Invited Talks

Foreword

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research papers in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues. The first MFCS conference was organized in 1972 in Jabłonna (near Warsaw, Poland). Since then, the conference traditionally moved between the Czech Republic, Slovakia, and Poland. A few years ago, the conference started traveling around Europe: in 2013 it was held in Austria, in 2014 in Hungary, in 2015 in Italy, and most recently, in 2016, the conference returned to Poland. We are happy that this year MFCS is organized in Denmark, the most northern place yet to host MFCS.

Over 200 abstracts were submitted, of which 192 materialized as papers, of which 80 were finally accepted. The authors of the submitted papers represent nearly 40 countries. The authors first registered their papers' abstracts (by the 24th of April, 2017) and only then their content (by the 28th of April, 2017). This division in two stages has helped with the assignment of the papers to the PC members. Each paper was assigned to three PC members, who reviewed and discussed them thoroughly over a period of nearly six weeks. As the co-chairs of the program committee, we would like to express our deep gratitude to all the committee members for their hard, dedicated work. The quality of the submitted papers was very high and many good papers had to be rejected. The conference featured five invited talks, by Glynn Winskel (University of Cambridge, UK), Michał Pilipczuk (University of Warsaw, Poland), Rasmus Pagh (IT University of Copenhagen, Denmark), Nicolas Markey (CNRS, Rennes, France), and Philippe Schnoebelen (LSV – CNRS & ENS Cachan, Université Paris-Saclay, France). We would like to thank them deeply for their contributions and their time.

This is the second time that the MFCS proceedings are published in the Dagstuhl/LIPIcs series. We would like to particularly thank Marc Herbstritt and the LIPIcs team for all the help and support. We believe that the cooperation between MFCS and Dagstuhl/LIPIcs in the future will continue to be as seamless and fruitful as ours.

Abstract

The Black-Box Hypothesis, introduced by Barak et al. [5], states that any property of boolean functions decided efficiently (e.g., in BPP) with inputs represented by circuits can also be decided efficiently in the black-box setting, where an algorithm is given an oracle access to the input function and an upper bound on its circuit size. If this hypothesis is true, then $\mathsf{P} \neq \mathsf{NP}$. We focus on the consequences of the hypothesis being false, showing that (under general conditions on the structure of a counterexample) it implies a non-trivial algorithm for Circuit-SAT. More specifically, we show that if there is a property F of boolean functions such that F has high sensitivity on some input function f of subexponential circuit complexity (which is a sufficient condition for F being a counterexample to the Black-Box Hypothesis), then Circuit-SAT is solvable by a subexponential-size circuit family. Moreover, if such a counterexample F is symmetric, then Circuit-SAT $\in \mathsf{P/poly}$. These results provide some evidence towards the conjecture (made in this paper) that the Black-Box Hypothesis is false if and only if Circuit-SAT is easy.

1 Introduction

Given access to a boolean function $f\colon \{0,1\}^n \to \{0,1\}$, how fast can we decide if $f \not\equiv 0$? If we can only access f as an oracle (i.e., in the "black-box" fashion), then it is well-known that one needs time $\Omega(2^n)$ for any deterministic or randomized algorithm (and time $\Omega(2^{n/2})$ for any quantum algorithm). What if f is computable by some small boolean circuit C, and we are given this circuit C (i.e., we can access f in the "white-box" fashion)? Then the question of deciding if $f \not\equiv 0$ is exactly the famous Circuit-SAT problem, and no non-trivial complexity lower bounds are known.

One possible approach to proving that $\mathsf{P} \neq \mathsf{NP}$ is to argue that being given an actual small circuit C computing a given boolean function f does not help much, compared to being given just oracle access to f, and being told the size of C. This could be formalized

as the *Black-Box Hypothesis (BBH)* (introduced by Barak et al. [5] as "Scaled-down Rice's Theorem" conjecture), which can be informally stated as follows:

> If a property F of boolean functions can be decided efficiently on circuits computing input functions, then F can also be decided efficiently in the black-box setting (that is, given oracle access to the input function and its circuit size bound).

If this hypothesis is true, then, for $F = \{f\colon \{0,1\}^n \to \{0,1\} \mid f \not\equiv 0\}$, we conclude that Circuit-SAT cannot be solved efficiently, since there are exponential lower bounds for deciding F in the black-box setting.

So proving the BBH is hard, as it would imply that $\mathsf{P} \neq \mathsf{NP}$. The hypothesis may well be false. Barak et al. [5] already proved that a version of the BBH (for promise problems) is false, assuming that one-way functions exist. Can we just disprove it then?

In this paper, we give some evidence that disproving the BBH is also hard, as it would have non-trivial algorithmic applications for Circuit-SAT. Note that if Circuit-SAT is efficiently solvable, then, as observed above, the Black-Box Hypothesis must be false. We conjecture that the converse implication also holds. Thus we conjecture the following:

> The BBH is false iff Circuit-SAT has a (somewhat) efficient algorithm.

We make a step towards proving this conjecture by showing that if the BBH fails *in a particular way*, then Circuit-SAT can be decided by a nonuniform family of subexponential-size circuits, which would disprove the nonuniform analogue of the Exponential-Time Hypothesis (ETH) of [13].

1.1 Our results

Before stating our results formally, let us discuss what it means for the BBH to fail. Clearly, if the BBH fails, there is a property F that is easy in the white-box setting (say, is in BPP), but requires superpolynomial complexity in the black-box setting. Note that for n-variate boolean functions f of circuit complexity $2^{\Omega(n)}$, there can't be any superpolynomial gap between the white-box and black-box complexities of deciding a given property F. This is because a white-box algorithm has to look at the input circuit, which is of size at least $2^{\Omega(n)}$, and the black-box algorithm can read the entire truth-table of f, build a trivial circuit of size about 2^n, and then just simulate the white-box algorithm on it, running in overall time at most $\mathsf{poly}(2^n)$. Thus any "magic" speed-up that we get for a property F violating the BBH must necessarily manifest itself over "easy" inputs, boolean n-variate functions f of circuit complexity at most $2^{o(n)}$. In other words, any black-box algorithm for F must be "slow" even if we care only about inputs f of low circuit complexity.

Recall that the sensitivity of a function F is the maximum, over all its inputs $x \in \{0,1\}^N$, of the number of positions $i \in [N]$ such that $F(x) \neq F(x^i)$, where x^i is x with the ith bit flipped. It is well-known that every F with sensitivity s requires $\Omega(s)$ queries to decide by any (randomized) black-box algorithm [15]. Thus, a sufficient condition for any black-box algorithm deciding F to be "slow" (taking time at least T) is that F has "high" sensitivity (at least $\Omega(T)$). In fact, the same argument from [15] actually implies that if F has a sensitive input x^*, then F requires large query complexity even when restricted to the inputs $x^*, (x^*)^1, (x^*)^2, \ldots, (x^*)^N$. The latter can be used to show (see Theorem 3.6 below) that a *sufficient condition for any black-box algorithm deciding F to be "slow" on all inputs f of subexponential circuit complexity* is the following:

> there exists a function $f^*\colon \{0,1\}^n \to \{0,1\}$ of circuit complexity $2^{o(n)}$ such that F has "high" sensitivity at f^*.

An important feature of the OR function (which explains why it requires high black-box complexity) is the existence of a highly sensitive input, the all-zero string. Moreover, this sensitive input has a very low circuit complexity (as a boolean function). We show that if the BBH fails because of a property F with similar conditions (i.e., that F has an "easy" but "highly sensitive" input), then Circuit-SAT admits a non-trivial algorithm.

▶ **Theorem 1.1** (Main theorem: Informal version)**.** *Suppose there is a property F of n-variate boolean functions such that*

1. *F is decidable in* BPP *in the white-box setting, but,*
2. *for almost all n, F has an input $f^*\colon \{0,1\}^n \to \{0,1\}$ of sensitivity $2^{\Omega(n)}$ and of circuit complexity $2^{o(n)}$ (which implies that F requires exponential time $2^{\Omega(n)}$ to decide in the black-box setting, even on inputs f of circuit complexity $2^{o(n)}$).*

Then Circuit-SAT *for n-input circuits of size at most $2^{o(n)}$ can be decided by a nonuniform family of circuits of size $2^{o(n)}$.*

Intuitively, Theorem 1.1 says that if the BBH fails in a strong way for some property F, with an exponential gap between the white-box and the black-box complexities, so that the high black-box complexity of F can be explained through the existence of a highly sensitive input f^* (of relatively low circuit complexity), then Circuit-SAT is decidable by a subexponential-time nonuniform algorithm.

We also observe that the assumption of Theorem 1.1 holds for any property F violating the BBH whenever F is one of the following:

- F is a symmetric function, or
- F is a subset of easy functions (i.e., $F \subseteq \{f \mid size(f) \leq 2^{o(n)}\}$).

Hence, if a counterexample to the BBH is of this kind, then Circuit-SAT is easy for nonuniform algorithms.

Finally, for the special case of *monotone* properties F, we get a version of Theorem 1.1 where it suffices to assume that a sensitive input in item (2) of Theorem 1.1 has just superpolynomial sensitivity $s > n^{\omega(1)}$ and circuit complexity $s^{o(1)}$ (rather than requiring an exponential sensitivity $s \geq 2^{\Omega(n)}$). More precisely, we prove the following.

▶ **Theorem 1.2** (Monotone Properties)**.** *Let F be a monotone property such that*

1. *F is decidable in* BPP *in the white-box setting, but,*
2. *for almost all n, F has an input $f^*\colon \{0,1\}^n \to \{0,1\}$ of sensitivity $s \geq n^{\omega(1)}$ and of circuit complexity $s^{o(1)} \geq \mathsf{poly}(n)$ (which implies that F requires superpolynomial time to decide in the black-box complexity setting, even on inputs of circuit complexity $s^{o(1)}$).*

Then Circuit-SAT *for n-input circuits of size at most $2^{o(n)}$ can be decided by a nonuniform family of circuits of size $2^{o(n)}$.*

We also use a "win-win" argument to show the following: If a monotone property is a counterexample to the Block-box Hypothesis (with appropriate parameters), then either Circuit-SAT is nonuniformly easy infinitely often, or BPP $\subseteq$ NP (see Theorem 5.2).

1.2 Related work

The Black-Box Hypothesis has its roots in a classical result of computability theory, Rice's theorem, which says that any non-trivial property of languages accepted by Turing machines is undecidable. There are two ways of interpreting Rice's theorem: (1) Given a Turing machine M, the only thing one can do is to run it, or (2) the Halting problem is the easiest non-trivial property of languages of Turing machines, in the sense that if any non-trivial property is decidable, then so is the Halting problem.

The intuition that it may be hard to understand what an algorithm does by looking at the algorithm description naturally extends to the class of non-uniform algorithms (i.e., circuits). The focus of this paper is on the second interpretation of Rice's theorem, with Circuit-SAT as a complexity counterpart of the Halting problem. In other words, we would like to show any "non-trivial" counterexample to the Black-Box Hypothesis implies a somewhat efficient algorithm for SAT.

There have been several attempts to scale down Rice's theorem to the complexity-theoretic realm, with different notions of 'non-trivial' and 'hard'. In Rice's theorem, 'non-trivial' means neither F nor $\bar{F}$ is empty, and 'hard' = undecidable. Borchert and Stephan [6] pioneered a line of research that looked at counting properties of circuits and stated an analogue of Rice's theorem for such properties: if a counting property is non-empty, then it is UP-hard. There, a property F is a counting property if it only depends on the number of solutions (i.e., F is a symmetric function). Subsequently, Hemaspaandra and Rothe [10] and Hemaspaandra and Thakur [11] improved the hardness result, obtaining a version of Rice's theorem with NP-hardness.

Barak et al. [5] also look at the properties of boolean functions computed by circuits, but consider a property trivial if it can be decided by checking the circuit value on relatively few points. That is, in their setting, the semantic property $f(00\ldots0) = f(11\ldots1)$ is trivial, but $\exists x\ f(x) = 1$ is not. Their 'Scaled-down Rice's theorem' conjecture states that every property of boolean functions f that can be computed in BPP given a circuit for f can be also computed in comparable probabilistic polynomial time given only oracle access to f and an upper bound on its circuit complexity. There is a clear relation to obfuscation: if it were possible to produce a circuit for any f so garbled that access to it is not much better than the black-box access, that would prove the conjecture. However, in the same paper they show impossibility of achieving such obfuscation. Nonetheless, [5] is able to disprove a certain "promise" version of the conjecture, under the assumption that one-way functions exist (using a special family of unobfuscatable circuits). The main statement, which we will call here 'the Black-Box Hypothesis', remains open.

1.3 Our techniques

Our starting point is the isolation lemma of Valiant and Vazirani [19], which can be interpreted to say that any white-box BPP algorithm deciding the property $F = XOR$ yields a BPP algorithm for Circuit-SAT. This can be extended to any property F computing a symmetric function, at the expense of introducing a small (polynomial) amount of nonuniformity. The main idea is to take advantage of the existence of a very sensitive input f for any symmetric property F. (For example, for the case of XOR, every input $f\colon \{0,1\}^n \to \{0,1\}$ has maximum sensitivity 2^n. In general, every symmetric F has a polysize input f of sensitivity at least $2^n/2$.)

Suppose that $f\colon \{0,1\}^n \to \{0,1\}$ is such a sensitive input for the property F, and moreover, suppose that f is computable by a small circuit C_f (say of $\mathsf{poly}(n)$ size). To decide if a given circuit C on n inputs is satisfiable, we first use the Valiant-Vazirani result to get from C a new circuit C' such that C' is uniquely satisfiable if C is satisfiable, and C' is unsatisfiable otherwise. By XORing the circuits C_f and C', we get a new (small) circuit that leaves f unchanged if C is unsatisfiable, and flips f in exactly one location if C is satisfiable. If the flipped location happens to land among the sensitive locations of f, we can detect this by running our assumed white-box algorithm on $C_f \oplus C'$ and noting that its output is different from that on C_f. To make sure that the flipped location is among the sensitive ones for f, we consider a random-shift version of C' so that its unique satisfying assignment

(if it exists) will be in a uniformly random location. As, by assumption, f has very many sensitive locations, this randomization will ensure that we detect if C is satisfiable with high probability. The runtime of the described algorithm is polynomial in the sizes of C_f and C. We think of a small circuit C_f as nonuniform advice, thereby getting a non-trivial nonuniform algorithm for Circuit-SAT.

The (nonuniform) algorithm for Circuit-SAT described above achieves high success probability in case a sensitive input $f\colon \{0,1\}^n \to \{0,1\}$ (provided as advice via a small circuit computing f) has very large sensitivity $s \geq \Omega(2^n)$. What if the sensitivity is only as large as $2^{\Omega(n)}$? (Such a lower bound is the best one can hope for if one assumes the Sensitivity Conjecture and that the given property F has exponential decision tree complexity.) In this case, our described algorithm would have success probability only about $2^{-\delta n}$, for some constant $0 < \delta < 1$, for solving Circuit-SAT on n-input circuits. However, if the algorithm runs in (non-uniform) time at most $2^{o(n)}$ (which will happen if the advice circuit C_f is of size at most $2^{o(n)}$), then we can use the amplification technique of Paturi and Pudlák [17] to get a new algorithm in non-uniform time $2^{o(n)}$ that succeeds with probability 1.

For the special case of monotone properties F, we show how to make do with even smaller sensitivity assumption on the advice function f, getting a subexponential-size Circuit-SAT algorithm for any superpolynomial sensitivity $s > n^{\omega(1)}$. The idea is to use hashing (which is also the main ingredient in the aforementioned result of [17]).

If we don't assume that a sensitive input f for a given property F would have a small circuit, we can still say something interesting by applying a "win-win" argument. Informally, we get that if F has sensitive inputs and an efficient white-box algorithm, then either Circuit-SAT is nonuniformly easy (in subexponential size, infinitely often), or we get an efficient "hardness tester": a polytime algorithm that accepts only truth tables of boolean functions of exponential circuit complexity, and accepts at least one such truth table. Getting such a hardness tester is a highly non-trivial task, and is not known unconditionally. Once you have this tester, you can, for example, conclude that BPP $\subseteq$ NP, using standard "hardness-randomness" trade-offs [16, 4, 14].

Remainder of the paper. We give some basic definitions and facts in Section 2. We state and discuss the Black-Box Hypothesis in Section 3. We prove Theorem 1.1 in Section 4. In Section 5, we consider the special case of monotone properties as counterexamples to the Black-Box Hypothesis, getting a proof of Theorem 1.2. In Section 6, we consider the case of properties defined using succinct versions of the Minimal Circuit Size Problem (MCSP). We consider some variants of the BBH for restricted circuit classes in Section 7. We conclude with some open problems in Section 8. This is a conference version of the paper, with some proofs omitted due to space limitations. The full version can be found online as [12].

2 Preliminaries

The truth table of a boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is denoted by $tt(f)$. With a boolean circuit C on n inputs, we associate the boolean function $f_n = [C]$ computed by C. Slightly abusing the notation, we use $tt(C)$ to denote the truth table of a boolean function computed by the circuit C. A standard encoding of C as a binary string is denoted $desc(C)$.

A *property of boolean functions* is a function $F\colon \{0,1\}^{2^n} \to \{0,1\}$, where strings over $\{0,1\}^{2^n}$ are interpreted as truth tables of boolean functions on n variables, for every n. A *meta-language* over circuits corresponding to a property F is $L_F = \{desc(C) \mid C \text{ is a boolean circuit and } tt(C) \in F\}$. In particular, if L_F is a meta-language over circuits, then for any circuits C_1 and C_2, if $[C_1] = [C_2]$ then $C_1 \in L_F \Leftrightarrow C_2 \in L_F$.

The size of a boolean circuit C is the number of gates plus the number of wires. Let $size(f) = \min_{C,[C]=f} |C|$. We say that $f \in \mathsf{SIZE}(t(n))$ if $size(f) \leq t(n)$.

We denote by $\mathsf{Circuit\text{-}SAT}_{n,m}$ the problem of deciding the satisfiability of a given n-input circuit of size at most m. For a time bound $t = t(n)$, we denote by $\mathsf{RTIME}(t)$ the class of languages decidable by randomized algorithms, with one-sided error at most $1/2$, in time t; as usual, $\mathsf{RP} = \mathsf{RTIME}(\mathsf{poly})$. For an advice size function $a = a(n)$, we denote by $\mathsf{RTIME}(t)/a$ the class of languages decidable by an $\mathsf{RTIME}(t)$ algorithm, given the correct advice of size at most a.[1]

For a function $F\colon \{0,1\}^N \to \{0,1\}$, with $N = 2^n$, we can think of inputs to F as truth tables of n-variate boolean functions $f\colon \{0,1\}^n \to \{0,1\}$. For a circuit size bound $t = t(n)$, we define the *randomized decision tree complexity of F on inputs of complexity at most t*, denoted $Rt_t(F)$, as the minimal depth of a randomized decision tree deciding F, with error probability at most $1/3$, on all inputs $f\colon \{0,1\}^n \to \{0,1\}$ of $size(f) \leq t(n)$.

A boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is *sensitive* on the ith bit of input x if flipping that bit changes the value of $f(x)$. Sensitivity of f on input $x \in \{0,1\}^n$, denoted by $\mathsf{sens}(f,x)$, is the number of bits in x to which f is sensitive. The sensitivity of f, denoted $\mathsf{sens}(f)$, is $\max_{x\in\{0,1\}^n} \mathsf{sens}(f,x)$.

Simon's lemma [18] gives a weak lower bound on $\mathsf{sens}(f)$. We will use the following corollary of this lemma from [3]:

▶ **Lemma 2.1** ([18]). *For every non-constant n-variate boolean function f, there exists an input $x \in f^{-1}(1)$ with $\mathsf{sens}(f,x) \geq n - \log|f^{-1}(1)|$.*

Although decision tree complexity of a boolean function is polynomially related to many other measures that we do not define here (see, for example, [7, 9]), its relationship with the sensitivity remains elusive. The question of whether there is a polynomial relation between $\mathsf{sens}(f)$ and the decision tree complexity $Dt(f)$, known as the Sensitivity Conjecture, has been formulated already in [15]. However, despite much work, it is still unresolved.

▶ **Conjecture 2.2** (Sensitivity conjecture). There exists an integer k such that, for any function f, $Rt(f) \leq \mathsf{sens}(f)^k$.

3 Black-Box Hypothesis

3.1 Defining BBH

To investigate whether having a circuit C_f for an input function f helps decide a property F of boolean functions, we compare the complexity of deciding F on f given a circuit C_f versus given an oracle access to f. In the latter case, following [5], an algorithm deciding $F(f)$ is also given as its input the size m of some C_f (or, rather, an upper bound on C_f), in unary (that is, the algorithm can "see how large the box is", but cannot peek inside). This makes the comparison of the running time in both frameworks more meaningful. With this intuition, we define "white-box" and "black-box" algorithms as follows.

▶ **Definition 3.1** (White-box vs. black-box algorithms). An algorithm A decides a property F in *white-box* if A decides the corresponding meta-language L_F. That is, given as input a string $desc(C)$ A accepts iff $[C] \in F$.

[1] For semantic complexity classes such as RTIME, it is customary to use the weaker notion of a class with advice, where the algorithm is required to behave as a true RTIME-type algorithm only when given a correct advice string, and can behave arbitrarily otherwise.

An algorithm A decides F in *black-box* if $A^f(1^n, 1^m)$ accepts iff $f \in F$, where $f\colon \{0,1\}^n \to \{0,1\}$, m is an upper bound on the circuit size of f and A^f denotes that the algorithm A has oracle access to the boolean function f; as usual, 1^n and 1^m represent n and m in unary.

▶ **Definition 3.2.** A property F is in *white-box* BPP, denoted $F \in$ wbBPP, if there is a BPP algorithm deciding L_F. We say F is in *black-box* BPP, denoted $F \in$ bbBPP, if there is a black-box randomized algorithm $A^f(1^n, 1^m)$ deciding F in time polynomial in $n + m$, with the probability of error at most $1/3$ over the choice of randomness, for every f, n, m.

With the above definitions, the Black-Box Hypothesis can be stated concisely as follows.

▶ **Hypothesis 3.3** (Black-Box Hypothesis (BBH))**.** *For any property F of boolean functions,*

$$F \in \text{wbBPP} \iff F \in \text{bbBPP}.$$

If the BBH holds, then P $\neq$ NP, as the well-known exponential black-box lower bounds for SAT would rule out even a subexponential-time probabilistic algorithm for SAT. On the other hand, if NP $\subseteq$ BPP, then the BBH is false, with SAT as a counterexample. Suppose the BBH is false. Would that imply that SAT is easy? We make the following conjecture.

▶ **Conjecture 3.4.** (Informal) BBH is false iff Circuit-SAT is easy.

As a step towards proving the conjecture, we show that if the BBH fails in a particular way (see the next subsection for the definition), then there is a family of circuits of subexponential size that decides Circuit-SAT.

3.2 Defining a Strong Counter-Example to BBH

As noted before, a property $F \in$ wbBPP can only be a counterexample to BBH when any black-box algorithm requires superpolynomial time on some input of subexponential size (otherwise white-box complexity and black-box complexity are polynomially related).

Thus, if F is not in black-box BPP, then any black-box algorithm deciding F requires superpolynomial time on some input of subexponential circuit size, which we call an easy input.

Ideally, we would like to prove that if the BBH fails, then Circuit-SATis easy. We do not know how to show such an implication yet. Instead, we consider the following *sufficient* condition for the BBH to fail.

▶ **Definition 3.5** (Strong counterexample to the BBH)**.** A property F is an *s-strong counterexample to the BBH* if

1. F is in wbBPP, but
2. for almost all n, F has an input $f^* : \{0,1\}^n \to \{0,1\}$ of *size*$(f^*) \leq 2^{o(n)}$ such that sens$(F, f^*) \geq s$.

We call a property a *strong counterexample* if it is $2^{\Omega(n)}$-strong.

Next we argue that a strong counterexample to the BBH as defined above would indeed violate the BBH. First, we recall the following result.

▶ **Lemma 3.6** (implicit in [15])**.** *Let F be a property of n-variate boolean functions. If* sens$(F, f) \geq s$ *for some boolean function $f \in$* SIZE(t)*, then $Rt_{(t+cn)} \geq (2/3)s$ (for some constant $c > 0$).*

Proof. Let f^i be the function that disagrees with f on the ith bit of the output, which is a sensitive bit of f. Thus, (the truth tables of) f and f^i are Hamming neighbours and circuit complexity of f^i is greater than f by at most a linear factor, i.e., $size(f^i) \leq size(f) + O(n)$. Now to distinguish f from each Hamming neighbour f^i with probability at least $2/3$, any randomized decision tree needs to query the ith bit with probability at least $2/3$. As there are s many sensitive bits for f, the expected number of queries is $(2/3)s$. Thus, there is one branch on which the randomized decision tree has to query $(2/3)s$ of the bits. ◀

Applying Theorem 3.6 immediately yields the required implication.

▶ **Corollary 3.7.** *If F is a $n^{\omega(1)}$-strong counterexample to the BBH, then $F \notin$ bbBPP (and hence, the BBH is false).*

3.3 Examples of properties with easy sensitive inputs

We give a few examples of properties with easy sensitive inputs. For each of these properties, violating the BBH is actually *equivalent* to being a strong counterexample to the BBH.

Symmetric properties. A property F is symmetric if the membership of $tt(f) \in F$ depends only on the number of 1s in $tt(f)$. Such properties were the focus of one of the previous formulations of a possible complexity analogue of Rice's theorem, due to Borchert and Stephan [6] (though their notion of hardness was somewhat different). A basic symmetric property of N-bit strings such as OR or XOR has an easy input (the all-0 string) of sensitivity N. We note that every symmetric property has an easy input of sensitivity at least $N/2$.

▶ **Lemma 3.8.** *If F is a non-trivial symmetric property of n-variate boolean functions, then there is a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ with $\mathsf{sens}(F, f) \geq 2^n/2$ such that f is computable by an AC^0 circuit of polynomial size.*

Proof. As F is a non-trivial property, there is a number $1 \leq k \leq 2^n$ such that a $tt(f)$ with $k-1$ ones is accepted by F (wlog), but any $tt(f)$ with k ones is rejected by F. If $k \geq 2^n/2$, then any string with k ones has sensitivity k. Otherwise, any string with $k-1$ ones has sensitivity $2^n - (k-1) \geq 2^n/2$.

Let k be the number of 1s in an input with sensitivity at least $2^n/2$. Define a required boolean function f with exactly k ones in its truth table by $f(x) = 1$ iff $x < k$, where x is interpreted as an integer in binary. It is easy to see that f has a polynomial-size circuit, even of AC^0 type (as the comparison of two n-bit integers can be implemented in AC^0 [8]). ◀

Subsets of easy functions. Consider a property F that only contains a subset of easy functions, that is, only functions of circuit complexity at most $t = 2^{o(n)}$. Easy functions form a very sparse set (the number of n-bit functions of circuit size at most t is at most 2^{t^2}). So by Simon's lemma (Theorem 2.1), F contains an (easy) instance of sensitivity at least $2^n - t^2 = 2^n - 2^{o(n)} = \Omega(2^n)$.

4 Circuit-SAT algorithm from strong counterexamples

The main theorem of this section shows that a strong counterexample to the BBH (as in Theorem 3.5) implies that Circuit-SAT on n-input circuits of subexponential size can be decided by subexponential-size circuits. Formally, we have the following.

▶ **Theorem 4.1.** *If there is a strong counterexample to the BBH, then*

$\mathsf{Circuit\text{-}SAT}_{n,2^{o(n)}} \in \mathsf{SIZE}(2^{o(n)})$.

We prove this theorem in two steps. First we show (in Section 4.1) how sensitivity can be exploited for deriving a randomized algorithm for satisfiability, whose success probability depends on the assumed sensitivity of a given counterexample to the BBH. Then (in Section 4.2) we amplify the success probability of our algorithm.

4.1 From high sensitivity to Circuit-SAT

Here we prove the following.

▶ **Lemma 4.2.** *Let F be an s-strong counterexample to the BBH, with an s-sensitive function family $f \in \mathsf{SIZE}(t)$. Then $\mathsf{Circuit\text{-}SAT}_{n,m}$ is decidable in randomized time $\mathsf{poly}(t,m)$, with success probability $\Omega(s/2^n)$, given the advice of size $\mathsf{poly}(t)$. In particular, we have that*

$\mathsf{Circuit\text{-}SAT}_{n,m} \in \mathsf{SIZE}(\mathsf{poly}(n \cdot (t(n)+m) \cdot 2^n/s(n)))$.

Proof. Let A_F be a BPP algorithm for L_F. By Adleman's argument [1], we can assume that A_F is a deterministic algorithm, using at most $\mathsf{poly}(m)$ bits of advice on inputs of length m.

As a warm-up, suppose that F has maximal sensitivity 2^n, and, moreover, for each n there is a maximally sensitive input $tt(f)$ where f has a circuit C_f of size t. Now, if C has at most 1 satisfying assignment, it is enough to check whether $A_F(C \oplus C_f) = A_F(C_f)$: if there is a satisfying assignment for C, it flips a sensitive bit of $tt(C_f)$, otherwise $tt(C \oplus C_f) = tt(C_f)$.

To use the idea described above we need to guarantee that the circuit C for which we want to decide satisfiability has at most one satisfiable assignment. This can be done by applying the Valiant-Vazirani reduction [19] to get new circuit C'. Assuming that f is a highly sensitive input, we have a non-trivial chance of hitting one of its sensitive bits if we randomly shift a unique satisfying assignment of C'. That is, we check $A_F(C'(x \oplus r) \oplus C_f)$, where r is a random binary string of length $|x|$. More formally, our algorithm for Circuit-SAT is as follows.

Algorithm for Circuit-SAT
Input: A circuit C on n inputs.
Advice: A circuit C_f of size at most t such that $tt(C_f)$ is an s-sensitive string for F.

1. Apply the Valiant-Vazirani reduction to C to obtain a list $C_1, \ldots, C_n$ satisfying the following: if C is unsatisfiable then so is every C_i on the list, and if C is satisfiable, then, with probability at least $1/2$, at least one C_i on the list has a unique satisfying assignment.
2. Pick a random $r \in \{0,1\}^n$. For each C_i on the list, check if

   $$A_F(C_f) \neq A_F(C_i(x \oplus r) \oplus C_f).$$

   If the check passes for at least one $1 \leq i \leq n$, then accept; otherwise, reject.

The running time of the described algorithm is $\mathsf{poly}(n, t+m)$. The advice size is $\mathsf{poly}(t)$, as we need C_f, plus the advice of size $\mathsf{poly}(|C|+|C_f|)$ used in Adleman's averaging argument. If C is unsatisfiable, then the algorithm rejects C with probability 1. If C is satisfiable, then the algorithm accepts with probability at least $(1/2) \cdot s/2^n$ (the success probability of the Valiant-Vazirani reduction in Step (1), times the probability of hitting a sensitive bit of the advice $tt(C_f)$ by a random shift r in Step (2)).

Finally, applying Adleman's argument to the randomized algorithm above, we get a nonuniform circuit family solving Circuit-SAT with the stated parameters. ◀

▶ **Corollary 4.3.** *Let F be a non-trivial symmetric property such that $L_F \in$ BPP. Then* Circuit-SAT $\in$ RP/poly $\subseteq$ P/poly.

Proof. The proof follows from Theorem 3.8 and Theorem 4.2. ◀

4.2 Amplifying the success probability

Theorem 4.2 is a weaker version of Theorem 4.1 which needs the sensitivity bound $s \geq 2^{n-o(n)}$. To handle a smaller sensitivity $2^{\delta n}$, for any $\delta > 0$, we need a better way of amplifying the success probability of our randomized Circuit-SAT algorithm above, without increasing the circuit size by too much. We will use the following Exponential Amplification lemma by Paturi and Pudlák [17].

▶ **Lemma 4.4** (Exponential amplification lemma[17])**.** *Let $\mathcal{G}$ be a family of probabilistic circuits of size bounded by $g(m,n)$ such that $\mathcal{G}$ decides* Circuit-SAT *with one-sided error, achieving the success probability $2^{-\delta n}$ on satisfiable instances. Then there exist a circuit family $\mathcal{G}'$ deciding* Circuit-SAT *with success probability $2^{-\delta^2 n}$ on satisfiable instances, for all large enough n, where the circuit size of $\mathcal{G}'$ is bounded by $g'(n,m) = O(g(\lceil \delta n \rceil) + 5, \tilde{O}(g(n,m))))$.*

Now we can prove Theorem 4.1.

Proof of Theorem 4.1. Let $G^0_{m,n}$ be the circuit family encoding the randomized algorithm from Theorem 4.2. For concreteness, let $desc(C_f) = 2^{n^\gamma}$ denote a bound on the size of $|C_f|$. The size of the complete circuit $G^0_{m,n}$ is $O(2^{kn^\gamma} \cdot n^{k\gamma+1} \cdot m^k)$, where k is the exponent of the running time of A_F. Assuming that $m \leq |C_f|$ to bound smaller factors, $|desc(G^0_{m,n})| = O(2^{kn^\gamma} \cdot n^{(k+1)\gamma+1} \cdot m^k)$.

Apply the Exponential amplification lemma for t iteration to $G^0_{m,n}$, where $t \in \omega(1)$ is a very slow growing function. If $2^{o(n)} = 2^{\alpha(n)}$ is the bound on the advice circuit $|C_f|$, then we need $k^t \cdot \alpha(n) < \beta(n)$, where $\beta(n) \in o(n)$. As t is non-constant, success probability becomes $2^{\delta^t n} \in 2^{o(n)}$. Now, using the standard techniques to amplify the success probability (with $2^{\delta^t n} + O(n)$ trials and fixing randomness by the averaging argument), we obtain a deterministic circuit of subexponential size solving Circuit-SAT for circuits of description size m on n variables. ◀

5 Monotone properties

Here we consider a special case of monotone properties F. First, we argue that it suffices to have a monotone counterexample to the BBH with just superpolynomial sensitivity in order to obtain a non-trivial Circuit-SAT algorithm (Section 5.1). Then we show that having a monotone property F in white box P such that F requires high decision tree complexity implies either a non-trivial Circuit-SAT algorithm or non-trivial derandomization of BPP (Section 5.2).

5.1 Handling a lower sensitivity bound

So far, to get a non-trivial Circuit-SAT algorithm from a counterexample F to the BBH, we assumed that we have an easy sensitive input $f^*\colon \{0,1\}^n \to \{0,1\}$ with $\mathsf{sens}(F, f^*) \geq 2^{\Omega(n)}$. Here we show that for a special case of *monotone* properties F, any superpolynomial sensitivity $s \in n^{\omega(1)}$ would suffice to get the same kind of Circuit-SAT algorithms.

▶ **Theorem 5.1.** *Let F be a monotone property such that*

1. *F is decidable in* BPP *in the white-box setting, but,*
2. *for almost all n, F has an input $f^*\colon \{0,1\}^n \to \{0,1\}$ of sensitivity $s \geq n^{\omega(1)}$ and of circuit complexity $s^{o(1)} \geq \mathsf{poly}(n)$ (which implies that F requires superpolynomial time to decide in the black-box complexity setting, even on functions of circuit complexity $s^{o(1)}$).*

Then $\mathsf{Circuit\text{-}SAT}_{n,2^{o(n)}} \in \mathsf{SIZE}(2^{o(n)})$.

Proof. Without loss of generality, assume that $F(f^*) = 1$. Given f^* as advice, we describe a Circuit-SAT algorithm for circuits on $k = \log_2 s$ inputs. We will use random hash functions. Recall that a universal hash family $\mathcal{H}_{n,k} = \{h\colon \{0,1\}^n \to \{0,1\}^k\}$ has the properties: (1) for every fixed $x \in \{0,1\}^n$, the value $h(x)$, for a random $h \in \mathcal{H}_{n,k}$, is uniform over $\{0,1\}^k$, and (2) for every $x \neq y \in \{0,1\}^n$, the values $h(x)$ and $h(y)$, for a random $h \in \mathcal{H}_{n,k}$, are independent and uniform over $\{0,1\}^k$. Our Circuit-SAT algorithm is as follows:

Given a Circuit-SAT instance C on k inputs of size $2^{o(k)}$,

1. pick a random hash function $h\colon \{0,1\}^n \to \{0,1\}^k$ from the universal hash family $\mathcal{H}_{n,k}$, and build a circuit for the following function f': for every $x \in \{0,1\}^n$, set

$$f'(x) = \begin{cases} f^*(x) & \text{if } f^*(x) = 0 \\ f^*(x) \oplus C(h(x)) & \text{otherwise} \end{cases}$$

2. Run the white-box BPP algorithm to decide $F(f')$. If $F(f') = 0$, output "C is satisfiable"; otherwise, output "C is unsatisfiable".

For the time analysis, note that the circuit size for f' defined above is $O(s^{o(1)}) + \mathsf{poly}(n) \leq O(s^{o(1)})$, as $f'(x) = f^*(x) \wedge \neg C(h(x))$, and h has a circuit of size $\mathsf{poly}(n)$.

Thus, the described algorithm runs in time $\mathsf{poly}(s^{o(1)}) \leq s^{o(1)}$, which is $2^{o(k)}$ for k-input Circuit-SAT instances C.

For correctness, note that if C is unsatisfiable, then $f' = f^*$, and so $F(f') = 1$. If C is satisfiable, say by an assignment $y \in \{0,1\}^k$, then, with probability at least $1/2$ over the choice of h, the set $h^{-1}(y)$ will contain at least one sensitive location $x \in \{0,1\}^n$ such that $f^*(x) = 1$, but flipping f^* at x results in the new function g such that $F(g) = 0$.

By monotonicity of F, flipping f^* at x *and at any other locations x' where $f(x') = 1$* results in a new function f' such that $F(f') = 0$. ◀

5.2 Win-win analysis

As the Sensitivity Conjecture is true for monotone properties, assuming that a monotone property F requires high decision tree complexity (i.e., non-uniform black-box complexity) implies that F has a (not necessarily easy) sensitive input. We use a "win-win" argument to prove the following.

▶ **Theorem 5.2.** *Let F be any monotone property such that*

1. *F is in* P *in the white-box setting, but,*
2. *for almost all input lengths n, F requires decision tree complexity at least $s > n^{\omega(1)}$ on inputs $f\colon \{0,1\}^n \to \{0,1\}$.*

Then either $\mathsf{Circuit\text{-}SAT}_{n,2^{o(n)}} \in \mathsf{SIZE}(2^{o(n)})$ *infinitely often, or* $\mathsf{BPP} \subseteq \mathsf{NP}$.

6 Circuit-SAT algorithm from variants of MCSP

So far we have considered a Circuit-SAT algorithm that relies on the sensitivity of a given counterexample F to the BBH. In this section we will show a different approach to designing Circuit-SAT algorithm from properties that are subsets of easy functions, the one that does not explicitly use the notion of sensitivity.[2]

We consider the following *succinct* version of MCSP, denoted SuccinctMCSP, where one is given a circuit as input, and is asked to determine if there is a smaller circuit computing the same boolean function; see, e.g., [2] for a recent use and some basic results about SuccinctMCSP. More formally, for $t = t(n)$, $\mathsf{SuccinctMCSP}_t(C)$ asks to decide if $f = [C]$ is in $\mathsf{SIZE}(t)$.

▶ **Theorem 6.1.** *For any efficiently computable $t(n) \in \omega(n)$, if $\mathsf{SuccinctMCSP}_t \in \mathsf{BPP}$, then*

$$\mathsf{Circuit\text{-}SAT}_{n,m} \in \mathsf{RTIME}(\mathsf{poly}(t(n), m)).$$

▶ **Theorem 6.2.** *Let F be a non-empty (for all n) property that contains only a subset of functions $f \in \mathsf{SIZE}(t(n))$, for some efficiently computable $t(n) \in \omega(n)$. If $F \in \mathsf{wbBPP}$, then*

$$\mathsf{Circuit\text{-}SAT}_{n,m} \in \mathsf{RTIME}(\mathsf{poly}(t(n), m))/t(n).$$

7 BBH for restricted circuit classes

We formulated the BBH with general circuits as inputs to the white-box algorithm. It is natural to consider its variants with other types of circuits. We observe that for a very weak type of circuits, e.g., read-once branching programs, the corresponding version of the BBH is unconditionally false. For AC^0 circuits, we show that a strong counterexample to this version of the BBH implies a non-trivial Circuit-SAT algorithm for AC^0 circuits. The case of CNF formulas remains an interesting open question.

8 Conclusions

We conjecture that the falsehood of the BBH is equivalent to the easiness of Circuit-SAT. In the present paper, we make a step in that direction, but many interesting questions remain open. Below we list a few of them.

1. Is it possible to prove our conjecture, assuming the Sensitivity Conjecture is true?
2. Is it possible to get a *uniform* algorithm for Circuit-SAT for a general class of counterexamples to BBH, thereby (conditionally) violating the ETH?
3. Are there any algorithmic SAT consequences from the assumption that there is a strong counterexample to the BBH for *CNF formulas* (rather than AC^0 or general circuits)?
4. The initial formulation of BBH by Barak et al. [5] was mainly inspired by the idea of virtual black-box obfuscation. Is it possible to use indistinguishability obfuscators for proving or disproving BBH?

Acknowledgements. We are very grateful to Marco Carmosino, Shachar Lovett and Avi Wigderson for many insightful discussions. We also thank Rahul Santhanam for his comments and suggestions on the earlier version of this work.

[2] Of course, as noted earlier, Simon's lemma implies that any such property does have an easy sensitive input, and so one can use the sensitivity-based Circuit-SAT algorithm described above. The point here, however, is to have a different type of a Circuit-SAT algorithm.

Abstract

The program-over-monoid model of computation originates with Barrington's proof that it captures the complexity class NC^1. Here we make progress in understanding the subtleties of the model. First, we identify a new tameness condition on a class of monoids that entails a natural characterization of the regular languages recognizable by programs over monoids from the class. Second, we prove that the class known as **DA** satisfies tameness and hence that the regular languages recognized by programs over monoids in **DA** are precisely those recognizable in the classical sense by morphisms from **QDA**. Third, we show by contrast that the well studied class of monoids called **J** is not tame and we exhibit a regular language, recognized by a program over a monoid from **J**, yet not recognizable classically by morphisms from the class **QJ**. Finally, we exhibit a program-length-based hierarchy within the class of languages recognized by programs over monoids from **DA**.

1 Introduction

A program of range n on alphabet Σ over a finite monoid M is a sequence of pairs (i, f) where i is a number between 1 and n and f is a function assigning an element of the monoid M to any letter of Σ. This program assigns to each word $w_1 w_2 \cdots w_n$ the monoid element obtained by multiplying out in M the elements $f(w_i)$, one per pair (i, f), in the order of the sequence. When associated with a subset F of M as an acceptance set, a program naturally defines the language L_n of words of length n to which it assigns a monoid element in F. A program sequence $(P_n)_{n\in\mathbb{N}}$ then defines the language formed by the union of the L_n.

Such sequences became the focus of attention when Barrington [3] made the striking discovery, in fact partly observed earlier [17], that polynomial length program sequences over the group S_5 and sequences of Boolean circuits of polynomial size, logarithmic depth and constant fan-in (defining the complexity class NC^1) recognize precisely the same languages.

A flurry of work followed. After all, a program over M is a mere generalization of a morphism from Σ^* to M and recognition by a morphism equates with acceptance by a finite automaton. Given the extensive algebraic automata theory available at the time [15, 11, 22],

* This work is supported by grants from Digiteo France.

it was to be a matter of a few years before the structure of NC^1 got elucidated by algebraic means.

The "optimism period" produced many significant results. The classes $\mathsf{AC}^0 \subset \mathsf{ACC}^0 \subseteq \mathsf{NC}^1$ were characterized by polynomial length programs over the aperiodic, the solvable, and all monoids respectively [3, 6]. More generally for any variety $\mathbf{V}$ of monoids (a variety being the undisputed best fit with the informal notion of a natural class of monoids) one can define the class $\mathcal{P}(\mathbf{V})$ of languages recognized by polynomial length programs over a monoid drawn from $\mathbf{V}$. In particular, if $\mathbf{A}$ is the variety of aperiodic monoids, then $\mathcal{P}(\mathbf{A})$ characterizes the complexity class AC^0 [6].

But sadly, the optimism period ended: although partial results in restricted settings were obtained, the holy grail of reproving significant circuit complexity results and forging ahead by recycling the deep theorems afforded by algebraic automata theory never materialized. The test case for the approach was to try to prove, independently from the known combinatorial arguments [1, 12, 14] and those based on approximating circuits by polynomials over some finite field [24, 27], that $\mathcal{P}(\mathbf{A})$ does not contain the parity language MOD_2, i.e., that $\mathrm{MOD}_2 \notin \mathsf{AC}^0$. But why has this failed?

The answer of course is that programs are much more complicated than morphisms: programs can read an input position more than once, in non-left-to-right order, possibly assigning a different monoid element each time. Linear-length programs can indeed trivially recognize non-regular languages. In the classical theory, any two varieties provably recognize distinct classes of languages [11, 22]. In the theory of recognition by polynomial length programs (we will speak then of p-recognition), distinct varieties can yield the same class, as do, for instance, any two varieties of monoids $\mathbf{V}$ and $\mathbf{W}$ that each contain a simple non-Abelian group, for which $\mathcal{P}(\mathbf{V}) = \mathcal{P}(\mathbf{W}) = \mathsf{NC}^1$ [18, Theorem 4.1].

To further illustrate the subtle behavior of programs, consider the variety of monoids known as $\mathbf{J}$. $\mathbf{J}$ is the variety of monoids generated by the syntactic monoids of the languages such that membership can be decided by looking for the presence or absence of certain *subwords*, where u is a subword of v if u can be obtained from v by removing some letters of v [26]. It follows that $\mathbf{J}$ is unable to recognize the language defined by the regular expression $(a+b)^*ac^+$. Yet $(a+b)^*ac^+$ is p-recognizable over $\mathbf{J}$. To see this consider the language L of all words having ca as a subword but not the subwords cca, caa and cb. L is therefore recognized by a morphism φ to some monoid M of $\mathbf{J}$, i.e. $L = \varphi^{-1}(F)$ for some $F \subseteq M$. A program of range n over M can recognize the words of length n of $(a+b)^*ac^+$ by using the following trick: reading the input letters in the order $2, 1, 3, 2, 4, 3, 5, 4, \ldots, n, n-1$, assigning to each letter read its image in M by φ and using the same acceptance set F as for L. For instance, on input $abacc$ the program outputs $\varphi(baabcacc)$ which is in F, while on inputs $abbcc$ and $abacca$ the program outputs respectively $\varphi(babbcbcc)$ and $\varphi(baabcaccac)$ which are not in F.

Our paper is motivated by the need to better understand such subtle behaviors of polynomial length programs over monoids. Quite a bit of knowledge on such programs has accumulated over nearly thirty years (consider [5, 20, 21, 16, 28] beyond the references already mentioned). Yet, even within the realm of questions that do not hold pretense to major complexity class separations, gaps remain.

One beaming such gap concerns the variety of monoids $\mathbf{DA}$. The importance of $\mathbf{DA}$ in algebraic automata theory and its connections with other fields are well established (see [30] for an eloquent testimony). $\mathbf{DA}$ is a relatively "small" variety, well within the variety of aperiodic monoids. One could argue that "small" varieties will be sensitive to duplications and rearrangements in the order in which input letters are read by a program. Presumably in part for that reason, programs over $\mathbf{DA}$ have seemingly not been successfully analyzed prior to our work.

Our main result is a characterization of the regular languages recognized by polynomial length programs over **DA**. We show that $\mathcal{P}(\mathbf{DA}) \cap \mathcal{R}\mathsf{eg}$ is precisely the class $\mathcal{L}(\mathbf{QDA})$ of languages recognized classically by morphisms in quasi-**DA** (**QDA**). A surjective morphism φ from Σ^* to a finite monoid M is quasi-**DA** if, though M might not be in **DA**, there is a number k such that the image by φ of all words over Σ whose length is a multiple of k forms a submonoid of M which is in **DA**. In this particular case, this statement is equivalent to the fact that the only power added by p-recognition relative to classical recognition through monoids in **DA** is the ability to count input positions modulo a constant. Our proof shows, independently from [1, 12, 14, 24, 27], that, for regular languages, p-recognition over **DA** does not distort the algebraic properties of the underlying morphisms beyond adding the ability for fixed modulo counting on lengths. (This is precisely the statement, once extended to the variety of all aperiodic monoids, that would yield the elusive semigroup-theoretic proof that $\mathrm{MOD}_2 \notin \mathsf{AC}^0$.)

Our main result builds upon a statement of independent interest, namely, that any variety of monoids **V** that fulfills an appropriate tameness condition satisfies $\mathcal{P}(\mathbf{V}) \cap \mathcal{R}\mathsf{eg} \subseteq \mathcal{L}(\mathbf{QV})$. The new tameness condition (see Definition 2) differs subtly but fundamentally from a similar notion developed for semigroups by Péladeau, Straubing and Thérien [21] and also studied in the case of monoids by Péladeau [20] and later Tesson [28] in their respective Ph.D. theses, and thus requires a separate treatment here. Proving that **DA** indeed satisfies our tameness condition is the main technical difficulty behind our characterization of $\mathcal{P}(\mathbf{DA}) \cap \mathcal{R}\mathsf{eg}$.

We further consider $\mathcal{P}(\mathbf{DA})$. With $\mathcal{C}_k$ the class of languages recognized by programs of length $\mathrm{O}(n^k)$ over **DA**, we prove that $\mathcal{C}_1 \subset \mathcal{C}_2 \subset \cdots \subset \mathcal{C}_k \subset \cdots \subset \mathcal{P}(\mathbf{DA})$ forms a strict hierarchy. We also relate this hierarchy to another algebraic characterization of **DA** and exhibit conditions on $M \in \mathbf{DA}$ under which any program over M can be rewritten as an equivalent subprogram (made of a subsequence of the original sequence of instructions) of length $\mathrm{O}(n^k)$, refining a result by Tesson and Thérien [29].

Our final result concerns the variety **J**. Observing that the regular language $(a+b)^*ac^+$ mentioned above is not recognizable by a morphism in **QJ**, we conclude that **J** is not a tame variety. Be it the chicken or the egg, this lack of tameness "explains" the unexpected power of $\mathcal{P}(\mathbf{J})$ witnessed in our example above. Furthermore, since **J** is a p-variety of monoids in the sense of [21, 20, 28], **J** explicitly shows that our notion of tameness and that of [21, 20, 28] differ.

Organization of the paper. In Section 2 we define programs over varieties of monoids, p-recognition by such programs and the necessary algebraic background. The definition of tameness for a variety **V** is given in Section 3 with our first result showing that regular languages recognized by $\mathcal{P}(\mathbf{V})$ are included in $\mathcal{L}(\mathbf{QV})$ when **V** is tame; we also quickly discuss the case of **J**, which isn't tame. We show that **DA** is tame in Section 4. Finally, Section 5 contains the hierarchy results about $\mathcal{P}(\mathbf{DA})$.

2 Preliminaries

This section is dedicated to introducing the mathematical material used throughout this paper. Concerning algebraic automata theory, we only quickly review the basics and refer the reader to the two classical references of the domain by Eilenberg [10, 11] and Pin [22].

General notations. Let $i, j \in \mathbb{N}$ be two natural numbers. We shall denote by $[\![i, j]\!]$ the set of all natural numbers $n \in \mathbb{N}$ verifying $i \leq n \leq j$. We shall also denote by $[i]$ the set $[\![1, i]\!]$.

Words and languages. Let Σ be a finite alphabet. We denote by Σ^* the set of all finite words over Σ. We also denote by Σ^+ the set of all finite non empty words over Σ, the empty word being denoted by ε. A *language over* Σ is a subset of Σ^*. A language is *regular* if it can be defined using a regular expression. Given a language L, its *syntactic congruence* $\sim_L$ is the relation on Σ^* relating two words u and v whenever for all $x, y \in \Sigma^*$, $xuy \in L$ if and only if $xvy \in L$. It is easy to check that $\sim_L$ is an equivalence relation and a congruence for concatenation. The *syntactic morphism of* L is the mapping sending any word u to its equivalence class in the syntactic congruence.

The *quotient of a language* L *over* Σ *relative to the words* u *and* v is the language, denoted by $u^{-1}Lv^{-1}$, of the words w such that $uwv \in L$.

Monoids, semigroups and varieties. A *semigroup* is a set equipped with an associative law that we will write multiplicatively. A *monoid* is a semigroup with an identity. An example of a semigroup is Σ^+, the free semigroup over Σ. Similarly Σ^* is the free monoid over Σ. A *morphism* φ *from a semigroup* S *to a semigroup* T is a function from S to T such that $\varphi(xy) = \varphi(x)\varphi(y)$ for all $x, y \in S$. A morphism of monoids additionally requires that the identity is preserved. A semigroup T is a *subsemigroup* of a semigroup S if T is a subset of S and is equipped with the restricted law of S. Additionally the notion of submonoids requires the presence of the identity. The *Cartesian (or direct) product* of two semigroups is simply the semigroup given by the Cartesian product of the two underlying sets equipped with the Cartesian product of their laws.

A language L over Σ is *recognized by a monoid* M if there is a morphism h from Σ^* to M and a subset F of M such that $L = h^{-1}(F)$. We also say that *the morphism* h *recognizes* L. It is well known that a language is regular if and only if it is recognized by a finite monoid. Actually, as $\sim_L$ is a congruence, the quotient $\Sigma^*/\sim_L$ is a monoid, called *the syntactic monoid of* L, that recognizes L via the syntactic morphism of L. The syntactic monoid of L is finite if and only if L is regular. The quotient $\Sigma^+/\sim_L$ is analogously called *the syntactic semigroup of* L.

A *variety of monoids* is a class of finite monoids closed under submonoids, Cartesian product and morphic images. A *variety of semigroups* is defined similarly. When dealing with varieties, we consider only finite monoids and semigroups.

An element s of a semigroup is *idempotent* if $ss = s$. For any finite semigroup S there is a positive number (the minimum such number), *the idempotent number of* S, often denoted ω, such that for any element $s \in S$, s^ω is idempotent.

A variety can be defined by means of identities [25]. The variety is then the class of monoids such that each of them has all its elements satisfy the identities. For instance, the variety of aperiodic monoids **A** can be defined as the class of monoids satisfying the identity $x^\omega = x^{\omega+1}$, where x ranges over the elements of the monoid while ω is the idempotent power of the monoid. The variety of monoids **DA** is defined by the identity $(xy)^\omega = (xy)^\omega x (xy)^\omega$. The variety of monoids **J** is defined by the identity $(xy)^\omega = (xy)^\omega x = y(xy)^\omega$.

Quasi and locally V languages, modular counting and predecessor. If S is a semigroup we denote by S^1 the monoid S if S is already a monoid and $S \cup \{1\}$ otherwise.

The following definitions are taken from [23]. Let φ be a surjective morphism from Σ^* to a finite monoid M. For all k consider the subset $\varphi(\Sigma^k)$ of M. As M is finite there is a k such that $\varphi(\Sigma^{2k}) = \varphi(\Sigma^k)$. This implies that $\varphi(\Sigma^k)$ is a semigroup. The semigroup given by the smallest such k is called the *stable semigroup of* φ. If S is the stable semigroup of φ, S^1 is called *the stable monoid of* φ. If **V** is a variety of monoids, then we shall denote by

$\mathbf{QV}$ the class of such surjective morphisms whose stable monoid is in $\mathbf{V}$ and by $\mathcal{L}(\mathbf{QV})$ the class of languages whose syntactic morphism is in $\mathbf{QV}$.

For $\mathbf{V}$ a variety of monoids, we say that a finite semigroup S is *locally* $\mathbf{V}$ if, for every idempotent e of S, the monoid eSe belongs to $\mathbf{V}$; we denote by $\mathbf{LV}$ the class of locally-$\mathbf{V}$ finite semigroups, which happens to be a variety of semigroups. Finally, $\mathcal{L}(\mathbf{LV})$ denotes the class of languages whose syntactic semigroup is in $\mathbf{LV}$.

We now define languages recognized by $\mathbf{V} * \mathbf{Mod}$ and $\mathbf{V} * \mathbf{D}$. We do not use the standard algebraic definition using the wreath product as we won't need it, but directly a characterization of the languages recognized by such algebraic objects [7, 31].

Let $\mathbf{V}$ be a variety of monoids. We say that a language L over Σ is in $\mathcal{L}(\mathbf{V} * \mathbf{Mod})$ if there is a number $k \in \mathbb{N}_{>0}$ and a language L' over $\Sigma \times \{0, \cdots, k-1\}$ whose syntactic monoid is in $\mathbf{V}$, such that L is the set of words w that belong to L' after adding to each letter of w its position modulo k.

Similarly we say that a language L over Σ is in $\mathcal{L}(\mathbf{V} * \mathbf{D})$ if there is a number $k \in \mathbb{N}$ and a language L' over $\Sigma \times \Sigma^{\leq k}$ (where $\Sigma^{\leq k}$ denotes all words over Σ of length at most k) whose syntactic monoid is in $\mathbf{V}$, such that L is the set of words w that belong to L' after adding to each letter of w the word composed of the k (or less when near the beginning of w) letters preceding that letter. The variety of semigroups $\mathbf{V} * \mathbf{D}$ can then be defined as the one generated by the syntactic semigroups of the languages in $\mathcal{L}(\mathbf{V} * \mathbf{D})$ as defined above.

A variety $\mathbf{V}$ is said to be *local* if $\mathcal{L}(\mathbf{V} * \mathbf{D}) = \mathcal{L}(\mathbf{LV})$. This is not the usual definition of locality, defined using categories, but it is equivalent to it [31, Theorem 17.3]. One of the consequences of locality that we will use is that $\mathcal{L}(\mathbf{V} * \mathbf{Mod}) = \mathcal{L}(\mathbf{QV})$ [9, Corollary 18] (see also [8, 19]).

Programs over varieties of monoids. Programs over monoids form a non-uniform model of computation, first defined by Barrington and Thérien [6], extending Barrington's permutation branching program model [3]. Let M be a finite monoid and Σ a finite alphabet. A program P over M is a finite sequence of instructions of the form (i, f) where i is a positive integer and f a function from Σ to M. The *length* of P is the number of its instructions. A program has *range* n if all its instructions use a number less than n. A program P of range n defines a function from Σ^n, the words of length n, to M as follows. On input $w \in \Sigma^n$, each instruction (i, f) outputs the monoid element $f(w_i)$. A sequence of instructions then yields a sequence of elements of M and their product is the output $P(w)$ of the program.

A language L over Σ is p-*recognized* by a sequence of programs $(P_n)_{n\in\mathbb{N}}$ if for each n, P_n has range n and length polynomial in n and there exists a subset F_n of M such that $L \cap \Sigma^n$ is precisely the set of words w of length n such that $P_n(w) \in F_n$.

We denote by $\mathcal{P}(M)$ the class of languages p-recognized by a sequence of programs $(P_n)_{n\in\mathbb{N}}$ over M. If $\mathbf{V}$ is a variety of monoids we denote by $\mathcal{P}(\mathbf{V})$ the union of all $\mathcal{P}(M)$ for $M \in \mathbf{V}$.

The following is a simple fact about $\mathcal{P}(\mathbf{V})$. Let Σ and Γ be two finite alphabets and $\mu\colon \Sigma^* \to \Gamma^*$ be a morphism. We say that μ is length multiplying, or that μ *is an* lm-*morphism*, if there is a constant k such that for all $a \in \Sigma$, the length of $\mu(a)$ is k.

▶ **Lemma 1** ([18], Corollary 3.5). *Let* $\mathbf{V}$ *be a variety of monoids, then* $\mathcal{P}(\mathbf{V})$ *is closed under Boolean operations, quotients and inverse images of* lm-*morphisms.*

3 General results about regular languages and programs

Let $\mathbf{V}$ be a variety of monoids. By definition any regular language recognized by a monoid in $\mathbf{V}$ is *p*-recognized by a sequence of programs over a monoid in $\mathbf{V}$. Actually, since in a program over some monoid in $\mathbf{V}$, the monoid element output for each instruction can depend on the position of the letter read, hence in particular on its position modulo some fixed number, it is easy to see that any regular language in $\mathcal{L}(\mathbf{V} * \mathbf{Mod})$ is *p*-recognized by a sequence of programs over some monoid in $\mathbf{V}$. In this section we show that for some "well behaved" varieties $\mathbf{V}$ the converse inclusion holds.

For this we introduce the notion of an *sp*-variety of monoids. This notion is inspired by the notion of *p*-varieties (program-varieties) of monoids, that seems to have been originally defined by Péladeau in his Ph.D. thesis [20] and later used by Tesson in his own Ph.D. thesis [28]. The notion of a *p*-variety has also been defined for semigroups by Péladeau, Straubing and Thérien in [21] in order to obtain results similar to ours for varieties of semigroups of the form $\mathbf{V} * \mathbf{D}$.

Let μ be a morphism from Σ^* to a finite monoid M. We denote by $\mathcal{W}(\mu)$ the set of languages L over Σ such that $L = \mu^{-1}(F)$ for some subset F of M. Given a semigroup S there is a unique morphism $\eta_S \colon S^* \to S^1$ extending the identity on S, called the *evaluation morphism of* S. We write $\mathcal{W}(S)$ for $\mathcal{W}(\eta_S)$. We define $\mathcal{W}(M)$ similarly for any monoid M. It is easy to see that if $M \in \mathbf{V}$ then $\mathcal{W}(M) \subseteq \mathcal{P}(\mathbf{V})$. The tameness condition requires a converse of this observation.

▶ **Definition 2.** An sp-*variety of monoids*, which we will call a *tame* variety, is a variety $\mathbf{V}$ of monoids such that for any finite semigroup S, if $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{V})$ then $S^1 \in \mathbf{V}$.

The *p*-variety of monoids in [20, 28] is similar to our *sp*-variety but the former only requires that any finite monoid M verifying $\mathcal{W}(M) \subseteq \mathcal{P}(\mathbf{V})$ must in fact belong to $\mathbf{V}$. This implies that any *sp*-variety of monoids is also a *p*-variety of monoids, but the converse is not always true. For instance, $\mathbf{J}$ is a *p*-variety of monoids [28], but Proposition 5 below states that $\mathbf{J}$ is not an *sp*-variety.

An example of an *sp*-variety of monoids is the class of aperiodic monoids $\mathbf{A}$. This is a consequence of the result that for any number $k > 1$, checking if the number of a modulo k in a word is congruent to 0 is not in $\mathsf{AC}^0 = \mathcal{P}(\mathbf{A})$ [12, 1] (a language we shall denote by $\mathrm{MOD_k}$ over the alphabet $\{0, 1\}$). Towards a contradiction, assume there would exist a semigroup S such that S^1 is not aperiodic but still $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{A})$. Then there is an x in S such that $x^\omega \neq x^{\omega+1}$. Consider the morphism $\mu \colon \{a, b\}^* \to S^1$ sending a to $x^{\omega+1}$ and b to x^ω, and the language $L = \mu^{-1}(x^\omega)$. It is easy to see that L is the language of all words with a number of a congruent to 0 modulo k, where k is the smallest number such that $x^{\omega+k} = x^\omega$. As $x^\omega \neq x^{\omega+1}$, $k > 1$. From $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{A})$ it follows that $\eta_S^{-1}(x^\omega)$ is *p*-recognized by a sequence of programs $(P_n)_{n\in\mathbb{N}}$ over an aperiodic monoid. For each $n \in \mathbb{N}$, we can transform P_n into P'_n where each instruction (i, f) in P_n simply becomes the instruction (i, f') in P'_n with $f'(\sigma) = f(\mu(\sigma))$ for all $\sigma \in \{a, b\}$, so that $P'_n(w) = P_n(\mu(w_1)\mu(w_2)\cdots\mu(w_n))$ for all $w \in \{a, b\}^n$. This entails that the sequence of programs $(P'_n)_{n\in\mathbb{N}}$ *p*-recognizes L, hence L is in $\mathcal{P}(\mathbf{A})$, a contradiction.

The following is the desired consequence of tameness.

▶ **Proposition 3.** *Let* $\mathbf{V}$ *be an* sp-*variety of monoids. Then* $\mathcal{P}(\mathbf{V}) \cap \mathcal{R}\mathsf{eg} \subseteq \mathcal{L}(\mathbf{QV})$.

A similar result was proven for varieties of semigroups of the form $\mathbf{V} * \mathbf{D}$: if $\mathbf{V} * \mathbf{D}$ is a *p*-variety then the regular languages in $\mathcal{P}(\mathbf{V} * \mathbf{D})$ are exactly those in $\mathcal{L}(\mathbf{V} * \mathbf{D} * \mathbf{Mod})$ [21] (programs over semigroups being defined in the obvious way). Our proof follows the same lines.

Proof. Let L be a regular language in $\mathcal{P}(M)$ for some $M \in \mathbf{V}$. Let M_L be the syntactic monoid of L and η_L its syntactic morphism. Let S be the stable semigroup of η_L, in particular $S = \eta_L(\Sigma^k)$ for some k. We wish to show that S^1 is in $\mathbf{V}$.

We show that $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{V})$ and conclude from the fact that $\mathbf{V}$ is an *sp*-variety that $S^1 \in \mathbf{V}$ as desired. Let $\eta_S \colon S^* \to S^1$ be the evaluation morphism of S. Consider $m \in S$ and consider $L' = \eta_S^{-1}(m)$. We wish to show that $L' \in \mathcal{P}(\mathbf{V})$. This implies that $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{V})$ by closure under union, Lemma 1.

Let $L'' = \eta_L^{-1}(m)$. Since m belongs to the syntactic monoid of L and η_L is the syntactic morphism of L, a classical algebraic argument [22, Chapter 2, proof of Lemma 2.6] shows that L'' is a Boolean combination of quotients of L or their complements. By Lemma 1, we conclude that $L'' \in \mathcal{P}(\mathbf{V})$.

By definition of S, for any element s of S there is a word u_s of length k such that $\eta_L(u_s) = s$. Notice that this is precisely where we need to work with S and not S^1.

Let $f \colon S^* \to \Sigma^*$ be the *lm*-morphism sending s to u_s and notice that $L' = f^{-1}(L'')$. The result follows by closure of $\mathcal{P}(\mathbf{V})$ under inverse images of *lm*-morphisms, Lemma 1. ◀

We don't know whether it is always true that for *sp*-varieties of monoids $\mathbf{V}$, $\mathcal{L}(\mathbf{QV})$ is included into $\mathcal{P}(\mathbf{V})$. We can only prove it for local varieties.

▶ **Proposition 4.** *Let* $\mathbf{V}$ *be a local* sp*-variety of monoids. Then* $\mathcal{P}(\mathbf{V}) \cap \mathcal{R}\mathsf{eg} = \mathcal{L}(\mathbf{QV})$.

Proof. This follows from the fact that for local varieties $\mathcal{L}(\mathbf{QV}) = \mathcal{L}(\mathbf{V} * \mathbf{Mod})$ [9]. The result follows from Proposition 3, as we always have $\mathcal{L}(\mathbf{V} * \mathbf{Mod}) \subseteq \mathcal{P}(\mathbf{V})$. ◀

As $\mathbf{A}$ is local [31, Example 15.5] and an *sp*-variety, it follows from Proposition 4 that the regular languages in $\mathcal{P}(\mathbf{A})$, hence in AC^0, are precisely those in $\mathcal{L}(\mathbf{QA})$, which is the characterization of the regular languages in AC^0 obtained by Barrington, Compton, Straubing and Thérien [4].

We will see in the next section that $\mathbf{DA}$ is an *sp*-variety. As it is also local [2], we get from Proposition 4 that the regular languages of $\mathcal{P}(\mathbf{DA})$ are precisely those in $\mathcal{L}(\mathbf{QDA})$.

As explained in the introduction, the language $(a+b)^*ac^+$ can be *p*-recognized by a program over $\mathbf{J}$. A simple algebraic argument shows that it is not in $\mathcal{L}(\mathbf{QJ})$. Hence, by Proposition 3, we have the following result:

▶ **Proposition 5.** $\mathbf{J}$ *is not an* sp*-variety of monoids.*

4 The case of DA

In this section, we prove that $\mathbf{DA}$ is an *sp*-variety of monoids. Combined with the fact that $\mathbf{DA}$ is local [2], we obtain the following result by Proposition 4.

▶ **Theorem 6.** $\mathcal{P}(\mathbf{DA}) \cap \mathcal{R}\mathsf{eg} = \mathcal{L}(\mathbf{QDA})$.

The result follows from the following main technical contribution:

▶ **Proposition 7.** $(c+ab)^*$, $(b+ab)^*$ *and* $((b^*ab^*)^k)^*$ *for any integer* $k \geq 2$ *are regular languages not in* $\mathcal{P}(\mathbf{DA})$.

Before proving the proposition we first show that it implies that $\mathbf{DA}$ is an *sp*-variety of monoids. Assume S is a finite semigroup such that $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{DA})$. Let $\eta_S \colon S^* \to S^1$ be the evaluation morphism of S. We need to show that S^1 is in $\mathbf{DA}$.

Assume first that S^1 is aperiodic. Towards a contradiction, assume S^1 is not in $\mathbf{DA}$. Then, there exist x, y in S such that $(xy)^\omega \neq (xy)^\omega x (xy)^\omega$.

Set $e = (xy)^\omega$, $f = (yx)^\omega$, $s = ex$ and $t = ye$. Our hypothesis says that $exe \neq e$. We now have two cases, depending on whether $fyf = f$ or not.

So, suppose $fyf \neq f$. In that case, let $\mu\colon \{a,b,c\}^* \to S^1$ be the morphism sending a to s, b to t and c to e and consider the language $L = \mu^{-1}(\{1,e\})$. Assume that L contains a word w with two consecutive a. Then $w = w_1aaw_2$ and as $w \in L$, either $e = \mu(w_1)exex\mu(w_2)$ or $1 = \mu(w_1)exex\mu(w_2)$. In both cases $e = u_1exeu_2$ for some suitable values of u_1 and u_2. This implies that $e = u_1^\omega e(xeu_2)^\omega = (u_1xe)^\omega eu_2^\omega$. Because S^1 is aperiodic, this implies: $e = exeu_2 = eu_2$. Hence $exe = e$, contradicting the fact that $exe \neq e$. Similar arguments show that L cannot contain a word with two consecutive b, a factor ac or a factor cb.

Any word in L is of the form $u_0v_1u_1\cdots u_{k-1}v_ku_k$ where $k \in \mathbb{N}$, $v_1,\ldots,v_k \in c^+$ and $u_0,\ldots,u_k \in (a+b)^*$. As w does not contain aa nor bb as a factor, we have that $u_0,\ldots,u_k \in (b+\varepsilon)(ab)^*(a+\varepsilon)$. When $k \geq 1$, as moreover w does not contain ac nor cb as a factor, it follows that $u_1,\ldots,u_{k-1} \in (ab)^*$, $u_0 \in (b+\varepsilon)(ab)^*$ and $u_k \in (ab)^*(a+\varepsilon)$; now since $\mu(ab) = exye = e$ by aperiodicity and $\mu(b)e = yee = ye \notin \{1,e\}$ (otherwise $fyf = f$), $e\mu(a) = eex = ex \notin \{1,e\}$ (otherwise $exe = e$), $\mu(b)e\mu(a) = yeeex = yex = f \notin \{1,e\}$ (by aperiodicity and as otherwise $exe = e$), w cannot start with b or end with a, hence $u_0, u_k \in (ab)^*$. And similarly, $u_0 \in (ab)^*$ when $k = 0$. Therefore, $L = (c+ab)^*$.

The other case, when $fyf = f$, is treated similarly using the morphism $\mu\colon \{a,b\}^* \to S^1$ sending a to s and b to t and considering the language $L = \mu^{-1}(\{1,e,t\})$. Using arguments as for the previous case, one can conclude that $L = (b+ab)^*$.

Assume now that S^1 is not aperiodic. As in the two previous cases, we can then prove that there exist a morphism $\mu\colon \{a,b\}^* \to S^1$ and a subset $F \subseteq S^1$ such that $L = \mu^{-1}(F)$ is the regular language $((b^*ab^*)^k)^*$ for some $k \in \mathbb{N}, k \geq 2$ of all words over $\{a,b\}$ with a number of a congruent to 0 modulo k.

In all cases, we have a language L defined as $\mu^{-1}(Q)$ for some subset Q of S^1 and some morphism μ to S^1 sending letters to elements of S. As $\mathcal{W}(S) \subseteq \mathcal{P}(\mathbf{DA})$, it follows that $\eta_S^{-1}(Q)$ is p-recognized by a sequence of programs $(P_n)_{n\in\mathbb{N}}$ over a monoid in $\mathbf{DA}$. As in the example prior to Proposition 3 in the previous section, for each $n \in \mathbb{N}$, we can transform P_n into P'_n over the same monoid so that the sequence of programs $(P'_n)_{n\in\mathbb{N}}$ p-recognizes L. In all cases, we get a contradiction with Proposition 7.

In the remaining part of this section we prove Proposition 7.

Proof of Proposition 7. The idea of the proof is the following. We work by contradiction and assume that we have a sequence of programs over some monoid M of $\mathbf{DA}$ deciding one of the targeted language. Let n be much larger than the size of M, and let P_n be the program running on words of length n. Consider a language of the form Δ^* for some finite set Δ of words (for instance assume $\Delta = \{c, ab\}$, $\Delta = \{b, ab\}$, ...). We will show that we can fix a constant (depending on M and Δ but not on n) number of entries to P_n such that P_n always accepts or always rejects and there is a completion of the fixed entries in Δ^*; hence, if Δ was chosen so that there is actually a completion of the fixed entries in the targeted language and one outside of it, P_n cannot recognize it. We cannot prove this for all Δ, in particular it will not work for $\Delta = \{ab\}$ and indeed $(ab)^*$ is in $\mathcal{P}(\mathbf{DA})$. The key property of our Δ is that after fixing any letter at any position, except maybe for a constant number of positions, one can still complete the word into one within Δ^*. This is not true for $\Delta = \{ab\}$ because after fixing a b in an odd position all completions fall outside of $(ab)^*$.

We now add some technical details.

Let Δ be a finite set of words. Let Σ be the corresponding finite alphabet and let $\perp$ be a letter not in Σ. A *mask* is a word over $\Sigma \cup \{\perp\}$. The positions of a mask carrying a $\perp$ are called *free* while the positions carrying a letter in Σ are called *fixed*. A mask λ' is a *submask* of a mask λ if it is formed from λ by replacing some occurrences of $\perp$ by a letter in Σ.

A *completion* of a mask λ is a word w over Σ that is built from λ by replacing all occurrences of $\perp$ by a letter in Σ. Notice that all completions of a mask have the same length as the mask itself. A mask λ is Δ-*compatible* if it has a completion in Δ^*.

The *dangerous* positions of a mask λ are the positions within distance $2l-2$ of the fixed positions or within distance $l-1$ of the beginning or the end of the mask, where l is the maximal length of a word in Δ. A position that is not dangerous is said to be *safe*.

We say that Δ is *safe* if the following holds. Let λ be a Δ-compatible mask. Let i be any free position of λ that is not dangerous. Let a be any letter in Σ. Then the submask of λ constructed by fixing a at position i is Δ-compatible. We have already seen that $\Delta = \{ab\}$ is not safe. However our targeted Δ, $\Delta = \{c, ab\}$, $\Delta = \{b, ab\}$, $\Delta = \{a, b\}$, are safe. We always consider Δ to be safe in the following.

Finally, we say that a completion w of a mask λ is *safe* if w is a completion of λ belonging to Δ^* or is constructed from a completion of λ in Δ^* by modifying only letters at safe positions of λ, the dangerous positions remaining unchanged.

The following lemma is the key to the proof. It shows that modulo fixing a few entries, one can fix the output.

▶ **Lemma 8.** *Let M be a monoid in* **DA**. *Let λ be a Δ-compatible mask of length n, let P be a program over M of range n, let u and v be elements of M. Then there is an element t of M and a Δ-compatible submask λ' of λ obtained by fixing a number of free positions independent from n such that any safe completion w of λ' verifies $uP(w)v = t$.*

The proof of Lemma 8 is technical. As often in this setting, it relies on Green's relations for decomposing monoids. Then, at each stage of the decomposition, a small number of safe positions are fixed accordingly. Details can be found in Appendix A.

Setting $\Delta = \{c, ab\}$ or $\Delta = \{b, ab\}$, when applying Lemma 8 for some monoid $M \in \mathbf{DA}$ with the trivial Δ-compatible mask λ of length n containing only free positions, with P some program over M of range n and with u and v the identity of M, the resulting mask λ' has the property that we have an element t of M such that $P(w) = t$ for any safe completion w of λ'. Since the mask λ' is Δ-compatible and as long as n is big enough, we have a safe completion $w_0 \in \Delta^*$ and a safe completion $w_1 \notin \Delta^*$. Hence P cannot recognize Δ^*. This implies that $(c+ab)^* \notin \mathcal{P}(M)$ and $(b+ab)^* \notin \mathcal{P}(M)$. Finally, for any $k \in \mathbb{N}, k \geq 2$, we can prove that $((b^*ab^*)^k)^* \notin \mathcal{P}(M)$ by setting $\Delta = \{a, b\}$ and completing the mask given by the lemma by setting the letters in such a way that we have the right number of a modulo k in one case and not in the other case.

This concludes the proof of Proposition 7 because the argument above holds for any monoid in **DA**.

5 A fine hierarchy in $\mathcal{P}(\mathbf{DA})$

The definition of p-recognition by a sequence of programs over a monoid given in Section 2 requires that for each n, the program reading the entries of length n has a length polynomial in n. In the case of $\mathcal{P}(\mathbf{DA})$, the polynomial length restriction is without loss of generality: any program over a monoid in **DA** is equivalent to one of polynomial length over the same monoid [29] (in the sense that they recognize the same languages). In this section, we show that this does not collapse further: in the case of **DA**, programs of length $O(n^{k+1})$ express strictly more than those of length $O(n^k)$.

Following [13], we use an alternative definition of the languages recognized by a monoid in **DA**. We define by induction a hierarchy of classes of languages $\mathcal{SUM}_k$, where $\mathcal{SUM}$ stands for *strongly unambiguous monomial*. A language L is in $\mathcal{SUM}_0$ if it is of the form

A^* for some finite alphabet A. A language L is in $\mathcal{SUM}_k$ if it is in $\mathcal{SUM}_{k-1}$ or $L = L_1 a L_2$ for some languages $L_1 \in \mathcal{SUM}_i$ and $L_2 \in \mathcal{SUM}_j$ and some letter a with $i + j = k - 1$ such that no word of L_1 contains the letter a or no word of L_2 contains the letter a.

Gavaldà and Thérien showed that a language L is recognized by a monoid in **DA** iff there is a k such that L is a Boolean combination of languages in $\mathcal{SUM}_k$ [13]. For each $k \in \mathbb{N}$, we denote by $\mathbf{DA_k}$ the variety of monoids generated by the syntactic monoids of the Boolean combinations of languages in $\mathcal{SUM}_k$. It can be checked that, for each k, $\mathbf{DA_k}$ forms a variety of monoids recognizing precisely Boolean combinations of languages in $\mathcal{SUM}_k$ (see Appendix B).

5.1 Strict hierarchy

For each k we exhibit a language $L_k \subseteq \{0,1\}^*$ that can be recognized by a sequence of programs of length $\mathrm{O}(n^k)$ over a monoid M_k in **DA** but cannot be recognized by any sequence of programs of length $\mathrm{O}(n^{k-1})$ over any monoid in **DA**.

The language L_k expresses a property of the first k occurrences of 1 in the input word. To define L_k we say that S is a *k-set over n* if S is a set where each element is an ordered tuple of k distinct elements of $[n]$. For any sequence $\Delta = (S_n)_{n\in\mathbb{N}}$ of k-sets over n, we set $L_\Delta = \bigcup_{n\in\mathbb{N}} K_{n,S_n}$, where K_{n,S_n} is the set of words over $\{0,1\}$ of length n such that for each of them, it contains at least k occurrences of 1 and the ordered k-tuple of the positions of the first k occurrences of 1 belongs to S_n.

On the one hand, we show that for all k there is a monoid M_k in **DA** such that for all Δ the language L_Δ is recognized by a sequence of programs over M_k of length $\mathrm{O}(n^k)$. The proof is done by an inductive argument on k.

On the other hand, we show that there is a Δ such that for any finite monoid M and any sequence of programs $(P_n)_{n\in\mathbb{N}}$ over M of length $\mathrm{O}(n^{k-1})$, L_Δ is not recognized by $(P_n)_{n\in\mathbb{N}}$. This is done using a counting argument: for some monoid size i, for n big enough, the number of languages in $\{0,1\}^n$ recognized by a program over some monoid of size i of length at most $\alpha \cdot n^{k-1}$ is upper-bounded by a number that turns out to be asymptotically smaller than the number of different possible K_{n,S_n}.

Upper bound. We start with the upper bound. Notice that for $\Delta = (S_n)_{n\in\mathbb{N}}$, the language of words of length n of L_Δ is exactly K_{n,S_n}. Hence the fact that L_Δ can be recognized by a sequence of programs over a monoid in **DA** of length $\mathrm{O}(n^k)$ is a consequence of the following proposition.

▶ **Proposition 9.** *For all $k \in \mathbb{N}_{>0}$ there is a monoid $M_k \in \mathbf{DA_k}$ such that for all $n \in \mathbb{N}$ and all S_n k-sets over n, the language K_{n,S_n} is recognized by a program over M_k of length at most $4n^k$.*

Proof. We first define by induction on k a family of languages Z_k over the alphabet $Y_k = \{\bot_l, \top_l \mid 1 \le l \le k\}$. For $k = 0$, Z_0 is $\{\varepsilon\}$. For $k > 0$, Z_k is the set of words containing $\top_k$ and such that the first occurrence of $\top_k$ has no $\bot_k$ to its left, and the sequence between the first occurrence of $\top_k$ and the first occurrence of $\bot_k$ or $\top_k$ to its right, or the end of the word if there is no such letter, belongs to Z_{k-1}. A simple induction on k shows that Z_k is defined by the following expression

$$Y_{k-1}^* \top_k Y_{k-2}^* \top_{k-1} \cdots Y_1^* \top_2 \top_1 Y_k^*$$

and therefore it is in $\mathcal{SUM}_k$ and its syntactic monoid M_k is in $\mathbf{DA_k}$.

Fix n. If $n = 0$, the proposition follows trivially, otherwise, we define by induction on k a program $P_k(i, S)$ for every k-set S over n and every $1 \leq i \leq n+1$ that will for the moment output letters of Y_k instead of outputting elements of M_k.

For any $k > 0$ and S a k-set over n, let $f_{j,S}$ be the function with $f_{j,S}(0) = \varepsilon$ and $f_{j,S}(1) = \top_k$ if j is the first element of some ordered k-tuple of S, $f_{j,S}(1) = \bot_k$ otherwise. We also let g_k be the function with $g_k(0) = \varepsilon$ and $g_k(1) = \bot_k$. If S is a k-set over n and $j \leq n$ then $S|j$ denotes the $(k-1)$-set over n containing the ordered $(k-1)$-tuples $\bar{t}$ such that $(j, \bar{t}) \in S$.

For $k > 0$, $1 \leq i \leq n+1$ and S a k-set over n, the program $P_k(i, S)$ is the following sequence of instructions:

$$(i, f_{i,S})P_{k-1}(i+1, S|i)(i, g_k) \cdots (n, f_{n,S})P_{k-1}(n+1, S|n)(n, g_k).$$

In other words, the program guesses the first occurrence $j \geq i$ of 1, returns $\bot_k$ or $\top_k$ depending on whether it is the first element of an ordered k-tuple in S, and then proceeds for the next occurrences of 1 by induction.

For $k = 0$, $1 \leq i \leq n+1$ and S a 0-set over n (that is empty or contains ε, the only ordered 0-tuple of elements of $[n]$), the program $P_0(i, S)$ is the empty program ε.

A simple computation shows that for any $k \in \mathbb{N}_{>0}$, $1 \leq i \leq n+1$ and S a k-set over n, the number of instructions in $P_k(i, S)$ is at most $4n^k$.

A simple induction on k shows that when running on a word $w \in \{0,1\}^n$, for any $k \in \mathbb{N}_{>0}$, $1 \leq i \leq n+1$ and S a k-set over n, $P_k(i, S)$ returns a word in Z_k iff the ordered k-tuple of the positions of the first k occurrences of 1 starting at position i in w exists and is an element of S.

For any $k > 0$ and S_n a k-set over n, it remains to apply the syntactic morphism of Z_k to the output of the functions in the instructions of $P_k(1, S_n)$ to get a program over M_k of length at most $4n^k$ recognizing K_{n,S_n}. ◀

Lower bound. The following claim is a simple counting argument.

▶ **Claim 10.** *For all $i \in \mathbb{N}_{>0}$ and $n \in \mathbb{N}$, the number of languages in $\{0,1\}^n$ recognized by programs over a monoid of size i, reading inputs of length n over the alphabet $\{0,1\}$, with at most $l \in \mathbb{N}$ instructions, is bounded by $i^{i^2} 2^i \cdot (n \cdot i^2)^l$.*

Proof. Fix a monoid M of size i. Since a program over M of range n with less than l instructions can always be completed into such a program with exactly l instructions recognizing the same languages in $\{0,1\}^n$ (using the identity of M), we only consider programs with exactly l instructions. As $\Sigma = \{0,1\}$, there are $n \cdot i^2$ choices for each of the l instructions of a range n program over M reading inputs in $\{0,1\}^*$. Such a program can recognize at most 2^i different languages in $\{0,1\}^n$. Hence, the number of languages in $\{0,1\}^n$ recognized by programs over M of length at most l is at most $2^i \cdot (n \cdot i^2)^l$. The result follows from the facts that there are at most i^{i^2} isomorphism classes of monoids of size i and that two isomorphic monoids allow to recognize the same languages in $\{0,1\}^n$. ◀

If for some $k \in \mathbb{N}_{>0}$ and $1 \leq i \leq \alpha$, $\alpha \in \mathbb{N}_{>0}$, we apply Claim 10 for all $n \in \mathbb{N}$, $l = \alpha \cdot n^{k-1}$, we get a number of languages upper-bounded by $n^{\mathrm{O}(n^{k-1})}$, which is asymptotically strictly smaller than the number of distinct K_{n,S_n}, which is $2^{\binom{n}{k}}$.

Hence, for all $j \in \mathbb{N}_{>0}$, there exist an $n_j \in \mathbb{N}$ and T_j a k-set over n_j such that no program over a monoid of size $1 \leq i \leq j$ and of length at most $j \cdot n^{k-1}$ recognizes K_{n_j,T_j}. Moreover, we can assume without loss of generality that the sequence $(n_j)_{j \in \mathbb{N}_{>0}}$ is increasing. Let

$\Delta = (S_n)_{n\in\mathbb{N}}$ be such that $S_{n_j} = T_j$ for all $j \in \mathbb{N}_{>0}$ and $S_n = \emptyset$ for any $n \in \mathbb{N}$ verifying that it is not equal to any n_j for $j \in \mathbb{N}_{>0}$. We show that no sequence of programs over a finite monoid of length $\mathrm{O}(n^{k-1})$ can recognize L_Δ. If this were the case, then let i be the size of the monoid. Let $j \geq i$ be such that for any $n \in \mathbb{N}$, the n-th program has length at most $j \cdot n^{k-1}$. But, by construction, we know that there does not exist any such program of range n_j recognizing K_{n_j,T_j}, a contradiction.

This implies the following hierarchy (where $\mathcal{P}(\mathbf{V}, s(n))$ for some variety of monoids $\mathbf{V}$ and a function $s\colon \mathbb{N} \to \mathbb{N}$ denotes the class of languages recognizable by a sequence of programs of length $\mathrm{O}(s(n))$):

▶ **Proposition 11.** *For all $k \in \mathbb{N}$, $\mathcal{P}(\mathbf{DA}, n^k) \subsetneq \mathcal{P}(\mathbf{DA}, n^{k+1})$.*

5.2 Collapse

Tesson and Thérien showed that any program over a monoid M in **DA** is equivalent to one of polynomial length [29]. We now show that if we further assume that M is in $\mathbf{DA_k}$ then the length can be assumed to be $\mathrm{O}(n^k)$.

▶ **Proposition 12.** *Let $k > 0$. Let $M \in \mathbf{DA_k}$. Then any program over M is equivalent to a program over M of length $\mathrm{O}(n^k)$.*

The equivalent program of length $\mathrm{O}(n^k)$ is actually a subprogram of the initial one. For each possible acceptance set, an input word to the program is accepted iff the word over the alphabet M produced by the program belongs to some fixed Boolean combination of languages in $\mathcal{SUM}_k$. The idea is then just to keep enough instructions so that membership of the produced word over M in each of these languages does not change. For each of those languages, the set of instructions to keep is defined by induction on k using the inductive definition of $\mathcal{SUM}_k$ given at the beginning of this section. Roughly, at each step, for each input letter and each input position, the small program keeps the first or last instruction of the big program producing the "pivot element" when reading this input letter at that position. The number of instructions kept in the end is then in $\mathrm{O}(n^k)$. The details can be found in Appendix C.

6 Conclusion

For local and tame varieties $\mathbf{V}$ we have shown that the regular languages recognized by programs over $\mathbf{V}$ are exactly those in $\mathcal{L}(\mathbf{QV})$. It is not clear whether locality is necessary. We don't have any example of a tame variety $\mathbf{V}$ for which $\mathcal{L}(\mathbf{QV})$ is not included into $\mathcal{P}(\mathbf{V})$. We leave this question for future work.

We have shown that **DA** is tame but that **J** is not. Another example of a tame variety is **A**. However we needed the fact that $\mathrm{MOD_m}$ is not in $\mathsf{AC^0}$ for all $m \geq 2$ in order to prove tameness. It would be interesting to give a direct algebraic proof of this result. As this would in particular imply that $\mathrm{MOD_2}$ is not in $\mathsf{AC^0}$ by Proposition 4, it is certainly a challenging task.

Finding the regular languages recognized by programs over **J** is left for future work.

To conclude we should add, in fairness, that the progress reported here does not obviously bring us closer to major $\mathsf{NC^1}$ complexity subclasses separations, but it does uncover new ways in which a program can or cannot circumvent the limitations imposed by the underlying monoid algebraic structure available to it.

A Missing proofs from Section 4

Let M be a monoid in **DA** whose identity we will denote by 1.

Given two elements u, u' of M we say that $u \leq_J u'$ if there are elements v, v' of M such that $u' = vuv'$. We write $u \sim_J u'$ if $u \leq_J u'$ and $u' \leq_J u$. We write $u <_J u'$ if $u \leq_J u'$ and $u' \not\sim_J u$. Given two elements u, u' of M we say that $u \leq_R u'$ if there is an element v of M such that $u' = uv$. We write $u \sim_R u'$ if $u \leq_R u'$ and $u' \leq_R u$. We write $u <_R u'$ if $u \leq_R u'$ and $u' \not\sim_R u$. Given two elements u, u' of M we say that $u \leq_L u'$ if there is an element v of M such that $u' = vu$. We write $u \sim_L u'$ if $u \leq_L u'$ and $u' \leq_L u$. We write $u <_L u'$ if $u \leq_L u'$ and $u' \not\sim_L u$.

We shall use the following well-known fact about these preorders and equivalence relations (see [22, Chapter 3, Proposition 1.4]).

▶ **Lemma 13.** *For all elements u and v of M, if $u \leq_R v$ and $u \sim_J v$, then $u \sim_R v$. Similarly, if $u \leq_L v$ and $u \sim_J v$, then $u \sim_L v$.*

An element r of M is R-bad for u if $u <_R ur$. Similarly an element r of M is L-bad for v if $u <_L rv$. It follows from $M \in$ **DA** that being R-bad or L-bad only depends on the $\sim_R$ or $\sim_L$ class, respectively:

▶ **Lemma 14.** *[Folklore] If M is in* **DA**, *then $u \sim_R u'$ and $ur \sim_R u$ implies $u'r \sim_R u$. Similarly $u \sim_L u'$ and $ru \sim_L u$ implies $ru' \sim_L u$.*

Let Δ be a finite set of words and Σ be the corresponding finite alphabet, Δ being safe, and let $n \in \mathbb{N}$. We are now going to prove the main technical lemma that allows us to assert that after fixing a constant number of positions in the input of a program over M, it can still be completed into a word of Δ^*, but the program cannot make the difference between any two possible completions anymore. To prove the lemma, we define a relation $\prec$ on the set of quadruplets (λ, P, u, v) where λ is a mask of length n, P is a program over M for words of length n and u and v are two elements. We will say that an element $(\lambda_1, P_1, u_1, v_1)$ is strictly smaller than $(\lambda_2, P_2, u_2, v_2)$, written $(\lambda_1, P_1, u_1, v_1) \prec (\lambda_2, P_2, u_2, v_2)$ if λ_1 is a submask of λ_2, P_1 is a subprogram of P_2 and one of the following cases occurs:

1. $u_2 <_R u_1$ and $v_1 = v_2$ and P_1 is a suffix of P_2 and $u_1P_1(w)v_1 = u_2P_2(w)v_2$ for all safe completions w of λ_1;
2. $v_2 <_L v_1$ and $u_1 = u_2$ and P_1 is a prefix of P_2 and $u_1P_1(w)v_1 = u_2P_2(w)v_2$ for all safe completions w of λ_1;
3. $u_2 = u_1$ and $v_1 = 1$ and P_1 is a prefix of P_2 and $u_1P_1(w)v_1 <_J u_2P_2(w)v_2$ for all safe completions w of λ_1;
4. $v_2 = v_1$ and $u_1 = 1$ and P_1 is a suffix of P_2 and $u_1P_1(w)v_1 <_J u_2P_2(w)v_2$ for all safe completions w of λ_1.

Note that, since M is finite, this relation is well-founded (that is, it has no infinite decreasing chain, an infinite sequence of quadruplets $\mu_0, \mu_1, \mu_2, \dots$ such that $\mu_{i+1} \prec \mu_i$ for all $i \in \mathbb{N}$) and the maximal length of any decreasing chain depends only on M.

▶ **Lemma 8** (restated). *Let λ be a Δ-compatible mask of length n, let P be a program over M of range n, let u and v be elements of M. Then there is an element t of M and a Δ-compatible submask λ' of λ obtained by fixing a number of free positions independent from n such that any safe completion w of λ' verifies $uP(w)v = t$.*

Proof. The proof goes by induction on $\prec$.

Let λ be a Δ-compatible mask of length n, let P be a program over M for words of length n, let u and v be elements of M such that (λ, P, u, v) is of height h, and assume that for any quadruplet (λ', P', u', v') strictly smaller than (λ, P, u, v), the lemma is verified. Consider the following conditions concerning the quadruplet (λ, P, u, v):

- **(a)** there does not exist any instruction (x, f) of P such that for some letter a the submask λ' of λ formed by setting position x to a (if it wasn't already the case) is Δ-compatible and $f(a)$ is R-bad for u;
- **(b)** v is not R-bad for u;
- **(c)** there does not exist any instruction (x, f) of P such that for some letter a the submask λ' of λ formed by setting position x to a (if it wasn't already the case) is Δ-compatible and $f(a)$ is L-bad for v;
- **(d)** u is not L-bad for v.

We will now do a case analysis based on which of these conditions are violated or not.

Case 1: condition 1 is violated. So there exists some instruction (x, f) of P such that for some letter a the submask λ' of λ formed by setting position x to a (if it wasn't already the case) is Δ-compatible and $f(a)$ is R-bad for u. Let i be the smallest number of such an instruction.

Let P' be the subprogram of P until instruction $i-1$. Let w be a safe completion of λ. By minimality of i and by Lemma 14, it follows that $u \sim_R uP'(w)$.

So, because $f(a)$ is R-bad for u, any safe completion w of λ', which is also a safe completion of λ, is such that $u \sim_R uP'(w) <_R uP'(w)f(a) \leq_R uP(w)v$ by Lemma 14, hence $uP'(w) <_J uP(w)v$ by Lemma 13. So $(\lambda', P', u, 1) \prec (\lambda, P, u, v)$, therefore, by induction we get a Δ-compatible submask λ_1 of λ' and a monoid element t_1 such that $uP'(w) = t_1$ for all safe completions w of λ_1.

Let P'' be the subprogram of P starting from instruction $i+1$. Notice that, since $u \sim_R t_1$ (by what we have proven just above), $u <_R t_1f(a)$ (by Lemma 14) and $t_1f(a)P''(w)v = uP'(w)f(a)P''(w)v = uP(w)v$ for all safe completions w of λ_1. Hence, $(\lambda_1, P'', t_1f(a), v)$ is strictly smaller than (λ_1, P, u, v) and by induction we get a Δ-compatible submask λ_2 of λ_1 and a monoid element t such that $t_1f(a)P''(w)v = t$ for all safe completions w of λ_2.

Hence any safe completion w of λ_2 is such that

$$uP(w)v = uP'(w)f(a)P''(w)v = t_1 f(a)P''(w)v = t\ .$$

Hence λ_2 and t are the desired solutions.

Case 2: condition 1 is verified but condition 2 is violated, so v is R-bad for u and Case 1 does not apply.

Let w be a safe completion of λ: for any instruction (x, f) of P, as the submask λ' of λ formed by setting position x to w_x (if it wasn't already the case) is Δ-compatible (by the fact that Δ is safe and w is a safe completion of λ), $f(w_x)$ cannot be R-bad for u, otherwise condition 1 would be violated, so $u \sim_R uf(w_x)$. Hence, by Lemma 14, $u \sim_R uP(w)$ for all safe completions w of λ. Notice then that $u \sim_R uP(w) <_R uP(w)v$ (by Lemma 14), hence $uP(w) <_J uP(w)v$ (by Lemma 13) for all safe completions w of λ. So $(\lambda, P, u, 1) \prec (\lambda, P, u, v)$, therefore we obtain a monoid element t_1 and a Δ-compatible submask λ' of λ by induction such that $uP(w) = t_1$ for all completions w of λ'. $t = t_1 v$ is the desired element of M.

Case 3: condition 3 is violated. So there exists some instruction (x, f) of P such that for some letter a the submask λ' of λ formed by setting position x to a (if it wasn't already the case) is Δ-compatible and $f(a)$ is L-bad for v.

We proceed as for Case 1 by symmetry.

Case 4: condition 3 is verified but condition 4 is violated, so u is L-bad for v and Case 3 does not apply.

We proceed as for Case 2 by symmetry.

Case 5: conditions 1, 2, 3 and 4 are verified.

As it Case 2 and Case 4 we get that $u \sim_R uP'(w)$ and $v \sim_L P''(w)v$ for any prefix P' of P, any suffix P'' of P and all safe completions w of λ. Moreover, since condition 2 and condition 4 are verified, by Lemma 14, we get that $uP(w)v \sim_R u$ and $uP(w)v \sim_L v$ for all safe completions w of λ.

Let w_0 be a completion of λ that is in Δ^*. Let λ' be the submask of λ fixing all dangerous positions of λ using w_0. Then, for any completion w of λ', which is a safe completion of λ by construction, we have that $uP(w)v \sim_R u$ and $uP(w)v \sim_L v$. As M is aperiodic, this implies that there is a t in M such that $uP(w)v = t$ for all completions w of λ' (see [22, Chapter 3, Proposition 4.2]).

This concludes the proof of the lemma. ◀

B $\mathcal{SUL}_k$ is a variety of languages

A *variety of languages* is a class of languages over arbitrary finite alphabets closed under Boolean operations, quotients and inverses of morphisms (i.e. if L is a language in the class over a finite alphabet Σ, if Γ is some other finite alphabet and $\varphi\colon \Gamma^* \to \Sigma^*$ is a morphism of monoids, then $\varphi^{-1}(L)$ is also in the class).

Eilenberg showed [11, Chapter VII, Section 3] that there is a bijective correspondence between varieties of monoids and varieties of languages: to each variety of monoids $\mathbf{V}$ we can bijectively associate $\mathcal{L}(\mathbf{V})$ the variety of languages whose syntactic monoids belong to $\mathbf{V}$ and, conversely, to each variety of languages $\mathcal{V}$ we can bijectively associate $\mathbf{M}(\mathcal{V})$ the variety of monoids generated by the syntactic monoids of the languages of $\mathcal{V}$, and these correspondences are mutually inverse.

We denote by $\mathcal{SUL}_k$ the class of regular languages that are Boolean combinations of languages in $\mathcal{SUM}_k$.

In this appendix, we show that, for all $k \in \mathbb{N}$, $\mathcal{SUL}_k$ is a variety of languages. As $\mathbf{DA_k}$ is the variety of monoids generated by the syntactic monoids of the languages in $\mathcal{SUL}_k$, by Eilenberg's theorem, we know that, conversely, all the regular languages whose syntactic monoids lie in $\mathbf{DA_k}$ are in $\mathcal{SUL}_k$.

Closure under Boolean operations is obvious by construction. Closure under quotients and inverses of morphisms is respectively given by the following two lemmas and by the fact that both quotients and inverses of morphisms commute with Boolean operations.

Given a word u over a given finite alphabet Σ, we will denote by $\mathrm{alph}(u)$ the set of letters of Σ that appear in u.

▶ **Lemma 15.** *For all $k \in \mathbb{N}$, for all $L \in \mathcal{SUM}_k$ over a finite alphabet Σ and $u \in \Sigma^*$, $u^{-1}L$ and Lu^{-1} both are a union of languages in $\mathcal{SUM}_k$ over Σ.*

Proof. We prove it by induction on k.

- Base case: $k = 0$.
  Let $L \in \mathcal{SUM}_0$ over a finite alphabet Σ and $u \in \Sigma^*$. This means that $L = A^*$ for some $A \subseteq \Sigma$. We have two cases: either $\mathrm{alph}(u) \nsubseteq A$ and then $u^{-1}L = Lu^{-1} = \emptyset$; or $\mathrm{alph}(u) \subseteq A$ and then $u^{-1}L = Lu^{-1} = A^* = L$. So $u^{-1}L$ and Lu^{-1} both are a union of languages in $\mathcal{SUM}_0$ over Σ. The base case is hence proved.
- Inductive step. Let $k \in \mathbb{N}_{>0}$ and assume that the lemma is true for all $k' \in \mathbb{N}, k' < k$.
  Let $L \in \mathcal{SUM}_k$ over a finite alphabet Σ and $u \in \Sigma^*$. This means that either L is in $\mathcal{SUM}_{k-1}$ and the lemma is proved by applying the inductive hypothesis directly for L and u, or $L = L_1 a L_2$ for some languages $L_1 \in \mathcal{SUM}_i$ and $L_2 \in \mathcal{SUM}_j$ and some letter $a \in \Sigma$ with $i + j = k - 1$ and, either no word of L_1 contains the letter a or no word of L_2 contains the letter a. We shall only treat the case in which a does not appear in any of the words of L_1; the other case is treated symmetrically.
  There are again two cases to consider, depending on whether a does appear in u or not. If $a \notin \mathrm{alph}(u)$, then it is straightforward to check that $u^{-1}L = (u^{-1}L_1)aL_2$ and $Lu^{-1} = L_1 a(L_2 u^{-1})$. By the inductive hypothesis, we get that $u^{-1}L_1$ is a union of languages in $\mathcal{SUM}_i$ over Σ and that L_2u^{-1} is a union of languages in $\mathcal{SUM}_j$ over Σ. Moreover, it is direct to see that no word of $u^{-1}L_1$ contains the letter a. By distributivity of concatenation over union, we finally get that $u^{-1}L$ and Lu^{-1} both are a union of languages in $\mathcal{SUM}_k$ over Σ.
  If $a \in \mathrm{alph}(u)$, then let $u = u_1 a u_2$ with $u_1, u_2 \in \Sigma^*$ and $a \notin \mathrm{alph}(u_1)$. It is again straightforward to see that

$$u^{-1}L = \begin{cases} {u_2}^{-1}L_2 & \text{if } u_1 \in L_1 \\ \emptyset & \text{otherwise} \end{cases}$$

  and

$$Lu^{-1} = L_1 a(L_2 u^{-1}) \cup \begin{cases} L_1 {u_1}^{-1} & \text{if } u_2 \in L_2 \\ \emptyset & \text{otherwise} \end{cases}.$$

  Again, by the inductive hypothesis, we get that $L_1{u_1}^{-1}$ is a union of languages in $\mathcal{SUM}_i$ over Σ and that both ${u_2}^{-1}L_2$ and L_2u^{-1} are unions of languages in $\mathcal{SUM}_j$ over Σ. And, again, by distributivity of concatenation over union, we get that $u^{-1}L$ and Lu^{-1} both are a union of languages in $\mathcal{SUM}_k$ over Σ.
  This concludes the inductive step and therefore the proof of the lemma. ◀

▶ **Lemma 16.** *For all $k \in \mathbb{N}$, for all $L \in \mathcal{SUM}_k$ over a finite alphabet Σ and $\varphi\colon \Gamma^* \to \Sigma^*$ a morphism of monoids where Γ is another finite alphabet, $\varphi^{-1}(L)$ is a union of languages in $\mathcal{SUM}_k$ over Γ.*

Proof. We prove it by induction on k.

- Base case: $k = 0$.
  Let $L \in \mathcal{SUM}_0$ over a finite alphabet Σ and $\varphi\colon \Gamma^* \to \Sigma^*$ a morphism of monoids where Γ is another finite alphabet. This means that $L = A^*$ for some $A \subseteq \Sigma$. It is straightforward to check that $\varphi^{-1}(L) = B^*$ where $B = \{b \in \Gamma \mid \varphi(b) \in A^*\}$. B^* is certainly a union of languages in $\mathcal{SUM}_0$ over Σ. The base case is hence proved.
- Inductive step. Let $k \in \mathbb{N}_{>0}$ and assume that the lemma is true for all $k' \in \mathbb{N}, k' < k$.
  Let $L \in \mathcal{SUM}_k$ over a finite alphabet Σ and $\varphi\colon \Gamma^* \to \Sigma^*$ a morphism of monoids where Γ is another finite alphabet. This means that either L is in $\mathcal{SUM}_{k-1}$ and the lemma is proved by applying the inductive hypothesis directly for L and φ, or $L = L_1 a L_2$ for some languages $L_1 \in \mathcal{SUM}_i$ and $L_2 \in \mathcal{SUM}_j$ and some letter $a \in \Sigma$ with $i + j = k - 1$ and, either no word of L_1 contains the letter a or no word of L_2 contains the letter a. We shall only treat the case in which a does not appear in any of the words of L_1; the other case is treated symmetrically.
  Let us define $B = \{b \in \Gamma \mid a \in \mathrm{alph}(\varphi(b))\}$ as the set of letters of Γ whose image word by φ contains the letter a. For each $b \in B$, we shall also let $\varphi(b) = u_{b,1} a u_{b,2}$ with $u_{b,1}, u_{b,2} \in \Sigma^*$ and $a \notin u_{b,1}$. It is not too difficult to see that we then have

  $$\varphi^{-1}(L) = \bigcup_{b \in B} \varphi^{-1}(L_1 {u_{b,1}}^{-1}) b \varphi^{-1}({u_{b,2}}^{-1} L_2) \ .$$

  By the inductive hypothesis, by Lemma 15 and by the fact that inverses of morphisms commute with unions, we get that $\varphi^{-1}(L_1 {u_{b,1}}^{-1})$ is a union of languages in $\mathcal{SUM}_i$ over Γ and that $\varphi^{-1}({u_{b,2}}^{-1} L_2)$ is a union of languages in $\mathcal{SUM}_j$ over Γ. Moreover, it is direct to see that no word of $\varphi^{-1}(L_1 {u_{b,1}}^{-1})$ contains the letter b for all $b \in B$. By distributivity of concatenation over union, we finally get that $\varphi^{-1}(L)$ is a union of languages in $\mathcal{SUM}_k$ over Γ.
  This concludes the inductive step and therefore the proof of the lemma. ◀

C Collapse

In this appendix we prove Proposition 12, stating that when M is in $\mathbf{DA_k}$ then any program over M is equivalent to one of length $\mathrm{O}(n^k)$.

Recall that if P is a program over some monoid M of range n, then $P(w)$ denotes the element of M resulting from the execution of the program P on w. It will be convenient here to also work with the word over M resulting from the sequence of executions of each instruction of P on w. We denote this word by $EP(w)$.

The result is a consequence of the following lemma and the fact that for any acceptance set $F \subseteq M$, a word $w \in \Sigma^n$ (where Σ is the input alphabet) is accepted iff $EP(w) \in L$ where L is a language in $\mathcal{SUL}_k$, a Boolean combination of languages in $\mathcal{SUM}_k$.

▶ **Lemma 17.** *Let Σ be a finite alphabet, M a finite monoid, and n, k natural numbers.*

For any program P over M of range n, any set $\Gamma \subseteq M$ and any language K over Γ in $\mathcal{SUM}_k$, there exists a subsequence Q of the sequence of instructions P of length $\mathrm{O}(n^{\max\{k,1\}})$ such that for any subsequence Q' of the sequence of instructions P containing Q as a subsequence, we have for all words w over Σ of length n:

$$EP(w) \in K \Leftrightarrow EQ'(w) \in K \ .$$

Proof. A program P over M of range n is a finite sequence (p_i, f_i) of instructions where each p_i is a natural number which is at most n and each f_i is a function from Σ to M. We denote by l the number of instructions of P. For each set $I \subseteq [l]$ we denote by $P[I]$ the program over M consisting of the subsequence of instructions of P obtained after removing all instructions whose index is not in I. In particular, $P[1, m]$ denotes the initial sequence of instructions of P, until instruction number m.

We prove the lemma by induction on k.

- Inductive step. Let $k \geq 2$ and assume the lemma proved for all $k' < k$. Let n be a natural number, P a program over M of range n and length l, $\Gamma \subseteq M$ and any language K over Γ in $\mathcal{SUM}_k$. By definition, $K = K_1 \gamma K_2$ for some languages $K_1 \in \mathcal{SUM}_i$ and $K_2 \in \mathcal{SUM}_j$ with $i + j = k - 1$. Moreover either γ does not occur in any of the words of K_1 or it does not occur in any of the words of K_2. We only treat the case where γ does not appear in any of the words in K_1. The other case is treated similarly by symmetry.

  For each $p \leq n$ and each $a \in \Sigma$ consider within the sequence of instructions of P the first instruction of the form (p, f) with $f(a) = \gamma$. We let I_γ be the set of indices of these instructions for all a and p. Notice that the size of I is in $\mathrm{O}(n)$.

  For all $i \in I_\gamma$, we let $J_{i,1}$ be the set of indices of the instructions within $P[1, i-1]$ obtained by induction for K_1 and $J_{i,2}$ be the same for $P[i+1, l]$ and K_2.

  We now let I be the union of I_γ and $J_{i,1}$ and $J'_{i,2} = \{j + i \mid j \in J_{i,2}\}$ for all $i \in I_\gamma$. We claim that $P[I]$ has the desired properties.

  First notice that by induction the sizes of $J_{i,1}$ and $J'_{i,2}$ for all $i \in I_\gamma$ are in $\mathrm{O}(n^{\max\{k-1,1\}})$ $= \mathrm{O}(n^{k-1})$ and because the size of I_γ is linear in n, the size of I is in $\mathrm{O}(n^k) = \mathrm{O}(n^{\max\{k,1\}})$ as required.

  Now take $w \in \Sigma^n$.

  Assume now that $EP(w) \in K$. Let i be the position in $EP(w)$ of label γ witnessing the membership in K. Let (p_i, f_i) be the corresponding instruction of P. In particular we have that $f_i(w_{p_i}) = \gamma$. Because γ does not occur in any word of K_1, for all $j < i$ such that $p_j = p_i$ we cannot have $f_j(w_{p_j}) = \gamma$. Hence $i \in I_\gamma$. By induction we have that $EP[1, i-1][J](w) \in K_1$ for any set J containing $J_{i,1}$ and $EP[i+1, l][J](w) \in K_2$ for any set J containing $J_{i,2}$. Hence, if we set $I_1 = \{j \in I \mid j < i\}$ as the subset of I of elements less than i and $I_2 = \{j - i \in I \mid j > i\}$ as the subset of I of elements greater than i translated by $-i$, we have $EP[I](w) = EP[1, i-1][I_1](w)\gamma EP[i+1, l][I_2](w) \in K_1 \gamma K_2 = K$ as desired.

  Assume finally that $EP[I](w) \in K$. Let i be the index in I whose instruction provides the letter γ witnessing the fact that $EP[I](w) \in K$. If $i \in I_\gamma$ we conclude easily by induction. If not this shows that there is an instruction (p_j, f_j) with $j < i$, $j \in I$, $p_j = p_i$ and $f_j(w_{p_j}) = \gamma$. But that would contradict the fact that γ cannot occur in K_1.

- Base case. There are two subcases to consider.
  - $k = 1$. Let n be a natural number, P a program over M of range n and length l, $\Gamma \subseteq M$ and any language K over Γ in $\mathcal{SUM}_1$.

    Then $K = A_1^* \gamma A_2^*$ for some finite alphabets $A_1 \subseteq \Gamma$ and $A_2 \subseteq \Gamma$. Moreover either $\gamma \notin A_1$ or $\gamma \notin A_2$. We only treat the case where γ does not belong to A_1, the other case is treated similarly by symmetry.

    We use the same idea as in the inductive step.

    For each $p \leq n$, each $\alpha \in \Gamma$ and $a \in \Sigma$ consider within the sequence of instructions of P the first and last instruction of the form (p, f) with $f(a) = \alpha$. We let I be the set of indices of these instructions for all a, α and p. Notice that the size of I is in $\mathrm{O}(n) = \mathrm{O}(n^{\max\{k,1\}})$.

We claim that $P[I]$ has the desired properties. Take $w \in \Sigma^n$.
Assume now that $EP(w) \in K$. Let i be the position in $EP(w)$ of label γ witnessing the membership in K. Let (p_i, f_i) be the corresponding instruction of P. In particular we have that $f_i(w_{p_i}) = \gamma$ and this is the γ witnessing the membership in K. Because $\gamma \notin A_1$, for all $j < i$ such that $p_j = p_i$ we cannot have $f_j(w_{p_j}) = \gamma$. Hence $i \in I$. From $EP(w) \in K$ it follows that $EP[I \cap [\![1, i-1]\!]](w) \in A_1$ and $EP[I \cap [\![i+1, l]\!]](w) \in A_2$ showing that $EP[I](w) = EP[I \cap [\![1, i-1]\!]](w)\gamma EP[I \cap [\![i+1, l]\!]](w) \in K$ as desired.
Assume finally that $EP[I](w) \in K$. This means that $EP[I \cap [\![1, i-1]\!]](w) \in A_1^*$ and $EP[I \cap [\![i+1, l]\!]](w) \in A_2^*$. Let i be the index in I whose instruction provides the letter γ witnessing the fact that $EP[I](w) \in K$. If there is an instruction (p_j, f_j), with $j < i$ and $f_j(w_{p_j}) \notin A_1$ then either $j \in I$ and we get a direct contradiction with the fact that $EP[I \cap [\![1, i-1]\!]](w) \in A_1^*$, or $j \notin I$ and we get a smaller $j' \in I$ with the same property, contradicting again the fact that $EP[I \cap [\![1, i-1]\!]](w) \in A_1^*$. Hence for all $j < i$, $f_j(w_{p_j}) \in A_1$. By symmetry we have that for all $j > i$, $f_j(w_{p_j}) \in A_2$, showing that $EP(w) \in A_1^* \gamma A_2^* = K$ as desired.

- $k = 0$. Let n be a natural number, P a program over M of range n and length l, $\Gamma \subseteq M$ and any language K over Γ in $\mathcal{SUM}_0$.
Then $K = A^*$ for some finite alphabet $A \subseteq \Gamma$.
We again use the same idea as before.
For each $p \leq n$, each $\alpha \in \Gamma$ and $a \in \Sigma$ consider within the sequence of instructions of P the first instruction of the form (p, f) with $f(a) = \alpha$. We let I be the set of indices of these instructions for all a, α and p. Notice that the size of I is in $\mathrm{O}(n) = \mathrm{O}(n^{\{k,1\}})$.
We claim that $P[I]$ has the desired properties. Take $w \in \Sigma^n$.
Assume now that $EP(w) \in K$. As $EP[I](w)$ is a subword of $EP(w)$, it follows directly that $EP[I](w) \in A^* = K$ as desired.
Assume finally that $EP[I](w) \in K$. If there is an instruction (p_j, f_j), with $j \in [l]$ and $f_j(w_{p_j}) \notin A$ then either $j \in I$ and we get a direct contradiction with the fact that $EP[I](w) \in A^* = K$, or $j \notin I$ and we get a smaller $j' \in I$ with the same property, contradicting again the fact that $EP[I](w) \in A^* = K$. Hence for all $j \in [l]$, $f_j(w_{p_j}) \in A$, showing that $EP(w) \in A^* = K$ as desired. ◀

Regular Language Distance and Entropy*

Abstract

This paper addresses the problem of determining the distance between two regular languages. It will show how to expand Jaccard distance, which works on finite sets, to potentially-infinite regular languages.

The entropy of a regular language plays a large role in the extension. Much of the paper is spent investigating the entropy of a regular language. This includes addressing issues that have required previous authors to rely on the upper limit of Shannon's traditional formulation of channel capacity, because its limit does not always exist. The paper also includes proposing a new limit based formulation for the entropy of a regular language and proves that formulation to both exist and be equivalent to Shannon's original formulation (when it exists). Additionally, the proposed formulation is shown to equal an analogous but formally quite different notion of topological entropy from Symbolic Dynamics – consequently also showing Shannon's original formulation to be equivalent to topological entropy.

Surprisingly, the natural Jaccard-like entropy distance is trivial in most cases. Instead, the *entropy sum* distance metric is suggested, and shown to be granular in certain situations.

1 Introduction

In this paper we study distances between regular expressions. There are many motivations for this analysis. Activities in bioinformatics, copy-detection [9], and network defense sometimes require large numbers of regular expressions be managed. Metrics aid in indexing and management of those regular expressions [4]. Further, understanding the distance between regular languages requires an investigation of the structure of regular languages that we hope eliminates the need for similar theoretical investigations in the future.

A natural definition of the distance between regular languages L_1 and L_2 containing strings of symbols from Σ is: $\lim_{n\to\infty} \frac{|(L_1 \Delta L_2) \cap \Sigma^n|}{|(L_1 \cup L_2) \cap \Sigma^n|}$ (where $L_1 \Delta L_2 = (L_1 \cup L_2) \setminus (L_1 \cap L_2)$ is the symmetric difference). However, the definition has a fundamental flaw: the limit does

* For a full version see [22].

not always exist. Consider the distance between $(aa)^*$ and a^*. When n is even, the fraction is 0, while when n is odd the fraction is 1. Thus, the limit given above is not well defined for those two languages.

This paper addresses that flaw and examines the question of entropy and distance between regular languages in a more general way. A fundamental contribution will be a limit-based distance related to the above that (1) exists, (2) can be computed from the Deterministic Finite Automaton for the associated regular languages, and (3) does not invalidate expectations about the distance between languages.

The core idea is two-fold: (1) to rely on the number of strings *up-to* a given length rather than strings *of* a given length and (2) to use Cesáro averages to smooth out the behavior of the limit. These ideas led us to develop the Cesáro Jaccard distance, which is proven to be well-defined in Theorem 7.

Tied up in this discussion will be the *entropy* of a regular language, which is again a concept whose common definition needs tweaking due to limit-related considerations.

This paper is structured as follows. In Section 2 we discuss related work and define terms that will be used in the paper. Of particular importance is Table 1, which includes all of the distance functions defined in the paper. As the Jaccard distance is a natural entry point into distances between sets, Section 3 will discuss the classical Jaccard distance and how best to extend it to infinite sets. Section 4 will discuss notions of regular language entropy, introducing a new formulation and proving it correct from both a channel capacity and a topological entropy point of view. Section 5 will introduce some distances based on entropy, and show that some of them behave well, while others do not. Finally, Section 6 provides a conclusion and details some potential future work.

2 Background

2.1 Related Work

Chomsky and Miller's seminal paper on regular languages [6] does not address distances between regular languages. It uses Shannon's notion of channel capacity (equation 7 from [6]) for the entropy of a regular language: $h(L) = \lim_{n\to\infty} \frac{\log|L\cap\Sigma^n|}{n}$.

While Shannon says of that limit that "the limit in question will exist as a finite number in most cases of interest" [27], its limit does not always exist for regular languages (consider $(\Sigma^2)^*$). This motivates much of the analysis in this paper. Chomsky and Miller also examine the number of sentences *up to* a given length, foreshadowing some other results in this paper. However, their analysis was based upon an assumption with deeper flaws than that the limit exists. In this paper we address those issues.

Several works since Chomsky and Miller have used this same *of length exactly n* formula to define the entropy of a regular language [3, 9, 17]. These works define entropy as Chomsky and Miller, but add the caveat that they use the upper limit when the limit does not exist. Here we provide foundation for those works by showing the upper limit to be correct (Theorem 13). Further, this paper suggests an equivalent expression for entropy that may be considered more elegant: it is a limit that exists as a finite number for all regular languages which equals the traditional notion of entropy when that limit exists.

Chomsky and Miller's technique was to develop a recursive formula for the number of words accepted by a regular language. That recursive formula comes from the characteristic polynomial of the adjacency matrix for an associated automaton. The eigenvalues of the adjacency matrix describe the growth of the language (we use the same technique, but apply stronger theorems from linear algebra that were discovered several decades after

Chomsky and Miller's work). The recursive formula can also be used to develop a generating function to describe the growth of the language (see [25]). Bodirsky, Gärtner, Oertzen, and Schwinghammer [2] used the generating functions to determine the growth of a regular language over alphabet Σ relative to $|\Sigma|^n$, and Kozik [16] used them to determine the growth of a regular language relative to a second regular language. Our approaches share significant details: they relate the growth of a regular language to the poles of its generating function – which are the zeroes of the corresponding recurrence relation – which are the eigenvalues of the associated adjacency matrix. Our technique establishes the "size" of a regular language independent of a reference alphabet or language.

There is work examining distances between *unary* regular languages, or regular languages on the single character alphabet ($|\Sigma| = 1$) [11]. It introduces a definition for Jaccard distance that will appear in this paper: $1 - \lim_{n\to\infty} \frac{|L_1 \cap L_2 \cap (\bigcup_{i=0}^{n} \Sigma^i)|}{|(L_1 \cup L_2) \cap (\bigcup_{i=0}^{n} \Sigma^i)|}$. Further, it gives a closed form for calculating that distance between two unary regular languages.

Besides the stronger results, our work differs from that of [2, 11, 16] in the analysis of the distance functions presented: in particular, one can conclude (as a consequence of Theorem 17) that the above equation is mostly trivial – it returns 0 or 1 "most" of the time.

More recently, Cui *et al* directly address distances between regular languages using a generalization of Jaccard distance [9]. That paper usefully expands the concept of Jaccard distance to regular languages by (1) using entropy to handle infinite sized regular languages (they use the upper limit notion of entropy described above), and (2) allowing operations other than intersection to be used in the numerator. Further, Cui *et al* suggest and prove properties of several specific distance functions between regular languages. The distance functions in this paper do not generalize the Jaccard distance in the same way, but are proven to be metrics or pseudo-metrics.

Ceccherini-Silberstein *et al* investigate the entropy of specific kinds of subsets of regular languages [3]. They present a novel proof of a known fact from Symbolic Dynamics. They use the same upper limit notion of entropy as above. Other entropy formulations include the number of prefixes of a regular language [5], but this has only been proven equivalent to entropy under restricted circumstances.

Symbolic dynamics [19] studies, among other things, an object called a sofic shift. Sofic shifts are analogous to deterministic finite automata and their shift spaces are related to regular languages. The formulation of entropy used in this field does not suffer from issues of potential non-existence. This paper includes a proof that the *topological entropy* of a sofic shift is equivalent to language-centric formulations in this paper: see Theorem 13.

Other related results from symbolic dynamics include an investigation into the computability of a sofic shift's entropy [28] and a discussion of the lack of relationship between entropy and complexity [18]. There is another proposal for the topological entropy of formal languages [26] that is zero for all regular languages (and hence not helpful as a distance function for regular languages).

A probabilistic automaton is an automaton with a probability distribution applied to outgoing transitions from each state. The words of a regular language thus inherit a probability. Using standard distance functions on probability distributions (such as L_p and Kullback-Leibler divergence), several distance functions [7, 8, 21] have been created for probabilistic languages. Note that in this model, the probability of a word exponentially decreases with its length, and hence these distance functions can be effectively estimated by words of bounded length. Chan [4] also describes several distance functions using only words of bounded length. Our paper will uncover features of several distance functions, which will fit nicely into the above frameworks.

Table 1 The distance functions considered in this paper are listed in this table.

$J'_n(L_1, L_2)$	n Jaccard Distance	$\frac{\lvert W_n(L_1 \triangle L_2)\rvert}{\lvert W_n(L_1 \cup L_2)\rvert}$
$J_n(L_1, L_2)$	$n_\leq$ Jaccard Distance	$\frac{\lvert W_{\leq n}(L_1 \triangle L_2)\rvert}{\lvert W_{\leq n}(L_1 \cup L_2)\rvert}$
$J_C(L_1, L_2)$	Cesàro Jaccard	$\lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} J_i(L_1, L_2)$
$H(L_1, L_2)$	Entropy Distance	$\frac{h(L_1 \triangle L_2)}{h(L_1 \cup L_2)}$
$H_S(L_1, L_2)$	Entropy Sum Distance	$h(L_1 \cap \overline{L_2}) + h(\overline{L_1} \cap L_2)$

2.2 Definitions and Notation

In this paper Σ will denote a set of *symbols* or the alphabet. *Strings* are concatenations of these symbols. All log operations in this paper will be taken base 2. Raising a string to the power n will represent the string resulting from n concatenations of the original string. A similar notion applies to sets. In this notation, Σ^5 represents all strings of length 5 composed of symbols from Σ. The Kleene star, $*$, when applied to a string (or a set) will represent the set containing strings resulting from any number of concatenations of that string (or of strings in that set), including the empty concatenation. Thus, Σ^* represents all possible strings comprised of symbols in Σ, including the empty string.

A *regular language* is a set $L \subset \Sigma^*$ which can be represented by a *Deterministic Finite Automaton*, DFA for short. A *DFA* is a 5-tuple $(Q, \Sigma, \delta, q_0, F)$, where Q is a set of states, Σ is the set of symbols, δ is a partial function from $Q \times \Sigma$ to Q, $q_0 \in Q$ is the *initial state* and $F \subset Q$ is a set of *final states*. A regular language can also be constructed by recursive applications of concatenation (denoted by placing regular expressions adjacent to one another), disjunction (denoted $|$), and Kleene star (denoted $*$), to strings and the empty string. That this construction and the DFA are equivalent is well known [14].

The DFA $(Q, \Sigma, \delta, q_0, F)$ can be thought of as a directed graph whose vertices are Q with edges from q to q' iff there is an $s \in \Sigma$ such that $q' = \delta(q, s)$. The transition function δ provides a labeling of the graph, where each edge (q, q') is labeled by the symbol s such that $\delta(q, s) = q'$. Note that there may be multiple edges between nodes, each with a different label. The adjacency matrix A for a DFA is the adjacency matrix for the corresponding graph. Thus, entries in A are given by $a_{q,q'}$, where $a_{q,q'}$ is the number of edges from vertex q to vertex q'.

For a regular language L, let $W_n(L)$ denote the set of words in L of length exactly n, i.e. $W_n(L) = L \cap \Sigma^n$, and let $W_{\leq n}(L)$ denote the set of words in L of length at most n, i.e. $W_{\leq n}(L) = L \cap (\bigcup_{i=0}^{n} \Sigma^i)$.

Finally, we will discuss when certain distance functions are metrics. A *metric* on the space X is a function $d : X \times X \to \mathbb{R}$ that satisfies

1. $d(x, y) \geq 0$ with equality if and only if $x = y$ for all $x, y \in X$
2. $d(x, y) = d(y, x)$ for all $x, y \in X$
3. $d(x, z) \leq d(x, y) + d(y, z)$ for all $x, y, z \in X$.

An *ultra-metric* is a stronger version of a metric, with the triangle inequality (the third condition above) replaced with the ultra-metric inequality: $d(x, z) \leq \max\{d(x, y), d(y, z)\}$ for all $x, y, z \in X$. Also, there exists a weaker version, called a *pseudo-metric*, which allows $d(x, y) = 0$ when $x \neq y$.

3 Jaccard Distances

The Jaccard distance is a well-known distance function between finite sets. For finite sets A and B, the *Jaccard distance* between them is given by $\frac{|A\triangle B|}{|A\cup B|} = 1 - \frac{|A\cap B|}{|A\cup B|}$ where $A\triangle B$ represents the symmetric difference between the two sets (if $A \cup B = \emptyset$ then the Jaccard distance is 0). This classical Jaccard distance is not defined for infinite sets and as such, is not a suitable distance function for infinite regular languages and will need to be modified.

3.1 Jaccard Distances using W_n and $W_{\leq n}$

A natural method for applying Jaccard distance to regular languages is to fix n, defined as follows:

▶ **Definition 1** (n Jaccard Distance)**.** Suppose L_1 and L_2 are regular languages. Define the n *Jaccard distance* by $J'_n(L_1, L_2) = \frac{|W_n(L_1\triangle L_2)|}{|W_n(L_1\cup L_2)|}$ if $|W_n(L_1 \cup L_2)| > 0$, otherwise $J'_n(L_1, L_2) = 0$.

For fixed n, the above is a pseudo-metric since it is simply the Jaccard distance among sets containing only length n strings. The following proposition points out one deficiency of J'_n.

▶ **Proposition 2.** There exists a set $S = \{L_1, L_2, L_3\}$ of infinite unary regular languages with $L_2, L_3 \subset L_1$ such that for all n there exists an $i \neq j$ such that $J'_n(L_i, L_j) = 0$.

One may also use $W_{\leq n}$ in the definition of a Jaccard-based distance function.

▶ **Definition 3** ($n_\leq$ Jaccard Distance)**.** For regular languages L_1 and L_2, define the $n_\leq$ *Jaccard distance* by $J_n(L_1, L_2) = \frac{|W_{\leq n}(L_1\triangle L_2)|}{|W_{\leq n}(L_1\cup L_2)|}$ if $|W_{\leq n}(L_1 \cup L_2)| > 0$, otherwise $J_n(L_1, L_2) = 0$.

The issue with J'_n pointed out by Proposition 2 can be proven to not be a problem for J_n: see the first point of Theorem 4. On the other hand, the second point of Theorem 4 shows that no universal n exists.

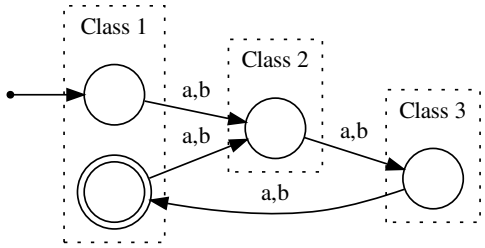
▶ **Theorem 4.** *The function J_n defined above is a pseudo-metric and satisfies the following:*

1. *Let $S = \{L_1, \ldots, L_k\}$ be a set of regular languages. There exists an n such that J_n is a metric over S. Moreover, we may choose n such that $n \leq \max_{i,j}(s(L_i)+1)(s(L_j)+1)-1$ where $s(L_i)$ represents the number of states in the minimal DFA corresponding to L_i.*
2. *For any fixed n there exist regular languages L, L' with $L \neq L'$ such that $J_n(L, L') = 0$.*

For any pseudo-metric, the relation $d(x, y) = 0$ is an equivalence relation. Thus, if we mod out by this equivalence relation, the pseudo-metric becomes a metric.

Due to the fact that one must choose a fixed n, J_n and J'_n cannot account for the infinite nature of regular languages. Limits based on J_n and J'_n are a natural next step. However, the natural limits involving J'_n and J_n do not always exist. An example showing this was given for J'_n in the beginning of the introduction (Section 1). A similar example applies to J_n. Consider the languages given by $L_1 = (a|b)^*$ and $L_2 = ((a|b)^2)^*$ ($\Sigma = \{a, b\}$). For these languages, $\lim_{n\to\infty} J_{2n}(L_1, L_2) = 2/3$ and $\lim_{n\to\infty} J_{2n+1}(L_1, L_2) = 1/3$. Hence, $\lim_{n\to\infty} J_n(L_1, L_2)$ does not exist.

The next theorem gives conditions for when the limit of J'_n exists as n goes to infinity. Before the theorem is stated we will need some more terminology. Suppose L is a regular language and M is the corresponding DFA. This DFA is a labeled directed graph. An *irreducible component* of M is a strongly connected component of the graph. That is, an



$$A^i = \begin{cases} \begin{pmatrix} 0 & 2^i & 0 & 0 \\ 0 & 0 & 2^i & 0 \\ 0 & 0 & 0 & 2^i \\ 0 & 2^i & 0 & 0 \end{pmatrix} & \text{if } i \equiv 1 \bmod 3 \\ \begin{pmatrix} 0 & 0 & 2^i & 0 \\ 0 & 0 & 0 & 2^i \\ 0 & 2^i & 0 & 0 \\ 0 & 0 & 2^i & 0 \end{pmatrix} & \text{if } i \equiv 2 \bmod 3 \\ \begin{pmatrix} 0 & 0 & 2^i & 0 \\ 0 & 2^i & 0 & 0 \\ 0 & 0 & 2^i & 0 \\ 0 & 0 & 0 & 2^i \end{pmatrix} & \text{if } i \equiv 0 \bmod 3 \end{cases}$$

Figure 1 The DFA for a period 3 language and the associated adjacency matrix raised to the i^{th} power.

irreducible component is composed of a maximal set of vertices such that for any pair, there is a directed path between them.

The *period* of an irreducible graph (or associated adjacency matrix) is the largest integer p such that the vertices can be grouped into classes $Q_0, Q_1, \ldots, Q_{p-1}$ such that if $x \in Q_i$, then all of the out neighbors of x are in Q_j, where $j = i + 1(mod\ p)$. The period of a reducible graph is the least common multiple of the periods of its irreducible components. See Figure 1 for an example of a regular language whose DFA has period 3. For a more formal definition of periodicity see [19]. If the graph (or matrix) has period 1 it will be called *aperiodic*. Matrices that are irreducible and aperiodic are called *primitive*. The definition of primitive presented here is equivalent to the condition that there is an n such that all entries of the adjacency matrix A raised to the n-th power (A^n) are positive [20]. This is illustrated in Figure 1, where the graph is periodic and reducible and all powers of that matrix contain multiple zeroes.

▶ **Theorem 5.** *Suppose L_1 and L_2 are regular languages. If each irreducible component of the DFA associated to $L_1 \triangle L_2$ and $L_1 \cup L_2$ are aperiodic, then $\lim_{n\to\infty} J'_n(L_1, L_2)$ converges.*

Let us build intuition prior to proving Theorem 5, which will also frame the question of convergence in the next subsection. We will first discuss Theorem 5 in the case where the DFA associated to regular languages $L_1 \triangle L_2$ and $L_1 \cup L_2$ are primitive. Suppose $A_\triangle$ and $A_\cup$ are the adjacency matrices for $L_1 \triangle L_2$ and $L_1 \cup L_2$ respectively. Perron-Frobenius theory tells us that the eigenvalue of largest modulus of a primitive matrix is real and unique. Let $(v_\triangle, \lambda_\triangle)$ and $(v_\cup, \lambda_\cup)$ be eigenpairs composed of the top eigenvalues for $A_\triangle$ and $A_\cup$ respectively. Notice that $i_\triangle A^n_\triangle f_\triangle$, where $i_\triangle$ is the row vector whose jth entry is 1 if j is an initial state in $A_\triangle$ and 0 otherwise (a similar definition for final states defining column vector $f_\triangle$ holds), represents words in $L_1 \triangle L_2$ of length n. If we write $f_\triangle = c_1 v_\triangle + c_2 w$ and $f_\cup = d_1 v_\cup + d_2 y$, then $i_\triangle A^n_\triangle f_\triangle$ converges to $\lambda^n_\triangle c_1 i_\triangle v_\triangle$, and $i_\cup A^n_\cup f_\cup$ converges to $\lambda^n_\cup d_1 i_\cup v_\cup$ as n goes to infinity. This convergence is guaranteed because $\lambda_\cup$ and $\lambda_\triangle$ are unique top eigenvalues. Thus,

$$\lim_{n\to\infty} J'_n(L_1, L_2) = \lim_{n\to\infty} \left(\frac{\lambda_\triangle}{\lambda_\cup}\right)^n \frac{c_1 i_\triangle v_\triangle}{d_1 i_\cup v_\cup}$$

and the limit converges ($\lambda_\triangle \leq \lambda_\cup$ because $L_1 \triangle L_2 \subseteq L_1 \cup L_2$).

The general case of Theorem 5, which does not assume $L_1 \triangle L_2$ and $L_1 \cup L_2$ have irreducible matrices, is more complicated. However, the outline of the argument is the same, and we will sketch it here. The key difference is the use of newer results. An understanding of the asymptotic behavior of A^n for large n was finally beginning to be developed several decades after Chomsky and Miller investigated regular languages. In 1981 Rothblum [23] proved that for each non-negative matrix A with largest eigenvalue λ, there exists $q \geq 1$ (which happens to be the period of A) and polynomials $S_0(x), S_1(x), \ldots, S_{q-1}(x)$ (whose domain is the set of real numbers and whose coefficients are matrices) such that for all whole numbers $0 \leq k \leq q-1$ we have that $\lim_{n\to\infty} (A/\lambda)^{qn+k} - S_k(n) = 0$. We will refer to this result later in the paper, where we will simply call it **Rothblum's Theorem** (a slow treatment of this theory with examples can be found in [24]). So the rest of the proof to Theorem 5 is observing that $q = 1$ in the case we are interested in, and so $\lim_{n\to\infty} J'_n(L_1, L_2)$ converges.

3.2 Cesàro Jaccard

For a sequence of numbers $a_1, a_2, \ldots$, a Cesàro summation is $\lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} a_i$ when the limit exists. The intuition behind a Cesàro summation is that it may give the "average value" of the limit of the sequence, even when the sequence does not converge. For example, the sequence $a_j = e^{\alpha ij}$ (where $i^2 = -1$) has Cesàro summation 0 for all real numbers $\alpha \neq 0$. This follows from the fact that rotations of the circle are uniquely ergodic [13]. Not all sequences have a Cesàro summation, even when we restrict our attention to sequences whose values lie in $[0, 1]$. For example, the sequence b_i, where $b_i = 1$ when $2^{2n} < i < 2^{2n+1}$ for some $n \in \mathbb{N}$ and $b_i = 0$ otherwise has no Cesàro summation. However, we will be able to show that the Cesàro average of Jaccard distances does exist.

To that end, another limit based distance is the Cesàro average of the J_n or J'_n.

▶ **Definition 6** (Cesàro Jaccard Distance)**.** Suppose L_1 and L_2 are regular languages. Define the *Cesàro Jaccard distance* by $J_C(L_1, L_2) = \lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} J_i(L_1, L_2)$.

The Cesàro Jaccard distance is theoretically better than the above suggestions in Section 3.1 since it can be shown to exist for all regular languages.

▶ **Theorem 7.** *Let L_1 and L_2 be two regular languages. Then, $J_C(L_1, L_2)$ is well-defined. That is, $\lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} J_i(L_1, L_2)$ exists.*

We will breifly sketch the proof to Theorem 7. Recall that $|W_n(L_1 \triangle L_2)|$ and $|W_n(L_1 \cup L_2)|$ can be calculated using powers of specific matrices. If we take Q to be the least common multiple of the period from each of the matrices associated with $|W_n(L_1 \triangle L_2)|$ and $|W_n(L_1 \cup L_2)|$, we can immediately see that $\lim_{n\to\infty} J'_{Qn+k}(L_1, L_2)$ exists, via Rothblum's Theorem. Moreover, it will equal zero if they have different values for the largest eigenvalue or the degree of $S_k(x)$. But if they have the same value for the largest eigenvalue and degree of $S_k(x)$, then $\lim_{n\to\infty} J'_{Qn+k}(L_1, L_2)$ will be the ratio of the leading coefficients of the polynomials $S_k(x)$ for the two matrices. The proof finishes by observing that $J'_C(L_1, L_2) = \frac{1}{n} \sum_{i=1}^{n} J'_i(L_1, L_2)$ will be the average of these values.

We will require a new result to show that the more interesting value $J_C(L_1, L_2)$ is well-defined (part (2) of the theorem is similar to a result in [23]).

▶ **Theorem 8.** *Let A be the adjacency matrix for a DFA representing a regular language L, and let λ be the largest eigenvalue of A. Let q and $S_0(x), S_1(x), \ldots, S_{q-1}(x)$ be as in Rothblum's theorem; let d be the largest degree of the polynomials $S_0(x), S_1(x), \ldots, S_{q-1}(x)$. Let $s_\ell = \lim_{n\to\infty} n^{-(d+1)} \sum_{i=1}^{n} S_\ell(i)$ and $t_\ell = \lim_{n\to\infty} n^{-d} S_\ell(n)$.*

1. *If* $\lambda < 1$*, then* L *is finite.*
2. *If* $\lambda = 1$*, then* $\lim_{n\to\infty} \frac{1}{n^{d+1}} \sum_{i=1}^{n} A^i = \sum_{i=0}^{q-1} s_\ell$.
3. *If* $\lambda > 1$*, then* $\lim_{n\to\infty} \frac{1}{(qn+k)^d} \lambda^{-(qn+k)} \sum_{i=1}^{qn+k} A^i = \frac{1}{1-\lambda^{-q}} \sum_{\ell=k-q+1}^{k} \lambda^{\ell-k} t_\ell$ *where the indices of the* t_i *are taken modulo* q.

Using our new result in place of Rothblum's theorem, we now see that $J_C(L_1, L_2)$ is well-defined. Note that in $J'_C(L_1, L_2)$ each congruence class k is handled independently and the final answer is the average of such results. On the other hand, in $J_C(L_1, L_2)$ each congruence class k has a limit that is a combination of results from all of the congruence classes. Thus the total answer is dominated by the overall asymptotic behavior and not just small periodic undercurrents. We illustrate this point via the next example.

▶ **Example 9.** Let $L_1 = ((a|b)^2)^*|c^*$ and $L_2 = ((a|b)^2)^*|d^*$. The languages L_1 and L_2 have $((a|b)^2)^*$ in common and so mutually shared words up to length n grow exponentially. The languages disagree on c^* and d^*, whose words only grow polynomially. Hence, L_1 and L_2 are very similar and should have a small distance. However, J'_C gives equal weight to words of even length and odd length, even though the languages are mostly made up of even-length words.

Rigorously, we have that $\lim_{n\to\infty} J_{2n}(L_1, L_2) = 0$ and $\lim_{n\to\infty} J'_{2n}(L_1, L_2) = 0$. Furthermore, $\lim_{n\to\infty} J_{2n+1}(L_1, L_2) = 0$ and $\lim_{n\to\infty} J'_{2n+1}(L_1, L_2) = 1$. Thus, $J_C(L_1, L_2) = 0$, while $J'_C(L_1, L_2) = \frac{1}{2}$.

We conclude this section with a fact about the Cesáro Jaccard distance.

▶ **Fact 10.** The Cesàro Jaccard distance inherits the pseudo-metric property from J_n.

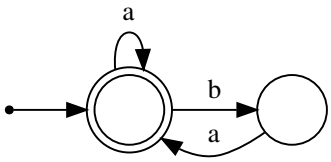
4 Entropy

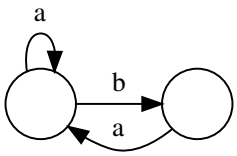
In this section we develop the idea of topological entropy for a certain type of dynamical system and show how it relates to a quantity that we have identified as the language entropy. Then, we will show how Cesáro Jaccard is related to entropy.

4.1 Topological Entropy

Topological entropy is a concept from dynamical systems where the space is a compact metric space and the map defined there is continuous [19]. In dynamics, successive applications of the map are applied and the long term behavior of the system is studied. An orbit of a point x for the map T is the set $\{T^n(x) \ : \ n \in \mathbb{Z}\}$. Topological entropy is an abstract concept meant to determine the exponential growth of distinguishable orbits of the dynamical system up to arbitrary scale. A positive quantity for topological entropy reflects chaos in the system [1]. This concept was motivated by Kolmogorov and Sinai's theory of measure-theoretic entropy in ergodic theory [15, 29], which in turn is related to Shannon entropy [27]. An example of a topological dynamical system is a sofic shift, which is a symbolic system that is intricately related to DFA. Instead of defining the topological entropy of a sofic shift symbolically, which is classical, we will use the graph theoretic description.

A *sofic shift* can be thought of as the space of biinfinite walks (i.e. walks with no beginning and no end) on a right-solving labeled directed graph (a right-solving labeled graph has a unique label for each edge leaving a given node). Suppose G is a directed graph where V is the set of vertices and E is the set of edges of G. Furthermore, suppose that every edge in E is labeled with a symbol from Σ, and that there is at most one outgoing edge from each





aaa, *aaba*, *ba*, *aaaaaaa*, *aaabaabaa*, ... *aabaabaabaaaabaaaaaabaaaaab* ...

Figure 2 A DFA with some accepted strings and a sofic shift with a portion of a derived biinfinite string.

vertex with a given label (i.e. *right-solving*). Note that this construction is similar to a DFA, however there are no initial and final states. A biinfinite walk on G with a specified base vertex is an infinite walk in both directions (forward and backward) from the base vertex on the graph. This biinfinite walk corresponds to a biinfinite string of symbols from Σ. See Figure 2.

We will call a finite block of symbols *admissible* if there is a biinfinite string of symbols corresponding to a biinfinite walk on G and this finite block appears somewhere within the biinfinite string. Note that all sufficiently long words in the DFA's language will contain a substring of almost the same length that is an admissible block, while not all admissible blocks will be in the associated DFA's language. Denote the set of admissible blocks of length n corresponding to G by $B_n(G)$. The *topological entropy* of the sofic shift represented by the right-solving labeled graph G is denoted by $h_t(G)$ and is defined by

$$h_t(G) = \lim_{n\to\infty} \frac{\log |B_n(G)|}{n}.$$

Using Perron-Frobenius theory it has been proven that the topological entropy of a sofic shift represented by a right-solving labeled graph G is equal to the log base 2 of the spectral radius of the adjacency matrix of G [19]. That is, the topological entropy is given by the log of the adjacency matrix's largest modulus eigenvalue. Algorithms for computing eigenvalues are well known and run in time polynomial in the width of the matrix [12].

As you can see, sofic shifts are very similar to DFA. Given a DFA, M, one can construct a sofic shift by thinking of M as a labeled directed graph and creating the *trim graph* by removing all states that are not part of an accepting path. Information regarding initial and final states is no longer needed. Note that the graph M is naturally right-solving because of the determinism of DFA. It is also easiest to remove from M all vertices that do not have both an outgoing and incoming edge (since we are now interested in biinfinite walks). The resulting graph is called the *essential graph*. At this point one is free to apply the above definition and compute the topological entropy of the sofic shift corresponding to the DFA. This quantity can be computed by analyzing the irreducible components.

▶ **Theorem 11** ([19]). *Suppose that G is the labeled directed graph associated to a sofic shift. If $G_1, \ldots, G_k$ are the irreducible components of G, then $h_t(G) = \max_{1\le i\le k} h_t(G_i)$.*

In the next subsection we will introduce the language entropy and show that it is the same as the topological entropy of the sofic shift corresponding to a DFA.

4.2 Language Entropy

Traditionally, the entropy of a regular language L (also called the *channel capacity* [6] or *information rate* [10]) is defined as $\limsup_{n\to\infty} \frac{\log|W_n(L)|}{n}$. This limit may not exist and so an upper limit is necessary. We will show that this upper limit is realized by the topological entropy of the corresponding sofic shift and define another notion of language entropy, which is preferable since an upper limit is not necessary.

▶ **Definition 12** (Language Entropy)**.** Given a regular language L define the *language entropy* by $h(L) = \lim_{n\to\infty} \frac{\log|W_{\leq n}(L)|}{n}$.

▶ **Theorem 13.** *Let L be a non-empty regular language over the set of symbols Σ, and let G be the labeled directed graph of the associated sofic shift. We have that*

$$\limsup_{n\to\infty} \frac{\log|W_n(L)|}{n} = h_t(G).$$

Moreover, for a fixed language L there exists a constant c such that there is an increasing sequence of integers n_i satisfying $0 < n_{i+1} - n_i \leq c$ and

$$\lim_{i\to\infty} \frac{\log|W_{n_i}(L)|}{n_i} = h_t(G).$$

As a corollary to this theorem we obtain an important statement regarding the connection between topological entropy (from dynamical systems) and language entropy (similar to Shannon's channel capacity). The following statement is consistent with remarks made by Chomsky and Miller [6] that involved undefined assumptions; we show rigorously that this formula is correct for all DFA.

▶ **Corollary 14.** *Let L be a non-empty regular language over the set of symbols Σ, and let G be the labeled directed graph of the associated sofic shift. Then,*

$$h(L) = \lim_{n\to\infty} \frac{\log|W_{\leq n}(L)|}{n} = h_t(G).$$

There are some simple properties of language entropy which will be useful later. The first is a simple re-phrasing of Corollary 14.

▶ **Lemma 15.** *For any regular language L, we have that $|W_{\leq n}(L)| = 2^{n(h(L)+o(1))}$.*

▶ **Lemma 16.** *Suppose L_1 and L_2 are regular languages over Σ. The following hold:*

1. *If $L_1 \subseteq L_2$, then $h(L_1) \leq h(L_2)$.*
2. *$h(L_1 \cup L_2) = max(h(L_1), h(L_2))$*
3. *$\max(h(L_1), h(\overline{L_1})) = \log|\Sigma|$*
4. *If $h(L_1) < h(L_2)$, then $h(L_2 \setminus L_1) = h(L_2)$.*
5. *If L_1 is finite, then $h(L_1) = 0$.*

4.3 Relationship between Entropy and Cesáro Jaccard

In Section 3.2 we proved that the Cesàro Jaccard distance is well-defined. As you will see, Cesáro Jaccard and entropy are mostly disjoint in what they measure.

▶ **Theorem 17.** *Let L_1, L_2 be two regular languages.*

1. *If $h(L_1 \triangle L_2) \neq h(L_1 \cup L_2)$, then $J_C(L_1, L_2) = 0$.*
2. *If $h(L_1 \cap L_2) \neq h(L_1 \cup L_2)$, then $J_C(L_1, L_2) = 1$.*
3. *If $0 < J_C(L_1, L_2) < 1$, then the following equal each other:*
   $h(L_1)$, $h(L_2)$, $h(L_1 \cap L_2)$, $h(L_1 \triangle L_2)$, $h(L_1 \cup L_2)$.

To better understand this theorem, consider the following examples corresponding to the three cases of the theorem: (1) let $L_1 = ((a|b)^2)^*|c^*$ and $L_2 = ((a|b)^2)^*|d^*$ as in Example 9, (2) let $L_1 = (a|b)^*|c^*$ and $L_2 = (d|e)^*|c^*$, and (3) let $L_1 = (aa)^*$ and $L_2 = a^*$ as in the Introduction.

5 Entropy Distances

Entropy provides a natural method for dealing with the infinite nature of regular languages. Because it is related to the eigenvalues of the regular language's DFA, it is computable in polynomial time given a DFA for the language. Note that the DFA does not have to be minimal. We can therefore compute the entropy of set-theoretic combinations of regular languages (intersection, disjoint union, etc) and use those values to determine a distance between the languages.

5.1 Entropy Distance

A natural Jaccard-esque distance function based on entropy is the entropy distance.

▶ **Definition 18** (Entropy Distance)**.** Suppose L_1 and L_2 are regular languages. Define the *entropy distance* to be $H(L_1, L_2) = \frac{h(L_1 \triangle L_2)}{h(L_1 \cup L_2)}$ if $h(L_1 \cup L_2) > 0$, otherwise $H(L_1, L_2) = 0$.

This turns out to be equivalent to a Jaccard limit with added log operations:

▶ **Corollary 19.** *Suppose L_1 and L_2 are regular languages. The following relation holds:*

$$\lim_{n\to\infty} \frac{\log |W_{\leq n}(L_1 \triangle L_2)|}{\log |W_{\leq n}(L_1 \cup L_2)|} = H(L_1, L_2).$$

Note that H is not always a good candidate for a distance function as it only produces non-trivial results for languages that have the same entropy.

▶ **Proposition 20.** Suppose L_1 and L_2 are regular languages. If $h(L_1) \neq h(L_2)$, then $H(L_1, L_2) = 1$.

As further evidence that H is not a good candidate for a distance function, we show it is an ultra-pseudo-metric. The ultra-metric condition, i.e. $d(x, z) \leq \max(d(x, y), d(y, z))$, is so strong that it can make it difficult for the differences encoded in the metric to be meaningful for practical applications.

▶ **Theorem 21.** *The function H is an ultra-pseudo-metric.*

5.2 Entropy Sum

In this subsection we will define a new (and natural) distance function for infinite regular languages. We call this distance function the *entropy sum distance*. We will prove that not only is this distance function a pseudo-metric, it is also sometimes granular. Granularity lends insight into the quality of a metric. Intuitively, granularity means that for any two points in the space, you can find a point between them. A metric d on the space X is *granular* if for every two points $x, z \in X$, there exists $y \in X$ such that $d(x, y) < d(x, z)$ and $d(y, z) < d(x, z)$, i.e. $d(x, z) > \max(d(x, y), d(y, z))$.

▶ **Definition 22** (Entropy Sum Distance)**.** Suppose L_1 and L_2 are regular languages. Define the *entropy sum distance* to be $H_S(L_1, L_2) = h(L_1 \cap \overline{L_2}) + h(\overline{L_1} \cap L_2)$.

The entropy sum distance was inspired by first considering the entropy of the symmetric difference directly, i.e. $h(L_1 \triangle L_2)$. However, since entropy measures the entropy of the most complex component (Theorem 11), more information is gathered by using a sum as above in the definition of entropy sum.

▶ **Theorem 23.** *The function H_S is a pseudo-metric.*

The next two propositions display when granularity is achieved and when it is not.

▶ **Proposition 24.** Let L_1 and L_2 be regular languages such that $h(L_1 \cap \overline{L_2}), h(\overline{L_1} \cap L_2) > 0$. Then, there exists two regular languages $R_1 \neq R_2$ such that $H_S(L_1, L_2) > \max(H_S(L_1, R_i), H_S(R_i, L_2))$ for each i.

▶ **Proposition 25.** Let L_1 and L_2 be regular languages such that $h(\overline{L_1} \cap L_2) = 0$. For all regular languages L we have that $H_S(L_1, L_2) \leq \max(H_S(L_1, L), H_S(L, L_2))$.

6 Conclusion and Future Work

This paper has covered some issues related to the entropy of regular languages and the distance between regular languages. It has proven correct the common upper limit formulation of language entropy and has provided a limit based entropy formula that can be shown to exist. Jaccard distance was shown to be related to language entropy, and various limit based extensions of the Jaccard distance were shown to exist or not exist. The natural entropy based distance function was shown to be an ultra-pseudo-metric, and some facts were proven about the function that show it likely to be impractical. Finally, the paper introduces an entropy-based distance function and proves that function to be a pseudo-metric, as well as granular under certain conditions.

In this paper several formulations of entropy are developed, and it is natural to consider which would be the best to use. In a practical sense it does not matter since all formulations are equivalent (Theorem 13) and can be computed using Shannon's determinant-based method [27]. However, conceptually, it can be argued that $\lim_{n\to\infty} \frac{log|W_{\leq n}(L)|}{n}$ is the preferable formulation. First, there is a notational argument that prefers using limits that exist. This is a limit that exists (Corollary 14), whereas many other limit formulations do not. Second, this limit captures more readily the concept of "number of bits per symbol" that Shannon intended. Because regular languages can have strings with staggered lengths, using W_n forces the consideration of possibly empty sets of strings of a given length. This creates dissonance when the language has non-zero entropy. Instead, the monotonically growing $W_{\leq n}$ more clearly encodes the intuition that the formulation is expressing the number of bits needed to express the next symbol among all words in the language.

Apart from expanding to consider context-free languages and other languages ([10]), one investigation that is absent from this paper is the determination of similarity between languages that are disjoint but obviously similar (i.e. aa^* and ba^*). A framework for addressing such problems is provided in [9], but finding metrics capturing such similarities can be fodder for future efforts.

Abstract

Valued constraint satisfaction problems (VCSPs) are discrete optimisation problems with a $\overline{\mathbb{Q}}$-valued objective function given as a sum of fixed-arity functions, where $\overline{\mathbb{Q}} = \mathbb{Q} \cup \{\infty\}$ is the set of extended rationals.

In Boolean surjective VCSPs variables take on labels from $D = \{0, 1\}$ and an optimal assignment is required to use both labels from D. A classic example is the *global min-cut* problem in graphs. Building on the work of Uppman, we establish a dichotomy theorem and thus give a complete complexity classification of Boolean surjective VCSPs. The newly discovered tractable case has an interesting structure related to projections of downsets and upsets. Our work generalises the dichotomy for $\{0, \infty\}$-valued constraint languages (corresponding to CSPs) obtained by Creignou and Hébrard, and the dichotomy for $\{0, 1\}$-valued constraint languages (corresponding to Min-CSPs) obtained by Uppman.

1 Introduction

The (s, t)-Min-Cut problem asks, given a digraph $G = (V, E)$ with source $s \in V$, sink $t \in V$, and edge weights $w : E \to \mathbb{Q}_{>0}$, for a subset $C \subseteq V$ with $s \in C$ and $t \notin C$ minimising $w(C) = \sum_{(u,v)\in E, u\in C, v\notin C} w(u, v)$ [22]. This fundamental problem is an example of a Boolean valued constraint satisfaction problem (VCSP).

Let D be an arbitrary finite set called the *domain*. A *valued constraint language*, or just a language, Γ is a set of weighted relations; each weighted relation $\gamma \in \Gamma$ is a function $\gamma : D^{\mathrm{ar}(\gamma)} \to \overline{\mathbb{Q}}$, where $\mathrm{ar}(\gamma) \in \mathbb{N}$ is the *arity* of γ and $\overline{\mathbb{Q}} = \mathbb{Q} \cup \{\infty\}$ is the set of extended rationals. If $|D| = 2$ then Γ is called a *Boolean* language. An *instance* $I = (V, D, \phi_I)$ of the VCSP on domain D is given by a finite set of n variables $V = \{x_1, \ldots, x_n\}$ and an objective function $\phi_I : D^n \to \overline{\mathbb{Q}}$ expressed as a weighted sum of *valued constraints* over V, i.e. $\phi_I(x_1, \ldots, x_n) = \sum_{i=1}^{q} w_i \cdot \gamma_i(\mathbf{x}_i)$, where γ_i is a weighted relation, $w_i \in \mathbb{Q}_{\geq 0}$ is the *weight*

* The authors were supported by a Royal Society Research Grant. Stanislav Živný was supported by a Royal Society University Research Fellowship. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 714532). The paper reflects only the authors' views and not the views of the ERC or the European Commission. The European Union is not liable for any use that may be made of the information contained therein.

and $\mathbf{x}_i \in V^{\mathrm{ar}(\gamma_i)}$ the *scope* of the ith valued constraint. (We note that we allow zero weights and for $w_i = 0$ we define $w_i \cdot \infty = \infty$.) Given an instance I, the goal is to find an assignment $s : V \to D$ of domain labels to the variables that *minimises* ϕ_I. Given a language Γ, we denote by VCSP(Γ) the class of all instances I that use only weighted relations from Γ in their objective function. Valued CSPS are also called general-valued CSPs to emphasise that (decision) CSPs are a special case of valued CSPs.

To continue with the (s,t)-Min-Cut example, let $D = \{0,1\}$. We will use the following three weighted relations: $\gamma : D^2 \to \overline{\mathbb{Q}}$ is defined by $\gamma(x,y) = 1$ if $x = 0$ and $y = 1$, and $\gamma(x,y) = 0$ otherwise; $\rho_d : D \to \overline{\mathbb{Q}}$, for $d \in D$, is defined by $\rho_d(x) = 0$ if $x = d$ and $\rho_d(x) = \infty$ if $x \neq d$. Now, given an (s,t)-Min-Cut instance $G = (V,E)$, $s,t \in V = \{x_1,\ldots,x_n\}$, and $w : E \to \mathbb{Q}_{>0}$ as before, the problem of finding an optimal (s,t)-Min-Cut in G is equivalent to solving the following instance of VCSP(Γ_{cut}), where $\Gamma_{\mathsf{cut}} = \{\gamma, \rho_0, \rho_1\}$: $I = (V, D, \phi_I)$ and $\phi_I(x_1,\ldots,x_n) = \sum_{(u,v)\in E} w(u,v) \cdot \gamma(x_u, x_v) + \rho_0(s) + \rho_1(t)$.

It is well known that the (s,t)-Min-Cut problem is solvable in polynomial time. Since every instance I of VCSP(Γ_{cut}) can be reduced to an instance of the (s,t)-Min-Cut problem, I is solvable in polynomial time. Thus, Γ_{cut} is an example of a *tractable* constraint language. When VCSP(Γ) is NP-hard, we call Γ an *intractable* language.

It is natural to ask about the complexity of VCSP(Γ) in terms of Γ. For *Boolean* valued constraint languages, we have a complete answer: Cohen et al. [8] showed that every Boolean valued constraint language is either tractable or intractable, thus obtaining what is known as a dichotomy theorem. In fact, [8] identified eight different types of tractable valued constraint languages; one of these types corresponds to submodularity [22] and includes Γ_{cut}. The dichotomy theorem from [8] is an extension of Schaefer's celebrated result, which gave a dichotomy for $\{0,\infty\}$-valued constraint languages [21], and the work of Creignou [9], who gave a dichotomy theorem for $\{0,1\}$-valued constraint languages.

The (global) Min-Cut problem asks, given a graph $G = (V,E)$ and edge weights $w : E \to \mathbb{Q}_{>0}$, for a subset $C \subseteq V$ with $\emptyset \subsetneq C \subsetneq V$ minimising $w(C) = \sum_{\{u,v\}\in E, |\{u,v\}\cap C|=1} w(u,v)$ [22]. This fundamental problem is an example of a Boolean *surjective* VCSP. Given a VCSP instance $I = (V, D, \phi_I)$, in the surjective setting the goal is to find a surjective assignment $s : V \to D$ minimising ϕ_I; here s is called surjective if for every $d \in D$ there is $x \in V$ such that $s(x) = d$. For Boolean VCSPs with $D = \{0,1\}$, this simply means that the all-zero and all-one assignments are not allowed. Given a language Γ, we denote by $\mathrm{VCSP_s}(\Gamma)$ the class of all instances I of the surjective VCSP that use only weighted relations from Γ in their objective function.

Let $D = \{0,1\}$ and define $\gamma : D \to \overline{\mathbb{Q}}$ by $\gamma(x,y) = 0$ if $x = y$ and $\gamma(x,y) = 1$ if $x \neq y$. $\mathrm{VCSP_s}(\{\gamma\})$ captures Min-Cut as every instance of $\mathrm{VCSP_s}(\{\gamma\})$ is a Min-Cut instance and vice versa. Since Min-Cut is solvable in polynomial time (say, by a reduction to the (s,t)-Min-Cut problem but other algorithms exist [23]), $\{\gamma\}$ is an example of a surjectively tractable, or *s-tractable* for short, valued constraint language. As before, if $\mathrm{VCSP_s}(\Gamma)$ is NP-hard we call Γ a surjectively intractable, or *s-intractable* for short, language.

Surjective VCSPs

What can we say about the complexity of $\mathrm{VCSP_s}(\Gamma)$ *for arbitrary* Γ*? In particular, is every* Γ *s-tractable or s-intractable? What is the mathematical structure of s-tractable languages?*

First, observe that for a language Γ defined on D, we have $\mathrm{VCSP}(\Gamma) \leq_p \mathrm{VCSP_s}(\Gamma)$. Indeed, given an instance I of VCSP(Γ), construct a new instance I' of $\mathrm{VCSP_s}(\Gamma)$ by adding $|D|$ extra variables. Then, any solution to I can be extended to a surjective solution to I' of the same value and conversely, any (surjective) solution to I' induces a solution to I of the same value.

Second, observe that for a language Γ defined on D, we have $\mathrm{VCSP_s}(\Gamma) \leq_p \mathrm{VCSP}(\Gamma \cup \mathcal{C}_D)$, where $\mathcal{C}_D$ is the set of constants on D; that is, $\mathcal{C}_D = \{\rho_d \mid d \in D\}$, where ρ_d is defined by $\rho_d(x) = 0$ if $x = d$ and $\rho_d(x) = \infty$ if $x \neq d$. Indeed, given an instance of $\mathrm{VCSP_s}(\Gamma)$, constants can be used to go through all $O(n^{|D|})$ ways to assign all the labels from D to a $|D|$-subset of the n variables, each resulting in an instance of $\mathrm{VCSP}(\Gamma \cup \mathcal{C}_D)$. Consequently, a tractable language Γ defined on D with $\mathcal{C}_D \subseteq \Gamma$ is also an s-tractable language.

In this paper we deal with Boolean valued constraint languages defined on $D = \{0, 1\}$. By the two observations above, the only Boolean valued constraint languages for which tractability could be different from s-tractability are tractable languages that do not include constants.

For Boolean $\{0, \infty\}$-valued languages, Schaefer's dichotomy [21] gives six tractable cases, four of which include constants. Creignou and Hébrard showed that the remaining two cases (0-valid and 1-valid) are s-intractable, thus obtaining a dichotomy in the surjective setting [10].

For Boolean $\{0, 1\}$-valued languages, Creignou's dichotomy [9] gives three tractable cases, one of which includes constants. Uppman showed that the remaining two cases (0-valid and 1-valid) are s-tractable if they are almost-min-min or almost-max-max, respectively, and s-intractable otherwise, thus obtaining a dichotomy in the surjective setting [24].

Contributions. As our main contribution we classify all Boolean valued constraint languages (i.e. $\overline{\mathbb{Q}}$-valued languages) as s-tractable or s-intractable. Our result extends the classifications from [10] and [24]. Six of the eight tractable cases identified for Boolean valued constraint languages [8] include constants and thus are also s-tractable. The remaining two cases (0-optimal and 1-optimal[1]) are s-tractable if they satisfy a certain condition. This condition, defined formally in Definition 5, says that both the feasibility and optimality relations of every weighted relation in the language have to be a projection of a downset (in the 0-optimal case), or a projection of an upset (in the 1-optimal case). This shows that, surprisingly, s-tractability of valued constraint languages (that are not covered by the tractable languages with constants) does not depend on the rational-values in the weighted relations. It is only the structure of the underlying feasibility and optimality relations that matters. (However, the running time of our algorithm depends on these values.) Identifying this condition and establishing that it captures the precise borderline of s-tractability is our main contribution.

The hardness part of our result is proved in the same spirit as for $\{0, \infty\}$-valued and $\{0, 1\}$-valued languages by carefully analysing the types of weighted relations that can be obtained in gadgets in the surjective setting, and relying on the explicit dichotomy for Boolean VCSPs [8].

While 0-optimal and 1-optimal languages are trivially tractable for VCSPs, the algorithm for surjective VCSPs over the newly identified languages is nontrivial. The s-tractability part of our result is established by a reduction from $\overline{\mathbb{Q}}$-valued $\mathrm{VCSP_s}$ to the *Generalised Min-Cut* problem (defined in Section 3), in which we require to find in polynomial time all α-optimal solutions, where α is a constant depending on the (finite) valued constraint language. The algorithm for the Generalised Min-Cut problem is essentially the same as in [24]. We show that the algorithm works in the more general setting with one part of the objective function being a $(\mathbb{Q}_{\geq 0} \cup \{\infty\})$-valued superadditive set function given by an oracle; see Section 3 for the details. By providing a tighter analysis we are able to improve the bound on the running time from roughly $O(n^{3^{3\alpha}})$ to $O(n^{20\alpha})$, thus answering one of the open problems from [24].

[1] A weighted relation is 0-optimal (1-optimal) if the all-zero (all-one) tuple minimises it.

We also show that the dependence of the running time on the language is unavoidable unless P = NP (cf. Example 27).

All omitted proofs are available in the full version of the paper [14].

Related work. Recent years have seen some remarkable progress on the computational complexity of CSPs and VCSPs parametrised by the (valued) constraint language, see [1] for a survey. We highlight the resolution of the "bounded width conjecture" [2] and the result that a dichotomy for CSPs, conjectured in [11], implies a dichotomy for VCSPs [19, 18]. All this work is for arbitrary (and thus not necessarily Boolean) finite domains and relies on the so-called algebraic approach initiated in [6] and nicely described in a recent survey [3]. One of the important aspects of the algebraic approach is the assumption that constants are present in (valued) constraint languages. (This is without loss of generality with respect to polynomial-time solvability.) It is the lack of constants in the surjective setting that makes it difficult, if not impossible, to employ the algebraic approach in this setting. See the work of Chen [7] for an initial attempt.

For a binary (unweighted) relation γ, $\mathrm{VCSP_s}(\{\gamma\})$ has been studied under the name of surjective γ-Colouring [4, 20] and vertex-compaction [26]. We remark that our notion of surjectivity is global. For the γ-Colouring problem, a local version of surjectivity has also been studied [13, 12].

2 Preliminaries

We denote by $\leq_p$ the standard polynomial-time Turing reduction. If $A \leq_p B$ and $B \leq_p A$ we write $A \equiv_p B$.

We use the notation $[n] = \{1, \dots, n\}$. For any tuple $\mathbf{x} \in D^r$, we refer to its ith element as x_i. For $\mathbf{x}, \mathbf{y} \in D^r$, we define $\mathbf{x} \leq \mathbf{y}$ if and only if $x_i \leq y_i$ for all $i \in [r]$.

We define *relations* as a special case of weighted relations with range $\{c, \infty\}$, where value $c \in \mathbb{Q}$ is assigned to tuples that are elements of the relation in the conventional sense. We will use both views interchangeably and choose $c = 0$ unless stated otherwise. Relations are also called unweighted or *crisp*.

If $\mathbf{s} \in [r]^n$ is a tuple of coordinates then for any $\mathbf{x} \in D^r$ we denote its projection to $\mathbf{s}$ by $\mathrm{Pr}_{\mathbf{s}}(\mathbf{x}) = (x_{s_1}, \dots, x_{s_n}) \in D^n$. For any relation ρ, we define $\mathrm{Pr}_{\mathbf{s}}(\rho) = \{\mathrm{Pr}_{\mathbf{s}}(\mathbf{x}) \mid \mathbf{x} \in \rho\}$. Note that the coordinates in $\mathbf{s}$ may repeat.

We denote by $\rho_=$ the binary equality relation $\{(x, x) \mid x \in D\}$. Recall from Section 1 that we denote, for any $d \in D$, by ρ_d the unary relation $\{(d)\}$, i.e. $\rho_d(x) = 0$ if $x = d$ and $\rho_d(x) = \infty$ if $x \neq d$.

▶ **Definition 1.** For a weighted relation $\gamma : D^r \to \overline{\mathbb{Q}}$, we denote by

- $\mathrm{Feas}(\gamma) = \{\mathbf{x} \in D^r \mid \gamma(\mathbf{x}) < \infty\}$ the underlying *feasibility relation*; and by
- $\mathrm{Opt}(\gamma) = \{\mathbf{x} \in \mathrm{Feas}(\gamma) \mid \gamma(\mathbf{x}) \leq \gamma(\mathbf{y}) \text{ for every } \mathbf{y} \in D^r\}$ the relation of *optimal* tuples.

We define $\mathrm{Feas}(\Gamma) = \{\mathrm{Feas}(\gamma) \mid \gamma \in \Gamma\}$ and $\mathrm{Opt}(\Gamma) = \{\mathrm{Opt}(\gamma) \mid \gamma \in \Gamma\}$.

An assignment $s : V \to D$ for a VCSP instance $I = (V, D, \phi_I)$ with $V = \{x_1, \dots, x_n\}$ is called *feasible* if $\phi_I(s(x_1), \dots, s(x_n)) < \infty$; s is called *optimal* if $\phi_I(s) \leq \phi_I(s')$ for every assignment s'.

Recall from Section 1 that any set of weighted relation Γ is called a valued constraint language. Γ is called *s-tractable* if for any finite subset $\Gamma' \subseteq \Gamma$ any instance of $\mathrm{VCSP_s}(\Gamma')$ can be solved in polynomial time. Γ is called *s-intractable* if $\mathrm{VCSP}(\Gamma')$ is NP-hard for some finite $\Gamma' \subseteq \Gamma$.

