similar, but now L has basis vectors $(3,0)$ and $(2,2)$. Now the dashed lines indicate that a 1-cell on the top of the figure is attached to a 0-cell on the bottom, but that 0-cell is translated horizontally (horizontal dashed lines are not shown in B; they are the same as in A). For both A,B, the code has distance 3, but B has smaller volume.

rows such that G is in the form

$$G = \begin{pmatrix} A \\ B \end{pmatrix}$$

where A, B are k-by-k and $(n-k)$-by-k matrices with A non-degenerate. Then, since A is non-degenerate there exists a sequence of elementary column operations that brings A to the identity matrix, where for a matrix over $\mathbb{F}_p^n$ an elementary column operation is one of: adding one column to another, multiplying a column by any nonzero element of the field, or interchanging two columns. These column operations bring G to the form

$$G = \begin{pmatrix} I \\ C \end{pmatrix},$$

where I is the k-by-k identity matrix and C is some $(n-k)$-by-k matrix. Since the entries of C are obtained by applying these column operations to the entries of B, the entries of C are chosen independently of each other and uniformly from $\mathbb{F}_p$, i.e., applying any elementary column operation to an ensemble of matrices with entries chosen uniformly and independently leaves this ensemble invariant. This is the form of G that we work with in the rest of this section.

▶ **Definition 1.** Let the lattice L_0 be the set of points $x_1, ..., x_n$ in $\mathbb{Z}^n$ such that the vector $(x_1 \mod p, ..., x_n \mod p)$ is in the linear code defined by G.

We now show that with high probability, G is non-degenerate. With probability $1 - (1/p)^n$, the first column of G has a nonzero entry. By elementary column operations, adding a multiple of the first column to other columns, we can set all other columns equal to zero

in the first row for which the first column has a nonzero entry. Then, with probability $1-(1/p)^{n-1}$, the second column has a nonzero entry in some other row. Add a multiple of the second column to the third, fourth,... column to set them equal to zero in the first row for which the second column has a nonzero entry. Continuing in this fashion, the probability that G is non-degenerate is $(1-(1/p)^n)(1-(1/p)^{n-1})\dots(1-(1/p)^{n-k+1})$ which indeed is $1-o(1)$.

The lattice L_0 is the set of integer linear combinations of the columns of G (interpreted as vectors of integers, rather than as vectors of elements of $\mathbb{F}_p$) and of the n vectors with a p in one coordinate and zeroes elsewhere. Then, the lattice L_0 is the set of integer linear combinations of the columns of the matrix

$$\begin{pmatrix} I & pI & 0 \\ C & 0 & pI \end{pmatrix},$$

where the row blocks have sizes k and $n-k$ respectively, while the column blocks have sizes k, k, $n-k$, and respectively, and where I is the identity matrix of appropriate size. However, any integer linear combination of column vectors of $\begin{pmatrix} pI \\ 0 \end{pmatrix}$ is also an integer linear combination of column vectors of

$$\begin{pmatrix} I & 0 \\ C & pI \end{pmatrix}.$$

To see this, consider any vector of integers $\vec{y} = (y_1, ..., y_k)$. Then,

$$\begin{pmatrix} pI \\ 0 \end{pmatrix} \vec{y} \quad = \quad \begin{pmatrix} I \\ C \end{pmatrix} p\vec{y} - \begin{pmatrix} 0 \\ pI \end{pmatrix} C\vec{y}. \tag{5}$$

Thus, L_0 is the set of integer linear combinations of columns of the matrix

$$B_0 = \begin{pmatrix} I & 0 \\ C & pI \end{pmatrix}.$$

A matrix B such that the lattice is the set of integer combinations of columns of B is called a generating matrix for the lattice. Two different generating matrices B_1, B_2 define the same lattice if and only if $B_1 = B_2 T$ where T is an integer matrix such that T^{-1} also is an integer matrix. In this case, the matrix B_1 can be turned into the matrix B_2 by a sequence of elementary column operations where an elementary column operations is one of: adding one column to another, changing the signs of all entries in a column, or interchanging two columns.

Given a lattice L with generating matrix B which is an n-by-k matrix, such that B has rank k, we define the volume of the lattice to equal $\mathrm{vol}(L) = \det(B^\dagger B)^{1/2}$. If $k = n$, then $\mathrm{vol}(L) = |\det(B)|$.

▶ **Definition 2.** Given any linearly independent set of vectors $x_1, ..., x_k$ in $\mathbb{Z}^n$ (or more generally in $\mathbb{R}^n$) we define their volume $\mathrm{vol}(x_1, ..., x_k)$ to be the volume of the lattice generated by the n-by-k matrix with columns $x_1, ..., x_k$.

This matrix B_0 is lower triangular and so $\det(B_0)$ is easily computed:

$$\mathrm{vol}(L_0) = |\det(B_0)| = p^{n-k}. \tag{6}$$

▶ **Definition 3.** An "integral lattice" is defined to be a lattice whose generating matrix has integer entries. A "primitive lattice" is defined to be an integral lattice such that there is no

other integral lattice of the same rank properly containing it, where the rank of a lattice is defined to be the dimension of the subspace spanned by points in the lattice. Equivalently, a primitive lattice is an integral lattice such that there is no integral lattice which spans the same subspace and properly contains it.

Example: in two dimensions, the lattice generated by the vector $(2, 1)$ is primitive, while that generated by $(4, 2)$ is not.

Unless specified, all lattices will be in n dimensions. We use $|\dots|$ to denote the ℓ_2 norm of a vector.

Finally, we define the Rankin invariant.

▶ **Definition 4.** The Rankin invariant $\gamma_{n,m}(L)$ for a lattice L with rank n is defined to be

$$\gamma_{n,m}(L) = \min_{\substack{v_1,\dots,v_m \in L \\ \mathrm{vol}(v_1,\dots,v_m)\neq 0}} \left(\frac{\mathrm{vol}(v_1,\dots,v_m)}{\mathrm{vol}(L)^{m/n}}\right)^2. \tag{7}$$

The square in the above definition is included for historical reasons. The factor m/n in the exponent of $\mathrm{vol}(L)$ is such that the invariant is unchanged under rescaling the lattice L by any constant factor. In the case $m = 1$, the Rankin invariants $\gamma_{n,1}(L)$ is related to the length of the shortest vector: $\gamma_{n,1}(L) = \min_{x\in L, x\neq 0} \frac{|x|^2}{\mathrm{vol}(L)^{2/n}}$. Clearly, $\gamma_{n,n}(L) = 1$ for all L.

The Rankin invariant $\gamma_{n,1}(L)$ is related to the length of the shortest vector in the lattice. To understand the higher Rankin invariants, consider a set of vectors $v_1, ..., v_m \in L$ with $\mathrm{vol}(v_1, ..., v_m) \neq 0$. Consider the torus $\mathbb{R}^n/L$. The m-dimensional hyperplane spanned by $v_1, ..., v_m$ represents a nontrivial integer homology class and has an m-dimensional volume (using the Euclidean metric) equal to $\mathrm{vol}(v_1, ..., v_m)$.

One can also understand the higher Rankin invariants in another way. A choice of vectors $v_1, ..., v_m \in L$ with $\mathrm{vol}(v_1, ..., v_m) \neq 0$ corresponds to a basis for a rank-m sublattice of L. Thus, the Rankin invariants are a lower bound on the volume of rank-m sublattices. This interpretation will be used later, in section 4.

3 Overview of Construction: Conjectures and Main Result on Distance

We will consider a family of CSS codes obtained by choosing a fixed $p > 1$ and taking LDA lattices with $k = n/2$ from the random ensemble above, for all (even) values of n. With high probability, this lattice has rank n. Given the integral lattice L_0, we take a cellulation of the torus $\mathbb{R}^n/L_0$ by hypercubes of length 1 on each side. Then, we consider a qubit toric code on this cellulation with degrees of freedom on q-cells for $q = n/2$. Then, the number of q-cells is equal to

$$N = \binom{n}{n/2} p^{n/2}. \tag{8}$$

The distance of the code is equal to the weight of the least weight logical X or Z operator. The vector corresponding to such an operator represents nontrivial homology or cohomology with $\mathbb{Z}_2$ coefficients. We conjecture that:

▶ **Conjecture 1.** *There exists a constant $C > 0$, such that for any n-dimensional integral lattice L, for the toric code obtained by the cellulation using integer hypercubes and degrees of freedom on q-cells for $q = n/2$, the distance is lower bounded by*

$$C^n \min_{\substack{v_1,\dots,v_q \in L \\ \mathrm{vol}(v_1,\dots,v_q)\neq 0}} \mathrm{vol}(v_1, ..., v_q) = C^n \mathrm{vol}(L)^{q/n} \gamma_{n,q}(L)^{1/2}$$

.

Let us motivate this conjecture. The least volume hyperplane representing nontrivial homology has volume equal to the Rankin invariant. This hyperplane need not lie on the q-cells that we have chosen. We can deform the hyperplane to get a cycle that lies on the q-cells using the Federer-Fleming deformation theorem[11]: this theorem is based on deforming the cycle to lie on the $(n-1)$-skeleton (i.e., the $(n-1)$-dimensional faces of the hypercubes of unit size), then on the $(n-2)$-skeleton, and so on, iteratively, until the cycle lies on the q-skeleton. The deformation to move cycle from the m-skeleton to the $(m-1)$-skeleton is done by choosing a point randomly in an m-dimensional hypercube and then projecting the cycle outwards from that point to the boundary. This deformation may increase the volume, but that is fine: what we are considered with is lower bounding the volume.

However, it is not clear that the optimal operator is obtained by such a deformation procedure starting from a hyperplane. There may be, for example, unoriented chains which are not hyperplanes but which represent nontrivial homology and have much smaller volume than the least volume hyperplane. The conjecture is that such cycles can have at most exponentially smaller (i.e., smaller by a factor C^n) volume.

Conjecture 1 considers the distance of the code, which is equal to the least volume of a $\mathbb{Z}_2$ cycle representing nontrivial homology. The cycles are in the chain complex obtained from the cellulation using hypercubes. One may be tempted to make a (possibly stronger) conjecture that a similar inequality holds for more general chains, such as smooth chains. This conjecture has a purely geometrical statement:

▶ **Conjecture 2.** *There exists a constant $C > 0$, such that for any n-dimensional lattice L, the $n/2$-systole with $\mathbb{Z}_2$ coefficients of the torus $\mathbb{R}^n/L$ is lower bounded by*

$$C^n \min_{\substack{v_1,\ldots,v_q \in L \\ \mathrm{vol}(v_1,\ldots,v_q)\neq 0}} \mathrm{vol}(v_1,...,v_q) = C^n \mathrm{vol}(L)^{q/n} \gamma_{n,q}(L)^{1/2} \ .$$

Conjecture 1 would follow from conjecture 2 since the systole is defined by taking the infimum over smooth cycles, while in conjecture 1 we restrict to cycles which lie on the cellulation by unit hypercubes. In this regard, we remark that the possible increase in volume from the Federer-Fleming deformation theorem may be superexponentially large: the upper bound is at most $2n^{n/2}\binom{n}{n/2}$ (see Ref. [12]).

In this paper, we prove that:

▶ **Theorem 5.** *Assume that conjecture 1 holds. Then, for any $\epsilon > 0$, there exists a family of quantum CSS codes on N qubits with distance $D = \Omega(N^{1-\epsilon})$ and weight $w = \mathcal{O}(\log(N))$ and with $\Theta(N^\delta)$ encoded qubits, where $\delta > 0$ (δ depends on ϵ).*

This theorem will follow from a corollary of theorem 23, which implies that for any constant $c < 1/\sqrt{2\pi e}$, with high probability we have $\min_{\substack{v_1,\ldots,v_q \in L \\ \mathrm{vol}(v_1,\ldots,v_q)\neq 0}} \mathrm{vol}(v_1,...,v_q) \geq (cp)^{n/2}$. Hence, with high probability, $D \geq (cC^2p)^{n/2}$. Since $N = \binom{n}{n/2}p^{n/2} \leq (4p)^{n/2}$, with high probability we have

$$D \geq (cC^2p)^{\log_{4p}(N)} = N^{\frac{\log(cC^2p)}{\log(4p)}} .$$

Fixing c to be any constant slightly smaller than $1/\sqrt{2\pi e}$, we find that for any $\epsilon > 0$ that for all sufficiently large p we have

$$1 - \epsilon \leq \frac{\log(cC^2p)}{\log(4p)}$$

so that $D \geq N^{1-\epsilon}$.

We have $w = \mathcal{O}(d) = \mathcal{O}(\log(N))$.

The number of encoded qubits is equal to $\binom{n}{k} = 2^{(1-o(1))n} = 2^{2(1-(o(1))\log_{4p}(N)} = N^{2(1-o(1))/\log(4p)} \equiv N^{\delta}$.

The main work will be theorem 23, to lower bound the Rankin invariant for this class of lattices. The reader may wonder why we introduce this class of lattices, instead of re-using previous results which show that there exist random lattices with a large Rankin invariant, $\gamma_{n,n/2}(L) \geq (\frac{k}{12})^{n/4}$. See theorem 3 in Ref. [16]. The reason is that the random lattices constructed there need not be integral lattices and so we do not have such an obvious cell decomposition to place on the lattices. We comment later on the relationship between the Rankin invariant for our lattice (which depends on n, p) and the invariant in Ref. [16]; this requires considering how large n needs to be compared to p in our construction.

Note that we choose p large so that the exponentially growing factor, $\approx 2^n$, arising from the factor $\binom{n}{n/2}$ in the number of cells will be polynomially smaller than the volume $p^{n/2}$. We have $2^n = (p^n)^{1/\log_2(p)}$.

We remark that similar code constructions can be made by choosing degrees of freedom on q-cells for $q \neq n/2$, taking n large at a fixed ratio q/n. In this case, a natural generalization of conjecture 1 is to assume that there is a constant C such that $d_Z \geq C^n \mathrm{vol}(L)^{q/n} \gamma_{n,q}(L)^{1/2}$ and $d_X \geq C^n \mathrm{vol}(L)^{(n-q)/n} \gamma_{n,n-q}(L)^{1/2}$. Assuming this conjecture, our construction would give a code with $d_X d_Z$ polynomially larger than N.

4 Rankin Invariants

In this section, we will prove lower bounds on the Rankin invariants[24] $\gamma_{n,m}(L_0)$ of L_0. The proof uses the probabilistic method; in particular, we use the first moment method. To motivate the proof, let us first sketch a proof method for $\gamma_{n,1}(L_0)$; then, we give a sketch a possible extension of the proof method to $\gamma_{n,m}(L_0)$ and explain some difficulties with this extension; finally, we outline the approach we use which is a modification of that. First, suppose we just want to lower bound $\gamma_{n,1}(L_0)$; i.e., we wish to lower bound the shortest vector in the lattice. This can be done by a first moment method: estimate the number of integer vectors with length less than some given length ℓ; then, compute the probability that any given integer vector is in the lattice (this probability is $p^{-(n-k)}$ for a randomly chosen code assuming G is non-degenerate); so, for sufficiently small ℓ, the average number of integer vectors with length less than ℓ in the lattice is small so it is unlikely that any integer vectors with length less than ℓ will be in the lattice. One might attempt to do something similar for the Rankin invariants: estimate the number of rank m integral lattices in n dimensions with volume at most V and then compute the probability that an integral lattice is in a randomly chosen linear code, i.e., that this integral lattice is a sublattice of L_0. Call this rank-m lattice K and call its generating matrix M_K. In fact, Ref. [25] provides asymptotic estimates (large V) for the number of such lattices K, so it might seem that one could directly use the results there in a first moment method. Indeed, this approach might work, but since the results of Ref. [25] hold in the asymptotic limit (large V), some additional estimates would be needed (we do use many results in Ref. [25]). However, the results we need are in some ways simpler than that of Ref. [25] because we do not care about an exact estimate of the number of such lattices, only an upper bound. Further, rather than applying the first moment method by estimating the number of lattices K with some given volume and estimating the probability that such a lattice is in the code and then showing that the product is small for small V, we will apply the first moment method to each column of the generating matrix M_K *separately* (with M_K written in Hermite normal form). That is, we

first estimate (this step is exactly analogous to the discussion at the start of this paragraph regarding how to lower bound $\gamma_{n,1}(L_0)$) the probability that there is a choice for the first column which has small length and which is in the code. Then, we estimate the probability that there is a choice for the second column which is also in the code such that the ratio of the volume of the lattice generated by the first two columns of M_K to the volume of the lattice generated by the first column of M_K is small. To do this calculation, we need the concept of "factor lattice" [25], reviewed below. We continue in this fashion over the other columns, showing that the ratio of the volume of the lattice generated by the first a rows of M_K to the volume of the lattice generated by the first $a-1$ rows of a is likely to be large, for each $a = 2, 3, \ldots$.

4.1 Counting Points

Let $V_d(r)$ denote the volume of a ball of radius r in d dimensions:

$$V_d(r) = \frac{\pi^{d/2}}{\Gamma(\frac{d}{2}+1)} r^d. \tag{9}$$

Given a rank-l lattice L which spans some space E, we define the Voronoi cell to be the set of points y in E such that $|y| \leq |y-v|$ for all lattice points $v \neq 0$. The l-dimensional volume of the Voronoi cell is equal to $\mathrm{vol}(L)$.

▶ **Definition 6.** Given a lattice L, let $N(L, z, r)$ denote the number of points in lattice L within distance r of some given point z.

▶ **Lemma 7.** *Let L be a rank-l lattice in d dimensions which spans some space E. Suppose the diameter of the Voronoi cell of L is bounded by some given D. Then, for any z, r,*

$$N(L, z, r) \leq \frac{1}{\mathrm{vol}(L)} V_l(r+D). \tag{10}$$

Proof. For every point $x \in L$ within distance r of z, let T_x be the set of points $y \in E$ such that $y-x$ is in the interior of the Voronoi cell. The sets T_x are non-overlapping and each has l-dimensional volume $\mathrm{vol}(L)$. So, the volume of $\cup_{x,|x-z|\leq r} T_x$ is equal to $N(L, z, r)\mathrm{vol}(L)$. Every x is within distance r of z and so every point in $\cup_{x,|x-z|\leq r} T_x$ is within distance $r+D$ of z, so $N(L, z, r)\mathrm{vol}(L) \leq V_k(r+D)$. ◀

We make some more definitions.

▶ **Definition 8.** Given a rank-l lattice L spanning a subspace E, the polar lattice L^P is the lattice of all vectors in E which have integral inner products with all vectors in L. The polar lattice also has rank l and $\mathrm{vol}(L^P)\mathrm{vol}(L) = 1$.

▶ **Definition 9.** Let Γ_0^n be the rank-n lattice in n dimensions consisting of all vectors for which all coordinates are integral.

▶ **Definition 10.** Given a primitive lattice L spanning subspace E, the orthogonal lattice $L^\perp$ consists of all vectors in Γ_0^n with vanishing inner product with all vectors in L.

▶ **Definition 11.** Let L be a rank-l primitive sublattice of Γ_0^n and let E be the subspace spanned by L. Let π project onto the orthogonal complement of E, which we write $E^\perp$. Let $\pi(\Gamma_0^n) \equiv \Gamma_0^n / L$. Then, Γ_0^n / L is also a lattice, called the factor lattice. It has rank $n-l$

We have[25]

$$\mathrm{vol}(L)\mathrm{vol}(\Gamma_0^n/L) = 1. \tag{11}$$

This equation follows from this lemma:

▶ **Lemma 12.**

$$\Gamma_0^n/L = ((L)^\perp)^P. \tag{12}$$

Proof. See Ref. [25]. ◀

▶ **Lemma 13.** *Let L be a rank-l primitive sublattice of Γ_0^n. Let π and Γ_0^n/L be as above. Then, the diameter of the Voronoi cell of Γ_0^n/L is bounded by $\sqrt{n-l}$.*

Proof. Since L has rank $l < n$, there must be some vector w_1 which has a 1 in one coordinate and zeroes in all other coordinates (i.e., w_1 is of the form $(0, \ldots, 0, 1, 0, \ldots, 0)$) which is not in E. Then, since the span of E and w_1 has dimension $l+1$, if $k < n-1$, there must be some other vector w_2 of the same form which is not in the span of E and l_1. Proceeding in this fashion, we construct vectors $w_1, ..., w_{n-l}$, all of which have zeroes in all but one coordinate and a 1 in that coordinate. The vectors $\pi(w_i)$ span $E^\perp$. So, every point y in $E^\perp$ can be written as a linear combination $y = \pi(\sum_i a_i w_i)$. If the a_i are integer, then y is a lattice point in $\pi(\Gamma_0^n)$. Every linear combination $\sum_i a_i w_i$ is within distance $(1/2)\sqrt{n-l}$ of some linear combination $\sum_i b_i w_i$ with integer b_i (to see this, simply round all a_i to the nearest integer). Since the norm does not increase under projection, every $\pi(\sum_i a_i w_i)$ is also within distance $(1/2)\sqrt{n-l}$ of some $\pi(\sum_i b_i w_i)$ for integer b_i and hence every point in E is within distance $(1/2)\sqrt{n-l}$ of a lattice point. ◀

We remark that the lattice with basis vectors $\pi(w_i)$ may not include all points in $\pi(\Gamma_0^n)$; as an example, consider $l = 1$ and $n = 2$ and let L be the lattice with basis vector $(2, 1)$ and let $w_1 = (0, 1)$. The vector $\pi((1, 0))$ is then not included in the lattice with basis vector $\pi(w_1)$.

▶ **Lemma 14.** *Let L be a rank-l primitive sublattice of Γ_0^n. Let π and Γ_0^n/L be as above. The number of points in Γ_0^n/L within distance r of the origin is bounded by*

$$N(\Gamma_0^n/L, 0, r) \leq \mathrm{vol}(L)V_l(r + \sqrt{n-l}). \tag{13}$$

Proof. This follows from lemmas 7,13 and Eq. (11). ◀

4.2 Hermite Normal Form For Lattices

Consider a rank-m integral lattice K in n dimensions. If this lattice has basis vectors $v_1, ..., v_m$, we write an n-by-m matrix M_K whose columns are these basis vectors. We label the rows of the matrix by integers $1, \ldots, n$ and label the columns by integers $1, \ldots, m$. Such a matrix is called a lattice generator matrix for the lattice. Then, the set of points in the integral lattice is the image under M_K of Γ_0^m. By a sequence of column operations (adding one column of M_K to another column, which does not change the image, or changing the sign of a column, which also does not change the image), we can bring always bring the matrix M_K to so-called "Hermite normal form"; further, there is a unique matrix M_K in Hermite normal form which generates K.

Our definition of Hermite normal form differs from that of other authors because we will *reverse* the order of columns and *reverse* the order of rows compared to the usual order. This is because we will be doing induction later and with the reversed order of columns, the notation will be much more natural later. See Eq. (17) for an example of Hermite normal form below.

▶ **Definition 15.** A matrix M_K is said to be in Hermite normal form if for every column j there is a row i_j with $1 \leq i_1 < i_2 < \ldots < i_m \leq n$ such that the entries of M_K obey:

$$i > i_j \quad \rightarrow \quad (M_K)_{i,j} = 0 \tag{14}$$

and

$$(M_K)_{i_j,j} > 0, \tag{15}$$

and

$$l > j \quad \rightarrow \quad 0 \leq (M_K)_{i_j,l} < (M_K)_{i_j,j}. \tag{16}$$

We say that "the first a columns of M_K are in Hermite normal form" if the submatrix of M_K consisting of the first a columns is in Hermite normal form. In this case, for every column j with $j \leq a$ there is a row i_j with $1 \leq i_1 < i_2 < \ldots < i_a \leq n$ such that Eqs. (14,15,16) hold when restricted to the case that $j \leq a$ and $l \leq a$.

We introduce some notation. This notation defines various vector spaces and vectors in terms of the matrix M_K; we do not explicitly write M_K in the definition, but rather the particular choice of M_K should be clear in context. The last nonzero entry in the j-th column occurs in the i_j-th row. Define a sequence of lattices $K_1, K_2, ..., K_m$, where K_j has rank j and K_j is defined to be the lattice generated by the submatrix of M_K containing the first j rows and the first i_j columns. Note that $K_m = K$. Note also that if K_a is primitive then K_b is primitive for all $b < a$.

We let $\vec{v}_j$ be the vector given by the first i_j rows of the j-th column.

This notation can be clarified with an example of $n = 5, m = 3$, with $i_1 = 2, i_2 = 4, i_3 = 5$, where we write

$$M_K = \begin{pmatrix} (\vec{v}_1)_1 & (\vec{v}_2)_1 & (\vec{v}_3)_1 \\ (\vec{v}_1)_2 & (\vec{v}_2)_2 & (\vec{v}_3)_2 \\ 0 & (\vec{v}_2)_3 & (\vec{v}_3)_3 \\ 0 & (\vec{v}_2)_4 & (\vec{v}_3)_4 \\ 0 & 0 & (\vec{v}_3)_5 \end{pmatrix}, \tag{17}$$

with $(\vec{v}_j)_i$ denoting the i-th entry of vector $\vec{v}_j$. For this matrix to be in Hermite normal form, we have $0 \leq (\vec{v}_2)_2, (\vec{v}_3)_2 < (\vec{v}_1)_2$ and $0 \leq (\vec{v}_3)_4 < (\vec{v}_2)_4$.

The lattice K_j is a sublattice of $\Gamma_0^{i_j}$. We let M_{K_j} be the submatrix of M_K consisting of the first j rows and the first i_j columns so that M_{K_j} generates K_j. We also define a lattice $\tilde{K}_j$ which is a sublattice of $\Gamma_0^{i_{j+1}}$. The lattice $\tilde{K}_j$ will be the sublattice generated by the submatrix of M_K consisting of the first j rows and the first i_{j+1} columns. We let $M_{\tilde{K}_j}$ be the submatrix of M_K consisting of the first j rows and the first i_{j+1} columns. Hence, the last $i_{j+1} - i_j$ entries of every vector in $\tilde{K}_j$ are equal to 0.

Let π_j project onto the orthogonal complement of the span of $\tilde{K}_j$.

▶ **Lemma 16.** *Let K be a rank-m lattice in n dimensions with generating matrix M_K in Hermite normal form. Then, there exist an n-by-m integer matrix M_{K^P} which is a lattice generating matrix in Hermite normal form (with the same i_j as M_K) for a primitive lattice, and an m-by-m integer matrix F which is upper triangular with positive diagonal entries such that we have*

$$M_K = M_{K^P} F. \tag{18}$$

Further, F, M_{K^P} are unique.

Proof. Let K^P be a primitive lattice spanning the same space as K and containing the lattice K. (Note that such a primitive K^P must exist and is unique: it is the lattice consisting of all integer points which are in the space spanned by K). Let K^P be generated by M_{K^P} with M_{K^P} in Hermite normal form; note that since K^P is unique, M_{K^P} is uniquely determined by K. Then, since K is contained in K^P, every column of M_K is an integer linear combination of columns of M_{K^P}. So, $M_K = M_{K^P}F$ for some integer matrix F.

M_K, M_{K^P} must have the same i_j or their columns would not span the same space.

Since M_K, M_{K^P} have the same i_j, it follows that F is upper triangular with positive diagonal entries: restrict M_K, M_{K^P} to the rows $i_1, i_2, \ldots, i_m$, giving upper triangular matrices of size m-by-m. Call these matrices A, B respectively. Then $A = BF$, so $F = B^{-1}A$. Since B is upper triangular, so is B^{-1} and so is F. ◀

4.3 Counting Column Choices

▶ **Definition 17.** A lattice L is *consistent* with a code generator matrix G if every point $(x_1, ..., x_n)$ in the lattice has the property that $(x_1 \mod p, \ldots, x_n \mod p)$ is in the code defined by G. A lattice generator matrix M_L is consistent with a code generator matrix G if the lattice generated by M_L is consistent with G.

We will use a to label a column choice, $1 \leq a \leq m$. We will construct lattices K_a in terms of K_{a-1} and $\vec{v}_a$.

▶ **Lemma 18.** *Let M_K be in Hermite normal form. Then,*

$$\mathrm{vol}(K_a) = \mathrm{vol}(K_{a-1})|\pi_{a-1}(\vec{v}_a)|. \tag{19}$$

Proof. Immediate from the definition of volume. ◀

Assume K_{a-1} is primitve. Then, the next lemma gives a one-to-one correspondence between vectors $\vec{v}_a$ obeying *one* of the conditions needed for Hermite normal form (the condition Eq. (16)) and vectors in a certain factor lattice. In lemma 20 we consider the case that K_{a-1} is not primitive. Note that there is an additional condition on v_a, namely that its first entry be positive, in order for the matrix M_{K_a} to be in Hermite normal form.

▶ **Lemma 19.** *Let the first $a-1$ columns of M_K be given and assume that the first $a-1$ columns of M_K are in Hermite normal form and assume that K_{a-1} is a primitive sublattice of Γ_0^n. Then, there is a one-to-one correspondence between vectors $\vec{v}_a$ such that*

$$j < a \quad \rightarrow \quad 0 \leq (M_K)_{i_j,a} < (M_K)_{i_j,j} \tag{20}$$

and points $\vec{x}$ of the lattice $\Gamma_0^{i_a}/\tilde{K}_{a-1}$, such that if $\vec{x}$ corresponds to $\vec{v}_a$ then $\pi_{a-1}(\vec{v}_a) = \vec{x}$.

Proof. We will show that for every $\vec{x} \in \Gamma_0^{i_a}/\tilde{K}_{a-1}$, there exists a unique $\vec{v}_a$ obeying Eq. (20) such that $\pi_{a-1}(\vec{v}_a) = \vec{x}$. This gives a map $\mathcal{F}$ from $\Gamma_0^{i_a}/\tilde{K}_{a-1}$ to vectors obeying Eq. (20). This map is one-to-one since distinct vectors $\vec{x}_1 \neq \vec{x}_2$ cannot both be the image of the same vector $\vec{v}_a$ under the map π_{a-1}. This map $\mathcal{F}$ is onto since any vector $\vec{v}_a$ obeying Eq. (20) is the image of $\pi_{a-1}(\vec{v}_a)$ under this map.

First we show existence of somer vector $\vec{v}_a$. Every vector $\vec{x}$ in $\Gamma_0^{i_a}/\tilde{K}_{a-1}$ is given by $\vec{x} = \pi_{a-1}(\vec{y})$ for some $\vec{y} \in \Gamma_0^{i_a}$. For any such vector $\vec{y}$, we can add lattice vectors in $\tilde{K}_{a-1}$ so that Eq. (20) (i.e., set $\vec{v}_a$ equal to $\vec{y}$ plus some sum of lattice vectors; this can be done iteratively, so that it holds first for $j = a-1$, then $j = a-2$, and so on). Adding these lattice vectors does not change the image of the result under π_{a-1}.

Now uniqueness. Suppose that $\pi_{a-1}(\vec{y}) = \pi_{a-1}(\vec{z})$ for $\vec{y}, \vec{z}$ being two possible choices of $\vec{v}_a$ such that Eq. (20) is obeyed. Then, $\pi_{a-1}(\vec{y}-\vec{z}) = 0$, so $\vec{y}-\vec{z}$ is in the span of $\tilde{K}_{a-1}$. Since K_{a-1} is primitive so is $\tilde{K}_{a-1}$ and so $\vec{y}-\vec{z}$ is in $\tilde{K}_{a-1}$. Let $M_K(i,j)$ denote the submatrix of M_K containing the first i rows and the first j columns, so that $M_K(i_a, a-1)$ is a lattice generating matrix for $\tilde{K}_{a-1}$. So, $\vec{y}-\vec{z} = M_K(i_a, a-1)\vec{u}$, where $\vec{u} \in \Gamma_0^{a-1}$. Then, Eq. (20) requires that $\vec{u} = 0$. This follows inductively: if the last entry of $\vec{u}$ is nonzero, then it is not possible for both $\vec{y}$ and $\vec{z}$ to obey Eq. (20) for $j = a-1$; to see this, note that then the $(a-1)$-th entries of $\vec{y}, \vec{z}$ must differ by a positive integer multiple of $(M_K)_{i_j,j}$ and so they cannot both fall in the range $0, 1, \ldots, (M_K)_{i_j,j} - 1$. So, $\vec{y}-\vec{z}$ differs by an elements of the lattice generated by $M_K(i_a, a-2)$ and so $\vec{y}-\vec{z} = M_K(i_a, a-2)\vec{u}'$ for $\vec{u}' \in \Gamma_0^{a-2}$. Again, the last entry of $\vec{u}'$ must equal zero so that Eq. (20) will be obeyed for $j = a-2$. We continue inductively for $j = a-3, \ldots$. ◀

The next lemma is similar to the previous except that we no longer assume that K_{a-1} is primitive.

▶ **Lemma 20.** *Let the first $a-1$ columns of M_K be given and assume that the first $a-1$ columns of M_K are in Hermite normal form.*

Let $M_K(i,j)$ denote the submatrix of M_K containing the first i rows and the first j columns, so that $M_{\tilde{K}_{a-1}} = M_K(i_a, a-1)$ is a lattice generating matrix for $\tilde{K}_{a-1}$. Use lemma 16 to write

$$M_{\tilde{K}_{a-1}} = M_{\tilde{K}^P_{a-1}} F.$$

Then, the possible choices of $\vec{v}_a$ such that

$$j < a \quad \rightarrow \quad 0 \leq (M_K)_{i_j,a} < (M_K)_{i_j,j} \tag{21}$$

are in one-to-one correspondence with choices of tuples $(\vec{x}, f_1, \ldots, f_{a-1})$, where $\vec{x}$ is a point in $\Gamma_0^{i_a}/\tilde{K}^P_{a-1}$ and $f_1, \ldots, f_{a-1}$ are integers obeying $0 \leq f_i < F_{i,i}$, such that if $(\vec{x}, f_1, \ldots, f_{a-1})$ corresponds to $\vec{v}_a$ then $\pi_{a-1}(\vec{v}_a) = \vec{x}$. Thus, there are $\det(F)$ distinct vectors $\vec{v}_a$ corresponding to $\vec{x}$.

Proof. We will show that for every $\vec{x} \in \Gamma_0^{i_a}/\tilde{K}_{a-1}$, there exist $\det(F)$ distinct vectors $\vec{v}_a$ obeying Eq. (21) such that $\pi_{a-1}(\vec{v}_a) = \vec{x}$. These $\det(F)$ vectors will be labelled by $f_1, \ldots, f_{a-1}$.

First we show existence. Every vector $\vec{x}$ in $\Gamma_0^{i_a}/\tilde{K}_{a-1}$ is given by $\vec{x} = \pi_{a-1}(\vec{y})$ for some $\vec{y} \in \Gamma_0^{i_a}$. For any such vector $\vec{y}$, we can add lattice vectors in $\tilde{K}_{a-1}$ so that Eq. (21) will hold (this can be done iteratively, so that it holds first for $j = a-1$, then $j = a-2$, and so on). Adding these lattice vectors does not change the image of the result under π_{a-1}.

Now, for each $\vec{x}$, let $\vec{z}$ be some fixed vector such that Eq. (21) holds for $\vec{v}_a = \vec{z}$ and such that $\vec{x} = \pi_{a-1}(\vec{z})$. Suppose that $\pi_{a-1}(\vec{y}) = \pi_{a-1}(\vec{z})$ for $\vec{y}$ some other possible choice of $\vec{v}_a$ such that Eq. (21) is obeyed. We count the number of possible choices of $\vec{y}$. Then, $\pi_{a-1}(\vec{y}-\vec{z}) = 0$, so $\vec{y}-\vec{z}$ is in the span of $\tilde{K}_{a-1}$. Since $\tilde{K}^P_{a-1}$ is primitive, $\vec{y}-\vec{z} = M_{\tilde{K}^P_{a-1}}\vec{u}$, where $\vec{u} \in \Gamma_0^{a-1}$. There are $F_{a-1,a-1}$ possible choices for the $(a-1)$-th entry of $\vec{u}$. To see this, note that $\vec{y}$ and $\vec{z}$ both obey Eq. (21) for $j = a-1$. For $j = a-1$, this equation gives a constraint that the $(a-1)$-th entry of $\vec{y}$ must fall in the range $0, \ldots, (M_K)_{i_{a-1},a-1} - 1$. The $(a-1)$-th entry of $\vec{y}$ is determined by the $(a-1)$-th entry of $\vec{u}$ and shifting that entry of $\vec{u}$ by one shifts the $(a-1)$-th entry of $\vec{y}$ by $(M_{\tilde{K}^P_{a-1}})_{i_{a-1},a-1}$. We have $(M_K)_{i_{a-1},a-1} = (M_{\tilde{K}^P_{a-1}})_{i_{a-1},a-1}F_{a-1,a-1}$ so that there are $F_{a-1,a-1}$ possible choices. Then, given this choice of the $(a-1)$-th entry of $\vec{u}$, there are $F_{a-2,a-2}$ possible choices for the $(a-2)$-th entry of $\vec{u}$, and so on. ◀

▶ **Lemma 21.** *Let M_K be a matrix in Hermite normal form which is a lattice generating matrix for a rank-m integral lattice K in n dimensions. Let K_{a-1} be given and let r be a real number. Let $C(r, K_{a-1})$ denote the number of choices of K_a such that*

$$\mathrm{vol}(K_a) \leq rK_{a-1}. \tag{22}$$

Then,

$$C(r, K_{a-1}) \leq \mathrm{vol}(K_{a-1})V_{i_a-a+1}(r + \sqrt{i_a - a + 1}). \tag{23}$$

If $r < 1$ then $C(r, K_{a-1}) = 0$.

Proof. Let $\vec{v}_a$ be as defined above. By lemma 18

$$\mathrm{vol}(K_a) = \mathrm{vol}(K_{a-1})|\pi_{a-1}(\vec{v}_a)|. \tag{24}$$

so $|\pi_{a-1}(v_a)| \leq r$. By Eq. (15), the first entry of $\vec{v}_a$ is ≥ 1, and since all vectors in K_{a-1} vanish in the first entry, we have $|\pi_{a-1}(\vec{v}_a)| \geq 1$, so indeed $C(r, K_{k-1}) = 0$ for $r < 1$.

By lemma 20, the vector $\vec{v}_a$ is in one-to-one correspondence with a tuple $(\vec{x}, f_1, \ldots, f_{a-1})$ where $\vec{x}$ is a vector in lattice $\Gamma_0^{i_a}/\tilde{K}_{a-1}^P$. By lemma 13, the lattice $\Gamma_0^{i_a}/\tilde{K}_{a-1}^P$ has the diameter of its Voronoi cells bounded by $\sqrt{i_a - a + 1}$. So, for given $\Gamma_0^{i_a}/\tilde{K}_{a-1}^P$ and given r, the number of possible choices of $\vec{x}$ such $|\pi_{a-1}(\vec{v}_a)| \leq r$ is bounded by

$$N(\Gamma_0^{i_a}/\tilde{K}_{a-1}^P, 0, r) \leq \frac{1}{\mathrm{vol}(\Gamma_0^{i_a}/\tilde{K}_{a-1}^P)} V_{i_a-a+1}(r + \sqrt{i_a - a + 1}). \tag{25}$$

So, by Eq. (11),

$$N(\Gamma_0^{i_a}/\tilde{K}_{a-1}^P, 0, r) \leq \mathrm{vol}(K_{a-1}^P)V_{i_a-a+1}(r + \sqrt{i_a - a + 1}). \tag{26}$$

Factorize $M_K(i_a, a-1) = M_{\tilde{K}_{a-1}^P} F$, as in lemma 20.

The number of possible choices of $f_1, \ldots, f_{a-1}$ is equal to $\det(F) = \mathrm{vol}(K_{a-1})/\mathrm{vol}(K_{a-1}^P)$.

So, the total number of choices of K_a is bounded by

$$\det(F)\mathrm{vol}(K_{a-1}^P)V_{i_a-a+1}(r + \sqrt{i_a - a + 1}) = \mathrm{vol}(K_{a-1})V_{i_a-a+1}(r + \sqrt{i_a - a + 1}), \tag{27}$$

as claimed. ◀

4.4 First Moment Bound

▶ **Lemma 22.** *Let G be an n-by-k code generator matrix for a code, chosen from the ensemble defined previously (entries chosen independently and uniformly from $\mathbb{F}_p$). Let M_K be an n-by-k lattice generator matrix. Let K_{a-1} be given and assume the first $a-1$ columns of M_K are in Hermite normal form. Let $Pr(K_{a-1}, r)$ denote the probability that, conditioned on K_{a-1} being consistent with G, there exists a choice of v_a such that K_a is consistent with G and such that the first a columns of M_K are in Hermite normal form and such that*

$$\mathrm{vol}(K_a) \leq rK_{a-1}. \tag{28}$$

Then, for $r < 1$, $Pr(K_{a-1}, r) = 0$, and for $r < p$,

$$Pr(K_{a-1}, r) \leq p^{-(n-k)}\mathrm{vol}(K_{a-1})V_{i_a-a+1}(r + \sqrt{i_a - a + 1}). \tag{29}$$

Proof. By lemma 21, indeed there are no choices of v_a such that $r < 1$. If $r < p$, then $0 < (\vec{v}_a)_1 < p$ so $(\vec{v}_a)_1 \neq 0 \mod p$. So, the a-th column of M_K is not in the span of the first $a-1$ columns of M_K modulo p. So, even though we have conditioned on K_{a-1} being consistent with G, the probability that a given choice of $\vec{v}_a$ is consistent with G is bounded by $p^{-(n-k)}$. (The probability is $p^{-(n-k)}$ if we condition on G being non-degenerate and smaller if G may be degenerate.)

So, by lemma 21, the average number of choices of $\vec{v}_k$ consistent with G is bounded by $p^{-(n-k)}\mathrm{vol}(K_{a-1})V_{i_a-a+1}(r+\sqrt{i_a-a+1})$. ◀

The next theorem estimates the probability that, for a randomly chosen code generator matrix, there is a rank-m lattice K of small volume which is consistent with that matrix. The bounds becomes effective for volume smaller than $(cp)^{\min(m,n-k)}$ with $c < 1/\sqrt{2\pi e}$.

▶ **Theorem 23.** *Let $P_{lat}(H,p,n,m)$ denote the probability that for a random code generator matrix G for a code over $\mathbb{F}_p^n$ there is a rank-m lattice K consistent with a code generator matrix such that* $\mathrm{vol}(K) \leq H$.

For any p, for any real number $x > \sqrt{2\pi e}$, for sufficiently large $n-m$,

$$P_{lat}((cp)^{\min(m,n-k)},p,n,m) \leq mc^m x^{n-m+1}. \tag{30}$$

The required $n-m$ is quadratic in $p(x-\sqrt{2\pi e})^{-1}$.

Proof. Note that if there is a lattice K of rank-m consistent with the code generator matrix, then the lattices $K_1,\ldots,K_{m-1}$ constructed above have ranks $1,\ldots,m-1$ respectively and are also consistent with the code generator matrix and have $\mathrm{vol}(K_a) \leq \mathrm{vol}(K)$. So, it suffices to consider the case $m \leq n-k$ (if $m > n-k$, then consider the lattice K_{n-k} instead).

For M_K in Hermite normal form, since $i_1 < i_2 < \ldots < i_m < n$, we have $i_a \leq n-m+a$ and so $i_a - a + 1 \leq n-m+1$. We use the bound (the inequality on the second line holds for all sufficiently large $n-m$)

$$\begin{aligned} V_{n-m+1}(r+\sqrt{n-m+1}) &= \frac{\pi^{\frac{n-m+1}{2}}}{\Gamma(\frac{n-m+1}{2})}(r+\sqrt{n-m+1})^{n-m+1} \\ &\leq \left(\frac{2\pi e}{n-m+1}\right)^{\frac{n-m+1}{2}}(r+\sqrt{n-m+1})^{n-m+1} \\ &= \left(\frac{r\sqrt{2\pi e}}{\sqrt{n-m+1}}+\sqrt{2\pi e}\right)^{n-m+1}, \end{aligned} \tag{31}$$

Let c be a real number, $0 < c < 1$. We will make a choice of c below.

By lemma 22 and Eq. (31), given K_{a-1}, if $\mathrm{vol}(K_{a-1}) \leq (cp)^m$, we have

$$\begin{aligned} Pr(K_{a-1},r) &\leq c^m p^{m-(n-k)}\left(\frac{r\sqrt{2\pi e}}{\sqrt{n-m+1}}+\sqrt{2\pi e}\right)^{n-m+1} \\ &\leq c^m\left(\frac{r\sqrt{2\pi e}}{\sqrt{n-m+1}}+\sqrt{2\pi e}\right)^{n-m+1}. \end{aligned} \tag{32}$$

For $r < p$, this is bounded by $c^m\left(\frac{p\sqrt{2\pi e}}{\sqrt{n-m+1}}+\sqrt{2\pi e}\right)^{n-m+1}$. For any p, for any real number $x > \sqrt{2\pi e}$, for sufficiently large $n-m$, this is bounded by $c^m x^{n-m+1}$. (The required $n-m$ is quadratic in $p(x-\sqrt{2\pi e})^{-1}$).

Suppose that $\mathrm{vol}(K) \leq (cp)^m$ for some $c < 1$. Then, $\mathrm{vol}(K_a) \leq (cp)^m$ for all a and for some a we have $\mathrm{vol}(K_a)/\mathrm{vol}(K_{a-1}) < p$. However, for $\mathrm{vol}(K_a) \leq (cp)^m$, the above calculation bounds the probability for given a that there is a choice of K_a such that

$\mathrm{vol}(K_a)/\mathrm{vol}(K_{a-1}) < p$ by $c^m x^{n-m+1}$ for all sufficiently large $n-m$. By a union bound, the probability that for some a there is a choice of K_a such that $\mathrm{vol}(K_a)/\mathrm{vol}(K_{a-1}) < p$ is bounded by $mc^m x^{n-m+1}$ for all sufficiently large $n-m$. So, $P_{lat}((cp)^m, p, n, m) \leq mc^m x^{n-m+1}$ for all sufficiently large $n-m$. ◀

This implies the following corollary for the Rankin invariant:

▶ **Corollary 24.** *For any p, k, for all sufficiently large n at fixed ratio m/n, for any $c < 1/\sqrt{2\pi e}$, with high probability we have*

$$\gamma_{n,m}(L_0) \geq (cp)^{2\min(m,n-k)} p^{-2m(n-k)/n}. \tag{33}$$

(Recall that with high probability G is non-degenerate so L_0 is rank n.)

We remark that it might be possible to tighten the bounds of theorem 23 to bound P_{lat} even for some range of x smaller than $\sqrt{2\pi e}$, especially for small m. One possible way to tighten the bounds is to use the fact that if there $\mathrm{vol}(K) < p^{m-z}$ for some integer $z > 0$ then there must be at least z different a such that $\mathrm{vol}(K_a)/\mathrm{vol}(K_{a-1}) < p$; in the proof above we only used that there was at least one such a.

We remark also that, up to the constant c, the value of the Rankin invariant at $m = k = n/2$ is optimal for an integral lattice; i.e., the dependence on p is optimal. The reason is that it implies that an $n/2$-dimensional sublattice of L_0 has the same volume (again, up to factors of c^m) as L_0 does.

It is also worth comparing the value of the Rankin invariant that we find to the Rankin invariant for random lattices (from a different ensemble) in Ref. [16]. The Rankin constant $\gamma_{n,m}$ is defined to be the maximum of $\gamma_{n,m}(L)$ over all lattices L. Those random lattices in Ref. [16] were used to lower bound the Rankin constant $\gamma_{n,n/2}$ by $\gamma_{n,n/2} \geq (\frac{k}{12})^{n/4}$. Since we need to take $n \sim p^2$ for the bounds of theorem 23 to be effective, if we choose $m = k = n/2$ and $p \sim \sqrt{n}$ we find that with high probability $\gamma_{n,n/2}(L_0) \geq (\text{const.} \times n)^{n/4}$. Thus, we find the same leading behavior $n^{n/4}$, with the Rankin invariants differing only by factors const.^{n}.