We apply a k-ary operation $h : D^k \to D$ to k r-tuples componentwise; i.e. $h(\mathbf{x}^1, \dots, \mathbf{x}^k) = (h(x_1^1, x_1^2, \dots, x_1^k), h(x_2^1, x_2^2, \dots, x_2^k), \dots, h(x_r^1, x_r^2, \dots, x_r^k))$.

The following notion is at the heart of the algebraic approach to decision CSPs [6].

▶ **Definition 2.** Let γ be a weighted relation on D. A k-ary operation $h : D^k \to D$ is a *polymorphism* of γ (and γ is *invariant under* or *admits* h) if, for every $\mathbf{x}^1, \dots, \mathbf{x}^k \in \mathrm{Feas}(\gamma)$, we have $h(\mathbf{x}^1, \dots, \mathbf{x}^k) \in \mathrm{Feas}(\gamma)$. We say that h is a polymorphism of a language Γ if it is a polymorphism of every $\gamma \in \Gamma$.

The following notion, which involves a collection of k k-ary polymorphisms, plays an important role in the complexity classification of Boolean valued constraint languages [8].

▶ **Definition 3.** Let γ be a weighted relation on D. A list $\langle h_1, \dots, h_k \rangle$ of k-ary polymorphisms of γ is a k-ary *multimorphism* of γ (and γ *admits* $\langle h_1, \dots, h_k \rangle$) if, for every $\mathbf{x}^1, \dots, \mathbf{x}^k \in \mathrm{Feas}(\gamma)$, we have

$$\sum_{i=1}^{k} \gamma(h_i(\mathbf{x}^1, \dots, \mathbf{x}^k)) \;\leq\; \sum_{i=1}^{k} \gamma(\mathbf{x}^i)\,.$$

$\langle h_1, \dots, h_k \rangle$ is a multimorphism of a language Γ if it is a multimorphism of every $\gamma \in \Gamma$.

Boolean VCSPs

For the rest of the paper let $D = \{0, 1\}$. We define some important operations on D. For any $a \in D$, c_a is the constant unary operation such that $c_a(x) = a$ for all $x \in D$. Operation $\neg$ is the unary negation, i.e. $\neg(0) = 1$ and $\neg(1) = 0$. Binary operation min (max) returns the smaller (larger) of its two arguments with respect to the order $0 < 1$. Ternary operation Mn (for minority) is the unique ternary operation on D satisfying $\mathrm{Mn}(x, x, y) = \mathrm{Mn}(x, y, x) = \mathrm{Mn}(y, x, x) = y$ for all $x, y \in D$. Ternary operation Mj (for majority) is the unique ternary operation on D satisfying $\mathrm{Mj}(x, x, y) = \mathrm{Mj}(x, y, x) = \mathrm{Mj}(y, x, x) = x$ for all $x, y \in D$.

▶ **Theorem 4** ([8])**.** *Let Γ be a Boolean valued constraint language. Then, Γ is tractable if it admits any the following eight multimorphisms $\langle c_0 \rangle$, $\langle c_1 \rangle$, $\langle \min, \min \rangle$, $\langle \max, \max \rangle$, $\langle \min, \max \rangle$, $\langle \mathrm{Mn}, \mathrm{Mn}, \mathrm{Mn} \rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mj} \rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn} \rangle$. Otherwise, Γ is intractable.*

We note that Theorem 4 is a generalisation of Schaefer's classification of $\{0, \infty\}$-valued constraint languages [21] and Creignou's classification of $\{0, 1\}$-valued constraint languages [9].

The following definition is new in this paper and crucial for our main result.

▶ **Definition 5.** A relation ρ is a *downset (upset)* if for any $\mathbf{x}, \mathbf{y}$ such that $\mathbf{x} \geq \mathbf{y}$ ($\mathbf{x} \leq \mathbf{y}$) and $\mathbf{x} \in \rho$ it holds $\mathbf{y} \in \rho$. We will refer to relations that are a projection of a downset (upset) as *PDS (PUS)*. A weighted relation γ is called a *PDS (PUS) weighted relation* if both $\mathrm{Feas}(\gamma)$ and $\mathrm{Opt}(\gamma)$ are PDS (PUS). A language Γ is called PDS (PUS) if every weighted relation from Γ is PDS (PUS).

▶ **Example 6.** Relation $\rho = \{(0, 0), (0, 1), (1, 0)\}$ is a downset and hence also a PDS, while $\rho' = \{(0, 0, 0), (0, 1, 1), (1, 0, 0)\}$ is a PDS (as $\rho' = \mathrm{Pr}_{(1,2,2)}(\rho)$) but not a downset. Relation $\rho_=$ is a PDS relation and also a PDS weighted relation.

As one of the reviewers pointed out, PDS (PUS) relations are characterised by the binary polymorphism $x \wedge \neg y$ ($\neg x \vee y$).

▶ **Observation 7.** *Any PDS relation can be written as a sum of a downset and binary equality relations. More formally, if $\rho : D^r \to \{0, \infty\}$ is a PDS then we can write*

$$\rho(x_1, \ldots, x_r) \;=\; \rho'(x_{\pi(1)}, \ldots, x_{\pi(r')}) + \sum_{j=r'+1}^{r} \rho_{=}(x_{\pi(j)}, x_{i_j}),$$

where $\rho' : D^{r'} \to \{0, \infty\}$ is a downset, π is a permutation of $[r]$, and $i_j \in \{\pi(1), \ldots, \pi(r')\}$ for every $r' + 1 \le j \le r$.

The following result is our main contribution.

▶ **Theorem 8 (Main).** *Let Γ be a Boolean valued constraint language. Then, Γ is s-tractable if it admits any of the following six multimorphisms $\langle \min, \min \rangle$, $\langle \max, \max \rangle$, $\langle \min, \max \rangle$, $\langle \mathrm{Mn}, \mathrm{Mn}, \mathrm{Mn} \rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mj} \rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn} \rangle$, or Γ is PDS, or Γ is PUS. Otherwise, Γ is s-intractable.*

Theorem 8 generalises the following two previously established results.

▶ **Theorem 9** ([10])**.** *Let Γ be a Boolean $\{0, \infty\}$-valued constraint language. Then, Γ is s-tractable if it admits any of the following four polymorphisms* min*,* max*,* Mn*,* Mj*. Otherwise, Γ is s-intractable.*

▶ **Theorem 10** ([24])**.** *Let Γ be a Boolean $\{0, 1\}$-valued constraint language. Then, Γ is s-tractable if it admits the $\langle \min, \max \rangle$ multimorphism, or Γ is PDS, or Γ is PUS. Otherwise, Γ is s-intractable.*

Theorem 10 is stated differently in [24] as the definition of PDS (PUS) languages is introduced in this paper. In fact, it was not a priori clear what the right condition for tractability should be for $\overline{\mathbb{Q}}$-valued constraint languages. Note that for $\{0, 1\}$-valued languages, the condition Feas(Γ) being PDS or PUS is vacuously true. Thus, a $\{0, 1\}$-valued language Γ is PDS (PUS) if Opt(Γ) is PDS (PUS) and this is equivalent to Γ being almost-min-min (almost-max-max) [24].

Recall that $\neg$ is the unary negation operation. For a weighted relation γ, we define $\neg(\gamma)$ to be the weighted relation $\neg(\gamma)(\mathbf{x}) = \gamma(\neg(\mathbf{x}))$. For a language Γ, we define $\neg(\Gamma) = \{\neg(\gamma) \mid \gamma \in \Gamma\}$.

The following observation follows from Definition 5.

▶ **Observation 11.** *A valued constraint language Γ is PDS if and only if $\neg(\Gamma)$ is PUS.*

▶ **Lemma 12.** *For a Boolean valued constraint language Γ, $\mathrm{VCSP}_{\mathrm{s}}(\Gamma) \equiv_p \mathrm{VCSP}_{\mathrm{s}}(\neg(\Gamma))$.*

Proof of Theorem 8. The s-tractability of languages admitting any of the six multimorphisms in the statement of the theorem follows from Theorem 4 via the reduction $\mathrm{VCSP}_{\mathrm{s}}(\Gamma) \le_p \mathrm{VCSP}(\Gamma \cup \{\rho_0, \rho_1\})$ discussed in the introduction. The s-tractability of PDS languages follows from Theorem 19, proved in Section 3. The s-tractability of PUS languages is then a simple corollary of Theorem 19, Observation 11, and Lemma 12.

The s-intractability of the remaining languages is proved in the full version of the paper [14]. The key in the hardness proof is to identify certain operators on weighted relations that preserve s-tractability, polymorphisms for crisp relations and multimorphisms for weighted relations, thus allowing for the construction of hardness gadgets. These operators include scaling by a nonnegative rational, adding a rational, permutation of arguments, identification of arguments, addition, the Feas($\cdot$) and Opt($\cdot$) operators, and pinning labels to variables (assuming the corresponding crisp constant is available). ◀

3 Tractability of PDS languages

We prove that PDS languages are s-tractable by a reduction to a generalised variant of the Min-Cut problem. The problem and the reduction are stated in Subsection 3.1. The tractability of the Generalised Min-Cut problem is established in Subsection 3.2.

3.1 Reduction to the Generalised Min-Cut problem

Let V be a finite set. A *set function* on V is a function $f : 2^V \to \mathbb{Q}_{\geq 0} \cup \{\infty\}$ with $f(\emptyset) = 0$.

▶ **Definition 13.** A set function $f : 2^V \to \mathbb{Q}_{\geq 0} \cup \{\infty\}$ is *increasing* if $f(X) \leq f(Y)$ for all $X \subseteq Y \subseteq V$; it is *superadditive* if $f(X) + f(Y) \leq f(X \cup Y)$ for all disjoint $X, Y \subseteq V$; it is *posimodular* if $f(X) + f(Y) \geq f(X \setminus Y) + f(Y \setminus X)$ for all $X, Y \subseteq V$; and finally it is *submodular* if $f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y)$ for all $X, Y \subseteq V$.

It is known and easy to show that any superadditive set function is also increasing.

▶ **Example 14.** Let U be a finite set and $T \subseteq U$ a non-empty subset. We define a set function f on U by $f(X) = 1$ if $T \subseteq X$ and $f(X) = 0$ otherwise. Intuitively, this corresponds to a soft NAND constraint if we interpret T as its scope and X as the set of variables assigned *true*. The set function f is superadditive, and hence also increasing.

We now formally define the Min-Cut problem introduced in Section 1.

▶ **Definition 15.** An instance of the *Min-Cut* (MC) problem is given by a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{Q}_{>0}$. The goal is to minimise the objective function g, which is a set function on V defined by $g(X) = \sum_{\{u,v\} \in E, |\{u,v\} \cap X| = 1} w(u, v)$.

Note that g from Definition 15 is posimodular.

Any set X such that $\emptyset \subsetneq X \subsetneq V$ is called a *solution* of the MC problem. Note that a cut $(X, V \setminus X)$ corresponds to two solutions, namely X and $V \setminus X$. Any solution that minimises the objective function g is called *optimal*, and any optimal solution with no proper subset being an optimal solution is called *minimal*. Note that any two different minimal optimal solutions X, Y are disjoint, as $X \setminus Y$ and $Y \setminus X$ are also optimal solutions (by the posimodularity of g).

We now define the Generalised Min-Cut problem, which is key to establishing Theorem 8.

▶ **Definition 16.** Let $G = (V, E)$ be an undirected graph with edge weights $w : E \to \mathbb{Q}_{>0}$. Let g be the objective function of the Min-Cut problem on G and f a superadditive set function on V given by an oracle. A solution to the *Generalised Min-Cut* (GMC) problem is any set X such that $\emptyset \subsetneq X \subsetneq V$, and the objective is to minimise the value of $f(X) + g(X)$.

We will denote this minimum by λ. A solution achieving the minimum is called *optimal*. In case of $0 < \lambda < \infty$, we will also be looking for all α-*optimal* solutions (for $\alpha \geq 1$) to the problem, i.e. solutions X such that $f(X) + g(X) \leq \alpha\lambda$. As shown in Subsection 3.2, Theorem 26, this can be done in polynomial time (for a fixed α).

Uppman [24] used the term "Generalised Min-Cut problem" for a special case of Definition 16, in which the superadditive function f is given explicitly as a weighted sum of soft NANDs (cf. Example 14).

Our reduction from the surjective VCSP over a PDS language to the GMC problem is based on the following notion.

▶ **Definition 17.** Let γ be an r-ary weighted relation on domain $D = \{0, 1\}$. We will associate any r-tuple $\mathbf{x} \in D^r$ with the set $X = \{i \in [r] \mid x_i = 1\}$ and use them interchangeably.

Let J be an instance of the GMC problem on vertices $[r]$ with $J(X)$ denoting the objective value for any $\mathbf{x} \in D^r$ (including the all-zero and all-one tuples, which correspond to non-solutions $\emptyset$ and $[r]$). For any $\alpha \geq 1$, we say that J *α-approximates* γ if $J(X) \leq \gamma(\mathbf{x}) \leq \alpha \cdot J(X)$ for all $\mathbf{x} \in D^r$.

▶ **Lemma 18.** *Let γ be a weighted relation such that* $\mathrm{Feas}(\gamma)$ *is a downset,* $\mathrm{Opt}(\gamma)$ *is a PDS, and $\gamma(\mathbf{x}) = 0$ for $\mathbf{x} \in \mathrm{Opt}(\gamma)$. There is a constant α and an instance of the GMC problem that α-approximates γ.*

Proof. We define a set function f_{Feas} on $[r]$ as $f_{\mathrm{Feas}}(X) = 0$ if $\mathbf{x} \in \mathrm{Feas}(\gamma)$ and $f_{\mathrm{Feas}}(X) = \infty$ otherwise. Because $\mathrm{Feas}(\gamma)$ is a downset, f_{Feas} is superadditive.

By Observation 7, we can write $\mathrm{Opt}(\gamma)$ as a sum of a downset ρ on coordinates $A \subseteq [r]$ and equalities $x_i = x_j$ for $(i, j) \in E$ with $|A| + |E| = r$. Let $\mathbf{x}|_A$ denote the projection of an r-tuple $\mathbf{x}$ to coordinates A in the same order as in ρ. We define a set function f_{Opt} on $[r]$ as $f_{\mathrm{Opt}}(X) = 0$ if $\mathbf{x}|_A \in \rho$ and $f_{\mathrm{Opt}}(X) = |X \cap A|$ otherwise. Because ρ is a downset, f_{Opt} is superadditive.

We define a GMC instance J' on vertices $[r]$, unit-weight edges E, and the superadditive set function $f_{\mathrm{Feas}} + f_{\mathrm{Opt}}$. By the construction, it holds

$$J'(X) = \infty \iff f_{\mathrm{Feas}}(X) = \infty \iff \mathbf{x} \notin \mathrm{Feas}(\gamma) \iff \gamma(\mathbf{x}) = \infty \tag{1}$$

and

$$\begin{aligned} J'(X) = 0 &\iff f_{\mathrm{Feas}}(X) = f_{\mathrm{Opt}}(X) = 0 \ \wedge\ |\{i, j\} \cap X| \neq 1 \text{ for all } (i, j) \in E && (2)\\ &\iff \mathbf{x} \in \mathrm{Feas}(\gamma) \ \wedge\ \mathbf{x}|_A \in \rho \ \wedge\ x_i = x_j \text{ for all } (i, j) \in E && (3)\\ &\iff \mathbf{x} \in \mathrm{Opt}(\gamma) \iff \gamma(\mathbf{x}) = 0\,. && (4) \end{aligned}$$

Moreover, for any X such that $0 < J'(X) < \infty$ it holds $1 \leq J'(X) \leq r$.

If γ is crisp then the instance J' 1-approximates γ; otherwise let $\delta_{\min}, \delta_{\max}$ denote the minimum and maximum of $\{\gamma(\mathbf{x}) \mid 0 < \gamma(\mathbf{x}) < \infty\}$. We scale the weights of the edges and the superadditive function of J' by a factor of $\delta_{\min}/r$ to obtain an instance J such that $J(X) \leq \gamma(\mathbf{x})$ for all X. Setting $\alpha = r \cdot \delta_{\max}/\delta_{\min}$ then gives $\gamma(\mathbf{x}) \leq \alpha \cdot J(X)$ for all X. ◀

Finally, we state the reduction.

▶ **Theorem 19.** *Let Γ be a Boolean valued constraint language. If Γ is PDS, then it is s-tractable.*

Proof. Let $\Gamma' \subseteq \Gamma$ be a finite language. The feasibility relation $\mathrm{Feas}(\gamma)$ for any $\gamma \in \Gamma'$ is a PDS and hence, by Observation 7, a sum of a downset and binary equality relations. A crisp equality constraint $\rho_=(x, y)$ in an instance can be omitted after identifying the variables x and y. Therefore, we will assume that $\mathrm{Feas}(\gamma)$ is a downset. Moreover, we will assume that the minimum value assigned by γ is 0, as changing values $\gamma(\mathbf{x})$ by the same constant for all $\mathbf{x} \in D^{\mathrm{ar}(\gamma)}$ affects all assignments equally.

By Lemma 18, for any $\gamma \in \Gamma'$, there is a constant α_γ and a GMC instance J_γ that α_γ-approximates γ. Let α be the smallest integer such that $\alpha \geq \alpha_\gamma$ for all $\gamma \in \Gamma'$.

Given a $\mathrm{VCSP_s}(\Gamma')$ instance I with an objective function $\phi_I(x_1, \ldots, x_n) = \sum_{i=1}^{q} w_i \cdot \gamma_i(\mathbf{x}^i)$, we construct a GMC instance J that α-approximates ϕ_I. For $i \in [q]$, we relabel the vertices of J_{γ_i} to match the variables in the scope $\mathbf{x}^i$ of the ith constraint (i.e. vertex j is relabelled

to x^i_j) and identify vertices in case of repeated variables. We also scale both the weights of the edges of J_{γ_i} and the superadditive function by w_i. The instance J is obtained by adding up the GMC instances J_{γ_i} for all $i \in [q]$.

Let $\mathbf{x} \in D^n$ denote a surjective assignment minimising ϕ_I and $\mathbf{y} \in D^n$ an optimal solution to J with $J(Y) = \lambda$. Because J α-approximates ϕ_I, it holds

$$\lambda \leq J(X) \leq \phi_I(\mathbf{x}) \leq \phi_I(\mathbf{y}) \leq \alpha \cdot J(Y) = \alpha\lambda\,, \tag{5}$$

and hence $\mathbf{x}$ is an α-optimal solution to J. By Lemma 20 in Subsection 3.2, we can determine whether $\lambda = 0$, in which case any optimal solution to J is also optimal for ϕ_I; and whether $\lambda = \infty$. If $0 < \lambda < \infty$, we find all α-optimal solutions by Theorem 26 in Subsection 3.2. ◀

3.2 Tractability of the Generalised Min-Cut problem

Proofs of Lemmas 20, 21, and 23 can be found in the full version of the paper [14].

▶ **Lemma 20.** *There is a polynomial-time algorithm that, given an instance of the GMC problem, either finds a solution X with $f(X) + g(X) = 0$, or determines that $\lambda = \infty$, or determines that $0 < \lambda < \infty$.*

In view of Lemma 20, we can assume that $0 < \lambda < \infty$. Our goal is to show that, for a given $\alpha \geq 1$, all α-optimal solutions to a GMC instance can be found in polynomial time. This will be proved in Theorem 26; before that we need to prove several auxiliary lemmas on properties of the MC and GMC problems.

▶ **Lemma 21.** *For any instance J of the GMC problem on a graph $G = (V, E)$ and any non-empty set $V' \subseteq V$, there is an instance J' on the induced subgraph $G[V']$ that preserves the objective value of all solutions $X \subsetneq V'$. In particular, any α-optimal solution X of J such that $X \subsetneq V'$ is α-optimal for J' as well.*

▶ **Lemma 22.** *Let X be an optimal solution to an instance of the GMC problem over vertices V with $\lambda < \infty$, and Y a minimal optimal solution to the underlying MC problem. Then $X \subseteq Y$, $X \subseteq V \setminus Y$, or X is an optimal solution to the underlying MC problem.*

Proof. Assume that $X \not\subseteq Y$ and $X \not\subseteq V \setminus Y$. If $Y \subseteq X$, we have $f(Y) \leq f(X)$ as f is increasing, and hence $f(Y) + g(Y) \leq f(X) + g(X) < \infty$. Therefore, Y is optimal for the GMC problem and X is optimal for the MC problem. In the rest, we assume that $Y \not\subseteq X$.

By the posimodularity of g we have $g(X) + g(Y) \geq g(X \setminus Y) + g(Y \setminus X)$. Because $Y \setminus X$ is a proper non-empty subset of Y, it holds $g(Y \setminus X) > g(Y)$, and hence $g(X) > g(X \setminus Y)$. But then $f(X) + g(X) > f(X \setminus Y) + g(X \setminus Y)$ as $\infty > f(X) \geq f(X \setminus Y)$. Set $X \setminus Y$ is non-empty, and therefore contradicts the optimality of X. ◀

The following lemma relates the number of optimal solutions and the number of minimal optimal solutions to the MC problem. Note that this bound is tight for (unweighted) paths and cycles with at most one path attached to each vertex.

▶ **Lemma 23.** *For any instance of the MC problem on a connected graph with n vertices and p minimal optimal solutions, there are at most $p(p-1) + 2(n-p)$ optimal solutions.*

▶ **Lemma 24.** *For any instance of the GMC problem on n vertices with $0 < \lambda < \infty$, the number of optimal solutions is at most $n(n-1)$. There is an algorithm that finds all of them in polynomial time.*

Note that the bound of $n(n-1)$ optimal solutions precisely matches the known upper bound of $\binom{n}{2}$ for the number of minimum cuts [17]; the bound is tight for cycles.

Proof. Let $t(n)$ denote the maximum number of optimal solutions for such instances on n vertices. We prove the bound by induction on n. If $n = 1$, there are no solutions and hence $t(1) = 0$. For $n \geq 2$, let $Y_1, \ldots, Y_p$ be the minimal optimal solutions to the underlying MC problem. As there exists at least one minimum cut and the minimal optimal solutions are all disjoint, it holds $2 \leq p \leq n$.

Suppose that the minimal optimal solutions cover all vertices, i.e. $\bigcup Y_i = V$. By Lemma 22, any optimal solution to the GMC problem is either a proper subset of some Y_i or an optimal solution to the underlying MC problem. Restricting solutions to a proper subset of Y_i is by Lemma 21 equivalent to considering a GMC problem instance on vertices Y_i, and hence the number of such optimal solutions is bounded by $t(|Y_i|) \leq |Y_i| \cdot (|Y_i| - 1)$. Note that the sum $\sum |Y_i| \cdot (|Y_i| - 1)$ is maximised when $p - 1$ of the sets Y_i are singletons and the size of the remaining one equals $n - p + 1$. If the graph is connected then, by Lemma 23, there are at most $p(p-1) + 2(n-p)$ optimal solutions to the underlying MC problem. Adding these upper bounds we get

$$p(p-1) + 2(n-p) + \sum_{i=1}^{p} |Y_i| \cdot (|Y_i| - 1) \tag{6}$$

$$\leq p(p-1) + 2(n-p) + (p-1) \cdot 1 \cdot 0 + (n-p+1) \cdot (n-p) \tag{7}$$

$$= n(n-1) - 2(p-2) \cdot (n-p) \tag{8}$$

$$\leq n(n-1)\,. \tag{9}$$

If the graph is disconnected, the sets $Y_1, \ldots, Y_p$ are precisely its connected components. The optimal solutions to the underlying MC problem are precisely unions of connected components (with the exception of $\emptyset$ and V), which means that there can be exponentially many of them. However, only the sets $Y_1, \ldots, Y_p$ themselves can be optimal solutions to the GMC problem: We have $0 < \lambda \leq f(Y_i) + g(Y_i) = f(Y_i)$. Because f is superadditive, it holds $f(Y_{i_1} \cup \cdots \cup Y_{i_k}) \geq f(Y_{i_1}) + \cdots + f(Y_{i_k}) \geq k\lambda$ for any distinct $i_1, \ldots, i_k$, and hence no union of two or more connected components can be an optimal solution to the GMC problem. This gives us an upper bound of $p \leq p(p-1) + 2(n-p)$, and the rest follows as in the previous case.

Finally, suppose that $\bigcup Y_i \neq V$, and hence the graph is connected. This case can be handled similarly as for $\bigcup Y_i = V$. (The full version of the paper [14] includes a complete proof.)

Using a procedure generating all minimum cuts [25], it is straightforward to turn the above proof into a recursive algorithm that finds all optimal solutions in polynomial time. ◀

▶ **Lemma 25.** *Let $\alpha, \beta \geq 1$. Let X be an α-optimal solution to an instance of the GMC problem over vertices V with $0 < \lambda < \infty$, and Y an optimal solution to the underlying MC problem. If $g(Y) < \lambda/\beta$, then*

$$(f(X \setminus Y) + g(X \setminus Y)) + (f(X \cap Y) + g(X \cap Y)) < \left(\alpha + \frac{2}{\beta}\right) \lambda\,; \tag{10}$$

if $g(Y) \geq \lambda/\beta$, then X is an $\alpha\beta$-optimal solution to the underlying MC problem.

Proof. If $g(Y) \geq \lambda/\beta$, it holds $g(X) \leq f(X) + g(X) \leq \alpha\lambda \leq \alpha\beta \cdot g(Y)$, and hence X is an $\alpha\beta$-optimal solution to the underlying MC problem. In the rest we assume that $g(Y) < \lambda/\beta$.

Because g is posimodular, we have

$$g(X) + g(Y) \geq g(X \setminus Y) + g(Y \setminus X) \tag{11}$$
$$g(Y) + g(Y \setminus X) \geq g(X \cap Y) + g(\emptyset)\,, \tag{12}$$

and hence

$$g(X) + 2g(Y) \geq g(X \setminus Y) + g(X \cap Y)\,. \tag{13}$$

By superadditivity of f, it holds $f(X) \geq f(X \setminus Y) + f(X \cap Y)$. The claim then follows from the fact that $f(X) + g(X) + 2g(Y) < (\alpha + 2/\beta)\lambda$. ◀

Finally, we prove that α-optimal solutions to the GMC problem can be found in polynomial time.

▶ **Theorem 26.** *For any instance of the GMC problem on n vertices with $0 < \lambda < \infty$ and $\alpha \in \mathbb{Z}_{\geq 1}$, the number of α-optimal solutions is at most $n^{20\alpha-15}$. There is an algorithm that finds all of them in polynomial time.*

Note that for a cycle on n vertices, the number of α-optimal solutions to the MC problem is $\Theta(n^{2\alpha})$, and thus the exponent in our bound is asymptotically tight in α.

Proof. Let $\beta \in \mathbb{Z}_{\geq 3}$ be a parameter. Throughout the proof, we relax the integrality restriction on α and require only that $\alpha\beta$ is an integer. For $\alpha = 1$, the claim follows from Lemma 24, therefore we assume $\alpha \geq 1 + 1/\beta$ in the rest of the proof.

Define $\ell(x) = \frac{2(\beta+1)}{\beta-2} \cdot (\beta x - 3)$. We will prove that the number of α-optimal solutions is at most $n^{\ell(\alpha)}$; taking $\beta = 4$ then gives the claimed bound. Function ℓ was chosen as a slowest growing function satisfying the following properties required in this proof: It holds $\ell(x) + \ell(y) \leq \ell(x + y - 3/\beta)$ for any x, y, and $\ell(x) \geq 2\beta x$ for any $x \geq 1 + 1/\beta$.

We prove the bound by induction on $n + \alpha\beta$. As it trivially holds for $n \leq 2$, we will assume $n \geq 3$ in the rest of the proof. Let Y be an optimal solution to the underlying MC problem with $k = |Y| \leq n/2$. If $g(Y) \geq \lambda/\beta$ then, by Lemma 25, any α-optimal solution to the GMC problem is an $\alpha\beta$-optimal solution to the underlying MC problem. Because $g(Y) \geq \lambda/\beta > 0$, the graph is connected, and hence there are at most $2^{2\alpha\beta}\binom{n}{2\alpha\beta} \leq n^{2\alpha\beta} \leq n^{\ell(\alpha)}$ such solutions by [17]. (In detail, [17, Theorem 6.2] shows that the number of $\alpha\beta$-optimal cuts in an n-vertex graph is $2^{2\alpha\beta-1}\binom{n}{2\alpha\beta}$, and every cut corresponds to two solutions.)

From now on we assume that $g(Y) < \lambda/\beta$ and hence inequality (10) holds. Upper bounds in this case may be quite loose; in particular, we will use the following inequalities:

$$(k/n)^{\ell(\alpha)} \leq (k/n)^{\ell(1+1/\beta)} = (k/n)^{2(\beta+1)} \leq (k/n)^8 \leq (k/n)(1/2)^7 = k/128n \tag{14}$$
$$(1/n)^{2\beta} \leq (1/n)^6 \leq (1/n)(1/3)^5 < 1/128n\,. \tag{15}$$

Consider any α-optimal solution to the GMC problem X.

If $X \subsetneq Y$ then, by Lemma 21, X is an α-optimal solution to an instance on vertices Y. By the induction hypothesis, there are at most $k^{\ell(\alpha)} \leq (k/128n) \cdot n^{\ell(\alpha)}$ such solutions.

Similarly, if $X \subsetneq V \setminus Y$, then X is an α-optimal solution to an instance on vertices $V \setminus Y$, and there are at most $(n-k)^{\ell(\alpha)} = (1-k/n)^{\ell(\alpha)} \cdot n^{\ell(\alpha)} \leq (1-k/n) \cdot n^{\ell(\alpha)}$ such solutions.

If $Y \subsetneq X$, then $X \setminus Y$ is an $(\alpha - 1 + 2/\beta)$-optimal solution on vertices $V \setminus Y$ by (10) and the fact that $f(X \cap Y) + g(X \cap Y) \geq \lambda$. Similarly, if $V \setminus Y \subsetneq X$, then $X \cap Y$ is an $(\alpha - 1 + 2/\beta)$-optimal solution on vertices Y. In either case, we bound the number of such solutions depending on the value of α: For $\alpha < 2 - 2/\beta$, there are trivially none; for

$\alpha = 2 - 2/\beta$, Lemma 24 gives a bound of $n(n-1) \leq n^{\ell(\alpha)-2\beta}$; and for $\alpha > 2 - 2/\beta$ we get an upper bound of $n^{\ell(\alpha-1+2/\beta)} \leq n^{\ell(\alpha)-2\beta}$ by the induction hypothesis. The number of solutions is thus at most $n^{\ell(\alpha)-2\beta} \leq (1/128n) \cdot n^{\ell(\alpha)}$ for any α.

Finally, we consider X such that $\emptyset \subsetneq X \setminus Y \subsetneq V \setminus Y$ and $\emptyset \subsetneq X \cap Y \subsetneq Y$, i.e. $X \setminus Y$ and $X \cap Y$ are solutions on vertices $V \setminus Y$ and Y respectively. Let i be the integer for which

$$\left(1 + \frac{i}{\beta}\right)\lambda \leq f(X \cap Y) + g(X \cap Y) < \left(1 + \frac{i+1}{\beta}\right)\lambda\,. \tag{16}$$

Then, by (10), it holds $f(X \setminus Y) + g(X \setminus Y) < (\alpha - 1 - (i-2)/\beta)\lambda$. Therefore, $X \cap Y$ is a $(1 + (i+1)/\beta)$-optimal solution on vertices Y and $X \setminus Y$ is an $(\alpha - 1 - (i-2)/\beta)$-optimal solution on vertices $V \setminus Y$. Because $0 \leq i \leq (\alpha - 2)\beta + 1$, we can bound the number of such solutions by the induction hypothesis as at most

$$k^{\ell\left(1+\frac{i+1}{\beta}\right)} \cdot (n-k)^{\ell\left(\alpha-1-\frac{i-2}{\beta}\right)} \leq \left(\frac{k}{n}\right)^{\ell\left(1+\frac{i+1}{\beta}\right)} \cdot n^{\ell\left(1+\frac{i+1}{\beta}\right)+\ell\left(\alpha-1-\frac{i-2}{\beta}\right)} \tag{17}$$

$$\leq \left(\frac{k}{n}\right)^{2(\beta+1)} \cdot \frac{1}{2^i} \cdot n^{\ell(\alpha)}\,, \tag{18}$$

which is at most $2 \cdot (k/128n) \cdot n^{\ell(\alpha)}$ in total for all i.

By adding up the bounds we get that the number of α-optimal solutions is at most $n^{\ell(\alpha)}$. A polynomial-time algorithm that finds the α-optimal solutions follows from the above proof using a procedure generating all $\alpha\beta$-optimal cuts [25]. ◀

4 Conclusions

While the complexity of (valued) constraint languages is, as in this paper, studied mostly for finite languages, all known results also hold for languages of infinite size. We now show that this is *not* the case for Boolean surjective VCSPs.

▶ **Example 27.** We give an example of an infinite Boolean valued constraint language Γ that is a PDS language but $\mathrm{VCSP_s}(\Gamma)$ is NP-hard.

Let $D = \{0, 1\}$. For any $w \in \mathbb{Z}_{\geq 1}$, we define $\gamma_w : D^3 \to \overline{\mathbb{Q}}$ by $\gamma(0,0,0) = 0$, $\gamma(\cdot,\cdot,0) = w$, $\gamma(x,y,1) = 2$ if $x = y$ and $\gamma(x,y,1) = 1$ if $x \neq y$. Note that $\mathrm{Feas}(\gamma_w) = D^3$ and $\mathrm{Opt}(\gamma_w) = \{(0,0,0)\}$ are PDS relations. Let $\Gamma = \{\gamma_w \mid w \in \mathbb{Z}_{\geq 1}\}$.

Given an instance $G = (V, E)$ of the Max-Cut problem with $V = \{x_1, \ldots, x_n\}$ and no isolated vertices, we choose a value $w > 2|E|$ and construct a $\mathrm{VCSP_s}(\Gamma)$ instance $I = (V \cup \{z\}, D, \phi_I)$ with $\phi_I(x_1, \ldots, x_n, z) = \sum_{\{i,j\} \in E, i<j} \gamma_w(x_i, x_j, z)$. Cuts in G are in one-to-one correspondence with assignments to I satisfying $z = 1$. In particular, a cut of value k corresponds to an assignment to I of value $k + 2(|E| - k) = 2|E| - k$. Moreover, any surjective assignment that assigns label 0 to variable z is of value at least $w > 2|E| \geq 2|E| - k$. Thus, solving I amounts to solving Max-Cut in G.

An obvious open problem is to consider surjective VCSPs on a three-element domain. A complexity classification is known for $\{0, \infty\}$-valued languages [5] and $\mathbb{Q}$-valued languages [15] (the latter generalises the $\{0, 1\}$-valued case obtained in [16]). In fact [18] implies a dichotomy for $\overline{\mathbb{Q}}$-valued languages on a three-element domain. However, all these results depend on the notion of core and the presence of constants in the language, and thus it is unclear how to use them to obtain a complexity classification in the surjective setting. Moreover, one special case of the CSP on a three-element domain is the *3-No-Rainbow-Colouring* problem [4], whose complexity status is open.

Abstract

In this paper we study the *shifts*, which are the shift-invariant and topologically closed sets of configurations over a finite alphabet in $\mathbb{Z}^d$. The *minimal shifts* are those shifts in which all configurations contain exactly the same patterns. Two classes of shifts play a prominent role in symbolic dynamics, in language theory and in the theory of computability: the *shifts of finite type* (obtained by forbidding a finite number of finite patterns) and the *effective shifts* (obtained by forbidding a computably enumerable set of finite patterns). We prove that every effective minimal shift can be represented as a factor of a projective subdynamics on a minimal shift *of finite type* in a bigger (by 1) dimension. This result transfers to the class of minimal shifts a theorem by M. Hochman known for the class of all effective shifts and thus answers an open question by E. Jeandel. We prove a similar result for quasiperiodic shifts and also show that there exists a quasiperiodic shift of finite type for which Kolmogorov complexity of all patterns of size $n \times n$ is $\Omega(n)$.

1 Introduction

The study of symbolic dynamics was initially motivated as a discretization of classic dynamical systems, [9]. Later, the focus of attention in this area shifted towards the questions related to computability theory. The central notion of symbolic dynamics is a *shift* (a.k.a. *subshift*), which is a set of configurations in $\mathbb{Z}^d$ over a finite alphabet, defined by a set of forbidden patterns. Two major notions – two classes of shifts – play now a crucial role in symbolic dynamics: shifts of *finite type* (SFT, the shift defined by a finite set of forbidden patterns) and *effective* shifts (a.k.a. *effectively closed* – shifts with an enumerable set of forbidden patterns). These classes are distinct: every SFT is effective, but in general the reverse implication does not hold. However, the differences between these classes is surprisingly subtle. It is known that every effective shift can be simulated in some sense by an SFT of higher dimension. More precisely, every effective shift in $\mathbb{Z}^d$ can be represented as a factor of the projective subdynamics of an SFT of dimension increased by 1, see [10, 6, 1].

Usually, the proofs of computability results in symbolic dynamics involve sophisticated algorithmic gadgets embedded in dynamical systems. The resulting constructions are typically intricate and somewhat artificial. So, even if the shifts (effective or SFT) in general are proven to have a certain algorithmic property, the known proof may be inappropriate for "natural"

* Supported by ANR-15-CE40-0016-01 RaCAF grant

dynamical systems. Thus, it is interesting to understand the limits of the known algorithmic techniques and find out whether the remarkable properties of algorithmic complexity can be extended to "simple" and mathematically "natural" types of shifts.

One of the classic natural types of dynamical systems is the class of *minimal shifts*. Minimal shifts are those containing no proper shift, or equivalently the shifts where all configurations have exactly the same patterns. The role minimal shifts play in symbolic dynamics is similar to the role simple groups play in group theory (in particular every nonempty shift contains a nonempty minimal shift, see a discussion in [4]). Notice that all minimal shifts are quasiperiodic (but the converse is not true). Intuitively it seems that the structure of a minimal shift must be simple (in terms of dynamical systems). Besides, minimal shifts cannot be "too complex" in algorithmic terms. Indeed, it is known that every effective minimal shift has a computable language of patterns, and it contains at least one computable configuration [10] (which is in general not the case for effective shifts and even for SFT). Nevertheless, minimal shifts can have quite nontrivial algorithmic properties [13, 11].

We have mentioned above that every effective shift $\mathcal{S}$ can be represented as a factor of a projective subdynamics of an SFT $\mathcal{S}'$ (of higher dimension). In the previously known proofs of this result [10, 6, 1], even if $\mathcal{S}$ is minimal, the structure of the corresponding SFT $\mathcal{S}'$ (that simulates by its projective subdynamics the given $\mathcal{S}$) can be very sophisticated (and far from being minimal). So, a natural question arises (E. Jeandel, [12]): is it true that every effective minimal (or quasiperiodic) shift can be represented as a factor of a projective subdynamics on a minimal (respectively, quasiperiodic) SFT of higher dimension? In this paper we give a positive answer to that questions.

The full proof of the main result of this paper is rather cumbersome for the following reason: we use the technique of self-simulating tilings (e.g., [6, 7, 16]) combined with some combinatorial lemmas on quasiperiodic configurations. Unfortunately, there is no clean separation between the generic technique of self-simulating tilings and the supplementary features embedded in this type of tilings, so we cannot use the (previously known) technique of self-simulation as a "black box". We have to re-explain the core techniques of fixed-point programming embedded in tilings and adjust the supplementary features within the construction. While explaining the proofs, we have to balance clarity with formality, and given the usual space limits of the conference paper we have to sketch some standard parts of the proof. An extended version of this paper is published on `arXiv:1705.01876`.

1.1 Notation and basic definitions

Let Σ be a finite set (an alphabet). Fix an integer $d > 0$. A Σ-*configuration* is a mapping $\mathbf{f} : \mathbb{Z}^d \to \Sigma$. A $\mathbb{Z}^d$-*shift* (or just a *shift* if d is clear from the context) is a set of configuration that is (i) shift-invariant (with respect to the translations along each coordinate axis), and (ii) closed in Cantor's topology.

A *pattern* is a mapping from a finite subset in $\mathbb{Z}^d$ to Σ (a coloring of a finite set of $\mathbb{Z}^d$). Every shift can be defined by a set of forbidden finite patterns F (a configuration belongs to the shift if and only if it does not contain any pattern from F). A shift is called *effective* (or *effectively closed*) if it can be defined by a computably enumerable set of forbidden patterns. A shift is called a *shift of finite type* (SFT), if it can be defined by a finite set of forbidden patterns.

A special class of a 2-dimensional SFT is defined in terms of *Wang tiles*. In this case we interpret the alphabet Σ as a set of *tiles* – unite squares with colored sides, assuming that all colors belong to some finite set C (we assign one color to each side of a tile, so technically Σ is a subset of C^4). A (valid) *tiling* is a set of all configurations where every two neighboring

tiles match, i.e., share the same color on the adjacent sides. Wang tiles are powerful enough to simulate any SFT in a very strong sense: for each SFT $\mathcal{S}$ there exists a set of Wang tiles τ such that the set of all τ-tilings is isomorphic to $\mathcal{S}$. In this paper we focus on tilings since Wang tiles perfectly suit the technique of self-simulation.

A shift $\mathcal{S}$ (in the full shift $\Sigma^{\mathbb{Z}^d}$) can be interpreted as a dynamical system. There are d shifts along each of the coordinates, and each of these shifts map $\mathcal{S}$ to itself. So, the group $\mathbb{Z}^d$ naturally acts on $\mathcal{S}$.

For any shift $\mathcal{S}$ on $\mathbb{Z}^d$ and for any k-dimensional sublattice L in $\mathbb{Z}^d$, the *L-projective subdynamics* $\mathcal{S}_L$ of $\mathcal{S}$ is the set of configurations of $\mathcal{S}$ restricted on L. The L-projective subdynamics of a $\mathbb{Z}^d$-shift can be understood as a $\mathbb{Z}^k$-shift (notice that L naturally acts on $\mathcal{S}_L$). In particular, for every $d' < d$ we have a *standard* $\mathbb{Z}^{d'}$-projective subdynamics on the shift $\mathcal{S}$ generated by the lattice spanned on the first d' coordinate axis. In the proofs of Theorems 1-2 we deal with the standard $\mathbb{Z}^{(d-1)}$-projective subdynamics on $\mathbb{Z}^d$-shifts.

A configuration ω is called *recurrent* if every pattern that appears in ω at least once, must then appear in this configuration infinitely often. A configuration ω is called *quasiperiodic* (or *uniformly recurrent*) if every pattern P that appears in ω at least once, must appear in every pattern Q large enough in ω. Notice that every periodic configuration is also quasiperiodic. It is easy to see that if a shift $\mathcal{S}$ is minimal, then every $\omega \in \mathcal{S}$ is quasiperiodic.

For a quasiperiodic configuration ω, its *function of a quasiperiodicity* is a mapping $\varphi : \mathbb{N} \to \mathbb{N}$ such that every finite pattern of diameter n either never appears in ω, or it appears in every pattern of size $\varphi(n)$ in ω, see [4]. Similarly, a shift $\mathcal{S}$ has a function of quasiperiodicity φ, if φ is a function of a quasiperiodicity for every configuration in $\mathcal{S}$.

If a shift $\mathcal{S}$ is minimal, then all configurations in $\mathcal{S}$ have exactly the same finite patterns. For every minimal shift $\mathcal{S}$, the function of quasiperiodicity is finite (for every n) and even computable. Moreover, for an effective minimal shift, the set of all finite patterns (that can appear in any configuration) is computable, see [10, 3]. From this fact it follows that every effective and minimal shift contains a computable configuration.

1.2 The main results

Our first theorem claims that every effective quasiperiodic $\mathbb{Z}^d$-shift can be simulated by a quasiperiodic SFT in $\mathbb{Z}^{d+1}$.

▶ **Theorem 1.** *Let $\mathcal{A}$ be an effective quasiperiodic $\mathbb{Z}^d$-shift over some alphabet Σ_A. Then there exists a quasiperiodic SFT $\mathcal{B}$ (over another alphabet Σ_B) of dimension $d+1$ such that $\mathcal{A}$ is isomorphic to a factor of a d-dimensional projective subdynamics on $\mathcal{B}$.*

A similar result holds for effective minimal shifts:

▶ **Theorem 2.** *For every effective minimal $\mathbb{Z}^d$-shift $\mathcal{A}$ there exists a minimal SFT $\mathcal{B}$ in $\mathbb{Z}^{d+1}$ such that $\mathcal{A}$ is isomorphic to a factor of a d-dimensional projective subdynamics on $\mathcal{B}$.*

Theorem 1 implies the following somewhat surprising corollary (a quasiperiodic $\mathbb{Z}^2$-SFT can have highly "complex" languages of patterns):

▶ **Corollary 3.** *There exists a quasiperiodic SFT $\mathcal{A}$ of dimension 2 such that Kolmogorov complexity of every $(N \times N)$-pattern in every configuration of $\mathcal{A}$ is $\Omega(N)$.*

▶ Remark. A standalone pattern of size $N \times N$ over an alphabet Σ (with at least two letters) can have a Kolmogorov complexity up to $\Theta(N^2)$. However, this density of information cannot be enforced by local rules, because in every SFT in $\mathbb{Z}^2$ there exists a configuration such that Kolmogorov complexity of all $N \times N$-patterns is bounded by $O(N)$, [5]. Thus, the lower bound $\Omega(N)$ in Corollary 3 is optimal in the class of all SFT.

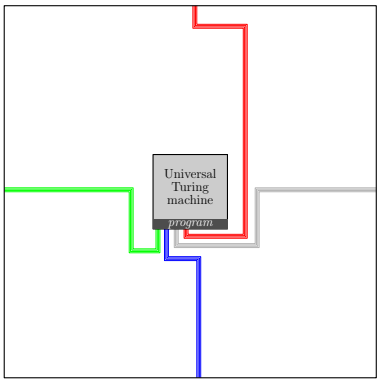

Figure 1 The structure of a macro-tile.

▶ Remark. Every effective (effectively-closed) minimal shift $\mathcal{A}$ is *computable* (given a pattern, we can algorithmically decide whether it belongs to the configurations of the shift). Patterns of high Kolmogorov complexity cannot be found algorithmically. So Corollary 3 cannot be extended to the class of minimal SFT.

To simplify notation and make the argument more visual, in what follows we focus on the case $d = 1$. The proofs extend to any $d > 1$ in a straightforward way, *mutatis mutandis*.

2 The general framework of self-simulating SFT

In what follows we extensively use the technique of *self-simulating tilesets* from [6] (this technique goes back to [8]). We use the idea of self-simulation to enforce a kind of *self-similar* structure in a tiling. In this section we remind the reader of the principal ingredients of this construction.

Let τ be a tileset and $N > 1$ be an integer. We call a τ-*macro-tile* an $N \times N$ square correctly tiled by tiles from τ. Every side of a τ-macro-tile contains a sequence of N colors (of tiles from τ); we refer to this sequence as a *macro-color*. A tileset τ *simulates* another tileset ρ, if there exists a set of τ-macro-tiles T such that

- there is one-to-one correspondence between ρ and T (the colors of two tiles from ρ match if and only if the macro-colors of the corresponding macro-tiles from T match),
- for every τ-tiling there exists a unique lattice of vertical and horizontal lines that splits this tiling into $N \times N$ macro-tiles from T, i.e., every τ-tiling represents a unique ρ-tiling.

For a large class of sufficiently "well-behaved" sequence of integers N_k we can construct a family of tilesets τ_k $(i = 0, 1, \ldots)$ such that each τ_{k-1} simulates the next τ_k with the zoom N_k (and, therefore, τ_0 simulates every τ_k with the zoom $L_k = N_1 \cdot N_2 \cdots N_k$).

If a k-level macro-tile M is a "cell" in a $(k+1)$-level macro-tile M', we refer to M' as a *father* of M; we call the $(k+1)$-level macro-tiles neighboring M' *uncles* of M.

In our construction each tile of τ_k "knows" its coordinates modulo N_k in the tiling: the colors on the left and on the bottom sides should involve (i, j), the color on the right side should involve $(i+1 \mod N_k, j)$, and the color on the top side, respectively, involves $(i, j+1 \mod N_k)$. So every τ_k-tiling can be uniquely split into blocks (macro-tiles) of size $N_k \times N_k$, where the coordinates of cells range from $(0, 0)$ in the bottom-left corner to $(N-1, N-1)$ in top-right corner. Intuitively, each tile "knows" its position in the corresponding macro-tile.

In addition to the coordinates, each tile in τ_k has some supplementary information encoded in the colors on its sides (the size of the supplementary information is always bounded by $O(1)$). In the middle of each side of a macro-tile we allocate $s_k \ll N_k$ positions where an

array of s_k bits represents a color of a tile from τ_{k+1} (these s_k bits are embedded in colors on the sides of s_k tiles of a macro-tile, one bit per a cell). We fix some cells in a macro-tile that serve as "communication wires" and then require that these tiles carry the same (transferred) bit on two sides (so the bits of "macro-colors" are transferred from the sides of macro-color towards its central part). The central part of a macro-tile (of size, say $m_k \times m_k$, where $m_k = \mathrm{poly}(\log N_k)$) is a *computation zone*; it represents a space-time diagram of a universal Turing machine (the tape is horizontal, time goes up), see Fig. 1.

The first line of the computation zone contains the following *fields* of the *input data*:

- **(i)** the program of a Turing machine π that verifies that a quadruple of macro-colors correspond to one valid macro-color,
- **(ii)** the binary expansion of the integer rank k of this macro-tile,
- **(iii)** the bits encoding the macro-colors – the position inside the "father" macro-tile of rank $(k+1)$ (two coordinates modulo N_{k+1}) and $O(1)$ bits of the supplementary information assigned to the macro-colors.

We require that the simulated computation terminates in an accepting state (if not, no correct tiling can be formed). The simulated computation guarantees that macro-tiles of level k are isomorphic to the tiles of τ_{k+1}. Notice that on each level k of the hierarchy we simulate in macro-tiles a computation of one and the same Turing machine π. Only the inputs for this machine (including the binary expansion of the rank number k) varies on different levels of the hierarchy.

This construction of a tileset can be implemented using the standard technique of self-referential programming, similar to the Kleene recursion theorem, as it is shown in [6]. The construction works if the size of a macro-tile (the zoom factor N_k) is large enough. First, we need enough space in a macro-tile to "communicate" s_k bits from each macro-colors to the computation zone; second, we need a large enough computation zone, so all accepting computations terminate in time m_k and on space m_k. In what follows we assume that $N_k = 3^{C^k}$ for some large enough k.

3 Embedding a bi-infinite sequence into a self-simulating tiling

In this section we adapt the technique from [6] and explain how to "encode" in a self-simulating tiling a bi-infinite sequence, and provide to the computation zones of macro-tiles of all ranks an access to the letters of the embedded sequences.

We are going to embed in our tiling a bi-infinite sequence $\mathbf{x} = (x_i)$ over an alphabet Σ. To this end we assume that each τ-tile "keeps" a letter from Σ that propagates without change in the vertical direction. Formally speaking, a letter from Σ should be a part of the top and bottom colors of every τ-tile (the letters assigned to both sides of a tile must be equal to each other). We want to guarantee that a Σ-sequence can be embedded in a τ-tiling, if and only if it belongs to some fixed effective $\mathcal{A}$ (so far quasiperiodicity is not assumed).

We want to "delegate" the factors of the embedded sequence to the computation zones of macro-tiles, where these factors will be validated (that is, we will check that they do not contain any forbidden subwords). While using tilings with growing zoom factor, we can guarantee that the size of the computation zone of a k-rank macro-tile grows with the rank k. So we have at our disposal the computational resources suitable to run all necessary validation tests on the embedded sequence. It remains to organize the propagation of the letters of the embedded sequence to the "conscious memory" (the computation zones) of macro-tiles of all ranks. In what follows we explain how this propagation is organized.

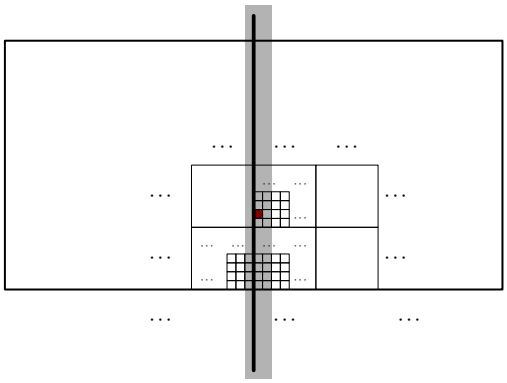

Figure 2 The zone of responsibility (the grey vertical stripe) for a macro-tile (the red square) is 3 times wider than the macro-tile itself.

Zone of responsibility of macro-tiles. In our construction, a macro-tile of level k is a square of size $L_k \times L_k$, with $L_k = N_1 \cdot N_2 \cdot \ldots \cdot N_k$ (where N_i is the zoom factor on level i of the hierarchy of macro-tiles). We say that a k-level macro-tile is *responsible* for the letters of the embedded sequence $\mathbf{x}$ assigned to the columns of (ground level) tiles of this macro-tile as well as to the columns of macro-tiles of the same rank on its left and on its right. That is, the *zone of responsibility* of a k-level macro-tile is a factor of length $3L_k$ from the embedded sequence, see Fig. 2. (The zones of responsibility of any two horizontally neighboring macro-tiles overlap.)

Letters assignment: The computation zone of a k-level macro-tile (of size $m_k \times m_k$) is too small to contain all letters from its zone of responsibility. So we require that the computation zone obtains as an input a (short enough) chunk of letters from its zone of responsibility. Let us say, that it is a factor of length $l_k = \log \log L_k$ from the stripe of $3L_k$ columns constituting the zone of responsibility of this macro-tile. We say that this chunk is *assigned* to this macro-tile.

The infinite stripe of vertically aligned k-level macro-tiles share the same zone of responsibility. However, different macro-tiles in such a stripe will obtain different assigned chunks. The choice of the assigned chunk varies from 0 to $(3L_k - l_k)$. We need to choose a position of a factor of length l_k in a word of length L_k. Let us say for certainty that for a macro-tile M of rank k the first position of the assigned chunk (in the stripe of length $3L_k$) is defined as the vertical position of M in the bigger macro-tile of rank $(k+1)$ (modulo $(3L_k - l_k)$).

▶ Remark. We have chosen the zoom factors N_k so that $N_{k+1} \gg 3L_k$. Hence, every chunk of length l_k from a stripe of width $3L_k$ is assigned to some of the macro-tiles "responsible" for these $3L_k$ letters. Since the zones of responsibility of neighboring k-level macro-tiles overlap by more than l_k, every finite factor of length l_k in the embedded sequence $\mathbf{x}$ is assigned to some k-level macro-tile (even if it involves columns of two macro-tiles of rank k).

Implementing the letters assignment by self-simulation. In the *letters assignment* paragraph above we presented some requirements – how the data must be propagated from the ground level (individual tiles) to k-level macro-tiles. Technically, for each k-level macro-tile $\mathcal{M}$ we specified which chunk of the embedded sequence should be a part of the data fields on the computation zone of $\mathcal{M}$. So far we have not explained how the assigned chunks arrive

to the high-level data fields. Now, we are going to explain how to implement the desired scheme of letter assignment in a self-simulating tiling. Technically, we append to the input data of the computation zones of macro-tiles some supplementary data fields:

(v) the block of l_k letters from the embedded sequence assigned to this macro-tile,

(vi) three blocks of bits of l_{k+1} letters of the embedded sequence assigned to this "father" macro-tile, and two "uncle" macro-tiles (the left and the right neighbors of the "father"),

(vii) the coordinates of the "father" macro-tile in the "grandfather" (of rank $(k+2)$).

Informally, each k-level macro-tile must check that the data in the fields (iv), (v) and (vi) is consistent. That is, if some letters from the fields (iv) and (v) correspond to the same vertical column (in the zone of responsibility), then these letters must be equal to each other. Also, if a k-level macro-tile plays the role of cell in the computation zone of the $(k+1)$-level father, it should check the consistency of its (v) and (vi) with the bits displayed in father's computation zone. Finally, we must ensure the coherence of the fields (v) and (vi) for each pair of neighboring k-level macro-tiles; so this data should make a part of the macro-colors.

Notice that the data from "uncles" macro-tiles is necessary to deal with the letters from the columns that physically belong to the neighboring macro-tiles. So the consistency of the fields (v) is imposed also on neighboring k-level macro-tiles that belong to different $(k+1)$-level fathers (the boarder line between these k-level macro-tiles is also the boarder line between their fathers).

The computations verifying the coherence of the new fields can be performed in polynomial time, and the required update of the construction fits the constraints on the parameter. See a more detailed discussion on "letter delegation" in [6, Section 7].

Final remarks: testing against forbidden factors. To guarantee that the embedded sequence $\mathbf{x}$ contains no forbidden patterns, each k-level macro-tile should allocate some part of its computation zone to enumerate (within the limits of available space and time) the forbidden pattern, and verify that the block of l_k letters assigned to this macro-tile contains none of the found forbidden factors.

The time and space allocated to enumerating the forbidden words grow as a function of k. To ensure that the embedded sequence contains no forbidden patterns, it is enough to guarantee that each forbidden pattern is found by macro-tiles of high enough rank, and every factor of the embedded sequence is compared (on some level of the hierarchy) with every forbidden factor. Thus, we have a general construction of a 2D tiling that simulates a given, effective 1D shift. In the next sections we explain how to make these tilings quasiperiodic in the case when the simulated 1D shift is also quasiperiodic.

4 Combinatorial lemmas: the direct product of quasiperiodic and periodic sequences

The technique from [6] allows to embed in a self-similar tiling a 1-dimensional sequence and handle factors of this sequence. However, the previously known constructions cannot guarantee minimality or even quasiperiodicity of the resulting tiling, even if the embedded sequences have very simple combinatorial structure. To achieve the property of quasiperiodicity we will need some new techniques. The new parts of the argument begins with two simple combinatorial lemmas concerning quasiperiodic sequences.

▶ **Lemma 4.** *(see [2, 15]) Let $\mathbf{x}$ be a bi-infinite recurrent sequence, w be a finite factor in $\mathbf{x}$, and q be a positive integer number. Then there exists an integer $t > 0$ such that another copy of w appears in $\mathbf{x}$ with a shift $q \cdot t$. In other words, there exists another instance of the same*

factor w with a shift divisible by q. Moreover, if $\mathbf{x}$ is quasiperiodic, then the gap $q \cdot t$ between neighboring appearances of w is bounded by some number L that depends on $\mathbf{x}$ and w (but not on a specific instance of the factor x in the sequence).

Notation: For a configuration $\mathbf{x}$ (over some finite alphabet) we denote with $\mathcal{S}(\mathbf{x})$ the shift that consists of all configurations $\mathbf{x}'$ containing only patterns from $\mathbf{x}$. If a shift $\mathcal{T}$ is minimal, then $\mathcal{S}(\mathbf{x}) = \mathcal{T}$ for all configurations $\mathbf{x} \in \mathcal{T}$.

▶ **Lemma 5.** *(a) Let $\mathcal{T}$ be an effective minimal shift. Then for every $\mathbf{x} = (x_i)$ from $\mathcal{T}$ and every periodic configuration $\mathbf{y} = (y_i)$ the direct product $\mathbf{x} \otimes \mathbf{y}$ (the bi-infinite sequence of pairs (x_i, y_i) for $i \in \mathbb{Z}$) generates a minimal shift, i.e., $\mathcal{S}(\mathbf{x} \otimes \mathbf{y})$ is minimal. (b) If in addition the sequence $\mathbf{x}$ are computable, then the set of patterns in $\mathcal{S}(\mathbf{x} \otimes \mathbf{y})$ is also computable.*

▶ Remark. In general, different configurations $\mathbf{x} \in \mathcal{T}$ in the product with one and the same periodic $\mathbf{y}$ can result in different shifts $\mathcal{S}(\mathbf{x} \otimes \mathbf{y})$.

Lemma 5 can be deduced from the fact that for every effective minimal shift the function of quasiperiodicity is computable, [10], and Lemma 4.

5 Towards quasiperiodic SFT

In this section we combine the combinatorial lemmas from the previous section with the technique of enforcing quasiperiodicity from [7], and prove our main results.

5.1 When macro-tiles are clones of each other

To show that (some) self-simulating tilings enjoy the property of quasiperiodicity, we need a tool to prove that every pattern in a tiling has "clones" (equal patterns) in each large enough fragment of this tiling. In our tiling every finite pattern is covered by a block of (at most) four macro-tiles of high enough rank, so we can focus on the search for "clones" in macro-tiles. The following lemma gives a natural characterization of the equality of two macro-tiles in a tiling: they must have the same information in their "conscious memory" (the data written on the tape of the Turing machine in the computation zone) and the same information hidden in their "deep subconscious" (the fragments of the embedded 1D sequence corresponding to the responsibility zones of these macro-tiles must be identical).

▶ **Lemma 6.** *Two macro-tiles of rank k are equal to each other if and only if they (a) contain the same bits in the fields (i) - (vi) in the input data on the computation zone, and (b) the factors of the encoded sequence corresponding to the zones of responsibility of these macro-tiles (in the corresponding vertical stripes of width $3N_k$) are equal to each other.*

Proof. Induction by the rank k. For the macro-tile of rank 1 the statement follows directly from the construction. For a pair of macro-tiles M_1 and M_2 of rank $(k+1)$ with identical data in the fields (i) - (vi) we observe that the corresponding "cells" in M_1 and M_2 (which are macro-tiles of rank k) contain the same data in their own fields (i) - (vi), since the communication wires of M_1 and M_2 carry the same information bits, their computation zones represent exactly the same computations, etc. If the factors (of length $3L_k$) from the encoded sequences in the zones of responsibility of M_1 and M_2 are also equal to each other, we can apply the inductive assumption. ◀

5.2 Supplementary features: constraints that can be imposed on the self-simulating tiling

The tiles involved in our self-simulating tiles set (as well as all macro-tile of each rank) can be classified into three types:

(a) the "skeleton" tiles that keep no information except for their coordinates in the father macro-tile; these tiles work as building blocks of the hierarchical structure;

(b) the "communication wires" that transmit the bits of macro-colors from the border line of the macro-tile to the computation zone;

(c) the tiles of the computation zone (intended to simulate the space-time diagram of the Universal Turing machine).

Each pattern that includes only "skeleton" tiles (or "skeleton" macro-tiles of some rank k) reappears infinitely often in all homologous position inside all macro-tiles of higher rank. Unfortunately, this property is not true for the patterns that involve the "communication zone" or the "communication wires". Thus, the general construction of a fixed-point tiling does not imply the property of quasiperiodicity. To overcome this difficulty we need some new technical tricks.

We can enforce the following additional properties (p1) - (p4) of a tiling with only a minor modification of the construction:

(p1) In each macro-tile, the size of the computation zone m_k is much less than the size of the macro-tile N. In what follows we need to reserve free space in a macro-tile to insert $O(1)$ (some constant number) of copies of each 2×2 pattern from the computation zone (of this macro-tile), right above the computation zone. This requirement is easy to meet. We assume that the size of a computation zone in a k-level macro-tile of size $N_k \times N_k$ is only $m_k = \text{poly}(\log N_k)$. So we can reserve an area of size $\Omega(m_k)$ above the computation zone, which is free of "communication wires" or any other functional gadgets (so far this area consisted of only skeleton tiles).

(p2) We require that the tiling inside the computation zone satisfies the property of 2×2-*determinacy*. If we know all the colors on the borderline of a 2×2-pattern inside of the computation zone (i.e., a tuple of 8 colors), then we can uniquely reconstruct the 4 tiles of this pattern. Again, to implement this property we do not need new ideas; this requirement is met if we represent the space-time diagram of a Turing machine in a natural way.

(p3) The communication channels in a macro-tile (the wires that transmit the information from the macro-color on the borderline of this macro-tile to the bottom line of its computation zone) must be isolated from each other. The distance between every two wires must be greater than 2. That is, each 2×2-pattern can touch at most one communication wire. Since the width of the wires in a k-level macro-tile is only $O(\log N_{k+1})$, we have enough free space to lay the "communication cables", so this requirement is easy to satisfy.

▶ Remark. Property (p3) is a new feature, it was not used in [7] or any other preceding constructions of self-simulating tilings.

(p4) In our construction the macro-colors of a k-level macro-tile are encoded by bit strings of some length $r_k = O(\log N_{k+1})$. We assumed that this encoding is natural in some way. So far the choice of encoding was of small importance; we only required that some natural manipulations with macro-colors can be implemented in polynomial time. Now, we add another (seemingly artificial) requirement: that each of r_k bits encoding the macro-colors (on the top, bottom, left and right sides of a macro-color) was equal to 0 and to 1 for quite a lot of macro-tiles (so the fact that some bit of some macro-color has this or that value,

must not be unique in a tiling). Technically, we require an even stronger property: at every position $s = 1, \dots, r_k$ and for every $i = 0, \dots, N_{k+1} - 1$ there must exist j_0, j_1 such that the s-th bit in the top, the left and the right macro-colors of the k-level macro-tile at the positions (i, j_0) and (i, j_1) in the $(k+1)$-level father macro-tile is equal to 0 and 1 respectively.

There are many (more or less artificial) ways to realize this constraint. For example, we may subdivide the array of r_k bits in three equal zones of size $r_k/3$ and require that for each macro-tile only one of these three zones contains the "meaningful" bits, and two other zones contain only zeros and ones respectively; we require then that the "roles" of these three zones cyclically exchange as we go upwards along a column of macro-tiles.

5.3 Enforcing quasiperiodicity

To achieve the property of quasiperiodicity, we should guarantee that every finite pattern that appears once in a tiling, must appear in each large enough square. If a tileset τ is self-similar, then in every τ-tiling each finite pattern can be covered by at most 4 macro-tiles (by a 2×2-pattern) of an appropriate rank. Thus, it is enough to show that every 2×2-block of macro-tiles of any rank k that appears in at least one τ-tiling, actually appears in this tiling in every large enough square.

Case 1: skeleton tiles. For a 2×2-block of four "skeleton" macro-tiles of level k this is easy. Indeed, we have exactly the same blocks with every vertical shift multiple of L_{k+1} (we have there a similar block of k-level "skeleton" macro-tiles within another macro-tile of rank $(k+1)$). A vertical shift does not change the embedded letters in the zone of responsibility, so we can apply Lemma 6.

To find a similar block of k-level "skeleton" macro-tiles with a different abscissa coordinate, we need a horizontal shift Q which is divisible by L_{k+1} (to preserve the position in the father macro-tile) and at the same time does not change the letters embedded in the zone of responsibility. This is possible due to Lemma 4, if the embedded sequence is quasiperiodic. Given a suitable horizontal shift, we can again apply Lemma 6.

Case 2: communication wires. Let us consider the case when a 2×2-block of k-level macro-tiles involves a part of a communication wire. Due to the property (p3) we may assume that only one wire is involved. The bit transmitted by this wire is either 0 or 1; in both cases, due to the property (p4) we can find another similar 2×2-block of k-level macro-tiles (at the same position within the father macro-tile of rank $(k+1)$ and with the same bit included in the communication wire) in every macro-tile of level $(k+2)$. In this case we need a vertical shift longer than in Case 1: we can find a duplicate of the given block with a vertical shift of size $O(L_{k+2})$.

As in Case 1, any vertical shift does not change the letters embedded in the zone of responsibility of the involved macro-tiles, and we can apply Lemma 6 immediately. If we are looking for a horizontal shift, we again use quasiperiodicity of the simulated shift and apply Lemma 4: there exists a horizontal shift that is divisible by L_{k+2} and does not change the letters embedded in the zone of responsibility. Then we again apply Lemma 6.

Case 3: computation zone. Now we consider the most difficult case: when a 2×2-block of k-level macro-tiles touches the computation zone. In this case we cannot obtain the property of quasiperiodicity for free, and we have to make one more (the last one) modification of our general construction of a self-simulating tiling.

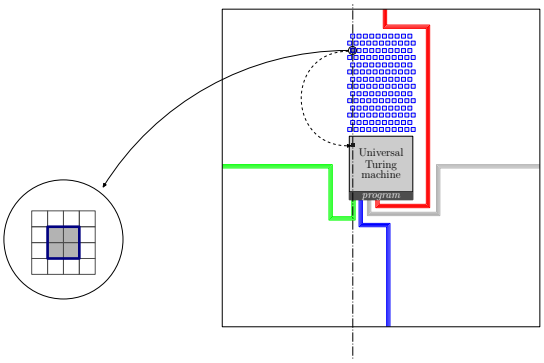

Figure 3 Positions of the slots for patterns from the computation zone.

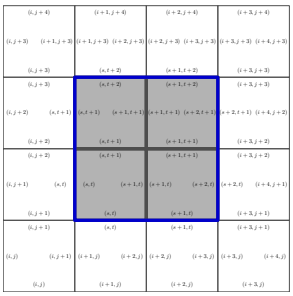

Figure 4 A slot for a 2×2-pattern from the computation zone.

Notice that for each 2×2-window that touches the computation zone of a macro-tile there exist only $O(1)$ ways to tile them correctly. For each possible position of a 2×2-window in the computation zone and for each possible filling of this window by tiles, we reserve a special 2×2-*slot* in a macro-tile, which is essentially a block of size 2×2 in the "free" zone of a macro-tile. It must be placed far away from the computation zone and from all communication wires, but in the same vertical stripe as the "original" position of this block, see Fig. 3. We have enough free space to place all necessary slots due to the property (p1). We define the neighbors around this slot in such a way that only one specific 2×2 pattern can patch it (here we use the property (p2)).

In our construction the tiles around this slot "know" their real coordinates in the bigger macro-tile, while the tiles inside the slot do not (they "believe" they are tiles in the computation zone, while in fact they belong to an artificial isolated *diversity preserving* "slot" far outside of any real computation), see Fig. 3 and Fig. 4. The frame of the slot consists of 12 "skeleton" tiles (the white squares in Fig. 4), they form a slot a 2×2-pattern from the computation zone (the grey squares in Fig. 4). In the picture we show the "coordinates" encoded in the colors on the sides of each tile. Notice that the colors of the bold lines (the blue lines between white and grey tiles and the bold black lines between grey tiles) should contain some information beyond coordinates – these colors involve the bits used to simulate a space-time diagram of the universal Turing machine. In this picture, the "real" coordinates of the bottom-left corner of this slot are $(i+1, j+1)$, while the "natural" coordinates of the pattern (when it appears in the computation zone) are (s, t).

We choose the positions of the "slots" in the macro-tile so that coordinates can be computed with a short program in time polynomial in $\log N$. We require that all slots are isolated from each other in space, so they do not damage the general structure of "skeleton" tiles building the macro-tiles.

Through construction, each of these slots is aligned with the "natural" position of the corresponding 2×2-block in the computation zone. This guarantees that the tiles in the computation zone and their "sibling" in the artificial slots share the same bits of the embedded sequences in the corresponding zone of responsibility. We have defined the slots so that the "conscious memory" of the tiles in the computation zone and in the corresponding slots is the same. Thus, we can apply Lemma 6 and conclude that a 2×2-blocks in diversity preserving slots are exactly equal to the corresponding 2×2-patterns in the computation zone. For a horizontal shift, similarly to the Cases 1–2 above, we use quasiperiodicity of the embedded sequences and apply Lemma 4.

▶ Remark (Concluding Remark). Formally speaking, we proved Lemma 6 before we introduced the last upgrades of our tileset. However, it is easy to verify that the updates of the main construction discussed in this Section do not affect the proof of that lemma.

Thus, we constructed a tileset τ such that every $L_k \times L_k$ pattern that appears in a τ-tiling must also appear in every large enough square in this tiling. So, the constructed tileset satisfies the requirements of Theorem 1.

The proof of Corollary 3. To prove Corollary 3 we only need to combine Theorem 1 with a fact from [14]: there exists a 1D shift $\mathcal{S}$ that is quasiperiodic, and for every configuration $\mathbf{x} \in \mathcal{S}$ the Kolmogorov complexity of all factors is linear, i.e., $K(x_i x_{i+1} \dots x_{i+n}) = \Omega(n)$ for all i. ◀

The proof of Theorem 2. First of all we notice that the proof of Theorem 1 discussed above does not imply Theorem 2. If we take an effective minimal 1D-shift $\mathcal{A}$ and plug it into the construction form the proof of Theorem 1, we obtain a tileset τ (simulating $\mathcal{A}$) which is *quasiperiodic* but not necessary *minimal*. The property of minimality can be lost even for a *periodic* shift $\mathcal{A}$. Indeed, assume that the minimal period $t > 0$ of the configurations in $\mathcal{A}$ is a factor of the size N_k of k-level macro-tiles in our self-simulating tiling, then we can extract from the resulting SFT τ nontrivial shifts T_i, $i = 0, 1, \dots, t-1$ corresponding to the position of the embedded 1D-configuration with respect to the grid of macro-tiles. To overcome this obstacle we will superimpose some additional constraints on the embedding of the simulated $\mathbb{Z}$-shift in a $\mathbb{Z}^2$-tiling. Roughly speaking, we will enforce only "standard" positioning of the embedded 1D sequences with respect to the grid of macro-tiles. This will not change the class of configurations that can be simulated (we still get all configurations from a given minimal shift $\mathcal{A}$), but the classes of all valid tilings will reduce to some minimal $\mathbb{Z}^2$-SFT.

The standardly aligned grid of macro-tiles: In general, the hierarchical structure of macro-tiles permits non-countably many ways of cutting the plane in macro-tiles of different ranks. We fix one particular version of this hierarchical structure and say that a grid of macro-tiles is *standardly aligned*, if for each level k the point $(0, 0)$ is the bottom-left corner of a k-level macro-tile. This means that the tiling is cut into k-level macro-tiles of size $L_k \times L_k$ by vertical lines with abscissae $x = L_k \cdot t'$ and ordinates $y = L_k \cdot t''$, with $t', t'' \in \mathbb{Z}$ (so the vertical line $(0, *)$ and the horizontal line $(*, 0)$ serve as separating lines for macro-tiles of all ranks). Of course, this structure of macro-tiles is computable.

The canonical representative of a minimal shift: A minimal effectively-closed 1D-shift $\mathcal{A}$ is always computable, i.e., the set of finite patterns that appear in configurations of this shift is computable. It follows immediately that $\mathcal{A}$ contains some computable configuration. Let us fix one computable configuration $\mathbf{x}$; in what follows we call it *canonical*.

The standard embedding of the canonical representative: We superimpose the standardly aligned grid of macro-tiles with the canonical representative of a minimal shift $\mathcal{A}$: we take the direct product of the hierarchical structures of the standardly aligned grid of macro-tiles with the canonical configuration $\mathbf{x}$ from $\mathcal{A}$ (that is, each tile with coordinates (i, j) "contains" the letter x_i from the canonical configuration).

Claim 1: Given a pattern w of size $n \le L_k$ and an integer i, we can algorithmically verify whether the factor w appears in the standard embedding of the canonical representative with the shift $(i \mod L_k)$ relative to the grid of k-level macro-tiles. This follows from Lemma 5(b) applied to the superposition of the canonical representative with the periodical grid of k-level macro-tiles).

▶ Remark. This verification procedure is computable, but its computational complexity can be very high. To perform the necessary computation we may need space and time much bigger than the length of w and L_k.

Upgrade of the main construction: Let us update the construction of self-simulating tiling from the proof of Theorem 1. So far we assumed that every macro-tile (of every level k) verifies that the delegated factor of the embedded sequences contains no factors forbidden for the shift $\mathcal{A}$. Now we make the constraint stronger: we require that the delegated factor contains only factors allowed in the shift $\mathcal{A}$ and placed in the positions (relative to the grid of macro-tiles) permitted for factors in the standard embedding of the canonical representative. This property is computable (Claim 1), so every forbidden pattern or a pattern in a forbidden position will be discovered in a computation in a macro-tile of some rank. The computational complexity of this procedure can be very high (see Remark after Claim 1), and we cannot guarantee that the forbidden patterns of small length are discovered by the computation in macro-tiles of small size. But we do guarantee that each forbidden pattern or a pattern in a forbidden position is discovered by a computation in some macro-tile of *high enough* rank.

Claim 2: The new tileset admits correct tilings of the plane. Indeed, at least one tiling is valid by the construction: the standard embedding of the canonical representative corresponds to a valid tiling of the plane, since macro-tiles of all rank never find any forbidden placement of patterns in the embedded sequence.

Claim 3: The new tileset simulates the shift $\mathcal{A}$. This follows immediately from the construction: the embedded sequence must be a configuration from $\mathcal{A}$.

Claim 4: For the constructed tileset τ the set of all tilings is a minimal shift. We need to show that *every* τ-tiling contains all patterns that can appear in *at least one* τ-tiling. Similarly to the proof of Theorem 1, it is enough to prove this property for 2×2-blocks of k-level macro-tile. The difference with the argument in the previous section is that for every 2×2-block of macro-tiles in one tiling T we must find a similar block of macro-tiles in another tiling T', so that this block has exactly the same position with respect to father macro-tile $\mathcal{M}$ of rank $(k + 1)$, and $\mathcal{M}$ and $\mathcal{M}'$ own exactly the same factor of the embedded sequence in their zones of responsibility. This is always possible due to Lemma 5(a) (applied to the canonical representative of $\mathcal{A}$ superimposed with the periodical grid of $(k + 1)$-level macro-tiles). This observation concludes the proof. ◀

Abstract

Clustering is a well-known and important problem with numerous applications. The graph-based model is one of the typical cluster models. In the graph model, clusters are generally defined as cliques. However, such an approach might be too restrictive as in some applications, not all objects from the same cluster must be connected. That is why different types of cliques relaxations often considered as clusters.

In our work, we consider a problem of partitioning graph into clusters and a problem of isolating cluster of a special type where by cluster we mean highly connected subgraph. Initially, such clusterization was proposed by Hartuv and Shamir. And their HCS clustering algorithm was extensively applied in practice. It was used to cluster cDNA fingerprints, to find complexes in protein-protein interaction data, to group protein sequences hierarchically into superfamily and family clusters, to find families of regulatory RNA structures. The HCS algorithm partitions graph in highly connected subgraphs. However, it is achieved by deletion of not necessarily the minimum number of edges. In our work, we try to minimize the number of edge deletions. We consider problems from the parameterized point of view where the main parameter is a number of allowed edge deletions. The presented algorithms significantly improve previous known running times for the Highly Connected Deletion (improved from $O^*\left(81^k\right)$ to $O^*\left(3^k\right)$), Isolated Highly Connected Subgraph (from $O^*(4^k)$ to $O^*\left(k^{O\left(k^{2/3}\right)}\right)$), Seeded Highly Connected Edge Deletion (from $O^*\left(16^{k^{3/4}}\right)$ to $O^*\left(k^{\sqrt{k}}\right)$) problems. Furthermore, we present a subexponential algorithm for Highly Connected Deletion problem if the number of clusters is bounded. Overall our work contains three subexponential algorithms which is unusual as very recently there were known very few problems admitting subexponential algorithms.

1 Introduction

Clustering is a problem of grouping objects such that objects in one group are more similar to each other than to objects in other groups. Clustering has numerous applications, including: machine learning, pattern recognition, image analysis, information retrieval, bioinformatics, data compression, and computer graphics. Graph-based model is one of the typical cluster

* This research was supported by Russian Science Foundation (project 16-11-10123)

models. In a graph-based model most commonly cluster is defined as a clique. However, in many applications, such definition of a cluster is too restrictive [17]. Moreover, clique model generally leads to computationally hard problems. For example clique problem is $W[1] - hard$ while s-club problem, with $s \geq 2$, is fixed-parameter tractable with respect to the parameters solution size and s [19]. Because of the two mentioned reasons researchers consider different clique relaxation models [17, 20]. We mention just some of the possible relaxations: s-club(the diameter is less than of equal to s), s-plex (the smallest degree is at least $|G| - s$), s-defective clique (missing s edges to complete graph), γ-quasi-clique ($|E|/\binom{|V|}{2} \geq \gamma$), highly connected graphs (smallest degree bigger than $|G|/2$) and others. With different degree of details all these relaxations were studied: s-club[19, 20], s-plex [14, 1], s-defective clique [21, 7], γ-quasi-clique [18, 16], highly connected graphs [12, 11, 9].

In this work, we study the clustering problem based on highly connected components model. A graph is *highly connected* if the edge connectivity of a graph(the minimum number of edges whose deletion results in a disconnected graph) is bigger than $\frac{n}{2}$ where n is the number of vertices in a graph. An equivalent characterization is for each vertex has degree bigger than $\frac{n}{2}$, it was proved in [3]. One of the reasons for this choice is a huge success in applications of the Highly Connected Subgraphs(HCS) clustering algorithm proposed by Hartuv and Shamir and the second reason is the lack of research for this model compared with the standard clique model. HCS algorithm was used [11] to cluster cDNA fingerprints [8], to find complexes in protein-protein interaction data [10], to group protein sequences hierarchically into superfamily and family clusters [13], to find families of regulatory RNA structures [15].

Hüffner et al. [11] noted that while Hartuv and Shamir's algorithm partitions a graph into highly connected components, it does not delete the minimum number of edges required for such partitioning. That is why they initiated study of the following problem

Highly Connected Deletion
Instance: Graph $G = (V, E)$.
Task: Find edge subset $E' \subseteq E$ of the minimum size such that each connected component of $G' = (V, E \setminus E')$ is highly connected.

For this problem, Hüffner et al. [11] proposed an algorithm which is based on the dynamic programming technique with the running time bounded by $O^*(3^n)$ where n is the number of vertices. For parameterized version of the problem they proposed an algorithm with the running time $O^*(81^k)$ where k is an upper bound on the size of E'. Additionally, they proved that the problem admits a kernel with the size $O(k^{1.5})$. Moreover, they proved conditional lower bound on the running time of algorithms for Highly Connected Deletion , in particular, the problem cannot be solved in time $2^{o(k)} \cdot n^{O(1)}$, $2^{o(n)} \cdot n^{O(1)}$, or $2^{o(m)} \cdot n^{O(1)}$ unless the exponential-time hypothesis (ETH) fails.

Moreover, in another work Hüffner et al. [12] studied a parameterized complexity of related problem of finding highly connected components in a graph.

Isolated Highly Connected Subgraph
Instance: Graph $G = (V, E)$, integer k, integer s.
Task: Is there a set of vertices S such that $|S| = s$, $G[S]$ is highly connected graph and $|E(S, V \setminus S)| \leq k$.

Seeded Highly Connected Edge Deletion
Instance: Graph $G = (V, E)$, subset $S \subseteq V$, integer a, integer k.
Task: Is there a subset of edges $E' \subseteq E$ of size at most k such that $G - E'$ contains only isolated vertices and one highly connected component C with $S \subseteq V(C)$ and $|V(C)| = |S| + a$.

They proposed algorithms with the running time $O^*(4^k)$ and $O^*(16^{k^{3/4}})$ respectively.

Table 1 Results.

Problem	Previous result	Our result
Highly Connected Deletion (exact)	$O^*(3^n)$	$O^*(2^n)$
Highly Connected Deletion (parameterized)	$O^*\left(81^k\right)$	$O^*\left(3^k\right)$
p-Highly Connected Deletion	-	$O^*\left(2^{O\left(\sqrt{pk}\right)}\right)$
Isolated Highly Connected Subgraph	$O^*(4^k)$	$O^*\left(k^{O\left(k^{2/3}\right)}\right)$
Seeded Highly Connected Edge Deletion	$O^*\left(16^{k^{3/4}}\right)$	$O^*\left(k^{\sqrt{k}}\right)$

Our results. We propose algorithms which significantly improve previous upper bounds. Running times of algorithms may be found in a Table 1. We would like to note that three of the algorithms have subexponential running time which is not common. Until very recently there were very few problems admitting subexponential running time. To our mind in algorithm for Isolated Highly Connected Subgraph problem we have an unusual branching procedure as in one branch parameter is not decreasing. However, the value of subsequent decrementation of parameter in this branch is increasing which leads to subexponential running time. We find the fact interesting as we have not met such behavior of branching procedures before. Presented analysis for this case might be useful in further development of subexponential algorithms.

2 Algorithms for partitioning

2.1 Highly Connected Deletion

In this section we present an algorithm for Highly Connected Deletion problem. Our algorithm is based on the fast subset convolution. Let $f, g : 2^X \to \{0, 1, \dots M\}$ be two functions and $|X| = n$. Björklund et al. in [2] proved that function $f * g : 2^X \to \{0, \dots, 2M\}$, where $(f * g)(S) = \min_{T \subseteq S} (f(T) + g(S \setminus T))$, can be computed on all subsets $S \subseteq X$ in time $O(2^n \text{poly}(n, M))$.

▶ **Theorem 1.** *There is a $O^*(2^n)$ time algorithm for* Highly Connected Deletion *problem.*

Proof. Let define function f in the following way

$$f(S) = \begin{cases} |E(S, V \setminus S)| & \text{if } G[S] \text{ is highly connected} \\ \infty & \text{otherwise} \end{cases}$$

Consider function $f^{*k}(V) = \underbrace{f * \cdots * f}_{\text{k times}}$.

Note that $f^{*k}(V) = \min_{S_1 \sqcup \cdots \sqcup S_k = V} (f(S_1) + \cdots + f(S_k))$. Hence, to solve the problem it is enough to find minimum of $f^{*k}(V)$ over all $1 \le k \le n$. Note that if $f^{*k}(V) = \infty$ then it is not possible to partition V into k highly connected components. So if the minimum value of $f^{*k}(V)$ is ∞ then there is no partitioning of G into highly connected components.

Our algorithm contains the following steps.

1. Compute f, i.e. compute value $f(S)$ for all $S \subset V$. It takes $O(2^n(n + m))$ time.
2. Using Björklund et al.[2] algorithm iteratively compute f^{*i} for all $1 \le i \le n$.
3. Find k such that $f^{*k}(V)$ is minimal.

After we perform above steps we will know values of functions f^{*i} on each subset $S \subseteq X$. Let $S_1 \sqcup S_2 \sqcup \cdots \sqcup S_k$ be an optimum partitioning of X into highly connected components. Knowing values of function f^{*k-1} and f it is straightforward to restore S_k in time 2^n. Moreover, knowing f^{*k-1}, S_k we can find value of S_{k-1}. Proceeding this way we obtain the optimum partitioning. As $k \leq n$, we spent at most $O(n2^n)$ time to find all S_i.

It is left to show how to compute all f^{*i} within $O^*(2^n)$ time. The only obstacle why we cannot straightforwardly apply Björklund's algorithm is that f sometimes takes infinite value. It is easy to fix the problem by replacing infinity value with $2m + 1$. We know that each convolution require $O(2^n \text{poly}(n, M))$ time and above we show that we can put M to be equal $2m + 1$. As we need to perform n subset convolutions. So, the running time of second step is $O^*(2^n)$. Hence, the overall running time is $O^*(2^n)$. ◀

Now we consider parameterized version of Highly Connected Deletion problem (one is asked whether it is possible to delete at most k edges and get a vertex disjoint union of highly connected subgraphs).

▶ **Theorem 2.** *There is an algorithm for* Highly Connected Deletion *problem with running time* $O^*(3^k)$.

Proof. Before we proceed with the proof of the theorem we list several simplification rules and lemmas proved by Hüffner et al. in [11].

▶ **Rule 3.** If G contains a connected component C which is highly connected then replace original instance with instance $(G[V \setminus V(C)], k)$.

▶ **Lemma 4.** *Let G be a highly connected graph and $u, v \in V(G)$ be two different vertices from $V(G)$. If $uv \in E$, then $|N(u) \cap N(v)| \geq 1$. If $uv \notin E$ then $|N(u) \cap N(v)| \geq 3$.*

▶ **Rule 5.** If $u, v \in E$ and $N(u) \cap N(v) = \varnothing$ then delete edge uv and decrease parameter k by 1. The obtained instance is $((V, E \setminus \{uv\}), k - 1)$.

▶ **Definition 6.** Let us call vertices u, v *k-connected* if any cut separating these two vertices has size bigger than k.

▶ **Rule 7.** Let S be an inclusion maximal set of pairwise k-connected vertices and $|S| > 2k$. If the induced graph $G[S]$ is not highly connected then our instance is a NO-instance(it is not possible to delete k edges and obtain vertex disjoint union of higly connected subgraphs). Otherwise, we replace original instance with an instance $(G[V \setminus S], k - |E(S, V \setminus S)|)$.

▶ **Lemma 8.** *If G is highly connected then $diam(G) \leq 2$.*

It was shown in [11] that all of the above rules are applicable in polynomial time.

Without loss of generality assume that G is connected. Otherwise, we consider several independent problems. One problem for each connected component. For each connected component we find minimum number of edges that we have to delete in order to partition this component into highly connected subgraphs. Note that in order to find a minimum number for each subproblem we simply consider all possible values of parameter starting from 0 to k.

From Lemma 8 follows that if $dist(u, v)$ (distance between two vertices u, v) is bigger than 2 then in optimal partitioning u and v belong to different connected components. Hence, if $dist(u, v) \geq 3$ then at least one edge from the shortest path between u and v belongs to E'. If $diam(G) > 2$ then it is possible to find two vertices u, v such that $dist(u, v) = 3$. So given the shortest path u, x, y, v we can branch to three instances $(G \setminus ux, k - 1)$, $(G \setminus xy, k - 1)$,

$(G \setminus yv, k-1)$. We apply such branching exhaustively. Finally, we obtain instance with a graph G' of diameter 2.

Now, for our algorithm it is enough to consider a case when graph G has the following properties: (i) $diam(G) \leq 2$; (ii) there are no subsets S of pairwise k-connected vertices with $|S| > 2k$; (iii) G is not highly connected.

From now on we assume that G has above mentioned properties. Suppose $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$ is an optimum partitioning of G into highly connected graphs and E' is a subset of removed edges. We call vertex *affected* if it is incident with an edge from E'. Otherwise, it is *unaffected*. Denote by U the set of all unaffected vertices and by T the set of all affected vertices. By $C(v)$ we denote a cluster C_i for which $v \in C_i$. Note that for affected vertex u there is vertex v such that $uv \in E(G)$ and $v \notin C(u)$.

▶ **Lemma 9.** *Let G be a graph with diameter 2 then for any optimum partitioning $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$ of G into highly connected graphs there is an i such that U is contained in C_i.*

Proof. Assume that there are two unaffected vertices $u, v \in U$ and $C(v) \neq C(u)$. Note that any path between u and v must contain an edge from E' and two different edges contained in $C(u), C(v)$ and incident to u and v correspondingly. So, the shortest path between u and v contains at least three edges which contradict our assumption that $diam(G) \leq 2$. Hence, there is an i such that $U \subseteq C_i$. ◀

▶ **Lemma 10.** *Let G be a graph with diameter 2 and optimum partitioning $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$ into highly connected graphs. If U is not empty then $|E'| \geq n - |C_i|$ where $U \subseteq C_i$.*

Proof. Consider an arbitrary unaffected vertex u. For any $v \in V$ we have $dist(v, u) \leq 2$. Hence, for any $v \notin C(u)$ there is an edge connecting component $C(u)$ with vertex v as otherwise we have $dist(u, v) > 2$. So we have $|E'| \geq n - |C(u)|$. ◀

For any YES-instance we have $k \geq |E'| \geq \frac{|T|}{2}$, $n = |T| + |U|$, and $|U| \leq 2k$.The inequality $|U| \leq 2k$ follows from the simplification Rule 7 and Lemma 9. As otherwise highly connected component which contains U is bigger than $2k$ and hence simplification Rule 7 can be applied which leads to contradiction. So, it means that $n = |T| + |U| \leq 4k$.

Below we present two algorithms. One of these algorithms solves the problem under assumption that optimum partitioning contains at least one unaffected vertex, the other one solves the problem under assumption that all vertices are affected in optimum partitioning. In order to estimate running time of the algorithms we use the following lemma.

▶ **Lemma 11.** *[5] For any non-negative integer a, b we have $\binom{a+b}{b} \leq 2^{2\sqrt{ab}}$.*

At first, consider a case when there is at least one unaffected vertex in optimum partitioning.

▶ **Lemma 12.** *Let G be a connected graph with diameter at most 2. If there is an optimum partitioning $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$ of G into highly connected graphs such that set of unaffected vertices is not empty then* Highly Connected Deletion *can be solved in $O^*(2^{\frac{3k}{2}})$ time.*

Proof. Let us fix some unaffected vertex u (in algorithm we simply brute-force all n possible values for unaffected vertex u). By Lemma 10 highly connected graph $C(u)$ contains at least $n-k$ vertices. As u is unaffected then $N(u) \subset C(u)$ and $|N(u)| > \frac{|C(u)|}{2}$. Consider set $V \setminus N[u]$. And partition it into two subsets $W_{1,2} \sqcup W_{\geq 3}$, where $W_{1,2} = \{v | 1 \leq |N(u) \cap N(v)| \leq 2\}$, and $W_{\geq 3} = \{v | 3 \leq |N(u) \cap N(v)|\}$. From lemma 4 follows that $W_{1,2} \cap C(u) = \varnothing$. Note that knowing set $C_{part} = C(u) \cap W_{\geq 3}$ we can find set $C(u) = C_{part} \cup N[u]$ and after this simply run algorithm from Theorem 1 on set $V(G) \setminus C(u)$. We implement this approach.

We know that $N[u] \sqcup C_{part} = C(u)$ and $C(u) \leq 2k$. As $|C_{part}| \leq \frac{C(u)}{2}$ it follows that $|C_{part}| \leq k$. Brute-force over all possible values of $s = |C_{part}|$. Having fixed value of s we enumerate all subsets of $W_{\geq 3}$ of size s. All such subsets are potential candidates for a C_{part} role. It is possible to enumerate candidates with polynomial delay i.e. in $O^*(\binom{|W_{\geq 3}|}{|C_{part}|})$ time.

For each listed candidate we run algorithm from Theorem 1. Let $R = W_{\geq 3} \setminus C_{part}$. Hence, the overall running time for a fixed $|C_{part}|$ is bounded by $O^*(2^{|R \cup W_{1,2}|})\binom{|W_{\geq 3}|}{|C_{part}|} = O^*(2^{|R \cup W_{1,2}|})\binom{|C_{part}|+|R|}{|C_{part}|}$. By Lemma 11 we have:

$O^*(2^{|R \cup W_{1,2}|})\binom{|C_{part}|+|R|}{|C_{part}|} = O^*(2^{2\sqrt{|C_{part}||R|}+|R|+|W_{1,2}|})$.

We know that $|C_{part}| \leq k$, $3|R| + |W_{1,2}| \leq k$, hence $O^*(2^{2\sqrt{|C_{part}||R|}+|R|+|W_{1,2}|}) \leq O^*(2^{2\sqrt{k|R|}-2|R|+k})$. The function $g(t) = 2\sqrt{kt} - 2t + k$ attains it maximum when $t = \frac{k}{4}$. So the running time in the worst case is $O^*(2^{1.5k})$. ◀

It is left to construct an algorithm for a case in which all vertices are affected in optimum partitioning. First of all note that if $n \leq 1.57k \leq k \log_2 3$ we can simply run Algorithm 1 and it finds an answer in $O^*(2^n) = O^*(3^k)$ time. Taking into account that all vertices are affected we have that $n \leq 2k$. So we may assume that $1.57k \leq n \leq 2k$.

▶ **Lemma 13.** *Let G be a graph with diameter 2 and $|V(G)| \geq 1.57k$. Moreover, (G, k)* Highly Connected Deletion *problem admits correct partitioning into highly connected components $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$ such that all vertices are affected in this partitioning. Then there are two highly connected components C_i, C_j such that $|C_i| + |C_j| \geq n - k$.*

Proof. Let E' be set of deleted edges for partitioning $C_1 \sqcup C_2 \sqcup \cdots \sqcup C_\ell$. From $n \geq 1.57k$ follows that in graph $(V(G), E')$ there is a vertex s of degree 1, let $st \in E'$ be the edge. We prove that $C(s), C(t)$ are desired highly connected components. As $diam(G) \leq 2$ then for any vertex $v \in V(G) \setminus C(s) \setminus C(t)$ there is path of length at most 2 from s to v. Hence, any vertex $v \in V(G) \setminus C(s) \setminus C(t)$ should be connected with $C(s) \cup C(t)$ in graph G. As $|E'| \leq k$ then $V(G) \setminus (C(s) \cup C(t)) \leq k$. So $|C(s)| + |C(t)| \geq n - k$. ◀

Now we brute-force all vertices as candidates for a role of vertex s, i.e. vertex of degree 1 in solution E'. Consider two possibilities either $|C(s)| > 2n - 3.14k$ or $|C(s)| \leq 2n - 3.14k$.

Consider the first case, if $|C(s)| > 2n - 3.14k$, then we find solution in $O^*(2^{n - \frac{|C(s)|}{2}}) = O^*(3^k)$ time. In order to do this we consider $deg_G(s)$ cases. Each case correspond to a different edge st incident with s. Such an edge we treat as the only edge incident with s from E'. Having fixed an edge st being from E' we know that all other edges incident with s belong to $E(C(s))$. Denote the set of endpoints of these edges to be U. So we can identify at least $\frac{|C(s)|}{2}$ vertices from $C(s)$. Now we can apply the same technique as in proof of Theorem 1.

We define three functions f, g, h over subsets of $W = V \setminus U$.

- $f(S) = |E(S, W \setminus S)|$ if $G[S]$ is highly connected, otherwise it is equal to ∞.
- $h(S) = \min_i(f^{*i}(S))$.
- $g(S) = 2|E(W \setminus S, U)| + |E(S, W \setminus S)|$ if $G[U \cup S]$ is highly connected otherwise it is ∞.

Let us provide some intuition standing behind the formulas. Value $f(S)$ indicate number of vertices that we have to delete in order to separate highly connected graph $G[S]$. $h(S)$ is a number of edges needed to be deleted in order to separate $G[S]$ into highly connected components. $g(S)$ in some sense is a number of edge deletion needed to create a highly connected component $U \cup S$ which contains vertex s. We show that to solve the problem it is enough to compute $(g * h)(W)$. In similar way to Theorem 1 $(g * h)(W)/2$ equals to a

number of optimum edge deletions. Note that all deleted edges not having endpoints in $C(s)$ will be calculated two times, one for each of its incident highly connected component, see definition of function h. Each edge of E' having an endpoint in U is counted twice in first term of function g. And finally each edge from E' having endpoint in $C(s) \setminus U$ is counted twice, once in second term of the formula of g, and once in the formula of h. So $(g * h)(W)/2$ is required number of edge deletions.

Second case, if $|C(s)| \leq 2n - 3.14k$ then $n - k \leq |C(s)| + |C(t)| \leq 2n - 3.14k + |C(t)|$.

It follows that $|C(t)| + 2n - 3.14k \geq n - k$. Hence, $C(t) \geq 2.14k - n \geq 0.14k$. It means that in $C(t)$ there is a vertex of degree at most 7 in graph $(V(G), E')$. We brute-force all candidates for such vertex and for such edges from E'. Having fixed the candidates, vertex t' and at most seven edges, we identify more than a half vertices from $C(t') = C(t)$ in the following way. All edges incident to t' except just fixed set of candidates belong to $C(t)$. Denote the endpoints of these edges as U_t. In the same way, all edges incident with s except st belong to $C(s)$. Denote by U_s endpoints of edges incident with s except the edge $st \in E'$. Let $U = U_s \cup U_t$. Below we show how to solve obtained problem in $O^*\left(2^{n-\frac{1}{2}(|C(s)|+|C(t)|)}\right)$ time. As in previous case we apply idea similar to algorithm from Theorem 1. Now we present only functions which convolution give an answer. As the further details are identical to Theorem 1.

Our functions are defined over subsets of a set $W = V \setminus U$.

- $f(S) = |E(S, W \setminus S)|$ if $G[S]$ is highly connected, otherwise ∞.
- $h(S) = \min_i \left(f^{*i}(S)\right)$.
- $g_s(S) = 2|E(S, U_t)| + |E(S, W \setminus S)|$ if $G[S \cup U_s]$ is highly connected, otherwise ∞.
- $g_t(S) = 2|E(S, U_s)| + |E(S, W \setminus S)|$ if $G[S \cup U_t]$ is highly connected, otherwise ∞.

The only difference from previous case is that we constructed two functions g_s, g_t instead of just one function g as now we know two halves of two guessed highly connected components. Minimum number of edge deletions in YES-instance separating clusters $C(s), C(t)$ ($U_s \subseteq C(s), U_t \subseteq C(t)$) is $(h * g_s * g_t)(W)/2$. So in this case we need $O^*(2^{|W|})$ running time which is $O^*\left(2^{n-\frac{(n-k)}{2}}\right) = O^*\left(2^{\frac{3k}{2}}\right)$. ◀

2.2 p-Highly Connected Deletion

p-Highly Connected Deletion
Instance: Graph $G = (V, E)$, integer numbers p and k.
Task: Is there a subset of edges $E' \subset E$ of size at most k such that $G - E'$ contains at most p connected components and each component is highly connected?

Our algorithm for p-Highly Connected Deletion is insipired by algorithm for p-Cluster Editing by Fomin et al. [5].

First of all, we prove an upper bound on the number of small cuts in highly connected graph.

▶ **Lemma 14.** *Let $G = (V, E)$ be highly connected graph, $X = \underset{\substack{S \subset V \\ \frac{|V|}{4} \leq |S| \leq \frac{3|V|}{4}}}{\arg\min} |E(S, V \setminus S)|$, and $Y = V \setminus X$, then*

(i) *If $|E(X, Y)| \geq \frac{|V|^2}{100}$ then for any partition of $V = A \sqcup B$ we have $|E(A, B)| \geq \frac{|A| \cdot |B|}{100}$.*

(ii) *If $|E(X, Y)| < \frac{|V|^2}{100}$ then for any partition of $V = A \sqcup B$ we have:*
$|E(A \cap X, B \cap X)| \geq \frac{|X \cap A| \cdot |X \cap B|}{100}$, $|E(A \cap Y, B \cap Y)| \geq \frac{|Y \cap A| \cdot |Y \cap B|}{100}$,
$|E(A, B)| \geq \frac{|X \cap A| \cdot |X \cap B|}{100} + \frac{|Y \cap A| \cdot |Y \cap B|}{100}$.

Proof. *i*) Let $V = A \sqcup B$. Without loss of generality $|A| < |B|$.

If $\frac{|V|}{4} \leq |A|$ then $|E(X,Y)| \leq |E(A,B)|$. Hence, $|E(A,B)| \geq |E(X,Y)| \geq \frac{|V|^2}{100} \geq \frac{|A|\cdot|B|}{100}$.

If $|A| < \frac{|V|}{4}$ then $|E(A,B)| \geq \sum_{v \in A} (\deg(v) - |A|)$. As $\deg(v) > \frac{|V|}{2}$ for all $v \in V(G)$, we have $|E(A,B)| \geq |A| \left(\frac{|V|}{2} - |A|\right) \geq \frac{|A|\cdot|V|}{4} \geq \frac{|A|\cdot|B|}{4} \geq \frac{|A|\cdot|B|}{100}$.

ii) Note that $|E(A,B)| \geq |E(A \cap X, B \cap X)| + |E(A \cap Y, B \cap Y)|$. So it is enough to prove that $|E(A \cap X, B \cap X)| \geq \frac{|A \cap X|\cdot|B \cap X|}{50}$, as the proof of $|E(A \cap Y, B \cap Y)| \geq \frac{|A \cap Y|\cdot|B \cap Y|}{50}$ is analogous. The sum of these two inequalities gives the proof of the theorem.

Without loss of generality $|B \cap X| \leq |A \cap X|$. Hence, $\frac{|V|}{8} \leq |A \cap X|$ and $|B \cap X| \leq \frac{3|V|}{8}$. Consider two cases: $|A \cap X| \geq \frac{|V|}{4}$ and $|A \cap X| < \frac{|V|}{4}$.

Consider case when $|A \cap X| \geq \frac{|V|}{4}$. At first we prove $|E(A \cap X, B \cap X)| \geq |E(B \cap X, Y)|$. It is known that:

$$|E(A \cap X, V \setminus (A \cap X))| = |E(X,Y)| - |E(B \cap X, Y)| + |E(A \cap X, B \cap X)|, \tag{1}$$

$|A \cap X| \geq \frac{|V|}{4}$, and $|V \setminus (A \cap X)| \geq |Y| \geq \frac{|V|}{4}$, it means $|E(A \cap X, V \setminus (A \cap X))| \geq |E(X,Y)|$. The last inequality and (1) imply $|E(A \cap X, B \cap X)| \geq |E(B \cap X, Y)|$. It follows that $2|E(A \cap X, B \cap X)| \geq |E(B \cap X, A \cap X)| + |E(B \cap X, Y)| = |E(B \cap X, V \setminus (B \cap X)|$.

As $\frac{3|V|}{8} \geq |B \cap X|$ and $|E(B \cap X, V \setminus (B \cap X))| \geq |B \cap X| \left(\frac{|V|}{2} - |B \cap X|\right)$ we have $|E(B \cap X, V \setminus (B \cap X))| \geq \frac{|B \cap X|\cdot|V|}{8}$. Hence, $|E(A \cap X, B \cap X)| \geq \frac{|B \cap X|\cdot|V|}{16} \geq \frac{|B \cap X|\cdot|V|}{100}$.

It is left to consider case $|A \cap X| < \frac{|V|}{4}$. Note that $|E(A \cap X, B \cap X)| = |E(A \cap X, V \setminus (A \cap X))| - |E(A \cap X, Y)|$. As $\frac{|V|}{4} > |A \cap X|$ we have $|E(A \cap X, V \setminus (A \cap X))| \geq |A \cap X| \left(\frac{|V|}{2} - |A \cap X|\right) \geq \frac{|V|}{8} \cdot \frac{|V|}{4} \geq \frac{|V|^2}{32}$. We know that $|E(A \cap X, Y)| \leq |E(X,Y)| \leq \frac{|V|^2}{100}$, hence $|E(A \cap X, B \cap X) \geq \frac{|V|^2}{32} - \frac{|V|^2}{100} > \frac{|V|^2}{50} \geq \frac{|A \cap X|\cdot|B \cap X|}{100}$. ◀

▶ **Definition 15.** A partition of $V = V_1 \sqcup V_2$ is called a k-cut of G if $|E(V_1, V_2)| \leq k$.

The following lemma limits number of k-cuts in a disjoint union of highly connected graphs.

▶ **Lemma 16.** *If $G = (V, E)$ is a union of p disjoint highly connected components and $p \leq k$ then the number of k-cuts in G is bounded by $2^{O\left(\sqrt{pk}\right)}$.*

Proof. Let G be a disjoint union of highly connected components $C_1, \ldots, C_p$. For each C_i we consider sets X_i, Y_i where $E(X_i, Y_i)$ is a minimum cut of C_i and $C_i = X_i \sqcup Y_i$. We construct a new partition $C'_1, \ldots, C'_q$ of $V(G)$. The new partition is obtained from partition $C_1 \sqcup \ldots \sqcup C_p$ in the following way: if $|E(X_i, Y_i)| < |C_i^2|/100$ then we split C_i into two sets X_i, Y_i otherwise we take C_i without splitting. Note that $p \leq q \leq 2p$ as we either split C_i into to parts or leave it as is.

We bound number of k-cuts of graph G in two steps. In first step we bound number of cuts V_1, V_2 such that $|V_1 \cap C'_i| = x_i$ and $|V_2 \cap C'_i| = y_i$ where x_i, y_i are some fixed integers. In second step we bound number of tuples $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ for which there is at least one k-cut V_1, V_2 satisfying conditions $|V_1 \cap C'_i| = x_i$, $|V_2 \cap C'_i| = y_i$.

If x_i, y_i are fixed and $x_i + y_i = |C'_i|$ the number of partitions of C'_i is equal to $\binom{x_i+y_i}{x_i}$. Note that by Lemma 11 we have $\binom{x_i+y_i}{x_i} \leq 2^{\sqrt{x_i y_i}}$. Observe that there are at least $\frac{x_i y_i}{100}$ edges between $V_1 \cap C'_i$ and $V_2 \cap C'_i$ by Lemma 14. So if $V_1 \sqcup V_2$ is partition of V then $\sum_{i=1}^{q} x_i y_i \leq 100k$.

Applying Cauchy–Schwarz inequality we infer that $\sum_{i=1}^{q} \sqrt{x_i y_i} \leq \sqrt{q} \cdot \sqrt{\sum_{i=1}^{q} x_i y_i} \leq \sqrt{200pk}$. Therefore, the number of considered cuts is at most $\prod_{i=1}^{q} \binom{x_i+y_i}{x_i} \leq 2^{2\sum_{i=1}^{q}\sqrt{x_i y_i}} \leq 2^{\sqrt{800pk}}$.

Now we show bound for a second step i.e. number of possible tuples $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ generating at least one k-cut. Note that $\min\{x_i, y_i\} \leq \sqrt{x_i y_i}$. Hence, $\sum_{i=1}^{q} \min(x_i, y_i) \leq \sqrt{100qk}$. Tuple $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ can be generated in the following way: at first we choose which value is smaller x_i or y_i. Then we express $\sqrt{\lfloor 100qk \rfloor}$ as a sum of $q+1$ non-negative numbers: $\min\{x_i, y_i\}$ for $1 \leq i \leq q$ and the rest $\sqrt{\lfloor 100qk \rfloor} - \sum_{i=1}^{q} \min(x_i, y_i)$.

The number of choices in the first step of generation is equal to $2^q \leq 2^{\sqrt{2qk}}$, and number of ways to expreess $\sqrt{100qk}$ as a sum of $q+1$ number is at most $\binom{\sqrt{100qk}+q+1}{q} \leq 2^{\sqrt{100qk}+q+1} \leq 2^{\sqrt{100qk}+\sqrt{2qk}+1}$. Therefore, the total number of partitions is bounded by $2^{c\sqrt{pk}}$ for some constant c. ◀

The last ingredient for our algorithm is the following lemma proved by Fomin et al.[5]

▶ **Lemma 17.** *[5] All cuts (V_1, V_2) such that $|E(V_1, V_2)| \leq k$ of a graph G can be enumerated with polynomial time delay.*

Now we are ready to present a final theorem.

▶ **Theorem 18.** *There is a $O^*(2^{O(\sqrt{pk})})$ time algorithm for p-*Highly Connected Deletion *problem.*

Proof. First of all we solve the problem in case of connected graph. Denote by $\mathcal{N}$ set of all k-cuts in graph G. All elements of set $\mathcal{N}$ can be enumerated with a polynomial time delay. If G is a union of p clusters plus some edges then the size of $\mathcal{N}$ is bounded by $2^{c\sqrt{pk}}$ by Lemma 16 (as additional edges only decrease number of k-cuts). Thus, we enumerate $\mathcal{N}$ in time $O^*(2^{O(\sqrt{pk})})$. If we exceed the bound $2^{c\sqrt{pk}}$ given by Lemma 16 we know that we can terminate our algorithm and return answer `NO`. So we may assume that we enumerate the whole $\mathcal{N}$ and it contains at most $2^{c\sqrt{pk}}$ elements.

We construct a directed graph D, whose vertices are elements of a set $\mathcal{N} \times \{0, 1, \ldots, p\} \times \{0, 1, \ldots, k\}$, note that $|V(D)| = 2^{O(\sqrt{pk})}$. We add arcs going from $((V_1, V_2), j, l)$ to $((V_1', V_2'), j+1, l')$, where $V_1 \subset V_1'$, $G[V_1' \setminus V_1]$ is highly connected graph, $j \in \{0, 1, \ldots, p-1\}$, and $l' = l + |E(V_1, V_1' \setminus V_1)|$. The arcs can be constructed in $2^{O(\sqrt{pk})}$ time. We claim that the answer for an instance (G, p, k) is equivalent to existence of path from a vertex $((V, \varnothing), 0, 0)$ to a vertex $((\varnothing, V), p', k')$ for some $p' \leq p, k' \leq k$.

In one direction, if there is a path from $((\varnothing, V), 0, 0)$ to $((V, \varnothing), p', k')$ for some $k' \leq k$ and $p' \leq p$, then the consecutive sets $V_1' \setminus V_1$ along the path form highly connected components. Moreover, number of deleted edges from G is equal to last coordinate which is smaller than k.

Let us prove the opposite direction. Let assume that we can delete at most k edges and get a graph with highly connected components $C_1, \ldots, C_p$. Let us denote $T_i = \cup_{j<i} V(C_i)$, $l_{i+1} = l_i + |E(T_{i+1} \setminus T_i, T_i)|$ then the vertices $((T_i, V \setminus T_i), i-1, l_i)$ constitute desired path in graph D.

Reachability in a graph can be tested in a linear time with respect to the number of vertices and arcs. To concude the algorithm we simply test the reachability in the graph D.

It is left co consider a case when G is not connected. Let assume that G consist of q connected components $C_1, \ldots, C_q$ then for each connected component C_i we find all $p' \leq p$ and $k' \leq k$ such that (C_i, p', k') is YES-instance. After this we construct auxiliary directed graph Q with a set of vertices $\{0, \ldots, q\} \times \{0, \ldots, p\} \times \{0, \ldots, k\}$. We add arcs going from (i, a, b) to $(i + 1, a + p', b + k')$ if (C_i, p', k') is a YES-instance. Using similar arguments as before it could be shown that reachability of vertex (q, p', k') from vertex $(0, 0, 0)$ is equivalent to possibility delete k' edges and get p' highly connected components. ◀

3 Algorithms for finding a subgraph

3.1 Seeded Highly Connected Edge Deletion

Seeded Highly Connected Edge Deletion
Instance: Graph $G = (V, E)$, subset $S \subseteq V$ and integer numbers a and k.
Task: Is there a subset of edges $E' \subseteq E$ of size at most k such that $G - E'$ contains only isolated vertices and one highly connected component C with $S \subseteq V(C)$ and $\lvert V(C)\rvert = \lvert S\rvert + a$.

Hüffner et al. [12] constructed an algorithm with running time $O(16^{k^{0.75}} + k^2nm)$ for Seeded Highly Connected Edge Deletion problem. We improve the result to $O^*\left(2^{O(\sqrt{k}\log k)}\right)$ time algorithm.

▶ **Theorem 19.** *There is $O^*(2^{O(\sqrt{k}\log k)})$ time algorithm for* Seeded Highly Connected Edge Deletion *problem.*

3.2 Isolated Highly Connected Subgraph

Isolated Highly Connected Subgraph
Instance: Graph $G = (V, E)$, integer k, integer s.
Task: Is there a set of vertices S such that $\lvert S\rvert = s$, $G[S]$ is highly connected graph and $\lvert E(S, V \setminus S)\rvert \leq k$.

Hüffner et al. [12] proposed $O^*(4^k)$ algorithm for Isolated Highly Connected Subgraph problem, in this work we construct subexponential algorithm for the same problem with running time $O^*(k^{O(k^{2/3})})$.

In order to solve Isolated Highly Connected Subgraph problem Hüffner et al. in [12] constructed algorithm for a more general problem:

f-Isolated Highly Connected Subgraph
Instance: Graph $G = (V, E)$, integer k, integer s, function $f : V \to \mathbb{N}$.
Task: Is there a set of vertices S such that $\lvert S\rvert = s$, $G[S]$ is highly connected and $\lvert E(S, V \setminus S)\rvert + \sum_{v \in S} f(v) \leq k$.

Our algorithm uses reduction rules proposed in [12]. Here, we state the reduction rules without proof, as the proofs can be found in [12].

▶ **Rule 20.** If G contains connected component C of size smaller than s then delete C i.e. solve instance $(G \setminus C, f, k)$.

▶ **Rule 21.** Let G contains connected component $C = (V', E')$ with minimal cut bigger than k. If C is highly connected graph, $\lvert V'\rvert = s$ and $\sum_{s \in V'} f(s) \leq k$ then output a trivial

YES-instance otherwise remove C, i.e. consider instance $(G \setminus C, f, k)$ of f-Isolated Highly Connected Subgraph problem.

▶ **Rule 22.** Let G contains connected component C with minimal cut (A, B) of size at most $\frac{s}{2}$. We define function f' in the following way: for each vertex $v \in A$ $f'(v) := f(v) + |N(v) \cap B|$ and for each $v \in B$ we let $f'(v) := f(v) + |N(v) \cap A|$. Replace original instance with an instance $(G \setminus E(A, B), f', k)$.

▶ **Lemma 23.** *Rules 20, 21, 22 can be exhaustively applied in time $O((sn + k)m)$. If rules 20, 21, 22 are not applicable then $k > \frac{s}{2}$.*

We also use following Fomin and Villanger's result.

▶ **Proposition 24.** [6] For each vertex v in graph G and integers $b, f \geq 0$ number of connected induced subgraphs $B \subseteq V(G)$ satisfying the following properties $v \in B$, $|B| = b + 1$, $|N(B)| = f$; is at most $\binom{b+f}{b}$. Moreover, all these sets can be enumerated in time $O\left(\binom{b+f}{b}(n + m)b(b + f)\right)$.

Now we have all ingredients for out algorithm.

▶ **Theorem 25.** f-Isolated Highly Connected Subgraph *can be solved in time $2^{O(k^{2/3} \log k)}$.*

Proof. First of all we exhaustively apply reduction rules 20, 21, 22. From Lemma 23 follows that we may assume $2k > s$. We consider two cases either $k^{2/3} < s$ or $k^{2/3} \geq s$.

Case 1: $s \leq k^{2/3}$. Enumerate all induced connected subgraphs $G' = (V', E')$ such that $|V'| = s$ and $N(V') \leq k$. If desired S exists than it is among enumerated sets. From Proposition 24 follows that number of such sets is at most $nkO^*(\binom{s+k}{s})$. As $s < 2k$ and $s < k^{2/3}$ we have $nkO^*(\binom{s+k}{s}) \leq O^*((s+k)^s) \leq O^*(2^{k^{2/3} \log k})$. Hence, in time $O^*(2^{k^{2/3} \log k})$ we can enumerate all potential candidates S'. For each candidate we check in polynomial time whether $G[S']$ is highly connected and $|E(S', V \setminus S')| + \sum\limits_{v \in S'} f(v) \leq k$.

Case 2: $k^{\frac{2}{3}} < s$. Let set S be a solution. Define edge set $E' = E(S, V \setminus S)$. Consider function $d : S \to \mathbb{N}$ where $d(v) = |N(v) \cap (V \setminus S)|$. As $\sum\limits_{v \in S} d(v) = |E(S, V \setminus S)| \leq k$ then there is a vertex $v \in S$ such that $d(v) \leq \frac{k}{s} < k^{\frac{1}{3}}$. Note that for such v we have $|N(v)| = |N(v) \cap S| + |N(v) \setminus S| \leq s + k^{\frac{1}{3}}$. We branch on possible values of such vertex and a set of its neighbors that do not belong to S. In order to do this we have to consider at most $n \sum\limits_{i \leq k^{1/3}} \binom{s+k^{1/3}}{i} \leq nk^{1/3}2^{2\sqrt{(s+k^{1/3}-i)i}} \leq nk^{1/3}2^{2\sqrt{3k^{4/3}}} = n2^{O(k^{2/3})}$ cases. Knowing vertex $v \in S$ and $N(v) \setminus S$ we find $N(v) \cap S$. So we already identified at least $\frac{s}{2} + 1$ vertices from S, let denote this set by W. Now we start branching procedure that in right branch extend set W into a solution set S. Branching procedure takes as an input tuple (G, k, s', W, B) where W is a set of vertices determined to be in solution S, B is a set of vertices determined to be not in solution, k number of allowed edge deletions, $s' = s - |W|$ number of vertices that is left to add. The procedure pick a vertex $w \notin W \cup B$ and consider two cases either $w \in S, w \notin B$ or $w \notin S, w \in B$. The first call of the procedure is performed on tuple $(G, k - |E(W, N(v) \setminus W)|, s - |W|, W, \varnothing)$.

Consider arbitrary vertex $x \in V \setminus (W \cup B)$. If $x \in S$ then $|N(x) \cap S| \geq \frac{s}{2}$. Hence, $|N(x) \cap W| \geq |N(x) \cap S| - |S \setminus W| \geq \frac{s}{2} - (s - |W|) = |W| - \frac{s}{2}$. So any vertex x such that

$|N(x) \cap W| < |W| - \frac{s}{2}$ cannot belong to solution S and we safely put x to B. Otherwise, we run our procedure on tuples $(G, k - |N(x) \cap B|, s' - 1, W \cup x, B)$ and $(G, k - |N(x) \cap W|, s', W, B \cup x)$. Note that we stop computation in a branch if $k' \leq 0$ or $s' = 0$. It is easy to see that the algorithm is correct.

It is left to determine the running time of the algorithm. Note that procedure contains two parameters k and s'. In one branch we decrease value of s' by one in the other branch we decrease value of k by $E(x, W)$. Note that in first branch we not only decrease value of s' but we also increase a lower bound on $|N(x) \cap W|$ by 1 as $|N(x) \cap W| \geq |W| - \frac{s}{2}$.

Let us consider a path $(x_1, x_2, \dots x_l)$ from root to leaf in our branching tree. To each node we assign a vertex x_i on which we are branching at this node. For each such path we construct unique sequence $a_1, a_2, \dots, a_m$ and a number b. We put b equal to the number of vertices from set $\{x_1, x_2, \dots, x_l\}$ that was assigned to solution S. And $a_i - 1$ is a number of vertices that was assigned to W in a sequence $x_1, x_2, \dots x_j$ where x_j is an $i-$th vertex assigned to B in this sequence. Note that $|N(x_j) \cap W| \geq a_i$, so $\sum_i a_i \leq k$. Note that for any path from root to leaf we can construct a corresponding sequence a_i and number b. Moreover, any sequence $a_1, a_2, \dots a_m$ and number b correspond to at most one path from root to node.

▶ **Proposition 26.** Given number b and non-decreasing sequence $a_1, a_2, \dots, a_m$ we can uniquely determine a corresponding path in a branching tree.

Proof. For a notation convenience we let $a_0 = 1$. For $1 \leq i \leq m$ we perform the following operation: we make $a_i - a_{i-1}$ steps of assigning vertices to a solution set, i.e. to set W and make one step in branch assigning vertex to a set B. After m such iterations we perform $b - m$ steps of assigning vertices to solution. As $a_1, a_2, \dots a_m$ is non-decreasing sequence we have constructed a unique path in branching tree. It is easy to see that the original sequence $a_1, \dots, a_m$ and number b correspond to a constructed path. So for each path from root to leaf there is a corresponding sequence and for each sequence with a number there is at most one corresponding path from root to node in a tree. ◀

▶ **Lemma 27.** *The number of tuples $(a_1, \dots, a_m, b)$ where $0 \leq b \leq s$, $1 \leq a_i \leq a_{i+1}$ for $i < m$, and $\sum_i a_i \leq k$ is bounded by $O^*\left(2^{O(\sqrt{k})}\right)$*

Proof. For fixed l, tuples $(a_1, \dots, a_m)$ such that $\sum_i a_i = l$ are well-known and are called partitions of l. Pribitkin [4] gave a simple upper bound $e^{2.57\sqrt{l}}$ on the number of partitions of l. Hence, number of tuples $(a_1, \dots, a_m)$ is bounded by $\sum_{i=0}^{k} e^{2.57\sqrt{i}} \leq (k+1)e^{2.57\sqrt{k}}$. Moreover, we know that $0 \leq b \leq s$. It means that the number of tuples $(a_1, \dots, a_m, b)$ is bounded by $(s+1)(k+1)2^{O(\sqrt{k})}$. ◀

From Proposition 26 and Lemma 27 follows that the number of nodes in a branching tree is at most $s2^{O(\sqrt{k})}$. Hence, the running time of the procedure is at most $s2^{O(\sqrt{k})}$.

Now, we compute required time for algorithm in this case(case 2). At first, we branch on a vertex and its neighbors from solution set S. We did it by creating at most $O^*\left(2^{O(k^{2/3})}\right)$ subcases. In each subcase we run a procedure with running time $O^*\left(2^{O(\sqrt{k})}\right)$. So, the overall runnning time equals to $O^*\left(2^{O(\sqrt{k})}2^{O(k^{2/3})}\right) = O^*\left(2^{O(k^{2/3})}\right)$.

The worst running time has **Case 1**, so the running time of the whole algorithms is $O^*\left(k^{O(k^{2/3})}\right)$. ◀

Hypercube LSH for Approximate near Neighbors

Thijs Laarhoven*

IBM Research, Rüschlikon, Switzerland
mail@thijs.com

Abstract

A celebrated technique for finding near neighbors for the angular distance involves using a set of *random* hyperplanes to partition the space into hash regions [Charikar, STOC 2002]. Experiments later showed that using a set of *orthogonal* hyperplanes, thereby partitioning the space into the Voronoi regions induced by a hypercube, leads to even better results [Terasawa and Tanaka, WADS 2007]. However, no theoretical explanation for this improvement was ever given, and it remained unclear how the resulting hypercube hash method scales in high dimensions.

In this work, we provide explicit asymptotics for the collision probabilities when using hypercubes to partition the space. For instance, two near-orthogonal vectors are expected to collide with probability $(\frac{1}{\pi})^{d+o(d)}$ in dimension d, compared to $(\frac{1}{2})^d$ when using random hyperplanes. Vectors at angle $\frac{\pi}{3}$ collide with probability $(\frac{\sqrt{3}}{\pi})^{d+o(d)}$, compared to $(\frac{2}{3})^d$ for random hyperplanes, and near-parallel vectors collide with similar asymptotic probabilities in both cases.

For c-approximate nearest neighbor searching, this translates to a decrease in the exponent ρ of locality-sensitive hashing (LSH) methods of a factor up to $\log_2(\pi) \approx 1.652$ compared to hyperplane LSH. For $c = 2$, we obtain $\rho \approx 0.302 + o(1)$ for hypercube LSH, improving upon the $\rho \approx 0.377$ for hyperplane LSH. We further describe how to use hypercube LSH in practice, and we consider an example application in the area of lattice algorithms.

1 Introduction

Finding (approximate) near neighbors. A key computational problem in various research areas, including machine learning, pattern recognition, data compression, coding theory, and cryptanalysis [34, 11, 15, 16, 29, 23], is finding near neighbors: given a data set $\mathcal{D} \subset \mathbb{R}^d$ of cardinality n, design a data structure and preprocess $\mathcal{D}$ in a way that, when given a query vector $\boldsymbol{q} \in \mathbb{R}^d$, one can efficiently find a near point to $\boldsymbol{q}$ in $\mathcal{D}$. Due to the "curse of dimensionality" [18] this problem is known to be hard to solve exactly (in the worst case) in high dimensions d, so a common relaxation of this problem is the (c, r)-*approximate near neighbor problem* ((c, r)-ANN): given that the nearest neighbor lies at distance at most r from $\boldsymbol{q}$, design an algorithm that finds an element $\boldsymbol{p} \in \mathcal{D}$ at distance at most $c \cdot r$ from $\boldsymbol{q}$.

Locality-sensitive hashing (LSH) and filtering (LSF). A prominent class of algorithms for finding near neighbors in high dimensions is formed by locality-sensitive hashing (LSH) [18] and locality-sensitive filtering (LSF) [9]. These solutions are based on partitioning the space

into regions, in a way that nearby vectors have a higher probability of ending up in the same hash region than distant vectors. By carefully tuning (i) the number of hash regions per hash table, and (ii) the number of randomized hash tables, one can then guarantee that with high probability (a) nearby vectors will *collide* in at least one of the hash tables, and (b) distant vectors will not collide in any of the hash tables. For LSH, a simple lookup in all of $\boldsymbol{q}$'s hash buckets then provides a fast way of finding near neighbors to $\boldsymbol{q}$, while for LSF the lookups are slightly more involved. For various metrics, LSH and LSF currently provide the best performance in high dimensions [8, 9, 7, 13].

Near neighbors on the sphere. In this work we will focus on the near neighbor problem under the *angular distance*, where two vectors $\boldsymbol{x}, \boldsymbol{y}$ are considered nearby iff their common angle θ is small [12, 35, 33, 5]. This equivalently corresponds to near neighbor searching for the ℓ_2-norm, where the entire data set is assumed to lie on a sphere. A special case of (c, r)-ANN on the sphere, often considered in the literature, is the *random* case $r = \frac{1}{c}\sqrt{2}$ and $c \cdot r = \sqrt{2}$, in part due to a reduction from near neighbor under the Euclidean metric for general data sets to (c, r)-ANN on the sphere with these parameters [8].

1.1 Related work

Upper bounds. Perhaps the most well-known and widely used solution for ANN for the angular distance is Charikar's hyperplane LSH [12], where a set of *random* hyperplanes is used to partition the space into regions. Due to its low computational complexity and the simple form of the collision probabilities (with no hidden order terms in d), this method is easy to instantiate in practice and commonly achieves the best performance out of all LSH methods when d is not too large. For large d, both spherical cap LSH [6, 8] and cross-polytope LSH [36, 17, 5, 21] are known to perform better than hyperplane LSH. Experiments from [36, 37] showed that using *orthogonal* hyperplanes, partitioning the space into Voronoi regions induced by the vertices of a hypercube, also leads to superior results compared to hyperplane LSH; however, no theoretical guarantees for the resulting hypercube LSH method were given, and it remained unclear whether the improvement persists in high dimensions.

Lower bounds. For the case of *random* data sets, lower bounds have also been found, matching the performance of spherical cap and cross-polytope LSH for large c [30, 32, 5]. These lower bounds are commonly in a model where it is assumed that collision probabilities are "not too small", and in particular not exponentially small in d. Therefore it is not clear whether one can further improve upon cross-polytope LSH when the number of hash regions is exponentially large, which would for instance be the case for hypercube LSH. Together with the experimental results from [36, 37], this naturally begs the question: how efficient is hypercube LSH? Is it better than hyperplane LSH and/or cross-polytope LSH? And how does hypercube LSH compare to other methods in practice?

1.2 Contributions

Hypercube LSH. By carefully analyzing the collision probabilities for hypercube LSH using results from large deviations theory, we show that hypercube LSH is indeed different from, and superior to hyperplane LSH for large d. The following main theorem states the asymptotic form of the collision probabilities when using hypercube LSH, which are also visualized in Figure 1 in comparison with hyperplane LSH.

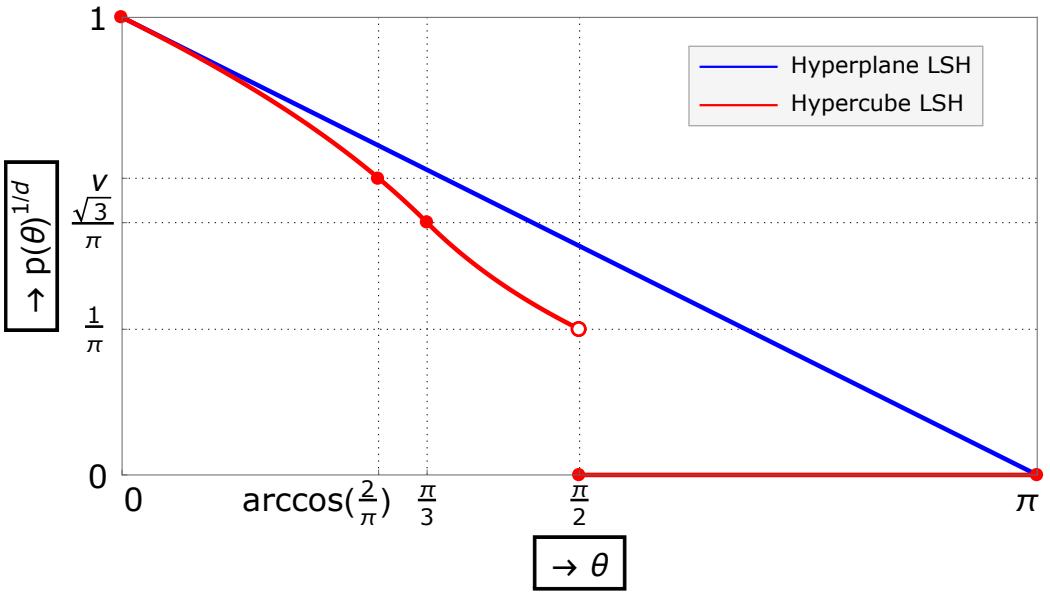

Figure 1 Asymptotics of collision probabilities for hypercube LSH, compared to hyperplane LSH. Here $\nu = \pi/(2\sqrt{\pi^2-4})$, and the dashed vertical lines correspond to boundary points of the piecewise parts of Theorem 1. The blue line indicates hyperplane LSH with d random hyperplanes.

▶ **Theorem 1** (Collision probabilities for hypercube LSH). *Let $\boldsymbol{X}, \boldsymbol{Y} \sim \mathcal{N}(0,1)^d$, let $\theta \in [0,\pi]$ denote the angle between $\boldsymbol{X}$ and $\boldsymbol{Y}$, and let $p(\theta)$ denote the probability that $\boldsymbol{X}$ and $\boldsymbol{Y}$ are mapped to the same hypercube hash region. For $\theta \in (0, \arccos\frac{2}{\pi})$ (respectively $\theta \in (\arccos\frac{2}{\pi}, \frac{\pi}{3})$), let $\beta_0 \in (1,\infty)$ (resp. $\beta_1 \in (1,\infty)$) be the unique solution to:*

$$\arccos\left(\frac{-1}{\beta_0}\right) = \frac{(\beta_0 - \cos\theta)\sqrt{\beta_0^2-1}}{\beta_0(\beta_0\cos\theta - 1)}, \qquad \arccos\left(\frac{1}{\beta_1}\right) = \frac{(\beta_1 + \cos\theta)\sqrt{\beta_1^2-1}}{\beta_1(\beta_1\cos\theta + 1)}. \tag{1}$$

Then, as d tends to infinity, $p(\theta)$ satisfies:

$$p(\theta) = \begin{cases} \left(\frac{(\beta_0-\cos\theta)^2}{\pi\beta_0(\beta_0\cos\theta-1)\sin\theta}\right)^{d+o(d)}, & \text{if } \theta \in [0, \arccos\frac{2}{\pi}]; \\ \left(\frac{(\beta_1+\cos\theta)^2}{\pi\beta_1(\beta_1\cos\theta+1)\sin\theta}\right)^{d+o(d)}, & \text{if } \theta \in [\arccos\frac{2}{\pi}, \frac{\pi}{3}]; \\ \left(\frac{1+\cos\theta}{\pi\sin\theta}\right)^{d+o(d)}, & \text{if } \theta \in [\frac{\pi}{3}, \frac{\pi}{2}); \\ 0, & \text{if } \theta \in [\frac{\pi}{2}, \pi]. \end{cases} \tag{2}$$

Denoting the query complexity of LSH methods by $n^{\rho+o(1)}$, the parameter ρ for hypercube LSH is up to $\log_2(\pi) \approx 1.65$ times smaller than for hyperplane LSH. For large d, hypercube LSH is dominated by cross-polytope LSH (unless $c \cdot r > \sqrt{2}$), but as the convergence to the limit is rather slow, in practice either method might be better, depending on the exact parameter setting. For the random setting, Figure 2 shows limiting values for ρ for hyperplane, hypercube and cross-polytope LSH. We again remark that these are asymptotics for $d \to \infty$, and may not accurately reflect the performance of these methods for moderate d. We further briefly discuss how the hashing for hypercube LSH can be made efficient.

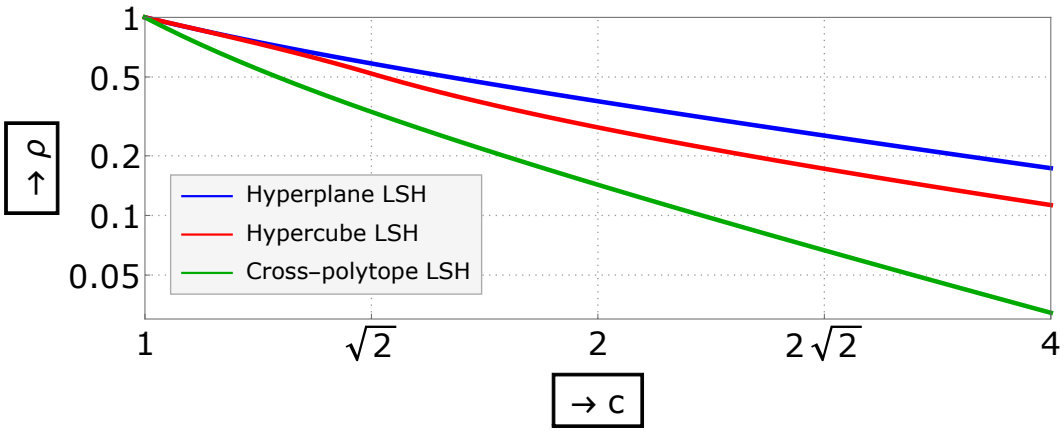

Figure 2 Asymptotics for the LSH exponent ρ when using hyperplane LSH, hypercube LSH, and cross-polytope LSH, for (c, r)-ANN with $c \cdot r = \sqrt{2}$. The curve for hyperplane LSH is exact for arbitrary d, while for the other two curves, order terms vanishing as $d \to \infty$ have been omitted.

Partial hypercube LSH. As the number of hash regions of a full-dimensional hypercube is often prohibitively large, we also consider *partial* hypercube LSH, where a d'-dimensional hypercube is used to partition a data set in dimension d. Building upon a result of Jiang [19], we characterize when hypercube and hyperplane LSH are asymptotically equivalent in terms of the relation between d' and d, and we empirically illustrate the convergence towards either hyperplane or hypercube LSH for larger d'. An important open problem remains to identify how large the ratio d'/d must be for the asymptotics of partial hypercube LSH to be equivalent to those of full-dimensional hypercube LSH.

Application to lattice sieving. Finally, we consider a specific use case of different LSH methods, in the context of lattice cryptanalysis. We show that the heuristic complexity of lattice sieving with hypercube LSH is expected to be slightly better than when using hyperplane LSH, and we discuss how experiments have previously indicated that in this application, hypercube LSH is superior to other dimensions up to dimensions $d \approx 80$.

2 Preliminaries

Notation. We denote probabilities with $\mathbb{P}(\cdot)$ and expectations with $\mathbb{E}(\cdot)$. Capital letters commonly denote random variables, and boldface letters denote vectors. We informally write $\mathbb{P}(X = x)$ for continuous X to denote the density of X at x. For probability distributions $\mathcal{D}$, we write $X \sim \mathcal{D}$ to denote that X is distributed according to $\mathcal{D}$. For sets S, with abuse of notation we further write $X \sim S$ to denote X is drawn uniformly at random from S. We write $\mathcal{N}(\mu, \sigma^2)$ for the normal distribution with mean μ and variance σ^2, and $\mathcal{H}(\mu, \sigma^2)$ for the distribution of $|X|$ when $X \sim \mathcal{N}(\mu, \sigma^2)$. For $\mu = 0$ the latter corresponds to the *half-normal* distribution. We write $\boldsymbol{X} \sim \mathcal{D}^d$ to denote a d-dimensional vector where each entry is independently distributed according to $\mathcal{D}$. In what follows, $\|\boldsymbol{x}\| = \sqrt{\sum_i x_i^2}$ denotes the Euclidean norm, and $\langle \boldsymbol{x}, \boldsymbol{y} \rangle = \sum_i x_i y_i$ denotes the standard inner product. We denote the angle between two vectors by $\phi(\boldsymbol{x}, \boldsymbol{y}) = \arccos\langle \boldsymbol{x}/\|\boldsymbol{x}\|, \boldsymbol{y}/\|\boldsymbol{y}\| \rangle$.

▶ **Lemma 2** (Distribution of angles between random vectors [9, Lemma 2]). *Let $\boldsymbol{X}, \boldsymbol{Y} \sim \mathcal{N}(0,1)^d$ be two independent standard normal vectors. Then $\mathbb{P}(\phi(\boldsymbol{X}, \boldsymbol{Y}) = \theta) = (\sin\theta)^{d+o(d)}$.*

Locality-sensitive hashing. Locality-sensitive hash functions [18] are functions h mapping a d-dimensional vector $\boldsymbol{x}$ to a low-dimensional *sketch* $h(\boldsymbol{x})$, such that vectors which are nearby in $\mathbb{R}^d$ are more likely to be mapped to the same sketch than distant vectors. For the angular distance[1] $\phi(\boldsymbol{x}, \boldsymbol{y})$, we quantify a set of hash functions $\mathcal{H}$ as follows (see [18]):

▶ **Definition 3.** A hash family $\mathcal{H}$ is called $(\theta_1, \theta_2, p_1, p_2)$-sensitive if for $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^d$ we have:
- If $\phi(\boldsymbol{x}, \boldsymbol{y}) \leq \theta_1$ then $\mathbb{P}_{h\sim\mathcal{H}}(h(\boldsymbol{x}) = h(\boldsymbol{y})) \geq p_1$;
- If $\phi(\boldsymbol{x}, \boldsymbol{y}) \geq \theta_2$ then $\mathbb{P}_{h\sim\mathcal{H}}(h(\boldsymbol{x}) = h(\boldsymbol{y})) \leq p_2$.

The existence of locality-sensitive hash families implies the existence of fast algorithms for (approximate) near neighbors, as the following lemma describes[2]. For more details on the general principles of LSH, we refer the reader to e.g. [18, 4].

▶ **Lemma 4** (Locality-sensitive hashing [18]). *Suppose there exists a $(\theta_1, \theta_2, p_1, p_2)$-sensitive family $\mathcal{H}$. Let $\rho = \frac{\log(p_1)}{\log(p_2)}$. Then w.h.p. we can either find an element $\boldsymbol{p} \in L$ at angle at most θ_2 from $\boldsymbol{q}$, or conclude that no elements $\boldsymbol{p} \in L$ at angle at most θ_1 from $\boldsymbol{q}$ exist, in time $n^{\rho+o(1)}$ with space and preprocessing costs $n^{1+\rho+o(1)}$.*

Hyperplane LSH. For the angular distance, Charikar [12] introduced the hash family $\mathcal{H} = \{h_{\boldsymbol{a}} : \boldsymbol{a} \sim \mathcal{D}\}$ where $\mathcal{D}$ is any spherically symmetric distribution on $\mathbb{R}^d$, and $h_{\boldsymbol{a}}$ satisfies:

$$h_{\boldsymbol{a}}(\boldsymbol{x}) = \begin{cases} +1, & \text{if } \langle \boldsymbol{a}, \boldsymbol{x} \rangle \geq 0; \\ -1, & \text{if } \langle \boldsymbol{a}, \boldsymbol{x} \rangle < 0. \end{cases} \tag{3}$$

The vector $\boldsymbol{a}$ can be interpreted as the normal vector of a random hyperplane, and the hash value depends on which side of the hyperplane $\boldsymbol{x}$ lies on. For this hash function, the probability of a collision is directly proportional to the angle between $\boldsymbol{x}$ and $\boldsymbol{y}$:

$$\mathbb{P}_{h\sim\mathcal{H}}\big(h(\boldsymbol{x}) = h(\boldsymbol{y})\big) = 1 - \frac{\phi(\boldsymbol{x}, \boldsymbol{y})}{\pi}. \tag{4}$$

For any two angles $\theta_1 < \theta_2$, the above family $\mathcal{H}$ is $(\theta_1, \theta_2, 1 - \frac{\theta_1}{\pi}, 1 - \frac{\theta_2}{\pi})$-sensitive.

Large deviations theory. Let $\{\boldsymbol{Z}_d\}_{d\in\mathbb{N}} \subset \mathbb{R}^k$ be a sequence of random vectors corresponding to an empirical mean, i.e. $\boldsymbol{Z}_d = \frac{1}{d}\sum_{i=1}^{d} \boldsymbol{U}_i$ with $\boldsymbol{U}_i$ i.i.d. We define the logarithmic moment generating function Λ of $\boldsymbol{Z}_d$ as:

$$\Lambda(\boldsymbol{\lambda}) = \ln \mathbb{E}_{\boldsymbol{U}_1}\left[\exp\langle \boldsymbol{\lambda}, \boldsymbol{U}_1 \rangle\right]. \tag{5}$$

Define $\mathcal{D}_\Lambda = \{\boldsymbol{\lambda} \in \mathbb{R}^k : \Lambda(\boldsymbol{\lambda}) < \infty\}$. The *Fenchel-Legendre* transform of Λ is defined as:

$$\Lambda^*(\boldsymbol{z}) = \sup_{\boldsymbol{\lambda}\in\mathbb{R}^k} \{\langle \boldsymbol{\lambda}, \boldsymbol{z} \rangle - \Lambda(\boldsymbol{\lambda})\}. \tag{6}$$

The following result describes that under certain conditions on $\{\boldsymbol{Z}'_d\}$, the asymptotics of the probability measure on a set F are related to the function Λ^*.

▶ **Lemma 5** (Gärtner-Ellis theorem [14, Theorem 2.3.6 and Corollary 6.1.6]). *Let $\mathbf{0}$ be contained in the interior of $\mathcal{D}_\Lambda$, and let $\boldsymbol{Z}_d$ be an empirical mean. Then for arbitrary sets F,*

$$\lim_{d\to\infty} \tfrac{1}{d} \ln \mathbb{P}(\boldsymbol{z} \in F) = -\inf_{\boldsymbol{z}\in F} \Lambda^*(\boldsymbol{z}). \tag{7}$$

The latter statement can be read as $\mathbb{P}(\boldsymbol{z} \in F) = \exp(-d \inf_{\boldsymbol{z}\in F} \Lambda^*(\boldsymbol{z}) + o(d))$, and thus tells us exactly how $\mathbb{P}(\boldsymbol{z} \in F)$ scales as d tends to infinity, up to order terms.

[1] Formally speaking, the angular distance is only a similarity measure, and not a metric.
[2] Various conditions and order terms (which are commonly $n^{o(1)}$) are omitted here for brevity.

3 Hypercube LSH

In this section, we will analyze full-dimensional hypercube hashing, with hash family $\mathcal{H} = \{h_A : A \in SO(d)\}$ where $SO(d) \subset \mathbb{R}^{d\times d}$ denotes the rotation group, and h_A satisfies:

$$h_A(\boldsymbol{x}) = (h_1(A\boldsymbol{x}), \dots, h_d(A\boldsymbol{x})), \qquad h_i(\boldsymbol{x}) = \begin{cases} +1, & \text{if } x_i \geq 0; \\ -1, & \text{if } x_i < 0. \end{cases} \tag{8}$$

In other words, a hypercube hash function first applies a uniformly random rotation, and then maps the resulting vector to the orthant it lies in. This equivalently corresponds to a concatenation of d hyperplane hash functions, where all hyperplanes are orthogonal. Collision probabilities for prescribed angles θ between $\boldsymbol{x}$ and $\boldsymbol{y}$ are denoted by:

$$p(\theta) = \mathbb{P}(h_A(\boldsymbol{x}) = h_A(\boldsymbol{y}) \mid \phi(\boldsymbol{x}, \boldsymbol{y}) = \theta). \tag{9}$$

Above, the randomness is over $h_A \sim \mathcal{H}$, with $\boldsymbol{x}$ and $\boldsymbol{y}$ arbitrary vectors at angle θ (e.g. $\boldsymbol{x} = \boldsymbol{e}_1$ and $\boldsymbol{y} = \boldsymbol{e}_1 \cos\theta + \boldsymbol{e}_2 \sin\theta$). Alternatively, the random rotation A inside h_A may be omitted, and the probability can be computed over $\boldsymbol{X}, \boldsymbol{Y}$ drawn uniformly at random from a spherically symmetric distribution, *conditioned* on their common angle being θ.

3.1 Outline of the proof of Theorem 1

Although Theorem 1 is a key result, due to space restrictions we have decided to defer the full proof (approximately 5.5 pages) to the appendix. The approach of the proof can be summarized by the following four steps:

- Rewrite the collision probabilities in terms of (normalized) half-normal vectors $\boldsymbol{X}, \boldsymbol{Y}$;
- Introduce dummy variables x, y for the norms of these half-normal vectors, so that the probability can be rewritten in terms of unnormalized half-normal vectors;
- Apply the Gärtner-Ellis theorem (Lemma 5) to the three-dimensional vector $\boldsymbol{Z} = \frac{1}{d}(\sum_i X_i Y_i, \sum_i X_i^2, \sum_i Y_i^2)$ to compute the resulting probabilities for arbitrary x, y;
- Maximize the resulting expressions over $x, y > 0$ to get the final result.

The majority of the technical part of the proof lies in computing $\Lambda^*(\boldsymbol{z})$, which involves a somewhat tedious optimization of a multivariate function through a case-by-case analysis.

A note on Gaussian approximations. From the (above outline of the) proof, and the observation that the final optimization over x, y yields $x = y = 1$ as the optimum, one might wonder whether a simpler analysis might be possible by assuming (half-)normal vectors are already normalized. Such a computation however would only lead to an approximate solution, which is perhaps easiest to see by computing collision probabilities for $\theta = 0$. In the exact computation, where vectors are normalized, $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = 1$ implies $\boldsymbol{X} = \boldsymbol{Y}$. If however we do not take into account the norms of $\boldsymbol{X}$ and $\boldsymbol{Y}$, and do not condition on the norms being equal to 1, then $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = 1$ could also mean that $\boldsymbol{X}, \boldsymbol{Y}$ are slightly longer than 1 and have a small, non-zero angle. In fact, such a computation would indeed yield $p(\theta)^{1/d} \not\to 0$ as $\theta \to 0$.

3.2 Consequences of Theorem 1

From Theorem 1, we can draw several conclusions. Substituting values for θ, we can find asymptotics for $p(\theta)$, such as $p(\frac{\pi}{3})^{1/d} = \frac{\sqrt{3}}{\pi} + o(1)$ and $p(\frac{\pi}{2})^{1/d} = \frac{1}{\pi} + o(1)$. We observe that the limiting function of Theorem 1 (without the order terms) is continuous everywhere except at $\theta = \frac{\pi}{2}$. To understand the boundary $\theta = \arccos\frac{2}{\pi}$ of the piece-wise limit function, note that two (normalized) half-normal vectors $\boldsymbol{X}, \boldsymbol{Y}$ have expected inner product $\mathbb{E}\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = \frac{2}{\pi}$.

LSH exponents ρ for random settings. Using Theorem 1, we can explicitly compute LSH exponents ρ for given angles θ_1 and θ_2 for large d. As an example, consider the random setting[3] with $c = \sqrt{2}$, corresponding to $\theta_2 = \frac{\pi}{2}$ and $\theta_1 = \frac{\pi}{3}$. Substituting the collision probabilities from Theorem 1, we get $\rho \to 1 - \frac{1}{2}\log_\pi(3) \approx 0.520$ as $d \to \infty$. To compare, if we had used random hyperplanes, we would have gotten a limiting value $\rho \to \log_2(\frac{3}{2}) \approx 0.585$. For the random case, Figure 2 compares limiting values ρ using random and orthogonal hyperplanes, and using the asymptotically superior cross-polytope LSH.

Scaling at $\theta \to 0$ and asymptotics of ρ for large c. For θ close to 0, by Theorem 1 we are in the regime defined by β_0. For $\cos\theta = 1 - \varepsilon$ with $\varepsilon > 0$ small, observe that $\beta_0 \approx 1$ satisfies $\beta_0 > 1/\cos\theta$. Computing a Taylor expansion around $\varepsilon = 0$, we eventually find $\beta_0 = 1 + \varepsilon + \frac{2\sqrt{2}}{\pi}\varepsilon^{3/2} + O(\varepsilon^2)$. Substituting this value β_0 into $p(\theta)$ with $\cos\theta = 1 - \varepsilon$, we find:

$$p(\theta) = \left(1 - \frac{\sqrt{2}}{\pi}\sqrt{\varepsilon} + O(\varepsilon)\right)^{d+o(d)}. \tag{10}$$

To compare this with hyperplane LSH, recall that the collision probability for d random hyperplanes is equal to $(1 - \frac{\theta}{\pi})^d$. Since $\cos\theta = 1 - \varepsilon$ translates to $\theta = \sqrt{2\varepsilon}(1 + O(\varepsilon))$, the collision probabilities for hyperplane hashing in this regime are also $(1 - \frac{\sqrt{2}}{\pi}\sqrt{\varepsilon} + O(\varepsilon))^d$. In other words, for angles $\theta \to 0$, the collision probabilities for hyperplane hashing and hypercube hashing are similar. This can also be observed in Figure 1. Based on this result, we further deduce that in random settings with large c, for hypercube LSH we have:

$$\rho \to \frac{\ln\left(1 - \frac{\sqrt{2}}{\pi c} + O\left(\frac{1}{c^2}\right)\right)}{\ln(1/\pi)} = \frac{\sqrt{2}}{\pi c \ln \pi} + O\left(\frac{1}{c^2}\right) \approx \frac{0.393}{c} + O\left(\frac{1}{c^2}\right). \tag{11}$$

For hyperplane LSH, the numerator is the same, while the denominator is $\ln(\frac{1}{2})$ instead of $\ln(\frac{1}{\pi})$, leading to values ρ which are a factor $\log_2 \pi + o(1) \approx 1.652 + o(1)$ larger. Both methods are inferior to cross-polytope LSH for large d, as there $\rho = O(1/c^2)$ for large c [5].

3.3 Convergence to the limit

To get an idea how hypercube LSH compares to other methods when d is not too large, we start by giving explicit collision probabilities for the first non-trivial case, namely $d = 2$.

▶ **Proposition 6** (Square LSH). *For $d = 2$, $p(\theta) = 1 - \frac{2\theta}{\pi}$ for $\theta \leq \frac{\pi}{2}$ and $p(\theta) = 0$ otherwise.*

Proof. In two dimensions, two randomly rotated vectors $\boldsymbol{X}, \boldsymbol{Y}$ at angle θ can be modeled as $\boldsymbol{X} = (\cos\psi, \sin\psi)$ and $\boldsymbol{Y} = (\cos(\psi+\theta), \sin(\psi+\theta))$ for $\psi \sim [0, 2\pi)$. The conditions $\boldsymbol{X}, \boldsymbol{Y} > 0$ are then equivalent to $\psi \in (0, \frac{\pi}{2}) \cap (-\theta, \frac{\pi}{2} - \theta)$, which for $\theta < \frac{\pi}{2}$ occurs with probability $\frac{\pi/2-\theta}{2\pi}$ over the randomness of ψ. As a collision can occur in any of the four quadrants, we finally multiply this probability by 4 to obtain the stated result. ◀

Figure 3 depicts $p(\theta)^{1/2}$ in green, along with hyperplane LSH (blue) and the asymptotics for hypercube LSH (red). For larger d, computing $p(\theta)$ exactly becomes more complicated,

[3] Here we assume that $c \cdot r \to (\sqrt{2})^-$, i.e. $c \cdot r$ approaches $\sqrt{2}$ from below. Alternatively, one might interpret this as that if distant points lie at distance $\sqrt{2} \pm o(1)$, then we might expect approximately half of them to lie at distance less than $\sqrt{2}$, with query complexity $O(n/2)^{\rho+o(1)} = n^{\rho+o(1)}$. If however $c \cdot r \geq \sqrt{2}$ then clearly $\rho = 0$, regardless of d and c.

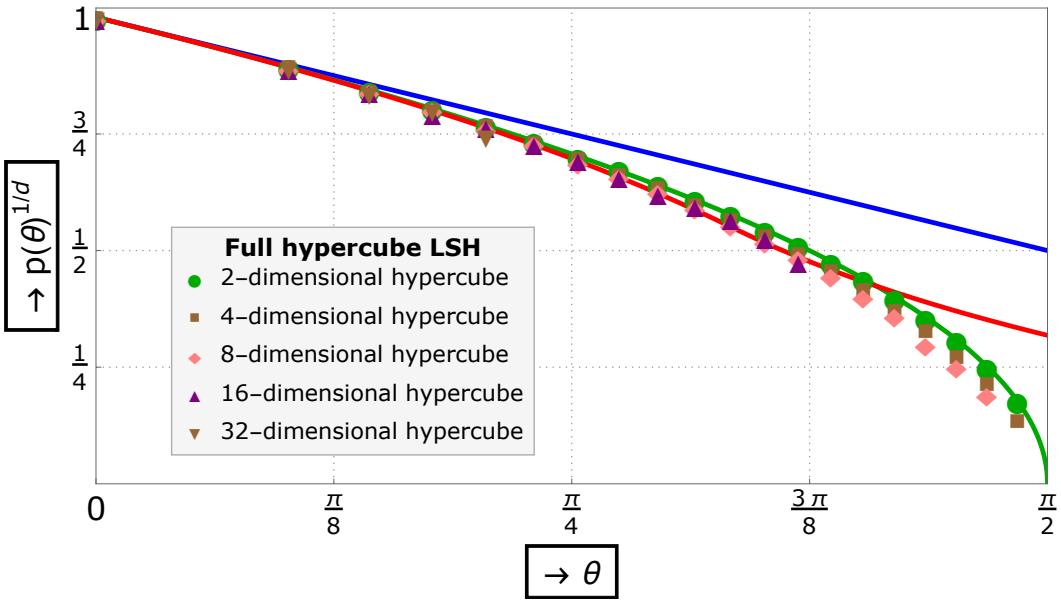

Figure 3 Empirical collision probabilities for hypercube LSH for small d. The green curve denotes the exact collision probabilities for $d = 2$ from Proposition 6.

and so instead we performed experiments to empirically obtain estimates for $p(\theta)$ as d increases. These estimates are also shown in Figure 3, and are based on 10^5 trials for each θ and d. Observe that as $\theta \to \frac{\pi}{2}$ and/or d grows larger, $p(\theta)$ decreases and the empirical estimates become less reliable. Points are omitted for cases where no successes occurred.

Based on these estimates and our intuition, we conjecture that (1) for $\theta \approx 0$, the scaling of $p(\theta)^{1/d}$ is similar for all d, and similar to the asymptotic behavior of Theorem 1; (2) the normalized collision probabilities for $\theta \approx \frac{\pi}{2}$ approach their limiting value from below; and (3) $p(\theta)$ is likely to be continuous for arbitrary d, implying that for $\theta \to \frac{\pi}{2}$, the collision probabilities tend to 0 for each d. These together suggest that values for ρ are actually *smaller* when d is small than when d is large, and the asymptotic estimate from Figure 2 might be pessimistic in practice. For the random setting, this would suggest that $\rho \approx 0$ regardless of c, as $p(\theta) \to 0$ as $\theta \to \frac{\pi}{2}$ for arbitrary d.

Comparison with hyperplane/cross-polytope LSH. Finally, [36, Figures 1 and 2] previously illustrated that among several LSH methods, the smallest values ρ (for their parameter sets) are obtained with hypercube LSH with $d = 16$, achieving smaller values ρ than e.g. cross-polytope LSH with $d = 256$. An explanation for this can be found in:

- The (conjectured) convergence of ρ to its limit from *below*, for hypercube LSH;
- The slow convergence of ρ to its limit (from above) for cross-polytope LSH[4].

This suggests that the actual values ρ for moderate dimensions d may well be smaller for hypercube LSH (and hyperplane LSH) than for cross-polytope LSH. Based on the limiting cases $d = 2$ and $d \to \infty$, we further conjecture that compared to hyperplane LSH, hypercube LSH achieves smaller values ρ for arbitrary d.

[4] [5, Theorem 1] shows that the leading term in the asymptotics for ρ scales as $\Theta(\ln d)$, with a first order term scaling as $O(\ln \ln d)$, i.e. a relative order term of the order $O(\ln \ln d / \ln d)$.

3.4 Fast hashing in practice

To further assess the practicality of hypercube LSH, recall that hashing is done as follows:

- Apply a uniformly random rotation A to $\boldsymbol{x}$;
- Look at the signs of $(A\boldsymbol{x})_i$.

Theoretically, a uniformly random rotation will be rather expensive to compute, with A being a real, dense matrix. As previously discussed in e.g. [3], it may suffice to only consider a sparse subset of all rotation matrices with a large enough amount of randomness, and as described in [5, 21] pseudo-random rotations may also be help speed up the computations in practice. As described in [21], this can even be made provable, to obtain a reduced $O(d \log d)$ computational complexity for applying a random rotation.

Finally, to compare this with cross-polytope LSH, note that cross-polytope LSH in dimension d partitions the space in $2d$ regions, as opposed to 2^d for hypercube hashing. To obtain a similar fine-grained partition of the space with cross-polytopes, one would have to concatenate $\Theta(d/\log d)$ random cross-polytope hashes, which corresponds to computing $\Theta(d/\log d)$ (pseudo-)random rotations, compared to only one rotation for hypercube LSH. We therefore expect hashing to be up to a factor $\Theta(d/\log d)$ less costly.

4 Partial hypercube LSH

Since a high-dimensional hypercube partitions the space in a large number of regions, for various applications one may only want to use hypercubes in a lower dimension $d' < d$. In those cases, one would first apply a random rotation to the data set, and then compute the hash based on the signs of the first d' coordinates of the rotated data set. This corresponds to the hash family $\mathcal{H} = \{h_{A,d'} : A \in SO(d)\}$, with $h_{A,d'}$ satisfying:

$$h_{A,d'}(\boldsymbol{x}) = (h_1(A\boldsymbol{x}), \ldots, h_{d'}(A\boldsymbol{x})), \qquad h_i(\boldsymbol{x}) = \begin{cases} +1, & \text{if } x_i \geq 0; \\ -1, & \text{if } x_i < 0. \end{cases} \tag{12}$$

When "projecting" down onto the first d' coordinates, observe that distances and angles are distorted: the angle between the vectors formed by the first d' coordinates of $\boldsymbol{x}$ and $\boldsymbol{y}$ may not be the same as $\phi(\boldsymbol{x}, \boldsymbol{y})$. The amount of distortion depends on the relation between d' and d. Below, we will investigate how the collision probabilities $p_{d',d}(\theta)$ for partial hypercube LSH scale with d' and d, where $p_{d',d}(\theta) = \mathbb{P}(h(\boldsymbol{x}) = h(\boldsymbol{y}) \mid \phi(\boldsymbol{x}, \boldsymbol{y}) = \theta)$.

4.1 Convergence to hyperplane LSH

First, observe that for $d' = 1$, partial hypercube LSH is *equal* to hyperplane LSH, i.e. $p_{1,d}(\theta) = 1 - \frac{\theta}{\pi}$. For $1 < d' \ll d$, we first observe that both (partial) hypercube LSH and hyperplane LSH can be modeled by a projection onto d' dimensions:

- Hyperplane LSH: $\boldsymbol{x} \mapsto A\boldsymbol{x}$ with $A \sim \mathcal{N}(0,1)^{d' \times d}$;
- Hypercube LSH: $\boldsymbol{x} \mapsto (A^*)\boldsymbol{x}$ with $A \sim \mathcal{N}(0,1)^{d' \times d}$.

Here A^* denotes the matrix obtained from A after applying Gram-Schmidt orthogonalization to the rows of A. In both cases, hashing is done after the projection by looking at the signs of the projected vector. Therefore, the only difference lies in the projection, and one could ask: for which d', as a function of d, are these projections equivalent? When is a set of random hyperplanes already (almost) orthogonal?

This question was answered in [19]: if $d' = o(d/\log d)$, then $\max_{i,j} |A_{i,j} - A^*_{i,j}| \to 0$ in probability as $d \to \infty$ (implying $A^* = (1 + o(1))A$), while for $d' = \Omega(d/\log d)$ this

maximum does not converge to 0 in probability. In other words, for large d a set of d' random hyperplanes in d dimensions is (approximately) orthogonal iff $d' = o(d/\log d)$.

▶ **Proposition 7** (Convergence to hyperplane LSH). *Let $p_{d',d}(\theta)$ denote the collision probabilities for partial hypercube LSH, and let $d' = o(d/\log d)$. Then $p_{d',d}(\theta)^{1/d'} \to 1 - \frac{\theta}{\pi}$.*

As $d' = \Omega(d/\log d)$ random vectors in d dimensions are asymptotically *not* orthogonal, in that case one might expect either convergence to full-dimensional hypercube LSH, or to something in between hyperplane and hypercube LSH.

4.2 Convergence to hypercube LSH

To characterize when partial hypercube LSH is equivalent to full hypercube LSH, we first observe that if d' is large compared to $\ln n$, then convergence to the hypercube LSH asymptotics follows from the Johnson-Lindenstrauss lemma.

▶ **Proposition 8** (Sparse data sets). *Let $d' = \omega(\ln n)$. Then the same asymptotics for the collision probabilities as those of full-dimensional hypercube LSH apply.*

Proof. Let $\theta \in (0, \frac{\pi}{2})$. By the Johnson-Lindenstrauss lemma [20], we can construct a projection $\boldsymbol{x} \mapsto A\boldsymbol{x}$ from d onto d' dimensions, preserving all pairwise distances up to a factor $1 \pm \varepsilon$ for $\varepsilon = \Theta((\ln n)/d') = o(1)$. For fixed $\theta \in (0, \frac{\pi}{2})$, this implies the angle ϕ between $A\boldsymbol{x}$ and $A\boldsymbol{y}$ will be in the interval $\theta \pm o(1)$, and so the collision probability lies in the interval $p(\theta \pm o(1))$. For large d, this means that the asymptotics of $p(\theta)$ are the same. ◀

To analyze collision probabilities for partial hypercube LSH when neither of the previous two propositions applies, note that through a series of transformations similar to those for full-dimensional hypercube LSH, it is possible to eventually end up with the following probability to compute, where $d_1 = d'$ and $d_2 = d - d'$:

$$\max_{x,y,u,v,\phi} \mathbb{P}\left(\frac{1}{d_1}\sum_{i=1}^{d_1} X_i Y_i = xy\cos\phi, \quad \frac{1}{d_1}\sum_{i=1}^{d_1} X_i^2 = x^2, \quad \frac{1}{d_1}\sum_{i=1}^{d_1} Y_i^2 = y^2, \right. \tag{13}$$

$$\left. \frac{1}{d_2}\sum_{i=1}^{d_2} U_i V_i = uvf(\phi,\theta), \quad \frac{1}{d_2}\sum_{i=1}^{d_2} U_i^2 = u^2, \quad \frac{1}{d_2}\sum_{i=1}^{d_2} V_i^2 = v^2 \right). \tag{14}$$

Here f is some function of ϕ and θ. The approach is comparable to how we ended up with a similar probability to compute in the proof of Theorem 1, except that we split the summation indices $I = [d]$ into two sets $I_1 = \{1, \ldots, d'\}$ of size d_1 and $I_2 = \{d'+1, \ldots, d\}$ of size d_2. We then substitute $U_i = X_{d'+i}$ and $V_i = Y_{d'+i}$, and add dummy variables x, y, u, v for the norms of the four partial vectors, and a dummy angle ϕ for the angle between the d_1-dimensional vectors, given the angle θ between the d-dimensional vectors.

Although the vector $\boldsymbol{Z}$ formed by the six random variables in (14) is not an empirical mean over a fixed number d of random vectors (the first three are over d_1 terms, the last three over d_2 terms), one may expect a similar large deviations result such as Lemma 5 to apply here. In that case, the function $\Lambda^*(\boldsymbol{z}) = \Lambda^*(z_1, \ldots, z_6)$ would be a function of six variables, which we would like to evaluate at $(xy\cos\phi, x^2, y^2, uvf(\phi,\theta), u^2, v^2)$. The function Λ^* itself involves an optimization (finding a supremum) over another six variables $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_6)$, so to compute collision probabilities for given d, d', θ exactly, using large deviations theory, one would have to compute an expression of the following form:

$$\min_{x,y,u,v,\phi} \left\{ \sup_{\lambda_1,\lambda_2,\lambda_3,\lambda_4,\lambda_5,\lambda_6} F_{d,d',\theta}(x,y,u,v,\phi,\lambda_1,\lambda_2,\lambda_3,\lambda_4,\lambda_5,\lambda_6) \right\}. \tag{15}$$

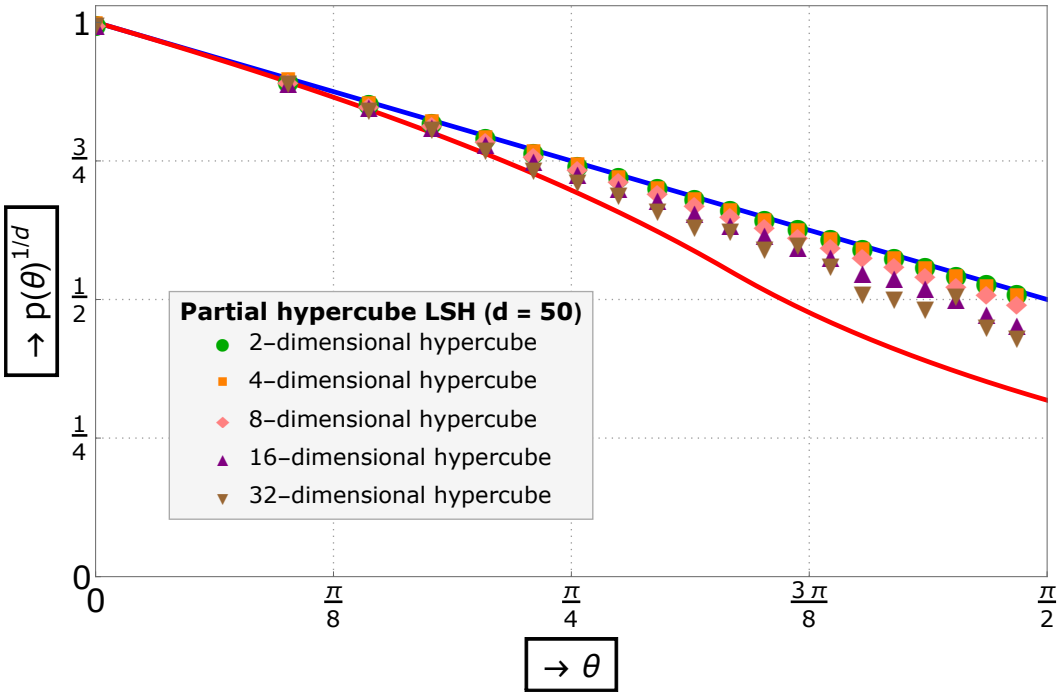

Figure 4 Experimental values of $p_{d',50}(\theta)^{1/d'}$, for different values d', compared with the asymptotics for hypercube LSH (red) and hyperplane LSH (blue).

As this is a very complex task, and the optimization will depend heavily on the parameters d, d', θ defined by the problem setting, we leave this optimization as an open problem. We only mention that intuitively, from the limiting cases of small and large d' we expect that depending on how d' scales with d (or n), we obtain a curve somewhere in between the two curves depicted in Figure 1.

4.3 Empirical collision probabilities

To get an idea of how $p_{d',d}(\theta)$ scales with d' in practice, we empirically computed several values for fixed $d = 50$. For fixed θ we then applied a least-squares fit of the form $e^{c_1 d + c_2}$ to the resulting data, and plotted e^{c_1} in Figure 4. These data points are again based on at least 10^5 experiments for each d' and θ. We expect that as d' increases, the collision probabilities slowly move from hyperplane hashing towards hypercube hashing, this can also be seen in the graph – for $d' = 2$, the least-squares fit is almost equal to the curve for hyperplane LSH, while as d' increases the curve slowly moves down towards the asymptotics for full hypercube LSH. Again, we stress that as d' becomes larger, the empirical estimates become less reliable, and so we did not consider even larger values for d'.

Compared to full hypercube LSH and Figure 3, we observe that we now approach the limit from above (although the fitted collision probabilities never seem to be smaller than those of hyperplane LSH), and therefore the values ρ for partial hypercube LSH are likely to lie in between those of hyperplane and (the asymptotics of) hypercube LSH.

5 Application: Lattice sieving for the shortest vector problem

We finally consider an explicit application for hypercube LSH, namely lattice sieving algorithms for the shortest vector problem. Given a basis $\boldsymbol{B} = \{\boldsymbol{b}_1, \dots, \boldsymbol{b}_d\} \subset \mathbb{R}^d$ of a lattice $\mathcal{L}(\boldsymbol{B}) = \{\sum_i \lambda_i \boldsymbol{b}_i : \lambda_i \in \mathbb{Z}\}$, the shortest vector problem (SVP) asks to find a shortest non-zero vector in this lattice. Various different methods for solving SVP in high dimensions are known, and currently the algorithm with the best heuristic time complexity in high dimensions is based on lattice sieving, combined with nearest neighbor searching [9].