5 Volume of Oriented Systole

In this section, we consider a weaker conjecture than 1. Throughout this section, we consider the case of homology using integer coefficients, rather than $\mathbb{Z}_2$ coefficients. In this setting, there is a general method, called "calibration" [17] for lower bounding weights. We will show that this method gives an effective lower bound for homology classes which have a particular form, which we call "split", but we will show that it does not give a useful lower bound in general. The reason for this is related to the existence of short vectors in the exterior q-th power of L_0.

Given an rank-n lattice L, we write its m-th exterior power as $\wedge^m L$. This exterior power is a lattice of vectors in $\binom{n}{m}$ dimensions; the vectors in this lattice are linear combinations (with integer coefficients) of vectors $v_1 \wedge v_2 \wedge \ldots \wedge v_m$, where $v_i \in L$ and the exterior product is anti-symmetric under interchange: $v_1 \wedge v_2 = -v_2 \wedge v_1$.

▶ **Definition 25.** A vector v in $\wedge^m L$ is called "split" if $v = x_1 \wedge \ldots \wedge x_m$ for $x_1, \ldots x_m \in L$.

The q-th homology classes of the torus T^n are in one-to-one correspondence with vectors in $\wedge^q \mathbb{Z}^n$. For the torus $\mathbb{R}^n/L_0$ that we consider, it will be more convenient to regard the classes as being in one-to-one correspondence with vectors in $\wedge^q L_0$. That is, the k-th homology class represented by a hyperplane which is a span of k basis vectors will correspond to the vector which is the exterior product of these k basis vectors.

The lattice $\wedge^m L$ inherits an inner product:

$$(x_1 \wedge \ldots \wedge x_m) \cdot (y_1 \wedge \ldots \wedge y_m) = \det(S),$$

where S has matrix elements $S_{i,j} = x_i \cdot y_j$. We write this norm $|X|$, where $X \in \wedge^m L_0$. Calibration allows one to lower bound the volume of a representative of a homology class in $\wedge^q L_0$ using this inner product.

We first explain this lower bound in the split case. The arguments are not new.

▶ **Lemma 26.** *Let* $\mathrm{vol}(v_1, \ldots, v_q) \neq 0$. *Then, the minimum volume of any closed chain (either a sum of faces of q-faces of the unit hypercubes used in the cubulation or more generally an arbitrary sum of simplices) representing homology class* $X = v_1 \wedge \ldots \wedge v_q$ *is greater than or equal to* $|v_1 \wedge \ldots \wedge v_q|$.

Proof. Let us write $v \cdot d\vec{x}$ to denote a differential 1-form $\sum_i (v)_i dx^i$, where $i = 1, \ldots, n$ are orthogonal basis directions in Euclidean space and $(v)_i$ are components of i. Consider the differerential q-form $\omega = (v_1 \cdot d\vec{x}) \wedge (v_2 \cdot d\vec{x}) \wedge \ldots \wedge (v_q \cdot d\vec{x})$. Let S denote the hyperplane spanned by vectors $v_1, \ldots, v_q$ (the hyperplane is oriented, so the order of vectors matters). We have $\int_S \omega = |X|^2$. Further, for any chain C in the same homology class as S, we have $\int_C \omega = \int_S \omega = |X|^2$, where the integral over C is given by writing C as a sum of q-faces of the unit hypercubes and integrating ω over each face. (Indeed, one can also consider more general C, such as sums of arbitrary simplices, and the same result holds). For a q-face (or indeed any sum of q-dimensional simplices), the integral of ω over that face is bounded by $|X|$ times the volume of the face. Hence, the volume of C must be at least equal to $(\int_C \omega)/|X| = |X|$. ◀

Now we consider the nonsplit case. In contrast to the split case where we were able to "calibrate" the hyperplane S (find a differential form assuming maximum value on that hyperplane), we might not be able to calibrate nonsplit homology classes. However, we can still obtain a lower bound.

▶ **Lemma 27.** *Let* $X \in \wedge^q L$, $X \neq 0$. *Then, the minimum volume of any closed chain representing homology class X is lower bounded by* $|X|$.

Proof. Write $X = \sum_a X_a$, where X_a are split vectors. For each $X_a = v_1^a \wedge \ldots \wedge v_q^a$, define a differential q-form $\omega_a = (v_1^a \cdot d\vec{x}) \wedge \ldots \wedge (v_q^a \cdot d\vec{x})$. Let $\omega = \sum_a \omega_a$.

Let S_a denote the hyperplane spanned by vectors $v_1^a, \ldots, v_q^a$. Let S denote the union of hyperplanes S_a. We have $\int_{S_a} \omega_b = (X_a, X_b)$. Hence, $\int_S \omega = |X|^2$.

We now consider the maximum of the integral of C over a q-face or q-dimensional simplex of unit volume. This is equal to

$$\max_{V \text{ split}, |V|=1} (V, X),$$

where we take the maximum over all split vectors $V \in \wedge^q \mathbb{R}^n$, with V not necessarily in $\wedge^q L$; i.e., $V = v_1 \wedge \ldots \wedge v_q$ for *arbitrary* $v_1, \ldots v_q$, with $v_1, \ldots, v_q$ not necessarily in the lattice L (i.e., we are upper bounding the integral over a unit volume square in the hyperplane spanned by $v_1, \ldots v_q$). If we relax the requirement that V be split, we have $\max_V (V, X) = |X|$. The restriction to split V can only reduce the maximum, so the maximum over split V is at most $|X|$. So, as in lemma 26, since the integral over ω over any chain representing the same homology class as X must be equal to the $\int_S \omega = |X|$, the volume of such a chain must be at least $|X|$. ◀

One may wonder whether the bound in lemma 27 can be significantly improved if we do not relax the requirement that V be split. Of course, if X is split, then

$$\max_{V \text{ split}, |V|=1}(V, X) \geq |X|/\sqrt{\binom{n}{q}} = |X|$$

and the maximum is achieved for $V = X$. However, for X not split, the maximum might be smaller and so the lower bound on the volume would be correspondingly: we can lower bound the volume of a closed chain representing homology class X by $|X|^2/\max_{V \text{ split}, |V|=1}(V, X)$. Unfortunately, this at best only leads to a small improvement in the bound. We claim that

$$\max_{V \text{ split}, |V|=1}(V, X) \geq |X|/\sqrt{\binom{n}{q}}, \tag{34}$$

so that at best we would lower bound the volume by $\sqrt{\binom{n}{q}}|X|$, and since $\sqrt{\binom{n}{q}} < 2^{n/2}$, this leads to only a small improvement (recall that there are $N = p^{n/2}$ qubits and we choose $p >> 1$). To see Eq. 34, consider the orthogonal basis for $\wedge^q\mathbb{R}^n$ of vectors $x_1 \wedge \ldots \wedge x_q$ where $x_1, \ldots, x_q$ are chosen from the n different coordinate directions. These basis vectors are all split. Since $\wedge^q\mathbb{R}^n$ is $\binom{n}{q}$-dimensional, there must be some basis vector V such that $|(V, X)| \geq |X|/\sqrt{\binom{n}{q}}$. Using this vector V (or its negation if the inner product (V, X) is negative) in the maximum gives Eq. (34).

The Rankin invariant is the minimal value of the norm $|X|$ over nonzero split vectors. Thus, the results on the Rankin invariant give a lower bound on the volume of representatives of split homology classes. However, in Ref. [8], it was shown that for certain lattices L the shortest nonzero vector in $\wedge^m L$ may be shorter than the Rankin invariant. Interestingly, the lattices we consider here provide another example where this occurs; in fact this occurs for any lattice with sufficiently large Rankin invariant.

▶ **Lemma 28.** *Let L be a rank-n lattice. Then, the shortest nonzero vector in $\wedge^m L$ has norm at most $\sqrt{\gamma_{\binom{n}{m}}}\text{vol}(L)^{m/n}$, where $\gamma_{\binom{n}{m}}$ denotes Hermite's constant in dimension $\binom{n}{m}$.*

Hence, if $\gamma_{n,m}(L) \geq \gamma_{\binom{n}{m}}$, then the shortest vector is not split.

Proof. We have $\text{vol}(\wedge^m L) = \text{vol}(L)^{\binom{n-1}{m-1}}$ by Proposition 1.10.4 of Ref. [21]. The lattice $\wedge^m L$ has rank $r = \binom{n}{m}$, and so the shortest nonzero vector in $\wedge^m L$ has length at most $\sqrt{\gamma_r}\text{vol}(\wedge^m L)^{1/r}$, where γ_r is Hermite's constant. So, the shortest nonzero vector in $\wedge^m L$ has length at most

$$\sqrt{\gamma_r}\text{vol}(L)^{\binom{n-1}{m-1}/\binom{n}{m}} = \sqrt{\gamma_r}\text{vol}(L)^{m/n}. \tag{35}$$

◀

For all r, we have $\gamma_r \leq 1 + r/4$, with an asymptotic behavior $\gamma_r \lesssim \frac{2r}{\pi e}$[22]. So, $\sqrt{\gamma_{\binom{n}{m}}} \leq \sqrt{1 + \binom{n}{m}/4}$. So, lemma 28 has an interesting interpretation for the application to quantum codes. If the bound in lemma 27 is saturated so that the least volume cycle representing a homology class has volume $|X|$, then we find that the code has roughly square-root distance. Thus, conjecture 1 implies that for some homology classes, the bound of lemma 27 is far from saturated. The possible improvement of Eq. (34) leads to only a small improvement here (though, it is possible that if the possible improvement of Eq. (34) holds for the homology classes with smallest $|X|$ and if the bound of lemma 28 is saturated then one might be able to prove a slightly above square-root distance for integer homology).

6 Quantum Locally Testable Codes from High-Dimensional Constructions

In this section, we give a construction of quantum codes which are "locally testable" [1] using high-dimensional constructions. The construction uses a different topology than above; the similarity in the constructions is simply that in both cases we consider a family of codes derived from manifolds of varying dimension, with the number of qubits in the code depending exponentially on the dimension of the manifold.

Let us write $\mathrm{wt}(O)$ to indicate the weight of an operator O. Similarly, given a vector v (in one of the vector spaces defining the chain complexes), we let $\mathrm{wt}(v)$ denote the number of nonzero entries in v.

Given a CSS stabilizer code defined from a chain complex $\ldots \mathcal{C}_{q+1} \stackrel{\partial_{q+1}}{\rightarrow} \mathcal{C}_q \stackrel{\partial_q}{\rightarrow} \mathcal{C}_{q-1} \ldots$, with the qudits associated with q-cells and the Z-type and X-type stabilizers associated with $(q+1)$-cells and $(q-1)$-cells, respectively, we define soundness parameters $\epsilon_X(w), \epsilon_Z(w)$ as follows:

▶ **Definition 29.** Define

$$\epsilon_Z(w) = \min_{v \in \mathcal{C}_q, \mathrm{wt}(v)=w, \partial_q v \neq 0} \left(\max_{u \in \mathcal{C}_q, \partial_q u = 0} \frac{\mathrm{wt}(\partial v)}{\mathrm{wt}(v+u)} \right). \tag{36}$$

Define $\epsilon_X(w)$ similarly, with ∂_q replaced with ∂_{q+1}^T, where the superscript T denotes transpose.

Equivalently, consider the minimum over all Z-type operators O, such that O has weight w and such that O does not commute with at least one stabilizer, of the following quantity: take the maximum, over all Z-type operators P which commute with all stabilizers, of the ratio of the number of stabilizers which do not commute with O to the weight of $O+P$. This minimum is ϵ_Z.

The codes of Ref. [26] have distance $\Theta(\sqrt{N})$, stabilizer weight $\mathcal{O}(1)$ and have $\epsilon_{X,Z}(w)$ bounded away from zero for $w \lesssim \sqrt{N}$, as shown in Ref. [19]. It is unclear whether or not families of codes exist which have distance which is $\Omega(\sqrt{N})$ and stabilizer weight $\mathcal{O}(1)$ and which have $\epsilon_{X,Z}(w)$ bounded away from zero for *all* w.

Here we give a simple construction of a family of qubit codes with 2 encoded qubits and with distance $\Theta(\sqrt{N})$, $\epsilon_{X,Z}(w)$ only polylogarithmically small for all w, and with *logarithmic* weight stabilizers. We warm up with a construction of a qubit code family with no encoded qubits (and hence the notion of distance is meaningless for this code) but with $\epsilon_{X,Z}(w)$ bounded away from zero for all w and with logarithmic weight stabilizers; we call this the "simplex code". We then give the full construction, which is based on a product of hyperspheres.

6.1 Simplex Code

Of course, with no encoded qubits, there are some fairly trivial constructions of code with $\epsilon_{X,Z}$ strictly bounded away from zero. For example, one can take a code with N qubits and stabilizers $Z_1, Z_2, \ldots, Z_N$. Thus, every product of Z operators commutes with all stabilizers (and so $\epsilon_Z(w)$ is a minimum over an empty set), while clearly $\epsilon_X(w) = 1$ for all w. However, the simplex code construction that we give obeys Poincare duality and has an entangled ground state.

The code we consider is obtained by taking a toric code on a n-dimensional sphere, with the degrees of freedom on q-cells for $q = n/2$. The exact value of q is not very important;

the important thing is that q/n is neither close to 0 nor close to 1 so that the number of q-cells will be exponential in n. However, the case $q = n/2$ is the self-dual case so this makes the proofs slightly simpler as we need to consider only one type of stabilizer.

The cellulation of the n-sphere that we use is to take the boundary of a $n+1$-dimensional simplex. We label the 0-cells by integers $1, \ldots, n+2$. For $0 \leq r \leq n$, there are $\binom{n+2}{r+1}$ distinct r-cells, labelled by subsets of $\Lambda \equiv \{1, \ldots, n+2\}$ with $r+1$ elements. We use qubits so the vector spaces are all over $\mathbb{F}_2$.

For $1 \leq r \leq n$, the boundary operator ∂_r acting on an r-cell labelled by some $(r+1)$-element set $S \subset \Lambda$ gives the sum of $r+1$ different $(r-1)$-cells, labelled by the distinct r-element subsets of S. For example, for $n \geq 2$, $\partial_2\{1,2,3\} = \{1,2\} + \{1,3\} + \{2,3\}$. We set $\partial_0 = 0$. One may verify that $\partial_{r-1}\partial_r = 0$ for all r.

For $q = n/2$, there are $N = \binom{n+2}{n/2+1}$ qubits, so N is exponentially large in n. Remark: in previous sections, the number of qubits we also had an exponential factor p^{n-k} which, for large p, was the dominant exponential scaling; in this subsection, we do not have such a factor.

Each qubit is acted on by $q+1$ stabilizers (as each q-cell has $q+1$ cells in its boundary) and each stabilizer acts on $q+2$ different qubits (as each $(q+1)$-cell has $q+2$ cells in its boundary and each $(q-1)$-cell has $q+2$ cells in its coboundary). Hence, the weight is indeed logarithmic in N, $w = (1/2 + o(1)) \cdot \log_2(N)$.

Finally, we show soundness. First, let us introduce notation.

▶ **Definition 30.** Given an r-cell σ labelled by some set S and a set $T \subset \Lambda$, we define $r \cup T$ to equal 0 if $S \cap T \neq \emptyset$ and otherwise $r \cup T$ is the $r + |T|$-cell labelled by $S \cup T$.

Given a vector $v \in \mathcal{C}_r$, we define $v \cup T$ by linearity. $v \cup T \in \mathcal{C}_{r+|T|}$ and the coefficient of $v \cup S$ corresponding to an $r + |T|$-cell labelled by a set U is equal to the coefficient of v corresponding to the r-cell labelled by $U \setminus T$ if $T \subset U$ and is equal to 0 is $T \not\subset U$.

▶ **Lemma 31.** *For the simplex code, for all w, $\epsilon_X(w) = \epsilon_Z(w) \geq 1$.*

Proof. Consider any $v \in \mathcal{C}_q$ with $\partial_q v \neq 0$. Set $w = (\partial_q v) \cup \{1\}$. Then, one may verify that $\partial_q x = \partial_q v$ (and hence, setting $w = x - v$, $\partial_q w = 0$) and that $\mathrm{wt}(x) \leq \mathrm{wt}(\partial_q v)$. ◀

The proof of soundness above has a very simple geometric interpretation. We take the boundary $\partial_q v$ and shrink it to a point (arbitrarily choosing the vertex $\{1\}$ as the point that we shrink it to).

6.2 Hypersphere Product Code

The above construction had constant soundness, but had no encoded qubits. We now give a different construction with 2 encoded qubits and distance $\sqrt{N}$ and inverse polylogarithmic soundness. We now consider the toric code on a product of spheres, $S^n \times S^n$.

We pick an integer $p \geq 1$ (p need not be prime); p will be chosen to equal $\log(N)$ below in order to achieve square-root distance. We choose a cellulation of S^n as follows: consider an $(n+1)$-dimensional hypercube of side length p on each side (we call this the "large" hyercube). Cellulate that large hypercube using hypercubes of side length 1 on each side; we call these the "small" hypercubes) (so that there are p^{n+1} small hypercubes in the cellulation). Then, take the boundary of the hypercube to get a cellulation of S^n.

A small $(n+1)$-dimensional hypercube has $\binom{n+1}{r}2^{n+1-r}$ different r-cells in its boundary (each r-cell is a product of 1-cells in r out of the $n+1$ directions and then for each of the remaining directions there are 2 possible choices of 0-cells). The number of r-cells in the

cellulation of the large hypercube is $\binom{n+1}{r}(p+1)^{n+1-r}p^r$. To see this, assign coordinates $[0,p]$ for each side of the large hypercube. Then, each r-cell is a product of 1-cells in r out of the $n+1$ directions with 0-cells in the remaining directions. The midpoints of the 1-cells are at half-integer coordinate in the interval $[0,p]$ and so there are p possible choices for each cell. There are $p+1$ possible choices for the coordinates of each 0-cell as these cells are at integer coordinates in the interval $[0,p]$. To determine the number of r-cells in the boundary of the large hypercube, restrict to the case that in at least one of the directions, the coordinate must be 0 or p. This gives the number equal to

$$\binom{n+1}{r}(p+1)^{n+1-r}p^r\Big(1-(\frac{p+1-2}{p+1})^{n+1-r}\Big),$$

where the ratio in parenthesis $\frac{p+1-2}{p+1}$ is the probability that for a random integer coordinate in the range $[0,p]$, the coordinate is not on the boundary 0 or p. Thus, there are at most $2^{(1-o(1))\cdot n}p^n$ cells (if $n >> p$) and at least $2^{1-o(1))\cdot n}p^{n-1}$ cells (if $n << p$).

We take the product of this cellulation with itself to get a cellulation of $S^n \times S^n$. The degrees of freedom will be on the q-cells for $q = n$, so that N is again exponential in n. We have $\log_2(N) = 2(1+\log_2(p)+o(1))\cdot n$ for $n >> p$ and $\log_2(N) = 2(1+\log_2(p)+o(1))\cdot n - 2\log_2(p)$ for $n << p$. We will take $p = 1/\log(N), n = \Theta(\log(N)/\log(\log(N)))$.

Each qubit is acted on by $2n$ stabilizers and each stabilizer acts on $2(n+1)$ qubits. Hence, the weight is logarithmic in N, $w = \Theta(\log(N)/\log(\log(N)))$.

The number of encoded qubits is equal to 2, as can be computed from the homology of $S^n \times S^n$ (by the Künneth formula, $H_i(S^n \times S^n; \mathbb{Z}_2) = 2$ for $i = n$, $H_i(S^n \times S^n; \mathbb{Z}_2) = 1$ for $i = 0, 2n$, and $H_n(S^n \times S^n; \mathbb{Z}_2) = 0$ otherwise).

▶ **Lemma 32.** *For the hypersphere product code,*

$$d_X(w) = d_Z(w) = (p+1)^{n+1}\Big(1-(\frac{p+1-2}{p+1})^{n+1}\Big) = \Theta(N^{\frac{p}{p+2}}). \tag{37}$$

For $p = \Omega(\log(N))$,

$$d_X(w) = d_Z(w) = \Theta(\sqrt{N})). \tag{38}$$

Proof. Let a be a 0-cell in the second S^n in the product $S^n \times S^n$. Let $Z(a,2)$ be the logical Z operator which is the product Z_i over all i which are the product of an n-cell in the first S^n with 0-cell a. Then, any logical X operator which anticommites with $Z(a,2)$ must have some support on some cell i which is a product of an n-cell in the first S^n with 0-cell a. However, since $Z(a,2)$ and $Z(b,2)$ are homologous for any two choices of 0-cells a, b in the second S^n ($Z(a,2), Z(b,2)$ differ by a product of stabilizers), that logical X operator must have some support on some cell i which is a product of an n-cell in the first S^n with 0-cell a for *all* 0-cells a in the second S^n. Hence, that logical X operator must have a number of cells in its support equal to the number of 0-cells in the second S^n. This number is equal to $(p+1)^{n+1}\Big(1-(\frac{p+1-2}{p+1})^{n+1}\Big)$.

This number is also an upper bound to $d_X(w)$, since the product of X over all cells which are a product of a fixed n-cell in the first S^n with an arbitrary 0-cells in the second S^n is a logical operator.

We can similarly lower bound the number of cells in the support of any logical X operator which anticommutes with the operator $Z(a,1)$, defined to be the logical Z operator which is the product Z_i over all i which are the product of an n-cell in the *second* S^n with 0-cell a in the *first* S^n. ◀

We now show soundness. Again, the geometric interpretation is to shrink the boundary to a point.

▶ **Lemma 33.** *For the hypersphere product code,* $\epsilon_X(w) = \epsilon_Z(w) \geq \Omega(1/\log(N)^2)$.

Proof. Consider any $v \in \mathcal{C}_q$ with $\partial_q v \neq 0$.

We place coordinates $[0,p]^{n+1}$ on the first large hypercube. Call the face where the first coordinate is equal to p the "top face". Call the face where the first coordinate is equal to 0 the "bottom face". Let $v_0 = v$. We will construct a sequence $v_1, v_2, \ldots, v_f \in \mathcal{C}_q$ for some integer f where we bound $\mathrm{wt}(v_{i+1} - v_i)$ with the final vector $v_f = 0$. In this way, we will bound $\mathrm{wt}(v_0)$. We construct the sequence so that the boundaries $\partial_q v_i$ are first removed from the top face of the first hypercube, then moved from the top face to the bottom face of the first hypercube, and finally moved to a point on the bottom face of the first hypercube.

Throughout this proof, when we refer to coordinates, we refer to the first hypercube in the product. We regard an r-cell as being a product of 0-cells and 1-cells. That is, each cell in the product of hypercubes is product of cells in each hypercube. Then, each r-cell in a hypercube is a product of r 1-cells and $n+1-r$ 0-cells. The $n+1$ different terms in the product correspond to different coordinates. When we say that a cell "is a 0-cell" in a given coordinate, we mean that the cell is a product of a 0-cell in that coordinate with some cells in other coordinates.

We first explain the middle step, moving from top face to bottom face. Suppose that some v_i has $\partial_q v_i$ vanishing on the top face. Indeed, suppose that $\partial_q v_i$ vanishes if the first coordinate is greater than x, for some integer x. Then, let $\pi_x(\partial_q v_i)$ be the projection of $\partial_q v_i$ onto cells with first coordinate equal to x. This projection consists only of cells which are 0-cells in the first coordinate. Let $v_{i+1} - v_i$ be defined by taking $\pi_x(\partial_q i)$ and replacing every 0-cell in the first coordinate at position x with a 1-cell at position $x - 1/2$. Then, $\pi_x(\partial_q v_{i+1}) = 0$. Iterating this procedure, decreasing x from p, to $p-1$, to $p-2$, and so on, we can construct a sequence $v_i, v_{i+1}, \ldots$ so that the final vector in the second has boundary only on the bottom face. There are at most p steps in the sequence. Note that because $\partial^2 = 0$, once we ensure that $\pi_x(\partial_q v_i) = 0$, then we know that $\partial_q v_i$ has not cells which are 1-cell in the first coordinate with midpoint as $x - 1/2$.