In short, lattice sieving works by generating a long list L of pairwise reduced lattice vectors, where $\boldsymbol{x}, \boldsymbol{y}$ are reduced iff $\|\boldsymbol{x} - \boldsymbol{y}\| \geq \min\{\|\boldsymbol{x}\|, \|\boldsymbol{y}\|\}$. The previous condition is equivalent to $\phi(\boldsymbol{x}, \boldsymbol{y}) \leq \frac{\pi}{3}$, and so the length of L can be bounded by the kissing constant in dimension d, which is conjectured to scale as $(4/3)^{d/2+o(d)}$. Therefore, if we have a list of size $n = (4/3)^{d/2+o(d)}$, any newly sampled lattice vector can be reduced against the list many times to obtain a very short lattice vector. The time complexity of this method is dominated by doing $\mathrm{poly}(d) \cdot n$ reductions (searches for nearby vectors) with a list of size n. A linear search trivially leads to a heuristic complexity of $n^{2+o(1)} = (4/3)^{d+o(d)}$ (with space $n^{1+o(1)}$), while nearest neighbor techniques can reduce the time complexity to $n^{1+\rho+o(1)}$ for $\rho < 1$ (increasing the space to $n^{1+\rho+o(1)}$). For more details, see e.g. [31, 23, 9].

Based on the collision probabilities for hypercube LSH, and assuming the asymptotics for partial hypercube LSH (with $d' = O(d)$) are similar to those of full-dimensional hypercube LSH, we obtain the following result. An outline of the proof is given in the appendix.

▶ **Proposition 9** (Complexity of lattice sieving with hypercube LSH)**.** *Suppose the asymptotics for full hypercube LSH also hold for partial hypercube LSH with $d' \approx 0.1335d$. Then lattice sieving with hypercube LSH heuristically solves SVP in time and space $2^{0.3222d+o(d)}$.*

As expected, the conjectured asymptotic performance of (sieving with) hypercube LSH lies in between those of hyperplane LSH and cross-polytope LSH.

- Linear search [31]: $2^{0.4150d+o(d)}$.
- Hyperplane LSH [23]: $2^{0.3366d+o(d)}$.
- **Hypercube LSH**: $2^{0.3222d+o(d)}$.
- Spherical cap LSH [24]: $2^{0.2972d+o(d)}$.
- Cross-polytope LSH [10]: $2^{0.2972d+o(d)}$.
- Spherical LSF [9]: $2^{0.2925d+o(d)}$.

In practice however, the picture is almost entirely reversed [1]. The lattice sieving method used to solve SVP in the highest dimension to date ($d = 116$) used a very optimized linear search [22]. The furthest that any nearest neighbor-based sieve has been able to go to date is $d = 107$, using hypercube LSH [27, 26][5]. Experiments further indicated that spherical LSF only becomes competitive with hypercube LSH as $d \gtrsim 80$ [9, 28], while sieving with cross-polytope LSH turned out to be rather slow compared to other methods [10, 25]. Although it remains unclear which nearest neighbor method is the "most practical" in the application of lattice sieving, hypercube LSH is one of the main contenders.

Acknowledgments. The author is indebted to Ofer Zeitouni for his suggestion to use results from large deviations theory, and for his many helpful comments regarding this application. The author further thanks Brendan McKay and Carlo Beenakker for their comments.

[5] Although phrased as hyperplane LSH, the implementations from [23, 27, 26] are using hypercube LSH.

A Proof of Theorem 1

Theorem 1 will be proved through a series of lemmas, each making partial progress towards a final solution. Reading only the claims made in the lemmas may give the reader an idea how the proof is built up. Before starting the proof, we begin with a useful lemma regarding integrals of (exponentials of) quadratic forms.

▶ **Lemma 10** (Integrating an exponential of a quadratic form in the positive quadrant)**.** *Let $a, b, c \in \mathbb{R}$ with $a, c < 0$ and $D = b^2 - 4ac < 0$. Then:*

$$\int_0^\infty \int_0^\infty \exp(ax^2 + bxy + cy^2)\, dx\, dy = \frac{\pi + 2\arctan\left(\frac{b}{\sqrt{-D}}\right)}{2\sqrt{-D}}. \tag{16}$$

Proof. The proof below is based on substituting $y = xs$ (and $dy = x\, ds$) before computing the integral over x. An integral over $1/(a + bs + cs^2)$ then remains, which leads to the arctangent solution in case $b^2 < 4ac$.

$$I = \int_{y=0}^\infty \int_0^\infty \exp(ax^2 + bxy + cy^2)\, dx\, dy \tag{17}$$

$$= \int_{s=0}^\infty \left(\int_0^\infty x \exp\left((a + bs + cs^2)x^2\right)\, dx \right) ds \tag{18}$$

$$= \int_0^\infty \left[\frac{\exp\left((a + bs + cs^2)x^2\right)}{2(a + bs + cs^2)} \right]_{x=0}^\infty ds \tag{19}$$

$$= \int_0^\infty \left[0 - \frac{1}{2(a + bs + cs^2)} \right] ds \tag{20}$$

$$= \frac{-1}{2} \int_0^\infty \frac{1}{a + bs + cs^2}\, ds. \tag{21}$$

The last equality used the assumptions $a, c < 0$ and $b^2 < 4ac$ so that $a + bs + cs^2 < 0$ for all $s > 0$. We then solve the last remaining integral (see e.g. [2, Equation (3.3.16)]) to obtain:

$$I = \frac{-1}{2} \left[\frac{2}{\sqrt{4ac - b^2}} \arctan\left(\frac{b + 2cs}{\sqrt{4ac - b^2}} \right) \right]_{s=0}^\infty \tag{22}$$

$$= \frac{-1}{2\sqrt{4ac - b^2}} \left(-\pi - 2\arctan\left(\frac{b}{\sqrt{4ac - b^2}} \right) \right). \tag{23}$$

Eliminating minus signs and substituting $D = b^2 - 4ac$, we obtain the stated result. ◀

Next, we begin by restating the collision probability between two vectors in terms of half-normal vectors.

▶ **Lemma 11** (Towards three-dimensional large deviations)**.** *Let $\mathcal{H}$ denote the hypercube hash family in d dimensions, and as before, let p be defined as:*

$$p(\theta) = \mathbb{P}_{h \sim \mathcal{H}}(h(\boldsymbol{x}) = h(\boldsymbol{y}) \mid \phi(\boldsymbol{x}, \boldsymbol{y}) = \theta). \tag{24}$$

Let $\hat{\boldsymbol{X}}, \hat{\boldsymbol{Y}} \sim \mathcal{H}(0,1)^d$ and let the sequence $\{\boldsymbol{Z}_d\}_{d \in \mathbb{N}} \subset \mathbb{R}^3$ be defined as:

$$\boldsymbol{Z}_d = \frac{1}{d} \left(\sum_{i=1}^d \hat{X}_i \hat{Y}_i, \sum_{i=1}^d \hat{X}_i^2, \sum_{i=1}^d \hat{Y}_i^2 \right). \tag{25}$$

Then:

$$p(\theta) = \left(\frac{1}{2\sin\theta} \right)^{d + o(d)} \max_{x,y>0} \mathbb{P}(\boldsymbol{Z}_d = (xy\cos\theta,\, x^2,\, y^2)). \tag{26}$$

Proof. First, we write out the definition of the conditional probability in p, and use the fact that each of the 2^d hash regions (orthants) has the same probability mass. Here

$\boldsymbol{X}, \boldsymbol{Y} \sim \mathcal{N}(0,1)^d$ denote random Gaussian vectors, and subscripts denoting what probabilities are computed over are omitted when implicit.

$$p(\theta) = \mathbb{P}_{h\sim\mathcal{H}}(h(\boldsymbol{x}) = h(\boldsymbol{y}) \mid \phi(\boldsymbol{x},\boldsymbol{y}) = \theta) \tag{27}$$

$$= 2^d \cdot \mathbb{P}_{\boldsymbol{X},\boldsymbol{Y}\sim\mathcal{N}(0,1)^d}(\boldsymbol{X} > 0,\, \boldsymbol{Y} > 0 \mid \phi(\boldsymbol{X},\boldsymbol{Y}) = \theta) \tag{28}$$

$$= \frac{2^d \cdot \mathbb{P}(\boldsymbol{X} > 0,\, \boldsymbol{Y} > 0,\, \phi(\boldsymbol{X},\boldsymbol{Y}) = \theta)}{\mathbb{P}(\phi(\boldsymbol{X},\boldsymbol{Y}) = \theta)}\,. \tag{29}$$

By Lemma 2, the denominator is equal to $(\sin\theta)^{d+o(d)}$. The numerator of (29) can further be rewritten as a conditional probability on $\{\boldsymbol{X} > 0, \boldsymbol{Y} > 0\}$, multiplied with $\mathbb{P}(\boldsymbol{X} > 0, \boldsymbol{Y} > 0) = 2^{-2d}$. To incorporate the conditionals $\boldsymbol{X}, \boldsymbol{Y} > 0$, we replace $\boldsymbol{X}, \boldsymbol{Y} \sim \mathcal{N}(0,1)^d$ by half-normal vectors $\hat{\boldsymbol{X}}, \hat{\boldsymbol{Y}} \sim \mathcal{H}(0,1)^d$, resulting in:

$$p(\theta) = \frac{\mathbb{P}_{\hat{\boldsymbol{X}},\hat{\boldsymbol{Y}}\sim\mathcal{H}(0,1)^d}(\phi(\hat{\boldsymbol{X}},\hat{\boldsymbol{Y}}) = \theta)}{(2\sin\theta)^{d+o(d)}} = \frac{q(\theta)}{(2\sin\theta)^{d+o(d)}}\,. \tag{30}$$

To incorporate the normalization over the (half-normal) vectors $\hat{\boldsymbol{X}}$ and $\hat{\boldsymbol{Y}}$, we introduce dummy variables x, y corresponding to the norms of $\hat{\boldsymbol{X}}/\sqrt{d}$ and $\hat{\boldsymbol{Y}}/\sqrt{d}$, and observe that as the probabilities are exponential in d, the integrals will be dominated by the maximum value of the integrand in the given range:

$$q(\theta) = \int_0^\infty \int_0^\infty \mathbb{P}(\langle\hat{\boldsymbol{X}},\hat{\boldsymbol{Y}}\rangle = x\,y\,d\,\cos\theta, \|\hat{\boldsymbol{X}}\|^2 = x^2 d, \|\hat{\boldsymbol{Y}}\|^2 = y^2 d)\,dx\,dy \tag{31}$$

$$= 2^{o(d)} \max_{x,y>0} \mathbb{P}\Big(\langle\hat{\boldsymbol{X}},\hat{\boldsymbol{Y}}\rangle = x\,y\,d\,\cos\theta, \|\hat{\boldsymbol{X}}\|^2 = x^2 d, \|\hat{\boldsymbol{Y}}\|^2 = y^2 d\Big)\,. \tag{32}$$

Substituting $\boldsymbol{Z}_d = \frac{1}{d}(\langle\hat{\boldsymbol{X}},\hat{\boldsymbol{Y}}\rangle, \|\hat{\boldsymbol{X}}\|^2, \|\hat{\boldsymbol{Y}}\|^2)$, we obtain the claimed result. ◀

Note that Z_1, Z_2, Z_3 are pairwise but not jointly independent. To compute the density of $\boldsymbol{Z}_d$ at $(xy\cos\theta, x^2, y^2)$ for $d \to \infty$, we use the Gärtner-Ellis theorem stated in Lemma 5.

▶ **Lemma 12** (Applying the Gärtner-Ellis theorem to $\boldsymbol{Z}_d$)**.** *Let $\{\boldsymbol{Z}_d\}_{d\in\mathbb{N}} \subset \mathbb{R}^3$ as in Lemma 11, and let Λ and Λ^* as in Section 2. Then $\mathbf{0}$ lies in the interior of $\mathcal{D}_\Lambda$, and therefore*

$$\mathbb{P}(\boldsymbol{Z}_d = (xy\cos\theta,\, x^2,\, y^2)) = \exp\left(-\Lambda^*(xy\cos\theta, x^2, y^2)d + o(d)\right). \tag{33}$$

Essentially, all that remains now is computing Λ^* at the appropriate point $\boldsymbol{z}$. To continue, we first compute the logarithmic moment generating function $\Lambda = \Lambda_d$ of $\boldsymbol{Z}_d$:

▶ **Lemma 13** (Computing Λ)**.** *Let $\boldsymbol{Z}_d$ as before, and let $D = D(\lambda_1,\lambda_2,\lambda_3) = \lambda_1^2 - (1 - 2\lambda_2)(1-2\lambda_3)$. Then for $\boldsymbol{\lambda} \in \mathcal{D}_\Lambda = \{\boldsymbol{\lambda} \in \mathbb{R}^3 : \lambda_2, \lambda_3 < \frac{1}{2}, D < 0\}$ we have:*

$$\Lambda(\boldsymbol{\lambda}) = \ln\left(\pi + 2\arctan\left(\frac{\lambda_1}{\sqrt{-D}}\right)\right) - \ln\pi - \tfrac{1}{2}\ln(-D). \tag{34}$$

Proof. By the definition of the LMGF, we have:

$$\Lambda(\boldsymbol{\lambda}) = \ln \mathbb{E}_{\hat{X}_1,\hat{Y}_1\sim\mathcal{H}(0,1)}\left[\exp\left(\lambda_1\hat{X}_1\hat{Y}_1 + \lambda_2\hat{X}_1^2 + \lambda_3\hat{Y}_1^2\right)\right]. \tag{35}$$

We next compute the inner expectation over the random variables $\hat{X}_1, \hat{Y}_1$, by writing out the double integral over the product of the argument with the densities of $\hat{X}_1$ and $\hat{Y}_1$.

$$\mathbb{E}_{X_1,Y_1}\left[\exp\left(\lambda_1 X_1 Y_1 + \lambda_2 X_1^2 + \lambda_3 Y_1^2\right)\right] \tag{36}$$

$$= \int_0^\infty \sqrt{\frac{2}{\pi}}\exp\left(-\frac{x^2}{2}\right)dx \int_0^\infty \sqrt{\frac{2}{\pi}}\exp\left(-\frac{y^2}{2}\right)dy\,\exp\left(\lambda_1 xy + \lambda_2 x^2 + \lambda_3 y^2\right) \tag{37}$$

$$= \frac{2}{\pi}\int_0^\infty\int_0^\infty \exp\left(\lambda_1 xy + \left(\lambda_2 - \tfrac{1}{2}\right)x^2 + \left(\lambda_3 - \tfrac{1}{2}\right)y^2\right)\,dx\,dy\,. \tag{38}$$

Applying Lemma 10 with $(a,b,c) = (\lambda_2 - \frac{1}{2}, \lambda_1, \lambda_3 - \frac{1}{2})$ yields the claimed expression for Λ, as well as the bounds stated in $\mathcal{D}_\Lambda$ which are necessary for the expectation to be finite. ◀

We now continue with computing the Fenchel-Legendre transform of Λ, which involves a rather complicated maximization (supremum) over $\boldsymbol{\lambda} \in \mathbb{R}^3$. The following lemma makes a first step towards computing this supremum.

▶ **Lemma 14** (Computing $\Lambda^*(\boldsymbol{z})$ – General form). *Let $\boldsymbol{z} \in \mathbb{R}^3$ such that $z_2, z_3 > 0$. Then the Fenchel-Legendre transform Λ^* of Λ at $\boldsymbol{z}$ satisfies*

$$\Lambda^*(\boldsymbol{z}) = \ln \pi + \sup_{\substack{\lambda_1,\beta \\ \beta>1}} \left\{ \frac{z_2}{2} + \frac{z_3}{2} + \lambda_1 z_1 - |\lambda_1|\beta\sqrt{z_2 z_3} + \frac{1}{2}\ln(\beta^2-1) + \ln|\lambda_1| \right. \tag{39}$$

$$\left. - \ln\left(\pi + 2\arctan\left(\frac{\lambda_1}{|\lambda_1|\sqrt{\beta^2-1}}\right)\right)\right\}. \tag{40}$$

Proof. First, we recall the definition of Λ^* and substitute the previous expression for Λ:

$$\Lambda^*(\boldsymbol{z}) = \sup_{\boldsymbol{\lambda}\in\mathbb{R}^3} \{\langle \boldsymbol{\lambda}, \boldsymbol{z}\rangle - \Lambda(\boldsymbol{\lambda})\} \tag{41}$$

$$= \ln\pi + \sup_{\boldsymbol{\lambda}\in\mathbb{R}^3} \left\{ \langle \boldsymbol{\lambda}, \boldsymbol{z}\rangle + \ln\sqrt{-D} - \ln\left(\pi + 2\arctan\left(\frac{\lambda_1}{\sqrt{-D}}\right)\right)\right\}. \tag{42}$$

Here as before $D = \lambda_1^2 - (1-2\lambda_2)(1-2\lambda_3) < 0$. Let the argument of the supremum above be denoted by $f(\boldsymbol{z}, \boldsymbol{\lambda})$. We make a change of variables by setting $t_2 = 1 - 2\lambda_2 > 0$ and $t_3 = 1 - 2\lambda_3 > 0$, so that D becomes $D = \lambda_1^2 - t_2 t_3 < 0$:

$$f(\boldsymbol{z}, \lambda_1, t_2, t_3) = \frac{z_2}{2} + \frac{z_3}{2} + \lambda_1 z_1 - \frac{t_2 z_2}{2} - \frac{t_3 z_3}{2} \tag{43}$$

$$+ \tfrac{1}{2}\ln(t_2 t_3 - \lambda_1^2) - \ln\left(\pi + 2\arctan\left(\tfrac{\lambda_1}{\sqrt{t_2 t_3 - \lambda_1^2}}\right)\right). \tag{44}$$

We continue by making a further change of variables $u = t_2 t_3 > \lambda_1^2$ so that $t_2 = u/t_3$. As a result the dependence of f on t_3 is only through the fourth and fifth terms above, from which one can easily deduce that the supremum over t_3 occurs at $t_3 = \sqrt{u z_2/z_3}$. This also implies that $t_2 = \sqrt{u z_3/z_2}$. Substituting these values for t_2, t_3, we obtain:

$$f(\boldsymbol{z}, \lambda_1, u) = \tfrac{z_2}{2} + \tfrac{z_3}{2} + \lambda_1 z_1 - \sqrt{u z_2 z_3} + \tfrac{1}{2}\ln(u - \lambda_1^2) - \ln\left(\pi + 2\arctan\left(\tfrac{\lambda_1}{\sqrt{u-\lambda_1^2}}\right)\right).$$

Finally, we use the substitution $u = \beta^2 \cdot \lambda_1^2$. From $D < 0$ it follows that $u/\lambda_1^2 = \beta > 1$. This substitution and some rewriting of f leads to the claimed result. ◀

The previous simplifications were regardless of z_1, z_2, z_3, where the only assumption that was made during the optimization of t_3 was that $z_2, z_3 > 0$. In our application, we want to compute Λ^* at $\boldsymbol{z} = (xy\cos\theta, x^2, y^2)$ for certain $x, y > 0$ and $\theta \in (0, \frac{\pi}{2})$. Substituting these values for $\boldsymbol{z}$, the expression from Lemma 11 becomes:

$$\Lambda^*(xy\cos\theta, x^2, y^2) = \ln\pi + \frac{x^2}{2} + \frac{y^2}{2} + \sup_{\substack{\lambda_1,\beta \\ \beta>1}} \left\{ (\lambda_1\cos\theta - |\lambda_1|\beta)xy + \frac{1}{2}\ln(\beta^2-1) \right. \tag{45}$$

$$\left. + \ln|\lambda_1| - \ln\left(\pi + 2\arctan\left(\frac{\lambda_1}{|\lambda_1|\sqrt{\beta^2-1}}\right)\right)\right\}. \tag{46}$$

The remaining optimization over λ_1, β now takes slightly different forms depending on whether $\lambda_1 < 0$ or $\lambda_1 > 0$. We will tackle these two cases separately, based on the identity:

$$\Lambda^*(\boldsymbol{z}) = \max\left\{ \sup_{\substack{\boldsymbol{\lambda}\in\mathbb{R}^3 \\ \lambda_1>0}} \{\langle \boldsymbol{\lambda}, \boldsymbol{z}\rangle - \Lambda(\boldsymbol{\lambda})\}, \sup_{\substack{\boldsymbol{\lambda}\in\mathbb{R}^3 \\ \lambda_1<0}} \{\langle \boldsymbol{\lambda}, \boldsymbol{z}\rangle - \Lambda(\boldsymbol{\lambda})\} \right\} = \max\{\Lambda^*_+(\boldsymbol{z}), \Lambda^*_-(\boldsymbol{z})\}.$$

▶ **Lemma 15** (Computing $\Lambda^*(\boldsymbol{z})$ for positive λ_1)**.** *Let $\boldsymbol{z} = (xy\cos\theta, x^2, y^2)$ with $x, y > 0$ and $\theta \in (0, \frac{\pi}{2})$. For $\theta \in (0, \arccos\frac{2}{\pi})$, let $\beta_0 = \beta_0(\theta) \in (1, \infty)$ be the unique solution to (1). Then the Fenchel-Legendre transform Λ^* at $\boldsymbol{z}$, restricted to $\lambda_1 > 0$, satisfies*

$$\Lambda^*_+(\boldsymbol{z}) = \frac{x^2}{2} + \frac{y^2}{2} - 1 - \ln(xy) + \begin{cases} \ln\left(\frac{\pi\beta_0(\beta_0\cos\theta - 1)}{2(\beta_0 - \cos\theta)^2}\right), & \text{if } \theta \in (0, \arccos\frac{2}{\pi}); \\ 0, & \text{if } \theta \in [\arccos\frac{2}{\pi}, \frac{\pi}{2}). \end{cases} \tag{47}$$

Proof. Substituting $\lambda_1 > 0$ into (46), we obtain:

$$\Lambda^*_+(xy\cos\theta, x^2, y^2) = \ln\pi + \frac{x^2}{2} + \frac{y^2}{2} + \sup_{\substack{\lambda_1>0 \\ \beta>1}} \Big\{ g_+(\lambda_1, \beta) \Big\}, \tag{48}$$

$$g_+(\lambda_1, \beta) = (\cos\theta - \beta)\lambda_1 xy + \frac{\ln(\beta^2 - 1)}{2} + \ln\lambda_1 - \ln\left(\pi + 2\arctan\left(\frac{1}{\sqrt{\beta^2 - 1}}\right)\right). \tag{49}$$

Differentiating w.r.t. λ_1 gives $(\cos\theta - \beta)xy + \frac{1}{\lambda_1}$. Recall that $\beta > 1 > \cos\theta$. For $\lambda_1 \to 0^+$ the derivative is therefore positive, for $\lambda_1 \to \infty$ it is negative, and there is a global maximum at the only root $\lambda_1 = 1/((\beta - \cos\theta)xy)$. In that case, the expression further simplifies and we can pull out more terms that do not depend on β, to obtain:

$$\Lambda^*_+(xy\cos\theta, x^2, y^2) = \ln\pi + \frac{x^2}{2} + \frac{y^2}{2} - 1 - \ln(xy) + \sup_{\beta>1} \Big\{ g_+(\beta) \Big\}, \tag{50}$$

$$g_+(\beta) = \ln\left(\frac{\sqrt{\beta^2 - 1}}{(\beta - \cos\theta)\left(\pi + 2\arcsin\frac{1}{\beta}\right)}\right) = \ln h_+(\beta). \tag{51}$$

Here we used the identity $\arctan(1/\sqrt{\beta^2 - 1}) = \arcsin(1/\beta)$. Now, for $\beta \to 1^+$ we have $h_+(\beta) \to 0^+$, while for $\beta \to \infty$, we have

$$h_+(\beta) = \frac{1}{\pi} + \frac{1}{\pi\beta}\left(\cos\theta - \frac{2}{\pi}\right) + O\left(\frac{1}{\beta^2}\right). \tag{52}$$

In other words, if $\cos\theta \le \frac{2}{\pi}$ or $\theta \ge \arccos\frac{2}{\pi}$, we have $h_+(\beta) \to (\frac{1}{\pi})^-$ (the second order term is negative for $\cos\theta = \frac{2}{\pi}$), while for $\theta < \arccos\frac{2}{\pi}$ we approach the same limit from above as $h_+(\beta) \to (\frac{1}{\pi})^+$. For $\theta < \arccos\frac{2}{\pi}$ there is a non-trivial maximum at some value $\beta = \beta_0 \in (1, \infty)$, while for $\theta \ge \arccos\frac{2}{\pi}$, we can see from the derivative $h'_+(\beta)$ that $h_+(\beta)$ is strictly increasing on $(1, \infty)$, and the supremum is attained at $\beta \to \infty$. We therefore obtain two different results, depending on whether $\theta < \arccos\frac{2}{\pi}$ or $\theta \ge \arccos\frac{2}{\pi}$.

Case 1: $\arccos\frac{2}{\pi} \le \theta < \frac{\pi}{2}$. The supremum is attained in the limit of $\beta \to \infty$, which leads to $h_+(\beta) \to \frac{1}{\pi}$ and the stated expression for $\Lambda^*_+(xy\cos\theta, x^2, y^2)$.

Case 2: $0 < \theta < \arccos\frac{2}{\pi}$. In this case there is a non-trivial maximum at some value $\beta = \beta_0$, namely there where the derivative $h'_+(\beta_0) = 0$. After computing the derivative, eliminating the (positive) denominator and rewriting, this condition is equivalent to (1). This allows us to rewrite g and Λ^* in terms of β_0, by substituting the given expression for $\arcsin\left(\frac{1}{\beta_0}\right)$, which ultimately leads to the stated formula for Λ^*_+. ◀

▶ **Lemma 16** (Computing $\Lambda^*(\boldsymbol{z})$ for negative λ_1)**.** *Let $\boldsymbol{z} = (xy\cos\theta, x^2, y^2)$ with $x, y > 0$ and $\theta \in (0, \frac{\pi}{2})$. For $\theta \in (\arccos\frac{2}{\pi}, \frac{\pi}{3})$, let $\beta_1 \in (1, \infty)$ be the unique solution to (1). Then the Fenchel-Legendre transform Λ^* at $\boldsymbol{z}$, restricted to $\lambda_1 < 0$, satisfies*

$$\Lambda^*_-(\boldsymbol{z}) = \frac{x^2}{2} + \frac{y^2}{2} - 1 - \ln(xy) + \begin{cases} 0, & \text{if } \theta \in (0, \arccos\frac{2}{\pi}]; \\ \ln\left(\frac{\pi\beta_1(\beta_1\cos\theta+1)}{2(\cos\theta+\beta_1)^2}\right), & \text{if } \theta \in (\arccos\frac{2}{\pi}, \frac{\pi}{3}); \\ \ln\left(\frac{\pi}{2(1+\cos\theta)}\right), & \text{if } \theta \in [\frac{\pi}{3}, \frac{\pi}{2}). \end{cases} \tag{53}$$

Proof. We again start by substituting $\lambda_1 < 0$ into (46):

$$\Lambda^*_-(xy\cos\theta, x^2, y^2) = \ln\pi + \frac{x^2}{2} + \frac{y^2}{2} + \sup_{\substack{\lambda_1<0 \\ \beta>1}}\Big\{g_-(\lambda_1,\beta)\Big\}, \tag{54}$$

$$g_-(\lambda_1,\beta) = (\cos\theta+\beta)\lambda_1 xy + \frac{\ln(\beta^2-1)}{2} + \ln(-\lambda_1) - \ln\left(\pi + 2\arctan\left(\frac{-1}{\sqrt{\beta^2-1}}\right)\right).$$

Differentiating w.r.t. λ_1 gives $(\cos\theta+\beta)xy + \frac{1}{\lambda_1}$. For $\lambda_1 \to -\infty$ this is positive, for $\lambda_1 \to 0^-$ this is negative, and so the maximum is at $\lambda_1 = -1/((\cos\theta+\beta)xy)$. Substituting this value for λ_1, and pulling out terms which do not depend on β yields:

$$\Lambda^*_-(xy\cos\theta, x^2, y^2) = \ln\left(\frac{\pi}{2}\right) + \frac{x^2}{2} + \frac{y^2}{2} - 1 - \ln(xy) + \sup_{\beta>1}\Big\{g_-(\beta)\Big\}, \tag{55}$$

$$g_-(\beta) = \ln\left(\frac{\sqrt{\beta^2-1}}{(\cos\theta+\beta)\arccos\frac{1}{\beta}}\right) = \ln h_-(\beta).$$

Above we used the identity $\pi + 2\arctan(-1/\sqrt{\beta^2-1}) = 2\arccos\frac{1}{\beta}$, where the factor 2 has been pulled outside the supremum. Now, differentiating h_- w.r.t. β results in:

$$h'_-(\beta) = \frac{\beta\sqrt{\beta^2-1}(\beta\cos\theta+1)\arccos\frac{1}{\beta} - \left(\beta^2-1\right)(\cos\theta+\beta)}{\beta\left(\beta^2-1\right)(\cos\theta+\beta)^2\arccos\frac{1}{\beta}}. \tag{56}$$

Clearly the denominator is positive, while for $\beta \to 1^+$ the limit is negative iff $\cos\theta < \frac{1}{2}$. For $\beta \to \infty$ we further have $h'_-(\beta) \to 0^-$ for $\cos\theta \le \frac{2}{\pi}$ and $h'_-(\beta) \to 0^+$ for $\cos\theta > \frac{2}{\pi}$. We therefore analyze three cases separately below.

Case 1: $\frac{\pi}{3} \le \theta < \frac{\pi}{2}$. In this parameter range, $h'_-(\beta)$ is negative for all $\beta > 1$, and the supremum lies at $\beta \to 1^+$ with limiting value $h_-(\beta) \to \frac{1}{1+\cos\theta}$. This yields the given expression for Λ^*_-.

Case 2: $\arccos\frac{2}{\pi} < \theta < \frac{\pi}{3}$. For θ in this range, $h'_-(\beta)$ is positive for $\beta \to 1^+$ and negative for $\beta \to \infty$, and changes sign exactly once, where it attains its maximum. After some rewriting, we find that this is at the value $\beta = \beta_1(\theta) \in (1, \infty)$ satisfying the relation from (1). Substituting this expression for $\arccos\frac{1}{\beta_1}$ into h_-, we obtain the result for Λ^*_-.

Case 3: $0 < \theta \le \arccos\frac{2}{\pi}$. In this case h'_- is positive for all $\beta > 1$, and the supremum lies at $\beta \to \infty$. For $\beta \to \infty$ we have $h_-(\beta) \to \frac{2}{\pi}$ (regardless of θ) and we therefore get the final claimed result. ◀

Proof of Theorem 1. Combining the previous two results with Lemma 12 and Equation 47, we obtain explicit asymptotics for $\mathbb{P}(\boldsymbol{Z}_d \approx (xy\cos\theta,\, x^2,\, y^2))$. What remains is a maximization over $x, y > 0$ of p, which translates to a minimization of Λ^*. As $\frac{x^2}{2} + \frac{y^2}{2} - 1 - \ln(xy)$ attains its minimum at $x = y = 1$ with value 0, we obtain Theorem 1. ◀

B Proof of Proposition 9

We will assume the reader is familiar with (the notation from) [23]. Let $t = 2^{c_t d + o(d)}$ denote the number of hash tables, and $n = (4/3)^{d/2+o(d)}$. Going through the proofs of [23, Appendix A] and replacing the explicit instantiation of the collision probabilities $(1 - \theta/\pi)$ by an arbitrary function $p(\theta)$, we get that the optimal number of hash functions concatenated into one function for each hash table, denoted k, satisfies

$$k = \frac{\ln t}{-\ln p(\theta_1)} = \frac{c_t d}{d' \log_2(\pi/\sqrt{3})}. \tag{57}$$

The latter equality follows when substituting $\theta_1 = \pi/3$ and substituting the collision probabilities for partial hypercube LSH in some dimension $d' \leq d$. As we need $k \geq 1$, the previous relation translates to a condition on d' as $d' \leq \frac{c_t}{\log_2(\pi/\sqrt{3})} d$. As we expect the collision probabilities to be closer to those of full-dimensional hypercube LSH when d' is closer to d, we replace the above inequality by an equality, and what remains is finding the minimum value c_t satisfying the given constraints.

By carefully checking the proofs of [23, Appendix A.2-A.3], the exact condition on c_t to obtain the minimum asymptotic time complexity is the following:

$$-c_n = \max_{\theta_2 \in (0,\pi)} \left\{ \log_2 \sin\theta_2 + \frac{c_t}{\rho(\frac{\pi}{3}, \theta_2)} \right\}. \tag{58}$$

Here $c_n = \frac{1}{2}\log_2(\frac{4}{3}) \approx 0.20752$, and $\rho(\theta_1, \theta_2) = \ln p(\theta_1)/\ln p(\theta_2)$ corresponds to the exponent ρ for given angles θ_1, θ_2. Note that in the above equation, only c_t is an unknown. Substituting the asymptotic collision probabilities from Theorem 1, we find a solution at $c_t \approx 0.11464$, with maximizing angle $\theta_2 \approx 0.45739\pi$. This corresponds to a time and space complexity of $(n \cdot t)^{1+o(1)} = 2^{(c_n + c_t)d + o(d)} \approx 2^{0.32216d + o(d)}$ as claimed.

Generalized Predecessor Existence Problems for Boolean Finite Dynamical Systems

Abstract

A Boolean Finite Synchronous Dynamical System (BFDS, for short) consists of a finite number of objects that each maintains a boolean state, where after individually receiving state assignments, the objects update their state with respect to object-specific time-independent boolean functions synchronously in discrete time steps. The present paper studies the computational complexity of determining, given a boolean finite synchronous dynamical system, a configuration, which is a boolean vector representing the states of the objects, and a positive integer t, whether there exists another configuration from which the given configuration can be reached in t steps. It was previously shown that this problem, which we call the t-Predecessor Problem, is NP-complete even for $t = 1$ if the update function of an object is either the conjunction of arbitrary fan-in or the disjunction of arbitrary fan-in.

This paper studies the computational complexity of the t-Predecessor Problem for a variety of sets of permissible update functions as well as for polynomially bounded t. It also studies the t-Garden-Of-Eden Problem, a variant of the t-Predecessor Problem that asks whether a configuration has a t-predecessor, which itself has no predecessor. The paper obtains complexity theoretical characterizations of all but one of these problems.

1 Introduction

A *dynamical system* is a time-dependent network of objects that models evolution, where each object holds a state value that is an element of a state set. The configuration of the system is the collective state of the objects and is the vector that assembles the states of all the objects in a certain order. Given an initial configuration, the system evolves over time through state update, where the state of an object is updated by a function that takes as input state values of some nodes, possibly its own state value. Variants of dynamical systems can be defined by considering the state set (binary, discrete, countably infinite, and uncountable), the types of permissible update functions, whether the number of states is fixed, and the order in which the updates are performed (either in a fixed order or all at the same time).

The simplest dynamical systems are those with the boolean state set, a fixed finite number of objects, and synchronous updates, where the state update function does not depend on the time distance from the start. These systems are called *boolean finite dynamical systems*

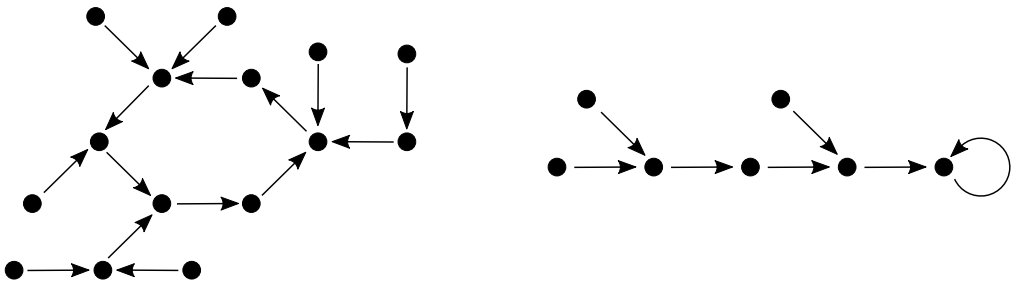

Figure 1 Configuration space with a loop, a fixed point, and flows into them. Dots represent configurations, and arrows do transitions. A node of in-degree 0 represents a Garden of Eden.

(BFDS) [1]. Quite often, the BFDS model is further simplified by assuming that the update functions are chosen from a collection of templates, such as the exclusive-or, the negation, the conjunction, and the disjunction.

Given a BFDS $\mathcal{F}$ of n objects, the number of possible configurations of the system is 2^n. Due to the assumptions that the updates are synchronized and that the update function does not change over time, the imposed finiteness of the system configuration space leads to important facts: for each initial configuration $\mathbf{a}$, the system starting from $\mathbf{a}$ either converges to a fixed point or enters some loop having length ≥ 2 and that the convergence or the entrance to a loop takes place within 2^n steps from departure (see Figure 1). These facts mean that the dichonomical fate of an initial configuration in a BFDS can be tested in the linear space. In fact, the fate-determination problem (or the convergence problem) as well as its variant, the reachability problem (whether a configuration be reached from another configuration with respect to a given BFDS), is PSPACE-complete if a complete boolean basis is available for building update functions and the complexity is lower for both problems otherwise [3]. The BDFS offers a rich theory not only in terms of fixed points, reachability, and cycles, but also in terms of the reversal, that is, the action of going back in time starting from a given configuration. Since the system changes two distinct configurations the same configuration with a single update, so a given configuration may have multiple predecessors. Also, there may exist configurations without predecessors. We call such a configuration *Garden of Eden (GOE)* (see Figure 1).

If the update functions are each polynomial time computable, which is indeed the case where the functions are chosen from a predetermined set of templates, testing whether a given configuration of a BFDS has a predecessor can be answered in NP, and thus, whether the configuration is a GOE can be answered in coNP. In fact, it is NP-complete to decide whether a configuration is *not* a GOE [2]. This paper makes a deeper investigation into this problem by asking how much simplification can be given the template set for update functions to retain this completeness. We show: if the templates are either only conjunction or only disjunction the GOE problem is in AC^0; if the templates are the two-fan-in conjunction and the two-fan-in disjunction, then the GOE problem is NL-complete; if the templates are either the combination of the two-fan-in conjunction and the three-fan-in disjunction or the combination of the two-fan-in disjunction and the three-fan-in conjunction, then the GOE problem is coNP-complete.

We generalize the GOE Problem further in two ways. First, for an integer $t \geq 1$, we ask whether we can go back from a given configuration successively t times, by cleverly choosing at each time one of the possible predecessors, if any at all. We call this problem the t-Predecessor Existence Problem (the t-PRED Problem, for short). Second, for an integer

$t \geq 0$, we ask whether we can go back from a given configuration successively t times and arrive at a GOE, by cleverly choosing at each time one of the possible predecessors, if any at all. We call this problem the t-Garden Of Eden Existence Problem (the t-GOE Problem, for short). The GOE Problem we mentioned earlier is indeed the 0-GOE Problem in this extension. It is easy to see that the 1-PRED Problem is exactly complementary to the 0-GOE Problem; but, for $t \geq 2$, the t-PRED is not necessarily complementary to the $(t-1)$-GOE Problem.

In this paper we ask the complexity of these two extensions with the functions restricted to be disjunction and conjunction. Except for the 1-GOE Problem with 2-fan-in disjunction and 2-fan-in conjunction, we obtain complete characterization of the constant-bounded as well as the polynomial-bounded t-PRED Problem and t-GOE Problem for all the templates consisting of conjunction and disjunction (see Table 1 in Section 2).

We note here that the papers [5, 6] show that the problem of computing fixed points in a BFDS exhibits a curious dichotomy between P and #P-complete and that [8] studies the problem of calculating the length of a cycle that an initial configuration is eventually taken to, and shows that the problem is polynomial-time solvable for some template sets, computable in UP for some, and PSPACE-complete for some. Along with these prior papers, our paper shows BFDS offers a rich theory of computational complexity.

This paper is organized as follows: In the next section we go over the definitions and prove some useful lemmas and propositions. We then show the results on the predecessor existence problems in Section 3 and the results on the Garden of Eden problems in Section 4. We will conclude the paper in Section 5.

2 Preliminaries

For an integer $n \geq 1$, a *synchronous boolean finite dynamical system* (synchronous BFDS, for short) $\mathcal{F}$ of n objects consists of n variables $x_1, \ldots, x_n$ and n boolean functions $(f_1, f_2, \ldots, f_n)$ such that for each i, $1 \leq i \leq n$, f_i is a boolean function that takes input from $x_1, \ldots, x_n$. A *state configuration* $\mathbf{a}$ (or simply a *configuration*) of $\mathcal{F}$ is an n-dimensional boolean vector and for each variable x, $\mathbf{a}[x] \in \{0, 1\}$ represents the component of $\mathbf{a}$ corresponding to x. The action of $\mathcal{F}$ on an state configuration $\mathbf{x}$ is defined by: $\mathcal{F}(\mathbf{x}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_n(\mathbf{x}))$. In other words, the elements of $\mathcal{F}(\mathbf{x})$ are obtained by applying the n boolean functions $f_1, \ldots, f_n$ concurrently on the variables $x_1, \ldots, x_n$.

In the remainder of the paper, boolean dynamical systems are defined without giving an explicit ordering among the objects. We will use the notation $\mathcal{F}[x]$ to mean the function of the dynamical system $\mathcal{F}$ for the object x.

Given an initial state configuration $\mathbf{x}^0$, the synchronous BFDS generates a sequence of state configurations by iterative applications of $\mathcal{F}$: For all $t \geq 0$, $\mathbf{x}^{t+1} = \mathcal{F}(\mathbf{x}^t)$, where $\mathbf{x}^t = (x_1^t, x_2^t, \ldots, x_n^t)$. In other words, for all $t \geq 0$, $\mathbf{x}^t = \mathcal{F}^t(\mathbf{x}^0)$.

Although we use the notation to mean that all the n variables are fed to each f_i, in reality some f_i may depend on a proper subset of the variables. Let g be a boolean function possibly with arity less than n. We say that f_i has template g to mean that f_i is equivalent to g with input variables properly chosen from $x_1, \ldots, x_n$. Given a collection of boolean functions, we say that $\mathcal{F}$ *has template set* $\mathcal{B}$ if each function in $\mathcal{F}$ has template in $\mathcal{B}$. We are interested in the following functions as template:

- id: this is the identity function with only one input that outputs the value of its input without changing it;
- AND_k, $k \geq 1$: this is the conjunction of arity k;
- OR_k, $k \geq 1$: this is the disjunction of arity k.

Note that for all $k \geq 2$ and $m < k$ AND_k (OR_k, respectively) can be used as a template for AND_m (OR_m, respectively) by repeating some of the inputs. Note also that both AND_1 and OR_1 are identical to id.

We are interested in the following template sets:

- $\mathcal{B}_{\mathrm{id}} = \{\mathrm{id}\}$,
- $\mathcal{B}_{2\mathrm{OR}} = \{\mathrm{OR}_2\}$ and $\mathcal{B}_{2\mathrm{AND}} = \{\mathrm{AND}_2\}$,
- $\mathcal{B}_{\mathrm{OR}} = \{\mathrm{OR}_k \mid k \geq 1\}$ and $\mathcal{B}_{\mathrm{AND}} = \{\mathrm{AND}_k \mid k \geq 1\}$,
- $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}} = \{\mathrm{OR}_2, \mathrm{AND}_2\}$,
- $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}} = \{\mathrm{OR}_3, \mathrm{AND}_2\}$ and $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}} = \{\mathrm{OR}_2, \mathrm{AND}_3\}$.

Given a synchronous BFDS $\mathcal{F}$ and a configuration $\mathbf{a}$ of $\mathcal{F}$, we say that another configuration $\mathbf{b}$ is the *t-th predecessor of* $\mathbf{a}$, $t \geq 1$, if $\mathcal{F}^t(\mathbf{b}) = \mathbf{a}$. We will omit the word *first* in the case where $t = 1$. By convention, we define the 0-th predecessor of $\mathbf{a}$ to be $\mathbf{a}$ itself. We say that $\mathbf{a}$ is a Garden of Eden if $\mathbf{a}$ has no predecessor. We then consider the following problems.

- Let t, $t \geq 1$, be a fixed constant. Given a synchronous BFDS $\mathcal{F}$ with template set $\mathcal{B}$ and a configuration $\mathbf{a}$, the t-PRED Problem for $\mathcal{B}$ asks whether $\mathbf{a}$ has a t-th predecessor.
- Let t, $t \geq 0$, be a fixed constant. Given a synchronous BFDS $\mathcal{F}$ with template set $\mathcal{B}$, a configuration $\mathbf{a}$, the t-GOE Problem for $\mathcal{B}$ asks whether $\mathbf{a}$ has a t-th Garden of Eden, i.e., a t-th predecessor that is a Garden of Eden.

We also consider the polynomial version of the two problems.

- Given a synchronous BFDS $\mathcal{F}$ with template set $\mathcal{B}$, a configuration $\mathbf{a}$, and p presented in unary as 1^p, the Poly-PRED Problem for $\mathcal{B}$ asks whether $\mathbf{a}$ has a p-th predecessor.
- Given a synchronous BFDS $\mathcal{F}$ with template set $\mathcal{B}$, a configuration $\mathbf{a}$, and p presented in unary as 1^p, the Poly-GOE Problem for $\mathcal{B}$ asks whether $\mathbf{a}$ has a p-th Garden of Eden.

Note that as long as the predecessor existence and Garden of Eden problems go, by exchanging simultaneously between AND and OR and between true and false, any complexity result with respect to $\mathcal{B}_{\mathrm{AND}}$ holds with respect to $\mathcal{B}_{\mathrm{OR}}$. The same relation holds between $\mathcal{B}_{2\mathrm{AND}}$ and $\mathcal{B}_{2\mathrm{OR}}$ and between $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$ and $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$.

The 1-PRED and 0-GOE are generally called the Predecessor Existence Problem and the Garden-of-Eden Problem, respectively, and have been well studied. We note here that the synchronous BFDS often assumes that for each object its update function takes its state as part of the input; that is, x_i is one of the inputs to f_i. In this paper we remove that restriction, since if for all i it holds that f_i is either disjunction or conjunction whose inputs include x_i, the system $\mathcal{F}$ is monotone and converges within n steps, which gives little room for exploration.

For GOE Problem, in [2] it is shown that for the sequential dynamical systems (that is, the systems in which updates are performed one variable at a time with respect to a predetermined order), t-PRED is NP-complete even if the template set consists of AND's and OR's of any arity. The proof of this result does not directly imply the same result for the synchronous dynamical system.

In the case of sequential and synchronous dynamical systems, we have the following:

▶ **Proposition 1** ([2]). *The Poly-PRED Problem is solvable in polynomial time if $\mathcal{B}$ is one of the following: (i) ANDs of any fan-in and their negation, (ii) ORs of any fan-in and their negation, and (iii) XORs of any fan-in and their negation.*

For GOE Problem, the following is known:

▶ **Proposition 2** ([2]). 0-*GOE Problem is* coNP-*complete in general, but is solvable in polynomial time if* 1-*PRED Problem is solvable in polynomial time.*

Table 1 The results from this paper. The left panel is for the PRED Problems and the right panel is for the GOE problems. For "?" it is only known that the problem is NL-hard and in NP. The "-C" stands for "-complete".

Table 1 summarizes the results shown in this paper.

We prove the following lemma, which will be useful in proving results on $\mathcal{B}_{\mathrm{OR}}$ and $\mathcal{B}_{2\mathrm{OR}}$.

▶ **Definition 3.** Let $\mathcal{F}$ be an n-variable synchronous BFDS, let $\mathbf{a}$ be a configuration of $\mathcal{F}$, and let $t \geq 1$ be an integer. Define a directed graph $G[\mathcal{F}, \mathbf{a}, t] = (V, E)$ with V partitioned into two groups K and L as follows:

- $V = V_0 \cup \ldots \cup V_t$ and for each i, $0 \leq i \leq t$, $V_i = \{v_{i,1}, \cdots, v_{i,n}\}$;
- $E = \{(v_{i,p}, v_{i+1,q}) \mid 0 \leq i \leq t-1$ and the function for x_p takes input from x_q $\}$.
- $L = L_0 \cup \ldots \cup L_t$, where $L_0 = \{v_{0,j} \mid$ the value of x_j in $\mathbf{a}$ is false $\}$ and for each i, $1 \leq i \leq t$, L_i is the set of all nodes in V_i that are reachable from L_0.
- $K = K_0 \cup \ldots \cup K_t$ and for each $i, 0 \leq i \leq t$, $K_i = V_i - L_i$; specifically, $K_0 = \{v_{0,j} \mid$ the value of x_j in $\mathbf{a}$ is true $\}$.

▶ **Lemma 4.** *Let $\mathcal{F}$ be an n-variable synchronous BFDS whose template set is the OR function. Let $t \geq 1$ and $\mathbf{a}$ a configuration of $\mathcal{F}$. Let $G = (V, E) = G[\mathcal{F}, \mathbf{a}, t]$ be as defined in the above and (K, L) be the partition of V. Then*

1. *$\mathbf{a}$ has a t-th predecessor if and only if for each $u \in K_0$ there is a path to a node in K_t that does not visit any node in L.*
2. *$\mathbf{a}$ has a t-th Garden-of-Eden predecessor if and only if there exist some $M = \{v_{t,j_1}, \ldots, v_{t,j_m}\} \subseteq V_t$ and $v_{t,j_0} \in K_t \backslash M (= V_t - (L_t \cup M))$ such that:*
   1. *for each $u \in K_0$ there is a path to a node in $K_t \setminus M$ that does not visit any node in $L \cup M$,*
   2. *each input of the function for x_{j_0} is an input of the function for one of $x_{j_1}, \cdots, x_{j_m}$, and*
   3. *the cardinality of M is no greater than the arity of the function for x_{j_0}.*

Proof. (The Predecessor Case) Suppose the condition in the lemma is satisfied. For each $u \in K_0$ choose one L-free path to some node in K_t. For each $i, 0 \leq i \leq t$, define $B_i = \{v_{i,j} \mid v_{i,j}$ appears on one of the chosen paths $\}$. Then $B_i \subseteq K_i$ for all i. For each $i, 0 \leq i \leq t$, define configuration $\mathbf{b}_i$ by setting the value of a variable x_j true if $v_{i,j} \in B_i$ and false otherwise. Then $\mathbf{b}_0 = \mathbf{a}$ and for all $i, 0 \leq i \leq t-1$, $\mathcal{F}(\mathbf{b}_{i+1}) = \mathbf{b}_i$. Thus, $\mathbf{b}_t$ is a t-th predecessor. On the other hand, suppose $\mathbf{a}$ has a t-th predecessor. Let $\mathbf{b}_0 = \mathbf{a}$. Select configurations $\mathbf{b}_1, \ldots, \mathbf{b}_t$ so that for each $i, 0 \leq i \leq t-1$, $\mathbf{b}_{i+1}$ is a predecessor of $\mathbf{b}_i$. For each $i, 0 \leq i \leq t$, let $S_i = \{v_{i,j} \mid \mathbf{b}_i$ assigns true to $x_{i,j}$ $\}$. Then $S_0 = K_0$. Because of the predecessor relations, for each $i, 1 \leq i \leq t$, $S_i \subseteq K_i$ and each node $u \in S_i$ has at least one incoming edge from S_{i-1}. Thus, the property holds for $\mathcal{F}$, $\mathbf{a}$, and t.

(The Garden Of Eden Case) Suppose that the conditions stated in the lemma hold. As before for each $u \in K_0$ choose a path that is free on $M \cup L$ but ensure that one of the paths arrive at some node in $K_t \setminus M$. Then, following the argument as before, the configurations induced by the path nodes form a series of t configurations arriving at $\mathbf{a}$. For $\mathbf{b}_t$, the value of x_{j_0} is true and the values of $x_{j_1}, \ldots, x_{j_m}$ are false. Each input of x_{j_0} is also an input of one of $x_{j_1}, \ldots, x_{j_m}$. Any predecessor of $\mathbf{b}_t$ must assign true to one of the inputs of x_{j_0} and must assign false to all of the inputs of $x_{j_1}, \ldots, x_{j_m}$, but that is not possible. Thus, there is no predecessor of $\mathbf{b}_t$.

On the other hand, suppose that there is a t-th predecessor of $\mathbf{a}$ that is a Garden of Eden. Select such one and define $\mathbf{b}_0, \ldots, \mathbf{b}_t$ and $S_0, \ldots, S_t$ as before. We have, as we have observed previously, for all $i, 0 \leq i \leq t$, $S_i \subseteq K_i$, and each node in $S_0 \cup \cdots \cup S_t$ is along an L-free path from K_0 (which is equal to S_0) to S_t. Let R be the variables that supply input to the variables corresponding to the nodes in $V_t - S_t$. In any predecessor of $\mathbf{b}_t$, the value of each variable in R must be false while each variable in $X - R$ can be set to true if needed. Then, that $\mathbf{b}_t$ is a Garden of Eden implies that there is some variable $u \in S_t$ all of whose input belong to R. Select one such u and for each input h of u, select a variable R that takes input from h. Construct M by placing the chosen variables from R. Then u and M satisfy the property in question. ◀

We have straightforward upper bounds on the predecessor and Garden-Of-Eden problems.

▶ **Proposition 5** ([2]). *Suppose the template set $\mathcal{B}$ consists only of polynomial-time computable boolean functions. Then the Poly-PRED Problem is in* NP.

▶ **Proposition 6.** *Suppose the template set $\mathcal{B}$ consists only of polynomial-time computable boolean functions. Then the Poly-GOE Problem is in Σ_2^p.*

The following proposition is useful to reduce the predecessor problems to Garden-Of-Eden problems.

▶ **Proposition 7.** *Given a synchronous BFDS $\mathcal{F}$, its configuration $\mathbf{a}$, and $t \geq 1$, we can add $t+2$ variables to $\mathcal{F}$ and $\mathbf{a}$ to create a new BFDS $\mathcal{F}'$ and $\mathbf{a}'$ so that:*

- *if $\mathbf{a}$ has a t-th predecessor in $\mathcal{F}$, then $\mathbf{a}'$ has a t-th predecessor in $\mathcal{F}'$ and none of its t-th predecessors have a predecessor; and*
- *if $\mathbf{a}$ does not have a t-th predecessor in $\mathcal{F}$, then $\mathbf{a}'$ does not have a t-th predecessor in $\mathcal{F}'$.*

Proof. Let $\mathcal{F}$, $\mathbf{a}$, and t be given. Introduce $t+2$ variables $e_0, \ldots, e_{t+1}$. We define the function of e_0 to be $\mathrm{id}(e_0)$ and the function for $e_i, 1 \leq i \leq t+1$, to be $\mathrm{id}(e_{i-1})$. This is $\mathcal{F}'$. We then add to $\mathbf{a}$ the values of e_i as all false except e_{t+1}. Then, for each i, $1 \leq i \leq t$, the i-th predecessor of the additional part has false for $e_0, \ldots, e_{t-i}$ and true for e_{t-i+1}. Specifically we have that the t-th predecessor on this part has false for e_0 and true for e_1. Since e_0 and e_1 take input from e_0 and is the identify function, clearly, such a t-th predecessor cannot have a predecessor. Since the new variables and functions are disjoint with those in the original, the new part does not affect the invertibility of the original part. This proves the proposition. ◀

The last general result we present in this section shows that if a predecessor problem with a certain template set (respectively, a GOE problem with a certain template set) for some t is hard a problem H, then the problem is hard for $t+1$. We omit the proof of this lemma.

▶ **Lemma 8.** *Let $\mathcal{B}$ be a template set containing the two-fan-in OR. Suppose there is a many-one reduction g from a problem H to the t-predecessor problem with $t \geq 1$ (respectively,*

the t-GOE problem with $t \geq 0$). Then there is a many-one reduction g' from H to the $(t+1)$-predecessor problem (respectively, the $(t+1)$-GOE problem). Furthermore, if g is logspace computable (polynomial-time computable) using $\mathcal{B}$ as the oracle, then so is g'.

3 The Complexity of Predecessor Problems

We first consider the case of $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$ and $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$, and prove that the problems are NP-complete.

▶ **Theorem 9.** *For $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$ and $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$, the t-PRED Problem is* NP*-complete for all constants $t \geq 1$.*

Proof. The inclusion in NP follows from Proposition 5.

We consider $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$ for NP-hardness and provide a polynomial-time many-one reduction from 3SAT to the 1-PRED Problem. Let φ be a 3CNF formula with n variables and m clauses. We introduce variables w, $c_1, \ldots, c_m$, $y_{1,0}, y_{1,1}, \ldots, y_{n,0}, y_{n,1}$, and $z_{1,0}, z_{1,1}, \ldots, z_{n,0}, z_{n,1}$. We associate $y_{i,1}$ with the positive literal of the i-th variable of y and $y_{i,0}$ with the negative literal of the i-th variable. We define the functions for these variables as follows:

- w, $y_{i,0}$, $y_{i,1}$: the function is $\mathrm{id}(w)$.
- $z_{i,0}$: $\mathrm{OR}(y_{i,0}, y_{i,1})$.
- $z_{i,1}$: $\mathrm{AND}(y_{i,0}, y_{i,1})$.
- c_j: Let the three literals of C_j be $y_{p,b}$, $y_{q,c}$, and $y_{r,d}$. Then the function is $\mathrm{OR}(y_{p,b}, y_{q,c}, y_{r,d})$.

We set the values of the variables in $\mathbf{a}$ to true for w, $y_{i,0}$, $y_{i,1}$, and $z_{i,0}$ and false for $z_{i,1}$.

Suppose $\mathbf{a}$ has a predecessor $\mathbf{b}$. Then for all i, since $z_{i,0}$ is true and $z_{i,1}$ is false in $\mathbf{a}$, in $\mathbf{b}$ exactly one of $y_{i,0}$ and $y_{i,1}$ is true and the values of y's in $\mathbf{b}$ can be viewed as a truth-assignment to the n variables of φ. Then, for all j, c_j is true in $\mathbf{a}$ and the inputs to the function for c_j correspond to the literals of C_j, it must be the case that the truth-assignment as represented by the y's in $\mathbf{b}$ form a satisfying assignment of φ. This means that φ is satisfiable.

On the other hand, suppose that φ is satisfiable. We take one satisfying assignment α of φ and build $\mathbf{b}$ by setting the values to y's according to α, true to w, and an arbitrary value to z's. Then $\mathcal{F}(\mathbf{b}) = \mathbf{a}$ and so $\mathbf{a}$ has a predecessor.

Clearly, this reduction can be computed in polynomial time, and so the theorem holds for $t = 1$. By combining this with Lemma 8, we obtain the proof for $t \geq 2$. ◀

We then consider the case of $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$. In this case, the problem is tractable only when $t = 1$.

▶ **Theorem 10.** *For $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$, the* 1*-PRED Problem is* NL*-complete and for all constants $t \geq 2$ the problem is* NP*-complete.*

Proof. It is easy to see that the above proof can be carried out for 2SAT with a logspace computable many-one reduction and so the 1-PRED Problem with $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$ is NL-hard. To show that the problem is in NL, note that in the case of $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$, given a configuration $\mathbf{a}$, the value assignments to its predecessor can be written as a 2CNF formula with possible single-literal clauses; e.g., $\mathrm{OR}(x, y) = \text{true}$ can be expressed as $x \vee y$.

For the 2-PRED Problem, the main idea is to break the computation of three-literal ORs into the OR to two two-variable ORs. We introduce alternating variables w_1 and w_2 whose functions are $\mathrm{id}(w_2)$ and $\mathrm{id}(w_1)$, respectively, and set their values in $\mathbf{a}$ to be true

and false, respectively. Then for any predecessor of $\mathbf{a}$, their values should be false and true, respectively, and for any second predecessor of $\mathbf{a}$, their values should be true and false, respectively. We use variables $y_{i,0}, y_{i,1}, z_{i,0}, z_{i,1}$ as in the case of $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$ and add $u_{i,0}, u_{i,1}$. For each j, we introduce three variables c_j, d_j, and e_j and define their functions to be $\mathrm{OR}(d_j, e_j)$, $\mathrm{OR}(y_{p,c}, y_{q,d})$, and $\mathrm{OR}(y_{p,c}, y_{r,e})$ where $y_{p,c}, y_{q,d}$, and $y_{r,e}$ are the three literals of C_j. We define the functions for $y_{i,b}$ to be $\mathrm{OR}(y_{i,b}, w_1)$ for each $b \in \{0,1\}$, the functions for $u_{i,b}$ to be $\mathrm{id}(z_{i,b})$, the functions for $z_{i,0}$ to be $\mathrm{OR}(y_{i,0}, y_{i,1})$, and the functions for $z_{i,1}$ to be $\mathrm{AND}(y_{i,0}, y_{i,1})$.

In $\mathbf{a}$ we set the value of w_2 and all $u_{i,1}$ to false and set everything else to true. Assume $\mathbf{a}$ has a predecessor $\mathbf{a}'$ and $\mathbf{a}'$ has a predecessor $\mathbf{a}''$. The values of $y_{i,0}$ and $y_{i,1}$ in $\mathbf{a}''$ are OR-ed and AND-ed and stored in $z_{i,0}$ and $z_{i,1}$, respectively, in $\mathbf{a}'$ and then preserved in $u_{i,0}$ and $u_{i,1}$, respectively, in $\mathbf{a}$. So, it must be the case that exactly one of $y_{i,0}$ and $y_{i,1}$ is true in $\mathbf{a}''$ and thus we can view these as truth-assignments to the variables of φ. For each clause C_j, the first and the second literals of C_j as appearing in $\mathbf{a}''$ are OR-ed and stored in $\mathbf{a}'$ as d_j as well as the first and the second literals as e_j. These two are then joined by an OR in $\mathbf{a}$ as c_j. Thus, for $\mathbf{a}''$ to exist the y's in $\mathbf{a}''$ must represent a satisfying assignment of φ. Because y's are OR-ed with w_1 and $\mathbf{a}''$ should have true for w_1, y's in $\mathbf{a}'$ are all true. This means that z's, d's, and e's become all true in $\mathbf{a}$. Thus, $\mathbf{a}$ has a second predecessor if and only if φ is satisfiable.

The hardness for the case $t \geq 3$ follows from Lemma 8. ◀

If $\mathcal{B}$ contains only conjunction or only disjunction, the problems are significantly easy.

▶ **Theorem 11.** *For $\mathcal{B}_{\mathrm{OR}}$ and $\mathcal{B}_{\mathrm{AND}}$, the t-PRED Problem is in AC^0 for all constants $t \geq 1$.*

Proof. Suppose that $\mathcal{B}$ is $\mathcal{B}_{\mathrm{OR}}$, and we are given $\mathcal{F}$ and $\mathbf{a}$. Let $G = (V, E) = G[\mathcal{F}, \mathbf{a}, t]$, and (K, L) be the partition of V as given in Definition 3. By Lemma 4, we have only to, for each $u \in K_0$, enumerate all the paths from u to V_t and then check if the reachable nodes in K_t can be reachable from L_0. Since the number of all the paths in G is $O(n^t)$, this can be carried out using an AC^0 circuit. Thus, we have done. ◀

We now consider Poly-PRED Problems where t is part of the input. By combining Proposition 5 and Theorem 9, we obtain the following corollary for the case where $\mathcal{B}$ contains both conjunction and disjunction.

▶ **Corollary 12.** *Suppose $\mathcal{B}$ is one of $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$, $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$, and $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$. Then the Poly-PRED Problem with template set $\mathcal{B}$ is* NP*-complete.*

In the case of $\mathcal{B}_{\mathrm{id}}$, the problem is L-complete, and in the case of $\mathcal{B}_{\mathrm{OR}}$ and $\mathcal{B}_{\mathrm{AND}}$, the problem is NL-complete. The proofs are omitted due to the page limitation.

▶ **Theorem 13.** *The Poly-PRED Problem with template set $\mathcal{B}_{\mathrm{id}}$ is* L*-complete under logspace-uniform AC^0-reductions.*

▶ **Theorem 14.** *Suppose $\mathcal{B}$ is either $\mathcal{B}_{\mathrm{OR}}$ or $\mathcal{B}_{\mathrm{AND}}$. Then the Poly-PRED Problem with template set $\mathcal{B}$ is* NL*-complete under logspace-uniform AC^0-reductions.*

4 The Complexity of Garden-of-Eden Problems

In this section we prove our results on the Garden of Eden problems. In the previous section we prove our hardness results by producing a many-one reduction from a language L to a synchronous BFDS and $\mathbf{a}$ so that there is a t-th predecessor if the input is a member of L and so that there is a $(t-1)$-st predecessor but no t-th predecessor if the input is not a

member of L. One may think that this construction can be used to produce a many-one reduction from the complement of L to the $(t-1)$-st GOE problem with respect to the same BFDS. Unfortunately, this is not the case because according to the construction there may be multiple first predecessors of $\mathbf{a}$ and so even in the case where the input is a member of L, not every $(t-1)$-st predecessor of $\mathbf{a}$ has a predecessor. Thus, to prove the hardness of a Garden of Eden problem for a language L the construction must be such that if the input is in L, there is a $(t-1)$-st predecessor that is a Garden of Eden and such that if the input is not in L, *every* $(t-1)$-st predecessor has a predecessor.

As mentioned earlier, unlike other $t \geq 1$, 0-GOE Problem is complementary to 1-PRED Problem. Noting that NL is closed under complementation [4, 7], we have the following result from Theorems 9 and 10.

▶ **Theorem 15.** *The* 0*-GOE Problem is in* AC^0 *if the template set is one of* $\mathcal{B}_{\mathrm{id}}$*,* $\mathcal{B}_{2\mathrm{OR}}$*,* $\mathcal{B}_{2\mathrm{AND}}$*,* $\mathcal{B}_{\mathrm{OR}}$*, and* $\mathcal{B}_{\mathrm{AND}}$*,* NL*-complete if the template set is* $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$*, and* coNP*-complete if the template set is either* $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$ *or* $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$*.*

Consider then the case where $t \geq 1$. We first observe an upper bound on the problems for the case of $\mathcal{B}_{\mathrm{OR}}$ and $\mathcal{B}_{\mathrm{AND}}$.

▶ **Lemma 16.** *The Poly-GOE Problem with template* $\mathcal{B}_{\mathrm{OR}}$ *or* $\mathcal{B}_{\mathrm{AND}}$ *is in* NP*.*

Proof. Let $\mathcal{F}$ be a synchronous BFDS with template $\mathcal{B}_{\mathrm{OR}}$ with n variables $x_1, \ldots, x_n$ and let $\mathbf{a}$ be a configuration of $\mathcal{F}$. Suppose we are testing whether $\mathbf{a}$ is a t-th predecessor and is a GOE in the system $\mathcal{F}$ and t is given as 1^t as part of input. Consider a layered digraph $G = (V, E)$ whose variable set V has $t+2$ layers, $X_0, \ldots, X_t, X_{t+1}$, where for each j, $0 \leq j \leq t+1$, X_j consists of n variables $x_{1,j}, \ldots, x_{n,j}$. We draw a directed edge $(x_{i,j}, x_{i',j'})$ if $0 \leq j \leq t$, $j' = j+1$, and $x_{i'}$ is an input to the OR function for x_i.

Let S be the set of all $x_{i,0}$ such that the value of x_i is true in $\mathbf{a}$ and Let S' be the set of all $x_{i,0}$ such that the value of x_i is false in $\mathbf{a}$. Let R be the set of all nodes reachable from S'. Let $T' = R \cap X_t$ and $T = X_t - T'$.

We claim that $\mathbf{a}$ has a t-th predecessor that is a GOE if and only if there exists a set $D \subseteq T$ such that (i) from each node in S there is a path to a node in D that does not visit R and (ii) there is a node u in D such that every node v in X_{t+1} is reached from u is reached from some node in $X_t - D$.

Suppose there is such a D. Define a configuration $\mathbf{b}$ by setting the value of u to true if and only if it belongs to D. Since D is reachable from S without going through the nodes in R and $D \cap R = \emptyset$, we have $\mathcal{F}^t(\mathbf{b}) = \mathbf{a}$ and so $\mathbf{a}$ is a t-th predecessor of $\mathbf{a}$. Each predecessor $\mathbf{b}$ of must have a value true for at least one of the variables v that is reachable from u, but since $\mathbf{b}$ has value false for all the nodes in $X_t - D$, all of them must have value false. These two requirements are conflicting with each other and cannot be satisfied at the same time. Thus, $\mathbf{b}$ is a GOE.

On the other hand, suppose there is no such a D. Suppose there is no D satisfying (i), it means that $\mathbf{a}$ does not have a t-th predecessor, and so, $\mathbf{a}$ does not have a t-th predecessor that is a GOE. Suppose there is a D satisfying (i) but each such D fails to satisfy (ii). For each such D we define $\mathbf{b}$ to be configuration that assigns true to all variables in D and false to the rest. Also, for each such D we can select for each $u \in D$ select one node v in $X_{t+1} - R$ that is reachable from u. By setting the value to true for all v's thus selected to false for the remainder, we obtain a configuration $\mathbf{c}$. Then $\mathbf{b}$ is a t-th predecessor of $\mathbf{a}$ and $\mathbf{c}$ is a predecessor of $\mathbf{b}$ and so every t-th predecessor of $\mathbf{a}$ has a predecessor.

To test the existence of a D in question, we calculate S, S', R, T', T and then try all possible combinations of $D \subseteq T$ and $u \in D$, and so the test can be carried out in NP.

This proves the lemma. ◀

Unlike predecessor problems, Garden-of-Eden problem is NP-complete even if $\mathcal{B}$ is either $\mathcal{B}_{\mathrm{OR}}$ or $\mathcal{B}_{\mathrm{AND}}$ and t is part of the input.

▶ **Theorem 17.** *The* 1*-GOE Problem with template* $\mathcal{B}_{\mathrm{OR}}$ *or* $\mathcal{B}_{\mathrm{AND}}$ *is* NP*-complete.*

Proof. Because we have Lemma 16, we have only to show that the 1-GOE Problem is NP-hard. We will reduce 3SAT to the problem. Let φ be a 3CNF formula of n variables and m clauses. Our synchronous BFDS uses variables, among other, $x_{i,0}, x_{i,1}, y_{i,0}, y_{i,1}, u_i, z_i, 1 \leq i \leq n$, $c_j, 1 \leq j \leq m$. The idea is to use $y_{i,0}$ and $y_{i,1}$ to encode purported value assignments to the negative and the positive literals of x_i. These assignments are not necessarily opposite to each other. We use the variable u_i to generate $y_{i,0}$ as the OR of $x_{i,0}$ and u_i and generate $y_{i,1}$ as the OR of $x_{i,1}$ and u_i. We generate z_i as the OR of $y_{i,0}$ and $y_{i,1}$. We use the value assignments to the literal $y_{i,b}$'s to evaluate the variables c_j's, which are corresponding to the clauses. If φ is satisfiable, it is possible to choose the values for $y_{i,b}$'s so that for each i, $y_{i,0}$ and $y_{i,1}$ are opposite to each other and so u_i is false. If φ is not satisfiable, to make the value of c_j true for all i, we need to assign true to both $y_{i,0}$ and $y_{i,1}$ and so for such an i, u_i can be set to true. So, assuming that z_i's and c_j's are all true, φ is satisfiable if and only if we can choose the values for $y_{i,b}$'s so that u_i's is all false.

We formalize this idea using additional variables p_0, p_1, p_2, u_0, and v_0. The functions for p_0, p_1, and p_2 are respectively $\mathrm{id}(p_2)$, $\mathrm{id}(p_0)$, and $\mathrm{id}(p_1)$; that is, they rotate the values among them, from p_0 to p_1, p_1 to p_2, and then p_2 to p_0. We set the values for them in $\mathbf{a}$ to be false, false, and true, and so, in each predecessor of $\mathbf{a}$, if any, their values should be false, true, false, and in each second predecessor of $\mathbf{a}$, if any, their values should be true, false, false. The function for u_0 is the OR of $u_1, \ldots, u_n$ and the function for v_0 is the OR of u_0 and p_0.

The functions for the other variables are as follows:

- u_i: the OR of u_i and p_0;
- z_i: the OR of $y_{i,0}, y_{i,1}$, and p_0;
- $y_{i,0}$: the OR of $x_{i,0}$ and u_i;
- $y_{i,1}$: the OR of $x_{i,1}$ and u_i;
- $x_{i,0}$: the OR of $x_{i,0}$ and p_0;
- $x_{i,1}$: the OR of $x_{i,1}$ and p_0;
- c_j: the OR of $y_{k,b}$, $y_{l,c}$, $y_{m,d}$, and p_0 where $y_{k,b}$, $y_{l,c}$, $y_{m,d}$ are the variables corresponding to the three literals of the jth clause in φ.

Figure 2 shows how these variables interact.

The configuration $\mathbf{a}$ is all true except for p_0 and p_1. Let us speak of a hypothetical predecessor $\mathbf{b}$ of $\mathbf{a}$ and a hypothetical predecessor $\mathbf{c}$ of $\mathbf{b}$. As mentioned earlier, the value of p_0 is true in $\mathbf{c}$ and false in $\mathbf{b}$. Because of this, all the variables that take p_0 as part of input must be true in $\mathbf{b}$; they are p_1, v_0, all u_i's, all z_i's, all c_j's, and all $x_{i,b}$'s. Since these are all true, in $\mathcal{F}(\mathbf{b})$ the value should be true for u_0, all u_i's, all $y_{i,b}$'s, and $x_{i,b}$'s, which is consistent with their value assignments in $\mathbf{a}$. Also, since v_0 has value true in $\mathbf{a}$, in $\mathbf{b}$ the value of u_0 should be true. The only values that are not determined in $\mathbf{b}$ are those of $y_{i,b}$'s. The constraints are that for each i, either $y_{i,0}$ or $y_{i,1}$ must be true and that these assignments satisfy all the clauses.

Suppose φ is satisfiable. We pick one satisfying assignment of φ and select the values of $y_{i,b}$ accordingly. Then $y_{i,0}$ and $y_{i,1}$ are opposite to each other for all i, and so in $\mathbf{c}$ u_i's must be all false. However, since u_0 has value true in $\mathbf{b}$ and it is the OR of all u_i's, to make it happen the value of at least one u_i must be true in $\mathbf{c}$. These two requirements are conflicting and so $\mathbf{c}$ cannot exist and thus $\mathbf{b}$ is a GOE.

On the other hand, suppose φ is not satisfiable. We determine the values of $y_{i,b}$'s in $\mathbf{b}$ so that they turn c_j's all true in $\mathbf{a}$ and for each i, at least one of $y_{i,0}$ and $y_{i,1}$ is true. Because φ

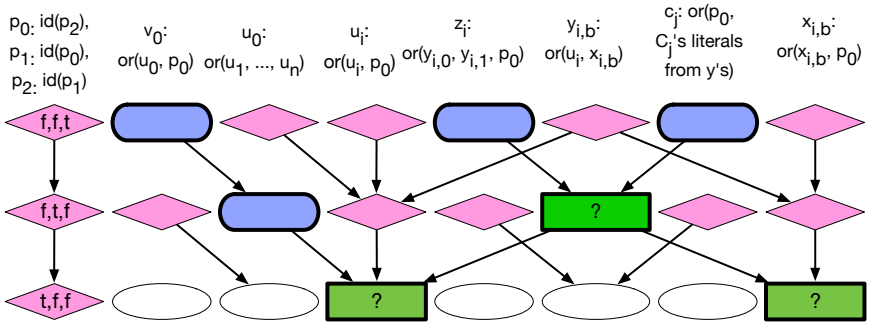

Figure 2 The construction for the 1-GOE Problem for $\mathcal{B}_{\mathrm{OR}}$. The top layer is **a**, the middle layer is a predecessor of **a**, and the bottom layer is a second predecessor of **a**. The arrows show where the inputs come from but inputs from p_i's are not shown. The variables in each diamond shaped are fixed because of the use of p_0. Unless specified, they are all true. The rectangles with rounded sides show blocks of variables whose values are expected to be true. They take input from the rectangles marked with the question mark. They are variables corresponding to the value assignments to the literals and the u_i's.

is not satisfiable, there must be at least one i such that both $y_{i,0}$ and $y_{i,1}$ are true. Select s to be such an i. In **c** set u_s to true and other u_i's to false and set the value of $x_{i,b}$ in **c** equal to the value of $y_{i,b}$ in **b**. Also, set all the remaining variables except the p_i's false. Then this **c** is indeed in a predecessor of **b**. This means that each predecessor **b** of **a** has a predecessor and thus there is no predecessor that is a GOE.

This proves the theorem. ◀

From the above and Lemmas 8 and 16, we have the following corollary.

▶ **Corollary 18.** *Let $\mathcal{B}$ be either $\mathcal{B}_{\mathrm{OR}}$ or $\mathcal{B}_{\mathrm{AND}}$. The Poly-GOE Problem with template $\mathcal{B}$ and t-GOE Problem for $t \geq 1$ with template $\mathcal{B}$ are* NP*-complete.*

If the arities of conjunction and disjunction are bounded by two, the problems are tractable.

▶ **Theorem 19.** *Let $\mathcal{B}$ be one of $\mathcal{B}_{\mathrm{id}}$, $\mathcal{B}_{2\mathrm{OR}}$, and $\mathcal{B}_{2\mathrm{AND}}$. For all constants $t \geq 0$, the t-GOE Problem with template $\mathcal{B}$ is in* AC^0.

Proof. We have only to test the conditions as stated in Lemma 4 part 2. Specifically, we need to compute $G = (V, E)$, the partition (K, L) of V, and then try all possible combinations for u and M to see whether the three properties hold. The conditions can be tested in AC^0 because M has cardinality at most 2. ◀

However, we show that the problem for $\mathcal{B}_{\mathrm{id}}$ and that for $\mathcal{B}_{2\mathrm{OR}}$ or $\mathcal{B}_{2\mathrm{AND}}$ belong to different complexity classes if t is part of the input.

▶ **Theorem 20.** *The Poly-GOE Problem with template $\mathcal{B}_{\mathrm{id}}$ is* L*-complete.*

Proof. Theorem 13 shows that the Poly-PRED Problem with template $\mathcal{B}_{\mathrm{id}}$ is L-complete. By Proposition 7, this implies that Theorem 13 shows that the Poly-GOE Problem with template $\mathcal{B}_{\mathrm{id}}$ is L-hard.

To show that the problem is in L, we use Lemma 4. Since the available function template is id, the set M in the proposition has cardinality 1. As we have seen in Theorem 13, the reachability part of the test can be carried out in L. As for the remaining properties, we have only to try all possible combinations of u and M. ◀

▶ **Theorem 21.** *The Poly-GOE Problem with template $\mathcal{B}_{2\mathrm{OR}}$ or $\mathcal{B}_{2\mathrm{AND}}$ is* NL*-complete.*

Proof. The NL-hardness follows from Theorem 14 and Proposition 7. To show that the problem is in NL, we use Lemma 4. Since the arity of the functions is at most 2, there are only polynomially many possibilities for the choice of z and M and so the test can be done in NL. ◀

In the case where $\mathcal{B}$ contains both conjunction and disjunction, the complexity of problems depends on whether $\mathcal{B}$ contains a function of arity more than two or not for any $t \geq 2$.

▶ **Theorem 22.** *The t-GOE Problem with template $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$ for $t \geq 2$ and the Poly-GOE Problem with template $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$ are* NP*-complete.*

Proof. The hardness follows from Theorem 10, Proposition 7, and Lemma 8. The membership in NP comes from the fact that in the case where the functions have arity 2, whether a configuration has a predecessor can be expressed as a 2CNF formula. We have only to guess a series of t configurations, verify the series flows into $\mathbf{a}$, and the t-th predecessor in the series does not have a predecessor. ◀

▶ **Theorem 23.** *Let $\mathcal{B}$ be either $\mathcal{B}_{2\mathrm{OR},3\mathrm{AND}}$ or $\mathcal{B}_{3\mathrm{OR},2\mathrm{AND}}$. The t-GOE Problem with template $\mathcal{B}$ for $t \geq 1$ and the Poly-GOE Problem with template $\mathcal{B}$ are Σ_2^p-complete.*

We omit the proof of Thorem 23.

5 Conclusions

In this paper we studied the complexity of the Predecessor Existence Problem and the Garden of Eden Problem for various orders of predecessor and for various template sets. Other than those stating containment in AC^0 and the 1-Garden of Eden Problem for $\mathcal{B}_{2\mathrm{OR},2\mathrm{AND}}$, the problems are shown to be complete for standard complexity classes and the classes that appear are diverse: $\mathrm{L}, \mathrm{NL}, \mathrm{NP}, \mathrm{coNP}$, and Σ_2^p. An obvious next step for the paper is to pinpoint the complexity for the remaining case. Also, it will be interesting to look at other template sets.

Dividing Splittable Goods Evenly and With Limited Fragmentation

Peter Damaschke

Department of Computer Science and Engineering, Chalmers University, Göteborg, Sweden
ptr@chalmers.se

Abstract

A splittable good provided in n pieces shall be divided as evenly as possible among m agents, where every agent can take shares of at most F pieces. We call F the fragmentation. For $F = 1$ we can solve the max-min and min-max problems in linear time. The case $F = 2$ has neat formulations and structural characterizations in terms of weighted graphs. Here we focus on perfectly balanced solutions. While the problem is strongly NP-hard in general, it can be solved in linear time if $m \geq n - 1$, and a solution always exists in this case. Moreover, case $F = 2$ is fixed-parameter tractable in the parameter $2m - n$. The results also give rise to various open problems.

1 Introduction

Suppose that we are given n pieces of a good, and these pieces have sizes $x_1, \ldots, x_n$. The good shall be divided among m agents, thereby respecting certain criteria and restrictions. In a solution, let $y_1, \ldots, y_m$ denote the amounts that the agents receive, and let z_{ij} be the amount that agent j receives from piece i. Clearly, we have $y_j = \sum_{i=1}^{n} z_{ij}$ for all agents j, and $\sum_{j=1}^{m} z_{ij} \leq x_i$ for all pieces i. All mentioned variables are non-negative. The agents are identical, and so are the pieces of the good (apart from their different sizes).

Ideally we would like to divide the good evenly and completely, that is: $y_1 = \ldots = y_m$ and $\sum_{i=1}^{n} x_i = \sum_{j=1}^{m} y_j$. Without further restrictions it is a trivial problem to find mn numbers z_{ij} that satisfy these demands. But suppose that we also want to limit the fragmentation, in the following sense. Let F be some fixed positive integer. Every agent shall get parts of at most F distinct pieces. Formally, for every j we allow $z_{ij} > 0$ for at most F indices i. (These indices can be chosen by the solution, but their number is limited by F.) However, every piece may be divided among an unlimited number of agents.

One possible motivation is that pieces of land, at n different locations and with areas $x_1, \ldots, x_n$, shall be assigned to farmers in a fair way. Besides fairness, it would be desirable for every single farmer to get only a few different fields, rather than several scattered ones, such that the farmer does not have to divide activities between many different locations. One may also think of applications in scheduling, where the x_i are durations of n jobs that shall be divided among m workers, in such a way that they get equal workloads, and every worker is concerned with only a few different jobs, in order to limit context switching. Of

course, in such a scenario we have to assume that the jobs can be arbitrarily split and also parallelized. An example where these assumptions are realistic is grading of the n exercises of an exam by m graders.

Prominent problems in Discrete Optimization, in various application domains, deal with cutting or connecting items from raw materials, e.g., the Cutting Stock and Skiving Stock problems; see [6]. An action equivalent to cutting is packing items into containers, as in the Bin Packing and Knapsack problems [5]. (In fact, Skiving Stock is also known as Dual Bin Packing). However, the problems we consider here differ from all the mentioned problems in one way or another, and to our best knowledge their complexities have not been studied before. For instance, in the "Stock" problems we are given large amounts of items of only a few different sizes, and in the Bin Packing and Knapsack problems the sizes of items to be packed (or cut out) are prescribed.

The paper is organized as follows. In Section 2 we define splitting problems where the good shall be divided completely and the minimum share shall be maximized, or vice versa. We call a solution perfect if all shares are equal. In Section 3 we solve the case of fragmentation $F = 1$ in linear time. However, we first derive weaker $O(n \log n)$ time bounds, because this makes the presentation easier, and the $O(n)$ solution relies on the (barely practical) linear-time selection but should still be of theoretical interest. In Section 4 we are concerned with the case of fragmentation $F = 2$. Here we focus on structural properties of the problem of getting perfect solutions, but this may also serve as a basis for, e.g., approximation algorithms for the more general optimization versions. We describe solutions in a natural way by weighted graphs. Then we present a linear-time elimination algorithm that finds a tree-like perfect solution whenever $m \geq n - 1$. Based on the graph-theoretic structure we also prove strong NP-completeness of the general problem, and NP-completeness already for the special case when m is slightly smaller than $n - 1$. For m being close to the smallest possible value $n/2$ we show fixed-parameter tractability. In Section 5 we point out possible directions of further research.

2 Preliminaries

For clarity we provide formal definitions of the problems. We always silently presume that F is a fixed positive integer called the *fragmentation*. Common to all problems are the input and some of the constraints:

Splitting:
Given are n positive numbers $x_1, \ldots, x_n$.
Find non-negative numbers z_{ij} and y_j (for $i = 1, \ldots, n$ and $j = 1, \ldots, m$) subject to:
$\forall j: \ y_j = \sum_{i=1}^{n} z_{ij}$,
$\forall i: \ \sum_{j=1}^{m} z_{ij} \leq x_i$,
$\forall j: \ |\{i \mid z_{ij} > 0\}| \leq F$,
and further constraints and objectives specified below.

To fully specify the actual problems we only mention these additional constraints, in order to avoid repetitions.

Perfect Splitting: $\forall i: \ \sum_{j=1}^{m} z_{ij} = x_i$, and all shares y_j are equal.

We refer to a solution of Perfect Splitting as a *perfect solution*. In such a solution, all agents get the same amount, and no goods are held back.

Min-Max Splitting: $\forall i: \ \sum_{j=1}^{m} z_{ij} = x_i$, and the largest share, $\max_j y_j$, is minimized.

Max-Min Splitting: $\forall i: \ \sum_{j=1}^{m} z_{ij} = x_i$, and the smallest share, $\min_j y_j$, is maximized.

In the last two problems, still all goods are distributed, but in general the agents get different shares. If a perfect solution exists, then this is also the optimal solution to both Min-Max and Max-Min Splitting. The Min-Max problem is more appropriate for applications where some work must be divided completely, and the goal is not to load any individual agents too much. The Max-Min problem aims at giving everyone a guaranteed amount of a good, as large as possible. However, a solution may be perceived as unfair, in the sense that other agents get significantly more because the entire good must be divided. Also, the size of the smallest piece is a trivial upper bound on the objective value. To circumvent these issues one may define modified Max-Min problems which aim at giving maximal but equal amounts to all agents, possibly leaving the remainder of goods unused. One could also relax the condition on fragmentation F and allow some outliers. However, we cannot study all variants in this paper, and we focus on the basic problems.

3 The Case Without Fragmentation (F=1)

First we study Min-Max Splitting and Max-Min Splitting, which also subsumes the special case of Perfect Splitting, for fragmentation $F = 1$.

As a trivial observation, either of the first two problems always permits an optimal solution where, for every piece i, all $z_{ij} > 0$ are equal. Otherwise we can balance these values without making the solution worse. Thus, such a solution is fully characterized by a vector $(p_1, \ldots, p_n)$ with $\sum_{i=1}^{n} p_i = m$, where p_i is the number of indices j with $z_{ij} > 0$. For every such i, j we obviously have $y_j = z_{ij} = x_i/p_i$. Due to this observation on the possible y_j-values we define the following sequence Y.

▶ **Definition 1.** Y is the sequence of all numbers x_i/p, where $i = 1, \ldots, n$ and $p = 1, \ldots, m$, sorted in decreasing order. For $k = 1, \ldots, mn$ let $Y[k]$ denote the value at position k in Y.

The same value x_i/p may come from different i and p, therefore a value may occur multiple times in Y. However, we can break ties arbitrarily and sort equal values in any order. Formally this can also be achieved by random and infinitesimal perturbations of the values x_i. We will henceforth assume that all values in Y are distinct, hence Y is strictly monotone decreasing. This avoids circumstantial treatment of specific cases.

Intuitively, the p_i should be roughly proportional to the given x_i. But the efficient computation of exact optimal solutions is a bit less obvious. We discuss this matter in the following subsections.

3.1 Maximizing the minimum

The following lemma deals with the simple problem being inverse to Max-Min Splitting.

▶ **Lemma 2.** *For any fixed y with $0 < y \leq \min_i x_i$, let k be the maximum number of agents*[1] *such that every agent can obtain an amount at least y. This number k satisfies:*

(a) $k = \sum_{i=1}^{n} p_i$, *where* $p_i := \lfloor x_i/y \rfloor > 0$.
(b) k *is the maximum index with* $Y[k] \geq y$.
(c) $Y[k] = \min_i x_i/p_i$.

Proof. (a): For every i we can split the ith piece among at most $\lfloor x_i/y \rfloor$ agents. Summation over all i yields the assertion. Due to the assumption on y we have $p_i > 0$ for all i.

[1] As y is fixed, for notational convenience we do not mention the argument y and call this number only k.

(b): Note that $x_i/s_i \geq y$ holds for all i and all $s_i \leq p_i$, and there exist k such pairs (i, s_i). Hence at least k members of Y are greater than or equal to y, that is, $Y[k] \geq y$. Since $x_i/(p_i + 1) < y$ holds for all i, we also see that no further members of Y have this property.

(c): As seen above, the k values x_i/s_i ($s_i \leq p_i$) are exactly those members of Y being greater than or equal to y, that is, they are the first k items in Y, and clearly $\min_i x_i/p_i$ is the last of them. ◀

Lemma 2 yields a characterization of the optimal solution.

▶ **Lemma 3.** *The optimal objective value for* Max-Min Splitting *with* $F = 1$ *is*

$$\max \min_j y_j = \min\{Y[m], \min_i x_i\},$$

where the maximum is taken over all solutions.

Proof. First suppose that $Y[m] < \min_i x_i$.

Then we can apply Lemma 2 to $y := Y[m]$. The maximum number k of agents that can be served is, due to (b), equal to the maximum index k with $Y[k] \geq Y[m]$. This implies $k = m$. In other words, m agents can obtain an amount of at least $Y[m]$ each.

Assume that m agents can obtain more, say an amount of $y' > y$ each, where still $y' < \min_i x_i$. We apply Lemma 2 to y'. The maximum number k' of agents that can be served is, due to (b), equal to the maximum index k' with $Y[k'] \geq y' > y = Y[m]$. This implies $k' < m$. Hence we have shown by contradiction that m agents cannot obtain any amount larger than y.

The other case to consider is $Y[m] \geq \min_i x_i$. Now we can apply Lemma 2 to $\min_i x_i$. Part (c) implies that $Y[k] = \min_i x_i/p_i \leq \min_i x_i \leq Y[m]$, thus $k \geq m$. That is, m agents can be served with an amount at least $\min_i x_i$. But due to the problem specification, $\min_i x_i$ is also a trivial upper bound on the objective value, which finally proves the assertion also in this case. ◀

The previous lemmas yield already an algorithm for Max-Min Splitting: First, it is trivial to figure out whether m agents can get a share of at least $\min_i x_i$ each. If so, then this solution is optimal, and we are done. If not, then $Y[m] < \min_i x_i$. In this case, find the value $y := Y[m]$ and then determine the p_i as in Lemma 2 (a), using this y.

However, in order to save time we want to get the value $Y[m]$ without naively following Definition 1 and generating all $m - 1$ preceding elements of Y. The intuition for a faster approach is to search the optimal value near the average. In the following we can always suppose $Y[m] < \min_i x_i$.

▶ **Lemma 4.** *Let* $\bar{y} := \sum_{i=1}^{n} x_i/m$ *be the average amount given to the* m *agents, and let* k *be the maximum number of agents such that every agent can actually obtain an amount at least* $\bar{y}$*. Then* $Y[k] \geq Y[m]$ *and* $m - k \leq n$*.*

Proof. Clearly, $\bar{y} \geq \min_j y_j$ holds in any solution, hence $\bar{y} \geq \max \min_j y_j$ (where the maximum is taken over all solutions). Now Lemma 3 yields $\bar{y} \geq Y[m]$, and Lemma 2 applied to $\bar{y}$ gives $Y[k] \geq \bar{y} \geq Y[m]$.

For $i = 1, \ldots, n$ we define $q_i := x_i/\bar{y}$, with integer and fractional part $p_i := \lfloor q_i \rfloor$ and $r_i := q_i - \lfloor q_i \rfloor$, respectively. Lemma 2 (a) states that $k = \sum_{i=1}^{n} p_i$. Thus we observe:

$$k = \sum_{i=1}^{n} p_i = \sum_{i=1}^{n} (q_i - r_i) \geq \sum_{i=1}^{n} q_i - n = m - n.$$

From this chain of inequalities we get $m - k \leq n$. ◀

Based on these inequalities we will now give an efficient algorithm for Max-Min Splitting. We adopt the unit cost measure where comparisons and algebraic operations with real numbers take constant time.

▶ **Theorem 5.** Max-Min Splitting *with* $F = 1$ *can be solved in* $O(n \log n)$ *time.*

Proof. First we compute $\bar{y}$ and all p_i (as defined in Lemma 2 with $y := \bar{y}$ and x_i/p_i), as well as k and $Y[k] = \min_i x_i/p_i$. The latter equation holds due to Lemma 2 (c). These calculations cost $O(n)$ time.

By Lemma 3, the optimal value is $Y[m]$. In the following we determine the value $Y[m]$. Note that k and $Y[k]$ are known from the calculations above, and $Y[k] \geq Y[m]$ and $m-k \leq n$ hold due to Lemma 4.

If $m \leq k$, then $Y[m] = Y[k]$, and we are done with this part. If $m > k$, then we only have to find the next $m-k$ members of Y after $Y[k]$, and since $m-k \leq n$, these are at most n further members. Now we describe a possible way to identify $Y[k], \ldots, Y[m]$.

Let us sort the n ratios x_i/p_i in decreasing order and call this sequence R. Since $Y[k] = \min_i x_i/p_i$, the last element of R is exactly $Y[k]$. We call it the *marked* element, for later reference. In R we store not only the values x_i/p_i but also x_i and p_i separately. We move a pointer in R from left to right. For every ratio encountered in R we compute the ratio with incremented denominator ($p_i := p_i + 1$) and insert it at the correct position in R. Note that this position is always to the right of the pointer; in particular, the new ratio may become the new rightmost element of R. This step is repeated until the pointer reaches a position $m-k$ elements to the right of the marked element, and then we stop.

The analysis is simple: Since new ratios are always inserted to the right of the pointer, and R comprises *all* elements of Y between the marked $Y[k]$ and the pointer, it follows that we are at $Y[m]$ when we stop, and we can output its value. In order to support fast insertion of a new ratio into R, we also host R in a balanced search tree. Therefore this procedure can be done in $O(n \log n)$ time.

For every i we recompute p_i by $p_i := \lfloor x_i/Y[m] \rfloor$, and the amount given to the p_i agents assigned to the ith piece is x_i/p_i. ◀

Some comments on the time bound are in order. Theorem 5 actually says that we need $O(n \log n)$ time to compute the numbers of agents assigned to each piece and their shares, in an optimal solution. Under the unit cost measure, this time bound is independent of m which may be arbitrarily larger than n. The "physical" division, i.e., assigning positive values to m variables z_{ij}, takes $O(m)$ additional time in a trivial postprocessing phase.

Modifications of the algorithm can also solve a variant of Max-Min Splitting with $F = 1$ where not all goods need to be distributed. Such an algorithm would not get to the pieces being smaller than the objective value.

3.2 Minimizing the maximum

In order to minimize $\max_j y_j$ we use the sequence Y from Definition 1 as well. For formal reasons we also set $Y[0] := \infty$. The scheme is pretty much the same as for Max-Min Splitting, but as the two problems are not symmetric, care must be taken for several details that are different. Similarly as before, we start from the simple problem being inverse to Min-Max Splitting.

▶ **Lemma 6.** *For any fixed* $y > 0$ *that does not appear in* Y*, let* $k \geq n$ *be the minimum number of agents needed such that every agent has to take an amount at most* y*. This number* k *satisfies:*

(a) $k = \sum_{i=1}^{n} p_i$, *where* $p_i := \lceil x_i/y \rceil$.
(b) k *is the maximum index with* $Y[k-n] \geq y$.
(c) $Y[k-n] = \min_i x_i/(p_i - 1)$.

Proof. (a): For every i we must split the ith piece among at least $\lfloor x_i/y \rfloor$ agents. Summation over all i yields the assertion.

(b): Note that $x_i/s_i \geq y$ holds for all i and all $s_i \leq p_i - 1$, and there exist $k - n$ such pairs (i, s_i). Hence at least $k - n$ members of Y are greater than or equal to y, that is, $Y[k-n] \geq y$. Since $x_i/p_i < y$ holds for all i, we also see that no further members of Y have this property.

(c): As seen above, the $k - n$ values x_i/s_i ($s_i \leq p_i - 1$) are exactly those members of Y being greater than or equal to y, that is, they are the first $k - n$ items in Y, and clearly $\min_i x_i/(p_i - 1)$ is the last of them. ◀

Again we get a simple characterization of the optimal solution.

▶ **Lemma 7.** *The optimal objective value for* Min-Max Splitting *with* $F = 1$ *is*

$$\min \max_j y_j = Y[m - n + 1],$$

where the maximum is taken over all solutions.

Proof. We apply Lemma 6 to $y := Y[m-n+1]+\delta$ with an infinitesimal $\delta > 0$, added in order to meet the requirement that y itself does not occur in Y. The minimum number k of agents needed is, due to (b), equal to the maximum index k with $Y[k-n] > Y[m-n+1]$. This implies $k = m$. In other words, m agents have to take an amount of at most $Y[m-n+1]+\delta$ each. Since δ can be made arbitrarily small, their maximum load is bounded by $Y[m-n+1]$.

Assume that the m agents have to take even less, say $y' < Y[m - n + 1]$. We apply Lemma 6 to y'. The minimum number k' of agents needed is, due to (b), equal to the maximum index k' with $Y[k' - n] \geq y'$. Since, in particular, $Y[m + 1 - n] \geq y'$, this implies $k' \geq m + 1$. This shows that more than m agents are needed to bound their maximum load by any amount smaller than $Y[m - n + 1]$. ◀

The proof of Theorem 5 showed already that we can determine $Y[m]$ from $\bar{y}$ in $O(n \log n)$ time. By a similar procedure we can also determine $Y[m - n + 1]$, which is optimal for Min-Max Splitting due to Lemma 7. (Note that n is known from the instance.) Again this costs only $O(n \log n)$ time, and the same remarks as earlier apply to the actual construction of the solution. We can readily state:

▶ **Theorem 8.** Min-Max Splitting *with* $F = 1$ *can be solved in* $O(n \log n)$ *time.*

3.3 Splitting in linear time

An obvious question is whether $O(n \log n)$ time is actually needed. Re-inspecting the proof of Theorem 5) we see: The non-trivial case is $r := m - k > 0$ (but $r \leq n$), and there we only need to find the rth largest ratio after the marked element $Y[k]$. Thus it may not be necessary to keep our sequence R of ratios sorted. But a difficulty is that the sought element is not simply the rth largest $x_i/(p_i + 1)$, where the p_i denote the initial values obtained from $\bar{y}$. Rather, several ratios x_i/p with the same index i but varying p may be larger than the sought element. It is not immediately clear in which order we should generate new ratios and do comparisons.

But, in fact, we can achieve $O(n)$ time. We present this improvement here separately, as it does not look very practical (see below). Yet the optimal time bound may be of interest. First we need a separation property of our sequence of ratios:

▶ **Lemma 9.** *For positive numbers x, x', p, q it is impossible that $x > x'$ and*

$$\frac{x}{q} > \frac{x'}{p} > \frac{x'}{p+1} > \frac{x}{q+1}.$$

Proof. Clearly, the ratio of the two outer numbers is larger than the ratio of the two inner numbers:

$$\frac{x}{q} \cdot \frac{q+1}{x} > \frac{x'}{p} \cdot \frac{p+1}{x'}.$$

It follows $q < p$. But this implies $(q+1)x' < (p+1)x$, which contradicts the last inequality in the given chain. ◀

Now we outline a linear-time algorithm for Max-Min Splitting, improving upon the implementation details in Theorem 5. First, a few preparations and definitions are needed. We find the maximum x_i in $O(n)$ time. Without loss of generality let $x_1 = \max_i x_i$. Considering the sequence of ratios x_1/q with integers q, to the right of the marked element $Y[k]$, we call every interval $(x_1/q, x_1/(q+1)]$ a *bin*. Note that every such interval includes its right endpoint. For a set S of ratios, the *generation step* is the following procedure. For every ratio x_i/p_i in S, we increment the denominator by 1 and compute the number q of the bin that contains $x_i/(p_i+1)$. Using divisions this requires only $O(1)$ time per element. The Selection problem is to find the tth smallest number in an unsorted set, for a prescribed number t.

First we apply the generation step to all initial values x_i/p_i (that is, with the p_i obtained from $\bar{y}$, as earlier). Then we scan the bins from left to right, i.e., for increasing q. For every q we take all ratios that are currently in the qth bin and apply the generation step to them. At the same time we count the total number of ratios seen so far, including the x_1/q. As soon as this number reaches r, we know that the sought ratio is in the current bin. Lemma 9 ensures that every bin contains at most one ratio x_i/p (p integer) for every index i, thus $O(n)$ ratios altogether. Let $t := r - s$, where s is the number of ratios in all previous bins. Hence we can finally apply an $O(n)$ time Selection algorithm [1] to the current bin, in order to find the sought ratio at the tth position in this bin. For the closely related Min-Max Splitting problem we can proceed similarly. This shows:

▶ **Theorem 10.** Max-Min Splitting *and* Min-Max Splitting *with $F = 1$ can be solved in $O(n)$ time.*

A caveat is that $O(n)$-time Selection algorithms suffer from a large hidden constant in the time bound. Instead of a deterministic algorithm we may use the randomized Quickselect, but then we only get $O(n)$ expected time. One may wonder if $O(n)$ worst-case time can be accomplished without invoking Selection. However this is not possible. For instance, if all x_i are close to each other and n does not divide m, then finding $Y[m]$ is equivalent to finding the (m mod n)th largest x_i.

Figuratively speaking, our splitting problems are "Selection-complete" under "simple" linear-time reductions. This statement could be formalized in an algebraic model of computation that cares about constant factors (e.g., by counting the exact depth in a decision tree model). In a more general perspective it may be interesting to – in this way – strictly classify problems that are all linear-time solvable but of different complexity when it comes to constant factors.

4 Perfect Solutions for Fragmentation F=2

In the following we study the case $F = 2$. It is natural to represent any instance of a splitting problem, along with its solution, as a weighted graph:

▶ **Definition 11.** The *solution graph* of a solution to a splitting problem with $F = 2$ is a graph with n vertices and m edges, specified as follows. We create a vertex of weight x_i for the ith piece. Every edge uv has two *ports* at the vertices u and v. The solution specifies a set of m edges and $2m$ weights of their ports. Specifically, if the jth edge has a port at the ith vertex, then the weight of this port is z_{ij}. Every y_j is the sum of the weights of the two ports of the jth edge. We consider y_j as the weight of the jth edge. Similarly, the weights of all ports at the ith vertex must sum up to x_i. An edge can also be a loop at one vertex, and in this case it is immaterial how its weight is divided into weights of the two ports.

In this section we want to characterize which instances, given by n positive vertex weights $x_1, \dots, x_n$ and an integer m, allow a perfect solution (see Section 2). Without loss of generality we can assume $\sum_{i=1}^{n} x_i = m$, hence a perfect solution must satisfy $y_j = 1$ for all j. That is, all edge weights are 1.

4.1 Many agents make it easy

▶ **Theorem 12.** *Every instance of* Perfect Splitting *with* $F = 2$ *and* $m \geq n - 1$ *has a solution whose solution graph is a tree, possibly with loops attached to some vertices. Moreover, such a solution can be computed in* $O(n)$ *time.*

Proof. We classify the vertices in several categories depending on their weights x_i. Vertex i is called large if $x_i > 1$, normal if $x_i = 1$, medium if $1/2 < x_i < 1$, and small if $0 < x_i \leq 1/2$.

Our strategy works as follows. We create certain edges of weight 1, reduce the remaining weights of the incident vertices accordingly (and obeying some simple rules), and recursively solve the residual instances. We only need to show that the process terminates only when the vertex weights are zero, and it can be implemented in $O(n)$ time. In detail:

First suppose that $m > n$. Then there exists a large vertex i. Hence we can attach a loop to it and update $x_i := x_i - 1$ and $m := m - 1$, while n is unchanged. By an inductive argument, we can attach $m - n$ loops to large vertices, until $m = n$ is reached. The number of loops attached to every large vertex can be decided, e.g., in a greedy fashion: Choose any large vertex i and create $\lceil x_i \rceil - 1$ loops, take another large vertex, and so on, but stop as soon as the total number of loops reaches $m - n$. The computations obviously require only $O(n)$ arithmetic operations.

Next suppose that $m = n$. If all vertices are normal, then we append another loop to each vertex, and we are done. If not all vertices are normal, then there still exists some large vertex, and we attach another loop to it, as above. Thus we reach $m = n - 1$.

From now on suppose that $m = n - 1$. Assume that we find two vertices i and j such that $x_i + x_j > 1$ and $x_j < 1$. Then we join these vertices by an edge of weight 1, which is divided as follows. The port at vertex j gets the weight x_j, and the port at vertex 1 gets the rest $1 - x_j$. Accordingly we update the vertex weights to $x_j := 0$ and $x_i := x_i - 1 + x_j > 0$. This means, there remain $n := n - 1$ vertices with positive weights, and $m := m - 1$ edges to fix. Hence the invariant $m = n - 1$ is preserved in the residual instance, and we can iterate this procedure as long as possible.

It remains to prove the existence of such a pair of vertices i and j satisfying $x_i + x_j > 1$ and $x_j < 1$, and to find some efficiently. Since $m < n$, at least one medium or small vertex

exists. As long as some large or normal vertex exists, too, we obviously get a pair as desired. Now suppose that all vertices are medium or small. We can also take a pair of medium vertices, if it exists. Thus suppose in the sequel that all vertices are small, except at most one medium vertex. Now the equation $m = n - 1$ restricts the possibilities as follows. If two small vertices exist, then these are the only vertices: We have $n = 2$ and $x_1 = x_2 = 1/2$, hence we can join the two vertices by a final edge. If only one vertex is small, then there exists exactly one other vertex which is medium. Hence we still have $n = 2$ and $x_1 + x_2 = 1$, and we can insert a final edge. The case that no vertex is small is impossible, since then $n = 1$ and $m = x_1 > 0$, a contradiction. Altogether this shows that we always find two desired vertices until $n = 2$ is reached, and then we can finish up the solution.

The above proof does not only show the existence of a perfect solution whenever $m \geq n-1$, but it describes already a simple elimination algorithm that computes a perfect solution. In each step, the updates take $O(1)$ time. The next edge is always built from two vertices from certain categories (large, normal, medium, small). Since arbitrary vertices from the respective categories can be chosen, it suffices to maintain four unsorted sets of vertices, hence we can also update these sets and pick the needed vertices in $O(1)$ time. Therefore the overall time is $O(n)$.

Consider the graph of non-loop edges inserted by the algorithm until any moment. Upon insertion of every edge, the weights of its vertices were positive, and the weight of exactly one of them drops to zero. This implies the invariant that every connected component of the graph retains exactly one vertex with positive weight. From this it follows, furthermore, that every new edge merges two connected components. Thus the final solution graph is a tree, possibly with additional loops. ◀

Similarly to the time bounds for $F = 1$, we have not counted in the time for the trivial postprocessing that actually splits the pieces: Constructing the $O(m)$ loops costs $O(m)$ additional time. But the solution graph, i.e., the tree and the numbers of loops at its vertices, are computed in $O(n)$ time.

It is apparent from the algorithm that the tree, and thus the solution, is in general not unique. This gives rise to interesting additional problems, also in view of the motivations in Section 1. For instance, assuming that the vertices have pairwise distances (spatial distances, dissimilarity of tasks, etc.) we may prefer perfect solutions where also some distance measure (maximum, total, weighted, etc.) is minimized for the chosen edges.

4.2 Structural characterization and hardness

Apart from the last remark, Theorem 12 completely settles the case $m \geq n - 1$. In the following we also allow $m < n$ (but $m \geq n/2$, since otherwise not all goods can be divided with fragmentation $F = 2$). The conditions in Theorem 12 suggest the following definition.

▶ **Definition 13.** Let V be a set of elements called vertices and indexed by $1, \ldots, n$. Every vertex i has a weight positive weight x_i. We call $I \subseteq V$ an *integral set* if $\sum_{i \in I} x_i$ is an integer. We call $I \subseteq V$ a *heavy set* if $\sum_{i \in I} x_i \geq |I| - 1$.

In fact, the existence of perfect solutions can now be characterized as follows.

▶ **Theorem 14.** *An instance $(x_1, \ldots, x_n)$ of* Perfect Splitting *with $F = 2$, where $\sum_{i=1}^{n} x_i = m$ (and m is the number of agents), admits a solution if and only if V can be partitioned into heavy integral sets.*

Proof. "only if": Suppose that there exists a perfect solution. Since $F = 2$, the solution can be represented as a solution graph G as in Definition 11, with vertex set V and with m edges (some of which may be loops). Let $C(k)$ denote the kth connected component of G, where the indexing is arbitrary. Let n_k and m_k denote the number of vertices and edges, respectively, in $C(k)$. Since $\sum_{i=1}^{n} x_i = m$, every agent gets an amount of 1. Hence, for every k, the vertex set V_k of C_k is integral. Specifically, the sum of vertex weights in $C(k)$ equals m_k which is trivially an integer. Due to connectivity we also have $m_k \geq n_k - 1$, thus V_k is a heavy set.

"if": Suppose that V has a partitioning into integral sets V_k which are also heavy. The latter means that $m_k \geq n_k - 1$, where n_k is the number of vertices of V_k, and m_k denotes their total weight. For every V_k we consider an instance of Perfect Splitting with the given vertex weights and m_k agents. Due to $m_k \geq n_k - 1$ and Theorem 12, this instance has a solution with m_k agents. Since $m = \sum_k m_k$, the solutions to all these k instances together form a solution of the entire instance. ◀

While Perfect Splitting with $F = 2$ is easy for $m \geq n - 1$ due to Theorem 12, the complexity jumps for $m < n - 1$. The reason is that, unfortunately, it is hard to find a partitioning as required in Theorem 14, as we show next. At first glance hardness might appear counterintuitive because with fragmentation $F = 2$ it should always be possible, within an elimination process as in Theorem 12, to take amounts missing to some $z_{ij} = 1$ from some other piece. But the catch is that all remaining pieces might be too small, and then the fragmentation $F = 2$ is not sufficient. Anyway, by a reduction from 3-Partition (which is a natural candidate that has been reduced earlier to similar packing and scheduling problems [2]) we can show:

▶ **Theorem 15.** Perfect Splitting *with* $F = 2$ *is strongly NP-complete, and so are* Max-Min Splitting *and* Min-Max Splitting.

Proof. We give a polynomial-time reduction from the strongly NP-complete 3-Partition problem to Perfect Splitting. A triplet is a set of exactly three elements. An instance P of 3-Partition consists of $3k$ positive rational numbers that shall be partitioned into k triplets such that the sum of the numbers in each triplet is the same. The instance is a multiset, i.e., the $3k$ numbers are not necessarily distinct. Without loss of generality let their sum be k, hence the sum in each triplet must be 1. Thus we can further assume $x \leq 1$ for all x in P, otherwise P has, trivially, no solution. We also fix some small number $d > 0$, in fact, any number with $0 < d < 1/3$ will do.

For the reduction we take any given instance P with the above properties, and we transform every number x from P into $2(1/3 + dx)/(1 + d)$. Let Q be the multiset of these transformed numbers. They enjoy the following properties:
(a) Any three numbers from P sum up to 1 if and only if the three transformed numbers in Q sum up to 2.
(b) The sum of all numbers in Q is $2(3k/3 + dk)/(1 + d) = 2k$.
Let $n := 3k$ and $m := 2k$. Now we can view Q as an instance of Perfect Splitting with $F = 2$, where n is the number of pieces, and $m = 2k$ is both the number of agents and the total amount to distribute.

Assume that P has a solution. Then each of its k triplets has the sum 1. Due to (a), the three transformed numbers in Q have the sum 2. Hence the triplets form a partitioning of Q into heavy integral sets. By Theorem 14, Q has a perfect solution.

Conversely, suppose that Q has a perfect solution. Using Theorem 14 again, Q can be partitioned into heavy integral sets. Since $n - m = k$ and the sets are heavy, the partitioning

must consist of at least k sets. Remember that $x \leq 1$ for all x from P. Hence any single number in Q is at most $2(1/3+d)/(1+d) < 1$. Any two numbers in Q have a sum at least $(4/3)/(1+d) > 1$ and at most $4(1/3+d)/(1+d) < 2$. Hence any integral set needs at least three elements. It follows that Q is partitioned into exactly k triplets. Using again that these sets are heavy, the sum in each triple is at least 2. Since, due to (b), the total sum equals $2k$, the sum in each triplet is exactly 2. Using (a) again, it follows that each corresponding triplet in P has the sum 1. That means, P has a solution.

Since Perfect Splitting is a special case of the two optimization problems, the last assertion follows immediately. ◀

Usual NP-hardness holds already when m is slightly smaller than $n-1$ (giving a clear dichotomy together with Theorem 12), and the proof is less technical:

▶ **Theorem 16.** Perfect Splitting *with $F = 2$ and $m = n - t$ is NP-complete for every fixed $t \geq 2$, and so are* Max-Min Splitting *and* Min-Max Splitting.

Proof. First let $t = 2$. Consider any instance where $m = n - 2$, and $x_i < 1$ for all i. Any partitioning into heavy integral sets necessarily consists of exactly two sets I and J, with $\sum_{i\in I} x_i = |I| - 1$ and $\sum_{j\in J} x_j = |J| - 1$. Due to Theorem 14, such an instance has a solution if and only if it can be partitioned into sets I and J with these properties.

On this basis we give a reduction from the NP-complete Subset Sum problem [2]. An instance of Subset Sum consists of positive rational numbers $y_1 \ldots, y_n$, and the goal is to find a subset I of indices such that $\sum_{i\in I} y_i$ equals a prescribed value s. Subset Sum is NP-complete already in the case that $s = \sum_{k=1}^{n} y_k/2$. By scaling we can also assume $\sum_{k=1}^{n} y_k = 2$, such that we have to divide the sum into $1+1$. Now we can also assume $y_k < 1$ for all k, otherwise the instance has, trivially, no solution. Finally, we simply set $x_k := 1 - y_k$ for all k. The equivalence to Perfect Splitting with $F = 2$ and $m = n - 2$ is evident.

For $t > 2$ we finally add $2(t-2)$ further items $x_i = 1/2$ to the instance. Arguments are similar; note that the additional items must form $t - 2$ pairs, in a partitioning into heavy integral sets. ◀

4.3 Few agents make it easy, too

The reductions showing hardness led to instances with $m/n \geq 2/3$. The problem becomes "easy" if m is close to the smallest possible value $n/2$. (Readers not being familiar with fixed-parameter tractability are referred to a textbook like [7].)

▶ **Theorem 17.** Perfect Splitting *with $F = 2$ is fixed-parameter tractable (FPT) in the parameter $t := 2m - n$.*

Proof. Consider graphs with n vertices and m edges. We refer to connected components with two and three vertices as pairs and triplets, respectively. As a preparatory consideration we construct extremal graphs where the number q of vertices not being in pairs is maximized. We can assume that some pairs exist, since otherwise $q = n$ is, trivially, maximal.

If some connected component C is not a tree, then we can remove an edge such that C remains connected. We use this edge to join some pair to another component. This strictly increases q. Hence assume that all connected components are trees. If some tree has at least four vertices, then we can remove a leaf and its incident edge. The remainder of the tree is still connected and is not a pair. We append the edge and the leaf to some pair, which strictly increases q again. Hence, if q is maximized, then all connected components are pairs and triples (unless $q = n$). With p pairs and t' triples we have $m = p + 2t'$ and $n = 2p + 3t'$, hence $t = 2m - n = t'$. Since the maximum q is shown to be $q = 3t' = 3t$, we get that at most $3t$ vertices are not in pairs.

Now consider any instance of Perfect Splitting with $F = 2$, and any two indices i and j with $x_i + x_j = 1$. Assume that the instance has a solution. We consider the partitioning specified in Theorem 14 and refer to its heavy integral sets as bags.

Assume that i and j are in different bags, say, in $I \cup \{i\}$ and $J \cup \{j\}$. We rearrange them to new bags $\{i, j\}$ and $I \cup J$. The pair is obviously a heavy integral set. Since the original bags were integral and the weight $x_i + x_j = 1$ has been removed, also $I \cup J$ is integral. Since the original bags were heavy, $I \cup \{i\}$ and $J \cup \{j\}$ have sums at least $|I|$ and $|J|$, respectively. Hence $I \cup J$ has a sum at least $|I| + |J| - 1$, which means that it is heavy. This shows, under the above assumption, the existence of an alternative solution where $\{i, j\}$ is a bag.

Assume that i and j are in the same bag, but together with further indices, say, $K \cup \{i, j\}$ with $K \neq \emptyset$ is a bag. We split it in two bags K and $\{i, j\}$. Clearly, K is integral. Since $K \cup \{i, j\}$ was heavy, it has a sum at least $|K| + 1$, such that at least a sum $|K|$ remains in K, which means that K is also heavy. This shows again the existence of an alternative solution where $\{i, j\}$ is a bag.

We are ready to devise an FPT algorithm: First we pair up indices i and j with $x_i + x_j = 1$, as long as possible. (This is the "data reduction" phase, in the terminology of FPT algorithms.) Then we solve the residual instance, that is, we search for a partitioning as in Theorem 14, of the remaining indices. The given instance has a perfect solution if and only if the residual instance has.

The pairing phase is correct due to the above exchange arguments: If a solution exists at all, then it can be transformed into a solution where any desired pair $\{i, j\}$ with $x_i + x_j = 1$ forms a bag. By traversing a sorted list of the weights simultaneously in ascending and descending order, this phase is easily implemented in $O(n \log n)$ time. The residual instance has a size at most $3t$, and we may solve it naively. ◀

By way of contrast, Theorem 16 excludes an FPT (even an XP) algorithm in the parameter $t = n - m$ (unless P=NP).

5 Further Research

By Theorem 15, the optimization versions of or splitting problems with $F = 2$ (and $n > m$) are strongly NP-complete and therefore do not allow FPTAS (unless P=NP). On the other hand, the structural result in Theorem 14 together with the algorithms in Theorem 12 suggests that one should try and partition the set of pieces into $n - m$ heavy subsets (bags) and then assign agents to them such that the average amounts per agent in the bag are as balanced as possible. The latter step would work as in case $F = 1$, treating the bags as pieces. In general, the bags will not be integral, but the smaller the fractional parts of the sums are, the better the solutions should be. Minimizing the fractional parts roughly resembles the minimum makespan scheduling problem (although the objectives are also quite different). The latter problem is well studied: It is also strongly NP-complete, but it has a PTAS, and even an FPTAS when the number of machines (here corresponding to the number $n - m$ of bags) is fixed; see [3, 4]. Altogether, we conjecture that similar approximation schemes can be obtained for our splitting problems. Another conjecture is that our FPT result for small $2m - n$ extends to the optimization versions.

Other open questions were mentioned in the technical sections. Furthermore, as we have seen, the "graph-theoretic" case $F = 2$ is already subtle, but several results may be generalized to $F > 2$.

Abstract

The *longest common extension* (*LCE*) problem is to preprocess a given string w of length n so that the length of the longest common prefix between suffixes of w that start at any two given positions is answered quickly. In this paper, we present a data structure of $O(z\tau^2 + \frac{n}{\tau})$ words of space which answers LCE queries in $O(1)$ time and can be built in $O(n \log \sigma)$ time, where $1 \leq \tau \leq \sqrt{n}$ is a parameter, z is the size of the Lempel-Ziv 77 factorization of w and σ is the alphabet size. The proposed LCE data structure does not access the input string w when answering queries, and thus w can be deleted after preprocessing. On top of this main result, we obtain further results using (variants of) our LCE data structure, which include the following:

- For highly repetitive strings where the $z\tau^2$ term is dominated by $\frac{n}{\tau}$, we obtain a *constant-time and sub-linear space* LCE query data structure.
- Even when the input string is not well compressible via Lempel-Ziv 77 factorization, we still can obtain a *constant-time and sub-linear space* LCE data structure for suitable τ and for $\sigma \leq 2^{o(\log n)}$.
- The time-space trade-off lower bounds for the LCE problem by Bille et al. [J. Discrete Algorithms, 25:42-50, 2014] and by Kosolobov [CoRR, abs/1611.02891, 2016] do not apply in some cases with our LCE data structure.

1 Introduction

1.1 The LCE problem

The *longest common extension* (*LCE*) problem is to preprocess a given string w of length n so that the length of the longest common prefix of suffixes of w starting at two query positions is answered quickly. The LCE problem often appears as a sub-problem of many different string processing problems, e.g., approximate pattern matching [35, 17], string comparison [34],

and finding string regularities such as maximal repetitions (a.k.a. runs) [30, 1], distinct squares [22, 2], gapped repeats [11, 31, 18, 14], palindromes and gapped palindromes [21, 29, 39], and 2D palindromes [20].

A well known solution to the LCE problem is achieved by the suffix tree [47] augmented with a constant-time linear-space longest common ancestor (LCA) data structure [23, 3], or equivalently the inverse suffix array (ISA) and longest common prefix (LCP) array augmented with a constant-time range minimum query (RMQ) data structure [37, 3]. Either combination uses $O(n)$ words of space, answer LCE queries in $O(1)$ time, and can be constructed using $O(n)$ words of working space, in $O(n)$ time for integer alphabets or in $O(n \log \sigma)$ time for general ordered alphabets of size σ. The $O(n)$ space requirements, however, can be prohibitive for massive text, and hence the main focus of recent research has been on more space-efficient solutions with trade-offs for query time.

1.2 Space-efficient LCE data structures

In this paper, we will call data structures that use $o(n)$ words, or equivalently $o(n \log n)$ bits as *sub-linear space* data structures. Bille et al. [9] proposed the first *sub-linear* space LCE query data structure which occupies $O(\frac{n}{\tau})$ words of space, answers LCE queries in $O(\tau^2)$ time, and can be built in $O(\frac{n^2}{\tau})$ time using $O(\frac{n}{\tau})$ words of working space, for parameter range $1 \leq \tau \leq \sqrt{n}$. Bille et al. [8] developed an improved sub-linear space data structure which occupies $O(\frac{n}{\tau})$ words of space, answers LCE queries in $O(\tau)$ time, and can be built in $O(n^{\frac{3}{2}})$ *expected* time using $O(\frac{n}{\tau})$ words of working space, or in $O(n^{2+\epsilon})$ time using $O(\frac{n}{\tau})$ words of working space for parameter $1 \leq \tau \leq n$, where $0 < \epsilon < 1$. Tanimura et al. [45] proposed an LCE data structure of $O(\frac{n}{\tau})$ words of space, which can be built in faster $O(n\tau)$ time using $O(\frac{n}{\tau})$ words of working space, but takes slower $O(\tau \log \min\{\tau, \frac{n}{\tau}\})$ time for LCE queries, for parameter $1 \leq \tau \leq n$. All of these sub-linear space LCE data structures need to access to the input string when answering queries. Therefore, these data structures require extra $n\lceil \log \sigma \rceil$ *bits* of space for storing the input string. An in-place LCE data structure based on fingerprints was recently proposed [42].

There also exist *compressed* LCE data structures which store a compressed form of the input string represented as a straight-line program (a.k.a. grammar-based text compression) [41, 25, 6, 7, 24]. For compressible strings, the space usage of these data structures can be sub-linear.

1.3 Our LCE data structure

This paper proposes the *first* $O(1)$*-time* LCE data structure which takes *sub-linear space* in several reasonable cases, namely, when the string is compressible, and/or, when the alphabet size is suitably small. Our data structure has both flavours of sub-linear space and compressed LCE data structures. Namely, for parameter $1 \leq \tau \leq \sqrt{n}$, we present an LCE data structure which takes $O(z\tau^2 + \frac{n}{\tau})$ words of space, answers LCE queries in $O(1)$ time, and can be built in $O(n \log \sigma)$ time for general ordered alphabets of size σ using $O(z\tau^2 + \frac{n}{\tau})$ words of working space, where z is the size of the Lempel-Ziv 77 factorization [48] of the input string. It is known that z is a lower bound on the size of *any* grammar-based compression of the string [44], and can be very small for highly repetitive strings. In such cases where the $z\tau^2$ term is dominated by $\frac{n}{\tau}$, our LCE data structure uses sub-linear space. An interesting feature is that we do *not* actually compress the input string, i.e., do not compute the Lempel-Ziv 77 factorization, but we construct a data structure whose size is bounded by $O(z\tau^2 + \frac{n}{\tau})$.

Table 1 Deterministic LCE query data structures. n is the length of the input string, σ is the alphabet size, z is the size of the Lempel-Ziv 77 factorization of w, l is the length of the LCE, ω is the machine word size, $\epsilon > 0$ is an arbitrarily small constant, and τ is a trade-off parameter ($\dagger : 1 \leq \tau \leq n$, $\diamond : 1 \leq \tau \leq \sqrt{n}$). ISA+ consists of the inverse suffix array of w, the LCP array and the RMQ data structure. $\star$ is valid for $\omega = \Theta(\log n)$ and $\sigma \leq 2^{o(\log n)}$.

Even when the input string is not well compressible via Lempel-Ziv 77, for suitably small alphabets, we can build a sub-linear space LCE data structure with $O(1)$ query time using appropriate values of τ. By choosing $\tau = (\frac{n}{z})^{\frac{1}{3}}$, our LCE query data structure takes $O(z^{\frac{1}{3}}n^{\frac{2}{3}})$ words of space, which translates to $O(n/(\log_\sigma n)^{\frac{1}{3}})$ using the well-known fact that $z = O(n/\log_\sigma n)$ (e.g. [26]). This means that our data structure can be stored in $O(n \log n/(\log_\sigma n)^{\frac{1}{3}}) = O(n(\log n)^{\frac{2}{3}}(\log \sigma)^{\frac{1}{3}})$ *bits* of space. This implies that for alphabets of size $\sigma \leq 2^{o(\log n)}$ (note that these contain polylogarithmic alphabets), our data structure takes only $o(n \log n)$ bits of space, yet answers LCE queries in $O(1)$ time. Also, our LCE data structure does not access the input string when answering queries, and hence the input string does not have to be kept. To our knowledge, this is the first sub-linear space LCE data structure for strings which are not well compressible with Lempel-Ziv 77.

The key to our efficient LCE query data structure is a hybrid use of the *truncated suffix trees* [38] and block-wise LCE queries based on t-covers [43, 9]. The q-truncated suffix tree of a string w is the compact trie (a.k.a. Patricia tree) which represents all substrings of w of length at most q. We observe that, for any $1 \leq q \leq n$, the q-truncated suffix tree can be stored in $O(zq)$ words of space, including a string to which the edges label pointers refer. We also show that the block-wise LCE query data structure based on t-covers can be efficiently built by the t-truncated suffix tree, leading to our result. Several variants of our data structure are considered, as summarized in Table 1.

The rest of this paper is organized as follows. Section 2 gives some definitions and introduces tools which will be used as building-blocks of our LCE data structure. In Section 3 we propose our new LCE data structure and analyze its time/space complexities. In Section 4 we review some lower bounds on the LCE problem and show that using our LCE data structure, these lower bounds do not apply in some cases. We conclude in Section 5.

2 Preliminaries

2.1 Notations

Let Σ be an ordered alphabet of size σ. Each element of Σ^* is called a *string*. The length of a string w is denoted by $|w|$. The empty string ε is the string of length zero, namely $|\varepsilon| = 0$. If $w = xyz$ for some strings w, x, y, z, then x, y, and z are respectively called a *prefix*, *substring*, and *suffix* of w. For any $1 \leq i \leq |w|$, let $w[i]$ denote the ith character of w. For any $1 \leq i \leq j \leq |w|$, let $w[i..j]$ denote the substring of w that begins at position i and ends at position j, namely, $w[i..j] = w[i] \cdots w[j]$. A string of length q is called a *q-gram*. For any $1 \leq q \leq |w|$, let $Substr_q(w)$ denote the set of all q-grams occurring in w and the $q-1$ suffixes of w of length shorter than q, namely, $Substr_q(w) = \{w[i..\min\{i+q-1, |w|\}] \mid 1 \leq i \leq |w|\}$.

For any string w, let $\mathsf{LCE}^w(i,j)$ denote the length of the longest common prefix of $w[i..|w|]$ and $w[j..|w|]$. We will write $\mathsf{LCE}(i,j)$ when w is clear from the context. Since $\mathsf{LCE}^w(i,i) = |w| - i$, we will only consider the case when $i \neq j$. For any integers $i \leq j$, let $[i..j]$ denote the set of integers from i to j (including i and j).

The *Lempel-Ziv 77 factorization with self-references* [48] of a string w is a sequence $\mathsf{LZ}(w) = f_1, \ldots, f_z$ of z non-empty substrings of w such that $w = f_1 \cdots f_z$ and for $1 \leq i \leq z$,

- $f_i = w[|f_1 \cdots f_{i-1}| + 1] \in \Sigma$ if $s[|f_1 \cdots f_{i-1}| + 1]$ is a character not occurring in $f_0 \cdots f_{i-1}$,
- f_i is the longest prefix of $f_i \cdots f_z$ such that f_i is a substring of w beginning at a position in range $[1..|f_1 \cdots f_{i-1}|]$,

where $f_0 = \varepsilon$. The *size* of $\mathsf{LZ}(w)$ is the number z of factors $f_1, \ldots, f_z$, and is denoted as $|\mathsf{LZ}(w)| = z$. For instance, for string $w = \mathtt{abababcababababcababababcd}$ of length 22, $\mathsf{LZ}(w) = \mathtt{a}, \mathtt{b}, \mathtt{abab}, \mathtt{c}, \mathtt{abababcababababc}, \mathtt{d}$ and $|\mathsf{LZ}(w)| = 6$.

Our model of computation is a standard word RAM with machine word size $\omega \geq \log n$. The space requirements will be evaluated by the number of words unless otherwise stated.

2.2 Tools

We will use the following tools as building blocks of our LCE data structure.

t-covers. For any positive integer t, a set $D \subseteq [0..t-1]$ is called a *t-difference-cover* if $[0..t-1] = \{(x-y) \bmod t \mid x, y \in D\}$, namely, every element in $[0..t-1]$ can be expressed by a difference between two elements in D modulo t. For any positive integer n, a set $S \subseteq [1..n]$ is called a *t-cover* of $[1..n]$ if $S = \{i \in [1..n] \mid (i \bmod t) \in D\}$ with some t-difference-cover D, and there is a constant-time computable function $h(i,j)$ that for any $1 \leq i, j \leq n-t$, $0 \leq h(i,j) \leq t$ and $i + h(i,j), j + h(i,j) \in S$.

▶ **Lemma 1** ([36]). *For any integer t, there exists a t-difference-cover $D(t)$ of size $O(\sqrt{t})$ which can be computed in $O(\sqrt{t})$ time.*

▶ **Lemma 2** ([12]). *For any integer t ($\leq n$), there exists a t-cover of size $O(\frac{n}{\sqrt{t}})$ which can be computed in $O(\frac{n}{\sqrt{t}})$ time.*

In what follows, we will denote by $S(t)$ an arbitrary t-cover of $[1..n]$ which satisfies the conditions of Lemma 2. See Figure 1 for an example of a t-cover $S(t)$.

Truncated suffix trees. For convenience, we assume that any string w ends with a special end-marker \$ that appears nowhere else in w. Let $n = |w|$. For any $1 \leq q \leq n$, the *q-truncated suffix tree* of w, denoted q-$\mathsf{TST}(w)$, is a Patricia tree which represents $Substr_q(w)$. Namely, q-$\mathsf{TST}(w)$ is an edge-labeled rooted tree such that: (1) Each edge is labeled with a non-empty

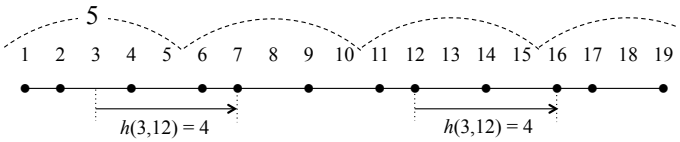

Figure 1 Let $t = 5$ and $D = \{1, 2, 4\}$. This figure shows an example of a 5-cover $S(5) = \{1, 2, 4, 6, 7, 9, 11, 12, 14, 16, 17, 19\}$. The black dots represent the elements in $S(5)$. For instance, we have $h(3, 12) = 4$, namely, $3 + 4, 12 + 4 \in S(5)$.

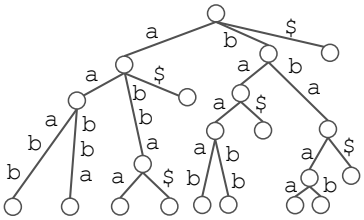

Figure 2 5-TST(w) with string $w =$ `baabbaabbaaabbaabba`\$.

substring of w; (2) Each internal node v has at least two children, and the labels of the out edges of v begin with distinct characters; (3) For any leaf u, there is at least one position $1 \leq i \leq n$ such that $w[i..\min\{i + q - 1, n\}]$ is the string obtained by concatenating the edge labels from the root to u; (4) For any position $1 \leq i \leq n$ in w, there is a unique leaf u such that $w[i..\min\{i + q - 1, n\}]$ is the string obtained by concatenating the edge labels from the root to u.

Informally speaking, q-TST(w) can be obtained by trimming the full suffix tree of w so that any path from the root represents a substring of length at most q. Clearly, the number of leaves in q-TST(w) is equal to $|Substr_q(w)|$. We assume that the leaves of q-TST(w) are sorted in lexicographical order. Figure 2 shows an example of a q-TST(w). For any node u of q-TST(w), $str(u)$ denotes the string spelled out by the path from the root to u.

In the case of the full suffix tree (n-TST(w)) of string w of length n, each edge label x is represented by a pair (i, j) of positions in w such that $x = w[i..j]$. We call w as the *reference string* for the full suffix tree, and this way the full suffix tree can be stored in $O(n)$ space. For q-TST(w), Vitale et al. [46] showed how to represent q-TST(w) in $O(|Substr_q(w)|)$ space, including the reference string, and how to construct them efficiently, both in time and space.

▶ **Lemma 3** ([46]). *Let w be any string of length n over an ordered alphabet of size σ. For any $1 \leq q \leq n$, let $y = |Substr_q(w)|$. Then, there exists a reference string w' of length $O(y)$ for q-TST(w). Moreover, q-TST(w) with the leaves sorted in lexicographical order, and a reference string w' can be constructed in $O(n \log \sigma)$ time with $O(y)$ working space.*

We also show the following lemma.

▶ **Lemma 4.** *q-TST(w) can be represented in $O(zq)$ space, where $z = |$LZ(w)$|$.*

Proof. By Lemma 3, it suffices to show that $|Substr_q(w)| = O(zq)$. For each q-gram $p \in Substr_q(w)$, let $locc_w(p)$ be the beginning position of the leftmost occurrence of p in w. If $q = 1$, then clearly $|Substr_1(w)| \leq z$ and hence the lemma holds. If $q \geq 2$ then the interval $[locc_w(p)..locc_w(p) + q - 1]$ must cross the boundary of two adjacent factors of LZ(w), since otherwise the interval is completely contained in a single factor of LZ(w) but this contradicts that $[locc_w(p)..locc_w(p) + q - 1]$ is the leftmost occurrence of p in w. Clearly, the maximum

number of q-grams that can cross a boundary of $\mathsf{LZ}(w)$ is $q-1$. Hence, the total number of distinct q-grams in w is $O(zq)$. Also, $Substr_q(w)$ contains q substrings $w[n-q+1], \ldots, w[n]$ of w which are shorter than q. Overall, we obtain $|Substr_q(w)| = O(zq)$. ◀

The next theorem follows from Lemmas 3 and 4 and an obvious fact that $|Substr_q(w)| \leq n$.

▶ **Theorem 5.** *Given a string w of length n over an ordered alphabet of size σ and integer $1 \leq q \leq n$, we can construct an $O(\min\{zq, n\})$-space representation of q-$\mathsf{TST}(w)$ in $O(n \log \sigma)$ time with $O(\min\{zq, n\})$ working space.*

In what follows, we will only consider interesting cases where $zq < n$ for a given $1 \leq q \leq n$, and will simply use $O(zq)$ to denote the size of q-$\mathsf{TST}(w)$.

3 Our LCE data structure

3.1 Overview of our algorithm

The general framework of our space-efficient LCE algorithm follows the approach of Gawrychowski et al.'s LCE algorithm for strings over a general ordered alphabet [19]. Namely, we compute $\mathsf{LCE}(i,j)$ using the two following types of queries:

$$\mathsf{ShortLCE}_t(i,j) = \min(\mathsf{LCE}(i,j), t),$$

$$\mathsf{LongLCE}_t(i,j) = \begin{cases} \lfloor \mathrm{LCE}(i,j)/t \rfloor & \text{if } i,j \in S(t), \\ \perp & \text{otherwise.} \end{cases}$$

$\mathsf{LCE}(i,j)$ is computed in the following manner. Let $\delta = h(i,j)$. Recall that $\delta \leq t$ can be computed in constant time and that $i+\delta, j+\delta \in S(t)$. First, we compare up to the first δ characters of $w[i..|w|]$ and $w[j..|w|]$ using $\mathsf{ShortLCE}_t(i,j)$. If $l_1 = \mathsf{ShortLCE}_t(i,j)$ is shorter than t, then $\mathsf{LCE}(i,j) = l_1$. If $l_1 = t$, then $\mathsf{LCE}(i,j)$ is at least t long. To check if it further extends, we compute $l_2 = \mathsf{LongLCE}_t(i+\delta, j+\delta)$, and $l_3 = \mathsf{ShortLCE}_t(i+\delta+l_2, j+\delta+l_2)$. Finally, we get $\mathsf{LCE}(i,j) = \delta + t \cdot l_2 + l_3$. See also Figure 3.

The main difference between Gawrychowski et al.'s method and ours is in how to compute $\mathsf{ShortLCE}_t(i,j)$. While they use a Union-Find structure that takes $O(n)$ working space (for $O(n)$ queries) as a main tool, we use an augmented $2t$-$\mathsf{TST}(w)$ for $Substr_{2t}(w)$ which occupies $O(zt + \frac{n}{\sqrt{t}})$ total space, answers $\mathsf{ShortLCE}_t(i,j)$ queries in $O(1)$ time, and can be constructed in $O(n \log \sigma)$ time with $O(zt)$ working space. How to answer $\mathsf{LongLCE}_t(i,j)$ queries is equivalent to Gawrychowski et al.'s, namely, we sample the positions from $S(t)$ so that LCE queries for these sampled positions can be answered in $O(1)$ time. We show how to build the data structure for $\mathsf{LongLCE}_t(i,j)$ queries by using t-$\mathsf{TST}(w)$ for $Substr_t(w)$ in $O(n \log \sigma)$ time with $O(zt)$ working space.

3.2 $\mathsf{ShortLCE}_t$ queries

For $\mathsf{ShortLCE}_t(i,j)$ queries, we use $2t$-$\mathsf{TST}(w)$ which represents the set $Substr_{2t}(w)$ of all substrings of w of length at most $2t$. For any position $1 \leq i \leq n$, let p_i denote the substring of w that begins at position i and is of length at most $2t$, namely, $p_i = w[i..\min\{i+2t-1, n\}]$. Notice that $Substr_{2t}(w) = \bigcup_{i=1}^{n} \{p_i\}$. For any position $1 \leq i \leq n$ in w, let $\ell(i) = u$ iff u is the leaf of $2t$-$\mathsf{TST}(w)$ such that $str(u) = p_i$. Basically, we will compute $\mathsf{ShortLCE}_t(i,j)$ by efficiently finding the LCA of the corresponding leaves $\ell(i)$ and $\ell(j)$ on $2t$-$\mathsf{TST}(w)$. The reason that we use $2t$-$\mathsf{TST}(w)$ rather than t-$\mathsf{TST}(w)$ will become clear later.

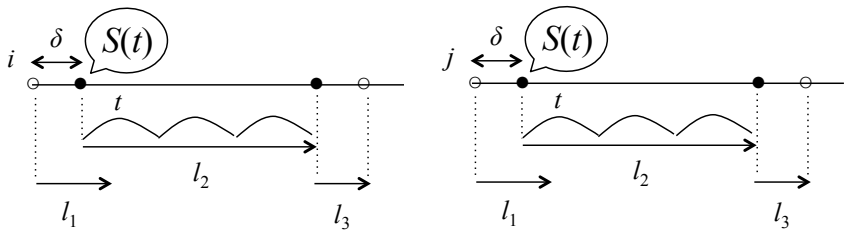

Figure 3 Illustration of an overview of our $\mathsf{LCE}(i,j)$ algorithm. We are given two positions i and j in string w. First, we compute $l_1 = \mathsf{ShortLCE}_t(i,j)$. If $l_1 < t$, then $\mathsf{LCE}(i,j) = l_1$. Otherwise, we compute $\mathsf{LongLCE}_t(i+\delta, j+\delta)$ where $i+\delta, j+\delta \in S(t)$ and $0 \le \delta \le t$. We finally compute $l_3 = \mathsf{ShortLCE}(i+\delta+l_2, j+\delta+l_2)$ where $l_2 = t\mathsf{LongLCE}_t(i+\delta, j+\delta)$. Then $\mathsf{LCE}(i,j) = \delta + l_2 + l_3$.

Now the key is how to access $\ell(i)$ for a given position i in w. As our goal is to build a sub-linear space data structure for $\mathsf{ShortLCE}_t$ queries, we cannot afford to store a pointer to $\ell(i)$ from every position $1 \le i \le n$. Thus, we store such a pointer only from every t-th positions in w. We call these positions as *sampled positions*. Formally, for every sampled position $j \in Q_{t,n} = \{1 + kt \mid 0 \le k \le \lceil \frac{n}{t} \rceil - 1\}$ we explicitly store a pointer from j to its corresponding leaf $\ell(j)$ on $2t$-$\mathsf{TST}(w)$. Also, for each position $1 \le i \le n$ in w, let $\alpha(i) = \max\{j \in Q_{t,n} \mid j \le i\}$. Namely, $\alpha(i)$ is the closest sampled position in $Q_{t,n}$ to the left of i (or it is i itself if $i \in Q_{t,n}$).

Given a position $1 \le i \le n$, $\alpha(i)$ can be computed in $O(1)$ time with a simple arithmetic operation. Hence, we can access the leaf $\ell(\alpha(i))$ for the closest sampled position $\alpha(i)$ in $O(1)$ time. The next task is to locate $\ell(i)$. To describe our constant-time algorithm, let us consider a conceptual graph $G = (V, E)$ such that $V = \mathit{Substr}_{2t}(w)$ and $E = \{(u, c, v) \mid u[1..2t-1] = v[2..2t], c = v[1]\}$, where (u, c, v) represents a directed edge labeled c from u to v. This graph G is equivalent to the edge-reversed de Bruijn graph of order $2t$, with extra nodes for the $2t-1$ suffixes of w which are shorter than $2t$. It is clear that there is a one-to-one correspondence between the leaves of $2t$-$\mathsf{TST}(w)$ and the nodes of the graph G. Thus, we will identify each leaf of $2t$-$\mathsf{TST}(w)$ with the nodes of graph G.

▶ **Lemma 6.** *Given $2t$-$\mathsf{TST}(w)$ for a string w of length n and for any $1 \le 2t \le n$, we can construct the graph G in $O(n)$ time using $O(zt)$ working space.*

Proof. The de Bruijn graph of order q for a string of length n can be constructed in $O(n)$ time using space linear in the size of the output de Bruijn graph, provided that q-$\mathsf{TST}(w)$ is already constructed [13]. By setting $q = 2t$, adding extra $2t-1$ nodes for the suffixes that are shorter than $2t$, and reversing all the edges, we obtain our graph $G = (V, E)$.

The number of nodes in V is clearly equal to $|\mathit{Substr}_{2t}(w)|$. Also, since each edge in E corresponds to a distinct substring in $\mathit{Substr}_{2t+1}(w)$, the number of edges in E is equal to $|\mathit{Substr}_{2t+1}(w)|$. By a similar argument to the proof of Lemma 4, we obtain $|V| = |\mathit{Substr}_{2t}(w)| = O(zt)$ and $|E| = |\mathit{Substr}_{2t+1}(w)| = O(zt)$. ◀

Let $d = i - \alpha(i)$. A key observation here is that there is a path of length d from node p_i to node $p_{\alpha(i)}$ in this graph G. Since G is a graph, however, it is not easy to quickly move from $p_{\alpha(i)}$ to p_i. To overcome this difficulty, we consider a spanning tree of G of which the root is $p_n = w[n] = \$$. Let T denote any spanning tree of G. See Figure 4 for examples of the graph G and its spanning tree T. Although some edges are lost in spanning tree T, it is enough for our purpose. Namely, the following lemma holds.

▶ **Lemma 7.** *Any spanning tree T of G satisfies the following properties: (1) There is a non-branching path of length $2t$ from the root p_n to the node p_{n-2t}. (2) For any $1 \leq i \leq n-2t-1$ and $0 \leq d < t$, let g be the d-th ancestor of $p_{\alpha(i)}$. Then, $g[1..t] = p_i[1..t]$.*

Proof. The first property is immediate from the fact that the last character $w[n] = \$$ occurs nowhere else in w and the root represents $p_n = \$$.

Since $d < t$ and $|p_{\alpha(i)}| = 2t$, we have $p_{\alpha(i)}[d..d+t-1] = p_i[1..t]$. By the first property and $\alpha(i) \leq i \leq n-2t-1$, the depth of node $p_{\alpha(i)}$ is at least $2t$. Also, by following the in-coming edge of each node in the reversed direction, we delete the first character of the corresponding string. Hence, $p_i[1..t]$ is a prefix of the d-th ancestor g of $p_{\alpha(i)}$. ◀

We are ready to show the main result of this section.

▶ **Theorem 8.** *For any string w of length n and integer $1 \leq t \leq n$, a data structure of size $O(zt + \frac{n}{t})$ can be constructed in $O(n \log \sigma)$ time using $O(zt)$ working space such that subsequent $\mathsf{ShortLCE}_t(i,j)$ queries for any $1 \leq i, j \leq n$ can be answered in $O(1)$ time, where $z = |\mathsf{LZ}(w)|$.*

Proof. We use a spanning tree T enhanced with a *level ancestor* data structure [5, 4] which can be constructed in time and space linear in the size of the input tree T.

Given two positions i, j in w, we answer $\mathsf{ShortLCE}_t(i,j)$ query as follows:

1. Compute the closest sampled positions $\alpha(i)$ and $\alpha(j)$ by simple arithmetics.
2. Access the nodes $p_{\alpha(i)}$ and $p_{\alpha(j)}$ in the spanning tree T using pointers from the sampled positions $\alpha(i)$ and $\alpha(j)$, respectively.
3. Let $d = i - \alpha(i)$ and $d' = j - \alpha(j)$. Access the d-th ancestor u of $p_{\alpha(i)}$ and the d'-th ancestor of $p_{\alpha(j)}$ using level ancestor queries on T.
4. Compute the LCA x of the two leaves u and v on $2t$-$\mathsf{TST}(w)$, and return $\min\{|str(x)|, t\}$.

The correctness follows from Lemma 7. Since each step of the above algorithm takes $O(1)$ time, we can answer $\mathsf{ShortLCE}_t(i,j)$ in $O(1)$ time. By Lemma 4, the size of $2t$-$\mathsf{TST}(w)$ with an LCA data structure is $O(zt)$, and also the size of the spanning tree T with a level ancestor data structure is $O(|Substr_{2t}(w)|) = O(zt)$. In addition, we store pointers from the $\Theta(\frac{n}{t})$ sampled positions to their corresponding nodes in T. Overall, the total space requirement of our data structures is $O(zt + \frac{n}{t})$. We can build these data structures in a total of $O(n \log \sigma)$ time using $O(zt)$ working space by Theorem 5 and Lemma 6. ◀

3.3 $\mathsf{LongLCE}_t$ queries

At a high level, our $\mathsf{LongLCE}_t(i,j)$ query algorithm is an adaptation of the t-cover based algorithm by Puglisi and Turpin [43], which was later re-discovered by Bille et al. [9]. Gawrychowski et al. [19] showed that an $O(\frac{n}{\sqrt{t}})$-space data structure, which answers $\mathsf{LongLCE}_t(i,j)$ query in $O(1)$ time, can be constructed in $O(n \log t)$ time with $t = \Omega(\log^2 n)$ for a string of length n over a general ordered alphabet. In this section, we show the same data structure as Gawrychowski et al. can be constructed in $O(n \log \sigma)$ time with $O(zt + \frac{n}{t})$ working space for a general ordered alphabet of size σ and any $1 \leq t \leq n$.

Consider a t-cover $S(t)$ of $[1..n]$ for some t-difference-cover D. For each position $i \in S(t)$ such that $i + t - 1 \leq n$, the substring $b_i = w[i..i+t-1]$ is said to be a *t-block*. The goal here is to answer the block-wise LCE value $\mathsf{LongLCE}_t(i,j)$ for two given positions in the t-cover $S(t)$. Since we query $\mathsf{LongLCE}_t(i,j)$ only for positions $i, j \in S(t)$ and the answer to $\mathsf{LongLCE}_t(i,j)$ is a multiple of t, we can regard each t-block as a single character. Thus,

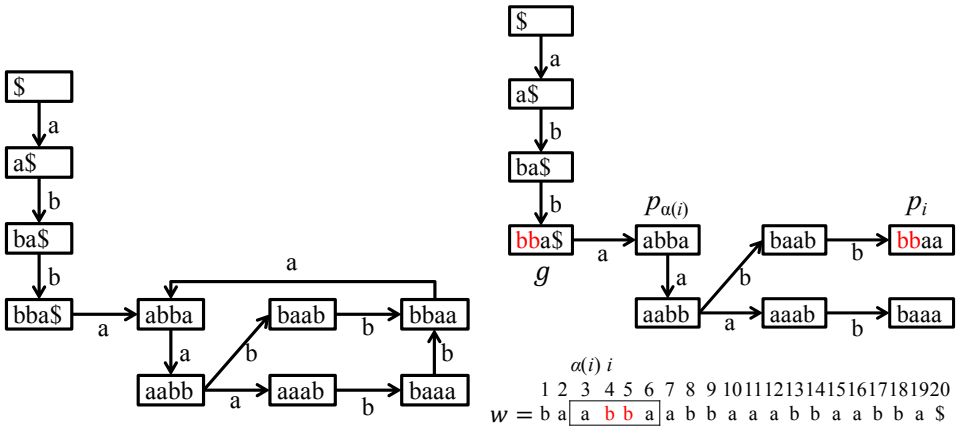

Figure 4 The left graph G is the edge-reversed de Bruijn graph of order $2t$, with extra nodes for the $2t-1$ suffixes of w which are shorter than $2t$, where $t=2$ and w is the same string as in Figure 2. An edge from u to v labeled character c represents $c \cdot u[1..2t-1] = v$. The right tree is a spanning tree of the left graph. Let $i=4$ and $\alpha(i)=3$. Then $p_i = bbaa$, $p_{\alpha(i)} = abba$. Let g be the d-th ancestor of $p_{\alpha(i)}$ in the right tree, where $0 \le d < t$. Then $g[1..t] = p_i[1..t]$ holds by Lemma 7.

we sort all t-blocks in lexicographical order, and encode each t-block by its lexicographical rank. Since each t-block is of length t, we can sort the t-blocks in $O(\frac{n}{\sqrt{t}} \log \frac{n}{\sqrt{t}})$ time with $O(zt + \frac{n}{\sqrt{t}})$ working space by using any suitable comparison-based sorting algorithm and our $O(1)$-time $\mathsf{ShortLCE}_t$ query data structure of Section 3.2. The next lemma shows that we can actually compute the lexicographical ranks of all t-blocks more efficiently.

▶ **Lemma 9.** *Let w be an input string of length n and $1 \le t \le n$ be an integer. Given the data structure for $\mathsf{ShortLCE}_t$ queries of Theorem 8 for w, we can sort all t-blocks of w in lexicographic order in $O(zt + \frac{n}{\sqrt{t}})$ time using $O(zt + \frac{n}{t})$ working space, where $z = |\mathsf{LZ}(w)|$.*

Proof. We insert new (non-branching) nodes to $2t$-$\mathsf{TST}(w)$ such that every t-gram in w is represented by an explicit node. This increases the size of the tree by a constant factor. We also associate each node u such that $|str(u)| = t$ with the lexicographical rank of the t-gram $str(u)$ among all t-grams in w. Then, we associate each leaf ℓ of the tree such that $|str(\ell)| \ge t$ with its ancestor v which represents a t-gram. All these can be preformed in $O(zt)$ total time by standard depth-first traversals on the tree.

Then, for each t-block $b_i = w[i..i+t-1]$, we can access a leaf ℓ of $2t$-$\mathsf{TST}(w)$ such that $str(\ell)[1..t] = w[i..i+t-1]$ in $O(1)$ time using the algorithm of Theorem 8, and we return the rank of the ancestor v of ℓ that represents $b_i = w[i..i+t-1]$. Since there are $O(\frac{n}{\sqrt{t}})$ t-blocks in w, it takes a total of $O(zt + \frac{n}{\sqrt{t}})$ time. The working space is $O(zt + \frac{n}{t})$ by Theorem 8. ◀

There is an alternative algorithm to sort the t-blocks, as follows:

▶ **Lemma 10.** *For any string w of length n over an alphabet of size σ, any integer $1 \le t \le n$, we can sort all t-blocks in lexicographic order in $O(n \log \sigma)$ time using $O(zt)$ working space, where $z = |\mathsf{LZ}(w)|$.*

Proof. We use t-$\mathsf{TST}(w)$ and the reversed de Bruijn graph of order t. We associate each leaf of the tree representing a t-gram with its lexicographical rank among all leaves in the tree.

Let r be the graph node which represents $w[n] = \$$. We simply traverse the graph while scanning the input string w from right to left. For each $1 \le i \le n$, this gives us the graph node representing $b_i = w[i..i+t-1]$ and hence the corresponding leaf of t-$\mathsf{TST}(w)$.

t-$\mathsf{TST}(w)$ and the reversed de Bruijn graph can be constructed in $O(n \log \sigma)$ time with $O(zt)$ working space. The ranks of the leaves in t-$\mathsf{TST}(w)$ can be easily computed in $O(zt)$ time by a standard tree traversal. Traversing the reversed de Bruijn graph takes $O(n \log \sigma)$ time. Hence the lemma holds. ◀

For each $i \in S(t)$, let r_i be the rank of the t-block $b_i = w[i..i+t-1]$ computed by any of the algorithms above. Clearly $r_i \in [1..n]$. For simplicity, assume $\sqrt{t}$ is an integer. For each position $i \in D$ (where D is the underlying t-difference cover), let $\#_i = r_i r_{i+t} \cdots r_{i+m_i t}$, where $m_i = \frac{n-i+1}{\sqrt{t}} - 1$. We create a string $code(w) = \#_1\$_1 \cdots \#_k\$_k$ of length $|S(t)| = O(\frac{n}{\sqrt{t}})$. Since each $\#_i$ is a string over the integer alphabet $[1..S(t)] \subset [1..n]$ and $|D| = O(\sqrt{t})$, we can regard $code(w)$ as a string over an integer alphabet of size $O(n)$. Then, we build the suffix array, the inverse suffix array, the LCP array [37] of $code(w)$ and an range minimum query (RMQ) data structure [3] for the LCP array. For any position $i \in S(t)$ on the original string w, we can compute its corresponding position i' on $code(w)$ as $i' = |\#_1\$_1\#_2\$_2 \cdots \#_{x-1}\$_{x-1}| + \frac{i-x}{t} + 1$ where $x = i \bmod t$. Now, $\mathsf{LongLCE}_t(i,j)$ query for two positions $i, j \in S(t)$ on the original string w reduces to an LCE query for the corresponding positions on $code(w)$, which can be answered in $O(1)$ time using an RMQ on the LCP array. All these arrays and the RMQ data structure can be built in $O(\frac{n}{\sqrt{t}})$ time [27, 28, 3].

▶ **Theorem 11.** *For any string of length n and integer $1 \le t \le n$, a data structure of size $O(\frac{n}{\sqrt{t}})$ can be constructed in $O(n \log \sigma)$ time using $O(zt + \frac{n}{t})$ working space such that subsequent $\mathsf{LongLCE}_t(i,j)$ queries for any $1 \le i, j \le n$ can be answered in $O(1)$ time, where $z = |\mathsf{LZ}(w)|$.*

Proof. We need $O(\frac{n}{\sqrt{t}})$ working space for the encoded string $code(w)$ and its suffix array plus LCP array enhanced with an RMQ data structure. Then the theorem follows from Theorem 8, and Lemma 9 or Lemma 10. ◀

3.4 Main result and variants

In what follows, let w be an input string of length n and $z = |\mathsf{LZ}(w)|$. By Theorem 8 and Theorem 11 shown in the previous subsections, we obtain the main theorem of this paper:

▶ **Theorem 12.** *For any integer $1 \le t \le n$, an LCE data structure of size $O(zt + \frac{n}{\sqrt{t}})$ can be constructed in $O(n \log \sigma)$ time with $O(zt + \frac{n}{\sqrt{t}})$ working space such that subsequent $\mathsf{LCE}(i,j)$ query for any $1 \le i, j \le n$ can be answered in $O(1)$ time.*

We can also obtain the following variants of our LCE data structure.

▶ **Corollary 13.** *For any integer $1 \le t \le n$, an LCE data structure of size $O(z^{\frac{1}{3}} n^{\frac{2}{3}})$ can be constructed in $O(n \log \sigma \log n)$ time with $O(z^{\frac{1}{3}} n^{\frac{2}{3}})$ working space such that subsequent $\mathsf{LCE}(i,j)$ query for any $1 \le i, j \le n$ can be answered in $O(1)$ time.*

Proof. The LCE data structure of Theorem 12 for $t = (\frac{n}{z})^{\frac{2}{3}} < n$ takes $O(z^{\frac{1}{3}} n^{\frac{2}{3}})$ space. Since we do not compute z, we are not able to compute the exact value of $(\frac{n}{z})^{\frac{2}{3}}$. However, we can find the value of t for which the difference between the actual size of t-$\mathsf{TST}(w)$ and $\lceil \frac{n}{\sqrt{t}} \rceil$ is smallest, by doubling-then-binary searches for t. Since the size of the resulting LCE data structure can be by a constant factor larger than the smallest variant of our LCE data structure, it is clearly bounded by $O(z^{\frac{1}{3}} n^{\frac{2}{3}})$. The above method takes $O(n \log \sigma \log n)$ total time and uses $O(z^{\frac{1}{3}} n^{\frac{2}{3}})$ total working space. ◀

▶ **Corollary 14.** *For alphabets of size $\sigma \leq 2^{o(\log n)}$, an LCE data structure of size $o(n \log n)$* bits *can be constructed in $o(n \log^2 n)$ time with $o(n \log n)$* bits *of working space such that subsequent $\mathsf{LCE}(i, j)$ query for any $1 \leq i, j \leq n$ can be answered in $O(1)$ time.*

Proof. By plugging the well-known fact that $z = O(n/\log_\sigma n)$ into the result of Corollary 13, we get $O(n/(\log_\sigma n)^{\frac{1}{3}})$ for the space bound. Thus our data structure can be stored in $\mathcal{S}(n) = O(n(\log n)^{\frac{2}{3}}(\log \sigma)^{\frac{1}{3}})$ *bits* of space in the transdichotomous word RAM [16] with machine word size $\omega = \Theta(\log n)$. Hence, for alphabets of size $\sigma \leq 2^{o(\log n)}$, we obtain an LCE data structure with the claimed bounds. ◀

We can also obtain a new time-space trade-off LCE data structure. Observe that using the data structure of Theorem 8 for $1 \leq d \leq n$, we can answer $\mathsf{ShortLCE}_t$ queries for any $1 \leq t \leq n$ in $O(\max\{1, \frac{t}{d}\})$ time. Hence the following theorem holds.

▶ **Theorem 15.** *For any integers $1 \leq t' \leq t \leq n$, a data structure of size $O(zt' + \frac{n}{\sqrt{t}} + \frac{n}{t'})$ can be constructed in $O(n \log \sigma)$ time with $O(zt + \frac{n}{\sqrt{t}} + \frac{n}{t'})$ working space such that subsequent $\mathsf{LCE}(i, j)$ query for any $1 \leq i, j \leq n$ can be answered in $O(\frac{t}{t'})$ time.*

Theorem 15 implies the following: (1) By setting $t' = t$, we obtain Theorem 12. Moreover, by choosing also $t \leftarrow (\frac{n}{z})^{2/3}$, we obtain a data structure of size $O(z^{1/3}n^{2/3})$ answering LCE queries in constant time, which coincides with Corollary 13. This is the smallest data structure among the fastest data structures with two parameters t and t'. (2) By setting $t' = \sqrt{t}$ and for $t = n/z$, we get a data structure of size $O(\sqrt{nz})$ answering LCE queries in $O(\sqrt{\frac{n}{z}})$ time. This is the fastest data structure among the smallest data structures with two parameters t and t'. Note that when we do not know z, this data structure of at most $O(\sqrt{nz})$ space can be constructed in $O(n \log \sigma \log n)$ preprocessing time and $O(\sqrt{nz})$ working space as in Corollary 13. Although the parameters cannot be arbitrarily chosen, the space-query time product obtained here is optimal with fastest construction to date.

Moreover, we can reduce the zt term in the working space of Theorem 15 to zt' by increasing the preprocessing time. The bottleneck of the working space is in sorting t-blocks, i.e., Lemma 9 or Lemma 10. Since any two t-blocks can be compared in $O(\frac{t}{t'})$ time using $O(\frac{t}{t'})$ $\mathsf{ShortLCE}_{t'}$ queries, we can get the following theorem using any suitable comparison-based sorting algorithm instead of Lemma 9 or Lemma 10.

▶ **Theorem 16.** *We can construct the data structure of Theorem 15 in $O(\frac{n}{t'} \log \frac{n}{t} + n \log \sigma)$ time and $O(zt' + \frac{n}{\sqrt{t}} + \frac{n}{t'})$ working space.*

4 Lower bounds vs upper bounds for the LCE problem

Let $\mathcal{T}(n)$ and $\mathcal{S}(n)$ respectively denote the query time and data structure size (in *bits*) of an arbitrary LCE data structure for an input string of length n.

Brodal et al. [10] showed that in the non-uniform cell probe model, any RMQ data structure for a string of length n which uses $\frac{n}{t}$ bits of additional space for any $1 \leq t \leq n$ must take $\Omega(t)$ query time (i.e., $\Omega(t)$ character accesses or cell probes). Their proof assumes that each character in the string is stored in a separate cell, and counted the minimum number of character accesses required to answer an RMQ. Although their proof uses a binary string of length n where each character takes only a single bit, the above assumption is valid in a commonly accepted case that the underlying alphabet size is 2^ω, where ω denotes the size of each cell (i.e. machine word). Then, Bille et al. [9] showed that RMQ queries on any binary string of length n can be reduced to LCE queries on the same binary string, with

$\Theta(\log n)$ additional bits of space. This implies that, again assuming that each character is stored in a separate cell, any LCE data structure for a binary string of length n which uses $\mathcal{S}(n) = \frac{n}{t} + \Theta(\log n)$ additional bits of space must take $\mathcal{T}(n) = \Omega(t)$ query time, for parameter $1 \leq t \leq \frac{n}{\log n}$. Recently, Kosolobov [33] showed another result on time-space product trade-off lower bound in the non-uniform cell probe model, which can be formalized as follows:

▶ **Theorem 17** ([33]). *In the non-uniform cell probe model where each character is stored in a separate cell, for any $\mathcal{S}(n)$, there exists $\sigma = 2^{\Omega(\mathcal{S}(n)/n)}$ such that for any LCE data structure for a string over the alphabet $\Sigma = \{1, \ldots, \sigma\}$, which takes $\mathcal{S}(n)$ bits of space and answers LCE queries in $\mathcal{T}(n)$ time (i.e., with $\mathcal{T}(n)$ character accesses or cell probes), $\mathcal{T}(n)\mathcal{S}(n) = \Omega(n \log n)$ holds.*

The lower bound by Kosolobov is optimal for the considered range of the alphabet size $\sigma = 2^{\Omega(\mathcal{S}(n)/n)}$, since the data structure of Bille et al. [8] achieves $\mathcal{T}(n)\mathcal{S}(n) = O(n \log n)$.

Interestingly, our LCE data structure proposed in Section 3 reveals that there are some cases where the above lower bounds do not apply. For highly compressible strings where zt is dominated by $\frac{n}{\sqrt{t}}$, our LCE data structure of Theorem 12 takes $O(\frac{n \log n}{t})$ *bits* of space for $1 \leq t \leq n$ with machine word of size $\omega = \Theta(\log n)$. Hence, for parameter $1 \leq t' \leq \frac{\sqrt{n}}{\log n}$ we get $\mathcal{S}(n) = O(\frac{n}{t'})$. Since our data structure of Theorem 12 always achieves $\mathcal{T}(n) = O(1)$ for any parameter setting, we observe that Bille et al.'s lower bound do not apply for highly repetitive strings. Notice also that our LCE data structure of Corollary 14 achieves $\mathcal{T}(n)\mathcal{S}(n) = o(n \log n)$ for alphabet size $\sigma \leq 2^{o(\log n)}$. This shows that the alphabet size $\sigma = 2^{\Omega(\mathcal{S}(n)/n)}$ is important for Kosolobov's lower bound to hold.

Kosolobov [33] did suggest a possibility to overcome his lower bound when σ is small, and the input string can be *packed*, where $\log_\sigma n$ characters can occupy a memory cell, allowing the algorithm to read $\log_\sigma n$ characters with one memory access. We show below that this is also possible. An input string of length n can be considered as a bit string of length $n \log \sigma$. Let $t = \log n$, and first consider the $\mathsf{ShortLCE}_{\log n}$ queries on the bit string. When the original string is available in a packed representation, the longest common prefix of two substrings strings of length $\log n$ bits can be computed in constant time using no extra space using bit operations, namely, by taking the bitwise exclusive or (XOR) and computing the position of the most significant set bit (msb), or without msb, by multiple lookups on a table of total size $o(n)$ bits. Next, consider the $\mathsf{LongLCE}_{\log n}$ queries on the bit string. By simply using the same data structure as described in Section 3.3 for the bit string of length $n \log \sigma$, we can answer $\mathsf{LongLCE}_{\log n}$ queries in constant time using a data structure of size $O(\frac{n \log \sigma}{\sqrt{\log n}} \log(n \log \sigma)) = O(n\sqrt{\log n} \log \sigma)$ bits. Using the two queries, we can answer an LCE query for arbitrary positions i, j of the original string in constant time with $\lfloor (\mathsf{LCE}(i \cdot \log \sigma, j \cdot \log \sigma)) / \log \sigma \rfloor$. Since the size of the data structure is $\mathcal{S}(n) = O(n\sqrt{\log n} \log \sigma)$ bits, we obtain $\mathcal{T}(n)\mathcal{S}(n) = o(n \log n)$ for $\sigma \leq 2^{o(\sqrt{\log n})}$. Our LCE data structure based on truncated suffix trees is superior for larger σ, and also when the input string is highly repetitive and compressible since it does not require the original string.

5 Conclusions and open questions

In this paper, we presented an LCE data structure which uses $O(zt + \frac{n}{\sqrt{t}})$ words of space and answers in LCE queries in $O(1)$ time, for parameter $1 \leq t \leq \sqrt{n}$. This data structure can be constructed in $O(n \log \sigma)$ time with $O(zt + \frac{n}{\sqrt{t}})$ working space. Using the fact that

$z = O(n/\log_\sigma n)$ and suitably choosing t, our method achieves the first $O(1)$-time sub-linear space LCE data structure for alphabets of size $\sigma \leq 2^{o(\log n)}$.

An interesting open question is whether we can improve the total space requirement to $O(zt+\frac{n}{t})$. The bottleneck is the $\mathsf{LongLCE}_t$ data structure that uses $O(zt+\frac{n}{\sqrt{t}})$ space. Another open question is whether we can compute the size z of the Lempel-Ziv 77 factorization in $O(n \log \sigma)$ time with sub-linear working space. This is motivated for computing the value of t which optimizes our space bound $O(zt + \frac{n}{t})$. A little has been done in this line of research: Nishimoto et al. [40] showed how to compute the Lempel-Ziv 77 factorization in $O(n\text{polylog}(n))$ time with $O(z \log n \log^* n)$ working space. Fischer et al. [15] showed an algorithm which computes an approximation of the Lempel-Ziv 77 factorization of size $(1+\epsilon)z$ in $O(\frac{1}{\epsilon} n \log n)$ time with $O(z)$ working space, for any $0 < \epsilon \leq 1$.

Another direction of further research is to give a tighter upper bound for the size of the t-truncated suffix trees than zt. We observed that there exists a string of length n for which zt is greater by a factor of $\sqrt{n}$ than the actual size of the t-truncated suffix tree for some t.

Acknowledgments. We thank Dmitry Kosolobov for explaining his work [33] to us.

Abstract

The ZX-Calculus is a powerful graphical language for quantum mechanics and quantum information processing. The completeness of the language – i.e. the ability to derive any true equation – is a crucial question. In the quest of a complete ZX-calculus, supplementarity has been recently proved to be necessary for quantum diagram reasoning (MFCS 2016). Roughly speaking, supplementarity consists in merging two subdiagrams when they are parameterized by antipodal angles. We introduce a generalised supplementarity – called cyclotomic supplementarity – which consists in merging n subdiagrams at once, when the n angles divide the circle into equal parts. We show that when n is an odd prime number, the cyclotomic supplementarity cannot be derived, leading to a countable family of new axioms for diagrammatic quantum reasoning.

We exhibit another new simple axiom that cannot be derived from the existing rules of the ZX-Calculus, implying in particular the incompleteness of the language for the so-called Clifford+T quantum mechanics. We end up with a new axiomatisation of an extended ZX-Calculus, including an axiom schema for the cyclotomic supplementarity.

1 Introduction

The ZX-Calculus is a powerful diagrammatic language for reasoning in quantum mechanics introduced by Coecke and Duncan [8]. Every diagram is composed of three kinds of vertices: red and green dots which are parametrised by an angle, and a yellow box; and each diagram represents a matrix thanks to the so-called standard interpretation. Moreover, any quantum transformation can be expressed using ZX-diagrams, meaning they are *universal*. For instance, some particular states can be represented as evidenced by [9]. The language initially describes pure quantum state transformations, though some work has been made to adapt it to non pure evolutions [7, 10] and measurement-based quantum computing [12].

Unlike quantum circuits, the ZX-Calculus comes with a set of equalities between diagrams that preserve the matrix that is represented. Hence, using a succession of locally applied

such equalities, one can prove that two diagrams represent the same matrix, for the language is *sound* i.e. all the equalities do indeed preserve the matrix.

The converse of soundness is called *completeness*. Here, it amounts to being able to transform any diagram into another one, as long as both represent the same matrix. Hence, the concept of completeness is here totally defined by one particular interpretation, the *standard interpretation*, unlike other definitions of completeness such as in [18] in which it is related to a whole family of interpretations.

It has been proven that the ZX-Calculus is in general not complete [17]. Yet, some restrictions have been proven to be complete. The $\frac{\pi}{2}$-fragment – the language restricted to angles that are multiples of $\frac{\pi}{2}$, which represents the *stabiliser quantum mechanics* – is complete [1], its pseudo-normal form using graph states introduced in the case of the ZX-Calculus in [11]. Moreover, this proof can be adapted to show the completeness of a ZX-like calculi used for graphically representing Spekken's toy model [4, 20] or for graphically representing the real matrices [15]. The π-fragment – representing the *real stabiliser quantum mechanics* – is also complete, with a slightly adapted set of rules [13].

A fragment is *approximately universal* when any quantum transformation can be approached with arbitrarily great precision using only the angles in the fragment. Sadly, the $\frac{\pi}{2}$-fragment is not approximately universal, but the $\frac{\pi}{4}$-fragment is [19]. It is called the *Clifford+T quantum mechanics*. Completeness for this fragment was an open question, one of the main ones in the fields of categorical quantum mechanics [6] – even though a partial answer has been given for the fragment composed of path diagrams involving angles multiple of $\frac{\pi}{4}$ [2].

In this paper, we show that in the ZX-Calculus, the $\frac{\pi}{4}$-fragment is not complete, showing that a scalar equality is derivable using matrices, but not diagrammatically. We propose to replace the "inverse rule" by this equality, and show that it can prove the former one as well as a third one: the "zero rule". Notice that this axiomatisation has been recently turned into complete axiomatisation of the ZX-calculus for this fragment [14].

We also show that an infinite number of fragments are also incomplete, by proving that a generalised form of the "supplementarity rule" [16] cannot be derived in them. Supplementarity, which has been proved to be necessary, consists in merging two subdiagrams when they are parameterized by antipodal angles. The generalised supplementarity – called cyclotomic supplementarity – consists in merging n subdiagrams at once, when the n angles divide the circle into equal parts. We show that when n is an odd prime number, the cyclotomic supplementarity cannot be derived, leading to a countable family of new axioms for diagrammatic quantum reasoning.

Finally, we propose to add the new scalar equation, as well as the cyclotomic supplementarity to the set of rules, and to get rid of the now obsolete "inverse" and "zero" rules. We address the question of the incompleteness of the – new – general ZX-calculus with a modified version of the proof by Zamdzhiev and Schröder de Witt [17], for theirs does not stand any more because of the introduction of the cyclotomic supplementarity.

We present the ZX-Calculus in section 2, prove the incompleteness of the $\frac{\pi}{4}$-fragment and give a new scalar rule in section 3, and in section 4 we show how to generalise the supplementarity rule, discuss the way some are derivable from others, present the altered set of rules and give a new proof of incompleteness of the general ZX-Calculus. Some proofs are omitted in this paper, you can find them at `https://hal.archives-ouvertes.fr/hal-01445707`.

2 ZX-Calculus

2.1 Diagrams and standard interpretation

A ZX-diagram $D : k \to l$ is an open graph with k inputs and l outputs – read from top to bottom – and is generated by:

$R_Z^{(n,m)}(\alpha) : n \to m$		$R_X^{(n,m)}(\alpha) : n \to m$	$H : 1 \to 1$		$e : 0 \to 0$	
$\mathbb{I} : 1 \to 1$		$\sigma : 2 \to 2$	
$\epsilon : 2 \to 0$		$\eta : 0 \to 2$	

where $n, m \in \mathbb{N}$ and $\alpha \in \mathbb{R}$

and the two compositions:

- Spacial Composition: for any $D_1 : a \to b$ and $D_2 : c \to d$, $D_1 \otimes D_2 : a + c \to b + d$ consists in placing D_1 and D_2 side by side, D_2 on the right of D_1.
- Sequential Composition: for any $D_1 : a \to b$ and $D_2 : b \to c$, $D_2 \circ D_1 : a \to c$ consists in placing D_1 on the top of D_2, connecting the outputs of D_1 to the inputs of D_2.

The standard interpretation of the stabiliser ZX-diagrams associates to any diagram $D : n \to m$ a linear map $[\![D]\!] : \mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$ inductively defined as follows:

$$[\![D_1 \otimes D_2]\!] := [\![D_1]\!] \otimes [\![D_2]\!] \qquad [\![D_2 \circ D_1]\!] := [\![D_2]\!] \circ [\![D_1]\!]$$

$$\left[\!\!\left[\; \right]\!\!\right] := (1) \qquad \left[\!\!\left[\; | \; \right]\!\!\right] := \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \qquad \left[\!\!\left[\; \right]\!\!\right] := \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$

$$[\![\;]\!] := \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \qquad [\![\;]\!] := \begin{pmatrix} 1 & 0 & 0 & 1 \end{pmatrix} \qquad [\![\;]\!] := \begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}$$

$$[\![\;]\!] := \left(1 + e^{i\alpha}\right) \qquad \left[\!\!\left[\; \right]\!\!\right] := 2^m \overbrace{\begin{pmatrix} 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & e^{i\alpha} \end{pmatrix}}^{2^n} \quad (n + m > 0)$$

For any $n, m \geq 0$ and $\alpha \in \mathbb{R}$, $\left[\!\!\left[\; \right]\!\!\right] = \left[\!\!\left[\; \right]\!\!\right]^{\otimes m} \circ \left[\!\!\left[\; \right]\!\!\right] \circ \left[\!\!\left[\; \right]\!\!\right]^{\otimes n}$

(where $M^{\otimes 0} = (1)$ and $M^{\otimes k} = M \otimes M^{\otimes k-1}$ for any $k \in \mathbb{N}^* := \mathbb{N} \setminus \{0\}$).

To simplify, the red and green nodes will be represented empty when holding a 0 angle:

Also in order to make the diagrams a little less heavy, when n copies of the same subdiagram occur, we will use the notation $(.)^{\otimes n}$ as defined above.

With the general calculus – with angles being in $\mathbb{R}$ – we can represent any matrix of size a power of 2 i.e. ZX-Diagrams are universal:

$$\forall A \in \mathbb{C}^{2^n} \times \mathbb{C}^{2^m}, \quad \exists D, \quad [\![D]\!] = A$$

This requires dealing with an uncountable set of angles, so it is generally preferred to work with *approximate* universality – the ability to approximate any linear map with arbitrary accuracy – in which only a finite set of angles is involved. The $\frac{\pi}{4}$-fragment – ZX-diagrams where all angles are multiples of $\frac{\pi}{4}$ – is one such approximately universal fragment, whereas the $\frac{\pi}{2}$-fragment is not.

2.2 Calculus

The diagrammatic representation of a matrix is not unique in the ZX-Calculus. Hence, a set of equalities has been proposed to axiomatise the language. This set is summed up in Figure 1.

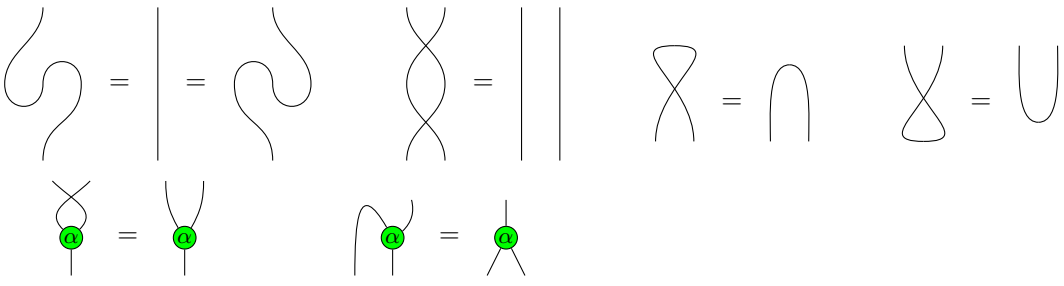
The initial set of axioms [8] included the rules (S1), (S2), (S3), (B1), (B2), (K1), (K2) and (H). The rule (EU) has been proven to be necessary in [11] and the rules (ZO) and (IV) result from [3, 5]. Finally, the rule (SUP) has been added in [16].

When we can show that a diagram D_1 is equal to another one, D_2, using a succession of equalities of this set, we write $ZX \vdash D_1 = D_2$. Given that the rules are sound, this implies that $[\![D_1]\!] = [\![D_2]\!]$. The rules can be applied to any subdiagram, meaning, for any diagram D:

$$(ZX \vdash D_1 = D_2) \quad \Rightarrow \quad \begin{cases} (ZX \vdash D_1 \circ D = D_2 \circ D) & \wedge \quad (ZX \vdash D \circ D_1 = D \circ D_2) \\ (ZX \vdash D_1 \otimes D = D_2 \otimes D) & \wedge \quad (ZX \vdash D \otimes D_1 = D \otimes D_2) \end{cases}$$

Scalars. We will identify diagrams with 0 input and 0 output – hence representing a 1×1 matrix – with scalars. We will not ignore them in this paper, while in some versions of the ZX-Calculus, the global phase or even all the scalars are ignored. Ignoring them would imply taking the risk of ignoring a zero scalar, which can lead to false statements – if $ZX \vdash 0 \times D_1 = 0 \times D_2$, we can not say that $ZX \vdash D_1 = D_2$. The first rules to palliate it appeared in [3] and were simplified in [5].

Only Topology Matters is a paradigm – to be taken as a rule – stating that any wire of a ZX-diagram can be bent at will, without changing its semantics:



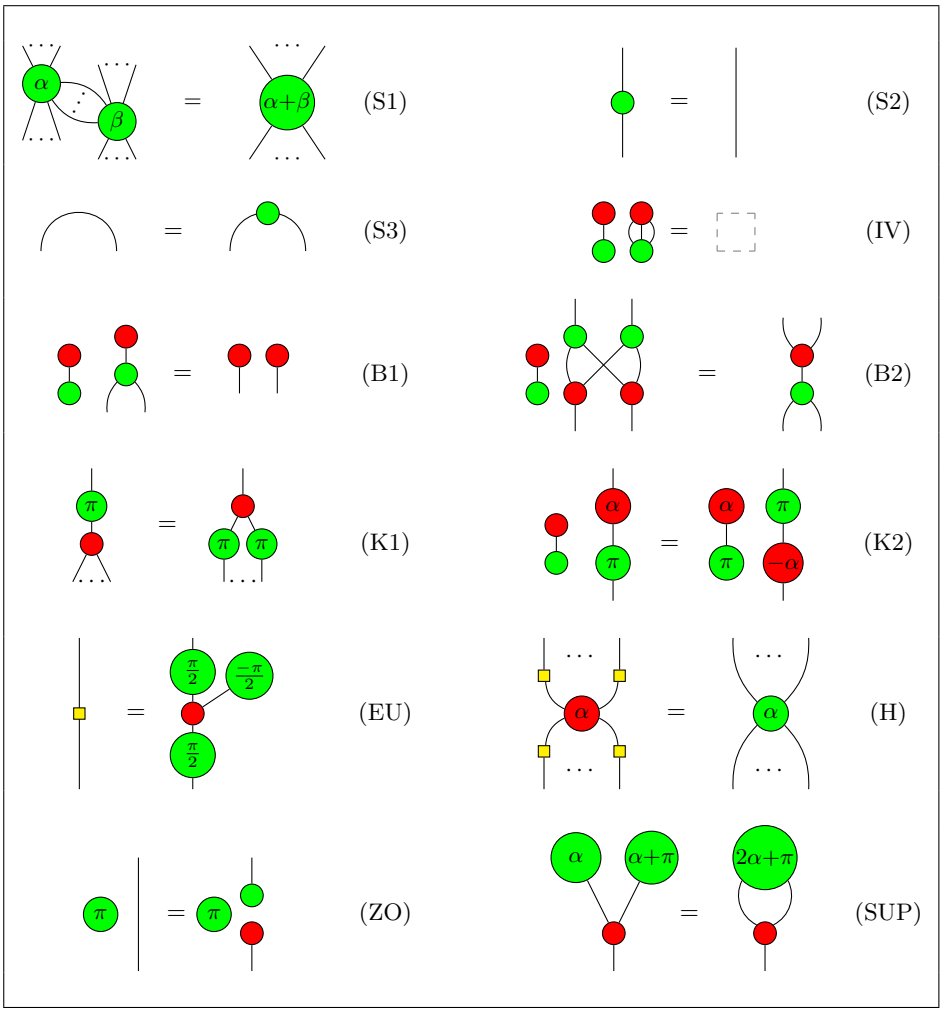


Figure 1 Rules for the ZX-calculus with scalars, augmented with the supplementarity rule [16]. All of these rules also hold when flipped upside-down, or with the colours red and green swapped. The right-hand side of (IV) is an empty diagram. $(\cdots)$ denote zero or more wires, while $(\vdots)$ denote one or more wires.

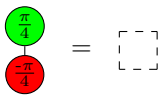
3 The $\frac{\pi}{4}$-Fragment is not Complete

In this section, we identify the following simple equation (E), which is sound – both sides of the equation represent the scalar 1 – but which cannot be derived from the rules of the ZX-Calculus expressed in Figure 1.



(E)

Since equation (E) only involves angles multiple of $\frac{\pi}{4}$, it implies the incompleteness of the $\frac{\pi}{4}$-fragment of the ZX-Calculus. In the following, we exhibit a simple invariant of the ZX-Calculus to prove that (E) is not derivable, and then we show that (E) subsumes two existing rules of the ZX-Calculus – namely (IV) and (ZO) –, leading to a simpler – (IV) and (ZO) rules are replaced by (E) – but more expressive ZX-Calculus that we call ZX_E.

3.1 A Graphical Invariant for the ZX-Calculus

We introduce a simple graphical quantity for ZX-diagrams, the parity of the number of odd-degree red dots plus the number of H-dots (yellow squares), formally defined as follows:

▶ **Definition 1.** Given a ZX-diagram $D : n \to m$, let $[\![D]\!]^{\bullet} \in \{0, 1\}$ be inductively defined as

$[\![D_1 \otimes D_2]\!]^{\bullet} = [\![D_1 \circ D_2]\!]^{\bullet} = [\![D_1]\!]^{\bullet} + [\![D_2]\!]^{\bullet} \bmod 2$, $\left[\!\!\left[\begin{array}{c} n \\ \cdots \\ \alpha \\ \cdots \\ m \end{array} \right]\!\!\right]^{\bullet} = n + m \bmod 2$, $\left[\!\!\left[\begin{array}{c} \\ \\ \blacksquare \\ \\ \\ \end{array} \right]\!\!\right]^{\bullet} = 1$,

and $[\![.]\!]^{\bullet} = 0$ for all the other generators.

One can define similarly $[\![.]\!]^{\circ}$ as the parity of the number of odd-degree green dots plus the number of H-dots. Notice that for any scalar $D : 0 \to 0$, $[\![D]\!]^{\circ} + [\![D]\!]^{\bullet} = 0 \bmod 2$, thanks to the well known degree sum formula which implies that the sum of the degree of the vertices of a graph is even. More generally, for any $D : n \to m$, $[\![D]\!]^{\circ} + [\![D]\!]^{\bullet} = n + m \bmod 2$, which is clearly an invariant of the ZX-calculus since all the rules preserve the number of inputs/outputs. As a consequence, a rule preserves $[\![.]\!]^{\circ}$ if and only if it preserves $[\![.]\!]^{\bullet}$.

▶ **Lemma 2** (Invariant). *For any ZX-diagram D_1, if $[\![D_1]\!] \neq 0$ and $ZX \vdash D_1 = D_2$, then $[\![D_1]\!]^{\bullet} = [\![D_2]\!]^{\bullet}$.*

Proof. Notice that all the rules in Figure 1, but (ZO), preserve $[\![.]\!]^{\bullet}$. Since $[\![D_1]\!] \neq 0$, the scalar π cannot appear in any derivation transforming D_1 into D_2, thus (ZO) is not applied, as a consequence $[\![D_1]\!]^{\bullet} = [\![D_2]\!]^{\bullet}$. ◀

▶ **Proposition 3.** *Equation* (E) *is not derivable using the rules in Figure 1: $ZX \nvdash$* (E).

Proof. The two diagrams of equation (E) are non zero, and they differ for $[\![.]\!]^{\bullet}$, so according to lemma 2, $ZX \nvdash$ (E). ◀

Since the diagrams of equation (E) are in the $\frac{\pi}{4}$-fragment, it implies that the $\frac{\pi}{4}$-fragment of the ZX-calculus is not complete.

▶ Remark. $\left[\!\!\left[\begin{array}{cc} \frac{\pi}{4} & \frac{\pi}{4} \\ \frac{-\pi}{4} & \frac{-\pi}{4} \end{array} \right]\!\!\right] = \left[\!\!\left[\begin{array}{c} \\ \\ \\ \end{array} \right]\!\!\right]$ the "doubled" version of (E), contrary to it, is derivable in the ZX-Calculus.

By completeness of the $\frac{\pi}{2}$-fragment, for any ZX-diagrams D_1 and D_2 in this particular fragment, if $[\![D_1]\!] = [\![D_2]\!] \neq 0$, then $[\![D_1]\!]^{\bullet} = [\![D_2]\!]^{\bullet}$. This property is obviously not true in the $\frac{\pi}{4}$-fragment, equation (E) being a counter example. However, this property is also satisfied by other, a priori not complete, fragments:

▶ **Proposition 4.** *For any $k \neq 0 \bmod 4$ and any two diagrams D_1, D_2 with angles multiple of $\frac{\pi}{k}$, if $[\![D_1]\!] = [\![D_2]\!] \neq 0$ then $[\![D_1]\!]^{\bullet} = [\![D_2]\!]^{\bullet}$.*

Proof. Given $k > 0$ and D a ZX-diagram with angles multiple of $\frac{\pi}{k}$, one can show, by induction on D, that $(\sqrt{2}^{[\![D]\!]^{\bullet}})\,[\![D]\!]$ is a matrix whose entries are in $\mathbb{Q}[e^{\frac{i\pi}{k}}]$, the smallest subfield of $\mathbb{C}$ which contains $e^{\frac{i\pi}{k}}$. Since there is a non-zero entry in $[\![D_1]\!]$, there exist $q_1, q_2 \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$ such that $\sqrt{2}^{[\![D_1]\!]^{\bullet}} q_1 = \sqrt{2}^{[\![D_2]\!]^{\bullet}} q_2 \neq 0$, so $\sqrt{2}^{([\![D_1]\!]^{\bullet} - [\![D_2]\!]^{\bullet})} \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$. Suppose $\sqrt{2} \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$:

(i) If $k = 2 \bmod 4$, then $i = e^{\frac{i\pi}{2}} \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$, so $e^{\frac{-i\pi}{4}} = \sqrt{2}\frac{1-i}{2} \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$. Therefore $e^{\frac{i\pi}{2k}} = (e^{\frac{i\pi}{k}})^{\frac{k+2}{4}} \times e^{\frac{-i\pi}{4}} \in \mathbb{Q}[e^{\frac{i\pi}{k}}]$. This implies $\mathbb{Q}[e^{\frac{i\pi}{2k}}] = \mathbb{Q}[e^{\frac{i\pi}{k}}]$ which is not possible as they are vector spaces over $\mathbb{Q}$ of dimension respectively $\varphi(4k) = 2\varphi(2k)$ and $\varphi(2k)$ where φ is Euler's totient function, and $\varphi(2k) \neq 0$.

(ii) If k is odd then $2k = 2 \bmod 4$. Moreover, since $\mathbb{Q}[e^{i\frac{\pi}{k}}] \subseteq \mathbb{Q}[e^{i\frac{\pi}{2k}}]$, $\sqrt{2} \in \mathbb{Q}[e^{i\frac{\pi}{2k}}]$ which is impossible according to the previous case (i).

Thus $\sqrt{2} \notin \mathbb{Q}[e^{\frac{i\pi}{k}}]$ when $k \neq 0 \bmod 4$, so $[\![D_1]\!]^{\bullet} = [\![D_2]\!]^{\bullet}$. ◀

3.2 A Simpler and More Expressive ZX-calculus

Equation (E) cannot be derived in the ZX-calculus (proposition 3), as a consequence we propose to add this equation (E) as a rule of the language to make it more expressive. We show in the following that the introduction of this new rule makes the two scalar rules (ZO) and (IV) obsolete, leading to a language with less rules than the one define in Figure 1.

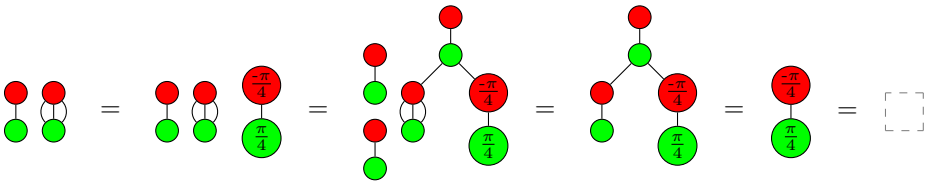
Let us define $ZX_E = \{(\text{E})\} \cup ZX \setminus \{(\text{IV}), (\text{ZO})\}$. First, notice that, thanks to [5], the so-called Hopf law is derivable from $ZX \setminus \{(\text{IV}), (\text{ZO})\}$, and hence from ZX_E:

▶ **Lemma 5.**

$ZX \setminus \{(\text{IV}), (\text{ZO})\} \vdash$  (HL)

▶ **Proposition 6.** (IV) *is derivable from* ZX_E.

Proof. Using (E), (B1), (HL), (S2) and (S1):



◀

▶ **Proposition 7.** (ZO) *is derivable from* ZX_E.

Hence $ZX_E \vdash (\text{IV}), (\text{ZO})$.

▶ Remark. The other rules of the language remain, a priori, necessary in the presence of equation (E). In particular the supplementarity which has been recently proved to be necessary in ZX [16] is necessary in ZX_E: one can prove using the interpretation $[\![.]\!]^{\sharp}_{k,l}$ – defined in [16] – with $k = 3$ and $l = 8$ that $ZX_E \setminus \{(\text{SUP})\} \nvdash (\text{SUP})$.

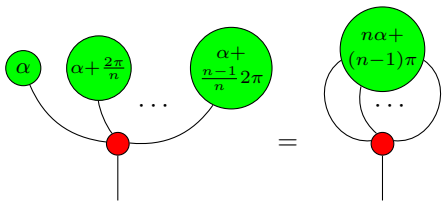
▶ Remark. One may want to generalise equation (E), replacing the particular angles $\pm\frac{\pi}{4}$ by some generic angle α. Proposition 4 is a strong evidence that such a generalisation is not possible and that the language requires at least one rule which is specific to the $\frac{\pi}{4}$ angle.

4 Cyclotomic Supplementarity

4.1 Generalisation of (SUP)

The concept of supplementarity in quantum diagram reasoning has been first introduced by Coecke and Edwards [9], turned into a simple but necessary rule (SUP in Figure 1) in [16]. Roughly speaking, supplementarity consists in merging two dots sharing the same neighbour when the difference of their angles is π, i.e. when the two angles are antipodal.

We generalize this concept to cyclotomic supplementarity as follows: for any $n \in \mathbb{N}^*$, n dots sharing the same neighbour can be merged when their angles divide the circle into equal parts (cyclotomy), i.e. when their angles are of the form $\alpha + \frac{2k\pi}{n}$ for $k \in [\![0; n-1]\!]$:



(SUP$_n$)

Notice that there are n green dots in the left diagram, and n parallel wires in the right diagram.

Any of these equations is valid for the standard interpretation of ZX-diagrams:

▶ **Proposition 8.** (SUP$_n$) *is sound.*

Cyclotomic supplementarity has a generalisation: the green dots can be merged not only when they share the same neighbour, but also when they share the same neighbourhood. It leads to the notion of cyclotomic twins, which generalise the notion of antiphase twins [13]:

▶ **Definition 9** (Cyclotomic Twins)**.** n dots in a ZX-diagram are cyclotomic twins if:

- they have the same colour
- their angles divide the circle into equal parts $\left(\alpha + \frac{2k\pi}{n} \text{ for } k \in [\![0; n-1]\!]\right)$
- they have the same neighbourhood: for any vertex, the number of wires connecting it to any of the twins is the same

▶ **Proposition 10** (Cyclotomic Twins and Supplementarity)**.** *With* $ZX \cup \{(\text{SUP}_n)\}_{n\in\mathbb{N}}$*, cyclotomic twins can be merged.*

The rest of the section is dedicated to the structures of this family of equations: we show that (SUP$_n$) is necessary when n is an odd prime number and that (SUP$_n$) can be derived when n is not prime. As a consequence, we exhibit a countable family of equations that cannot be derived in the ZX-calculus.

4.2 The Set of Supplementarity Rules for Prime Numbers

It is not necessary to define the supplementarity rules for all numbers $n \in \mathbb{N}$ as axioms. For instance, we will prove that their restriction to the set of prime numbers is enough to show all the others.

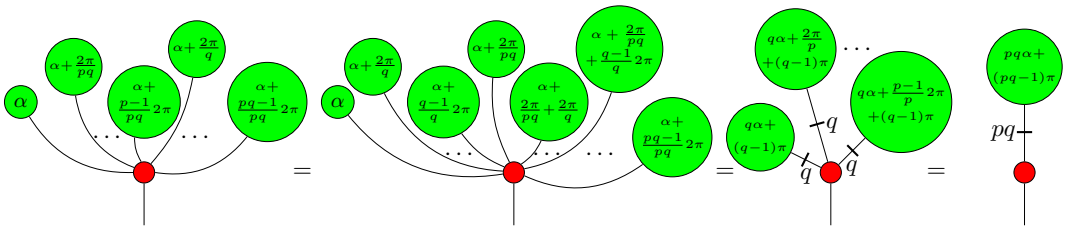
Let $\mathbb{P}$ be the set of prime numbers.

▶ **Theorem 11.**

- $\forall p, q \in \mathbb{N}^*, \quad ZX_E \cup \{(\text{SUP}_p), (\text{SUP}_q)\} \vdash (\text{SUP}_{pq})$
- $\forall n \in \mathbb{N}^*, \quad ZX_E \cup \{(\text{SUP}_p)\}_{p\in\mathbb{P}} \vdash (\text{SUP}_n)$
- $\forall p \in \mathbb{P}, p \geq 3, \quad ZX_E \cup \{(\text{SUP}_q)\}_{q\in\mathbb{P}\setminus\{p\}} \nvdash (\text{SUP}_p)$

Proof.

First statement: If n is not prime, its supplementarity can be derived. Indeed, suppose n can be decomposed in two numbers p and q ($n = pq$), for which we know the supplementarity rule.

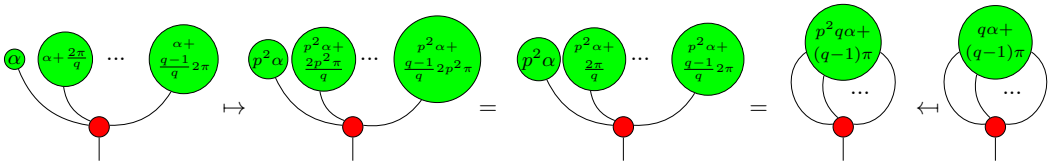


with p-ticked edge representing p parallel wires. The first equality is just a rearranging of the branches, the second uses (SUP_q) p times and the last one exploits Proposition 10 with $p(q\alpha + (q-1)\pi) + (p-1)\pi = pq\alpha + (pq-1)\pi$.

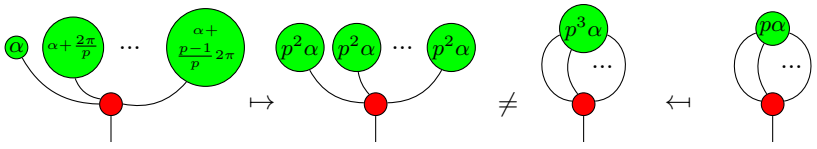
Second Statement: As a direct consequence of the previous statement, since (SUP_1) is trivial, the supplementarity rules for prime numbers are enough to derive all the others.

Third Statement: Let $p \in \mathbb{P}$ and $p \geq 3$. Let us consider the interpretation $[\![.]\!]_{p^2}$ which amounts to multiplying all the angles of a diagram by p^2.

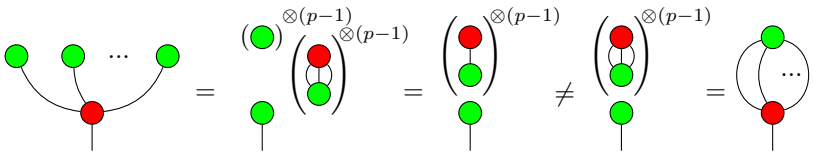
- The interpretation $[\![.]\!]_{p^2}$ coincides with the interpretation $[\![.]\!]^\sharp_{1,p^2-1}$ defined in [16]. As stated in this article, since the first parameter is odd and the second one is even, all the rules of ZX\{(SUP_2)} hold.
- The rule (E) also holds. Indeed, p is odd, and whether p mod 8 is $1, 3, 5$ or 7, p^2 mod $8 = 1$, so $p^2\frac{\pi}{4} = \frac{\pi}{4}$ mod 2π.
- The rule (SUP_q) when $q \in \mathbb{P}$, $q \neq p$ holds, since $gcd(p^2, q) = 1$:



- The rule (SUP_p) does not hold:



Indeed, when $\alpha = 0$, for instance, using on the left side $p-1$ times (B1) and (IV), and on the right side (IV) and $\frac{p-1}{2}$ times the Hopf law (HL), since $p \geq 3$:



Every rule but the p-supplementarity (with $p \in \mathbb{P}$ and $p \geq 3$) holds with this interpretation, so it cannot be derived from the others:
$\forall p \in \mathbb{P}, p \geq 3, \quad ZX_E \cup \{(\mathrm{SUP}_n)\}_{n\in\mathbb{P}} \setminus \{(\mathrm{SUP}_p)\} \nvdash (\mathrm{SUP}_p)$ ◀

▶ **Corollary 12.** *For any $n \geq 3$ odd, the $\frac{\pi}{2n}$-fragment of the ZX_E-Calculus is incomplete.*

Proof. Let p be an odd prime factor of n. Theorem 11 proves that $ZX_E \nvdash (SUP_p)$, and notice that all the angles involved in the rule are multiples of $\frac{\pi}{2p}$, hence in the $\frac{\pi}{2n}$-fragment. ◀

▶ Remark. We can also notice that all the rules (SUP_n) respect the quantity $[\![.]\!]$, so that the rule (E) remains necessary.

4.3 Discussion on the Supplementarity's Derivability Structure

Let p and q be two natural numbers. We have previously shown $ZX_E \cup \{(\text{SUP}_p), (\text{SUP}_q)\} \vdash (\text{SUP}_{pq})$. In other words, (SUP_p) can be deduced from the supplementarity of the dividers of p. Now, can we deduce this same equality from the supplementarity of some of its multiples?

The first result comes when p is odd:

▶ **Proposition 13.**

$$\forall p, q \in \mathbb{N}^*, \qquad (p = 1 \bmod 2) \quad \Rightarrow \quad \{(\text{HL}), (\text{IV}), (\text{SUP}_p), (\text{SUP}_{pq})\} \vdash (\text{SUP}_q)$$

There exists another – weaker – derivation when p is even:

▶ **Proposition 14.**

$$\forall p, q \in \mathbb{N}^*, \qquad \{(\text{HL}), (\text{IV}), (\text{SUP}_p), (\text{SUP}_{p^2q})\} \vdash (\text{SUP}_{pq})$$

▶ Remark. In the last two propositions, we require that the ZX be "general" i.e. with angles either real or a rational multiple of π because we need α/p to be in the fragment in both cases. Though, the result can be expanded to any fragment for some α provided α/p be in the fragment.

To sum up:

$$ZX_E \cup \{(\text{SUP}_p), (\text{SUP}_q)\} \vdash (\text{SUP}_{pq})$$

$$ZX_E \cup \{(\text{SUP}_p), (\text{SUP}_{p^2q})\} \vdash (\text{SUP}_{pq})$$

$$(p = 1 \bmod 2) \quad \Rightarrow \quad ZX_E \cup \{(\text{SUP}_p), (\text{SUP}_{pq})\} \vdash (\text{SUP}_q)$$

4.4 Updated Set of Rules

We propose to add the generalisation of the supplementarity rule to the set of rules of the ZX-Calculus, and to restrict to the set necessary when dealing with particular fragments. We notice that the rule (K1) is derivable from the others [5] so we can get rid of it, and the new set of rules of the ZX-Calculus is shown in figure 2.

▶ Remark. We can prove that (SUP_2) is not derivable from $ZX_E \setminus \{(\text{SUP}_2)\}$, using the interpretation $[\![.]\!]^\sharp_{k,l}$ defined in [16] with $k = 3$ and $l = 8$.

However, it is important to notice that we have not proven that (SUP_2) can not be derived from the rest once the cyclotomic supplementarity is added. Indeed, the family of interpretations used in the proof of Theorem 11 only works when p is odd, and the one used previously, $[\![.]\!]^\sharp_{k,l}$, does not hold for many supplementarity rules.

The rule (SUP_2) is all the more peculiar as, due to the Hopf law (HL), it is the only supplementarity rule that creates a non-trivial scalar – except for the supplementarity rules for even numbers, which anyway derive from (SUP_2). For instance it may create a scalar worth 0 – when applied with $\alpha = 0$ – which is the first step towards proving the rule (ZO) in the $\frac{\pi}{4}$-fragment. Moreover, it is the only supplementarity that can not be proven to be necessary by simply multiplying the angles by a constant.

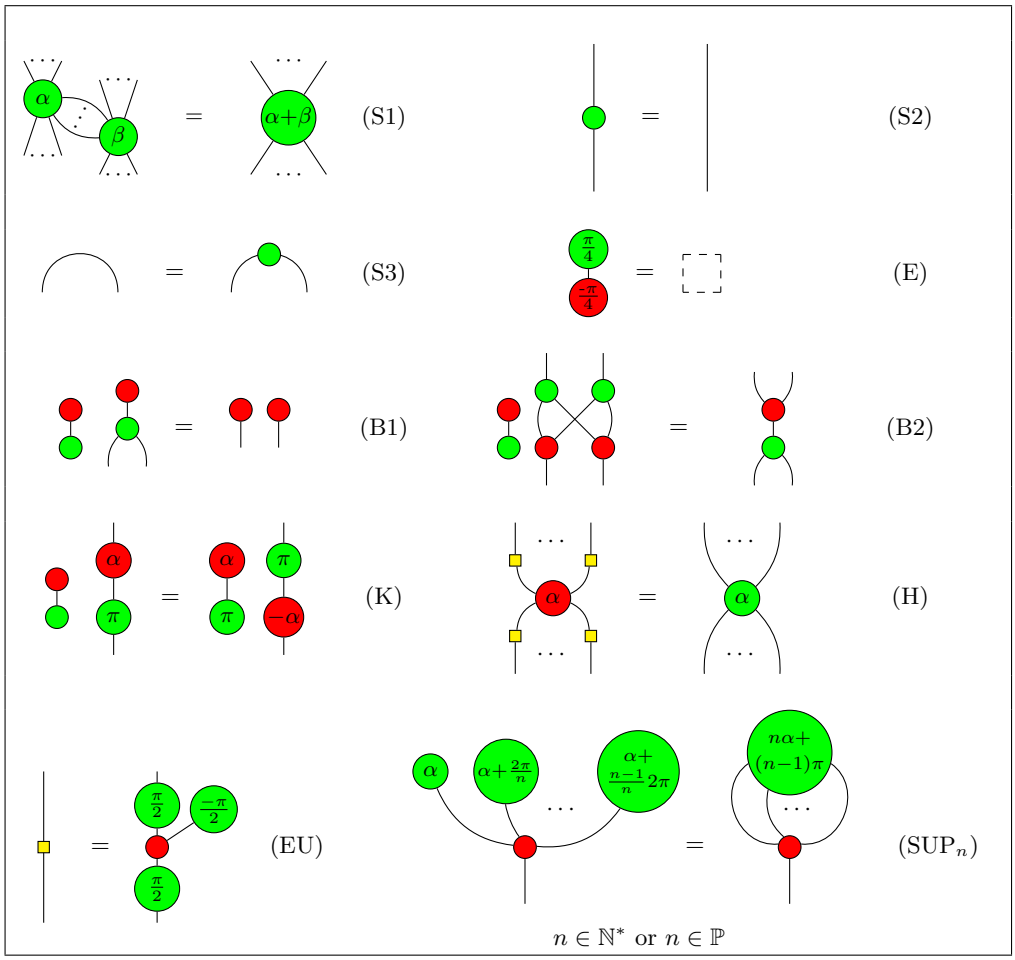


Figure 2 New set of rules for the ZX-calculus with scalars. All of these rules also hold when flipped upside-down, or with the colours red and green swapped. The right-hand side of (E) is an empty diagram. $(\cdots)$ in (S1) and (H) denote 0 or more wires, while $(\overset{\cdot}{.}\overset{\cdot}{.})$ denote 1 or more wires.

4.5 The General ZX-Calculus is still Not Complete

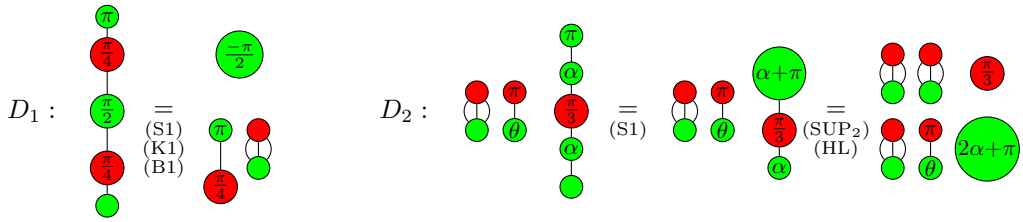
The argument given by Schröder de Witt and Zamdzhiev [17] to show the incompleteness of the general ZX-Calculus is not valid anymore – when multiplying the angles by any integer, there is at least one supplementarity that does not hold. But we can patch the demonstration to make it valid again.

▶ **Theorem 15.** *The general ZX-Calculus is incomplete with the set of rules in figure 2.*

Proof. We will make the proof using a combination of ZX-rules and matrix calculus on the interpretations of the diagrams. Consider the following diagrams:

$D_1 :=$  and $D_2 :=$ 
We will try to express D_1 in the form D_2. One can notice that $[\![D_1]\!] = [\![D_2]\!]$ when $\alpha_0 = \frac{\pi}{2} - \arccos\left(\sqrt{\frac{2}{3}}\right)$ and $\theta_0 = \arccos\left(\frac{\sqrt{2}}{2} + \frac{\sqrt{3}}{6}\right)$. We can even show:

No more than four values for α are possible when decomposing D_1 in the form D_2: When applying the π green state at the top and the 0 green state at the bottom of both D_1 and D_2, we end up with:



In order for their interpretations to be equal, we need:

$$e^{i\frac{\pi}{4}}\sqrt{2}e^{-i\frac{\pi}{4}} = \frac{1}{2}e^{i\theta}(1+e^{i\frac{\pi}{3}})(1+e^{i(2\alpha+\pi)}) \quad \text{i.e.} \quad \frac{\sqrt{2}}{2} = e^{i(\theta+\frac{\pi}{6}+\alpha+\frac{\pi}{2})}\cos\left(\frac{\pi}{6}\right)\cos\left(\alpha+\frac{\pi}{2}\right)$$

So using the modulus, $\left|\cos\left(\alpha+\frac{\pi}{2}\right)\right| = \sqrt{\frac{2}{3}}$, thus $\alpha = \pm\frac{\pi}{2} \pm \arccos\left(\sqrt{\frac{2}{3}}\right) \bmod 2\pi$.

α is not a rational multiple of π: One can check that $e^{i\alpha_0}$ is a root of the polynomial $3X^4 + 2X^2 + 3$ which is irreducible in $\mathbb{Z}$ (since 30203 is a prime number, thanks to Cohn's irreducibility criterion, $3X^4+2X^2+3$ is irreducible in $\mathbb{Z}$). The polynomial is not cyclotomic because its coefficient of higher degree is not 1, hence $e^{i\alpha_0}$ is not a root of unity, i.e. α_0 is not a rational multiple of π. As a consequence, none of the $\pm\frac{\pi}{2} \pm \arccos\left(\sqrt{\frac{2}{3}}\right)$ are rational multiples of π.

Now, let us put back all the pieces together. Assume $ZX \vdash D_1 = D_2$ for some α and θ. Then there exists a finite sequence of rules of the ZX that transforms D_2 into D_1. We define $q \in \mathbb{N}^*$ such that for any (SUP_p) in the sequence, $p \leq q$, and $S = \{k(q+4)! + 1 \mid k \in \mathbb{N}\}$. For all $q' \in S$ and for $(\!|.|\!)_{q'}$ the interpretation that multiplies the angles by q', the rules of the ZX are preserved, $(\!|D_1|\!)_{q'} = D_1$, and $(\!|D_2|\!)_{q'}$ is in the form D_2. Indeed:

- $(q+4)!$ is clearly a multiple of 8 so $q'\frac{\pi}{4} = \frac{\pi}{4} \bmod 2\pi$, so all the rules but the supplementarity rules hold, and $(\!|D_1|\!)_{q'} = D_1$ since it is in the $\frac{\pi}{4}$-fragment.
- for any $p \in \mathbb{P}$ such that $p \leq q$, then $(q+4)! = 0 \bmod p$ so $gcd(p, q') = 1$, which implies that (SUP_p) also holds.
- $(q+4)!$ is a multiple of 6 so $q'\frac{\pi}{3} = \frac{\pi}{3} \bmod 2\pi$ hence $(\!|D_2|\!)_{q'}$ is in the form D_2.

Then, $ZX \vdash D_1 = (\!|D_2|\!)_{q'}$.

D_1 has a finite number of decompositions in the form D_2, but $\left\{(\!|D_2|\!)_{q'} \mid q' \in S\right\}$ is infinite – since α is an irrational multiple of π – and all these diagrams are decompositions of D_1 in the form D_2, hence we end up with a contradiction.
So $ZX \nvdash D_1 = D_2$, which proves the incompleteness. ◀

Abstract

Given finite-state automata (or context-free grammars) $\mathcal{A}, \mathcal{B}$ over the same alphabet and a Parikh vector $\vec{p}$, we study the complexity of deciding whether the number of words in the language of $\mathcal{A}$ with Parikh image $\vec{p}$ is greater than the number of such words in the language of $\mathcal{B}$. Recently, this problem turned out to be tightly related to the cost problem for weighted Markov chains. We classify the complexity according to whether $\mathcal{A}$ and $\mathcal{B}$ are deterministic, the size of the alphabet, and the encoding of $\vec{p}$ (binary or unary).

1 Introduction

In our recent papers [5, 7], the authors started an investigation of the so called *cost problem*: Given a Markov chain whose transitions are labelled with non-negative integers and which has a designated target state t, a probability threshold τ, and a Boolean combination of linear inequalities over one variable $\varphi(x)$, the cost problem asks whether the accumulated probability p_φ of paths achieving a value consistent with φ when reaching t is at least τ. It has been shown in [5] by the first two authors that the cost problem can be decided in PSPACE. In [7] the upper bound was improved to membership in the counting hierarchy CH, and the same upper bound has been shown for the related problem of computing a certain bit of the aforementioned probability p_φ. At the algorithmic core of those complexity results [5, 7] are the following two counting problems: Given a finite-state automaton $\mathcal{A}$ over a finite alphabet Σ and a Parikh vector $\vec{p}$ (i.e., a function mapping every alphabet symbol from Σ to $\mathbb{N}$), we denote by $N(\mathcal{A}, \vec{p})$ the number of words accepted by $\mathcal{A}$ whose Parikh image is $\vec{p}$. Then BitParikh is the problem of computing a certain bit of the number $N(\mathcal{A}, \vec{p})$ for a given finite-state automaton $\mathcal{A}$ and a Parikh vector $\vec{p}$. Further, PosParikh is the problem of checking whether $N(\mathcal{A}, \vec{p}) > N(\mathcal{B}, \vec{p})$ for two given automata $\mathcal{A}$ and $\mathcal{B}$ (over the same alphabet) and a Parikh vector $\vec{p}$. We proved in [7] that BitParikh and PosParikh both belong to the counting hierarchy if the input automata are deterministic and the Parikh vectors are encoded in binary, and we used these results to show that the cost problem belongs to CH.

The counting hierarchy is defined similarly to the polynomial-time hierarchy using counting quantifiers, see [1] or Section 2.3 for more details. It is contained in PSPACE and this inclusion is believed to be strict. In recent years, several numerical problems, for which only PSPACE upper bounds had been known, have been shown to be in CH. Two of the most important and fundamental such problems are PosSLP and BitSLP: PosSLP is the problem of deciding whether a given arithmetic circuit over the operations $+$, $-$ and $\times$ evaluates to a positive

Table 1 The complexity landscape of PosParikh. References to propositions proving the stated complexity bounds are in parentheses.

number, and BitSLP asks whether a certain bit of the computed number is equal to 1. Note that an arithmetic circuit with n gates can evaluate to a number in the order of 2^{2^n}; hence the number of output bits can be exponential and a certain bit of the output number can be specified with polynomially many bits. It has been shown in [5, Prop. 5] that the cost problem is hard for both PosSLP and PP (probabilistic polynomial time).

The tight relationship between the cost problem and counting problems for Parikh images motivates the investigation of the complexity of BitParikh and PosParikh also for other variants: Instead of a DFA, one can specify the language by an NFA or even a context-free grammar (CFG). Indeed, Kopczyński [9] recently asked about the complexity of computing the number of words with a given Parikh image accepted by a CFG. Other natural input parameters are the alphabet size (variable size, fixed size or even singleton) and the encoding of Parikh vectors (unary or binary). In this paper we carry out a detailed complexity analysis of PosParikh for the different settings. Our complexity results are collected in Table 1. In Section 6 we discuss possible extensions to BitParikh.

Interestingly, we show that PosParikh for DFA over a two-letter alphabet and Parikh vectors encoded in binary is hard for PosMatPow. The latter problem was recently introduced by Galby, Ouaknine and Worrell [3] and asks, given a square integer matrix $M \in \mathbb{Z}^{m\times m}$, a linear function $f\colon \mathbb{Z}^{m\times m} \to \mathbb{Z}$ with integer coefficients, and a positive integer n, whether $f(M^n) \geq 0$, where all numbers in M, f and n are encoded in binary. Note that the entries of M^n are generally of size exponential in the size of n. It is shown in [3] that PosMatPow can be decided in polynomial time for fixed dimension $m = 2$. The same holds for $m = 3$ provided that M is given in unary [3]. The general PosMatPow problem is in CH; in fact, it is is reducible to PosSLP, but the complexity of PosMatPow is left open in [3]. In particular, it is not known whether PosMatPow is easier to decide than PosSLP. Our result that PosParikh is PosMatPow-hard already for a fixed-size alphabet while PosSLP-hardness seems to require an alphabet of variable size [5] could be seen as an indication that PosMatPow is easier to decide than PosSLP.

Due to space constraints, we can only sketch some proofs in the main part. Full proofs can be found in [6].

1.1 Related Work

A problem related to the problem PosParikh is the computation of the number of all words of a given length n in a language L. If n is given in unary encoding, then this problem can be solved in NC^2 for every fixed unambiguous context-free language L [2]. On the other hand, there exists a fixed context-free language $L \subseteq \Sigma^*$ (of ambiguity degree

two) such that if the function $a^n \mapsto \#(L \cap \Sigma^n)$ can be computed in polynomial time, then EXPTIME = NEXPTIME [2]. Counting the number of words of a given length encoded in unary that are accepted by a given NFA (which is part of the input in contrast to the results of [2]) is #P-complete [10, Remark 3.4]. The corresponding problem for DFA is equivalent to counting the number of paths between two nodes in a directed acyclic graph, which is the canonical #L-complete problem. Note that for a fixed alphabet and Parikh vectors encoded in unary, the computation of $N(\mathcal{A}, \vec{p})$ for an NFA (resp. DFA) $\mathcal{A}$ can be reduced to the computation of the number of words of a given length encoded in unary accepted by an NFA (resp. DFA) $\mathcal{A}'$: In that case, one can easily compute in logspace a DFA $\mathcal{A}_{\vec{p}}$ for the set of all words with Parikh image $\vec{p}$ and then construct the product automaton of $\mathcal{A}$ and $\mathcal{A}_{\vec{p}}$.

2 Preliminaries

2.1 Counting Problems for Parikh Images

Let $\Sigma = \{a_1, \ldots, a_m\}$ be a finite alphabet. A Parikh vector is vector of m non-negative integers, i.e., an element of $\mathbb{N}^m$. Let $u \in \Sigma^*$ be a word. For $a \in \Sigma$, we denote by $|u|_a$ the number of times a occurs in u. The Parikh image $\Psi(u) \in \mathbb{N}^m$ of u is the Parikh vector counting how often every alphabet symbol of Σ occurs in u, i.e., $\Psi(u) := (|u|_{a_1}, \ldots, |u|_{a_m})$. The Parikh image of a language $L \subseteq \Sigma^*$ is defined as $\Psi(L) := \{\Psi(u) : u \in L\} \subseteq \mathbb{N}^m$.

We use standard language accepting devices in this paper. A non-deterministic finite-state automaton (NFA) is a tuple $\mathcal{A} = (Q, \Sigma, q_0, F, \Delta)$, where Q is a finite set of control states, Σ is a finite alphabet, $q_0 \in Q$ is an initial state, $F \subseteq Q$ is a set of final states, and $\Delta \subseteq Q \times \Sigma \times Q$ is a set of transitions. We write $p \xrightarrow{a} q$ whenever $(p, a, q) \in \Delta$. For convenience, we sometimes label transitions with words $w \in \Sigma^+$. Such a transition corresponds to a chain of transitions that are consecutively labelled with the symbols of w. We call $\mathcal{A}$ a deterministic finite-state automaton (DFA) if for all $p \in Q$ and all $a \in \Sigma$ there is at most one state $q \in Q$ with $p \xrightarrow{a} q$. Given $u = a_1 a_2 \cdots a_n \in \Sigma^*$, a run ϱ of $\mathcal{A}$ on u is a finite sequence of control states $\varrho = p_0 p_1 \cdots p_n$ such that $p_0 = q_0$ and $p_{i-1} \xrightarrow{a_i} p_i$ for all $1 \leq i \leq n$. We call ϱ accepting whenever $p_n \in F$ and define the language accepted by $\mathcal{A}$ as $L(\mathcal{A}) := \{u \in \Sigma^* : \mathcal{A} \text{ has an accepting run on } u\}$. Finally, context-free grammars (CFG) are defined as usual.

Let Σ be an alphabet of size m and $\vec{p} \in \mathbb{N}^m$ be a Parikh vector. For a language acceptor $\mathcal{A}$ (a DFA, NFA, or CFG), we denote by $N(\mathcal{A}, \vec{p})$ the number of words in $L(\mathcal{A})$ with Parikh image $\vec{p}$, i.e.,

$$N(\mathcal{A}, \vec{p}) := \#\{u \in L(\mathcal{A}) : \Psi(u) = \vec{p}\}.$$

We denote the counting function that maps $(\mathcal{A}, \vec{p})$ to $N(\mathcal{A}, \vec{p})$ by #Parikh. For complexity considerations, we have to specify

- the type of $\mathcal{A}$ (DFA, NFA, CFG),
- the encoding of (the numbers in) $\vec{p}$ (unary or binary), and
- whether the underlying alphabet is fixed or part of the input (variable).

For instance, we speak of #Parikh for DFA over a fixed alphabet and Parikh vectors encoded in binary. The same terminology is used for the following computational problems:

PosParikh

INPUT: Language acceptors $\mathcal{A}, \mathcal{B}$ over an alphabet Σ of size m and a Parikh vector $\vec{p} \in \mathbb{N}^m$.

QUESTION: Is $N(\mathcal{A}, \vec{p}) > N(\mathcal{B}, \vec{p})$?

BitParikh

INPUT: Language acceptor $\mathcal{A}$ over an alphabet Σ of size m, a Parikh vector $\vec{p} \in \mathbb{N}^m$, and a number $i \in \mathbb{N}$ encoded binary.

QUESTION: Is the i-th bit of $N(\mathcal{A}, \vec{p})$ equal to one?

Note that for a Parikh vector $\vec{p}$ encoded in binary, the number $N(\mathcal{A}, \vec{p})$ is at most doubly exponential in the input length (size of $\mathcal{A}$ plus number of bits in $\vec{p}$), and this bound can be reached. Hence, the number of bits in $N(\mathcal{A}, \vec{p})$ is at most exponential, and a certain position in the binary encoding of $N(\mathcal{A}, \vec{p})$ can be specified with polynomially many bits.

The following two results from [5, 7] are the starting point for our further investigations in this paper (see Section 2.3 below for the formal definition of the counting hierarchy):

▶ **Theorem 1** ([5, 7]). *For DFA over a variable alphabet and Parikh vectors encoded in binary, the problems* BitParikh *and* PosParikh *belong to the counting hierarchy. Moreover, the problem* PosParikh *(resp.,* BitParikh*) is* PosSLP*-hard (resp.,* BitSLP*-hard).*[1]

2.2 Graphs

A (finite directed) multi-graph is a tuple $G = (V, E, s, t)$, where V is a finite set of nodes, E is a finite set of edges, and the mapping $s\colon E \to V$ (resp., $t\colon E \to V$) assigns to each edge its source node (resp., target node). A loop is an edge $e \in E$ with $s(e) = t(e)$. A path (of length n) in G from u to v is a sequence of edges $e_1, e_2, \ldots, e_n$ such that $s(e_1) = u$, $t(e_n) = v$, and $t(e_i) = s(e_{i+1})$ for all $1 \leq i \leq n-1$. The out-degree of a node $v \in V$ is the number $\#s^{-1}(v)$ of outgoing edges of v.

An edge-weighted multi-graph is a tuple $G = (V, E, s, t, w)$, where (V, E, s, t) is a multi-graph and $w\colon E \to \mathbb{N}$ assigns a weight to every edge. We can define the ordinary multi-graph $\tilde{G}$ induced by G by replacing every edge $e \in E$ by $k = w(e)$ many edges $e_1, \ldots, e_k$ with $s(e_i) = s(e)$ and $t(e_i) = t(e)$. For $u, v \in V$ and $n \in \mathbb{N}$, define $N(G, u, v, n)$ as the number of paths in $\tilde{G}$ from u to v of length n. Note that the different edges $e_1, \ldots, e_k$ that replaced an edge e with $w(e) = k$ are distinguished in paths.

2.3 Computational Complexity

We assume familiarity with basic complexity classes such as L (deterministic logspace), NL, P, NP, PH (the polynomial time hierarchy) and PSPACE. The class DP is the class of all intersections $K \cap L$ with $K \in \mathsf{NP}$ and $L \in \mathsf{coNP}$. Hardness for a complexity class will always refer to logspace reductions.

A counting problem is a function $f\colon \Sigma^* \to \mathbb{N}$ for a finite alphabet Σ. A counting class is a set of counting problems. A logspace reduction from a counting problem $f\colon \Sigma^* \to \mathbb{N}$ to a counting problem $g\colon \Gamma^* \to \mathbb{N}$ is a logspace computable function $h\colon \Sigma^* \to \Gamma^*$ such that for all $x \in \Sigma^*$: $f(x) = g(h(x))$. Note that no post-computation is allowed. Such reductions are also called parsimonious. Hardness for a counting class will always refer to parsimonious logspace reductions.

The counting class $\#\mathsf{P}$ contains all functions $f\colon \Sigma^* \to \mathbb{N}$ for which there exists a non-deterministic polynomial-time Turing machine M such that for every $x \in \Sigma^*$, $f(x)$ is the number of accepting computation paths of M on input x. The class PP (probabilistic polynomial time) contains all problems A for which there exists a non-deterministic polynomial-time

[1] In [5] only the PosSLP-hardness of PosParikh is explicitly shown, but the construction from [5] implies that BitParikh is BitSLP-hard.

Turing machine M such that for every input x, $x \in A$ if and only if more than half of all computation paths of M on input x are accepting. By a famous result of Toda [16], $\mathsf{PH} \subseteq \mathsf{P}^{\mathsf{PP}}$, where P^{PP} is the class of all languages that can be decided in deterministic polynomial time with the help of an oracle from PP. Hence, if a problem is PP-hard, then this can be seen as a strong indication that the problem does not belong to PH (otherwise PH would collapse). If we replace in the definitions of #P and PP non-deterministic polynomial-time Turing machines by non-deterministic logspace Turing machines (resp., non-deterministic polynomial-space Turing machines; non-deterministic exponential-time Turing machines), we obtain the classes #L and PL (resp., #PSPACE and PPSPACE; #EXP and PEXP). Ladner [11] has shown that a function f belongs to #PSPACE if and only if for a given input x and a binary encoded number i the i-th bit of $f(x)$ can be computed in PSPACE. It follows that PPSPACE = PSPACE. It is well known that PP can be also defined as the class of all languages L for which there exist two #P-functions f_1 and f_2 such that $x \in L$ if and only if $f_1(x) > f_2(x)$, and similarly for PL and PEXP.

The levels of the *counting hierarchy* C_i^p ($i \geq 0$) are inductively defined as follows: $\mathsf{C}_0^p = \mathsf{P}$ and $\mathsf{C}_{i+1}^p = \mathsf{PP}^{\mathsf{C}_i^p}$ (the set of languages accepted by a PP-machine as above with an oracle from C_i^p) for all $i \geq 0$. Let $\mathsf{CH} = \bigcup_{i \geq 0} \mathsf{C}_i^p$ be the counting hierarchy. It is not difficult to show that $\mathsf{CH} \subseteq \mathsf{PSPACE}$, and most complexity theorists conjecture that $\mathsf{CH} \subsetneq \mathsf{PSPACE}$. Hence, if a problem belongs to the counting hierarchy, then the problem is probably not PSPACE-complete. More details on the counting hierarchy can be found in [1].

3 Parikh Counting Problems for DFA

Recall that PosParikh (resp., BitParikh) is PosSLP-hard (resp., BitSLP-hard), see Theorem 1. The variable alphabet and binary encoding of Parikh vectors are crucial for the proof of the lower bound. In this section, we complement Theorem 1 by showing further results for DFA when the alphabet is not unary. The results of this section are collected in the following proposition.

▶ **Proposition 2.** *For DFA, we have:*

(i) #Parikh *(resp.* PosParikh*) is* #L*-complete (resp.* PL*-complete) for a* fixed *alphabet of size at least two and Parikh vectors encoded in* unary*.*

(ii) #Parikh *(resp.* PosParikh*) is* #P*-complete (resp.* PP*-complete) for a* variable *alphabet and Parikh vectors encoded in* unary*.*

(iii) PosParikh *is* PosMatPow*-hard for a* fixed binary *alphabet and Parikh vectors encoded in* binary*.*

Proof sketch of Proposition 2(i) and (ii). We only sketch the main ideas, all details can be found in [6]. Regarding (i), the lower bound for #L follows via a reduction from the canonical #L-complete problem of computing the number of paths between two nodes in a directed acyclic graph [12], and for the PL lower bound one reduces from the problem whether the number of paths from s to t_0 is larger than the number of paths from s to t_1. For the upper bound, let $\mathcal{A}$ be a DFA over a fixed alphabet and $\vec{p}$ be a Parikh vector encoded in unary. A non-deterministic logspace machine can guess an input word for $\mathcal{A}$ symbol by symbol. Thereby, the machine only stores the current state of $\mathcal{A}$ (which needs logspace) and the binary encoding of the Parikh image of the word produced so far. The machine stops when the Parikh image reaches the input vector $\vec{p}$ and accepts iff the current state is final. Note that since the input Parikh vector $\vec{p}$ is encoded in unary notation, all numbers that appear in the accumulated Parikh image stored by the machine need only logarithmic space.

Moreover, since the alphabet has fixed size, logarithmic space suffices to store the whole Parikh image. The number of accepting computations of the machine is exactly $N(\mathcal{A}, \vec{p})$, which yields the upper bound for #L as well as for PL.

Regarding (ii), the #P-lower bound for #Parikh follows from a reduction from #3SAT, see e.g. [13, p. 442], where the unfixed alphabet allows for representing assignments of Boolean variables via individual alphabet symbols. For the #P-upper bound, let $\mathcal{A}$ be a DFA and $\vec{p}$ be a Parikh vector encoded in unary. A non-deterministic polynomial-time Turing machine can first non-deterministically produce an arbitrary word w with $\Psi(w) = \vec{p}$. Then, it checks in polynomial time whether $w \in L(\mathcal{A})$, in which case it accepts. The proof that PosParikh is PP-complete is similar and can be found in [6]. ◀

Statement (iii) is the most difficult part of Proposition 2. We split the proof into several lemmas below. As stated in Section 1, the PosMatPow problem asks, given a square integer matrix $M \in \mathbb{Z}^{m\times m}$, a linear function $f\colon \mathbb{Z}^{m\times m} \to \mathbb{Z}$ with integer coefficients, and a positive integer n, whether $f(M^n) \geq 0$. Unless stated otherwise, subsequently we assume that all numbers are encoded in binary. Here, we show that PosParikh is PosMatPow-hard for DFA over two-letter alphabets and Parikh vectors encoded in binary. We first establish several lemmas that will enable us to prove this proposition. The first lemma is a variant of the well-known correspondence between matrix powering and counting paths in a directed graph. In the following, by $M_{i,j}$ we denote the entry at position (i, j) of the matrix M.

▶ **Lemma 3.** *Given a matrix $M \in \mathbb{Z}^{m\times m}$, and $i, j \in \{1, \ldots, m\}$, one can compute in logspace an edge-weighted multi-graph $G = (V, E, s, t, w)$ and $v_i^+, v_j^+, v_j^- \in V$ such that for all $n \in \mathbb{N}$ we have $(M^n)_{i,j} = N(G, v_i^+, v_j^+, n) - N(G, v_i^+, v_j^-, n)$.*

Proof. In the following we write $M_{i,j}^n$ to mean $(M^n)_{i,j}$. Define an edge-weighted multi-graph $G = (V, E, s, t, w)$ as follows. Let $V := \{v_k^+, v_k^- : 1 \leq k \leq m\}$. For all $k, \ell \in \{1, \ldots, m\}$, if $M_{k,\ell} > 0$ then include in E an edge e from v_k^+ to v_ℓ^+ with $w(e) = M_{k,\ell}$, and an edge e from v_k^- to v_ℓ^- with $w(e) = M_{k,\ell}$. Similarly, if $M_{k,\ell} < 0$ then include in E an edge e from v_k^+ to v_ℓ^- with $w(e) = -M_{k,\ell}$, and an edge e from v_k^- to v_ℓ^+ with $w(e) = -M_{k,\ell}$. We prove by induction on n that we have for all $k, \ell \in \{1, \ldots, m\}$:

$$M_{k,\ell}^n = N(G, v_k^+, v_\ell^+, n) - N(G, v_k^+, v_\ell^-, n)$$

Note that this implies the statement of the lemma. For the induction base, let $n = 0$. If $k = \ell$ then $M_{k,\ell}^n = 1$, $N(G, v_k^+, v_\ell^+, 0) = 1$, and $N(G, v_k^+, v_\ell^-, 0) = 0$. If $k \neq \ell$ then $M_{k,\ell}^n = 0 = N(G, v_k^+, v_\ell^+, 0) = N(G, v_k^+, v_\ell^-, 0)$. For the inductive step, let $n \in \mathbb{N}$ and suppose $M_{k,\ell}^n = N(G, v_k^+, v_\ell^+, n) - N(G, v_k^+, v_\ell^-, n)$ for all k, ℓ. For $s \in \{1, \ldots, m\}$ write $I^+(s) := \{\ell \in \{1, \ldots, m\} : M_{\ell,s} > 0\}$ and $I^-(s) := \{\ell \in \{1, \ldots, m\} : M_{\ell,s} < 0\}$. For $v, v', v'' \in V$ write $\tilde{N}(G, v, v', v'', n+1)$ for the number of paths in $\tilde{G}$ (the unweighted version of G) from v to v'' of length $n+1$ such that v' is the vertex visited after n steps. We have for all $k, s \in \{1, \ldots, m\}$:

$$\begin{aligned}
M_{k,s}^{n+1} &= \sum_{\ell=1}^{m} M_{k,\ell}^n M_{\ell,s} \\
&\overset{\text{(ind. hyp.)}}{=} \sum_{\ell=1}^{m} N(G, v_k^+, v_\ell^+, n) M_{\ell,s} \; - \; \sum_{\ell=1}^{m} N(G, v_k^+, v_\ell^-, n) M_{\ell,s} \\
&= \sum_{\ell \in I^+(s)} N(G, v_k^+, v_\ell^+, n) M_{\ell,s} \; + \; \sum_{\ell \in I^-(s)} N(G, v_k^+, v_\ell^-, n)(-M_{\ell,s}) \; -
\end{aligned}$$

$$\begin{aligned}
& \sum_{\ell \in I^+(s)} N(G, v_k^+, v_\ell^-, n) M_{\ell,s} \; - \sum_{\ell \in I^-(s)} N(G, v_k^+, v_\ell^+, n)(-M_{\ell,s}) \\
= \; & \sum_{\ell \in I^+(s)} \tilde{N}(G, v_k^+, v_\ell^+, v_s^+, n+1) \; + \sum_{\ell \in I^-(s)} \tilde{N}(G, v_k^+, v_\ell^-, v_s^+, n+1) \; - \\
& \sum_{\ell \in I^+(s)} \tilde{N}(G, v_k^+, v_\ell^-, v_s^-, n+1) \; - \sum_{\ell \in I^-(s)} \tilde{N}(G, v_k^+, v_\ell^+, v_s^-, n+1) \\
= \; & N(G, v_k^+, v_s^+, n+1) - N(G, v_k^+, v_s^-, n+1)
\end{aligned}$$

This completes the induction proof. ◀

In a next step, we extend the previous lemma to matrix powering followed by the application of a linear function:

▶ **Lemma 4.** *Given a matrix $M \in \mathbb{Z}^{m \times m}$ and a linear function $f \colon \mathbb{Z}^{m \times m} \to \mathbb{Z}$ with integer coefficients, one can compute in logspace an edge-weighted multi-graph $G = (V, E, s, t, w)$ and $v_0, v^+, v^- \in V$ such that $f(M^n) = N(G, v_0, v^+, n+2) - N(G, v_0, v^-, n+2)$ for all $n \in \mathbb{N}$.*

Proof. Denote by $b_{i,j} \in \mathbb{Z}$ the coefficients of f, i.e., for $i, j \in \{1, \ldots, m\}$ let $b_{i,j} \in \mathbb{Z}$ such that for all $A \in \mathbb{Z}^{m \times m}$ we have $f(A) = \sum_{i=1}^m \sum_{j=1}^m b_{i,j} A_{i,j}$. By Lemma 3, one can compute in logspace for all $i, j \in \{1, \ldots, m\}$ an edge-weighted multi-graph $G_{i,j}$ with vertex set $V_{i,j}$, and vertices $v_{i,j}^0, v_{i,j}^+, v_{i,j}^- \in V_{i,j}$ such that for all $n \in \mathbb{N}$ we have:

$$M_{i,j}^n = N(G_{i,j}, v_{i,j}^0, v_{i,j}^+, n) - N(G_{i,j}, v_{i,j}^0, v_{i,j}^-, n) \tag{1}$$

Compute the desired edge-weighted multi-graph G as follows. For each $i, j \in \{1, \ldots, m\}$ include in G (a fresh copy of) the edge-weighted multi-graph $G_{i,j}$. Further, include in G fresh vertices v_0, v^+, v^-, and edges with weight 1 from v_0 to $v_{i,j}^0$, for each $i, j \in \{1, \ldots, m\}$. Further, for each $i, j \in \{1, \ldots, m\}$ with $b_{i,j} > 0$, include in G an edge from $v_{i,j}^+$ to v^+ with weight $b_{i,j}$, and an edge from $v_{i,j}^-$ to v^- with weight $b_{i,j}$. Similarly, for each $i, j \in \{1, \ldots, m\}$ with $b_{i,j} < 0$, include in G an edge from $v_{i,j}^+$ to v^- with weight $-b_{i,j}$, and an edge from $v_{i,j}^-$ to v^+ with weight $-b_{i,j}$. It remains to show that $f(M^n) = N(G, v_0, v^+, n+2) - N(G, v_0, v^-, n+2)$ for all $n \in \mathbb{N}$. Indeed, any path of length $n+2$ from v_0 to v^+ must start with an edge from v_0 to $v_{i,j}^0$ for some i, j, continue with a path of length n from $v_{i,j}^0$ to either $v_{i,j}^+$ or $v_{i,j}^-$, and finish with an edge to v^+. Hence, writing $I^+ := \{(i,j) : 1 \le i, j \le m,\ b_{i,j} > 0\}$ and $I^- := \{(i,j) : 1 \le i, j \le m,\ b_{i,j} < 0\}$ we have

$$N(G, v_0, v^+, n+2) = \sum_{(i,j) \in I^+} N(G, v_{i,j}^0, v_{i,j}^+, n) \cdot b_{i,j} + \sum_{(i,j) \in I^-} N(G, v_{i,j}^0, v_{i,j}^-, n) \cdot (-b_{i,j}).$$

Similarly we have:

$$N(G, v_0, v^-, n+2) = \sum_{(i,j) \in I^+} N(G, v_{i,j}^0, v_{i,j}^-, n) \cdot b_{i,j} + \sum_{(i,j) \in I^-} N(G, v_{i,j}^0, v_{i,j}^+, n) \cdot (-b_{i,j}).$$

Hence we have:

$$\begin{aligned}
f(M^n) &= \sum_{i=1}^m \sum_{j=1}^m M_{i,j}^n \cdot b_{i,j} \\
&\overset{(1)}{=} \sum_{i=1}^m \sum_{j=1}^m N(G, v_{i,j}^0, v_{i,j}^+, n) \cdot b_{i,j} \; - \sum_{i=1}^m \sum_{j=1}^m N(G, v_{i,j}^0, v_{i,j}^-, n) \cdot b_{i,j} \\
&= N(G, v_0, v^+, n+2) - N(G, v_0, v^-, n+2)
\end{aligned}$$

This proves the lemma. ◀

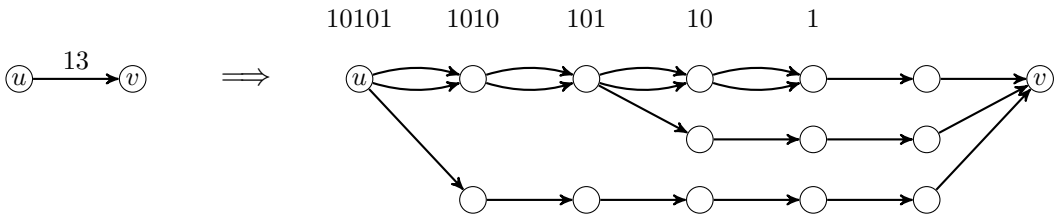

Figure 1 Illustration of the construction of the unweighted multi-graph from Lemma 5. We assume $k = 6$. The binary representation of 13 is 10101. The binary numbers over the nodes on the right hand side correspond to w-values that occur during the construction, but are not part of the output. Each binary number over a node indicates the number of paths to v.

Next, we show that one can obtain from an edge-weighted multi-graph a corresponding DFA such that the number of paths in the graph corresponds to the number of words with a certain Parikh image accepted by the DFA. The proof is split into a couple of intermediate steps.

▶ **Lemma 5.** *Given an edge-weighted multi-graph $G = (V, E, s, t, w)$ (with w in binary), $v_0, v_1 \in V$ and a number $k \in \mathbb{N}$ in unary such that $k \geq 1 + \max_{e \in E} \lfloor \log_2 w(e) \rfloor$, one can compute in logspace an unweighted multi-graph $G' := (V', E', s', t')$ with $V' \supseteq V$ such that for all $n \in \mathbb{N}$ we have $N(G, v_0, v_1, n) = N(G', v_0, v_1, n \cdot k)$.*

Proof. Note that k is at least the size of the binary representation of the largest weight in G. Define a mapping $b\colon E \to \mathbb{N}$ with $b(e) = k$ for all $e \in E$. Define G' so that it is obtained from G by iterating the following construction. Let $e \in E$ with $b(e) > 1$. If $w(e) = 1$ then replace e by a fresh path of length $b(e)$ (with $w(e') = b(e') = 1$ for all edges e' on that path). If $w(e) = 2j$ for some $j \in \mathbb{N}$ then introduce a fresh vertex v and two fresh edges e_1, e_2 from $s(e)$ to v with $b(e_1) = b(e_2) = w(e_1) = w(e_2) = 1$ and another fresh edge e_3 from v to $t(e)$ with $b(e_3) = b(e) - 1$ and $w(e_3) = j$. Finally, if $w(e) = 2j + 1$ for some $j \in \mathbb{N}$ then proceed similarly, but additionally introduce fresh vertices that create a new path of length $b(e)$ from $s(e)$ to $t(e)$ (with $w(e') = b(e') = 1$ for all edges e' on that path). By this construction, every edge e is eventually replaced by $w(e)$ paths of length k. The construction is illustrated in Figure 1.

For the logspace claim, note that it is not necessary to store the whole graph for this construction. The binary representation of k has logarithmic size and can be stored, and a copy of k can be counted down, keeping track of the b-values in the construction. The edges can be dealt with one by one. It is not necessary to store the values $w(e') = j$ for the created fresh edges; rather those values can be derived from the binary representation of the original weight $w(e)$ and the current b-value (acting as a "pointer" into the binary representation of $w(e)$). ◀

▶ **Lemma 6.** *Given an unweighted multi-graph $G = (V, E, s, t)$ and $v_0, v_1 \in V$, one can compute in logspace unweighted multi-graphs $G_0 = (V_0, E_0, s_0, t_0)$ and $G_1 = (V_1, E_1, s_1, t_1)$ with $V_0 \supseteq V$ and $V_1 \supseteq V$ such that for all $n \in \mathbb{N}$ we have $N(G_0, v_0, v_1, n+2) = N(G, v_0, v_1, n)$ and $N(G_1, v_0, v_1, n + 2) = N(G, v_0, v_1, n) + 1$.*

Proof. For G_0 redirect all edges adjacent to v_0 to a fresh vertex v_0^*, and similarly redirect all edges adjacent to v_1 to a fresh vertex v_1^*. Then add an edge from v_0 to v_0^*, and an edge from v_1^* to v_1.

For G_1 do the same, and in addition add a fresh vertex v, and add edges from v_0 to v, and from v to v_1, and a loop on v. This adds a path from v_0 to v_1 of length $n + 2$. ◀

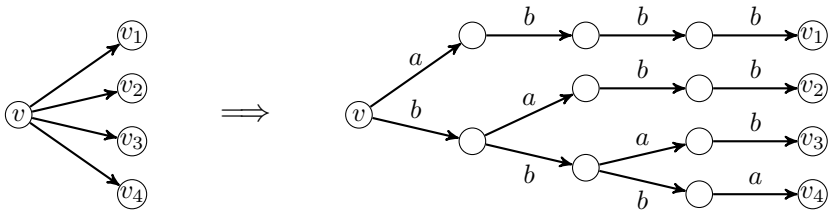

Figure 2 Illustration of the construction of the DFA from Lemma 7. We assume $d = 4$.

▶ **Lemma 7.** *Given an unweighted multi-graph $G = (V, E, s, t)$, $v_0, v_1 \in V$ and a number d in unary so that d is at least the maximal out-degree of any node in G, one can compute in logspace a DFA $\mathcal{A} = (Q, \Sigma, q_0, F, \Delta)$ with $\Sigma = \{a, b\}$ such that for all $n \in \mathbb{N}$ we have $N(G, v_0, v_1, n) = N(\mathcal{A}, \vec{p})$ where $\vec{p}(a) = n$ and $\vec{p}(b) = n \cdot (d-1)$.*

Proof. Define $\mathcal{A}$ so that $Q \supseteq V$, $q_0 = v_0$, and $F = \{v_1\}$. Include states and transitions in $\mathcal{A}$ so that for every edge e (from v to v', say) in G there is a run from v to v' in $\mathcal{A}$ of length d so that exactly one transition on this run is labelled with a, and the other $d-1$ transitions are labelled with b. Importantly, each edge e is associated to exactly one such run. The construction is illustrated in Figure 2. The DFA $\mathcal{A}$ is of quadratic size and can be computed in logspace. It follows from the construction that any path of length n in G corresponds to a run of length $n \cdot d$ in $\mathcal{A}$, with n transitions labelled with a, and $n \cdot (d-1)$ transitions labelled with b. This implies the statement of the lemma. ◀

Proof of Proposition 2(iii). The above lemmas enable us to prove part (iii) from Proposition 2. Consider an instance of PosMatPow, i.e., a square integer matrix $M \in \mathbb{Z}^{m \times m}$, a linear function $f \colon \mathbb{Z}^{m \times m} \to \mathbb{Z}$ with integer coefficients, and a positive integer n. Using Lemma 4 we can compute in logspace edge-weighted multi-graphs G_+ with vertices v_0^+, v^+ and G_- with vertices v_0^-, v^- such that

$$f(M^n) = N(G_+, v_0^+, v^+, n+2) - N(G_-, v_0^-, v^-, n+2)\,.$$

Let $k := 1 + \max_{e \in E} \lfloor \log_2 w(e) \rfloor$, where E is the union of the edge sets of G_+ and G_-. Using Lemma 5 we can compute unweighted multi-graphs G'_+, G'_- such that

$$N(G_+, v_0^+, v^+, n+2) = N(G'_+, v_0^+, v^+, (n+2) \cdot k) \text{ and}$$
$$N(G_-, v_0^-, v^-, n+2) = N(G'_-, v_0^-, v^-, (n+2) \cdot k)\,.$$

Hence,

$$f(M^n) = N(G'_+, v_0^+, v^+, (n+2) \cdot k) - N(G'_-, v_0^-, v^-, (n+2) \cdot k)\,.$$

Using Lemma 6 we can compute unweighted multi-graphs G''_+, G''_- such that

$$1 + N(G'_+, v_0^+, v^+, (n+2) \cdot k) = N(G''_+, v_0^+, v^+, (n+2) \cdot k + 2) \text{ and}$$
$$N(G'_-, v_0^-, v^-, (n+2) \cdot k) = N(G''_-, v_0^-, v^-, (n+2) \cdot k + 2)\,.$$

Hence,

$$f(M^n) + 1 = N(G''_+, v_0^+, v^+, (n+2) \cdot k + 2) - N(G''_-, v_0^-, v^-, (n+2) \cdot k + 2)\,.$$

Let d denote the maximal out-degree of any node in G''_+ or G''_-. Let $\vec{p}\colon \{a,b\} \to \mathbb{N}$ with $\vec{p}(a) = (n+2)\cdot k + 2$ and $\vec{p}(b) = ((n+2)\cdot k + 2)\cdot(d-1)$. Using Lemma 7 we can compute DFA $\mathcal{A}, \mathcal{B}$ over the alphabet $\{a,b\}$ such that

$$N(G''_+, v_0^+, v^+, (n+2)\cdot k+2) = N(\mathcal{A}, \vec{p}) \qquad \text{and} \qquad N(G''_-, v_0^-, v^-, (n+2)\cdot k+2) = N(\mathcal{B}, \vec{p})\,.$$

Hence, $f(M^n) + 1 = N(\mathcal{A}, \vec{p}) - N(\mathcal{B}, \vec{p})$. So $f(M^n) \geq 0$ if and only if $f(M^n) + 1 > 0$ if and only if $N(\mathcal{A}, \vec{p}) > N(\mathcal{B}, \vec{p})$. All mentioned computations can be performed in logspace. ◀

4 Parikh Counting Problems for NFA and CFG

In this section, we show the remaining results for NFA and CFG from Table 1 when the alphabet is not unary. The following theorem states upper bounds for PosParikh and #Parikh for NFA and CFG.

▶ **Proposition 8.** *For an alphabet of variable size, #Parikh (resp., PosParikh) is in*
(i) *#P (resp., PP) for CFG with Parikh vectors encoded in unary;*
(ii) *#PSPACE (resp., PSPACE) for NFA with Parikh vectors encoded in binary; and*
(iii) *#EXP (resp., PEXP) for CFG with Parikh vectors encoded in binary.*

Proof (sketch). In all cases, the proof is a straightforward adaption of the proof for the upper bounds in Proposition 2(i), see [6]. ◀

The following proposition states matching lower bounds for PosParikh for the cases considered in Proposition 8:

▶ **Proposition 9.** *For a fixed alphabet of size two, PosParikh is hard for*
(i) PP *for NFA and Parikh vectors encoded in* unary*;*
(ii) PSPACE *for NFA and Parikh vectors encoded in* binary*; and*
(iii) PEXP *for CFG and Parikh vectors encoded in* binary*.*

Proof (sketch). We only provide the main ideas for the lower bounds, all details can be found in [6]. Let us sketch the proof for (i). The proof is based on the fact that those strings (over an alphabet Σ) that do not encode a valid computation (called erroneous below) of a polynomial-time bounded non-deterministic Turing machine M started on an input x (with $|x| = n$) can be produced by a small NFA [15] (and this holds also for polynomial-space bounded machines, which is important for (ii)). Suppose the NFA $\mathcal{A}$ generates all words that end in an accepting configuration of M, or that are erroneous and end in a rejecting configuration. Symmetrically, suppose that $\mathcal{B}$ generates all words that are erroneous and end in an accepting configuration, or that end in a rejecting configuration. We then have that $\#(L(\mathcal{A}) \cap \Sigma^{g(n)}) - \#(L(\mathcal{B}) \cap \Sigma^{g(n)})$ equals the difference between the number of accepting paths and rejecting paths of M. Here, $g(n)$ is a suitably chosen polynomial.

Let $h\colon \Sigma^* \to \{0,1\}^*$ be the morphism that maps the i-th element of Σ (in some enumeration) to $0^{i-1}10^{\#\Sigma - i}$. Moreover, let $\mathcal{A}_h$ and $\mathcal{B}_h$ be NFA for $h(L(\mathcal{A}))$ and $h(L(\mathcal{B}))$, respectively, and let $\vec{p}$ be the Parikh vector with $\vec{p}(0) := g(n)\cdot(\#\Sigma - 1)$ and $\vec{p}(1) := g(n)$. Then $N(\mathcal{A}_h, \vec{p}) - N(\mathcal{B}_h, \vec{p}) = \#(L(\mathcal{A}) \cap \Sigma^{g(n)}) - \#(L(\mathcal{B}) \cap \Sigma^{g(n)})$ equals the difference between the number of accepting paths and rejecting paths of M.

The proof for (ii) is similar. For (iii) we use the fact that those strings that do not encode a valid computation of an exponential-time bounded non-deterministic Turing machine started on an input x can be produced by a small CFG [8]. ◀

In our construction above, we do not construct an NFA (resp., CFG) $\mathcal{A}$ and a Parikh vector $\vec{p}$ such that $N(\mathcal{A}, \vec{p})$ is *exactly* the number of accepting computations of M on the given input. This is the reason for not stating hardness for #P (resp., #PSPACE #EXP) in the above proposition (we could only show hardness under Turing reductions, but not parsimonious reductions).

5 Unary alphabets

A special case of PosParikh that has been ignored so far is that of a unary alphabet. Of course, for a unary alphabet a word is determined by its length, and a Parikh vector is a single number. Moreover, there is not much to count: Either a language $L \subseteq \{a\}^*$ contains no word of length n or exactly one word of length n. Thus, PosParikh reduces to the question whether for a given length n (encoded in unary or binary) the word a^n is accepted by $\mathcal{A}$ and rejected by $\mathcal{B}$. In this section we clarify the complexity of this problem for (i) unary DFA, NFA, and CFG, and (ii) lengths encoded in unary and binary. In the case of lengths encoded in binary, PosParikh is tightly connected to the *compressed word problem*: Given a unary DFA (resp., NFA, CFG) $\mathcal{A}$ and a number n in binary encoding, determine if $a^n \in L(\mathcal{A})$. In particular, if this problem belongs to a complexity class that is closed under complement (e.g. L, NL, P), then PosParikh belongs to the same class.

▶ **Proposition 10.** *For unary alphabets,* PosParikh *is*
(i) *in* L *for DFA with Parikh vectors encoded in* binary*;*
(ii) NL*-complete for NFA irrespective of the encoding of the Parikh vector; and*
(iii) P*-complete for CFG with Parikh vectors encoded in unary.*
(iv) DP*-complete for CFG with Parikh vectors encoded in binary.*

We only give the proof for Part (ii), all remaining proofs can be found in [6]. To this end, we employ a recent result of Sawa [14]. For $a, b \in \mathbb{N}$ we write $a + b\mathbb{N}$ for the set $\{a + b \cdot i : i \in \mathbb{N}\}$. Given a unary NFA $\mathcal{A} = (Q, \{a\}, q_0, F, \Delta)$ with $p, q \in Q$ and $n \in \mathbb{N}$ we write $p \xrightarrow{n} q$ if there is a run of length n from p to q. The subsequent lemma gives an easy criterion that allows for deciding when a word is in the language of a unary NFA.

▶ **Lemma 11** ([14, Lemma 3.1])**.** *Let $\mathcal{A} = (Q, \{a\}, q_0, F, \Delta)$ be a unary NFA with $m := |Q| \geq 2$. Let $n \geq m^2$. Then $a^n \in L(\mathcal{A})$ if and only if there are $q \in Q$, $q_f \in F$, $b \in \{1, \ldots, m\}$, and $c \in \{m^2 - b - 1, \ldots, m^2 - 2\}$ with $n \in c + b\mathbb{N}$ and $q_0 \xrightarrow{m-1} q \xrightarrow{b} q \xrightarrow{c-(m-1)} q_f$.*

We can now give the proof of Proposition 10 (ii):

Proof of Proposition 10(ii). We first show that the compressed word problem for unary NFA is in NL, from which we can conclude NL-membership for PosParikh for unary NFA with Parikh vectors encoded in binary.

Let $\mathcal{A} = (Q, \{a\}, q_0, F, \Delta)$ be the given unary NFA, and let $n \in \mathbb{N}$ be given in binary. We claim that, given two states $p_1, p_2 \in Q$ and a number $c \in \mathbb{N}$ whose binary representation is of size logarithmic in the input size, we can check in NL whether $p_1 \xrightarrow{c} p_2$ holds. To prove the claim, consider the directed graph G with vertex set $Q \times \{0, \ldots, c\}$ and an edge from (q_1, i) to (q_2, j) if and only if $q_1 \xrightarrow{1} q_2$ and $j = i + 1$. The graph G can be computed by a logspace transducer. Then $p_1 \xrightarrow{c} p_2$ holds if and only if (p_2, c) is reachable from $(p_1, 0)$ in G. The claim follows as graph reachability is in NL.

Now we give an NL algorithm for the compressed word problem. If $n < m^2$ then guess $q_f \in F$ and check, using the claim above, in NL whether $q_0 \xrightarrow{n} q_f$. If $n \geq m^2$ we use Lemma 11

as follows. We run over all $q \in Q$, $q_f \in F$, $b \in \{1, \ldots, m\}$, and $c \in \{m^2 - b - 1, \ldots, m^2 - 2\}$ (all four values can be stored in logspace), and check (i) whether $n \in c + b\mathbb{N}$ and (ii) $q_0 \xrightarrow{m-1} q \xrightarrow{b} q \xrightarrow{c-(m-1)} q_f$ holds. Condition (i) can be checked in logspace (as in the proof of Proposition 10), and condition (ii) can be checked in NL by the above claim.

It follows that PosParikh is in NL for unary NFA with Parikh vectors encoded in binary: Given NFA $\mathcal{A}, \mathcal{B}$ and $n \in \mathbb{N}$ in binary, we have $N(\mathcal{A}, n) > N(\mathcal{B}, n)$ (where we identify the mapping $\vec{p} : \{a\} \to \mathbb{N}$ with the single number $\vec{p}(a)$) if and only if $N(\mathcal{A}, n) = 1$ and $N(\mathcal{B}, n) = 0$, which holds if and only if $a^n \in L(\mathcal{A})$ and $a^n \notin L(\mathcal{B})$. Since NL is closed under complement, the latter condition can be checked in NL.

It remains to show the NL lower bound, which we obtain via a reduction from the graph reachability problem. This problem is to decide whether for a given directed graph $G = (V, E)$ and vertices $s, t \in V$ there is a path from s to t. By adding a loop at node t, this is equivalent to the existence of a path in G from s to t of length $n = \#V$. Let $\mathcal{A}$ be the NFA obtained from G by labelling every edge with the terminal symbol a and making s (resp., t) the initial (resp., unique final) state. Moreover, let $\mathcal{B}$ be an NFA with $L(\mathcal{B}) = \emptyset$. Then $N(\mathcal{A}, n) > N(\mathcal{B}, n)$ if and only if $a^n \in L(\mathcal{A})$ if and only if there is a path in G from s to t of length $n = |V|$. ◀

6 Open problems

Our PEXP-hardness proof for PosParikh on context-free languages and binary encoded Parikh vectors requires non-deterministic context-free languages. It might be interesting to see whether this problem belongs to the counting hierarchy for deterministic pushdown automata or the subclass of visibly pushdown automata. For this, one might try to generalise our techniques for DFA from [7], which rely on results from algebraic graph theory (Tutte's matrix tree theorem and the BEST theorem for counting Eulerian cycles in digraphs), to deterministic pushdown automata or visibly pushdown automata.

We believe that results similar to those shown for PosParikh can be also shown for BitParikh. For instance, the proof of Proposition 2(ii) (showing that #Parikh is #P-complete for DFA over a variable alphabet and Parikh vectors encoded in unary) shows that BitParikh for DFA over a variable alphabet and Parikh vectors encoded in unary is complete for the complexity class MP. The class MP contains all problems which can be solved in polynomial time with the additional information of one bit from a #P-function [4]. Moreover, one might also consider the problem of computing $N(\mathcal{A}, \vec{p})$ modulo a fixed number k. This should yield completeness results for Mod_k-classes.

Communication Complexity of Pairs of Graph Families with Applications*

Sudeshna Kolay[1], Fahad Panolan[2], and Saket Saurabh[3]

1 **Eindhoven University of Technology, Netherlands**
2 **Department of Informatics, University of Bergen, Norway**
3 **Department of Informatics, University of Bergen, Norway, and The Institute of Mathematical Sciences, HBNI, Chennai, India**

Abstract

Given a graph G and a pair $(\mathcal{F}_1, \mathcal{F}_2)$ of graph families, the function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ takes as input, two induced subgraphs G_1 and G_2 of G, such that $G_1 \in \mathcal{F}_1$ and $G_2 \in \mathcal{F}_2$ and returns 1 if $V(G_1) \cap V(G_2) = \emptyset$ and 0 otherwise. We study the communication complexity of this problem in the two-party model. In particular, we look at pairs of hereditary graph families. We show that the communication complexity of this function, when the two graph families are hereditary, is sublinear if and only if there are finitely many graphs in the intersection of these two families. Then, using concepts from parameterized complexity, we obtain nuanced upper bounds on the communication complexity of $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$. A concept related to communication protocols is that of a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family of a graph G. A collection $\mathcal{F}$ of subsets of $V(G)$ is called a $(\mathcal{F}_1, \mathcal{F}_2)$-*separating family* for G, if for any two vertex disjoint induced subgraphs $G_1 \in \mathcal{F}_1, G_2 \in \mathcal{F}_2$, there is a set $F \in \mathcal{F}$ with $V(G_1) \subseteq F$ and $V(G_2) \cap F = \emptyset$. Given a graph G on n vertices, for any pair $(\mathcal{F}_1, \mathcal{F}_2)$ of hereditary graph families with sublinear communication complexity for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, we give an enumeration algorithm that finds a subexponential sized $(\mathcal{F}_1, \mathcal{F}_2)$-separating family. In fact, we give an enumeration algorithm that finds a $2^{o(k)}n^{\mathcal{O}(1)}$ sized $(\mathcal{F}_1, \mathcal{F}_2)$-separating family; where k denotes the size of a minimum sized set S of vertices such that $V(G) \setminus S$ has a bipartition (V_1, V_2) with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. We exhibit a wide range of applications for these separating families, to obtain combinatorial bounds, enumeration algorithms as well as exact and FPT algorithms for several problems.

1 Introduction

The two party communication complexity, introduced by Yao [17], is an important research area in theoretical computer science with many applications. This notion of complexity is particularly useful for proving lower bounds for VLSI computation, parallel computation, data structures as well as circuit lower bounds. In this model of communication, there are two players, Alice and Bob, holding inputs $x \in X$ and $y \in Y$ respectively, and they want to compute a given function $f : X \times Y \to \{0, 1\}$, by communicating as few bits as possible. It is assumed that both players have infinite computational power. However, communicating the results to the other player could be very costly. The minimum number of

bits communicated, for any pair of inputs (x, y), to compute the function f, is called the (deterministic) communication complexity of f, denoted by $D(f)$. One such communication complexity problem, which has garnered a lot of attention, is the Clique vs Independent Set problem, introduced by Yannakakis [16]. For an n-vertex graph G, the Clique vs Independent Set problem is defined as follows. Alice gets a clique C in G and Bob gets an independent set I in G. Here both Alice and Bob know the graph G and their goal is to decide whether the clique and the independent set intersect in some vertex, by exchanging as few bits as possible. In other words, define the function $\mathsf{CIS}_G(C, I)$ as the cardinality of $V(C) \cap V(I)$ (note that $|V(C) \cap V(I)| \in \{0, 1\}$) and, Alice and Bob want to compute $\mathsf{CIS}_G(C, I)$. It can be shown that $D(\mathsf{CIS}_G) = \mathcal{O}(\log^2 n)$. One can also show that $D(\mathsf{CIS}_G) = \Omega(\log n)$, using the fooling set technique, a method to show communication lower bounds. Closing the gap between the upper and lower bound of CIS_G is a long standing open problem. Very recently, in 2015, Göös et al. [9] showed a near optimal lower bound of $\tilde{\Omega}(\log^2 n)$ for the problem, where $\tilde{\Omega}(m)$ hides divisors poly-logarithmic in m. Later, Göös et al. [8] showed that the same lower bound holds even for randomized communication complexity of the problem. Other versions of two party communication protocols deal with the concepts of nondeterministic and co-nondeterministic protocols. There are many works which study the cost of co-nondeterministic communication protocols of the Clique vs Independent Set problem [11, 1, 15, 7]. For more details on non-deterministic, co-nondeterministic and randomized communication complexities, [13] can be referred.

In this work, we study the communication complexity of graph properties that generalize the function CIS_G. Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be two hereditary graph properties. That is, $\mathcal{F}_1$ and $\mathcal{F}_2$ are two families of graphs such that if $G \in \mathcal{F}_i, i \in \{1, 2\}$, then all induced subgraphs of G are also in $\mathcal{F}_i$. We define a $(\mathcal{F}_1, \mathcal{F}_2)$ communication problem as follows. For any fixed n-vertex graph G, Alice gets an induced subgraph G_1 of G and Bob gets an induced subgraph G_2 of G, such that $G_i \in \mathcal{F}_i, i \in \{1, 2\}$, and their objective is to check whether $V(G_1)$ and $V(G_2)$ intersect, by communicating as few bits as possible. In other words, we define a function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ as $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}(G_1, G_2) = 1$ if $V(G_1)$ and $V(G_2)$ do not intersect and 0 otherwise, where G_1 and G_2 are induced subgraphs of G and $G_i \in \mathcal{F}_i, i \in \{1, 2\}$. Alice and Bob want to find the value of the function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ on (G_1, G_2). Notice that, when $\mathcal{F}_1$ is the family of cliques and $\mathcal{F}_2$ is the family of independent sets, then $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}(C, I) = 1$ if and only if $\mathsf{CIS}_G(C, I) = 0$. A trivial protocol for computing $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ is as follows: Alice sends a bit vector of $V(G_1)$ to Bob and Bob checks whether it intersects with the vertex set $V(G_2)$; the number of bits communicated in this protocol is n. One of our main theorems characterizes pairs of graph families for which the trivial protocol is the best one.

▶ **Theorem 1.1.** *For any two hereditary families of graphs $\mathcal{F}_1$ and $\mathcal{F}_2$, for any $n \in \mathbb{N}$, there is an n-vertex graph G such that $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}) = \Omega(n)$ if and only if $\mathcal{F}_1 \cap \mathcal{F}_2$ is an infinite family.*

We give a sketch of the proof for this Theorem. We observe that when a pair of hereditary graph families have finitely many graphs in their intersection, they have the following property: In one family, all graphs have their independence number (the maximum size of an independent set) bounded by a constant, while in the other family, all graphs have their clique number (the maximum size of a clique) bounded by some other constant. Thus, we consider the communication complexity for computing $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ when $\mathcal{F}_1$ and $\mathcal{F}_2$ are specific families. Let $\mathcal{C}_r$ be the family of graphs such that the independence number is at most r, and $\mathcal{I}_\ell$ be the family of graphs such that the clique number is at most ℓ. Such pairs of families were considered in the study made in [6]. Deriving from Theorem 5 in [10], we show that $D(\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}) = \mathcal{O}(\log^2 n)$ and, therefore, conclude the hypothesis of Theorem 1.1.

One of our main motivation, to carry out the study done in this article, was to introduce ideas from parameterized complexity in the study of communication complexity and vice versa. Parameterized complexity theory is a framework for a refined analysis of primarily hard (NP-hard) problems. Here, every input instance I of a problem Π is accompanied with an integer parameter k, and the running time is measured in terms of the associated parameter k and the input size. The main idea of parameterized algorithms is to *measure* the running time in terms of both input size as well as a parameter that captures structural properties of the input instance. Using ideas from parameterized complexity, we obtain the following nuanced upper bounds on the communication complexity of the function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$. A pair $(\mathcal{F}_1,\mathcal{F}_2)$ of hereditary graph families where $\mathcal{F}_1 \cap \mathcal{F}_2$ is finite, will be referred to as a *good pair of graph families*.

▶ **Theorem 1.2.** *Let G be an n-vertex graph and $(\mathcal{F}_1,\mathcal{F}_2)$ be a good pair of graph families. Let $\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}$ be the size of a minimum set S of vertices such that $V(G)\setminus S$ has a bipartition (V_1,V_2) with $G[V_1]\in\mathcal{F}_1$ and $G[V_2]\in\mathcal{F}_2$. Then there is a protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ that has $\mathcal{O}(\log^2(\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2})+\log n)$ communication complexity.*

For the special case of Clique vs Independent Set problem we get a protocol that has $\mathcal{O}(\log^2(\mathsf{opt}^G_{\mathcal{C}_1,\mathcal{I}_1})+\log n)$ communication complexity. We would like to mention that the protocol used to show that $D(\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell})=\mathcal{O}(\log^2 n)$ uses the full computational power of Alice and Bob. In the protocol, both players are able to compute the communication matrix of the function $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$. In contrast, we design a protocol to study communication complexity in terms of the degeneracy of graphs in the given family, where all the computations of both players are polynomial time operations. In particular, we consider the pair of families $(\mathcal{C}_1,\mathcal{D}_\ell)$, where $\mathcal{D}_\ell$ is the set of all ℓ-degenerate graphs and $\mathcal{C}_1$ is the set of all complete graphs. Note that $\mathcal{D}_0$ is the family of independent sets. Hence, this is still a generalization of the Clique vs Independent Set problem. We prove the following theorem regarding the communication complexity of $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{D}_\ell}$, with the help of a protocol where both the players only execute polynomial time computations. This will be utilized later.

▶ **Theorem 1.3.** *For any constant $\ell\in\mathbb{N}$ and an n-vertex graph G, there is a deterministic protocol that computes the function $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{D}_\ell}$ using $\mathcal{O}(\ell\log^2 n)$ bits and where both players have polynomial computational power.*

Separating Families

The main motivation for Yannakakis to introduce the Clique vs Independent Set problem was to study the number of constraints in the linear programming of a vertex packing polytope. As a spin-off of this study, he provided relations between the Clique vs Independent set problem and a CI-separating family (Clique-Independent set separating family): for a graph G, a family $\mathcal{F}$, of subsets of $V(G)$, is called a CI-separating family if for any disjoint clique C and independent set I in G, there is a set $F\in\mathcal{F}$ such that $C\subseteq F$ and $I\cap F=\emptyset$. He showed that the co-nondeterministic communication complexity of CIS_G is $\log q(G)$, where $q(G)$ is the cardinality of a CI-separating family of G. Yannakakis also provided a polynomial sized CI-separating family on comparability graphs and their complements, chordal graphs and their complements, and asked whether there is a polynomial sized family on general graphs, or even on perfect graphs. Lovász [14] extended the work of Yannakakis to t-perfect graphs and gave a polynomial sized CI-separating family on t-perfect graphs. Bousquet et al. [2] proved the existance of polynomial sized CI-separating families for the following class of graphs: random graphs, split-free graphs (here the graph does not have a fixed split graph

as an induced subgraph), graphs with no induced path P_k on k vertices nor its complement (here k is a constant), and graphs with no induced P_5. But, a result of Göös [7], that shows that the co-nondeterministic communication complexity of CIS_G is $\Omega(\log^{1.128} n)$, implies that the cardinality of CI-separating family on general graphs is super polynomial in the number of vertices.

The communication complexity of CIS_G, $D(\mathsf{CIS}_G) = \mathcal{O}(\log^2 n)$ implies that there is a CI-separating family of cardinality $n^{\mathcal{O}(\log n)}$ (See [13]). We would like to remark that the existence of a CI-separating family does not imply that such a family can be enumerated in time polynomial in the size of the family. The best known bound on the cardinality of a enumerable CI-separating family on general graphs is $\mathcal{O}(n^{\frac{\log n}{2}})$, by Hajnal (unpublished, cited in [14]). Cygan et. al. [4] also enumerated a CI-separating family, of cardinality $n^{\mathcal{O}(\log n)}$, in time $n^{\mathcal{O}(\log n)}$. In the special case of finding a CI-separating family, one can use the communication protocol of CIS_G, given in [14], to enumerate such a family in time $n^{\mathcal{O}(\log n)}$. To generalize from the definition of CI-separating families, for a graph G, and a pair of families $\mathcal{F}_1$ and $\mathcal{F}_2$, a notion of $(\mathcal{F}_1, \mathcal{F}_2)$-separating family was introduced. A family $\mathcal{P}$ of vertex subsets of $V(G)$ is called a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family if for any two disjoint vertex subsets V_1 and V_2 with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$, there is a set $A \in \mathcal{P}$ such that $V_1 \subseteq A$ and $V_2 \cap A = \emptyset$.

From an observation made in [13], it is implied that a non-deterministic protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ corresponds to a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family. This implies that if $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}) = c$, then there is a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family of size 2^c. Similar to the case of CI-separating families, describing an enumeration algorithm to find the best separating family is a problem of wide interest. In this paper, we show that a $(\mathcal{C}_r, \mathcal{I}_\ell)$-separating family of size $2^{\mathcal{O}(\log^{r+\ell} n)}$ can be enumerated in time $2^{\mathcal{O}(\log^{r+\ell} n)}$. This, in turn, implies the following theorem.

▶ **Theorem 1.4.** *For any two hereditary families of graphs $\mathcal{F}_1$ and $\mathcal{F}_2$, for each integer $n > 0$, there is an n-vertex graph G such that any $(\mathcal{F}_1, \mathcal{F}_2)$-separating family must be of size $2^{\Omega(n)}$ if and only if $\mathcal{F}_1 \cap \mathcal{F}_2$ is an infinite family.*

Note that although $D(\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}) = \mathcal{O}(\log^2 n)$, we are not able to find a $(\mathcal{C}_r, \mathcal{I}_\ell)$-separating family of size $2^{\mathcal{O}(\log^2 n)}$ that can be enumerated in time $2^{\mathcal{O}(\log^{r+\ell} n)}$. We also get the following theorem as a "separating family" analogue of Theorem 1.2. This theorem is extremely useful in designing parameterized algorithms.

▶ **Theorem 1.5.** *Let $(\mathcal{F}_1, \mathcal{F}_2)$ be a good pair of graph families and G be an n-vertex graph. Let S be a minimum sized vertex set of G such that $V(G) \setminus S$ has a bipartition (V_1, V_2) with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. Let $|S| = \mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}$. Then a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family, for G, of cardinality $2^{\mathcal{O}(\log^c \mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2})} n^{\mathcal{O}(1)}$ can be enumerated in time $2^{\mathcal{O}(\log^c \mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2})} n^{\mathcal{O}(1)}$, where c is a constant.*

Another pair of graph properties (families of graphs) we consider is the family of complete graphs, $\mathcal{C}_1$ and that of ℓ-degenerate graphs, $\mathcal{D}_\ell$. By Theorem 1.3, we already know that $D(\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{D}_\ell})$ is $\mathcal{O}(\ell \log^2 n)$. We also give an algorithm to enumerate a $(\mathcal{C}_1, \mathcal{D}_\ell)$-separating family for an n-vertex graph, of cardinality $n^{\mathcal{O}(\ell \log n)}$, in time $n^{\mathcal{O}(\ell \log n)}$. In other words, we succeed in efficiently enumerating a $(\mathcal{C}_1, \mathcal{D}_\ell)$-separating family of size $n^{\mathcal{O}(\ell \log n)}$, the existence of which results from $D(\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{D}_\ell}) = \mathcal{O}(\ell \log^2 n)$.

Applications

In 2013, Cygan et al. [4] drew a very interesting relation between the field of enumerating separating families and designing algorithms. As mentioned earlier, a CI-separating family of cardinality $n^{\mathcal{O}(\log n)}$ is enumerated in time $n^{\mathcal{O}(\log n)}$, and this family is used to design fast exact and parameterized algorithms. They showed that Split Vertex Deletion, where we want to delete at most k vertices from a given n-vertex graph to get a split graph, can be solved in time $\mathcal{O}(1.2738^k k^{\mathcal{O}(\log k)} + n^3)$. They also showed that all induced split subgraphs of a given n-vertex graph can be listed in time $\mathcal{O}(3^{n/3} n^{\mathcal{O}(\log n)})$ time. This work motivated the last part of our study: designing exact and FPT algorithms. Not only are the enumeration algorithms for separating families interesting combinatorial questions in their own right, but they also help to design fast FPT and exact exponential time algorithms for a class of problems. A generic class of problems for which a separating family based approach works is as follows. Let $\mathcal{G}$ be a family of graphs. Then $\mathcal{G} + kv$ contains all graphs G such that there is a vertex set $S \subseteq V(G)$, of size at most k, with the property that the graph $G \setminus S \in \mathcal{G}$. Given two graph families $\mathcal{F}_1, \mathcal{F}_2$, we consider the following problem in this paper.

$(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition **Parameter:** k
Input: A graph G and a non-negative integer k
Question: Is there a vertex set $S \subseteq V(G)$, of size at most k, such that there is a partition $V_1 \uplus V_2$ of $V(G) \setminus S$ and $G[V_i] \in \mathcal{F}_i$, $i \in \{1, 2\}$?

The optimization version of $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition is denoted by $(\mathcal{F}_1, \mathcal{F}_2)$-Partition. Here, the aim is to find the minimum size of a vertex set S such that $V(G) \setminus S$ has a bipartition (V_1, V_2) with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families. For any positive integer k, let the families $\mathcal{F}_1 + kv$ and $\mathcal{F}_2 + kv$ have FPT recognition algorithms. That is, there are algorithms which take as input a graph G and an integer k, decide whether $G \in \mathcal{F}_i + kv, i \in \{1, 2\}$ and run in time $f(k)|V(G)|^{\mathcal{O}(1)}$. For ease of notation, if $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families, and the families $\mathcal{F}_1 + kv$ and $\mathcal{F}_2 + kv$ have FPT recognition algorithms, then we call $(\mathcal{F}_1, \mathcal{F}_2)$ an FPT-*good pair of families*.

▶ **Theorem 1.6.** *Let $(\mathcal{F}_1, \mathcal{F}_2)$ be an* FPT*-good pair of families. Also, let $\mathcal{A}_1$ and $\mathcal{A}_2$ be the best recognition algorithms for $\mathcal{F}_1 + kv$ and $\mathcal{F}_2 + kv$ respectively. For an n-vertex input graph and non-negative integer k, let the running time of $\mathcal{A}_i, i \in \{1, 2\}$, be $T_i(n, k)$. Then $(\mathcal{F}_1, \mathcal{F}_2)$-*p-Partition *on an instance (G, k) can be solved in time $2^{\mathcal{O}(\log^c k)} n^{\mathcal{O}(1)} \cdot \max\{T_1(n, k), T_2(n, k)\}$.*

One could obtain a result analogous to Theorem 1.6 for $(\mathcal{F}_1, \mathcal{F}_2)$-Partition. Some of the problems for which we get faster FPT and exact algorithms are (Clique,Planar)-p-Partition, (Clique,Triangle-free)-p-Partition, (Clique,Forest)-p-Partition and (Clique, Treewidth-t)-p-Partition.

2 Preliminaries

We use $\mathbb{N}$ to denote the set of natural numbers. For $n \in \mathbb{N}$, we use $[n]$ to denote $\{1, \ldots, n\}$. Through out the paper we use n to denote the number of vertices in the graph used in the context. In this paper, the function log is used to denote the logarithm function with *base* 2. We use standard notations from graph theory [5]. The vertex set and edge set of a graph are denoted as $V(G)$ and $E(G)$ respectively. The complement of the graph G is denoted by $\overline{G}$. The *neighbourhood* of a vertex v is represented as $N_G(v)$, or, when the context of the graph is clear, simply as $N(v)$. The *closed neighbourhood* of a vertex v, denoted by $N[v]$, is

subset $N(v) \cup \{v\}$.The *non-neighbourhood* of a vertex v is denoted by $\overline{N}_G(v)$. The *degree* of a vertex v, or the number of neighbours of v, is denoted by $d_G(v)$. Similarly, the *non-degree* of v, or the number of non-neighbours of v, is denoted by $\overline{d}_G(v)$. An *induced subgraph* of G on the vertex set $V' \subseteq V$ is written as $G[V']$. For a vertex subset $V' \subseteq V$, $G[V \setminus V']$ is also denoted as $G - V'$. We denote by $\omega(G)$ the size of a maximum clique in G. Similarly, $\alpha(G)$ denotes the size of a maximum independent set in G. A subgraph G' of G is denoted as $G' \leq_s G$. A complete graph on n vertices is denoted by K_n. A stable graph on n vertices is a graph G with edge set $\emptyset$, and is denoted by $\overline{K}_n$. An *empty graph* is a graph which does not have any vertices, and therefore no edges as well. Given two subgraphs $G_1, G_2 \leq_s G$, $G_1 \cap G_2$ is the induced subgraph $G[V(G_1) \cap V(G_2)]$. Similarly, $G_1 \cup G_2$ denoted the induced subgraph $G[V(G_1) \cup V(G_2)]$. For any positive integers r, ℓ, we use $R(r, \ell)$ to denote the *Ramsey number*. That is, any graph on at least $R(r, \ell)$ vertices will have either a clique of size r or an independent set of size ℓ. A family $\mathcal{F}$ of graphs is said to be *hereditary* if for any graph $G \in \mathcal{F}$, every induced subgraph of G is also contained in $\mathcal{F}$. Let $\mathcal{G}$ be a family of graphs. Then $\mathcal{G} + kv$ contains all graphs G such that there is a vertex set $S \subseteq V(G)$, of size at most k, with the property that the graph $G - S \in \mathcal{G}$.

Informally, a protocol can be thought of as a communication between two players, Alice and Bob. They have decided on some function f and wish to evaluate $f(x, y)$, for some input $x \in X$ and $y \in Y$. The catch is that x is only known to Alice and y is only known to Bob. Now we give a formal definition of a communication protocol.

▶ **Definition 2.1** ([12]). A protocol Π over a domain $X \times Y$ with range Z is a binary tree where each internal node v is labelled either by a function $a_v : X \to \{0, 1\}$ or by a function $b_v : Y \to \{0, 1\}$, and each leaf is labelled with an element $z \in Z$. The value of the protocol Π on an input (x, y) is the label of the leaf reached by starting at the root, and walking along a path in the tree. At each internal node v labelled by a_v, the walk takes left if $a_v(x) = 0$ and right if $a_v(x) = 1$, and at each internal node labelled by b_v, the walk takes left if $b_v(y) = 0$ and right if $b_v(y) = 1$. The cost of the protocol Π on an input (x, y) is the length of the path taken on the input (x, y). The cost of the protocol Π is the height of the binary tree.

▶ **Definition 2.2** ([12]). For a function $f : X \times Y \to Z$, the deterministic communication complexity of f is the minimum cost of Π, over all protocols Π that compute f. We denote the deterministic communication complexity of f by $D(f)$.

For further reading on Communication Complexity, including the concepts of non-deterministic and co-nondeterministic communication complexity of a function, we refer the reader to [12, 13]. One of the first functions, whose communication complexity was studied, is the Disjointness function. For any $x, y \in \{0, 1\}^n$, the function is defined as,

$$\mathsf{DISJ}_n(x, y) = \begin{cases} 0 & \text{if there exists } i \in [n], x[i] = y[i] = 1 \\ 1 & \text{otherwise} \end{cases}$$

▶ **Proposition 2.3** ([12]). $D(\mathit{DISJ}_n) \geq n$

We study a variant of the DISJ_n function, called the Graphic Disjointness function. Let G be a graph on n vertices and m edges. Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be two hereditary graph families. The following function is defined for the graph G, and the families $\mathcal{F}_1, \mathcal{F}_2$ as follows. For any two vertex subsets V_1 and V_2 such that $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$,

$$\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}(V_1, V_2) = \begin{cases} 1 & \text{if } V_1 \cap V_2 = \emptyset \\ 0 & \text{otherwise} \end{cases}$$

A problem, related to that of computing $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, is the problem of enumerating separating families for two graph families.

▶ **Definition 2.4.** Let G be a graph on n vertices, $\mathcal{F}_1$ and $\mathcal{F}_2$ be two graph families. Suppose $\mathcal{F}$ is a family of subsets of $V(G)$ with the following property: If we take any two vertex disjoint induced subgraphs $G_1, G_2 \leq_s G$, such that $G_1 \in \mathcal{F}_1$ and $G_2 \in \mathcal{F}_2$, there is a set $F \in \mathcal{F}$ such that $V(G_1) \subseteq F$ and $V(G_2) \cap F = \emptyset$. Then $\mathcal{F}$ is called an $(\mathcal{F}_1, \mathcal{F}_2)$-separating family in G. Such a set F is called a separating set for G_1 and G_2.

▶ **Observation 2.5.** *Let G be an n-vertex graph. Let G_1, G_2 be induced subgraphs of G. Suppose for each $v \in V(G_1)$, $\overline{d}_G(v) < n/2$ and for each $w \in V(G_2)$, $d_G(w) < n/2$. Then, $V(G_1) \cap V(G_2) = \emptyset$ and $\{v \mid v \in V(G), \overline{d}_G(v) < n/2\}$ is a separating set for G_1 and G_2.*

3 Communication protocols for pairs of Hereditary graph families

To prove Theorem 1.1, we first need to prove a sublinear communication complexity bound for a specific pair of graph families. More formally, in this section we consider a pair of hereditary families of graphs, $\mathcal{C}_r = \{H \mid \alpha(H) \leq r\}$ and $\mathcal{I}_\ell = \{H \mid \omega(H) \leq \ell\}$. Here, r and ℓ are two positive integers. In this section, we consider the communication complexity of $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$. Using this, we complete the proof of Theorem 1.1. In the later half of this Section, we give upper bounds on the communication complexity of the function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, in terms of a structural parameter of the graph G. We consider one such structural parameter and design a protocol with the help of this additional parameter.

3.1 Communication Protocol for Families of Sparse and Dense graphs

As a corollary to Theorem 5 of [10], we obtain the following Lemma:

▶ **Lemma 3.1.** *For any $r, \ell \in \mathbb{N}$, $D(GDISJ_{G,\mathcal{C}_r,\mathcal{I}_\ell}) = \mathcal{O}(R(r+1, \ell+1)\log^2 n)$.*

The protocol designed to show that $D(\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}) = \mathcal{O}(R(r+1,\ell+1)\log^2 n)$ heavily relies on the infinite computational power of both the players (See full version). In this section, we describe a protocol, with much worse communication complexity, but where both players resort to polynomial time computations only. The communication complexity of this protocol is still sublinear in $|V(G)|$. This protocol will be very useful when we design enumeration algorithms for $(\mathcal{C}_r, \mathcal{I}_\ell)$-separating families in Section 4.

We will describe a communication protocol for $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$, with complexity $\mathcal{O}(\log^{r+\ell} n)$, for any $r, \ell \in \mathbb{N}$. Here, Alice receives an induced subgraph G_1 of G such that $G_1 \in \mathcal{C}_r$, and Bob receives an induced subgraph G_2 of G such that $G_2 \in \mathcal{I}_\ell$. They have to determine whether $V(G_1) \cap V(G_2) = \emptyset$ or not. Note that both Alice and Bob receive the graph G.

First, we give a protocol $\Pi_{1,2}$ for $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{I}_2}$, with a cost of $\mathcal{O}(\log^3 n)$. This protocol uses a protocol $\Pi_{1,1}$, for $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{I}_1}$, as a sub-protocol. As mentioned earlier, for any pair of induced subgraphs $C, I \in G$, with $C \in \mathcal{C}_1, I \in \mathcal{I}_1$, $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{I}_1}(C, I) = 1$ if and only if $\mathsf{CIS}_G(C, I) = 0$. The function CIS_G has a deterministic protocol of cost $\mathcal{O}(\log^2 n)$ [16]. Therefore, there is a protocol $\Pi_{1,1}$ of cost $\mathcal{O}(\log^2 n)$ for $\mathsf{GDISJ}_{G,\mathcal{C}_1,\mathcal{I}_1}$. The protocol for the general case $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$ can be designed in a recursive manner that uses protocols of $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_{\ell-1}}$ and $\mathsf{GDISJ}_{G,\mathcal{C}_{r-1},\mathcal{I}_\ell}$ as subprotocols.

▶ **Lemma 3.2.** *For a graph G, there is a deterministic protocol for computing $GDISJ_{G,\mathcal{C}_1,\mathcal{I}_2}$ using $\mathcal{O}(\log^3 n)$ bits and where both players have polynomial computational power.*

Proof sketch. Let Alice get the induced subgraph G_1 and Bob get the induced subgraph G_2. The following is a protocol $\Pi_{1,2}$ that Alice and Bob will execute. Alice and Bob continue with the protocol till either they detect a vertex in the intersection of $V(G_1)$ and $V(G_2)$,

or one of G, G_1 and G_2 becomes an empty graph. The protocol is executed in top down fashion, i.e., the two players resort to a step only if the previous steps are not applicable.

1. If either G_1 or G_2 is an empty graph, then the players declare that the graphs are disjoint.
2. Alice looks for a vertex $v \in V(G_1)$ with $\overline{d}_G(v) \geq n/2$. She sends the vertex v to Bob. If $v \in V(G_2)$, then Bob lets Alice know and they terminate the protocol. Otherwise, both players delete the vertices of $\overline{N}_G(v) \cup \{v\}$ from the graph G to obtain graph $G' = G - (\overline{N}_G(v) \cup \{v\})$. Alice defines $G'_1 = G_1 - \{v\}$ while Bob defines $G'_2 = G_2 - \overline{N}_G(v)$. Then, they continue the protocol for determining whether $V(G'_1) \cap V(G'_2) = \emptyset$ in G'.
3. Bob looks for a vertex $v \in V(G_2)$ with $d_G(v) \geq n/2$. Bob sends the vertex v to Alice. If $v \in V(G_1)$, then Alice lets Bob know and they terminate the protocol. Otherwise, both players use the protocol $\Pi_{1,1}$ to compute $\mathsf{GDISJ}_{G[N_G(v)],\mathcal{C}_1,\mathcal{I}_1}(G[N_G(v) \cap V(G_1)], G[N_G(v) \cap V(G_2)])$. If the output is 0, then they declare that $V(G_1) \cap V(G_2) \neq \emptyset$ and stop. Otherwise, they delete the vertices of $N_G[v]$ from G to get $G' = G - N_G[v]$. Alice defines $G'_1 = G_1 - N_G[v]$ while Bob defines $G'_2 = G_2 - N_G[v]$. Then, they continue the protocol for determining whether $V(G'_1) \cap V(G'_2) = \emptyset$ in G'.
4. Suppose all the above steps fails, then, both players declare that $V(G_1) \cap V(G_2) = \emptyset$.

The full proof is given in the full version of this paper. ◀

▶ **Corollary 3.3.** *For any graph G, there is a deterministic protocol for $\mathsf{GDISJ}_{G,\mathcal{C}_2,\mathcal{I}_1}$ using $\mathcal{O}(\log^3 n)$ bits, where both players have polynomial computational power.*

We can give a protocol $\Pi_{r,\ell}$, for the problem $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$, of cost $\mathcal{O}(\log^{r+\ell} n)$, using a protocol for $\Pi_{r,\ell-1}$ or $\Pi_{r-1,\ell}$. We use similar arguments as in the protocol $\Pi_{1,2}$, to design the protocol $\Pi_{r,\ell}$. Thus, we can prove the following theorem using induction on $r + \ell$.

▶ **Lemma 3.4.** *For $r, \ell \in \mathbb{N}$ and graph G, there is a deterministic protocol for $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$ using $\mathcal{O}(\log^{r+\ell} n)$ bits and where both players have polynomial computational power.*

3.2 Characterization for Hereditary graph families

We are ready to prove Theorem 1.1. That is, we try to determine $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2})$ for any given pair of hereditary families $\mathcal{F}_1, \mathcal{F}_2$. If one of $\mathcal{F}_1$ or $\mathcal{F}_2$ is finite, then the number of vertices of each graph in one of the families is bounded by a constant. Thus, a trivial protocol would be for the player, who receives the bounded-sized subgraph, to send the full subgraph over to the other player, using $\mathcal{O}(\log n)$ bits. This implies, $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}) = \mathcal{O}(\log n)$. So, the interesting case is when both $\mathcal{F}_1$ and $\mathcal{F}_2$ are infinite. Now we prove Theorem 1.1.

Proof of Theorem 1.1. Without loss of generality we can assume that both $\mathcal{F}_1$ and $\mathcal{F}_2$ are infinite. Suppose the intersection family is finite. This means that there is a constant r such that a complete graph K_r, on r vertices, does not belong to the intersection family, because of finiteness. Since K_r does not belong to $\mathcal{F}_1 \cap \mathcal{F}_2$, it must not belong to at least one of the families. Let this be $\mathcal{F}_1$. Since $\mathcal{F}_1$ is hereditary, no graph in $\mathcal{F}_1$ has K_r as an induced subgraph. This implies that for any graph G in $\mathcal{F}_1$, $\omega(G) \leq r - 1$. Now we show that for any graph G in $\mathcal{F}_2$, $\alpha(G) \leq \ell - 1$ for some constant ℓ. Towards that, we first claim that $\mathcal{F}_1$ contains all stable graphs. Otherwise, since $\mathcal{F}_1$ is a hereditary family, if $\mathcal{F}_1$ does not contain a stable graph on ℓ' vertices, all graphs in $\mathcal{F}_1$ neither have a r-sized clique as an induced subgraph nor an ℓ'-sized independent set as an induced subgraph. However, by Ramsey's theorem, each graph in $\mathcal{F}_1$ has at most $R(r, \ell')$ vertices, thus contradicting the infiniteness of $\mathcal{F}_1$. So far we know that, $\mathcal{F}_1 \cap \mathcal{F}_2$ is finite and $\mathcal{F}_1$ contains all stable graphs. This implies that $\mathcal{F}_2$ does not contain all stable graphs. Let ℓ be an integer such that $\overline{K}_\ell \notin \mathcal{F}_2$. By the

hereditary property of $\mathcal{F}_2$, no graph in $\mathcal{F}_2$ contains $\overline{K}_\ell$ as an induced subgraph. That is, for all graph G in $\mathcal{F}_2$, $\alpha(G) \leq \ell - 1$. Thus, Lemma 3.1 gives us a deterministic protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, with $o(n)$ communication complexity.

For the reverse direction, suppose $\mathcal{F}_1 \cap \mathcal{F}_2$ is an infinite family. To prove $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}) = \Omega(n)$ we give a simple reduction from DISJ_n. In DISJ_n, Alice is given $x \in \{0,1\}^n$ and Bob is given $y \in \{0,1\}^n$ and they want to check whether there is an $i \in [n]$ such that $x[i] = y[i] = 1$. Now we create an instance of $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ as follows. We fix an n-vertex graph $G \in \mathcal{F}_1 \cap \mathcal{F}_2$ (such a graph exists because of hereditary property), with $V(G) = \{v_1, \ldots, v_n\}$. Let $V_x = \{v_i \in V(G) \mid i \in [n], x[i] = 1\}$ and $V_y = \{v_i \in V(G) \mid i \in [n], y[i] = 1\}$. Since $G \in \mathcal{F}_1 \cap \mathcal{F}_2$, $G[V_x] \in \mathcal{F}_1$ and $G[V_y] \in \mathcal{F}_2$. In the $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ problem, Alice gets $G[V_x]$ and Bob gets $G[V_y]$. Clearly $V_x \cap V_y \neq \emptyset$ if and only if there is an $i \in [n]$ such that $x[i] = y[i] = 1$. Hence, by Proposition 2.3, $D(\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}) = \Omega(n)$. ◀

For the rest of this paper, a pair $(\mathcal{F}_1, \mathcal{F}_2)$ of hereditary graph families where $\mathcal{F}_1 \cap \mathcal{F}_2$ is a finite graph family, will be referred to as a *good pair of graph families*. The proof of Theorem 1.1 also gives us the following folklore corollary.

▶ **Corollary 3.5.** *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families. Then, there are constants r and ℓ, such that for any graph $G_1 \in \mathcal{F}_1$ and $G_2 \in \mathcal{F}_2$, $\omega(G_1) \leq r$ and $\alpha(G_2) \leq \ell$.*

Corollary 3.5 and Ramsey theorem leads us to another useful corollary.

▶ **Corollary 3.6.** *Let G be a graph. Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families. Then there are constant r and ℓ (same as the constants mentioned in Corollary 3.5) such that, for any pair (G_1, G_2) of induced subgraphs of G, if $G_1 \in \mathcal{F}_1$ and $G_2 \in \mathcal{F}_2$, then $|V(G_1) \cap V(G_2)| < R(r+1, \ell+1)$.*

3.3 A Parameterized approach to designing protocols

In Section 3.1, for each pair of constants r, ℓ, we saw a protocol for $\mathsf{GDISJ}_{G,\mathcal{C}_r,\mathcal{I}_\ell}$ with sublinear communication complexity. We also showed that any good pair $(\mathcal{F}_1, \mathcal{F}_2)$ of graph families must be such that there are constants r, ℓ with $\mathcal{F}_1 \subseteq \mathcal{C}_r, \mathcal{F}_2 \subseteq \mathcal{I}_\ell$. In this section, we give an alternate protocol that uses the structure of the input graph G, to obtain a more refined upper bound on the communication complexity of $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$. For a graph, let $\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}$ denote the size of a minimum set S of vertices such that $V(G) \setminus S$ has a bipartition (V_1, V_2) with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. In this section, for a graph G and a good pair of graph families $(\mathcal{F}_1, \mathcal{F}_2)$, we give a protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ that has $\mathcal{O}(\log^2(\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}) + \log n)$ communication complexity.

Proof of Theorem 1.2. We can assume that Alice and Bob both have a minimum vertex set S such that $V(G) \setminus S$ has a bipartition (V_1, V_2) with $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. Thus $|S| = \mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}$. The players also have a bipartition (V_1, V_2) of $V(G) \setminus S$, such that $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$.

Now let Alice receive the induced subgraph $G_1 \in \mathcal{F}_1$ and Bob receive the induced subgraph $G_2 \in \mathcal{F}_2$. The following is a protocol Π that Alice and Bob will execute. The protocol is executed in top down fashion, i.e., the two players resort to a step only if the previous steps are not applicable.

1. If either G_1 or G_2 is an empty graph, then they declare that the graphs are disjoint.
2. Alice and Bob run the protocol $\Pi_{r,\ell}$ to compute $\mathsf{GDISJ}_{G[S],\mathcal{C}_r,\mathcal{I}_\ell}(G_1[S], G_2[S])$. If there is a vertex intersection between $G_1[S]$ and $G_2[S]$, then they declare that the graphs G_1 and G_2 intersect and stop the protocol.

3. Suppose there is no vertex intersection between $G_1[S]$ and $G_2[S]$. Alice sends the vertices of the subgraph $G_1 \cap G[V_2]$ to Bob. If Bob finds that $V(G_2) \cap V(G_1 \cap G[V_2]) \neq \emptyset$, then Bob lets Alice know and they terminate the protocol.
4. Suppose Bob does not find any vertex common to both $V(G_1 \cap G[V_2])$ and $V(G_2)$. Then Bob sends the vertices of the subgraph $G_2 \cap G[V_1]$ to Alice. If Alice finds that $V(G_1) \cap V(G_2 \cap G[V_2]) \neq \emptyset$, then Alice lets Bob know and they terminate the protocol.

Otherwise, they declare that the two graphs G_1 and G_2 do not intersect on any vertex. If $V(G_1[S]) \cap V(G_2[S]) \neq \emptyset$, then the subprotocol $\Pi_{r,\ell}$ correctly detects the intersection in step 2. Otherwise, $V(G_1)$ and $V(G_2)$ can intersect either in V_1 or in V_2 and they detect in step 3 or step 4. If neither of the above cases happen, then $V(G_1) \cap V(G_2) = \emptyset$.

Next, we show the bound on the communication complexity. Following from Lemma 3.1, $\mathsf{GDISJ}_{G[S],\mathcal{C}_r,\mathcal{I}_\ell}(G_1[S], G_2[S])$ can be computed with the communication of $\mathcal{O}(\log^2 \mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2})$ bits. By definition, $G_1 \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. Then, by Corollary 3.6, $|V(G_1) \cap V(G[V_2])| < R(r+1, \ell+1)$. Thus, in step 3, Alice sends at most $R(r+1,\ell+1)\log n$ bits to Bob. By a similar argument, in step 4, Bob sends at most $R(r+1,\ell+1)\log n$ bits to Alice. Therefore, the communication complexity of Π is $\mathcal{O}(\log^{r+\ell}(\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}) + \log n)$. ◀

Suppose $(\mathcal{F}_1, \mathcal{F}_2)$ is a pair of hereditary graph families that are not good. By Theorem 1.1, for an n-vertex graph G, any protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ must have communication complexity $\Omega(n)$. This gives us the following corollary.

▶ **Corollary 3.7.** *Let $(\mathcal{F}_1, \mathcal{F}_2)$ be a pair of hereditary graph families that have infinitely many graphs in their intersection. Then, for each integer $n > 0$, there is a graph G such that for any computable function f, there cannot be a protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, that has communication complexity $f(\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}) + o(n)$.*

4 Separating families

In this section, we design enumeration algorithms for separating families for a good pair of graph families. It was stated in [13] that a non-deterministic protocol for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ corresponds to a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family. This means that if $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$ has deterministic, and hence non-deterministic, complexity c, then there exists a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family of size 2^c. From Corollary 3.5 and Lemma 3.1, this means that, for an n-vertex graph, there exists a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family of size $2^{\mathcal{O}(\log^2 n)}$, for any constants r, ℓ. However, since the protocols use players with unlimited power of computation, this does not mean that there is an enumeration algorithm that finds such a separating family in time $2^{\mathcal{O}(\log^2 n)} n^{\mathcal{O}(1)}$. First, for an n-vertex graph G, we design an algorithm to enumerate a $(\mathcal{C}_r, \mathcal{I}_\ell)$-separating family of size $2^{\mathcal{O}(\log^{r+\ell} n)}$, in time $2^{\mathcal{O}(\log^{r+\ell} n)} n^{\mathcal{O}(1)}$. This uses ideas from the protocol given in Lemma 3.4. Then, for a good pair $(\mathcal{F}_1, \mathcal{F}_2)$ of graph families, we utilize the structure of G, for a different approach to design enumeration algorithms for $(\mathcal{F}_1, \mathcal{F}_2)$-separating families.

▶ **Lemma 4.1.** *For any $r, \ell \in \mathbb{N}$, every graph with n vertices has a $(\mathcal{C}_r, \mathcal{I}_\ell)$-separating family of cardinality $2^{\mathcal{O}(\log^{r+\ell} n)}$. Moreover, such a family can be enumerated in time $2^{\mathcal{O}(\log^{r+\ell} n)}$.*

Lemma 4.1 and Corollary 3.5 gives us the following Corollary.

▶ **Corollary 4.2.** *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families. Then, there are constants r and ℓ, such that every n-vertex graph has a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family of cardinality $2^{\mathcal{O}(\log^{r+\ell} n)}$ and it can be enumerated in time $2^{\mathcal{O}(\log^{r+\ell} n)}$.*

In fact, we obtain Theorem 1.4 from Lemma 4.1 and Corollary 3.5.

Separating families and parameterization

We give the proof of Theorem 1.5. We show that the upper bound obtained due to Corollary 4.2 can be improved if we use ideas from Parameterized Complexity, as we did for Theorem 1.2. This is extremely useful for designing FPT algorithms. Again, the ideas from the protocol of Lemma 3.4 comes to more use than the protocol of Lemma 3.1. To show this, we first prove the following lemma.

▶ **Lemma 4.3.** *Let $(\mathcal{F}_1, \mathcal{F}_2)$ be a good pair of graph families. Given, as input, $G, S \subseteq V(G)$ and partition $V_1 \uplus V_2$ of $V(G) \setminus S$ such that $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$, there is an algorithm to enumerate $(\mathcal{F}_1, \mathcal{F}_2)$-separating family $\mathcal{S}$ for G of cardinality $2^{\mathcal{O}(\log^c(|S|))}n^{\mathcal{O}(1)}$ in time $2^{\mathcal{O}(\log^c(|S|))}n^{\mathcal{O}(1)}$, where c is a constant.*

Proof. We know that $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. Since $(\mathcal{F}_1, \mathcal{F}_2)$ is a good pair of graph families, by Corollary 3.5, we know that there are constants r, ℓ, such that for any $G_1 \in \mathcal{F}_1$ and $G_2 \in \mathcal{F}_2$, $\omega(G_1) \leq r$ and $\alpha(G_2) \leq \ell$. Let us define $c = r + \ell$. By Lemma 4.1, the graph $G[S]$ has a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family $\mathcal{S}'$ of cardinality $2^{\mathcal{O}(\log^{r+\ell}|S|)}$. Moreover, such a family can be enumerated in time $2^{\mathcal{O}(\log^{r+\ell}(|S|))}$. Now consider the family.

$$\mathcal{S} = \left\{A \cup (V_1 \setminus S_1) \cup S_2 \mid A \in \mathcal{S}', S_1 \subseteq V_1, S_2 \subseteq V_2, |S_1| < R(r+1, \ell+1), |S_2| < R(r+1, \ell+1)\right\}$$

The cardinality of $\mathcal{S}$ is bounded by $2^{\mathcal{O}(\log^c(|S|))}n^{\mathcal{O}(2R(r+1,\ell+1))}$ and it can be enumerated in time $2^{\mathcal{O}(\log^c(|S|))}n^{\mathcal{O}(2R(r+1,\ell+1))}$. We show that $\mathcal{S}$ is indeed a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family for G. Consider any disjoint vertex subsets U_1 and U_2 of $V(G)$ such that $G[U_1] \in \mathcal{F}_1$ and $G[U_2] \in \mathcal{F}_2$. We need to show that there is a set $T \in \mathcal{S}$ such that $U_1 \subseteq T$ and $T \cap U_2 = \emptyset$. Since the two families $\mathcal{F}_1$ and $\mathcal{F}_2$ are hereditary, $G[U_1 \cap S] \in \mathcal{F}_1$ and $G[U_2 \cap S] \in \mathcal{F}_2$. Since $\mathcal{S}'$ is a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family for $G[S]$ there is a set $A \in \mathcal{S}'$ such that $S \cap U_1 \subseteq A$ and $(S \cap U_2) \cap A = \emptyset$. Since $G[U_1], G[V_1] \in \mathcal{F}_1$ and $G[U_2], G[V_2] \in \mathcal{F}_2$, by Corollary 3.6, we know that $|U_1 \cap V_2| < R(r+1, \ell+1)$ and $|U_2 \cap V_1| < R(r+1, \ell+1)$. Now consider the set $T = A \cup (V_1 \setminus (U_2 \cap V_1)) \cup (U_1 \cap V_2)$. Since $|U_1 \cap V_2| < R(r+1, \ell+1)$ and $|U_2 \cap V_1| < R(r+1, \ell+1)$, by the definition of $\mathcal{S}$, $T \in \mathcal{S}$. Notice that $U_1 \subseteq T$ and $U_2 \cap T = \emptyset$. Hence, we are done. ◀

Lemma 4.3 gives us Theorem 1.5. Suppose there was an approximation algorithm $\mathcal{A}$ for $(\mathcal{F}_1, \mathcal{F}_2)$-Partition, where the approximation factor is defined by a computable function f depending only on the size of an optimal solution, and let the running time of $\mathcal{A}$ be $T(n)$ on an n-vertex input graph. Then, a $(\mathcal{F}_1, \mathcal{F}_2)$-seperating family, for G, of cardinality $2^{\mathcal{O}(\log^c f(\mathsf{opt}^G_{\mathcal{F}_1,\mathcal{F}_2}))}n^{\mathcal{O}(1)}$ can be enumerated in time $2^{\mathcal{O}(\log^c f(\mathsf{opt}))}n^{\mathcal{O}(1)}$, where c is the same constant as in Theorem 1.5, which is at most $r + \ell$.

5 Applications in Parameterized and Exact Algorithms

In this section we relate the results obtained in previous sections to exact and FPT algorithms. The main result of this section is to show that the $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition problem is FPT. In fact, we propose an algorithm strategy that might result in faster running times than that of the best known algorithms for certain pairs $(\mathcal{F}_1, \mathcal{F}_2)$. We also provide combinatorial bounds on the number of maximal induced subgraphs that have a vertex bipartition (A, B), where $G[A] \in \mathcal{F}_1$ and $G[B] \in \mathcal{F}_2$. We also give a strategy to design an enumeration algorithm for all such maximal induced subgraphs. Similarly, we can find the maximum(minimum) size of such an induced subgraph. These results and their corollaries can be found in the full version of the paper.

Parameterized Algorithms

The question of what is the maximum size of an induced subgraph, that has a vertex bipartition (A, B) with $G[A] \in \mathcal{F}_1$ and $G[B] \in \mathcal{F}_2$, brings us to the question of how 'far' a graph is from becoming a graph with the desired bipartition. The $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition problem addresses this question. In this part, we look at this problem and a technique to solve this problem, when the pair of families are a good pair of families. The technique we use is an adaptation of the popular iterative compression technique.

▶ **Observation 5.1.** *If an instance (G, k) is a* YES *instance of $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition, then for any induced subgraph $G' \leq_s G$, (G', k) is also a* YES *instance of $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition.*

Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families, and for any positive integer k, the families $\mathcal{F}_1 + kv$ and $\mathcal{F}_2 + kv$ have FPT recognition algorithms, that is, there are algorithms which take as input a graph G and an integer k, decides whether $G \in \mathcal{F}_i + kv, i \in \{1, 2\}$ and runs in time $f(k)|V(G)|^{\mathcal{O}(1)}$. For ease of notation, if $\mathcal{F}_1$ and $\mathcal{F}_2$ be a good pair of graph families, and the families $\mathcal{F}_1 + kv$ and $\mathcal{F}_2 + kv$ have FPT recognition algorithms, then we call $(\mathcal{F}_1, \mathcal{F}_2)$ an FPT-*good pair of families*.

We obtain a fast FPT algorithm for $(\mathcal{F}_1, \mathcal{F}_2)$-p-Partition, as claimed in Theorem 1.6 by incorporating the iterative compression technique. For more details about the algorithmic technique of iterative compression we refer to the book (chapter 4 [3]).

Proof Sketch for Theorem 1.6. Let (G, k) be an input instance. The algorithm is based on the iterative compression technique. Due to Observation 5.1, the iterative compression technique is meaningful for this problem. The iteration step is exactly as described in [3](chapter 4). The description of the compression problem and an algorithm to solve the same is given below.

The input of the compression problem is a graph G' and a vertex set $S \subseteq V(G')$, of size at most $k + 1$. The set S satisfies the property that there is a partition $V_1 \uplus V_2$ of $V(G) \setminus S$ such that $G[V_1] \in \mathcal{F}_1$ and $G[V_2] \in \mathcal{F}_2$. The compression problem outputs YES if there is a vertex set S' of size at most k such that there is a partition $V_1' \uplus V_2'$ of $V(G) \setminus S'$ with $G[V_1'] \in \mathcal{F}_1$ and $G[V_2'] \in \mathcal{F}_2$. Otherwise, the output is NO. Lemma 4.3 can be used to solve the compression problem in time $2^{\mathcal{O}(\log^c k)} n^{\mathcal{O}(1)} \cdot 2k \max\{T_1(n, k), T_2(n, k)\}$.

By Lemma 4.3, we know that there is an enumeration algorithm which outputs a $(\mathcal{F}_1, \mathcal{F}_2)$-separating family $\mathcal{S}$ of cardinality $2^{\mathcal{O}(\log^c |S|)} n^{\mathcal{O}(1)}$ in time $2^{\mathcal{O}(\log^c |S|)} n^{\mathcal{O}(1)}$. Now for each $S \in \mathcal{S}$ and each pair of non-negative integers k_1, k_2 such that $k_1 + k_2 \leq k$, we run $\mathcal{A}_1$ on $(G[S], k_1)$ and $\mathcal{A}_2$ on $(G - S, k_2)$. We output YES if both $\mathcal{A}_1$ and $\mathcal{A}_2$ outputs YES. Otherwise our algorithm will output NO. The full proof is in the full version of the paper. ◀

There are several corollaries of Theorem 1.6, to be found in the full version.

6 Conclusion

In this paper, we studied the parameterized communication complexity of the function $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$. We also obtained separating families for good pairs of families, and used them to give combinatorial bounds, exact algorithms and FPT algorithms. An important question here is to see if the lower bounds for CIS_G can be used to obtain non-trivial lower bounds for $\mathsf{GDISJ}_{G,\mathcal{F}_1,\mathcal{F}_2}$, when $(\mathcal{F}_1, \mathcal{F}_2)$ is a good pair of graph families. Also, it would be interesting to study the communication complexity of these functions in terms of other parameters of the input. We would like to thank Pranabendu Misra and an anonymous reviewer for insightful comments.

Abstract

We introduce a new logic called Monitor Logic and show that it is expressively equivalent to Quantitative Monitor Automata.

1998 ACM Subject Classification F.4.1 Mathematical Logic

Keywords and phrases Quantitative Monitor Automata, Nested Weighted Automata, Monitor Logics, Weighted Logics

1 Introduction

In the last years, there has been increasing interest in quantitative features of the specification and analysis of systems. Such quantitative aspects include the consumption of a certain resource or the output of a benefit. Both weighted automata and weighted logics [7] are means to achieve this quantitative description of systems. They can be employed for both finite and infinite input.

Very recently, Chatterjee et al. introduced a new automaton model operating on infinite words [4]. *Quantitative Monitor Automata* are equipped with a finite number of monitor counters. At each transition, a counter can be started, terminated, or the value of the counter can be increased or decreased. The term "monitor" stems from the fact that the values of the counters do not influence the behavior of the automaton. The values of the counters when they are terminated provide an infinite sequence of weights, which is evaluated into a single weight using a *valuation function*.

Quantitative Monitor Automata possess several interesting features. They are expressively equivalent to a subclass of *Nested Weighted Automata* [3], an automaton model which for many valuation functions has decidable emptiness and universality problems. Quantitative Monitor Automata are also very expressive. As an example, imagine a storehouse with a resource which is restocked at regular intervals. Between restocks, demands can remove one unit of this resource at a time. Such a succession of restocks and demands can be modeled as an infinite sequence over the alphabet $\{\mathsf{restock}, \mathsf{demand}\}$. Interesting quantitative properties of such a sequence include the long-term average demand, the minimum demand and the maximum demand between restocks. These properties can be described using Quantitative Monitor Automata. At every restock a counter is started, counting the number of demands until the next restock. An appropriate valuation function then computes the desired property. For the average demand, this can be achieved with the *Cesàro mean* which was introduced to automata theory by Chatterjee et. al in [2]. Note that behaviors like these cannot be

* This work was supported by Deutsche Forschungsgemeinschaft (DFG), Graduiertenkolleg 1763 (QuantLA).

modeled using *weighted Büchi-automata* [11, 12] or their extension with valuation functions [8]. In the latter model, the Cesàro mean of any sequence is bounded by the largest transition weight in the automaton. This is not the case for Quantitative Monitor Automata.

In this paper, we develop a logic which is expressively equivalent to Quantitative Monitor Automata. Our main results are the following.

- We introduce a new logic which we call *Monitor Logic*.
- We show that this Monitor Logic is expressively equivalent to Quantitative Monitor Automata.
- We show various closure properties of Quantitative Monitor Automata and prove that Muller and Büchi acceptance conditions provide the same expressive power.

The relationship between automata and logics plays a large role in specification and verification. Statements are often easier to formulate in the form of a logic formula rather than directly as an automaton. Consequently, the fundamental Büchi-Elgot-Trakhtenbrot Theorem [1, 10, 17], which established the coincidence of regular languages with languages definable in monadic second order logic, has found use in many areas of application. An extension to semiring weighted automata was later given by Droste and Gastin [6].

Our logic is equipped with three quantifiers. A sum quantifier to handle the computations on the counters, a valuation quantifier to handle the valuation, and a third quantifier to combine the weights of all runs on a word. Our biggest challenge was to find appropriate restrictions on the use of the quantifiers. Without any restrictions the logic would be too powerful, which we also formally prove using counter examples. The most important result of our considerations is that the computations of the sum quantifier should depend on an MSO-definable condition.

We note that our constructions are effective. Given a formula from our logic, we can effectively construct a Quantitative Monitor Automaton describing this formula. Conversely, for every automaton we can effectively construct a formula with the automaton's behavior.

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$ denote the natural numbers, $\mathbb{Z}$ the integers and $\mathbb{R}$ the reals. An alphabet Σ is a finite set. An infinite word over Σ is a sequence $w = a_0 a_1 a_2 \ldots$ from Σ. The set of infinite words over Σ is denoted by Σ^ω. The set of finite words Σ^* over Σ is defined as the set of finite sequences $a_0 a_1 \ldots a_n$ from Σ. The empty word is denoted by ε. A mapping $\Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ is called a *series*.

A *(nondeterministic) Muller automaton over* Σ (NMA) is a tuple $\mathcal{A} = (\Sigma, Q, q_0, \mathcal{F}, \delta)$ where (1) Σ is an alphabet, (2) Q is a finite set of states, (3) $q_0 \in Q$ is the initial state, (4) $\mathcal{F} \subseteq \mathcal{P}(Q)$ is the set of final sets and (5) $\delta \subseteq Q \times \Sigma \times Q$ is the set of transitions.

Let $a_0 a_1 \ldots \in \Sigma^\omega$ be an infinite word. A *run of* $\mathcal{A}$ *over* w is an infinite sequence of transitions $r_w = (t_i)_{i \geq 0}$ so that $t_i = (q_i, a_i, q_{i+1}) \in \delta$ for all $i \geq 0$. We denote by $\mathrm{In}^Q(r_w)$ the set of states which appear infinitely many times in r_w, i.e.

$$\mathrm{In}^Q(r_w) = \{q \in Q \mid \forall i \exists j \geq i : t_j = (q, a_j, q_{j+1})\}.$$

A run r_w of $\mathcal{A}$ over $w \in \Sigma^\omega$ is called *accepting* if $\mathrm{In}^Q(r_w) \in \mathcal{F}$, that is, if the states which appear infinitely many times in r_w form a set in $\mathcal{F}$. In this case we say that w is *recognized (accepted) by* $\mathcal{A}$. The set of accepting runs over a word $w \in \Sigma^\omega$ is denoted by $\mathrm{Acc}_{\mathcal{A}}(w)$. The *infinitary language* of $\mathcal{A}$, denoted by $\mathcal{L}_\omega(\mathcal{A})$, is the set of all infinite words that are accepted by $\mathcal{A}$. A language $L \subseteq \Sigma^\omega$ is called ω-recognizable if there is a Muller automaton $\mathcal{A}$ so that $L = \mathcal{L}_\omega(\mathcal{A})$.

A Muller automaton $\mathcal{A} = (\Sigma, Q, q_0, \mathcal{F}, \delta)$ is called *deterministic* if the set of transitions δ can be interpreted as a function $Q \times A \to Q$, i.e. if for every $(p, a) \in Q \times A$ there exists exactly one $q \in Q$ with $(p, a, q) \in \delta$. It is well known and will be important to us that for each Muller automaton $\mathcal{A}$, we can effectively construct a deterministic Muller automaton with the same language [15, 16].

3 Quantitative Monitor Automata

An *ω-valuation function* is a mapping $\mathrm{Val}\colon \mathbb{Z}^{\mathbb{N}} \to \mathbb{R} \cup \{\infty\}$ that assigns real values or ∞ to infinite sequences of integers. Typical examples of such functions are the Cesàro mean

$$\textsc{Ces}((z_i)_{i\geq 0}) = \begin{cases} \lim_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} z_i & \text{if this limit exists} \\ \infty & \text{otherwise,} \end{cases}$$

the supremum $\textsc{Sup}((z_i)_{i\geq 0}) = \sup_{i\geq 0} z_i$, the infimum $\textsc{Inf}((z_i)_{i\geq 0}) = \inf_{i\geq 0} z_i$, the limit superior $\textsc{LimSup}((z_i)_{i\geq 0}) = \lim_{n\to\infty} \sup_{i\geq n} z_i$ and the limit inferior $\textsc{LimInf}((z_i)_{i\geq 0}) = \lim_{n\to\infty} \inf_{i\geq n} z_i$.

For a new symbol $\mathbb{1}$ and an ω-valuation function Val, we extend the domain of Val to sequences $\mathbf{z} = (z_i)_{i\geq 0}$ from $\mathbb{Z} \cup \{\mathbb{1}\}$ as follows. If at some point $\mathbf{z}$ becomes constantly $\mathbb{1}$, we let $\mathrm{Val}(\mathbf{z}) = \infty$. Otherwise we let $\mathbf{z}'$ be the subsequence of $\mathbf{z}$ which contains all elements that are not $\mathbb{1}$ and define $\mathrm{Val}(\mathbf{z}) = \mathrm{Val}(\mathbf{z}')$.

We now define Quantitative Monitor Automata. We use a different name, however, in order to distinguish between Büchi and Muller acceptance conditions.

A *Büchi automaton with monitor counters* (BMCA) $\mathcal{A}$ is a tuple $(\Sigma, Q, I, F, \delta, n, \mathrm{Val})$ where (1) Σ is the alphabet, (2) Q is a finite set of states, (3) $I \subseteq Q$ is the set of initial states, (4) F is the set of accepting states, (5) δ is a finite subset of $Q \times \Sigma \times Q \times (\mathbb{Z} \cup \{s, t\})^n$, called the transition relation, such that for every $(q, a, q', \mathbf{u}) \in \delta$ at most one component of $\mathbf{u}$ contains s, (6) n is the number of counters and (7) Val is an ω-valuation function.

Intuitively, the meaning of a transition $(q, a, q', \mathbf{u})$ is that if the automaton is in state q and reads an a, it can move to state q' and start counter j if $u^j = s$, add u^j to the current value of counter j if this counter is activated and $u^j \in \mathbb{Z}$, or stop counter j if $u^j = t$. Initially, all counters are inactive. We will also call $\mathcal{A}$ an n-BMCA or a Val-BMCA, thereby stressing the number of counters or the ω-valuation function used.

Let $a_0 a_1 \ldots \in \Sigma^\omega$ be an infinite word. A *run of $\mathcal{A}$ over w* is an infinite sequence of transitions $r_w = (t_i)_{i\geq 0}$ so that $t_i = (q_i, a_i, q_{i+1}, \mathbf{u}_i) \in \delta$ for all $i \geq 0$.

A run r_w of $\mathcal{A}$ over $w \in \Sigma^\omega$ is called *accepting* if (1) $q_0 \in I$, (2) $\mathrm{In}^Q(r_w) \cap F \neq \emptyset$, (3) if $u_i^j = s$ for some $i \geq 0$, then there exists $l > i$ such that $u_l^j = t$ and for all $k \in \{i+1, \ldots, l-1\}$ we have $u_k^j \in \mathbb{Z}$, (4) if $u_i^j = t$ for some $i \geq 0$, then there exists $l < i$ such that $u_l^j = s$ and for all $k \in \{l+1, \ldots, i-1\}$ we have $u_k^j \in \mathbb{Z}$ and (5) infinitely often some counter is activated, i.e.

$$\{i \geq 0 \mid u_i^j = s \text{ for some } j\}$$

is an infinite set. The set of accepting runs over a word $w \in \Sigma^\omega$ is denoted by $\mathrm{Acc}_{\mathcal{A}}(w)$.

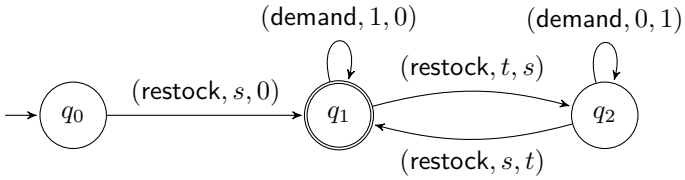
An accepting run r_w defines a sequence $\mathbf{z} = (z_i)_{i\geq 0}$ from $\mathbb{Z} \cup \{\mathbb{1}\}$ as follows. If $u_i^j = s$ for some $j \in \{1, \ldots, n\}$ and $l > i$ is such that $u_l^j = t$ and for all $k \in \{i+1, \ldots, l-1\}$ we have $u_k^j \in \mathbb{Z}$, then $z_i = \sum_{k=i+1}^{l-1} u_k^j$. If $u_i^j \neq s$ for all $j \in \{1, \ldots, n\}$, then $z_i = \mathbb{1}$. We also call $\mathbf{z}$ the *weight-sequence associated to r_w*. The weight of the run r_w is defined as $\mathrm{Val}(r_w) = \mathrm{Val}(\mathbf{z})$. The behavior of the automaton $\mathcal{A}$ is the series $[\![\mathcal{A}]\!]\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$

defined by $[\![\mathcal{A}]\!](w) = \inf_{r_w \in \mathrm{Acc}(w)} \mathrm{Val}(r_w)$, where the infimum over the empty set is defined as ∞. A series $\Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ is called *MC-recognizable* if there exists a BMCA $\mathcal{A}$ such that $[\![\mathcal{A}]\!] = S$. The notions of *n-MC-recognizable* and Val-*MC-recognizable* are defined likewise.

A *Muller automaton with monitor counters* (MMCA) is defined like a BMCA, but instead of a set of accepting states we have a set of accepting sets $\mathcal{F} \subseteq \mathcal{P}(Q)$. The condition (2) for a run r_w on a word $w \in \Sigma^\omega$ to be accepting is then replaced by $\mathrm{In}^Q(r_w) \in \mathcal{F}$, i.e. a Muller acceptance condition.

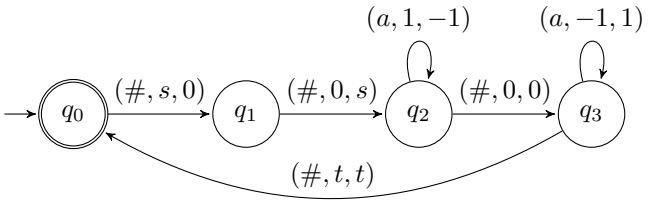
Büchi automata with monitor counters use a Büchi acceptance condition, i.e. at least one accepting state has to appear infinitely often. Lemma 3 shows that using a Muller acceptance condition does not influence the expressive power.

▶ **Example 1.** Consider the the alphabet $\Sigma = \{\mathsf{demand}, \mathsf{restock}\}$ with the ω-valuation function Val = Ces. We model a storehouse with some sort of supply that is restocked whenever restock is encountered, and one unit of the supply is removed at every demand. Given an infinite sequence of restocks and demands, we are interested in the long-time average demand between restocks. Under the assumption that every such sequence starts with a restock, this behavior is modeled by the following automaton with two monitor counters.



When for the valuation function we take Inf or Sup, the automaton above describes the lowest or highest demand ever encountered, for the latter assuming that the demands are bounded.

▶ **Example 2** ([4])**.** Consider the alphabet $\Sigma = \{a, \#\}$ and the language L consisting of words $(\#^2 a^* \# a^* \#)^\omega$. On these words, we consider the quantitative property "the maximal block-length difference between even and odd positions", i.e. the value of the word $\#\#a^{m_1}\#a^{m_2}\#\#\#\ldots$ shall be $\sup_{i \geq 1} |m_{2i-1} - m_{2i}|$. With the choice Val = Sup, a BMCA realizing this behavior is the following.



Each $(\#^2 a^{m_1} \# a^{m_2} \#)$-block is processed by starting both counters on the first two #'s, accumulating m_1 into the first counter and accumulating $-m_1$ into the second, reading #, then accumulating $m_1 - m_2$ into the first counter and $-m_1 + m_2$ into the second, and finally terminating both counters on the last #. Thus, the associated weight-sequence for only this block is $(m_1 - m_2, -m_1 + m_2, \mathbb{1}, \ldots, \mathbb{1})$. Clearly, the final value of counter one is always the negative of the final value in counter two. Since our ω-valuation function is Sup, only the positive counter value actually plays a role in the value assigned to the whole word, and this positive value is $|m_1 - m_2|$.

In the rest of this section, we prove various closure properties for automata with monitor counters and that BMCA and MMCA have the same expressive power.

▶ **Lemma 3.** *Büchi automata with monitor counters are expressively equivalent to Muller automata with monitor counters.*

Proof. The proof is similar to the standard construction to show that Büchi automata are expressively equivalent to Muller automata, see for example [9]. ◀

The next lemma shows that MC-recognizable series are closed under projections and their preimage. Given two alphabets Σ and Γ and a mapping $h\colon \Sigma \to \Gamma$ and thus a homomorphism $h\colon \Sigma^\omega \to \Gamma^\omega$, we define for every $S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ the *projection* $h(S)\colon \Gamma^\omega \to \mathbb{R} \cup \{\infty\}$ by

$$h(S)(w) = \inf\{S(v) \mid h(v) = w\}$$

for every $w \in \Gamma^\omega$. Moreover, if $S'\colon \Gamma^\omega \to \mathbb{R} \cup \{\infty\}$, then we put $h^{-1}(S') = S' \circ h$, i.e. $h^{-1}(S')\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\},\ w \mapsto S'(h(w))$.

▶ **Lemma 4.** *Let Σ and Γ be two alphabets, $h\colon \Sigma \to \Gamma$ be a mapping and* Val *be an ω-valuation function.*

(i) *If $S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ is* Val*-MC-recognizable, then the projection $h(S)\colon \Gamma^\omega \to \mathbb{R} \cup \{\infty\}$ is also* Val*-MC-recognizable.*

(ii) *If $S'\colon \Gamma^\omega \to \mathbb{R} \cup \{\infty\}$ is* Val*-MC-recognizable, then $h^{-1}(S')\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ is also* Val*-MC-recognizable.*

For two series $S_1, S_2\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$, the minimum $\min(S_1, S_2)$ of S_1 and S_2 is defined pointwise, i.e.

$$\min(S_1, S_2)(w) = \min\{S_1(w), S_2(w)\}.$$

Applying the usual union construction for automata, we can show that the minimum of two MC-recognizable series is MC-recognizable as well.

▶ **Lemma 5.** *For any given ω-valuation function* Val*, the* Val*-MC-recognizable series are closed under minimum.*

Let $L \subseteq \Sigma^\omega$ and $S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$. The *intersection of L and S* is the series $L \cap S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ defined for $w \in \Sigma^\omega$ by

$$L \cap S(w) = \begin{cases} S(w) & \text{if } w \in L \\ \infty & \text{otherwise.} \end{cases}$$

The intersection of a recognizable language with an MC-recognizable series is MC-recognizable as well.

▶ **Lemma 6.** *Let* Val *be an ω-valuation function, let $L \subseteq \Sigma^\omega$ be ω-recognizable and $S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ be* Val*-MC-recognizable. Then $L \cap S$ is also* Val*-MC-recognizable.*

Proof. The proof is similar to the standard product construction to show that recognizable languages are closed under intersection. ◀

4 Monitor MSO logic

We first want to give a motivation for the quantifiers and restrictions we use in our logic. We are looking for a logic which is expressively equivalent to automata with monitor counters. It is clear that we need a valuation quantifier in order to model the valuation done by the automata. The question is which types of formulas should be allowed in the scope of the valuation quantifier. From [8] it follows that allowing only *almost Boolean* formulas (see below) is too weak. We would only describe Muller automata over valuation monoids, and these are strictly weaker than automata with monitor counters [4].

We therefore have to allow at least some other quantifier in the scope of the valuation quantifier. Taking into account the automaton model we want to describe, this should be a sum quantifier. Most weighted logics [6, 9, 8, 13, 14, 5] use quantifiers that act unconditionally on the whole input, i.e. on the whole word, tree or picture. However, in Lemma 11 we will see that in our case, an unrestricted sum quantifier quickly gets out of hand.

The intention of the sum quantifier as we define it here is to have a sum quantifier which acts on infinite words, but still computes only finite sums on a given word. The computation of the sum quantifier depends on a first order variable x and a second order variable X provided to it. The variable X serves as a "list" of start and stop positions, and the variable x indicates where the summation on the infinite word should take place. Simply put, the sum is evaluated to $\mathbb{1}$ if x does not point to a position in X or there is no successor of x in X. Otherwise, if y is x's successor in X, the sum is taken from $x+1$ to $y-1$.

Intuitively, each sum quantifier corresponds to a counter. In a run of an automaton with monitor counters, not more than one counter can be started at each letter of the given word. Therefore, we use Boolean formulas to choose which counter to use. We combine these choices between counters into so-called *x-summing* formulas, where x is the first order variable provided to each sum quantifier in the formula.

We provide a countable set $\mathcal{V}$ of first and second order variables, where lower case letters like x and y denote first order variables and capital letters like X and Y denote second order variables. We define a three step logic over an alphabet Σ according to the following grammars.

$$\begin{aligned}
\beta &::= P_a(x) \mid x \leq y \mid x \in X \mid \neg\beta \mid \beta \vee \beta \mid \exists x.\beta \mid \exists X.\beta \\
\psi &::= k \mid \beta \,?\, \psi : \psi \\
\zeta_x &::= \mathbb{1} \mid \beta \,?\, \zeta_x : \zeta_x \mid \bigoplus\nolimits^{x,X} y.\psi \\
\varphi &::= \beta \,?\, \varphi : \varphi \mid \min(\varphi,\varphi) \mid \inf x.\varphi \mid \inf X.\varphi \mid \operatorname{Val} x.\zeta_x
\end{aligned}$$

where $x, y, X \in \mathcal{V}$, $a \in \Sigma$ and $k \in \mathbb{Z}$. The formulas β are called *Boolean* or *MSO* formulas, the formulas ψ *almost Boolean* formulas, the formulas ζ_x *x-summing* formulas and the formulas φ *monitor MSO* (mMSO) formulas. We remark that within an x-summing formula, the first order variable provided to each sum quantifier is always x. This restriction is not imposed on the second order quantifiers, i.e. $\beta \,?\, \bigoplus^{x,X} y.\psi_1 : \bigoplus^{x,Z} y.\psi_2$ is an x-summing formula, but $\beta \,?\, \bigoplus^{x,X} y.\psi_1 : \bigoplus^{z,Z} y.\psi_2$ is neither an x-summing nor a z-summing formula. Also note that the x-summing formulas are only auxiliary formulas, see Remark 7 later on.

The set of free variables $\operatorname{Free}(\varphi)$ is defined as usual, i.e. $\exists, \inf$ and Val bind variables, and in $\bigoplus^{x,X} y.\psi$ the variable y is bound. A formula without free variables is called a *sentence*.

Let $w \in \Sigma^\omega$. We put $\operatorname{dom}(w) = \{0, 1, 2, \ldots\}$ and denote the i-th letter of w by w_i, i.e. $w = w_0 w_1 w_2 \ldots$. Let $\mathcal{V}$ be a finite set of first and second order variables with $\operatorname{Free}(\varphi) \subseteq \mathcal{V}$. A $(\mathcal{V}, w)$-assignment is a mapping $\rho\colon \mathcal{V} \to \operatorname{dom}(w) \cup \mathcal{P}(\operatorname{dom}(w))$ where every first order

variable is mapped to an element of $\mathrm{dom}(w)$ and every second order variable is mapped to a subset of $\mathrm{dom}(w)$. The update $\rho[x \to i]$ for $i \in \mathrm{dom}(w)$ is defined as $\rho[x \to i](x) = i$ and $\rho[x \to i](\mathcal{X}) = \rho(\mathcal{X})$ for all $\mathcal{X} \in \mathcal{V} \setminus \{x\}$. The update $\rho[X \to I]$ for $I \subseteq \mathrm{dom}(w)$ is defined similarly. We encode $(\mathcal{V}, w)$-assignments as usual with an extended alphabet $\Sigma_\mathcal{V} = \Sigma \times \{0,1\}^\mathcal{V}$. Here, we refer to a word over the alphabet $\Sigma_\mathcal{V}$ by (w, ρ), where w is the projection to Σ and ρ is the projection to $\{0,1\}^\mathcal{V}$. A word over $\Sigma_\mathcal{V}$ represents an assignment if and only if for every first order variable the respective row in the extended word contains exactly one 1, in which case (w, ρ) is called *valid*.

It is not difficult to see that the set

$$N_\mathcal{V} = \{(w, \rho) \in \Sigma_\mathcal{V}^\omega \mid (w, \rho) \text{ is valid}\}$$

is ω-recognizable. Let $(w, \rho) \in \Sigma_\mathcal{V}^\omega$. For a Boolean formula β we define the satisfaction relation $(w, \rho) \models \beta$ as usual: if (w, ρ) is not valid, then $(w, \rho) \models \beta$ does not hold; otherwise we define it as follows.

$$\begin{array}{lcl}
(w,\rho) \models P_a(x) & \iff & w_{\rho(x)} = a \\
(w,\rho) \models x \le y & \iff & \rho(x) \le \rho(y) \\
(w,\rho) \models x \in X & \iff & \rho(x) \in \rho(X) \\
(w,\rho) \models \neg\beta & \iff & (w,\rho) \models \beta \text{ does not hold} \\
(w,\rho) \models \beta_1 \vee \beta_2 & \iff & (w,\rho) \models \beta_1 \text{ or } (w,\rho) \models \beta_2 \\
(w,\rho) \models \exists x.\beta & \iff & (w,\rho[x \to i]) \models \beta \text{ for some } i \in \mathrm{dom}(w) \\
(w,\rho) \models \exists X.\beta & \iff & (w,\rho[X \to I]) \models \beta \text{ for some } I \subseteq \mathrm{dom}(w).
\end{array}$$

Let β be an MSO formula. We will write Σ_β for $\Sigma_{\mathrm{Free}(\beta)}$ and N_β for $N_{\mathrm{Free}(\beta)}$. We recall the fundamental Büchi Theorem [1], namely that for $\mathrm{Free}(\beta) \subseteq \mathcal{V}$ the language

$$\mathcal{L}_\mathcal{V}(\beta) = \{(w, \rho) \in N_\mathcal{V} \mid (w, \rho) \models \beta\}$$

defined by β over $\Sigma_\mathcal{V}$ is ω-recognizable. We abbreviate $\mathcal{L}(\beta) = \mathcal{L}_{\mathrm{Free}(\beta)}(\beta)$.

Conversely, every ω-recognizable language $L \subseteq \Sigma^\omega$ is definable by an MSO sentence β, i.e. $L = \mathcal{L}(\beta)$.

We now come to the semantics of the remaining formulas. Let Val be an ω-valuation function. For an almost Boolean, x-summing or monitor MSO formula η we define the *semantics* $[\![\eta]\!]_\mathcal{V}(w, \rho)$ *of* η *under the* $(\mathcal{V}, w)$*-assignment* ρ as follows: if (w, ρ) is not valid, then $[\![\eta]\!]_\mathcal{V}(w, \rho) = \infty$; otherwise the semantics are defined as follows.

$$\begin{array}{rcl}
[\![k]\!]_\mathcal{V}(w,\rho) & = & k \\
[\![\beta \,?\, \psi_1 : \psi_2]\!]_\mathcal{V}(w,\rho) & = & \begin{cases} [\![\psi_1]\!]_\mathcal{V}(w,\rho) & \text{if } (w,\rho) \models \beta \\ [\![\psi_2]\!]_\mathcal{V}(w,\rho) & \text{otherwise} \end{cases} \\
[\![\bigoplus^{x,X} y.\psi]\!]_\mathcal{V}(w,\rho) & = & \begin{cases} \displaystyle\sum_{i=\rho(x)+1}^{\min\{j \in \rho(X) \mid j > \rho(x)\}-1} [\![\psi]\!]_\mathcal{V}(w, \rho[y \to i]) & \text{if } \rho(x) \in \rho(X) \text{ and} \\ & \{j \in \rho(X) \mid j > \rho(x)\} \neq \emptyset \\ \mathbb{1} & \text{otherwise.} \end{cases} \\
[\![\min(\varphi_1, \varphi_2)]\!]_\mathcal{V}(w,\rho) & = & \min\{[\![\varphi_1]\!]_\mathcal{V}(w,\rho), [\![\varphi_2]\!]_\mathcal{V}(w,\rho)\} \\
[\![\inf x.\varphi]\!]_\mathcal{V}(w,\rho) & = & \inf_{i \in \mathrm{dom}(w)} [\![\varphi]\!]_\mathcal{V}(w, \rho[x \to i]) \\
[\![\inf X.\varphi]\!]_\mathcal{V}(w,\rho) & = & \inf_{I \subseteq \mathrm{dom}(w)} [\![\varphi]\!]_\mathcal{V}(w, \rho[X \to I]) \\
[\![\mathrm{Val}\, x.\zeta_x]\!]_\mathcal{V}(w,\rho) & = & \mathrm{Val}((([\![\zeta_x]\!]_\mathcal{V}(w, \rho[x \to i]))_{i \in \mathrm{dom}(w)}).
\end{array}$$

We write $[\![\eta]\!]$ for $[\![\eta]\!]_{\mathrm{Free}(\eta)}$. To indicate the ω-valuation function Val or the alphabet Σ used, we may denote the set of monitor MSO formulas by $\mathrm{mMSO}(\Sigma, \mathrm{Val})$.

▶ Remark 7. From the semantics defined here it is clear that any x-summing sentence ζ_x is semantically equivalent to $\mathbb{1}$. In this sense, the x-summing formulas constitute no meaningful fragment of our logic, and are only auxiliary formulas for the construction of monitor MSO formulas.

Note also that for (w, ρ) valid, we have $[\![\mathrm{Val}\, x.\mathbb{1}]\!](w, \rho) = \infty$. By abuse of notation, we can thus define the abbreviation $\infty = \mathrm{Val}\, x.\mathbb{1}$.

▶ Remark 8. The condition used in the definition of the sum quantifier is definable by the MSO formula

$$\mathrm{notLast}(x, X) = x \in X \wedge \exists y.(y \in X \wedge x < y),$$

where $x < y$ is an abbreviation for $x \leq y \wedge \neg(y \leq x)$. We can therefore also write

$$[\![\bigoplus\nolimits^{x,X} y.\psi]\!](w, \rho) = \begin{cases} \sum_{i=\rho(x)+1}^{\min\{j \in \rho(X) \mid j > \rho(x)\}-1} [\![\psi]\!](w, \rho[y \to i]) & \text{if } (w, \rho) \models \mathrm{notLast}(x, X) \\ \mathbb{1} & \text{otherwise.} \end{cases}$$

In Lemma 12 we will see that the first order variable x is necessarily also the variable which is quantified by Val. If we define an unrestricted sum quantifier $\bigoplus y.\psi$ by

$$[\![\bigoplus y.\psi]\!](w, \rho) = \textstyle\sum_{i \in \mathrm{dom}(w)} [\![\psi]\!](w, \rho[y \to i]),$$

we can write our restricted sum quantifier as

$$[\![\bigoplus\nolimits^{x,X} y.\psi]\!](w, \rho) =$$
$$[\![\mathrm{notLast}(x, X)\ ?\ \textstyle\bigoplus y.(x < y \wedge \forall z.((x < z \wedge z \leq y) \to \neg z \in X)\ ?\ \psi : 0) : \mathbb{1}]\!](w, \rho).$$

▶ **Example 9.** Consider Example 1 again, i.e. the alphabet $\Sigma = \{\mathsf{demand}, \mathsf{restock}\}$ with the ω-valuation function $\mathrm{Val} = \textsc{Ces}$. Then the formula

$$\varphi = \inf X.\left(\forall z.(z \in X \leftrightarrow P_{\mathsf{restock}}(z))\ ?\ \mathrm{Val}\, x.\bigoplus\nolimits^{x,X} y.1 : \infty\right)$$

describes the average total demand between two restocks. We recall that ∞ is simply an abbreviation for the formula $\mathrm{Val}\, x.\mathbb{1}$. As in Example 1, if we take Inf or Sup for the valuation function, the formula above describes the lowest or highest demand ever encountered.

▶ **Lemma 10** (Consistency Lemma). *Let $\varphi \in \mathrm{mMSO}(\Sigma, \mathrm{Val})$ and $\mathcal{V}$ be a finite set of variables with $\mathcal{V} \supseteq \mathrm{Free}(\varphi)$.*

(i) *For any valid $(w, \rho) \in \Sigma_{\mathcal{V}}^{\omega}$ we have $[\![\varphi]\!]_{\mathcal{V}}(w, \rho) = [\![\varphi]\!](w, \rho{\restriction_{\mathrm{Free}(\varphi)}})$.*

(ii) *$[\![\varphi]\!]$ is MC-recognizable if and only if $[\![\varphi]\!]_{\mathcal{V}}$ is MC-recognizable.*

The following lemma shows that the use of an unrestricted sum quantifier leads to not MC-recognizable series.