Now we explain the first step, moving the boundary off the top face. We apply above the above procedure to the *second* coordinate. We let $\pi_{p,x}(\partial_q v_i)$ be the projection $\partial_q v_i$ onto cells with first coordinate equal to p and second coordinate equal to x, for integer x. We then construct a sequence so that this projection vanishes for $x = p, p-1, \ldots$, following the same procedure as in the above paragraph. There are at most p steps in this sequence. We then repeat this for the second coordinate, third coordinate, and so on; giving at most pn steps.

The final step is the same as the first step, with the top face replaced by the bottom face.

So, there are at most $\mathcal{O}(pn)$ steps in the sequence. We have $\mathrm{wt}(\partial_q v_i) \leq \mathrm{wt}(\partial_q v)$ for all vectors in the sequence, and there are at most $\mathcal{O}(pn)$ steps, so this gives $\epsilon_X(w) \geq \Omega(1/pn) = \Omega(1/\log(N)^2)$. ◀

In the above construction, we lost a factor of n due to having n steps in the sequence to move the boundary. Likely for this construction, this factor cannot be avoided since the diameter of the hypercube is pn. One might wonder whether other geometries (such as a geometry that more closely approximates a sphere) would improve on this factor; note however that since the volume of a sphere of radius r in n-dimensional Euclidean space scales roughly as $(r/n)^{n/2}$, one would need to take the radius proportional to n in order to obtain a large volume so again one would need to have a large diameter for the geometry.

7 Discussion

We have presented several different code constructions based on the toric code on families of higher-dimensional manifolds. Rather than varying the geometry or topology at fixed dimension, as is more commonly done, we have considered varying dimension. This leads to a scaling in which the number of qubits, N, scales exponentially with dimension, n, so that the weight of the stabilizers w is proportional $n \propto \log(N)$. Assuming conjecture 1, we have constructed a code family with almost linear distance and logarithmic weight.

Acknowledgments. I thank L. Eldar and M. Freedman for useful discussions.

Abstract

In recent years it has become popular to study dynamic problems in a sensitivity setting: Instead of allowing for an arbitrary sequence of updates, the sensitivity model only allows to apply batch updates of small size to the *original* input data. The sensitivity model is particularly appealing since recent strong conditional lower bounds ruled out fast algorithms for many dynamic problems, such as shortest paths, reachability, or subgraph connectivity.

In this paper we prove conditional lower bounds for these and additional problems in a sensitivity setting. For example, we show that under the Boolean Matrix Multiplication (BMM) conjecture combinatorial algorithms cannot compute the $(4/3-\varepsilon)$-approximate diameter of an undirected unweighted dense graph with truly subcubic preprocessing time and truly subquadratic update/query time. This result is surprising since in the static setting it is not clear whether a reduction from BMM to diameter is possible. We further show under the BMM conjecture that many problems, such as reachability or approximate shortest paths, cannot be solved faster than by recomputation from scratch even after *only one or two* edge insertions. We extend our reduction from BMM to Diameter to give a reduction from All Pairs Shortest Paths to Diameter under one deletion in weighted graphs. This is intriguing, as in the static setting it is a big open problem whether Diameter is as hard as APSP. We further get a nearly tight lower bound for shortest paths after two edge deletions based on the APSP conjecture. We give more lower bounds under the Strong Exponential Time Hypothesis. Many of our lower bounds also hold for static oracle data structures where no sensitivity is required.

Finally, we give the first algorithm for the $(1+\varepsilon)$-approximate radius, diameter, and eccentricity problems in directed or undirected unweighted graphs in case of single edges failures. The algorithm has a truly subcubic running time for graphs with a truly subquadratic number of edges; it is tight w.r.t. the conditional lower bounds we obtain.

1 Introduction

A dynamic algorithm is an algorithm that is able to handle changes in the input data: It is given an input instance x and is required to maintain certain properties of x while x undergoes (possibly very many) updates. For example, an algorithm might maintain a graph, which undergoes edge insertions and deletions, and a query is supposed to the return the diameter of the graph after the updates. Often dynamic algorithms are also referred to as data structures. During the last few years strong conditional lower bounds for many dynamic problems were derived (see, e.g., [36, 3, 27, 4, 21, 1, 32]), which rule out better algorithms than simple recomputation from scratch after each update or before each query.

Partially due to this, in recent years it has become popular to study dynamic problems in a more restricted setting that only allows for a *bounded* number of changes to the input instance (see, for example, [37, 23, 10, 19], and the references in Table 4). These algorithms are usually referred to as *sensitivity*[1] data structures. The hope is to obtain algorithms in the sensitivity setting which are faster than the conditional lower bounds for the general setting.

More formally, a *data structure with sensitivity* d for a problem P has the following properties: It obtains an instance p of P and is allowed polynomial preprocessing time on p. After the preprocessing, the data structure must provide the following operations:

(Batch) Update. Up to d changes are performed to the *initial* problem instance p, e.g., d edges are added to or removed from p.

Query. The user queries a specific property about the instance of the problem after the last update, e.g., the shortest path between two nodes avoiding the edges deleted in the last update.

The parameter d bounding the batch update size is referred to as the *sensitivity* of the data structure. Note that every batch update is performed on the *original* problem instance. Thus, in contrast to "classic" dynamic algorithms (without sensitivity), a query only reflects the changes made to p by the *last* batch update and *not* by previous batch updates. As the size of a batch update is constrained to at most d, each query is executed on a graph that differs from p by at most d edges. After a batch update an arbitrary number of queries may be performed.

Some data structures (usually called *oracles*) combine a query and an update into a single operation, i.e., the combined operation obtains an input tuple (Q, U), where Q is a query and U is an update. A special case are *static oracles*, which have $U = \emptyset$. The conditional lower bounds we derive in this paper also hold in this setting, since oracles with an efficient combined operation can be used to solve sensitivity problems.

While some existing sensitivity data structures can preprocess the answers to all possible updates and queries during their preprocessing time, this is not possible in general (due to constraints in the preprocessing time and the fact that the number of possible updates/queries grows exponentially in the parameter d). Hence, we still consider a sensitivity data structure a dynamic (instead of static) algorithm.

[1] Sometimes sensitivity data structures are also called "fault-tolerant" or "emergency planning" algorithms. See Appendix A.2 for a discussion of terminology.

The Hypotheses

We state the hypotheses on which we base the conditional lower bounds in this paper. By now they are all considered standard in proving fine-grained reduction-based lower bounds. For a more detailed description of the hypotheses, see, e.g., Abboud and Williams [3] and the references therein. As usual we work in the word-RAM model of computation with word length of $O(\log n)$ bits. The hypotheses below concern the complexity of the Boolean Matrix Multiplication (BMM), Satisfiability of Boolean Formulas in Conjunctive Normal Form (CNF-SAT), All Pairs Shortest Paths (APSP), Triangle Detection and Online Boolean Matrix Vector Multiplication (OMv) problems. Other popular hypotheses from prior work consider other famous problems such as 3SUM and other sparsity regimes such as triangle detection in very sparse graphs (see, e.g. [3]).

▶ **Conjecture 1** (Impagliazzo, Paturi and Zane [29, 30]). *The Strong Exponential Time Hypothesis (SETH) states that for each $\varepsilon > 0$, there exists a $k \in \mathbb{N}$, such that k-SAT cannot be solved in time $O(2^{n(1-\varepsilon)} \operatorname{poly}(n))$.*

▶ **Conjecture 2.** *The Boolean Matrix Multiplication (BMM) conjecture states that for all $\varepsilon > 0$, there exists no* combinatorial *algorithm that computes the product of two $n \times n$ matrices in expected time $O(n^{3-\varepsilon})$.*

Note that BMM can be solved in truly subcubic using fast matrix multiplication (FMM): the current fastest algorithms run in $O(n^{2.373})$ time [41, 25]. However, algorithms using FMM are not considered to be combinatorial. Formally, the term *combinatorial* algorithm is not well-defined and it is common to rule out the use of FMM or other "Strassen-like" methods in the design of such algorithms as most of them are not considered practical. True combinatorial algorithms are not only considered practical but also easily extendable. For instance, prior work on combinatorial BMM algorithms has almost always led to an algorithm for APSP with similar running time (e.g. [5] and [17]).

One of the simplest graph problems is that of detecting whether the graph contains a triangle, i.e., three nodes with all three edges between them. Itai and Rodeh [31] showed that any algorithm for BMM can solve Triangle detection in the same time. Conversely, Vassilevska Williams and Williams [42] showed that any truly subcubic combinatorial algorithm for Triangle Detection can be converted into a truly subcubic combinatorial algorithm for BMM. Hence, the BMM conjecture implies there is no truly subcubic *combinatorial* algorithm for Triangle Detection. We use this fact and the resulting Triangle Conjecture that there is no truly subcubic algorithm for Triangle Detection in our reductions based on BMM.

The following is a popular conjecture about the APSP problem.

▶ **Conjecture 3.** *The APSP conjecture states that given a graph G with n vertices, m edges, and edge weights in $\{1, \ldots, n^c\}$ for some constant c, the All Pairs Shortest Paths problem (APSP) cannot be solved in $O(n^{3-\varepsilon})$ expected time for any $\varepsilon > 0$.*

Similar to the relationship between BMM and Triangle Detection, [42] showed that there is a triangle problem in weighted graphs, Negative Triangle, that is equivalent under subcubic reductions to APSP. We use that problem in our reductions.

Our final conjecture concerns Boolean matrix vector product.

▶ **Conjecture 4** (Henzinger et al. [27]). *Let B be a Boolean matrix of size $n \times n$. In the Online Matrix-vector (OMv) problem, n binary vectors $v_1, \ldots, v_n$ of size n appear online and an algorithm solving the problem must output the vector Bv_i before the next vector v_{i+1} arrives.*

The OMv conjecture states that for all $\varepsilon > 0$ and after any polynomial time preprocessing of B, it takes $\Omega(n^{3-\varepsilon})$ time to solve the OMv problem with error probability at most $1/3$.

Most of the conjectures are stated w.r.t. *expected* time, i.e., the conjectures rule out randomized algorithms. In case of dynamic algorithms using randomness, it is common to argue if an oblivious or a non-oblivious adversary is allowed. Previous literature on conditional lower bounds for dynamic algorithms did not explicitly state what kind of adversaries are allowed for their lower bounds. We give a quick discussion of this topic in Appendix A.3.

Our Results

In this paper we develop a better understanding of the possibilities and limitations of the sensitivity setting by providing conditional lower bounds for sensitivity problems. We show that under plausible assumptions for many dynamic graph problems even the update of only *one or two* edges cannot be solved faster than by re-computation from scratch. See Table 2 and Table 3 in the Appendix for a list of all our conditional lower bounds for sensitivity data structures, and our lower bounds for static oracles respectively. Table 1 gives explanations of the problems. The abbreviations used in the tables are explained in its captions. We next discuss our main results.

New reductions

We give several new reductions for data structures with small sensitivity.

(1) We give a novel reduction from triangle detection and BMM to maintaining an approximation of the diameter of the graph and eccentricities of all vertices, under a single edge failure. This is particularly surprising because in the static case it is unknown how to reduce BMM to diameter computation. Using the BMM conjecture this results in lower bounds of $n^{3-o(1)}$ on the preprocessing time or of $n^{2-o(1)}$ update or query time for $(4/3-\varepsilon)$-approximate decremental diameter and eccentricity in unweighted graphs *with sensitivity 1*, i.e., when a single edge is deleted. Those results are tight w.r.t. the algorithm we present in Section 5.

(2) A particular strength of BMM-based reductions is that they can very often be converted into APSP-based lower bounds for weighted variants of the problems. APSP-based lower bounds, in turn, no longer require the "combinatorial"-condition on the algorithms, making the lower bounds stronger. We show how our BMM-based lower bounds for approximate diameter with sensitivity 1 can be converted into an APSP-based lower bound for diameter with sensitivity 1 in weighted graphs. In particular, we show that unless APSP has a truly subcubic algorithm, any data structure that can support diameter queries for a single edge deletion must either have essentially cubic preprocessing time, or essentially quadratic query time. This lower bound is tight w.r.t. to a trivial algorithm using the data structure of [10]. The APSP to 1-sensitive Diameter lower bound is significant also because it is a big open problem whether in the static case Diameter and APSP are actually subcubically equivalent (see e.g. [2]).

(3) We consider the problem of maintaining the distance between two fixed nodes s and t in an undirected weighted graph under edge failures. The case of a *single edge failure* can be solved in m edge, n node graphs with essentially optimal $O(m\alpha(n))$ preprocessing time and $O(1)$ query time with an algorithm of Nardelli et al. [33]. The case of two edge failures has been open for some time. We give compelling reasons for this by showing that under the APSP conjecture, maintaining the s-t distance in an unweighted graph under two edge failures requires either $n^{3-o(1)}$ preprocessing time or $n^{2-o(1)}$ query time. Notice that with no preprocessing time, just by using Dijkstra's algorithm at query time, one can obtain $O(n^2)$ query time. Similarly, one can achieve $\tilde{O}(n^3)$ preprocessing time and $O(1)$

query time by applying the single edge failure algorithm of [33] n times at preprocessing, once for $G \setminus \{e\}$ for every e on the shortest st path. Thus our lower bound shows that under the APSP conjecture, the naive recomputation time is essentially optimal.

(4) We show lower bounds with sensitivity d for deletions-only and insertions-only $(2-\varepsilon)$-approximate single source and $(5/3-\varepsilon)$-approximate st-shortest paths in undirected unweighted graphs, as well as for weighted bipartite matching problems under the OMv conjecture. The lower bounds show that with polynomial in n preprocessing either the update time must be super-polynomial in d or the query time must be $d^{1-o(1)}$.

New upper bounds

We complement our lower bounds with an algorithm showing that some of our lower bounds are tight: In particular, we present a deterministic combinatorial algorithm that can compute a $(1+\varepsilon)$-approximation (for any $\varepsilon > 0$) for the eccentricity of any given vertex, the radius and the diameter of a directed or undirected unweighted graph after single edge failures. The preprocessing time of the data structure is $\tilde{O}(mn + n^{1.5}\sqrt{Dm/\varepsilon})$, where D is the diameter of the graph and m and n are the number of edges and vertices; the query time is constant. Since $D \leq n$, the data structure can be preprocessed in time $\tilde{O}(n^2\sqrt{m/\varepsilon})$. In particular, for sparse graphs with $m = \tilde{O}(n)$, it takes time $\tilde{O}(n^{2.5}\varepsilon^{-\frac{1}{2}})$ to build the data structure. Our lower bounds from BMM state that even getting a $(4/3-\varepsilon)$-approximation for diameter or eccentricity after a *single* edge deletion requires either $n^{3-o(1)}$ preprocessing time, or $n^{2-o(1)}$ query or update time. Hence, our algorithm's preprocessing time is tight (under the conjecture) since it has constant time queries.

Conditional Lower Bounds based on modifications of prior reductions

Some reductions in prior work [42, 3] only perform very few updates before a query is performed or they can be modified to do so. After the query, the updates are "undone" by rolling back to the initial instance of the input problem. Hence, some of their reductions also hold in a sensitivity setting. Specifically we achieve the following results in this way:

(1) Based on the BMM conjecture we show that for reachability problems with st-queries already *two* edge insertions require $n^{3-o(1)}$ preprocessing time or $n^{2-o(1)}$ update or query time; for ss-queries we obtain the same bounds even for a *single* edge insertion. This lower bound is matched by an algorithm that recomputes at each step.

(2) We present strong conditional lower bounds for static oracle data structures. We show that under the BMM conjecture, oracle data structures that answer about the reachability between any two queried vertices cannot have truly subcubic preprocessing time *and* truly subquadratic query time. This implies that combinatorial algorithms *either* essentially need to compute the transitive closure matrix of the graph during the preprocessing time *or* essentially need to traverse the graph at each query. We show the same lower bounds for static oracles that solve the $(5/3-\varepsilon)$-approximate ap-shortest paths problem in undirected unweighted graphs. This shows that we essentially cannot do better than solving APSP in the preprocessing or computing the distance in each query.

(3) The subcubic equivalence between the replacement paths problem and APSP [42] immediately leads to a conditional lower bound for s-t distance queries with sensitivity 1 in *directed*, weighted graphs. Our lower bound for s-t distance queries with sensitivity 2 in undirected graphs is inspired by this reduction. The lower bound for sensitivity 1 is matched by the algorithm of Bernstein and Karger [10].

Similarly, a reduction from BMM to replacement paths in directed unweighted graphs from [42] shows that the $O(m\sqrt{n})$ time algorithm of Roditty and Zwick [38] is optimal among all combinatorial algorithms, for every choice of m as a function of n. It also immediately implies that under the BMM conjecture, combinatorial s-t distance 1-sensitivity oracles in unweighted graphs require either $mn^{0.5-o(1)}$ preprocessing time or $m/n^{0.5+o(1)}$ query time, for every choice of m as a function of n; this is tight due to Roditty and Zwick's algorithm. (The combinatorial restriction is important here as there is a faster $\tilde{O}(n^{2.373})$ time non-combinatorial algorithm for replacement paths [40] and hence for distance sensitivity oracles in directed unweighted graphs.)

(4) We additionally provide new lower bounds under SETH: We show that assuming SETH the #SSR problem cannot be solved with truly subquadratic update and query times when any constant number of edge insertions is allowed; this matches the lower bound for the general dynamic setting. For the ST-reachability problem and the computation of $(4/3-\varepsilon)$-approximate diameter we show that under SETH truly sublinear update and query times are not possible even when only a constant number of edge insertions are supported. The sensitivity of the reductions is a constant $K(\varepsilon,t)$ that is determined by the preprocessing time $O(n^t)$ we allow and some properties of the sparsification lemma [30]. Notice that while the constant $K(\varepsilon,t)$ depends on the preprocessing time and the constant in the sparsification lemma, it does *not* depend on any property of the SAT instance in the reduction. See Section 4 for a thorough discussion of the parameter $K(\varepsilon,t)$. The lower bound for #SSR shows that we cannot do better than recomputation after each update.

(5) Using a reduction from OMv we show lower bounds with sensitivity d for deletions-only or insertions-only st-reachability, strong connectivity in directed graphs. The lower bounds show that with polynomial in n preprocessing either the update time must be super-polynomial d or the query time must be $\Omega(d^{1-\varepsilon})$.

Related Work

In the last few years many conditional lower bounds were derived for dynamic algorithms. Abboud and Williams [3] gave such lower bounds under several different conjectures. New lower bounds were given by Henzinger et al. [27], who introduced the OMv conjecture, and by Abboud, Williams and Yu [4], who stated combined conjectures that hold as long as either the 3SUM conjecture *or* SETH *or* the APSP conjecture is correct. Dahlgaard [21] gave novel lower bounds for partially dynamic algorithms. Abboud and Dahlgaard [1] showed the first hardness results for dynamic algorithms on planar graphs and Kopelowitz, Pettie and Porat [32] gave stronger lower bounds from the 3SUM conjecture. However, none of the lower bounds mentioned in the above papers explicitly handled the sensitivity setting.

During the last decade there have been many new algorithms designed for the sensitivity setting. In Section A.5 we give a short discussion summarizing many existing algorithms.

2 Lower Bounds From Boolean Matrix Multiplication

The following theorem summarizes the lower bounds we derived from the BMM conjecture.

▶ **Theorem 5.** *Assuming the BMM conjecture, combinatorial algorithms cannot solve the following problems with preprocessing time $O(n^{3-\varepsilon})$, and update and query times $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$:*

1. *incremental st-reachability with sensitivity 2,*

2. *incremental ss-reachability with sensitivity 1,*
3. *static ap-reachability,*
4. *$(7/5-\varepsilon)$-approximate st shortest paths in undirected unweighted graphs with sensitivity 2,*
5. *$(3/2-\varepsilon)$-approximate ss shortest paths in undirected unweighted graphs with sensitivity 1,*
6. *static $(5/3-\varepsilon)$-approximate ap shortest paths*
7. *decremental $(4/3-\varepsilon)$-approx. diameter in undirected unweighted graphs with sensitivity 1,*
8. *decremental $(4/3-\varepsilon)$-approx. eccentricity in undirected unweighted graphs with sensitivity 1.*

Additionally, under the BMM conjecture, decremental st-shortest paths with sensitivity 1 *in directed unweighted graphs with n vertices and $m \geq n$ edges require either $m^{1-o(1)}\sqrt{n}$ preprocessing time or $m^{1-o(1)}/\sqrt{n}$ query time for every function m of n.*

A strength of the reductions from BMM is that they can usually be extended to provide APSP-based reductions for weighted problems without the restriction to combinatorial algorithms; we do this in Section 3. While we state our results in the theorem only for combinatorial algorithms under the BMM conjecture, we would like to point out that they also hold *for any kind of algorithm* under a popular version of the triangle detection conjecture for sparse graphs that states that finding a triangle in an m-edge graph requires $m^{1+\delta-o(1)}$ time for some $\delta > 0$. Our lower bounds then rule out algorithms with a preprocessing time of $O(m^{1+\delta-\varepsilon})$ and update and query times $O(m^{2\delta-\varepsilon})$ for any $\varepsilon > 0$.

Many of the bullets of the theorem follow from prior work via a few observations, which we discuss in Appendix A.6. Our results on decremental diameter and eccentricity, however, are completely novel. In fact, it was completely unclear before this work whether such results are possible. Impagliazzo et al. [16] define a strengthening of SETH under which there can be no deterministic fine-grained reduction from problems such as APSP and BMM to problems such as orthogonal vectors or diameter in sparse graphs. It is not clear whether a reduction from BMM to diameter in dense graphs is possible, as the same "quantifier issues" that arise in the sparse graph case arise in the dense graph case as well: Diameter is an $\exists\forall$-type problem (i.e., do there exist two nodes such that all paths between them are long?), and BMM is equivalent to Triangle detection which is an $\exists$-type problem (i.e., do there exist three nodes that form a clique?).

Decremental Diameter

We give the reduction from BMM to decremental diameter in undirected unweighted graphs with sensitivity 1. Note that the lower bound also holds for eccentricity oracles: Instead of querying the diameter n times, we can query the eccentricity of a variable vertex n times.

Let $G = (V, E)$ be an undirected unweighted graph for Triangle Detection. We construct a graph G' as follows.

We create four copies of V denoted by V_1, V_2, V_3, V_4, and for $i = 1, 2, 3$, we add edges between nodes $u_i \in V_i$ and $v_{i+1} \in V_{i+1}$ if $(u, v) \in E$. We create vertices a_v and b_v for each $v \in V$, and denote the set of all a_v by A and the set of all b_v by B. We connect the vertices in A to a clique and also those of B. For each $v \in V$, we add an edge (v_1, a_v) and an edge (a_v, b_v). A node b_v is connected to all vertices in V_4. We further introduce two additional vertices c, d, which are connected by an edge. We add edges between c and all nodes in V_2 and V_3, and between d and all nodes in V_3 and V_4. The node c has an edge to each vertex in A and the node d has an edge to each vertex in B. Notice that the resulting graph has $O(n)$ vertices and $O(n^2)$ edges. We visualized the graph in Figure 2 in the appendix.

Note that even without the edges from $B \times V_4$, no pair of nodes has distance larger than 3, except for pairs of nodes from $V_1 \times V_4$. If a node v participates in a triangle in G, then in

G' there is a path of length 3 from v_1 to v_4 without an edge from $B \times V_4$. Otherwise, there is no such path, i.e., the diameter increases to 4 after the deletion of (b_v, v_4).

We perform one stage per vertex $v \in V$: Consider the copy $v_4 \in V_4$ of v. We remove the edge (b_v, v_4) and query the diameter of the graph. We claim that G has a triangle iff one of the queries returns diameter 3.