▶ **Lemma 11.** *Consider the unrestricted sum quantifier from Remark 8*

$$[\![\bigoplus y.\psi]\!](w, \rho) = \textstyle\sum_{i \in \mathrm{dom}(w)} [\![\psi]\!](w, \rho[y \to i]),$$

the ω-valuation function Val *defined by*

$$\mathrm{Val}((z_i)_{i \geq 0}) = \begin{cases} \sum_{i=0}^{\infty} z_i & \textit{if this sum converges} \\ \infty & \textit{otherwise} \end{cases}$$

and the alphabet $\Sigma = \{a, b\}$. Then for the almost Boolean formula

$$\psi = y \leq x \wedge \forall z.(z \leq x \to P_a(z))\ ?\ -1 : 0,$$

the formula $\varphi = \mathrm{Val}\, x.\bigoplus y.\psi$ is not Val*-MC-recognizable.*

Proof (sketch). One easily checks that

$$[\![\varphi]\!](w) = \begin{cases} -\frac{m(m+1)}{2} & \text{if } w = a^m b w' \text{ for some } w' \in \Sigma^\omega \\ \infty & \text{if } w = a^\omega. \end{cases}$$

The idea is now that with only finitely many transitions, and therefore only finitely many different weights, this quadratic growth cannot be realized if only transitions up to the first b in each word influence the weight of the runs. But once the automaton has read this first b, it cannot distinguish between the words anymore. Under appropriate assumptions, we can therefore combine runs from different words to obtain a contradiction. ◀

The next lemma shows that the first order variable x provided to the sum quantifier is necessarily the variable that Val quantifies.

▶ **Lemma 12.** *Consider the ω-valuation function* Val *defined by*

$$\mathrm{Val}((z_i)_{i\geq 0}) = \begin{cases} \frac{1}{z_0} & \text{if } 0 < z_0 = z_1 = z_2 = \dots \\ -1 & \text{otherwise.} \end{cases}$$

and the alphabet $\Sigma = \{a\}$. We define the abbreviation

$$(y = x + 1) = x \leq y \wedge \neg(y \leq x) \wedge \forall z.(z \leq x \vee y \leq z).$$

Then for the Boolean formula

$$\beta(X) = \forall x_1.\forall x_2.((x_1 \in X \wedge x_2 = x_1 + 1) \to \neg(x_2 \in X)),$$

the formula $\varphi = \inf X.\inf z.\left(\beta(X)\ ?\ \mathrm{Val}\, x.\bigoplus^{z,X} y.1 : \infty\right)$ is not Val*-MC-recognizable.*

Proof (sketch). One can check that $[\![\varphi]\!](a^\omega) = 0$. For a BMCA $\mathcal{A}$ realizing this series, the weight-sequence associated to each run has to be constant, and there must be a sequence of runs such that this constant grows arbitrarily large. The latter fact can be exploited to show that there must be a run whose associated weight-sequence is not constant, which leads to the contradiction $[\![\mathcal{A}]\!](a^\omega) = -1$. ◀

5 The main result

In this section, we want to show that the MC-recognizable series coincide with the series definable by monitor MSO formulas from our logic. In Lemma 14, we show how a given MMCA can be described by a monitor MSO formula. To show that every series definable by a monitor MSO formula is also MC-recognizable, we show by induction on the structure of the formula how to construct an MMCA with the same behavior as the formula. We first formulate our main theorem.

▶ **Theorem 13.** *Let Σ be an alphabet and* Val *an ω-valuation function. A series $S\colon \Sigma^\omega \to \mathbb{R} \cup \{\infty\}$ is* Val*-MC-recognizable if and only if there is a monitor MSO sentence $\varphi \in \mathrm{mMSO}(\Sigma, \mathrm{Val})$ with $[\![\varphi]\!] = S$.*

In the following lemma, we show the first direction, namely how to obtain a formula for a given MMCA.

▶ **Lemma 14.** *For every* Val*-MMCA $\mathcal{A}$, there exists a sentence $\varphi \in \mathrm{mMSO}(\Sigma, \mathrm{Val})$ with $[\![\mathcal{A}]\!] = [\![\varphi]\!]$.*

Proof. For first order variables x and y and second order variables $X_1, \dots, X_k$ we define the MSO formulas

$$\begin{aligned}
\mathrm{first}(x) &= \forall y.x \leq y \\
x < y &= x \leq y \wedge \neg(y \leq x) \\
(y = x+1) &= x < y \wedge \forall z.(z \leq x \vee y \leq z) \\
\mathrm{partition}(X_1, \dots, X_k) &= \forall x. \bigvee_{i=1}^{k} \left(x \in X_i \wedge \bigwedge_{j \neq i} \neg(x \in X_j) \right).
\end{aligned}$$

Now let $\mathcal{A} = (\Sigma, Q, I, \mathcal{F}, \delta, n, \mathrm{Val})$ be an n-MMCA. For every $(p, a, q, \mathbf{u}) \in \delta$ we choose a second order variable $X_{(p,a,q,\mathbf{u})}$ and with $k = |\delta|$ we fix a bijection $v\colon \{1, \dots, k\} \to \delta$. For $i \in \{1, \dots, k\}$ we write X_i for $X_{v(i)}$ and $\bar{X}$ for $(X_1, \dots, X_k)$. Furthermore, we fix second order variables $Y_1, \dots, Y_n$ and write $\bar{Y}$ for $(Y_1, \dots, Y_n)$. For $j \in \{1, \dots, n\}$ and $\star \in \{s, t\}$ we abbreviate

$$(u^j(x) = \star) = \bigvee_{\substack{(p,a,q,\mathbf{u}) \in \delta \\ u^j = \star}} x \in X_{(p,a,q,\mathbf{u})}.$$

Intuitively, we use the variables $\bar{X}$ to encode runs, i.e. by assigning the transition $v(i)$ to every position in X_i. The variables $\bar{Y}$ are used to mark the starts and stops of the counters in $\bar{X}$. In the following, we define the MSO formula $\mathrm{muller}(\bar{X})$ which checks that $\bar{X}$ encodes a run of $\mathcal{A}$ satisfying the Muller acceptance condition, and the MSO formula $\mathrm{valid}(\bar{X})$ which checks that $\bar{X}$ encodes an accepting run. The MSO formula $\mathrm{valid}^*(\bar{X}, \bar{Y})$ asserts that the positions in $\bar{Y}$ conform to the starts and stops of the counters in $\bar{X}$. The precise formulas are as follows.

$$\begin{aligned}
&\mathrm{matched}(\bar{X}) = \bigwedge_{(p,a,q,\mathbf{u}) \in \delta} \forall x. \big(x \in X_{(p,a,q,\mathbf{u})} \to P_a(x)\big) \\
&\wedge \forall x. \forall y. \left(y = x+1 \to \bigvee_{q \in Q} \left(\bigvee_{(p,a,q,\mathbf{u}),(q,a',p',\mathbf{u}') \in \delta} (x \in X_{(p,a,q,\mathbf{u})} \wedge y \in X_{(q,a',p',\mathbf{u}')}) \right) \right) \\
&\mathrm{muller}(\bar{X}) = \mathrm{partition}(\bar{X}) \wedge \mathrm{matched}(\bar{X}) \wedge \exists x. \left(\mathrm{first}(x) \wedge \bigvee_{\substack{(p,a,q,\mathbf{u}) \in \delta \\ p \in I}} x \in X_{(p,a,q,\mathbf{u})} \right) \\
&\wedge \bigvee_{F \in \mathcal{F}} \left(\exists x. \forall y. x \leq y \to \left(\left(\bigvee_{\substack{(p,a,q,\mathbf{u}) \in \delta \\ q \in F}} y \in X_{(p,a,q,\mathbf{u})} \right) \right. \right. \\
&\qquad \left. \left. \wedge \bigwedge_{q \in F} \exists z. \left(y \leq z \wedge \bigvee_{(p,a,q,\mathbf{u}) \in \delta} z \in X_{(p,a,q,\mathbf{u})} \right) \right) \right) \\
&\mathrm{valid}(\bar{X}) = \mathrm{muller}(\bar{X}) \wedge \forall x. \exists y. (x \leq y \wedge \bigvee_{j=1}^{n} u^j(y) = s) \wedge \\
&\bigwedge_{j=1}^{n} \forall x. \Big(\big((u^j(x) = s) \to \exists y. (x < y \wedge u^j(y) = t \wedge \forall z. ((x < z \wedge z < y) \to \neg(u^j(z) = s))) \big) \\
&\qquad \wedge \big((u^j(x) = t) \to \exists y. (y < x \wedge u^j(y) = s \wedge \forall z. ((y < z \wedge z < x) \to \neg(u^j(z) = t))) \big) \Big)
\end{aligned}$$

$$\mathrm{valid}^*(\bar{X},\bar{Y}) = \mathrm{valid}(\bar{X}) \wedge \bigwedge_{j=1}^{n} \forall x.(x \in Y_j \leftrightarrow (u^j(x) = s \vee u^j(x) = t)).$$

For $(p,a,q,\mathbf{u}) \in \delta$ we let $\mathrm{wt}_j(p,a,q,\mathbf{u}) = u^j$ and for $i \in \{1,\dots,k-2\}$ and $j \in \{1,\dots,n\}$ define inductively

$$\begin{aligned}
\psi^j_{k-1} &= (y \in X_{k-1} \,?\, \mathrm{wt}_j(v(k-1)) : \mathrm{wt}_j(v(k))) \\
\psi^j_i &= \left(y \in X_i \,?\, \mathrm{wt}_j(v(i)) : \psi^j_{i+1}\right) \\
\zeta_{n+1} &= \mathbb{1} \\
\zeta_j &= \left((u^j(x) = s) \,?\, \bigoplus\nolimits^{x,Y_j} y.\psi^j_1 : \zeta_{j+1}\right).
\end{aligned}$$

Then with $\varphi = \inf \bar{X}.\inf \bar{Y}.(\mathrm{valid}^*(\bar{X},\bar{Y}) \,?\, \mathrm{Val}\, x.\zeta_1 : \infty)$, we have $[\![\mathcal{A}]\!] = [\![\varphi]\!]$. The formula ψ^j_1 evaluates to the weight for counter j in the transition at position y, i.e. it is $\mathrm{wt}_j(v(i))$ iff y is in X_i. The formula ζ_1 evaluates to the output of the counter started at position x in the run encoded by $\bar{X}$. More precisely, ζ_1 evaluates to $\bigoplus^{x,Y_j} y.\psi^j_1$ if counter j is started at position x, and to $\mathbb{1}$ if no counter is started at x. Finally, the formula φ takes the infimum over the weights of all "runs" $\bar{X}$, in the sense that assignments to $\bar{X}$ and $\bar{Y}$ only influence the value of φ if $\bar{X}$ encodes an accepting run and $\bar{Y}$ mirrors its counter starts and stops. ◀

The remainder of this section is dedicated to show the converse, namely that for every monitor MSO formula there is an MMCA with the same behavior as the formula.

▶ **Lemma 15.** *Let β be an MSO formula and $\varphi_1,\varphi_2 \in \mathrm{mMSO}(\Sigma,\mathrm{Val})$ such that $[\![\varphi_1]\!]$ and $[\![\varphi_2]\!]$ are MC-recognizable. Then with $\varphi = \beta \,?\, \varphi_1 : \varphi_2$, the series $[\![\varphi]\!]$ is also MC-recognizable.*

Proof. Let $\mathcal{V} = \mathrm{Free}(\varphi)$. Then we have $\mathrm{Free}(\varphi_1) \subseteq \mathcal{V}$ and $\mathrm{Free}(\varphi_2) \subseteq \mathcal{V}$ and hence by Lemma 10 $[\![\varphi_1]\!]_\mathcal{V}$ and $[\![\varphi_2]\!]_\mathcal{V}$ are MC-recognizable. Due to $\mathrm{Free}(\beta) \subseteq \mathcal{V}$, the classical Büchi theorem tells us that both $\mathcal{L}_\mathcal{V}(\beta)$ and $\mathcal{L}_\mathcal{V}(\neg\beta)$ are ω-recognizable. Hence by Lemma 5 and Lemma 6, $[\![\varphi]\!] = \min(\mathcal{L}_\mathcal{V}(\beta) \cap [\![\varphi_1]\!]_\mathcal{V}, \mathcal{L}_\mathcal{V}(\neg\beta) \cap [\![\varphi_2]\!]_\mathcal{V})$ is also MC-recognizable. ◀

▶ **Lemma 16.** *Let $\varphi_1,\varphi_2 \in \mathrm{mMSO}(\Sigma,\mathrm{Val})$ be such that $[\![\varphi_1]\!]$ and $[\![\varphi_2]\!]$ are MC-recognizable. Then $\varphi = \min(\varphi_1,\varphi_2)$, the series $[\![\varphi]\!]$ is also MC-recognizable.*

Proof. Let $\mathcal{V} = \mathrm{Free}(\varphi_1) \cup \mathrm{Free}(\varphi_2)$, then by Lemma 10, $[\![\varphi_1]\!]_\mathcal{V}$ and $[\![\varphi_2]\!]_\mathcal{V}$ are also MC-recognizable. Hence by Lemma 5, $[\![\varphi]\!] = \min([\![\varphi_1]\!]_\mathcal{V}, [\![\varphi_2]\!]_\mathcal{V})$ is also MC-recognizable. ◀

▶ **Lemma 17.** *Let $\varphi \in \mathrm{mMSO}(\Sigma,\mathrm{Val})$ such that $[\![\varphi]\!]$ is MC-recognizable. Then $\inf x.\varphi$ and $\inf X.\varphi$ are also MC-recognizable.*

Proof. We show the lemma for $\inf x.\varphi$. The proof for $\inf X.\varphi$ is similar. Let $\mathcal{V} = \mathrm{Free}(\inf x.\varphi)$, then $x \notin \mathcal{V}$. We now consider the homomorphism $h\colon \Sigma^\omega_{\mathcal{V}\cup\{x\}} \to \Sigma^\omega_\mathcal{V}$, which erases the x-row. Then for any $(w,\rho) \in \Sigma^\omega_\mathcal{V}$, we have that

$$[\![\inf x.\varphi]\!]_\mathcal{V}(w,\rho) = \inf\{[\![\varphi]\!]_{\mathcal{V}\cup\{x\}}(w,\rho[x \to i]) \mid i \geq 0\} = h([\![\varphi]\!]_{\mathcal{V}\cup\{x\}})(w,\rho).$$

As $\mathrm{Free}(\varphi) \subseteq \mathcal{V} \cup \{x\}$, Lemma 10 shows that $[\![\varphi]\!]_{\mathcal{V}\cup\{x\}}$ is MC-recognizable and therefore by Lemma 4 (i) the series $[\![\inf x.\varphi]\!]_\mathcal{V}$ is MC-recognizable as well. ◀

▶ **Lemma 18.** *Let ψ be an almost Boolean formula and $\mathcal{V} \supseteq \mathrm{Free}(\psi)$. Then there are MSO formulas $\beta_1,\dots,\beta_n$ and weights $z_1,\dots,z_n \in \mathbb{Z}$ such that $\mathrm{Free}(\psi) = \bigcup_{i=1}^n \mathrm{Free}(\beta_i)$, $N_\mathcal{V} = \bigcup_{i=1}^n \mathcal{L}_\mathcal{V}(\beta_i)$, for $i \neq j$ we have $\mathcal{L}_\mathcal{V}(\beta_i) \cap \mathcal{L}_\mathcal{V}(\beta_j) = \emptyset$ and for $(w,\rho) \in N_\mathcal{V}$ we have $[\![\psi]\!]_\mathcal{V}(w,\rho) = z_i$ if and only if $(w,\rho) \in \mathcal{L}_\mathcal{V}(\beta_i)$.*

Proof. For $\psi = k$ with $k \in \mathbb{Z}$, we choose β_1 as any tautology, for example $\beta_1 = \exists x.x \leq x$, and $z_1 = k$.

For $\psi = \beta \mathbin{?} \psi_1 : \psi_2$ we assume that the lemma is true for ψ_1 with $\beta_1^{(1)}, \dots, \beta_{n_1}^{(1)}$ and $z_1^{(1)}, \dots, z_{n_1}^{(1)}$ and for ψ_2 with $\beta_1^{(2)}, \dots, \beta_{n_2}^{(2)}$ and $z_1^{(2)}, \dots, z_{n_2}^{(2)}$. Then for ψ we choose $\beta_1, \dots, \beta_{n_1+n_2}$ and $z_1, \dots, z_{n_1+n_2}$ as follows. For $i \in \{1, \dots, n_1\}$ we set $\beta_i = \beta \wedge \beta_i^{(1)}$ and $z_i = z_i^{(1)}$ and for $i \in \{1, \dots, n_2\}$ we set $\beta_{n_1+i} = \neg\beta \wedge \beta_i^{(2)}$ and $z_{n_1+i} = z_i^{(2)}$. ◀

▶ **Lemma 19.** *Let ζ be an x-summing formula and $\mathcal{V} \supseteq \mathrm{Free}(\zeta)$. Then there are MSO formulas $\beta_1, \dots, \beta_n$ and formulas $\zeta_1, \dots, \zeta_n$ with $\zeta_i = \bigoplus^{x,Y_i} y.\psi_i$ for some almost Boolean formula ψ_i such that $\mathrm{Free}(\zeta) = \bigcup_{i=1}^n \mathrm{Free}(\beta_i) \cup \mathrm{Free}(\zeta_i)$, for $i \neq j$ we have $\mathcal{L}_\mathcal{V}(\beta_i) \cap \mathcal{L}_\mathcal{V}(\beta_j) = \emptyset$, for $(w, \rho) \in N_\mathcal{V}$ we have $[\![\zeta]\!]_\mathcal{V}(w, \rho) = [\![\zeta_i]\!]_\mathcal{V}(w, \rho)$ if and only if $(w, \rho) \in \mathcal{L}_\mathcal{V}(\beta_i)$ and if $(w, \rho) \notin \bigcup_{i=1}^n \mathcal{L}_\mathcal{V}(\beta_i)$ then $[\![\zeta]\!](w, \rho) = \mathbb{1}$. We can assume the variables Y_i to be pairwise distinct.*

▶ **Theorem 20.** *Let ζ be an x-summing formula. Then $[\![\mathrm{Val}\, x.\zeta]\!]$ is MC-recognizable.*

Proof (sketch). We adapt and expand an idea from [9]. Let $\beta_1, \dots, \beta_n$ and $\zeta_1, \dots, \zeta_n$ be the formulas we can find for ζ according to Lemma 19. We write $\zeta_i = \bigoplus^{x,Y_i} y.\psi_i$. Then for each $i \in \{1, \dots, n\}$, let $\beta_{i1}, \dots, \beta_{in_i}$ and $z_{i1}, \dots, z_{in_i}$ be the formulas and weights we can find for ψ_i according to Lemma 18.

The proof idea is as follows. For $\mathcal{V} = \mathrm{Free}(\mathrm{Val}\, x.\zeta)$, the mapping $[\![\mathrm{Val}\, x.\zeta]\!]$ assigns values to words from $\Sigma_\mathcal{V}^\omega$. Consider $(w, \rho) \in \Sigma_\mathcal{V}^\omega$. We can interpret each ζ_i as a counter which is stopped and then restarted at the k-th letter of w depending on whether $(w, \rho[x \to k])$ satisfies β_i. As our automata cannot stop and start a single counter at the same time, each counter i will correspond to two counters i and i' in the automaton we construct. The computations of counter i depend on $\beta_{i1}, \dots, \beta_{in_i}$. We extend the alphabet $\Sigma_\mathcal{V}$ by adding two entries for each counter to each letter in $\Sigma_\mathcal{V}$. The entries for counter i can contain an s to indicate the start of the counter, a t to indicate a stop, a number $j \in \{1, \dots, n_i\}$ to indicate that the counter is active and should add z_{ij} to its current value, or a $\perp$ to indicate that the counter is inactive. Let $\tilde{\Sigma}_\mathcal{V}$ be this new alphabet. We show that we can define an ω-recognizable language L over $\tilde{\Sigma}_\mathcal{V}$ which has all information about the counter operations encoded in the word. For example, if $(w, \rho[x \to k]) \models \beta_i$, then in the word $(w, \rho, v) \in \tilde{\Sigma}_\mathcal{V}^\omega$ corresponding to (w, ρ) the entry for counter i in the k-th letter should contain an s. Then if $(w, \rho[x \to k, y \to k+1]) \models \beta_{ij}$, the i-entry of the $k+1$-th letter should contain a j. The precise formulation of this is involved.

When we have shown that the language L is recognizable, we can construct a deterministic Muller automaton $\tilde{\mathcal{A}}$ which recognizes L. Turning $\tilde{\mathcal{A}}$ into an MMCA and applying a projection, we finally obtain the recognizability of $[\![\mathrm{Val}\, x.\zeta]\!]$. ◀

This concludes our induction, and thus the proof of Theorem 13.

6 Conclusion

We introduced a new logic which is expressively equivalent to Quantitative Monitor Automata. Since our proofs are constructive, we immediately obtain the possibility to reduce the satisfiability and equivalence problems of our logic to the emptiness and equivalence problems of Quantitative Monitor Automata. Future work could therefore focus on the investigation of this automaton model, and on the related model of Nested Weighted Automata [3].

The Complexity of Quantum Disjointness*

Hartmut Klauck

Centre for Quantum Technologies and Nanyang Technological University, Singapore
hklauck@gmail.com

Abstract

We introduce the communication problem QNDISJ, short for *Quantum (Unique) Non-Disjointness*, and study its complexity under different modes of communication complexity. The main motivation for the problem is that it is a candidate for the separation of the quantum communication complexity classes QMA and QCMA. The problem generalizes the Vector-in-Subspace and Non-Disjointness problems. We give tight bounds for the QMA, quantum, randomized communication complexities of the problem. We show polynomially related upper and lower bounds for the MA complexity. We also show an upper bound for QCMA protocols, and show that the bound is tight for a natural class of QCMA protocols for the problem. The latter lower bound is based on a geometric lemma, that states that every subset of the n-dimensional sphere of measure 2^{-p} must contain an ortho-normal set of points of size $\Omega(n/p)$.

We also study a "small-spaces" version of the problem, and give upper and lower bounds for its randomized complexity that show that the QNDISJ problem is harder than Non-disjointness for randomized protocols. Interestingly, for quantum modes the complexity depends only on the dimension of the smaller space, whereas for classical modes the dimension of the larger space matters.

1 Introduction

Communication complexity [30, 23] is a central area in computational complexity and the source of many lower bounds for other computational (nonuniform) models. Because of this much of the research in communication complexity is focused on lower bounds. Most of these lower bound applications employ the lower bound to the Disjointness problem shown by Kalyanasundaram and Schnitger [14] (see also [26, 7] for simpler proofs), or, in the quantum case the lower bound by Razborov [27] (see also [28]).

The present paper is mainly motivated by the following open problem. The complexity class QMA (in the Turing machine world) is the quantum analogue of NP (or rather of MA), namely the class of problems, that can be verified efficiently given a (non-interactive) quantum proof (by a quantum verifier). Similarly, QCMA is the class of problems where a *classical* proof can be verified efficiently by a quantum verifier. Obviously, the relationship between the two classes is highly interesting. This relates to the problem of whether more

information can be present in a quantum state than in a classical state (of the same size), in this case based on the capacity to function as a proof. This problem was first suggested by Aharonov and Naveh [5].

Aharonov and Naveh have conjectured that $QCMA = QMA$, because the local Hamiltonian problem is complete for QMA (Turing machine model, [15]), and hence in some sense only a constant number of qubits in a quantum proof need to be touched by the verifier at once, so only localized entanglement seems necessary. Nevertheless such a result has not been established since. On the other hand, obviously we are far away from proving such separations as $QCMA \neq QMA$ for the Turing machine model (one implication would be $P \neq PSPACE$). Aaronson and Kuperberg [3] have shown a separation of the classes relative to a *quantum* oracle, a result that does not imply the usual relativization obstacle to showing that the classes are equal. It remains open whether $QCMA \neq QMA$ relative to some *classical oracle* (which would imply that anyone who wants to show that $QMA = QCMA$ must use non-relativizing techniques). Aaronson and Wigderson [4] have proposed the stronger *algebrization* obstacle to showing complexity theoretic results, and give many examples of such results requiring non-algebrizing techniques. One of their methods is to use separations of complexity classes in communication complexity (see [6]) in order to show algebrization separations. This motivates trying to separate QCMA and QMA in communication complexity (besides the power of quantum proofs being interesting in any model). The main reason why this is preferable over trying to solve the (usually easier) separation in the query complexity model (which would give an oracle separation) is that we have a proper candidate problem for the separation, namely the problem Linear-Space-Distance (LSD) introduced by Raz and Shpilka [25], who show that LSD is QMA-complete (for the communication complexity model).

Due the QMA-completeness of LSD, if there is a separation of QMA from QCMA (in communication complexity), then there is one using LSD. However, the problem is awkward in the sense that the 1-inputs (resp. the 0-inputs) do not form a manifold. This complicates reasoning about the problem, which is of a geometrical nature, and is best studied in its non-discretized version. We propose a subproblem of LSD that has the following nice properties: its input sets are Riemannian manifolds and there are nontrivial protocols for various modes of communication for the problem, exhibiting limits on lower bounds that can be shown, guiding our intuition.

The problem we propose is called Quantum (Unique) Non-Disjointness (short QNDISJ). Informally, the 0-inputs of QNDISJ are pairs (W_A, W_B) of subspaces of $\mathbb{R}^n$ that are orthogonal to each other, while the 1-inputs are pairs such that $W_A \cap W_B$ has dimension 1, and the spaces are orthogonal outside of their intersection.

We view QNDISJ as a natural quantum analogue of the Disjointness problem. This works as follows: For a fixed ortho-normal basis of $\mathbb{R}^n$ a subset $x \subseteq \{1, \ldots, n\}$ can be identified with a subspace (by taking the span of the basis vectors indexed by x). Hence, if Alice and Bob have sets of size s, t respectively that are disjoint, then their inputs correspond to two orthogonal subspaces, i.e., a 0-inputs of QNDISJ. If the sets intersect on 1 element, then the two subspaces have a 1-dimensional intersection, and they are (also) a 1-input. The difference between (the complement) of Disjointness and QNDISJ is then that there is no fixed basis for the latter problem, but rather that Alice and Bob know their own subspaces, but no good basis of the whole space, in which the intersecting (unit) vector is a basis vector.

Another problem of which QNDISJ is a generalization is the Vector-in-Subspace problem [22, 24, 16], which is the same problem, only that Alice has a 1-dimensional subspace, and Bob an $n/2$-dimensional subspace. For this problem Klartag and Regev give a $\Omega(n^{1/3})$ lower

bound on the randomized communication complexity and Raz gives a randomized $O(\sqrt{n})$ upper bound, with the upper bound likely tight. The quantum complexity of this problem is $O(\log n)$.

We explore the communication complexity of QNDISJ for the following modes of communication: QMA, QCMA, MA, randomized, quantum. We also consider the version of the problem, where the dimensions of the subspaces are s, t with $s \leq t \leq n/2$. We give (almost) matching upper and lower bounds for randomized, quantum, QMA-protocols in the case $s = t = n/4$. We give non-trivial bounds for smaller spaces as well (see the table later on). One interesting conclusion is that for the quantum modes (Q, QCMA, QMA) the complexity depends (up to small factors) only on s, the dimension of the smaller space, whereas for the classical modes (R, MA) the complexity of the larger space matters. We also give a lower bound for QCMA protocols for QNDISJ under a restriction on the protocols. This restriction is that the proof (sent by Merlin, who sees both subspaces) depends on the intersection of the subspaces *only* (and can hence be viewed as an (arbitrary) subset of the sphere). We prove a geometric lemma about large subsets of the sphere that allows us to reduce a smaller instance of Disjointness to the "leftover" problem of QNDISJ, once one of the classical proofs is fixed (namely the problem of accepting all 1-inputs for which this proof is good, while rejecting all 0-inputs).

Our restriction seems natural, because it is difficult to imagine how other information from Merlin could be useful to Alice (who knows her space, just not the intersection) or Bob. So our conditional bound can be seen as some evidence that quantum proofs are really more powerful than classical proofs. We note that a separation between QMA- and QCMA-communication complexity in the one-way model is known [21], but that result has no bearing on algebrization and the analogous problem for Turing machines.

2 Organization of the Paper

This is an extended abstract. In the next section we give a formal definition of $QNDISJ_{s,t}$. In Section 4 we have a table describing our results and define the property under which our conditional QCMA lower bound holds. In Section 5 we have preliminaries, and in Section 6 a rough overview of our main techniques. See the full paper for more formal statements and for proofs.

3 Definition of the Problem

Denote by $S^{n-1} = \{x \in \mathbb{R}^n : ||x|| = 1\}$ the sphere. The Grassmannian is $G_{n,m} = \{V : V \subseteq \mathbb{R}^n$ and V is an m-dimensional subspace$\}$. We define our main problem on two manifolds. Throughout the paper we will fix n as the dimension of the underlying space when talking about our problem. s, t are the dimensions of Alice's and Bob's subspace and we will always have $s \leq t \leq n/2$.

▶ **Definition 1.** The *orthogonal manifold* $O_{s,t}$ is the set of pairs of subspaces W_A, W_B, where W_A is an s-dimensional subspace of $\mathbb{R}^n$, W_B a t-dimensional subspace of $\mathbb{R}^n$, and $W_A \perp W_B$.

▶ **Definition 2.** The *intersection manifold* $I_{s,t}$ is the set of pairs of subspaces W_A, W_B, where W_B is an s-dimensional subspace of $\mathbb{R}^n$, W_B a t-dimensional subspace of $\mathbb{R}^n$, and W_A, W_B intersect in a 1-dimensional subspace spanned by some vector z. Furthermore $(W_A \cap z^{\perp}) \perp (W_B \cap z^{\perp})$.

Table 1 Complexity of $QNDISJ_{s,t}$ for $s \leq t$.

Mode	Upper Bound	Lower Bound
QMA	$O(\log n)$	$\Omega(\sqrt{\log t})$ 1)
R	$O(\min\{s\sqrt{t}, n \log n\})$	$\Omega(s(t/s)^{1/3})$
Q	$O(\sqrt{s} \log n)$	$\Omega(\sqrt{s})$
MA	$O(\sqrt{s\sqrt{t}})$	$\Omega(t^{1/6})$
QCMA	$O(s^{1/3} \log n)$	$\Omega(s^{1/3})$ (*)

1) The lower bound becomes $\Omega(\log t)$, if Alice and Bob do not share entanglement.
(*) This lower bound is conditional on assumption (*) about protocols (see below).

▶ **Definition 3.** The problem $QNDISJ_{s,t}$ is a partial function. The set of 1-inputs is $I_{s,t}$. The set of 0-inputs is $O_{s,t}$. For all other pairs of subspaces the function is undefined.

When we don't indicate s, t, then $s = t = \frac{n}{4}$. We leave n, the dimension of the underlying space, implicit.

To provide some insight as to the name of the problem, consider Razborov's hard distribution for the Disjointness problem [26]: disjoint inputs are disjoint pairs of sets of size $n/4$, intersecting inputs are pairs of sets of size $n/4$ that have intersection size 1. If we fix an ortho-normal basis of $\mathbb{R}^n$, we can view each set as picking $n/4$ basis vectors and hence consider Alice and Bob's inputs as subspaces of dimension $n/4$. The subspaces are orthogonal for disjoint sets and are in the intersection manifold for intersecting inputs.

The difference between Non-disjointness and $QNDISJ$ is that Alice and Bob *do not know a good basis* for the whole space. Alice knows her space, and she can find a basis for her space, but the intersecting vector is a basis vector only in a hidden basis neither she nor Bob know. The situation is as if someone would take the Non-disjointness example above, and apply a secret unitary transformation to the bases of the subspaces, and then only hand the transformed basis of W_A to Alice and only the transformed basis of W_B to Bob.

The Vector-in-Subspace problem is $QNDISJ_{1,n/2}$. Similar to the reduction from Non-Disjointness above, there is a reduction from $INDEX_n$ (see Section 5.1) to this problem. Furthermore note that $QNDISJ_{1,1}$ is a somewhat natural real version of the Equality problem.

We don't explicitly consider discretized versions of QNDISJ in this paper. Obviously one can easily encode an approximation of the problem by providing Alice and Bob with a basis of their subspaces rounded to precision $1/poly(n)$.

4 Results

Our results concerning the communication complexity of $QNDISJ_{s,t}$ are collected in the following table. Alice receives the s-dimensional subspace, Bob the t-dimensional subspace, and $s \leq t$. The bounds for QMA, Q, R are tight up to logarithmic factors in the case $s = t = n/4$. Note that unless mentioned, we allow entanglement shared by Alice and Bob for the lower bounds (but don't use entanglement in our protocols).

We now explain the lower bound for QCMA protocols which holds under a certain assumption on the protocols. It is natural to assume that the prover should send information about the intersection to one of the players. The intersection (in the case of a 1-input) is a 1-dimensional subspace, and hence the prover should probably send some information about

the (normalized) vector that spans it. A message from the prover would then correspond to a subset of the unit sphere, e.g. could be a spherical cap (or something else).

Our assumption about Merlin's proof is hence that the prover sends messages that correspond to subsets P of the unit sphere. All 1-inputs, where $W_A \cap W_B \in P$ should be accepted on such a proof with high probability.

What this means is that the prover communicates arbitrary information about the intersection, *but nothing more*. One more point is: which sphere? There are 3 possibilities: the sphere in $\mathbb{R}^n$, the sphere in W_A, and the sphere in W_B. Each of these is fine regarding our assumption. Indeed in the case of $s = t = n/4$ this difference does not matter much. For smaller spaces it is more convenient to use the sphere in W_A (assuming that Merlin sends his message to Alice).

We now make the assumption formal. in a QCMA-protocol the prover Merlin sends a classical message (the proof) to Alice, after which Alice and Bob verify the proof, using quantum communication. See Section 5.1 for the definition. We can identify Merlin's proof message with the subset of 1-inputs, which will be accepted with probability at least 2/3 by the verifier(s) when given this proof. So besides the actual message, we also refer to said subset of the 1-inputs as a proof. Hence, with a proof length of p we get a set of at most 2^p proofs that cover the set of 1-inputs. In particular, under any given distribution, the average proof must have measure at least 2^{-p} on the 1-inputs. For QNDISJ, the set of 1-inputs is the intersection manifold $I_{n/4,n/4}$.

A proof that satisfies our assumption also corresponds to a subset of the sphere S^{n-1}.

▶ **Definition 4.** A subset P' of the intersection manifold $I_{n/4,n/4}$ is called *intersectional*, if there is a subset $P \subseteq S^{n-1}$ such that $P' = \{(W_A, W_B) : (W_A, W_B) \in I_{n/4,n/4}$ and $(W_A \cap W_B)$ is spanned by some $z \in P\}$.

▶ **Definition 5.** A QCMA-protocol for a function f satisfies assumption (*), if it is a valid QCMA protocol, and if there is a strategy for Merlin, in which he can convince Alice and Bob to accept with probability at least 2/3 for every 1-input by using intersectional proofs only.

5 Preliminaries

5.1 Communication Complexity

We assume familiarity with the standard modes of communication complexity, and use $R(f)$ to denote the randomized communication complexity (for simplicity we choose public coin randomness), and $Q(f)$ to denote the (entanglement assisted) quantum communication complexity, with error 1/3 in each case. For details we refer to [29].

Proof systems have been introduced into communication complexity in [6], and studied further in e.g. [18, 25, 1, 4, 19, 20, 10, 12]. We now define the main models involving a prover that we use.

▶ **Definition 6.** In a Merlin Arthur protocol a prover (Merlin) sends a string to Alice, who then communicates with Bob. Merlin sees both inputs x, y while Alice sees only x and Bob only y. The goal is to compute a Boolean function $f(x, y)$. Alice and Bob have shared randomness that is invisible to Merlin. Such a protocol is *sound*, if all 0-inputs are accepted with probability at most 1/3 given any message of Merlin, and *complete*, if all 1-inputs are accepted with probability at least 2/3 for some message of Merlin.

The cost of the protocol is the total communication length used, in the worst case, i.e., the total length of the messages sent by Merlin, Alice and Bob. The Merlin Arthur

communication complexity of f is the minimum complexity over all sound and complete protocols for f. It is denoted by $MA(f)$.

If we fix the proof length to some parameter p, then it is natural to only count the length of the communication among Alice and Bob. We denote the MA complexity with fixed proof length p by $MA^p(f)$.

It is easy to see that for all $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ we have $MA^n(f) = O(1)$. One can also establish easily by a counting argument that for most such f we have $MA(f) = \Theta(n)$. It is open to prove a larger lower bound than $\Omega(\sqrt{n})$ for any explicit function.

We now turn to quantum versions of this model.

▶ **Definition 7.** In a QCMA protocol Merlin sends a classical message to Alice, while Alice and Bob can communicate using quantum messages and may hold parts of an arbitrary entangled state (not accessible by Merlin). The remaining description is as for MA-protocols. The QCMA-complexity of f is denoted by $QCMA(f)$. If we restrict the length of the proof to p, then we count only the length of the communication between Alice and Bob. The corresponding complexity measure is denoted by $QCMA^p(f)$.

In a QMA protocol Merlin may send a quantum message to Alice. Otherwise the definition is as above. The notations are $QMA(f)$ and $QMA^p(f)$.

Finally, we consider the model where Merlin, Alice, Bob additionally share a classical public coin. Merlin then sends a quantum message to Alice, and Alice and Bob communicate with quantum messages (but have no shared entanglement). This can be called Arthur Quantum Merlin Arthur, because the shared public coin could be seen as a challenge to Merlin. The complexity is denoted $AQMA(f)$.

We define AQMA protocols because we can precisely capture the complexity of $QNDISJ_{s,t}$ in this model (see the full paper, the bound is $\Theta(\log t)$).

Besides the problem $QNDISJ_{s,t}$, and Vector-in-Subspace= $QNDISJ_{1,n/2}$ we also consider the following problems:

▶ **Definition 8.** The disjointness problem $DISJ_{s,t}$, or short DISJ in case $s = t = n/4$, is the problem where Alice gets $x \in \{0,1\}^n$, Bob gets $y \in \{0,1\}^n$, and they should accept if and only if $\vee_i(x_i \wedge y_i) = 0$ (and we have $|x| = s$ and $|y| = t$). The complement of this problem is NDISJ.

In the problem $INDEX_n$ Alice receives $x \in \{0,1\}^n$, Bob receives $i \in [n]$, and the required output is x_i. This is (more or less) equivalent to $NDISJ_{n/2,1}$.

In the problem IP_n Alice and Bob receive $x, y \in \{0,1\}^n$, and the required output is $\bigoplus_i x_i \wedge y_i$.

One of the main techniques of quantum computing is amplitude amplification, a generalization of Grover search [8, 13].

▶ **Fact 9.** *Suppose we are given a quantum protocol that, depending on the input x, y, either accepts with probability δ, or never accepts, with communication c, and hence computes a function $f(x, y)$ with large, but one-sided error.*

Then there is a quantum protocol for f with communication $O(\sqrt{1/\delta} \cdot c)$ and constant (one-sided) error.

▶ **Definition 10.** A *reduction* from a problem $f : X \times Y \to \{0,1\}$ to a problem $g : U \times V \to \{0,1\}$ consists of two mappings $\rho : X \to U$ and $\tau : Y \to V$ such that

$g(\rho(x), \tau(y)) = f(x, y)$ for all x, y.

Clearly, when there is a reduction from f to g, then for every mode of communication complexity g is at least as hard as f, because Alice and Bob can perform arbitrary local computations for free.

Finally, we note that by standard techniques we may assume that all amplitudes in all our quantum protocols are real.

5.2 Spherical Caps

Let S^{n-1} denote the $(n-1)$-dimensional sphere (i.e., the set of unit vectors in $\mathbb{R}^n$). By μ we usually denote the uniform distribution on a manifold, i.e., the Haar measure. A *spherical cap* centered on a unit vector c is the set $C_\epsilon^c = \{w \in S^{n-1} : \langle v, c\rangle \geq \epsilon\}$, where we leave n implicit and $\epsilon \geq 0$. If we care only about the area or measure of a cap, we drop the center c, because the caps are isomorphic to each other.

We are interested in the measure $\mu(C_\epsilon)$. For this we should know the area of both the sphere and a spherical cap. Let A_{n-1} denote the area of S^{n-1}. An explicit formula is $A_{n-1} = \frac{2\pi^{\frac{n}{2}}}{\Gamma(\frac{n}{2})}$. This is maximized (over integers) at $n = 7$. It can be shown that $A_{n-2}/A_{n-1} \geq \frac{\sqrt{n}}{4}$ for all $n \geq 2$.

Next we state upper and lower bounds on the area or measure of a cap C_ϵ in S^{n-1}.

▶ **Lemma 11.** *Let $\epsilon \leq 1/2$.*

1. *The measure $\mu(C_\epsilon)$ is at most $e^{-n\epsilon^2/2}$.*
2. *The area of C_ϵ is at least $A_{n-2}e^{-n\epsilon^2}/(8n\epsilon)$.*
3. *$\mu(C_\epsilon) \geq e^{-n\epsilon^2}/(32\epsilon\sqrt{n})$.*
4. *If $v \in S^{n-1}$ is a fixed vector, and w is randomly drawn from S^{n-1} under μ, then the probability that $\langle v, w\rangle^2 \geq \frac{k}{n}$ is $\leq 2e^{-k/2}$ and $\geq e^{-k}/(16\sqrt{k})$ for all $1 \leq k \leq n/4$.*

5.3 Concentration of Measure

We now consider projecting random unit vectors on larger subspaces. Unsurprisingly, the larger the subspace gets, the better the concentration of measure is. First note, that when a random unit vector from $\mathbb{R}^n$ is projected onto a fixed subspace of dimension t, then the expected squared projection length is t/n. The following bounds can be found in [11].

▶ **Fact 12.** *Let v be a uniformly random vector from S^{n-1}, W a fixed t-dimensional subspace of $\mathbb{R}^n$, and L denote $||Proj_W v||^2$.*

1. *For $0 < \beta < 1$: $Prob(L \leq (1-\beta)\frac{t}{n}) \leq e^{-t\beta^2/4}$.*
2. *For $0 < \beta < 1$: $Prob(L \geq (1+\beta)\frac{t}{n}) \leq e^{-t\beta^2/8}$.*

We also state a version of the Johnson-Lindenstrauss Theorem, for inner products, see [11].

▶ **Fact 13.** *Let $0 < \epsilon < 0.5$, $n, m > 0$ integers and k such that $k \geq 64/\epsilon^2 \cdot \ln m$. Then for any set $\{v_1, \ldots v_m\} \subseteq \mathbb{R}^n \cap S^{n-1}$ a random projection $g : \mathbb{R}^n \to \mathbb{R}^k$ plus re-normalization (together a mapping f) has the property that for all i, j*

$$\langle v_i|v_j\rangle - \epsilon \leq \langle f(v_i)|f(v_j)\rangle \leq \langle v_i|v_g\rangle + \epsilon.$$

5.4 Sampling by Equators

This is the core technical result from [16].

▶ **Fact 14.** *Let $A \subseteq S^{n-1}$ be a set of measure $\mu(A) \geq 2^{-p}$. Let $v \in S^{n-1}$ be a uniformly random vector from the unit sphere, and $v^{\perp} \subseteq \mathbb{R}^n$ the corresponding uniformly random subspace of dimension $n-1$ orthogonal to v. For any $\frac{p+1}{n} < k < 1$ we have*

$$Prob[|\frac{\mu_{v^{\perp}}(v^{\perp} \cap A)}{2^{-p}} - 1| \geq k] \leq e^{-\gamma n k/(p+1)},$$

where $\gamma > 0$ is a constant, and $\mu_{v^{\perp}}$ is the uniform measure on $S^{n-1} \cap v^{\perp}$.

5.5 Nets on the Sphere

A reasonable short proof of intersection for QNDISJ is the nearest center (to the intersection) of a cap in an ϵ-net consisting of spherical caps on the sphere. For us ϵ (usually the maximum distance between any vector and the nearest cap center) will be much larger than in the standard literature about ϵ-nets, i.e., ϵ will be close to $\sqrt{2}$. Therefore we prefer to simply call a set of vectors such that the union of caps around them covers the sphere a *net*. For the matter of quantum measurements, one can also allow the union of caps and corresponding anti-caps as elements of a net. An anti-cap is simple the set $\{-v : v \in C_{\epsilon}^{c}\}$. Recall that for C_{ϵ} we use the inner product between the cap center and the vectors in the cap as the defining closeness parameter.

▶ **Lemma 15.** *For $1 \leq p \leq n/4$ there is a set M of $20e^{2p}n^2$ vectors such that for every vector $v \in S^{n-1}$ there is a vector $w \in M$ with $\langle v, w \rangle^2 \geq \frac{p}{n}$.*

6 Techniques

Here we briefly sketch the main ideas in the paper.

6.1 QMA

There is a simple protocol with complexity $O(\log n)$: For a 1-input (W_A, W_B) Merlin sends a unit vector in the intersection $W_A \cap W_B$ as a quantum state to Alice. Alice measures this with an observable containing W_A. If the measurement does not yield W_A as the result, she rejects. Otherwise she sends the measured state to Bob, who measures with an observable containing W_B, and accepts iff the result is W_B.

We explore lower bounds, and are able to show a lower bound of $\Omega(\sqrt{\log t})$ via a reduction from the inner product function $IP_{\log t}$ to $QNDISJ_{1,t}$. We can get rid of the square root if we don't allow entanglement between Alice and Bob via a reduction from a random function $f : \{0,1\}^m \times \{0,1\}^m \to \{0,1\}$ for $m = \log t$ together with a proof that $QMA(f)$ is $\Theta(m)$ with high probability.

The $\log t$ upper bound is tight, if we allow a public coin to be shared by Alice, Bob, and Merlin. This holds via dimension reduction with the Johnson-Lindenstrauss Theorem (Fact 13). Without the public coin it remains open whether there is a better upper bound than $\log n$. For very small s, t we can use the randomized protocol (described below) to beat this bound.

6.2 Randomized

For $s = t = n/4$ the complexity is $\widetilde{\Theta}(n)$, with the lower bound inherited from the standard disjointness problem DISJ and the upper bound by Alice sending a uniformly random unit

vector $v \in W_A \cap S^{n-1}$ encoded with additive error $1/poly(n)$ for each position. Bob then checks if this vector has projection $\approx 4/n$ or only $1/poly(n)$ onto W_B.

For smaller $s \leq t$ things become interesting. We give a protocol of complexity $O(s\sqrt{t})$ extending the protocol of [24] for the Vector-in-Subspace problem. In that protocol one tries to communicate a vector by using a public coin containing a lot of random unit vectors, and indicating which of them has the largest inner product with the vector one tries to communicate.

The extension is to do this for vectors that have a small overlap with the desired vector only, and to the case of differently sized spaces. This extension is like trying to run the mentioned protocol twice, and a careful analysis is needed using concentration of measure on the sphere and for random projections on subspaces. Basically, Alice has a vector with a given projection onto Bob's space, and tries to communicate the overlap, by pointing out the random vector (in the public coin) that has the best overlap with her vector. For the part of her vector that is in Bob's space to be 'visible' it must be larger than the 'noise', namely the usual deviation of a random vector from its expected projection onto the space. Furthermore it is also important for larger values of s, t to communicate the inner product between her vector and the chosen random vector, because otherwise the noise makes the signal useless. We note that for $s\sqrt{t} \geq n \log n$ our protocol becomes useless.

We also show a lower bound. This builds on the lower bound for the Vector-in-Subspace problem in [16]. The idea is to use a direct sum argument. The conditional external information cost [7] has a direct sum property for the OR of s instances of a problem. It is easy to embed an OR of s instances of $QNDISJ_{1,t/s}$ into one instance of $QNDISJ_{s,t}$. We then extend the result of [16] about $QNDISJ_{1,n/2}$ to conditional external information cost. Originally, this result uses the rectangle/corruption bound. The difficulty is that for the direct sum argument we must lower bound the *conditional* information cost. For this we define a partition (a random subspace V of dimension $n/3$ is drawn, then $W_A \in S^{n-1} \cap V$ and $W_B \subseteq V^{\perp}$ are chosen randomly and independently). We then have to bound the information cost conditioned on V.

Overall we get a lower bond of $\Omega(s(t/s)^{1/3})$. This approach might be improved to $\Omega(\sqrt{st})$ by improving the lower bound for $QNDISJ_{1,t}$.

We note some special cases in the following corollary.

▶ **Corollary 16.**

1. $R(QNDISJ)$ *is between* $\Omega(n)$ *and* $O(n \log n)$.
2. $R(QNDISJ_{\sqrt{n},n/2})$ *is between* $\Omega(n^{2/3})$ *and* $O(n)$.
3. $R(QNDISJ_{\sqrt{n},\sqrt{n}})$ *is between* $\Omega(n^{1/2})$ *and* $O(n^{3/4})$.
4. $R(QNDISJ_{O(1),O(1)})$ *is* $\Theta(1)$.

6.3 Quantum

The upper bound $O(\sqrt{s} \log n)$ is by amplitude amplification (see Fact 9): if Alice sends the uniform superposition over a basis of her space W_A to Bob, who measures with an observable containing W_B as an element, then for 1-inputs the probability of acceptance is $1/s$. Note that for 0-inputs this protocol never accepts.

The lower bound of $\Omega(\sqrt{s})$ is by reduction from the classical disjointness problem DISJ and Razborov's lower bound for the latter [27].

It remains open, whether the log-factor can be shaved off of the upper bound (compare [2]).

The protocol in our upper bound uses many rounds. Round-dependant lower bounds can be derived from the corresponding Disjointness lower bounds, see [9]. In particular, the

one-way quantum complexity of $QNDISJ_{s,t}$ (Alice to Bob) is $\Omega(s)$ (by a reduction from $INDEX_s$, see [17]).

▶ **Theorem 17.** *There is a quantum protocol with k rounds (Alice starting) that computes $QNDISJ_{s,t}$ with communication $O(s/k \cdot \log n)$ as long as $k \leq \sqrt{s}$. The protocol is optimal up to poly-logarithmic factors.*

Proof. The lower bound is by reduction from Disjointness and the main result in [9]. For the upper bounds we use amplitude amplification on the following protocol: Alice sends s/k^2 copies of the state used in our quantum protocol above. Bob measures those copies, and accepts with probability $1/k^2$. ◀

6.4 QCMA

We give a protocol of complexity $O(s^{1/3} \log n)$ in which Merlin can use caps on the sphere are his proofs. The verification is via amplitude amplification.

Merlin and Alice agree beforehand on a net of spherical caps on the sphere in W_A for all subspaces W_A of dimension s. This net has 2^p centers. On a 1-input (W_A, W_B) Merlin sends Alice the closest center to an intersecting unit vector in $W_A \cap W_B$ from the agreed upon net. Alice and Bob then use the same amplitude amplification protocol as in the prover-less case. Since the cap-center is better than a uniform superposition we get a better upper bound. The reason is that the cap center $|c\rangle$ satisfies $\langle c|x\rangle^2 \geq p/s$ for the intersection $|x\rangle$, whereas a uniform superposition $|u\rangle$ over some ortho-normal basis guarantees only $\langle u|x\rangle^2 \geq 1/s$.

▶ **Theorem 18.**
1. *For all $\log s \leq p \leq s$: $QCMA^p(QNDISJ_{s,t}) \leq O(\sqrt{s/p} \log n)$.*
2. *$QCMA(QNDISJ_{s,t}) \leq O(s^{1/3} \log n)$*

We give a conditional lower bound, for protocols with property (*). Such protocols need communication $\Omega(s^{1/3})$. It is enough to show that $QCMA(QNDISJ) = \Omega(n^{1/3})$ by padding.

The idea is that under the condition (*) an (intersectional) proof corresponds to a large subset of the sphere, and we can then, by a new geometrical lemma, find an ortho-normal set of size $\Omega(n/p)$ in any subset of the sphere of measure 2^{-p}. This result can be used to give a reduction from $DISJ_{n/p,n/p}$ to the subfunction of $QNDISJ$ that accepts all 1-inputs in the proof and rejects all 0-inputs.

For this we fix one large, intersectional proof. We then have a quantum protocol that accepts all 1-inputs in the proof, while rejecting all 0-inputs. We find our large ortho-normal set inside the proof, and then embed the classical $DISJ_{n/p,n/p}$ instance. The lower bound follows via the quantum lower bound for $DISJ_{n/p,n/p}$ [27].

This is the geometric lemma mentioned above.

▶ **Lemma 19.** *Let $A \subseteq S^{n-1}$ be a set of measure at least $\mu(A) \geq 2^{-p}$ for $o(\sqrt{n}) \geq p \geq \omega(1)$. Then A contains a set of $\ell = n/(40p)$ vectors $v_1, \ldots, v_\ell$ such the x_i form an ortho-normal system (i.e., every v_i is orthogonal to the span of the other vectors).*

The lower bound statement is as follows.

▶ **Theorem 20.** *Under the condition (*)*
1. *$QCMA^p(QNDISJ_{n/4,n/4}) \geq \Omega(\sqrt{n/p})$ for $p \leq o(\sqrt{n})$.*
2. *$QCMA(QNDISJ_{s,t}) \geq \Omega(s^{1/3})$.*

6.5 MA

We "Merlinize" our randomized protocol (proofs are still spherical caps as in the QCMA case). The result is an upper bound that is the square root of the randomized upper bound.

▶ **Theorem 21.**
1. *For all* $\log s \leq p \leq s$: $MA^p(QNDISJ_{s,t}) \leq O(s\sqrt{t}/p)$.
2. $MA(QNDISJ_{s,t}) \leq O(\sqrt{s\sqrt{t}})$.

Lower bounds for MA-communication complexity can be shown by using the rectangle bound [18]. [16] give such a lower bound, and we get a lower bound that depends polynomially on t. Sadly, no direct sum result is known for the rectangle bound, and our bound is simply a lower bound for $QNDISJ_{1,t}$. We note that the Grassmannian manifold is much harder to handle than the sphere, and so going for an improved rectangle bound heads on seems difficult.

▶ **Fact 22.** $MA(QNDISJ_{1,t}) = \Omega(t^{1/6})$.

It is interesting that this lower bound depends polynomially on the dimension of the *larger* subspace, whereas our QCMA upper bound depends only on the dimension of the smaller subspace.

7 Open Problems

We list a number of interesting open problems.
1. Show an unconditional, large lower bound on $QCMA(QNDISJ)$.
2. Give better bounds for the randomized and MA complexities of $QNDISJ_{s,t}$.
3. Since the randomized and MA protocols we give are one-way protocols, it might be interesting to also get one-way lower bounds.
4. Is $Q(QNDISJ_{s,t}) = O(\sqrt{s})$?
5. Our QMA upper and lower bounds are not close for small dimensional subspaces. For instance we only know that $QMA(QNDISJ_{\log n,\log n})$ is between $\sqrt{\log\log n}$ and $\log n$.
6. Raz and Shpilka [25] show that QMA protocols can be made one-way, but in general only at a polynomial blowup in communication. Can a gap be shown (for instance for Disjointness)?
7. We show that $AQMA(INDEX_n) \geq \Omega(\log n)$. Larger lower bounds for any explicit functions for even AM-complexity are wide open.
8. There is still a gap between the best lower and upper bound known for $QMA(DISJ)$ [20].
9. What is the QMA communication complexity (with entanglement) of a random function?
10. It would be nice if applications of our bounds could be found. Most applications of communication complexity employ Disjointness, so it is quite likely that the 'hidden basis" version of the problem (in particular also the Vector-in-Subspace problem) has interesting applications, e.g. in data-streaming.

Abstract

The approximation ratio has become one of the dominant measures in mechanism design problems. In light of analysis of algorithms, we define the *smoothed approximation ratio* to compare the performance of the optimal mechanism and a truthful mechanism when the inputs are subject to random perturbations of the worst-case inputs, and define the *average-case approximation ratio* to compare the performance of these two mechanisms when the inputs follow a distribution. For the one-sided matching problem, Filos-Ratsikas et al. [21] show that, amongst all truthful mechanisms, *random priority* achieves the tight approximation ratio bound of $\Theta(\sqrt{n})$. We prove that, despite of this worst-case bound, random priority has a *constant smoothed approximation ratio*. This is, to our limited knowledge, the first work that asymptotically differentiates the smoothed approximation ratio from the worst-case approximation ratio for mechanism design problems. For the average-case, we show that our approximation ratio can be improved to $1 + e$. These results partially explain why random priority has been successfully used in practice, although in the worst case the optimal social welfare is $\Theta(\sqrt{n})$ times of what random priority achieves. These results also pave the way for further studies of smoothed and average-case analysis for approximate mechanism design problems, beyond the worst-case analysis.

1 Introduction

Algorithmic mechanism design [35, 36] deals with optimization problems where the input is provided by self-interested agents that participate in the mechanism by reporting their private information. If it best serves their purpose, they might have incentives to report false information. The goal of the designer is to motivate agents to always report truthfully. At the same time, the mechanism designer aims to optimize some objective function over

the agents' reports, subject to a polynomial-time implementability constraint. Examples of applications include scheduling problems [17, 28, 29], facility location problems [22, 39], kidney exchange problems [6], assignment problems [19], one-sided matching [21], resource allocation [24], and auction design [3, 4, 26, 30, 34]. For a more detailed investigation, we refer the reader to [37]. The canonical measure of evaluating how well a truthful mechanism approximately optimizes the objective is the *approximation ratio* [39]. Given any instance, the approximation ratio compares the performance of the optimal mechanism (which always outputs an optimal solution but is not necessarily truthful) against the performance of a truthful mechanism. The worst-case ratio is the largest value of this ratio, amongst all possible inputs.

The difference of mechanism design to algorithm design is the additional constraint of motivating agents to act truthfully in the mechanism. In algorithm design problems, in contrast, the inputs are not controlled by rational agents, and the *worst-case time complexity* is one of the dominant measures to evaluate the performance of algorithms. However, this is a very pessimistic measure. On one hand, if it is possible to obtain a small worst-case complexity, then it is a very strong guarantee on the performance of the algorithm no matter what input is given. On the other hand, there are algorithms that perform well in practice but have a high worst-case complexity bound. To address this disparity, the *average-case* time complexity of an algorithm is an alternative measure to the worst-case complexity; it measures the time complexity of the algorithm, averaged over all possible inputs when they follow a certain distribution. The main motivation of studying average-case complexity is that some algorithms may have to run for a high-order polynomial-time or even exponential time in the worst case, but the input for this to happen may rarely or never occur in practice. So instead of only focusing on unrealistic worst-case instances, researchers consider the performance of the algorithm on average. One criticism to average-case complexity, however, is that it requires assumptions about the distribution of inputs, and these are not guaranteed to hold in practice. Even for the same algorithm, when it is applied to different application areas, the real-world distribution may vary. In light of this, *smoothed complexity* is a hybrid of the worst-case and average-case analysis that inherits advantages of both. Specifically, it measures the expected performance of algorithms under slight random perturbations of the worst-case inputs. If the smoothed complexity of an algorithm is low, then it is unlikely that the algorithm will take a long time to solve practical instances whose data are subject to slight noise and imprecisions. Although average-case and smoothed analysis are usually more complex than the worst-case analysis, they provide different measures from the worst-case complexity.

In this paper, we extend the classical worst-case approximation ratio analysis of mechanisms to the smoothed approximation ratio and average-case approximation ratio analysis. *Average-case approximation ratio*, on average, measures the performance of a truthful mechanism in approximately maximizing social welfare (or minimizing social cost) against the performance of the optimal mechanism; the *smoothed approximation ratio* compares the performance of these two mechanisms when the inputs are subject to random perturbations of worst-case inputs. Therefore, the central questions in smoothed analysis and average-case analysis in mechanism design framework are:

Given a mechanism design problem, in case the worst-case approximation ratio is asymptotically large, are there any mechanisms that achieve a constant smoothed approximation ratio and a constant average-case approximation ratio? Given a concrete mechanism for the problem, does it have a constant smoothed approximation ratio and a constant average-case approximation ratio?

As a first step of extending the worst-case analysis to the smoothed and average-case analysis in mechanism design, we study the problem of approximate social welfare maximization (without money) in the *one-sided matching settings* (also referred to as the *house allocation problem*). These settings consider the fundamental resource allocation problem of assigning items to agents, such that each agent receives exactly one item. It has numerous applications, such as assigning workers to shifts, students to courses, and patients to doctor appointments. In this problem, agents are asked to provide their preferences over items. In game-theoretic terms, these are the agents' von Neumann-Morgenstern utilities [49, 50]. Social welfare is the sum of all agents' utilities. It is easy to see that agents, as self-interested identities, have an incentive to misreport their preferences if they can benefit from this behavior. The *random priority* mechanism, apart from being truthful, also satisfies the desirable properties of anonymity and ex-post Pareto efficiency. In term of social welfare maximization, Filos-Ratsikas et al. [21] show that amongst all truthful mechanisms, random priority achieves the worst-case approximation ratio tight bound of $\Theta(\sqrt{n})$. That is, random priority can guarantee an upper bound of $O(\sqrt{n})$ and there is a worst-case instance on which no mechanism can do better than $\Omega(\sqrt{n})$. Nevertheless, the tight bound instance has a very unique structure such that it is very unlikely to happen in practice. Therefore, we are in great request to understand how well random priority performs on average, when the instances are sampled from a certain distribution. How well it performs under some random perturbations of the worst-case inputs? We address these questions in this paper.

1.1 Our contribution

To the best of our knowledge, this is the first work that asymptotically differentiates the smoothed approximation ratio from the worst-case approximation ratio for mechanism design problems. In particular, we show the following results:

- The random priority mechanism has a constant smoothed approximation ratio.
- The average-case approximation ratio of random priority is upper bounded by a constant $1 + e$, when agents' valuations are drawn from the uniform distribution $\mathrm{U}(0, 1)$.

Our results imply that, although in the worst-case the optimal social welfare is $\Theta(\sqrt{n})$ times of the social welfare attainable by random priority, under polynomial small perturbation around the worst-case inputs and on average, random priority achieves a constant factor of the optimal social welfare.

In [21], the tight bound examples for the worst-case approximation ratio have a unique structure where the preferences of all agents over the items have the same ordering, and the values are all close to either 1 or 0. From the average-case perspective, these examples rarely happen if the valuations are independently and identically drawn from a uniform distribution. From the smoothed analysis perspective, this unanimous ordering would break up after any random perturbation. This is the high-level intuition behind why the smoothed and average-case approximation ratios could be asymptotically different from the worst-case approximation ratio.

1.2 Related work

Spielman and Teng [43, 44] first propose the methodology of smoothed analysis of algorithms with the attempt to explain why the simplex algorithms usually run in polynomial time in practice. They start with the shadow-vertex pivot rule and show its polynomial smoothed complexity. Since then, smoothed analysis has been studied on a variety of different problems

and algorithms, including linear programming [11, 40, 44], online and approximation algorithms [9, 10, 41], searching and sorting [7, 23, 31], game theory [14, 16], local search [5, 20], clustering and knapsack problem [32]. A comprehensive survey can be found in [45].

For average-case analysis of algorithms, different results have been obtained in, for example, quicksort for sorting problem [18] and the simplex algorithm for solving linear programming [13]. We refer the reader to [48] for a comprehensive survey.

In the presence of incentives, the one-sided matching problem was originally defined by Hylland and Zeckhauser [27], and has been studied extensively ever since [12, 19, 33, 46, 51]. We refer the interested reader to surveys on this problem [2, 42]. The *random priority* mechanism, also known as *random serial dictatorship*, has been extensively studied [1, 12, 47]. It has also been widely used in practice, for example, the supplementary round of school student assignment mechanism in New York City, is shown to be equivalent to a random priority mechanism [38].

In the Bayesian auction design literature [15, 25], the focus is on how well a truthful mechanism can approximately maximize the expected revenue, when instances are taken from the entire input space. More specifically, the dominant approach in the study of Bayesian auction design is the *ratio of expectations*. One disadvantage of this approach is that it does not directly compare the performance of the two mechanisms on specific inputs. To address this problem, in what follows, we present a different approach, the *expectation of the ratio*, and compare them in more detail.

2 Preliminaries

We study the one-sided matching problem that consists of n agents and n indivisible items. All the agents are endowed with von Neumann - Morgenstern utilities over the items. The VNM utility theorem states that any rational agent whose preference satisfies four axioms, namely *completeness*, *transitivity*, *continuity*, and *independence*, is endowed with a utility function to represent its preference. These agents report their preferences to a mediator; based on their report, the problem is to allocate items to agents, according to a random permutation such that every agent receives exactly one item.

In this paper, we adopt the *unit-range* canonical representation of agents' valuation [8, 51]. That is, for the utility a_{ij} of agent i receiving item j, we have $\max_j\{a_{ij}\} = 1, \min_j\{a_{ij}\} = 0$, for any $i \in [n]$ [1]. Following this, a valuation profile (or instance) of agents' preferences can be represented by a matrix $\mathrm{A} = [a_{ij}]_{n\times n}$, where row vector $\mathbf{a_i} = (a_{i1}, \ldots, a_{in})$ indicates the valuation of agent i's preference. An *allocation* is an assignment of items to agents. We denote an allocation by a matrix $\mathrm{X} = [x_{ij}]_{n\times n}$, where x_{ij} indicates the probability of agent i receiving item j. Given any preferences of the agents as input, a *mechanism* is a mapping from the input to an allocation X as output.

We denote the set of all possible instances by $\mathcal{A}$ and denote the set of all possible allocation by $\mathcal{X}$. Given a mechanism M and a valuation profile $\mathrm{A} \in \mathcal{A}$, as well as its allocation $\mathrm{X(A)} \in \mathcal{X}$, we denote the utility of agent i by $u_i(\mathrm{X(A)}) = \sum_j a_{ij}x_{ij}$ and denote the social welfare by $SW_{\mathrm{M}}(\mathrm{X(A)}) = \sum_i u_i(\mathrm{X(A)})$. When the context is clear, we drop the allocation notation and simplely refer them by $u_i(\mathrm{A})$ and $SW_{\mathrm{M}}(\mathrm{A})$. We note that there is another interpretation

[1] We note here that our model would be more general and some calculations would be simpler if we drop the constraint $\max_j\{a_{ij}\} = 1$ and $\min_j\{a_{ij}\} = 0$, but only require that $0 \le a_{ij} \le 1$, for all $i, j \in [n]$. The only reason to have such a constraint is to follow the *unit-range* canonical representation of agents' valuation studied in literature.

of our one-sided matching problem: items are divisible and x_{ij} is the fraction of agent i receiving item j. Since the number of agents is equal to the number of items, and every agent receives exactly one item, the allocation matrix X is a doubly stochastic matrix, i.e., $\sum_j x_{ij} = 1$ for any i, and $\sum_i x_{ij} = 1$ for any j. According to the Birkhoff - von Neumann theorem, every doubly stochastic matrix can be decomposed into a convex combination of some permutation matrices. Therefore, $u_i(\mathrm{A})$ and $SW_{\mathrm{M}}(\mathrm{A})$ can be interpreted as expected utilities and expected social welfare in the indivisible items setting, and can be interpreted as exact utilities and exact social welfare in the divisible items setting.

Agents are self-interested and look to maximize their utilities by giving a mendacious preference to the mechanism as part of the input. In approximate mechanism design, we restrict our interest to the class of *truthful mechanisms*, i.e., the mechanisms in which agents cannot improve their utilities by misreporting. The canonical measure of efficiency of a truthful mechanism M is the *worst-case approximation ratio*,

$$r_{\mathrm{worst}}(\mathrm{M}) = \sup_{\mathrm{A}\in\mathcal{A}} \frac{SW_{\mathrm{OPT}}(\mathrm{A})}{SW_{\mathrm{M}}(\mathrm{A})},$$

where $SW_{\mathrm{OPT}}(\mathrm{A}) = \max_{\mathrm{X}\in\mathcal{X}} \sum_{i=1}^{n} u_i(\mathrm{X})$ is the optimal social welfare which is equal to the value of the maximum weight matching between agents and items. This ratio compares social welfare of the optimal allocation against social welfare of a truthful mechanism M. Note that the ratio is no less than 1.

Random priority mechanism fixes an ordering of the agents uniformly at random and then lets them pick their most preferred item from the set of available items based on this ordering. It is shown in [21] that random priority achieves the matching approximation ratio bound of $\Theta(\sqrt{n})$. This result implies that random priority is asymptotically the best truthful mechanism.

2.1 Smoothed and average-case approximation ratios

Analogously to the definition of smoothed complexity of algorithms, we define the *smoothed approximation ratio* as follows:

$$r_{\mathrm{smoothed}}(\mathrm{M}) = \max_{\mathrm{A}} \mathop{\mathbb{E}}_{g_{ij}\sim\mathrm{N}(0,1)} \left[\frac{SW_{\mathrm{OPT}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}{SW_{\mathrm{M}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})} \right],$$

where the parameter σ is the size of the perturbation and $\mathrm{G} = [g_{ij}]_{n\times n}$. That is to say, $\sigma||\mathrm{A}||\mathrm{G}$ is a matrix of independent Gaussian variables of mean 0 and standard deviation $\sigma||\mathrm{A}||$. We multiply by $||\mathrm{A}||$ to relate the magnitude of the perturbation to the magnitude of the input A. We say that a mechanism has a *constant smoothed approximation ratio* if its smoothed approximation ratio is polynomial only in $1/\sigma$, when the size of the input n approaches infinity [2]. Following the natural of the unit-range representation, we consider the *property-preserving perturbation* by restricting a natural perturbation model to preserve

[2] We will show that the smoothed approximation ratio of random priority is polynomial only in $1/\sigma$ but not in n. This is in contrast to its worst-case approximation ratio $\Theta(\sqrt{n})$. For this reason our result asymptotically differentiates the smoothed approximation ratio from the worst-case ratio. It is a scenery analogously to the analysis of algorithms, where in some problems the smoothed complexity is polynomial in n and $1/\sigma$ but the worst-case complexity is exponential in n. In both studies, the point of smoothed analysis is to show that although the mechanism (algorithm) may perform poorly in the worst case, it performs well under slight random perturbations of worst-case inputs.

certain properties of the input. Specifically, the perturbation preserves agents' 0 and 1 valuation and all valuations stay in the interval $[0, 1]$ [3].

Similarly, we define the *average-case approximation ratio* of mechanisms as follows:

$$r_{\text{average}}(\text{M}) = \mathop{\mathbb{E}}_{a_{ij}\sim \text{U}} \left[\frac{SW_{\text{OPT}}(\text{A})}{SW_{\text{M}}(\text{A})} \right],$$

where the elements a_{ij} of input A is chosen from a distribution U. In this paper, we consider the case that agent's values a_{ij} are independent variables and follow the uniform distribution $\text{U}(0, 1)$. For any agent i, since $a_{ij}, j = 1, \ldots, n$, are independent and identically distributed $\text{U}(0, 1)$ random variables, the sum $\sum_{j=1}^{n} a_{ij}$ follows the *Irwin-Hall distribution*. So,

$$\Pr\left[\sum_{j=1}^{n} a_{ij} \le x\right] = \frac{1}{n!} \sum_{k=0}^{\lfloor x-1 \rfloor} (-1)^k \binom{n}{k} (x-1-k)^n,$$

where $\lfloor \cdot \rfloor$ is the floor function.

In the following, we contrast this approach to the established literature on Bayesian mechanism design.

2.2 Bayesian mechanism design approach

In Bayesian mechanism design [15, 25], there is also a prior distribution from which the agent types come from, but the objective is to characterize the maximum ratio (for some given distribution of the agent types) of the expected social welfare of a truthful mechanism over the expected social welfare of the optimal mechanism, i.e., the ratio of expectations. That is, the objective is to characterize the ratio r in the following formula,

$$\mathbb{E}\left[SW_{\text{OPT}}(\text{A})\right] \le r \cdot \mathbb{E}\left[SW_{\text{M}}(\text{A})\right].$$

Thus, the key difference to our approach is that this measurement does not directly compare the performance of the two mechanisms on specific inputs. We discuss this in more detail in the following.

2.3 Comparison of the two approaches

We note that the worst-case approximation ratio compares the performance of the two mechanisms on a *case-by-case basis*. In addition, the smoothed analysis of algorithms is defined as the performance of the algorithm on the worst-case input when it is subject to a slight random perturbation. Therefore, it measures the averaged performance of the algorithm in a small neighbourhood area of *an individual input*. In essence, both metrics consider a specific input (or some small noise around a specific input). Indeed, our approach is informed by these two metrics.

Average-case approximation ratio and the Bayesian approach each has their strength in measuring how good a truthful mechanism approximates the optimal mechanism. The random priority mechanism for the one-sided matching problem is used for example, in the supplementary round of school student assignment in the New York City once in a while. In

[3] We note that the choice of Gaussian perturbation is standard in classical smoothed analysis of algorithms, and restriction of property-preserving perturbations is necessary and meaningful even in average-case analysis of algorithms.

this case, we are interested in how likely a truthful mechanism performs well on a particular instance. Therefore, the average-case approximation ratio, which is the expectation of ratio, fits in this need. On the other hand, online auction mechanisms, as the revenue source for Internet businesses, are used one a daily base. In that case, we are interested in how well a truthful mechanism performs comparing to the optimal mechanism when instances are sampled throughout the entire input space. Therefore, the Bayesian approach, which is the ratio of expectations, is more suitable.

We note that our definitions, the expectation of ratio, introduce more technical challenges. As we are interested in characterizing the expectation of a non-linear function (ratio of two variables), we can no longer handle expectations of two different variables separately. Let us take for example when agents' valuations are drawn independently and identically from the uniform distribution $\mathrm{U}(0,1)$. In the Bayesian approach, it is trivial to see that the expected social welfare of the completely random mechanism (by ignoring agents' valuations and allocate items totally random) is $n/2$, and the expected social welfare of the optimal mechanism is less than n. So the ratio of two expectations is less than 2. However, for the case-by-case comparison in the average-case approximation ratio, it is not directly clear what the ratio would be. In this paper, as a first step, we study the uniform distribution for the average-case ratio and the smoothed ratio. We suspect that different distributions would result in different ratios. In contrast, by the linearity of the ratio in two expectations, in the well-studied Bayesian auction design literature, it is common that positive results hold for a class of distributions, such as monotone hazard distributions [25].

3 Smoothed Analysis

In this section we show that random priority has a constant smoothed approximation ratio.

Firstly, let us understand the structure of the profile space $\mathcal{A}$ in the unit-range setting. For each agent i with valuations $\mathbf{a}_i = (a_{i1}, \ldots, a_{in})$, it has utility 0 on its least preferred item and has utility 1 on its most preferred item. So there remains $n-2$ elements which are random variables following the uniform distribution $\mathrm{U}(0,1)$. Note that there are $n(n-1)$ possible choices to select $n-2$ out of n elements to be random variables, while the other two elements being either 0 or 1. So there are $(n(n-1))^n$ possible configuration of such random variables. Therefore, we can decompose the sample space $\mathcal{A}$ into sets $\mathrm{S_k}, k = 1, \ldots, (n(n-1))^n$, where each set $\mathrm{S_k}$ contains the instances A that the specific two out of n values of $a_{ij}, j \in [n]$ are fixed for each agent i.

Given any valuation profile A, its 0 and 1 entries are fixed so it must belong to exactly one of the set S_k. Let $\mathrm{S(A)} \in \{\mathrm{S}_k\}_{k\in[(n(n-1))^n]}$ denote the set where A belongs to. Let $\mathrm{H(A)} = \{(i,j) : a_{ij} = 0 \text{ or } a_{ij} = 1\}$, clearly $\mathrm{H(A)}$ has $2n$ elements. Given any set $\mathrm{S_k}$ and any two instances A_1 and A_2 chosen from $\mathrm{S_k}$, it is easy to see that $\mathrm{H(A}_1) = \mathrm{H(A}_2)$.

For convenience, denote $\Gamma = (\gamma_{ij})_{n\times n} = \sigma||\mathrm{A}||\mathrm{G}$. The probability density function of Γ is

$$f(\Gamma) = K \cdot e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}} = K \cdot e^{-\sum_{i=1}^{n}\sum_{j=1}^{n}\frac{\gamma_{ij}^2}{2\sigma^2||\mathrm{A}||^2}},$$

where K is a constant, $|\Gamma|^2 = \sum_{i=1}^{n}\sum_{j=1}^{n}\gamma_{ij}^2$. Therefore, our problem of characterizing the smoothed approximation ratio of random priority is reduced to computing the upper bound of

$$\max_{\mathrm{A}\in\mathcal{A}} \int_{\mathrm{A}+\Gamma\in\mathrm{S(A)}} \frac{1}{K'} \cdot e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}} \cdot \frac{SW_{OPT}(\mathrm{A}+\Gamma)}{SW_{RP}(\mathrm{A}+\Gamma)} d\Gamma,$$

where $K' = \int_{\mathrm{A}+\Gamma\in\mathrm{S(A)}} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}} d\Gamma$. As we clarified in the Preliminaries, we consider the property-preserving perturbation that preserves agents' 0 and 1 valuation and all valuations stay in the interval $[0,1]$. Therefore, our integral is taken over the space $\mathrm{A}+\Gamma \in \mathrm{S(A)}$. We would need the following auxiliary lemma. The proof is omitted due to the page limit.

▶ **Lemma 1.** *For any valuation profile* $\mathrm{A} \in \mathcal{A}$ *and standard vector norm such as Euclidean norm, p-norm and maximum norm, we have* $||\mathrm{A}|| \geq 1$.

Our main result of this section is the following.

▶ **Theorem 2.** *Random priority has a constant smoothed approximation ratio. That is to say, its smoothed approximation ratio is polynomial in* $1/\sigma$*, when the input size* n *approaches infinity.*

Obviously, when $\frac{1}{\sigma} \geq \sqrt{n}$, since the smoothed approximation ratio is upper bounded by worst-case approximation ratio $O(\sqrt{n})$, there $\exists M > 0$, such that

$$r_{\text{smoothed}} \leq r_{\text{worst}} \leq O(\sqrt{n}) \leq M \cdot \frac{1}{\sigma}$$

In the following we focus on the case when $\frac{1}{\sigma} < \sqrt{n}$. We further divide our analysis into two cases, depending on the size of the perturbation σ and the magnitude of A.

Case 1: $\sigma||\mathrm{A}|| \leq 1$.

Firstly, the following lemma lower bounds the constant K'.

▶ **Lemma 3.** *When* $\sigma||\mathrm{A}|| \leq 1$*, for any instance* A *and Gaussian perturbation* Γ*, we have*

$$K' = \int_{\mathrm{A}+\Gamma\in\mathrm{S(A)}} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}} d\Gamma \geq \left(e^{-\frac{1}{2}} \cdot \sigma||\mathrm{A}||\right)^{n(n-2)}$$

Proof.

$$\begin{aligned}
K' &= \int_{\mathrm{A}+\Gamma\in\mathrm{S(A)}} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}} d\Gamma = \prod_{(i,j)\in\mathrm{H(A)}} e^{-\frac{0}{2\sigma^2||\mathrm{A}||^2}} \prod_{(i,j)\notin\mathrm{H(A)}} \int_{a_{ij}+\gamma_{ij}\in[0,1]} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \\
&= 1 \cdot \prod_{(i,j)\notin\mathrm{H(A)}} \int_{-a_{ij}}^{1-a_{ij}} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \\
&= \prod_{(i,j)\notin\mathrm{H(A)}} \left(\int_{0}^{1-a_{ij}} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} + \int_{0}^{a_{ij}} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \right) \\
&\geq \prod_{(i,j)\notin\mathrm{H(A)}} \left(\int_{0}^{1-a_{ij}} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} + \int_{1-a_{ij}}^{1} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \right) = \prod_{(i,j)\notin\mathrm{H(A)}} \int_{0}^{1} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \\
&= \left(\int_{0}^{1} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \right)^{n(n-2)} \geq \left(\int_{0}^{\sigma||\mathrm{A}||} e^{-\frac{|\gamma_{ij}|^2}{2\sigma^2||\mathrm{A}||^2}} d\gamma_{ij} \right)^{n(n-2)} \\
&\geq \left(\int_{0}^{\sigma||\mathrm{A}||} e^{-\frac{1}{2}} d\gamma_{ij} \right)^{n(n-2)} = \left(e^{-\frac{1}{2}} \cdot \sigma||\mathrm{A}||\right)^{n(n-2)}
\end{aligned}$$

◀

Secondly, given any instance A and its associated set S(A), we further partition the set S(A) into two subsets, according to the value of social welfare of random priority on its elements, namely $\mathrm{S}_c(\mathrm{A}) = \{\mathrm{B} \in \mathrm{S(A)} : SW_{RP(\mathrm{B})} \leq n^c\}$ and the residual $\mathrm{S(A)}/\mathrm{S}_c(\mathrm{A}) = \{\mathrm{B} \in \mathrm{S(A)} :$

$SW_{RP(\mathrm{B})} > n^c\}$, where $0 < c < 1$ is a parameter that will facilitate us to prove our main theorem. Let $\mathrm{V}(\mathrm{S_c(A)})$ and $\mathrm{V}(\mathrm{S(A)})$ be the volume of $\mathrm{S}_c(\mathrm{A})$ and $\mathrm{S(A)}$, respectively. We upper bound the fraction of the elements of the set $\mathrm{S(A)}$ for which the social welfare of random priority on its elements is no more than n^c. A useful observation here is that, this objective is equivalent to computing the probability that the social welfare of random priority on any instance A is no more than n^c, when the agents' values a_{ij} are independently and identically drawn from the uniform distribution $\mathrm{U}(0,1)$.

▶ **Lemma 4.** *Given any n, for every $0 < c < 1$, we have*

$$\frac{\mathrm{V}(\mathrm{S_c(A)})}{\mathrm{V}(\mathrm{S(A)})} \le \frac{\mathrm{e}^{2n}}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)}.$$

Proof. We note that random priority is a truthful mechanism, and it fixes an ordering of agents uniformly at random. Every agent i has a probability of $1/n$ to be selected first to choose an item, a probability of $2/n$ to be selected first or second to choose an item, and so on. That is to say, for each agent i, if we sort the items in decreasing order according to agent i's preference, then the allocation vector $\mathbf{x}_i = (x_{ij})$ obtained by random priority would stochastically dominates the vector $(\frac{1}{n}, \ldots, \frac{1}{n})$. I.e., for every $k = 1, \ldots, n$, it holds that $\sum_{j=1}^{k} x_{ij} \ge k/n$.

Therefore, the utility of agent i in any instance A is $u_i(\mathrm{A}) = \sum_{j=1}^{n} a_{ij}x_{ij} \ge \frac{1}{n} \cdot \sum_{j=1}^{n} a_{ij}$. Hence, we have social welfare $\mathrm{SW_{RP}(A)} = \sum_i u_i(\mathrm{A}) \ge \frac{1}{n}\sum_{i,j} a_{ij}$. So, $\mathrm{SW_{RP}(A)} \le n^c$ implies $\sum_{i\in[n],j\in[n]} a_{ij} \le n^{1+c}$. Together with the observation noted above, we utilize the Irwin-Hall distribution to prove the lemma.

$$\begin{aligned}
&\frac{\mathrm{V}(\mathrm{S_c(A)})}{\mathrm{V}(\mathrm{S(A)})} = \Pr\left[\mathrm{SW_{RP}(A)} \le n^c\right] \le \Pr\left[\sum\nolimits_{i\in[n],j\in[n]} a_{ij} \le n^{1+c}\right] \\
&= \Pr\left[\sum\nolimits_{(i,j)\notin \mathrm{H(A)}} a_{ij} \le n^{1+c} - n\right] \\
&= \frac{1}{(n(n-2))!} \sum_{k=0}^{\lfloor n^{1+c}-n\rfloor} (-1)^k \binom{n(n-2)}{k} (n^{1+c} - n - k)^{n(n-2)} \\
&\le \frac{1}{(n(n-2))!} \sum_{k=0}^{n(n-2)} \binom{n(n-2)}{k} n^{(1+c)(n(n-2))} = \frac{1}{(n(n-2))!} \cdot (2n^{1+c})^{n(n-2)} \\
&\le \frac{(2n^{1+c})^{n(n-2)}}{\sqrt{2\pi(n(n-2))} \cdot \left(\frac{n(n-2)}{\mathrm{e}}\right)^{n(n-2)}} = \frac{(2n^{1+c})^{n(n-2)}}{\sqrt{2\pi n} \cdot \left(\frac{n^2}{\mathrm{e}}\right)^{n(n-2)}} \cdot \frac{\sqrt{2\pi n} \cdot \left(\frac{n^2}{\mathrm{e}}\right)^{n(n-2)}}{\sqrt{2\pi(n(n-2))} \cdot \left(\frac{n(n-2)}{\mathrm{e}}\right)^{n(n-2)}} \\
&= \frac{1}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)} \cdot \left(1 + \frac{2}{n-2}\right)^{n(n-2)+\frac{1}{2}} \\
&\le \frac{1}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)} \cdot \mathrm{e}^{2n} = \frac{\mathrm{e}^{2n}}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)}
\end{aligned}$$

◀

Combing these two lemmas we can prove our main theorem under this case.

Proof of Case 1 of Theorem 2. Note that when $\mathrm{A} + \Gamma \notin \mathrm{S}_c(\mathrm{A})$, we can upper bound $\frac{SW_{OPT(\mathrm{A}+\Gamma)}}{SW_{RP(\mathrm{A}+\Gamma)}} \le n^{1-c}$, and in all cases $\frac{SW_{OPT(\mathrm{A}+\Gamma)}}{SW_{RP(\mathrm{A}+\Gamma)}} \le O(\sqrt{n})$ according to the worst-case approximation ratio result [21]. In addition, by Lemma 4 we have,

$$\mathrm{V}(\mathrm{S_c(A)}) \le \frac{\mathrm{e}^{2n}}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)} \cdot \mathrm{V}(\mathrm{S(A)}) = \frac{\mathrm{e}^{2n}}{\sqrt{2\pi n}} \cdot \left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n(n-2)} \cdot 1$$

Therefore,

$$\mathop{\mathbb{E}}_{g_{ij}\sim \mathrm{N}(0,1)}\left[\frac{SW_{\mathrm{OPT}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}{SW_{\mathrm{RP}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}\right] = \int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} \frac{e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}}{\int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}d\Gamma}\cdot\frac{SW_{OPT(\mathrm{A}+\Gamma)}}{SW_{RP(\mathrm{A}+\Gamma)}}d\Gamma$$

$$= \int_{\mathrm{A}+\Gamma\notin\mathrm{S}_c(\mathrm{A})} \frac{e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}\cdot\frac{SW_{OPT(\mathrm{A}+\Gamma)}}{SW_{RP(\mathrm{A}+\Gamma)}}}{\int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}d\Gamma}d\Gamma + \int_{\mathrm{A}+\Gamma\in\mathrm{S}_c(\mathrm{A})} \frac{e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}\cdot\frac{SW_{OPT(\mathrm{A}+\Gamma)}}{SW_{RP(\mathrm{A}+\Gamma)}}}{\int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}d\Gamma}d\Gamma$$

$$\le \int_{\mathrm{A}+\Gamma\notin\mathrm{S}_c(\mathrm{A})} \frac{e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}\cdot n^{1-c}}{\int_{A+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||A||^2}}d\Gamma}d\Gamma + \int_{\mathrm{A}+\Gamma\in\mathrm{S}_c(\mathrm{A})} \frac{e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}\cdot O(\sqrt{n})}{\int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||\mathrm{A}||^2}}d\Gamma}d\Gamma$$

$$\le n^{1-c} + \frac{\mathrm{V}(\mathrm{S_c}(\mathrm{A}))\cdot 1\cdot O(\sqrt{n})}{\int_{\mathrm{A}+\Gamma\in\mathrm{S}(\mathrm{A})} e^{-\frac{|\Gamma|^2}{2\sigma^2||A||^2}}d\Gamma} \le n^{1-c} + \frac{\frac{e^{2n}}{\sqrt{2\pi n}}\cdot\left(\frac{2e}{n^{1-c}}\right)^{(n(n-2))}\cdot O(\sqrt{n})}{\left(e^{-\frac{1}{2}}\cdot\sigma||\mathrm{A}||\right)^{n(n-2)}} \quad \text{(by Lemma 3)}$$

$$= n^{1-c} + \frac{e^{2n}}{\sqrt{2\pi n}}\cdot O(\sqrt{n})\cdot\left(\frac{2e^{\frac{3}{2}}}{n^{1-c}\sigma||\mathrm{A}||}\right)^{(n(n-2))}$$

Now let $1-c = \frac{2}{(n-2)\log n} + \frac{\log(2e^{\frac{3}{2}})}{\log n} + \frac{\log(1/\sigma||\mathrm{A}||)}{\log n}$. According to Lemma 1, we have $||\mathrm{A}|| \ge 1$, combining with the assumption $\frac{1}{\sigma} < \sqrt{n}$, we get that $\frac{\log(1/\sigma||\mathrm{A}||)}{\log n} \le \frac{\log(1/\sigma)}{\log n} < \frac{\log(\sqrt{n})}{\log n} = \frac{1}{2}$, which means $0 < 1-c < \frac{1}{2}$, as n approaches infinity. Therefore the value of $1-c$ is feasible. Then,

$$\mathop{\mathbb{E}}_{g_{ij}\sim \mathrm{N}(0,1)}\left[\frac{SW_{\mathrm{OPT}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}{SW_{\mathrm{RP}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}\right] \le 2e^{\frac{3}{2}}\cdot e^{\frac{2}{n-2}}\cdot\frac{1}{\sigma||\mathrm{A}||} + \frac{O(\sqrt{n})}{\sqrt{2\pi n}} \le 2e^{\frac{3}{2}}\cdot e^{\frac{2}{n-2}}\cdot\frac{1}{\sigma} + \frac{O(\sqrt{n})}{\sqrt{2\pi n}}$$

So, when $\sigma||\mathrm{A}|| \le 1$ and $\frac{1}{\sigma} < \sqrt{n}$, we have $\mathbb{E}_{g_{ij}\sim \mathrm{N}(0,1)}\left[\frac{SW_{\mathrm{OPT}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}{SW_{\mathrm{RP}}(\mathrm{A}+\sigma||\mathrm{A}||\mathrm{G})}\right] < 2e^{\frac{3}{2}}\cdot\frac{1}{\sigma}$ as n approaches infinity.

Case 2 $\sigma||\mathrm{A}|| > 1$. The proof is omitted due to the page limit.

Combining these two cases we complete our proof of Theorem 2. ◀

4 Average-case Analysis

In this section we show the average-case approximation ratio of the random priority mechanism can be improved to $1+e$.

Firstly, we upper bound the probability of the social welfare of random priority when it is smaller than a value n^c, for a certain parameter c.

▶ **Lemma 5.** *Given any n, for every $0 < c < 1$, such that $\frac{\mathrm{e}^2}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2} < 1$, we have*

$$\Pr[SW_{RP}(\mathrm{A}) \le n^c] \le \frac{\mathrm{e}^2}{\sqrt{2\pi}}\cdot\sqrt{n}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}.$$

Proof. For any agent i, since $a_{ij}, j = 1,\ldots,n$, are independent and identically distributed $\mathrm{U}(0,1)$ random variables, the sum $\sum_{j=1}^{n} a_{ij}$ follows the *Irwin-Hall distribution*. In addition, in the unit-range setting, there exist j_1 and j_2 such that $a_{ij_1} = 1, a_{ij_2} = 0$, so $\sum_{j=1}^{n} a_{ij} \le x$ is equivalent to $\sum_{j\ne j_1,j_2} a_{ij} \le x-1$, given any $x > 0$. Therefore,

$$\Pr\left[\sum\nolimits_{j=1}^{n} a_{ij} \le x\right] = \Pr\left[\sum\nolimits_{j\ne j_1,j_2} a_{ij} \le x-1\right] = \frac{1}{(n-2)!}\sum_{k=0}^{\lfloor x-1\rfloor}(-1)^k\binom{n-2}{k}(x-1-k)^{n-2}$$

where $\lfloor\cdot\rfloor$ is the floor function. So,

$$\begin{aligned}
&\Pr\left[\sum_{j=1}^{n} a_{ij} \leqslant n^c\right] = \frac{1}{(n-2)!}\sum_{k=0}^{\lfloor n^c-1\rfloor}(-1)^k\binom{n-2}{k}(n^c-1-k)^{n-2}\\
&\leq \frac{1}{(n-2)!}\sum_{k=0}^{\lfloor n^c-1\rfloor}\binom{n-2}{k}(n^c)^{n-2} \leq \frac{1}{(n-2)!}\sum_{k=0}^{n-2}\binom{n-2}{k}n^{c(n-2)}\\
&= \frac{1}{(n-2)!}\cdot(2n^c)^{n-2} \leq \frac{(2n^c)^{n-2}}{\sqrt{2\pi(n-2)}\cdot\left(\frac{n-2}{\mathrm{e}}\right)^{n-2}} \qquad (1)\\
&= \frac{(2n^c)^{n-2}}{\sqrt{2\pi n}\cdot\left(\frac{n}{\mathrm{e}}\right)^{n-2}}\cdot\frac{\sqrt{2\pi n}\cdot\left(\frac{n}{\mathrm{e}}\right)^{n-2}}{\sqrt{2\pi(n-2)}\cdot\left(\frac{n-2}{\mathrm{e}}\right)^{n-2}}\\
&= \frac{1}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}\cdot\left(1+\frac{2}{n-2}\right)^{n-2+\frac{1}{2}}\\
&\leq \frac{1}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}\cdot\mathrm{e}^2 = \frac{\mathrm{e}^2}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}
\end{aligned}$$

where inequality (1) is due to Stirling's formula.

As we have shown in Lemma 4, in random priority mechanism, agent i's utility $u_i(\mathrm{A}) = \sum_{j=1}^{n} a_{ij}x_{ij} \geq \frac{1}{n}\cdot\sum_{j=1}^{n} a_{ij}$. It implies that $\Pr\left[u_i(\mathrm{A}) > x\right] \geq \Pr\left[\frac{1}{n}\sum_{j=1}^{n} a_{ij} > x\right]$. Therefore,

$$\begin{aligned}
&\Pr\left[SW_{RP}(\mathrm{A}) > n^c\right] = \Pr\left[\sum_{i=1}^{n} u_i(\mathrm{A}) > n^c\right] \geq \prod_{i=1}^{n}\Pr\left[u_i(\mathrm{A}) > \frac{1}{n}\cdot n^c\right]\\
&\geq \prod_{i=1}^{n}\Pr\left[\frac{1}{n}\sum_{j=1}^{n} a_{ij} > \frac{1}{n}\cdot n^c\right] = \prod_{i=1}^{n}\Pr\left[\sum_{j=1}^{n} a_{ij} > n^c\right] = \prod_{i=1}^{n}\left(1-\Pr\left[\sum_{j=1}^{n} a_{ij} \leqslant n^c\right]\right)\\
&\geq \left(1-\frac{\mathrm{e}^2}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}\right)^n \geq 1-n\cdot\frac{\mathrm{e}^2}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2} \qquad (2)\\
&= 1-\frac{\mathrm{e}^2}{\sqrt{2\pi}}\cdot\sqrt{n}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}
\end{aligned}$$

where inequality (2) is due to Bernoulli's inequality and the condition that $\frac{\mathrm{e}^2}{\sqrt{2\pi n}}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2} < 1$. Hence,

$$\Pr[SW_{RP}(\mathrm{A}) \leq n^c] \leq \frac{\mathrm{e}^2}{\sqrt{2\pi}}\cdot\sqrt{n}\cdot\left(\frac{2\mathrm{e}}{n^{1-c}}\right)^{n-2}. \qquad \blacktriangleleft$$

Secondly, we lower bound the probability of the social welfare of random priority when it is lager than $\frac{n}{2}$.

▶ **Lemma 6.** *Given any n, we have* $\Pr[SW_{RP}(\mathrm{A}) \geq \frac{n}{2}] \geq \frac{1}{2}$.

Proof. Firstly, as we show in Lemma 4, the utility of agent i in any instance A is $u_i(\mathrm{A}) = \sum_{j=1}^{n} a_{ij}x_{ij} \geq \frac{1}{n}\cdot\sum_{j=1}^{n} a_{ij}$, and the social welfate $\mathrm{SW}_{\mathrm{RP(A)}} = \sum_i u_i(\mathrm{A}) \geq \frac{1}{n}\sum_{i,j} a_{ij}$. Therefore, event $\left\{\sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right\}$ implies $\left\{\mathrm{SW}_{\mathrm{RP(A)}} \geq \frac{n}{2}\right\}$. So, we have $\Pr\left[\sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right] \leq \Pr\left[\mathrm{SW}_{\mathrm{RP}}(\mathrm{A}) \geq \frac{n}{2}\right]$.

Secondly, let E be the $n \times n$ all-ones matrix. Denote matrix $\mathrm{A}' = (a'_{ij})_{n\times n} = \mathrm{E} - \mathrm{A}$. Obviously $\sum_{i,j} a_{ij} + \sum_{i,j} a'_{ij} = n^2$. Since all a_{ij}'s follow the uniform distribution,

$$\Pr\left[\sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right] = \Pr\left[\sum_{i,j} a'_{ij} \geq \frac{n^2}{2}\right] = \Pr\left[n^2 - \sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right] = \Pr\left[\sum_{i,j} a_{ij} \leq \frac{n^2}{2}\right].$$

So $\Pr\left[\sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right] = \frac{1}{2}$. Hence, $\Pr\left[\mathrm{SW}_{\mathrm{RP}}(\mathrm{A}) \geq \frac{n}{2}\right] \geq \Pr\left[\sum_{i,j} a_{ij} \geq \frac{n^2}{2}\right] = \frac{1}{2}$. ◀

Next we will use Lemma 5 and Lemma 6 to prove our main result in this section. Essentially, Lemma 5 and Lemma 6 bound the probability of the social welfare of random priority on valuation profile A. By carefully choosing parameter c, we can divide the valuation space into three sets: $\{SW_{RP(\mathrm{A})} \leq n^c\}$, $\{n^c < SW_{RP(\mathrm{A})} < \frac{n}{2}\}$ and $\{SW_{RP(\mathrm{A})} \geq \frac{n}{2}\}$. We bound the probabilities of instance A falling into each set and the ratios of optimal social welfare against the social welfare of random priority mechanism. Note that in any cases, the worst-case ratio is upper bounded by $O(\sqrt{n})$. By adding them up together, we obtain our upper bound of $1 + e$.

▶ **Theorem 7.** *The average case approximation ratio is upper bounded by* $1 + e$. *That is,*

$$r_{average} = \mathop{\mathbb{E}}_{a_{ij}\sim \mathrm{U}}\left[\frac{SW_{OPT(\mathrm{A})}}{SW_{RP(\mathrm{A})}}\right] \leq 1 + e.$$

Proof. Let $1 - c = \log_n(2e) + \frac{2}{n-2}$. It is easy to verify that c satisfies the condition of Lemma 5 and $n^c < \frac{n}{2}$. So the above three sets are collectively exhaustive and mutually exclusive, and we have

$$\begin{aligned}
&\mathop{\mathbb{E}}_{a_{ij}\sim \mathrm{U}}\left[\frac{SW_{OPT(\mathrm{A})}}{SW_{RP(\mathrm{A})}}\right] = \Pr\left[SW_{RP(\mathrm{A})} \geq \frac{n}{2}\right] \cdot \mathop{\mathbb{E}}_{SW_{RP(\mathrm{A})} \geq \frac{n}{2}}\left[\frac{SW_{OPT(\mathrm{A})}}{SW_{RP(\mathrm{A})}}\right] + \\
&\Pr\left[n^c < SW_{RP(\mathrm{A})} < \frac{n}{2}\right] \cdot \mathop{\mathbb{E}}_{n^c < SW_{RP(\mathrm{A})} < \frac{n}{2}}\left[\frac{SW_{OPT(\mathrm{A})}}{SW_{RP(\mathrm{A})}}\right] + \\
&\Pr\left[SW_{RP(\mathrm{A})} \leq n^c\right] \cdot \mathop{\mathbb{E}}_{SW_{RP(\mathrm{A})} \leq n^c}\left[\frac{SW_{OPT(\mathrm{A})}}{SW_{RP(\mathrm{A})}}\right] \\
&\leq \Pr\left[SW_{RP(\mathrm{A})} \geq \frac{n}{2}\right] \cdot \frac{n}{n/2} + (1 - \Pr\left[SW_{RP(\mathrm{A})} \geq \frac{n}{2}\right]) \cdot \frac{n}{n^c} + \Pr\left[SW_{RP(\mathrm{A})} \leq n^c\right] \cdot O(\sqrt{n}) \\
&< n^{1-c} + (2 - n^{1-c}) \cdot \Pr\left[SW_{RP(\mathrm{A})} \geq \frac{n}{2}\right] + \frac{e^2}{\sqrt{2\pi}} \cdot \sqrt{n} \cdot \left(\frac{2e}{n^{1-c}}\right)^{n-2} \cdot O(\sqrt{n})
\end{aligned}$$

By our choice of c, we have $n^{1-c} = 2e \cdot n^{\frac{2}{n-2}}$. So,

$$\begin{aligned}
r_{average} &< 2e \cdot n^{\frac{2}{n-2}} - (2e \cdot n^{\frac{2}{n-2}} - 2) \cdot \Pr\left[SW_{RP(\mathrm{A})} \geq \frac{n}{2}\right] + \frac{e^2}{\sqrt{2\pi}} \cdot \sqrt{n} \cdot \left(\frac{2e}{2e \cdot n^{\frac{2}{n-2}}}\right)^{n-2} \cdot O(\sqrt{n}) \\
&\leq 2e \cdot n^{\frac{2}{n-2}} - (2e \cdot n^{\frac{2}{n-2}} - 2) \cdot \frac{1}{2} + \frac{e^2}{\sqrt{2\pi}} \cdot \frac{1}{n^2} \cdot O(n) \\
&= e \cdot n^{\frac{2}{n-2}} + 1 + \frac{e^2}{\sqrt{2\pi}} \cdot \frac{1}{n^2} \cdot O(n) < 1 + e.
\end{aligned}$$

◀

5 Conclusion and Discussion

In this paper, we extend the worst-case approximation ratio analysis in mechanism design to the smoothed approximation ratio and average-case approximation ratio analysis. For social welfare maximization in one-sided matching problem, we show a clear separation of

the approximation ratio bounds from the smoothed analysis and average-case analysis to the worst-case analysis. Our results partially explain why random priority has been successfully used in practice, although in the worst case the optimal social welfare is $\Theta(\sqrt{n})$ times of what random priority achieves.

There are quite a few emerging open questions in the smoothed and average-case approximation ratio analysis of mechanisms. Firstly, it would be good to improve our upper bounds and to characterize matching lower bound. Secondly, our average-case analysis is based on a uniform distribution; it is open to consider other distributions that resembles real-life applications of the one-sided matching mechanisms. Thirdly, beside unit-range representation, another interesting valuation normalization is unit-sum; it is open to study the smoothed and average-case analysis in that setting. Last but most importantly, our analysis pave the way of characterizing the smoothed and average-case approximation ratio in other mechanism design problems, such as the scheduling problem.

Abstract

The *exponential-time hypothesis* (ETH) states that 3-SAT is not solvable in subexponential time, i.e. not solvable in $O(c^n)$ time for arbitrary $c > 1$, where n denotes the number of variables. Problems like k-SAT can be viewed as special cases of the *constraint satisfaction problem* (CSP), which is the problem of determining whether a set of constraints is satisfiable. In this paper we study the worst-case time complexity of NP-complete CSPs. Our main interest is in the CSP problem parameterized by a constraint language Γ (CSP(Γ)), and how the choice of Γ affects the time complexity. It is believed that CSP(Γ) is either tractable or NP-complete, and the *algebraic CSP dichotomy conjecture* gives a sharp delineation of these two classes based on algebraic properties of constraint languages. Under this conjecture and the ETH, we first rule out the existence of subexponential algorithms for finite-domain NP-complete CSP(Γ) problems. This result also extends to certain infinite-domain CSPs and structurally restricted CSP(Γ) problems. We then begin a study of the complexity of NP-complete CSPs where one is allowed to arbitrarily restrict the values of individual variables, which is a very well-studied subclass of CSPs. For such CSPs with finite domain D, we identify a relation S_D such that (1) CSP($\{S_D\}$) is NP-complete and (2) if CSP(Γ) over D is NP-complete and solvable in $O(c^n)$ time, then CSP($\{S_D\}$) is solvable in $O(c^n)$ time, too. Hence, the time complexity of CSP($\{S_D\}$) is a lower bound for all CSPs of this particular kind. We also prove that the complexity of CSP($\{S_D\}$) is decreasing when $|D|$ increases, unless the ETH is false. This implies, for instance, that for every $c > 1$ there exists a finite-domain Γ such that CSP(Γ) is NP-complete and solvable in $O(c^n)$ time.

1 Introduction

The *constraint satisfaction problem* over a constraint language Γ (CSP(Γ)) is the computational decision problem of verifying whether a set of constraints over Γ is satisfiable or not.

* The second author has received funding from the DFG-funded project "Homogene Strukturen, Bedingungserfüllungsprobleme, und topologische Klone" (Project number 622397). The third author is partially supported by the *National Graduate School in Computer Science* (CUGS), Sweden.

This problem is widely studied from both a theoretical and a practical standpoint. From a practical point of view this problem can be used to model many natural problems occurring in real-world applications. From a more theoretical point of view the CSP problem is (among several other things) of great interest due to its connections with *universal algebra*. It is widely believed that finite-domain CSP problems admit a dichotomy between tractable and NP-complete problems, and the so-called *algebraic approach* has been used to conjecture an exact borderline between tractable and NP-complete problems [15]. This conjectured borderline is sometimes called the *algebraic CSP dichotomy conjecture*. The gist of the algebraic approach is to associate an algebra, a set of functions satisfying a certain closure property, to each constraint language. This associated algebra is usually referred to as the *polymorphisms* of a constraint language, and is known to determine the complexity of a CSP problem up to polynomial-time many-one reductions [26]. However, the mere fact that two CSPs are polynomial-time interreducible does not offer much insight into their relative worst-case time complexity. For example, on the one hand, it has been conjectured that the Boolean satisfiability problem with unrestricted clause length, SAT, is not solvable strictly faster than $O(2^n)$, where n denotes the number of variables [23]. On the other hand, k-SAT is known to be solvable strictly faster than $O(2^n)$ for every $k \geq 1$ [22], and even more efficient algorithms are known for severely restricted satisfiability problems such as 1-in-3-SAT [36]. This discrepancy in complexity stems from the fact that a polynomial time reduction can change the structure of an instance and e.g. introduce a large number of fresh variables. Hence, it is worthwhile to study the complexity of NP-complete CSPs using more fine-grained notions of reductions. To make this a bit more precise, given a constraint language Γ we let

$$\mathsf{T}(\Gamma) = \inf\{c \mid \mathrm{CSP}(\Gamma) \text{ is solvable in time } 2^{cn}\}$$

where n denotes the number of variables. If $\mathsf{T}(\Gamma) = 0$ then $\mathrm{CSP}(\Gamma)$ is said to be solvable in *subexponential time*, and the conjecture that 3-SAT is not solvable in subexponential time is known as the *exponential-time hypothesis* (ETH) [23]. It is worth remarking that no concrete values of $\mathsf{T}(\Gamma)$ are known when $\mathrm{CSP}(\Gamma)$ is NP-complete. Despite this, studying properties of the function T can still be of great interest since such properties can be used to compare and relate the worst-case running times of NP-complete CSP problems. Moreover, for Boolean constraint languages, several properties of the function T are known. For example, it is known that there exists a finite Boolean constraint language Γ such that $\mathrm{CSP}(\Gamma)$ is NP-complete and $\mathsf{T}(\Gamma) = 0$ if and only if $\mathsf{T}(\Gamma) = 0$ for *every* Boolean constraint language Γ [27]. Hence, even though the status of the ETH is unclear at the moment, finding a subexponential time algorithm for one NP-complete Boolean CSP problem is tantamount to being able to solve every Boolean CSP problem in subexponential time. It is also known that there exists a Boolean relation R such that $\mathrm{CSP}(\{R\})$ is NP-complete but $\mathsf{T}(\{R\}) \leq \mathsf{T}(\Gamma)$ for *every* Boolean constraint language Γ such that $\mathrm{CSP}(\Gamma)$ is NP-complete. In Jonsson et al. [27] this problem is referred to as the *easiest NP-complete Boolean CSP problem*. The existence of this relation e.g. rules out the possibility that for each Boolean constraint language Γ there exists Δ such that $\mathsf{T}(\Delta) < \mathsf{T}(\Gamma)$ — a scenario which otherwise would have been compatible with the ETH. These results were obtained by considering more refined algebras than polymorphisms, so-called *partial polymorphisms*. We will describe this algebraic approach in greater detail later on, but the most important property is that the partial polymorphisms of finite constraint languages give rise to a partial order $\sqsubseteq$ with the property that if $\Gamma \sqsubseteq \Delta$, then $\mathsf{T}(\Gamma) \leq \mathsf{T}(\Delta)$. We remark that partial polymorphisms are not only useful when studying CSPs with this very fine-grained notion of complexity, but have also been used to study the classical complexity of many different computational problems where polymorphisms are not applicable [3, 4, 11, 14, 21].

Hence, even though no concrete values are known for $\mathsf{T}(\Gamma)$ when CSP(Γ) is NP-complete, quite a lot is known concerning the relationship between $\mathsf{T}(\Gamma)$ and $\mathsf{T}(\Delta)$ for Boolean Γ and Δ. In this paper we study similar properties of the function T for constraint languages defined over arbitrary finite domains. After having introduced the necessary definitions in Section 2, in Section 3 we consider the existence of subexponential time algorithms for NP-complete CSP problems, in light of the ETH and the algebraic CSP dichotomy conjecture. For this question we obtain a complete understanding and prove that, assuming the algebraic CSP dichotomy conjecture, the ETH is false if and only if (1) there exists a finite constraint language Γ over a finite domain such that CSP(Γ) is NP-complete and $\mathsf{T}(\Gamma) = 0$, if and only if (2) $\mathsf{T}(\Gamma) = 0$ for every finite constraint language Γ defined over a finite domain. In other words, finding a subexponential time algorithm for a single NP-complete, finite-domain CSP problem is tantamount to being able to solve all CSP problems in subexponential time. We also study structurally restricted CSPs where the maximum number of constraints a variable may appear in is bounded by a constant B (CSP(Γ)-B). For problems of this form our results are not as sharp, but we prove that, again assuming the algebraic CSP dichotomy conjecture, that if CSP(Γ) is NP-complete and Γ satisfies an additional algebraic condition, then there exists a constant B such that CSP(Γ)-B is not solvable in subexponential time (unless the ETH is false). We also remark that our proof extends to certain constraint languages defined over infinite domain, and give several examples of infinite-domain NP-complete CSP problems that are not solvable in subexponential time, unless the ETH is false. These results may be interesting to compare to those of de Haan et al. [17], who study subexponential algorithms for structurally restricted CSPs. One crucial difference to our results is that de Haan et al. do not consider constraint language restrictions. For example, it is proven that CSP(Δ)-2, where Δ is the set of all finitary relations of finite cardinality, is not solvable in subexponential time unless the ETH is false. However, a result of this form tells us very little about the complexity of CSP(Γ)-2 for specific constraint languages, since it does not imply that CSP(Γ)-2 is not solvable in subexponential time for every NP-complete CSP(Γ)-2.

We have thus established that $\mathsf{T}(\Gamma) > 0$ for every NP-complete, finite-domain CSP(Γ), assuming the ETH and the algebraic CSP dichotomy conjecture. This immediately raises the question of which further insights can be gained concerning the behaviour of the function T. For example, for a fixed finite domain, is it possible to construct an infinite chain of NP-complete CSPs with strictly decreasing complexity such that T tends to 0? We study such questions in Section 4 for CSPs where one in an instance is allowed to restrict the values of individual variables arbitrarily. This restricted CSP problem is particularly well-studied, and it is used as *the* definition of CSPs in many cases: see, for instance, the textbook by Russell and Norvig [33, Section 3.7] and the handbook by Rossi et al. [32, Section 2]. This may be viewed as restricting oneself to constraint languages that contain all unary relations. A closely related restriction (that is typically used when studying CSPs from the algebraic viewpoint) is that every unary relation is primitively positively definable in Γ (see Section 2). Such constraint languages are known as *conservative*. These two restrictions are computationally equivalent up to polynomial-time many-one reductions but it is not known whether they are equivalent under reductions that preserve time complexity. Thus, we need to separate them, so we say that a constraint language that contains all unary relations is *ultraconservative*. We note that the algebraic CSP dichotomy conjecture has been verified to hold for the conservative CSPs [12] so it holds for ultraconservative CSPs, too. We show that for every finite domain D there exists a relation S_D such that CSP($\{S_D\}$) is NP-complete and $\mathsf{T}(\{S_D\}) = \mathsf{T}(\{S_D\} \cup 2^D) \leq \mathsf{T}(\Gamma)$ for every ultraconservative and NP-complete CSP(Γ) over D. This relation will be formally defined in Section 4.1, but is worth pointing out that S_D

contains only three tuples and that CSP($\{S_D\}$) can be viewed as a higher-domain variant of the monotone 1-in-3-SAT problem. We refer to CSP($\{S_D\} \cup 2^D$) as the *easiest NP-complete ultraconservative CSP problem over* D[1]. Note that the properties of the relation S_D rule out the possibility of an infinite sequence of ultraconservative languages $\Gamma_1, \Gamma_2, \ldots$ such that each CSP(Γ_i) is NP-complete and $\mathsf{T}(\Gamma_i)$ tends to 0, but also have stronger implications, since the value $\mathsf{T}(\{S_D\})$ is a conditional lower bound for the complexity of *all* NP-complete, ultraconservative CSPs over D.

To prove these results we have to overcome several major obstacles. Similar to Jonsson et al. [27]) we use partial polymorphisms instead of total polymorphisms in order to achieve more fine-grained notions of reductions. However, the proof strategy used in Jonsson et al. [27] does not work for arbitrary finite domains since it requires a comprehensive understanding of the polymorphisms of constraint languages resulting in NP-complete CSPs, which is only known for the Boolean domain [29]. Our first observation to tackle this difficulty is that the reformulation of conservative CSP dichotomy theorem making use of *primitive positive interpretations* (pp-interpretations) is useful in our context. At the moment, we may think of a pp-interpretation as a tool which allows us to compare the expressitivity of constraint languages defined over different domains, modulo logical formulas consisting of existential quantification, conjunction, and equality constraints. It is well-known that pp-interpretations can be used to obtain polynomial-time reductions between CSPs, and that a conservative CSP(Γ) problem is NP-complete if and only if Γ pp-interprets 3-SAT [1, 12]. However, as already pointed out, such reductions are not useful when studying CSPs with respect to the function T, and it is a priori not evident how the assumption that Γ can pp-interpret 3-SAT can be used to show that $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\Gamma)$. Using properties of conservative constraint languages and quantifier-elimination techniques we in Section 4.1 first show that this assumption can be used to prove there exists a relation R over D of cardinality 3 such that (1) CSP($\{R\}$) is NP-complete and (2) $\mathsf{T}(\{R\}) \leq \mathsf{T}(\Gamma)$. However, this is not enough in order to isolate a unique easiest problem, since there for every finite domain exists a large number of such relations. In Section 4.2, using a combination of partial clone theory and size-preserving reductions, we show that $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\{R\})$ for every such relation R of cardinality 3. We then analyse the time complexity of the problem CSP($\{S_D\}$) and prove that $\mathsf{T}(\{S_D\})$ tends to 0 for increasing values of $|D|$. This also shows, despite the fact that no finite-domain NP-complete CSP(Γ) is solvable in subexponential time (if the algebraic CSP dichotomy conjecture and the ETH are true), that one for every $c > 0$ can find Γ over a finite domain such that CSP(Γ) is NP-complete and solvable in $O(2^{cn})$ time. When all of these results are adjoined, they demonstrate that the function T can indeed be analysed without an extensive knowledge of the polymorphisms related to a constraint language.

2 Preliminaries

2.1 Constraint Languages and the Constraint Satisfaction Problem

A k-ary *relation* R over a set D is a subset of D^k, and we write $\mathrm{ar}(R) = k$ to denote its arity. A finite set of relations Γ over a set D is called a *constraint language*. Given two tuples s and t we let $s^\frown t$ denote the concatenation of s and t, i.e., if $s = (s_1, \ldots, s_{k_1})$ and $t = (t_1, \ldots, t_{k_2})$ then $s^\frown t = (s_1, \ldots, s_{k_1}, t_1, \ldots, t_{k_2})$. If t is an n-ary tuple we let $t[i]$ denote its ith element and $\mathrm{Proj}_{i_1,\ldots,i_{n'}}(t) = (t[i_1], \ldots, t[i_{n'}])$, $n' \leq n$, denote the *projection*

[1] Note that 2^D is the set of all unary relations over D.

of t on the coordinates $i_1, \ldots, i_{n'} \in \{1, \ldots, n\}$. Similarly, if R is an n-ary relation we let $\mathrm{Proj}_{i_1,\ldots,i_{n'}}(R) = \{\mathrm{Proj}_{i_1,\ldots,i_{n'}}(t) \mid t \in R\}$. We write Eq_D for the equality relation $\{(x, x) \mid x \in D\}$. If there is no risk for confusion we omit the subscript and simply write Eq. For each $d \in D$ we write R^d for the unary, constant relation $\{(d)\}$. We will occasionally represent relations by first-order formulas, and if $\varphi(x_1, \ldots, x_k)$ is a first-order formula with free variables $x_1, \ldots, x_k$ then we write $R(x_1, \ldots, x_k) \equiv \varphi(x_1, \ldots, x_k)$ to define the relation $R = \{(f(x_1), \ldots, f(x_k)) \mid f \text{ is a model of } \varphi(x_1, \ldots, x_k)\}$. As a graphical representation, we will sometimes view a k-ary relation $R = \{t_1, \ldots, t_m\}$ as an $m \times k$ matrix where the columns of the matrix enumerate the arguments of the relation (in some fixed ordering). For example, $\left(\begin{smallmatrix} 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 \end{smallmatrix}\right)$ represents the relation $\{(0, 0, 1, 1), (0, 1, 0, 1)\}$.

The *constraint satisfaction problem* over a constraint language Γ over D ($\mathrm{CSP}(\Gamma)$) is the computational decision problem defined as follows.

INSTANCE: A set V of variables and a set C of constraint applications $R(x_1, \ldots, x_k)$ where $R \in \Gamma$, $\mathrm{ar}(R) = k$, and $x_1, \ldots, x_k \in V$.
QUESTION: Does there exist $f : V \to D$ such that $(f(x_1), \ldots, f(x_k)) \in R$ for each $R(x_1, \ldots, x_k)$ in C?

If $\Gamma = \{R\}$ is singleton then we write $\mathrm{CSP}(R)$ instead of $\mathrm{CSP}(\{R\})$, and if Γ is Boolean we typically write $\mathrm{SAT}(\Gamma)$ instead of $\mathrm{CSP}(\Gamma)$. We let $\mathbb{B} = \{0, 1\}$. For example, let $R_{1/3}^{\neq\neq\neq 01} = \{(0, 0, 1, 1, 1, 0, 0, 1), (0, 1, 0, 1, 0, 1, 0, 1), (1, 0, 0, 0, 1, 1, 0, 1)\}$. The SAT problem over $R_{1/3}^{\neq\neq\neq 01}$ can be seen as a variant of 1-in-3-SAT where each variable in each constraint has a complementary variable. We will return to this SAT problem several times in the sequel. For each $k \geq 3$ let Γ_{SAT}^k be the constraint language which for every $t \in \mathbb{B}^k$ contains the relation $\mathbb{B}^k \setminus \{t\}$. Hence, $\mathrm{SAT}(\Gamma_{\mathrm{SAT}}^k)$ can be viewed as an alternative formulation of k-SAT.

2.2 Primitive Positive Definitions and Interpretations

Let Γ be a constraint language. A k-ary relation R is said to have a *primitive positive definition* (pp-definition) over Γ if $R(x_1, \ldots, x_k) \equiv \exists y_1, \ldots, y_{k'} . R_1(\mathbf{x_1}) \wedge \ldots \wedge R_m(\mathbf{x_m})$, where each $R_i \in \Gamma \cup \{\mathrm{Eq}\}$ and each $\mathbf{x_i}$ is an $\mathrm{ar}(R_i)$-ary tuple of variables over $x_1, \ldots, x_k$, $y_1, \ldots, y_{k'}$. In addition, if the primitive positive formula does not contain any existentially quantified variables, we say that it is a *quantifier-free primitive positive formula* (qfpp), and if it does not contain any equality constraints we say that it is a *equality-free primitive positive formula* (efpp). For example, the reader can verify that the textbook reduction from k-SAT to $(k-1)$-SAT, where a clause of length k is replaced by clauses of length $k-1$ making use of one fresh variable, can be formulated as a pp-definition but not as a qfpp-definition. We write $\langle\Gamma\rangle$ (respectively $\langle\Gamma\rangle_{\exists}$) to denote the smallest set of relations containing Γ and which is closed under pp-definitions (respectively qfpp-definitions). If $\Gamma = \{R\}$ is singleton then we instead write $\langle R\rangle$ and $\langle R\rangle_{\exists}$. Note that $\langle\Gamma\rangle$ is closed under projections, in the sense that if $R \in \langle\Gamma\rangle$ then $\mathrm{Proj}_{i_1,\ldots,i_n}(R) \in \langle\Gamma\rangle$ for all $i_1, \ldots, i_n \in \{1, \ldots, \mathrm{ar}(R)\}$, but that this does not necessarily hold for $\langle\Gamma\rangle_{\exists}$. Jeavons [25] proved the following important result.

▶ **Theorem 1.** *If Γ is a constraint language and Δ is a finite subset of $\langle\Gamma\rangle$, then CSP(Δ) is polynomial-time reducible to CSP(Γ).*

Theorem 1 naturally holds also for relations defined by qfpp- or efpp-formulas. However, there are additional advantages of these more restricted ways of defining relations and we will return to them later on. We are now ready to define the concept of primitive positive interpretations.

▶ **Definition 2.** Let D and E be two domains and let Γ and Δ be two constraint languages over D and E, respectively. A *primitive positive interpretation* (pp-interpretation) of Δ over Γ consists of a d-ary relation $F \subseteq D^d$ and a surjective function $f : F \to E$ such that $F, f^{-1}(\mathrm{Eq}_E) \in \langle\Gamma\rangle$ and $f^{-1}(R) \in \langle\Gamma\rangle$ for every $R \in \Delta$, where $f^{-1}(R)$, $\mathrm{ar}(R) = k$, denotes the $(k \cdot d)$-ary relation

$$\{(x_{1,1}, \ldots, x_{1,d}, \ldots, x_{k,1}, \ldots, x_{k,d}) \in D^{k \cdot d} \mid (f(x_{1,1}, \ldots, x_{1,d}), \ldots, f(x_{k,1}, \ldots, x_{k,d})) \in R\}.$$

The main purpose of pp-interpretations is to relate constraint languages which might be incomparable with respect to pp-definitions. For an example, let us consider the relation $R_{\neq} = \{(x, y) \in \{0, 1, 2\}^2 \mid x \neq y\}$, and observe that $\mathrm{CSP}(\{R_{\neq}\})$ corresponds to the 3-coloring problem. We invite the reader to verify that the standard reduction from 3-coloring to 3-SAT can be phrased as a pp-interpretation of $R_{\neq}$ over Γ^3_{SAT}, but that this reduction cannot be expressed via pp-definitions due to the different domains. Hence, pp-interpretations are generalizations of pp-definitions, and can be used to obtain polynomial-time reductions between CSPs.

▶ **Theorem 3** (cf. Theorem 5.5.6 in Bodirsky [5]). *If Γ, Δ are constraint languages and there is a pp-interpretation of Δ over Γ, then CSP(Δ) is polynomial-time reducible to CSP(Γ).*

2.3 Polymorphisms and Partial Polymorphisms

Let f be a k-ary function over a finite domain D. We say that f is a *polymorphism* of an n-ary relation R over D if $f(t_1, \ldots, t_k) \in R$ for each k-ary sequence of tuples $t_1, \ldots, t_k \in R$. Here, and in the sequel, we use $f(t_1, \ldots, t_k)$ to denote the componentwise application of the function f to the tuples $t_1, \ldots, t_k$, i.e., $f(t_1, \ldots, t_k)$ is a shorthand for the n-ary tuple $(f(t_1[1], \ldots, t_k[1]), \ldots, f(t_1[n], \ldots, t_k[n]))$. Similarly, if f is a partial function over D, we say that f is a *partial polymorphism* of an n-ary relation R over D if $f(t_1, \ldots, t_k) \in R$ for every sequence $t_1, \ldots, t_k$ such that $f(t_1, \ldots, t_k)$ is defined for each componentwise application. If f is a polymorphism or a partial polymorphism of a relation R then we occasionally also say that R is *invariant* under f. We let $\mathrm{Pol}(R)$ and $\mathrm{pPol}(R)$ denote the set of all polymorphisms, respectively partial polymorphisms, of the relation R. Similarly, for a constraint language Γ, we write $\mathrm{Pol}(\Gamma)$ for the set $\bigcap_{R \in \Gamma} \mathrm{Pol}(R)$, and $\mathrm{pPol}(\Gamma)$ for the set $\bigcap_{R \in \Gamma} \mathrm{pPol}(R)$. We write $\mathrm{Inv}(F)$ to denote the set of all relations invariant under the set of total or partial functions F. It is known that $\mathrm{Inv}(\mathrm{Pol}(\Gamma)) = \langle\Gamma\rangle$ and that $\mathrm{Inv}(\mathrm{pPol}(\Gamma)) = \langle\Gamma\rangle_{\not\exists}$, giving rise to the following *Galois connections*.

▶ **Theorem 4** ([9, 10, 19, 31]). *Let Γ and Γ' be two constraint languages. Then $\Gamma \subseteq \langle\Gamma'\rangle$ if and only if $\mathrm{Pol}(\Gamma') \subseteq \mathrm{Pol}(\Gamma)$ and $\Gamma \subseteq \langle\Gamma'\rangle_{\not\exists}$ if and only if $\mathrm{pPol}(\Gamma') \subseteq \mathrm{pPol}(\Gamma)$.*

2.4 Time Complexity and Size-Preserving Reductions

Given a constraint language Γ we let $\mathsf{T}(\Gamma) = \inf\{c \mid \mathrm{CSP}(\Gamma) \text{ is solvable in time } 2^{cn}\}$ where n denotes the number of variables in a given instance. If $\mathsf{T}(\Gamma) = 0$ then $\mathrm{CSP}(\Gamma)$ is said to be solvable in *subexponential time*. The conjecture that $\mathrm{SAT}(\Gamma^3_{\mathrm{SAT}}) > 0$ is known as the *exponential-time hypothesis* (ETH) [24]. We now introduce a type of reduction useful for studying the complexity of CSPs with respect to the function T.

▶ **Definition 5.** Let Γ and Δ be two constraint languages. The function f from the instances of $\mathrm{CSP}(\Gamma)$ to the instances of $\mathrm{CSP}(\Delta)$ is a *many-one linear variable reduction* (LV-reduction) with parameter $d \geq 0$ if (1) f is a polynomial-time many-one reduction from $\mathrm{CSP}(\Gamma)$ to

$\mathrm{CSP}(\Delta)$ and (2) $|V'| = d \cdot |V| + O(1)$ where V, V' are the set of variables in I and $f(I)$, respectively.

The term CV-reduction, short for *constant variable reduction*, is used to denote LV-reductions with parameter 1, and we write $\mathrm{CSP}(\Gamma) \leq^{\mathrm{CV}} \mathrm{CSP}(\Delta)$ when $\mathrm{CSP}(\Gamma)$ has a CV-reduction to $\mathrm{CSP}(\Delta)$. It follows that if $\mathrm{CSP}(\Gamma) \leq^{\mathrm{CV}} \mathrm{CSP}(\Delta)$ then $\mathsf{T}(\Gamma) \leq \mathsf{T}(\Delta)$, and if $\mathrm{CSP}(\Gamma)$ LV-reduces to $\mathrm{CSP}(\Delta)$ then $\mathsf{T}(\Gamma) = 0$ if $\mathsf{T}(\Delta) = 0$. We have the following theorem from Jonsson et al. [27], relating the partial polymorphisms of constraint languages with the existence of CV-reductions.

▶ **Theorem 6** ([27]). *Let D be a finite domain and let Γ and Δ be two constraint languages over D. If $\mathrm{pPol}(\Delta) \subseteq \mathrm{pPol}(\Gamma)$ then $\mathrm{CSP}(\Gamma) \leq^{\mathrm{CV}} \mathrm{CSP}(\Delta)$.*

We remark that the original proof only concerned Boolean constraint languages but that the same proof also works for arbitrary finite domains. Using Theorem 6 and algebraic techniques from Schnoor and Schnoor [35], Jonsson et al. [27] proved that $\mathsf{T}(\{R_{1/3}^{\neq\neq 01}\}) \leq \mathsf{T}(\Gamma)$ for any finite Γ such that $\mathrm{SAT}(\Gamma)$ is NP-complete. This problem was referred to as the *easiest NP-complete* SAT *problem*. We will not go into the details but remark that the proof idea does not work for arbitrary finite domains since it requires a characterisation of every $\mathrm{Pol}(\Gamma)$ such that $\mathrm{CSP}(\Gamma)$ is NP-complete. Such a list is known for the Boolean domain due to Post [29] and Schaefer [34], but not for larger domains.

2.5 Complexity of CSP

Let Γ be a constraint language over a finite domain D. We say that Γ is *idempotent* if $R^d \in \langle\Gamma\rangle$ for every $d \in D$, *conservative* if $2^D \subseteq \langle\Gamma\rangle$, and *ultraconservative* if $2^D \subseteq \Gamma$. A unary function $f \in \mathrm{Pol}(\Gamma)$ is said to be an *endomorphism*, and if f in addition is bijective it is said to be an *automorphism*. A constraint language Γ is a *core* if every endomorphism is an automorphism. The following theorem is well-known, see e.g. Barto [1], but is usually expressed in term of polynomial-time many-one reductions instead of CV-reductions.

▶ **Theorem 7.** *Let Γ be a core constraint language over the domain $\{d_0, \ldots, d_{k-1}\}$. Then $\mathrm{CSP}(\Gamma \cup \{R^{d_0}, \ldots, R^{d_{k-1}}\}) \leq^{\mathrm{CV}} \mathrm{CSP}(\Gamma)$.*

If Γ is a constraint language over $D = \{d_0, \ldots, d_{k-1}\}$, then $\Gamma \cup \{R^{d_0}, \ldots, R^{d_{k-1}}\}$ is both idempotent and a core since its only endomorphism is the identity function on D. The *CSP dichotomy conjecture* states that for any Γ over a finite domain, $\mathrm{CSP}(\Gamma)$ is either tractable or NP-complete [18]. This conjecture was later refined by Bulatov et al. [15] to also induce a sharp characterization of the tractable and intractable cases, expressed in terms of algebraic properties of the constraint language, and is usually called the *algebraic CSP dichotomy conjecture*. We will use the following variant of the conjecture which is expressed in terms of pp-interpretations.

▶ **Conjecture 8.** *[1, 15] Let Γ be an idempotent constraint language over a finite domain. Then $\mathrm{CSP}(\Gamma)$ is NP-complete if Γ pp-interprets Γ_{SAT}^3 and tractable otherwise.*

It is worth remarking that if Γ pp-interprets Γ_{SAT}^3 then Γ can pp-interpret every finite-domain relation [5, Theorem 5.5.17].

3 Subexponential Time Complexity

For Boolean constraint languages it has been proven that $\mathrm{SAT}(\Gamma_{\mathrm{SAT}}^3)$ is solvable in subexponential time if and only if there exists a finite Boolean constraint language Γ such that

SAT(Γ) is NP-complete and solvable in subexponential time [27]. We will strengthen this result to arbitrary domains and prove that CSP(Γ) is never solvable in subexponential time if Γ can pp-interpret Γ^3_{SAT}, unless the ETH is false. The result can also be extended to certain structurally restricted CSPs. The *degree* of a variable $x \in V$ of an instance (V, C) of CSP(Γ) is the number of constraints in C containing x. We let CSP(Γ)-B, $B \geq 1$, denote the restricted CSP(Γ) problem where each variable occurring in an instance has degree at most B. We then obtain the following theorem, whose proof can be found in the extended preprint [28].

▶ **Theorem 9.** *Assume that the ETH is true and let* Γ *be a finite constraint language over a domain* D *such that* Γ *pp-interprets* Γ^3_{SAT}*. Then* CSP(Γ) *is not solvable in subexponential time, and if* Γ *efpp-defines* Eq_D *then there exists a constant* B*, depending only on* Γ*, such that* CSP(Γ)-B *is not solvable in subexponential time.*

We have now obtained a complete understanding of subexponential solvability of finite-domain CSPs modulo the ETH.

▶ **Corollary 10.** *Assume that the algebraic CSP dichotomy conjecture is true. Then the following statements are equivalent: (1) the ETH is false, (2),* CSP(Γ) *is solvable in subexponential time for every finite* Γ *over a finite domain, and (3) there exists a finite constraint language* Γ *over a finite domain* D *such that* CSP(Γ) *is NP-complete and subexponential.*

Proof. The implication from (1) to (2) follows from Impagliazzo et al. [24, Theorem 3]. The implication from (2) to (3) is trivial. For the implication from (3) to (1), we first note that $\mathrm{CSP}(\Gamma^c) \leq^{\mathrm{CV}} \mathrm{CSP}(\Gamma)$, where Γ^c is the core of Γ [1, Theorem 3.5]. If Γ^c is expanded with all constants, then Theorem 7 shows that the complexity does not change, and, last, this language can pp-interpret Γ^3_{SAT}, due to the assumption that the algebraic CSP dichotomy conjecture is true, which via Theorem 9 implies that 3-SAT is solvable in subexponential time, and thus that the ETH is false. ◀

For CSP(Γ)-B our results are not as precise since we need the additional assumption that the equality relation is efpp-definable. This is not surprising since the most powerful dichotomy results for CSPs are usually concerned with either constraint language restrictions [12, 15], structural restrictions [17, 20], but rarely both simultaneously. However, in the Boolean domain there are plenty of examples which illustrates how the equality relation may be efpp-defined [16, 27], suggesting that similar techniques may also exist for larger domains.

Theorem 9 also applies to many interesting classes of infinite-domain CSPs. For example, if we consider Γ such that each $R \in \Gamma$ has a first-order definition over the structure $(\mathbb{Q}; <)$, it is known that CSP(Γ) is NP-complete if and only if Γ can pp-interpret Γ^3_{SAT} [5, 7]. Hence, Theorem 9 is applicable, implying that if CSP(Γ) is not solvable in subexponential time if it is NP-complete, unless the ETH fails. More examples of infinite-domain CSPs where Theorem 9 is applicable includes graph satisfiability problems [8] and phylogeny constraints [6]. Note that all of these results hold independently of whether the algebraic CSP dichotomy is true or not. We also remark that the intractable cases of the CSP dichotomy conjecture for certain infinite-domain CSPs are all based on pp-interpretability of Γ^3_{SAT} [2]. If this conjecture is correct, Theorem 9 and the ETH implies that none of these problems are solvable in subexponential time.

4 The Easiest NP-Complete Ultraconservative CSP Problem

The results from Section 3, assuming the algebraic CSP dichotomy conjecture and the ETH, implies that $\mathsf{T}(\Gamma) > 0$ for any finite-domain and NP-complete CSP(Γ). However, it is safe to

say that very little is known about the behaviour of the function T in more general terms. For example, is there for an arbitrary NP-complete CSP(Γ) possible to find an NP-complete CSP(Δ) such that $\mathsf{T}(\Delta) < \mathsf{T}(\Gamma)$? Such a scenario would be compatible with the consequences of Theorem 9. We will show that this is unlikely, and prove that there for every finite domain D exists a relation S_D such that CSP(S_D) is NP-complete but $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\Gamma)$ for any ultraconservative Γ over D such that CSP(Γ) is NP-complete. To prove this we have divided this section into two parts. In Section 4.1 we show that if Γ is ultraconservative and CSP(Γ) is NP-complete, then there exists a relation $R \in \langle\Gamma\rangle_{\exists'}$ which shares certain properties with the relation $R_{1/3}^{\neq\neq\neq 01}$. In Section 4.2 we use properties of these relations in order to prove that there for every finite domain D is possible to find a relation S_D such that CSP(S_D) is CV-reducible to any other NP-complete and ultraconservative CSP(Γ) problem.

4.1 $S_{\mathbb{B}}$-Extensions

The columns of the matrix representation of the relation $R_{1/3}^{\neq\neq\neq 01}$ from Jonsson et al. [27] (resulting in the easiest NP-complete SAT problem) enumerates all Boolean ternary tuples. We generalize this relation to arbitrary finite domains as follows.

▶ **Definition 11.** For each finite D let $S_D = \{t_1, t_2, t_3\}$ denote the $|D|^3$-ary relation such that there for every $(d_1, d_2, d_3) \in D^3$ exists $1 \leq i \leq |D|^3$ such that $(t_1[i], t_2[i], t_3[i]) = (d_1, d_2, d_3)$.

Hence, similar to $R_{1/3}^{\neq\neq\neq 01}$, the columns of the matrix representation of S_D enumerates all ternary tuples over D. For each D the relation S_D is unique up to permutation of arguments, and although we will usually not be concerned with the exact ordering, we sometimes assume that $S_{\mathbb{B}} = R_{1/3}^{\neq\neq\neq 01}$ and that $\mathrm{Proj}_{1,\ldots,8}(S_D) = S_{\mathbb{B}}$. The notation S_D is a mnemonic for *saturated*, and the reason behind this will become evident in Section 4.2.1. For example, for $\{0, 1, 2\}$ we obtain a relation $\{t_1, t_2, t_3\}$ with 27 distinct arguments such that $(t_1[i], t_2[i], t_3[i]) \in \{0, 1, 2\}^3$ for each $1 \leq i \leq 27$. Jonsson et al. [27] proved that $S_{\mathbb{B}} \in \langle\Gamma\rangle_{\exists'}$ for every Boolean and idempotent constraint language Γ such that SAT(Γ) is NP-complete. This is not true for arbitrary finite domains, and in order to prove an analogous result we will need the following definition.

▶ **Definition 12.** Let R be an n-ary relation of cardinality 3 over a domain D, $|D| \geq 2$. Let $a, b \in D$ be two distinct values. If there exists $i_1, \ldots, i_8 \in \{1, \ldots, n\}$ such that

$$\mathrm{Proj}_{i_1,\ldots,i_8}(R) = \{(a,a,b,b,b,a,a,b), (a,b,a,b,a,b,a,b), (b,a,a,a,b,b,a,b)\},$$

then we say that R is an *$S_{\mathbb{B}}$-extension*.

For example, S_D is an $S_{\mathbb{B}}$-extension for every domain D. Note that CSP(R) is always NP-complete when R is an $S_{\mathbb{B}}$-extension. We will now prove that if CSP(Γ) is NP-complete and Γ is ultraconservative, then Γ can pp-define an $S_{\mathbb{B}}$-extension.

▶ **Lemma 13.** *Let Γ be an ultraconservative constraint language over a finite domain D such that* CSP(Γ) *is NP-complete. Then there exists a relation $R \in \langle\Gamma\rangle$ which is an $S_{\mathbb{B}}$-extension.*

Proof. Since CSP(Γ) is NP-complete and Γ is ultraconservative, Γ can pp-interpret every Boolean relation. Therefore let $f : F \to \mathbb{B}$, $F \subseteq D^d$ denote the parameters in the pp-interpretation of $S_{\mathbb{B}}$, and note that $f^{-1}(S_{\mathbb{B}}) \in \langle\Gamma\rangle$, but that $f^{-1}(S_{\mathbb{B}})$ is not necessarily an $S_{\mathbb{B}}$-extension since it could be the case that $|f^{-1}(S_{\mathbb{B}})| > 3$. Pick two tuples s and t in F such that $f(s) = 0$ and $f(t) = 1$. Such tuples must exist since f is surjective. Now consider the relation $F_1(x_1, \ldots, x_d) \equiv F(x_1, \ldots, x_d) \wedge \{(s[1]), (t[1])\}(x_1) \wedge \ldots \wedge \{(s[d], t[d])\}(x_d)$.

This relation is pp-definable over Γ since Γ is ultraconservative and since $F \in \langle\Gamma\rangle$. By construction, it is clear that $s, t \in F_1$. Assume furthermore than $|F_1| > 2$, i.e., that there exists $u \in F_1 \setminus \{s, t\}$. Assume without loss of generality that $f(u) = 0$, and observe that there for each $i \in \{1, \dots, d\}$ holds that $u[i] \in \{s[i], t[i]\}$. We claim that there exists some $i \in \{1, \dots, d\}$ such that $u[i] = t[i] \neq s[i]$. To see this, observe that there must exist i such that $u[i] \neq s[i]$, since otherwise $u = s$, and it then follows that $u[i] = t[i]$. Construct the relation $F_2(x_1, \dots, x_d) \equiv F_1(x_1, \dots, x_d) \wedge \{(u[1]), (t[1])\}(x_1) \wedge \dots \wedge \{(u[d]), (t[d])\}(x_d)$, and note that $F_2 \subset F_1$ since $s \notin F_2$. By repeating this procedure we will obtain a relation $F' \subseteq F$ such that $F' = \{s_0, s_1\}$ and such that $f(s_0) = 0$, $f(s_1) = 1$. Using F' we can then pp-define

$$R(x_{1,1}, \dots, x_{1,d}, \dots, x_{8,1}, \dots, x_{8,d}) \equiv f^{-1}(S_{\mathbb{B}})(x_{1,1}, \dots, x_{1,d}, \dots, x_{8,1}, \dots, x_{8,d}) \wedge F'(x_{1,1}, \dots, x_{1,d}) \wedge \dots \wedge F'(x_{8,1}, \dots, x_{8,d}).$$

Clearly, if $(a_{1,1}, \dots, a_{1,d}, \dots, a_{8,1}, \dots, a_{8,d}) \in R$, then $(a_{i,1}, \dots, a_{i,d}) \in \{s_0, s_1\}$ for each $1 \leq i \leq 8$, and $(f(a_{1,1}, \dots, a_{1,d}), \dots, f(a_{8,1}, \dots, a_{8,d})) \in S_{\mathbb{B}}$ if and only if $(a_{1,1}, \dots, a_{1,d}, \dots, a_{8,1}, \dots, a_{8,d}) \in f^{-1}(S_{\mathbb{B}})$. Since $R \subseteq f^{-1}(S_{\mathbb{B}})$, this implies that $(f(a_{1,1}, \dots, a_{1,d}), \dots, f(a_{8,1}, \dots, a_{8,d})) \in S_{\mathbb{B}}$ if and only if $(a_{1,1}, \dots, a_{1,d}, \dots, a_{8,1}, \dots, a_{8,d}) \in R$ and each $(a_{i,1}, \dots, a_{i,d}) \in \{s_0, s_1\}$. In other words each element $f(a_{i,1}, \dots, a_{i,d})$ in a tuple of $S_{\mathbb{B}}$ uniquely correponds to d arguments $a_{i,1}, \dots, a_{i,d}$ in the corresponding tuple of R, since $(a_{i,1}, \dots, a_{i,d}) = s_0$ if $f(a_{i,1}, \dots, a_{i,d}) = 0$, and $(a_{i,1}, \dots, a_{i,d}) = s_1$ if $f(a_{i,1}, \dots, a_{i,d}) = 1$. It follows that

$$R = \{s_0^\frown s_0^\frown s_1^\frown s_1^\frown s_1^\frown s_0^\frown s_0^\frown s_1, s_0^\frown s_1^\frown s_0^\frown s_1^\frown s_0^\frown s_1^\frown s_0^\frown s_1, s_1^\frown s_0^\frown s_0^\frown s_0^\frown s_1^\frown s_1^\frown s_0^\frown s_1\},$$

and therefore also that R is an $S_{\mathbb{B}}$-extension. ◀

Observe that the existence of an $S_{\mathbb{B}}$-extension $R \in \langle\Gamma\rangle$ does not imply that $\mathrm{CSP}(R) \leq^{\mathrm{CV}} \mathrm{CSP}(\Gamma)$. To accomplish this, we need to show that Γ can also qfpp-define an $S_{\mathbb{B}}$-extension. The proof is available in the extended preprint [28].

▶ **Lemma 14.** *Let Γ be an ultraconservative constraint language over a finite domain D such that $\mathrm{CSP}(\Gamma)$ is NP-complete. Then there exists a relation in $\langle\Gamma\rangle_{\exists}$ which is an $S_{\mathbb{B}}$-extension.*

4.2 Properties of and Reductions between $S_{\mathbb{B}}$-Extensions

By Lemma 14, we can completely concentrate on $S_{\mathbb{B}}$-extensions. We will prove that $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\Gamma)$ for every ultraconservative Γ over D such that $\mathrm{CSP}(\Gamma)$ is NP-complete. To prove this, we begin in Section 4.2.1 by investigating properties of $S_{\mathbb{B}}$-extensions, which we use to simplify the total number of distinct cases we need to consider. With the help of these results we in Section 4.2.2 develop techniques in order to show that $\mathrm{CSP}(S_D) \leq^{\mathrm{CV}} \mathrm{CSP}(R)$ for every $S_{\mathbb{B}}$-extension over D.

4.2.1 Saturated $S_{\mathbb{B}}$-Extensions

In this section we simplify the number of cases we need to consider in Section 4.2.2. First note that if $R = \{t_1, t_2, t_3\}$ over D is a relation with $\mathrm{ar}(R) > |D|^3$ then there exists i and j such that $(t_1[i], t_2[i], t_3[i]) = (t_1[j], t_2[j], t_3[j])$. We say that the jth argument is *redundant*, and it is possible to get rid of this by identifying the ith and jth argument with the qfpp-definition

$$R'(x_1, \dots, x_i, \dots, x_{j-1}, x_{j+1}, \dots, x_n) \equiv R(x_1, \dots, x_i, \dots, x_{j-1}, x_i, x_{j+1}, \dots, x_n).$$

This procedure can be repeated until no redundant arguments exist, and we will therefore always implicitly assume that $\mathrm{ar}(R) \leq |D|^3$ and that R has no redundant arguments. If R is an n-ary $S_{\mathbb{B}}$-extension then the argument $i \in \{1, \ldots, n\}$ is said to be *1-choice*, or *constant*, if $|\mathrm{Proj}_i(R)| = 1$, *2-choice* if $|\mathrm{Proj}_i(R)| = 2$, and *3-choice* if $|\mathrm{Proj}_i(R)| = 3$.

▶ **Definition 15.** An n-ary $S_{\mathbb{B}}$-extension $R = \{t_1, t_2, t_3\}$ is said to be *saturated* if there for each $1 \leq i \leq n$ and every function $\tau : \{1, 2, 3\} \to \{1, 2, 3\}$, exists $1 \leq j \leq n$ such that $(t_{\tau(1)}[i], t_{\tau(2)}[i], t_{\tau(3)}[i]) = (t_1[j], t_2[j], t_3[j])$.

▶ **Example 16.** The relation S_D is saturated for every D, but if we consider the relations R and R' defined by the matrices $\left(\begin{smallmatrix} 0&0&1&1&1&0&0&0&1&2 \\ 0&1&0&1&0&1&0&0&1&2 \\ 1&0&0&0&1&1&2&0&1&2 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} 0&0&1&1&1&0&0&0&1&2 \\ 0&1&0&1&0&1&1&0&1&2 \\ 1&0&0&0&1&1&2&0&1&2 \end{smallmatrix}\right)$ then neither relation is saturated. First, R is not saturated since its matrix representation, for example, does not contain the column $(0, 2, 0)$. Second, R' is not saturated due to the 3-choice argument in position 7.

We will now see that we without loss of generality may assume that an $S_{\mathbb{B}}$-extension is saturated (see the extended preprint for proof [28]).

▶ **Lemma 17.** *Let R be an $S_{\mathbb{B}}$-extension. Then there exists a saturated $S_{\mathbb{B}}$-extension $R' \in \langle R \rangle_{\not\exists}$.*

▶ **Example 18.** If R is the relation from Example 16 then the saturated relation R' in $\langle R \rangle_{\not\exists}$ from Lemma 17 is given by $R' = \left(\begin{smallmatrix} 0&0&1&1&1&0&0&0&2&2&2&0&0&1&2 \\ 0&1&0&1&0&1&0&2&0&2&0&2&0&1&2 \\ 1&0&0&0&1&1&2&0&0&0&2&2&0&1&2 \end{smallmatrix}\right)$.

4.2.2 Reductions Between $S_{\mathbb{B}}$-Extensions

The main result of this section (Theorem 23 and Theorem 24) show that $\mathsf{T}(\{S_D\}) = \mathsf{T}(\{S_D\} \cup 2^D) \leq \mathsf{T}(\Gamma)$ whenever Γ is an ultraconservative constraint language over D such that $\mathrm{CSP}(\Gamma)$ is NP-complete. The result is proven by a series of CV-reductions that we present in Lemmas 19–22. Due to space constraints, we only present the proof of Lemma 20 which illustrates several useful techniques, and the remaining proofs can be found in the extended preprint [28]. Before we begin, we note that if R is an $S_{\mathbb{B}}$-extension over D then $\{R\}$ is not necessarily a core. For a simple counterexample, $\{S_{\mathbb{B}}\}$ is not a core over $\{0, 1, 2\}$ since the endomorphism $e(0) = 0$, $e(1) = 1$, $e(2) = 0$, is not an automorphism. However, if R is an $S_{\mathbb{B}}$-extension and $E = \{d_1, \ldots, d_m\}$ the set $\bigcup_{1 \leq i \leq \mathrm{ar}(R)} \mathrm{Proj}_i(R)$, every endomorphism $e : E \to E$ of R must be an automorphism. Hence, Theorem 7 is applicable, and we conclude that $\mathrm{CSP}(\{R, R^{d_1}, \ldots, R^{d_m}\}) \leq^{\mathrm{CV}} \mathrm{CSP}(R)$. When working with reductions between $S_{\mathbb{B}}$-extensions we may therefore freely make use of constant relations. Given an instance (V, C) of $\mathrm{CSP}(R)$, where R is an $S_{\mathbb{B}}$-extension, we say that a variable $x \in V$ occurring in a k-choice position in a constraint in C, $1 \leq k \leq 3$, is a *k-choice variable*.

▶ **Lemma 19.** *Let R be a saturated $S_{\mathbb{B}}$-extension. Then there exists a CV-reduction f from $\mathrm{CSP}(R)$ to $\mathrm{CSP}(R)$ such that for every instance I of $\mathrm{CSP}(R)$, each variable in $f(I)$ occurs as a 3-choice variable in at most one constraint.*

▶ **Lemma 20.** *Let R be a saturated $S_{\mathbb{B}}$-extension and let R' be R with one or more 3-choice arguments removed, such that R' is still saturated. Then $\mathrm{CSP}(R) \leq^{\mathrm{CV}} \mathrm{CSP}(R')$.*

Proof. Let $R = \{t_1, t_2, t_3\}$, $n = \mathrm{ar}(R)$, $n' = \mathrm{ar}(R')$, and assume that $\mathrm{Proj}_{1,\ldots,n'}(R) = R'$. Let $I = (V, C)$ be an instance of $\mathrm{CSP}(R)$. First apply Lemma 19 in order to obtain an instance $I_1 = (V_1, C_1)$ of $\mathrm{CSP}(R)$ such that each 3-choice variable only occurs in a 3-choice position in a single constraint. Assume there exists $x \in V_1$ and two distinct constraints $c, c' \in C_1$

such that x occurs in positions $i \in \{n'+1,\dots,n\}$ in c and in a 1- or 2-choice position $j \in \{1,\dots,n\}$ in c'. Let $S = \mathrm{Proj}_i(R) \cap \mathrm{Proj}_j(R)$, and note that $|S| \leq 2$. Assume first that $|S| = 2$, let $S = \{d_1, d_2\}$, and assume without loss of generality that $t_1[i] = t_1[j] = d_1$, $t_2[i] = t_2[j] = d_2$, and that $t_3[i] \neq t_3[j]$ (the other cases can be treated similarly). Since R is saturated there exists a 2-choice argument $i' \in \{1,\dots,n\}$ such that $t_1[i'] = t_1[i] = t_1[j]$, $t_2[i'] = t_2[i] = t_2[j]$, and such that $t_3[i'] \neq t_3[i]$. Let y be the variable occurring in the i'th position of c. Create a fresh variable $\hat{x}$, replace x in position i with $\hat{x}$, and for each constraint where x occurs as a 1- or 2-choice variable, replace x with y. Repeat this procedure until every 3-choice variable occurring in position $n'+1,\dots,n$ only occurs in a single constraint, and let $I_2 = (V_2, C_2)$ be the resulting instance. Assume there exists $x \in V_2$ and a constraint $c \in C_2$ such that x occurs as a 3-choice variable in position $i \in \{n'+1,\dots,n\}$ and also in a distinct position $j \in \{1,\dots,n\}$ in c. Let $L = \{t_r \mid 1 \leq r \leq 3, t_r[i] = t_r[j]\}$. Since R does not have any redundant arguments it must be the case that $|L| < 3$. If $|L| = 0$ then the instance is unsatisfiable, in which case we output an arbitrary unsatisfiable instance, and if $|L| = 1$ it is easy to see that any variable occurring in c can be assigned a fixed value, and the constraint may be removed. Therefore, assume that $|L| = 2$, and e.g. that $L = \{t_1, t_2\}$. Since R is saturated there exists a 2-choice argument $j' \in \{1,\dots,n\}$ such that $t_1[j'] = t_2[j'] \neq t_3[j']$. Let y be the variable occurring in position j' in c and add the constraint $R^{t_1[j']}(y)$. Repeat this for every variable occurring in position $n'+1,\dots,n$ in a constraint in C_2, and then replace each constraint $R(x_1,\dots,x'_n,\dots,x_n)$ by $R'(x_1,\dots,x_n)$. Note that any variable $\hat{x}$ introduced in the previous step of this reduction will be removed. Hence, the reduction is a CV-reduction. ◀

▶ **Lemma 21.** *Let R be an $S_{\mathbb{B}}$-extension and let R' be an $S_{\mathbb{B}}$-extension obtained by adding additional 2-choice arguments to R. Then* $\mathrm{CSP}(R') \leq^{\mathrm{CV}} \mathrm{CSP}(R)$.

▶ **Lemma 22.** *Let R be a saturated $S_{\mathbb{B}}$-extension over D with 3-choice arguments. Then* $\mathrm{CSP}(S_D) \leq^{\mathrm{CV}} \mathrm{CSP}(R)$.

We have thus proved the main result of this section.

▶ **Theorem 23.** *Let D be a finite domain and let Γ be a finite, ultraconservative constraint language over D. If* $\mathrm{CSP}(\Gamma)$ *is NP-complete then* $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\Gamma)$.

Proof. We first observe that if R is an $S_{\mathbb{B}}$-extension over a finite domain D, then $\mathrm{CSP}(S_D) \leq^{\mathrm{CV}} \mathrm{CSP}(R)$. By Lemma 17 we may assume that R is saturated. If R does not contain any 3-choice arguments we use Lemma 20 together with Lemma 21 and obtain a CV-reduction from $\mathrm{CSP}(S_D)$ to $\mathrm{CSP}(R)$. Hence, assume that R contains one or more 3-choice arguments. In this case we use Lemma 22 and obtain a CV-reduction from $\mathrm{CSP}(S_D)$ to $\mathrm{CSP}(R)$. By Lemma 14 there exists an $S_{\mathbb{B}}$-extension $R \in \langle\Gamma\rangle_{\not\exists}$, implying that $\mathrm{CSP}(R) \leq^{\mathrm{CV}} \mathrm{CSP}(\Gamma)$ via Theorem 6, and we know that $\mathrm{CSP}(S_D) \leq^{\mathrm{CV}} \mathrm{CSP}(R)$. We conclude that $\mathsf{T}(\{S_D\}) \leq \mathsf{T}(\{R\}) \leq \mathsf{T}(\Gamma)$. ◀

Clearly, $\{S_D\}$ is not an ultraconservative constraint language but the complexity of $\mathrm{CSP}(S_D)$ does not change when we expand the language by adding all unary relations over D (the proof can be found in the extended preprint [28]).

▶ **Theorem 24.** *Let D be a finite domain. Then* $\mathsf{T}(\{S_D\}) = \mathsf{T}(\{S_D\} \cup 2^D)$.

Thus, no NP-complete CSP over an ultraconservative constraint language over D is solvable strictly faster than $\mathrm{CSP}(S_D)$, and, in particular, $\mathsf{T}(\{S_{D'}\}) \leq \mathsf{T}(\{S_D\})$ whenever $D' \supseteq D$. This raises the question of whether $\mathsf{T}(S_D) = \mathsf{T}(S_{D'})$ for all $D, D' \supseteq \{0,1\}$, or if

it is possible to find D and D' such that $\mathsf{T}(\{S_{D'}\}) < \mathsf{T}(\{S_D\})$. As the following theorem shows, this is indeed the case, unless $\mathsf{T}(\{S_D\}) = 0$ for every finite D and the ETH fails.

▶ **Theorem 25.** $\inf\{\mathsf{T}(\{S_D\}) \mid D \textit{ finite and } |D| \geq 2\} = 0$.

Proof. Let $D_k = \{0, \ldots, k-1\}$, $k \geq 5$. We will analyse a simple algorithm for $\mathrm{CSP}(S_{D_k})$. Let $I = (V, C)$ be an arbitrary instance of $\mathrm{CSP}(S_{D_k})$. Extend the instance with variables $Z = \{z_0, \ldots, z_{k-1}\}$ and the constraints $R^i(z_i)$, $0 \leq i \leq k-1$. Arbitrarily choose a constraint $c = S_{D_k}(x_1, \ldots, x_{k^3})$ and let $X = \{x_1, \ldots, x_{k^3}\}$. It is straightforward to verify that if a variable x appears in k^2+1 or more positions, then c cannot be satisfied. Thus, $|X| \geq k$. If $X \cap Z = \emptyset$, then we branch on the three tuples in S_{D_k} and in each branch at least k variables in $V \setminus Z$ will be given fixed values. If a variable, say x_i, is given the fixed value d, then we identify x_i with z_d. Thus, at least k variables in $V \setminus Z$ are removed. Assume to the contrary that $X \cap Z \neq \emptyset$. If a variable $z \in Z$ occurs in a 3-choice position, then the variables in $X \setminus Z$ can be assigned fixed values and no branching is needed. If no variable $z \in Z$ occurs in a 3-choice position, then there are $k(k-1)(k-2)$ 3-choice positions in S_{D_k} and they are all covered by variables in $V \setminus Z$. Thus, we perform three branches based on the tuples in S_{D_k}. Recall that a variable can occur in at most k^2 positions in the constraint c since c is otherwise not satisfiable. This implies that at least $\lfloor \frac{k(k-1)(k-2)}{k^2} \rfloor \geq 1$ variables in $V \setminus Z$ are given fixed values (and are removed from $V \setminus Z$) in each branch. When there are no S_{D_k} constraints left, we check whether the remaining set of unary constraints are satisfiable or not. It is straightforward to perform this test in polynomial time. A recursive equation that gives an upper bound on the time complexity of this algorithm is thus $T(1) = poly(||I||), T(n) = 3T(n - \lfloor \frac{k(k-1)(k-2)}{k^2} \rfloor) + poly(||I||))$ (where n denotes the number of variables and $||I||$ the number of bits required to represent I) so $T(n) \in O(3^{n \cdot \frac{k^2}{k(k-1)(k-2)}} \cdot poly(||I||))$. The function $\frac{k^2}{k(k-1)(k-2)}$ obviously tends to 0 with increasing k so the infimum of the set $\{\mathsf{T}(\{S_D\}) \mid D \text{ is finite and } |D| \geq 2\}$ is equal to 0. ◀

5 Concluding Remarks and Future Research

In this paper we have studied the time complexity of NP-complete CSPs. Assuming the algebraic CSP dichotomy conjecture, we have ruled out subexponential time algorithms for NP-complete, finite-domain CSPs, unless the ETH is false. This proof also extends to degree-bounded CSPs and many classes of CSPs over infinite domains. We then proceeded to study the time complexity of CSPs over ultraconservative constraint languages, and proved that no such NP-complete CSP is solvable strictly faster than $\mathsf{T}(\{S_D\})$. These results raise several directions for future research.

First, Theorem 9 shows that the algebraic approach is viable for analysing the existence of subexponential algorithms for certain structurally restricted $\mathrm{CSP}(\Gamma)$ problems. An interesting continuation would be to determine which of the structurally (but not constraint language) restricted CSPs investigated by de Haan et al. [17] could be used to prove similar results. For example, is it the case that $\mathrm{CSP}(\Gamma)$ is not solvable in subexponential time whenever $\mathrm{CSP}(\Gamma)$ is NP-complete and the primal treewidth of an instance is bounded by $\Omega(n)$, unless the ETH fails?

Second, Several independent solutions to the algebraic CSP dichotomy conjecture have recently been announced [13, 30, 37]. If any of these proposed proofs is correct, it is tempting to extend Theorem 23 to constraint languages that are not necessarily ultraconservative or conservative. As a starting point, one could try to strengthen the results in Section 4.1, in order to prove that $\langle\Gamma\rangle_{\not\equiv}$ contains an $S_{\mathbb{B}}$-extension whenever $\mathrm{CSP}(\Gamma)$ is NP-complete and Γ is conservative (but not ultraconservative).

Acknowledgements. We thank Hannes Uppman for several helpful discussions on the topic of this paper.

Abstract

We investigate the class of regular-ordered word equations. In such equations, each variable occurs at most once in each side and the order of the variables occurring in both left and right hand sides is preserved (the variables can be, however, separated by potentially distinct constant factors). Surprisingly, we obtain that solving such simple equations, even when the sides contain exactly the same variables, is NP-hard. By considerations regarding the combinatorial structure of the minimal solutions of the more general quadratic equations we obtain that the satisfiability problem for regular-ordered equations is in NP. The complexity of solving such word equations under regular constraints is also settled. Finally, we show that a related class of simple word equations, that generalises one-variable equations, is in P.

1 Introduction

A *word equation* is an equality $\alpha = \beta$, where α and β are words over an alphabet $\Sigma \cup X$ (called the left, respectively, right side of the equation); $\Sigma = \{\mathtt{a}, \mathtt{b}, \mathtt{c}, \ldots\}$ is the alphabet of *constants* and $X = \{x_1, x_2, x_3, \ldots\}$ is the alphabet set of *variables*. A *solution* to the equation $\alpha = \beta$ is a morphism $h : (\Sigma \cup X)^* \to \Sigma^*$ that acts as the identity on Σ and satisfies $h(\alpha) = h(\beta)$. For instance, $\alpha = x_1\mathtt{ab}x_2$ and $\beta = \mathtt{a}x_1x_2\mathtt{b}$ define the equation $x_1\mathtt{ab}x_2 = \mathtt{a}x_1x_2\mathtt{b}$, whose solutions are the morphisms h with $h(x_1) = \mathtt{a}^k$, for $k \geq 0$, and $h(x_2) = \mathtt{b}^\ell$, for $\ell \geq 0$.

The study of word equations (or the existential theory of equations over free monoids) is an important topic found at the intersection of algebra and computer science, with significant connections to, e.g., combinatorial group or monoid theory [19, 18, 2], unification [25, 11, 12], and, more recently, data base theory [9, 8]. The problem of deciding whether a given word equation $\alpha = \beta$ has a solution or not, known as the satisfiability problem, was shown to be decidable by Makanin [20] (see Chapter 12 of [17] for a survey). Later it was shown that the satisfiability problem is in PSPACE by Plandowski [22]; a new proof of this result was obtained in [14], based on a new simple technique called recompression. However, it is conjectured that the satisfiability problem is in NP; this would match the known lower bounds: the satisfiability of word equations is NP-hard, as it follows immediately from, e.g., [4]. This hardness result holds in fact for much simpler classes of word equations, like quadratic equations (where the number of occurrences of each variable in $\alpha\beta$ is at most two), as shown in [3]. There are also cases when the satisfiability problem is tractable. For

instance, word equations with only one variable can be solved in linear time in the size of the equation, see [13]; equations with two variables can be solved in time $\mathcal{O}(|\alpha\beta|^5)$, see [1].

In most cases, the NP-hardness of the satisfiability problem for classes of word equations was shown as following from the NP-completeness of the *matching problem* for corresponding classes of patterns with variables. In the matching problem we essentially have to decide whether an equation $\alpha = \beta$, with $\alpha \in (\Sigma \cup X)^*$ and $\beta \in \Sigma^*$, has a solution; that is, only one side of the equation, called pattern, contains variables. The aforementioned results [4, 3] show, in fact, that the matching problem is NP-complete for general α, respectively when α is quadratic. Many more tractability and intractability results concerning the matching problem are known (see [24, 6, 7]). In [5], efficient algorithms were defined for, among others, patterns which are *regular* (each variable has at most one occurrence), *non-cross* (between any two occurrences of a variable, no other distinct variable occurs), or patterns with only a constant number of variables occurring more than once.

Naturally, for a class of patterns that can be matched efficiently, the hardness of the satisfiability problem for word equations with sides in the respective class is no longer immediate. A study of such word equations was initiated in [21], where the following results were obtained. Firstly, the satisfiability problem for word equations with non-cross sides (for short non-cross equations) remains NP-hard. In particular, solving non-cross equations $\alpha = \beta$ where each variable occurs at most three times, at most twice in α and exactly once in β, is NP-hard. Secondly, the satisfiability of one-repeated variable equations (where at most one variable occurs more than once in $\alpha\beta$, but arbitrarily many other variables occur only once) having at least one non-repeated variable on each side, was shown to be trivially in P.

In this paper we mainly address the class of regular-ordered equations, whose sides are regular patterns and, moreover, the order of the variables occurring in both sides is the same. This seems to be one of the structurally simplest classes of equations whose number of variables is not bounded by a constant. One central motivation for studying these equations with a simple structure is that understanding their complexity and combinatorial properties may help us to identify a boundary between classes of word equations whose satisfiability is tractable and intractable. Moreover, we wish to gain a better understanding of the core reasons why solving word equations is hard. In the following, we overview our results, methods, and their connection to existing works from the literature.

Lower bounds. Our first result closes the main problem left open in [21]. Namely, we show that it is (still) NP-hard to solve regular (ordered) word equations. Note that in these word equations each variable occurs at most twice: at most once in every side. They are particular cases of both quadratic equations and non-cross equations, so the reductions showing the hardness of solving these more general equations do not carry over. To begin with, matching quadratic patterns is NP-hard, while matching regular patterns can be done in linear time. Showing the hardness of the matching problem for quadratic patterns in [3] relied on a simple reduction from 3-SAT, where the two occurrences of each variable were used to simulate an assignment of a corresponding variable in the SAT formula, respectively to ensure that this assignment satisfies the formula. To facilitate this final part, the second occurrences of the variables were grouped together, so the equation constructed in this reduction was not non-cross. Indeed, matching non-cross patterns can be done in polynomial time. So showing that solving non-cross equations is hard, in [21], required slightly different techniques. This time, the reduction was from an assignment problem in graphs. The (single) occurrences of the variables in one side of the equation were used to simulate an assignment in the graph, while the (two) occurrences of the variables from the other side were used for two reasons:

to ensure that the previously mentioned assignment is correctly constructed and to ensure that it also satisfies the requirements of the problem. For the second part it was also useful to allow the variables to occur in one side in a different order as in the other side.

As stated in [21], showing that the satisfiability problem for regular equations seems to require a totally different approach. Our hardness reduction relies on some novel ideas, and, unlike the aforementioned proofs, has a deep word-combinatorics core. As a first step, we define a reachability problem for a certain type of (regulated) string rewriting systems, and show it is NP-complete (in Lemma 7). This is achieved via a reduction from the strongly NP-complete problem 3-Partition [10]. Then we show that this reachability problem can be reduced to the satisfiability of regular-ordered word equations; in this reduction (described in the successive Lemmas 9, 10, and 11), we essentially try to encode the applications of the rewriting rules of the system into the periods of the words assigned to the variables in a solution to the equation. In doing this, we are able to only use one occurrence of each variable per side, and moreover to even have the variables in the same order in both sides.

Our reduction suggests the ability of this simple class of equations to model other natural problems in rewriting, combinatorics on words, and beyond. In this respect, our construction seems interesting with respect to the expressibility of word equations, as studied in [15].

Upper bounds. A consequence of the results in [23] is that the satisfiability problem for a certain class of word equations is in NP if the lengths of the minimal solutions of such equations (where the length of the solution defined by a morphism h is the image of the equation's sides under h) are at most exponential. With this in mind, we show Lemma 14, which gives us an insight in the combinatorial structure of the minimal solutions of quadratic equations: if we follow around the minimal solutions the positions that are fixed inside the images of the variables by each terminal of the original equation (in order, starting with that terminal), we obtain sequences that should not contain repetitions. Consequently, in Proposition 17, we give a simple and concise proof of the fact that the image of any variable in a minimal solution to a regular-ordered equation is at most linear in the size of the equation. It immediately follows that the satisfiability problem for regular-ordered equations is in NP. While this result was expected, the approach we use to obtain it seems rather interesting to us, and also a promising approach to showing that other, more complicated, classes of restricted word equations can be solved in NP-time. For instance, it is an open problem to show this for arbitrary regular or quadratic equations. It is worth noting that our polynomial upper bound on length of minimal solutions of regular-ordered equations does not hold even for slightly relaxed versions of such equations. More precisely, non-cross equations $\alpha = \beta$ where the order of the variables is the same in both sides and each variable occurs exactly three times in $\alpha\beta$, but never only on one side, may already have exponentially long minimal solutions (see Proposition 2). To this end, it seems even more surprising that it is NP-hard to solve equations with such a simple structure (regular-ordered), which, moreover, have quadratically short solutions. As such, regular-ordered equations seem to be among the structurally simplest word-equations, whose satisfiability problem is intractable.

Extending our ideas, we settle the complexity of solving regular-ordered equations with regular constraints (as defined in [3], where each variable is associated with an NFA), which is in NP for regular-ordered equations whose sides contain exactly the same variables, or when the languages defining the scope of the variables are all accepted by NFAs with at most c states, where c is a constant. For regular-ordered equations with regular constraints without these restrictions, the problem remains PSPACE-complete.

Finally, we use again a reasoning on the structure of the minimal solutions of equations, similar to the above, to show that if we preserve the non-cross structure of the sides of the

considered word equations, but allow only one variable to occur an arbitrary number of times (all the others occur exactly once in total, and hence in at most one side), we get a class of equations whose satisfiability problem is in P. This problem is related to the one-repeated variable equations considered in [21]; in this case, we restrict the equations to a non-cross structure of the sides, but drop the condition that at least one non-repeated variable should occur on each side. Moreover, this problem generalises the one-variable equations [13], while preserving the tractability of their satisfiability problem. Last, but not least, this result shows that the pattern searching problem, in which, given a pattern $\alpha \in (\Sigma \cup \{x_1\})^*$ containing constants and exactly one variable x_1 (occurring several times) and a text $\beta \in (\Sigma \cup \{x_1\})^*$ containing constants and the same single (repeated) variable, we check whether there exists an assignment of x_1 that makes α a factor of β, is tractable; indeed, this problem is the same as checking whether the word equation $x_2 \alpha x_3 = \beta$, with $\alpha, \beta \in (\Sigma \cup \{x_1\})^*$, is satisfiable.

2 Preliminaries

Let Σ be an *alphabet*. We denote by Σ^* the set of all words over Σ; by ε we denote the empty word. Let $|w|$ denote the *length* of a word w. For $1 \leq i \leq j \leq |w|$ we denote by $w[i]$ the letter on the i^{th} position of w and $w[i..j] = w[i]w[i+1]\cdots w[j]$. A word w is *p-periodic* for $p \in \mathbb{N}$ (and p is called a period of w) if $w[i] = w[i+p]$ for all $1 \leq i \leq |w| - p$; the smallest period of a word is called its *period*. By extension, for a word w of period p, we sometimes call $w[1..p]$ the period of w. Let $w = xyz$ for some words $x, y, z \in \Sigma^*$, then x is called *prefix* of w, y is a *factor* of w, and z is a *suffix* of w. Two words w and u are called *conjugate* if there exist non-empty words x, y such that $w = xy$ and $u = yx$. The powers of w are defined by $w^0 = \varepsilon$, $w^n = ww^{n-1}$ for $n \geq 1$, and $w^\omega = ww\cdots$, an infinite concatenation of the word w.

Let $\Sigma = \{\mathtt{a}, \mathtt{b}, \mathtt{c}, \ldots\}$ be an alphabet of *constants* and let $X = \{x_1, x_2, x_3, \ldots\}$ be an alphabet of *variables*. We assume that X and Σ are disjoint. A word $\alpha \in (\Sigma \cup X)^*$ is usually called *pattern*. For a pattern α and a letter $z \in \Sigma \cup X$, let $|\alpha|_z$ denote the number of occurrences of z in α; $\mathsf{var}(\alpha)$ denotes the set of variables from X occurring in α. A morphism $h : (\Sigma \cup X)^* \to \Sigma^*$ with $h(a) = a$ for every $a \in \Sigma$ is called a *substitution*. We say that $\alpha \in (\Sigma \cup X)^*$ is *regular* if, for every $x \in \mathsf{var}(\alpha)$, we have $|\alpha|_x = 1$; e. g., $\mathtt{a}x_1\mathtt{a}x_2\mathtt{c}x_3x_4\mathtt{b}$ is regular. Note that $L(\alpha) = \{h(\alpha) \mid h \text{ is a substitution}\}$ (the pattern language of α) is regular when α is regular, hence the name of such patterns. The pattern α is *non-cross* if between any two occurrences of the same variable x no other variable different from x occurs, e. g., $\mathtt{a}x_1\mathtt{ba}x_1x_2\mathtt{a}x_2x_2\mathtt{b}$ is non-cross, but $x_1\mathtt{b}x_2x_2\mathtt{b}x_1$ is not.

A *word equation* is a tuple $(\alpha, \beta) \in (\Sigma \cup X)^+ \times (\Sigma \cup X)^+$; we usually denote such an equation by $\alpha = \beta$, where α is the left-hand side (LHS, for short) and β the right-hand side (RHS) of the equation. A *solution* to an equation $\alpha = \beta$ is a substitution h with $h(\alpha) = h(\beta)$, and $h(\alpha)$ is called the *solution word* (*defined by* h); the length of a solution h of the equation $\alpha = \beta$ is $|h(\alpha)|$. A solution of shortest length to an equation is also called *minimal*.

A word equation is *satisfiable* if it has a solution and the *satisfiability problem* is to decide for a given word equation whether or not it is satisfiable. The satisfiability problem for general word equations can be solved non-deterministically in time polynomial in $n \log N$, where n is the length of the equation and N the length of its minimal solution [23]. The next result follows.

▶ **Lemma 1.** *Let $\mathcal{E}$ be a class of word equations. Suppose there exists a polynomial P such that for any equation in $\mathcal{E}$ its minimal solution, if it exists, has length at most $2^{P(n)}$ where n is the length of the equation. Then the satisfiability problem for $\mathcal{E}$ is in* NP.

A word equation $\alpha = \beta$ is *regular* or *non-cross*, if both α and β are regular or both α and β are non-cross, respectively; $\alpha = \beta$ is *quadratic* if each variable occurs at most twice in $\alpha\beta$. We call a regular or non-cross equation *ordered* if the order in which the variables occur in both sides of the equation is the same. That is, if x and y are variables occurring both in α and β, then all occurrences of x occur before all occurrences of y in α if and only if all occurrences of x occur before all occurrences of y in β. Note, however, that variables may occur only in one side of a regular or non-cross ordered equation. For instance $x_1x_1\mathtt{a}x_2x_3\mathtt{b}x_4 = x_1\mathtt{a}x_1x_2\mathtt{b}x_3$ is ordered non-cross, while $x_1x_1\mathtt{a}x_3x_2\mathtt{b} = x_1\mathtt{a}x_1x_2\mathtt{b}x_3$ is still non-cross but not ordered. Next we give an example of very simple word equations whose minimal solution has exponential length, whose structure follows that in [16, Theorem 4.8].

▶ **Proposition 2.** *The minimal solution to the word equation* $x_n\mathtt{a}x_n\mathtt{b}x_{n-1}\mathtt{b}x_{n-2}\cdots\mathtt{b}x_1 = \mathtt{a}x_nx_{n-1}^2\mathtt{b}x_{n-2}^2\mathtt{b}...\mathtt{b}x_1^2\mathtt{ba}^2$ *has length* $\Theta(2^n)$.

For a word equation $\alpha = \beta$ and an $x \in \mathsf{var}(\alpha\beta)$, a *regular constraint* (*for* x) is a regular language L_x. A solution h for $\alpha = \beta$ *satisfies* the regular constraint L_x if $h(x) \in L_x$. The satisfiability problem for word equations with regular constraints is to decide on whether an equation $\alpha = \beta$ with regular constraints L_x, $x \in \mathsf{var}(\alpha\beta)$, given as an NFA, has a solution that satisfies all regular constraints.

Finally, we recall the 3-Partition problem (see [10]). This problem is NP-complete in the strong sense, i.e., it remains NP-hard even when the input numbers are given in unary.

▶ **Problem 3** (3-Partition – 3-PAR).
Instance: $3m$ nonnegative integers (given in unary) $A = (k_1, \ldots, k_{3m})$, whose sum is ms
Question: Is there a partition of A into m disjoint groups of three elements, such that each group sums exactly to s.

3 Lower bounds

In this section, we show that the highly restricted class of regular-ordered word equations is NP-hard, and, thus, that even when the order in which the variables occur in an equation is fixed, and each variable may only repeat once – and never on the same side of the equation – satisfiability remains intractable. As mentioned in the introduction, our result shows the intractability of the satisfiability problem for a class of equations considerably simpler than the simplest intractable classes of equations known so far. Our result seems also particularly interesting since we are able to provide a corresponding upper bound in the next section, and even show that the minimal solutions of regular-ordered equations are "optimally short".

▶ **Theorem 4.** *The satisfiability problem for regular-ordered word equations is* NP*-hard.*

In order to show NP-hardness, we shall provide a reduction from a reachability problem for a simple type of regulated string-rewriting system. Essentially, given two words – a starting point, and a target – and an ordered series of n rewriting rules (a rewriting program, in a sense), the problem asks whether this series of rules may be applied consecutively (in the predefined order) to the starting word such that the result matches the target. We stress that the order of the rules is predefined, but the place where a rule is to be applied within the sentential form is non-deterministically chosen.

▶ **Problem 5** (Rewriting with Programmed Rules – REP).
Instance: Words $u_{start}, u_{end} \in \Sigma^*$ and an ordered series of n substitution rules $w_i \to w_i'$, with $w_i, w_i' \in \Sigma^*$, for $1 \leq i \leq n$.

Question: Can u_{end} be obtained from u_{start} by applying each rule (i.e., replacing an occurrence of w_i with w'_i), in order, to u_{start}.

▶ **Example 6.** Let $u_{start} = b^5$ and $u_{end} = (a^{11}bc^2)^5$; for $1 \leq i \leq 10$, consider the rules $w_i \to w'_i$ with $w_i = b$ and $w'_i = a^i bc$. We can obtain u_{end} from u_{start} by first applying $w_1 \to w'_1$ to the first b, then $w_2 \to w'_2$ to the second b, and further, in order for $3 \leq i \leq 5$, by applying $w_i \to w'_i$ to the i^{th} b. Then, we apply w_6 to the fifth b (counting from left to right). Further we apply in order, for $7 \leq i \leq 10$, $w_i \to w'_i$ to the $(11-i)^{th}$ occurrence of b.

It is not so hard to see that REP is NP-complete (the size of the input is the sum of the lengths of u_{start}, u_{end}, w_i and w'_i). A reduction can be given from 3-PAR, in a manner similar to the construction in the example above. Importantly for our proof, 3-PAR is strongly NP-complete, so it is simpler to reduce it to a problem whose input consists of words.

▶ **Lemma 7.** REP *is* NP*-complete.*

Our reduction centres on the construction, for any instance μ of REP, of a regular-ordered word equation $\alpha_\mu = \beta_\mu$ which possesses a specific form of solution – which we shall call *overlapping* – if and only if the instance of REP has a solution. By restricting the form of solutions in this way, the exposition of the rest of the reduction is simplified considerably. The main idea is that the applications of the rewriting rules are encoded in the periods of each variable in the solution.

▶ **Definition 8.** Let $n \in \mathbb{N}$, μ be an instance of REP with u_{start}, u_{end} and rules $w_i \to w'_i$ for $1 \leq i \leq n$. Let # be a 'new' letter not occurring in any component of REP. We define the regular-ordered equation $\alpha_\mu = \beta_\mu$ such that:
$\alpha_\mu := x_1\ w_1\ x_2\ w_2\ \cdots\ x_n\ w_n\ x_{n+1}\ \#\ u_{end}$, $\beta_\mu := \#\ u_{start}\ x_1\ w'_1\ x_2\ w'_2\ \cdots\ x_n\ w'_n\ x_{n+1}$.
A solution $h : (X \cup \Sigma)^* \to \Sigma^*$ is called *overlapping* if, for every $1 \leq i \leq n$, there exists $z_i \in \Sigma^*$ such that $w_i z_i$ is a suffix of $h(x_i)$ and $h(\#u_{start}x_1 \cdots w'_{i-1}x_i) = h(x_1 w_1 \cdots x_i w_i)z_i$.

Of course, satisfiability of a class of word equations asks whether any solution exists, rather than just overlapping solutions. Hence, before we prove our claim that $\alpha_\mu = \beta_\mu$ has an overlapping solution if and only if μ satisfies REP, we present a construction of an equation $\alpha = \beta$ which has a solution if and only if $\alpha_\mu = \beta_\mu$ has an overlapping solution. Essentially, this shows that solving the satisfiability of regular-ordered equations is as hard as solving the satisfiability of word equations when we restrict our search to overlapping solutions.

▶ **Lemma 9.** *Let μ be an instance of* REP*. There exists a regular-ordered equation $\alpha = \beta$ of size $O(|\alpha_\mu \beta_\mu|)$ such that $\alpha = \beta$ is satisfiable if and only if $\alpha_\mu = \beta_\mu$ has an overlapping solution.*

The rest of the proof relies on the following technical characterisation of overlapping solutions to $\alpha_\mu = \beta_\mu$ in terms of periods v_i of the images $h(x_i)$. The y_i factors will correspond to the z_i factors discussed in the definition of overlapping solutions (see also Figure 1).

▶ **Lemma 10.** *Let μ be a an instance of* REP *with u_{start}, u_{end} and rules $w_i \to w'_i$ for $1 \leq i \leq n$. A substitution $h : (X \cup \Sigma)^* \to \Sigma^*$ is an overlapping solution to $\alpha_\mu = \beta_\mu$ if and only if there exist prefixes $v_1, v_2, \ldots, v_n$ of $h(x_1), h(x_2), \ldots, h(x_n)$ such that:*
1. *$h(x_i)\ w_i$ is a prefix of v_i^ω for $1 \leq i \leq n$, and*
2. *$v_1 = \#u_{start}$, and for $2 \leq i \leq n$, $v_i = y_{i-1}w'_{i-1}$, and*
3. *$y_n\ w'_n\ h(x_{n+1}) = h(x_{n+1})\ \#u_{end}$,*
where for $1 \leq i \leq n$, y_i is the suffix of $h(x_i)$ of length $|v_i| - |w_i|$.

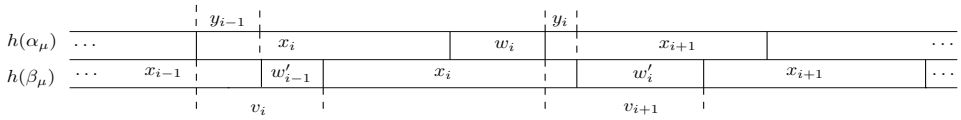

Figure 1 The period of $h(x_i)$ is v_i, and since w_iy_i is a suffix of $h(x_i)$ and $|w_iy_i| = |v_i|$, we have that w_iy_i is a cyclic shift of v_i (i.e., they are conjugate) – so $v_i = sw_it$ and $w_iy_i = w_its$ for some s, t. v_{i+1} is conjugate to sw'_it since $v_{i+1} = y_iw'_i = tsw'_i$. Thus v_{i+1} is obtained from v_i by "applying" the rule $w_i \to w'_i$ (and conjugating, but we can keep track of this due to the unique occurrence of #).

We shall now take advantage of Lemma 10 in order to demonstrate the correctness of our construction of $\alpha_\mu = \beta_\mu$ – i.e., that it has an overlapping solution if and only if μ satisfies REP. In particular, the periods v_i of the images $h(x_i)$ of the variables – which are obtained as the 'overlap' between the two occurrences of $h(x_i)$ – store the i^{th} stage of a rewriting $u_{start} \to \ldots \to u_{end}$. In fact, this is obtained as the conjugate of v_i starting with #. Thus the solution-word, when it exists, stores a sort-of rolling computation history.

▶ **Lemma 11.** *Let μ be a an instance of* REP *with u_{start}, u_{end} and rules $w_i \to w'_i$ for $1 \le i \le n$. There exists an overlapping solution $h : (X \cup \Sigma)^* \to \Sigma^*$ to the equation $\alpha_\mu = \beta_\mu$ if and only if μ satisfies* REP*.*

Proof. Suppose firstly that μ satisfies REP. Then there exist $s_1, s_2, \ldots, s_n, t_1, t_2, \ldots, t_n$ such that $u_{start} = s_1w_1t_1$, for $1 \le i \le n-1$, $s_iw'_it_i = s_{i+1}w_{i+1}t_{i+1}$ and $s_nw'_nt_n = u_{end}$. Let $h : (X \cup \Sigma)^* \to \Sigma^*$ be the substitution such that $h(x_1) = \#s_1w_1t_1\#s_1$, $h(x_{n+1}) = t_n\#s_nw'_nt_n\#s_nw'_nt_n$, and for $2 \le i \le n$, $h(x_i) = t_{i-1}\#s_{i-1}w'_{i-1}t_{i-1}\#s_i$. We shall now show that h satisfies Lemma 10, and hence that h is an overlapping solution to $\alpha_\mu = \beta_\mu$.

Let $v_1 = \#s_1w_1t_1$, let $y_1 := t_1\#s_1$, and for $2 \le i \le n$, let $v_i := t_{i-1}\#s_{i-1}w'_{i-1}$ and let $y_i := t_i\#s_i$. Note that for $1 \le i \le n$, v_i is a prefix of $h(x_i)$, and moreover, since $s_{i-1}w'_{i-1}t_{i-1} = s_iw_it_i$, y_i is the suffix of $h(x_i)$ of length $|v_i| - |w_i|$.

It is clear that h satisfies Condition (1) of Lemma 10 for $i = 1$. For $2 \le i \le n$, we have $h(x_i)w_it_i = t_{i-1}\#s_{i-1}w_{i-1}t_{i-1}\#s_iw_it_i = t_{i-1}\#s_{i-1}w_{i-1}t_{i-1}\#s_{i-1}w_{i-1}t_{i-1}$, which is a prefix of v_i^ω, and hence $h(x_i)w_i$ is also a prefix of v_i^ω. Thus h satisfies Condition (1) for all i. Moreover, $v_1 = \#u_{start}$, and for $2 \le i \le n$, $y_{i-1}w'_{i-1} = t_{i-1}\#s_{i-1}w'_{i-1} = v_i$, so h satisfies Condition (2). Finally, $y_nw'_nh(x_{n+1}) = t_n\#s_nw'_nt_n\#s_nw'_nt_n\#s_nw'_nt_n = h(x_{n+1})\#u_{end}$ so h also satisfies Condition (3).

Now suppose that h is an overlapping solution to $\alpha_\mu = \beta_\mu$. Then h satisfies Conditions (1), (2) and (3) of Lemma 10. Let v_i, y_i be defined according to the lemma for $1 \le i \le n$, and let $v_{n+1} = y_nw'_n$. We shall show that μ satisfies REP as follows. We begin with the following observations, whose proofs are omitted due to space constraints.

▶ **Claim 12.** *For $1 \le i \le n$, y_iw_i and v_i are conjugate. Hence, for $1 \le i \le n+1$, $|v_i|_\# = 1$.*

Let $\tilde{v}_i$ be the (unique) conjugate of v_i which has # as a prefix. Then we have the following:

▶ **Claim 13.** *For $1 \le i \le n$, there exist s_i, t_i such that $\tilde{v}_i = \#s_iw_it_i$ and $\tilde{v}_{i+1} = \#s_iw'_it_i$.*

Recall from Condition (3) of Lemma 10 that $v_{n+1}h(x_{n+1}) = y_nw'_nh(x_{n+1}) = h(x_{n+1})\#u_{end}$. Consequently, v_{n+1} and $\#u_{end}$ are conjugate, so $\tilde{v}_{n+1} = \#u_{end}$. Moreover, by Condition (2) of Lemma 10, $v_1 = \tilde{v}_1 = \#u_{start}$. Thus, it follows from Claim 13 that μ satisfies REP. ◀

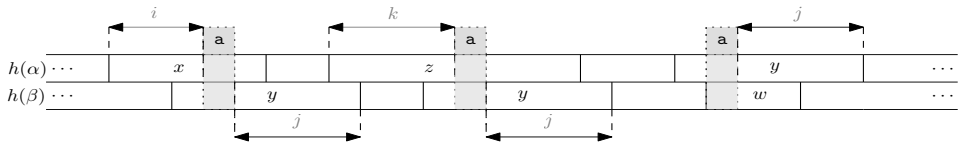

Figure 2 Fixing positions: since an occurrence of the i^{th} letter of $h(x)$ corresponds to an occurrence of the $(|h(y)| - j)^{th}$ letter of y, whose other occurrences correspond to the k^{th} letter of $h(z)$ and first letter of $h(w)$, all these positions are equivalent and contain the same letter, e.g., `a`.

It is clear that the equation $\alpha_\mu = \beta_\mu$ (and hence also the equation $\alpha = \beta$ given in Lemma 9) may be constructed in polynomial time, therefore our reduction from REP is complete. So, by Lemmas 7 and 11, we have shown Theorem 4.

4 NP-upper bound

In this section, we discuss a series of results related to the satisfiability of regular-ordered word equations. To this end, we extend the classical approach of filling the positions (see e.g., [15] and the references therein). This method essentially comprises of assuming that for a given equation $\alpha = \beta$, we have a solution h with specified lengths $|h(x)|$ for each variable x. The assumption that h satisfies the equation induces an equivalence relation on the positions of each $h(x)$: if a certain position in the solution-word is produced by an occurrence of the i^{th} letter of $h(x)$ on the RHS and an occurrence of the j^{th} letter of $h(y)$ on the LHS, then these two positions must obviously have the same value/letter and we shall say that these occurrences *correspond*. These individual equivalences can be combined to form equivalence classes, and if no contradictions occur (i.e., two different terminal symbols `a` and `b` do not belong to the same class), a valid solution can be derived.

Such an approach already allows for some straightforward observations regarding the (non-)minimality of a solution h. In particular, if an equivalence class of positions is not associated with any terminal symbol, then all positions in this class can be mapped to ε, resulting in a strictly shorter solution. On the other hand, even for our restricted setting, this observation is insufficient to provide a bound on the length of minimal solutions. In fact, in the construction of the equivalence classes we ignore, or at least hide, some of the structural information about the solution. In what follows, we shall see that by considering the exact 'order' in which positions are equated, we are able to give some more general conditions under which a solution is not minimal.

For our approach, rather than just constructing these equivalence classes, we shall construct sequences of equivalent positions, and then analyse "similar" sequences. For example, one occurrence of a position i in $h(x)$ might correspond to an occurrence of position j in $h(y)$, while another occurrence of position j in $h(y)$ might correspond to position k in $h(z)$, and so on, in which case we would consider the sequence: $\ldots \to (x, i) \to (y, j) \to (z, k) \to \ldots$.

The sequence terminates when either a variable which occurs only once or a terminal symbol is reached. For general equations, considering all such sequences leads naturally to a graph structure where the nodes are positions $(x, i) \in X \times \mathbb{N}$, and number of edges from each node is determined by the number of occurrences of the associated variable. Each connected component of such a graph corresponds to an equivalence class of positions as before. In the case of quadratic (and therefore also regular) equations, where each variable occurs at most twice, each 'node' (x, i) has at most two edges, and hence our graph is simply a set of disjoint chains, without any loops. As before, each chain (called in the following sequence) must be

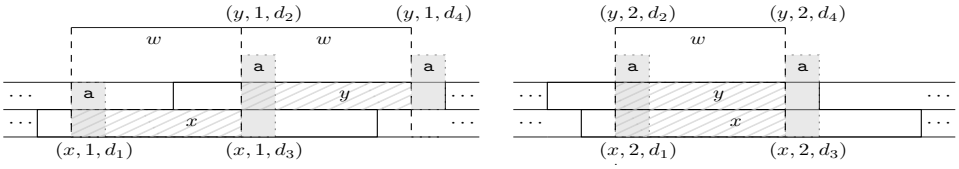

Figure 3 Illustration of Lemma 14 in the case of a short subsequence $\ldots,(x,1,d_1),(y,2,d_2),(x,1,d_3),(y,2,d_4),\ldots$: since the two sequences starting at $(x,1,d_1)$ and $(x,1,d_3)$ are similar, they define a common region w (shaded). Since they are consecutive, the first and last occurrences of w are adjacent, and on opposite sides of the equation. Thus, removing the region w from $h(x)$ and $h(y)$ does not alter the fact that h satisfies the equation.

associated with some occurrence of a terminal symbol, which must occur either at the start or the end. Hence we have $k < n$ sequences, where n is the length of the equation, such that every position (x,i), where x is a variable and $1 \leq i \leq |h(x)|$, occurs in exactly one sequence. It is also not hard to see that the total length of the sequences is upper bounded by $2|h(\alpha)|$.

In order to be fully precise, we will distinguish between different occurrences of a variable/terminal symbol by associating each with an index $z \in \mathbb{N}$ by enumerating occurrences from left to right in $\alpha\beta$. When considering quadratic equations, $z \in \{1,2\}$ for each variable x.

Formally, we define our sequences for a given solution h to a quadratic equation $\alpha = \beta$ as follows: a *position* is a tuple (x,z,d) such that x is a variable or terminal symbol occurring in $\alpha\beta$, $1 \leq z \leq |\alpha\beta|_x$, and $1 \leq d \leq |h(x)|$. Two positions (x,z,d) and (y,z',d') *correspond* if they generate the same position in the solution-word. The positions are *similar* if they belong to the same occurrence of the same variable (i.e., $x = y$ and $z = z'$). For each position p associated with either a terminal symbol or a variable occurring only once in $\alpha\beta$, we construct a sequence $S_p = p_1, p_2, \ldots$ such that

- $p_1 = p$ and p_2 is the (unique) position corresponding with p_1, and
- for $i \geq 2$, if $p_i = (x,z,d)$ such that x is a terminal symbol or occurs only once in $\alpha\beta$, then the sequence terminates, and
- for $i \geq 2$, if $p_i = (x,z,d)$, such that x is a variable occurring twice, then p_{i+1} is the position corresponding to the (unique) position (x,z',d) with $z' \neq z$ (i.e., the 'other' occurrence of the i^{th} letter in $h(x)$).

We extend the idea of similarity from positions to sequences of positions in the natural way: two sequences $p_1, p_2, \ldots, p_i$ and $q_1, q_2, \ldots, q_i$ are *similar* whenever p_j and q_j are similar for all $j \in \{1,2,\ldots,i\}$. Our main tool is the following lemma, which essentially shows that if a sequence contains two similar consecutive subsequences, then the solution defining that sequence is not minimal.

▶ **Lemma 14.** *Let h be a solution to a quadratic equation $\alpha = \beta$, and let p be a position associated with a single-occurring variable or terminal symbol. If the sequence S_p has a subsequence $p_1, p_2, \ldots, p_t, p_{t+1}, p_{t+2}, \ldots, p_{2t}$ such that $p_1, p_2, \ldots, p_t$ and $p_{t+1}, p_{t+2}, \ldots, p_{2t}$ are similar, then h is not minimal.*

Proof. Assume that S_p has such a subsequence and assume w.l.o.g. that it is length-minimal (so t is chosen to be as small as possible). For $1 \leq i \leq 2t$, let $p_i = (x_i, z_i, d_i)$ and note that by definition of similarity, for $1 \leq i \leq t$, $x_i = x_{i+t}$ and $z_i = z_{i+t}$. Assume that $d_1 < d_{t+1}$ (the case where $d_1 > d_{t+1}$ may be treated identically). We need the following two claims, whose proofs are omitted due to space constraints.

▶ **Claim 15.** *Suppose that* $(x, z, d), (x, z, d'), (x, z, d'')$ *are positions with* $d \leq d' < d''$ *such that* (x, z, d) *and* (x, z, d'') *correspond to* (y, z', e) *and* (y, z', e'') *respectively. Then* $e'' - e = d'' - d$*, and there exists* e' *with* $e' - e = d' - d$ *such that* (x, z, d') *and* (y, z', e') *correspond.*

A straightforward consequence of Claim 1 is that there exists a constant $C \in \mathbb{N}$ such that for all $i \in \{1, 2, \ldots, t\}$, $d_{i+t} - d_i = C$. Intuitively, each pair of similar positions $p_i = (x_i, z_i, d_i)$ and $p_{i+t} = (x_i, z_i, d_i + C)$ are the first and last positions of a factor $h(x_i)[d_i..d_i + C - 1]$, which as we shall see later on in the proof, can be removed to produce a shorter solution g.

It also follows from Claim 1, along with the fact that we chose t to be minimal, that there does not exist a position $p_i = (x_1, z_1, k)$ in the chain such that $d_1 < k < d_1 + C$. Symmetrically, there does not exist a position $p_i = (x_t, z_t, k)$ such that $d_t < k < d_t + C$:

▶ **Claim 16.** *Let* $j \in \{2, \ldots, t, t + 2, \ldots, 2t\}$ *such that* $x_j = x_1 (= x_{t+1})$ *and* $z_j = z_1 (= z_{t+1})$*. Then* $d_j \notin \{d_1, \ldots, d_{t+1} (= d_1 + C)\}$*. Likewise, if* $j \in \{1, \ldots, t - 1, t + 1, \ldots, 2t - 1\}$ *such that* $x_j = x_t$ *and* $z_j = z_t$*, then* $d_j \notin \{d_t, \ldots, d_{2t}\}$*.*

Using the observations above, we shall remove parts of the solution h to obtain a new, strictly shorter solution and thus show that h is not minimal as required.

To do this, we shall define a new equation $\alpha' = \beta'$ obtained by replacing the second occurrence of each variable x (when it exists) with a new variable x'. The reason is so we may delete factors independently from different occurrences of $h(x_i)$, and more easily keep track of the equivalence of the left and right hand side of the equation. Note that we can derive a solution h' to $\alpha' = \beta'$ from the solution h to our original equation by simply setting $h'(x) = h'(x') = h(x)$ for all $x \in \mathsf{var}(\alpha\beta)$. Likewise, any solution to $\alpha' = \beta'$ for which this condition holds (i.e., $h'(x) = h'(x')$ for all $x \in \mathsf{var}(\alpha\beta)$) induces a solution g to our original equation $\alpha = \beta$ given by $g(x) = h'(x) (= h'(x'))$. Finally, for each position (x, z, d) in the original solution h, there exists a unique "associated position" in h' given by $h(x)[d]$ if $z = 1$ and $h(x')[d]$ if $z = 2$. Furthermore, it follows from the definitions that for any pair of positions p, q which correspond (in terms of h), we can remove the associated positions from h' and the result will still be a valid solution to our modified equation $\alpha' = \beta'$ (although such a solution may no longer induce a valid solution to our original equation, since it is no longer necessarily the case where $h'(x) = h'(x')$ for all x).

We construct our shorter solution g to $\alpha = \beta$ as follows. Let h' be the solution to $\alpha' = \beta'$ derived directly from h. Recall from the definition of S_p that, for $1 \leq i < t$, the positions $(x_i, \overline{z}_i, d_i)$ and $(x_{i+1}, z_{i+1}, d_{i+1})$ correspond, where $\overline{z} = (z + 1) \mod 2$ (i.e., so that $\overline{z} \neq z$). Moreover, $(x_i, \overline{z}_i, d_i + C)$ and $(x_{i+1}, z_{i+1}, d_{i+1} + C)$ correspond, and thus by Claim 1, $(x_i, \overline{z}_i, d_i + k)$ and $(x_{i+1}, z_{i+1}, d_{i+1} + k)$ correspond for $0 \leq k \leq C - 1$. Since corresponding positions must have the same value/letter, it follows that there exists a factor $w \in \Sigma^+$ such that $w = h(x_i)[d_i..d_i + C - 1] (= h'(x)[d_i..d_i + C - 1] = h'(x')[d_i..d_i + C - 1])$ for $1 \leq i \leq t$.

We now produce a new solution, h'' to $\alpha' = \beta'$ as follows. For each i such that $1 \leq i \leq t-1$ and for each k such that $d_i \leq k \leq d_i + C - 1$, delete from h' the pair of positions associated with $(x_i, \overline{z}_i, d_i + k)$ and $(x_{i+1}, z_{i+1}, d_{i+1} + k)$. Note that since these positions correspond, in deleting them, we continue to have a valid solution to $\alpha' = \beta'$. Notice also that for every position associated with $(x_i, \overline{z}_i, d_i + k)$ such that $1 < i \leq t$, we also delete the position associated with $(x_i, z_i, d_i + k)$. Hence, for all $x \notin \{x_1, x_t\}$, $h''(x) = h''(x')$. The same does not necessarily hold for x_1 and x_t, however. In particular, we deleted positions associated with $(x_1, \overline{z_1}, d_1 + k)$ and $(x_t, z_t, d_t + k)$ for $0 \leq k \leq C - 1$, but not their counterparts $(x_1, z_1, d_1 + k)$ and $(x_t, \overline{z}_t, d_t + k)$. Hence, to derive a valid solution g, we must also delete these positions. To see that, in doing so, we still have a valid solution to $\alpha' = \beta'$, note firstly that, by Claim 2, we have not deleted any of these positions already. Moreover, it

follows from the sequence S_p that $(x_t, \overline{z}_t, d_t)$ corresponds to $(x_1, z_1, d_1 + C)$. Assume $z_1 = 1$ (the case $z_1 = 2$ is symmetric). It follows that $z_t = 1$ (since $\overline{z}_t \neq z_1$). Thus there exists an index m such that $h''(x_1)[d_1..d_1 + C - 1]$ generates the factor w starting at position m in $h''(\alpha')$ and $h''(x_t)[d_t..d_t + C - 1]$ generates the (same) factor w starting at position $m + |w|$ in $h''(\beta)$. It is straightforward to see that removing these factors (i.e., deleting the positions associated with $(x_1, z_1, d_1 + k)$ and $(x_t, \overline{z}_t, d_t + k)$ for $0 \leq k \leq C - 1$) does not affect the agreement of the two sides of the equation. Thus we obtain a shorter solution h'' to $\alpha' = \beta'$ such that $h(x) = h(x')$ for all variables x, hence a shorter solution g given by $g(x) = h''(x)$ to $\alpha = \beta$. ◀

An important fact related to the representation of the minimal solutions of quadratic equations as oriented sequences of positions, that start or end with a terminal symbol, is that the number of such sequences is linear in the size of the equation. Also, for variables that occur only once in a quadratic equation (so, only in one side), each of their positions is the start or end of a chain, so their length can be at most linear in the size of the equation. Thus, when interested in showing that a certain class of quadratic equation is in NP, we can assume that these equations do not contain variables occurring only once. Such variables could be non-deterministically replaced by words of at most linear size, and we would have to solve a new equation, whose size is at most quadratic in the size of the original one.

Further, using Lemma 14 and the observations above, we obtain immediately that minimal solutions to regular-ordered equations are at most linear in the length of the equation.

▶ **Proposition 17.** *Let E be a regular-ordered word equation with length n, and let h be a minimal solution to E. Then $|h(x)| < n$ for each variable x occurring in E.*

Proof. Every position of a minimal solution h to E occurs somewhere in one of the associated sequences S_p, and there are no more than n such sequences. So, it is sufficient to show that each one contains at most one position (x, z, d) for each variable x. This follows easily from the fact that E is regular and ordered and h is minimal, so it fulfils the restrictions of Lemma 14. ◀

We can see that, in terms of restricting the lengths of individual variables, the result in Proposition 17 is optimal. For instance, in a minimal solution h to the equation $w\mathsf{c}x_1 = x_1\mathsf{c}w$, with $w \in \{a, b\}^*$, the variable x_1 is mapped to w, so $|h(x)| = |E| - 2 \in O(|E|)$. Furthermore, Theorem 18 follows now as a direct consequence of Proposition 17 and Lemma 1, as the length of a minimal solution to a regular-ordered equation $\alpha = \beta$ is $O(|\alpha\beta|^2)$.

▶ **Theorem 18.** *The satisfiability problem for regular-ordered equations is in* NP.

It is a simple consequence of Proposition 17 that the satisfiability of a regular-ordered equation E with a constant number k of variables can be checked in P-time.

We now consider the satisfiability problem for regular equations with regular constraints, where we can make further use of the ideas presented so far in this section. Firstly, we observe that the problem is, in general, PSPACE-complete, even for regular-ordered equations (the proof given in [21] that the problem is PSPACE-complete for regular equations is also sufficient for the regular-ordered case).

▶ **Proposition 19.** *The satisfiability of regular-ordered equations with regular constraints is* PSPACE*-complete*

However, when considering regular equations whose sides contain exactly the same variables, and, moreover, in the same order, we get the following result, which shows an

important difference between the unrestricted regular-ordered equations, where the variables occurring only on one side do not affect the complexity of the satisfiability problem, and the same type of equations subject to regular constraints.

▶ **Theorem 20.** *The satisfiability of regular-ordered equations whose sides contain exactly the same variables, with regular constraints, is in* NP.

The same upper bound holds also for regular-ordered equations with regular constraints, when the regular constraints are regular languages accepted by NFAs with at most c states, where c is a constant (called constant regular constraints in the following).

▶ **Theorem 21.** *The satisfiability problem for regular-ordered equations with constant regular constraints is in* NP.

The proofs of the last two results rely also on the approach outlined in Lemma 14, but they are more involved. We first define the sequences of positions fixed by the terminals in a minimal solution of an equation. While this time the sequences may contain repetitions, we show that they cannot contain repetitions of non-constant exponent (where the constant, however, depends exponentially on c). This provides, again, a polynomial upper bound on the length of minimal solutions of such equations.

5 Tractable equations

Finally, we discuss a class of equations for which satisfiability is in P. Tractability was obtained so far from two sources: bound the number of variables by a constant (e.g., one or two-variable equations [13, 1]), or heavily restrict their structure (e.g., regular equations whose sides do not have common variable, or equations that only have one repeated variable, but at least one non-repeated variable on each side [21]). The class we consider slightly relaxes the previous restrictions. As the satisfiability of quadratic or even regular-ordered equations is NP-hard it seems reasonable to consider here patterns where the number of repeated variables is bounded by a constant (but may have an arbitrary number of non-repeated variables). More precisely, we consider here non-cross equations with only one repeated variable. This class generalises naturally the class of one-repeated variables.

▶ **Theorem 22.** *Let $x \in X$ be a variable and $\mathcal{D}$ be the class of word equations $\alpha = \beta$ such that $\alpha, \beta \in (\Sigma \cup X)^*$ are non-cross and each variable of X other than x occurs at most once in $\alpha\beta$. Then the satisfiability problem for $\mathcal{D}$ is in* P.

In the light of the results from [21], it follows that the interesting case of the above theorem is when the equation $\alpha = \beta$ is such that $\alpha = xu_1xu_2 \cdots u_kx$ and $\beta = \beta' v_0 x v_1 x v_2 \cdots x v_k \beta''$ where $v_0, v_1, \ldots, v_k, u_1, u_2, \ldots, u_k \in \Sigma^*$ and β', β'' are regular patterns that do not contain x and are variable disjoint. Essentially, this is a matching problem in which we try to align two non-cross patterns, one that only contains a repeated variable and constants, while the other contains the repeated variable, constants, and some wild-cards that can match any factor. As the proofs of [21] used essentially the non-repeated variables occurring in each of the sides, a novel and much more involved approach was needed here. The idea of our proof is to first show that such equations have minimal solutions of polynomial length. Further, we note that if we know the length of β' (w.r.t. the length of α) then we can determine the position where the factor $v_0xv_1xv_2 \cdots xv_k$ occurs in α, so the problem boils down to seeing how the positions of x are fixed by the constant factors v_i. Once this is done, we check if there exists an assignment of the variables of β' and β'' such that the constant factors of these patterns fit correctly to the corresponding prefix, respectively, suffix of α.

6 Conclusions and Prospects

The main result of this paper is the NP-completeness of the satisfiability problem for regular-ordered equations. While the lower bound seems remarkable to us because it shows that solving very simple equations, which also always have short solutions, is NP-hard, the upper bound seems more interesting from the point of view of the tools we developed to show it. We expect the combinatorial analysis of sequences of equivalent positions in a minimal solution to an equation (which culminated here in Lemma 14) can be applied to obtain upper bounds on the length of the minimal solutions to more general equations than just the regular-ordered ones. It would be interesting to see whether this type of reasoning leads to polynomial upper bounds on the length of minimal solutions to regular (not ordered) or quadratic equations, or to exponential upper bounds on the length of minimal solutions of non-cross or cubic equations. In the latter cases, a more general approach should be used, as the equivalent positions can no longer be represented as linear sequences, but rather as directed graphs.

Regarding the final section our paper, it seems interesting to us to see whether deciding the satisfiability of word equations with one repeated variable (so without the non-cross sides restriction) is still tractable. Also, it seems interesting to analyse the complexity of word equations where the number of repeated variables is bounded by a constant.

Abstract

Weighted automata over the tropical semiring $\mathbb{Z}_{\max} = (\mathbb{Z} \cup \{-\infty\}, \max, +)$ are closely related to finitely generated semigroups of matrices over $\mathbb{Z}_{\max}$. In this paper, we use results in automata theory to study two quantities associated with sets of matrices: the joint spectral radius and the ultimate rank. We prove that these two quantities are not computable over the tropical semiring, *i.e.* there is no algorithm that takes as input a finite set of matrices Γ and provides as output the joint spectral radius (resp. the ultimate rank) of Γ. On the other hand, we prove that the joint spectral radius is nevertheless approximable and we exhibit restricted cases in which the joint spectral radius and the ultimate rank are computable. To reach this aim, we study the problem of comparing functions computed by weighted automata over the tropical semiring. This problem is known to be undecidable, and we prove that it remains undecidable in some specific subclasses of automata.

1 Introduction

Weighted automata were introduced by Schützenberger in [25] as a quantitative extension of nondeterministic finite automata. They compute functions from the set of words over a finite alphabet to the set of values of a semiring, allowing one to model quantities such as costs, gains or probabilities. In this paper, we particularly focus on max-plus automata: automata weighted within the tropical semiring $\mathbb{Z}_{\max} = (\mathbb{Z} \cup \{-\infty\}, \max, +)$. A max-plus automaton is thus a nondeterministic finite automaton whose transitions are weighted by integers. The value associated to a word w depends on the runs labelled by w: the weight of a given run is the sum of the weights of the transitions in the run, and the weight of w is the maximum of the weights of the accepting runs labelled by w. This kind of automata is

particularly suitable to model gain maximisation, to study worst-case complexity [8] and to describe discrete event systems [12, 14]. The so-called linear presentation gives a matrix representation of such an automaton. More precisely, there is a canonical way to associate a max-plus automaton with a finitely generated semigroup of matrices over $\mathbb{Z}_{\max}$. Usually, the matrix representation is used to provide algebraic proofs of automata results. In this paper, we use results in automata theory to study two quantities related to sets of matrices: the joint spectral radius and the ultimate rank. The joint spectral radius generalises the notion of spectral radius for sets of matrices. The ultimate rank unifies some usual other notions of ranks. We link some comparison problems on max-plus automata with the computation of these two quantities. This leads to (1) proving results about comparison problems in some restricted classes of max-plus automata that we believe to be interesting for themselves and (2) applying these results to the study of the computability of the joint spectral radius and the ultimate rank.

Decidability questions about the description of functions computed by max-plus automata have been intensively studied. In his celebrated paper [20], Krob proves the undecidability of the equivalence problem for max-plus automata: there is no algorithm to decide if two max-plus automata compute the same function. In fact, his proof gives a stronger result: it is undecidable to determine whether a max-plus automaton computes a positive function. More recent approaches are based on a reduction from the halting problem of two-counter machines [1, 6]. By various reductions, this leads to the undecidability of several properties of automata with weights in different versions of the tropical semiring: $(\mathbb{N} \cup \{-\infty\}, \max, +)$, $(\mathbb{N} \cup \{+\infty\}, \min, +)$... The reader is referred to [21] for a survey on these questions.

By encoding the alphabet, and splitting each transition into several transitions with weight 1 and -1, it can be derived that the undecidability remains even if the automata are restricted to have weights within $\{-1, 1\}$ (Theorem 2). In [10], Gaubert and Katz notice that the undecidability of the comparison also remains true even if the number of states of the automata is bounded by a certain integer d. This extension is based on Krob's original proof and on the use of a universal diophantine equation. However, they ask for a more direct proof that would allow one to control the bound d. As an attempt to answer this question, we extend the proofs through two-counter machines. This allows a much sharper bound on the number of states for which comparison is undecidable (Theorem 2) than the one that would have followed from a universal diophantine equation.

The class of functions computed by max-plus automata that have all their states both initial and final is strictly included in the class of functions computed by max-plus automata. It is closely related to the study of finitely generated semigroup of tropical matrices. In this paper, we prove that comparison remains undecidable in this restricted class (Theorem 4). (In [1], it is proved that the undecidability remains for min-plus automata with all states final; we can deduce the same result for max-plus automata.)

The tropical (sub-)joint spectral radius is a natural counterpart of the usual joint spectral radius over the semiring $(\mathbb{R}, +, \times)$. Although the latter is a well-studied notion when considering the semiring $(\mathbb{R}, +, \times)$ (see [18] and the references therein) only few results are known when considering the tropical semiring. As far as we know, the best known result concerning its computability is given in [4], where it is shown that the joint spectral radius is NP-hard to compute and to approximate for tropical matrices. The tropical spectral radius as we defined it latter in this paper can be used to approximate the usual one in the spirit of [2] or [9], and from an applied point of view, for a max-plus linear system, it corresponds to the cycle time for an optimal scheduling of tasks, already studied in [12, 11, 14].

We drastically improve the NP-hardness result, by proving that the joint spectral radius is not computable in the tropical semiring, *i.e.* there is no algorithm that takes as input a

finite set Γ of matrices and provides as output the joint spectral radius of Γ (Theorem 8). As a corollary of this result, we also get the uncomputability of the ultimate rank, a notion introduced – and a question raised – in [15] (Theorem 9).

On the other hand, we also give positive results. By making a link with a result in [7] about approximate comparison of max-plus automata, we prove that the joint spectral radius is approximable in EXPSPACE (Theorem 10). We also show that, when restricted to matrices with only finite rational entries, computing the joint spectral radius or the ultimate rank is PSPACE-complete (Theorem 12).

2 Definitions and first properties

We introduce definitions and notation of tropical matrices and max-plus automata.

2.1 Tropical matrices

A *semigroup* $(S, \cdot)$ is a set S equipped with an associative binary operation '$\cdot$'. If, furthermore, the product has a neutral element 1, $(S, \cdot, 1)$ is called a *monoid*. The monoid is said to be *commutative* if $\cdot$ is commutative. A *semiring* $(S, \oplus, \otimes, 0_S, 1_S)$ is a set S equipped with two binary operations $\oplus$ and $\otimes$ such that $(S, \oplus, 0_S)$ is a commutative monoid, $(S - \{0_S\}, \otimes, 1_S)$ is a monoid, 0_S is absorbing for $\otimes$, and $\otimes$ distributes over $\oplus$. We shall use the *tropical semiring*:

$$\mathbb{Z}_{\max} = (\mathbb{Z} \cup \{-\infty\}, \max, +, -\infty, 0)$$

Note that $0_{\mathbb{Z}_{\max}} = -\infty$ and $1_{\mathbb{Z}_{\max}} = 0$. We may also use the restriction of $\mathbb{Z}_{\max}$ to the nonnegative integers, $(\mathbb{N} \cup \{-\infty\}, \max, +, -\infty, 0)$ denoted by $\mathbb{N}_{\max}$.

Semigroups of matrices. Let S be a semiring. The set of matrices with d rows and d' columns over S is denoted $\mathcal{M}^{d\times d'}(S)$, or simply $\mathcal{M}^d(S)$ if $d = d'$. The set of all matrices over S is $\mathcal{M}(S)$. As usual, the product AB for two matrices A, B (provided that the width of A and the height of B, denoted d, coincide) is defined as:

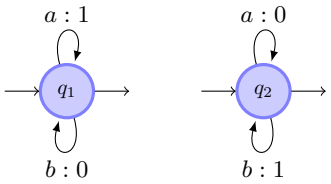
$$(AB)_{i,j} = \bigoplus_{1\leqslant k\leqslant d} (A_{i,k} \otimes B_{k,j}) \quad \left(= \max_{1\leqslant k\leqslant d} (A_{i,k} + B_{k,j}) \quad \text{for } S = \mathbb{Z}_{\max}\right)$$

The diagonal matrix with 1_S (*i.e.* 0 for $\mathbb{Z}_{\max}$) on the diagonal, and 0_S (*i.e.* $-\infty$ for $\mathbb{Z}_{\max}$) elsewhere is denoted I_d. It is a standard result that $(\mathcal{M}^d(S), \cdot, I_d)$ is a monoid.

For a positive integer k, we denote by M^k the product of M by itself k times. Moreover, $\|M\|_\infty$ denotes the maximal entry of a matrix M (it is not a norm). For $k \in \mathbb{Z}_{\max}$ and $A \in \mathcal{M}(\mathbb{Z}_{\max})$, $k \odot A$ is defined by $(k \odot A)_{ij} = k + A_{ij}$. For a set of matrices Γ, this notation is extended by $k \odot \Gamma = \{k \odot A | A \in \Gamma\}$. Finally, if $\Gamma \subset \mathcal{M}^d(S)$, we denote by $\langle\Gamma\rangle$ the submonoid generated by Γ.

Graph of a matrix. Any square matrix $A \in \mathcal{M}^d(\mathbb{Z}_{\max})$, for a positive integer d, can be represented by a graph $\mathcal{G}(A)$: the vertices are the indices $1, \ldots, d$, and there is an edge from i to j, labelled $A_{i,j}$, if and only if the latter is finite. The *spectral radius* $\rho(A)$ of a square matrix $A \in \mathcal{M}^d(\mathbb{Z}_{\max})$, for some positive integer d, known to be the limit $\lim_{n\to+\infty} \frac{1}{n} \|A^n\|_\infty$, can be seen as the maximal average weight of the cycles in $\mathcal{G}(A)$:

$$\rho(A) = \sup_{\substack{\ell\in\mathbb{N}\setminus\{0\} \\ 1\leqslant i_1,\ldots,i_\ell\leqslant d}} \left(\frac{1}{\ell}\left(A_{i_1,i_2} + A_{i_2,i_3} + \ldots + A_{i_{\ell-1},i_\ell} + A_{i_\ell,i_1}\right)\right)$$



$$\mu(a) = \begin{pmatrix} 1 & -\infty \\ -\infty & 0 \end{pmatrix} \qquad \mu(b) = \begin{pmatrix} 0 & -\infty \\ -\infty & 1 \end{pmatrix}$$

$$I = \begin{pmatrix} 0 & 0 \end{pmatrix} \qquad F = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

Figure 1 Graph and matrix representations of a max-plus automaton.

The *critical graph* $\mathcal{G}_c(A)$ is the union of cycles $(i_1, \dots, i_\ell)$ that achieve this maximum. Its *strongly connected components* are the maximal subgraphs $C \subseteq \mathcal{G}_c(A)$ such that for any vertices i, j of C there is a path from i to j in $\mathcal{G}_c(A)$. The *cyclicity of a strongly connected component* is the greatest common divisor of the length of its cycles. The *cyclicity of* $\mathcal{G}_c(A)$ is the least common multiple of the cyclicities of its strongly connected components. The reader is referred to [3, 16, 5] for more detailed explanations.

2.2 Max-plus automata

We give the definition of max-plus automata that can be viewed as graphs or as sets of matrices. A *max-plus automaton* $\mathcal{A}$ over the alphabet Σ with d states is a map μ from Σ to $\mathcal{M}^d(\mathbb{Z}_{\max})$ together with an initial vector $I \in \mathcal{M}^{1\times d}(\{0, -\infty\})$ and a final vector $F \in \mathcal{M}^{d\times 1}(\{0, -\infty\})$[1]. The map μ is uniquely extended into a morphism, also denoted μ, from the semigroup Σ^+ of nonempty finite words over alphabet Σ into $\mathcal{M}^d(\mathbb{Z}_{\max})$. The *function computed by the automaton*, $[\![\mathcal{A}]\!]$, maps each word $w \in \Sigma^+$ to $I\mu(w)F \in \mathbb{Z}_{\max}$. Sometimes, 0 will denote the function constantly equal to 0, and $\geqslant$ the induced partial order over functions $\Sigma^+ \to \mathbb{Z}_{\max}$ (so that we can write things like $[\![\mathcal{A}]\!] \geqslant 0$).

Another way to represent a max-plus automaton is in terms of graphs. Given a map μ from Σ^+ to $\mathcal{M}^d(\mathbb{Z}_{\max})$, the corresponding automaton has d states $q_1, \dots q_d$, that correspond to the lines, or to the columns of the matrices. There is a transition from q_i to q_j labelled by a letter $a \in \Sigma$, with weight $\mu(a)_{i,j}$, if and only if the latter is finite. The initial (resp. final) states are the states q_i such that $I_i = 0$ (resp. $F_i = 0$). A run over the word w is a path (a sequence of compatible transitions) in the graph, labelled by w. Its weight is the sum of the weights of the transitions. The weight of a given word w is the maximum of the weights of the accepting runs (runs going from an initial state to a final state) labelled by w. The weight of w, given by the graph representation, is exactly the value $I\mu(w)F$, given by the matrix presentation.

Given a positive integer d and a max-plus automaton $\mathcal{A}$ defined by some map $\mu : \Sigma \to \mathcal{M}^d(\mathbb{Z}_{\max})$, we denote $\Gamma_{\mathcal{A}} = \{\, \mu(a) |\, a \in \Sigma\}$. Then the set of weights on the transitions of $\mathcal{A}$ corresponds to the finite entries appearing in matrices of $\Gamma_{\mathcal{A}}$.

▶ **Example 1.** Figure 1 gives the matrix and graph presentations of a max-plus automaton with 2 states, both initial (ingoing arrow) and final (outgoing arrow), over the alphabet $\{a, b\}$. The function that it computes associates a word w to the value $\max(|w|_a, |w|_b)$ where $|w|_x$ denotes the number of occurrences of the letter $x \in \{a, b\}$ in w.

This work aims to link results in automata theory with the study of semigroups of matrices. Concepts defined over semigroups of matrices correspond to concepts over the

[1] Note that, unlike variants in the literature, our weighted automata have no input or output weight (that is, I and F have entries in $\{0, -\infty\}$), but this does not restrict the set of computed functions.

subclass of automata in which all states are both initial and final, because if $M \in \mathcal{M}^d(\mathbb{Z}_{\max})$, and I and F have only 0 entries, then $IMF = \|M\|_\infty$, so that for this class of automata, $[\![\mathcal{A}]\!](w) = \|\mu(w)\|_\infty$ for every word w.

3 Undecidability of the comparison of max-plus automata

We are interested in the comparison problem, *i.e.* deciding, given two max-plus automata $\mathcal{A}$ and $\mathcal{B}$, whether $[\![\mathcal{A}]\!] \leqslant [\![\mathcal{B}]\!]$. There exist (at least) two different approaches to prove the undecidability of this problem. The original one by Krob [20] is a reduction from the tenth problem of Hilbert about diophantine equations. The proof is nicely written in [21], where it encodes a homogeneous polynomial P of degree 4 on n variables with integer coefficients into a max-plus automaton $\mathcal{A}$ computing a function with values in $\mathbb{N}$, such that $P-1$ has a root in $\mathbb{N}^n$ if and only if there is a word w such that $[\![\mathcal{A}]\!](w) = 0$, *i.e.* if $[\![\mathcal{A}]\!] \geq 1$. A more recent approach [1, 6], consists of a reduction from the halting problem of a two-counter machine. This computational model was introduced by Minsky [23, 24], and is as powerful as a Turing machine. It can be viewed as a finite-state machine with two counters. The equality of the counters with 0 can be tested and the counters can be incremented and decremented if not 0. The idea of the proof is to embed it into a max-plus automaton.

3.1 Restriction on the parameters

Different parameters can be taken into account when dealing with the size of a max-plus automaton: we will focus on the number of states, the maximal and minimal weights appearing on the transitions and the size of the alphabet. When considering the matrix representation of an automaton $\mathcal{A}$, these parameters correspond respectively to the dimension, the maximal and minimal finite entries and the number of matrices in $\Gamma_{\mathcal{A}}$.

Regarding the size of the alphabet, by a classical encoding from an arbitrary alphabet to a two-letter alphabet, one can see that the comparison problem remains undecidable when restricting to the class of automata on the binary alphabet.

Regarding the two other parameters, if they are both bounded, the problem becomes decidable since we are now only considering a finite number of max-plus automata. What is more interesting to study is when one of the parameter is bounded and not the other. We will see that this problem remains undecidable in these cases, and our purpose is to give bounds on these parameters that allow to keep the undecidability.

On the one hand, Gaubert and Katz notice in [10] that the original proof of Krob, applied to some specific diophantine equations gives that the problem remains undecidable when bounding the number of states. They also raised the question of finding an alternative proof that could allow to control this number of states. We roughly counted how many states we would obtain by using a so-called universal diophantine equation given in [17], of degree 4 with 58 unknowns. At the very least, we would be able to bound the number of states by 8700 on a 6-letter alphabet. On the other hand, the proof via two-counter machines allows to drastically improve this number, as we are going to see.

Define $\mathtt{Pos}^k(S)$ (resp. $\mathtt{Pos}^k_d(S)$) as the following problem: *Given a max-plus automaton $\mathcal{A}$ on a k-letter alphabet, with weights in $S \subseteq \mathbb{Z}_{\max}$ (resp. and d states), determine whether* $[\![\mathcal{A}]\!] \geqslant 0$.

▶ **Theorem 2.** *Problems $\mathtt{Pos}^2(\{-1,1\})$ and $\mathtt{Pos}^6_{553}(\mathbb{Z}_{\max})$ are undecidable.*

The first statement is easily derived from the general undecidability: given a max-plus automaton $\mathcal{A}$, one can first decompose all the transitions from $\mathcal{A}$ into a sequence of transitions

with weights 1 or -1 and 0 thanks to a suitable encoding of the alphabet, such that $\mathcal{A}$ computes a non negative function if and only if the newly created automaton computes a non negative function. Using then a usual encoding of any alphabet in a two-letter alphabet, we can obtain an automaton over two letters and with weights still in $\{-1, 0, 1\}$. Then, we transform again the automaton by multiplying all the weights by 2, so that a transition weighted by 1 (resp. -1) is now weighted by 2 (resp. -2). Finally, we decompose a transition labelled by a letter a with weight 2 (resp. -2) into two transitions each labelled by a with weight 1 (resp. -1), and a transition labelled by a with weight 0 into two transitions each labelled by a, one with weight 1 and the other with weight -1. For example, the word ab^2a is now encoded by $a^2b^4a^2$. All the words that are not composed with square of the letters (which form a rational language) are given weight $\geqslant 0$ (by using only weights in $\{1, -1\}$). It is easy to see that the obtained automaton computes a nonnegative function if and only if $[\![\mathcal{A}]\!] \geqslant 0$. Moreover the obtained automaton is on a two letter alphabet with weights within $\{-1, 1\}$.

The undecidability of $\mathtt{Pos}^6_{553}(\mathbb{Z}_{\max})$ is a contribution of the present paper. The halting problem is undecidable for a universal two-counter machine on any input (the initial value of the first counter). We construct a max-plus automaton simulating the runs of a two-counter machine where the input $n \in \mathbb{N}$ is now encoded by an additional widget involving two edges with weights n and $-n$. Thus we construct a max-plus automaton with a fixed number of states (depending only on the number of states of the universal two-counter machine) but arbitrary weights (induced by the value of the input of the universal two-counter machine).

3.2 Restriction on initial and final states

It is easy to see that max-plus automata having all their states initial and final compute only subadditive functions, that is to say functions f such that for any two words u and v, $f(uv) \leqslant f(u) + f(v)$. In particular, the support of such a function is closed by taking factors (if uvw is in the support then v is also in the support). Thus, as for unweighted automata [19], this subclass of automata defines a strict subclass of functions of the functions computed by max-plus automata. However, the following lemma shows that the comparison problem remains undecidable within this subclass.

▶ **Lemma 3.** *Let Σ be a finite alphabet and $\star \notin \Sigma$ be a special symbol. Given a max-plus automaton $\mathcal{A}$ on Σ, with d states and weights within a set S, one can build a max-plus automaton $\mathcal{A}'$ on $\Sigma' = \Sigma \cup \{\star\}$, with $d+1$ states, all of which are initial and final, and weights within $S \cup \{0\}$, such that:*

$$\min(\inf_{u\in\Sigma^+} \frac{[\![\mathcal{A}]\!](u)}{|u|}, 0) \leq \inf_{w\in\Sigma'^+} \frac{[\![\mathcal{A}']\!](w)}{|w|} \quad \text{and} \quad \inf_{u\in\Sigma'^+} \frac{[\![\mathcal{A}']\!](u)}{|u|} \leq \inf_{w\in\Sigma^+} \frac{[\![\mathcal{A}]\!](w)}{|w|+1}$$

In particular, $[\![\mathcal{A}]\!] \geqslant 0$ if and only if $[\![\mathcal{A}']\!] \geqslant 0$.

Proof. Consider a max-plus automaton $\mathcal{A}$ defined by a map $\mu : \Sigma \to \mathcal{M}^d(\mathbb{Z}_{\max})$, an initial vector I and a final vector F, and a new symbol $\star$. Let $\Sigma' = \Sigma \cup \{\star\}$. The idea is to construct a new automaton $\mathcal{A}'$ by adding a new state q and transitions from every final state of $\mathcal{A}$ to every initial state of $\mathcal{A}$ as well as transitions from every final state of $\mathcal{A}$ to q, loops around q and transitions from q to every initial state of $\mathcal{A}$, all labelled by $\star$ with weight 0. All the states of the new automaton $\mathcal{A}'$ are initial and final. Let us note μ', I' and F' defining this new automaton.

Any word $w \in \Sigma'^{+}\backslash\{\star\}^*$ can be written: $w = \star^{n_0} w_1 \star^{n_1} w_2 \star^{n_2} \dots w_k \star^{n_k}$ where for all $1 \leqslant i \leqslant k$, $w_i \in \Sigma^+$ and for all $0 < i < k$, $n_i > 0$, $n_0 \geqslant 0$ and $n_k \geqslant 0$. We get:

$$[\![\mathcal{A}']\!](w) = \|\mu'(w)\|_\infty \geq \sum_{i=1}^{k} I\mu(w_i)F$$

since the weight of $\star$ is 0. This is at least $\sum_{i=1}^{k} |w_i| \inf_u \frac{[\![\mathcal{A}]\!](u)}{|u|}$. If $[\![\mathcal{A}]\!] \geq 0$, then we get $[\![\mathcal{A}']\!](w) \geq 0$. Otherwise, $\inf_u \frac{[\![\mathcal{A}]\!](u)}{|u|} < 0$, and since $\sum_i |w_i| \leq |w|$, we get $\frac{[\![\mathcal{A}']\!](w)}{|w|} \geq \inf_u \frac{[\![\mathcal{A}]\!](u)}{|u|}$. Moreover, since the weights of the words in $\{\star\}^*$ is 0 in $\mathcal{A}'$, then the first inequality holds.

The other inequality is obtained by observing how arcs labelled $\star$ are positioned in $\mathcal{A}'$. Indeed, if a transition labelled by $\star$ is taken, then it has to start from a final state or q, and has to end in an initial state or q. Moreover, no other letter labels a transition starting or ending in q. So, when reading a word $w \in \Sigma^+$ between two $\star$, this word is read on a run that was already an existing accepting run in $\mathcal{A}$.

Thus, we see that for all words $w \in \Sigma^+$ and all $k \in \mathbb{N}$: $[\![\mathcal{A}']\!]((\star w)^k \star) = k\,[\![\mathcal{A}]\!](w)$, so that:

$$\inf_{u \in \Sigma'^+} \frac{[\![\mathcal{A}']\!](u)}{|u|} \leq \inf_{\substack{w \in \Sigma^+ \\ k \in \mathbb{N}}} \frac{[\![\mathcal{A}']\!]((\star w)^k \star)}{k(|w|+1)+1} \leq \inf_{\substack{w \in \Sigma^+ \\ k \in \mathbb{N}}} \frac{[\![\mathcal{A}]\!](w)}{|w|+1+1/k}\,. \qquad \blacktriangleleft$$

As a corollary of this lemma and of the previous results on the undecidability of comparison, we get the following theorem.

▶ **Theorem 4.** *The restrictions of Problems* $\texttt{Pos}^3(\{-1,0,1\})$ *and* $\texttt{Pos}^7_{554}(\mathbb{Z}_{\max})$ *to automata whose states are all initial and final are still undecidable.*

Simultaneously to the latter construction, one can also encode the alphabet into the binary alphabet in a smart way, yielding to the following result:

▶ **Theorem 5.** *The restrictions of Problems* $\texttt{Pos}^2(\{-1,0,1\})$ *and* $\texttt{Pos}^2_{3319}(\mathbb{Z}_{\max})$ *to automata whose states are all initial and final are still undecidable.*

4 Joint spectral radius and ultimate rank of tropical matrices

4.1 Joint spectral radius

The definition of spectral radius extends to the *joint spectral radius* of a set $\Gamma \subseteq \mathcal{M}^d(\mathbb{Z}_{\max})$ of matrices, as follows:

$$\rho(\Gamma) = \inf_{\ell > 0} \left\{ \frac{1}{\ell} \|M_1 \cdots M_\ell\|_\infty \,\middle|\, M_1, \dots, M_\ell \in \Gamma \right\}$$

The following lemma, which gives other equivalent definitions[2], is a known application of Fekete's subadditive lemma (see for example [11, Theorem 3.4]).

[2] Note that here we use the inf definition for the joint spectral radius instead of the sup definition used in the literature (see [18] and references therein). The latter is easy to compute in $\mathbb{Z}_{\max}$ since it is the spectral radius of the generators' tropical sum, unlike the notion considered here (sometimes called lower spectral radius or joint spectral subradius).

▶ **Lemma 6.** *For any set Γ of matrices in $\mathcal{M}^d(\mathbb{Z}_{\max})$, we have:*

$$\rho(\Gamma) = \lim_{\ell\to\infty} \min\left\{ \frac{1}{\ell} \left\|M_1 \cdots M_\ell\right\|_\infty \middle| M_1, \ldots, M_\ell \in \Gamma \right\} \tag{1}$$

$$= \inf_{\ell>0} \left\{ \frac{1}{\ell}\rho(M_1 \cdots M_\ell) \middle| M_1, \ldots, M_\ell \in \Gamma \right\} \tag{2}$$

Proof. Let $u_\ell = \inf\{ \left\|M_1 \cdots M_\ell\right\|_\infty \mid M_1, \ldots, M_\ell \in \Gamma\}$. The sequence $(u_\ell)_\ell$ is subadditive *i.e.* for all ℓ, ℓ', $u_{\ell+\ell'} \leqslant u_\ell + u_{\ell'}$. Indeed for all $M_1, \ldots, M_{\ell+\ell'} \in \Gamma$, $\left\|M_1 \cdots M_{\ell+\ell'}\right\|_\infty \leqslant \left\|M_1 \cdots M_\ell\right\|_\infty + \left\|M_{\ell+1} \cdots M_{\ell+\ell'}\right\|_\infty$. Thus by Fekete's lemma, $\lim_{\ell\to\infty} \frac{u_\ell}{\ell}$ is well defined and $\inf_{\ell>0} \frac{u_\ell}{\ell} = \lim_{\ell\to\infty} \frac{u_\ell}{\ell}$, which implies (1).

For the second equality, let us set: $\rho'(\Gamma) = \inf_{\ell>0} \left\{ \frac{1}{\ell}\rho(M_1 \cdots M_\ell) \middle| M_1, \ldots, M_\ell \in \Gamma \right\}$. Since for all matrices M, $\rho(M) \leqslant \left\|M\right\|_\infty$, we have $\rho'(\Gamma) \leqslant \rho(\Gamma)$. Let us show the reverse inequality. For all $\varepsilon > 0$, there is $\ell > 0$ and $M_1, \ldots, M_\ell \in \Gamma$ such that $\frac{1}{\ell}\rho(M_1 \cdots M_\ell) \leqslant \rho'(\Gamma) + \varepsilon$. By definition, it means that $\frac{1}{\ell} \lim_n \frac{1}{n} \left\|(M_1 \cdots M_\ell)^n\right\|_\infty \leqslant \rho'(\Gamma) + \varepsilon$, or equivalently, $\lim_n \frac{1}{n\ell} \left\|(M_1 \cdots M_\ell)^n\right\|_\infty \leqslant \rho'(\Gamma) + \varepsilon$. By definition, $\rho(\Gamma) \leqslant \lim_n \frac{1}{n\ell} \left\|(M_1 \cdots M_\ell)^n\right\|_\infty$, thus, for all $\varepsilon > 0$, $\rho(\Gamma) \leqslant \rho'(\Gamma) + \varepsilon$, that concludes the proof. ◀

It can be easily seen that $\rho(k \odot \Gamma) = \rho(\Gamma) + k$.

4.2 Ultimate rank

In the classical setting of a field, the notion of rank enjoys many equivalent definitions. These notions do not coincide in the case of $\mathbb{Z}_{\max}$. However, it was noticed in [15] that they coincide on the limit points of the powers of the matrix, when properly normalized (or considered projectively). This is formalized in [15, Theorem 5.2], and equivalent to the following definition: the *ultimate rank* $\operatorname{urk}(M)$ of a matrix $M \in \mathcal{M}^d(\mathbb{Z}_{\max})$ is the sum of the cyclicities of the strongly connected components of its critical graph. Clearly, $\operatorname{urk}(M) = 0$ (M has empty critical graph) if and only if $\rho(M) = -\infty$, and this corresponds to the nilpotency of M. As for the joint spectral radius, this notion can be generalized to sets of matrices. The *ultimate rank* of a set $\Gamma \subseteq \mathcal{M}^d(\mathbb{Z}_{\max})$ of matrices is: $\operatorname{urk}(\Gamma) = \min\{ \operatorname{urk}(M) \mid M \in \langle\Gamma\rangle\}$.

Clearly, $\operatorname{urk}(\Gamma) = 0$ if and only if $\rho(\Gamma) = -\infty$, and this corresponds to the mortality of the semigroup generated by Γ. It can be seen (or read in [15, Theorem 5.2]) that the ultimate rank is a projective notion: $\operatorname{urk}(k \odot \Gamma) = \operatorname{urk}(\Gamma)$ for any $k \in \mathbb{Z}$.

In some interesting cases, $\operatorname{urk}(\Gamma)$ is indeed the reached minimum of the ranks in the semigroup, so that it is the dimension of the limit set of the action of Γ on $\mathbb{R}^d$. Those cases include sets with irreducible fixed structure (all matrices have the same infinite entries), and sets of matrices with no line of $-\infty$ that contain one matrix with only finite entries. This is implicitely used in [22] and allows to extend some nice properties of products of random matrices from matrices with the so-called memory-loss property (case $\operatorname{urk}(\Gamma) = 1$) to more general ones (see [22, Corollary 1.2]).

4.3 Uncomputability and link with automata

Finitely generated semigroups of matrices exactly correspond to max-plus automata that have all their states initial and final. In particular, the following lemma links the computation of the joint spectral radius of the former to the comparison of the latter.

▶ **Lemma 7.** *Let $\mathcal{A}$ be a max-plus automaton over an alphabet Σ whose all states are both initial and final. The following statements are equivalent.*

1. $[\![\mathcal{A}]\!] \geqslant 0$.
2. *For all matrices M in $\langle\Gamma_{\mathcal{A}}\rangle$, $\left\|M\right\|_\infty \geqslant 0$.*

3. *For all matrices M in $\langle \Gamma_{\mathcal{A}} \rangle$, $\rho(M) \geqslant 0$.*
4. $\rho(\Gamma_{\mathcal{A}}) \geqslant 0$.

According to the terminology in [1], this also corresponds to the case when $\mathcal{A}$ is called *universal with threshold* 0.

Proof. Items 1. and 2. are equivalent since all the states of $\mathcal{A}$ are both initial and final. Thus, for all words w, $[\![\mathcal{A}]\!](w) = \|\mu(w)\|_\infty$. Moreover, $\langle \Gamma_{\mathcal{A}} \rangle$ is exactly the set $\{\mu(w) | w \in \Sigma^+\}$. Items 2. and 3. are equivalent by definition of the joint spectral radius. Finally, Items 3. and 4. are equivalent by Lemma 6. ◀

The uncomputability of the joint spectral radius is deduced from the equivalence in Lemma 7 and from Theorem 4 and 5. More precisely, define $\mathtt{JSR}^k(S)$ (resp. $\mathtt{JSR}^k_d(S)$) as the following problem: *Given a finite set of k matrices with coefficients in $S \subseteq \mathbb{Z}_{\max}$ (resp. and dimension d), determine whether their joint spectral radius is greater than or equal to* 0.

▶ **Theorem 8.** *Problems $\mathtt{JSR}^2(\{-\infty, -1, 0, 1\})$ and $\mathtt{JSR}^7_{554}(\mathbb{Z}_{\max})$ are undecidable.*

Proof. The undecidability comes from a reduction from the problem stated in Theorem 4 and 5. Consider a max-plus automaton $\mathcal{A}$ whose states are all initial and final. By Lemma 7, $[\![\mathcal{A}]\!] \geqslant 0$ if and only if $\rho(\Gamma_{\mathcal{A}}) \geqslant 0$. Thus $\mathtt{JSR}^2(\{-\infty, -1, 0, 1\})$ and $\mathtt{JSR}^7_{554}(\mathbb{Z}_{\max})$ are undecidable. ◀

By reduction from Theorem 8, we prove that the ultimate rank is also uncomputable. Define $\mathtt{UR}^k(S)$ (resp. $\mathtt{UR}^k_d(S)$) as the following problem: *Given a finite set of k matrices with coefficients in S (resp. and dimension d), determine whether the ultimate rank of the semigroup that they generate is equal to* 1.

▶ **Theorem 9.** *Problems $\mathtt{UR}^2(\{-\infty, -1, 0, 1\})$ and $\mathtt{UR}^7_{1109}(\mathbb{Z}_{\max})$ are undecidable.*

Proof. From any matrix M, one can build: $\widehat{M} = \begin{bmatrix} M & -\infty & -\infty \\ -\infty & M & -\infty \\ -\infty & -\infty & 0 \end{bmatrix}$. It is then clear that, for any finite family of matrices Γ, the semigroup generated by $\widehat{\Gamma} = \left\{ \widehat{M} \middle| M \in \Gamma \right\}$ is $\left\langle \widehat{\Gamma} \right\rangle = \left\{ \widehat{M} \middle| M \in \langle \Gamma \rangle \right\}$.

If M has size d and entries in S, then $\widehat{M}$ has size $2d + 1$ and entries in $S \cup \{-\infty, 0\}$. Moreover, if $\rho(M) < 0$, then the critical graph of $\widehat{M}$ is simply the loop over the last vertex (last line of the matrix $\widehat{M}$), so that $\mathrm{urk}(\widehat{M}) = 1$. Otherwise, the critical graph of $\widehat{M}$ contains at least two copies of that of M (which is nonempty), so that $\mathrm{urk}(\widehat{M}) \geq 2$. Thus, $\rho(M) \geqslant 0$ if and only if $\mathrm{urk}(\widehat{M}) \geq 2$. By reduction from the undecidable problems of Theorem 8, we can deduce that $\mathtt{UR}^2(\{-\infty, -1, 0, 1\})$ and $\mathtt{UR}^7_{1109}(\mathbb{Z}_{\max})$ are undecidable. ◀

▶ Remark. As noted above, the joint spectral radius and ultimate rank are not altered through translation by a constant; thus uncomputability is preserved with other restrictions over the entries. Regarding the joint spectral radius, the comparison to 0 may no longer be undecidable, but the comparison to some other constants will be. For instance, if $\Gamma \subset \mathcal{M}(\mathbb{N}_{\max})$, positivity is always true, but the question whether $\rho(\Gamma) \geqslant 1$ is undecidable.

4.4 Approximation of the joint spectral radius

Still by using results in automata theory, we prove that even though the joint spectral radius is not computable in general, it is approximable and computable in restricted cases in the following sense.

▶ **Theorem 10.** *There is an algorithm that, given a finite set* Γ *of matrices and* $n \in \mathbb{N} \setminus \{0\}$*, computes a value* $\alpha \in \mathbb{Q} \cup \{-\infty\}$ *such that* $\alpha - \frac{1}{n} \leqslant \rho(\Gamma) \leqslant \alpha + \frac{1}{n}$*.*

Proof. The proof uses the main result of [7]. This result is originally stated for min-plus automata using only positive weights. These automata are defined over the *min-plus semiring* $(\mathbb{Z} \cup \{+\infty\}, \min, +, +\infty, 0)$. By using the morphism from the min-plus to the max-plus semiring that associates k to $-k$, we can state the result of [7] in the max-plus case: there is an algorithm $\mathfrak{A}$ that, given a max-plus automaton $\mathcal{A}$ over an alphabet Σ using only nonpositive weights and $n \in \mathbb{N} \setminus \{0\}$, computes a value $\alpha \in \mathbb{Q} \cup \{+\infty\}$ such that: $\alpha - \frac{1}{n} \leqslant \inf_{w \in \Sigma^+} \frac{[\![\mathcal{A}]\!](w)}{|w|} \leqslant \alpha + \frac{1}{n}$.

Now, let us exhibit an algorithm that gives an approximation of the joint spectral radius of any finite set of matrices with only nonpositive entries. Consider a finite set of matrices Γ with only nonpositive entries, and a max-plus automaton $\mathcal{A}$ such that $\Gamma = \Gamma_{\mathcal{A}}$. From [7], $\mathfrak{A}$ also gives an approximation of the joint spectral radius of Γ, since we have:

$$\rho(\Gamma) = \inf_{\ell > 0} \left\{ \frac{1}{\ell} \left\| M_1 \cdots M_\ell \right\|_\infty \middle| M_1, \ldots, M_\ell \in \Gamma \right\} = \inf_{\ell > 0} \left\{ \frac{1}{\ell} [\![\mathcal{A}]\!](w) \middle| w \in \Sigma^\ell \right\}$$
$$= \inf_{w \in \Sigma^+} \frac{[\![\mathcal{A}]\!](w)}{|w|} .$$

Consider now a finite set of matrices Γ with arbitrary entries. Let k denote the greatest entry that appears in at least one of the matrices of Γ. Construct the set $\Gamma' = -k \odot \Gamma$. The set Γ' is then a finite set of matrices with only nonpositive entries, on which we can apply $\mathfrak{A}$. We then get an approximation of the joint spectral radius of Γ by adding k to the value given by the algorithm. ◀

This implies, in particular, that the joint spectral radius of every finite set of matrices is a computable real number.

Remarks about the complexity. The algorithm of [7] is EXPSPACE in the size of the automaton and in n. Moreover the problem is PSPACE-hard by reduction from the universality problem of a nondeterministic automaton: *Given a nondeterministic finite automaton* $\mathcal{A}$ *over a* 2*-letter alphabet* Σ*, the problem to determine whether the language accepted by* $\mathcal{A}$ *is* Σ^+ *is PSPACE-complete.* A precise statement of the reduction is given in the following lemma.

▶ **Lemma 11.** *Given a nondeterministic finite automaton* $\mathcal{A}$ *over a* 2*-letter alphabet* Σ*, one can construct in polynomial time a set of* 3 *matrices* Γ *with entries in* $\{-\infty, 0\}$ *such that* $\mathcal{A}$ *accepts* Σ^+ *if and only if the joint spectral radius of* Γ *is equal to* 0*. Otherwise, the joint spectral radius of* Γ *is equal to* $-\infty$*.*

Proof. Consider a nondeterministic finite automaton $\mathcal{A}$ over a 2-letter alphabet Σ. We construct a max-plus automaton $\mathcal{A}'$ from $\mathcal{A}$ by weighting the transitions by 0. Then, $\mathcal{A}$ accepts Σ^+ if and only if $[\![\mathcal{A}']\!] = 0$ (otherwise there is a word w such that $[\![\mathcal{A}']\!](w) = -\infty$). By Lemma 3, one can construct a max-plus automaton $\mathcal{B}$ over a 3-letter alphabet such that every state of $\mathcal{B}$ is both initial and final, $\mathcal{B}$ has only weight 0 on its transitions, and $[\![\mathcal{A}']\!] \geqslant 0$ if and only if $[\![\mathcal{B}]\!] \geqslant 0$. Hence, $[\![\mathcal{A}']\!] = 0$ if and only if $[\![\mathcal{B}]\!] = 0$. By Lemma 7, $[\![\mathcal{B}]\!] \geqslant 0$ if and

only if the joint spectral radius of $\Gamma_{\mathcal{B}}$ is nonnegative. Since, $\Gamma_{\mathcal{B}}$ contains only matrices with entries in $\{0, -\infty\}$, it implies that $[\![\mathcal{B}]\!] = 0$ if and only if the joint spectral radius of $\Gamma_{\mathcal{B}}$ is equal to 0. All the constructions are polynomial. ◀

Notice that Lemma 11 also proves that $\mathtt{JSR}^3(\{0, -\infty\})$ is PSPACE-hard. A result in [1] implies that $\mathtt{JSR}^k(\mathbb{Z}^- \cup \{-\infty\})$ is also PSPACE, where $\mathbb{Z}^-$ denotes the set of nonpositive integers. Hence, Problem $\mathtt{JSR}^3(\{0, -\infty\})$ is also PSPACE-complete.

4.5 Restriction to finite entries

Let us consider the restriction to matrices with only finite entries. In terms of automata, it means that for all letters a, there is a transition labelled by a between any pair of states. In this case, the joint spectral radius and ultimate rank are computable.

▶ **Theorem 12.** *There are PSPACE algorithms to compute the joint spectral radius and the ultimate rank of any finite set of matrices with finite entries. In particular, in this case, the joint spectral radius is a rational number. Moreover,* $\mathtt{JSR}^3(\{0, -1\})$ *and* $\mathtt{UR}^3(\{0, -1\})$ *are PSPACE-complete.*

PSPACE algorithm. To prove that the problems are PSPACE, the key point is the following lemma:

▶ **Lemma 13** ([13])**.** *Let* $\Gamma \subset \mathcal{M}^d(\{-b, \dots, b\})$ *for some nonnegative integers* b *and* d*. Then for all matrices* $M \in \langle\Gamma\rangle$ *and all indices* i, j*, the quantity* $M_{i,j} - M_{1,1}$ *belongs to* $\{-2b, \dots, 2b\}$*.*

Let Γ be a finite set of matrices with entries in $\{-b, \dots, b\}$. By Lemma 13, the set $\Lambda = \{-M_{1,1} \odot M \mid M \in \langle\Gamma\rangle\}$ contains at most $(4b+1)^{d^2-1}$ matrices.

Moreover, since the operation of adding the same constant to all the entries of a matrix commutes with the product of matrices, Λ is the set of matrices $-M_{1,1} \odot M$ such that M is a product of at most $(4b+1)^{d^2-1}$ matrices of Γ. Finally, the ultimate rank of Γ is the minimum of the ultimate rank of the matrices in Λ, which can be computed by the following algorithm in NPSPACE. Start with a matrix $M = M_1 \in \Gamma$ and a counter ℓ with value 1. At each (nondeterministic) step, either compute $\mathrm{urk}(M)$ and stop, or increase ℓ by one and multiply M by some matrix $M_\ell \in \Gamma$. If $\ell = (4b+1)^{d^2-1}$, then compute $\mathrm{urk}(M)$ and stop.

Since the maximum value of ℓ is simply exponential in the size $|\Gamma| d^2 \log(b)$ of the input, both ℓ and the size of the entries of $M = M_1 \cdots M_\ell$ are simply exponential and thus can be stored in polynomial space. Since the product of matrices and ultimate rank of one matrix can be computed in P the algorithm is in NPSPACE=PSPACE.

For the joint spectral radius, let us prove that

$$\rho(\Gamma) = \min_{\substack{\ell \leqslant (4b+1)^d \\ M_1, \dots, M_\ell \in \Gamma}} \left\{ \frac{1}{\ell} \rho(M_1 \cdots M_\ell) \right\} \tag{3}$$

and conclude in the same way. Let us consider a product $M_1 \cdots M_\ell$ of matrices in Γ and the orbit of the vector with all entries equal to 0 under the action of $M_1, M_2, \dots, M_\ell, M_1, M_2, \dots$. By Lemma 13, this orbit projectively has size at most $(4b+1)^d$. Hence, it cycles after t steps for some $t \leqslant (4b+1)^d$ and has a period $p \leqslant (4b+1)^d$. Each time the orbit goes back to the same vector projectively, all coordinates have increased by some value, which is the spectral radius of $M_{(t+1) \bmod \ell} M_{(t+2) \bmod \ell} \cdots M_{(t+p) \bmod \ell}$. Indeed, for matrices with only finite entries, the spectral radius is the only eigenvalue. Finally, we get $\frac{1}{\ell}\rho(M_1 \cdots M_\ell) = \frac{1}{p}\rho(M_{(t+1) \bmod \ell} M_{(t+2) \bmod \ell} \cdots M_{(t+p) \bmod \ell})$, which proves (3).

PSPACE-hardness. Let Γ be a finite set of matrices with entries in $\{0, -\infty\}$. Let Γ' be the set Γ where every entry with value $-\infty$ has been replaced by -1. The joint spectral radius of Γ is equal to 0 if and only if the joint spectral radius of Γ' is equal to 0. Otherwise, $\rho(\Gamma) = -\infty$ and $\rho(\Gamma')$ is strictly negative. By Lemma 11, $\mathtt{JSR}^3(\{0, -\infty\})$ is PSPACE-hard, and thus $\mathtt{JSR}^3(\{0, -1\})$ is PSPACE-hard.

Now, let us reduce $\mathtt{JSR}^3([\{0, -1\})$ to $\mathtt{UR}^3(\{0, -1\})$. From any matrix $M \in \mathcal{M}^d(\{0, -1\})$, with $d \in \mathbb{N} \setminus \{0\}$, one can build the matrix: $\widetilde{M} = \begin{bmatrix} M & (-1) \\ (-1) & 0 \end{bmatrix} \in \mathcal{M}^{d+1}(\{0, -1\})$, where (-1) is the vector with appropriate size whose entries are all -1.

It is then clear that, for any finite family of matrices Γ, the semigroup generated by $\widetilde{\Gamma} = \left\{ \widetilde{M} \middle| M \in \Gamma \right\}$ is $\left\langle \widetilde{\Gamma} \right\rangle = \left\{ \widetilde{M} \middle| M \in \langle \Gamma \rangle \right\}$.

Moreover, note that if $\rho(M) < 0$, then the critical graph of $\widetilde{M}$ is the loop over the last vertex, so that $\mathrm{urk}(\widetilde{M}) = 1$. Otherwise, $\rho(M) = 0$, and the critical graph is the union of this loop and the critical graph of M, so that $\mathrm{urk}(\widetilde{M}) = 1 + \mathrm{urk}(M)$. We deduce that the ultimate rank of $\widetilde{\Gamma}$ is greater than or equal to 2 if and only if $\rho(\Gamma) \geqslant 0$.

▶ Remark. Lemma 13 is implicitely used in [12, Corollary 2] to prove that the functions computed by max-plus automata with rational entries whose linear representation generates a so-called primitive semigroup (which includes matrices with finite entries) can be computed by a deterministic automaton.

It is also shown (as Corollary 4) that the minimal growth rate of a deterministic automaton, *i.e.* the joint spectral radius of its linear representation, can be computed as the spectral radius of one matrix whose indices are the states of the automaton.

This gives another algorithm to compute the joint spectral radius of a finite set of matrices with finite integers, but not a PSPACE one, since the size of the deterministic automaton is only bounded by $(4b + 1)^{d^2}$, while Equation (3) allows to compute only matrices of size d without storing them.

5 Conclusion and open questions

In this paper, we have proved that the joint spectral radius and the ultimate rank of a finite set of matrices over the tropical semiring are not computable (from the proof it can be seen that they are actually computably-enumerable-complete). To this end, we have proved the undecidability of the comparison of max-plus automata in restricted cases: when all the states are both initial and final and when the number of states is bounded.

As for the restriction on the number of states, we proved that comparison is undecidable when restricted to 553 states. Now, the question is to understand what happens between 2 and 552 states. Even when restricted to 2 states, it seems quite a difficult question to answer. Moreover, the various proofs highlight a link between several universal models: diophantine equations and two-counter machines. Having better size bounds on these models would give a better bound for our undecidable problem, but conversely, getting the decidability of comparison for max-plus automata with at most a certain number of states could lead to improve the known lower bounds on the size of these universal objects.

As for the joint spectral radius, one could ask if it is always rational or if, on the opposite, the set of joint spectral radii of finite families of matrices admits some computability-theoretic characterization. With respect to complexity, the main open question is whether it is PSPACE to approximate the joint spectral radius.

Abstract

In the classical binary search in a path the aim is to detect an unknown target by asking as few queries as possible, where each query reveals the direction to the target. This binary search algorithm has been recently extended by [Emamjomeh-Zadeh et al., *STOC*, 2016] to the problem of detecting a target in an arbitrary graph. Similarly to the classical case in the path, the algorithm of Emamjomeh-Zadeh et al. maintains a candidates' set for the target, while each query asks an appropriately chosen vertex – the "median" – which minimises a potential Φ among the vertices of the candidates' set. In this paper we address three open questions posed by Emamjomeh-Zadeh et al., namely (a) detecting a target when the query response is a direction to an *approximately shortest path* to the target, (b) detecting a target when querying a vertex that is an *approximate median* of the current candidates' set (instead of an exact one), and (c) detecting *multiple targets*, for which to the best of our knowledge no progress has been made so far. We resolve questions (a) and (b) by providing appropriate upper and lower bounds, as well as a new potential Γ that guarantees efficient target detection even by querying an approximate median each time. With respect to (c), we initiate a systematic study for detecting two targets in graphs and we identify sufficient conditions on the queries that allow for strong (linear) lower bounds and strong (polylogarithmic) upper bounds for the number of queries. All of our positive results can be derived using our new potential Γ that allows querying approximate medians.

1 Introduction

The classical binary search algorithm detects an unknown target (or "treasure") t on a path with n vertices by asking at most $\log n$ queries to an oracle which always returns the direction from the queried vertex to t. To achieve this upper bound on the number of queries, the algorithm maintains a set of candidates for the place of t; this set is always a sub-path, and initially it is the whole path. Then, at every iteration, the algorithm queries the middle vertex ("median") of this candidates' set and, using the response of the query, it excludes

either the left or the right half of the set. This way of searching for a target in a path can be naturally extended to the case where t lies on an n-vertex tree, again by asking at most $\log n$ queries that reveal the direction in the (unique) path to t [22]. The principle of the binary search algorithm on trees is based on the same idea as in the case of a path: for every tree there exists a separator vertex such that each of its subtrees contains at most half of the vertices of the tree [14], which can be also efficiently computed.

Due to its prevalent nature in numerous applications, the problem of detecting an unknown target in an arbitrary graph or, more generally in a search space, has attracted many research attempts from different viewpoints. Only recently the binary search algorithm with $\log n$ direction queries has been extended to arbitrary graphs by Emamjomeh-Zadeh et al. [10]. In this case there may exist multiple paths, or even multiple shortest paths form the queried vertex to t. The direction query considered in [10] either returns that the queried vertex q is the sought target t, or it returns an arbitrary direction from q to t, i.e. an arbitrary edge incident to q which lies on a shortest path from q to t. The main idea of this algorithm follows again the same principle as for paths and trees: it always queries a vertex that is the "median" of the current candidates' set and any response to the query is enough to shrink the size of the candidates' set by a factor of at least 2. Defining what the "median" is in the case of general graphs now becomes more tricky: Emamjomeh-Zadeh et al. [10] define the median of a set S as the vertex q that minimizes a potential function Φ, namely the sum of the distances from q to all vertices of S.

Apart from searching for upper bounds on the number of queries needed to detect a target t in graphs, another point of interest is to derive algorithms which, given a graph G, compute the *optimal* number of queries needed to detect an unknown target in G (in the worst case). This line of research was initiated in [18] where the authors studied directed acyclic graphs (DAGs). Although computing a query-optimal algorithm is known to be NP-hard on general graphs [4,8,16], there exist efficient algorithms for trees; after a sequence of papers [1, 13, 17, 19, 26], linear time algorithms were found in [19, 22]. Different models with queries of non-uniform costs or with a probability distribution over the target locations were studied in [5–7, 15].

A different line of research is to search for upper bounds and information-theoretic bounds on the number of queries needed to detect a target t, assuming that the queries incorporate some degree of "noise". In one of the variations of this model [2, 10, 11], each query independently returns with probability $p > \frac{1}{2}$ a direction to a shortest path from the queried vertex q to the target, and with probability $1 - p$ an arbitrary edge (possibly adversarially chosen) incident to q. The study of this problem was initiated in [11], where $\Omega(\log n)$ and $O(\log n)$ bounds on the number of queries were established for a path with n vertices. This information-theoretic lower bound of [11] was matched by an improved upper bound in [2]. The same matching bound was extended to general graphs in [10].

In a further "noisy" variation of binary search, every vertex v of the graph is assigned a fixed edge incident to v (also called the "advice" at v). Then, for a fraction $p > \frac{1}{2}$ of the vertices, the advice directs to a shortest path towards t, while for the rest of the vertices the advice is arbitrary, i.e. potentially misleading or adversarially chosen [3]. This problem setting is motivated by the situation of a tourist driving a car in an unknown country that was hit by a hurricane which resulted in some fraction of road-signs being turned in an arbitrary and unrecognizable way. The question now becomes whether it is still possible to navigate through such a disturbed and misleading environment and to detect the unknown target by asking only few queries (i.e. taking advice only from a few road-signs). It turns out that, apart from its obvious relevance to data structure search, this problem also appears in

artificial intelligence as it can model searching using unreliable heuristics [3, 20, 23]. Moreover this problem also finds applications outside computer science, such as in navigation issues in the context of collaborative transport by ants [12].

Another way of incorporating some "noise" in the query responses, while trying to detect a target, is to have *multiple targets* hidden in the graph. Even if there exist only two unknown targets t_1 and t_2, the response of each query is potentially confusing even if *every* query correctly directs to a shortest path from the queried vertex to one of the targets. The reason of confusion is that now a detecting algorithm does not know to *which* of the hidden targets each query directs. In the context of the above example of a tourist driving a car in an unknown country, imagine there are two main football teams, each having its own stadium. A fraction $0 < p_1 < 1$ of the population supports the first team and a fraction $p_2 = 1 - p_1$ the second one, while the supporters of each team are evenly distributed across the country. The driver can now ask questions of the type "where is the football stadium?" to random local people along the way, in an attempt to visit *both* stadiums. Although every response will be honest, the driver can never be sure which of the two stadiums the local person meant. Can the tourist still detect both stadiums quickly enough? To the best of our knowledge the problem of detecting multiple targets in graphs has not been studied so far; this is one of the main topics of the present paper.

The problem of detecting a target within a graph can be seen as a special case of a two-player game introduced by Renyi [25] and rediscovered by Ulam [27]. This game does not necessarily involve graphs: the first player seeks to detect an element known to the second player in some search space with n elements. To this end, the first player may ask arbitrary yes/no questions and the second player replies to them honestly or not (according to the details of each specific model). Pelc [24] gives a detailed taxonomy for this kind of games. *Group testing* is a sub-category of these games, where the aim is to detect all unknown objects in a search space (not necessarily a graph) [9]. Thus, group testing is related to the problem of detecting multiple targets in graphs, which we study in this paper.

1.1 Our contribution

In this paper we systematically investigate the problem of detecting one or multiple hidden targets in a graph. Our work is driven by the open questions posed by the recent paper of Emamjomeh-Zadeh et al. [10] which dealt with the detection of a single target with and without "noise". More specifically, Emamjomeh-Zadeh et al. [10] asked for further fundamental generalizations of the model which would be of interest, namely (a) detecting a single target when the query response is a direction to an *approximately shortest path*, (b) detecting a single target when querying a vertex that is an *approximate median* of the current candidates' set S (instead of an exact one), and (c) detecting *multiple targets*, for which to the best of our knowledge no progress has been made so far.

We resolve question (a) in Section 2.1 by proving that *any* algorithm requires $\Omega(n)$ queries to detect a single target t, assuming that a query directs to a path with an approximately shortest length to t. Our results hold essentially for any approximation guarantee, i.e. for 1-additive and for $(1+\varepsilon)$-multiplicative approximations.

Regarding question (b), we first prove in Section 2.2 that, for any constant $0 < \varepsilon < 1$, the algorithm of [10] requires at least $\Omega(\sqrt{n})$ queries when we query each time an $(1+\varepsilon)$-approximate median (i.e. an $(1+\varepsilon)$-approximate minimizer of the potential Φ over the candidates' set S). Second, to resolve this lower bound, we introduce in Section 2.3 a new potential Γ. This new potential can be efficiently computed and, in addition, guarantees that, for any constant $0 \leq \varepsilon < 1$, the target t can be detected in $O(\log n)$ queries even when an $(1+\varepsilon)$-approximate median (with respect to Γ) is queried each time.

Regarding question (c), we initiate in Section 3 the study for detecting multiple targets on graphs by focusing mainly to the case of two targets t_1 and t_2. We assume throughout that every query provides a correct answer, in the sense that it always returns a direction to a shortest path from the queried vertex either to t_1 or to t_2. The "noise" in this case is that the algorithm does not know whether a query is returning a direction to t_1 or to t_2. Initially we observe in Section 3 that *any* algorithm requires $\frac{n}{2} - 1$ (resp. $n - 2$) queries in the worst case to detect one target (resp. both targets) if each query directs adversarially to one of the two targets. Hence, in the remainder of Section 3, we consider the case where each query independently directs to the first target t_1 with a constant probability p_1 and to the second target t_2 with probability $p_2 = 1 - p_1$. For the case of trees, we prove in Section 3 that both targets can be detected with high probability within $O(\log n)$ queries.

For general graphs, we distinguish between *biased* queries ($p_1 > p_2$) in Section 3.1 and *unbiased* queries ($p_1 = p_2 = \frac{1}{2}$) in Section 3.2. For biased queries, we observe that we can utilize the algorithm of Emamjomeh-Zadeh et al. [10] to detect the first target t_1 with high probability in $O(\log n)$ queries; this can be done by considering the queries that direct to t_2 as "noise". Thus our objective becomes to detect the target t_2 in a polylogarithmic number of queries. Notice here that we cannot apply the "noisy" framework of [10] to detect the second target t_2 , since now the "noise" is larger than $\frac{1}{2}$. We derive a probabilistic algorithm that overcomes this problem and detects the target t_2 with high probability in $O(\Delta \log^2 n)$ queries, where Δ is the maximum degree of a vertex in the graph. Thus, whenever $\Delta = O(poly \log n)$, a polylogarithmic number of queries suffices to detect t_2. In contrast, we prove in Section 3.2 that, for unbiased queries, *any* deterministic (possibly adaptive) algorithm that detects at least one of the targets requires at least $\frac{n}{2} - 1$ queries, even in an unweighted cycle. Extending this lower bound for two targets, we prove that, assuming $2c \geq 2$ different targets and unbiased queries, *any* deterministic (possibly adaptive) algorithm requires at least $\frac{n}{2} - c$ queries to detect one of the targets.

Departing from the fact that our best upper bound on the number of biased queries in Section 3.1 is not polylogarithmic when the maximum degree Δ is not polylogarithmic, we investigate in Section 4 several variations of queries that provide more informative responses. In Section 4.1 we turn our attention to "direction-distance" biased queries which return with probability p_i both the direction to a shortest path to t_i and the distance between the queried vertex and t_i. In Section 4.2 we consider another type of a biased query which combines the classical "direction" query and an edge-variation of it. For both query types of Sections 4.1 and 4.2 we prove that the second target t_2 can be detected with high probability in $O(\log^3 n)$ queries. Furthermore, in Sections 4.3 and 4.4 we investigate two further generalizations of the "direction" query which make the target detection problem trivially hard and trivially easy to solve, respectively.

1.2 Our Model and Notation

We consider connected, simple, and undirected graphs. A graph $G = (V, E)$, where $|V| = n$, is given along with a *weight function* $w : E \to \mathbb{R}^+$ on its edges; if $w(e) = 1$ for every $e \in E$ then G is *unweighted*. An edge between two vertices v and u of G is denoted by vu, and in this case v and u are said to be *adjacent* . The distance $d(v, u)$ between vertices v and u is the length of a shortest path between v and u with respect to the weight function w. Since the graphs we consider are undirected, $d(u, v) = d(v, u)$ for every pair of vertices v, u. Unless specified otherwise, all logarithms are taken with base 2. Whenever an event happens with probability at least $1 - \frac{1}{n^\alpha}$ for some $\alpha > 0$, we say that it happens *with high probability*.

The *neighborhood* of a vertex $v \in V$ is the set $N(v) = \{u \in V : vu \in E\}$ of its adjacent vertices. The cardinality of $N(v)$ is the *degree* $\deg(v)$ of v. The maximum degree among

all vertices in G is denoted by $\Delta(G)$, i.e. $\Delta(G) = \max\{\deg(v) : v \in V\}$. For two vertices v and $u \in N(v)$ we denote by $N(v,u) = \{x \in V : d(v,x) = w(vu) + d(u,x)\}$ the set of vertices $x \in V$ for which there exists a shortest path from v to x, starting with the edge vu. Note that, in general, $N(u,v) \neq N(v,u)$. Let $T = \{t_1, t_2, \cdots, t_{|T|}\} \subseteq V$ be a set of (initially unknown) *target vertices* . A *direction query* (or simply *query*) at vertex $v \in V$ returns with probability p_i a neighbor $u \in N(v)$ such that $t_i \in N(u,v)$, where $\sum_{i=1}^{|T|} p_i = 1$. If there exist more than one such vertices $u \in N(v)$ leading to t_i via a shortest path, the direction query returns an arbitrary one among them, i.e. possibly chosen adversarially, unless specified otherwise. Moreover, if the queried vertex v is equal to one of the targets $t_i \in T$, this is revealed by the query with probability p_i.

2 Detecting a Unique Target

In this section we consider the case where there is only one unknown target $t = t_1$, i.e. $T = \{t\}$. In this case the direction query at vertex v always returns a neighbor $u \in N(v)$ such that $t \in N(u,v)$. For this problem setting, Emamjomeh-Zadeh et al. [10] provided a polynomial-time algorithm which detects the target t in at most $\log n$ direction queries. During its execution, the algorithm of [10] maintains a "candidates' set" $S \subseteq V$ such that always $t \in S$, where initially $S = V$. At every iteration the algorithm computes in polynomial time a vertex v (called the *median* of S) which minimizes a potential $\Phi_S(v)$ among all vertices of the current set S. Then it queries a median v of S and it reduces the candidates' set S to $S \cap N(v,u)$, where u is the vertex returned by the direction query at v. The upper bound $\log n$ of the number of queries in this algorithm follows by the fact that always $|S \cap N(v,u)| \leq \frac{|S|}{2}$, whenever v is the median of S.

2.1 Bounds for Approximately Shortest Paths

We provide lower bounds for both additive and multiplicative approximation queries. A *c-additive approximation query* at vertex $v \in V$ returns a neighbor $u \in N(v)$ such that $w(vu) + d(u,t) \leq d(v,t) + c$. Similarly, an $(1+\varepsilon)$-*multiplicative approximation query* at vertex $v \in V$ returns a neighbor $u \in N(v)$ such that $w(vu) + d(u,t) \leq (1+\varepsilon) \cdot d(v,t)$.

It is not hard to see that in the unweighted clique with n vertices any algorithm requires in worst case $n-1$ 1-additive approximation queries to detect the target t. Indeed, in this case $d(v,t) = 1$ for every vertex $v \neq t$, while every vertex $u \notin \{v,t\}$ is a valid response of an 1 -additive approximation query at v. Since in the case of the unweighted clique an additive 1-approximation is the same as a multiplicative 2-approximation of the shortest path, it remains unclear whether 1 -additive approximation queries allow more efficient algorithms for graphs with large diameter. In the next theorem we strengthen this result to graphs with unbounded diameter.

▶ **Theorem 1.** *Assuming* 1*-additive approximation queries, any algorithm requires at least* $n-1$ *queries to detect the target* t*, even in graphs with unbounded diameter.*

In the next theorem we extend Theorem 1 by showing a lower bound of $n \cdot \frac{\varepsilon}{4}$ queries when we assume $(1+\varepsilon)$-multiplicative approximation queries.

▶ **Theorem 2.** *Let* $\varepsilon > 0$*. Assuming* $(1+\varepsilon)$ *-multiplicative approximation queries, any algorithm requires at least at least* $n \cdot \frac{\varepsilon}{4}$ *queries to detect the target* t*.*

2.2 Lower Bound for querying the Approximate Median

The potential $\Phi_S : V \to \mathbb{R}^+$ of [10], where $S \subseteq V$, is defined as follows. For any set $S \subseteq V$ and any vertex $v \in V$, the potential of v is $\Phi_S(v) = \sum_{u \in S} d(v,u)$. A vertex $x \in V$ is an $(1+\varepsilon)$-approximate minimizer for the potential Φ over a set S (i.e. an $(1+\varepsilon)$-median of S) if $\Phi_S(x) \leq (1+\varepsilon)\min_{v \in V} \Phi_S(v)$, where $\varepsilon > 0$. We prove that an algorithm querying at each iteration always an $(1+\varepsilon)$-median of the current candidates' set S needs $\Omega(\sqrt{n})$ queries.

▶ **Theorem 3.** *Let $\varepsilon > 0$. If the algorithm of [10] queries at each iteration an $(1+\varepsilon)$-median for the potential function Φ, then at least $\Omega(\sqrt{n})$ queries are required to detect the target t in a graph G with n vertices, even if the graph G is a tree.*

2.3 Upper Bound for querying the Approximate Median

In this section we introduce a new potential function $\Gamma_S : V \to \mathbb{N}$ for every $S \subseteq V$, which overcomes the problem occured in Section 2.2. This new potential guarantees efficient detection of t in at most $O(\log n)$ queries, even when we always query an $(1+\varepsilon)$-median of the current candidates' set S (with respect to the new potential Γ), for any constant $0 < \varepsilon < 1$. Our algorithm is based on the approach of [10], however we now query an approximate median of the current set S with respect to Γ (instead of an exact median with respect to Φ of [10]).

▶ **Definition 4** (Potential Γ). Let $S \subseteq V$ and $v \in V$. Then $\Gamma_S(v) = \max\{|N(v,u) \cap S| : u \in N(v)\}$.

▶ **Theorem 5.** *Let $0 \leq \varepsilon < 1$. There exists an efficient adaptive algorithm which detects the target t in at most $\frac{\log n}{1-\log(1+\varepsilon)}$ queries, by querying at each iteration an $(1+\varepsilon)$-median for the potential function Γ.*

Proof. Our proof closely follows the proof of Theorem 3 of [10]. Let $S \subseteq V$ be an arbitrary set of vertices of G such that $t \in S$. We will show that there exists a vertex $v \in V$ such that $\Gamma_S(v) \leq \frac{|S|}{2}$. First recall the potential $\Phi_S(v) = \sum_{x \in S} d(v,x)$. Let now $v_0 \in V$ be a vertex such that $\Phi_S(v_0)$ is minimized, i.e. $\Phi_S(v_0) \leq \Phi_S(v)$ for every $v \in V$. Let $u \in N(v_0)$ be an *arbitrary* vertex adjacent to v_0. We will prove that $|N(v_0,u) \cap S| \leq \frac{|S|}{2}$. Denote $S^+ = N(v_0,u) \cap S$ and $S^- = S \setminus S^+$. By definition, for every $x \in S^+$, the edge v_0u lies on a shortest path from v_0 to x, and thus $d(u,x) = d(v_0,x) - w(v_0u)$. On the other hand, trivially $d(u,x) \leq d(v_0,x) + w(v_0u)$ for every $x \in S$, and thus in particular for every $x \in S^-$. Therefore $\Phi_S(v_0) \leq \Phi_S(u) \leq \Phi_S(v_0) + (|S^-| - |S^+|) \cdot w(v_0u)$, and thus $|S^+| \leq |S^-|$. That is, $|N(v_0,u) \cap S| = |S^+| \leq \frac{|S|}{2}$, since $S^- = S \setminus S^+$. Therefore which then implies that $\Gamma_S(v_0) \leq \frac{|S|}{2}$ as the choice of the vertex $u \in N(v_0)$ is arbitrary.

Let $v_m \in V$ be an exact median of S with respect to Γ. That is, $\Gamma_S(v_m) \leq \Gamma_S(v)$ for every $v \in V$. Note that $\Gamma_S(v_m) \leq \Gamma_S(v_0) \leq \frac{|S|}{2}$. Now let $0 \leq \varepsilon < 1$ and let $v_a \in V$ be an $(1+\varepsilon)$-median of S with respect to Γ. Then $\Gamma_S(v_a) \leq (1+\varepsilon)\Gamma_S(v_m) \leq \frac{1+\varepsilon}{2}|S|$. Our adaptive algorithm proceeds as follows. Similarly to the algorithm of [10] (see Theorem 3 of [10]), our adaptive algorithm maintains a candidates' set S, where initially $S = V$. At every iteration our algorithm queries an arbitrary $(1+\varepsilon)$-median $v_m \in V$ of the current set S with respect to the potential Γ. Let $u \in N(v_m)$ be the vertex returned by this query; the algorithm updates S with the set $N(v,u) \cap S$. Since $\Gamma_S(v_a) \leq \frac{1+\varepsilon}{2}|S|$ as we proved above, it follows that the updated candidates' set has cardinality at most $\frac{1+\varepsilon}{2}|S|$. Thus, since initially $|S| = n$, our algorithm detects the target t after at most $\log_{(\frac{2}{1+\varepsilon})} n = \frac{\log n}{1-\log(1+\varepsilon)}$ queries. ◀

Notice in the statement of Theorem 5 that for $\varepsilon = 0$ (i.e. when we always query an exact median) we get an upper bound of $\log n$ queries, as in this case the size of the candidates' set decreases by a factor of at least 2. Furthermore notice that the reason that the algorithm of [10] is not query-efficient when querying an $(1+\varepsilon)$-median is that the potential $\Phi_S(v)$ of [10] can become quadratic in $|S|$, while on the other hand the value of our potential $\Gamma_S(v)$ can be at most $|S|$ by Definition 4, for every $S \subseteq V$ and every $v \in V$. Furthermore notice that, knowing only the value $\Phi_S(v)$ for some vertex $v \in V$ is not sufficient to provide a guarantee for the proportional reduction of the set S when querying v. In contrast, just knowing the value $\Gamma_S(v)$ directly provides a guarantee that, if we query vertex v the set S will be reduced by a proportion of $\frac{\Gamma_S(v)}{|S|}$, regardless of the response of the query. Therefore, in practical applications, we may not need to necessarily compute an (exact or approximate) median of S to make significant progress.

3 Detecting Two Targets

In this section we consider the case where there are two unknown targets t_1 and t_2, i.e. $T = \{t_1, t_2\}$. In this case the direction query at vertex v returns with probability p_1 (resp. with probability $p_2 = 1 - p_1$) a neighbor $u \in N(v)$ such that $t_1 \in N(v,u)$ (resp. $t_2 \in N(v,u)$). Detecting more than one unknown targets has been raised as an open question by Emamjomeh-Zadeh et al. [10], while to the best of our knowledge no progress has been made so far in this direction. Here we deal with both problems of detecting at least one of the targets and detecting both targets. We study several different settings and derive both positive and negative results for them. Each setting differs from the other ones on the "freedom" the adversary has on responding to queries, or on the power of the queries themselves. We will say that the response to a query *directs to* t_i, where $i \in \{1,2\}$, if the vertex returned by the query lies on a shortest path between the queried vertex and t_i.

It is worth mentioning here that, if an adversary would be free to arbitrarily choose which t_i each query directs to (i.e. instead of directing to t_i with probability p_i), then any algorithm would require at least $\lfloor \frac{n}{2} \rfloor$ (resp. $n-2$) queries to detect at least one of the targets (resp. both targets), even when the graph is a path. Indeed, consider a path $v_1, \ldots, v_n$ where $t_1 \in \{v_1, \ldots, v_{\lfloor \frac{n}{2} \rfloor}\}$ and $t_2 \in \{v_{\lfloor \frac{n}{2} \rfloor + 1}, \ldots, v_n\}$. Then, for every $i \in \{1, \ldots, \lfloor \frac{n}{2} \rfloor\}$, the query at v_i would return v_{i+1}, i.e. it would direct to t_2. Similarly, for every $i \in \{\lfloor \frac{n}{2} \rfloor + 1, \ldots, n\}$, the query at v_i would return v_{i-1}, i.e. it would direct to t_1. It is not hard to verify that in this case the adversary could "hide" the target t_1 at any of the first $\lfloor \frac{n}{2} \rfloor$ vertices which is not queried by the algorithm and the target t_2 on any of the last $n - \lfloor \frac{n}{2} \rfloor$ vertices which is not queried. Hence, at least $\lfloor \frac{n}{2} \rfloor$ queries (resp. $n-2$ queries) would be required to detect one of the targets (resp. both targets) in the worst case.

As a warm-up, we provide in the next theorem an efficient algorithm that detects with high probability both targets in a tree using $O(\log^2 n)$ queries.

▶ **Theorem 6.** *For any constant $0 < p_1 < 1$, we can detect with probability at least $\left(1 - \frac{\log n}{n}\right)^2$ both targets in a tree with n vertices using $O(\log^2 n)$ queries.*

Since in a tree both targets t_1, t_2 can be detected with high probability in $O(\log^2 n)$ queries by Theorem 6, we consider in the remainder of the section arbitrary graphs instead of trees. First we consider in Section 3.1 *biased* queries, i.e. queries with $p_1 > \frac{1}{2}$. Second we consider in Section 3.2 *unbiased* queries, i.e. queries with $p_1 = p_2 = \frac{1}{2}$.

Algorithm 1 Given t_1, detect t_2 with high probability with $O(\Delta \log^2 n)$ queries

$S \leftarrow V$; $c \leftarrow \frac{7(1+p_1)^2}{p_1(1-p_1)^2}$
while $|S| > 1$ **do**
  Compute an (approximate) median v of S with respect to potential Γ; Compute $E_{t_1}(v)$
  Query $c\Delta \log n$ times vertex v; Compute the multiset $Q(v)$ of these query responses
  if $Q(v) \setminus E_{t_1}(v) \neq \emptyset$ **then**
    Pick a vertex $u \in Q(v) \setminus E_{t_1}(v)$ and set $S \leftarrow S \cap N(v, u)$
  else
    Pick a most frequent vertex $u \in Q(v)$ and set $S \leftarrow S \cap N(v, u)$
return the unique vertex in S

3.1 Upper Bounds for Biased Queries

In this section we consider biased queries which direct to t_1 with probability $p_1 > \frac{1}{2}$ and to t_2 with probability $p_2 = 1 - p_1 < \frac{1}{2}$. As we can detect in this case the first target t_1 with high probability in $O(\log n)$ queries by using the "noisy" framework of [10], our aim becomes to detect the second target t_2 with the fewest possible queries, once we have already detected t_1.

For every vertex v and every $i \in \{1, 2\}$, denote by $E_{t_i}(v) = \{u \in N(v) : t_i \in N(v, u)\}$ the set of neighbors of v such that the edge uv lies on a shortest path from v to t_i. Note that the sets $E_{t_1}(v)$ and $E_{t_2}(v)$ can be computed in polynomial time, e.g. using Dijkstra's algorithm. We assume that, once a query at vertex v has chosen which target t_i it directs to, it returns each vertex of $E_{t_i}(v)$ equiprobably and independently from all other queries. Therefore, each of the vertices of $E_{t_1}(v) \setminus E_{t_2}(v)$ is returned by the query at v with probability $\frac{p_1}{|E_{t_1}(v)|}$, each vertex of $E_{t_2}(v) \setminus E_{t_1}(v)$ is returned with probability $\frac{1-p_1}{|E_{t_2}(v)|}$, and each vertex of $E_{t_1}(v) \cap E_{t_2}(v)$ is returned with probability $\frac{p_1}{|E_{t_1}(v)|} + \frac{1-p_1}{|E_{t_2}(v)|}$. We will show in Theorem 8 that, under these assumptions, we detect the second target t_2 with high probability in $O(\Delta \log^2 n)$ queries where Δ is the maximum degree of the graph.

The high level description of our algorithm (Algorithm 1) is as follows. Throughout the algorithm we maintain a candidates' set S of vertices in which t_2 belongs with high probability. Initially $S = V$. In each iteration we first compute an (exact or approximate) median v of S with respect to the potential Γ (see Section 2.3). Then we compute the set $E_{t_1}(v)$ (this can be done as t_1 has already been detected) and we query $c\Delta \log n$ times vertex v, where $c = \frac{7(1+p_1)^2}{p_1(1-p_1)^2}$ is a constant. Denote by $Q(v)$ the multiset of size $c\Delta \log n$ that contains the vertices returned by these queries at v. If at least one of these $O(\Delta \log n)$ queries at v returns a vertex $u \notin E_{t_1}(v)$, then we can conclude that $u \in E_{t_2}(v)$, and thus we update the set S by $S \cap N(v, u)$. Assume otherwise that all $O(\Delta \log n)$ queries at v return vertices of $E_{t_1}(v)$. Then we pick a vertex $u_0 \in N(v)$ that has been returned most frequently among the $O(\Delta \log n)$ queries at v, and we update the set S by $S \cap N(v, u_0)$. As it turns out, $u_0 \in E_{t_2}(v)$ with high probability. Since we always query an (exact or approximate) median v of the current candidates' set S with respect to the potential Γ, the size of S decreases by a constant factor each time. Therefore, after $O(\log n)$ updates we obtain $|S| = 1$. It turns out that, with high probability, each update of the candidates' set was correct, i.e. $S = \{t_2\}$. Since for each update of S we perform $O(\Delta \log n)$ queries, we detect t_2 with high probability in $O(\Delta \log^2 n)$ queries in total.

Recall that every query at v returns a vertex $u \in E_{t_1}(v)$ with probability p_1 and a vertex $u \in E_{t_2}(v)$ with probability $1 - p_1$. Therefore, for every $v \in V$ the multiset $Q(v)$ contains at

least one vertex $u \in E_{t_2}(v)$ with probability at least $1 - p_1^{|Q(v)|} = 1 - p_1^{|c\Delta \log n|}$. In the next lemma we prove that, every time we update S using Step 8, the updated set contains t_2 with high probability.

▶ **Lemma 7.** *Let $S \subseteq V$ such that $t_2 \in S$ and let $S' = S \cap N(v, u)$ be the updated set at Step 8 of Algorithm 1. Then $t_2 \in S'$ with probability at least $1 - \frac{2}{n}$.*

Proof. Let $\delta = \frac{1-p_1}{1+p_1}$ and $c = \frac{7(1+p_1)^2}{p_1(1-p_1)^2}$ be two constants. Recall that each of the vertices of $E_{t_1}(v) \setminus E_{t_2}(v)$ is returned by the query at v with probability $\frac{p_1}{|E_{t_1}(v)|}$, each vertex of $E_{t_2}(v) \setminus E_{t_1}(v)$ is returned with probability $\frac{1-p_1}{|E_{t_2}(v)|}$, and each vertex of $E_{t_1}(v) \cap E_{t_2}(v)$ is returned with probability $\frac{p_1}{|E_{t_1}(v)|} + \frac{1-p_1}{|E_{t_2}(v)|}$. Observe that these probabilities are the expected frequencies for these vertices in $Q(v)$. Recall that Step 8 is executed only in the case where $Q(v) \subseteq E_{t_1}(v)$. To prove the lemma it suffices to show that, whenever $Q(v) \subseteq E_{t_1}(v)$, the most frequent element of $Q(v)$ belongs to $E_{t_1}(v) \cap E_{t_2}(v)$ with high probability.

First note that, for the chosen value of δ,

$$(1+\delta)\frac{p_1}{|E_{t_1}(v)|} < (1-\delta)\left(\frac{p_1}{|E_{t_1}(v)|} + \frac{1-p_1}{|E_{t_2}(v)|}\right) \tag{1}$$

Let $u \in E_{t_1}(v) \setminus E_{t_2}(v)$, i.e. the query at v directs to t_1 but not to t_2. We define the random variable $Z_i(u)$, such that $Z_i(u) = 1$ if u is returned by the i-th query at v and $Z_i(u) = 0$ otherwise. Furthermore define $Z(u) = \sum_{i=1}^{c\Delta \log n} Z_i(u)$. Since $\Pr(Z_i(u) = 1) = \frac{p_1}{|E_{t_1}(v)|}$, it follows that $E(Z(u)) = c\Delta \log n \frac{p_1}{|E_{t_1}(v)|}$ by the linearity of expectation. Then, using Chernoff's bounds we can prove that

$$\Pr(Z(u) \geq (1+\delta)E(Z(u))) \leq \frac{1}{n^2}. \tag{2}$$

Thus (2) implies that the probability that there exists at least one $u \in E_{t_1}(v) \setminus E_{t_2}(v)$ such that $Z(u) \geq (1+\delta)E(Z(u))$ is

$$\Pr\left(\exists u \in E_{t_1}(v) \setminus E_{t_2}(v) : Z(u) \geq (1+\delta)\frac{p_1}{|E_{t_1}(v)|}\right) < (\Delta - 1)\frac{1}{n^2} < \frac{1}{n}. \tag{3}$$

Now let $u' \in E_{t_1}(v) \cap E_{t_2}(v)$. Similarly to the above we define the random variable $Z'_i(u')$, such that $Z'_i(u') = 1$ if u' is returned by the i -th query at v and $Z'_i(u') = 0$ otherwise. Furthermore define $Z'(u') = \sum_{i=1}^{c\Delta \log n} Z'_i(u')$. Since $\Pr(Z'_i(u') = 1) = \frac{p_1}{|E_{t_1}(v)|} + \frac{1-p_1}{|E_{t_2}(v)|}$, it follows that $E(Z(u)) = c\Delta \log n \left(\frac{p_1}{|E_{t_1}(v)|} + \frac{1-p_1}{|E_{t_2}(v)|}\right)$ by the linearity of expectation. Then we obtain similarly to (2) that

$$\Pr(Z'(u') \leq (1-\delta)E(Z'(u'))) < \frac{1}{n^2} \tag{4}$$

Thus, it follows by the union bound and by (1), (3), and (4) that

$$\Pr(\exists u \in E_{t_1}(v) \setminus E_{t_2}(v) : Z(u) \geq Z'(u')) \leq \frac{2}{n}. \tag{5}$$

That is, the most frequent element of $Q(v)$ belongs to $E_{t_1}(v) \cap E_{t_2}(v)$ with probability at least $1 - \frac{2}{n}$. This completes the proof of the lemma. ◀

With Lemma 7 in hand we can now prove the main theorem of the section.

▶ **Theorem 8.** *Given t_1, Algorithm 1 detects t_2 in $O(\Delta \log^2 n)$ queries with probability at least $(1 - \frac{2}{n})^{O(\log n)}$.*

Note by Theorem 8 that, whenever $\Delta = O(poly \log n)$ we can detect both targets t_1 and t_2 in $O(poly \log n)$ queries. However, for graphs with larger maximum degree Δ, the value of the maximum degree dominates any polylogarithmic factor in the number of queries. The intuitive reason behind this is that, for an (exact or approximate) median v of the current set S, whenever $\deg(v)$ and $E_{t_1}(v)$ are large and $E_{t_2}(v) \subseteq E_{t_1}(v)$, we can not discriminate with a polylogarithmic number of queries between the vertices of $E_{t_2}(v)$ and the vertices of $E_{t_1}(v) \setminus E_{t_2}(v)$ with large enough probability. Although this argument does not give any lower bound for the number of queries in the general case (i.e. when Δ is unbounded), it seems that more informative queries are needed to detect both targets with polylogarithmic queries in general graphs. We explore such more informative queries in Section 4.

3.2 Lower Bounds for Unbiased Queries

In this section we consider unbiased queries, i.e. queries which direct to each of the targets t_1, t_2 with equal probability $p_1 = p_2 = \frac{1}{2}$. In this setting every query is indifferent between the two targets, and thus the "noisy" framework of [10] cannot be applied for detecting any of the two targets. In particular we prove in the next theorem that any deterministic (possibly adaptive) algorithm needs at least $\frac{n}{2} - 1$ queries to detect one of the two targets.

▶ **Theorem 9.** *Let $p_1 = p_2 = \frac{1}{2}$. Then any deterministic (possibly adaptive) algorithm needs at least $\frac{n}{2} - 1$ queries to detect one of the two targets, even in an unweighted cycle.*

In the next theorem we generalize the lower bound of Theorem 9 to the case of $2c \geq 2$ different targets $T = \{t_1, t_2, \ldots, t_{2c}\}$ and the query to any vertex $v \notin T$ is unbiased, i.e. $p_i = \frac{1}{2c}$ for every $i \in \{1, 2, \ldots, 2c\}$.

▶ **Theorem 10.** *Suppose that there are $2c$ targets in the graph and let $p_i = \frac{1}{2c}$ for every $i \in \{1, 2, \ldots, 2c\}$. Then, any deterministic (possibly adaptive) algorithm requires at least $\frac{n}{2} - c$ queries to locate at least one target, even in an unweighted cycle.*

4 More Informative Queries for Two Targets

A natural alternative to obtain query-efficient algorithms for multiple targets, instead of restricting the maximum degree Δ of the graph (see Section 3.1), is to consider queries that provide more informative responses in general graphs. As we have already observed in Section 3.1, it is not clear whether it is possible to detect multiple targets with $O(poly \log n)$ *direction queries* in an arbitrary graph. In this section we investigate natural variations and extensions of the direction query for multiple targets which we studied in Section 3.

4.1 Direction-Distance Biased Queries

In this section we strengthen the direction query in a way that it also returns the value of the distance between the queried vertex and one of the targets. More formally, a *direction-distance query* at vertex $v \in V$ returns with probability p_i a pair (u, ℓ), where $u \in N(v)$ such that $t_i \in N(u, v)$ and $d(v, t_i) = \ell$. Note that here we impose again that all p_i's are constant and that $\sum_{i=1}^{|T|} p_i = 1$, where $T = \{t_1, t_2, \ldots, t_{|T|}\}$ is the set of targets. We will say that the response (u, ℓ) to a direction-distance query at vertex v *directs to* t_i if $t_i \in N(v, u)$ and $\ell = d(v, t_i)$. Similarly to our assumptions on the direction query, whenever there exist more than one such vertices $u \in N(v)$ leading to t_i via a shortest path, the direction-distance query returns an arbitrary vertex u among them (possibly chosen adversarially). Moreover,

Algorithm 2 Given t_1, detect t_2 with high probability with $O(\log^3 n)$ direction-distance queries

1: $S \leftarrow V$
2: **while** $|S| > 1$ **do**
3: Compute an (approximate) median v of S with respect to potential Γ; Compute $E_{t_1}(v)$
4: Query $\log n$ times vertex v; Compute the set $Q(v)$ of different query responses
5: **if** there exists a pair $(u, \ell) \in Q(v)$ such that $u \notin E_{t_1}(v)$ or $\ell \neq d(v, t_1)$ **then**
6: $S \leftarrow S \cap N(v, u)$
7: **else**
8: **for** every $(u, \ell) \in Q(v)$ **do**
9: Query $\log n$ times vertex u; Compute the set $Q(u)$ of different query responses
10: **if** for every $(z, \ell') \in Q(u)$ we have $\ell' = \ell - w(vu)$ **then**
11: $S \leftarrow S \cap N(v, u)$; Goto line 2
12: **return** the unique vertex of S

if the queried vertex v is equal to one of the targets $t_i \in T$, this is revealed by the query with probability p_i. These direction-distance queries have also been used in [10] for detecting one single target in directed graphs.

Here we consider the case of two targets and *biased queries*, i.e. $T = \{t_1, t_2\}$ where $p_1 > p_2$. Similarly to Section 3.1, initially we can detect the first target t_1 with high probability in $O(\log n)$ queries using the "noisy" model of [10]. Thus, in what follows we assume that t_1 has already been detected. We will show that the second target t_2 can be detected with high probability with $O(\log^3 n)$ additional direction-distance queries using Algorithm 2. The high level description of our algorithm is the following. We maintain a candidates' set S such that at every iteration $t_2 \in S$ with high probability. Each time we update the set S, its size decreases by a constant factor. Thus we need to shrink the set S at most $\log n$ times. In order to shrink S one time, we first compute an $(1 + \varepsilon)$ -median v of the current set S and we query $\log n$ times this vertex v. Denote by $Q(v)$ the set of all different responses of these $\log n$ direction-distance queries at v. As it turns out, the responses in $Q(v)$ might not always be enough to shrink S such that it still contains t_2 with high probability. For this reason we also query $\log n$ times each of the $\log n$ neighbors $u \in N(v)$, such that $(u, \ell) \in Q(v)$ for some $\ell \in \mathbb{N}$. After these $\log^2 n$ queries at v and its neighbors, we can safely shrink S by a constant factor, thus detecting the target t_2 with high probability in $\log^3 n$ queries.

For the description of our algorithm (see Algorithm 2) recall that, for every vertex v, the set $E_{t_1}(v) = \{u \in N(v) : t_1 \in N(v, u)\}$ contains all neighbors of v such that the edge uv lies on a shortest path from v to t_1.

▶ **Theorem 11.** *Given t_1, Algorithm 2 detects t_2 in at most $O(\log^3 n)$ queries with probability at least $1 - O\left(\log n \cdot p_1^{\log n}\right)$.*

4.2 Vertex-Direction and Edge-Direction Biased Queries

An alternative natural variation of the direction query is to *query an edge* instead of querying a vertex. More specifically, the direction query (as defined in Section 1.2) queries a vertex $v \in V$ and returns with probability p_i a neighbor $u \in N(v)$ such that $t_i \in N(u, v)$. Thus, as this query always queries a vertex, it can be also referred to as a *vertex-direction query*. Now

we define the *edge-direction query* as follows: it queries an ordered pair of adjacent vertices (v, u) and it returns with probability p_i `YES` (resp. `NO`) if $t_i \in N(v, u)$ (resp. if $t_i \notin N(v, u)$). Similarly to our notation in the case of vertex-direction queries, we will say that the response `YES` (resp. `NO`) to an edge-direction query at the vertex pair (v, u) *refers* to t_i if $t_i \in N(v, u)$ (resp. if $t_i \notin N(v, u)$). Similar but different edge queries for detecting one single target on trees have been investigated in [10, 13, 21, 26].

Here we consider the case where both vertex-direction and edge-direction queries are available to the algorithm, and we focus again to the case of two targets and *biased queries*, i.e. $T = \{t_1, t_2\}$ where $p_1 > p_2$. Similarly to Sections 3.1 and 4.1, we initially detect t_1 with high probability in $O(\log n)$ vertex-direction queries using the "noisy" model of [10]. Thus, in the following we assume that t_1 has already been detected.

▶ **Theorem 12.** *Given t_1, it is possible to detect t_2 in at most $O(\log^2 n)$ vertex-direction queries and $O(\log^3 n)$ edge–direction queries with probability at least $1 - O(\log n \cdot p_1^{\log n})$.*

4.3 Two-Direction Queries

In this section we consider another variation of the direction query that was defined in Section 1.2 (or "vertex-direction query" in the terminology of Section 4.2), which we call *two-direction query*. Formally, a two-direction query at vertex v returns an *unordered pair* of (not necessarily distinct) vertices $\{u, u'\}$ such that $t_1 \in N(v, u)$ and $t_2 \in N(v, u')$. Note here that, as $\{u, u'\}$ is an unordered pair, the response of the two-direction query does not clarify which of the two targets belongs to $N(v, u)$ and which to $N(v, u')$.

Although this type of query may seem at first to be more informative than the standard direction query studied in Section 3, we show that this is not the case. Intuitively, this type of query resembles the unbiased direction query of Section 3.2. To see this, consider e.g. the unweighted cycle where the two targets are placed at two anti-diametrical vertices; then, applying many times the unbiased direction query of Section 3.2 at any specific vertex v reveals with high probability the same information as applying a single two-direction query at v. Based on this intuition the next theorem can be proved with exactly the same arguments as Theorem 9 of Section 3.2.

▶ **Theorem 13.** *Any deterministic (possibly adaptive) algorithm needs at least $\frac{n}{2} - 1$ two-direction queries to detect one of the two targets, even in an unweighted cycle.*

4.4 Restricted Set Queries

The last type of queries we consider is when the query is applied not only to a vertex v of the graph, but also to a subset $S \subseteq V$ of the vertices, and the response of the query is a vertex $u \in N(v)$ such that $t \in N(v, u)$ for at least one of the targets t that belong to the set S. Formally, let T be the set of targets. The *restricted-set query* at the pair (v, S), where $v \in V$ and $S \subseteq V$ such that $T \cap S \neq \emptyset$, returns a vertex $u \in N(v)$ such that $t \in N(v, u)$ for at least one target $t \in T \cap S$. If there exist multiple such vertices $u \in N(v)$, the query returns one of them adversarially. Finally, if we query a pair (v, S) such that $T \cap S = \emptyset$, then the query returns adversarially an arbitrary vertex $u \in N(v)$, regardless of whether the edge vu leads to a shortest path from v to any target in T. That is, the response of the query can be considered in this case as "noise". In the next theorem we prove that this query is very powerful, as $|T| \cdot \log n$ restricted-set queries suffice to detect all targets of the set T.

▶ **Theorem 14.** *Let T be the set of targets. There exists an adaptive deterministic algorithm that detects all targets of T with at most $|T| \cdot \log n$ restricted-set queries.*

A Formal Semantics of Influence in Bayesian Reasoning

Bart Jacobs[1] **and Fabio Zanasi**[2]

1 **Radboud Universiteit, Nijmegen, The Netherlands**

Abstract

This paper proposes a formal definition of influence in Bayesian reasoning, based on the notions of state (as probability distribution), predicate, validity and conditioning. Our approach highlights how conditioning a joint entwined/entangled state with a predicate on one of its components has 'crossover' influence on the other components. We use the total variation metric on probability distributions to quantitatively measure such influence. These insights are applied to give a rigorous explanation of the fundamental concept of d-separation in Bayesian networks.

1 Introduction

A key feature of Bayesian (probabilistic) reasoning is that an observation leads to an update of knowledge. This is best seen in Bayesian networks: in these graph-like models, dependency relations between events are visually depicted as arcs between nodes. Information about a node-event A will update knowledge of all the nodes connected by an arc to A. However, influence may act also in more indirect ways, classified by Pearl [13] as the following "d-separation" scenarios:

- **(i)** in a **serial** connection $\boxed{\text{A}} \to \boxed{\text{B}} \to \boxed{\text{C}}$, event A influences C through B (and viceversa), but knowledge of B "blocks" this mutual influence – one also says that B *d-separates* A and C.
- **(ii)** in a **fork** connection $\boxed{\text{A}} \leftarrow \boxed{\text{B}} \to \boxed{\text{C}}$, information on A will influence C and viceversa, but this flow is blocked once B is known.
- **(iii)** in a **collider** situation $\boxed{\text{A}} \to \boxed{\text{B}} \leftarrow \boxed{\text{C}}$, any evidence about B (and its descendants) will make A and C depend on each other.

In these three scenarios one may observe many phenomena at work which are usually explained informally in terms of influence, dependence, blocking and evidence. But what is the formal semantics underpinning these concepts? The basic language of conditional probability, based on the reading of $\Pr(A|B)$ as "the probability of A given B", appears to be unsuitable for such an account. For instance, it cannot express that, in the collider situation, *any* evidence on the occurrence of B will make A and C dependent, whereas the blocking of the first two scenarios only occurs when B is known with certainty (probability 1).

This paper proposes a rigorous formal treatment of influence in Bayesian reasoning, yielding an expressive and firmly established language for describing the above scenarios. Our methodology draws inspiration from the area of programming language semantics, and in particular from *Effectus theory* [4, 2], a comprehensive logical framework for probabilistic and quantum computation. At the foundation of our approach there is a conceptual distinction

between the knowledge of an event, called a *state*, and an observation/evidence of such event, called a *predicate*. Concretely, a state on a 'sample' space X will be a (finite) discrete probability distributions ω on X, whereas a (fuzzy) predicate p on X is a function $X \to [0,1]$. The 'knowledge update' is then given by a conditioned distribution, which we write as $\omega|_p$, pronounced as: ω given p. Moreover, our approach includes predicate and state transformers, adding expressive power to the language.

Our first contribution (§ 3) is a semantic description of d-separation in the serial (i) and fork connection (ii): we reduce these scenarios into formal statements, whose proofs are made straightforward by our formalism. Here the phenomenon at stake is influence *blocking*, for which the basic language of states and predicates suffices. However, the collider scenario (iii), in which influence is not blocked but rather *enabled*, demands a deeper analysis.

This leads to our second contribution (§ 4), namely the concept of *state entwinedness*. Intuitively, for a joint state/distribution being entwined means, by analogy with the quantum world, that its components are entangled or, in the Bayesian jargon, they model dependent events. In order to capture the collider situation, the key observation is that the join (tensor product) of non-entwined states (say, in (iii), the join of A and C) may become entwined after conditioning (information about B); from that moment on, any new information on one component of the joint state will have influence also on the other component.

As a third contribution (§ 5), we introduce a formal, quantitative definition of such influence: we call it *crossover influence*, as it measures the non-local action between components of a joint states. We also define a notion of *direct influence*, which measures the local action of a predicate (an information update) on a certain state. Both definitions take as a parameter a notion of 'distance' between states: for our scenarios we pick the *total variation* metric on probability distributions, which coincides with the Kantorovich metric [17] on discrete metric spaces (sets). We make no claim on total variation being 'canonical' in the sense of [10]. Our emphasis is rather on the abstract definition of influence: this is independent of the choice of the underlying metric, which is not itself an essential part of our analysis, see also § 7. As far as we know, probabilistic influence has not been formalised and investigated in this quantitative form before.

We conclude our developments with a reprise of the collider scenario (§ 6), which we are now able to adequately describe using the toolkit introduced in § 4 and § 5. Our analysis clarifies that the commonly used description in the literature (see *e.g.* [14, 8, 15]) for describing the serial (i) and fork (ii) scenarios only works for very special 'singleton' predicates – which we call Dirac predicates, whereas in the collider scenario (iii) *any* predicate on B creates dependence (entwinedness) between A and C.

2 Background: states, predicates, and conditional probability

In this background section we introduce the notation, terminology and basic definitions for several constructions in (finite) discrete probability. There is a categorical formalisation using monads behind this, see e.g. [5], but we prefer to keep constructions more concrete.

States, predicates and validity. A (finite, discrete) distribution over a 'sample' set A is a weighted combination of elements of A, where weights are probabilities from the unit interval $[0,1]$ that add up to 1. We call such a distribution a *state*, as it expresses knowledge the occurrence of elements of A. As mentioned in §1, we pursue an analogy with quantum states, emphasised by the use of the 'ket' notation: a state ω is written as $\omega = r_1 \,|a_1\rangle + \cdots + r_n \,|a_n\rangle$, where $a_i \in A$, $r_i \in [0,1]$ and $\sum_i r_i = 1$. Also, $\mathcal{D}(A)$ is the set of states/distributions on

A. We will sometimes treat $\omega \in \mathcal{D}(A)$ equivalently as a function $\omega\colon A \to [0,1]$ with finite support $\mathrm{supp}(\omega) = \{a \in A \mid \omega(a) \neq 0\}$ and with $\sum_{a\in A} \omega(a) = 1$.

An *event* is a subset $E \subseteq A$ of the sample space. We prefer to use a more general 'fuzzy' kind of predicate, namely functions $p\colon A \to [0,1]$. In this discrete case, states (distributions) are predicates, but not the other way around. Events can be identified with 'sharp' predicates taking values in the subset of booleans $\{0,1\} \subseteq [0,1]$. For $x \in A$, we write ∂_x for the (sharp) *Dirac* predicate over x, defined as $\partial_x(a) = 1$ if $x = a$ and $\partial_x(a) = 0$ otherwise.

For predicates $p, q \in [0,1]^A$ and scalar $r \in [0,1]$ we define $p \,\&\, q$ as $a \mapsto p(a) \cdot q(a)$ and $r \cdot p$ as $a \mapsto r \cdot p(a)$. States and predicates are most effectively reasoned about using the language of *Kleisli categories*. We call a function of shape $f\colon A \to \mathcal{D}(B)$ a 'Kleisli' map from A to B and write its type as $A \kto B$. Kleisli maps can be understood as *channels*, or as *stochastic matrices*, especially when A, B are finite sets. The (Kleisli) composition of maps $f\colon A \kto B$ and $g\colon B \kto C$ is written as $g \bullet f\colon A \kto C$. It is essentially matrix multiplication:

$$\big(g \bullet f\big)(a) = \sum_{c\in C} \big(\textstyle\sum_{b\in B} f(a)(b) \cdot g(b)(c)\big) \big| c \big\rangle. \tag{1}$$

We write $\mathcal{K}\ell(\mathcal{D})$ for the Kleisli category whose objects are sets, and whose arrows from A to B are the Kleisli maps $A \kto B$. The identity map $A \kto A$ in $\mathcal{K}\ell(\mathcal{D})$ is the function $a \mapsto 1\,|a\rangle$. Note that arrows $1 \kto B$ in $\mathcal{K}\ell(\mathcal{D})$ identify elements of $\mathcal{D}(B)$, *i.e.* the states on B, and arrows $B \kto 2$ are elements of $[0,1]^B$, *i.e.* the predicates on B.

Each (ordinary) function $g\colon A \to B$ gives a trivial (diagonal) matrix map $\langle g \rangle\colon A \kto B$ via $\langle g \rangle(a) = 1\,|g(a)\rangle$. Then: $\langle h \rangle \bullet \langle g \rangle = \langle h \circ g \rangle$.

We will see later, in Example 3, how Bayesian networks can be seen as graphs of Kleisli maps in $\mathcal{K}\ell(\mathcal{D})$. For this interpretation, it is of importance that $\mathcal{K}\ell(\mathcal{D})$ forms a monoidal category. The monoidal product $\otimes$ is defined on objects as the cartesian product $\times$ of sets, with tensor unit the one-element set 1. On Kleisli maps $f\colon A \kto X$ and $g\colon B \kto Y$ the map $f \otimes g\colon A \otimes B \kto X \otimes Y$ is defined as $(f \otimes g)(a,b)(x,y) = f(a)(x) \cdot g(b)(y)$.

▶ **Definition 1.** Let $\omega \in \mathcal{D}(A)$ be a state and $p \in [0,1]^A$ be a predicate, both on the same set A. We write $\omega \models p$ for the *validity* or *expected value* of p in state ω. This validity is a number in the unit interval $[0,1]$ defined as:

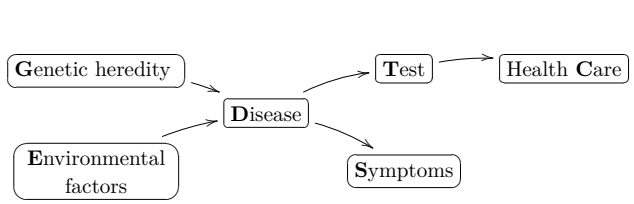
$$\omega \models p \;:=\; \textstyle\sum_{a\in A} \omega(a) \cdot p(a) \;=\; \big(A \overset{p}{\kto} 2\big) \bullet \big(1 \overset{\omega}{\kto} A\big). \tag{2}$$

If this validity is non-zero, it yields a *conditioning* operation on ω. We write $\omega|_p$ or for the conditional state "ω given p", defined as formal convex sum:

$$\omega|_p := \sum_{a\in A} \frac{\omega(a) \cdot p(a)}{\omega \models p} \big| a \big\rangle. \tag{3}$$

▶ **Lemma 2** (From [5]).
(a) $p \,\&\, \partial_x = p(x) \cdot \partial_x$ *and* $\omega \models \partial_x = \omega(x)$ *and* $\omega|_{\partial_x} = 1\,|x\rangle$;
(b) $\omega|_{r\cdot p} = \omega|_p$ *for* $r \neq 0$ *and* $\omega|_{p\&\partial_x} = 1\,|x\rangle$ *when* $p(x) \neq 0$ *and* $\omega(x) \neq 0$;
(c) *Bayes' rule holds for fuzzy predicates:* $\omega|_p \models q = \dfrac{\omega \models p \,\&\, q}{\omega \models p}$.

▶ **Example 3.** As a running example we will use the situation of a disease that can be caused by environmental factors or by genetic heredity. The presence of the disease in a patient will determine whether she manifests symptoms and also whether she tests positively. The test outcome will also influence whether she receives health care. We express these data with a Bayesian network, consisting of a graph together with conditional probability tables.



$\Pr(G) = 1/50$
$\Pr(E) = 1/10$

D	$\Pr(T)$
t	$9/10$
f	$1/20$

G	E	$\Pr(D)$
t	t	$9/10$
t	f	$8/10$
f	t	$4/10$
f	f	0

D	$\Pr(S)$
t	$9/10$
f	$1/15$

T	$\Pr(C)$
t	$4/5$
f	$1/10$

(4)

As illustrated in [7] (*cf.* also [3]), there is a canonical way to interpret our Bayesian network (4) as an arrow in the Kleisli category $\mathcal{KL}(\mathcal{D})$. Each node N of the graph, say with k incoming edges from nodes $N_1, N_2, \ldots, N_k$, is associated with an arrow $N\colon 2^k \nrightarrow 2$ in $\mathcal{KL}(\mathcal{D})$; as a stochastic matrix, N is defined by the probability table of the node N. It will be convenient to write $2_N := \{n, n^\perp\}$ for the two-element target set of the node-arrow N, where n represents occurrence and $n^\perp$ non-occurrence of the event N. For instance, the arrow $D\colon 2_G \otimes 2_E \nrightarrow 2_D$ for the disease node is defined by the channel $2_G \times 2_E \to \mathcal{D}(2_D)$

$$\begin{array}{ll} (g,e) \mapsto \frac{9}{10}\,|d\rangle + \frac{1}{10}\,|d^\perp\rangle & (g,e^\perp) \mapsto \frac{8}{10}\,|d\rangle + \frac{2}{10}\,|d^\perp\rangle \\ (g^\perp,e) \mapsto \frac{4}{10}\,|d\rangle + \frac{6}{10}\,|d^\perp\rangle & (g^\perp,e^\perp) \mapsto 1\,|d^\perp\rangle\,. \end{array}$$

Another example is the initial map $G\colon 1 \nrightarrow 2_G$ for the genetic heredity node, which amounts to the distribution $1/50\,|g\rangle + 49/50\,|g^\perp\rangle$ in $\mathcal{D}(2_G) \cong [0,1]$. In order to recover the whole network (4), one pastes node-arrows together using the monoidal structure of $\mathcal{KL}(\mathcal{D})$. Nodes in (4) that have multiple outgoing edges are modeled by composing the corresponding arrow $2^k \nrightarrow 2$ with the pairing map $\Delta\colon 2 \nrightarrow 2 \otimes 2$ defined by $x \mapsto 1\,|(x,x)\rangle$. The Bayesian network (4) in its entirety is then expressed as the following arrow in $\mathcal{KL}(\mathcal{D})$.

$$1 \xrightarrow{G\otimes E} 2_G \otimes 2_E \xrightarrow{D} 2_D \xrightarrow{\Delta} 2_D \otimes 2_D \xrightarrow{T\otimes S} 2_T \otimes 2_S \xrightarrow{C\otimes \mathrm{id}} 2_C \otimes 2_S \tag{5}$$

Inference via predicate/state transformers. Associated with a Kleisli map $f\colon A \nrightarrow B$ there are *state transformer* and *predicate transformer* maps f_* and f^*. For a state $\omega \in \mathcal{D}(A)$ and a predicate $p \in [0,1]^B$ we define $f_*(\omega) \in \mathcal{D}(B)$ and $f^*(p) \in [0,1]^A$ as:

$$f_*(\omega) = \sum_{b\in B} \big(\textstyle\sum_{a\in A} f(a)(b)\cdot\omega(a)\big)\,|b\rangle \qquad f^*(p)(a) = \sum_{b\in B} f(a)(b)\cdot p(b). \tag{6}$$

Notice that f_* works forwardly, transforming a state on A into a state on B, whereas f^* works backwardly, transforming a predicate on B into a predicate on A. One can understand these definitions in terms of Kleisli composition: $f_*(\omega) = f \bullet \omega$ and $f^*(p) = p \bullet f$. We collect a few basic results from [5].

▶ **Lemma 4.**

(a) *For a Kleisli map $f\colon A \nrightarrow B$, a state $\omega \in \mathcal{D}(A)$ and a predicate $p \in [0,1]^B$, $f_*(\omega) \models p = p \bullet f \bullet \omega = \omega \models f^*(p)$.*

(b) *Predicate transformers f^* preserve $\mathbf{1}$, $\mathbf{0}$, negation $(-)^\perp$ and scalar multiplication $r\cdot(-)$.*

(c) *For an ordinary function $g\colon A \to B$ we have $\langle g\rangle_*(\omega)|_p = \langle g\rangle_*(\omega|_{\langle g\rangle^*(p)})$.*

Using transformers and conditioning one can formulate Bayesian inference (learning). We illustrate the relevant constructions with an example and refer to [7] for more details.

▶ **Example 5** (Backward inference.)**.** A typical learning task wrt. a Bayesian network is backward inference: how the occurrence of a certain event changes the likelihood of its causes. A formalisation of backward inference is proposed in [7] as "predicate transformation followed

by conditioning". We illustrate this for Example 3, focusing on the part of the graph that describes the influence of having the disease on receiving health care. First, we compute our *a priori* knowledge on the likelihood of a disease. In the formalisation (5), this is the Kleisli arrow $D \bullet (G \otimes E) \colon 1 \nrightarrow 2_D$, *i.e.* a state on 2_D.

$$\begin{aligned} G \otimes E &= 0.002\,|g, e\rangle + 0.018\,|g, e^\perp\rangle + 0.098\,|g^\perp, e\rangle + 0.882\,|g^\perp, e^\perp\rangle \\ D \bullet (G \otimes E) &= 0.055\,|d\rangle + 0.945\,|d^\perp\rangle \end{aligned} \tag{7}$$

The event of a positive test is interpreted as the Dirac predicate $\partial_t \in [0,1]^{2_T}$ on 2_T, *i.e.* it maps t to 1 and $t^\perp$ to 0. We can now ask a backward inference question: if the patient tested positive, what is the likelihood that she had the disease? The answer is enclosed in the state $(D \bullet (G \otimes E))|_{T^*(\partial_t)} \colon 1 \nrightarrow 2_D$, obtained by first using $T \colon 2_D \nrightarrow 2_T$ to transform the predicate ∂_t on 2_T into a predicate $T^*(\partial_t)$ on 2_D, and then conditioning the state $D \bullet (G \otimes E)$ over $T^*(\partial_t)$. The latter predicate maps d to $9/10$ and $d^\perp$ to $1/20$. Next,

$$\begin{aligned} D \bullet (G \otimes E) \models T^*(\partial_t) &= 0.097\,|d\rangle + 0.903\,|d^\perp\rangle \\ (D \bullet (G \otimes E))|_{T^*(\partial_t)} &= \textstyle\sum_{x \in 2_D} \frac{D \bullet (G \otimes E)(x) \cdot T^*(\partial_t)(x)}{D \bullet (G \otimes E) \models T^*(\partial_t)}\,|x\rangle \\ &= \tfrac{0.055 \cdot 9/10}{0.097}\,|d\rangle + \tfrac{0.945 \cdot 1/20}{0.097}\,|d^\perp\rangle = 0.51\,|d\rangle + 0.49\,|d^\perp\rangle\,. \end{aligned}$$

Thus evidence of a positive test raises the chances of a disease from 0.055 to 0.51.

Forward inference. A second kind of learning task is *forward inference*: how the occurrence of an event changes the likelihood of its effects. Again following [7], forward inference is formalised as "conditioning and then state transformation". To illustrate this in our leading example, consider a predicate p on 2_G given by $g \mapsto 88\%$ and $g^\perp \mapsto 0.1\%$: it expresses that medical records of a patient show high likelihood of a genetic transmission of the disease. Our forward inference question is: "how does the knowledge update given by predicate p influence the positivity of the test?" For the answer, one first extends p to a (weakened) predicate p' on $2_G \otimes 2_E$, then conditions $G \otimes E$ over p'. Finally, one applies $T \bullet D$ as state transformer to $(G \otimes E)|_{p'}$. Conditioning over p' makes a positive test much more likely:

$$(T \bullet D)_*(G \otimes E) = 0.1\,|t\rangle + 0.9\,|t^\perp\rangle \qquad (T \bullet D)_*((G \otimes E)|_{p'}) = 0.505\,|t\rangle + 0.495\,|t^\perp\rangle\,.$$

3 Influence in d-separation

This section applies the language introduced in § 2 to give a precise explanation of the fundamental concept of 'd-separation' in Bayesian networks, which is used as a criterion for independence, via connections between nodes. These connections can be of three forms, namely 'serial', 'fork', and 'collider'. As we shall see, the language introduced so far is only adapted to describe the first two scenarios. The third scenario needs a richer formalism, which justifies the developments in the next sections.

3.1 Serial connections

$$\boxed{A} \xrightarrow{f} \boxed{B} \xrightarrow{g} \boxed{C} \tag{8}$$

Consider a 'serial connection' Bayesian network as on the right. Clearly, what we know about A influences our knowledge about C, and vice-versa. In the context of d-separation one considers the special cases when there is evidence about the state of B, so that the

mutual influencing between A and B is blocked. We first quote how this is formulated in standard references (names of the nodes in the second quote are adapted to make them consistent with diagram (8)).

(i) [8, §1.2]: Obviously, evidence on A will influence the certainty of B, which then influences the certainty of C. Similarly, evidence on C will influence the certainty on A through B. On the other hand, if the state of B is known, then the channel is blocked, and A and C become independent.

(ii) [14, §1.2.3]: Figuratively, conditioning on B appears to "block" the flow of information along the path, since learning about A has no effect on the probability of C, given B.

These descriptions are rather informal. (i) speaks about (mutual) independence, and (ii) only about having no effect in the forward direction. We will make precise what is going on. Consider the same diagram (8), but now with f, g interpreted as maps in the Kleisli category $\mathcal{K}\ell(\mathcal{D})$ and with predicates as below. The three predicates are inhabitants $p \in [0,1]^A$, $\partial_x \in [0,1]^B$, $q \in [0,1]^C$.

$$\begin{array}{ccccc} A & \xrightarrow{f} & B & \xrightarrow{g} & C \\ {\scriptstyle p}\downarrow & & {\scriptstyle \partial_x}\downarrow & & \downarrow{\scriptstyle q} \\ 2 & & 2 & & 2 \end{array} \tag{9}$$

▶ **Proposition 6** (Blocking I). *Consider the serial connection* (9)*, with Dirac evidence ∂_x on the middle node B, for some fixed $x \in B$. Then there is no influence from A to C, nor from C to A, in the sense that for each distribution/state $\omega \in \mathcal{D}(A)$,*

(a) *for any predicate p on A with $\omega \models p \neq 0$, there is an equality of states on C:*

$$g_*\big(f_*(\omega)|_{\partial_x}\big) = g_*\big(f_*(\omega|_p)|_{\partial_x}\big).$$

(b) *for any predicate q on C there is an equality of states on A:*

$$\omega|_{f^*(\partial_x)} = \omega|_{f^*(\partial_x \& g^*(q))}.$$

We recall how to read the equation in point (a): given a state ω on A, we can transform it to a state $f_*(\omega)$ on B. We can also first condition ω to $\omega|_p$ and then push forward to $f_*(\omega|_p)$ on B. These different states $f_*(\omega)$ and $f_*(\omega|_p)$ become equal when we condition with the Dirac predicate ∂_x, and then push them forward to C via g_*. Thus, the influence of p is 'annihilated' or 'blocked' via the knowledge $x \in B$ used in conditioning with ∂_x.

Proof. For the first point it suffices to prove $f_*(\omega)|_{\partial_x} = f_*(\omega|_p)|_{\partial_x}$. But this equation follows directly from Lemma 2 (a) since both sides are equal to $1\,|x\rangle$.

For the second point we have $f^*(\partial_x \,\&\, g^*(q)) = f^*(g^*(q)(x) \cdot \partial_x)$ by Lemma 2(a), which is then equal to $g^*(q)(x) \cdot f^*(\partial_x)$ by Lemma 4(b). Finally, by Lemma 2(b), $\omega|_{f^*(\partial_x \& g^*(q))} = \omega|_{g^*(q)(x)\cdot f^*(\partial_x)} = \omega|_{f^*(\partial_x)}$. ◀

▶ **Example 7.**

$$\begin{array}{ccccc} 2_D & \xrightarrow{T} & 2_T & \xrightarrow{C} & 2_C \\ {\scriptstyle \omega}\uparrow & & \downarrow{\scriptstyle \partial_t} & & \\ 1 & & 2 & & \end{array} \tag{10}$$

Nodes 'Disease', 'Test' and 'Health Care' in the network of Example 3 form a serial connection, with Kleisli interpretation given by solid arrows as in (10) below. Clearly, new information about the Disease will impact the likelihood of receiving Health Care,

and viceversa, via the intermediate Test node. We examined these phenomena as forward and backward inference in Example 5, following [7]. We now show that, as prescribed by d-separation, mutual influence may be blocked: a positive test will determine the availability of health care, disregarding whether the patient actually has the disease or not. Viceversa, a positive test will nullify any influence of receiving health care on having the disease, as health care is entirely determined by the test outcome. The dotted arrows in (10) describe a state $\omega = \frac{1}{100}\,|d\rangle + \frac{99}{100}\,|d^\perp\rangle$ on 2_D, giving a 1% disease probability, and the Dirac predicate $\partial_t \in [0,1]^{2_T}$, asserting the positivity of the test. For the transformed predicate $T^*(\partial_x)$ on 2_D we have:

$$\begin{cases} T^*(\partial_t)(d) = \frac{9}{10} \\ T^*(\partial_t)(d^\perp) = \frac{1}{20} \end{cases} \qquad \omega \models T^*(\partial_t) = \tfrac{117}{2000} \qquad \omega|_{T^*(\partial_t)} = \tfrac{18}{117}\,|d\rangle + \tfrac{99}{117}\,|d^\perp\rangle\,.$$

The latter distribution $\omega|_{T^*(\partial_t)}$ equals $\omega|_{T^*(\partial_t \& C^*(q))}$ for each predicate $q \in [0,1]^{2_C}$ on 2_C, by Proposition 6 ((b)).

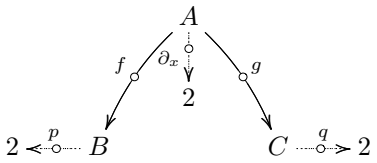
▶ Remark. We emphasise that, if we replace the predicate ∂_t on 2_D by a non-Dirac predicate $p \in [0,1]^{2_D}$, then there is *no blocking*, in general. For instance, take: $p(t) = \frac{1}{3}$, $p(t^\perp) = \frac{1}{4}$, $q(c) = \frac{1}{5}$ and $q(c^\perp) = 1$. Then we compute a difference between the following states on 2_D.

$$\omega|_{T^*(p)} = 0.013\,|d\rangle + 0.987\,|d^\perp\rangle \qquad \omega|_{T^*(p \& c^*(q))} = 0.006\,|d\rangle + 0.994\,|d^\perp\rangle$$

Hence, influence from right to left in (10) does exist for non-sharp predicates.

3.2 Fork connections

Next we consider a "fork" Bayesian network with predicates p, ∂_x, q, for a given element $x \in A$, as below. The informal description of this situation is: influence can pass between the children B and C via A, unless the state of A is known, as formulated *e.g.* in [8].



(11)

▶ **Example 8.** The Bayesian network of Example 3 contains a fork, given by 'Disease', 'Test' and 'Symptoms'. If a patient tests positively, it gets more likely that she has the disease, and thus shows symptoms. However, if one gets to know with certainty that she has the disease, then any evidence about the test will not change the likelihood of showing symptoms.

▶ **Proposition 9 (Blocking II).** *In the fork network* (11)*, with Dirac evidence on the middle node A, there is no influence from B to C, nor from C to B. This lack of influence from B to C is expressed via the equation:*

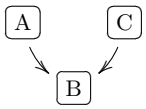
$$g_*\big(\omega|_{\partial_x}\big) = g_*\big(\omega|_{f^*(p)\&\partial_x}\big) \tag{12}$$

for each state ω on A and predicate p on B, and $x \in A$. The other direction is analogous.

Proof. The state transformer g_* is irrelevant, as $\omega|_{\partial_x} = 1\,|x\rangle = \omega|_{f^*(p)\&\partial_x}$. The first equation is in point (a) in Lemma 2, and the second one in point (b). ◀

3.3 Collider connections

The last d-separation scenario is the one of a collider:



which becomes in $\mathcal{KL}(\mathcal{D})$, with the addition of a predicate q,

$$\begin{array}{c} A \otimes C \\ {\scriptstyle f}\downarrow \\ B \xrightarrow{q} 2. \end{array} \tag{13}$$

In [14] one can read about this situation: "if the two extreme variables are (marginally) independent, they will become dependent (*i.e.* connected through unblocked path) once we condition on the middle variable (*i.e.* the common effect) or any of its descendants."

In our formalisms, this explanation unravels as follows. We fix states $\sigma \in \mathcal{D}(A)$ and $\tau \in \mathcal{D}(C)$, giving rise to a product state $\sigma \otimes \tau \in \mathcal{D}(A \otimes C)$. If we have evidence $q\colon B \to 2$ on B, then we can pull it back to evidence $f^*(q)\colon A \otimes C \to 2$. Now, in order to complete our formalisation, we would like to express that σ and τ are initially independent of each other when joint in $\sigma \otimes \tau$, but they get correlated after conditioning $(\sigma \otimes \tau)|_{f^*(q)}$. This correlation should be witnessed by the fact that from now on any predicate on the A-component σ will also have influence on the C-component τ, and viceversa. However, our formalisms of § 2 still lacks the means of expressing such 'crossover' properties, which echo the entanglement phenomena commonly studied in quantum theory. We devote the next two sections to rigorously describe them within our approach, and return to the collider scenario in § 6.

4 Joint states and entwinedness

We now commence the formal investigation of correlation phenomena which will lead to the notion of *crossover* influence. We give an elementary illustration first.

▶ **Example 10.** Consider two diseases A_1 and A_2 which may occur together, as given by the prior joint probability distribution: $\omega = \frac{1}{6}\,|a_1 a_2\rangle + \frac{1}{4}\,|a_1 a_2^\perp\rangle + \frac{1}{3}\,|a_1^\perp a_2\rangle + \frac{1}{4}\,|a_1^\perp a_2^\perp\rangle$. Assume that there is a test for disease A_1 with sensitivity 90% positive when a patient has the disease A_1, and 5% positive when the patient does not. It turns out the prior probability of A_2 is $\frac{1}{2}$, but decreases to $\frac{40}{97}$ after a A_1-positive test. We shall see how this works in Example 15.

For two states/distributions $\sigma \in \mathcal{D}(A_1)$ and $\tau \in \mathcal{D}(A_2)$ we can form the joint 'product' distribution $\sigma \otimes \tau \in \mathcal{D}(A_1 \otimes A_2)$ as $(\sigma \otimes \tau)(a_1, a_2) = \sigma(a_1) \cdot \tau(a_2)$, as already used in (7). The two original states σ and τ can be recovered as marginals of this product state: $\mathsf{M}_1(\sigma \otimes \tau) = \sigma$ and $\mathsf{M}_2(\sigma \otimes \tau) = \tau$. Marginalisation (of states) and weakening (of predicates) are special cases of state and predicate transformation, namely for the (Kleisli) projection maps $\pi_i\colon A_1 \otimes A_2 \to A_i$, given by $\pi_i(a_1, a_2) = 1\,|a_i\rangle$. Marginalisation moves a 'joint' state on a product to one of the components, and weakening moves a predicate on a component to the product. These two operations play a special role in the sequel, and therefore we introduce explicit notation M and W. First, for a joint state $\omega \in \mathcal{D}(A_1 \otimes A_2)$ we have first and second marginalisation $\mathsf{M}_i(\omega) = (\pi_i)_*(\omega) \in \mathcal{D}(A_i)$ determined by (6) as:

$$\mathsf{M}_1(\omega)(a_1) = \textstyle\sum_{a_2 \in A_2} \omega(a_1, a_2) \qquad \mathsf{M}_2(\omega)(a_2) = \textstyle\sum_{a_a \in A_1} \omega(a_1, a_2). \tag{14}$$

Similarly we have weakening operations $\mathsf{W}_i(p_i) = (\pi_i)^*(p_i) \in [0,1]^{A_1 \otimes A_2}$ for predicates $p_i \in [0,1]^{A_i}$ given by:

$$\mathsf{W}_1(p_1)(a_1, a_2) = p_1(a_1) \qquad \mathsf{W}_2(p_2)(a_1, a_2) = p_2(a_2). \tag{15}$$

Also, for two predicates $p_i \in [0,1]^{A_i}$, we introduce their *parallel conjunction* $p_1 \odot p_2 \in [0,1]^{A_1 \times A_2}$, mapping (a_1, a_2) to $p_1(a_1) \cdot p_2(a_2)$. The following definition describes the interaction – dependence, in Bayesian jargon – between the components of a joint state.

▶ **Definition 11.** A joint state $\omega \in \mathcal{D}(A_1 \otimes A_2)$ is called *non-entwined* if it is the product of its marginals: $\omega = \mathsf{M}_1(\omega) \otimes \mathsf{M}_2(\omega)$. It is called *entwined* otherwise.

▶ **Lemma 12.**
(a) $\mathsf{M}_1(\omega) \models p \;=\; \omega \models \mathsf{W}_1(p)$ *and* $\mathsf{M}_2(\omega) \models p \;=\; \omega \models \mathsf{W}_2(p)$.
(b) $\mathsf{W}_1(p) = p \odot \mathbf{1}$ *and* $\mathsf{W}_2(q) = \mathbf{1} \odot q$ *and* $p \odot q = \mathsf{W}_1(p) \,\&\, \mathsf{W}_2(q)$.
(c) $(\sigma \otimes \tau) \models (p \odot q) = (\sigma \models p) \cdot (\tau \models q)$ *and* $(\sigma \otimes \tau)|_{p \odot q} = (\sigma|_p) \otimes (\tau|_q)$.

The next result plays an important role in the sequel. The first equation below says that if one takes the marginal of a joint state conditioned with a weakened predicate, then one may as well condition the marginal directly. This holds if the weakening and marginalisation use the same component. But it fails if the components are different, see the subsequent inequality $\neq$ below. The latter fact is remarkable, because it involves a form of influence between components. This is also called 'signalling' in the quantum world, but apparently already appears in the current probabilistic setting – only for entwinted states.

▶ **Proposition 13.** *Let $p \in [0,1]^A$ be a predicate on a set A.*
(a) *For an arbitrary joint state $\omega \in \mathcal{D}(A \otimes B)$,*

$$\mathsf{M}_1\big(\omega|_{\mathsf{W}_1(p)}\big) \;=\; \mathsf{M}_1(\omega)|_p \qquad \textit{but in general} \qquad \mathsf{M}_2\big(\omega|_{\mathsf{W}_1(p)}\big) \;\neq\; \mathsf{M}_2(\omega).$$

(b) *For the special case of a (non-entwined) product state $\sigma \otimes \tau \in \mathcal{D}(A \otimes B)$,*

$$\mathsf{M}_1\big((\sigma \otimes \tau)|_{\mathsf{W}_1(p)}\big) \;=\; \sigma|_p \qquad \mathsf{M}_2\big((\sigma \otimes \tau)|_{\mathsf{W}_1(p)}\big) \;=\; \tau.$$

Proof. We only prove the equality in point (a), and refer to Example 14 (b) for the inequality in point (b), where a counterexample is given.

$$\begin{aligned}
\mathsf{M}_1\big(\omega|_{\mathsf{W}_1(p)}\big)(a) &\overset{(14)}{=} \textstyle\sum_b \omega|_{\mathsf{W}_1(p)}(a,b) \overset{(3)}{=} \sum_b \frac{\omega(a,b) \cdot \mathsf{W}_1(p)(a,b)}{\omega \models \mathsf{W}_1(p)} \overset{(15)}{=} \frac{\sum_b \omega(a,b) \cdot p(a)}{\omega \models \mathsf{W}_1(p)} \\
&\overset{\text{Lem.12(a)}}{=} \frac{\mathsf{M}_1(\omega)(a) \cdot p(a)}{\mathsf{M}_1(\omega) \models p} \\
&\overset{(3)}{=} \mathsf{M}_1(\omega)|_p(a). \qquad \blacktriangleleft
\end{aligned}$$

We illustrate two significant related phenomena via an example.

▶ **Example 14.** Given sets $X = \{x, y\}$ and $A = \{a, b\}$, one can prove that a state $\omega = r_1 \,|x,a\rangle + r_2 \,|x,b\rangle + r_3 \,|y,a\rangle + r_4 \,|y,b\rangle \in \mathcal{D}(X \otimes A)$, where $r_1 + r_2 + r_3 + r_4 = 1$, is non-entwined if and only if $r_1 \cdot r_4 = r_2 \cdot r_3$. This fact also holds in the quantum case, see *e.g.* [12, §1.5]. It plays a role in the next two illustrations.

(a) **Conditioning creates entwinedness**. Recall from Example 3 the joint state $G \otimes E$ on $2_G \otimes 2_E$, defined as in (7). Consider now a predicate $p \in [0,1]^{2_D}$ defined by $d \mapsto 85\%$ and $d^\perp \mapsto 20\%$. It models, for instance, the information that pallor appears as a symptom in 85% of patients with the disease, but also healthy patients may be pale for other reasons, 20% of the times. Using D as a predicate transformer, we can form the conditioned state $\omega = (G \otimes E)|_{D^*(p)} = 0.007 \,|g,e\rangle + 0.055 \,|g,e^\perp\rangle + 0.191 \,|g^\perp,e\rangle + 0.747 \,|g^\perp,e^\perp\rangle$. This state is now entwined, see the above characterisation of non-entwinedness.

(b) Influence between marginals of entwined states. Let's now start with an entwined state $\sigma = \frac{1}{3}\,|g,e\rangle + \frac{1}{4}\,|g,e^\perp\rangle + \frac{1}{6}\,|g^\perp,e\rangle + \frac{1}{4}\,|g^\perp,e^\perp\rangle \in \mathcal{D}(2_G \otimes 2_E)$ and a predicate $q = \partial_g \in [0,1]^{2_G}$. By weakening we get $\mathsf{W}_1(q) = q \bullet \pi_1 \in [0,1]^{2_G \otimes 2_E}$. Then: $\sigma \models \mathsf{W}_1(q) = \frac{1}{3}\cdot 1 + \frac{1}{4}\cdot 1 = \frac{7}{12}$, so that:

$$\sigma|_{\mathsf{W}_1(q)} \;=\; \tfrac{1/3}{7/12}\,|g,e\rangle + \tfrac{1/4}{7/12}\,|g,e^\perp\rangle \;=\; \tfrac{4}{7}\,|g,e\rangle + \tfrac{3}{7}\,|g,e^\perp\rangle\,.$$

Below, the second marginal of the original state σ differs from the second marginal of this conditioned state, illustrating the inequality $\neq$ in Proposition 13 (a).

$$\mathsf{M}_2(\sigma) \;=\; \tfrac{1}{2}\,|e\rangle + \tfrac{1}{2}\,|e^\perp\rangle \qquad \text{whereas} \qquad \mathsf{M}_2\big(\sigma|_{\mathsf{W}_1(q)}\big) \;=\; \tfrac{4}{7}\,|e\rangle + \tfrac{3}{7}\,|e^\perp\rangle\,.$$

▶ **Example 15.** We conclude with the formal description of the two-disease scenario with which we started this section (Example 10). The test is a map $T\colon 2_{A_1} \to 2_T$ given by $T(a_1) = \frac{9}{10}\,|t\rangle + \frac{1}{10}\,|t^\perp\rangle$ and $T(a_1^\perp) = \frac{1}{20}\,|t\rangle + \frac{19}{20}\,|t^\perp\rangle$. The impact of a positive test on the disease A_2 is given by the marginal of the conditional: $\mathsf{M}_2(\omega|_{\mathsf{W}_1(T^*(\partial_t))}) = \frac{40}{97}\,|a_2\rangle + \frac{57}{97}\,|a_2^\perp\rangle$.

5 A quantitative definition of influence

Last section showed how evidence on one component of an entwined state may influence the other component. But *how much* did it change the latter component with respect to our prior belief? This section addresses such aspect by introducing a quantitative semantics for our influence vocabulary. We begin by recalling the total variation metric on distributions.

▶ **Definition 16.** Let $\sigma, \tau \in \mathcal{D}(X)$ be two distributions on a set X. Their *total variation distance* $\mathsf{d}(\sigma,\tau)$ is defined as the following number in the unit interval $[0,1]$.

$$\mathsf{d}(\sigma,\tau) \;=\; \frac{1}{2}\sum_{x\in X} \big|\sigma(x) - \tau(x)\big|.$$

▶ **Lemma 17.** *Let $f\colon X \nrightarrow Y$ be a Kleisli map. The associated state transformer $f_*\colon \mathcal{D}(X) \to \mathcal{D}(Y)$ from (6) is non-expansive: $\mathsf{d}(f_*(\sigma), f_*(\tau)) \leq \mathsf{d}(\sigma,\tau)$. This yields a functor $\mathcal{K}\ell(\mathcal{D}) \to \mathbf{Met}_1$, where $\mathbf{Met}_1$ is the category of 1-bounded metric spaces and non-expansive maps.*

Proof.

$$\begin{aligned}
\mathsf{d}(f_*(\sigma), f_*(\tau)) \;&=\; \tfrac{1}{2}\textstyle\sum_{y\in Y} \big|\, f_*(\sigma)(y) - f_*(\tau)(y) \,\big| \\
&\overset{(6)}{=}\; \tfrac{1}{2}\textstyle\sum_{y\in Y} \Big|\, \sum_{x\in X} f(x)(y)\cdot\sigma(x) - \sum_{x\in X} f(x)(y)\cdot\tau(x) \,\Big| \\
&\leq\; \tfrac{1}{2}\textstyle\sum_{x\in X}\sum_{y\in Y} f(x)(y)\cdot \big|\, \sigma(x) - \tau(x) \,\big| \\
&=\; \tfrac{1}{2}\textstyle\sum_{x\in X} 1\cdot \big|\, \sigma(x) - \tau(x) \,\big| \;=\; \mathsf{d}(\sigma,\tau).
\end{aligned}$$

◀

We refer to [6] for more information about total variation (and Kantorovich) distance and the distribution monad $\mathcal{D}$, and turn to our formal definition of influence. First we define it in direct form, as a number indicating how much a predicate p influences a state σ via conditioning $\sigma|_p$, given by the (total variation) distance between σ and $\sigma|_p$. This seems fairly simple. But, as we have seen in Section 4, there may also be indirect, 'crossover' influence between the components of a joint entwined state: this is the content of our second definition.

▶ **Definition 18.** Let $p \in [0,1]^A$ be a predicate on a set A with discrete metric.

1. For a state $\sigma \in \mathcal{D}(A)$ on A the *direct influence* of p on σ is defined as:

$$\mathcal{I}_d(p,\sigma) \;:=\; \mathsf{d}\big(\sigma, \sigma|_p\big) \qquad \text{provided} \;\; \sigma \models p \neq 0.$$

2. For a joint state $\omega \in \mathcal{D}(A \otimes B)$ the *crossover influence* of p on ω is:

$$\mathcal{I}_c(p, \omega) := \mathsf{d}\big(\mathsf{M}_2(\omega), \mathsf{M}_2(\omega|_{\mathsf{W}_1(p)})\big) \qquad \text{provided } \omega \models \mathsf{W}_1(p) \neq 0.$$

In general we say that a predicate has *no* (direct or crossover) influence on a state if the corresponding influence function ($\mathcal{I}_d$ or $\mathcal{I}_c$) has outcome zero.