▶ **Lemma 6.** *For each vertex v in G, the diameter of $G' \setminus \{(b_v, v_4)\}$ is larger than 3 if and only if v does not participate in a triangle in G.*

Proof. Assume that G has a triangle $(v, u, w) \in V^3$ and consider the stage for v. Notice that only the shortest paths change that used edge (b_v, v_4); this is not the case for any $z \neq v$, because the path $z_1 \to a_z \to b_z \to z_4$ is not affected by the edge deletion. We only need to consider the path $v_1 \to a_v \to b_v \to v_4$. Since G has a triangle (v, u, w), there exists the path $v_1 \to u_2 \to w_3 \to v_4$ of length 3 as desired. Hence, the diameter is 3.

Assume the query in the stage for vertex $v \in V$ returned diameter 3. Since we deleted the edge (b_v, v_4), there is no path of length 3 from v_1 to v_4 via A and B. Hence, the new shortest path from v_1 to v_4 must have the form $v_1 \to u_2 \to w_3 \to v_4$. By construction of the graph, this implies that G has a triangle (v, u, w). ◀

Altogether we perform n queries and n updates. Thus under the BMM conjecture any combinatorial algorithm requires $n^{3-o(1)}$ preprocessing time or $n^{2-o(1)}$ update or query time.

3 Sensitivity Lower Bounds from the APSP Conjecture

In this section we present new lower bounds based on the APSP conjecture. These lower bounds hold for arbitrary, not necessarily combinatorial, algorithms. We present our results in the following theorem and give the proofs in Appendix A.7.

▶ **Theorem 7.** *Assuming the APSP conjecture, no algorithms can solve the following problems with preprocessing time $O(n^{3-\varepsilon})$, and update and query times $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$:*

1. *Decremental st-shortest paths in directed weighted graphs with sensitivity* 1,
2. *decremental st-shortest paths in undirected weighted with sensitivity* 2,
3. *decremental diameter in undirected weighted graphs with sensitivity* 1.

Decremental *st*-shortest paths in directed weighted graphs with sensitivity 1

In 2010, Vassilevska Williams and Williams [42] showed that the so called Replacement Paths (RP) problem is subcubically equivalent to APSP. RP is defined as follows: given a directed weighted graph G and two nodes s and t, compute for every edge e in G, the distance between s and t in $G \setminus \{e\}$. Note that only the deletion of the at most $n-1$ edges on the shortest path from s to t affect the distance from s to t. This has an immediate implication for 1-sensitivity oracles for st-shortest paths: The APSP conjecture would be violated by any 1-sensitivity oracle that uses $O(n^{3-\varepsilon})$ preprocessing time and can answer distance queries between two fixed nodes s and t with one edge deletion in time $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$.

Decremental *st*-shortest paths in undirected weighted with sensitivity 2

With this we are able to show that on *undirected* weighted graphs finding a shortest path between fixed s and t with 2 edge deletions cannot be done with truly sub-cubic preprocessing time and truly subquadratic query time assuming the APSP conjecture. This is surprising

because in the case of a *single edge failure* Nardelli et al. [33] show that shortest paths can be solved with an essentially optimal $O(m\alpha(n))$ preprocessing time and $O(1)$ query time. Thus, assuming the APSP conjecture we show a separation between 1 sensitivity and 2 sensitivity. Additionally, with sensitivity 2 and no preprocessing time $O(n^2)$ update time is achievable, and with $\tilde{O}(n^3)$ preprocessing time using Nardelli et al. we can get an $O(1)$ query time. Thus, we show these approaches are essentially tight assuming the APSP conjecture. The full reduction is in Appendix 3.

Decremental diameter in undirected weighted graphs with sensitivity 1

A nice property of BMM-based reductions is that they can very often be converted to APSP-based reductions to weighted versions of problems. Here we convert our BMM-based reduction for decremental 1-sensitive Diameter to a reduction from APSP into decremental 1-sensitive diameter in undirected weighted graphs. Note that, as in the BMM case we can get the same lower bounds for eccentricity.

4 SETH Lower Bounds with Constant Sensitivity

In this section, we prove conditional lower bounds with constant sensitivity from SETH. Before we give the reductions, we first argue about what their sensitivities are.

▶ **Theorem 8.** *Let $\varepsilon > 0$, $t \in \mathbb{N}$. The SETH implies that there exists no algorithm with preprocessing time $O(n^t)$, update time $u(n)$ and query time $q(n)$, such that $\max\{u(n), q(n)\} = O(n^{1-\varepsilon})$ for the following problems:*

1. *Incremental #SSR with constant sensitivity $K(\varepsilon, t)$,*
2. *$(4/3-\varepsilon)$-approximate incremental diameter with constant sensitivity $K(\varepsilon, t)$,*
3. *incremental ST-Reach with constant sensitivity $K(\varepsilon, t)$.*

We prove the theorem in Appendix A.8. The parameter $K(\varepsilon, t)$ is explained in the following paragraph*.

The Sensitivity of the Reductions

The conditional lower bounds we prove from SETH hold even for constant sensitivity; however, the derivation of these constants is somewhat unnatural. Nonetheless, we stress that our lower bounds hold for constant sensitivity and in particular for every algorithm with sensitivity $\omega(1)$.

To derive the sensitivity of our reductions, we use a similar approach as Proposition 1 in [3], but we need a few more details. We start by revisiting the sparsification lemma.

▶ **Lemma 9** (Sparsification Lemma, [30]). *For $\varepsilon > 0$ and $k \in \mathbb{N}$, there exists a constant $C = C(\varepsilon, k)$, such that any k-SAT formula F with $\tilde{n}$ variables can be expressed as $F = \bigvee_{i=1}^{l} F_i$, where $l = O(2^{\varepsilon\tilde{n}})$ and each F_i is a k-SAT formula with at most $C\tilde{n}$ clauses. This disjunction can be computed in time $O(2^{\varepsilon\tilde{n}}\operatorname{poly}(\tilde{n}))$.*

We set $C(\varepsilon)$ to the smallest $C(\varepsilon, k)$, over all k such that k-SAT cannot be solved faster than in $O^*(2^{(1-\varepsilon)\tilde{n}})$ time[2]; formally, $C(\varepsilon) = \min\{C(\varepsilon', k) : \varepsilon' < \varepsilon$ and $k \in \mathbb{N}$ with k-SAT $\notin O^*(2^{(1-\varepsilon')\tilde{n}})\}$. Note that $C(\varepsilon)$ is well-defined if we assume that SETH is true (see also

[2] The $O^*(\cdot)$ notation hides $\operatorname{poly}(\tilde{n})$ factors.

Proposition 1 in [3]). Finally, for any $\varepsilon > 0$ and $t \in \mathbb{N}$, we set $K(\varepsilon, t) = C(\varepsilon) \cdot t/(1-\varepsilon)$, which gives the sensitivity of our reductions.

In our reductions, $t \in \mathbb{N}$ is the exponent of the allowed preprocessing time and $\varepsilon > 0$ denotes the improvement in the exponent of the running time over the 2^n-time algorithm. We note that $K(\varepsilon, t)$ gives a tradeoff: For small t (i.e., less preprocessing time), the lower bounds hold for smaller sensitivities; a smaller choice of ε yields larger sensitivities.

In the reductions we will write K to denote $K(\varepsilon, t)$ and c to denote $C(\varepsilon, k)$ whenever it is clear from the context.

The Reductions

Our reductions are conceptually similar to the ones in [3], but the graph instances we construct are based on a novel idea to minimize the size of the batch updates we need to perform. Here we describe the construction of the graphs we use in the reductions and refer to Appendix A.8 for full proofs.

We give two graphs, H_δ and D_δ, for $\delta \in (0, 1)$. For the construction, let F be a SAT formula over a set V of $\tilde{n}$ variables and $c \cdot \tilde{n}$ clauses. Let $U \subset V$ be a subset of $\delta\tilde{n}$ variables.

Construction of H_δ: For each partial assignment to the variables in U we introduce a node. The set of these nodes is denoted by $\bar{U}$. For each clause of F we introduce a node and denote the set of these nodes by C. We add an edge between a partial assignment $\bar{u} \in \bar{U}$ and a clause $c \in C$ if $\bar{u}$ does not satisfy c. Observe that H_δ has $O(2^{\delta\tilde{n}})$ vertices and $O^*(2^{\delta\tilde{n}})$ edges.

Construction of D_δ: We partition the set of clauses C into $K = c/\delta$ groups of size $\delta\tilde{n}$ each and denote these groups by $G_1, \ldots, G_K$. For all groups G_i, we introduce a vertex into the graph for each non-empty subset g of G_i. The edges to and from the nodes of D_δ will be introduced during reductions. Observe that for each group we introduce $O(2^{\delta\tilde{n}})$ vertices and D_δ has $O(K \cdot 2^{\delta\tilde{n}})$ vertices in total.

Our reductions have small sensitivity since we will only need to insert a single edge from H_δ to each group of clauses in D_δ. Hence, we only need to insert $K = O(1)$ edges in order to connect H_δ and D_δ at each stage in the reduction. However, we will need to argue how we can efficiently pick the correct sets in D_δ.

5 Diameter Upper Bound

In this section, we present deterministic algorithms, which can compute a $(1+\varepsilon)$-approximation for the eccentricity, the radius and the diameter of directed and undirected unweighted graphs after single edge deletions. All of these algorithms run in time truly subcubic time for graphs with a truly subquadratic number of edges.

Bernstein and Karger [10] give an algorithm for the related problem of all-pairs shortest paths in a directed weighted graph $G = (V, E)$ in case of single edge deletions. Their oracle data structure requires $\tilde{O}(mn)$ preprocessing time. Given a triplet $(u, v, e) \in V^2 \times E$, the oracle can output the distance from u to v in $G \setminus e$ in $O(1)$ time.

For the diameter problem with single edge deletions, note that only deletions of the edges in the shortest paths trees can have an effect on the diameter. Using this property, a trivial algorithm to compute the exact diameter after the deletion of a single edge works as follows: Build the oracle data structure of Bernstein and Karger [10]. For each vertex v, consider its shortest paths tree T_v. Delete each tree-edge once and query the distance from v to u in $G \setminus e$ for all vertices u in the subtree of the deleted tree-edge. By keeping track of the maximum distances, the diameter of G after a single edge deletion is computed exactly. As

there are $n-1$ edges in T_v, we spend $O(n^2)$ time for each vertex. Thus, the trivial algorithm requires $O(n^3)$ time.

In this section, we improve upon this result as follows.

▶ **Theorem 10.** *Let $G=(V,E)$ be a directed or undirected unweighted graph with n vertices and m edges, let $\varepsilon > 0$, and let D be the diameter of G. There exists a data structure that given a single edge $e \in E$ returns for $G \setminus e$ in constant time (1) the diameter, (2) the radius, and (3) the eccentricity of any vertex $v \in V$ within an approximation ratio of $1+\varepsilon$. It takes $\tilde{O}(n^{1.5}\sqrt{Dm/\varepsilon} + mn)$ preprocessing time to build this data structure.*

The rest of this section is devoted to the proof of the theorem. We give the proof of the theorem for directed graphs and point out the same proof also works for undirected graphs. We first describe how we can answer queries for the eccentricity of a fixed vertex $v \in V$ after a single edge deletion. After this, we explain how to extend this algorithm to solve the diameter and the radius problems after single edge deletions, and analyse the correctness and running time of the algorithm.

The data structure preprocesses the answers to all queries. Then queries can be answered via table lookup in $O(1)$ time.

Preliminaries

Let $G=(V,E)$ be a directed unweighted graph. For two vertices $u, u' \in V$ we denote the distance of u and u' in G by $d_G(u,u')$. For an edge $e \in E$ and vertices $u, u' \in V$, we denote the distance in the graph $G \setminus e$ by $d_{G\setminus e}(u,u')$. Given a tree T with root v and a tree-edge $e \in T$, we denote the subtree of T that is created when e is removed from T and that does *not* contain v by T_e. We let d_e be the height of T_e. A node u in T has *level* i, if $d_G(v,u) = i$.

Let $F \in \mathbb{N}$ be some suitably chosen parameter (see the last paragraph* of this section). Then given a tree T with root v, we call a tree-edge e *high*, if both of its endpoints have level less than F from v; we call all other edges *low*. We denote the set of all high edges by $T_<$, i.e., $T_< = \{e=(w,w') \in T : d_G(v,w) < F, d_G(v,w') < F\}$; the set of all low edges is given by $T_>$.

The Algorithm

Our data structure preprocesses the answers to all queries, and then queries can be answered via table lookup in $O(1)$ time. The preprocessing has three steps: First, in the initialization phase, we compute several subsets of vertices that are required in the next steps. Second, we compute the eccentricity of v after the deletion of a high edge exactly. We compute it exactly, since after the deletion of a tree-edge high up in the shortest path tree T_v of v, the nodes close to v in T_v might "fall down" a lot. This possibly affects all vertices in the corresponding subtrees and, hence, we need to be careful which changes occur after deleting a high edge. On the other side, the relative distance of nodes which are "far away" from v in G before any edge deletion cannot increase too much. Thus, we simply estimate their new distances in the third step. More precisely, in the third step we compute a $(1+\varepsilon)$-approximation of the eccentricity of v after the deletion of a low edge.

Step 1: Initialization. We build the data structure of Bernstein and Karger [10], in mn time which for each triplet (u,v,e) can answer queries of the form $d_{G\setminus e}(u,v)$ in $O(1)$ time.
We compute the shortest path tree $T = T_v$ of v in time $O(nm)$ and denote its depth by d_v. By traversing T bottom-up, we compute the height d_e of the subtree T_e for each

tree-edge e; this takes time $O(n)$. We further construct the sets $T_<$ and $T_>$ of high and low tree-edges, respectively.

Fix $\varepsilon > 0$. We construct a set $S_v \subset V$ as follows: First add v to S_v. Then add each $u \in V$ which has the following two properties: (1) u is at level $i\varepsilon F$ for some integer[3] $i > 0$ and (2) there exists a node u' in the subtree of u in T_v, such that u' has distance $\varepsilon F/2$ in T_v from u. Note that we can add the root, but every other node we add can be charged to the $\varepsilon F/2$ parent nodes that come before it. Thus, we can have at most $1 + \frac{2n}{\varepsilon F}$ nodes in S_v. Note that for every $z \in V$ there exists a $y \in S_v$, s.t. y is an ancestor of z in T_v and there exists a path from y to z in T_v of length at most εF.

Using a second bottom-up traversal of T, for each tree-edge $e \in T$, we compute the set $S_e = T_e \cap S_v$, i.e., the intersection of the vertices in T_e and those in S_v. This can be done in $O(n)$ time by, instead of storing S_e explicitly for each edge $e = (w, w')$, storing a reference to the set containing the closest children of w' which are in S_v; then S_e can be constructed in $O(|S_e|)$ time by recursively following the references.

For each non-tree-edge e, we store d_v as the value for the eccentricity of v when e is deleted.

Step 2: Handling high edges. For each level $j = 1, \ldots, F-1$, we proceed as follows. We consider each tree-edge $e = (w, w') \in T_<$ with $d(v, w) < d(v, w') = j$, there are at most n of these. We build a graph G_e containing all nodes of T_e together with a additional directed path P of length $d_e + 4$ with startpoint r. The nodes in P are new vertices added to G_e. Each edge on P has weight 1, except the single edge incident to r, which has weight $d_G(v, w') - 1$. Additionally to the path, the graph contains as edges: (1) all edges from E, which have both endpoints in T_e, and (2) for each $e = (z, z')$ which has its startpoint $z \notin T_e$ and its endpoint $z' \in T_e$, an edge (z'', z'), where z'' is the node on P with distance $d_G(v, z)$ from r.

Observe that G_e has the property that all distances after the deletion of e are maintained *exactly*: By construction, the shortest path from r to $u \in T_e$ in G_e has exactly length $d_{G\setminus e}(v, u)$ (we prove this formally in Lemma 11).

After building G_e, we compute its depth starting from node r and store this value for edge e.

Step 3: Handling low edges. For each tree-edge $e = (w, w') \in T_>$, we do the following: Let $S = S_e \cup \{w'\}$. As answer for a deleted edge e, we store $\max\{d_v, (1+\varepsilon)\max_{y \in S} d_{G\setminus e}(v, y)\}$. To determine $d_{G\setminus e}(v, y)$, we use the data structure of [10].

Extension to $(1+\varepsilon)$-approximate Diameter and Radius. We repeat the previously described procedure for all $v \in V$ (but we build the data structure for Bernstein and Karger only once). To compute the diameter, we keep track of the maximum value we encounter for each deleted edge e. To compute the radius, we keep track of the minimum value we encounter for each deleted edge e.

Correctness

Observe that it is enough to show correctness for a fixed $v \in V$. We first prove the correctness of the algorithm after removing high edges.

▶ **Lemma 11.** *After the deletion of a high edge $e \in T_<$, we compute the eccentricity of v exactly.*

[3] For readability we leave out the floors, however, we are considering the integer levels $\lfloor i\varepsilon F \rfloor$.

Proof. Consider any vertex $u \in T_e$ and consider the shortest path p from v to u in $G \setminus e$.

We can assume that p has exactly one edge (z, z'), s.t. $z \notin T_e$ and $z' \in T_e$: Assume that there is a path p' with two edges (x, x') and (y, y'), s.t. $x, y \notin T_e$, $x', y' \in T_e$ and y appears later on p' than x. Since $y \notin T_e$, there exists a path from v to y that does not use any vertex from T_e and that is of the same length as the subpath of p' from v to y in T, because T is a shortest-path tree with root v. Hence, we can choose a path to y without entering T_e.

Let z, z' be as before. Then $d_{G\setminus e}(v, u) = d_{G\setminus e}(v, z) + 1 + d_G(z', u)$. By construction of G_e, there exists a vertex on P in G_e with distance $d_{G\setminus e}(v, z)$ from r and which has an edge to z'. All paths which only traverse vertices from T_e are unaffected by the deletion of e. Hence, in G_e there exists a path of length $d_{G\setminus e}(u, v)$.

Also, there is no shorter path in G_e from r to u, because this would imply a shorter path in $G \setminus e$ by construction. ◀

Next we prove the correctness of the algorithm after the removal of low edges. Consider a tree-edge $e = (w, w') \in T_>$ with $F \geq d(v, w') > d(v, w)$. Let $S = S_e \cup \{w'\}$.

▶ **Lemma 12.** *For each node $z \in T_e$, there exists a vertex $y \in S$ s.t. $d_{G\setminus e}(y, z) \leq \varepsilon F$.*

Proof. Since $w' \in S$, the claim is true for all nodes $z \in T_e$ with $d(w', z) \leq \varepsilon F$. By construction of S_v, any (directed) tree path of length εF contains a node of S_v. For any node $z \in T_e$ with $d(w', z) > \varepsilon F$, there exists an ancestor u of z in T_e with $d(u, z) \leq \varepsilon F$. The path from u to z is a directed tree path and, thus, must contain a node in S_v. Thus, for each node in T_e there is a path of length at most εF from some node in S_v. ◀

▶ **Lemma 13.** *Consider two vertices $y, z \in T_e$ and assume there exists a path from y to z in $G \setminus e$. Then $d_{G\setminus e}(y, z) \leq X$ implies $d_{G\setminus e}(v, z) \leq d_{G\setminus e}(v, y) + X$.*

Proof. Concatenate the shortest paths from v to y in $G \setminus e$ and from y to z in $G \setminus E$, which both avoid e. This path cannot be shorter than the shortest path from v to z in $G \setminus e$. ◀

We define the maximum height achieved by the vertices of T_e in $G \setminus e$ by

$$n(v, e) = \max_{z \in T_e} d_{G\setminus e}(v, z).$$

Notice that the eccentricity of v in $G \setminus e$ is given by $\max\{d_v, n(v, e)\}$. Hence, by giving a $(1 + \varepsilon)$-approximation of $n(v, e)$, we obtain a $(1 + \varepsilon)$-approximation for the eccentricity of v in $G \setminus e$. In the remainder of this subsection, we show this guarantee on the approximation ratio of $n(v, e)$.

▶ **Lemma 14.** $n(v, e) \leq (1 + \varepsilon) \max_{y \in S} d_{G\setminus e}(v, y)$.

Proof. Let z' be any vertex in T_e such that $d_{G\setminus e}(v, z') = n(v, e)$. By Lemma 12 there exists a vertex $y' \in S$ with $d_{G\setminus e}(y', z') \leq \varepsilon F$. Then by Lemma 13,

$$\begin{aligned} n(v, e) &= d_{G\setminus e}(z', v) \\ &\leq d_{G\setminus e}(v, y') + \varepsilon F \\ &\leq \max_{y \in S} d_{G\setminus e}(v, y) + \varepsilon d_G(v, w') \\ &\leq (1 + \varepsilon) \max_{y \in S} d_{G\setminus e}(v, y), \end{aligned}$$

where in the second last step we used $F \leq d_G(v, w')$ and in the last step we used that $w' \in S$. ◀

▶ **Lemma 15.** $(1 + \varepsilon) \max_{y \in S} d_{G\setminus e}(v, y) \leq (1 + \varepsilon) n(v, e)$.

Proof. This follows from the definition of $n(v, e)$, since S is a subset of the vertices in T_e. ◀

Running Time Analysis.

Let us first consider the time spent on step 1, preprocessing. We build the data structure of Bernstein and Karger [10] in time $\tilde{O}(mn)$. For each node v, computing the shortest path tree of v takes time $\tilde{O}(m)$ and we spend time $O(n)$ computing the heights of the subtrees of T and computing the sets $T_<$, $T_>$, S_v. The sets S_e can as well be computed in $O(n)$ time by storing them only implicitly.

Now let us consider the time spent on step 2, the high edges. For the high edges e at level $j \leq F$, observe that the trees T_e are mutually disjoint. Hence, for a fixed level j, in time $\tilde{O}(m)$ we can compute the depths of *all* graphs G_e with e at level j. Since we have to do this for each level less than F, the total time for this step is $\tilde{O}(Fm)$.

Finally, let us consider the time spent on step 3, the low edges. For all low edges at level $j > F$, we query all nodes of S_v with height more than j. These are $O(\frac{n}{\varepsilon F})$ many such nodes. Thus, the total time we spend for all edges in T is $O(d_v \cdot \frac{n}{\varepsilon F})$.

To compute the diameter, we have to execute the above steps once for each $v \in V$, but we only need to build the data structure of Bernstein and Karger once. Hence, the total time is $\tilde{O}(mn + Fmn + nd_v \cdot \frac{n}{\varepsilon F})$. Denote the diameter of G by D. Then setting $F = \sqrt{\frac{Dn}{\varepsilon m}}$ yields a total running time of $\tilde{O}(n^{1.5}\sqrt{Dm/\varepsilon} + mn)$. Since $D \leq n$, this is $\tilde{O}(n^2\sqrt{m/\varepsilon})$.

A Appendix

A.1 Definitions of the Problems

We give definitions of the problems we consider in this paper in Table 1.

A.2 A Note on Terminology

The terminology used in the literature for dynamic data structures in the spirit of Section 1 is not consistent. The phrases which are used contain "fault-tolerant algorithms", "algorithms with sensitivity", "algorithms for emergency planning" and "algorithms for failure prone graphs".

In the community of spanners and computational graph theory, it is common to speak about "fault-tolerant subgraphs". In this area, this term is used consistently.

In the dynamic graph algorithms community, multiple phrases have been used to describe algorithms for the model proposed in Section 1. First, the field was introduced by [37] as algorithms for "emergency planning". Later, the terminologies "sensitivity" and "failure prone graphs" were used (e.g., [19, 18, 23, 24]). When the number of failures in the graph was fixed (e.g. 1 or 2), then often this was stated explicitly (without further mentioning sensitivity or failure prone graphs). However, it appears that in the dynamic graph algorithms community the phrase "sensitivity" is the most widely used one.

A.3 A Note on Adversaries

Some of the conditional lower bounds we obtain are for *randomized* algorithms. Previous literature [3, 27, 32] also gave conditional lower bounds for randomized dynamic algorithms; however, it was not discussed under which kind of adversary the obtained lower bounds hold. This depends on the conjecture from which the lower bound was obtained. We observe that in reductions from the static triangle problem, the only randomness is over the input distribution of the static problem. Hence, for lower bounds from the triangle conjecture, we can assume an oblivious adversary. Furthermore, we assume the OMv conjecture in its strongest possible form, i.e. for oblivious adversaries. (In [27] the authors did not explicitly state which kind of adversary they assume for their conjecture.) Thus, all conditional lower bounds we obtain for randomized algorithms hold for oblivious adversaries. Note that a lower bound which holds for oblivious adversaries must always hold for non-oblivious ones.

We would like to point out another subtlety of our lower bounds: In reductions from the triangle detection conjecture, the running time of the algorithm is assumed to be a random variable, but the algorithm must always answer correctly. However, in reductions from OMv the running time of the algorithm is determinstic, but the probability of obtaining a correct answer must be at least $2/3$.

Table 1 The problems we consider in this paper.

Problem		
Maintain	Update	Query
Reachability		
Directed graph	Edge insertions/deletions	Given two vertices u, v, can v be reached from u?
#SSR		
Directed graph and a fixed source vertex s.	Edge insertions/deletions	How many vertices can be reached from s?
Strong Connectivity (SC)		
Directed graph	Edge insertions/deletions	Is the graph strongly connected?
2 Strong Components (SC2)		
Directed graph	Edge insertions/deletions	Are there more than 2 SCCs?
2 vs k Strong Components (AppxSCC)		
Directed graph	Edge insertions/deletions	Is the number of SCCs 2 or more than k?
Maximum SCC Size (MaxSCC)		
Directed graph	Edge insertions/deletions	What is the size of the largest SCC?
Subgraph Connectivity		
Fixed undirected graph, with some vertices on and some off.	Turn on/off vertex	Given two vertices u, v, are u and v connected by a path only traversing vertices that are on?
α-approximate Shortest Paths		
Directed or undirected (possibly weighted) graph	Edge insertions/deletions	Given two vertices u, v, return an α-approximation of the length of the shortest path from u to v.
α-approximate Eccentricity		
Undirected graph	Edge insertions/deletions	Given a vertex u, return an α-approximation of the eccentricity of v.
α-approximate Radius		
Undirected graph	Edge insertions/deletions	Return an α-approximation of the radius of the graph.
α-approximate Diameter		
Undirected graph	Edge insertions/deletions	Return an α-approximation of the diameter of the graph.
Bipartite Perfect Matching (BPMatch)		
Undirected bipartite graph	Edge insertions/deletions	Does the graph have a perfect matching?
Bipartite Maximum Weight Matching (BWMatch)		
Undirected bipartite graph with integer edge weights	Edge insertions/deletions	Return the weight of the maximum weight perfect matching.

A.4 Our Lower Bounds

In Table 2 we summarize summarize our lower bounds for sensitivity data structures. Table 3 states our lower bounds for static oracle data structures.

A.5 Existing Sensitivity Data Structures

In Table 4 we summarize existing sensitivity data structures.

In the table, we also list algorithms for "fault-tolerant subgraphs" although they are not algorithms for the sensitivity setting in the classical sense. However, the fault-tolerant subgraphs are often much smaller than the input graphs and by traversing the fault-tolerant subgraph during queries, one can obtain better query times than by running the static algorithm on the original graph. Unfortunately, the construction time of these subgraphs is often very expensive, though still polynomial; the goal of these papers is to optimize the trade-offs between the size of the subgraphs and the approximation ratios achieved for the specific problem.

It is striking that (to the best of our knowledge) most of the existing algorithmic work was obtained for the case of *decremental* algorithms with a limited number of failures. While this is natural for the construction of fault-tolerant subgraphs, this is somewhat surprising from an algorithmic point of view. Our lower bounds might give an explanation of this phenomenon as they indicate that for many problems there is a natural bottleneck when it comes to the insertion of edges.

A.6 Triangle Detection Proofs

We provide full details of the reachability and shortest paths sensitivity results from Theorem 5.

Reachability

Let $G = (V, E)$ be an undirected unweighted graph for Triangle Detection. We create four copies of V denoted by V_1, V_2, V_3, V_4, and for $i = 1, 2, 3$, we add edges between nodes $u_i \in V_i$ and $v_{i+1} \in V_{i+1}$ if $(u, v) \in E$.

For a fixed source $s \in V$ and sink $t \in V$, Abboud and Williams [3] give the following reduction: For each vertex $v \in V$, they insert the edges (s, v_1) and (v_4, t), and query if there exists a path from s to t. They show that there exists a triangle in G iff one of the queries is answered positively. We observe that this reduction requires n batch updates of size 2 and n queries. Hence, it holds for sensitivity 2.

Now keep s fixed, but remove the sink t, and allow single-source reachability queries[4]. We perform a stage for each $v \in V$, in which we add the single edge (s, v_1) and query if there exists a path from s to v_4. By the same reasoning as before, there exists a triangle in G iff one of the queries returns true. The reduction requires n updates of size 1 and n queries. Thus, it has sensitivity 1.

Finally, we remove the source node s and ask all-pairs reachability queries[5]. We perform a stage for each $v \in V$, which queries if there exists a path from v_1 to v_4. There exists a triangle in G iff one if the queries returns true. This reduction has sensitivity 0, i.e., it uses

[4] Given $v \in V$, a query returns true iff there exists a path from s to v.
[5] Given two nodes $u, v \in V$, a query returns true iff there exists a path from u to v.

Table 2 The conditional lower bounds we obtained for non-zero sensitivity. Problems for which there exists a tight upper bound are marked bold. Regarding the sensitivities, the lower bounds hold for any data structure that supports *at least* the sensitivity given in the table; d is a parameter that can be picked arbitrarily, and $K(\varepsilon, t)$ is a constant depending on properties of SAT and the allowed preprocessing time (see Section 4). Lower bounds for constant sensitivities hold in particular for any dynamic algorithm which allows for *any* larger fixed constant sensitivity or sensitivity $\omega(1)$. For the query type we use the following abbreviations: *st* – fixed source and sink, *ss* – single source, *ap* – all pairs, *ST* – a fixed set of sources and a fixed set of sinks. The rest of the abbreviations are as follows: sh. paths means shortest paths, conn. means connectivity, SC means strongly connected components, SC2 means whether the number of strongly connected components is more than 2, Reach. means Reachability, BPMatch is bipartite matching, BWMatch is bipartite maximum weight matching, ecc. is eccentricity, dir. means directed, und. means undirected, w. means weighted, unw. means unweighted, Conj. means Conjecture.

no updates, and n queries. Hence, we have derived a very simple conditional lower bound for static reachability oracles.

These reductions prove the first three results of Theorem 5.

Shortest Paths

The above reduction for *st*-reachability can be easily altered to work for $(7/5-\varepsilon)$-approximate *st*-shortest paths in *undirected* unweighted graphs (for any $\varepsilon > 0$) with the same running time lower bounds: Just observe that the graphs in the reduction are bipartite. Thus, either there is a path from s to t of length 5 and there is a triangle in the original graph, or the shortest path between s and t has length at least 7. Thus distinguishing between length 7 and 5 solves the triangle problem.

To obtain a lower bound for $(3/2-\varepsilon)$-approximate *ss*-shortest paths, we take the construction for *ss*-reachability and again observe that the graph is bipartite so that if there is no path of length 4 between s and a node $v \in V$, then the shortest path between them must have length at least 6.

With the same bipartiteness observation, we obtain a conditional lower bound for $(5/3-\varepsilon)$-approximate static *ap*-shortest paths. In a stage for node $v \in V$, we query the shortest path from v_1 to v_4. The query returns 3 if there exists a triangle in the original graph containing the vertex v and ≥ 5 otherwise. Thus, distinguishing between 3 and ≥ 5 suffices to solve the problem.

Finally, let us discuss how we obtain a lower bound for incremental shortest paths with sensitivity 1 in directed graphs. Vassilevska Williams and Williams [42] reduce BMM to the replacement paths problem in directed unweighted graphs: given a directed graph G on m edges and n nodes and two nodes s and t, compute for every $e \in E$, the distance between s and t in $G \setminus \{e\}$. [42] shows that if a combinatorial algorithm can solve the latter problem in $O(mn^{1/2-\varepsilon})$ time for any $\varepsilon > 0$ (for any choice of m as a function of n), then BMM has a truly subcubic combinatorial algorithm. This showed that the $O(m\sqrt{n})$ time algorithm of Roditty and Zwick [39] is tight.

Here we observe that the [42] reduction immediately implies a 1-sensitivity oracle lower bound, as any 1-sensitivity oracle for *st* distances must be able to answer the replacement paths problem by querying the less than n nodes on the shortest s-t path: either the preprocessing time is at least $mn^{0.5-o(1)}$ or the query time is at least $m/n^{0.5+o(1)}$. For dense graphs this gives a lower bound of either $n^{2.5-o(1)}$ preprocessing or $n^{1.5-o(1)}$ query time. The lower bound is again tight via Roditty and Zwick's algorithm [39] for replacement paths.

Table 4 Upper Bounds. We omit polylog factors in the stated running times and spaces usages. We use the following abbreviations: "ap" means "all pairs", "ss" means "single source", "st" denotes problems with a fixed source and a fixed sink. Oracles combine update and query into a single operation. For algorithms with an additive approximation guarantee, we included the optimal result $\mathcal{O}$; all other approximation algorithms achieve multiplicative approximation guarantees. See table 5 for APSP upper bounds.

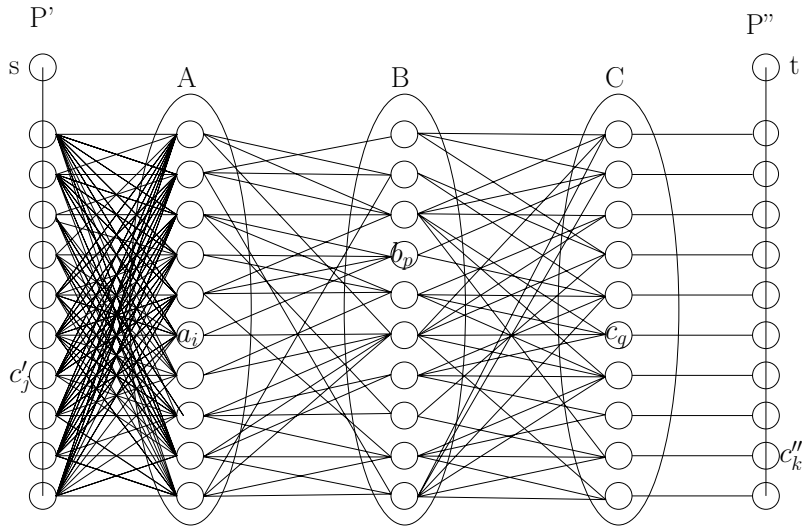

Figure 1 The graph G.

A.7 All Pairs Shortest Paths Proofs

We prove the statements of Theorem 7 in Lemma 16 and Lemma 17.

▶ **Lemma 16.** *Assuming the APSP conjecture, decremental st-shortest paths in undirected weighted graphs with sensitivity 2 cannot be solved with preprocessing time $O(n^{3-\varepsilon})$, and update and query times $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$.*

Proof. We use a reduction similar to the reduction from APSP to RP from [42], but to deal with the undirected edges we add more weights and we add additional nodes to the graph. As in [42], we start by taking an instance of APSP and turning it into a tripartite graph for the negative triangle detection problem[6]; denote resulting graph H'.

If H' has no negative edge weights, we are done (there are no negative triangles). If H' has negative edge weights, let $M = \min\{w(e)|e \in E_{H'}\}$ and add $-M+1$ to all edges (thus making all edges have positive weights). Now we want to detect if there is a triangle with (positive) weight less than $-3M+3$. Denote the new graph by H and denote the three tripartite groups A, B and C; each set A, B and C has n nodes.

We construct a graph G in which n shortest paths queries with two edge deletions determine if there exist any triangles with weight less than $-3M+3$ in H. Let $W = 4\max\{w(e)|e \in E_H\}$ and observe that W is larger than the maximum possible difference in the weight of two triangles. We will use this weight to enforce that we must take certain paths.

We add two vertices s and t to G. We add a path P' of length n to s, where each edge on the path has weight 0; the first node after s on P' is denoted c'_1, the next node on P' is denoted c'_2, and the i'th node on P' is denoted c'_i. Next, we add a path P'' of length n to t, where each edge on the path has weight 0; the first node after t on P'' is denoted c''_n, second node on P'' is denoted c''_{n-1} and the i^{th} node away from t on P'' is denoted c''_{n-i+1}. We add the nodes in A, B and C from H to G and keep all edges from $A \times B$ and from $B \times C$,

[6] In the negative triangle detection problem we are given an edge-weighted graph $G = (V, E)$ with possibly negative edge-weights from $\mathbb{Z}$, and we must determine if G contains a triangle consisting of vertices u, v, x such that $w(u, v) + w(v, x) + w(x, u) < 0$.

however, we delete all edges from $A \times C$. We increase the weight of all edges from A to B and of all edges from B to C by $6nW$. We add edges between all nodes in A and all nodes on the path P'; specifically, for all $a_i \in A$ and for all $j \in [1, n]$, we add an edge (a_i, c'_j) of weight $(7n - j)W + w((a_i, c_j))$. We further add edges from C to the path P''; specifically, we add an edge from $c_i \in C$ to c''_i of weight $(6n + i)W$. The resulting graph is given in Figure 1.

Note that all edges in the graph G either have weight 0 or their weight is from the range $[6nW, 7nW + W/4]$. All edges of weight 0 are on the paths P' and P''; all paths from s to t must contain at least one edge from P' to A, one from A to B, one from B to C and finally one edge from C to P''. Each of the non-path-edges has weight from the range $[6nW, 7nW + W/4]$ and we must take at least four of them in total. If we backtrack (and go from A back to P' or from B back to A, etc) then we must take at least six non-zero edges; hence, it is never optimal to backtrack since $(7nW + W/4)4 < 6\dot{6}nW$.

We explain which n queries answer the negative triangle question in H. For each $i = 1, \ldots, n$, we delete the edge (c'_i, c'_{i+1}) from path P' and the edge (c''_i, c''_{i-1}) from path P'', and we query the shortest path from s to t. Note that with these edges deleted to take only four "heavy" edges, one must leave from a c'_j where $j \leq i$ and enter a c''_k where $k \geq i$. The length from s to c'_j and from c''_k to t is zero. So a shortest path from s to t has length

$$(7n - j)W + w(a_p, c_j) + w(a_p, b_q) + 6nW + w(b_q, c_k) + 6nW + (6n + k)W.$$

Note that because W is large and we want to minimize the length of the shortest path, we want to maximize j and minimize k. Due to the deleted edges, the maximum plausible value of j is i and the minimum plausible value of k is i. In that case, the path length is

$$(7n - i)W + w(a_p, c_i) + w(a_p, b_q) + 6nW + w(b_q, c_i) + 6nW + (6n + i)W.$$

This simplifies to $25nW + w(a_p, c_i) + w(a_p, b_q) + w(b_q, c_i)$. If the length of the shortest st-path is less than $25nW - 3M + 3$, then there exists a negative triangle in the graph H' containing c_i. Otherwise, there is no such triangle. ◀

▶ **Lemma 17.** *Assuming the APSP conjecture, decremental diameter in undirected weighted graphs with sensitivity 1 cannot be solved with preprocessing time $O(n^{3-\varepsilon})$, and update and query times $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$.*

Proof. As in [42] we start by taking an instance of APSP and turning it into a weighted tripartite graph for the negative triangle detection problem; denote the resulting graph for the negative triangle detection problem H'.

Let M be a positive integer such that all edges in H' have weights between $-M$ and M. We increase all edge weights in H by $5M$ (thus making all edges have weight at least $4M$). We denote this new graph H and call the three tripartite groups X, Y and Z. Note that X, Y and Z each have n nodes. Now we want to detect if there is a triangle with weight less than $15M$ in H.

We construct the graph G depicted in Figure 2 as follows. We create sets V_1 and V_4 containing copies of the nodes in X, the set V_2 containing copies of the nodes from Y, and the set V_3 containing copies of the nodes from Z. We additionally create two groups of vertices, A and B, containing copies of X. Finally, we add two vertices c and d to G. For convenience, we denote the different copies of $x_i \in X$ as follows: The copy in V_1 as x_i^1, the copy in V_4 as x_i^4, the copy in A as x_i^A, and the copy in B as x_i^B.

We introduce edges between V_1 and V_2 if the corresponding nodes in X and Y have an edge; the edges between V_2 and V_3 are determined by the edges between Y and Z; the edges between V_3 and V_4 are determined by the corresponding edges between nodes of X and Z.

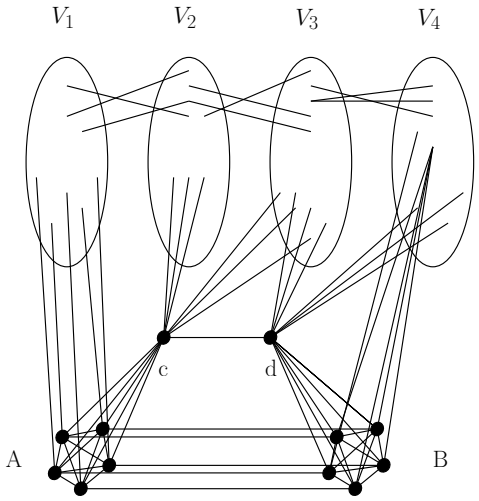

Figure 2 The graph G'.

All edges we added to the graph have the same weight as their corresponding copies in H. Note that there are no edges between V_1 and V_3, nor between V_1 and V_4, nor between V_2 and V_4.

For all $i = 1, \ldots, n$, we add edges of weight $4M$ between x_i^1 and x_i^A, and between x_i^A and x_i^B. Additionally, for all $i = 1, \ldots, n$ and all $j = 1, \ldots, n$, we add an edge between x_i^B and x_j^4 of weight $4M$. For all $v \in V_2 \cup V_3 \cup A$, we add an edge of weight $4M$ between c and v, and for all $v \in V_3 \cup V_4 \cup B$, we add an edge of weight $4M$ between d and v. We add edges with weight $4M$ to connect all vertices in A into a clique, and we do the same for B. Finally, we add an edge of weight $4M$ between c and d.

Note that all edges in this graph have weights between $4M$ and $6M$. Further note that in G all pairs of nodes have a path of length at most $12M$ between them.

Our n queries are picked as follows: For all $i = 1, \ldots, n$, we delete the edge between x_i^B and x_i^4 and query the diameter. Observe that the only path lengths that could become greater than $12M$ are between the nodes in V_1 and the node x_i^4. However, for all x_j^1 where $j \neq i$, the path $x_j^1 \to x_j^A \to x_j^B \to x_i^4$ still has all of its edges, and there exists a path of length $12M$ for these vertices.

Thus the only pair of vertices for the path length might increase is x_i^1 to x_i^4. One must use at most three edges to obatain a path of length at most $15M$ (since any path with four hops has length at least $16M$ because every edge in G has weight at least $4M$). Hence, any path of length less than $15M$ between x_i^1 and x_i^4 must go from x_i^1 to V_2 to V_3 to x_i^4. Thus, if a path of length less than $15M$ exists between x_i^1 and x_i^4 after the edge deletion between x_i^B and x_i^4, then there is a negative triangle in H' containing node x_i.

Thus, we can detect if any negative triangle exists in the tripartite graph H' by asking these n queries, determining for all $x_i \in X$ if a negative triangle containing x_i exists. ◀

Note that if for all $i = 1, \ldots, n$ we delete edge (x_i^B, x_i^4), then the eccentricity of x_i^1 is less than $15M$ if and only if the diameter of the graph is less than $15M$. Thus, this serves as lower bound for eccentricity as well.

A.8 SETH Proofs

▶ **Lemma 18.** *Let $\varepsilon > 0$, $t \in \mathbb{N}$. SETH implies that there exists no algorithm for incremental #SSR with sensitivity $K(\varepsilon, t)$, which has preprocessing time $O(n^t)$, update time $u(n)$ and query time $q(n)$, such that* $\max\{u(n), q(n)\} = O(n^{1-\varepsilon})$.

Proof. Set $\delta = (1-\varepsilon)/t$. Assume that the k-CNFSAT formula F has $c \cdot \tilde{n}$ clauses for some constant c. Partition the clauses into $K = c/\delta$ groups of size $\delta\tilde{n}$ and denote these groups by $G_1, \ldots, G_K$. Further let U be a subset of the $\tilde{n}$ variables of F of size $\delta\tilde{n}$, and let $\bar{U}$ denote the set of all partial assignments to the variables in the U.

We construct a graph G as the union of D_δ and H_δ. It consists of $\bar{U}$ and the set C of clauses. We direct the edges in H_δ from C to $\bar{U}$, and add a directed edge from a node $d \in D_\delta$ to $c \in C$ iff $c \in d$. We further add a single node s to the graph. The resulting graph has $n = O(2^{\delta\tilde{n}})$ nodes and $O(2^{\delta\tilde{n}}\tilde{n})$ edges.

We proceed in stages with one stage for each partial assignment to the variables in $V \setminus U$. At a stage for a partial assignment ϕ to the variables in $V \setminus U$, we proceed as follows: For each group $G_i \subset C$, we add an edge from s to the largest non-empty subset d_i of G_i which only contains clauses that are not satisfied by ϕ, i.e., to the set $d_i = \{c \in G_i : \phi \not\models c\}$; if d_i is empty, then we do not introduce an edge. Let D' be the set of nodes d_i that received an edge from s and let $d(s) = |D'|$. Note that $d(s) \leq K$, since we introduce at most one edge for each of the K groups. Further, let B denote the number of clauses in C reachable from the sets $d_i \in D'$, i.e., $B = \sum_{i=1}^{K} |d_i|$. We query if the number of nodes reachable from s is less than $d(s) + B + 2^{\delta\tilde{n}}$. If the answer to the query is true, then we return that F is satisfiable, otherwise, we proceed to the next partial assignment to the variables in $V \setminus U$.

We prove the correctness of the reduction: Assume that F is satisfiable. Then there exist partial assignments ϕ and ϕ' to the variables in $V \setminus U$ and U, such that $\phi \cdot \phi'$ satisfies F. Hence, for each subset of clauses $d \subset C$ we have that each clause $c \in d$ is satisfied by ϕ or by ϕ'. Thus, the node $u \in \bar{U}$ corresponding to ϕ' cannot be reachable from s and there must be less than $d(s) + B + 2^{\delta\tilde{n}}$ nodes reachable from s. Now assume that at a stage for the partial assignment ϕ the result to the query is true, i.e., less than $d(s) + B + 2^{\delta\tilde{n}}$ nodes are reachable from s; namely $d(s)$ at distance 1, B at distance 2, and less than $2^{\delta\tilde{n}}$ at distance 3. In this case, there must be a node $u \in \bar{U}$ which is not reachable from s: In D_δ there are exactly $d(s)$ nodes reachable and in C there are exactly B nodes reachable by construction of the graph and definition of $d(s)$ and B. This implies that for the partial assignment ϕ' corresponding to u, each clause $c \in C$ must be satisfied by ϕ or ϕ'. Hence, F is satisfiable.

Note that determining the sets $d_i \in D'$ can be done in time $O(\delta\tilde{n}^2)$ per group G_i as for each clause we can check in time $O(\tilde{n})$ whether it is satisfied by ϕ. Thus the set D' and the value B can be computed in total time $O(cn)$ and the total time for all stages is $O(2^{1-\delta\tilde{n}}(\tilde{n}^2 + Ku(n) + Kq(n))$. If both $u(n)$ and $q(n)$ are $O(n^{1-\varepsilon}) = O(2^{\delta\tilde{n}(1-\varepsilon)})$, then SAT can be solved in time $O^*(2^{\tilde{n}(1-\varepsilon\delta)})$. ◀

▶ **Lemma 19.** *Let $\varepsilon > 0$, $t \in \mathbb{N}$. SETH implies that there exists no $(4/3-\varepsilon)$-approximation algorithm for incremental diameter with sensitivity $K(\varepsilon, t)$, which has preprocessing time $O(n^t)$, update time $u(n)$ and query time $q(n)$, such that* $\max\{u(n), q(n)\} = O(n^{1-\varepsilon})$.