▶ **Example 19.** We give an example of *direct* influence, postponing a detailed illustration of *crossover* influence to the collider scenario in Section 6. Recall the Kleisli map (5) modeling the Bayesian network of Example 3. We fix three different states on $2_D = \{d, d^\perp\}$:

$$\omega = \tfrac{4}{5}\,|d\rangle + \tfrac{1}{5}\,|d^\perp\rangle \qquad \rho = \tfrac{1}{2}\,|d\rangle + \tfrac{1}{2}\,|d^\perp\rangle \qquad \sigma = \tfrac{1}{5}\,|d\rangle + \tfrac{4}{5}\,|d^\perp\rangle\,.$$

Intuitively, in state ω it is likely that the patient has the disease, in state σ it is rather unlikely, and ρ sits in the middle. Consider the Dirac predicate $\partial_t \in [0,1]^{2_T}$ expressing positivity of the test: we first use the predicate transformer T^* associated with the Kleilsi map $T\colon 2_D \nrightarrow 2_T$ to obtain a predicate $T^*(\partial_t) \in [0,1]^{2_D}$; subsequently, we compute the influence of $T^*(\partial_t)$ on the above three states. This is done via a script.

$$\mathcal{I}_d\big(T^*(\partial_t), \omega\big) = 0.19 \qquad \mathcal{I}_d\big(T^*(\partial_t), \rho\big) = 0.45 \qquad \mathcal{I}_d\big(T^*(\partial_t), \sigma\big) = 0.62$$

Influence measures how radically the positivity of the test challenges our belief on the disease: a positive test does not come at surprise in state ω, but it is more unexpected in state σ.

▶ **Example 20.** Clearly, $\mathcal{I}_d(\mathbf{1}, \omega) = 0$, for the truth predicate $\mathbf{1}$, since $\omega|_{\mathbf{1}} = \omega$. Is there also an example where the (direct and crossover) influence reaches the maximal distance 1? We show how to approximate it. Take $A = \{a, b\}$ with predicate $p(a) = 1, p(b) = 0$ and state $\sigma = \epsilon\,|a\rangle + (1-\epsilon)\,|b\rangle$. The direct influence $\mathcal{I}_d(p, \sigma)$ goes to 1 as $\epsilon \to 0$. Similarly, by taking $\omega = \epsilon\,|aa\rangle + (1-\epsilon)\,|bb\rangle \in \mathcal{D}(A \times A)$ we get $\mathcal{I}_c(p, \omega) \to 1$ as $\epsilon \to 0$ for crossover influence.

We now establish some facts on crossover influence: (1) it only makes sense if the state is entwined, since for a product state the crossover influence is zero; (2) weakening and marginalisation must work in different components, since otherwise we have direct influence; (3) crossover influences is always less than direct influence. In the context of Definition 18:

▶ **Lemma 21.**

1. $\mathcal{I}_c(p, \sigma \otimes \tau) = 0$;
2. $\mathsf{d}\big(\mathsf{M}_1(\omega), \mathsf{M}_1(\omega|_{\mathsf{W}_1(p)})\big) = \mathcal{I}_d(p, \mathsf{M}_1(\omega))$;
3. $\mathcal{I}_c(p, \omega) \leq \mathcal{I}_d(\mathsf{W}_1(p), \omega)$
4. *For each function* $g\colon X \to Y$, *considered as a Kleisli map* $\langle g \rangle\colon X \to \mathcal{D}(Y)$, *we have:* $\mathcal{I}_d(p, \langle g \rangle_*(\sigma)) \leq \mathcal{I}_d(\langle g \rangle^*(p), \sigma)$, *where* $\sigma \in \mathcal{D}(X)$.

Proof. The first two points follow directly from Proposition 13 (b) and (a). The inequality in point (3) from the fact that marginalisation is a special form of state transformation, which, as we know from Lemma 17, is non-expansive:

$$\begin{aligned}\mathcal{I}_c(p, \omega) = \mathsf{d}\big(\mathsf{M}_2(\omega), \mathsf{M}_2(\omega|_{\mathsf{W}_1(p)})\big) &= \mathsf{d}\big((\pi_2)_*(\omega), (\pi_2)_*(\omega|_{\mathsf{W}_1(p)})\big) \\ &\leq \mathsf{d}\big(\omega, \omega|_{\mathsf{W}_1(p)}\big) = \mathcal{I}_d(\mathsf{W}_1(p), \omega).\end{aligned}$$

Finally, for point (4) we use both Lemma 4 (c) and Lemma 17 in:

$$\begin{aligned}\mathcal{I}_d(p, \langle g \rangle_*(\omega)) &= \mathsf{d}\big(\langle g \rangle_*(\omega), \langle g \rangle_*(\omega)|_p\big) \\ &= \mathsf{d}\big(\langle g \rangle_*(\omega), \langle g \rangle_*(\omega|_{\langle g \rangle^*(p)})\big) \leq \mathsf{d}\big(\omega, \omega|_{\langle g \rangle^*(p)}\big) = \mathcal{I}_d(\langle g \rangle^*(p), \omega).\end{aligned}$$

◀

▶ Remark. Crossover and direct influence are instances of a more general definition of influence of a predicate $p \in [0,1]^{A_j}$ on the i-th marginal A_i of a joint state $\omega \in \mathcal{D}(A_1 \otimes \ldots \otimes A_n)$. For $n = 2$ and $i \neq j$, this corresponds to crossover influence, whereas for $n = i = j = 1$ it would be direct influence. We chose not to work within this uniform approach as we believe that it is more insightful to think of the two notions of Definition 18 as conceptually distinct.

As observed in §3, the blocking action of Dirac predicates plays a key role in d-separation. We can use Definition 18 to express that no predicate p has any influence on a Dirac-conditioned state $\omega|_{\partial_x}$ – by Lemma 2, $(\omega|_{\partial_x})|_p = (\omega|_p)|_{\partial_x} = 1\,|x\rangle = \omega|_{\partial_x}$, so $\mathcal{I}_d(p, \omega|_{\partial_x}) = 0$.

▶ **Example 22.** For instance, we can reformulate the fork scenario as follows. Because conditioning is commutative, (12) is the same as: $\omega|_{\partial_x} = \big(\omega|_{\partial_x}\big)|_{f^*(p)}$. Thus Proposition 9 says that $\mathcal{I}_d(f^*(p), \omega|_{\partial_x}) = 0$, *i.e.* $f^*(p)$ has no influence on $\omega|_{\partial_x}$.

In the same vein, one may also revisit Example 8, an instance of the serial connection scenario: in short, from (5), use states D, $T \bullet D$ and $S \bullet T \bullet D$ to construct a joint state on $2_D \otimes 2_T \otimes 2_S$; check that a 'positive test' predicate $\partial_t \in [0,1]^{2_T}$ has crossover influence on the marginal 2_S, then prove that a 'disease' predicate $\partial_d \in [0,1]^{2_D}$ blocks such influence.

6 Influence in d-separation (reprise)

We conclude with a return on the collider scenario, left unfinished at the end of § 3. With the notation introduced therein, we now explain the collider situation in Diagram (13): the initial joint (product) state $\sigma \otimes \tau$ is non-entwined, but it becomes entwined after conditioning with evidence q on B, as in $(\sigma \otimes \tau)|_{f^*(q)}$. Now any new evidence $p \in [0,1]^A$ on A may have *crossover* influence on C – *cf.* Example 14 (b). It can be explicitly quantified by computing $\mathcal{I}_c\big(p, (\sigma \otimes \tau)|_{f^*(q)}\big)$.

A conceptual insight stemming from our analysis is the asymmetry between blocking and enabling influence: while in the serial and fork scenarios only Dirac predicates are able to block, in a collider *any* predicate may enable. We give a concrete example below.

▶ **Example 23.** The Bayesian network of Example 3 includes a collider, given by nodes 'Genetic Heredity' and 'Environmental Factors' both pointing to 'Disease'. The two possible causes for the disease are represented as a joint state $G \otimes E$ on $2_G \otimes 2_E$, see (7). *A priori*, they are unrelated. For instance, a Dirac predicate $\partial_{g^\perp} \in [0,1]^{2_G}$ that excludes any genetic disorder of the patient has no effect on the chances that she has been exposed to the environmental factors: formally, the crossover influence $\mathcal{I}_c(\partial_{g^\perp}, G \otimes E)$ is 0, as guaranteed by Lemma 21.1. However, let's include the information that pallor is a symptom of the disease, modeled as a predicate $p \in [0,1]^{2_D}$ as in Example 14(a): it turns $G \otimes E$ into an entwined state $(G \otimes E)|_{D^*(p)}$. In this changed scenario, d-separation tells that ruling out genetic heredity (predicate $\partial_{g^\perp}$) *does* influence the belief that environment was the cause. We can formally expressed it with crossover influence:

$$\mathcal{I}_c(\partial_{g^\perp}, G \otimes E) = 0 \qquad \mathcal{I}_c(\partial_{g^\perp}, (G \otimes E)|_{D^*(p)}) = 0.006.$$

Note that a Dirac predicate $\partial_d \in [0,1]^{2_D}$ expressing certainty of the disease entwines G and E much more: indeed $\mathcal{I}_c(\partial_{g^\perp}, (G \otimes E)|_{D^*(\partial_d)}) = 0.26 > \mathcal{I}_c(\partial_{g^\perp}, (G \otimes E)|_{D^*(p)})$.

7 Discussion

Our ambition in this paper was to develop a framework where grounding concepts of Bayesian reasoning (influence, dependence, blocking, evidence, ...) are given a clear, completely formal meaning, building on [7], and can be reasoned about in an abstract and flexible

manner. As a proof of concept, we analysed d-separation: the intention was to show how event interactions with a subtle and potentially ambiguous natural language description can be reduced to elementary formulas of our language, with a simple and transparent proof.

We based our approach on Kleisli categories, in harmony with the increasing importance of algebraic methods from program semantics in the analysis of probabilistic systems [11, 16, 10]. The highlight of our developments is the notion of crossover influence, which we believe may foster research in two directions. First, it draws a parallelism with non-locality phenomena of quantum theory, see also [6]: we plan investigate the meaning of our definitions in that setting, exploiting the formal bridge offered by Effectus theory [4, 2]. Second, our definition is abstract enough to accommodate different choices for the underlying notion of distance between states. The total variation metric suits the applications of this paper, but other choices are also worth investigating: we think in particular of the Kantorovich metric [17], for when the sample set has a non-discrete metric, and quantitative analyses of information leakage [1]. Also connections with Kullback-Leibler divergence [9], focussing on loss of information, in Shannon style, and to mutual information, remain to be investigated.

A related point concerns the relationship between the total variation distance and Bayesian influence. In our choice, we simply aimed at the most basic additive distance which does not (unlike Kantorovich) builds on a pre-existing metric, as our sample sets have none. Admittedly, the suitability of total variation is only empirically justified by examples. In future work we aim at a more satisfactory investigation: recent advances on an axiomatic treatment of metrics [10] appear to be very suitable for the purpose.

Abstract

Single occurrence regular expressions (SORE) are a special kind of deterministic regular expressions, which are extensively used in the schema languages DTD and XSD for XML documents. In this paper, with motivations from the simplification of XML schemas, we consider the *SORE-definability problem*: Given a regular expression, decide whether it has an equivalent SORE. We investigate extensively the complexity of the SORE-definability problem: We consider both (standard) regular expressions and regular expressions with counting, and distinguish between the alphabets of size at least two and unary alphabets. In all cases, we obtain tight complexity bounds. In addition, we consider another variant of this problem, the bounded SORE-definability problem, which is to decide, given a regular expression E and a number M (encoded in unary or binary), whether there is an SORE, which is equivalent to E on the set of words of length at most M. We show that in several cases, there is an exponential decrease in the complexity when switching from the SORE-definability problem to its bounded variant.

1 Introduction

Background. Deterministic regular expressions are a special kind of regular expressions, which are mainly used in DTD and XML Schema [11]. Intuitively, deterministic regular expressions require that when reading from left to right a word in the language, each symbol in the word can directly match the symbol in the expression without knowing the next symbol or the length of the word [35, 1]. For example, $(a+b)a^*$ is deterministic. Since for each word w in $\mathcal{L}((a+b)a^*)$, if the first symbol in w is a, then it matches the first a in $(a+b)a^*$, and the other occurrences of a match the second one. On the other hand, $a^*(a+b)$ is not deterministic. Because given a word $w = aa$, without knowing the length of the word, we do not know whether the first a in w should match the first a in $a^*(a+b)$ or the second one.

Although deterministic regular expressions ensure the effective processing of XML documents [11, 16], it is not an easy task to design schema for XML documents with deterministic regular expressions. The major obstacle is that they are defined in a semantic manner, and do not have syntax rules to guide the design [1]. Considerable efforts have been made to solve this problem [2, 3, 4, 13, 23, 21, 7]. Among these is the introduction of single occurrence regular expressions (SORE) [2, 3, 4, 13]. SORE are regular expressions where each alphabet symbol appears at most once [2]. For example, $E = abc$ is an SORE, since there is only one of a, b, and c in E. While $E = aa^*b$ is not, because the symbol a appears twice in E.

Motivation. XML schemas defined with SORE are desirable, since they are very simple and intuitive to comprehend, and it is easy to check the conformance of XML documents with respect to them. As a result, though SORE constitute a restricted class of regular expressions, it turns out that deterministic regular expressions used in DTDs of XML documents from the practice are mostly SORE [29]. In view of this, XML schema designers may tempt to know whether the schema they proposed can in fact be changed into an equivalent, but simpler, schema defined with SORE. This brings the *SORE-definability problem*: *Given a regular expression, decide whether there is an SORE defining the same language.*

In this paper, we start an extensive investigation on the complexity of the SORE-definability problem: We consider both (standard) regular expressions and regular expressions with counting, and distinguish between the alphabets of size at least two and unary alphabets. In all cases, we obtain tight complexity bounds.

In addition, we consider another variant of the SORE-definability problem, the bounded SORE-definability problem, which is to decide, given a regular expression E (without or with counting) and a number M (encoded in unary or binary), whether there is an SORE, which is equivalent to E on the set of words of length at most M. The motivation of this problem comes from the observation that in practice, there may exist some additional information about the number of children that a node in XML documents can have, and this information can be utilised to ease the design of XML schemas. Given a node n, suppose that its content model (the format of its child elements) is defined by a regular expression E. Although $\mathcal{L}(E)$, the language defined by E, might be not deterministic (thus not in SORE), if there is a bound M on the number of children of n, then we may still construct a SORE E_1 such that E and E_1 are equivalent over the set of words up to length M. In this way, we can obtain a regular expression E_1 with a simpler structure to define its content model. Moreover, E_1 covers all the possible XML documents. Checking the existence of SORE E_1 such that $E =_{<=M} E_1$ is the bounded-definability problem. In addition, the bounded-definability problem is related to the bounded nonuniversality problem investigated in [10]. The bounded nonuniversality problem is to decide for a given nondeterministic finite-state automaton A and a number M encoded in unary, whether $\mathcal{L}(A) \cap \Sigma^{\leq M} \neq \Sigma^{\leq M}$. Note that this problem can be rephrased as $\mathcal{L}(A) \neq_{\leq M} \Sigma^*$, where $\Sigma = \{a_1, \ldots, a_n\}$ and Σ^* is the abbreviation of $(a_1 + \ldots + a_n)^*$, which is obviously an SORE.

Contributions. The results obtained in this work are summarised in Table 1. In the table, R stands for the set of (standard) regular expressions, and $R(\#)$ stands for the set of regular expressions with counting. We highlight some of them below.

(1) We first show that the SORE-definability problem is **PSPACE**-complete for regular expressions, and **EXPSPACE**-complete for regular expressions with counting.

(2) We then consider the special case of unary alphabets. We show that the SORE-definability problem becomes **coNP**-complete for regular expressions and $\mathbf{\Pi_2^p}$-complete for regular

Table 1 The results of this paper: An overview.

The SORE-definability problem			
		$\|\Sigma\| = 1$	$\|\Sigma\| \geq 2$
R		**coNP**-c (Thm 6)	**PSPACE**-c (Thm 4)
$R(\#)$		$\mathbf{\Pi_2^P}$-c (Thm 7)	**EXPSPACE**-c (Thm 5)
The bounded SORE-definability problem			
R	M is unary	**PTIME** (Thm 15)	**coNP**-c (Cor 14)
	M is binary	**coNP**-c (Cor 19)	**PSPACE**-c (Cor 17)
$R(\#)$	M is unary	**PTIME** (Thm 15)	**coNP**-c (Thm 13)
	M is binary	$\mathbf{\Pi_2^P}$-c (Cor 18)	**coNEXPTIME**-c (Thm 16)

expressions with counting. Moreover, by using the same idea of the lower bound proof, we can show that the definability problem of deterministic regular expressions is $\mathbf{\Pi_2^P}$-complete for regular expressions with counting, which solves an open problem in [27].

(3) For the bounded SORE-definability problem, a bit surprisingly, we show that the complexity is **coNP**-complete for both regular expressions and regular expressions with counting, if the length bound M is encoded in unary. On the other hand, if M is encoded in binary, the complexity is **PSPACE**-complete for regular expressions and **coNEXPTIME**-complete for regular expressions with counting. In addition, when unary alphabets are considered and M is encoded in unary, the bounded SORE-definability problem can be solved in *polynomial time*, even for regular expressions with counting. These results show that if the length bound M is encoded in unary, there is an exponential decrease when switching from the SORE-definability problem to its bounded variant.

Related work. Single occurrence regular expressions were introduced in [2, 3, 4]. Most works on SORE focus on inferring an SORE from a set of sample words. The basic idea of these works is that given a set of sample words, we first construct a single occurrence automaton (SOA) A, then derive an SORE E from A. The main technical difficulty is how to construct E from A. To this end, Bex et al. [3, 4] developed an $O(|A|^5)$ algorithm. Recently, Freydenberger et al. [13] reduced the complexity of the construction to linear time.

There are also works investigating how to automatically construct deterministic regular expressions from (non-deterministic) regular expressions given by users. This problem entails the definability problem of deterministic regular expressions: Given a regular expression, decide whether there exists an equivalent deterministic regular expression. It was shown in [1, 12, 26] that this problem is **PSPACE**-complete. For regular expressions with counting, there are two notations of determinism, *i.e.,* weak and strong determinism (see [14]). The definability problem of weakly (resp. strongly) deterministic regular expressions with counting can also be defined similarly. It was shown in [24] that the definability problem of weakly deterministic regular expressions with counting is in **2-EXPSPACE** when the inputs are regular expressions, and in **3-EXPSPACE** when the inputs are regular expressions with counting, whereas the exact complexity of these problems are still open.

Researchers also investigated how to decide whether a given regular expression is deterministic [5, 6, 23, 21, 7, 16] (Note that this problem is different from the definability problem of deterministic regular expressions in the sense that we do not check the existence of an equivalent albeit potentially different deterministic regular expression). Remarkably, it

was shown in [16] that the problem of whether a regular expression is deterministic can be decided in linear time. In addition, in [16], it was also shown that the problem of whether a regular expression with counting is weakly deterministic can be decided with the same complexity bound. On the other hand, the work [8] provided a linear time algorithm to decide whether a regular expression with counting is strongly deterministic. Moreover, in [18, 19], efficient matching algorithms were provided for strongly deterministic regular expressions with counting by using finite automata with counters.

Outline. This paper is structured as follows. Section 2 fixes some notations. Section 3 is devoted to the SORE-definability problem. The bounded SORE-definability problem is investigated in Section 4. We conclude this paper in Section 5.

2 Preliminaries

For a natural number $n \in \mathbb{N}$, let $[n]$ denote $\{1, \cdots, n\}$. In addition, for two natural numbers $m, n \in \mathbb{N}$ such that $m \leq n$, let $[m, n]$ denote the set $\{m, m+1, \cdots, n\}$.

An *alphabet* Σ is a finite set of symbols $\{a_1, a_2, \ldots, a_n\}$. We will use $a, b, \cdots$ to denote symbols from Σ. A *word* over Σ is a sequence of symbols from Σ. We will use $u, v, w, \cdots$ to denote words and ε to denote the empty word. A *language* over Σ is a set of words on Σ. For two languages L_1 and L_2, we use $L_1 \cdot L_2$ to denote the language $\{uv \mid u \in L_1, v \in L_2\}$. In addition, for a language L, we define $L^0 = \{\varepsilon\}$, and $L^{n+1} = L \cdot L^n$ for each natural number n. We also use L^* to denote $\bigcup_{n \in \mathbb{N}} L^n$. A (standard) *regular expression* over Σ is inductively defined as follows: ε and a are regular expressions for any $a \in \Sigma$; for any regular expressions E_1 and E_2, the disjunction $E_1 + E_2$, the concatenation $E_1 \cdot E_2$ (or $E_1 E_2$), and the star E_1^* are also regular expressions. The semantics of a regular expression E is given by a language $\mathcal{L}(E)$ defined as follows: $\mathcal{L}(\varepsilon) = \{\varepsilon\}$, $\mathcal{L}(a) = \{a\}$, $\mathcal{L}(E_1 + E_2) = \mathcal{L}(E_1) \cup \mathcal{L}(E_2)$, $\mathcal{L}(E_1 \cdot E_2) = \mathcal{L}(E_1) \cdot \mathcal{L}(E_2)$, and $\mathcal{L}(E_1^*) = (\mathcal{L}(E_1))^*$. Let R denote the set of all regular expressions. For a regular expression E, let Σ_E denote the set of all symbols from Σ that appear in E.

Next, we define deterministic regular expressions. Before that, we introduce some notations. Given a regular expression E, we replace every symbol a in E by a subscripted symbol a_i such that a_i appears only once. Let $\overline{E}$ denote the resulting expression obtained by this replacement. For instance, let $E = (\varepsilon + a) \cdot a^*$, then $\overline{E} = (\varepsilon + a_1) \cdot a_2^*$. A regular expression E is *deterministic* iff the following condition holds: for every two words $uxw, uyv \in \mathcal{L}(\overline{E})$, if $x = a_i$ and $y = a_j$, then $i = j$. A regular language L is deterministic, if there exists a deterministic regular expression E such that $\mathcal{L}(E) = L$. For $E = (\varepsilon + a) \cdot a^*$, consider two words $a_1 a_2, a_2 \in \mathcal{L}(\overline{E})$. Let $u = \varepsilon$, $x = a_1$, $w = a_2$, $y = a_2$, and $v = \varepsilon$, then $uxw, uyv \in \mathcal{L}(\overline{E})$, $x = a_1$, $y = a_2$, but $1 \neq 2$. By the definition, $(\varepsilon + a) \cdot a^*$ is not deterministic. But the language $\mathcal{L}((\varepsilon + a) \cdot a^*)$ is deterministic, since $\mathcal{L}((\varepsilon + a) \cdot a^*) = \mathcal{L}(a^*)$ and a^* is deterministic.

Next, we define the Glushkov automata of regular expressions [15, 30]. Given a regular expression E, we first define the following sets: $first(E) = \{a \mid aw_1 \in \mathcal{L}(E)\}$, $follow(E, a) = \{b \mid w_1 a b w_2 \in \mathcal{L}(E)\}$, and $last(E) = \{a \mid w_1 a \in \mathcal{L}(E)\}$. Intuitively, $first(E)$ comprises the first symbols of words in $\mathcal{L}(E)$, $follow(E, a)$ is the set of symbols, which can appear immediately after a in a word from $\mathcal{L}(E)$, and $last(E)$ contains the last symbols of words in $\mathcal{L}(E)$. Then the Glushkov automaton of E, denoted by $G_E = (Q_E \cup \{q_I\}, \Sigma, \delta_E, q_I, F_E)$, is constructed as follows:

1. Q_E is the set of symbols in $\overline{E}$, and q_I is the initial state;
2. For any $a \in \Sigma_E$, let $\delta_E(q_I, a) = \{a_i \mid a_i \in first(\overline{E})\}$;

3. For any $a, b \in \Sigma_E$, let $\delta_E(a_i, b) = \{b_j \mid b_j \in follow(\overline{E}, a_i)\}$;
4. $F_E = \begin{cases} \{a_i \mid a_i \in last(\overline{E})\} \cup \{q_I\} & \text{if } \varepsilon \in L(E), \\ \{a_i \mid a_i \in last(\overline{E})\} & \text{otherwise.} \end{cases}$

Given a regular expression E, the Glushkov automaton G_E can be constructed in polynomial time [6]. See Example 1 in the next section for an example of Glushkov automata.

Single occurrence regular expressions (SORE)[3, 4] are a special kind of deterministic regular expressions, which require that every symbol in the alphabet appears at most once. Moreover, SORE use the following operators: the disjunction $(+)$, the concatenation $(\cdot)$, the iteration $(^+)$, and the optional $(?)$, where the iteration E^+ and the optional $E?$ are the abbreviations of $E \cdot E^*$ and $\varepsilon + E$, respectively. Since $\mathcal{L}(E^*) = \mathcal{L}((E^+)?)$, SORE do not use the star operation. For example, a^+bc is an SORE, but aa^+ is not, since the symbol a appears twice. Additionally, we require that the iteration (resp. the optional) cannot be nested in an SORE, that is, the expressions of the form $(E?)?$ or $(E^+)^+$ are forbidden. We also forbid the expressions of the form $((E^+)?)^+$ or $((E?)^+)?$. These constraints ensure that for a fixed alphabet Σ, there are only a fixed number of SORE over Σ. Nevertheless, these constraints do not affect the expressive power of SORE. For an SORE, its Glushkov automaton can also be constructed in polynomial time [2].

A single occurrence automaton (SOA) $S = (Q, \Sigma, \delta, q_I, F)$ over an alphabet Σ is defined as follows [13]: $Q \subseteq \Sigma \cup \{q_I\}$, where q_I is the initial state; $\delta : Q \times \Sigma \to Q$ is the transition function such that whenever $\delta(q_1, b) = q_2$, we have $q_2 = b$; and $F \subseteq Q$ is the set of final states. Although SOA defined here are slightly different from those in [13], one can easily add a sink state to each SOA defined in this paper to obtain an SOA in [13]. Later on, we will ignore this difference and apply the algorithms in [13] directly on SOA in this paper.

A regular expression with counting is an extension of regular expressions, which additionally allows using the counting modalities $E^{[m,n]}$ or $E^{[m,\infty]}$. For a regular expression with counting E, the language $\mathcal{L}(E^{[m,n]}) = \bigcup_{i \in [m,n]} (\mathcal{L}(E))^i$. The language $\mathcal{L}(E^{[m,\infty]})$ can be defined similarly. Let $R(\#)$ denote the set of regular expressions with counting.

3 The SORE-definability problem

In this section, we study the complexity of the SORE-definability problem: Given a regular expression E, decide whether there exists an SORE E^c such that $\mathcal{L}(E^c) = \mathcal{L}(E)$. We first consider the general case of non-unary alphabets, then the special case of unary alphabets.

3.1 Non-unary alphabets

We start with regular expressions and consider regular expressions with counting later on[1].

To solve the SORE-definability problem, our main idea is to construct for a regular expression E, an SORE E^c such that $\mathcal{L}(E) = \mathcal{L}(E^c)$ iff there exists an SORE E_1 satisfying that $\mathcal{L}(E) = \mathcal{L}(E_1)$. With such an SORE E^c, we can solve the SORE-definability problem by checking whether $\mathcal{L}(E) = \mathcal{L}(E^c)$.

The construction of the SORE E^c is divided into two steps: We first construct an SOA S_E from E, then an SORE E^c from S_E.

Given a regular expression E, let $G_E = (Q_E \cup \{q_I\}, \Sigma, \delta_E, q_I, F_E)$ be the Glushkov automaton of E, we construct the SOA $S_E = (\Sigma_E \cup \{q_I\}, \Sigma_E, \delta'_E, q_I, F'_E)$ as follows:

[1] Several results in this section are based on Chapter 7 of the PhD. thesis of Ping Lu (cf. [25]).

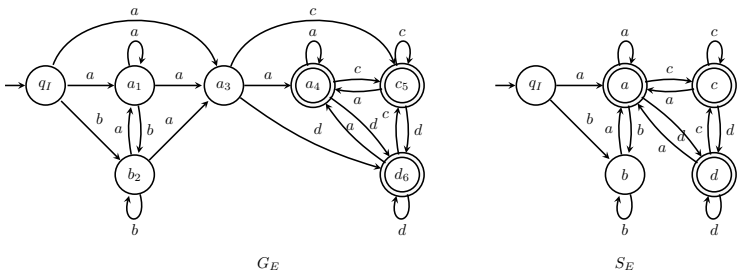

Figure 1 G_E and S_E.

1. For any $a \in \Sigma_E$, let $\delta'_E(q_I, a) = \{a \mid \exists i.\ a_i \in \delta_E(q_I, a)\}$;
2. For any $a, b \in \Sigma_E$, let $\delta'_E(a, b) = \{b \mid \exists i, j.\ b_j \in \delta_E(a_i, b)\}$;
3. $F'_E = \begin{cases} \{a \mid \exists i.\ a_i \in F_E\} \cup \{q_I\} & \text{if } q_I \in F_E, \\ \{a \mid \exists i.\ a_i \in F_E\} & \text{otherwise.} \end{cases}$

Intuitively, the SOA S_E is constructed from G_E by merging for each $a \in \Sigma_E$, all the states a_i of G_E into one state a and modifying the transition relation correspondingly.

▶ **Example 1.** Let $E = (a + b)^* a(a + c + d)^*$. Then $\overline{E} = (a_1 + b_2)^* a_3 (a_4 + c_5 + d_6)^*$. The Glushkov automaton G_E and the SOA S_E constructed from G_E are given in Figure 1. Note that the states a_1, a_3, and a_4 in G_E are merged into one state a in S_E, and the other states remain the same (modulo names).

The SOA S_E enjoys the following property.

▶ **Lemma 2.** *Given a regular expression E, $\mathcal{L}(E)$ can be defined by an SOA iff $\mathcal{L}(G_E) = \mathcal{L}(S_E)$.*

To construct the desired SORE E^c, we apply the algorithm REWRITE in [3, 4] or Soa2Sore in [13] to S_E, and get an SORE E^c enjoying the following property: S_E can be represented by an SORE iff $\mathcal{L}(S_E) = \mathcal{L}(E^c)$. From Lemma 2, we deduce the following fact.

▶ **Proposition 3.** *$\mathcal{L}(E)$ can be defined by an SORE iff $\mathcal{L}(E) = \mathcal{L}(E^c)$.*

The arguments for Proposition 3 proceed as follows: The "if" direction is trivial. For the "only if" direction, suppose that $\mathcal{L}(E)$ is defined by an SORE E_1. Then it can also be defined by an SOA, since the Glushkov automaton of E_1 is an SOA. By Lemma 2, we must have that $\mathcal{L}(E_1) = \mathcal{L}(E) = \mathcal{L}(G_E) = \mathcal{L}(S_E)$. Hence, S_E is represented by the SORE E_1. From the property of E^c, we know that $\mathcal{L}(S_E) = \mathcal{L}(E^c)$. We conclude that $\mathcal{L}(E) = \mathcal{L}(S_E) = \mathcal{L}(E^c)$.

Given a regular expression E, by using Proposition 3, we solve the SORE-definability problem of E as follows:
(1) Construct the SOA S_E;
(2) Construct the candidate SORE E^c;
(3) Check whether $\mathcal{L}(E) = \mathcal{L}(E^c)$. If so, return **true**; otherwise, return **false**.

The correctness of the algorithm follows from Proposition 3. In the following, we analyze the complexity of this algorithm. From the results in [6, 3, 4, 13], we know that steps (1) and (2) can be done in polynomial time. Since the equivalence problem of regular expressions is PSPACE-complete [31], we know that step (3) can be fulfilled in polynomial space. It follows that the SORE-definability problem of regular expressions is in **PSPACE**. For the lower bound, we apply a reduction from the complement of the acceptance problem of polynomial-space bounded Turing machines. Then we get the following result.

▶ **Theorem 4.** *The SORE-definability problem is* **PSPACE***-complete for regular expressions.*

When E is a regular expression in $R(\#)$, *i.e.,* a regular expression with counting, we can expand E into a (standard) regular expression E', and then use the above algorithm to decide the SORE-definability problem. Since expanding E into E' takes exponential time, and the equivalence problem of regular expressions is **PSPACE**-complete [31], we conclude that the SORE-definability problem of $R(\#)$ is in **EXPSPACE**. For the **EXPSPACE** lower bound, we prove it by a reduction from the universality problem of regular expressions in $R(\#)$, which is known to be **EXPSPACE**-complete [31].

▶ **Theorem 5.** *The SORE-definability problem is* **EXPSPACE***-complete for $R(\#)$.*

3.2 Unary alphabets

In this section, we mainly consider the complexity of the SORE-definability problem for unary alphabets. As a by-product, we also solve an open problem in [27].

Let $\Sigma = \{a\}$. One can verify that an SORE E_1 over Σ must satisfy one of the following constraints: $\mathcal{L}(E_1) = \mathcal{L}(\varepsilon)$, $\mathcal{L}(E_1) = \mathcal{L}(a)$, $\mathcal{L}(E_1) = \mathcal{L}(a?)$, $\mathcal{L}(E_1) = \mathcal{L}(a^+)$, or $\mathcal{L}(E_1) = \mathcal{L}((a^+)?)$. Then to check whether $\mathcal{L}(E)$ can be defined by an SORE, we only need to check whether $\mathcal{L}(E) = \mathcal{L}(\varepsilon)$, $\mathcal{L}(E) = \mathcal{L}(a)$, $\mathcal{L}(E) = \mathcal{L}(a?)$, $\mathcal{L}(E) = \mathcal{L}(a^+)$, or $\mathcal{L}(E) = \mathcal{L}((a^+)?)$. Since the equivalence problems of regular expressions and regular expressions with counting over a unary alphabet are **coNP**-complete [34] and $\mathbf{\Pi_2^P}$-complete [34, 20] respectively, we get the **coNP** and $\mathbf{\Pi_2^P}$ upper bounds respectively for their SORE-definability problems over a unary alphabet. Moreover, we show the corresponding lower bounds by a reduction from the universality problem of regular expressions over a unary alphabet and the connectedness problem of integer expressions respectively, which are known to be **coNP**-complete [34] and $\mathbf{\Pi_2^P}$-complete [36, 33] respectively. Therefore, we get the following results.

▶ **Theorem 6.** *Over a unary alphabet, the SORE-definability problem is* **coNP***-complete for regular expressions.*

▶ **Theorem 7.** *Over a unary alphabet, the SORE-definability problem is $\mathbf{\Pi_2^P}$-complete for $R(\#)$.*

The work in [27] showed that the definability problem of deterministic regular expressions over a unary alphabet is in $\mathbf{\Pi_2^P}$ for $R(\#)$, but left the lower bound open. By using a reduction similar to the proof of the lower bound in Theorem 7, we can solve the open problem and get the following result.

▶ **Theorem 8.** *Over a unary alphabet, the definability problem of deterministic regular expressions is $\mathbf{\Pi_2^P}$-complete for $R(\#)$.*

Although the lower bound in Theorem 7 can also be proved by using the construction in [9], that construction cannot be used to prove the lower bound in Theorem 8, since the language defined by the regular expression constructed in [9] is already deterministic.

4 The Bounded SORE-definability problem

In this section, we will study the complexity of the bounded SORE-definability problem: Given a regular expression E (without or with counting) and a number M, whether there exists an SORE E_1 such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E_1)$, *i.e.*, for every word w such that $|w| \leq M$,

$w \in \mathcal{L}(E)$ iff $w \in L(E_1)$. As mentioned in the introduction, if the content model E in a DTD or XML Schema does not denote a deterministic regular language, if there is a bound M on the maximum number of children of nodes in XML documents, then we only need to give a deterministic content model E_1 to ensure that the language $\mathcal{L}(E_1)$ is equivalent to $\mathcal{L}(E)$ within the bound M.

We assume that in the bounded SORE-definability problem, the given regular expression (without or with counting) E and the number M satisfy that $M \geq 2 \cdot |\Sigma_E|$. This assumption is essential for the results in this section and it is open whether this assumption can be lifted.

Similar to the SORE-definability problem, the decision procedure for the bounded SORE-definability problem proceeds as follows:

1. At first, an SOA S_E is constructed from E such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(S_E)$ iff there exists an SOA A such that $\mathcal{L}(A) =_{\leq M} \mathcal{L}(E)$.
2. Then by using the algorithm Soa2Sore in [13], an SORE E^c is constructed from S_E such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$ iff there exists an SORE E' such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E')$.
3. Finally, decide whether $L(E) =_{\leq M} L(E^c)$.

In the following, we will first show how to construct S_E from E and E^c from S_E in Section 4.1, then based on these constructions, we derive the complexity results of the bounded SORE-definability problem in Section 4.2.

4.1 The construction of S_E and E^c

In this section, we assume that E is in $R(\#)$ and demonstrate how to construct an SOA S_E and an SORE E^c from E. The construction for regular expressions without counting is relatively easy and taken as a special case.

For the construction of S_E, one naive approach is to expand the expression E into a regular expression (without counting) E', and construct $S_{E'}$ from E'. But since the expansion of E incurs an exponential blow-up, we would not be able to achieve the tight complexity bounds (see, *e.g.,* Theorem 13 in Section 4.2). In the following, we show how we can circumvent the exponential blow-up and construct a desired SOA S_E in polynomial time.

▶ **Lemma 9.** *Given a regular expression E in $R(\#)$ and a number M encoded in binary, an SOA S_E satisfying the following constraint can be computed in polynomial time: $\mathcal{L}(S_E) =_{\leq M} \mathcal{L}(E)$ iff there exists an SOA A such that $\mathcal{L}(A) =_{\leq M} \mathcal{L}(E)$.*

Before presenting the construction of S_E, we introduce some additional notations. Let us assume that $M > 0$ in the following. For an expression E in $R(\#)$ and a natural number M, we define $first_M(E) = \{a \in \Sigma_E \mid \exists w_1.\ aw_1 \in \mathcal{L}(E) \cap (\Sigma_E)^{\leq M}\}$, $follow_M(E) = \{(a,b) \in \Sigma_E \times \Sigma_E \mid \exists w_1, w_2.\ w_1abw_2 \in \mathcal{L}(E) \cap (\Sigma_E)^{\leq M}\}$, and $last_M(E) = \{a \in \Sigma_E \mid \exists w_1.\ w_1a \in \mathcal{L}(E) \cap (\Sigma_E)^{\leq M}\}$.

For an expression E in $R(\#)$ and a natural number M, we construct an SOA $S_E = (\Sigma_E \cup \{q_I\}, \Sigma_E, \delta'_E, q_I, F'_E)$ satisfying the following constraints:

- $\{a \in \Sigma_E \mid \delta'_E(q_I, a) = a\} = first_M(E)$;
- $\{(a,b) \in \Sigma_E \times \Sigma_E \mid \delta'_E(a,b) = b\} = follow_M(E)$;
- if $\varepsilon \in L(E)$, then $F'_E = last_M(E) \cup \{q_I\}$; otherwise, $F'_E = last_M(E)$.

Therefore, the construction of S_E is equivalent to the computations of $first_M(E)$, $follow_M(E)$ and $last_M(E)$, which, we will show, can be done in polynomial time.

For the computations of $first_M(E)$, $follow_M(E)$ and $last_M(E)$, for each subexpression E' of E, we will compute an *up-to-M counting abstraction* of E' over Σ_E, denoted by $\mathsf{Abs}_{\Sigma_E,M}(E') = (x, T, F, L)$, in polynomial time, such that

- $x \in \{\mathbf{true}, \mathbf{false}\}$ denotes whether $\varepsilon \in \mathcal{L}(E')$;
- T is a function from $\Sigma_E \times \Sigma_E$ to $[M] \cup \{\infty\}$ such that $T(a,b) = \min(\{|w| \mid w \in \mathcal{L}(E') \cap (\Sigma_E)^{\leq M}, w = w_1abw_2 \text{ for some } w_1, w_2\})$, where $\min(\emptyset) = \infty$ by convention;
- F is a function from Σ_E to $[M] \cup \{\infty\}$ such that $F(a) = \min(\{|w| \mid w \in \mathcal{L}(E') \cap (\Sigma_E)^{\leq M}, w = aw_1 \text{ for some } w_1\})$;
- L is a function from Σ_E to $[M] \cup \{\infty\}$ such that $L(a) = \min(\{|w| \mid w \in \mathcal{L}(E') \cap (\Sigma_E)^{\leq M}, w = w_1a \text{ for some } w_1\})$.

Moreover, given $\mathsf{Abs}_{\Sigma_E,M}(E') = (x,T,F,L)$, we define $N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'))$ as the minimum length of the words in $\mathcal{L}(E') \cap (\Sigma_E)^{\leq M}$, that is, if $x = \mathbf{true}$, then $N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E')) = 0$; otherwise, $N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E')) = \min(\mathsf{rng}(T) \cup \mathsf{rng}(F) \cup \mathsf{rng}(L))$, where $\mathsf{rng}(T)$ denotes the range of T, similarly for $\mathsf{rng}(F)$ and $\mathsf{rng}(L)$. It is assumed that $n < \infty$ for each $n \in [M]$.

Evidently, given $\mathsf{Abs}_{\Sigma_E,M}(E) = (x,T,F,L)$, we have that $first_M(E) = \{a \in \Sigma_E \mid F(a) \neq \infty\}$, $follow_M(E) = \{(a,b) \in \Sigma_E \times \Sigma_E \mid T(a,b) \neq \infty\}$ and $last_M(E) = \{a \in \Sigma_E \mid L(a) \neq \infty\}$.

Next, we show how to compute $\mathsf{Abs}_{\Sigma_E,M}(E')$ from E' by a structural induction on E'.

(1) $E' = \varepsilon$. In this case, $\mathsf{Abs}_{\Sigma_E,M}(E') = (\mathbf{true}, T_\infty, F_\infty, L_\infty)$, where T_∞ denotes the function where $T_\infty(a,b) = \infty$ for each $a,b \in \Sigma_E$.

(2) $E' = a$ for any $a \in \Sigma_E$. In this case, $\mathsf{Abs}_{\Sigma_E,M}(E') = (\mathbf{false}, T_\infty, a \to 1, a \to 1)$, where $a \to 1$ denotes the function that maps a to 1 and maps all the other symbols from Σ_E to ∞.

(3) $E' = E'_1 + E'_2$. In this case, suppose that $\mathsf{Abs}_{\Sigma_E,M}(E'_i) = (x_i, T_i, F_i, L_i)$ for $i = 1,2$, then $\mathsf{Abs}_{\Sigma_E,M}(E') = (x,T,F,L)$, where

- $x = x_1 \vee x_2$ (x is the disjunction of x_1 and x_2);
- for each $(a,b) \in \Sigma_E \times \Sigma_E$, $T(a,b) = \min(\{T_1(a,b), T_2(a,b)\})$;
- for each $a \in \Sigma_E$, $F(a) = \min(\{F_1(a), F_2(a)\})$;
- for each $a \in \Sigma_E$, $L(a) = \min(\{L_1(a), L_2(a)\})$.

(4) $E' = E'_1E'_2$. In this case, suppose that $\mathsf{Abs}_{\Sigma_E,M}(E'_i) = (x_i, T_i, E_i, L_i)$ for $i = 1,2$, then $\mathsf{Abs}_{\Sigma_E,M}(E') = (x,T,F,L)$, where

- $x = x_1 \wedge x_2$ (x is the conjunction of x_1 and x_2);
- for each $(a,b) \in \Sigma_E \times \Sigma_E$, let

$$T(a,b) = \min\left([M] \bigcap \left(\begin{array}{l}\{T_1(a,b) + N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_2))\} \\ \cup \{T_2(a,b) + N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\} \\ \cup \{L_1(a) + F_2(b)\}\end{array}\right)\right),$$

  note that here we assume $\infty + \infty = \infty + n = n + \infty = \infty$ for every natural number n;
- for each $a \in \Sigma_E$, let

$$F(a) = \min\left([M] \bigcap \left(\{F_1(a) + N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_2))\} \cup \{F_2(a) \mid x_1 = \mathbf{true}\}\right)\right);$$

- for each $a \in \Sigma_E$, let

$$L(a) = \min\left([M] \bigcap \left(\{L_2(a) + N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\} \cup \{L_1(a) \mid x_2 = \mathbf{true}\}\right)\right).$$

(5) $E' = (E'_1)^{[m,n]}$ or $E' = (E'_1)^{[m,\infty]}$. Since the analysis of $E' = (E'_1)^{[m,\infty]}$ is almost the same as $E' = (E'_1)^{[m,n]}$, we only show the analysis of $E' = (E'_1)^{[m,n]}$. Let $\mathsf{Abs}_{\Sigma_E,M}(E'_1) = (x_1, T_1, F_1, L_1)$. Then $\mathsf{Abs}_{\Sigma_E,M}(E') = (x,T,F,L)$, where

- if $m \geq 2$, then
  - $x = x_1$,

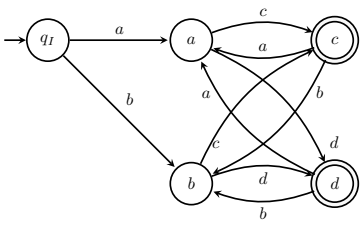

Figure 2 The SOA S_E.

- for each $(a, b) \in \Sigma_E \times \Sigma_E$, let

$$T(a,b) = \min\left([M] \bigcap \left(\begin{array}{l} \{T_1(a,b) + (m-1)N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\} \cup \\ \{L_1(a) + F_1(b) + (m-2)N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\} \end{array} \right)\right),$$

  note that here we assume that $0 \times \infty = 0$ and $n \times \infty = \infty$ for each $n > 0$,
- for each $a \in \Sigma_E$, let

$$F(a) = \min\left([M] \bigcap \{F_1(a) + (m-1)N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\}\right),$$

- for each $a \in \Sigma_E$, let

$$L(a) = \min\left([M] \bigcap \{L_1(a) + (m-1)N_{\min}(\mathsf{Abs}_{\Sigma_E,M}(E'_1))\}\right);$$

- if $m = 1$ and $n = 1$, then $\mathsf{Abs}_{\Sigma_E,M}((E'_1)^{[m,n]}) = \mathsf{Abs}_{\Sigma_E,M}(E'_1)$;
- if $m = 1$ and $n \geq 2$, then $\mathsf{Abs}_{\Sigma_E,M}((E'_1)^{[m,n]}) = \mathsf{Abs}_{\Sigma_E,M}(E'_1 + (E'_1)^{[m+1,n]})$, which can be computed from $\mathsf{Abs}_{\Sigma_E,M}(E'_1)$ and $\mathsf{Abs}_{\Sigma_E,M}((E'_1)^{[m+1,n]})$ by the aforementioned construction for the $+$ operator (note that $(E'_1)^{[m+1,n]}$ satisfies that $m + 1 \geq 2$);
- if $m = 0$ and $n = 0$, then $\mathsf{Abs}_{\Sigma_E,M}((E'_1)^{[m,n]}) = \mathsf{Abs}_{\Sigma_E,M}(\varepsilon)$;
- if $m = 0$ and $n \geq 1$, then $\mathsf{Abs}_{\Sigma_E,M}((E'_1)^{[m,n]}) = \mathsf{Abs}_{\Sigma_E,M}(\varepsilon + (E'_1)^{[m+1,n]})$ (note that $(E'_1)^{[m+1,n]}$ satisfies that $m + 1 \geq 1$).

The above computation of $\mathsf{Abs}_{\Sigma_E,M}(E)$ can be done in polynomial time, since each $\mathsf{Abs}_{\Sigma_E,M}(E')$ occupies only polynomial space and the computation takes at most $O(|E|)$ steps.

▶ **Example 10.** We will use the following example to show all the constructions. Let $E = ((a + b) \cdot (c + d) \cdot (\varepsilon + (ae)^{[5,5]}))^{[2,\infty]}$ and $M = 9$. The computation of $\mathsf{Abs}_{\Sigma_E,M}(E')$ is shown in Table 2, where **T** stands for **true**, **F** stands for **false**, and the pairs (a, b) such that $T(a, b) = \infty$ are omitted, similarly for F and L. Consider the computation of $\mathsf{Abs}_{\Sigma_E,M}((ae)^{[5,5]})$. It is easy to verify that $\mathsf{Abs}_{\Sigma_E,M}(ae) = (\mathbf{false}, \{(a, e)\to 2\}, a\to 2, e\to 2)$. Since $M = 9$, and ae is the shortest word in $\mathcal{L}(ae)$, we have that $2 + (m - 1) \times 2 = 2 + 4 \times 2 = 10 > M$. Therefore, $\mathsf{Abs}_{\Sigma_E,M}((ae)^{[5,5]}) = (\mathbf{false}, T_\infty, T_\infty, T_\infty)$, which means that any word in $\mathcal{L}((ae)^{[5,5]})$ cannot be a sub-word of w in $\mathcal{L}(E)$ such that $|w| \leq M$. Let $\mathsf{Abs}_{\Sigma_E,M}(E) = (x, T, F, L)$. Then $follow_M(E) = \{(a', b') \in \Sigma_E \times \Sigma_E \mid T(a', b') \neq \infty\} = \{(a, c), (b, c), (a, d), (b, d), (c, a), (d, a), (c, b), (d, b)\}$. Similarly, $first_M(E) = \{a' \in \Sigma_E \mid F(a') \neq \infty\} = \{a, b\}$, and $last_M(E) = \{a' \in \Sigma_E \mid L(a') \neq \infty\} = \{c, d\}$. From the sets $first_M$, $follow_M$, and $last_M$, we construct an SOA S_E illustrated in Figure 2.

By using S_E, we can construct the candidate SORE E^c for E in Example 12.

Computation of E^c. Again, we use the algorithm Soa2Sore [13] mentioned in Section 3 to compute an SORE E^c from S_E in polynomial time. As a result of the assumption that $M \geq 2 \cdot |\Sigma_E|$, the SORE E^c enjoys the following property.

Table 2 The computation of $\mathsf{Abs}_{\Sigma_E,M}(E')$.

E'	$\mathsf{Abs}_{\Sigma_E,M}(E')$	E'	$\mathsf{Abs}_{\Sigma_E,M}(E')$
a	$(\mathbf{F}, T_\infty, a\to 1, a\to 1)$	$c+d$	$(\mathbf{F}, T_\infty, \left\{\begin{smallmatrix} c\to 1 \\ d\to 1 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} c\to 1 \\ d\to 1 \end{smallmatrix}\right\})$
b	$(\mathbf{F}, T_\infty, b\to 1, b\to 1)$	ae	$(\mathbf{F}, \{(a,e)\to 2\}, a\to 2, e\to 2)$
c	$(\mathbf{F}, T_\infty, c\to 1, c\to 1)$	$(a+b)(c+d)$	$(\mathbf{F}, \left\{\begin{smallmatrix} (a,c)\to 2 \\ (b,c)\to 2 \\ (a,d)\to 2 \\ (b,d)\to 2 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} a\to 2 \\ b\to 2 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} c\to 2 \\ d\to 2 \end{smallmatrix}\right\})$
d	$(\mathbf{F}, T_\infty, d\to 1, d\to 1)$	$(ae)^{[5,5]}$	$(\mathbf{F}, T_\infty, T_\infty, T_\infty)$
e	$(\mathbf{F}, T_\infty, e\to 1, e\to 1)$	$\varepsilon+(ae)^{[5,5]}$	$(\mathbf{T}, T_\infty, T_\infty, T_\infty)$
$a+b$	$(\mathbf{F}, T_\infty, \left\{\begin{smallmatrix} a\to 1 \\ b\to 1 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} a\to 1 \\ b\to 1 \end{smallmatrix}\right\})$	$(a+b)(c+d)(\varepsilon+(ae)^{[5,5]})$	$(\mathbf{F}, \left\{\begin{smallmatrix} (a,c)\to 2 \\ (b,c)\to 2 \\ (a,d)\to 2 \\ (b,d)\to 2 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} a\to 2 \\ b\to 2 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} c\to 2 \\ d\to 2 \end{smallmatrix}\right\})$
$((a+b)(c+d)(\varepsilon+(ae)^{[5,5]}))^{[2,\infty]}$		$(\mathbf{F}, \left\{\begin{smallmatrix} (a,c)\to 4 & (c,a)\to 4 \\ (b,c)\to 4 & (d,a)\to 4 \\ (a,d)\to 4 & (c,b)\to 4 \\ (b,d)\to 4 & (d,b)\to 4 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} a\to 4 \\ b\to 4 \end{smallmatrix}\right\}, \left\{\begin{smallmatrix} c\to 4 \\ d\to 4 \end{smallmatrix}\right\})$	

▶ **Proposition 11.** *$\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$ iff there exists an SORE E' such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E')$.*

The arguments for Proposition 11 proceed as follows: The "only if" direction is trivial. For the "if" direction, suppose that there exists an SORE E' such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E')$. Then from the fact that $\mathcal{L}(E')$ can be defined by an SOA, according to Lemma 9, we know that $\mathcal{L}(S_E) =_{\leq M} \mathcal{L}(E)$. Therefore, we have $\mathcal{L}(S_E) =_{\leq M} \mathcal{L}(E')$. From the assumption $M \geq 2 \cdot |\Sigma_E|$, we can further show that $\mathcal{L}(S_E) = \mathcal{L}(E')$. Moreover, in [13], it was proved that the SORE E^c satisfies the "SORE-descriptive" property, *i.e.* there does not exist an SORE E'' such that $\mathcal{L}(S_E) \subseteq \mathcal{L}(E'') \subset \mathcal{L}(E^c)$. Therefore, we must have $\mathcal{L}(S_E) = \mathcal{L}(E^c)$. From $\mathcal{L}(S_E) =_{\leq M} \mathcal{L}(E)$, we conclude that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$.

▶ **Example 12.** Let us continue Example 10. By using the algorithm Soa2Sore in [13], from the SOA S_E in Figure 2, we obtain the following SORE: $((a+b)(c+d))^+$. It is easy to verify that $\mathcal{L}(E) =_{\leq 9} \mathcal{L}(((a+b)(c+d))^+)$. Then E can be represented by an SORE within the bound $M = 9$. On the other hand, by the results in Section 3, we can check that $\mathcal{L}(E)$ cannot be defined by an SORE.

4.2 The Complexity

In this section, we establish the complexity results of the bounded SORE-definability problem. Given a regular expression E in $R(\#)$ and a number M, by using Proposition 11, we can develop the following algorithm to decide the bounded SORE-definability problem:

(1) Compute the set $\mathsf{Abs}_{\Sigma_E,M}(E)$;
(2) Construct $first_M(E)$, $follow_M(E)$, $last_M(E)$, and the candidate SORE E^c;
(3) Check whether $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$. If so, return **true**; otherwise, return **false**.

The correctness of this algorithm follows from Proposition 11. In the following, we analyse the complexity of the algorithm. From the computations of $\mathsf{Abs}_{\Sigma_E,M}(E)$, $first_M$, $follow_M$, $last_M$, and E^c in Section 4.1, we know that steps (1) and (2) can be done in polynomial time. For step (3), we distinguish between the unary and binary encoding of M.

M is encoded in unary.

Since M is encoded in unary, to check whether $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$, we first guess a word w such that $|w| \leq M$, then check whether $w \in (\mathcal{L}(E) \setminus \mathcal{L}(E^c))$ or $w \in (\mathcal{L}(E^c) \setminus \mathcal{L}(E))$.

Since checking whether $w \in \mathcal{L}(E)$ and $w \in \mathcal{L}(E^c)$ is in **PTIME** [22], we deduce that the bounded SORE-definability problem for $R(\#)$ is in **coNP**. By a reduction from the bounded universality problem, which is known to be **coNP**-complete [10], we also show that the bounded SORE-definability problem for $R(\#)$ is **coNP**-hard.

▶ **Theorem 13.** *The bounded SORE-definability problem is* **coNP***-complete for $R(\#)$ and natural numbers M encoded in unary.*

One may wonder whether the bounded SORE-definability problem would be easier to solve, if E is a regular expression. The answer to this question is negative, since the expression constructed in the lower-bound proof of Theorem 13 is already a regular expression.

▶ **Corollary 14.** *The bounded SORE-definability problem is* **coNP***-complete for regular expressions and natural numbers M encoded in unary.*

If $|\Sigma_E| = 1$, then $(\Sigma_E)^{\leq M}$ contains at most $M + 1$ words. Therefore, in this case, when M is encoded in unary, step (3) can be done in **PTIME** and we have the following result.

▶ **Theorem 15.** *The bounded SORE-definability problem is in* **PTIME** *for unary regular expressions in $R(\#)$ and natural numbers M encoded in unary.*

From the aforementioned results and the ones in Section 3, we can see that if M is encoded in unary, then there is an exponential decrease in the complexity when switching from the SORE-definability problem to its bounded variant. For instance, for $R(\#)$, the SORE-definability problem is **EXPSPACE**-complete, while the bounded SORE-definability problem is **coNP**-complete if M is encoded in unary.

M is encoded in binary.

As mentioned above, $\mathsf{Abs}_{\Sigma_E,M}(E)$ can be computed in polynomial time even if M is encoded in binary. Nevertheless, since M is encoded in binary, the complexity of step (3) may increase exponentially.

Similar to the algorithm for Theorem 13, step (3) can also be done by guessing a word w such that $|w| \leq M$. Since M is encoded in binary, w can be exponentially large. Then checking whether $w \in \mathcal{L}(E)$ and $w \in \mathcal{L}(E^c)$ can be done in exponential time and we get a **coNEXPTIME** upper bound for bounded SORE-definability problem problem of $R(\#)$. For the **coNEXPTIME** lower bound, we get a reduction from the complement of the acceptance problem of nondeterministic exponential-time Turing machines. Therefore, we obtain the following result.

▶ **Theorem 16.** *The bounded SORE-definability problem is* **coNEXPTIME***-complete for $R(\#)$ and natural numbers M encoded in binary.*

Next, we consider the case when E is a regular expression. Step (1) and (2) can still be done in polynomial time. To check whether $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E^c)$, we can construct two NFA from E and E^c respectively, guess a word w such that $|w| \leq M$, and check whether $w \in \mathcal{L}(E) \setminus \mathcal{L}(E^c)$ or $w \in \mathcal{L}(E^c) \setminus \mathcal{L}(E)$. The nondeterministic algorithm uses polynomial space. By Savitch's Theorem [32], we conclude that the bounded SORE-definability problem for regular expressions is in PSPACE. For the lower bound, we can directly use the same reduction in Theorem 4, and let $M = 2^{|E|}$. The correctness follows from the following arguments: Since the number of states of the minimum DFA for E is at most M [17], it is easy to check that there exists an SORE E_1 such that $\mathcal{L}(E) =_{\leq M} \mathcal{L}(E_1)$ iff there exists an SORE E_2 such that $\mathcal{L}(E) = \mathcal{L}(E_2)$.

▶ **Corollary 17.** *The bounded SORE-definability problem is* **PSPACE***-complete for regular expressions and natural numbers M encoded in binary.*

It is interesting to observe that the complexities of the SORE-definability problem and its bounded variant are the same for regular expressions, while the complexities of the two problems are different for $R(\#)$. This distinction is attributed to the following facts: (1) given a regular expression E, $\mathcal{L}(E) = \Sigma_E^*$, if and only if, $\mathcal{L}(E) =_{\leq 2^{|E|}} \Sigma_E^*$; while (2) given $E \in R(\#)$, $\mathcal{L}(E) = \Sigma_E^*$, if and only if, $\mathcal{L}(E) =_{\leq 2^{2^{|E|}}} \Sigma_E^*$ [31]. That is, to decide whether $\mathcal{L}(E) = \Sigma_E^*$ for $E \in R(\#)$, we have to check double-exponentially many words in $\mathcal{L}(E)$, while for regular expressions, we only need to check exponentially many words. So the bounded SORE-definability problem is simpler than the SORE-definability problem for $R(\#)$.

Given a regular expression E in $R(\#)$ over a unary alphabet, since the minimum DFA for E has at most $M = 2^{2\cdot|E|+4} + 1$ states [27], we have the following results.

▶ **Corollary 18.** *Over a unary alphabet, the bounded SORE-definability problem is* $\mathbf{\Pi_2^p}$*-complete for $R(\#)$ and natural numbers M encoded in binary.*

▶ **Corollary 19.** *Over a unary alphabet, the bounded SORE-definability problem is* **coNP***-complete for regular expressions and natural numbers M encoded in binary.*

5 Conclusion

In this paper, we study the complexity of the SORE-definability problem as well as its bounded variant. The results of the paper were summarised in Table 1. As a by-product of the results obtained in this paper, we also solved an open problem in [27] and showed that over a unary alphabet, the definability problem of deterministic regular expressions is $\mathbf{\Pi_2^p}$-complete for regular expressions with counting.

There are several directions for the future work. An obvious question left open in this paper is whether the assumption $M \geq 2 \cdot |\Sigma_E|$ for the bounded SORE-definability problem can be lifted. Without this assumption, given an SOA A, it is unclear whether it is still in **PTIME** to decide whether there exists an SORE E_1 such that $\mathcal{L}(E_1) =_{\leq M} \mathcal{L}(A)$. Another interesting question is to investigate the definability problem for single occurrence regular expressions with counting (SORE(#)). The main technical challenge is how to obtain a candidate SORE(#). Similarly, one can also consider the CHARE-definability problem (see [3, 28] for the definition of CHARE).

TC^0 Circuits for Algorithmic Problems in Nilpotent Groups

Alexei Myasnikov[1] and Armin Weiß[2]

1 **Stevens Institute of Technology, Hoboken, NJ, USA**
2 **Universität Stuttgart, Germany**

Abstract

Recently, Macdonald et. al. showed that many algorithmic problems for finitely generated nilpotent groups including computation of normal forms, the subgroup membership problem, the conjugacy problem, and computation of subgroup presentations can be done in LOGSPACE. Here we follow their approach and show that all these problems are complete for the uniform circuit class TC^0 – uniformly for all r-generated nilpotent groups of class at most c for fixed r and c.

Moreover, if we allow a certain binary representation of the inputs, then the word problem and computation of normal forms is still in uniform TC^0, while all the other problems we examine are shown to be TC^0-Turing reducible to the problem of computing greatest common divisors and expressing them as linear combinations.

1 Introduction

The word problem (given a word over the generators, does it represent the identity?) is one of the fundamental algorithmic problems in group theory introduced by Dehn in 1911 [3]. While for general finitely presented groups all these problems are undecidable [22, 2], for many particular classes of groups decidability results have been established – not just for the word problem but also for a wide range of other problems. Finitely generated nilpotent groups are a class where many algorithmic problems are (efficiently) decidable (with some exceptions like the problem of solving equations – see e. g. [6]). In 1958, Mal'cev [17] established decidability of the word and subgroup membership problem by investigating finite approximations of nilpotent groups. In 1965, Blackburn [1] showed decidability of the conjugacy problem. However, these methods did not allow any efficient (e. g. polynomial time) algorithms. Nevertheless, in 1966 Mostowski provided "practical" algorithms for the word problem and several other problems [18]. In terms of complexity, a major step was the result by Lipton and Zalcstein [15] that the word problem of linear groups is in LOGSPACE. Together with the fact that finitely generated nilpotent groups are linear (see e. g. [7, 10]) this gives a LOGSPACE solution to the word problem of nilpotent groups, which was later improved to uniform TC^0 by Robinson [23]. A typical algorithmic approach to nilpotent groups is using so-called Mal'cev (or Hall–Mal'cev) bases (see e. g. [7, 10]), which allow to carry out group operations by evaluating polynomials (see Lemma 2). This approach was systematically used in [11] and [18] or – in the more general setting of polycyclic presentations – in [24] for solving (among others) the subgroup membership and conjugacy

problem of polycyclic groups. Recently in [19, 20] polynomial time bounds for the equalizer and subgroup membership problems in nilpotent groups have been given. Finally, in [16] the following problems were shown to be in LOGSPACE using the Mal'cev basis approach. Here, $\mathcal{N}_{c,r}$ denotes the class of nilpotent groups of nilpotency class at most c generated by at most r elements.

- The *word problem*: given $G \in \mathcal{N}_{c,r}$ and $g \in G$, is $g = 1$ in G?
- Given $G \in \mathcal{N}_{c,r}$ and $g \in G$, compute the (Mal'cev) normal form of g.
- The *subgroup membership problem*: Given $G \in \mathcal{N}_{c,r}$ and $g, h_1, \ldots, h_n \in G$, decide whether $g \in \langle h_1, \ldots, h_n \rangle$ and, if so, express g as a word over the subgroup generators $h_1, \ldots, h_n$ (in [16] only the decision version was shown to be in LOGSPACE – for expressing g as a word over the original subgroup generators a polynomial time bound was given).
- Given $G, H \in \mathcal{N}_{c,r}$ and $K = \langle g_1, \ldots, g_n \rangle \leq G$, together with a homomorphism $\varphi : K \to H$ specified by $\varphi(g_i) = h_i$, and some $h \in \mathrm{Im}(\varphi)$, compute a generating set for $\ker(\varphi)$ and find $g \in G$ such that $\varphi(g) = h$.
- Given $G \in \mathcal{N}_{c,r}$ and $K = \langle g_1, \ldots, g_n \rangle \leq G$, compute a presentation for K.
- Given $G \in \mathcal{N}_{c,r}$ and $g \in G$, compute a generating set for the centralizer of g.
- The *conjugacy problem*: Given $G \in \mathcal{N}_{c,r}$ and $g, h \in G$, decide whether or not there exists $u \in G$ such that $u^{-1}gu = h$ and if so find such an element u.

Notice that these problems are not only of interest in themselves, but also might serve as building blocks for solving the same problems in polycyclic groups – which are of particular interest because of their possible application in non-commutative cryptography [4]. In this work we follow [16] and extend these results in several ways:

- We give a complexity bound of uniform TC^0 for all the above problems.
- In order to derive this bound, we show that the extended gcd problem with unary coefficients is in TC^0.
- Our description of circuits is for the uniform setting where $G \in \mathcal{N}_{c,r}$ is part of the input (in [16] the uniform setting is also considered; however, only in some short remarks).
- Since nilpotent groups have polynomial growth, it is natural to allow compressed inputs: we give a uniform TC^0 solution for the word problem allowing words with binary exponents as input – this contrasts with the situation with straight-line programs (i. e., context-free grammars which produces precisely one word – another method of exponential compression) as input: then the word problem is hard for $\mathsf{C}_=\mathsf{L}$ [12]. Thus, the difficulty of the word problem with straight-line programs is not due to their compression but rather due to the difficulty of evaluating a straight-line program.
- We show that the other of the above problems are uniform-TC^0-Turing-reducible to the extended gcd problem (compute the greatest common divisor and express it as a linear combination) when the inputs (both the ambient group and the subgroup etc.) are given as words with binary exponents.

Thus, in the unary case we settle the complexity of the above problems completely. Moreover, it also seems rather unlikely that the subgroup membership problem can be solved without computing gcds – in this case our results on binary inputs would be also optimal. Altogether, our results mean that many algorithmic problems are no more complicated in nilpotent groups than in abelian groups. Notice that while in [16] explicit length bounds on the outputs for all these problems are proven, we obtain polynomial length bounds simply by the fact that everything can be computed in uniform TC^0 (for which in the following we only write TC^0). Throughout the paper we follow the outline of [16]. For a concise presentation, we copy many definitions from [16]. Most of our theorems involve two statements: one for unary encoded inputs and one for binary encoded inputs. In order to have a concise presentation, we always put them in one statement. We only consider finitely generated nilpotent groups without mentioning that further.

Outline. We start with basic definitions on complexity as well as on nilpotent groups. In Section 2 we describe how subgroups of nilpotent groups can be represented and develop a "nice" presentation for all groups in $\mathcal{N}_{c,r}$. Section 3 deals with the word problem and computation of normal forms. Based on this we introduce the so-called matrix reduction and solve the subgroup membership problem. Finally, in Section 5 we present our result for the remaining of the above problems – the proofs are essentially repeated applications of the matrix reduction. Due to space constraints many of the proofs are omitted – they can be found in the full version on arXiv [21].

1.1 Preliminaries on Complexity

For a finite *alphabet* Σ, the set of *words* over Σ is denoted by Σ^*. Computation or decision problems are given by functions $f : \Delta^* \to \Sigma^*$ for some finite alphabets Δ and Σ. A decision problem (= formal language) L is identified with its characteristic function $\chi_L : \Delta^* \to \{0, 1\}$ with $\chi_L(x) = 1$ if, and only if, $x \in L$. (In particular, the word and conjugacy problems can be seen as functions $\Sigma^* \to \{0, 1\}$.) We use circuit complexity as described in [25].

Circuit Classes. The class TC^0 is defined as the class of functions computed by families of circuits of constant depth and polynomial size with unbounded fan-in Boolean gates (and, or, not) and majority gates. A majority gate (denoted by Maj) returns 1 if the number of 1s in its input is greater or equal to the number of 0s. In the following we always assume that the alphabets Δ and Σ are encoded over the binary alphabet $\{0, 1\}$ such that each letter uses the same number of bits. We say a function f is TC^0-*computable* if $f \in \mathsf{TC}^0$.

In the following, we only consider Dlogtime-uniform circuit families and we simply write TC^0 as shorthand for Dlogtime-uniform TC^0. Dlogtime-uniform means that there is a deterministic Turing machine which decides in time $\mathcal{O}(\log n)$ on input of two gate numbers (given in binary) and the string 1^n whether there is a wire between the two gates in the n-input circuit and also computes of which type some gates is. Note that the binary encoding of the gate numbers requires only $\mathcal{O}(\log n)$ bits – thus, the Turing machine is allowed to use time linear in the length of the encodings of the gates. For more details on these definitions we refer to [25]. We have the inclusions $\mathsf{AC}^0 \subsetneq \mathsf{TC}^0 \subseteq \mathsf{LOGSPACE} \subseteq \mathsf{P}$ (note that even $\mathsf{TC}^0 \subseteq \mathsf{P}$ is not known to be strict).

Reductions. A function f is TC^0-*Turing-reducible* to a function g if there is a Dlogtime-uniform family of TC^0 circuits computing f which, in addition to the Boolean and majority gates, also may use oracle gates for g (i. e., gates which on input x output $g(x)$). This is expressed by $f \in \mathsf{TC}^0(g)$. Note that if $f_1, \ldots, f_k$ are in TC^0, then $\mathsf{TC}^0(f_1, \ldots, f_k) = \mathsf{TC}^0$.

In particular, if f and g are TC^0-computable functions, then also the composition $g \circ f$ is TC^0-computable. We will extensively make use of this observation – which will also guarantee the polynomial size bound on the outputs of our circuits without additional calculations.

We will also use another fact frequently without giving further reference: on input of two alphabets Σ and Δ (coded over the binary alphabet), a list of pairs (a, v_a) with $a \in \Sigma$ and $v_a \in \Delta^*$ such that each $a \in \Sigma$ occurs in precisely one pair, and a word $w \in \Sigma^*$, the image $\varphi(w)$ under the homomorphism φ defined by $\varphi(a) = v_a$ can be computed in TC^0 [13].

Encoding numbers: unary vs. binary. There are essentially two ways of representing integer numbers: the usual way as a binary number where a string $a_0 \cdots a_n$ with $a_i \in \{0, 1\}$ represents $\sum a_i 2^{n-i}$, and as a unary number where $k \in \mathbb{N}$ is represented by $1^k = \underbrace{11 \cdots 1}_{k}$ (respectively by $0^{n-k}1^k$ if n is the number of input bits).

We will state most results in this paper with both representations. The unary representation corresponds to group elements given as words over the generators, whereas the binary encoding will be used if inputs are given in a compressed form.

Arithmetic in TC^0. Iterated Addition (resp. Iterated Multiplication) are the following computation problems: On input of n binary integers $a_1, \ldots, a_n$ each having n bits (i. e., the input length is $N = n^2$), compute the binary representation of the sum $\sum_{i=1}^{n} a_i$ (resp. product $\prod_{i=1}^{n} a_i$). For Integer Division the input are two binary n-bit integers a, b; the binary representation of the integer $c = \lfloor a/b \rfloor$ has to be computed. The first statement of Theorem 1 is a standard fact, see [25]; the other statements are due to Hesse, [8, 9].

▶ **Theorem 1** ([8, 9, 25]). *The problems* Iterated Addition, Iterated Multiplication, Integer Division *are all in* TC^0 *no matter whether inputs are given in unary or binary.*

Note that if the numbers a and b are encoded in unary (as strings 1^a and 1^b), division can be seen to be in TC^0 very easily: just try for all $0 \leq c \leq a$ whether $0 \leq a - bc < b$.

Representing groups for algorithmic problems. We consider finitely generated groups G together with finite generating sets A. Group elements are represented as words over the generators and their inverses (i. e., as elements of $(A \cup A^{-1})^*$). We make no distinction between words and the group elements they represent. Whenever it might be unclear whether we mean equality of words or of group elements, we write "$g = h$ in G" for equality in G.

Words over the generators ± 1 of $\mathbb{Z}$ correspond to unary representation of integers. As a generalization of binary encoded integers, we introduce the following notion: a *word with binary exponents* is a sequence $w_1, \ldots, w_n$ where the w_i are from a fixed generating set of the group together with a sequence of exponents $x_1, \ldots, x_n$ where the $x_i \in \mathbb{Z}$ are encoded in binary. The word with binary exponents represents the word (or group element) $w = w_1^{x_1} \cdots w_n^{x_n}$. Note that in a fixed nilpotent group *every* word of length n can be rewritten as a word with binary exponents using $\mathcal{O}(\log n)$ bits (this fact is well-known and also a consequence of Theorem 5 below); thus, words with binary exponents are a natural way of representing inputs for algorithmic problems in nilpotent groups.

1.2 Preliminaries on Nilpotent groups and Mal'cev coordinates

Let G be a group. For $x, y \in G$ we write $[x, y] = x^{-1}y^{-1}xy$ for the *commutator* of x and y. For subgroups $H_1, H_2 \leq G$, we have $[H_1, H_2] = \langle \{[h_1, h_2] \mid h_1 \in H_1, h_2 \in H_2\} \rangle$. A group G is called *nilpotent* if it has a finite central series, i.e.

$$G = G_1 \geq G_2 \geq \cdots \geq G_c \geq G_{c+1} = 1 \tag{1}$$

such that $[G, G_i] \leq G_{i+1}$ for all $i = 1, \ldots, c$. If G is finitely generated, so are the abelian quotients G_i/G_{i+1}, $1 \leq i \leq c$. Let $a_{i1}, \ldots, a_{im_i}$ be a basis of G_i/G_{i+1}, i.e. a generating set such that G_i/G_{i+1} has a presentation $\left\langle a_{i1}, \ldots, a_{im_i} \,\middle|\, a_{ij}^{e_{ij}}, [a_{ik}, a_{i\ell}], \text{ for } j \in \mathcal{T}_i,\ k, \ell \in \{1, \ldots, m_i\} \right\rangle$, where $\mathcal{T}_i \subseteq \{1, \ldots, m_i\}$ (here $\mathcal{T}$ stands for torsion) and $e_{ij} \in \mathbb{Z}_{>0}$ (be aware that we explicitly allow $e_{ij} = 1$, which is necessary for our definition of quotient presentations in Section 2). Formally, we put $e_{ij} = \infty$ for $j \notin \mathcal{T}_i$. We call $A = (a_{11}, a_{12}, \ldots, a_{cm_c})$ a *Mal'cev basis associated to the central series* (1). Sometimes we use A interchangeably also for the set $A = \{a_{11}, a_{12}, \ldots, a_{cm_c}\}$.

For convenience, we will also use a simplified notation, in which the generators a_{ij} and exponents e_{ij} are renumbered by replacing each subscript ij with $j + \sum_{\ell<j} m_\ell$, so the generating

sequence A can be written as $A = (a_1, \ldots, a_m)$. We allow the expression ij to stand for $j + \sum_{\ell<j} m_\ell$ in other notations as well. We also denote $\mathcal{T} = \{i \mid e_i < \infty\}$. By the choice of $\{a_1, \ldots, a_m\}$, every element $g \in G$ may be written uniquely in the form $g = a_1^{\alpha_1} \cdots a_m^{\alpha_m}$, where $\alpha_i \in \mathbb{Z}$ and $0 \le \alpha_i < e_i$ whenever $i \in \mathcal{T}$. The m-tuple $(\alpha_1, \ldots, \alpha_m)$ is called the *coordinate vector* or *Mal'cev coordinates* of g and is denoted $\mathrm{Coord}(g)$, and the expression $a_1^{\alpha_1} \cdots a_m^{\alpha_m}$ is called the *(Mal'cev) normal form* of g. We also denote $\alpha_i = \mathrm{Coord}_i(g)$.

To a Mal'cev basis A we associate a presentation of G as follows. For each $1 \le i \le m$, let n_i be such that $a_i \in G_{n_i} \setminus G_{n_i+1}$. If $i \in \mathcal{T}$, then $a_i^{e_i} \in G_{n_i+1}$, hence a relation

$$a_i^{e_i} = a_\ell^{\mu_{i\ell}} \cdots a_m^{\mu_{im}} \tag{2}$$

holds in G for $\mu_{ij} \in \mathbb{Z}$ and $\ell > i$ such that $a_\ell, \ldots, a_m \in G_{n_i+1}$. We call this the *power relation* for a_i. Let $1 \le i < j \le m$. Since the series (1) is central, relations of the form

$$a_j a_i = a_i a_j a_\ell^{\alpha_{ij\ell}} \cdots a_m^{\alpha_{ijm}} \qquad\qquad a_j^{-1} a_i = a_i a_j^{-1} a_\ell^{\beta_{ij\ell}} \cdots a_m^{\beta_{ijm}} \tag{3}$$

hold in G for $\alpha_{ijk}, \beta_{ijk} \in \mathbb{Z}$ and $l > j$ such that $a_\ell, \ldots, a_m \in G_{n_j+1}$. Now, G is the group with generators $\{a_1, \ldots, a_m\}$ subject to the relation of the the form (2)–(3).

A presentation with relations of the form (2)–(3) for all i resp. i and j is called a *nilpotent presentation*. Indeed, any presentation of this form will define a nilpotent group. It is called *consistent* if the order of a_i modulo $\langle a_{i+1}, \ldots, a_m \rangle$ is precisely e_i for all i. While presentations of this form need not, in general, be consistent, those derived from a central series of a group G as above are consistent. Given a consistent nilpotent presentation, there is an easy way to solve the word problem: simply apply the rules of the form (3) to move all occurrences of $a_1^{\pm 1}$ in the input word to the left, then apply the power relations (2) to reduce their number modulo e_1; finally, continue with a_2 and so on.

Multiplication functions. An crucial feature of the coordinate vectors for nilpotent groups is that the coordinates of a product $(a_1^{\alpha_1} \cdots a_m^{\alpha_m})(a_1^{\beta_1} \cdots a_m^{\beta_m})$ may be computed as a "nice" function (polynomial if $\mathcal{T} = \emptyset$) of the integers $\alpha_1, \ldots, \alpha_m, \beta_1, \ldots, \beta_m$.

▶ **Lemma 2** ([7, 10]). *Let G be a nilpotent group with Mal'cev basis $a_1, \ldots, a_m$ and $\mathcal{T} = \emptyset$. There exist $p_1, \ldots, p_m \in \mathbb{Z}[x_1, \ldots, x_m, y_1, \ldots, y_m]$ and $q_1, \ldots, q_m \in \mathbb{Z}[x_1, \ldots, x_m, z]$ such that for $g, h \in G$ with $\mathrm{Coord}(g) = (\gamma_1, \ldots, \gamma_m)$ and $\mathrm{Coord}(h) = (\delta_1, \ldots, \delta_m)$ and $l \in \mathbb{Z}$ we have*

- **(i)** $\mathrm{Coord}_i(gh) = p_i(\gamma_1, \ldots, \gamma_m, \delta_1, \ldots, \delta_m)$,
- **(ii)** $\mathrm{Coord}_i(g^l) = q_i(\gamma_1, \ldots, \gamma_m, l)$,
- **(iii)** $\mathrm{Coord}_1(gh) = \gamma_1 + \delta_1$ *and* $\mathrm{Coord}_1(g^l) = l\gamma_1$.

Notice that an explicit algorithm to construct the polynomials p_i, q_i is given in [14]. For further background on nilpotent groups we refer to [7, 10].

2 Presentation of subgroups

Before we start with algorithmic problems, we introduce a canonical way how to represent subgroups of nilpotent groups. This is important for two reasons: first, of course we need it to solve the subgroup membership problem, and, second, for the uniform setting it allows us to represent nilpotent groups as free nilpotent group modulo a kernel which is represented as a subgroup. Let $h_1, \ldots, h_n$ be elements of G given in normal form by $h_i = a_1^{\alpha_{i1}} \cdots a_m^{\alpha_{im}}$, for

$i = 1, \ldots, n$, and let $H = \langle h_1, \ldots, h_n \rangle$. We associate the *matrix of coordinates*

$$A = \begin{pmatrix} \alpha_{11} & \cdots & \alpha_{1m} \\ \vdots & \ddots & \vdots \\ \alpha_{n1} & \cdots & \alpha_{nm} \end{pmatrix}, \tag{4}$$

to the tuple $(h_1, \ldots, h_n)$ and conversely, to any $n \times m$ integer matrix, we associate an n-tuple of elements of G, whose Mal'cev coordinates are given as the rows of the matrix, and the subgroup H generated by the tuple. For each $i = 1, \ldots, n$ where row i is non-zero, let π_i be the column of the first non-zero entry ('pivot') in row i. The sequence $(h_1, \ldots, h_n)$ is said to be in *standard form* if the matrix of coordinates A is in row-echelon form and its pivot columns are maximally reduced, more specifically, if A satisfies the following properties:

(i) all rows of A are non-zero (i.e. no h_i is trivial),
(ii) $\pi_1 < \pi_2 < \cdots < \pi_s$ (where s is the number of pivots),
(iii) $\alpha_{i\pi_i} > 0$, for all $i = 1, \ldots, n$,
(iv) $0 \leq \alpha_{k\pi_i} < \alpha_{i\pi_i}$, for all $1 \leq k < i \leq s$
(v) if $\pi_i \in \mathcal{T}$, then $\alpha_{i\pi_i}$ divides e_{π_i}, for $i = 1, \ldots, s$.

The sequence (resp. matrix) is called *full* if in addition

(vi) $H \cap \langle a_i, a_{i+1}, \ldots, a_m \rangle$ is generated by $\{h_j \mid \pi_j \geq i\}$, for all $1 \leq i \leq m$.

Note that $\{h_j \mid \pi_j \geq i\}$ consists of those elements having 0 in their first $i-1$ coordinates. It is an easy exercise (see also [16]) to show that 6 holds for a given i if and only if

- for all $1 \leq k < j \leq s$ with $\pi_k < i$, $h_k^{-1} h_j h_k$ and $h_k h_j h_k^{-1}$ are elements of $\langle\, h_l \mid l > k \,\rangle$, and
- for all $1 \leq k \leq s$ with $\pi_k < i$ and $\pi_k \in \mathcal{T}$, $h_k^{e_{\pi_k}/\alpha_{k\pi_k}} \in \langle\, h_l \mid l > k \,\rangle$.

We will use full sequences and the associated matrices in full form interchangeably without mentioning it explicitly. For simplicity we assume that the inputs of algorithms are given as matrices. The importance of full sequences is described in the following lemma – a proof can be found in [24] Propositions 9.5.2 and 9.5.3.

▶ **Lemma 3** ([16, Lem. 3.1]). *Let $H \leq G$. There is a unique full sequence $U = (h_1, \ldots, h_s)$ that generates H. We have $s \leq m$ and $H = \{h_1^{\beta_1} \cdots h_s^{\beta_s} \mid \beta_i \in \mathbb{Z}$ and $0 \leq \beta_i < e_{\pi_i}$ if $\pi_i \in \mathcal{T}\}$.*

Thus, computing a full sequence will be the essential tool for solving the subgroup membership problem. Before we focus on subgroup membership, we will first solve the word problem and introduce how the nilpotent group can be part of the input.

Quotient Mal'cev presentations. Let $c, r \in \mathbb{N}$ be fixed. The free nilpotent group $F_{c,r}$ of class c and rank r is defined as $F_{c,r} = \langle\, a_1, \ldots, a_r \mid [x_1, \ldots, x_{c+1}] = 1 \text{ for } x_1, \ldots, x_{c+1} \in F_{c,r} \,\rangle$ where $[x_1, \ldots, x_{c+1}] = [[x_1, \ldots, x_c], x_{c+1}]$, i. e., $F_{c,r}$ is the r-generated group only subject to the relations that weight $c+1$ commutators are trivial. Throughout, we fix a Mal'cev basis $A = (a_1, \ldots, a_m)$ (which we call the *standard Mal'cev basis*) associated to the lower central series of $F_{c,r}$ such that the associated nilpotent presentation consists only of relations of the form (3) (i. e., $\mathcal{T} = \emptyset$ – such a presentation exists since $F_{c,r}$ is torsion-free), $a_1, \ldots, a_r$ generates $F_{c,r}$, and all other Mal'cev generators are iterated commutators of $a_1, \ldots, a_r$.

Denote by $\mathcal{N}_{c,r}$ the set of r-generated nilpotent groups of class at most c. Every group $G \in \mathcal{N}_{c,r}$ is a quotient of the free nilpotent group $F_{c,r}$, i. e., $G = F_{c,r}/N$ for some normal subgroup $N \leq F_{c,r}$. Assume that $T = (h_1, \ldots, h_s)$ is a full sequence generating N. Adding T to the set of relators of the free nilpotent group yields a new nilpotent presentation. This presentation will be called *quotient presentation* of G. For inputs of algorithms, we assume that a quotient presentation is always given as its matrix of coordinates in full form.

Depending whether the entries of the matrix are encoded in unary or binary, we call the quotient presentation be given in *unary* or *binary*.

▶ **Lemma 4** ([16, Prop. 5.1]). *Let c and r be fixed integers and let $A = (a_1, \dots, a_m)$ be the standard Mal'cev basis of $F_{c,r}$. Moreover, denote by S the set of relators of $F_{c,r}$ with respect to A. Let $G \in \mathcal{N}_{c,r}$ with $G = F_{c,r}/N$ and let T be the full-form sequence for the subgroup N of $F_{c,r}$. Then, $\langle A \mid S \cup T \rangle$ is a consistent nilpotent presentation of G.*

For a proof of Lemma 4 see [21]. For the following we always assume that a quotient presentation is part of the input, but c and r are fixed. Later, we will show how to compute quotient presentations from an arbitrary presentation.

▶ Remark. Lemma 4 ensures that each group element has a unique normal form with respect to the quotient presentation; thus, it guarantees that all our manipulations of Mal'cev coordinates are well-defined.

3 Word problem and computation of Mal'cev coordinates

In this section we deal with the word problem of nilpotent groups, which is well-known to be in TC^0 [23]. Here, we generalize this result by allowing words with binary exponents (recall that *word with binary exponents* is a sequence $w = w_1^{x_1} \cdots w_n^{x_n}$ where $w_i \in \{a_1, \dots, a_m\}$ and the $x_i \in \mathbb{Z}$). By using words with binary exponents the input can be compressed exponentially – making the word problem, a priori, harder to solve. Nevertheless, it turns out that the word problem still can be solved in TC^0 when allowing the input to be given as a word with binary exponents. Note that this contrasts with the situation where the input is given as straight-line program (which like words with binary exponents allow an exponential compression) – then the word problem is complete for the counting class $\mathsf{C_=L}$ [12].

▶ **Theorem 5.** *Let $c, r \geq 1$ be fixed and let $(a_1, \dots, a_m)$ be the standard Mal'cev basis of $F_{c,r}$. The following problem is TC^0-complete: on input of $G \in \mathcal{N}_{c,r}$ given as a binary encoded quotient presentation and a word with binary exponents $w = w_1^{x_1} \cdots w_n^{x_n}$, compute integers $y_1, \dots, y_m$ (in binary) such that $w = a_1^{y_1} \cdots a_m^{y_m}$ in G and $0 \leq y_i < e_i$ for $i \in \mathcal{T}$. Moreover, if the input is given in unary (both G and w), then the output is in unary.*

Note that the statement for unary inputs is essentially the one of [23]. Be aware that in the formulation of the theorem, $\mathcal{T}$ and e_i for $i \in \mathcal{T}$ depend on the input group G. These parameters can be read from the full matrix of coordinates representing G (recall that π_i denotes the column index of the i-th pivot): $\mathcal{T} = \{\pi_i \mid i \in \{1, \dots, n\}\}$ (all columns which have a pivot) and $e_i = \alpha_{ji}$ if $\pi_j = i$. As an immediate consequence of Theorem 5, we obtain:

▶ **Corollary 6.** *Let $c, r \geq 1$ be fixed. The uniform, binary version of the word problem for groups in $\mathcal{N}_{c,r}$ is TC^0-complete (where the input is given as in Theorem 5).*

The proof of Theorem 5 follows the outline given in Section 1.2; however, we cannot apply the rules (2)–(3) one by one. Instead we do only two steps for each generator: first apply all possible rules (3) in one step and then apply the rules (2) in one step.

Proof of Theorem 5. The hardness part is clear since already the word problem of $\mathbb{Z}$ is TC^0-complete. For describing a TC^0 circuit, we proceed by induction along the standard Mal'cev basis $(a_1, \dots, a_m)$ of the free nilpotent group $F_{c,r}$. If w does not contain any letter a_1, we have $y_1 = 0$ and we can compute y_i for $i > 1$ by induction.

Otherwise, we rewrite w as $a_1^{y_1}uv$ (with $0 \leq y_1 < e_1$ if $1 \in \mathcal{T}$) such that u and v are words with binary exponents not containing any a_1s. Once this is completed, uv can be rewritten as $a_2^{y_2} \cdots a_m^{y_m}$ by induction. For computing y_1, u and v, we proceed in two steps:

First, we rewrite w as $a_1^{\tilde{y}_1}v$ with $\tilde{y}_1 = \sum_{w_i=a_1} x_i$ (this is possible by Lemma 2 (iii)). The exponent $\tilde{y}_1$ can be computed by iterated addition, which by Theorem 1 is in TC^0 (in the unary case $\tilde{y}_1$ can be written down in unary). Now, v consists of what remains from w after a_1 has been "eliminated": for every position i in w with $w_i \neq a_1$, we compute $z_i = \sum_{w_j=a_1}^{j>i} x_j$ using iterated addition. Let $w_i = a_k$. By Lemma 2 (i) there are fixed polynomials $p_{k,k+1}, \ldots, p_{k,m} \in \mathbb{Z}[x,y]$ such that in the free nilpotent group holds $a_k^x a_1^y = a_1^y a_k^x a_{k+1}^{p_{k,k+1}(x,y)} \cdots a_m^{p_{k,m}(x,y)}$ for all $x, y \in \mathbb{Z}$. Hence, in order to obtain $\tilde{w}$, it remains to replace every $w_i^{x_i}$ with $w_i = a_1$ by the empty word and every $w_i^{x_i}$ with $w_i = a_k \neq a_1$ by $a_k^{x_i} a_{k+1}^{p_{k,k+1}(x_i,z_i)} \cdots a_m^{p_{k,m}(x_i,z_i)}$, which is a word with binary exponents (resp. as a word of polynomial length in the unary case), for $k = 2, \ldots, m$. The exponents can be computed in TC^0 by Theorem 1. Since the $p_{k,i}$ are bounded by polynomials, in the unary case, $a_k^{x_i} a_{k+1}^{p_{k,k+1}(x_i,z_i)} \cdots a_m^{p_{k,m}(x_i,z_i)}$ can be written as a word without exponents.

The second step is only applied if $1 \in \mathcal{T}$ (as explained above, this can be decided and e_i can be read directly from the quotient presentation by checking whether there is a pivot in the first column) – otherwise $y_1 = \tilde{y}_1$ and u is the empty word. We rewrite $a_1^{\tilde{y}_1}$ to $a_1^{y_1}u$ with $y_1 = \tilde{y}_1 \bmod e_1$ and a word with binary exponents u not containing any a_1. Again y_1 can be computed in TC^0 by Theorem 1. Let $a_1^{e_1} = a_2^{\mu_{12}} \cdots a_m^{\mu_{1m}}$ be the power relation for a_1 (which can be read from the quotient presentation – it is just the row where the pivot is in the first column) and write $\tilde{y}_1 = s \cdot e_1 + y_1$. Now, u should be equal to $(a_2^{\mu_{12}} \cdots a_m^{\mu_{1m}})^s$ in $F_{c,r}$. We use the fixed polynomials $q_i \in \mathbb{Z}[x_1, \ldots, x_m, z]$ from Lemma 2 (ii) for $F_{c,r}$ yielding $u = a_2^{q_2(0,\mu_{12},\ldots,\mu_{1m},s)} \cdots a_m^{q_m(0,\mu_{12},\ldots,\mu_{1m},s)}$ (which, in the binary setting, is a word with binary exponents, and in the unary setting a word without exponents of polynomial length). Now, we have $w = a_1^{y_1}uv$ in G as desired. ◀

4 Matrix reduction and subgroup membership problem

Before we solve the subgroup membership problem, let us take a look at one essential step, namely the problem of computing greatest common divisors. Indeed, consider the nilpotent group $\mathbb{Z}$ and let $a, b, c \in \mathbb{Z}$. Then $c \in \langle a, b \rangle$ if, and only if, $\gcd(a, b) \mid c$.

Binary gcds. The *extended gcd problem* (ExtGCD) is the following problem: on input of binary encoded numbers $a_1, \ldots, a_n \in \mathbb{Z}$, compute $x_1, \ldots, x_n \in \mathbb{Z}$ such that $x_1a_1 + \cdots + x_na_n = \gcd(a_1, \ldots, a_n)$. Clearly this can be done in P using the Euclidean algorithm, but it is not known whether it is actually in NC. Since we need to compute greatest common divisors, we will reduce the subgroup membership problem to the computation of gcds.

Unary gcds. Computing the gcd of numbers encoded in unary is straightforward in TC^0 by an exhaustive search. Also, for just two numbers $a, b \in \mathbb{Z}$ the gcd easily can be expressed as a linear combination in TC^0: there are $x, y \leq \max\{|a|, |b|\}$ such that $ax + by = \gcd(a, b)$. Now, x, y can be computed in TC^0 by simply checking all values with $|x|, |y| \leq \max\{|a|, |b|\}$. Similarly, there are $x_1, \ldots, x_n \leq |\max\{|a_1|, \ldots, |a_n|\}|$ with $x_1a_1 + \cdots + x_na_n = \gcd(a_1, \ldots, a_n)$. However, for computing these x_i, we cannot check all possible combinations of values in TC^0 because there are $|\max\{|a_1|, \ldots, |a_n|\}|^n$ (i. e., exponentially) many. Expressing the gcd as a linear combination can be viewed as a linear equation with integral coefficients. Recently, in [5, Thm. 3.14] it has been shown that, if all the coefficients are given in unary, it can be

decided in TC^0 whether such an equation or a system of a fixed number of equations has a solution. Since from the proof of [5, Thm. 3.14] it is not obvious how to find an actual solution, we prove the following result in our full version on arXiv [21]:

▶ **Proposition 7.** *The following problem is in TC^0: Given integers $a_1, \dots, a_n$ in unary, compute $x_1, \dots, x_n \in \mathbb{Z}$ (either in unary or binary) such that $x_1a_1 + \cdots + x_na_n = \gcd(a_1, \dots, a_n)$ and $|x_i| \leq (n+1)\left(\max\{|a_1|, \dots, |a_n|\}\right)^2$.*

Matrix reduction. The matrix reduction procedure converts an arbitrary matrix of coordinates into its full form and, thus, is an essential step for solving the subgroup membership problem and several other problems. It was first described in [24] – however, without a precise complexity estimate. In this section, we repeat the presentation from [16] and show that for fixed c and r, it can be actually computed uniformly for groups in $\mathcal{N}_{c,r}$ in TC^0 – in the case that the inputs are given in unary (as words). If the inputs are represented as words with binary exponents, then we still can show that it is TC^0-Turing-reducible to ExtGCD. In Section 2, we defined the matrix representation of subgroups of nilpotent groups. We adopt all notation from Section 2.

As before, let $c, r \in \mathbb{N}$ be fixed and let $(a_1, \dots, a_m)$ be the standard Mal'cev basis of $F_{c,r}$. Let $G \in \mathcal{N}_{c,r}$ be given as quotient presentation, i. e., as a matrix in full form (either with unary or binary coefficients). We define the following operations on tuples $(h_1, \dots, h_n)$ (our subgroup generators) of elements of G and the corresponding operations on the associated matrix, with the goal of converting $(h_1, \dots, h_n)$ to a sequence in full form generating the same subgroup $H = \langle h_1, \dots, h_n \rangle$:

1. Swap h_i with h_j. This corresponds to swapping row i with row j.
2. Replace h_i by $h_i h_j^l$ ($i \neq j$, $l \in \mathbb{Z}$). This corresponds to replacing row i by $\mathrm{Coord}(h_i h_j^l)$.
3. Add or remove a trivial element from the tuple. This corresponds to adding or removing a row of zeros; or (3') a row of the form $(0 \ \dots \ 0 \ e_i \ \alpha_{i+1} \ \dots \ \alpha_m)$, where $i \in \mathcal{T}$ and $a_i^{-e_i} = a_{i+1}^{\alpha_{i+1}} \cdots a_m^{\alpha_m}$.
4. Replace h_i with h_i^{-1}. This corresponds to replacing row i by $\mathrm{Coord}(h_i^{-1})$.
5. Append an arbitrary product $h_{i_1}^{l_1} \cdots h_{i_k}^{l_k}$ with $i_1, \dots, i_k \in \{1, \dots, n\}$ and $l_1, \dots, l_k \in \mathbb{Z}$ to the tuple: add a new row with $\mathrm{Coord}(h_{i_1}^{l_1} \cdots h_{i_k}^{l_k})$.

Clearly, all these operations preserve H.

▶ **Lemma 8.** *On input of a quotient presentation of $G \in \mathcal{N}_{c,r}$ in unary (resp. binary) and a matrix of coordinates A given in unary (resp. binary), operations (1)–(5) can be done in TC^0. The output matrix will be also encoded in unary (resp. binary). For operations (2) and (5), we require that the exponents l, $l_1, \dots, l_k$ are given in unary (resp. binary).*

Moreover, as long as the rows in the matrix which are changed are pairwise distinct, a polynomial number of such steps can be done in parallel in TC^0.

Proof. Operations (1) and (3), clearly can be done in TC^0. Notice that operation (3') means simply that a row of the quotient presentation of G is appended to the matrix.

In the unary case, it follows directly from Theorem 5 that operations (2), (4), and (5) are in TC^0 because, since l, $l_1, \dots, l_k$ are given in unary, the respective group elements can be written down as words.

In the case of binary inputs, (5) works as follows ((2) and (4) analogously): by Lemma 2 (ii), there are functions $q_1, \dots, q_m \in \mathbb{Z}[x_1, \dots, x_m, z]$ such that for every $h \in F_{c,r}$ with $\mathrm{Coord}(h) = (\gamma_1, \dots, \gamma_m)$ anda $l \in \mathbb{Z}$, we have $\mathrm{Coord}_i(h^l) = q_i(\gamma_1, \dots, \gamma_m, l)$ in $F_{c,r}$. These functions can be used to compute $\mathrm{Coord}(h_{i_j}^{l_j})$ for $j = 1, \dots, k$. After that, $h_{i_1}^{l_1} \cdots h_{i_k}^{l_k}$ can be written down as word with binary exponents and Theorem 5 can be applied. ◀

Using the row operations defined above, in [16] it is shown how to reduce any coordinate matrix to its unique full form. Let us repeat these steps:

Let A_0 be a matrix of coordinates, as in (4) in Section 2. Recall that π_k denotes the column index of the k-th pivot (of the full form of A_0). We produce matrices $A_1, \ldots, A_s$, where s is the number of pivots in the full form of A_0, such that for every $k = 1, \ldots, s$ the first π_k columns of A_k form a matrix satisfying conditions 2-5 of being a full sequence, condition 6 is satisfied for all $i < \pi_{k+1}$, and A_s is the full form of A_0. Here we formally denote $\pi_{s+1} = m + 1$. Set $\pi_0 = 0$ and assume that A_{k-1} has been constructed for some $k \geq 1$. In the steps below we construct A_k. We let n and m denote the number of rows and columns, respectively, of A_{k-1}. At all times during the computation, h_i denotes the group element corresponding to row i of A_k and α_{ij} denotes the (i,j)-entry of A_k, which is $\mathrm{Coord}_j(h_i)$. These may change after every operation.

Step 1. Locate the column π_k of the next pivot, which is the minimum integer $\pi_{k-1} < \pi_k \leq m$ such that $\alpha_{i\pi_k} \neq 0$ for at least one $k \leq i \leq n$. If no such integer exists, then $k-1 = s$ and A_s is already constructed. Otherwise, set A_k to be a copy of A_{k-1} and denote $\pi = \pi_k$. Compute a linear expression of $d = \gcd(\alpha_{k\pi}, \ldots, \alpha_{n\pi}) = l_k\alpha_{k\pi} + \cdots + l_n\alpha_{n\pi}$. Let $h_{n+1} = h_k^{l_k} \cdots h_n^{l_n}$ and note that h_{n+1} has coordinates of the form $\mathrm{Coord}(h_{n+1}) = (0, \ldots, 0, d, \ldots)$ with d occurring in position π. Perform operation 5 to append h_{n+1} as row $n+1$ of A_k.

Step 2. For each $i = k, \ldots, n$, perform operation 2 to replace row i by $\mathrm{Coord}(h_i \cdot h_{n+1}^{-\alpha_{i\pi}/d})$. and for each $i = 1, \ldots, k-1$, use 2 to replace row i by $\mathrm{Coord}(h_i \cdot h_{n+1}^{-\lfloor \alpha_{i\pi}/d \rfloor})$. After that, swap row k with row $n+1$ using 1. At this point, properties 2-4 hold on the first k columns of A_k.

Step 3. If $\pi \in \mathcal{T}$, we additionally ensure condition 5 as follows. Perform row operation (3'), with respect to π, to append a trivial element h_{n+2} with $\mathrm{Coord}(h_{n+2}) = (0, \ldots, 0, e_\pi, \ldots)$ to A_k. Let $\delta = \gcd(d, e_\pi)$ and compute the linear expression $\delta = n_1 d + n_2 e_\pi$, with $|n_1|, |n_2| \leq \max\{d, e_\pi\}$. Let $h_{n+3} = h_k^{n_1} h_{n+2}^{n_2}$ and append this row to A_k, as row $n+3$. Note that $\mathrm{Coord}(h_{n+3}) = (0, \ldots, 0, \delta, \ldots)$, with δ in position π. Replace row k by $\mathrm{Coord}(h_k \cdot h_{n+3}^{-d/\delta})$ and row $n+2$ by $\mathrm{Coord}(h_{n+2} \cdot h_{n+3}^{-e_\pi/\delta})$, producing zeros in column π in these rows. Swap row k with row $n+3$. At this point, 2, 3, and 5 hold (for the first π_k columns) but 4 need not, since the pivot entry is now δ instead of d. For each $j = 1, \ldots, k-1$, replace row j by $\mathrm{Coord}(h_j \cdot h_k^{-\lfloor \alpha_{j\pi}/\delta \rfloor})$, ensuring 4.

Step 4. Identify the next pivot π_{k+1} (like in Step 1). If π_k is the last pivot, we set $\pi_{k+1} = m+1$. We now ensure condition 6 for $i < \pi_{k+1}$. Observe that Steps 1-3 preserve $\langle\, h_j \mid \pi_j \geq i \,\rangle$ for all $i < \pi_k$. Hence 6 holds in A_k for $i < \pi_k$ since it holds in A_{k-1} for the same range. Now consider i in the range $\pi_k \leq i < \pi_{k+1}$. It suffices to establish (vi.i) for all $j > k$ and (vi.ii) for π_k only. To obtain (vi.i), notice that $h_k^{-1} h_j h_k, h_k h_j h_k^{-1} \in \langle\, h_\ell \mid \ell > k \,\rangle$ if, and only if, $[h_j, h_k^{\pm 1}] \in \langle\, h_\ell \mid \ell > k \,\rangle$. Further, note that the subgroup generated by $S_j = \{1, h_j, [h_j, h_k], \ldots, [h_j, h_k, \ldots, h_k]\}$, where h_k appears $m - \pi_k$ times in the last commutator, is closed under commutation with h_k since if h_k appears more than $m - \pi_k$ times then the commutator is trivial. An inductive argument shows that the subgroup $\langle S_j \rangle$ coincides with $\langle h_k^{-\ell} h_j h_k^{\ell} \mid 0 \leq \ell \leq m - \pi_k \rangle$. Similar observations can be made for conjugation by h_k^{-1}. Therefore, appending via operation 5 rows $\mathrm{Coord}(h_k^{-\ell} h_j h_k^{\ell})$ for all $1 \leq |\ell| \leq m - \pi_k$ and all $k < j \leq n+3$ delivers (vi.i) for all $j > k$. Note that (vi.i) remains true for $i < \pi_k$.

To obtain (vi.ii), in the case $\pi_k \in \mathcal{T}$, we add row $\mathrm{Coord}(h_k^{e_k/\alpha_{k\pi_k}})$. Note that this element commutes with h_k and therefore (vi.i) is preserved.

Step 5. Using operation 3, eliminate all zero rows. The matrix A_k is now constructed.

We have to show that each step can be performed in TC^0 given that all Mal'cev coordinates

are encoded in unary (resp. in $\mathsf{TC}^0(\text{ExtGCD})$ if Mal'cev coordinates are encoded in binary). Since the total number of steps is constant (only depending on the nilpotency class and number of generators), this gives a TC^0 (resp. $\mathsf{TC}^0(\text{ExtGCD})$) circuit for computing the full form of a given subgroup.

Step 1. The next pivot can be found in TC^0 since it is simply the next column in the matrix with a non-zero entry, which can be found as a simple Boolean combination of test whether the entries are zero. In the unary case, by Proposition 7, $d = \gcd(\alpha_{k\pi}, \dots, \alpha_{n\pi})$ can computed in TC^0 together with $l_k, \dots, l_n$ encoded in unary such that $d = l_k\alpha_{k\pi} + \dots + l_n\alpha_{n\pi}$. Now, by Lemma 8, Step 1 can be done in TC^0.

In the binary case, d and $l_k, \dots, l_n$ can be computed using ExtGCD. Hence, by Lemma 8, Step 1 can be done in $\mathsf{TC}^0(\text{ExtGCD})$.

Step 2. The numbers $\lfloor \alpha_{i\pi}/d \rfloor$ (either in unary or binary) can be computed in TC^0 for all i in parallel by Theorem 1. After that one operation (2) is applied to each row of the matrix. By Lemma 8, this can be done in parallel for all rows in TC^0. Finally, swapping rows k and $n+1$ can be done in TC^0.

Step 3. As explained in Section 3, $\mathcal{T}$ and e_i for $i \in \mathcal{T}$ can be read directly from the quotient presentation. Thus, it can be decided in TC^0 whether Step 3 has to be executed. Appending a new row is in TC^0. Computing $\gcd(d, e_\pi) = d = n_1 d n_2 e_\pi$ is in TC^0 by Proposition 7 (in the unary case) and in $\mathsf{TC}^0(\text{ExtGCD})$ in the binary case. After that one operation (5) is followed by two operations (2), one operation (1), and, finally, $k-1$ times operation (2), which all can be done in TC^0 again by Lemma 8.

Step 4. The next pivot can be found in TC^0 as outlined in Step 1. After that, Step 4 consists of an application of a constant number (only depending on the nilpotency class and number of generators) of operations (5) and thus, by Lemma 8, is in TC^0.

Step 5. Clearly that is in TC^0.

Thus, we have completed the proof of our main result:

▶ **Theorem 9.** *Let $c, r \in \mathbb{N}$ be fixed. The following problem is in TC^0: given a unary encoded quotient presentation of $G \in \mathcal{N}_{c,r}$ and $h_1, \dots, h_n \in G$, compute the full form of the associated matrix of coordinates encoded in unary and hence the unique full-form sequence $(g_1, \dots, g_s)$ generating $\langle h_1, \dots, h_n \rangle$. Moreover, if the G and $h_1, \dots, h_n$ are given in binary, then the full-form sequence with binary coefficients can be computed in $\mathsf{TC}^0(\text{ExtGCD})$.*

Subgroup membership problem. As an easy application of the matrix reduction we can solve the subgroup membership problem in TC^0 – for a proof details see [21].

▶ **Corollary 10.** *Let $c, r \in \mathbb{N}$ be fixed. The following problem is in TC^0 (resp. $\mathsf{TC}^0(\text{ExtGCD})$ for binary inputs): given a quotient presentation of $G \in \mathcal{N}_{c,r}$, elements $h_1, \dots, h_n \in G$ and $h \in G$, decide whether or not h is an element of the subgroup $H = \langle h_1, \dots, h_n \rangle$.*

Moreover, if $h \in H$, the circuit computes the unique expression $h = g_1^{\gamma_1} \cdots g_s^{\gamma_s}$ where $(g_1, \dots, g_s)$ is the full-form sequence for H with the γ_i encoded in unary (resp. binary).

Alternatively, for unary inputs, the output can be given as word $h = h_{i_1}^{\epsilon_1} \cdots h_{i_t}^{\epsilon_t}$ where $i_j \in \{1, \dots, n\}$ and $\epsilon_j = \pm 1$.

Note that we do not know whether there is an analog of the second type of output for binary inputs. A possible way of expressing the output would be as a word with binary exponents over $h_1, \dots, h_n$. However, simply applying the same procedure as for unary inputs will not lead to a word with binary exponents.

Subgroup presentations. The full-form sequence associated to a subgroup H forms a Mal'cev basis for H. This allows us to compute a consistent nilpotent presentation for H. Note, however, that the resulting presentation is *not* a quotient presentation (although it can be transformed into one, see Proposition 14) – partly this is due to the fact that, in general, $H \notin \mathcal{N}_{c,r}$. The following is the TC^0 version of [16, Thm. 3.11]:

▶ **Corollary 11.** *Let $c, r \in \mathbb{N}$ be fixed. The following is in TC^0 for unary inputs and in $\mathsf{TC}^0(\text{ExtGCD})$ for binary inputs:*

Input: *a quotient presentation for $G \in \mathcal{N}_{c,r}$ and elements $h_1, \dots, h_n \in G$.*

Output: *a consistent nilpotent presentation for $H = \langle h_1, \dots, h_n \rangle$ given by a list of generators $(g_1, \dots, g_s)$ and numbers $\mu_{ij}, \alpha_{ijk}, \beta_{ijk} \in \mathbb{Z}$ encoded in unary (resp. binary) for $1 \le i < j < k \le s$ representing the relations (2)-(3).*

5 More algorithmic problems

The next two theorems are applications of Theorem 9. Their proofs (in [21]) follow essentially the proofs of their counterparts Theorems 4.1 and 4.6 in [16].

▶ **Theorem 12** (Kernels and preimages)**.** *Let $c, r \in \mathbb{N}$ be fixed. The following is in TC^0 for unary inputs and in $\mathsf{TC}^0(\text{ExtGCD})$ for binary inputs: On input of*

- *$G, H \in \mathcal{N}_{c,r}$ given as quotient presentations,*
- *a subgroup $K = \langle g_1, \dots, g_n \rangle \le G$,*
- *a list of elements $h_1, \dots, h_n$ defining a homomorphism $\varphi : K \to H$ via $\varphi(g_i) = h_i$, and*
- *optionally, an element $h \in H$ guaranteed to be in the image of φ,*

compute a generating set X for the kernel of φ, and an element $g \in G$ such that $\varphi(g) = h$.

In case of unary inputs, X and g will be returned as words, and for binary inputs, as words with binary exponents.

▶ **Theorem 13** (Conjugacy Problem)**.** *Let $c, r \in \mathbb{N}$ be fixed. The following is in TC^0 for unary inputs and in $\mathsf{TC}^0(\text{ExtGCD})$ for binary inputs: On input of some $G \in \mathcal{N}_{c,r}$ given as quotient presentation and elements $g, h \in G$, either produce some $u \in G$ such that $g = u^{-1}hu$, or determine that no such element u exists. In case of unary inputs, u will be returned as a word, for binary inputs, as a word with binary exponents.*

Computing quotient presentations. The results in the previous sections always required that the group is given as a quotient presentation. However, we can use Theorem 9 to transform an arbitrary presentation with at most r generators of a group in $\mathcal{N}_{c,r}$ into a quotient presentation. For a proof see [21].

▶ **Proposition 14.** *Let c and r be fixed integers. The following is in TC^0: given an arbitrary finite presentation with generators $a_1, \dots, a_r$ of a group $G \in \mathcal{N}_{c,r}$ (as a list of relators given as words over $\{a_1, \dots, a_r\}^{\pm 1}$), compute a quotient presentation of G (encoded in unary) and an explicit isomorphism. Moreover, if the relators are given as words with binary exponents, then the binary encoded quotient presentation can be computed in $\mathsf{TC}^0(\text{ExtGCD})$.*

▶ Remark. Because of Proposition 14, in all theorems above where the input is a quotient presentation, we can also take an arbitrary r-generated presentation of a group in $\mathcal{N}_{c,r}$ as input. However, be aware that for the word problem (Theorem 5 and Corollary 6) the complexity changes from TC^0 to $\mathsf{TC}^0(\text{ExtGCD})$ in the binary case.

Conclusion and Open Problems. We have seen that most problems which in [16] were shown to be in LOGSPACE indeed are in TC^0 even in the uniform setting where the number of generators and nilpotency class is fixed. Moreover, their binary versions are in $\mathsf{TC}^0(\text{ExtGCD})$ meaning that nilpotent groups are no more complicated than abelian groups in many algorithmic aspects. This contrasts with the slightly larger class of polycyclic groups: there the word problem is still in TC^0 [23, 12], but the conjugacy problem is not even known to be in NP. We conclude with some possible generalizations of our results:

- Does a uniform version of Theorem 5 hold (i. e., is the uniform word problem still in TC^0) for fixed nilpotency class but an arbitrary number of generators? What happens to the complexity if also the nilpotency class is part of the input? Note that in that case it is even not clear whether the word problem is still in polynomial time.
- Is there a way to solve the conjugacy problem for nilpotent groups with binary exponents in TC^0? Notice that we needed to compute gcds to solve the subgroup membership problem. However, the conjugacy problem might be solved using another method.
- What is the complexity of the uniform conjugacy problem with arbitrary nilpotency class?

Abstract

Cost register automata (CRAs) are one-way finite automata whose transitions have the side effect that a register is set to the result of applying a state-dependent semiring operation to a pair of registers. Here it is shown that CRAs over the tropical semiring $(\mathbb{N} \cup \{\infty\}, \min, +)$ can simulate polynomial time computation, proving along the way that a naturally defined width-k circuit value problem over the tropical semiring is P-complete. Then the copyless variant of the CRA, requiring that semiring operations be applied to distinct registers, is shown no more powerful than NC^1 when the semiring is $(\mathbb{Z}, +, \times)$ or $(\Gamma^* \cup \{\perp\}, \max, \text{concat})$. This relates questions left open in recent work on the complexity of CRA-computable functions to long-standing class separation conjectures in complexity theory, such as NC versus P and NC^1 versus GapNC^1.

1 Introduction

A weighted finite automaton on a given input computes the sum, over every computation path, of the product, over the transitions encountered along that path, of the semiring elements assigned to those transitions. Weighted automata have a long history and extensive theoretical support (see [17]) but their utility for the purpose of computer-aided verification is limited. This motivated Alur and his co-authors to introduce the streaming string transducer [3], soon followed by the cost register automaton (CRA) [5].

CRAs are deterministic and are yet strictly more expressive than weighted automata [5]. A CRA computes a so-called *regular function* from strings to a cost domain. (This should not be confused with Colcombet's regular cost functions, which are intended to capture asymptotic behavior [13].) A "copyless" variant (CCRA) of the CRA has the expressivity of single-valued weighted automata [5, Thm 4]. Another variant of CRAs restricts the multiplicative operation, by only allowing multiplication by constants; this model has the full expressivity of weighted automata [5, Thm 9]. A theory of CRAs, largely concerned with expressivity and decidability properties, was developed in a series of papers, including [5, 7, 6].

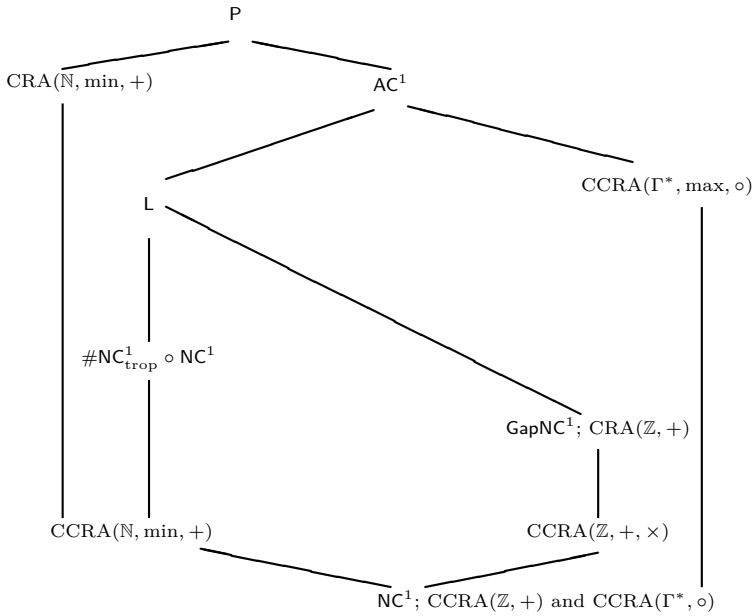

Figure 1 Prior state of knowledge, from [1]. When a class of CRA functions and a complexity class appear together, it means that containment of the CRA class in the complexity class is tight, since some of the CRA functions are complete for the complexity class. (Definitions of the complexity classes can be found in Section 2.)

None of the above work considered the computational complexity of the functions expressed by CRAs. Yet the CRA model is interesting from that viewpoint because it combines a parallelizable component (logarithmic depth boolean circuits indeed recognize regular languages) with a less structured component that builds and evaluates expressions over the cost domain. The three variants of the CRA discussed above (CRAs, CCRAs, and CRAs with restricted multiplication) in fact are reminiscent of three variants of algebraic circuits (general, tree-like, and skew). This raises the question of whether CRA variants over various domains capture interesting complexity classes, such as the (functional) class P and subclasses of NC. These considerations prompted Allender and Mertz to develop complexity bounds for the functions computable by CRAs and CCRAs [1]. This line of inquiry for various models was also pursued and extended in [22, 25, 24, 16, 15, 12].

The main results obtained by Allender and Mertz are depicted on Figure 1. Most results involve the (weaker) CCRA model with integer arithmetic, but also with "tropical" arithmetic, that is, over domains such as $(\mathbb{N} \cup \{infty\}, \min, +)$ and $(\Gamma^*, \max, \circ)$. We note that tropical semirings arise frequently in the study of weighted automata (see for instance [14, Sect. 1.1] and [5, Thm 9]). Computationally, min and max are "forgetful" operations that should intuitively lend themselves to simpler simulations.

Our contribution here is to improve some of the bounds from [1]. In particular, the closing section of [1] listed the following four open questions:

- Are there any CCRA functions over $(\mathbb{Z}, +, \times)$ that are complete for GapNC^1?
- Are there any CCRA functions over the tropical semiring that are hard for $\#\mathsf{NC}^1_{\text{trop}}$?
- The gap between the upper and lower bounds for CCRA functions over $(\Gamma^*, \max, \circ)$ is quite large (NC^1 versus $\mathsf{OptLogCFL} \subseteq \mathsf{AC}^1$). Can this be improved?
- Is there an NC upper bound for CRA functions (without the copyless restriction) over the tropical semiring?

We essentially answer all of these questions, modulo long-standing open questions in complexity theory. We show that CCRA functions over each of $(\mathbb{Z}, +, \times)$, $(\Gamma^*, \max, \circ)$, and the tropical semiring are all computable in NC^1. We thus give the improvement asked for in the third question, and we show that the answers to the first two questions are equivalent to $\mathsf{NC}^1 = \mathsf{GapNC}^1$ and $\mathsf{NC}^1 = \#\mathsf{NC}^1_{\text{trop}}$, respectively. We also provide a negative answer to the fourth question (assuming $\mathsf{NC} \neq \mathsf{P}$), by reducing a P-complete problem to the computation of a CRA function over the tropical semiring. It follows from the latter that for any k larger than a small constant, the width-k circuit value problem over structures such as $(\mathbb{N}, \max, +)$ and $(\mathbb{N}, \min, +)$ is P-complete under AC^0-Turing reductions. (See Section 2 for the precise definition of the problem and then Corollary 5.) Figure 2 summarizes our results.

2 Preliminaries

We assume familiarity with some common complexity classes and with basic notions of circuit complexity, such as can be found in any textbook on complexity theory.

Recall that a language $A \subseteq \{0,1\}^*$ is accepted by a Boolean circuit family $(C_n)_{\in\mathbb{N}}$ if for all x it holds that $x \in A$ iff $C_{|x|}(x) = 1$. Circuit families encountered in this paper will be *uniform*. Uniformity is a somewhat technical issue because of subtleties encountered at low complexity levels. We will not be concerned with such subtleties, and thus we refer the reader to a standard text (such as [29, Sect. 4.5]) for a precise definition of what it means for a circuit family $(C_n)_{n\geq 0}$ to be U_E-uniform. (Informally, this notion of uniformity means that there is a linear-time machine that takes inputs of the form (n, g, h, p) and determines if p encodes a path from gate h to gate g in C_n, and also determines what type of gate g and h are.) We will encounter the following circuit complexity classes.

- $\mathsf{NC}^i = \{A : A$ is accepted by a U_E-uniform family of circuits of bounded fan-in AND, OR and NOT gates, having size $n^{O(1)}$ and depth $O(\log^i n)\}$.
- $\mathsf{AC}^i = \{A : A$ is accepted by a U_E-uniform family of circuits of unbounded fan-in AND, OR and NOT gates, having size $n^{O(1)}$ and depth $O(\log^i n)\}$.
- $\mathsf{TC}^i = \{A : A$ is accepted by a U_E-uniform family of circuits of unbounded fan-in MAJORITY gates, having size $n^{O(1)}$ and depth $O(\log^i n)\}$.

We remark that, for constant-depth classes such as AC^0 and TC^0, U_E-uniformity coincides with U_D-uniformity, which is also frequently called DLOGTIME-uniformity. (Again, we refer the reader to [29] for more details on uniformity.)

Following the standard convention, we also use these same names to refer to the associated classes of *functions* computed by the corresponding classes of circuits. For instance, a function $f : \{0,1\}^* \to \{0,1\}^*$ is said to be in NC^1 if there is U_E-uniform family of circuits $\{C_n\}$ of bounded fan-in AND, OR and NOT gates, having size $n^{O(1)}$ and depth $O(\log n)$, where C_n has several output gates, and on input x of length n, C_n outputs an encoding of $f(x)$. (We say that an "encoding" of the output is produced, to allow the possibility that there are strings x and y of length n, such that $f(x)$ and $f(y)$ have different lengths.) It is easy to observe that, if the length of $f(x)$ is polynomial in $|x|$, then f is in NC^1 if and only if the language $\{(x, i, b) :$ the i-th symbol of $f(x)$ is $b\}$ is in NC^1. Similar observations hold for other classes.

A structure $(\mathcal{A}, +, \times)$ is a semiring if $(\mathcal{A}, +)$ is a commutative monoid with an additive identity element 0, and $(\mathcal{A}, \times)$ is a (not necessarily commutative) monoid with a multiplicative identity element 1, such that, for all a, b, c, we have $a \times (b + c) = (a \times b) + (a \times c)$, $(b + c) \times a = (ba \times ca)$, and $0 \times a = a \times 0 = 0$.

▶ **Definition 1.** An *arithmetic circuit* over a semiring $(R, +, \times)$ is a directed acyclic graph. Each vertex of the graph is called a "gate"; each gate is labeled with a "type" from the set $\{+, \times$, input, constant$\}$, where each input gate is labeled by one of the inputs $x_1, \ldots, x_n$, and each constant gate is labeled with an element of R. (Input and constant gates have indegree zero.) The is a unique sink called the "output gate". The *size* of a circuit is the number of gates, and the *depth* of the circuit is the length of the longest path in the circuit. We shall also need to refer to the *width* of a circuit, and here we use the notion of circuit width that was provided by Pippenger [27]: We will consider *layered* circuits, which means that the set of gates is partitioned into layers, where wires connect only gates in adjacent layers. The width of a circuit is the largest number of gates that occurs in any layer.

If an arithmetic circuit C_n over $(R, +, \times)$ has n input gates, then C_n computes a function $f : R^n \to R$ in the obvious way.

▶ **Definition 2.** A *straight-line program* over a semiring R with registers $\{r_1, \ldots, r_k\}$ consists of a sequence of statements of the form $r_i \leftarrow r_j \odot r_k$ where $\odot$ is one of the semiring operations, and each r_ℓ is a register, a value from R, or from the set of input variables. Straight-line programs have been studied at least as far back as [23], and they are frequently used as an alternative formulation of arithmetic circuits. Note that each line in a straight-line program can be viewed as a gate in an arithmetic circuit.

▶ **Definition 3.** The *width-k circuit value problem* over a semiring R is that of determining, given a width-k arithmetic circuit C over R (where C has no input gates, and hence all gates with indegree zero are labeled by a constant in R), and given a pair (i, b) whether the i-th bit of the binary representation of the output of C is b.

- $\#\mathsf{NC}^1{}_S$ is the class of functions $f : \bigcup_n R^n \to R$ for which there is a U_E-uniform family of arithmetic circuits $\{C_n\}$ of logarithmic depth, such that C_n computes f on R^n.
- By convention, when there is no subscript, $\#\mathsf{NC}^1$ denotes $\#\mathsf{NC}^1{}_{(\mathbb{N},+,\times)}$, with the additional restriction that the functions in $\#\mathsf{NC}^1$ are considered to have domain $\bigcup_n \{0,1\}^n$. That is, we restrict the inputs to the Boolean domain. (Boolean negation is also allowed at the input gates.)
- GapNC^1 is defined as $\#\mathsf{NC}^1 - \#\mathsf{NC}^1$; that is: the class of all functions that can be expressed as the difference of two $\#\mathsf{NC}^1$ functions. It is the same as $\#\mathsf{NC}^1{}_{\mathbb{Z}}$ restricted to the Boolean domain. See [29, 2] for more on $\#\mathsf{NC}^1$ and GapNC^1.

The following inclusions are known:

$$\mathsf{NC}^0 \subseteq \mathsf{AC}^0 \subseteq \mathsf{TC}^0 \subseteq \mathsf{NC}^1 \subseteq \#\mathsf{NC}^1 \subseteq \mathsf{GapNC}^1 \subseteq \mathsf{L} \subseteq \mathsf{AC}^1 \subseteq \mathsf{P}.$$

All inclusions are straightforward, except for $\mathsf{GapNC}^1 \subseteq \mathsf{L}$ [19].

2.1 Cost-register automata

A *cost-register automaton* (CRA) is a deterministic finite automaton (with a read-once input tape) augmented with a fixed finite set of *registers* that store elements of some algebraic domain $\mathcal{A}$. At each step in its computation, the machine

- consumes the next input symbol (call it a),
- moves to a new state (based on a and the current state (call it q)),
- based on q and a, updates each register r_i using updates of the form $r_i \leftarrow f(r_1, r_2, \ldots, r_k)$, where f is an expression built using the registers $r_1, \ldots, r_k$ using the operations of the algebra $\mathcal{A}$.

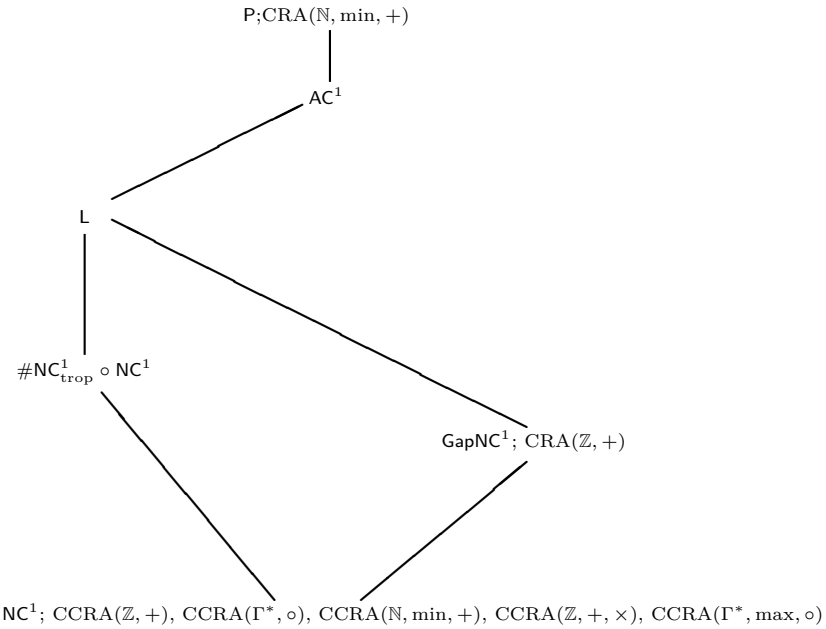

Figure 2 Update of the preceding figure, showing the improved state of our knowledge regarding CRA($\mathbb{N}, \min, +$) and the copyless CRA classes CCRA($\mathbb{N}, \min, +$), CCRA($\mathbb{Z}, +, \times$), and CCRA($\Gamma^*, \max, \circ$). All bounds listed are now tight.

There is also an "output" function μ defined on the set of states; μ is a partial function – it is possible for $\mu(q)$ to be undefined. Otherwise, if $\mu(q)$ is defined, then $\mu(q)$ is some expression of the form $f(r_1, r_2, \ldots, r_k)$, and the output of the CRA on input x is $\mu(q)$ if the computation ends with the machine in state q.

More formally, here is the definition as presented by Alur *et al.* [5].

A cost-register automaton M is a tuple $(\Sigma, Q, q_0, X, \delta, \rho, \mu)$, where

- Σ is a finite input alphabet.
- Q is a finite set of states.
- $q_0 \in Q$ is the initial state.
- X is a finite set of *registers*.
- $\delta : Q \times \Sigma \to Q$ is the state-transition function.
- $\rho : Q \times \Sigma \times X \to E$ is the register update function (where E is a set of algebraic expressions over the domain $\mathcal{A}$ and variable names for the registers in X).
- $\mu : Q \to E$ is a (partial) final cost function.

A *configuration* of a CRA is a pair (q, ν), where ν maps each element of X to an algebraic expression over $\mathcal{A}$. The *initial configuration* is (q_0, ν_0), where ν_0 assigns the value 0 to each register (or some other "default" element of the underlying algebra). Given a string $w = a_1 \ldots a_n$, the *run* of M on w is the sequence of configurations $(q_0, \nu_0), \ldots (q_n, \nu_n)$ such that, for each $i \in \{1, \ldots, n\}$ $\delta(q_{i-1}, a_i) = q_i$ and, for each $x \in X$, $\nu_i(x)$ is the result of composing the expression $\rho(q_{i-1}, a_i, x)$ to the expressions in ν_{i-1} (by substituting in the expression $\nu_{i-1}(y)$ for each occurrence of the variable $y \in X$ in $\rho(q_{i-1}, a_i, x)$). The output of M on w is undefined if $\mu(q_n)$ is undefined. Otherwise, it is the result of evaluating the expression $\mu(q_n)$ (by substituting in the expression $\nu_n(y)$ for each occurrence of the variable $y \in X$ in $\mu(q_n)$).

It is frequently useful to restrict the algebraic expressions that are allowed to appear in the transition function $\rho : Q \times \Sigma \times X \to E$. One restriction that is important in previous work [5] is the "copyless" restriction.

A CRA is *copyless* if, for every register $r \in X$, for each $q \in Q$ and each $a \in \Sigma$, the variable "r" appears at most once in the multiset $\{\rho(q, a, s) : s \in X\}$. In other words, for a given transition, no register can be used more than once in computing the new values for the registers. Following [6], we refer to copyless CRAs as CCRAs. Over many algebras, unless the copyless restriction is imposed, CRAs compute functions that can not be computed in polynomial time. For instance, CRAs that can concatenate string-valued registers and CRAs that can multiply integer-valued registers can perform "repeated squaring" and thereby obtain results that require exponentially-many symbols to write down.

3 CRAs over the Tropical Semiring

CRAs *without* the copyless restriction over the tropical semiring still yield only functions that are computable in polynomial time. The "repeated squaring" operation, when the "multiplicative" operation is $+$, yields only numbers whose binary representation remains linear in the length of the input. In this section, we show that some CRA functions over the tropical semiring are hard for P.

The name "tropical semiring" is used to refer to several related algebras. Most often it refers to $(\mathbb{R} \cup \{\infty\}, \min, +)$ (that is, the "additive" operation is min, and the "multiplicative" operation is $+$. However, frequently $(\mathbb{R} \cup \{-\infty\}, \max, +)$ is used instead. In discrete applications, $\mathbb{R}$ is frequently replaced with $\mathbb{Q}$, $\mathbb{Z}$, or even $\mathbb{N}$. For more details, we refer the reader to [26]. We will not need to make any use of ∞ or $-\infty$ in our hardness argument, and we will prove P-hardness over $\mathbb{N}$, which thus implies hardness for the other settings as well. Our arguments will be slightly different for both the max and the min versions, and thus we will consider both.

The standard reference for P-completeness, [18], credits Venkateswaran with the proof that the Min-plus Circuit Value Problem is P-complete. This shows that evaluating straight-line programs over $(\mathbb{N}, \min, +)$ is a P-complete problem, as long as they are allowed to have an unbounded number of registers.

Our focus will be more on straight-line programs with a *bounded* number of registers. Ben-Or and Cleve [11] showed that straight-line programs with $O(1)$ registers can simulate arithmetic formulae, and Koucky [21] has shown that these models are in fact *equivalent*, if the straight-line programs are restricted to compute only formal polynomials whose degree is bounded by a polynomial in the number of variables. It is observed in [1] that arithmetic formulae (that is, straight-line programs with $O(1)$ registers *and a polynomial degree restriction*) over the tropical semiring can be evaluated in logspace. Our P-completeness result demonstrates that, in the *absence* of any degree restriction, restricting straight-line programs over the tropical semiring to have only $O(1)$ registers yields a model that is as powerful as having an unlimited number of registers.

▶ **Theorem 4.** *There is a function f computable by a CRA operating over the tropical semiring (either $(\mathbb{N} \cup \{\infty\}, \min, +)$ or $(\mathbb{N} \cup \{-\infty\}, \max, +)$) such that computing f is hard for* P *under* AC^0*-Turing reductions.*

Proof. We will present a reduction from the P-complete problem Iterated Mod (problem A.8.5 in [18]), which was shown to be P-complete under logspace reductions by Karloff and Ruzzo [20]. The proof in [20] actually shows that the problem is complete under many-one reductions computable by dlogtime-uniform AC^0 circuits. (Incidentally, the proof sketch in [18] has a minor error, in that some indices are listed in the wrong order. The reader is advised to consult the original [20] proof.)

The input to the Iterated Mod problem is a list of natural numbers $v, m_1, m_2, \ldots, m_n$, and the question is to determine if $((\cdots((v \bmod m_1) \bmod m_2)\cdots) \bmod m_n) = 0$.

Let c be chosen so that 2^c is greater than any of the numbers $v, m_1, m_2, \ldots, m_n$. Then the naïve division algorithm that one would use to compute $v \bmod m$ can be seen to involve computing the following sequence:

- $v_0 = v$
- $v_i = v_{i-1} - max(0, v_{i-1} - m \cdot 2^{c-i})$

By induction, one can see that each $v_i \equiv v \pmod m$ and $v_i < m2^{c-i}$, and hence v_c is the remainder when one divides v by m.

Thus $v \bmod m$ can be seen to be computed by the following straight-line program over $\mathbb{Z}$ with operations $+, -, \max$:

```
1:  for i ≤ c do
2:     shift_of_m ← m
3:     for k ≤ c − i do
4:        shift_of_m ← shift_of_m + shift_of_m
5:     end for
6:     {At end of this loop, shift_of_m = m2^{c−i}}
7:     temp ← v−shift_of_m
8:     temp ← max(0, temp)
9:     v ← v − temp
10: end for
```

Of course, by definition, straight-line programs contain no loop statements, but the algorithm can be computed by a program described by an AC^0-computable sequence of symbols from the 5-letter alphabet $\{$*shift_of_m* $\leftarrow m$, *temp* $\leftarrow v-$ *shift_of_m*, $v \leftarrow v-$*temp*, *shift_of_m* $\leftarrow$ *shift_of_m* + *shift_of_m*, *temp* $\leftarrow \max(0,$*temp*$)\}$.

A number v, presented as a sequence of b binary digits v_i, can be loaded into a register r by initially setting r to 0, and then executing b instructions of the form $r \leftarrow r + r + v_i$. Thus, the naïve polynomial-time algorithm for computing Iterated Mod can be implemented via a polynomial-size straight-line program over $\mathbb{Z}$ with operations $+, -, \max$, by first inputting the numbers v and m_1, executing the algorithm above to compute $v \bmod m_1$, then inputting m_2, repeating the procedure to compute $((v \bmod m_1) \bmod m_2)$, etc.

We observe next that $\max(a, b) = (-1) \cdot \min(-a, -b)$. Thus there is a polynomial-size straight-line program over $\mathbb{Z}$ with operations $+, -, \min$ that outputs 0 if and only if $(v, m_1, \ldots, m_n)$ is a positive instance of Iterated Mod, where the process to input a number in binary has each instruction $r \leftarrow r + r + v_i$ replaced by $r \leftarrow r + r - v_i$. Similarly, in the code to compute $v \bmod m$, each occurrence of the instruction *temp* $\leftarrow \max(0,$*temp*$)$ is replaced by *temp* $\leftarrow \min(0,$*temp*$)$, and each occurrence of $r \leftarrow v - s$ for $\{r, s\} \subseteq \{v,$ *temp*, *shift_of_m*$\}$ is replaced by $r \leftarrow s - v$.

The next observation is that, given any straight-line program Q over $\mathbb{Z}$, it is easy to build a straight-line program Q' over $\mathbb{Z}$, such that each register of Q' always holds a nonnegative integer, and such that the value of each register r of Q at the end of the computation is equal to the value of the difference $r - r_0$ of Q' at the end, where r_0 is a new special register of Q'. We accomplish this by initially setting r_0 to 2^c (using repeated addition), where 2^c is larger than any value that is stored by any register of Q during its computation. (This is possible by taking c to be larger than the length of Q.) Then for every other register $r \neq r_0$, perform the operation $r \leftarrow r_0$. Now we will maintain the invariant that the value of register r of Q is obtained by subtracting r_0 from the value of register r of Q'. This is accomplished

as follows: Replace any assignment $r \leftarrow b$ where b is a constant, with $r \leftarrow r_0 + b$. Replace each operation $r \leftarrow s - u$ by $r \leftarrow s - u + r_0$, and replace each operation $r \leftarrow s + u$ by the operations: $r \leftarrow s + u; r' \leftarrow s + r_0$ (for every $r' \neq r$); $r_0 \leftarrow r_0 + r_0$.

The final step is to replace every straight-line program Q over $(\mathbb{Z}, \max, +, -)$ or ($\mathbb{Z}$,min,+, -) where every register holds only nonnegative values by a new program Q' over $(\mathbb{N}, \max, +)$ or $(\mathbb{N}, \min, +)$, where the value of every register r of Q at the end is equal to the value of the difference $r - r_{-1}$ of registers of Q', where r_{-1} is a new register of Q'. Initially, $r_{-1} \leftarrow 0$. Operations that involve min or max need no modification. If Q has the operation $r \leftarrow s + u$, then Q' has the operations $r \leftarrow s + u; r' \leftarrow s + r_{-1}$ (for every $r' \neq r$); $r_{-1} \leftarrow r_{-1} + r_{-1}$. (This is exactly the same replacement as was used in the preceding paragraph.) Finally, if Q has the operation $r \leftarrow s - u$, then Q' has the operations: $r \leftarrow s + r_{-1}; r_{-1} \leftarrow r_{-1} + u; r' \leftarrow r' + u$ for every $r' \notin \{r, u\}$ (including $r' = r_{-1}$); and then $u \leftarrow u + u$. A straightforward induction shows that the invariant is maintained, that each register r of Q has the value $r - r_{-1}$ of Q'.

Thus, given an instance y of Iterated Mod, an AC^0 reduction can produce a straight-line program Q over $(\mathbb{N}, \min, +)$ or $(\mathbb{N}, \max, +)$, such that $y \in$ Iterated Mod iff the output register of Q has a value equal to the value of r_0.

Note that there is a CRA that takes as input strings over an alphabet whose symbols encode straight-line program instructions with $O(1)$ registers, and simulates the operation of the straight-line program. The function f that is computed by this CRA is the function whose existence is asserted in the statement of the theorem. ◀

▶ **Corollary 5.** *Let R be the semiring $(\mathbb{N} \cup \{\infty\}, \min, +)$ or $(\mathbb{N} \cup \{-\infty\}, \max, +)$. There is a constant c such that for every $k \geq c$, the width-k circuit value problem over R is* P*-complete under* AC^0*-Turing reductions.*

Proof. The P upper bounds are clear since each semiring operation is polynomial-time computable. Hardness follows by appealing to the straight-line programs with a bounded number of registers that are constructed in the proof of Theorem 4. A further AC^0-Turing reduction can transform a straight-line program that uses k registers into an arithmetic circuit of width $O(k)$. (Each layer in the arithmetic circuit contains a gate for each register, as well as gates for each constant that is used in the next time step. If a register r is not changed at time t, then the gate for register r in layer t is simply set to 0 + the value of register r at in layer $t - 1$.) ◀

Completeness under AC^0-many-one reductions (or even logspace many-one reductions) is still open.

4 CCRAs over Commutative Semirings

In this section, we study two classes of functions defined by CCRAs operating over commutative algebras with two operations satisfying the semiring axioms:

- CRAs operating over the commutative ring $(\mathbb{Z}, +, \times)$
- CRAs operating over the tropical semiring, that is, over the commutative semiring $(\mathbb{Z} \cup \{\infty\}, \min, +)$.

▶ **Theorem 6.** *Let $(\mathcal{A}, +, \times)$ be a commutative semiring such that the functions*

$$(x_1, x_2, \ldots, x_n) \mapsto \sum_i x_i \text{ and } (x_1, x_2, \ldots, x_n) \mapsto \prod_i x_i$$

can be computed in NC^1*. Then CCRA($\mathcal{A}$) $\subseteq \mathsf{NC}^1$.*

We remark that both the tropical semiring and the integers satisfy this hypothesis. We refer the reader to [29, 19] for more details about the inclusions:

- unbounded-fan-in min $\in \mathsf{AC}^0$.
- unbounded-fan-in $+ \in \mathsf{TC}^0$.
- unbounded-fan-in $\times \in \mathsf{TC}^0$.

Proof. Let $M = (Q, \Sigma, \delta, q_0, X, \rho, \mu)$ be a copyless CRA operating over $\mathcal{A}$. Let M have k registers $r_1, \ldots, r_k$.

As in the proof of [1, Theorem 1], it is straightforward to see that the following functions are computable in NC^1:

- $(x, i) \mapsto q$, such that M is in state q after reading the prefix of x of length i. Note that this also allows us to determine the state q that M is in while scanning the final symbol of x, and thus we can determine whether the output $\mu(q)$ is defined.
- $(x, i) \mapsto G_i$, where G_i is a labeled directed bipartite graph on $[2k] \times [k]$, with the property that there is an edge from j on the left-hand side to ℓ on the right hand side, if the register update operation that takes place when M consumes the i-th input symbol includes the update $r_\ell \leftarrow \alpha \otimes \beta$ where $r_j \in \{\alpha, \beta\}$ and $\otimes \in \{+, \times\}$. In addition, vertex ℓ is labeled with the operation $\otimes$. If one of $\{\alpha, \beta\}$ is a constant c (rather than being a register), then label vertex $k + \ell$ in the left-hand column with the constant c, and add an edge from vertex $k + \ell$ in the left-hand column to ℓ in the right-hand column. (To see that this is computable in NC^1, note that by the previous item, in NC^1 we can determine the state q that M is in as it consumes the i-th input symbol. Thus G_i is merely a graphical representation of the register update function corresponding to state q.) Note that the outdegree of each vertex in G_i is at most one, because M is copyless. (The indegree is at most two.) To simplify the subsequent discussion, define G_{n+1} to be the graph resulting from the "register update function" $r_\ell \leftarrow \mu(q)$ for $1 \le \ell \le k$, where q is the state that M is in after scanning the final symbol x_n.

Now consider the graph G that is obtained by concatenating the graphs G_i (by identifying the left-hand side of G_{i+1} with the first k vertices of the right-hand side of G_i for each i). This graph shows how the registers at time $i + 1$ depend on the registers at time i. G is a constant-width graph, and it is known that reachability in constant-width graphs is computable in NC^1 [8, 9].

The proof of the theorem proceeds by induction on the number of registers $k = |X|$. When $k = 1$, note that the graph G consists of a path of length $n + 1$, where each vertex v_i on the path is connected to two vertices on the preceding level, one of which is a leaf. (Here, we are ignoring degenerate cases, where the path back from the output node does not extend all the way back to the start, but instead stops at some vertex v_i where the corresponding register assignment function sets the register to a constant. An NC^1 computation can find where the path actually does start.) That is, when $k = 1$, the graph G has width two. We will thus really do our induction on the width of the graph G, starting with width two.

In $\mathsf{TC}^0 \subseteq \mathsf{NC}^1$, we can partition the index set $I = \{0, \ldots, n + 1\}$ into consecutive subsequences $S_1, P_1, S_2, P_2, \ldots, S_m, P_m$, where $i \in S_j$ implies that vertex v_i on the path is labeled with $+$, and $i \in P_j$ implies that vertex v_i on the path is labeled with $\times$. (Assume for convenience that the first operation on the path is $+$ and the last one is $\times$; otherwise add dummy initial and final operations that add 0 and multiply by 1, respectively.) That is, $i \in S_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} + c_{i-1}$, and $i \in P_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} \times c_{i-1}$ for some sequence of constants $c_0, \ldots, c_n$.

In NC^1 we can compute the values $s_j = \sum_{i \in S_j} c_{i-1}$ and $p_j = \prod_{i \in P_j} c_{i-1}$. Thus the output computed by M on x is

$$(\ldots(((s_1 \times p_1) + s_2) \times p_2) \ldots \times p_m) = \sum_j s_j \prod_{\ell \geq j} p_\ell.$$

This expression can also be evaluated in NC^1. This completes the proof of the basis case, when $k = 1$.

Now assume that functions expressible in this way when the width of the graph G is at most k can be evaluated in NC^1. Consider the case when G has width $k+1$, and assume that vertex 1 in the final level is the vertex that evaluates to the value of the function. In NC^1 we can identify a path of longest length leading to the output. Let this path start in level i_0. Since there is no path from a vertex in any level $i < i_0$ to the output, we can ignore everything before level i_0 and just deal with the part of G starting at level i_0. Thus, for simplicity, assume that $i_0 = 0$. Let the vertices appearing on this path be $v_1, v_2, \ldots, v_{n+1}$, where each vertex v_i is labeled with the operation $v_i \leftarrow v_{i-1} \otimes_i w_i$ for some operation $\otimes_i$ and some vertex w_i. Let H_i be the subgraph consisting of all vertices that have a path to vertex w_i. Since the outdegree of each vertex in G is one, and since no w_i appears on the path, it follows that each H_i has width at most k, and thus the value computed by w_i (which we will also denote by w_i) can be computed in NC^1. (This is the only place where we use the restriction that M is a *copyless* CRA.)

Now, as before partition this path into subsequences $S_1, P_1, S_2, P_2, \ldots, S_m, P_m$, where $i \in S_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} + w_{i-1}$, and $i \in P_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} \times w_{i-1}$ for some NC^1-computable sequence of values $w_0, \ldots, w_n$.

Thus, as above, in NC^1 we can compute the values $s_j = \sum_{i \in S_j} w_{i-1}$ and $p_j = \prod_{i \in P_j} w_{i-1}$. Thus the output computed by M on x is

$$(\ldots(((s_1 \times p_1) + s_2) \times p_2) \ldots \times p_m) = \sum_j s_j \prod_{\ell \geq j} p_\ell.$$

This expression can also be evaluated in NC^1. ◀

5 CCRAs over Noncommutative Semirings

In this section, we show that the techniques of the preceding section can easily be adapted to work for noncommutative semirings.

The canonical example of such a semiring is $(\Gamma^* \cup \{\bot\}, \max, \circ)$. Here, the max operation takes two strings x, y in Γ^* as input, and produces as output the lexicographically-larger of the two. (Lexicographic order on Γ^* is defined as usual, where $x < y$ if $|x| < |y|$ or ($|x| = |y|$ and x precedes y, viewed as the representation of a number in $|\Gamma|$-ary notation). $\bot$ is the additive identity element. (One obtains a similar example of a noncommutative semiring, by using min in place of max.)

It is useful to describe how elements of Γ^* will be represented in an NC^1 circuit, in a way that allows efficient computation. For an input length n, let $m = n^{O(1)}$ be the maximum number of symbols in any string that will need to be manipulated while processing inputs of length n. Then a string y of length j will be represented as a sequence of $\log m + m \log |\Gamma|$ bits, where the first $\log m$ bits store the number j, followed by m blocks of length $\log |\Gamma|$, where the first j blocks store the symbols of y. Given a sequence of $l_1, r_1, l_2, r_2, \ldots, l_s, r_s$ represented in this way, we need to can compute the representation of the string $l_s l_{s-1} \ldots l_2 l_1 r_1 r_2 \ldots r_{s-1} r_s$.

It is easy to verify that this computation is in TC^0, since the i-th symbol of the concatenated string is equal to the j-th symbol of the ℓ-th string in this list, where j and ℓ are easy to compute by performing iterated addition on the lengths of the various strings, and comparing the result with i. In the max, $\circ$ semiring, where concatenation is the "multiplicative" operation, this corresponds to iterated product, and it is computable in $\mathsf{TC}^0 \subseteq \mathsf{NC}^1$.

▶ **Theorem 7.** *Let $(\mathcal{A}, +, \times)$ be a (possibly noncommutative) semiring such that the functions $(x_1, x_2, \ldots, x_n) \mapsto \sum_i x_i$ and $(x_1, x_2, \ldots, x_n) \mapsto \prod_i x_i$ can be computed in NC^1. Then CCRA($\mathcal{A}$) $\subseteq \mathsf{NC}^1$.*

Proof. The proof is a slight modification of the proof in the commutative case.

Given a CCRA M, we build the same graph G. Again, the proof proceeds by induction on the width of G (related to the number of registers in M).

Let us consider the basis case, where G has width two.

In $\mathsf{TC}^0 \subseteq \mathsf{NC}^1$, we can partition the index set $I = \{0, \ldots, n+1\}$ into consecutive subsequences $S_1, P_1, S_2, P_2, \ldots, S_m, P_m$, where $i \in S_j$ implies that vertex v_i on the path is labeled with $+$, and $i \in P_j$ implies that vertex v_i on the path is labeled with $\times$. (Assume for convenience that the first operation on the path is $+$ and the last one is $\times$; otherwise add dummy initial and final operations that add 0 and multiply by 1, respectively.) That is, $i \in S_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} + c_{i-1}$, and $i \in P_j$ implies that the i-th operation is of the form $v_i \leftarrow v_{i-1} \times c_{i-1}$ or $v_i \leftarrow c_{i-1} \times v_{i-1}$ for some sequence of constants $c_0, \ldots, c_n$.

In NC^1 we can compute the value $s_j = \sum_{i \in S_j} c_{i-1}$. The product segments P_j require just a bit more work. Let $l_{j,1}, l_{j,2}, \ldots, l_{j,m_{j_l}}$ be the list of indices, such that $l_{j,s}$ is the s-th element of $\{i \in P_j : \text{the multiplication operation at } v_i \text{ is of the form } v_i \leftarrow c_{i-1} \times v_{i-1}\}$, and similarly let $r_{j,1}, r_{j,2}, \ldots, r_{j,m_{j_r}}$ be the list of indices, such that $r_{j,s}$ is the s-th element of $\{i \in P_j : \text{the multiplication operation at } v_i \text{ is of the form } v_i \leftarrow v_{i-1} \times c_{i-1}\}$.

Let

$$l_j = c_{l_{j,m_{j_l}}-1} \times c_{l_{j,m_{j_l}-1}-1} \times \ldots c_{l_{j,2}-1} \times c_{l_{j,1}-1}$$

and let

$$r_j = c_{r_{j,1}-1} \times c_{r_{j,2}-1} \times c_{r_{j,m_{j_r}-1}-1} \times c_{r_{j,m_{j_r}}-1}.$$

Then if the value of the path when it enters segment P_j is y, it follows that the value computed when the path leaves segment P_j is $l_j y r_j$. Note that this value can be computed in NC^1.

Thus the output computed by M on x is

$$l_1 \times ((l_2 \times (\ldots (l_2 \times ((l_1 \times s_1 \times r_1) + s_2) \times r_2) \ldots) \times r_2) + s_1) \times r_1$$

which is equal to

$$\sum_j (\prod_{\ell \geq j} l_j) s_j (\prod_{\ell \geq j} r_\ell).$$

This expression can be evaluated in NC^1. This completes the proof of the basis case, when G has width two.

The proof for the inductive step is similar to the commutative case, combined with the algorithm for the basis case. ◀

6 Conclusion

We have obtained a polynomial time lower bound, conditional on $\mathsf{NC} \neq \mathsf{P}$, for some functions computed by CRAs over $(\mathbb{N}, \min, +)$ and other tropical semirings. This was done by proving that a straight-line program over such semirings using $O(1)$ registers can solve a P-complete problem. It followed that for some small k, the "width-k circuit value problem" over $(\mathbb{N}, \min, +)$ is P-complete. We have also shown that any function computed by a copyless CRA over such semirings belongs to (functional) NC^1.

An open question of interest would be to characterize the semirings $(R, +, \times)$ over which the width-k circuit value problem is P-complete. Given the P-completeness of the circuit value problem over the group A_5 [10], one possible approach would be to try to map R onto A_5 in such a way that iterating the evaluation of a fixed semiring expression over R would allow retrieving the result of a linear number of compositions of permutations from A_5.

A future direction in the study of copyless CRAs might be to refine our NC^1 analysis by restricting the algebraic properties of the underlying finite automaton, along the lines described in the context of ordinary finite automata (see Straubing [28] for a broader perspective). The way to proceed is not immediately clear however since merely restricting the finite automaton (say to an aperiodic automaton) would not reduce the strength of the model unless the interplay between the registers is also restricted.

Acknowledgments. Some of this research was performed at the 29th McGill Invitational Workshop on Computational Complexity, held at the Bellairs Research Institute of McGill University, in February, 2017.

Abstract

In this paper, we consider variants of the Geometric Subset General Position problem. In defining this problem, a geometric subsystem is specified, like a subsystem of lines, hyperplanes or spheres. The input of the problem is a set of n points in $\mathbb{R}^d$ and a positive integer k. The objective is to find a subset of at least k input points such that this subset is in general position with respect to the specified subsystem. For example, a set of points is in general position with respect to a subsystem of hyperplanes in $\mathbb{R}^d$ if no $d+1$ points lie on the same hyperplane. In this paper, we study the Hyperplane Subset General Position problem under two parameterizations. When parameterized by k then we exhibit a polynomial kernelization for the problem. When parameterized by $h = n - k$, or the dual parameter, then we exhibit polynomial kernels which are also tight, under standard complexity theoretic assumptions. We can also exhibit similar kernelization results for d-Polynomial Subset General Position, where a vector space of polynomials of degree at most d are specified as the underlying subsystem such that the size of the basis for this vector space is b. The objective is to find a set of at least k input points, or in the dual delete at most $h = n-k$ points, such that no $b+1$ points lie on the same polynomial. Notice that this is a generalization of many well-studied geometric variants of the Set Cover problem, such as Circle Subset General Position. We also study general projective variants of these problems. These problems are also related to other geometric problems like Subset Delaunay Triangulation problem.

1 Introduction

In the *geometric subset general position* problem, the input is a *family* of *algebraic objects*, e.g. lines, circles, hyperplanes, zero set of quadratic functions, and a point set P in $\mathbb{R}^d$. The objective is to extract a large subset S of P such that the subset S is in *general position* with respect to the geometric objects. The definition of general position is different for different families of geometric objects. For the case of hyperplanes in $\mathbb{R}^d$, a set S, assume $|S| > d$, will be in general position with respect to the family of hyperplanes in $\mathbb{R}^d$ if no more than d points of S lie on a hyperplane. For the case of spheres in $\mathbb{R}^d$, a set S with $|S| > d+1$, will be in general position with respect to the family of spheres in $\mathbb{R}^d$ if no more than $d+1$ points of S lie on a sphere. In this paper, we will assume that d is a constant.

In computational geometry it is generally assumed that the point set is in general position, such as no more than d points lie on a hyperplane in the case of convex hull computation or no more than $d+1$ points lie on a sphere for Delaunay triangulation computation (see [6]). Also, algebraic techniques like *simulation of simplicity* have been introduced to handle degenerate cases in practice [10].

The problem of determining whether a given point set in $\mathbb{R}^d$ is in general position with respect to family of spheres and family of hyperplanes has been extensively studied in computational geometry. Edelsbrunner, O'Rourke and Seidel [11] gave an $O(n^d)$ (and $O(n^{d+1})$) space and time complexity algorithm to determine if a point set is in general position with respect to hyperplanes (resp. spheres) in $\mathbb{R}^d$. Edelsbrunner and Guibas [8, 9] later improved the space bound to $O(n)$. Erickson and Seidel [12, 13] showed in the worst case $\Omega(n^d)$ (and $\Omega(n^{d+1})$) sided queries are required to determine whether a set of n points in $\mathbb{R}^d$ is in general position with respect to hyperplanes (resp. spheres). We have mentioned a small sample of the papers on this topic and for a more complete picture of this area and the more general problem of *arrangement of hyperplanes* please refer to the survey by Agarwal and Sharir [1].

More recently, the problem of finding a maximum-cardinality subset of points in general position has been studied in parameterized complexity, approximation algorithm, and combinatorial geometry [14, 18, 4]. Payne et al. [18] and Cardinal [4] gave a non-trivial lower bound on the size of a largest size subset in general position from a point set with bounded *coplanarity* in $\mathbb{R}^2$ and $\mathbb{R}^d$. A point set in $\mathbb{R}^2$ (and $\mathbb{R}^d$) has bounded coplanarity if the number of points from the set that lie on a given plane (or hyperplane) is bounded. Cao [3] and Froese et al. [14] studied the geometric subset general position problem in $\mathbb{R}^2$ with respect to lines in $\mathbb{R}^2$ through the lens of parameterized complexity. Cao [3] also gave an $\mathcal{O}(\sqrt{\mathsf{opt}})$-factor approximation algorithm for the general position subset selection problem with respect to lines in $\mathbb{R}^2$.

In this paper we generalize the results of [14] by studying the kernelization aspect of the following *primal* problem:

Hyperplane Subset General Position	**Parameter:** k
Input: An n point set P in $\mathbb{R}^d$, for a fixed constant d, and a positive integer k	
Question: Is there a subset $S \subseteq P$ of size at least k such that S is in general position with respect to hyperplanes in $\mathbb{R}^d$?	

We will also study a more general version of the above problem for *bounded degree polynomial families* (see Section 2 and 3):

d-Polynomial Sub. General Pos.	**Parameter:** k
Input: A set P of n points in $\mathbb{R}^d$, for a fixed constant d, a bounded degree polynomial family $\mathcal{F}$ in $\mathbb{R}^d$ and a positive integer k	
Question: Is there a subset $S \subseteq P$ of size at least k such that S is in general position with respect to $\mathcal{F}$ in $\mathbb{R}^d$?	

Therefore, the general position subset selection problems with respect to natural set families like the vector space of spheres, ellipses, etc. are special cases of the d-Polynomial Subset General Position problem. We also study the problems with respect to the dual parameter $h = n - k$. That is, the problem of Hyperplane Subset General Position or d-Polynomial Subset General Position still have the same input and aim for the same decision problem. However, the parameter for the problem becomes h.

Note that both these problems are NP-hard following from the results of [14] on Subset General Position in $\mathbb{R}^2$.

Our contribution

In this paper, we exhibit polynomial kernels for Hyperplane Subset General Position in $\mathbb{R}^d$. This is a generalization to higher dimensions of the results on kernelization obtained in [14], with more carefully designed reduction rules to take care of the higher dimension. We further generalize the result with the help of a variant of the Veronese mapping, to obtain polynomial kernels for d-Polynomial Subset General Position in $\mathbb{R}^t$, where the bounded degree polynomial family is a vector space of d-degree polynomials. Special cases of the d-Polynomial Subset General Position problem include variants where the polynomial family is that of spheres or quadratic surfaces. Also, Delaunay Subset Selection is a special case of this problem. We further study the general projective variants of these problems. These results are described in Section 3

We also give tight polynomial kernels for Hyperplane Subset General Position in $\mathbb{R}^d$ parameterized by h, the dual parameter, as described in Section 4. In Section 4, we obtain tight results for the number of elements in a polynomial kernel for Hyperplane Subset General Position in $\mathbb{R}^d$. These results are similar to those obtained in [15]. Finally, in Section 5, we are able to generalize this result for certain variants of d-Polynomial Subset General Position.

2 Preliminaries

Hypergraphs

A set of consecutive integers $\{1, 2, \ldots n\}$ will be written as $[n]$ in short. A hypergraph G is a set system where $V(G)$ denotes the universe and $E(G)$ denotes the family of sets. We refer to the objects in the universe $V(G)$ by either vertices or elements, and each subset of $E(G)$ as a *hyperedge*. For a hyperedge $e \in E(G)$ the set of vertices belonging to e is denoted as V_e. A *d-uniform hypergraph* is a hypergraph where each hyperedge has exactly d vertices. Similarly, a *d-hypergraph* is a hypergraph where each hyperedge has at most d vertices. An *independent set* in a hypergraph G is a subset $I \subseteq V(G)$ such that there is no $e \in E(G)$ where all vertices in e belong to I. The d-Hypergraph Independent Set problem takes as input a d-hypergraph and a positive integer k and determines whether the input hypergraph has an independent set of size at least k.

The d-Hitting Set problem takes as input a d-hypergraph G and a positive integer k and determines whether there is a set $S \subseteq V(G)$ of size at most k such that for each $e \in E(G)$, $V_e \cap S \neq \emptyset$. Such a set S is called a d-hitting set.

General position in Geometry

An i-flat in $\mathbb{R}^d$ is the affine hull of $i+1$ affinely independent points. The dimension of a (possibly infinite) set of points P, denoted as $dim(P)$, is the minimum i such that the entire set P is contained in an i-flat of $\mathbb{R}^d$ [16]. We use the term hyperplanes interchangeably for $(d-1)$-flats. A set P of points in $\mathbb{R}^d$ is said to be in general position with respect to hyperplanes, if for each i-flat, $i \leq d-1$, in $\mathbb{R}^d$ there are at most $i+1$ points from P lying on the i-flat.

As described earlier, the Geometric Subset General Position problem, defined on a subsystem of geometric objects, takes as input a set of points P and a positive integer k and determines whether there is a subset of at least k points that are in general position with respect to the specified subsystem of geometric objects. For example, Hyperplane Subset General Position in $\mathbb{R}^d$ takes in a set of points in $\mathbb{R}^d$ and a positive integer k

and determines whether there is a subset of at least k points that are in general position with respect to hyperplanes in $\mathbb{R}^d$.

Similarly, we can define the notion of general position with respect to multivariate polynomials. Given a set $\{X_1, X_2, \ldots, X_t\}$ of variables, a real multivariate polynomial on these variables is of the form $P(X_1, \ldots, X_t) = \sum_{i_1,i_2,\ldots,i_t} a_{i_1 i_2 \ldots i_t} \prod_{j\in[t]} X_j^{i_j}$ where $[t] = \{1, \ldots, t\}$ and $a_{i_1 i_2 \ldots i_t} \in \mathbb{R}$. The set of all real multivariate polynomials in the variables $\{X_1, \ldots, X_t\}$ will be denoted by $\mathbb{R}[X_1, X_2, \ldots, X_t]$. The degree of such a polynomial $P(X_1, \ldots, X_t)$ is defined as $\deg(P) := \max\{i_1 + i_2 + \ldots + i_t \mid a_{i_1 i_2 \ldots i_t} \neq 0\}$. A polynomial is said to be a degree d polynomial is its degree is d.

In this paper, we are interested in the set/subsets of polynomials whose degree is bounded by d, for some $d \in \mathbb{N}$. In this context we define $\text{Poly}_d[X_1, \ldots, X_t] := \{f(X_1, \ldots, X_t) \in \mathbb{R}[X_1, X_2, \ldots, X_t] \mid \deg(f) \leq d\}$. Observe that $\text{Poly}_d[X_1, \ldots, X_t]$ is a vector space over $\mathbb{R}$ with the *monomials* $\left\{X_1^{i_1} \ldots X_t^{i_t} \mid 0 \leq \sum_{j=1}^t i_j \leq d\right\}$ as the basis. Notice that $\left|\left\{X_1^{i_1} \ldots X_t^{i_t} \mid 0 \leq \sum_{j=1}^t i_j \leq d\right\}\right| = \binom{d+t}{d}$.

In d-Polynomial Subset General Position in $\mathbb{R}^t$, a subspace $\mathcal{F}$ of $\text{Poly}_d[X_1, \ldots, X_t]$ is given with a basis $\{f_1(X), f_2(X), \ldots, f_b(X), 1\}$, where $X = (X_1, \ldots, X_t)$ and $f_i(X) \in \text{Poly}_d[X_1, \ldots, X_t]$, and a set of n points from $\mathbb{R}^t$. The objective is to find a subset of points in general position with respect to the vector space of polynomials, i.e., no more than b points from the subset satisfy any equation of the form $f(X) := \sum_{i=1}^b \lambda_i f_i(X) + \lambda_{b+1} = 0$, where for each $j \in \{1, \ldots, b\}$, $\lambda_j \in \mathbb{R}$ and not all the λ_j's can be zero simultaneously. Here are some concrete examples of d-Polynomial Subset General Position.

▶ **Example 1.**

1. Hyperplanes in $\mathbb{R}^t$ are zero sets of linear combinations of polynomials $\{X_1, \ldots, X_t, 1\}$.
2. Union of spheres and hyperplanes in $\mathbb{R}^d$ are zero sets of linear combinations of polynomials $\left\{\sum_{i=1}^t X_i^2, X_1, \ldots, X_t, 1\right\}$.
3. Polynomial surfaces with degree bounded by d are zero sets of $\text{Poly}_d[X_1, \ldots, X_t]$.
4. Quadratic surfaces are zero set of polynomials in $\text{Poly}_2[X_1, \ldots, X_t]$.

Veronese mapping

In this paper, one of our strategies for generalizing our results is to convert d-Polynomial Subset General Position in $\mathbb{R}^t$ to Hyperplane Subset General Position in $\mathbb{R}^b$ by using a variant of Veronese mapping [17] from $\mathbb{R}^t \to \mathbb{R}^b$. The Veronese mapping of a vector space $\mathcal{F}$ of d-degree polynomials will be as the following: $\Phi_{\mathcal{F}} : \mathbb{R}^t \to \mathbb{R}^b$, where for a vector $X = (X_1, \ldots, X_t)$, $\Phi_{\mathcal{F}}(X) = (f_1(X), \ldots, f_b(X))$. Observe that if $p = (p_1, \ldots, p_t)$ satisfies the equation $f(X) := \sum_{i=1}^b \lambda_i f_i(X) + \lambda_{b+1} = 0$ then, for a vector of variables $Z = (Z_1, \ldots, Z_b)$, $\Phi_{\mathcal{F}}(p)$ will also satisfy the linear equation $\sum_{j=1}^b \lambda_j Z_j + \lambda_{b+1} = 0$. In other words, for any set of points P in $\mathbb{R}^t$ and the vector space $\mathcal{F}$, the incidences between P and $\mathcal{F}$ and incidences between $\Phi_{\mathcal{F}}(P)$ and $\text{Poly}_1[Z_1, \ldots, Z_b]$ (these are hyperplanes in $\mathbb{R}^b$) are preserved under the mapping $\Phi_{\mathcal{F}}$. Also, observe that there is a bijection between polynomials in $\mathcal{F}$ and hyperplanes in $\mathbb{R}^b$.

Parameterized Complexity

The instance of a parameterized problem/language is a pair containing the actual problem instance of size n and a positive integer called a parameter, usually represented as k. The problem is said to be in FPT if there exists an algorithm that solves the problem in $f(k)n^{\mathcal{O}(1)}$ time, where f is a computable function. The problem is said to *admit a $g(k)$-sized kernel*, if

there exists an polynomial time algorithm that converts the actual instance to a reduced instance of size $g(k)$, while preserving the answer. When g is a polynomial function, then the problem is said to admit a polynomial kernel. A *reduction rule* is a polynomial time procedure that changes a given instance I_1 of a problem Π to another instance I_2 of the same problem Π. We say that the reduction rule is *safe* when I_1 is a YES instance of Π if and only if I_2 is a YES instance. Readers are requested to refer [5] for more details on Parameterized Complexity.

Lower bounds in Parameterized Algorithms

There are several methods of showing lower bounds in parameterized complexity under standard assumptions in complexity theory. One such technique is *polynomial parameter transformation*. For two parameterized problems Π, Π', a polynomial time algorithm $\mathcal{A}$ is called a polynomial parameter transformation (or ppt) from Π to Π' if, given an instance (x, k) of Π, $\mathcal{A}$ outputs in polynomial time an instance (x', k') of Π' such that $(x, k) \in \Pi$ if and only if $(x', k') \in \Pi'$ and $k' \leq k^{\mathcal{O}(1)}$. By a result of [2], if Π, Π' are two parameterized problems such that Π is NP-hard, $\Pi \in$ NP and there exists a polynomial parameter transformation from Π to Π', then, if Π does not admit a polynomial kernel neither does Π'.

We also require a lower bound technique given in [7]. This technique links kernelization to oracle protocols.

▶ **Definition 2.** [7] Given a language L, an oracle communication protocol for L is a two-player communication protocol. The first player gets an input x and can only execute computations taking time polynomial in $|x|$. The second player is computationally unbounded, but does not know x. At the end of the protocol, the first player has to decide correctly whether $x \in L$. The cost of the protocol is the number of bits of communication from the first player to the second player.

▶ **Proposition 3.** *[7] Let $d \geq 2$ be an integer, and ϵ be a positive real number. If* co-NP $\not\subseteq$ NP*/poly, then there is no protocol of cost $\mathcal{O}(n^{d-\epsilon})$ to decide whether a d-uniform hypergraph on n vertices has a d-hitting set of at most k vertices, even when the first player is co-nondeterministic.*

As noted in [7], this implies that for any $d \geq 2$ and any positive real number ϵ, if co-NP $\not\subseteq$ NP/poly, then there is no kernel of size $k^{d-\epsilon}$ for d-HITTING SET. In general, a lower bound for oracle communication protocols for a parameterized language L gives a lower bound for kernelization for L.

Kernels: size vs. number of elements

In literature, a lower bound on the kernel means the lower bound on the size of the kernel, but not necessarily on the number of input elements in the kernel. Kratsch et al. [15] were one of the first to study lower bounds in terms of the number of input elements in the kernel. They used the results of Dell and Melkebeek [7] along with results in two dimensional geometry to build a new technique to show lower bounds for the number of input elements in a kernel for a problem. In this paper, we have adhered to the general convention by saying that a kernel has a lower bound on its size if it has a lower bound on its representation in bits, while explicitly mentioning the cases where the kernel has a lower bound on the number of input elements.

3 Kernel Upper Bounds for primal parameter

In this section, we consider the Hyperplane Subset General Position problem in $\mathbb{R}^d$ parameterized by the primal parameter k. We describe a polynomial kernelization for this problem. This method is similar to that described in [14]. However, there is an error in the analysis of kernel size in [14]. Our proof, when restricted to the case of Line Subset General Position problem gives the correct bound on the kernel. We will point out the place where there is an error in [14], while describing our proof. Moreover, using the well-known Veronese mapping, we can generalize this result to give polynomial kernels for d-Polynomial Subset General Position in $\mathbb{R}^d$ parameterized by k.