Proof. Set $\delta = (1-\varepsilon)/t$. During the proof we will assume that the k-CNFSAT formula F has $c \cdot \tilde{n}$ clauses for some constant c. We partition these clauses into $K = c/\delta$ groups of size $\delta\tilde{n}$ and denote these groups by $G_1, \ldots, G_K$.

We construct a graph as follows: For $U \subset V$ of size $\delta\tilde{n}$ we create the graph H_δ with the set of all partial assignments to the variables in U denoted by $\bar{U}$ and the set of clauses C.

We also add the graph D_δ containing all the subsets of the groups G_i. Furthermore, we introduce four additional nodes x, y, z and t. Observe that the graph has $O(2^{\delta\tilde{n}})$ vertices.

We add an edge from x to each node in $\bar{U}$. We connect y to all nodes in C and to all nodes in D_δ. We add further edges between a clause c and a set $g \in D_\delta$ if $c \in g$. We also add the following edges to E: $\{x, y\}$, $\{y, z\}$ and $\{z, t\}$. Hence, we have $O(2^{\delta\tilde{n}}\tilde{n})$ edges in total.

If during the construction of the graph we encounter that a clause is satisfied by all partial assignments in $\bar{U}$, then we remove this clause. Also, if there exists a partial assignment from $\bar{U}$ which satisfies all clauses, we return that the formula is satisfiable. Thus, we can assume that each node in $\bar{U}$ must have an edge to a node in C and vice versa.

We proceed in stages with one stage for each partial assignment to the variables in $V \setminus U$. Denote the partial assignment of the current stage by ϕ. For each G_i, we add an edge between t and the subset of G_i that contains all clauses of G_i which are not satisfied by ϕ, i.e., we add an edge between t and $\{c \in G_i : \phi \nvDash c\}$ for all $i = 1, \ldots, K$. Hence, in each stage we have $O(K) = O(1)$ updates. We query the diameter of the resulting graph. The diameter is 3, if the formula F is not satisfiable, and it is 4, otherwise. After that we remove the edges that were added in the update.

We prove the correctness of our construction: Observe that via x and y all nodes from $\bar{U} \cup C \cup G$ have a distance of at most 3. From z we can reach all vertices of G and C via y within two steps and all nodes of $\bar{U}$ within three steps via y and x. From t we can reach all nodes of $\{x, y, z\} \cup C \cup G$ within three steps using the path $t \to z \to y \to v$, where $v \in C \cup D_\delta \cup \{x\}$. Hence, all nodes in $\{x, y, z, t\} \cup C \cup G$ have a maximum distance of 3. From $\bar{u} \in \bar{U}$ we can reach t in four steps with the path $\bar{u} \to x \to y \to z \to t$.

Assume that for $\bar{u}$ there exists a path $\bar{u} \to c \to g \to t$, then by construction $\bar{u} \nvDash c$ and $\phi \nvDash c$, since $c \in g$. Hence, F is not satisfied by $\bar{u} \cdot \phi$. Thus, if the diameter is 3, then F is not satisfiable. On the other hand, if F is not satisfiable, then for each pair of partial assignments $\bar{u}$ and ϕ, there must be a clause c which both partial assignments do not satisfy. Hence, there must be a path of the form $\bar{u} \to c \to g \to \phi$ for some g with $c \in g$ and g has an edge to t. Thus, if F is not satisfiable, then the graph has diameter 3.

The sets d_i can be computed as in the previous proof. ◀

▶ **Lemma 20.** *Let $\varepsilon > 0$, $t \in \mathbb{N}$. SETH implies that there exists no algorithm for incremental ST-Reach with sensitivity $K(\varepsilon, t)$, which has preprocessing time $O(n^t)$, update time $u(n)$ and query time $q(n)$, such that $\max\{u(n), q(n)\} = O(n^{1-\varepsilon})$.*

Proof. We reuse the graph from the proof of Lemma 19. We update it by removing the vertices x, y, z. We further set $S = \bar{U}$ and $T = \{t\}$.

We proceed in stages with one stage for each partial assignment to the variables in $V \setminus U$. Denote the partial assignment of the current stage by ϕ. For each G_i, we add an edge between t and the subset of G_i that contains all clauses of G_i which are not satisfied by ϕ, i.e. we add an edge between t and $\{c \in G_i : \phi \nvDash c\}$ for all $i = 1, \ldots, K$. Hence, in each stage we have $O(K) = O(1)$ updates. We query for ST-Reachability. If the answer is true, then F is not satisfiable, otherwise, it is.

We prove the correctness of our construction: If F is not satisfiable, then for each pair of partial assignments $\bar{u}$ and ϕ, there must be a clause c which both partial assignments do not satisfy. Hence, there must be a path of the form $\bar{u} \to c \to g \to \phi$ for some g with $c \in g$ and g has an edge to t. Thus, if F is not satisfiable, then all nodes in S will be able to reach t. On the other hand, assume that for $\bar{u}$ there exists a path $\bar{u} \to c \to g \to t$, then by construction $\bar{u} \nvDash c$ and $\phi \nvDash c$, since $c \in g$. Hence, F is not satisfied by $\bar{u} \cdot \phi$. Thus, if all nodes from S can reach t, then F is not satisfiable.

The sets d_i can be computed as in the first proof of the section. ◀

A.9 Conditional Lower Bounds For Variable Sensitivity

In this section we prove conditional lower bounds for algorithms where the sensitivity is not fixed, but given a parameter d. Before we give our results, we shortly argue why this setting is relevant.

First, several results were obtained in the setting with sensitivity d. Some of these results are by Patrascu and Thorup [37] for decremental reachability, by Duan and Pettie [23, 24] and by Henzinger and Neumann [28] for subgraph connectivity and by Chechik et al. [19, 18] for decremental all pairs shortest paths. Our lower bounds show that the results in [23, 24] and the incremental algorithm in [28] are tight.

Second, when d is not fixed and we can prove a meaningful lower bound, this will help us understand whether updates or queries are more sensitive to changes of the problem instance.

Third, when d is fixed to a constant, the problems might become easier in the sense that constant or polylogarithmic update and query times can be achieved. For example, for APSP with single edge failures one can achieve query and update times $O(1)$ (see [10]); for APSP with two edge failures one can achieve query and update times $O(\log n)$ (see [22]). In these cases we cannot prove any non-trivial conditional lower bounds for them. However, with an additional parameter d we can derive conditional lower bounds which are polynomial in the parameter d.

Our results are summarized in the following theorem.

▶ **Theorem 21.** *Under the OMv conjecture for any $\varepsilon > 0$, there exists no algorithm with preprocessing time* $\text{poly}(n)$*, update time* $\text{poly}(d)$ *and query time $\Omega(d^{1-\varepsilon})$ for the following problems:*

1. *Decremental/incremental st-SubConn in undirected graphs with sensitivity d*
2. *decremental/incremental st-reach in directed graphs with sensitivity d,*
3. *decremental/incremental BP-Match in undirected bipartite graphs with sensitivity d, and*
4. *decremental/incremental SC in directed graphs with sensitivity d.*
5. *$(2-\varepsilon)$-approximate ss-shortest paths with sensitivity d in undirected unweighted graphs,*
6. *$(5/3-\varepsilon)$-approximate st-shortest paths with sensitivity d in undirected unweighted graphs,*
7. *BW-Matching with sensitivity d.*

Conditional Lower Bounds for Directed Graphs

We observe that some existing reductions can be used to obtain conditional lower bounds for sensitivity problems. In this section, we summarize the results that can be obtained this way.

We call a reduction from a dynamic problem A to another dynamic problem B *sensitivity-preserving* if in the reduction a single update in problem A propagates to problem B as at most one update. We observe that the reductions in [3] from *st*-subgraph-connectivity to *st*-reachability (Lemma 6.1) and from *st*-reachability to BP-Match (Lemma 6.2) and SC (Lemma 6.4) are sensitivity-preserving. Henzinger et al. [27] give conditional lower bounds for the *st*-subgraph-connectivity problem with sensitivity d. The previous observations about sensitivity preserving reductions imply that we get the same lower bounds for st-reach, BP-Match and SC with sensitivity d. This implies the first four points of Theorem 21.

The construction of the lower bound in [27] required $d = m^\delta$ for some $\delta \in (0, 1/2]$. This appears somewhat artifical, since in practice one would rather expect situations with much smaller values for d, e.g., $d = O(1)$ or $d = \text{poly}\log(n)$. However, the lower bound is still interesting because it applies to all algorithms that allow setting $d = m^\delta$. For example, the sensitive subgraph connectivty algorithms of Duan and Pettie [23, 24] is tight w.r.t. to the above lower bound.

Conditional Lower Bounds for Undirected Graphs

In this subsection, we prove the last three points of Theorem 21. We give a reduction from the γ-uMv-problem, which was introduced by Henzinger et al. [27]. The γ-uMv-problem is as follows: Let $\gamma > 0$. An algorithm for the γ-uMv problem is given an $n_1 \times n_2$ binary matrix M with $n_1 = \lfloor n_2^\gamma \rfloor$, that can be preprocessed. Then two vectors u and v appear and the algorithm must output the result of the Boolean vector-matrix-vector-product $u^t M v$.

Henzinger et al. [27, Corollary 2.8] show that under the OMv conjecture for all $\varepsilon > 0$, no algorithm exists for the γ-uMv-problem that has preprocessing time $\text{poly}(n_1, n_2)$, computation time $O(n_1^{1-\varepsilon} n_2 + n_1 n_2^{1-\varepsilon})$, and error probability at most $1/3$. We give a reduction from the γ-uMv-problem to $(2-\varepsilon)$-approximate ss-shortest-paths with sensitivity d in the following lemma. This lemma and the proof of Corollary 3.12 in [27] imply the result in Theorem 21 for ss-shortest-paths.

▶ **Lemma 22.** *Let $\delta \in (0, 1/2]$. Given an algorithm $\mathcal{A}$ for incremental/decremental $(2-\varepsilon)$-ss-shortest paths with sensitivity d, one can solve $(\frac{\delta}{1-\delta})$-uMv with parameters n_1 and n_2 by running the preprocessing step of $\mathcal{A}$ on a graph with $O(m)$ edges and $O(m^{1-\delta})$ vertices, then making a single batch update of size $O(d)$ and $O(m^{1-\delta})$ queries, where m is such that $m^{1-\delta} = n_1$ and $d = m^\delta = n_2$.*

Proof. We prove the lower bound for the incremental problem.

Let M be a $n_1 \times n_2$ binary matrix for $(\frac{\delta}{1-\delta})$-uMv. We construct a bipartite graph G_M from the matrix M: Set $G_M = ((L \cup R), E)$, where $L = \{l_1, \ldots, l_{n_1}\}$, $R = \{r_1, \ldots, r_{n_2}\}$ and the edges are given by $E = \{(l_i, r_j) : M_{ij} = 1\}$. We add an additional vertex s to G_M and attach a path of length 3 to s, the vertex on the path with distance 3 from s has edges to all vertices in L. Observe that G_M has $O(n_1 n_2) = O(m)$ edges and $n_1 + n_2 = \Theta(m^\delta + m^{1-\delta}) = \Theta(m^{1-\delta})$ vertices.

When the vectors u and v arrive, we add an edge (s, r_j) for each $v_j = 1$ in a single batch of $O(d)$ updates. After that for each $u_i = 1$, we query the shortest path from s to l_i. In total, we perform $O(m^{1-\delta})$ queries and only use a single batch update consisting of $O(d)$ insertions. We claim that one of the queries returns less than 4 iff $u^t M v = 1$.

First assume that $u^t M v = 1$. Then there exist indices i, j such that $u_i = M_{ij} = v_j = 1$. Hence, there must be a path $l_i \to r_j \to s$ of length 2 in G_M and since $l_i = 1$ we ask the query for l_i. Hence, any $(2-\varepsilon)$-approximation algorithm must return less than 4 in the query for l_i. Now assume that a query for vertex l_i returns less than 4. Since any path from a vertex in L to s must have length $2k$ for some $k \in \mathbb{N}$, there exists a path $l_i \to r_j \to s$. Since query for l_i, we have $u_i = 1$. Due to the edge $l_i \to r_j$, $M_{ij} = 1$, and due to edge $r_j \to s$, $v_j = 1$. Thus, $u_i M_{ij} v_j = 1$ and $u^t M v = 1$.

The proof for the decremental problem works by initially adding all edges from s to R to the graph and then removing edges corresponding to the 0-entries of v. ◀

To obtain the result of Theorem 21 for st-shortest-paths, observe that the above reduction can be changed to work for this problem: We add additional vertices s, t to the original bipartite graph and connect s and t by a path of length 5 (i.e., introducing 3 additional vertices). Then a similar proof to the above shows that any algorithm for st-reachability that can distinguish between a shortest path of length at most 3 or at least 5 can be used to decide if $u^t M v = 1$. The result for BW-Match follows from the reduction in [3].

B No (globally) fixed constant sensitivity with polynomial preprocessing time

In this section, we will first discuss how SETH reductions depend on their sensitivity. In particular, we will see that even though some of our previous reductions had constant sensitivities, these constants are not bounded globally. Afterwards we will prove that if we allow for polynomial preprocessing time, then there cannot be a globally fixed upper bound on the sensitivities.

B.1 A note on SETH reductions

Let us recall that the sensitivities of the reductions in Section 4 had the form $K = c/\delta$, where cn was the number of clauses in the k-CNFSAT formula and $\delta < 1$ was a parameter indicating the size of our initial graph. We will first discuss the dependency of K on δ and after that on c.

Firstly, let us discuss how the SETH reductions depend on the parameter δ. Let F be a k-CNFSAT formula with n variables and $O(n)$ clauses. Notice that if the input graph that we construct in the reduction had size $N = O(2^{n/2})$, then the preprocessing time of an algorithm refuting SETH would have to be $O(N^{2-\varepsilon})$. In order to allow for arbitrary polynomial preprocessing times of the algorithm, the reductions in [3] (and also the ones from the section before) were parameterized such that the initial graphs have size $O(2^{\delta n})$ (disregarding poly(n) factors). Then for an algorithm with preprocessing time $O(N^t)$ we can pick $\delta < 1/t$ and hence the preprocessing takes time $O(2^{\delta nt}) = O(2^{(1-\gamma)n})$ for some $\gamma > 0$. Thus, despite the "large" preprocessing time we could still refute the SETH. However, the sensitivities $K = c/\delta$ are not bounded if we consider δ as a parameter, i.e. $K \to \infty$ as $\delta \to 0$. If we consider δ as the inverse of the power of the preprocessing time $O(N^t)$, i.e. $\delta = 1/t$, then this can be interpreted as "large preprocessing time" corresponds to "large sensitivity" (since $\delta \to 0$ iff $t \to \infty$).

Now one might want to fix δ (and thus bound the preprocessing time) in order to get (globally) fixed constant sensitivities. Unfortunately, this approach is also not feasible; in the SETH reductions for proving an algorithm that solves k-CNFSAT in time $2^{(1-\varepsilon)n}$, there is another parameter c which denotes the number of clauses of the k-CNFSAT instance after the application of the sparsification lemma by Impagliazzo, Paturi and Zane [30]. Looking at the proof of the lemma one can see that $c = c(k, \varepsilon)$ and that $c \to \infty$ as $k \to \infty$, as well as $c \to \infty$ as $\varepsilon \to 0$. Hence, if we use the sparsification lemma and fix δ, then we still cannot refute the SETH.

B.2 Upper bound in case of polynomial preprocessing

The former reasoning heavily relies on the constructions in our proofs and does not rule the possibility of a reduction with (globally) fixed constant sensitivity from SETH. However, the following theorem and the corollary after it will show that if we allow for polynomial preprocessing time, then there cannot be a polynomial time upper bound on update and query time under any conjecture.

▶ **Theorem 23.** *Let P be a fully dynamic graph problem*[7] *with sensitivity K on a graph*

[7] We only argue about dynamic graph problems to simplify our language. The theorem holds for all dynamic problems with the given properties.

$G = (V, E)$ with n vertices and m edges where edges are added and removed. Assume that for the static version of P there exists an algorithm running in time $\mathrm{poly}(n)$.

Then there exists an algorithm with $p(n) = n^t$ for some $t = t(K)$, $u(n) = O(K)$ and $q(n) = \log(n)$. The algorithm uses space $O(n^t)$.

Proof. The basic idea of the algorithm is to preprocess the results of all possible queries that might be encountered during P. Since we have only sensitivity K, we will only have polynomially many graphs during the running time of the algorithm. We can save all of these results in a balanced tree of height $O(\log n)$ and during a query we just traverse the tree in logarithmic time.

Denote the initial input graph by G_0.

Since we know that after each update has size at most K and after the update we roll back to the initial graph, we can count how many graphs can be created while running P. Particularly, notice that a graph $G_1 = (V, E_1)$ can be created while running P if and only if $S = E_0 \triangle E_1$ has $|S| \leq K$.[8] Then in total the number of graphs which P will have to answer queries on can be bounded by computing how many such sets S exist:

$$\sum_{i=0}^{K} \binom{n^2}{i} \leq K \max_{i=0,\ldots,K} \binom{n^2}{i} = K\,\mathrm{poly}(n) = n^t,$$

for some t (where in the second step we used that K is constant).

Now consider the naïve algorithm which just preprocesses all trees and stores the results: We enumerate all n^t possible trees and run the static algorithm on them. This can be done in time $O(\mathrm{poly}(n))$. We store the results of the static algorithm in a balanced binary tree with $O(n^t)$ leaves which is of height $O(\log n)$. The traversal of the tree can be done, e.g., in the following way: We fix some order $\prec$ on $V \times V$; this implicitly gives an order $\prec$ on the set $\{S \subseteq V \times V\}$. For a graph G_1 we compute $S = E_1 \triangle E_0$ and traverse according to S.

During updates the algorithm maintains an array of size K which contains the edges that are to be removed or added ordered by $\prec$. This can be done in time $O(K) = O(1)$.

During a query the algorithm will traverse the binary tree from the preprocessing according to $\prec$ and the updates that were saved during the updates. This takes time $O(\log n)$.

Hence, we have found algorithm with $p(n) = \mathrm{poly}(n)$ and $u(n) = O(1)$ and $q(n) = O(\log n)$. ◀

▶ **Corollary 24.** *If for a problem with the properties from Theorem 23 there exists a reduction from conjecture $\mathcal{C}$ to P with $p(n) = \mathrm{poly}(n)$ and $\max\{u(n), q(n)\} = \Omega(n^{\gamma-\varepsilon})$ for any $\gamma > 0$ and all $\varepsilon \in (0, \gamma)$. Then $\mathcal{C}$ is false.*

Proof. We use Theorem 23 to obtain an algorithm which is better than the lower bound given in the assumption of the corollary. Hence, we obtain a contradiction to $\mathcal{C}$. ◀

Notice that Corollary 24 implies that in order to obtain meaningful lower bounds for dynamic problems with a certain sensitivity, we must either bound the preprocessing time of the algorithm or bound the space usage of the algorithm or allow the sensitivity to become arbitrarily large.

[8] $A \triangle B$ denotes the symmetric difference of A and B, i.e. $A \triangle B = A \setminus B \cup B \setminus A$.

An Improved Homomorphism Preservation Theorem From Lower Bounds in Circuit Complexity*

Benjamin Rossman

University of Toronto, Canada
ben.rossman@utoronto.ca

Abstract

Previous work of the author [39] showed that the Homomorphism Preservation Theorem of classical model theory remains valid when its statement is restricted to finite structures. In this paper, we give a new proof of this result via a reduction to lower bounds in circuit complexity, specifically on the AC^0 formula size of the colored subgraph isomorphism problem. Formally, we show the following: if a first-order sentence Φ of quantifier-rank k is preserved under homomorphisms on finite structures, then it is equivalent on finite structures to an existential-positive sentence Ψ of quantifier-rank $k^{O(1)}$. Quantitatively, this improves the result of [39], where the upper bound on the quantifier-rank of Ψ is a non-elementary function of k.

1 Introduction

Preservation theorems are a family of results in classical model theory that equate semantic and syntactic properties of first-order formulas. A prominent example — and the subject of this paper — is the Homomorphism Preservation Theorem, which states that a first-order sentence is preserved under homomorphisms if, and only if, it is equivalent to an existential-positive sentence. (Definitions for the various terms in this theorem are given in Section 3.) Two related classical preservation theorems are the Łoś-Tarski Theorem (preserved under *embedding* homomorphisms $\Leftrightarrow$ equivalent to an *existential* sentence) and Lyndon's Theorem (preserved under *surjective* homomorphism $\Leftrightarrow$ equivalent to a *positive* sentence).

In all classical preservation theorems, the "syntactic property $\Rightarrow$ semantic property" direction is straightforward, while the "semantic property $\Rightarrow$ syntactic property" direction is typically proved by an application of the Compactness Theorem.[1] In order to use compactness, it is essential that the semantic property (i.e. preservation under a certain relationship between structures) holds with respect to *all* structures, that is, both finite and infinite. One may also ask about the status of classical preservation theorems relative to a class of structures $\mathscr{C}$. So long as compactness holds in $\mathscr{C}$ (for example, whenever $\mathscr{C}$ is first-order axiomatizable),

* Supported by NSERC and the JST ERATO Kawarabayashi Large Graph Project. This paper was partially written at the National Institute of Informatics in Tokyo and during a visit to IMPA, the National Institute for Pure and Applied Mathematics in Rio de Janeiro.

[1] The Compactness Theorem states that a first-order theory T (i.e. set of first-order sentences) is consistent (i.e. there exists a structure $\mathcal{A}$ which satisfies every sentence in T) if every finite sub-theory of T is consistent. (See [24] for background and proofs of various preservation/amalgamation/interpolation theorems in classical model theory.)

so too will all of the classical preservation theorems. The situation is less clear when $\mathscr{C}$ is the class of finite structures (or a subclass thereof), as the Compactness Theorem is easily seen to be false when restricted to finite structures.[2]

The program of classifying theorems in classical model theory according to their validity over finite structures was a major line of research, initiated by Gurevich [20], in the area known as *finite model theory* (see [15, 17, 28]). The status of preservation theorems in particular was systematically investigated in [3, 38]. Given the failure of the Compactness Theorem on finite structures, it is not surprising that nearly all of the classical preservation theorems become false when their statements are restricted to finite structures. A counterexample of Tait [44] from 1959 showed that the Łoś-Tarski Theorem is false over finite structures, while Ajtai and Gurevich [1] in 1987 gave the demise of Lyndon's Theorem via a stronger result in circuit complexity. Namely, they showed that Monotone $\cap$ $\mathrm{AC}^0 \neq$ Monotone-AC^0, that is, there is a (semantically) monotone Boolean function that is computable by AC^0 circuits, but not by (syntactically) monotone AC^0 circuits. The failure of Lyndon's theorem on finite structures follows via the *descriptive complexity* correspondence between AC^0 and first-order logic. (See [26] about the nexus between logics and complexity classes.)

Given the failure of both the Łoś-Tarski and Lyndon Theorems, it might be expected that the Homomorphism Preservation Theorem also fails over finite structures (as it seems to live at the intersection of Łoś-Tarski and Lyndon). On the contrary, however, previous work of the author [39] showed that the Homomorphism Preservation Theorem remains valid over finite structures. The technique of [39] is model-theoretic: its starting point is a new compactness-free proof of the classical theorem, which is then adapted to finite structures. (A summary of the argument is included in Section 8.) In the present paper, we give a completely different proof of this result — and moreover obtain a quantitative improvement — via a reduction to lower bounds in circuit complexity. In particular, we rely on a recent result (of independent interest) that the AC^0 formula size of the colored G-subgraph isomorphism problem is $n^{\Omega(\mathbf{tree\text{-}depth}(G)^{\varepsilon})}$ for an absolute constant $\varepsilon > 0$.

Related Work

Prior to [39], the status of the Homomorphism Preservation Theorem on finite structures was investigated by Feder and Vardi [16], Gräedel and Rosen [18], and Rosen [37], who resolved special cases of the question for restricted classes of first-order sentences. Another special case is due to Atserias [7] in the context of CSP dualities. (See [39] for a discussion of these results.) A different — and incomparable — line of results [6, 14, 31] proves versions of the Homomorphism Preservation Theorems restricted to various *sparse* classes of finite structures (see Ch. 10 of [33], as well as [8] related to the Łoś-Tarski Theorem). See Stolboushkin [43] for an alternative counterexample showing that Lyndon's Theorem fails on finite structures, which is simpler than Ajtai and Gurevich [1] (but doesn't extend to show Monotone-$\mathrm{AC}^0 \neq$ Monotone $\cap$ AC^0).

Outline

The rest of the paper is organized as follows. Because our narrative jumps between logic, graph theory and circuit complexity, for readability sake the various preliminaries — which may be familiar (at least in part) to many readers — are presented in separate sections as

[2] Consider the theory $T = \{\Phi_n : n \in \mathbb{N}\}$ where Φ_n expresses "there exist $\geq n$ distinct elements". Every finite sub-theory of T has a finite model, but T itself does not.

needed throughout the paper. In Section 2, we review basic definitions related to structures, homomorphisms, and first-order logic. In Section 3, we formally state the various preservation theorems discussed in the introduction, including our main result (Theorem 6). Section 4 includes the necessary background on circuit complexity (AC^0 and monotone projections) and graph theory (tree-width, tree-depth, and minor-monotonicity). In Section 5, we introduce the colored G-subgraph isomorphism problem and state the known bounds on its complexity for AC^0 circuits and AC^0 formulas. Section 6 states a needed lemma from descriptive complexity ($FO = AC^0$) and a result connecting quantifier-rank to tree-depth. In Section 7, we prove our main result (Theorem 6) via a reduction to lower bounds for colored G-subgraph isomorphism. (After all the preliminaries, the reduction itself is relatively simple.) For comparison sake, the previous model-theoretic proof technique of [39] is summarized in Section 8. We conclude in Section 9 with a brief discussion of syntax vs. semantics in circuit complexity.

2 Preliminaries, I

2.1 Structures and Homomorphisms

Throughout this paper, let σ be a fixed finite relational signature, that is, a list of relation symbols $R^{(r)}$ (where $r \in \mathbb{N}$ denotes the arity of R). A *structure* $\mathcal{A}$ consists of a set A (called the unverse of $\mathcal{A}$) together with interpretations $R^{\mathcal{A}} \subseteq A^r$ for each relation symbol $R^{(r)}$ in σ. A priori, structures may be finite or infinite.

A *homomorphism* from a structure $\mathcal{A}$ to a structure $\mathcal{B}$ is a map $f : A \to B$ such that $(a_1, \ldots, a_r) \in R^{\mathcal{A}} \implies (f(a_1), \ldots, f(a_r)) \in R^{\mathcal{B}}$ for every $R^{(r)} \in \sigma$ and $(a_1, \ldots, a_r) \in A^r$. Notation $\mathcal{A} \to \mathcal{B}$ asserts the existence of a homomorphism from $\mathcal{A}$ to $\mathcal{B}$.

A homomorphism $f : \mathcal{A} \to \mathcal{B}$ is an *embedding* if f is one-to-one and satisfies $(a_1, \ldots, a_r) \in R^{\mathcal{A}} \iff (f(a_1), \ldots, f(a_r)) \in R^{\mathcal{B}}$ for every $R^{(r)} \in \sigma$ and $(a_1, \ldots, a_r) \in A^r$.

2.2 First-Order Logic

First-order formulas (in the relational signature σ) are constructed out of atomic formulas (of the form $x_1 = x_2$ or $R(x_1, \ldots, x_r)$ where $R^{(r)} \in \sigma$ and x_i's are variables) via boolean connectives ($\varphi \wedge \psi$, $\varphi \vee \psi$, and $\neg\varphi$) and universal and existential quantification ($\forall x\ \varphi(x)$ and $\exists x\ \varphi(x)$). For a structure $\mathcal{A}$ and a first-order formula $\varphi(x_1, \ldots, x_k)$ and a tuple of elements $\vec{a} \in A^k$, notation $\mathcal{A} \models \varphi(\vec{a})$ is the statement that $\mathcal{A}$ satisfies φ with $\vec{a}$ instantiating the free variables $\vec{x}$. First-order formulas with no free variables are called *sentences* and represented by capital Greek letters Φ and Ψ.

A first-order sentence (or formula) is said to be:

- *positive* if it does not contain any negations (that is, it has no sub-formula of the form $\neg\varphi$),
- *existential* if it contains only existential quantifiers (that is, it has no universal quantifiers) and has no negations outside the scope of any quantifier, and
- *existential-positive* if it is both existential and positive.

Two important parameters first-order sentences are quantifier-rank and variable-width. *Quantifier-rank* is the maximum nesting depth of quantifiers. *Variable-width* is the maximum number of free variables in a sub-formula. As we will see in Section 6, under the descriptive complexity characterization of first-order logic in terms of AC^0 circuits, variable-width corresponds to AC^0 circuit size and quantifier-rank corresponds to AC^0 formula size (or, more accurately, AC^0 formula depth when fan-in is restricted to $O(n)$).

Note that first-order sentences are not assumed to be in prenex form. For example, the formula $(\exists x\ P(x)) \vee (\exists y\ \neg Q(y))$ is existential (but not positive) and has quantifier-rank 1 and variable-width 1.

3 The Homomorphism Preservation Theorem

▶ **Definition 1.** A first-order sentence Φ is *preserved under homomorphisms* [*on finite structures*] if $(\mathcal{A} \models \Phi$ and $\mathcal{A} \to \mathcal{B}) \Longrightarrow \mathcal{B} \models \Phi$ for all [finite] structures $\mathcal{A}$ and $\mathcal{B}$. The notions of *preserved under embeddings* and *preserved under surjective homomorphisms* are defined similarly.

We now formally state the three classical preservations mentioned in the introduction.

▶ **Theorem 2** (Łoś-Tarski / Lyndon / Homomorphism Preservation Theorems [29])**.** *A first-order sentence is preserved under* [*embedding / surjective / all*] *homomorphisms if, and only if, it is equivalent to an* [*existential / positive / existential-positive*] *sentence.*

As discussed in the introduction, Łoś-Tarski and Lyndon's Theorems become false when restricted to finite structures.

▶ **Theorem 3** (Failure of Łoś-Tarski and Lyndon Theorems on Finite Structures [1, 44])**.** *There exists a first-order sentence that is preserved under* [*embedding / surjective*] *homomorphisms on finite structures, but is not equivalent on finite structures to any* [*existential / positive*] *sentence.*

In contrast, the Homomorphism Preservation Theorem remains valid over finite structures.

▶ **Theorem 4** (Homomorphism Preservation Theorem on Finite Structures [39])**.** *If a first-order sentence of quantifier-rank k is preserved under homomorphisms on finite structures, then it is equivalent on finite structures to an existential-positive sentence of quantifier-rank $\beta(k)$, for some computable function $\beta : \mathbb{N} \to \mathbb{N}$.*

We will refer to $\beta : \mathbb{N} \to \mathbb{N}$ in Theorem 4 as the "quantifier-rank blow-up". (Formally, there is one computable function $\beta_\sigma : \mathbb{N} \to \mathbb{N}$ for each finite relational signature σ.) We remark that the upper bound on $\beta(k)$ given by the proof of Theorem 4 is a non-elementary function of k (i.e. it is grows faster than any bounded-height tower of exponentials). In contrast, a second result in [39] shows that the optimal bound $\beta(k) = k$ holds in the classical Homomorphism Preservation Theorem.

▶ **Theorem 5** ("Equi-rank" Homomorphism Preservation Theorem [39])**.** *If a first-order sentence of quantifier-rank k is preserved under homomorphism, then it is equivalent to an existential-positive sentence of quantifier-rank k.*

Due to reliance on the Compactness Theorem, the original proof of the classical Homomorphism Preservation Theorem gives no computable upper bound whatsoever on the quantifier-rank blow-up. Theorem 5 is proved by a constructive, compactness-free argument (see Section 8). In [39] I conjectured that this stronger "equi-rank" theorem is valid over finite structures. However, new techniques were clearly needed to improve the non-elementary upper bound on $\beta(k)$.

The main result of the present paper is a completely new proof of Theorem 4, which moreover gives a polynomial upper bound on $\beta(k)$.

▶ **Theorem 6** ("Poly-rank" Homomorphism Preservation Theorem on Finite Structures)**.** *If a first-order sentence of quantifier-rank k is preserved under homomorphisms on finite structures, then it is equivalent on finite structures to an existential-positive sentence of quantifier-rank $k^{O(1)}$.*

The proof of Theorem 6 involves a reduction to the AC^0 formula size of SUB_G, the colored G-subgraph isomorphism problem. This reduction transforms lower bounds on the AC^0 formula size of SUB_G into upper bounds on the quantifier-rank blow-up $\beta(k)$ in Theorem 4. In Section 7.1, we derive an exponential upper bound $\beta(k) \leq 2^{O(k)}$ from an existing lower bound of [41] on the AC^0 formula size of SUB_{P_k} (also known as the distance-k connectivity problem). Two further steps, described in Section 7.2, are required for the polynomial upper bound $\beta(k) \leq k^{O(1)}$ of Theorem 6. The first is a new result in graph minor theory from [25] (joint work with Ken-ichi Kawarabayashi), which gives a "polynomial excluded-minor approximation" of tree-depth, analogous to the Polynomial Grid-Minor Theorem of Chekuri and Chuzhoy [12]. The second ingredient, in a forthcoming paper of the author [42], is a lower bound on AC^0 formula size of SUB_G in the special case where G is complete binary tree.

4 Preliminaries, II

4.1 Circuit Complexity

We consider *Boolean circuits* with unbounded fan-in AND and OR gates and negations on inputs. That is, inputs are labelled by variables x_i or negated variables $\overline{x}_i$ (where i comes from some finite index set, typically $\{1, \ldots, n\}$). We measure *size* by the number of gates and *depth* by the maximum number of gates on an input-to-output path. Boolean circuits with fan-out 1 (i.e. tree-like Boolean circuits) are called *Boolean formulas*. (Boolean formulas are precisely the same as quantifier-free first-order formulas.)

The *depth-d circuit/formula size* of a Boolean function f is the minimum size of a depth-d circuit/formula that computes f. AC^0 refers to constant-depth, $\mathrm{poly}(n)$-size sequences of Boolean circuits/formula on $\mathrm{poly}(n)$ variables. For a sequence (f_n) of Boolean functions on $\mathrm{poly}(n)$ variables and a constant $c > 0$, we say that "(f_n) has AC^0 circuit/formula size $O(n^c)$ (resp. $\Omega(n^c)$)" if for some d (resp. for all d), the depth-d circuit/formula size of f_n is $O_d(n^c)$ (resp. $\Omega_d(n^c)$) for all n.

One slightly unusual complexity measure (which arises in the descriptive complexity correspondence between AC^0 and first-order logic in Section 6) is *fan-in n depth*, that is, the minimum depth required to compute a Boolean function by AC^0 circuits with fan-in restricted to n. Note that AC^0 formula size lower bounds imply fan-in n depth lower bounds: if f has AC^0 formula size $\omega(n^c)$, then its fan-in n formula depth is at least c (for sufficiently large n). (This follows from the observation that every depth-d formula with fan-in n is equivalent to a depth-d formula of size at most n^d.)

4.2 Monotone Projections

▶ **Definition 7** (Monotone-Projection Reductions)**.** For Boolean functions $f : \{0,1\}^I \to \{0,1\}$ and $g : \{0,1\}^J \to \{0,1\}$, a *monotone-projection reduction* from f to g is a map $\rho : J \to$

$I \cup \{0,1\}$ such that $f(x) = g(\rho^*(x))$ for all $x \in \{0,1\}^I$ where $\rho^*(x) \in \{0,1\}^J$ is defined by

$$(\rho^*(x))_j = \begin{cases} x_i & \text{if } \rho(j) = i \in I, \\ 0 & \text{if } \rho(j) = 0, \\ 1 & \text{if } \rho(j) = 1. \end{cases}$$

(Properly speaking, the "reduction" from f to g is the map $\rho^* : \{0,1\}^I \to \{0,1\}^J$ induced by ρ.) Notation $f \leq_{\text{mp}} g$ denotes the existence of a monotone-projection reduction from f to g.

When describing monotone-projection reductions later in this paper, it will be natural to speak in terms of indexed sets of Boolean variables $\{X_i\}_{i \in I}$ and $\{Y_j\}_{j \in J}$, rather than sets I and J themselves. Thus, a monotone-projection reduction $\rho : J \to I \cup \{0,1\}$ associates each variable Y_j with either a constant (0 or 1) or some variable X_i.

Note that $\leq_{\text{mp}}$ is a partial order on Boolean functions. This is the simplest kind of reduction in complexity theory. It has the nice property that every standard complexity measure on Boolean functions is monotone under $\leq_{\text{mp}}$. For instance, letting $L_d(f)$ denote the depth-d formula size of f, we have $f \leq_{\text{mp}} g \implies L_d(f) \leq L_d(g)$.

4.3 Tree-Width and Tree-Depth

Graphs in this paper are finite simple graphs. (In contrast to the previous discussion of infinite structures, we assume finiteness whenever we speak of graphs.) Formally, a graph G is a pair $(V(G), E(G))$ where $V(G)$ is a finite set and $E(G) \subseteq \binom{V(G)}{2}$ is a set of unordered pairs of vertices.

Four specific graphs that arise in this paper: for $k \geq 1$, let K_k denote the complete graph of order k, let P_k denote the path of order k, let B_k denote the complete binary tree of height k (where every leaf-to-root path has order k), and let $Grid_{k \times k}$ denote the $k \times k$ grid graph. (In the case $k = 1$, all four of these graphs are a single vertex.)

We recall the definitions of two structural parameters, tree-width and tree-depth, which play an important role in this paper. A *tree decomposition* of a graph G consists of a tree T and a family $\mathcal{W} = \{W_t\}_{t \in V(T)}$ of sets $W_t \subseteq V(G)$ satisfying

- $\bigcup_{t \in V(T)} W_t = V(G)$ and every edge of G has both ends in some W_t, and
- if $t, t', t'' \in V(T)$ and t' lies on the path in T between t and t'', then $W_t \cap W_{t''} \subseteq W_{t'}$.

The *tree-width* of G, denoted $\mathbf{tw}(G)$, is the minimum of $\max_{t \in V(T)} |W_t| - 1$ over all tree decompositions $(T, \mathcal{W})$ of G.

The *tree-depth* of G, denoted $\mathbf{td}(G)$, is the minimum height of a rooted forest F such that $V(F) = V(G)$ and every edge of G has both ends in some branch in F (i.e. for every $\{v, w\} \in E(G)$, vertices v and w have an ancestor-descendant relationship in F). There is also an inductive characterization of tree-depth: if G has connected components $G_1, \ldots, G_t$, then

$$\mathbf{td}(G) = \begin{cases} 1 & \text{if } |V(G)| = 1, \\ 1 + \min\limits_{v \in V(G)} \mathbf{td}(G - v) & \text{if } t = 1 \text{ and } |V(G)| > 1, \\ \max\limits_{i \in \{1,\ldots,t\}} \mathbf{td}(G_i) & \text{if } t > 1. \end{cases}$$

These two structural parameters, tree-width and tree-depth, are related by inequalities:

$$\mathbf{tw}(G) \leq \mathbf{td}(G) - 1 \leq \mathbf{tw}(G) \cdot \log |V(G)|. \tag{1}$$

Tree-depth is also related the length of the longest path in G, denoted $\mathbf{lp}(G)$:

$$\log(\mathbf{lp}(G)+1) \leq \mathbf{td}(G) \leq \mathbf{lp}(G). \tag{2}$$

(See Ch. 6 of [33] for background on tree-depth and proofs of these inequalities.)

Graph parameters $\mathbf{tw}(\cdot)$ and $\mathbf{td}(\cdot)$, as well as $\mathbf{lp}(\cdot)$, are easily seen to be monotone under the graph-minor relation. A reminder what this means: recall that a graph H is a *minor* of a graph G, denoted $H \preceq G$, if H can be obtained from G by a sequence of edge contractions and vertex/edge deletions. A graph parameter $f : \{\text{graphs}\} \to \mathbb{N}$ is said to be *minor-monotone* if $H \preceq G \implies f(H) \leq f(G)$ for all graphs H and G.

5 The Colored G-Subgraph Isomorphism Problem

In this section, we introduce the colored G-subgraph isomorphism problem and state the known upper and lower bounds on its complexity with respect to AC^0 circuits and formulas.

▶ **Definition 8.** For a graph G and $n \in \mathbb{N}$, the *blow-up* $G^{\uparrow n}$ is the graph defined by

$$V(G^{\uparrow n}) = V(G) \times [n],$$
$$E(G^{\uparrow n}) = \big\{\{(v,a),(w,b)\} : \{v,w\} \in E(G),\ a,b \in [n]\big\}.$$

For $\alpha \in [n]^{V(G)}$, let $G^{(\alpha)}$ denote the subgraph of $G^{\uparrow n}$ defined by

$$V(G^{(\alpha)}) = \big\{(v,\alpha_v) : v \in V(G)\big\},$$
$$E(G^{(\alpha)}) = \big\{\{(v,\alpha_v),(w,\alpha_w)\} : \{v,w\} \in E(G)\big\}.$$

(Note that each $G^{(\alpha)}$ is an isomorphic copy of G.)

▶ **Definition 9.** For any fixed graph G, the *colored G-subgraph isomorphism problem* asks, given a subgraph $X \subseteq G^{\uparrow n}$, to determine whether or not there exists $\alpha \in [n]^{V(G)}$ such that $G^{(\alpha)} \subseteq X$. For complexity purposes, we view this problem as a Boolean function $\mathrm{SUB}_{G,n} : \{0,1\}^{|E(G)|\cdot n^2} \to \{0,1\}$ with variables $\{X_e\}_{e \in E(G^{\uparrow n})}$. We write SUB_G for the sequence of Boolean functions $\{\mathrm{SUB}_{G,n}\}_{n\in\mathbb{N}}$.

5.1 Minor-Monotonicity

The following observation appears in [27].

▶ **Proposition 10.** *If H is a minor of G, then $\mathrm{SUB}_H \leq_{\mathrm{mp}} \mathrm{SUB}_G$ (i.e. $\mathrm{SUB}_{H,n} \leq_{\mathrm{mp}} \mathrm{SUB}_{G,n}$ for all $n \in \mathbb{N}$).*

Proof. By transitivity of $\leq_{\mathrm{mp}}$, it suffices to consider the two cases where H is obtained from G via deleting or contracting a single edge $\{v,w\} \in E(G)$. In both cases, the monotone projection maps each variable $X_{\{(v',a),(w',b)\}}$ of SUB_G with $\{v',w'\} \neq \{v,w\}$ to the correspond variable $Y_{\{(v',a),(w',b)\}}$ of SUB_H. In the deletion case, we set the variable $X_{\{(v,a),(w,b)\}}$ to the constant 1 for all $a,b \in [n]$. In the contraction case, we set $X_{\{(v,a),(w,b)\}}$ to 1 if $a = b$ and to 0 if $a \neq b$. (This "planted perfect matching" has the effect of gluing the v-fibre and the w-fibre for instances of SUB_H.) ◀

Proposition 10 implies that the graph parameter $G \mapsto \mu(\mathrm{SUB}_G)$ is minor-monotone for any standard complexity measure $\mu : \{\text{Boolean functions}\} \to \mathbb{N}$ (e.g. depth-d AC^0 formula size). It also implies:

▶ **Corollary 11.** *For all graphs G,* $\mathrm{SUB}_{P_{\mathbf{td}(G)}} \leq_{\mathrm{mp}} \mathrm{SUB}_G$.

Proof. Recall that $\mathbf{td}(G) \leq \mathbf{lp}(G)$ by inequality (2). That is, every graph G contains a path of length $\mathbf{td}(G)$.[3] Since subgraphs are minors, we have $P_{\mathbf{td}(G)} \preceq G$ and therefore $\mathrm{SUB}_{P_{\mathbf{td}(G)}} \leq_{\mathrm{mp}} \mathrm{SUB}_G$ by Proposition 10. ◀

5.2 Upper Bounds

The obvious "brute-force" way of solving SUB_G has running time $O(n^{|V(G)|})$: given an input $X \subseteq G^{\uparrow n}$, check if $G^{(\alpha)} \subseteq X$ for each $\alpha \in [n]^{V(G)}$. A better upper bound comes from tree-width: based on an optimal tree-decomposition $(T, \mathcal{W})$, there is a dynamic-programming algorithm with running time $n^{\mathbf{tw}(G)+O(1)}$ [34]. This algorithm can be implemented by AC^0 circuits of size $n^{\mathbf{tw}(G)+O(1)}$ and depth $O(|V(G)|)$.[4]

Unlike circuits, formulas cannot faithfully implement dynamic-programming algorithms. The fastest known formulas for SUB_G are tied to tree-depth: based on a minimum-height rooted forest F witnessing $\mathbf{td}(G)$, there are AC^0 formulas of size $n^{\mathbf{td}(G)+O(1)}$ solving SUB_G (which come from AC^0 circuits of depth $\mathbf{td}(G)+O(1)$ and fan-in $O(n)$). For future reference, these upper bounds are stated in the following proposition.[5]

▶ **Proposition 12.** *For all graphs G,* SUB_G *is solvable by* AC^0 *circuits of size* $n^{\mathbf{tw}(G)+O(1)}$, *as well as by* AC^0 *formulas of size* $n^{\mathbf{td}(G)+O(1)}$.

5.3 Lower Bounds: AC^0 Circuit Size

Previous work of the author [40] showed that the AC^0 circuit size of SUB_{K_k} (a.k.a. the (colored) k-CLIQUE problem) is $n^{\Omega(k)}$ for every $k \in \mathbb{N}$. Generalizing the technique of [40], Amano [5] gave a lower bound on the AC^0 circuit size of SUB_G for arbitrary graphs G. In particular, he showed that the AC^0 circuit size of $\mathrm{SUB}_{Grid_{k\times k}}$ is $n^{\Omega(k)}$. This result, combined with the recent Polynomial Grid-Minor Theorem[6] of Chekuri and Chuznoy [12], implies that the AC^0 circuit size of SUB_G is $n^{\Omega(\mathbf{tw}(G)^{\varepsilon})}$ for an absolute constant $\varepsilon > 0$. An even stronger lower bound was subsequently proved by Li, Razborov and Rossman [27] (without appealing to the Polynomial Grid-Minor Theorem).

▶ **Theorem 13.** *For all graphs G, the* AC^0 *circuit size of* SUB_G *is* $n^{\Omega(\mathbf{tw}(G)/\log \mathbf{tw}(G))}$.

This result is nearly tight, as it matches the upper bound of Proposition 12 up to the $O(\log \mathbf{tw}(G))$ factor in the exponent.

---

[3] This fact is straightforward to prove. Consider the case that G is connected. Starting at any vertex of G, constructed a rooted tree T by a depth-first search. Observe that for every edge $\{v, w\} \in E(G)$, it must be the case that v and w lie in a common branch of T. Therefore, the height of T is an upper bound on $\mathbf{td}(G)$. On the other hand, note that each root-to-leaf branch of T is a path in G. Therefore, the height of T is a lower bound on $\mathbf{lp}(G)$.

[4] It may be possible to achieve running times of $n^{\delta \cdot \mathbf{tw}(G)+O(1)}$ for constants $\delta < 1$ using fast matrix multiplication algorithms (cp. [46]). However, these algorithms appear to require logarithmic-depth circuits. For unrestricted Boolean circuits, no upper bound better than $n^{O(\mathbf{tw}(G))}$ is known, and in fact Marx [30] has shown that the Strong Exponential Time Hypothesis rules out circuits smaller than $n^{O(\mathbf{tw}(G)/\log \mathbf{tw}(G))}$.

[5] For the *uncolored* G-subgraph isomorphism graph, one gets essentially the same upper bounds via a reduction to SUB_G using the "color-coding" technique of Alon, Yuster and Zwick [4]. Amano [5] observed that this uncolored-to-colored reduction can be implemented by AC^0 circuits.