3.1 Hyperplane case

First, we consider an easy variant of the Hyperplane Subset General Position problem in $\mathbb{R}^d$, where the input point set P is such that for every subset S of P of size less than d, $\mathsf{dim}(S) = |S| - 1$. In this case, the i-flats are said to be *non-degenerate*. In this case, parameterization by k gives us a polynomial kernel by a generalization of the results obtained in [14]. For the sake of completeness, we describe the kernelization. We apply a reduction rule that bounds the coplanarity of hyperplanes in $\mathbb{R}^d$.

▶ **Reduction Rule 4.** *Given an instance (P, k) of* Hyperplane Subset General Position *in $\mathbb{R}^d$, if there is a hyperplane H with at least $(d-1)\binom{k-d}{d} + d$ points then we delete all the points in $H \cap P$ and set $k = k - d$.*

▶ **Lemma 5.** *Reduction Rule 4 is safe.*

We apply this Reduction Rule exhaustively. In the end, we know that each hyperplane can contain $\mathcal{O}(k^d)$ input points. Together with the bound on coplanarity, we will also use the following result by Cardinal et al. [4, Theorem 4.1] to get a kernel.

▶ **Theorem 6** (Cardinal et al. [4])**.** *Let P be a set of n points in $\mathbb{R}^d$ with at most ℓ cohyperplanar points, where $\ell = O(\sqrt{n})$. Then P contains a subset of size $\Omega\left((n/\log l)^{1/d}\right)$ of points in general position.*

▶ **Theorem 7.** Hyperplane Subset General Position *in $\mathbb{R}^d$, parameterized by k and with an input point set where all lower dimensional flats are non-degenerate, has a $\mathcal{O}(k^{2d})$ kernel.*

Proof. We know from Theorem 6 that for a point set of size n and *cohyperplanarity* ℓ, i.e., at most ℓ points from the point set can lie on a given hyperplane, such that $\ell \leq \sqrt{n}$, there is a point set in general position of size at least $C(\frac{n}{\log \ell})^{1/d}$ where $C = C(d)$ is a constant. Thus, when $\ell \leq \sqrt{n}$, if $C(\frac{n}{\log \ell})^{1/d} > k$, we correctly say Yes. Substituting ℓ by its upper bound of $\mathcal{O}(k^d)$, this equation is true when $n \geq \Omega(k^{d+1})$. When $n = \mathcal{O}(k^{d+1})$, then anyway we obtain a kernel of size $\mathcal{O}(k^{d+1})$. The remaining case is when $\ell > \sqrt{n}$. Then, substituting ℓ by its upper bound of $\mathcal{O}(k^d)$, we know that $n = \mathcal{O}(k^{2d})$. Thus, we obtain the required polynomial kernel. ◀

Now we consider the general problem. To design a kernel for the general problem, point subsets lying in lower dimensional flats also have to be kept in mind. The approach is to first reduce the number of points that can lie in a lower dimensional flat before we can employ a strategy similar to the kernelization of Theorem 7. First, we describe a reduction rule such that in the reduced instance, the coplanarity of each i-flat with $i \leq d$ is bounded by a

function of k. This reduction rule is similar to Reduction Rule 4, except that it has to take care of point subsets lying in lower dimensional flats before it considers point subsets lying in hyperplanes of $\mathbb{R}^d$.

▶ **Reduction Rule 8.** *Let (P, k) be an instance of* Hyperplane Subset General Position *parameterized by k. Let i be the smallest integer between 2 and d, auch that there is an $(i-1)$-flat that contains at least $c(d) \cdot k^{id} + 1$ points. Then we delete all but $c(d)k^{id}$ points. Here $c(d) = 15(d-1)$ is a constant.*

▶ **Lemma 9.** *Reduction Rule 8 is safe.*

Proof sketch. We prove the correctness of the reduction rule by induction on i. In the base case, suppose $i = 2$. Suppose there is a line L containing at least $c(d)k^4 + 1$. Then by the reduction rule, we construct an instance (P', k) such that P is modified to P' by deleting all but $c(d)k^4$ points. We show that P has a k-sized set in general position if and only if P' has a k-sized set in general position. Since, $P' \subset P$, if P' has a k-sized set in general position, so does P.

In the forward direction, suppose P has a k-sized set S in general position. Let P_L be the set of points in $L \cap P$ and P'_L be the set of points in $L \cap P'$. By definition of general position, there are $\Sigma_{j \leq d}\binom{k}{j}$ flats of dimension at most d that can be formed by the points in S. Consider the intersection of these flats with the line L. Each intersection is of dimension at most 1. That is, if the intersection is not the line L itself, then it is a point in L. Thus there are at most $\Sigma_{j \leq d}\binom{k}{j}$ points of intersection. Since, the set S is in general position, at most two points from S lie on L. If there are no points or if all the points in $S \cap L$ belong to P' then S is also a k-sized set in general position for the instance (P', k). Otherwise, suppose there are at most $t \leq 2$ points from $P_L \setminus P'_L$. The number of intersection points is at most $\Sigma_{j \leq d}\binom{k}{j} < c(d)k^{2d}$. Thus there is a set $\hat{S} = \{p_t | t \leq 2\}$ on L that are not intersection points. Let $S' = S \setminus (P \cap L) \cup \hat{S}$. We show that S' is also a set in general position. Consider a flat defined by points from S'. If they do not contain points from $\hat{S}$, then they remain non-degenerate flats. Suppose a flat contains points from $\hat{S}$. Also, for the sake of contradiction, suppose the flat is degenerate. If the flat contains all the points in $\hat{S}$ then it contains the line L and therefore the points from $L \cap P$. Thus, in P the set S was not in general position, which is a contradiction. Now, suppose the flat F contains a single point, say p_1, from $\hat{S}$. Then the points from $F \cap S$ were in general position and therefore the flat was either the line L or $L \cap F$ was an intersection point. This contradicts the fact that p_1 belongs to F, as p_1 is chosen to be a point that is not an intersection point. Thus, $S' \subseteq P'$ is in general position and of size k. Note that this means that after exhaustive application of this rule all lines contain at most $\lambda_2 = c(d)k^{2d}$ points.

The arguments of the other values of i are similar but with more case analysis. The full proof can be found in the full version of this paper. ◀

This Reduction Rule is exhaustively applied and in the end the reduced instance is such that for any hyperplane in $\mathbb{R}^d$, the coplanarity is $\mathcal{O}(k^{d^2})$. Now, we can exhibit a polynomial kernel for Hyperplane Subset General Position in $\mathbb{R}^d$ parameterized by k. The proof is same as that of Theorem 7, while taking into account that the collinearity bound in this case is $\mathcal{O}(k^{d^2})$.

▶ **Theorem 10.** Hyperplane Subset General Position *in $\mathbb{R}^d$ parameterized by k has a kernel of size $\mathcal{O}(k^{2d^2})$.*

Using the techniques in the proof of Theorem 10 we can also solve the *projective version* of the general position problem. For a given point set P in $\mathbb{R}^d$, $S \subseteq P \setminus \{0\}$ is said to be in

projective general position if no more than $d-1$ points from S lie on a hyperplane in $\mathcal{R}^d$ that passes through the origin. The parameterized version of the problem is the following:

Projective Hyperplane Subset General Position	**Parameter:** k
Input: An n point set P in $\mathbb{R}^d$, for a fixed constant d, and a positive integer k	
Question: Is there a subset $S \subseteq P$ of size at least k such that S is in projective general position?	

Notice that this problem in $\mathbb{R}^2$ is polynomial time solvable, as the problem is equivalent to asking whether the projection of the points on a unit sphere, centered at the origin, equals to at least k points where no two lie on the same line through the origin.

We will apply the following reduction rule to reduce the coplanarity of the hyperplanes passing through the origin.

▶ **Reduction Rule 11.** *Let (P,k) be an instance of* Projective Hyperplane Subset General Position *parameterized by k. Let i be the smallest integer between 2 and $d-1$, such that there is an $(i-1)$-flat passing through the origin that contains at least $c'(d)\cdot k^{id}+1$ points. Then we delete all but $c'(d)k^{i(d-1)}$ points. Here, as in the case with Reduction Rule 8, $c'(d)$ is a large constant depending linearly on d.*

The correctness of this Reduction Rule is same as the inductive proof of Reduction Rule 8. Applying the above reduction rule exhaustively, as was the case with Hyperplane Subset General Position problem, we will get that any hyperplane passing through the origin has $O(k^{(d-1)^2})$ input points on them. To get a polynomial kernel for the Projective Hyperplane Subset General Position problem we will need the following analogue to Theorem 6 with bounded coplanarity.

▶ **Lemma 12** (Projective version of Theorem 6). *Let P be a set of n points in $\mathbb{R}^d$ such that for any hyperplane H passing through the origin, we have $|H\cap P|\leq \ell$, where $\ell = O(n^{1/3})$. Then P contains a subset of size $\Omega\left(\left(\frac{n^{2/3}}{\log \ell}\right)^{1/(d-1)}\right)$ of points in projective general position.*

Proof. The proof of this lemma will use Theorem 6. Without loss of generality we will assume that the hyperplane $X_1 = 1$, intersects all the lines passing through the origin and one point of P. Let L denotes the set of lines passing through the origin and one point of P. Observe that since for any hyperplane H passing through the origin, $|H\cap P|\leq \ell$, therefore $|L|\geq \frac{n}{\ell}$. Let P' be the set points we get by intersecting lines in L with the hyperplane $X_1 = 1$. Again observe that $|P'|\geq \frac{n}{\ell}$, and for any $(d-2)$-hyperplane H' contained in the hyperplane $X_1 = 1$, we have $|H'\cap P'|\leq \ell$, otherwise we can get a hyperplane passing through origin containing more than ℓ points from P. Using the fact that $\ell = O\left(\sqrt{n/\ell}\right)$ and Theorem 6, we get that P' contains a subset P'_1 of size $\Omega\left(\left(\frac{n^{2/3}}{\log \ell}\right)^{1/(d-1)}\right)$ with no more than ℓ points from P'_1 lying on any $(d-2)$-dimensional subflat of the hyperplane $X_1 = 1$. For each point $p'\in P'_1$, include in the set P_1 a point p from the set P such that p and p' are on the same line passing through the origin. By construction the set P_1 is in projective general position and $|P_1| = \Omega\left(\left(\frac{n^{2/3}}{\log \ell}\right)^{1/(d-1)}\right)$. ◀

Now, using the fact that any hyperplane passing through the origin has $O(k^{(d-1)^2})$ input points on them after application of Reduction Rule 11 and Lemma 12, we can prove the following result in the same way we proved Theorem 10.

▶ **Theorem 13.** Projective Hyperplane Subset General Position *in* $\mathbb{R}^d$ *parameterized by* k *has a kernel of size* $\mathcal{O}(k^{3(d-1)^2})$.

3.2 Bounded degree polynomials

The following lemma will show the direct connection between the d-Polynomial Subset General Position problem and Hyperplane Subset General Position problem:

▶ **Lemma 14.** *Let* P *be a set of points in* $\mathbb{R}^t$*, and* $\mathcal{F}$ *be a subspace of* $\text{Poly}_d[X_1, \ldots, X_t]$ *with a basis* $\{f_1(X), \ldots, f_b(X), 1\}$*, where* $X = (X_1, \ldots, X_t)$.

1. *If* P *is a set of* ℓ *points in general position with respect to the polynomial family* $\mathcal{F}$ *(defined earlier in the section) then* $\Phi_{\mathcal{F}}(P)$ *(*$\Phi_{\mathcal{F}}$ *is defined earlier in Section 2) is a set of* ℓ *points in general position with respect to hyperplanes in* $\mathbb{R}^b$.
2. *Let* $S = \{q_1, \ldots, q_\ell\} \subseteq \Phi_{\mathcal{F}}(P)$ *be a set of* ℓ *points in general position with respect to hyperplanes in* $\mathbb{R}^b$*. Then the set* $S' = \{p_1, \ldots, p_\ell\}$*, where* $p_i \in \Phi_{\mathcal{F}}^{-1}(q_i) \cap P$*, will be a set of* ℓ *points in general position with respect to* $\mathcal{F}$.

Proof.

1. First, observe that it is enough to show that the map $\Phi_{\mathcal{F}}$ is injective on P. In general, the map $\Phi_{\mathcal{F}}$ need not be an injective mapping on an arbitrary set of n points in $\mathbb{R}^t$. However, we show that Φ is injective when restricted to P if P is in general position with respect to $\mathcal{F}$. To reach a contradiction, let $\Phi_{\mathcal{F}}(p_1) = \Phi_{\mathcal{F}}(p_2)$ where $p_1, p_2 (\neq p_1) \in P$. Let $S \subseteq P$ be of size $b+1$ and $p_1, p_2 \in S$. Observe that the set $\Phi_{\mathcal{F}}(S)$ will have less than $b+1$ points and this will imply that there exists a hyperplane $\sum_{i=1}^{b} \lambda_i Z_i + \lambda_{b+1} = 0$ on which the set $\Phi_{\mathcal{F}}(S)$ will lie. But this implies that the polynomial $\sum_{i=1}^{b} \lambda_i f_i(X) + \lambda_{b+1} = 0$ will be satisfied by all the points in S. This is a contradiction to the fact that the point set P is in general position.
2. This result follows directly from the construction of the mapping $\Phi_{\mathcal{F}}$. ◀

With the above result and Theorem 10 we get the following theorem.

▶ **Theorem 15.** d-Polynomial Subset General Position *in* $\mathbb{R}^t$ *parameterized by* k*, has a polynomial kernel of size* $\mathcal{O}(k^{2b^2})$*. Here* b *is the size of the basis generating the underlying vector space of polynomials.*

As in the case with Theorem 10 we can also get a projective version of Theorem 15. Let $\mathcal{F}$ be a subspace of $\text{Poly}_d[X_1, \ldots, X_t]$ with basis $\{f_1(X), \ldots, f_b(X)\}$ where $X = (X_1, \ldots, X_t)$ and none of the polynomial functions $f_i(X)$ are constants. Then we can define projective analog of the general position problem for polynomial families like $\mathcal{F}$. For a given point set P in $\mathbb{R}^t$, a subset S of P will be in general position with respect to $\mathcal{F}$ if no more than $b-1$ points from S lie on any $f(X) \in \mathcal{F}$.

Using the same techniques as in the proof of Theorem 10 we will get the following result:

▶ **Corollary 16.** Projective Polynomial Subset General Position *in* $\mathbb{R}^t$ *parameterized by* k *has a kernel of size* $\mathcal{O}(k^{3(b-1)^2})$.

Upper bounds for non-vector space families

Observe that we may be interested in getting general position point set with respect to families of polynomials that are not vector spaces of $\text{Poly}_d[X_1, \ldots, X_t]$. For example, consider the case of hyperplanes in R^t of the following type $H := \sum_{i=1}^{t-1} \lambda_i X_i + X_t + \beta$, where λ_i's and β

are in $\mathbb{R}^+$. One might be interested in getting a general position set in $\mathbb{R}^t$ with respect to these hyperplanes.

Note that our upper bound on the kernel size in the primal parameter extends to these families as well.

▶ **Corollary 17.** *Let $\mathcal{F}$ be a subfamily of $\text{Poly}_d[X_1, \ldots, X_t]$ such that there exists polynomial functions $f_1(X), \ldots, f_b(X)$ in $\text{Poly}_d[X_1, \ldots, X_t]$ and for any $f(X) \in \mathcal{F}$, $f(X) = \sum_{i=1}^{b} \lambda_i f_i(X)$ where the λ_i's are in $\mathbb{R}$. Subset general position problem with respect to $\mathcal{F}$ parameterized by primal parameter k has a kernel of size $\mathcal{O}(k^{3(b-1)^2})$.*

4 Tight kernels for hyperplanes in dual parameter

In this Section, we show that Hyperplane Subset General Position in $\mathbb{R}^d$, parameterized by the dual parameter h, cannot have a kernel of size $h^{d-\epsilon}$ if co-NP $\not\subseteq$ NP/poly. We show this result by the standard technique of polynomial parameter transformation. For a fixed d, we reduce the d-Hitting Set problem on d-uniform graphs to the problem of Hyperplane Subset General Position in $\mathbb{R}^d$. By Proposition 3, this gives us a lower bound for Hyperplane Subset General Position in $\mathbb{R}^d$.

For the main result, we construct for each positive integer n and each d, a set of n points in $\mathbb{R}^d$ with some special properties.

▶ **Lemma 18.** *For every d-uniform hypergraph G in n vertices and m hyperedges, there is a transformation to a set $P \uplus B = \{p_1, p_2, \ldots, p_n\} \uplus \{b_1, b_2, \ldots, b_m\}$ of $n + m$ points in $\mathbb{R}^d$ that have the following properties:*

1. *The points $\{p_1, p_2, \ldots, p_n\}$ are in general position.*
2. *Each vertex $v_i \in V(G)$ is mapped to the point $p_i \in P$.*
3. *Each hyperedge $e_j \in E(G)$ is mapped to the point $b_j \in B$.*
4. *For a hyperedge $e_j \in E(G)$, if there are d points $\{p_{i_1}, p_{i_2}, \ldots, p_{i_d}\} \in P$ such that $b_j, p_{i_1}, p_{i_2}, \ldots, p_{i_d}$ are cohyperplanar, then it must be the case that $e_j = \{v_{i_1}, v_{i_2}, \ldots, v_{i_d}\}$.*
5. *For any set of $i \leq d$ points of B and $d + 1 - i$ points of P cannot be cohyperplanar.*
6. *The points in B are in general position. In other words, no $d + 1$ points in B are cohyperplanar.*

Proof Idea. The main idea behind the proof is that the sets P and B satisfying the conditions of Lemma 18 can be generated in a greedy manner from considering large grids. We will first construct the point set P of n points in a greedy manner such that P comes from a large grid and is in general position. After P is constructed, the set B is again greedily constructed, this time using a lower dimensional grid lying in a particular hyperplane. ◀

This transformation from a graph to a point set leads to the following observation.

▶ **Observation 19.** *Let G be a d-uniform hypergraph and $P \uplus B$ be the set of points in $\mathbb{R}^d$ corresponding to G. For any maximal set S of points in general position, there is a set of size at least $|S|$ that contains all the points in B.*

This helps us to design a reduction from d-Hypergraph Independent Set to Hyperplane Subset General Position in $\mathbb{R}^d$.

▶ **Lemma 20.** *There is a many-one reduction from d-Hypergraph Independent Set on d-uniform hypergraphs to Hyperplane Subset General Position in $\mathbb{R}^d$.*

Finally, we are ready to prove the main result.

▶ **Theorem 21.** Hyperplane Subset General Position *in* $\mathbb{R}^d$ *parameterized by the dual parameter cannot have a kernel of size* $\mathcal{O}(h^{d-\epsilon})$ *if* co-NP $\not\subseteq$ NP*/poly.*

Proof. We give a reduction from d-Hitting Set on d-uniform hypergraphs. Given an instance (G, h) of d-Hitting Set on d-uniform hypergraphs, we consider the equivalent d-Hypergraph Independent Set instance $(G, |V(G)| - h)$. By Lemma 20, we construct an instance $(P \uplus B, |V(G)| + |E(G)| - h)$. Note that the transformation is such that $|P| = |V(G)|$ and $|B| = |E(G)|$. Thus, G has a d-hitting set of size k if and only if G has an independent set of size $|V(G)| - h$, which by Lemma 20 happens if and only if $P \uplus B$ has a point subset of size $k' = |P \uplus B| - h$ that is in general position with respect to hyperplanes in $\mathbb{R}^d$. This means that the dual parameter $|P \uplus B| - k'$ is equal to h, which is the d-hitting set size in G. This implies the lower bound on the kernel size of Hyperplane Subset General Position in $\mathbb{R}^d$ parameterized by the dual parameter. ◀

We obtain tight polynomial kernels from the following Proposition, derived from a folklore result.

▶ **Proposition 22.** Hyperplane Subset General Position *in* $\mathbb{R}^d$ *parameterized by the dual parameter* h *has a kernel of size* h^d*.*

Proof. We state the folklore reduction from Hyperplane Subset General Position in $\mathbb{R}^d$ to $(d+1)$-Hitting Set. Given an instance (P, h) of Hyperplane Subset General Position in $\mathbb{R}^d$, we construct the following instance (G, h) of $(d+1)$-Hitting Set. Corresponding to each point in P we create a vertex in $V(G)$. For any $d+1$ point in P that are coplanar in $\mathbb{R}^d$, we create a hyperedge with the corresponding vertices. Consider the vertices in a hyperedge of G. At least one of the corresponding points has to be deleted in order to construct a subset of P that is in general position with respect to hyperplanes in $\mathbb{R}^d$. Thus, the set of points deleted correspond to a hitting set of G. Therefore, the reduction is correct.

$(d+1)$-Hitting Set has a kernel where the universe size if $\mathcal{O}(h^d)$ [19]. This gives us an $\mathcal{O}(h^d)$ kernel for Hyperplane Subset General Position in $\mathbb{R}^d$ parameterized by the dual parameter. ◀

Lower bounds on elements in a kernel for hyperplanes in dual parameter

In this section, we show that by the method suggested by Dell and Melkebeek [7], we can show a lower bound on the number of points in a polynomial kernel for Hyperplane Subset General Position in $\mathbb{R}^d$, for each fixed positive integer d. This result is a direct extension of the results obtained in [15] and [14].

▶ **Theorem 23.** Hyperplane Subset General Position *in* $\mathbb{R}^d$*, parameterized by* h*, cannot have a kernel with* $\mathcal{O}(h^{d-\epsilon})$ *points if* co-NP $\not\subseteq$ NP*/poly.*

5 Bounded degree polynomials and the dual parameter

In this section we discuss about the generalization of Theorems 21 and 23. Note that, for any given point set P with n points, both theorems can be proved for finding a point set of size $n - h$, h being the dual parameter, if the construction of Lemma 18 can be replicated for a particular family $\mathcal{F}$. In particular, consider a family $\mathcal{F}$ of polynomials of degree at most d with basis $\{f_1(X), \ldots, f_b(X), 1\}$, where $X = \{X_1, \ldots, X_t\}$. Suppose for each b-uniform hypergraph G with n vertices and m edges it is possible to make a transformation as follows:

1. The points $\{p_1, p_2, \ldots, p_n\}$ are in general position with respect to $\mathcal{F}$ and have bounded representation.
2. Each vertex $v_i \in V(G)$ is mapped to the point $p_i \in P$.
3. Each hyperedge $e_j \in E(G)$ is mapped to the point $b_j \in B$.
4. For a hyperedge $e_j \in E(G)$, if there are d points $\{p_{i_1}, p_{i_2}, \ldots, p_{i_b}\} \in P$ such that $b_j, p_{i_1}, p_{i_2}, \ldots, p_{i_b}$ lie on a polynomial from $\mathcal{F}$, then it must be the case that $e_j = \{p_{i_1}, p_{i_2}, \ldots, p_{i_b}\}$.
5. For any set of $i \leq b$ points of B and $b+1-i$ points of P cannot be on any polynomial of $\mathcal{F}$.
6. The points in B are in general position. In other words, no $b+1$ points in B can be on any polynomial of $\mathcal{F}$.

Let us call such a transformation a *good* transformation. Then with respect to such a family $\mathcal{F}$, equivalent tight kernelizations for the dual parameter can be given. When $\mathcal{F}$ is the family of spheres, then such a construction is possible.

▶ **Corollary 24.** *Given the family of spheres in $\mathbb{R}^d$, for each $(d+1)$-uniform hypergraph with n vertices and m points there is a good transformation to a set $P \uplus B$ of $n+m$ points.*

Proof. The construction is similar as that of Lemma 18, as we again can construct the sets greedily. The point set P can be extracted from a large enough grid as in the construction given in Lemma 18. The construction of the points in B is also done inductively. Suppose the points of a subset $B' \subset B$ have already been placed on rational points such that all the necessary conditions are satisfied. Let $b_e \in B \setminus B'$. Consider the sphere S_e defined by the d-sized point set P_e corresponding to the vertices of $e \in E(G)$. Consider the family $\mathcal{F}$ of spheres formed by (i) a set of any d points in P other than the set P_e, (ii) any d points from B', and (iii) a set S of d points with at least one point from P and at least one point from B'. The intersection of this family of spheres with S_e is a family $\mathcal{F}'$ of lower dimensional spaces. Since the points in P have bounded representation, so do the intersection spaces. It is possible to determine in polynomial time the arrangement of the lower dimensional intersections on S_e [1]. From this arrangement, we select a point with bounded representation that does not belong to any of the lower dimensional flats in $\mathcal{F}'$ and set the point to b_e. The set $B' \cup b_e$ again satisfies all the necessary conditions. We continue till all the points in B have been determined. Thus, we construct the required set $P \uplus B$. ◀

6 Open Problems

One of the major open questions in this area is regarding techniques for showing kernel lower bounds with respect to the primal parameter. Currently, no non-trivial lower bound is known for even Hyperplane Subset General Position in $\mathbb{R}^2$.

In Section 5, we gave tight lower bounds with respect to the dual parameter under some restricted vector spaces of d-degree polynomials. It will be interesting to understand the problem better for general vector spaces of d-degree polynomials. In fact, it might be useful for both algorithmic as well as combinatorial studies to understand the Geometric Subset General Position in both the primal and dual parameter for families of d-degree polynomials that are not vector spaces or a subset of a vector space. We are interested in studying families that fall outside these frameworks.

General position with respect to spheres is also connected to Delaunay Subset Selection problem where we are given a point set $P \subset \mathbb{R}^d$ as input and the problem is to extract a maximum size subset S of P such that the Delaunay complex $\mathrm{Del}(S)$ is a triangulation

of the convex hull $\text{conv}(S)$ of S. Although the upper bounds for kernelization given in this paper hold for this problem, lower bound questions remain open for both primal and dual parameter.

Abstract

We consider satisfiable Tseitin formulas $\mathrm{TS}_{G,c}$ based on d-regular expanders G with the absolute value of the second largest eigenvalue less than $\frac{d}{3}$. We prove that any nondeterministic read-once branching program (1-NBP) representing $\mathrm{TS}_{G,c}$ has size $2^{\Omega(n)}$, where n is the number of vertices in G. It extends the recent result by Itsykson at el. [9] from OBDD to 1-NBP.

On the other hand it is easy to see that $\mathrm{TS}_{G,c}$ can be represented as a read-2 branching program (2-BP) of size $O(n)$, as the negation of a nondeterministic read-once branching program (1-coNBP) of size $O(n)$ and as a CNF formula of size $O(n)$. Thus $\mathrm{TS}_{G,c}$ gives the best possible separations (up to a constant in the exponent) between 1-NBP and 2-BP, 1-NBP and 1-coNBP and between 1-NBP and CNF.

1 Introduction

1.1 Satisfiable and unsatisfiable Tseitin formulas

A Tseitin formula $\mathrm{TS}_{G,c}$ is defined for every undirected graph $G(V, E)$ and labelling function $c : V \to \{0, 1\}$. We introduce a propositional variable for every edge of G. The Tseitin formula $\mathrm{TS}_{G,c}$ represents a linear system over the field GF(2) that for every vertex $v \in V$ states that the sum of all edges adjacent to v equals $c(v)$.

A Tseitin formula is satisfiable if and only if the sum of values of the labeling function for all vertices in every connected component is even [17]. The study of Tseitin formulas is motivated by Proof Complexity. Proof Complexity basically deal with unsatisfiable Tseitin formulas that roughly speaking encode that it is impossible that a graph has an odd number of vertices with odd degree. It is important for Proof Complexity that propositional formulas have small CNF representations; thus it is usually assumed that G has constant degree;

* The research was supported by Russian Science Foundation (Project 16-11-10123).

for such graphs Tseitin formulas have CNF representations of size $O(n)$ and it contains $O(n)$ variables where n is the number of vertices in G. Tseitin formulas were invented by Tseitin in 1968 for the graph of $n \times n$ cellular square and were used for the proving of the first superpolynomial lower bound for regular resolution. In 1987 Urquhart extended this result and proved exponential lower bound on the complexity of resolution refutations of Tseitin formulas based on expanders. Unsatisfiable Tseitin formulas are one of the basic examples of hard formulas for many proof systems; in particular, Tseitin formulas are hard for bounded depth Frege [3], [15], Polynomial Calculus over the field $\mathbb{F}$ with $\mathrm{char}(\mathbb{F}) \neq 2$, tree-like Lovasz-Schrijver proof system [8], etc.

Satisfiable Tseitin formulas have been studied less intensively. In the recent paper by Itsykson at el. [9] satisfiable Tseitin formulas appeared in the proof of an exponential lower bound on the size of the derivation of unsatisfiable Tseitin formulas in the proof system OBDD(join, reordering). An OBDD is a partial case of a read-once deterministic branching program, where in every path from the source to a sink all variables appear in the same order. The key step in the proof of the mentioned lower bound is the proof of an exponential lower bound on the OBDD representation of satisfiable Tseitin formulas based on constant degree expanders. The latter lower bound motivated us for the current research. There are known examples of Boolean functions that are easy for read-once branching program but hard for OBDD (see for example Theorem 6.1.2 in [18]). Is it possible to extend the mentioned lower bound from OBDD to read-once branching program?

It is well known that the size of the shortest regular resolution proof of any unsatisfiable CNF formula ϕ equals the size of the minimal read-once branching program for the following search problem $Search_\phi$: given an assignment of variables of ϕ, find a clause that is refuted by this assignment [12]. Thus lower bounds for the size of resolution proofs of ϕ implies lower bounds on the size of read-once branching program for $Search_\phi$. However it is unclear whether the sizes of read-once branching programs for $Search_\phi$ for unsatisfiable Tseitin formula ϕ and for the evaluation of a satisfiable Tseitin formula are connected. The difference is the following:

1. the first case is about unsatisfiable Tseitin formulas while the second case is about satisfiable Tseitin formulas;
2. to find a clause that is refuted may be harder than just to say that the value of a function is 0.

1.2 Results

In this paper we prove that every nondeterministic read-once branching program (1-NBP) representing a satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ based on d-regular expander with the absolute value of the second largest eigenvalue less than $\frac{d}{3}$ has size $2^{\Omega(n)}$, where n is the number of vertices in G and d is a constant. As a corollary we get a lower bound $2^{\Omega(n)}$ on the size of nondeterministic read-once branching programs for Tseitin formulas based on complete graph K_n. All mentioned lower bounds are tight up to a constant in the exponent since every satisfiable Tseitin formula based on graph with n vertices and m edges may be represented as OBDD of size $O(m2^n)$ (see Proposition 3 below).

1.3 Comparison with other works

If we consider a Tseitin formula as a system of linear equations then every variable will have exactly two occurrences. Therefore by straightforward transformation every satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ may be represented as read-2 deterministic branching program

(2-BP) of size $O(m)$, where m is the number of edges in G. Thus satisfiable Tseitin formulas based on constant-degree expanders strongly exponentially separate 1-NBP and 2-BP. And this separation is optimal up to a constant in the exponent. Consider a function $\text{CLIQUE\_ONLY}_n : \{0,1\}^{n(n-1)/2} \to \{0,1\}$ that detect whether a undirected graph on n vertices is exactly a clique on $\lfloor n/2 \rfloor$ vertices. Borodin, Razborov and Smolensky [4] proved that any nondeterministic read-once branching program representing CLIQUE_ONLY_n has size $2^{\Omega(n)}$ (note that CLIQUE_ONLY_n depends on $\Theta(n^2)$ variables) while there is a deterministic read-twice branching program of size $\text{poly}(n)$. Thathachar [16] gave, for every natural k, an explicit function that can be evaluated by deterministic read-$(k+1)$ branching program of linear size but every nondeterministic read-k branching program for this function has size at least $2^{\Omega\left(n^{1/(k+1)}\right)}$. As far as we know, the best previously known gap between sizes of 1-NBP and 2-BP was $2^{\Omega(\sqrt{n})}$ and we improved it to $2^{\Omega(n)}$.

First explicit Boolean function with strongly exponential lower bound on the size of 1-NBP was constructed in [4], however this function was rather artificial. Duros at el. [7] proved strongly exponential lower bounds on the size of 1-NBP for the function $\oplus cl_{3,n}$ that computes the parity of the number of triangles in the graph (and this extends the result of Babai at el.[2] from 1-BP to 1-NBP) and for the function $\Delta_{3,n}$ that is true iff the input graph does not contain triangles. So satisfiable Tseitin formulas based on constant-degree expanders is one more natural example of functions that require strongly exponential 1-NBP.

A satisfiable Tseitin formula based on a d-regular graph on n vertices is a characteristic function of an affine subspace of $\{0,1\}^{dn/2}$. Characteristic functions of affine (linear) subspaces were already studied in the context of complexity of deterministic and nondeterministic reak-k branching programs, namely characteristic functions of linear error-correcting codes were studied by Okolnishnikova [14] and Jukna [10]. Jukna [10] proved lower bound $2^{\Omega(\sqrt{n})}$ on the size of nondeterministic read-k branching program for characteristic functions of error-correcting codes $\mathcal{C} \subseteq \{0,1\}^n$. Duris at el. [7] presented a probabilistic construction of a linear code such that its characteristic function require 1-NBP of the size at least $2^{\Omega(n)}$. Jukna [10] noted that the negation of a characteristic function of an affine subspace may be represented by linear size (in the size of linear system that defines this subspace) nondeterministic read-once branching program. Indeed we just need to guess an equation that is not satisfied and then check this equation. Duris at el. [7] also showed that the characteristic function of a linear subspace of $\{0,1\}^n$ (and hence it is also true for affine subspaces) may be represented by a randomized read-once branching program with one-sided error 2^{-r} of size $O(n^r)$ for all natural r. As far as we know, satisfiable Tseitin formulas based on explicit constant-degree expanders are the only example of *explicit* functions (randomized construction was presented in [7]) that strongly exponentially separate nondeterministic and co-nondeterministic read-once branching program. And also our separation between nondeterministic and randomized read-once branching program seems to be the best known for the explicit functions.

We finally note that Tseitin formulas based on constant degree graphs may be represented as CNF formulas of size $O(n)$, so we get a strongly exponential separation between sizes of 1-NBP and CNF.

2 Preliminaries

2.1 Branching programs

A deterministic branching program (BP) is a form of representation of Boolean functions. A Boolean function $\{0,1\}^n \to \{0,1\}$ is represented by a directed acyclic graph with exactly one source and two sinks. All nodes except sinks are labeled with a variable; every internal

node has exactly two outgoing edges: one is labeled with 1 and the other is labeled with 0. One of the sinks is labeled with 1 and the other is labeled with 0. The value of the function for a given values of variables is evaluated as follows: we start a path from the source such that for every node on its path we go along the edge that is labeled with the value of the corresponding variable. This path will end in a sink. The label of this sink is the value of the function.

A nondeterministic branching program (NBP) differs from a deterministic in the way that we also allow guessing nodes that are unlabeled and have two outgoing unlabeled edges. So nondeterministic branching program may have three type of nodes: guessing nodes, nodes labeled with a variable (we call them just labeled nodes) and two sinks; the source may be either a guessing node or labeled node. The result of a function represented by a nondeterministic branching program equals 1, if there exists at least one path from the source to the sink labeled with 1 such that for every node labeled with a variable on its path we go along an edge that is labeled with the value of the corresponding variable, while for guessing nodes we are allowed to choose any of two outgoing edges.

Note that deterministic branching programs constitute a special case of nondeterministic branching programs.

A deterministic or nondeterministic branching program is (syntactic) read-k (k-BP or k-NBP) if every path from the source to a sink contains at most k occurrences of every variable.

An ordered binary decision diagram (OBDD) is a partial case of 1-BP, where on every path from the source to a sink all variables appear in the same order.

2.2 Tseitin formulas

Let $G(V, E)$ be an undirected graph without loops but possibly with multiple edges, $c : V \to \{0, 1\}$ be a labeling function that matches every vertex with a boolean value. Let us match every edge $e \in E$ with a propositional variable x_e. Tseitin formula $\mathrm{TS}_{G,c}$ based on a graph G and a labeling function c is the conjunction of the following conditions: for every vertex v the sum of variables x_e for all edges e that are incident to v equals $c(v)$ modulo 2. More formally: $\bigwedge\limits_{v \in V} \left(\sum\limits_{e \text{ is incident to } v} x_e = c(v) \bmod 2 \right)$.

If the maximal degree of a graph G is bounded by a constant d, then a sum modulo 2 can be written as a d-CNF formula with size at most $O(2^d d)$. Hence the size of CNF representation of $\mathrm{TS}_{G,c}$ does not exceed $O(2^d dn)$.

We will use the following criterion of the satisfiability of Tseitin formulas:

▶ **Proposition 1** ([17]). A Tseitin formula $\mathrm{TS}_{G,c}$ is satisfiable if and only if for every connected component U the following holds: $\sum\limits_{v \in U} c(v) = 0 \bmod 2$.

▶ Remark. Note that a substitution of a value to a variable $x_e := \alpha$ transforms Tseitin formula $\mathrm{TS}_{G,c}$ to a Tseitin formula $\mathrm{TS}_{G',c'}$, where graph G' is obtained from the graph G by deleting the edge e, c' equals c in every vertex except two vertices that are incident to edge e. On these two vertices the values of c and c' differ by α. In particular it follows that if $\mathrm{TS}_{G,c}$ is satisfiable and an edge e is not a bridge in the graph G, then the formula $\mathrm{TS}_{G',c'}$ is also satisfiable by Proposition 1 since the parity of sum of labels in G' in every connected component is the same as in G.

▶ **Lemma 2.** *Let $G(V, E)$ be a graph with k connected components. If the Tseitin formula $\mathrm{TS}_{G,c}$ is satisfiable, then the number of its satisfying assignments equals $2^{|E|-|V|+k}$.*

Proof. Let us fix some spanning forest F of the graph G; F contains exactly $|V| - k$ edges. Consider some partial substitution ρ to the edges of G that are not in F. By the Remark we know that after the application of the partial substitution ρ to $\mathrm{TS}_{G,c}$ we will get a satisfiable Tseitin formula based on the graph F. Since F is a forest the resulting Tseitin formula has exactly one satisfying assignment. Indeed a forest always has a vertex with degree 1 which helps us unambiguously determine the value of the incident edge. After that we can delete this edge from the forest and we will get a forest again; and so on. Hence the number of satisfying assignment of $\mathrm{TS}_{G,c}$ equals the number of different partial substitutions to the edges that are not in F; so the number of satisfying assignment equals $2^{|E|-|V|+k}$. ◀

▶ **Proposition 3.** Any satisfiable Tseitin formula based on a graph with n vertices and m edges can be represented as OBDD of size $O(m2^n)$.

Proof. Let us fix some order on the edges of the graph. The described OBDD will have m levels. Nodes on the i-th level are labeled with i-th edge of the graph.

Assume that we already ask for the value of the first $i-1$ edges. For every vertex of the graph we compute the sum modulo 2 of values of edges from these $i-1$ that are incident to the vertex. So we will have a vector of n parities. The i-th level of the OBDD contains 2^n nodes corresponding to the all possible values of vector of parities that we get after the reading of the first $(i-1)$ edges. Every node on the i-th level has two outgoing edges to nodes on the $(i+1)$-th level corresponding to the way how values on the edges change the parity of vertices. The node on the first level corresponding to all zero values of parities is the source of the OBDD (all nodes that are not reachable from the source should be removed). Outgoing edges for every node on the last level will go to a sink corresponding to the fact, whether the labeling function of the Tseitin formula is consistent with the resulting values of parities. ◀

▶ **Proposition 4.** 1) Every two satisfying assignments of a satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ differ in at least two positions. 2) Every path from the source to the sink labeled with 1 in 1-NBP representing a satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ contains variables for all edges of G.

Proof. 1) If we change a value of any edge in a satisfying assignment of $\mathrm{TS}_{G,c}$, the parity condition will be violated on two ends of this edge. 2) Assume that some acceptance path does not contains a variable x. Then there are two satisfying assignments of $\mathrm{TS}_{G,c}$ that differ only in the value of the variable x; this contradicts item 1. ◀

2.3 Expanders

Let $G(V,E)$ be an undirected graph without loops but possibly with multiple edges. G is an algebraic (n,d,α)-expander if G is d-regular, $|V| = n$ and the absolute value of the second largest eigenvalue of the adjacency matrix of G is not greater than αd.

It is well known that for all $1 > \alpha > 0$ and all large enough constants d there exist natural number n_0 and a family $\{G_n\}_{n=n_0}^{\infty}$ of (n,d,α)-algebraic expanders. There are explicit constructions such that G_n can be constructed in $\mathrm{poly}(n)$ time [13]. Also, it is known that a random d-regular graph is an expander with high probability.

Let us denote by $E(A,B)$ a multiset of edges that have one end in A and another end in B. Note that in the case where both ends of an edge are simultaneously in A and in B, we count this edge twice.

▶ **Lemma 5** (Cheeger inequality [5]). *Let $G(V,E)$ be an (n,d,α)-expander. Then for all $A \subseteq V$ such that $|A| \le \frac{n}{2}$ the following inequality holds: $|E(A, V \setminus A)| \ge \frac{1-\alpha}{2} d|A|$.*

▶ **Corollary 6.** *Every (n, d, α)-expander with $0 < \alpha < 1$ is connected.*

Proof. If G is not connected, then we will get a contradiction with Lemma 5 if we choose A to be a smallest connected component. ◀

▶ **Lemma 7** (Expander mixing lemma [1])**.** *Let $G(V, E)$ be (n, d, α)-expander, $A, B \subseteq V$. Then $\left||E(A, B)| - \frac{d|A||B|}{n}\right| \leq \alpha d\sqrt{|A||B|}$.*

Using Lemma 7 we can improve the estimation of the number of edges that go from A to the complement of A for small sets A.

▶ **Proposition 8.** For every (n, d, α)-expander for every $A \subseteq V$ the following inequality holds: $|E(A, V \setminus A)| \geq d|A|(1 - \frac{|A|}{n} - \alpha)$.

Proof. $|E(A, V \setminus A)| = |E(A, V)| - |E(A, A)| = d \cdot |A| - |E(A, A)| \geq d \cdot |A|(1 - \frac{|A|}{n} - \alpha)$. The last inequality follows from Lemma 7. ◀

3 Lower bound

Our main goal is to prove the following theorem:

▶ **Theorem 9.** *Let $G(V, E)$ be an algebraic (n, d, α)-expander, where $\alpha < \frac{1}{3}$. Let $\mathrm{TS}_{G,c}$ be a satisfiable Tseitin formula. Then the size of every* 1-NBP *that represents $\mathrm{TS}_{G,c}$ is $2^{\Omega(n)}$.*

Let us describe the plan of the proof. Consider a minimal 1-NBP that evaluates $\mathrm{TS}_{G,c}$. For every node of this branching program, except the sink labeled with 0 there exists a path to the sink labeled with 1. In the opposite case this node could be merged with a sink labeled with 0 and it would decrease the size of the 1-NBP.

For nondeterministic branching program, by *the length of a path* we will mean the number of labeled edges in it (i.e. we do not count outgoing edges from guessing nodes). For every labeled node v in a branching program we define its level as the minimal length of paths from the source to v. We choose a level $l = \Omega(n)$ and prove that the minimal 1-NBP contains many label nodes on the level l. The proof consists of two parts:

1. We show that every minimal 1-NBP that evaluates $\mathrm{TS}_{G,c}$ contains at least $2^{C_1 n}$ paths of length l from the source to a labeled node that correspond to different partial substitutions, where C_1 is a constant.
2. We show that in every minimal 1-NBP that evaluates $\mathrm{TS}_{G,c}$ for every labeled node v on the level l there are at most $2^{C_2 n}$ different partial substitutions that correspond to different paths from the source to the vertex v, where $C_2 < C_1$ is a constant.

These two propositions imply that the number of label nodes on the level l is at least $2^{(C_1 - C_2)n}$.

3.1 Lower bound on the number of paths

In this section we perform the first part of the plan and estimate the number of paths of length l from the source of the minimal 1-NBP that end in a labeled node and correspond to different partial substitutions.

▶ **Lemma 10.** *Let $G(V, E)$ be a connected graph. Let k be the maximum number of connected components that can be obtained after deleting of l edges from G. Then every minimal* 1-NBP *evaluating a satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ contains at least $2^{l-(k-1)}$ paths of length l from the source that end in a labeled node and correspond to different partial substitutions.*

Proof. By Lemma 2 the number of satisfying assignments of the formula $\mathrm{TS}_{G,c}$ equals $2^{|E|-|V|+1}$.

For every satisfying assignment of $\mathrm{TS}_{G,c}$ there exists a path in the minimal 1-NBP from the source to the sink labeled with 1 of length $|E|$ that is consistent with the assignment. By Proposition 4 it is impossible that there are paths from the source to the sink labeled with 1 that are shorter than $|E|$. Let P be the set of paths from the source to the sink labeled with 1 such that for every satisfying assignment of $\mathrm{TS}_{G,c}$ there are exactly one path in P that represents this assignment.

We estimate the number of paths in P that define the same partial substitution ρ that corresponds to the first l labeled edges of the path.

If we apply ρ to $\mathrm{TS}_{G,c}$ we will get a Tseitin formula $\mathrm{TS}_{G',c'}$, where G' is obtained from G by deleting l edges corresponding to the path p (the labeling function also changes after the application of ρ, see Remark 2.2 for details). All paths from P that are consistent with ρ satisfy the formula $\mathrm{TS}_{G',c'}$. Recall that all paths from P correspond to different satisfying assignments, hence the number of paths that are consistent with ρ is not greater than the number of satisfying assignments of the formula $\mathrm{TS}_{G',c'}$. By Lemma 2 the number of satisfying assignments of the formula $\mathrm{TS}_{G',c'}$ equals $2^{|E|-l-|V|+m}$, where m is the number of connected components in the graph G'. By the statement of the lemma $m \leq k$, therefore the number of satisfying assignments of $\mathrm{TS}_{G',c'}$ is not greater than $2^{|E|-l-|V|+k}$. So we get that every partial substitution of l variables may be a prefix of length l (we assume that prefixes end in labeled nodes) of at most $2^{|E|-l-|V|+k}$ paths from P. Hence there are at least $\frac{2^{|E|-|V|+1}}{2^{|E|-l-|V|+k}} = 2^{l-(k-1)}$ different partial substitutions that correspond to prefixes of length l of paths from P, and these prefixes we will consider as the paths which number we estimate in the lemma. ◀

▶ **Lemma 11.** *Every graph that can be obtained by deleting $l \leq \frac{n}{4}$ edges from an algebraic (n, d, α)-expander G contains at most $\frac{2l}{d(1-\alpha)} + 1$ connected components.*

Proof.

▶ **Claim 12.** Let graph $H(V, E)$ have n vertices and k connected components, where $1 < k \leq \frac{n}{4} + 1$. Then there exists $M \subseteq V$ such that M consists of the union of all vertices of several connected components and $k - 1 \leq |M| \leq \frac{n}{2}$.

Proof of Claim 12. We construct M iteratively. Assume that initially M is empty. Let us sort all connected components in the increasing order of their sizes: $s_1, s_2, \ldots, s_k$. We add connected components to M starting from the smallest one while the sum of the sizes of these components is less than $k - 1$. Let i be the number of connected components that we added to M. If $|M| \leq \frac{n}{2}$ then we are already done. Assume that $|M| > \frac{n}{2}$. Note that $|M \setminus s_i| < k - 1$ by the construction of M. Hence $|s_i| > \frac{n}{2} - (k - 1) \geq k - 1$ since $k - 1 \leq \frac{n}{4}$. If $|s_i| \leq \frac{n}{2}$ then the we can take $M = s_i$. So we may assume that $|s_i| > n/2$, therefore s_i is the biggest connected component and $i = k$. Since every connected component contains at least one vertex the number of vertices in $M \setminus s_i$ should be at least $k - 1$ that contradicts the construction of M. ◀

Consider some subgraph H that may be obtained from G by deleting of at most l edges. By Corollary 6 G is connected, hence H contains at most $\frac{n}{4} + 1$ connected components. Consider the set M from Claim 12. Let us estimate the number of edges that we need to delete from G in order to separate M from other vertices of the graph. By Lemma 5 $l \geq \frac{|M| \cdot d \cdot (1-\alpha)}{2} \geq \frac{(k-1) \cdot d \cdot (1-\alpha)}{2}$. Hence $k - 1 \leq \frac{2l}{d \cdot (1-\alpha)}$. ◀

Altogether Lemma 10 and Lemma 11 imply the following lemma:

▶ **Lemma 13.** *In every minimal* 1-NBP *that represents a satisfiable Tseitin formula based on an* (n, d, α)*-expander for every* $l \leq \frac{n}{4}$ *there are at least* $2^{l\left(1-\frac{2}{d(1-\alpha)}\right)}$ *paths of length* l *from the source to a labeled node that correspond to different partial substitutions.*

3.2 Upper bound on the number of paths that end at the same vertex

In this section we estimate the maximum number of paths with length l that ends in a fixed labeled node v and correspond to different partial substitutions. In particular we prove the following lemma:

▶ **Lemma 14.** *For every minimal* 1-NBP *that evaluates a satisfiable Tseitin formula* $\mathrm{TS}_{G,c}$ *based on an* (n, d, α)*-expander* G *for every* $\beta \in (0; 1)$ *for every labeled node* v *of the* 1-NBP *there are at most* $2^{l\left(1-\frac{1}{d(\alpha+\beta)}\right)}$ *different partial substitutions that correspond to paths of length* l *from the source to* v*, where* $l \leq \beta n - 1$*.*

Proof.

▶ **Claim 15.** Consider some labeled node v of the 1-NBP. Let p_1 and p_2 be two different paths from the source to the node v. Then

1. the sets of variables that correspond to labeled nodes on the paths p_1 and p_2 are equal;
2. if we apply to $\mathrm{TS}_{G,c}$ a partial substitution corresponding to p_1, we get the same Tseitin formula as if we apply to $\mathrm{TS}_{G,c}$ a partial substitution corresponding to p_2.

Proof of Claim 15. 1. Since v is a labeled node and the 1-NBP is minimal there is a path s from v to the sink labeled with 1. Both paths $p_1 s$ and $p_2 s$ go from the source to the sink labeled with 1. Every variable appears in both of these paths at most once. Let x be a variable that appears in p_1 but doesn't appear in p_2 then the substitution corresponding to the path $p_2 s$ satisfy $\mathrm{TS}_{G,c}$. By Proposition 4 p_2 should contain the variable x.

2. By Remark 2.2 if we apply a partial substitution to a Tseitin formula we also get a Tseitin formula. The sets of satisfying assignments of two different Tseitin formulas do not intersect, because every satisfying assignment of variables unambiguously determines the labeling function of Tseitin formula. Paths $p_1 s$ and $p_2 s$ satisfy the initial formula hence the path s should satisfy both Tseitin formulas, the one corresponding to the path p_1 and the one corresponding to the path p_2. Hence these two Tseitin formulas should be equal. ◀

Let v be some labeled node that has level l. By Claim 15 every path from the source to the node v contains the same set of variables and if we apply to $\mathrm{TS}_{G,c}$ any of the substitutions corresponding to these paths we get the same Tseitin formula $\mathrm{TS}_{H,c'}$. Consider some path from the source to v of length l and denote the set of labels (i.e. variables) of the first l labeled nodes on this path by I. By Claim 15 I does not depend on the choice of the path. Let F be a set of edges that correspond to variables from I. Then $I = \{x_e \mid e \in F\}$ and H is obtained from G by deleting of all edges from F.

We define a system of linear equations depending on variables from I. This system states that the substitution to variables from I change labeling function from c to c' as follows:

$$\bigwedge_{u \in V} \left(\sum_{\substack{e \in F: \\ e \text{ is incident to } u}} x_e = c(u) + c'(u) \bmod 2 \right) \tag{1}$$

For every path from the source to v a partial substitution corresponding to this path is a solution of the system (1). The opposite is not always true since that it is not necessary that a path corresponding to the solution of the system (1) exists in the branching program.

▶ **Claim 16.** The number of solutions of the system (1) is equal to 2^{l-t}, where t is the number of the edges in the spanning forest of a graph $H(V, F)$ that is obtained from G by the deletion of all edges that are not in F.

Proof. Notice that the system (1) is precisely the Tseitin formula $\mathrm{TS}_{H,c+c'}$ based on the graph H and labelling function $c + c'$. We know that the system (1) has solutions, hence the number of its solutions by Lemma 2 equals $2^{|F|-|V|+k}$, where k is the number of connected components in H. The claim is proved since $|F| = l$ and $t = |V| - k$. ◀

▶ **Corollary 17.** *The number of different partial substitutions that correspond to paths going from the source to v is at most 2^{l-t}.*

▶ **Claim 18.** Let G be an algebraic (n, d, α)-expander. Assume that we deleted all edges from the graph except l edges, where $l = \beta n - 1$ and $0 < \beta < 1$. Then the number of edges in the spanning forest of the resulting graph H is at most $\frac{l}{d\cdot(\alpha+\beta)}$.

Proof. Consider any connected component $C \subseteq V$ in the resulting graph H. Let m be the number of edges and t be the number of vertices in C. We estimate the maximal number of edges that connect two vertices from C in the original graph G.

Since G is an algebraic (n, d, α)-expander by Proposition 8 there are at least $dt(1 - \frac{t}{n} - \alpha)$ edges connecting vertices from C with vertices from $V \setminus C$ in the graph G. Hence there are at most $\frac{dt - dt + \frac{dt^2}{n} + \alpha\cdot dt}{2} = \frac{\frac{dt^2}{n} + \alpha\cdot dt}{2}$ edges in G that connect two vertices from C.

Let us note that $t \le m + 1 \le l + 1 \le \beta n$, hence $m \le \frac{dt\cdot(\alpha+\beta)}{2}$. The latter implies that

$$t \ge \frac{2m}{d \cdot (\alpha + \beta)}. \tag{2}$$

Let t_i and m_i be the numbers of vertices and edges in the i-th connected component respectively. Note that the size of the spanning forest in H equals $\sum\limits_i (t_i - 1) = \sum\limits_{i:t_i\ge 2} (t_i - 1) \ge \sum\limits_{i:t_i\ge 2} \frac{t_i}{2}$. Note that all edges of H are in the components of size at least two.

By the inequality (2) we get $\sum\limits_{i:t_i\ge 2} t_i \ge \sum\limits_{i:t_i\ge 2} \frac{2m_i}{d\cdot(\alpha+\beta)} = \frac{2l}{d\cdot(\alpha+\beta)}$. Hence the resulting size of the spanning forest is at least $\frac{l}{d\cdot(\alpha+\beta)}$. ◀

Lemma 14 follows from Corollary 17 and Claim 18. ◀

3.3 Proof of Theorem 9

Proof of Theorem 9. Let $\beta = \min\{\frac{1}{4}, \frac{1-3\alpha}{3}\}$ and $l = \beta n - 1$. Consider the minimal 1-NBP for the Tseitin formula $\mathrm{TS}_{G,c}$.

By Lemma 13 there exist at least $2^{l\left(1-\frac{2}{d(1-\alpha)}\right)}$ paths of length l from the source that end in a labeled node that correspond to different partial substitutions. By Lemma 14 for every labeled node v on the level l there are at most $2^{l\left(1-\frac{1}{d(\alpha+\beta)}\right)}$ different partial substitutions that correspond to paths from the source to v.

Hence there are at least $2^{\frac{l}{d}\left(\frac{1}{\alpha+\beta}-\frac{2}{1-\alpha}\right)}$ labeled nodes on the distance l from the source. The latter is $2^{\Omega(n)}$ since $\beta < \frac{1-3\alpha}{2}$. ◀

3.4 Tseitin formula for complete graph

▶ **Corollary 19.** *Let* $\mathrm{TS}_{K_n,c}$ *be a satisfiable Tseitin formula, where* K_n *is a complete graph on* n *vertices. Then the size of every* 1-NBP *for* $\mathrm{TS}_{K_n,c}$ *is* $2^{\Omega(n)}$.

Proof. Consider a 1-NBP D that evaluates the formula $\mathrm{TS}_{K_n,c}$. Consider a graph G on n vertices that is an algebraic (n,d,α)-expander with $\alpha < \frac{1}{3}$ (note that G may have multiple edges). Consider a partial substitution ρ that assigns 0 for every edge that is in K_n but is not in G. Let D' be a 1-NBP that represents the result of the application of ρ to D. It is straightforward that the size of D' is at most the size of D. D' evaluates satisfiable Tseitin formula $\mathrm{TS}_{G',c}$, where G' is a graph that differs from G only by the fact that G may contain multiple edges (G' does not contain multiple edges). I.e., between every two vertices in the graph G' there is an edge if and only if there is at least one edge between these two vertices in G. Now we show how to obtain the diagram for $\mathrm{TS}_{G,c}$ from the diagram D'. Let graph G contain k edges between vertices u and v: $e_1, e_2, \ldots, e_k$. Note that $k \leq d$. It is well known that there exists a read-once deterministic branching program that evaluates $x_{e_1} + x_{e_2} + \cdots + x_{e_k}$ of size $k+2$. Let us denote this branching program by R. We put the source of R in the nodes labeled with variable $x_{u,v}$; the sink labeled with 0 in R should be identified with the end of the edge that correspond to the decision $x_{u,v} = 0$. And similarly we do with the sink labeled with 1. We do such substitutions for every pair of vertices that has multiple edges. The resulting program will be read-once because the original diagram was read-once. The size of the resulting program is at most d times greater than the size of the original branching program. By Theorem 9 the size of the resulting program is $2^{\Omega(n)}$ hence the size of D is $2^{\Omega(n)}$. ◀

3.5 Lower bound for arbitrary graphs

Let for connected graph $G(V,E)$ the value $k_G(l)$ denote the maximal number of connected components that can be obtained from G by deleting of l edges.

Lemma 10 and Corollary 17 imply:

▶ **Corollary 20.** *For all connected graphs* $G(V,E)$ *and arbitrary* $1 \leq l \leq |E|$ *the size of any* 1-NBP *evaluating a satisfiable Tseitin formula* $\mathrm{TS}_{G,c}$ *is at least* $2^{|V|-k_G(l)-k_G(|E|-l)+1}$.

Proof. Consider the minimal 1-NBP for the Tseitin formula $\mathrm{TS}_{G,c}$.

By Lemma 10 there exist at least $2^{l-k_G(l)+1}$ paths of length l from the source that end in a labeled node that correspond to different partial substitutions. By Corollary 17 for every labeled node v on the level l there are at most $2^{l-|V|+k_G(|E|-l)}$ different partial substitutions that correspond to paths from the source to v.

Hence there are at least $2^{|V|-k_G(l)-k_G(|E|-l)+1}$ labeled nodes on the distance l from the source. ◀

In the proof of Theorem 9 we actually show that for (n,d,α)-expander with $\alpha < \frac{1}{3}$ $k_G(l) - k_G(|E|-l) < (1-\epsilon)n$ for some l and some constant $\epsilon > 0$. It implies that Theorem 9 also holds for graphs that differ from (n,d,α) expander by at most $\epsilon n/4$ edges since modification of $\epsilon n/4$ edges changes $k_G(l) + k_G(|E|-l)$ by at most $\epsilon n/2$.

It was proved in the paper [9] that for all connected graphs $G(V,E)$ and arbitrary $1 \leq l \leq |E|$ the size of OBDD evaluating a satisfiable Tseitin formula $\mathrm{TS}_{G,c}$ is at least $2^{|V|-k'_G(l)}$, where $k'_G(l)$ is the maximum over all sets $E' \subseteq E$ of size l of the total number of connected components in graphs G' and G'', where G' is a graph with vertices V and edges E', G'' is a graph with vertices V and edges $E \setminus E'$. It is straightforward that

$k_G(l) + k_G(|E| - l) \geq k'_G(l)$. Thus theoretically the lower bound on the size of OBDD from [9] may be slightly stronger then the lower bound from Corollary 20 for some specific graphs.

4 Futher research

Jukna [10] defined the notion of semantic nondeterministic read-k branching programs that have weaker requirement about occurrences of variables. Namely on every consistent path from the source to a sink labeled with 1 every variable should be tested in at most k times. Jukna showed that semantic nondeterministic read-once branching programs are strictly stronger than syntactic ones and formulated an open question to prove superpolynomial lower bound on the size of semantic 1-NBP. Currently such lower bounds are known only for explicit functions from $D^n \to \{0, 1\}$ with non-binary domains D of size at least 3 [6, 11]. Perhaps a satisfiable Tseitin formula is a good candidate for the binary case.

Abstract

Let $\mathbb{A}$ be an idempotent algebra on a finite domain. We combine results of Chen [7], Zhuk [20] and Carvalho et al. [5] to argue that if $\mathbb{A}$ satisfies the polynomially generated powers property (PGP), then QCSP(Inv($\mathbb{A}$)) is in NP. We then use the result of Zhuk to prove a converse, that if Inv($\mathbb{A}$) satisfies the exponentially generated powers property (EGP), then QCSP(Inv($\mathbb{A}$)) is co-NP-hard. Since Zhuk proved that only PGP and EGP are possible, we derive a full dichotomy for the QCSP, justifying the moral correctness of what we term the Chen Conjecture (see [8]).

We examine in closer detail the situation for domains of size three. Over any finite domain, the only type of PGP that can occur is switchability. Switchability was introduced by Chen in [7] as a generalisation of the already-known Collapsibility [6]. For three-element domain algebras $\mathbb{A}$ that are Switchable, we prove that for every finite subset Δ of Inv($\mathbb{A}$), Pol(Δ) is Collapsible. The significance of this is that, for QCSP on finite structures (over three-element domain), all QCSP tractability explained by Switchability is already explained by Collapsibility.

Finally, we present a three-element domain complexity classification vignette, using known as well as derived results.

1 Introduction

A large body of work exists from the past twenty years on applications of universal algebra to the computational complexity of *constraint satisfaction problems* (CSPs) and a number of celebrated results have been obtained through this method. One considers the problem CSP($\mathcal{B}$) in which it is asked whether an input sentence φ holds on $\mathcal{B}$, where φ is *primitive positive*, that is using only $\exists$, $\wedge$ and $=$. The CSP is one of a wide class of model-checking problems obtained from restrictions of first-order logic. For almost every one of these classes, we can give a complexity classification [14]: the two outstanding classes are CSPs and its popular extension *quantified CSPs* (QCSPs) for positive Horn sentences – where $\forall$ is also present – which is used in Artificial Intelligence to model non-monotone reasoning or uncertainty [11].

The outstanding conjecture in the area is that all finite-domain CSPs are either in P or are NP-complete, something surprising given these CSPs appear to form a large microcosm of NP, and NP itself is unlikely to have this dichotomy property. This Feder-Vardi conjecture [12], given more concretely in the algebraic language in [4], remains unsettled, but is now

known for large classes of structures. It is well-known that the complexity classification for QCSPs embeds the classification for CSPs: if $\mathcal{B}+1$ is $\mathcal{B}$ with the addition of a new isolated element not appearing in any relations, then $\mathrm{CSP}(\mathcal{B})$ and $\mathrm{QCSP}(\mathcal{B}+1)$ are polynomially equivalent. Thus the classification for QCSPs may be considered a project at least as hard as that for CSPs. The following is the merger of Conjectures 6 and 7 in [8] which we call the *Chen Conjecture*.

▶ **Conjecture 1** (Chen Conjecture). *Let $\mathcal{B}$ be a finite relational structure expanded with all constants. If Pol($\mathcal{B}$) has PGP, then QCSP($\mathcal{B}$) is in NP; otherwise QCSP($\mathcal{B}$) is Pspace-complete.*

In [8], Conjecture 6 gives the NP membership and Conjecture 7 the Pspace-completeness. We now know from [20] and [5] that the NP membership of Conjecture 6 is indeed true. The most interesting result of this paper is Theorem 2 below, but note that we permit infinite signatures (languages) although our domains remain finite. This aspect of our work will be discussed in detail later.

▶ **Theorem 2** (Revised Chen Conjecture). *Let $\mathbb{A}$ be an idempotent algebra on a finite domain A. If $\mathbb{A}$ satisfies PGP, then QCSP($\mathrm{Inv}(\mathbb{A})$) is in NP. Otherwise, QCSP($\mathrm{Inv}(\mathbb{A})$) is co-NP-hard.*

Zhuk has previously proved [20] that only the cases PGP and EGP may occur, even in the non-idempotent case. With infinite languages, the NP-membership for Theorem 2 is no longer immediate from [5], but requires a little extra work. We are also able to refute the following form.

▶ **Conjecture 3** (Alternative Chen Conjecture). *Let $\mathbb{A}$ be an idempotent algebra on a finite domain A. If $\mathbb{A}$ satisfies PGP, then for every finite subset $\Delta \subseteq \mathrm{Inv}(\mathbb{A})$, QCSP($\Delta$) is in NP. Otherwise, there exists a finite subset $\Delta \subseteq \mathrm{Inv}(\mathbb{A})$ so that QCSP(Δ) is co-NP-hard.*

In proving Theorem 2 we are saying that the complexity of QCSPs, with all constants included, is classified modulo the complexity of CSPs.

▶ **Corollary 4.** *Let $\mathbb{A}$ be an idempotent algebra on a finite domain A. Either QCSP($\mathrm{Inv}(\mathbb{A})$) is co-NP-hard or QCSP($\mathrm{Inv}(\mathbb{A})$) has the same complexity as CSP($\mathrm{Inv}(\mathbb{A})$).*

In this manner, our result follows in the footsteps of the similar result for the Valued CSP, which has also had its complexity classified modulo the CSP, as culminated in the paper [13].

For a finite-domain algebra $\mathbb{A}$ we associate a function $f_{\mathbb{A}} : \mathbb{N} \to \mathbb{N}$, giving the cardinality of the minimal generating sets of the sequence $\mathbb{A}, \mathbb{A}^2, \mathbb{A}^3, \ldots$ as $f_{\mathbb{A}}(1), f_{\mathbb{A}}(2), f_{\mathbb{A}}(3), \ldots$, respectively. A subset Λ of A^m is a generating set for $\mathbb{A}^m$ exactly if, for every $(a_1, \ldots, a_m) \in A^m$, there exists a k-ary term operation f of $\mathbb{A}$ and $(b_1^1, \ldots, b_m^1), \ldots, (b_1^k, \ldots, b_m^k) \in \Lambda$ so that $f(b_1^1, \ldots, b_1^k) = a_1, \ldots, f(b_m^1, \ldots, b_m^k) = a_m$. We may say $\mathbb{A}$ has the g-GP if $f_{\mathbb{A}}(m) \leq g(m)$ for all m. The question then arises as to the growth rate of $f_{\mathbb{A}}$ and specifically regarding the behaviours constant, logarithmic, linear, polynomial and exponential. Wiegold proved in [19] that if $\mathbb{A}$ is a finite semigroup then $f_{\mathbb{A}}$ is either linear or exponential, with the former prevailing precisely when $\mathbb{A}$ is a monoid. This dichotomy classification may be seen as a gap theorem because no growth rates intermediate between linear and exponential may occur. We say $\mathbb{A}$ enjoys the *polynomially generated powers* property (PGP) if there exists a polynomial p so that $f_{\mathbb{A}} = O(p)$ and the *exponentially generated powers* property (EGP) if there exists a constant b so that $f_{\mathbb{A}} = \Omega(g)$ where $g(i) = b^i$.

In Hubie Chen's [7], a new link between algebra and QCSP was discovered. Chen's previous work in QCSP tractability largely involved the special notion of *Collapsibility*

[6], but in [7] this was extended to a *computationally effective* version of the PGP. For a finite-domain, idempotent algebra $\mathbb{A}$, *k-collapsibility* may be seen as that special form of the PGP in which the generating set for $\mathbb{A}^m$ is constituted of all tuples $(x_1, \ldots, x_m)$ in which at least $m - k$ of these elements are equal. *k-switchability* may be seen as another special form of the PGP in which the generating set for $\mathbb{A}^m$ is constituted of all tuples $(x_1, \ldots, x_m)$ in which there exists $a_i < \ldots < a_{k'}$, for $k' \leq k$, so that

$$(x_1, \ldots, x_m) = (x_1, \ldots, x_{a_1}, x_{a_1+1}, \ldots, x_{a_2}, x_{a_2+1}, \ldots, \ldots, x_{a'_k}, x_{a'_k+1}, \ldots, x_m),$$

where $x_1 = \ldots = x_{a_1-1}$, $x_{a_1} = \ldots = x_{a_2-1}$, $\ldots$, $x_{a_{k'}} = \ldots = x_{a_m}$. Thus, $a_1, a_2, \ldots, a_{k'}$ are the indices where the tuple switches value. Note that these are not the original definitions, which we will see shortly, but they are proved equivalent to the original definitions (at least for finite signatures) in [5]. Moreover, these are the definitions that we will use. We say that $\mathbb{A}$ is collapsible (switchable) if there exists k such that it is k-collapsible (k-switchable). We note that Zhuk uses this definition of switchability in [20] in which he proved that the only kind of PGP for finite-domain algebras is switchability.

Let us capitalise Collapsibility and Switchability to indicate Chen's original definitions from [7] are used, following an example for *arithmetic* versus *Arithmetic* by Raymond Smullyan in [18]. There is the potential for confusion at the start of the sentence but, as was the case with Smullyan, the two will transpire to be interchangeable throughout our discourse. It is straightforward to see that k-Switchability implies k-switchability and k-Collapsibility implies k-collapsibility. The converses, for finite signatures, also hold, but this requires rather more work [5]. For any finite algebra, k-Collapsibility implies k-Switchability, and for any 2-element algebra, k-Switchability implies k-Collapsibility. Chen originally introduced Switchability because he found a 3-element algebra that enjoyed the PGP but was not Collapsible [7]. He went on to prove that Switchability of $\mathbb{A}$ implies that the corresponding QCSP is in P, what one might informally state as QCSP(Inv($\mathbb{A}$)) in P, where Inv($\mathbb{A}$) can be seen as the structure over the same domain as $\mathbb{A}$ whose relations are precisely those that are preserved by (invariant under) all the operations of $\mathbb{A}$. However, the QCSP was traditionally defined only on finite sets of relations (else the question arises as to encoding), thus a more formal definition might be that, for any finite subset Δ of Inv($\mathbb{A}$), QCSP(Δ) is in P. What we prove in this paper is that, as far as the QCSP is concerned, Switchability on a three-element algebra $\mathbb{A}$ is something of a mirage. What we mean by this is that when $\mathbb{A}$ is Switchable, for all finite subsets Δ of Inv($\mathbb{A}$), already Pol(Δ) is Collapsible. Thus, for QCSP complexity for three-element structures, we do not need the additional notion of Switchability to explain tractability, as Collapsibility will already suffice. Since these notions were originally introduced in connection with the QCSP this is particularly surprising. Note that the parameter k of Collapsibility is unbounded over these increasing finite subsets Δ while the parameter of Switchability clearly remains bounded. In some way we are suggesting that Switchability itself might be seen as a limit phenomenon of Collapsibility.

1.1 Infinite languages

Our use of infinite languages (i.e. signatures, since we work on a finite domain) is the only controversial part of our discourse and merits special discussion. We wish to argue that a necessary corollary of the algebraic approach to (Q)CSP is a reconciliation with infinite languages. The traditional approach to consider arbitrary finite subsets of Inv($\mathbb{A}$) is unsatisfactory in the sense that choosing this way to escape the – naturally infinite – set Inv($\mathbb{A}$) is as arbitrary as the choice of encoding required for infinite languages. However, the difficulty in that choice is of course the reason why this route is often eschewed. The

first possibility that comes to mind for encoding a relation in Inv($\mathbb{A}$) is probably to list its tuples, while the second is likely to be to describe the relation in some kind of "simple" logic. Both these possibilities are discussed in [10], for the Boolean domain, where the "simple" logic is the propositional calculus. For larger domains, this would be equivalent to quantifier-free propositions over equality with constants. Both Conjunctive Normal Form (CNF) and Disjunctive Normal Form (DNF) representations are considered in [10] and a similar discussion in [2] exposes the advantages of the DNF encoding. The point here is that testing non-emptiness of a relation encoded in CNF may already be NP-hard, while for DNF this will be tractable. Since DNF has some benign properties, we might consider it a "nice, simple" logic while for "simple" logic we encompass all quantifier-free sentences, that include DNF and CNF as special cases. The reason we describe this as "simple" logic is to compare against something stronger, say all first-order sentences over equality with constants. Here recognising non-emptiness becomes Pspace-hard and since QCSPs already sit in Pspace, this complexity is unreasonable.

For the QCSP over infinite languages Inv($\mathbb{A}$), Chen and Mayr [9] have declared for our first, tuple-listing, encoding. In this paper we will choose the "simple" logic encoding, occasionally giving more refined results for its "nice, simple" restriction to DNF. Our choice of the "simple" logic encoding over the tuple-listing encoding will ultimately be justified by the (Revised) Chen Conjecture holding for "simple" logic yet failing for tuple-listings. Note that our demonstration of the (Revised) Chen Conjecture for infinite languages with the "simple" logic encoding does not resolve the original Chen Conjecture for finite languages $\mathcal{B}$ with constants because QCSP(Inv(Pol($\mathcal{B}$))) could conceivably have higher complexity than QCSP($\mathcal{B}$) due to a succinct representation of relations in Inv(Pol($\mathcal{B}$)). Indeed, this belies one justification for the preferential study of finite subsets of Inv(Pol($\mathcal{B}$)), since for finite signature $\mathcal{B}$ we can then say QCSP($\mathcal{B}$) and QCSP(Inv(Pol$\mathcal{B}$)) must have the same complexity. Note that for finite relational bases $\mathcal{B}', \mathcal{B}''$ of Inv(Pol($\mathcal{B}$)), QCSP($\mathcal{B}'$) and QCSP($\mathcal{B}''$) must have the same complexity. Further, we do not know of any concrete finite $\mathcal{B}$ with constants, so that QCSP(Inv(Pol($\mathcal{B}$))) and QCSP($\mathcal{B}$) have different complexity.

Let us consider examples of our encodings. For the domain $\{1, 2, 3\}$, we may give a binary relation either by the tuples $\{(1, 2), (2, 1), (2, 3), (3, 2), (1, 3), (3, 1), (1, 1)\}$ or by the "simple" logic formula $(x \neq y \vee x = 1)$. For the domain $\{0, 1\}$, we may give the ternary (not-all-equal) relation by the tuples $\{(1, 0, 0), (0, 1, 0), (0, 0, 1), (1, 1, 0), (1, 0, 1), (1, 1, 0)\}$ or by the "simple" logic formula $(x \neq y \vee y \neq z)$. In both of these examples, the simple formula is also in DNF.

Nota Bene. The results of this paper apply for the "simple" logic encoding as well as the "nice, simple" encoding in DNF except where specifically stated otherwise. These exceptions are Proposition 13 and Corollary 14 (which uses the "nice, simple" DNF) and Proposition 16 (which uses the tuple encoding).

Related work. This paper is the merger of [16, 15], neither of which was submitted for publication, considerably extended.

2 Preliminaries

Let $[k] := \{1, \ldots, k\}$. A *k-ary polymorphism* of a relational structure $\mathcal{B}$ is a homomorphism f from $\mathcal{B}^k$ to $\mathcal{B}$. Let Pol($\mathcal{B}$) be the set of polymorphisms of $\mathcal{B}$ and let Inv($\mathbb{A}$) be the set of relations on A which are invariant under (each of) the operations of some finite algebra $\mathbb{A}$. Pol($\mathcal{B}$) is an object known in Universal Algebra as a *clone*, which is a set of operations

containing all projections and closed under composition (superposition). A *term operation* of an algebra $\mathbb{A}$ is an operation which is a member of the clone generated by $\mathbb{A}$.

We will conflate sets of operations over the same domain and algebras just as we do sets of relations over the same domain and constraint languages (relational structures). Indeed, the only technical difference between such objects is the movement away from an ordered signature, which is not something we will ever need. A *reduct* of a relational structure $\mathcal{B}$ is a relational structure $\mathcal{B}'$ over the same domain obtained by forgetting some of the relations. If Δ is some finite subset of $\mathrm{Inv}(\mathbb{A})$, then we may view Δ a being a finite reduct of the structure (associated with) $\mathrm{Inv}(\mathbb{A})$.

A k-ary operation f over A is a *projection* if $f(x_1, \ldots, x_k) = x_i$, for some $i \in [k]$. When α, β are strict subsets of A so that $\alpha \cup \beta = A$, then a k-ary operation f on A is said to be *$\alpha\beta$-projective* if there exists $i \in [k]$ so that if $x_i \in \alpha$ (respectively, $x_i \in \beta$), then $f(x_1, \ldots, x_k) \in \alpha$ (respectively, $f(x_1, \ldots, x_k) \in \beta$).

We recall $\mathrm{QCSP}(\mathcal{B})$, where $\mathcal{B}$ is some structure on a finite-domain, is a decision problem with input ϕ, a pH-sentence (i.e. using just $\forall$, $\exists$, $\wedge$ and $=$) involving (a finite set of) relations of $\mathcal{B}$, encoded in propositional logic with equality and constants. The yes-instances are those ϕ for which $\mathcal{B} \models \phi$. If the input sentence is restricted to have alternation Π_k then the corresponding problem is designated Π_k-$\mathrm{CSP}(\mathcal{B})$.

2.1 Games, adversaries and reactive composition

We now recall some terminology due to Chen [6, 7], for his natural adaptation of the model checking game to the context of pH-sentences. We shall not need to explicitly play these games but only to handle strategies for the existential player. This will enable us to give the original definitions for Collapsibility and Switchability. An *adversary* $\mathcal{B}$ of length $m \geq 1$ is an m-ary relation over A. When $\mathcal{B}$ is precisely the set $B_1 \times B_2 \times \ldots \times B_m$ for some non-empty subsets $B_1, B_2, \ldots, B_m$ of A, we speak of a *rectangular adversary* (we will sometimes specify this as a tuple rather than a product). Let ϕ be a pH-sentence with universal variables $x_1, \ldots, x_m$ and quantifier-free part ψ. We write $\mathcal{A} \models \phi_{\restriction \mathcal{B}}$ and say that *the existential player has a winning strategy in the $(\mathcal{A}, \phi)$-game against adversary $\mathcal{B}$* iff there exists a set of Skolem functions $\{\sigma_x : \text{`}\exists x\text{'} \in \phi\}$ such that for any assignment π of the universally quantified variables of ϕ to A, where $\big(\pi(x_1), \ldots, \pi(x_m)\big) \in \mathcal{B}$, the map h_π is a homomorphism from $\mathcal{D}_\psi$ (the canonical database) to $\mathcal{A}$, where

$$h_\pi(x) := \begin{cases} \pi(x) & \text{, if } x \text{ is a universal variable; and,} \\ \sigma_x(\pi|_{Y_x}) & \text{, otherwise.} \end{cases}$$

(Here, Y_x denotes the set of universal variables preceding x and $\pi|_{Y_x}$ the restriction of π to Y_x.) Clearly, $\mathcal{A} \models \phi$ iff the existential player has a winning strategy in the $(\mathcal{A}, \phi)$-game against the so-called *full (rectangular) adversary* $A \times A \times \ldots \times A$ (which we will denote hereafter by A^m). We say that an adversary $\mathcal{B}$ of length m *dominates* an adversary $\mathcal{B}'$ of length m when $\mathcal{B}' \subseteq \mathcal{B}$. Note that $\mathcal{B}' \subseteq \mathcal{B}$ and $\mathcal{A} \models \phi_{\restriction \mathcal{B}}$ implies $\mathcal{A} \models \phi_{\restriction \mathcal{B}'}$. We will also consider sets of adversaries of the same length, denoted by uppercase Greek letters as in Ω_m (here the length is m); and, sequences thereof, which we denote with bold uppercase Greek letters as in $\mathbf{\Omega} = \big(\Omega_m\big)_{m \in \mathbb{N}}$. We will write $\mathcal{A} \models \phi_{\restriction \Omega_m}$ to denote that $\mathcal{A} \models \phi_{\restriction \mathcal{B}}$ holds for every adversary $\mathcal{B}$ in Ω_m.

We now introduce reactive composition as a means to obtain larger adversaries from a number of smaller adversaries. Let f be a k-ary operation of $\mathcal{A}$ and $\mathcal{A}, \mathcal{B}_1, \ldots, \mathcal{B}_k$ be adversaries of length m. We say that $\mathcal{A}$ is *reactively composable* from the adversaries

$\mathcal{B}_1, \ldots, \mathcal{B}_k$ via f, and we write $\mathcal{A} \trianglelefteq f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$ iff there exist partial functions $g_i^j : A^i \to A$ for every i in $[m]$ and every j in $[k]$ such that, for every tuple $(a_1, \ldots, a_m)$ in adversary $\mathcal{A}$ the following holds.

- for every j in $[k]$, the values $g_1^j(a_1), g_2^j(a_1, a_2), \ldots, g_m^j(a_1, a_2, \ldots, a_m)$ are defined and the tuple $\big(g_1^j(a_1), g_2^j(a_1, a_2), \ldots, g_m^j(a_1, a_2, \ldots, a_m)\big)$ is in adversary $\mathcal{B}_j$; and,
- for every i in $[m]$, $a_i = f\big(g_i^1(a_1, a_2, \ldots, a_i), g_i^2(a_1, a_2, \ldots, a_i), \ldots, g_i^k(a_1, a_2, \ldots, a_i)\big)$.

We write $\mathcal{A} \trianglelefteq \{\mathcal{B}_1, \ldots, \mathcal{B}_k\}$ if there exists a k-ary operation f such that $\mathcal{A} \trianglelefteq f(\mathcal{B}_1, \ldots, \mathcal{B}_k)$ Reactive composition allows to interpolate complete Skolem functions from partial ones.

▶ **Theorem 5** ([7, Theorem 7.6]). *Let ϕ be a pH-sentence with m universal variables. Let $\mathcal{A}$ be an adversary and Ω_m a set of adversaries, both of length m.*

If $\mathcal{A} \models \phi_{\restriction \Omega_m}$ and $\mathcal{A} \trianglelefteq \Omega_m$ then $\mathcal{A} \models \phi_{\restriction \mathcal{A}}$.

As a concrete example of an interesting sequence of adversaries, consider the adversaries for the notion of *p-Collapsibility*. Let $p \geq 0$ be some fixed integer. For x in A, let $\Upsilon_{m,p,x}$ be the set of all rectangular adversaries of length m with p co-ordinates that are the set A and all the others that are the fixed singleton $\{x\}$. For $B \subseteq A$, let $\Upsilon_{m,p,B}$ be the union of $\Upsilon_{m,p,x}$ for all x in B. Let $\boldsymbol{\Upsilon}_{p,B}$ be the sequence of adversaries $(\Upsilon_{m,p,B})_{m\in\mathbb{N}}$. We will define a structure $\mathcal{A}$ to be *p-Collapsible from source B* iff for every m and for all pH-sentence ϕ with m universal variables, $\mathcal{A} \models \phi_{\restriction \Upsilon_{m,p,B}}$ implies $\mathcal{A} \models \phi$.

For p-Switchability, the set of adversaries will be of the form $\Xi_{m,p}$, where each adversary is built from the set of tuples that have some $k' < p$ switches at specific points $0 < a_1 < \ldots < a_{k'} \leq m$.

For rectangular adversaries, such as $\Upsilon_{m,p,x}$, reactive composition is rather simpler than in the definition above, becoming just (ordinary) composition, as follows. $\mathcal{A}$ is *composable* from the adversaries $\mathcal{B}_1, \ldots, \mathcal{B}_k$ via f if $f(B_1^i, \ldots, B_i^k) \supseteq A^i$, where $\mathcal{A} = (A^1, \ldots, A^m)$ and each $\mathcal{B}_j = (B_j^1, \ldots, B_j^m)$. Reactive composition plays a key role in the proof of our main theorem but its use appears only in other papers that we will cite. Ordinary composition is the only type of reactive composition that will be used in this paper.

3 The Chen Conjecture

3.1 NP-membership

We need to revisit the main result of [5] to show that it holds not just for finite signatures but for infinite signatures also. In its original the following theorem discussed "projective sequences of adversaries, none of which are degenerate". This includes Switching adversaries and we give it in this latter form. We furthermore remove some parts of the theorem that are not currently relevant to us.

▶ **Theorem 6** (In abstracto [5]). *Let $\boldsymbol{\Omega} = (\Omega_m)_{m\in\mathbb{N}}$ be the sequence of the set of all (k-)Switching m-ary adversaries over the domain of $\mathcal{A}$, a finite structure. The following are equivalent.*

(i) *For every $m \geq 1$, for every pH-sentence ψ with m universal variables, $\mathcal{A} \models \psi_{\restriction \Omega_m}$ implies $\mathcal{A} \models \psi$.*

(vi) *For every $m \geq 1$, Ω_m generates $\mathrm{Pol}(\mathcal{A})^m$.*

▶ **Corollary 7** (In abstracto levavi). *Let $\boldsymbol{\Omega} = (\Omega_m)_{m\in\mathbb{N}}$ be the sequence of the set of all (k-)Switching m-ary adversaries over the domain of $\mathcal{A}$, a finite-domain structure with an infinite signature. The following are equivalent.*

(i) *For every $m \geq 1$, for every pH-sentence ψ with m universal variables, $\mathcal{A} \models \psi_{\restriction \Omega_m}$ implies $\mathcal{A} \models \psi$.*

(vi) *For every $m \geq 1$, Ω_m generates* $\mathrm{Pol}(\mathcal{A})^m$.

Proof. We know from Theorem 6 that the following are equivalent:

(i') For every finite-signature reduct $\mathcal{A}'$ of $\mathcal{A}$ and $m \geq 1$, for every pH-sentence ψ with m universal variables, $\mathcal{A}' \models \psi_{\restriction \Omega_m}$ implies $\mathcal{A}' \models \psi$.

(vi') For every finite-signature reduct $\mathcal{A}'$ of $\mathcal{A}$ and every $m \geq 1$, Ω_m generates $\mathrm{Pol}(\mathcal{A}')^m$.

Since it is clear that both $(i) \Rightarrow (i')$ and $(vi) \Rightarrow (vi')$, it remains to argue that $(i') \Rightarrow (i)$ and $(vi') \Rightarrow (vi)$.

$[(i') \Rightarrow (i).]$ By contraposition, if (i) fails then it fails on some specific pH-sentence ψ which only mentions a finite number of relations of $\mathcal{A}'$. Thus (i') also fails on some finite reduct of $\mathcal{A}'$ mentioning these relations.

$[(vi') \Rightarrow (vi).]$ Let m be given. Consider some chain of finite reducts $\mathcal{A}_1, \ldots, \mathcal{A}_i, \ldots$ of $\mathcal{A}$ so that each $\mathcal{A}_i$ is a reduct of $\mathcal{A}_j$ for $i < j$ and every relation of $\mathcal{A}$ appears in some $\mathcal{A}_i$. We can assume from $(vi)'$ that Ω_m generates $\mathrm{Pol}(\mathcal{A}_i)^m$, for each i. However, since the number of tuples $(a_1, \ldots, a_m)$ and operations mapping Ω_m pointwise to $(a_1, \ldots, a_m)$, witnessing generation in $\mathrm{Pol}(\mathcal{A}')^m$, is finite, the sequence of operations $(f^i_1, \ldots, f^i_{|A|^m})$ (where f^i_j witnesses generation of the jth tuple in A^m) witnessing these must have an infinitely recurring element as i tends to infinity. One such recurring element we call $(f_1, \ldots, f_{|A|^m})$ and this witnesses generation in $\mathrm{Pol}(\mathcal{A})^m$. ◀

Note that in $(vi') \Rightarrow (vi)$ above we did not need to argue uniformly across the different $(a_1, \ldots, a_m)$ and it is enough to find an infinitely recurring operation for each of these individually.

The following result is essentially a corollary of the works of Chen and Zhuk [7, 20] via [5].

▶ **Theorem 8.** *Let $\mathbb{A}$ be an idempotent algebra on a finite domain A. If $\mathbb{A}$ satisfies PGP, then QCSP*$(\mathrm{Inv}(\mathbb{A}))$ *reduces to a polynomial number of instances of CSP*$(\mathrm{Inv}(\mathbb{A}))$ *and is in NP.*

Proof. We know from Theorem 7 in [20] that $\mathbb{A}$ is Switchable, whereupon we apply Corollary 7, $(vi) \Rightarrow (i)$. By considering instances whose universal variables involve only the polynomial number of tuples from the Switching Adversary, one can see that $\mathrm{QCSP}(\mathrm{Inv}(\mathbb{A}))$ reduces to a polynomial number of instances of $\mathrm{CSP}(\mathrm{Inv}(\mathbb{A}))$ and is therefore in NP. Further details of the NP algorithm are given in Corollary 38 of [5] but the argument here follows exactly Section 7 from [7], in which it was originally proved that Switchability yields the corresponding QCSP in NP. ◀

Note that Chen's original definition of Switchability, based on adversaries and reactive composability, plays a key role in the NP membership algorithm in Theorem 8. It is the result from [5] that is required to reconcile the two definitions of switchability as equivalent, and indeed Corollary 7 is needed in this process for infinite signatures. If we were to use just our definition of switchability then it is only possible to prove, à la Proposition 3.3 in [7], that the bounded alternation Π_n-$\mathrm{CSP}(\mathrm{Inv}(\mathbb{A}))$ is in NP. Thus, using just the methods from [7] and [20], we cannot prove the Revised Chen Conjecture, but rather some bounded alternation (re)revision.

3.2 co-NP-hardness

Suppose there exist α, β strict subsets of A so that $\alpha \cup \beta = A$, define the relation $\tau_k(x_1, y_1, z_1 \ldots, x_k, y_k, z_k)$ by

$$\tau_k(x_1, y_1, z_1 \ldots, x_k, y_k, z_k) := \rho'(x_1, y_1, z_1) \vee \ldots \vee \rho'(x_k, y_k, z_k),$$

where $\rho'(x, y, z) = (\alpha \times \alpha \times \alpha) \cup (\beta \times \beta \times \beta)$. Strictly speaking, the α and β are parameters of τ_k but we dispense with adding them to the notation since they will be fixed at any point in which we invoke the τ_k. The purpose of the relations τ_k is to encode co-NP-hardness through the complement of the problem (monotone) 3-*not-all-equal-satisfiability* (3NAESAT). Let us introduce also the important relations $\sigma_k(x_1, y_1, \ldots, x_k, y_k)$ defined by

$$\sigma_k(x_1, y_1, \ldots, x_k, y_k) := \rho(x_1, y_1) \vee \ldots \vee \rho(x_k, y_k),$$

where $\rho(x, y) = (\alpha \times \alpha) \cup (\beta \times \beta)$.

▶ **Lemma 9.** *The relation τ_k is pp-definable in σ_k.*

Proof. We will argue that τ_k is definable by the conjunction Φ of 3^k instances of σ_k that each consider the ways in which two variables may be chosen from each of the (x_i, y_i, z_i), i.e. $x_i \sim y_i$ or $y_i \sim z_i$ or $x_i \sim z_i$ (where $\sim$ is infix for ρ). We need to show that this conjunction Φ entails τ_k (the converse is trivial). We will assume for contradiction that Φ is satisfiable but τ_k not. In the first instance of σ_k of Φ some atom must be true, and it will be of the form $x_i \sim y_i$ or $y_i \sim z_i$ or $x_i \sim z_i$. Once we have settled on one of these three, $p_i \sim q_i$, then we immediately satisfy 3^{k-1} of the conjunctions of Φ, leaving $2 \cdot 3^{k-1}$ unsatisfied. Now we can evaluate to true no more than one other among $\{x_i \sim y_i, y_i \sim z_i, x_i \sim z_i\} \setminus \{p_i \sim q_i\}$, without contradicting our assumptions. If we do evaluate this to true also, then we leave 3^{k-1} conjunctions unsatisfied. Thus we are now down to looking at variables with subscript other than i and in this fashion we have made the space one smaller, in total $k - 1$. Now, we will need to evaluate in Φ some other atom of the form $x_j \sim y_j$ or $y_j \sim z_j$ or $x_j \sim z_j$, for $j \neq i$. Once we have settled on at most two of these three then we immediately satisfy 3^{k-2} of the conjunctions remaining of Φ, leaving 3^{k-2} still unsatisfied. Iterating this thinking, we arrive at a situation in which 1 clause is unsatisfied after we have gone through all k subscripts, which is a contradiction. ◀

▶ **Theorem 10.** *Let $\mathbb{A}$ be an idempotent algebra on a finite domain A. If $\mathbb{A}$ satisfies EGP, then QCSP*(Inv($\mathbb{A}$)) *is co-NP-hard.*

Proof. We know from Lemma 11 in [20] that there exist α, β strict subsets of A so that $\alpha \cup \beta = A$ and the relation σ_k is in Inv($\mathbb{A}$), for each $k \in \mathbb{N}$. From Lemma 9, we know also that τ_k is in Inv($\mathbb{A}$), for each $k \in \mathbb{N}$.

We will next argue that τ_k enjoys a relatively small specification in DNF (at least, polynomial in k). We first give such a specification for $\rho'(x, y, z)$.

$$\rho'(x, y, z) := \bigvee_{a, a', a'' \in \alpha} x = a \wedge y = a' \wedge z = a'' \vee \bigvee_{b, b', b'' \in \beta} x = b \wedge y = b' \wedge z = b''$$

which is constant in size when A is fixed. Now it is clear from the definition that the size of τ_n is polynomial in n.

We will now give a very simple reduction from the complement of 3NAESAT to QCSP(Inv($\mathbb{A}$)). 3NAESAT is well-known to be NP-complete [17] and our result will follow.

Take an instance ϕ of 3NAESAT which is the existential quantification of a conjunction of k atoms $\mathrm{NAE}(x,y,z)$. Thus $\neg\phi$ is the universal quantification of a disjunction of k atoms $x=y=z$. We build our instance ψ of $\mathrm{QCSP}(\mathrm{Inv}(\mathbb{A}))$ from $\neg\phi$ by transforming the quantifier-free part $x_1=y_1=z_1\vee\ldots\vee x_k=y_k=z_k$ to $\tau_k=\rho'(x_1,y_1,z_1)\vee\ldots\vee\rho'(x_k,y_k,z_k)$.

($\neg\phi\in$ co-3NAESAT implies $\psi\in\mathrm{QCSP}(\mathrm{Inv}(\mathbb{A}))$.) From an assignment to the universal variables $v_1,\ldots,v_m$ of ψ to elements $x_1,\ldots,x_m$ of A, consider elements $x'_1,\ldots,x'_m\in\{0,1\}$ according to

- $x_i\in\alpha\setminus\beta$ implies $x'_i=0$,
- $x_i\in\beta\setminus\alpha$ implies $x'_i=1$, and
- $x_i\in\alpha\cap\beta$ implies we don't care, so w.l.o.g. say $x'_i=0$.

The disjunct that is satisfied in the quantifier-free part of $\neg\phi$ now gives the corresponding disjunct that will be satisfied in τ_k.

($\psi\in\mathrm{QCSP}(\mathrm{Inv}(\mathbb{A}))$ implies $\neg\phi\in$ co-3NAESAT.) From an assignment to the universal variables $v_1,\ldots,v_m$ of $\neg\phi$ to elements $x_1,\ldots,x_m$ of $\{0,1\}$, consider elements $x'_1,\ldots,x'_m\in A$ according to

- $x_i=0$ implies x'_i is some arbitrarily chosen element in $\alpha\setminus\beta$, and
- $x_i=1$ implies x'_i is some arbitrarily chosen element in $\beta\setminus\alpha$.

The disjunct that is satisfied in τ_k now gives the corresponding disjunct that will be satisfied in the quantifier-free part of $\neg\phi$. ◀

The demonstration of co-NP-hardness in the previous theorem was inspired by a similar proof in [1]. Note that an alternative proof that τ_k is in $\mathrm{Inv}(\mathbb{A})$ is furnished by the observation that it is preserved by all $\alpha\beta$-projections (see [20]). We note surprisingly that co-NP-hardness in Theorem 10 is optimal, in the sense that some (but not all!) of the cases just proved co-NP-hard are also in co-NP.

▶ **Proposition 11.** *Let α,β strict subsets of $A:=\{a_1,\ldots,a_n\}$ so that $\alpha\cup\beta=A$ and $\alpha\cap\beta\neq\emptyset$. Then QCSP$(A;\{\tau_k:k\in\mathbb{N}\},a_1,\ldots,a_n)$ is in co-NP.*

Proof. Assume $|A|>1$, i.e. $n>1$ (note that the proof is trivial otherwise). Let ϕ be an input to $\mathrm{QCSP}(A;\{\tau_k:k\in\mathbb{N}\},a_1,\ldots,a_n)$. We will now seek to eliminate atoms $v=a$ ($a\in\{a_1,\ldots,a_n\}$) from ϕ. Suppose ϕ has an atom $v=a$. If v is universally quantified, then ϕ is false (since $|A|>1$). Otherwise, either the atom $v=a$ may be eliminated with the variable v since v does not appear in a non-equality relation; or ϕ is false because there is another atom $v=a'$ for $a\neq a'$; or $v=a$ may be removed by substitution of a into all non-equality instances of relations involving v. This preprocessing procedure is polynomial and we will assume w.l.o.g. that ϕ contains no atoms $v=a$. We now argue that ϕ is a yes-instance iff ϕ' is a yes-instance, where ϕ' is built from ϕ by instantiating all existentially quantified variables as any $a\in\alpha\cap\beta$. The universal ϕ' can be evaluated in co-NP (one may prefer to imagine the complement as an existential $\neg\phi'$ to be evaluated in NP) and the result follows. ◀

In fact, this being an algebraic paper, we can even do better. Let $\mathcal{B}$ signify a set of relations on a finite domain but not necessarily itself finite. For convenience, we will assume the set of relations of $\mathcal{B}$ is closed under all co-ordinate projections and instantiations of constants. Call $\mathcal{B}$ *existentially trivial* if there exists an element $c\in B$ (which we call a *canon*) such that for each k-ary relation R of $\mathcal{B}$ and each $i\in[k]$, and for every $x_1,\ldots,x_k\in B$, whenever $(x_1,\ldots,x_{i-1},x_i,x_{i+1},\ldots,x_k)\in R^{\mathcal{B}}$ then also $(x_1,\ldots,x_{i-1},c,x_{i+1},\ldots,x_k)\in R^{\mathcal{B}}$. We want to expand this class to *almost existentially trivial* by permitting conjunctions of the form $v=a_i$ or $v=v'$ with relations that are existentially trivial.

▶ **Lemma 12.** *Let α, β be strict subsets of $A := \{a_1, \ldots, a_n\}$ so that $\alpha \cup \beta = A$ and $\alpha \cap \beta \neq \emptyset$. The set of relations pp-definable in $(A; \{\tau_k : k \in \mathbb{N}\}, a_1, \ldots, a_n)$ is almost existentially trivial.*

Proof. Consider a formula with a pp-definition in $(A; \{\tau_k : k \in \mathbb{N}\}, a_1, \ldots, a_n)$. We assume that only free variables appear in equalities since otherwise we can remove these equalities by substitution. Now existential quantifiers can be removed and their variables instantiated as the canon c. Indeed, their atoms τ_n may now be removed since they will always be satisfied. Thus we are left with a conjunction of equalities and atoms τ_n, and the result follows. ◀

▶ **Proposition 13.** *If $\mathcal{B}$ is comprised exclusively of relations that are almost existentially trivial, then QCSP($\mathcal{B}$) is in co-NP under the **DNF encoding**.*

Proof. The argument here is quite similar to that of Proposition 11 except that there is some additional preprocessing to find out variables that are forced in some relation to being a single constant or pairs of variables within a relation that are forced to be equal. In the first instance that some variable is forced to be constant in a k-ary relation, we should replace with the $(k-1)$-ary relation with the requisite forcing. In the second instance that a pair of variables are forced equal then we replace again the k-ary relation with a $(k-1)$-ary relation as well as an equality. Note that projecting a relation to a single or two co-ordinates can be done in polynomial time because the relations are encoded in DNF. After following these rules to their conclusion one obtains a conjunction of equalities together with relations that are existentially trivial. Now is the time to propagate variables to remove equalities (or find that there is no solution). Finally, when only existentially trivial relations are left, all remaining existential variables may be evaluated to the canon c. ◀

▶ **Corollary 14.** *Let α, β be strict subsets of $A := \{a_1, \ldots, a_n\}$ so that $\alpha \cup \beta = A$ and $\alpha \cap \beta \neq \emptyset$. Then QCSP($\mathrm{Inv}(\mathrm{Pol}(A; \{\tau_k : k \in \mathbb{N}\}, a, \ldots, a_n))$) is in co-NP under the **DNF encoding**.*

This last result, together with its supporting proposition, is the only time we seem to require the "nice, simple" DNF encoding, rather than arbitrary propositional logic. We do not require DNF for Proposition 11 as we have just a single relation in the signature for each arity and this is easy to keep track of. We note that the set of relations $\{\tau_k : k \in \mathbb{N}\}$ is not maximal with the property that with the constants it forms a co-clone of existentially trivial relations. One may add, for example, $\alpha \times \beta \cup \beta \times \alpha$.

The following, together with our previous results, gives the refutation of the Alternative Chen Conjecture.

▶ **Proposition 15.** *Let α, β strict subsets of $A := \{a_1, \ldots, a_n\}$ so that $\alpha \cup \beta = A$ and $\alpha \cap \beta \neq \emptyset$. Then, for each finite signature reduct $\mathcal{B}$ of $(A; \{\tau_k : k \in \mathbb{N}\}, a_1, \ldots, a_n)$, QCSP($\mathcal{B}$) is in NL.*

Proof. We will assume $\mathcal{B}$ contains all constants (since we prove this case gives a QCSP in NL, it naturally follows that the same holds without constants). Take m so that, for each $\tau_i \in \mathcal{B}$, $i \leq m$. Recall from Lemma 9 that τ_i is pp-definable in σ_i. We will prove that the structure $\mathcal{B}'$ given by $(A; \{\sigma_k : k \leq m\}, a_1, \ldots, a_n)$ admits a $(3m+1)$-ary near-unanimity operation f as a polymorphism, whereupon it follows that $\mathcal{B}$ admits the same near-unanimity polymorphism. We choose f so that all tuples whose map is not automatically defined by the near-unanimity criterion map to some arbitrary $a \in \alpha \cap \beta$. To see this, imagine that this f were not a polymorphism. Then some $(3m+1)$ m-tuples in σ_i would be mapped to some tuple not in σ_i which must be a tuple $\bar{t}$ of elements from $\alpha \setminus \beta \cup \beta \setminus \alpha$. Note that column-wise

this map may only come from $(3m+1)$-tuples that have $3m$ instances of the same element. By the pigeonhole principle, the tuple $\bar{t}$ must appear as one of the $(3m+1)$ m-tuples in σ_i and this is clearly a contradiction.

It follows from [6] that QCSP($\mathcal{B}$) reduces to a polynomially bounded ensemble of $\binom{n}{3m} \cdot n \cdot n^{3m}$ instances CSP($\mathcal{B}$), and the result follows. ◀

3.3 The question of the tuple encoding

▶ **Proposition 16.** *Let* $\alpha := \{0,1\}$ *and* $\beta := \{0,2\}$. *Then, QCSP*$(\{0,1,2\}; \{\tau_k : k \in \mathbb{N}\}, 0, 1, 2)$ *is in P under the* ***tuple encoding****.*

Proof. Consider an instance ϕ of this QCSP of size n involving relation τ_m but no relation τ_k for $k > m$. The number of tuples in τ_m is $> 3^m$. Following Proposition 11 together with its proof, we may assume that the instance is strictly universally quantified over a conjunction of atoms (involving also constants). Now, a universally quantified conjunction is true iff the conjunction of its universally quantified atoms is true. We can further say that there are at most n atoms each of which involves at most $3m$ variables. Therefore there is an exhaustive algorithm that takes at most $O(n \cdot 3^{3m})$ steps with is $O(n^4)$. ◀

The proof of Proposition 16 suggests an alternative proof of Proposition 15, but placing the corresponding QCSP in P instead of NL. Proposition 16 shows that Chen's Conjecture fails for the tuple encoding in the sense that it provides a language $\mathcal{B}$, expanded with constants, so that Pol($\mathcal{B}$) has EGP, yet QCSP($\mathcal{B}$) is in P under the tuple encoding. However, it does not imply that the algebraic approach to QCSP violates Chen's Conjecture under the tuple encoding. This is because $(\{0,1,2\}; \{\tau_k : k \in \mathbb{N}\}, 0, 1, 2)$ is not of the form Inv($\mathbb{A}$) for some idempotent algebra $\mathbb{A}$. For this stronger result, we would need to prove QCSP(Inv(Pol($\{0,1,2\}; \{\tau_k : k \in \mathbb{N}\}, 0, 1, 2$))) is in P under the tuple encoding.

4 Switchability, Collapsability and the three-element case

An algebra $\mathbb{A}$ is a *G-set* if its domain is not one-element and every of its operations f is of the form $f(x_1, \ldots, x_k) = \pi(x_i)$ where $i \in [k]$ and π is a permutation on A. An algebra $\mathbb{A}$ contains a G-set as a *factor* if some homomorphic image of a subalgebra of $\mathbb{A}$ is a G-set. A *Gap Algebra* [6] is a three-element idempotent algebra that omits a G-set as a factor and is not Collapsible.

Our first task is the deduction of the following theorem, whose lengthy proof is omitted. For each of the following two theorems, α and β are chosen such that α, β are strict subsets of $\{0,1,2\}$, $\alpha \cup \beta = \{0,1,2\}$ and $\alpha \cap \beta \neq \emptyset$.

▶ **Theorem 17.** *Suppose* $\mathbb{A}$ *is a Gap Algebra that is not* $\alpha\beta$*-projective. Then, for every finite subset of* Δ *of Inv*($\mathbb{A}$)*, Pol*(Δ) *is Collapsible.*

Our second task is the deduction of the following theorem, whose lengthy proof is omitted.

▶ **Theorem 18.** *Suppose* $\mathbb{A}$ *is a* 3*-element idempotent algebra that is not* $\alpha\beta$*-projective, containing a* 2*-element G-set as a subalgebra. Then,* $\mathbb{A}$ *is Collapsible.*

▶ **Corollary 19.** *Suppose* $\mathbb{A}$ *is a* 3*-element idempotent algebra that is not EGP, i.e. is Switchable. Then, for every finite subset of* Δ *of Inv*($\mathbb{A}$)*, Pol*(Δ) *is Collapsible.*

Proof. Recall Lemma 11 in [20] that $\mathbb{A}$ has EGP iff there exists α and β such that α, β are strict subsets of D, $\alpha \cup \beta = D$, and all operations of $\mathbb{A}$ are $\alpha\beta$-projective.

If $\mathbb{A}$ does not contain a G-set as a factor, then $\mathbb{A}$ is a Gap Algebra and the result follows from Theorem 17. Otherwise, $\mathbb{A}$ contains a G-set as a factor. If $\mathbb{A}$ contains a G-set as a homomorphic image then $\mathbb{A}$ has EGP from [7]. Else, since $\mathbb{A}$ is 3-element, $\mathbb{A}$ contains a 2-element G-set as a subalgebra and we are in the situation of Theorem 18. ◀

5 A three-element vignette

We would love to be able to improve Theorem 2 to describe the boundary between those cases that are co-NP-complete and those that are Pspace-complete, if indeed such a result is true. However, even in the three-element case this appears challenging, but we are able to provide a variant vignette, whose proof is omitted.

▶ **Theorem 20.** *Let $\mathbb{A}$ be an idempotent algebra on a 3-element domain. Either*

- Π_k-*CSP*(Inv($\mathbb{A}$)) *is in NP, for all k; or*
- Π_k-*CSP*(Inv($\mathbb{A}$)) *is co-NP-complete, for all k; or*
- Π_k-*CSP*(Inv($\mathbb{A}$)) *is Π_2^{P}-hard, for some k.*

Note that the trichotomy of Theorem 20 does not hold for QCSP along the same boundary for, respectively, NP, co-NP-complete and Pspace-complete. For the semilattice-without-unit s it is known that Π_k-CSP(Inv(s)) is co-NP-complete, for all k, while QCSP(Inv(s)) is Pspace-complete [3].

6 Discussion

The major contribution of this paper is its discussion of the Chen Conjecture with two infinite-signature variants one of which is proved to hold (with encoding in "simple logic") and one of which fails (with the tuple listing).

In addition to this, the contribution is largely mathematical, examining the relationship between Switchability and Collapsibility in the three-element case. However, this mathematical study uncovers something of importance to the computer scientist who is not reconciled to infinite signatures! Since here it demonstrates that all three-element domain NP-memberships that may be shown by Switchability, may already be shown by Collapsibility.

The work associated with Theorem 17 is distinctly non-trivial and involves a new method, whereas the work associated with Theorem 18 uses known methods and involves mostly turning the handle with these. Similarly, the work involved with the three element vignette uses known methods on top of our earlier new results.

The Chen Conjecture in its original form remains open. As does the general question (for arbitrary finite domains) as to whether, if $\mathbb{A}$ is Switchable, all finite subsets $\mathcal{B}$ of Inv($\mathbb{A}$) are so that Pol($\mathcal{B}$) is Collapsible. However, to now prove the Chen Conjecture it is sufficient to prove, for any finite $\mathcal{B}$ expanded with all constants such that Pol($\mathcal{B}$) has EGP, that there exists polynomially (in i) computable pp-definitions (over $\mathcal{B}$) of the relations τ_i (where α and β are suitably chosen to witness EGP). A first step towards this is to establish whether there are even polynomially sized pp-definitions of these τ_i.

The appearance of a co-NP-complete QCSP is likely to be an anomaly of our introduction of infinite signatures. Such a QCSP is unlikely to exist with a finite signature (at least, nothing like this is hitherto known). Indeed, its presence might be used as an argument against the acceptance of infinite signatures, if it is interpreted as an aberration. For the reader in this mind, we ask to please review the earlier paean to infinite signatures.

Abstract

Let d be a positive integer. Can a given graph G be realized in $\mathbb{R}^d$ so that vertices are mapped to distinct points, two vertices being adjacent if and only if the corresponding points lie on a common line that is parallel to some axis? Graphs admitting such realizations have been studied in the literature for decades under different names. Peterson asked in [Discrete Appl. Math., 2003] about the complexity of the recognition problem. While the two-dimensional case corresponds to the class of line graphs of bipartite graphs and is well-understood, the complexity question has remained open for all higher dimensions.

In this paper, we answer this question. We establish the NP-completeness of the recognition problem for any fixed dimension, even in the class of bipartite graphs. To do this, we strengthen a characterization of induced subgraphs of 3-dimensional Hamming graphs due to Klavžar and Peterin. We complement the hardness result by showing that for some important classes of perfect graphs – including chordal graphs and distance-hereditary graphs – the minimum dimension of the Euclidean space in which the graph can be realized, or the impossibility of doing so, can be determined in linear time.

1 Introduction

The main question addressed in this paper is the following: How difficult is it to determine if a given graph G can be realized in $\mathbb{R}^d$ so that vertices are mapped to distinct points and two vertices are adjacent if and only if the corresponding points are on a common line that is parallel to some axis? Let us refer to any such mapping as a *d-realization* of G and say that a graph is *d-realizable* if it has a d-realization. The class of d-realizable graphs was studied in the literature for decades, under diverse names such as arrow graphs (Cook, 1974 [13]), $(d-1)$-plane graphs and $(d-1)$-line graphs of d-partite d-uniform hypergraphs (Bermond et al., 1977 [3]; see also [29]), d-dimensional cellular graphs (Gurvich and Temkin, 1992 [25]), d-dimensional chessboard graphs (Staton and Wingard, 1998 [50]), and d-dimensional gridline

* The authors acknowledge the financial support from the Slovenian Research Agency (research core funding No. I0-0035 and P1-0285, projects N1-0032, J1-5433, J1-6720, J1-6743, and J1-7051).

graphs (Peterson, 2003 [46]). Recently, Sangha and Zito studied d-realizable graphs in the more general context of the so-called Line-of-Sight (LoS) networks [49] and showed that the independent set problem, known to be polynomially solvable in the class of 2-realizable graphs, is NP-complete in the class of 3-realizable graphs. For the small-dimensional cases, $d \in \{2, 3\}$, Peterson suggested an application of d-realizable graphs to robotics [46]: if the movement of a robot is restricted to be along axis-parallel directions only and turns are allowable only at certain points, then a shortest path in a d-realized graph gives the number of turns required. Further possible applications of d-realizable graphs belong to the area of wireless networks, via their connection with Line-of-Sight networks [23].

Despite many studies on d-realizable graphs in the literature, determining the computational complexity of recognizing d-realizable graphs has been elusive except for $d \in \{1, 2\}$, when d-realizable graphs coincide with complete graphs and with line graphs of bipartite graphs, respectively (and can be recognized in polynomial time). The main aim of this paper is to settle the question about recognition complexity of d-realizable graphs for $d \geq 3$, asked explicitly by Peterson in 2003 [46]. We show that for all $d \geq 3$, determining if a given graph is d-realizable is NP-complete, even for bipartite graphs. We also identify some tractable cases. We characterize d-realizable graphs (for any positive integer d) in the class of HHD-free graphs, a large class of perfect graphs containing chordal graphs and distance-hereditary graphs. The characterization leads to a linear time recognition algorithm.

Our approach is based on the fact that a graph G is d-realizable if and only if G is an induced subgraph of a Cartesian product of d complete graphs. Given two graphs G and H, their *Cartesian product* is the graph $G\Box H$ with vertex set $V(G) \times V(H)$ in which two vertices (u_1, u_2) and (v_1, v_2) are adjacent if and only if either $u_1v_1 \in E(G)$ and $u_2 = v_2$, or $u_1 = v_1$ and $u_2v_2 \in E(H)$. The Cartesian product is associative and commutative (in the sense that $G\Box H \cong H\Box G$ where $\cong$ denotes the graph isomorphism relation). Another name for Cartesian products of complete graphs is *Hamming graphs*; a Hamming graph is *d-dimensional* if it is the Cartesian product of d nontrivial complete graphs. The 3-dimensional Hamming graphs having all factors of the same size were studied in the literature under the name *cubic lattice graphs* [37, 12, 11, 1, 16], hence, 3-realizable graphs are exactly the induced subgraphs of cubic lattice graphs. Our results are based on a characterization of induced subgraphs of d-dimensional Hamming graphs due to Klavžar and Peterin [33], expressed in terms of the existence of a particular edge labeling. For the 3-dimensional case, we develop a more specific characterization based on induced cycles of the graph and use it to prove hardness of recognizing 3-realizable graphs via a reduction from the 3-edge-coloring problem in cubic graphs. The hardness of the 3-dimensional case forms the basis for establishing hardness for all higher dimensions.

Since a d-realizable graph is also $(d+1)$-realizable, the notion of d-realizability suggests a natural graph parameter. The *Cartesian dimension* of a graph $G = (V, E)$, denoted $\mathrm{Cdim}(G)$, is defined as the minimum non-negative integer d such that G is *d-realizable*, if such an integer exists, and ∞, otherwise. The infinite case can indeed occur, even some small graphs – the diamond, the 5-cycle, and the complete bipartite graph $K_{2,3}$, for example – cannot be realized in any dimension. Note that $\mathrm{Cdim}(G)$, when finite and strictly positive, is the minimum positive integer d such that G is an induced subgraph of the Cartesian product of d complete graphs. This point of view adds the Cartesian dimension of a graph to the list of graph dimensions studied in the literature related to various embeddings of graphs into Cartesian product graphs [24, 20, 27, 34]. Other dimensions were studied related to the strong product [22, 15, 32, 47] and the direct product of graphs [41, 48].

Related work. As already mentioned, concepts equivalent to d-realizable graphs were studied in the literature in various contexts [13, 3, 29, 25, 50, 46, 49]. Much further work in the literature deals exclusively with the two-dimensional case [26, 28, 14, 46, 2], which (as we will discuss in Section 2) corresponds to the class of line graphs of bipartite graphs, one of the basic building blocks in the structural decomposition of perfect graphs [10].

Among the many dimension parameters of graphs defined via product graphs, let us mention two that seem to be most closely related to the Cartesian dimension. A d-realization is said to be *irredundant* [34] (or: *d-dimensionally spanning* [49]) if for each $i \in \{1, \ldots, d\}$ some pair of adjacent vertices of G is mapped to a pair of points spanning a line that is parallel to the i-th coordinate axis. Based on this notion, Klavžar et al. [34] defined the Hamming dimension of a graph G, denoted by $\mathrm{Hdim}(G)$, as the largest integer d such that G has an irredundant d-realization, if such an integer exists, and ∞, otherwise. Note that the Cartesian dimension can be defined analogously, with "smallest" instead of "largest"; in particular, $\mathrm{Cdim}(G) \leq \mathrm{Hdim}(G)$. Strict inequality is possible (for example, if P_4 denotes the 4-vertex path, then $\mathrm{Cdim}(P_4) = 2$ and $\mathrm{Hdim}(P_4) = 3$) and the two dimensions are finite on the same set of graphs.

The second relevant dimension is a Dushnik-Miller type dimension of a graph, the so-called *product dimension*. This parameter, denoted simply by $\dim(G)$, is defined analogously to the Cartesian dimension but with respect to the direct product. Given two graphs G and H, their direct product is the graph $G \times H$ with vertex set $V(G) \times V(H)$ in which two vertices (u_1, u_2) and (v_1, v_2) are adjacent if and only if $u_1v_1 \in E(G)$ and $u_2v_2 \in E(H)$. The product dimension was introduced by Nešetřil and Rödl in [41] and studied by Lovász et al. in [39] and more recently by Chandran et al. [8]; see also [21]. Unlike the Cartesian dimension, the product dimension is finite for all graphs. The problem of computing the product dimension of a given graph was shown to be NP-hard [40], even in the special case of recognizing three-dimensional instances [36]. The Cartesian and the product dimensions of graphs are closely related in the two-dimensional case: since the Cartesian product of two complete graphs is isomorphic to the complement of their direct product, we have $\mathrm{Cdim}(G) \leq 2$ if and only if $\mathrm{Hdim}(\overline{G}) \leq 2$, where $\overline{G}$ denotes the complement of G.

The Cartesian dimension of graphs introduced in this paper should not be confused with any of the "Cartesian dimensions" of a graph studied by Burosch and Ceccherini [7]. They are defined similarly to the Hamming dimension $\mathrm{Hdim}(G)$ from [34], but with respect to various inclusion relations and with the relaxation that the factors are not restricted to be complete.

Structure of the paper. In Section 2 we collect the necessary definitions, summarize some characterizations of the two-dimensional case and a necessary condition for the general, d-dimensional case. In Section 3 we review a characterization of induced subgraphs of d-dimensional Hamming graphs due to Klavžar and Peterin and introduce two related results regarding the three-dimensional case. We build on these results in Section 4, where the NP-completeness of recognizing d-realizable graphs is established for all $d \geq 3$. A linear time algorithm for computing the Cartesian dimension of a given HHD-free graph is developed in Section 5, after the general problem is reduced to the biconnected case. We conclude the paper in Section 6. Due to space limitations, several proofs are omitted.

2 Preliminaries

All graphs considered in this paper will be finite, simple and undirected. By K_n, P_n, and C_n we denote the complete graph, the path, and the cycle with n vertices. By $K_{m,n}$ we denote the complete bipartite graph with parts of sizes m and n; the *claw* is the graph $K_{1,3}$. A *clique* (resp., *independent set*) in a graph G is a set of pairwise adjacent (resp., pairwise non-adjacent) vertices. By $\alpha(G)$ we denote the independence number of G, that is, the maximum size of an independent set in G. A *triangle* in G is a clique of size 3 in G. The *diamond* is the graph obtained by removing an edge from a K_4. For a vertex v in G, the *neighborhood* of v is the set of vertices in G adjacent to v. It is denoted by $N_G(v)$ (or simply by $N(v)$ if the graph will be clear from the context). The *degree* of v (in G) is the size of its neighborhood. A graph is *cubic* if all its vertices have degree 3. The *girth* of a graph G is the length of the shortest cycle in G (and ∞ if G is acyclic). Given a graph G and a set $U \subseteq V(G)$, we denote by $G[U]$ the subgraph of G induced by U. Given a set of graphs $\mathcal{F}$, a graph G is said to be *$\mathcal{F}$-free* if no induced subgraph of G is isomorphic to a graph from $\mathcal{F}$. A *cut vertex* in a connected graph G is a vertex whose removal disconnects the graph. Given a graph G, a *block* of G is a maximal connected subgraph of G without cut vertices. A graph G is *biconnected* if G itself is its only block. The disjoint union of two graphs G and H is denoted by $G + H$. For graph theoretic terms not defined here, see, e.g., [51].

Given a positive integer d, a *d-realization* of a graph $G = (V, E)$ is an injective mapping $\varphi_G : V \to \mathbb{R}^d$ such that two vertices $u, v \in V$ are adjacent if and only if $\varphi_G(u)$ and $\varphi_G(v)$ differ in exactly one coordinate. A graph G is said to be *d-realizable* if it has a d-realization. Note that G is d-realizable if and only if G has a d-realization $\varphi_G : V \to \mathbb{N}^d$. The *Cartesian dimension* of a graph $G = (V, E)$, denoted $\mathrm{Cdim}(G)$, is defined as the minimum non-negative integer d such that G is *d-realizable*, if such an integer exists, and ∞, otherwise. (Note that K_1 is the only graph of Cartesian dimension 0.)

Clearly, the only graphs of Cartesian dimension 1 are complete graphs of order at least two. Graphs of Cartesian dimension at most 2 coincide with line graphs of bipartite graphs, for which various characterizations and linear time recognition algorithms are known. Recall that a graph G is said to be *bipartite* it has a *bipartition*, that is, a pair (X, Y) of disjoint independent sets such that $X \cup Y = V(G)$. The *line graph* of a graph G is the graph denoted by $L(G)$ with vertex set $E(G)$, in which two distinct vertices are adjacent if and only if they have a common endpoint as edges in G. Line graphs of bipartite graphs were studied in the literature under various names such as graphs of $(0, 1)$-matrices [28], matrix graphs [14], two-dimensional chessboard graphs [50], (two-dimensional) gridline graphs [46], cellular graphs [25], and rooks graphs [2]. The characterization of line graphs of bipartite graphs in terms of forbidden induced subgraph was discovered and rediscovered many times: by Chartrand in 1964 [9], by Hedetniemi in 1971 [28], by Harary and Holzman in 1974[26], by Staton and Wingard in 1998 [50], and by Peterson in 2003 [46]. Furthermore, Staton and Wingard [50] and Peterson [46] established the connection with the Cartesian dimension. These characterizations are summarized in the following theorem.

▶ **Theorem 1.** *For every graph G, the following conditions are equivalent:*

1. $\mathrm{Cdim}(G) \leq 2$.
2. *G is the line graph of a bipartite graph.*
3. *G is $\{$claw, diamond, C_5, $C_7, \ldots\}$-free.*

For any positive integer d, Staton and Wingard proved the following necessary condition for a graph to be d-realizable.

▶ **Theorem 2** (Staton and Wingard [50]). *Every d-realizable graph is $\{K_{1,d+1}$, diamond, $K_{2,3}, C_5\}$-free.*

Staton and Wingard asked whether for $d \geq 3$, the list of forbidden induced subgraphs for the class of d-realizable graphs given by Theorem 2 is complete. This is not the case: Peterson constructed an infinite family of graphs that are minimally forbidden for d-realizability for all $d \geq 3$ [46, Figure 4] (see also [45]). However, the complete list of forbidden induced subgraphs is not known for any $d \geq 3$.

3 The Klavžar-Peterin characterization

In this section, we recall the characterization of induced subgraphs of d-dimensional Hamming graphs due to Klavžar and Peterin [33] and strengthen it in the 3-dimensional case. The characterization is expressed in terms of the existence of a particular edge labeling. Given a graph G, a *d-edge-labeling of G* is a mapping from $E(G)$ to some set L of *labels*, where $|L| = d$ (we often have $L = \{1, \ldots, d\}$). Given a d-edge-labeling ℓ of G and a set $F \subseteq E(G)$, we say that F is *ℓ-monochromatic* (or simply *monochromatic* if the labeling is clear from the context) if the labeling is constant on F, that is, if $e, e' \in F$ implies $\ell(e) = \ell(e')$. We extend the definition of monochromaticity to subgraphs of G in the obvious way. A *(d-)edge-coloring* is a (d-)edge-labeling such that no two incident edges share the same label. In the case of edge-colorings, labels may also be referred to as *colors*.

We say that a d-edge-labeling of G is a *(d-)KP-labeling* if it satisfies the following two conditions:

- **Condition 1**: every triangle is monochromatic.
- **Condition 2**: for every pair of distinct non-adjacent vertices u, v, there exist different labels i and j which both appear on every induced u, v-path.

Note that in a KP-labeling, every induced P_3 will be 2-edge-colored due to Condition 2; in particular, this implies that for triangle-free graphs, KP-labelings coincide with edge-colorings.

Since induced subgraphs of Hamming graphs are exactly the graphs of finite Cartesian dimension, the result of Klavžar and Peterin given by [33, Theorem 3.3] can be equivalently stated as follows.

▶ **Theorem 3** (Klavžar and Peterin [33]). *Let G be a connected graph. Then $\mathrm{Cdim}(G) < \infty$ if and only if G has a KP-labeling.*

The proof of Theorem 3 given in [33] actually shows the following more specific equivalence:

▶ **Theorem 4.** *For every connected graph G and a positive integer d, we have $\mathrm{Cdim}(G) \leq d$ if and only if G has a d-KP-labeling.*

We can find d-realizations of two graphs G and H such that $\mathrm{Cdim}(G) \leq \mathrm{Cdim}(H) = d$ when $d > 1$, using d-tuples over disjoint sets for the two graphs. The case $d = 1$ is exceptional: by definition, two different 1-tuples result in a pair of adjacent vertices. Thus, as all graphs of Cartesian dimension 1 are complete, the Cartesian dimension of any disconnected graph is at least 2. We record these observations for later use.

▶ **Observation 5.** *For every two graphs G and H, we have $\mathrm{Cdim}(G + H) = \max\{\mathrm{Cdim}(G), \mathrm{Cdim}(H), 2\}$.*

We now present two results for the 3-dimensional case. Both are related to the Klavžar-Peterin characterization and will be needed in our hardness proof for recognizing 3-realizable

graphs developed in Section 5. First, we show that the defining properties of a 3-KP-labeling are satisfied for a graph as soon as they are satisfied for the family of all its induced subgraphs isomorphic to a cycle or to a P_3.

▶ **Theorem 6.** *Let G be a graph. A 3-edge-labeling of G is a KP-labeling if and only if it satisfies the following two conditions:*

- **Condition 3***: for every induced cycle C of G, the restriction of the labeling to $E(C)$ is a KP-labeling of C.*
- **Condition 4***: no induced P_3 is monochromatic.*

Proof. The necessity of the two conditions is easy to see. If G is 3-KP-labeled and H is an induced subgraph of G, then the restriction of the labeling to $E(H)$ is a 3-KP-labeling of H, hence Condition 3 is necessary. Condition 4 follows from Condition 2.

In order to prove sufficiency, note that Condition 3 immediately implies Condition 1. Now, by way of contradiction suppose that there is a 3-edge-labeling $\ell : E(G) \to \{1, 2, 3\}$ satisfying Conditions 3 and 4, but not Condition 2. Since G violates Condition 2, it contains two different induced paths of length at least two, say P and Q, intersecting at their endpoints – call these vertices u and v – such that no pair of different labels appears on both P and Q. Due to Condition 4, on each of the paths P and Q at least two different labels appear. Since no pair of different labels appears on both P and Q, we may assume that P and Q take – alternatingly – labels $1, 2$ and $1, 3$, respectively. Moreover, assume that

(∗) P and Q were chosen so as to minimize $|V(P)| + |V(Q)|$.

Given a path R and two of its vertices x and y, denote by R_{xy} the subpath of R between x and y, and by V_R^{-xy} the set $V(R) \setminus \{x, y\}$. We say that a path is *k-labeled* if exactly k different labels appear on its edges.

We claim that $V_P^{-uv} \cap V_Q^{-uv} = \emptyset$. Indeed, suppose for a contradiction that $w \in V_P^{-uv} \cap V_Q^{-uv}$. Then, P_{uw} and Q_{uw} would be both 2-labeled (u and w cannot be adjacent due to $(*)$), only agreeing on label 1; thus, $P_{uw} \cup Q_{uw}$ would be 3-labeled, contradicting $(*)$.

For $t \in \{u, v\}$ and $xy \in E(G)$ with $(x, y) \in V_P^{-uv} \times V_Q^{-uv}$, a cycle $C = P_{tx}$-xy-Q_{yt} such that either P_{tx}-xy or xy-Q_{yt} is an induced path will be called a *PQ-cycle*. Note that a PQ-cycle cannot be 3-labeled: if – say – $P' = P_{tx}$-xy was an induced path, then P' and Q_{yt} would make evident a violation to $(*)$.

Condition 3 implies that the cycle $C_0 = P \cup Q$ cannot be induced. Let xy be a chord in C_0 ($\{x, y\} \cap \{u, v\} = \emptyset$) such that $x \in V(P)$ is closest to u (where the distance is measured within P), and y is the neighbor of x in Q closest to v (where the distance is measured within Q). Observe that each of $C_1 = P_{ux}$-xy-Q_{yu} and $C_2 = P_{vx}$-xy-Q_{yv} is either a PQ-cycle or a triangle, implying that neither of them is 3-labeled. Neither of them can be monochromatic either: if – say – C_1 was monochromatic then, as $E(C_0) \subset E(C_1) \cup E(C_2)$ while C_1 and C_2 share the label of xy, it would follow that C_2 was 3-labeled. Thus, C_1 and C_2 are 2-labeled.

As C_1 and C_2 are 2-labeled, they share exactly one label. By definition, any PQ-cycle contains a P_3 from either P or Q, hence (recalling that P and Q alternate labels $1, 2$ and $1, 3$, respectively), C_1 and C_2 share label 1. Such is then the label of xy. However, one of the two edges incident to x in P is also labeled with 1, forming with xy a monochromatic induced P_3 (as part of either C_1 or C_2), which contradicts Condition 4. ◀

Next, we characterize 3-KP-labelings of cycles. By Condition 1 in the definition of a KP-labeling, every 3-KP-labeling of a 3-cycle is constant. The next lemma analyzes longer cycles.

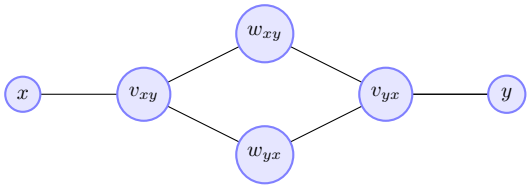

Figure 1 A gadget replacing each edge xy.

▶ **Lemma 7.** *Let C be a cycle of length at least 4. A 3-edge-coloring of C with colors $1, 2, 3$ is a KP-labeling if and only if*

- *either it is a 2-edge-coloring of C, or*
- *possibly after permuting the labels $1, 2, 3$, cycle C contains a cyclically ordered sequence of 6 distinct (not necessarily consecutive) edges labeled $1, 2, 3, 1, 2, 3$, respectively. We call this the* **123123-*condition***.

4 NP-completeness of testing realizability in $d \geq 3$ dimensions

In this section, we show that for every $d \geq 3$, determining whether $\mathrm{Cdim}(G) \leq d$ is NP-complete. First we establish the result for $d = 3$ and then derive from it the general case.

▶ **Theorem 8.** *Given a graph G, determining whether $\mathrm{Cdim}(G) \leq 3$ is NP-complete, even for connected bipartite graphs of maximum degree at most 3.*

Proof. A polynomially checkable certificate of the fact that $\mathrm{Cdim}(G) \leq 3$ is any 3-realization of G of the form $\varphi_G : V \to \mathbb{N}^3$. Therefore, the problem is in NP (on any class of input graphs).

To show hardness, we make a reduction from the 3-edge-coloring problem in cubic graphs, proved to be NP-complete by Holyer [30]. Let G be a cubic graph that is the input for the 3-edge-coloring problem. We may assume that G is connected. Construct a graph G' from G by replacing each edge xy of G with the structure shown in Fig. 1. Formally,

$$V(G') = V(G) \cup \bigcup_{xy \in E(G)} \{v_{xy}, w_{xy}, w_{yx}, v_{yx}\},$$

$$E(G') = \bigcup_{xy \in E(G)} \{xv_{xy}, v_{xy}w_{xy}, v_{xy}w_{yx}, v_{yx}w_{xy}, v_{yx}w_{yx}, yv_{yx}\}.$$

Letting $V_1 = V(G) \cup \bigcup_{xy \in E(G)} \{w_{xy}, w_{yx}\}$ and $V_2 = \bigcup_{xy \in E(G)} \{v_{xy}, v_{yx}\}$, we see that (V_1, V_2) is a bipartition of G'. Thus, G' is a bipartite graph with vertices of degrees 2 and 3 only. We will show that G is 3-edge-colorable if and only if $\mathrm{Cdim}(G') \leq 3$.

We first prove the (simpler) backward direction. Let $\mathrm{Cdim}(G') \leq 3$. By Theorem 4, G' has a 3-KP-labeling. Then for each $xy \in E(G)$ the 4-cycle $C = v_{xy}$-w_{xy}-v_{yx}-w_{yx}-v_{xy} in G' must be 2-KP-labeled. This implies that the edges xv_{xy} and yv_{yx} must have the same label ℓ_{xy} – the one not used in C. Since G' is triangle-free, any KP-labeling of G' is an edge-coloring (otherwise, Condition 4 would be violated). Therefore, by labeling each edge $xy \in E(G)$ with ℓ_{xy}, we get a 3-edge-coloring of G.

Now suppose that G has a 3-edge-coloring using colors $1, 2, 3$. For each edge xy of G labeled $i \in \{1, 2, 3\}$, let $\{j, k\} = \{1, 2, 3\} \setminus \{i\}$ and label the associated edges of G' as follows: edges xv_{xy} and yv_{yx} with i, edges $v_{xy}w_{xy}$ and $v_{yx}w_{yx}$ with j, and edges $v_{xy}w_{yx}$ and $v_{yx}w_{xy}$ with k.

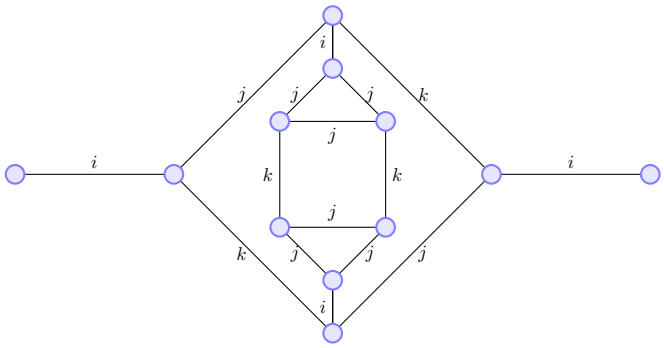

Figure 2 A gadget replacing each edge for proving hardness in cubic graphs.

We claim that the so obtained labeling of G' is a KP-labeling. By Theorem 6, it suffices to check that Conditions 3 and 4 are satisfied. The latter condition is obviously satisfied.

In order to verify that Condition 3 holds, note that G' has two types of induced cycles:

- 4-cycles. They only appear in the gadget of Fig. 1; they are properly 2-edge-colored and hence KP-labeled by Lemma 7.
- Cycles of length greater than 4. Each such cycle C has length $4p$ for some $p \geq 3$, and arises from a (not necessarily induced) p-cycle C' in G. We will show that such cycles satisfy the 123123-condition and apply Lemma 7. Let $x_1, x_2, \ldots, x_p$ be a cyclic order of vertices in C'. Without loss of generality, let $1, 2, 3, 1$ be the labels (in this order) on some shortest path from x_1 to x_2 in C. Then, the sequence of labels on the edges of any shortest path from x_2 to x_3 in C is one of the following: $(2, 1, 3, 2)$, $(2, 3, 1, 2)$, $(3, 1, 2, 3)$, or $(3, 2, 1, 3)$. Thus, along cycle C we find 6 distinct edges labeled $1, 2, 3, 1, 2, 3$ in order. This shows that C satisfies the 123123-condition.

It follows that Condition 3 is satisfied, hence by Theorem 6 G' has a 3-KP-labeling. By Theorem 4, we conclude that $\mathrm{Cdim}(G') \leq 3$. ◀

▶ Remark. A simple modification of the above construction, using a somewhat more involved gadget, can be used to show NP-completeness of testing whether $\mathrm{Cdim}(G) \leq 3$ for cubic (non-bipartite) graphs. We omit the details but show the gadget in Fig. 2 together with edge labels indicating how to extend a 3-edge-coloring of G to a 3-KP-labeling of G'.

▶ Remark. Recall that Peterson constructed an infinite family of graphs that are minimally forbidden for 3-realizability [46]. All those graphs are of girth 3. The above proof implies that the landscape of forbidden induced subgraphs for 3-realizability is much more complicated, consisting of graphs of arbitrarily large girth. To see this, note that for every positive integer g, there exists a graph F_g of maximum degree at most 3 and of girth at least g with $\mathrm{Cdim}(F_g) > 3$. This follows from the proof of Theorem 8 and the fact that there exist cubic graphs of arbitrarily large girth that are not 3-edge-colorable [35]. Since $\mathrm{Cdim}(F_g) > 3$, graph F_g contains a forbidden induced subgraph for 3-realizability, say F'_g. Since every acyclic graph of maximum degree at most 3 is 3-realizable (this follows, e.g., from Corollary 15 in Section 5.2), graph F'_g has a cycle and is therefore of (finite) girth at least g.

From Theorem 8 we derive hardness of recognizing graphs of any constant Cartesian dimension.

▶ **Theorem 9.** *For every $d \geq 3$, determining whether a given graph G satisfies $\mathrm{Cdim}(G) \leq d$ is NP-complete, even for connected bipartite graphs.*

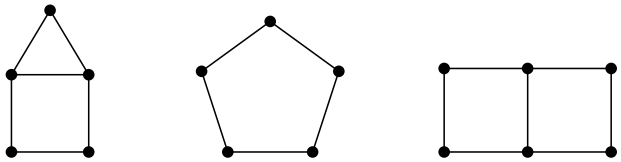

Figure 3 The house (left), the smallest hole (middle), and the domino (right).

Proof idea. The base case, $d = 3$, is given by Theorem 8. The inductive step can be established using the observation that for every connected bipartite graph G, the Cartesian product $G\Box K_2$ is also connected and bipartite, and satisfies $\mathrm{Cdim}(G\Box K_2) = \mathrm{Cdim}(G)+1$. ◀

5 Tractable cases: chordal graphs and distance-hereditary graphs

Since bipartite graphs are perfect, Theorem 8 implies that the problem of recognizing graphs of Cartesian dimension 3 is NP-complete in the class of perfect graphs. In this section, we show that the problem can be solved in linear time in two well-studied classes of perfect graphs: chordal graphs and distance-hereditary graphs. A graph G is *chordal* if it has no induced cycle of length at least four and *distance-hereditary* if in every connected induced subgraph of G, the distance between any pair of vertices is the same as in G. We characterize chordal graphs and distance-hereditary graphs of given Cartesian dimension. The characterizations will imply linear time algorithms for computing the Cartesian dimension of a given chordal or distance-hereditary graph.

We develop a unified approach that will imply both results, by considering the class of HHD-free graphs. We define a *hole* to be a cycle of length at least five.[1] A graph G is said to be *HHD-free* if it does not contain an induced subgraph isomorphic to the house, a hole, or the domino (see Fig. 3).

HHD-free graphs were introduced by Olariu [44] as a class of perfect graph generalizing both chordal and distance-hereditary graphs. They can be equivalently defined as the *(5,2)-chordal graphs*, that is, graphs in which every cycle of length at least five has at least two chords (see, e.g., [4]). Jamison and Olariu [31] characterized HHD-free graphs in terms of properties of the Lexicographic Breadth First Search algorithm, and Nikolopoulos and Palios gave an $O(|V(G)||E(G)|)$ time recognition algorithm [43]. Many other studies looked into metric, structural, and algorithmic properties of HHD-free graphs (see, e.g., [18, 6, 19, 42, 19, 17, 5]).

We characterize HHD-free graphs of a given Cartesian dimension and derive the corresponding results for chordal and distance-hereditary graphs as corollaries. We do this by first showing that the problem of computing the Cartesian dimension of an arbitrary graph can be reduced to its blocks (Lemma 10), and by identifying two particularly nice cases of this reduction (Lemmas 11 and 12). Next, we characterize biconnected HHD-free graphs of a given Cartesian dimension. To this end, we apply the necessary conditions for graphs of finite Cartesian dimension given by Theorem 2 to reduce the problem to the biconnected {diamond, $K_{2,3}$}-free HHD-free graphs, which we characterize in Lemma 13. Finally, the simple structure of the biconnected {diamond, $K_{2,3}$}-free HHD-free graphs (they can only be complete or 4-cycles) is used to prove the desired characterization (Theorem 14) and a linear time algorithm for computing the Cartesian dimension of an HHD-free graphs (Theorem 16).

[1] We remark that the terminology on holes is not completely uniform in the graph theory literature. In many papers, holes are defined as cycles of length at least four.

5.1 Reduction to blocks

For a graph G and a vertex $v \in V(G)$, we set $\alpha_G(v) = \alpha(G[N(v)])$ and $\alpha_1(G) = \max\{\alpha_G(v) : v \in V(G)\}$. Note that $\alpha_1(G)$ is the maximum value of n such that $K_{1,n}$ is an induced subgraph of G. Hence, by Theorem 2, every graph G has $\mathrm{Cdim}(G) \geq \alpha_1(G)$. The following lemma specifies the reduction for the problem of computing the Cartesian dimension of a given graph to the biconnected case.

▶ **Lemma 10.** *Let G be a connected graph with a cut vertex v, let $V(G) = \{v\} \cup V_1 \cup V_2$ where V_1 and V_2 are disjoint non-empty subsets of $V(G) \setminus \{v\}$ such that no vertex from V_1 is adjacent to a vertex in V_2, and let $G_i = G[\{v\} \cup V_i]$ for $i \in \{1, 2\}$. Then,* $\mathrm{Cdim}(G) = \max\{\mathrm{Cdim}(G_1), \mathrm{Cdim}(G_2), \alpha_G(v)\}$.

Lemma 10 has two useful consequences. For a connected graph G, we denote by C_G the set of cut vertices of G and by $\mathcal{B}_G$ the set of blocks of G. The *block-cutpoint tree* of a connected graph G is the bipartite graph T with vertex set $\mathcal{B}_G \cup C_G$ in which $B \in \mathcal{B}_G$ is adjacent to $v \in C_G$ if and only if $v \in V(B)$. It is well known that T is a tree such that all leaves of T are blocks of G (see, e.g., [51]). A class of graphs is *hereditary* if it is closed under vertex deletion. We say that a graph G is *maxstar-dimensional* if $\mathrm{Cdim}(G) = \alpha_1(G)$.

▶ **Lemma 11.** *Let $\mathcal{G}$ be a hereditary class of graphs such that every biconnected graph in $\mathcal{G}$ is maxstar-dimensional. Then every connected graph in $\mathcal{G}$ is maxstar-dimensional.*

Let us call a graph *star-dimensional* if $\mathrm{Cdim}(G) = \alpha_G(v)$ for every $v \in V(G)$.

▶ **Lemma 12.** *Let $\mathcal{G}$ be a hereditary class of graphs such that every biconnected graph in $\mathcal{G}$ is star-dimensional. Then, every connected graph $G \in \mathcal{G}$ with a cut vertex satisfies*

$$\mathrm{Cdim}(G) = \max_{v \in C_G} \sum_{B \in \mathcal{B}_G : v \in B} \mathrm{Cdim}(B)\,.$$

5.2 Cartesian dimension of HHD-free graphs

The following lemma characterizes biconnected {diamond, $K_{2,3}$}-free HHD-free graphs. In the proof we will need the notion of a *block graph*, that is, a connected graph every block of which is complete.

▶ **Lemma 13.** *Let G be a biconnected {diamond, $K_{2,3}$}-free HHD-free graph. Then, G is either complete or a C_4.*

Proof. Let G be a biconnected {diamond, $K_{2,3}$}-free HHD-free graph. Consider first the case when G is chordal. Since connected diamond-free chordal graphs are exactly the block graphs (see, e.g., [38]), G is a block graph. Thus, since G is biconnected, it is complete.

Suppose now that G is not chordal. Since G has no induced cycles of length 5 or more but is not chordal, G has an induced C_4, say C. We want to show that $G = C$. First, note that every vertex of G not in C has at most one neighbor in C. Indeed, the neighborhood on C of a vertex $v \in V(G) \setminus V(C)$ consisting of at least three neighbors, exactly two neighbors that are adjacent, or exactly two neighbors that are non-adjacent, would lead to an induced subgraph of G isomorphic to an diamond, a house, or a $K_{2,3}$, respectively.

Let (v_1, v_2, v_3, v_4) be a cyclic order of vertices along C and let U denote the set of vertices in $V(G) \setminus V(C)$ adjacent to a vertex of C. Since every vertex in U has exactly one neighbor in C, the set U can be partitioned into pairwise disjoint sets, $U = U_1 \cup U_2 \cup U_3 \cup U_4$, where U_i is the set of vertices in U adjacent to v_i. Note that since G is domino-free, no vertex in

U_i is adjacent to a vertex in U_{i+1} (indices modulo 4). Moreover, since G is C_5-free, no vertex in U_i is adjacent to a vertex in U_{i+2} (indices modulo 4). Thus, if $i \neq j$, then no vertex in U_i is adjacent to a vertex in U_j.

Suppose for a contradiction that $G \neq C$. Since G is connected, the fact that $G \neq C$ implies that one of the sets U_i is non-empty, say (w.l.o.g.) $U_1 \neq \emptyset$. Let $X = V(C) \setminus \{v_1\}$. Since G is biconnected, it contains a U_1, X-path avoiding v_1. Let P be a shortest such path. Let us enumerate the vertices of P along the path as $w_1, \ldots, w_k$ where $w_1 \in U_1$ and $w_k \in X$, more specifically, $w_k = v_i$ for some (unique) $i \in \{2, 3, 4\}$. By minimality, P is an induced path in $G - v_1$; moreover, since there are no edges connecting a vertex in U_1 with a vertex in U_j for $j \neq 1$, we infer that $k \geq 4$. By the minimality of P, no internal vertex of P is in $U_1 \cup X$, moreover, $w_{k-1} \in U_i$ and $V(P) \cap (U_2 \cup U_3 \cup U_4) = \{w_{k-1}\}$. It follows that w_1 and possibly w_k are the only neighbors of v_1 on P. Now, if $i \in \{2, 4\}$, then $V(P) \cup \{v_1\}$ induces a cycle of length at least five in G, which is not possible. Similarly, if $i = 3$, then $V(P) \cup \{v_1, v_2\}$ induces a cycle of length at least six in G, again a contradiction. This shows that $G = C$, as claimed, and completes the proof. ◀

It is not difficult to verify that every graph $G \in \{C_4\} \cup \{K_n : n \geq 1\}$ is star-dimensional, with

$$\mathrm{Cdim}(G) = \alpha_1(G) = \begin{cases} 0, & \text{if } G \text{ is a } K_1; \\ 1, & \text{if } G \text{ is a } K_n \text{ with } n \geq 2; \\ 2, & \text{if } G \text{ is a } C_4. \end{cases}$$

By Lemma 13, every biconnected {diamond, $K_{2,3}$}-free HHD-free graph is star-dimensional.

Recall that the inequality $\mathrm{Cdim}(G) \geq \alpha_1(G)$ holds for every graph G, where $\alpha_1(G)$ is the maximum value of n such that $K_{1,n}$ is an induced subgraph of G. Lemmas 11 and 13 imply that equality holds in the case of HHD-free graphs of finite Cartesian dimension.

▶ **Theorem 14.** *For every connected HHD-free graph G,*

$$\mathrm{Cdim}(G) = \begin{cases} \alpha_1(G), & \textit{if } G \textit{ is } \{\textit{diamond}, K_{2,3}\}\textit{-free;} \\ \infty, & \textit{otherwise.} \end{cases}$$

Since the house, the domino, and each hole contain an induced cycle of length at least four, every chordal graph is HHD-free. Every distance-hereditary graph is also HHD-free; in fact, distance-hereditary graphs are known to be exactly the gem-free HHD-free graphs (see, e.g. [4]), where the *gem* is the graph obtained from the four-vertex path by adding to it a universal vertex. Theorem 14 therefore implies the following result.

▶ **Corollary 15.** *If a connected graph G is chordal or distance-hereditary, then*

$$\mathrm{Cdim}(G) = \begin{cases} \alpha_1(G), & \textit{if } G \textit{ is } \{\textit{diamond}, K_{2,3}\}\textit{-free;} \\ \infty, & \textit{otherwise.} \end{cases}$$

Observation 5 and Lemma 12 imply a linear time algorithm for computing the Cartesian dimension of a given HHD-free graph. We summarize its pseudocode in Algorithm 1 below and prove its correctness in Theorem 16.

▶ **Theorem 16.** *Algorithm 1 runs in time $O(|V(G)| + |E(G)|)$ and correctly computes the Cartesian dimension of a given HHD-free graph G (in particular, G may be a chordal graph or a distance-hereditary graph).*

Algorithm 1: Computing the Cartesian dimension of an HHD-free graph

Input: An HHD-free graph $G = (V, E)$.
Output: The value of $\mathrm{Cdim}(G)$.

compute the connected components $G_1, \ldots, G_r$ of G;
if $r > 1$ **then**
  run the algorithm recursively on each component of G;
  return $\max\{\max_{1 \le i \le r} \mathrm{Cdim}(G_i), 2\}$;
`// from now on,` G `is connected`
compute T, the block-cutpoint tree of G, C_G, the set of cut vertices of G, and $\mathcal{B}_G$, the set of its blocks;
if *G has a block that is not complete or a C_4* **then**
  return ∞;
`// from now on, each block of` G `is either complete or a` C_4
foreach $B \in \mathcal{B}_G$ **do**
  $$\mathrm{Cdim}(B) \leftarrow \begin{cases} 0, & \text{if } |V(B)| = 1 \\ 1, & \text{if } |V(B)| \ge 2 \text{ and } B_i \text{ is complete} \\ 2, & \text{if } B \text{ is a } C_4; \end{cases}$$
if $|\mathcal{B}_G| = 1$ **then**
  let $B \in \mathcal{B}_G$ and **return** $\mathrm{Cdim}(B)$;
foreach $v \in \mathcal{C}_G$ **do**
  $\alpha_G(v) \leftarrow \sum_{B \in \mathcal{B}_G : v \in B} \mathrm{Cdim}(B)$;
return $\max_{v \in C_G} \alpha_G(v)$;

▶ Remark. Lemma 10 determines how to efficiently combine KP-labelings of the blocks of a given graph G into a KP-labeling of G. Moreover, the proof of [33, Theorem 3.3] shows that a d-realization of a given d-KP-labeled graph can be computed in polynomial time. Hence, there exists a polynomial time algorithm that takes as input an HHD-free graph G of finite Cartesian dimension and outputs a d-realization of G where $d = \mathrm{Cdim}(G)$.

6 Conclusion

The main contribution of the present work is settling the computational complexity status of recognizing d-realizable graphs for any $d \ge 3$, answering thereby a question by Peterson from 2003. While the hardness result is valid already for the class of bipartite graphs, we identified an important class of perfect graphs for which the problem is solvable in linear time – the class of HHD-free graphs. Besides the question of identifying further graph classes where the problem of d-realizability is (in)tractable, the main question left open by this work is to determine the complexity status of the problem of deciding if a given graph G is d-realizable for some d (or, equivalently, whether its Cartesian dimension is finite). It would also be interesting to study in more detail the relation between the Cartesian and the Hamming dimensions of a graph, as both parameters can be defined in terms of the set of integers d such that the graph has an irredundant d-realization.

Abstract

We initiate the algorithmic study of the following "structured augmentation" question: is it possible to increase the connectivity of a given graph G by superposing it with another given graph H? More precisely, graph F is the superposition of G and H with respect to injective mapping $\varphi\colon V(H) \to V(G)$ if every edge uv of F is either an edge of G, or $\varphi^{-1}(u)\varphi^{-1}(v)$ is an edge of H. Thus F contains both G and H as subgraphs, and the edge set of F is the union of the edge sets of G and $\varphi(H)$. We consider the following optimization problem. Given graphs G, H, and a weight function ω assigning non-negative weights to pairs of vertices of $V(G)$, the task is to find φ of minimum weight $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y))$ such that the edge connectivity of the superposition F of G and H with respect to φ is higher than the edge connectivity of G. Our main result is the following "dichotomy" complexity classification. We say that a class of graphs $\mathcal{C}$ has *bounded vertex-cover number*, if there is a constant t depending on $\mathcal{C}$ only such that the vertex-cover number of every graph from $\mathcal{C}$ does not exceed t. We show that for every class of graphs $\mathcal{C}$ with bounded vertex-cover number, the problems of superposing into a connected graph F and to 2-edge connected graph F, are solvable in polynomial time when $H \in \mathcal{C}$. On the other hand, for *any* hereditary class $\mathcal{C}$ with unbounded vertex-cover number, both problems are NP-hard when $H \in \mathcal{C}$. For the unweighted variants of structured augmentation problems, i.e. the problems where the task is to identify whether there is a superposition of graphs of required connectivity, we provide necessary and sufficient combinatorial conditions on the existence of such superpositions. These conditions imply polynomial time algorithms solving the unweighted variants of the problems.

1 Introduction

In connectivity augmentation problems, the input is a (multi) graph and the objective is to increase edge or vertex connectivity by adding the minimum number (weight) of additional edges, called links. This is a fundamental combinatorial problem with a number of important applications, we refer to the books of Nagamochi and Ibaraki [12] and Frank [6] for a detailed introduction to the topic. In this paper we initiate the study of a "structural" connectivity augmentation problem, where the set of additional edges should satisfy some additional

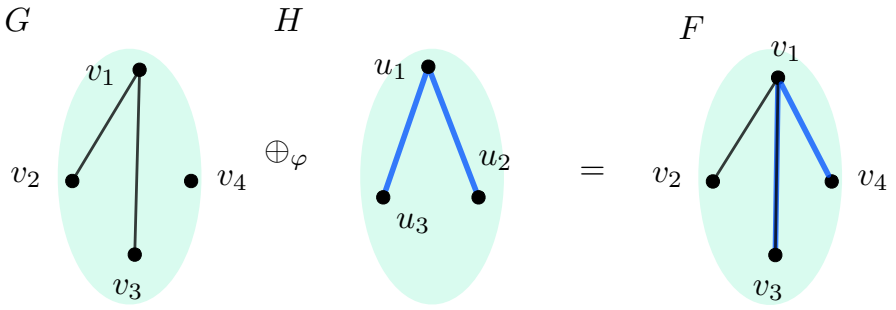

Figure 1 For injective mapping $\varphi\colon V(H) \to V(G)$ such that $\varphi(u_1) = v_1$, $\varphi(u_2) = v_4$, and $\varphi(u_3) = v_3$, we have $F = G \oplus_\varphi H$.

constrains. For example, such constrains can be that all new edges should be visible from one vertex, i.e. the new set of edges forms a star, forms a cycle, or can be controlled from a small set of vertices, i.e. the graph formed by the additional edges has a small vertex cover.

It is convenient to model such an augmentation problem as a *graph superposition* problem. Let G and H be simple graphs (i.e. graphs without loops and multiple edges), $|V(G)| \geq |V(H)|$, and let $\varphi\colon V(H) \to V(G)$ be an injective mapping of the vertices of H to the set of vertices of $V(G)$. We say that a simple graph F is the *superposition of G and H with respect to φ* and write $F = G \oplus_\varphi H$ if $V(F) = V(G)$ and two distinct vertices $u, v \in V(F)$ are adjacent in F if and only if $uv \in E(G)$ or $u, v \in \varphi(V(H))$ and $\varphi^{-1}(u)\varphi^{-1}(v) \in E(H)$. See Fig. 1 for an example. Thus graph F contains G and H as subgraphs, and the edge set of F is the union of the edge sets of G and $\varphi(H)$.

We study the algorithmic problem of increasing the edge-connectivity of graph G by superposing it with a graph H. We are interested in the weighted variant of the problem, where for every pair of vertices v and u of G, mapping the endpoints of an edge of H to u and v has a specified weight $\omega(uv)$. We consider the following problem.

Structured Connectivity Augmentation

Input:	Graphs G and H, a weight function $\omega\colon \binom{V(G)}{2} \to \mathbb{N}_0$, and a nonnegative integer W.
Task:	Decide whether there is an injective mapping $\varphi\colon V(H) \to V(G)$ such that graph $F = G \oplus_\varphi H$ is connected and the *weight* of the mapping $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y)) \leq W$.

We also study the problem of obtaining a 2-edge connected graph F by superposing graphs G and H. More precisely, we consider the following problem.

Structured 2-Connectivity Augmentation

Input:	Connected graph G and a graph H, a weight function $\omega\colon \binom{V(G)}{2} \to \mathbb{N}_0$ and a nonnegative integer W.
Task:	Decide whether there is an injective mapping $\varphi\colon V(H) \to V(G)$ of weight at most W such that $F = G \oplus_\varphi H$ is 2-edge connected.

Our results. Our main result is the following "dichotomy" complexity classification of structured augmentation problems. We say that a class of graphs $\mathcal{C}$ has *bounded vertex-cover number*, if there is a constant t depending on $\mathcal{C}$ only such that the vertex-cover number of every graph from $\mathcal{C}$ does not exceed t. We show that for every class of graphs $\mathcal{C}$ with bounded

vertex-cover number, Structured Connectivity Augmentation and Structured 2-Connectivity Augmentation are solvable in polynomial time when $H \in \mathcal{C}$. We complement this result by showing that for *any* hereditary class $\mathcal{C}$ with unbounded vertex-cover number, both problems are NP-complete when $H \in \mathcal{C}$. Thus for any hereditary class $\mathcal{C}$ both problems with $H \in \mathcal{C}$ are NP-complete if and only if $\mathcal{C}$ has unbounded vertex-cover number.

The running times of our algorithms solving Structured Connectivity Augmentation and Structured 2-Connectivity Augmentation are of the form $|V(G)|^{\mathcal{O}(f(t))} \cdot \log W$, where f is some function and t is the vertex cover of H. Thus our algorithms are not fixed-parameter tractable when t is the parameter. We show that from the perspective of parameterized complexity, this situation is unavoidable. More precisely, we show that both problems are W[1]-hard when parameterized by t. We refer to the book of Downey and Fellows [2] for an introduction to parameterized complexity.

We also consider the unweighted variants of Structured Connectivity Augmentation and Structured 2-Connectivity Augmentation. In these cases, the weight is $\omega(uv) = 0$ for every pair of vertices of G and $W = 0$. The task is to identify whether there is a superposition of graphs G and H of edge connectivity 1 or 2, correspondingly. Here we obtain necessary and sufficient combinatorial conditions of the existence of an injective function φ such that $F = G \oplus_\varphi H$ is edge k-connected provided that G is edge $(k-1)$-connected, $k = 1, 2$. These conditions imply polynomial time algorithms solving the unweighted variants of the problems.

Due to space constraints some proof are either just sketched or omitted in this extended abstract. The full details are available in [4].

Related work. The problem of increasing graph connectivity by adding additional edges is the classic and well-studied problem. It was first studied by Eswaran and Tarjan [3] and Plesnik [13] who showed that increasing the edge connectivity of a given graph to 2 by adding minimum number of additional augmenting edges is polynomial time solvable. Subsequent work in [14, 5] showed that this problem is also polynomial time solvable for any given target value of edge connectivity to be achieved. However, if the set of augmenting edges is restricted, that is, there are pairs of vertices in the graph which do not constitute a new edge, or if the augmenting edges have (non-identical) weights on them, then the problem of computing the minimum size (or weight) augmenting set is NP-complete [3]. Augmentation problems with constraints like simplicity-preserving augmentations, augmentations with partition constraints, or planarity requirements can be found in the literature, see the book of Nagamochi and Ibaraki [12] for further references.

Strongly relevant to structural augmentation is the Minimum Star Augmentation problem, see e.g. [12, Section 3.3.3] and [10]. Here one wants to increase the edge-connectivity of a given graph by adding a new vertices and connecting it with a small number of edges to the remaining vertices of the graph. In our setting this corresponds to the case of graph G having an isolate vertex, and graph H being a star (a tree with vertex-cover number 1). Tibor and Szigeti [10] studied a generalization of this problem where one wants to make a graph edge r-connected by attaching p stars of specified degrees. In particular, they provided combinatorial conditions which are necessary and sufficient for such an augmentation. Again, this problem can be seen as a special case of structural augmentation, where graph G has p isolated vertices and graph H is the union of stars of specified degrees.

2 Preliminaries

We consider only finite undirected graphs. For a graph G, $\binom{V(G)}{2}$ denotes the set of unordered pairs of distinct vertices of G. For uniformity, we denote the elements of $\binom{V(G)}{2}$ in the same way as edges, i.e., we write $uv \in \binom{V(G)}{2}$. A subgraph H of G is *spanning* if $V(H) = V(G)$. For a graph G and a subset $U \subseteq V(G)$ of vertices, we write $G[U]$ to denote the subgraph of G induced by U. We write $G - U$ to denote the graph $G[V(G) \setminus U]$. Let $S \subseteq E(G)$ for a graph G. By $G - S$ we denote by $G - S$ the graph obtained by the deletion of the edges of S. We write $G - e$ instead of $G - \{e\}$ for an edge e. For a vertex v, we denote by $N_G(v)$ the *(open) neighborhood* of v, i.e., the set of vertices that are adjacent to v in G. Two nonadjacent vertices u and v are *(false) twins* if $N_G(u) = N_G(v)$. A set of edges with pairwise distinct end-vertices is called a *matching*. A matching M is *induced* if the end-vertices of M are pairwise nonadjacent. A vertex v is *saturated* in a matching M if v is incident to an edge of M. We say that the disjoint union of copies of K_2 is a *matching graph*. A graph class $\mathcal{C}$ is said to be *hereditary* if for every $G \in \mathcal{C}$ and every induced subgraph H of G, $H \in \mathcal{C}$. A set of vertices $X \subseteq V(G)$ is a *vertex cover* of a graph G if every edge of G has at least one of its end-vertices in X. The minimum size of a vertex cover is called the *vertex-cover number* of G and is denoted by $\beta(G)$.

Let k be a positive integer. A graph G is *(edge) k-connected* if for every $S \subseteq E(G)$ with $|S| \leq k - 1$, $G - S$ is connected. Since we consider only edge connectivity, whenever we say that a graph G is k-connected, we mean that G is edge k-connected. We assume that every graph is 0-connected. A set of edges $S \subseteq E(G)$ of a connected graph G is an *edge separator* if $G - S$ is disconnected. An edge e of a connected graph G is a *bridge* if $\{e\}$ is a separator. Clearly, a connected graph is 2-connected if and only if it has no bridge. Let B be the set of bridges of a connected graph G. We call a component of $G - B$ a *biconnected component* of G. In other words, a biconnected component is an inclusion-wise maximal induced 2-connected subgraph of G. We say that a biconnected component L of a graph G is a *pendant biconnected component* (or simply a *pendant*) if a unique bridge of G is incident to $V(L)$. A biconnected component is *trivial* if it has a single vertex. For a graph G, we denote by $c(G)$ the number a components of G, and for a connected graph G, $p(G)$ is the number of pendants. We also denote by $i(G)$ the number of isolated vertices of G.

Let S be an inclusion-wise minimal edge separator of a connected graph G. Then $G - S$ has exactly two components C_1 and C_2. Let G be a spanning subgraph of F. We say that an edge $e \in E(F) \setminus E(G)$ *covers* a minimal separator S of G if e has its end-vertices in C_1 and C_2. The following observation about separators is useful.

▶ **Observation 1.** *Let $k \geq 2$ be an integer and let a $(k-1)$-connected graph G be a spanning subgraph of F. Then F is k-connected if and only if for each edge separator S of G with $|S| = k - 1$, F has an edge that covers it.*

We also need some additional terminology and folklore observations for the augmentation of a connected graph to a 2-connected graph. Let G be a connected graph and let x and y be distinct vertices of G. We say that a bridge uv of G *belongs* to an (x, y)-path P if $uv \in E(P)$. Similarly, a biconnected component Q is *crossed* by P if $V(Q) \cap V(P) \neq \emptyset$. The following observation show that the choice of an (x, y)-path is irrelevant if the biconnected components containing the end-vertices are given.

▶ **Observation 2.** *Let distinct $\{x_1, y_1\}$ and $\{x_1, y_2\}$ be pairs of distinct vertices of a connected graph G such that x_1, x_2 are in the same biconnected component of G and, similarly, y_1, y_2*

are in the same biconnected component of G. Let also P_1 and P_2 be (x_1, y_1) and (x_2, y_2)-paths respectively. Then the following holds:

- *a bridge uv of G belongs to P_1 if and only if uv belongs to P_2,*
- *a biconnected component Q is crossed by P_1 if and only if Q is crossed by P_2.*

▶ **Observation 3.** *Let u and v be distinct nonadjacent vertices of a connected graph G and let F be a graph obtained from G by the addition of the edge uv. Then uv covers all bridges that belongs to a (u, v)-path P in G, and for the biconnected components $Q_1, \ldots, Q_s$ that are crossed by P, $F[V(Q_1) \cup \ldots \cup V(Q_s)]$ is a biconnected component of F.*

In the remaining part of the paper, we will be always assuming that in the instance of the structured augmentation problem, we have

(i) $|V(H)| \leq |V(G)|$;

(ii) Graph H has no isolated vertices.

Indeed, if $|V(H)| > |V(G)|$, then there is no superposition of G and H, and thus such an instance is a no-instance. For (ii), it is sufficient to observe that mapping of isolated vertices of H to vertices of G does not influence the connectivity of the superposition. Another technical detail should be mentioned here. In Theorems 5 and 7, we evaluate the running times of algorithms as a function of $|V(G)|$ and the vertex cover number of H. In order to do this, we should be able to recognize within this time the (trivial) no-instances, where $|V(H)| > |V(G)|$. We can verify this condition in time $|V(G)|^{\mathcal{O}(1)}$ just by refuting the instances of size more than $|V(G)|^{\mathcal{O}(1)}$ after reading the first $|V(G)|^{\mathcal{O}(1)}$ bits.

3 Augmenting by graphs with small vertex cover

In this section we consider the situation when graph H is from a graph class $\mathcal{C}$ with bounded vertex-cover number. In Subsection 3.1 we show that in this case Structured Connectivity Augmentation and Structured 2-Connectivity Augmentation are solvable in polynomial time. In Subsection 3.2 we show that this condition is tight by proving that for any hereditary graph class $\mathcal{C}$ with unbounded vertex-cover number, both problems are NP-hard. Due to space restrictions, we only sketch our results.

3.1 Algorithms

We start with a solution for Structured Connectivity Augmentation, which is simpler than the solution for Structured 2-Connectivity Augmentation.

Structured Connectivity Augmentation. We need the following lemma.

▶ **Lemma 4.** *Let G and H be graphs and let $\varphi\colon V(H) \to V(G)$ be an injection such that $F = G \oplus_\varphi H$ is connected. Let also X be a vertex cover of H of size t. Then there is a set $Y \subseteq V(H) \setminus X$ of size at most $2(t-1)$ such that for graph $H' = H[X \cup Y]$ and mapping $\psi = \varphi|_{X \cup Y}$, the vertices of $\psi(X \cup Y)$ are in the same connected component of $F' = G \oplus_\psi H'$.*

Let us remind, that, given a positive integer t, a graph class $\mathcal{C}$ has vertex-cover number at most t if every graph $H \in \mathcal{C}$ has a vertex cover of size at most t. We are ready to prove the main theorem about Structured Connectivity Augmentation.

▶ **Theorem 5.** *Let t be a positive integer and $\mathcal{C}$ be a graph class of vertex-cover number at most t. Then for any $H \in \mathcal{C}$,* Structured Connectivity Augmentation *is solvable in time $|V(G)|^{\mathcal{O}(t)} \cdot \log W$.*

Sketch of the proof. Let G and $H \in \mathcal{C}$ be graphs and let $\omega\colon \binom{V(G)}{2} \to \mathbb{N}_0$ be a weight function. We show that we can find in time $|V(G)|^{\mathcal{O}(t)} \cdot \log W$ an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is connected and $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y))$ is minimum if φ exists.

Let us remind that without loss of generality, we can assume that $|V(H)| \leq |V(G)|$ and H has no isolated vertices.

We start from finding a vertex cover X of size at most t in H. Since we aim for an algorithm with running time $|V(G)|^{\mathcal{O}(t)} \cdot \log W$, vertex cover X can be found by brute-force checking of all subsets of $V(H)$ of size at most t. If we fail to find X of size at most t, it means that $H \notin \mathcal{C}$, in this case we return the answer NO and stop. Assume that X exists.

Suppose that there is an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is connected and assume that for φ, $\omega(\varphi)$ is minimum. By Lemma 4, there is a set $Y \subseteq V(H) \setminus X$ of size at most $2(t-1)$ such that for $H' = H[X \cup Y]$ and $\psi = \varphi|_{X \cup Y}$, the vertices of $\psi(X \cup Y)$ are in the same component of $F' = G \oplus_\psi H'$. Considering all possibilities, we guess Y in time $|V(H)|^{\mathcal{O}(t)}$.

Now we consider all possible injective mapping $\psi\colon X \cup Y \to V(G)$ such that the vertices of $\psi(X \cup Y)$ are in the same connected component of $F' = G \oplus_\psi H'$, where $H' = H[X \cup Y]$. Notice that there are at most $|V(G)|^{3t-2}$ such mappings that can be generated in time $|V(G)|^{\mathcal{O}(t)}$. If we fail to find ψ, we reject the current choice of Y. Otherwise, for every ψ, we try to extend it to an injection $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is connected, and among all extensions we choose one that provides the minimum weight $\omega(\varphi)$.

Let $Z = V(H) \setminus (X \cup Y)$. The vertices of $\psi(X \cup Y)$ are in the same component of F'. Denote this component by F_0 and denote by $F_1, \ldots, F_r$ the other components of this graphs. Recall that Z is an independent set of H and each vertex of Z has an incident edge with one endpoint in X. It follows that for an injection $\varphi\colon V(H) \to V(G)$ such that $\psi = \varphi|_{X \cup Y}$, $F = G \oplus_\varphi H$ is connected if and only if for every $i \in \{1, \ldots, r\}$, there is $v \in V(F_i)$ such that $v \in \varphi(Z)$. Hence, if $r > |Z|$, we cannot extend ψ. In this case we discard the current choice of ψ.

Assume from now that Y and ψ are fixed, $F' = G \oplus_\psi H'$ is connected and $r \leq |Z|$. For $z \in Z$ and $v \in V(G) \setminus \psi(X \cup Y)$, we define the weight of mapping z to v as

$$w(z, v) = \sum_{u \in N_G(v) \cap \psi(N_H(z))} \omega(uv),$$

that is, $w(z, x)$ is the weight of edges that is added to the weight of mapping if we decide to extend ψ by mapping z to v. Let $W = \max\{w(z, v) \mid z \in Z, v \in V(G) \setminus \psi(X \cup Y)\} + 1$. We construct the weighted auxiliary bipartite graph $\mathcal{G}$ with the bipartition (A, B) of its vertex set and the weight function $f\colon E(\mathcal{G}) \to \mathbb{N}_0$ as follows.

- Set $A = (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_r) = V(G) \setminus \psi(X \cup Y)$.
- Construct a set of vertices S_0 of size $|V(F_0)| - |X \cup Y|$ and sets S_i of size $|V(F_i)| - 1$ for $i \in \{1, \ldots, r\}$.
- Set $B = Z \cup S_0 \cup \ldots \cup S_r$.
- For each $z \in Z$ and $v \in A$, construct an edge zv and set $f(zv) = w(z, v)$.
- For each $u \in S_0$ and $v \in V(F_0) \setminus \psi(X \cup Y)$, construct an edge uv and set $f(uv) = W$.
- For each $\in \{1, \ldots, r\}$, do the following: for each $u \in S_i$ and $v \in V(F_i)$, construct an edge uv and set $f(uv) = W$.

We find a matching M in $\mathcal{G}$ that saturates every vertex of A and has the minimum weight using the Hungarian algorithm [7, 11] in time $\mathcal{O}(|V(G)|^3 \cdot \log W)$.

Observe that a matching that saturates every vertex of A exists, because $r \leq Z$. We can construct such a matching by selecting one vertex in $V(F_i)$ for each $i \in \{1, \ldots, r\}$ and matching it with a vertex of Z. Then we complement this set of edges to a matching saturating A by adding edges incident to $S_0 \cup \ldots \cup S_r$. For the matching M that has minimum weight, we can also observe the following.

First, note that

- every vertex of Z is saturated by M. (1)

Indeed, targeting towards a contradiction, assume that $z \in Z$ is not saturated. Since $|V(H)| \leq |V(G)|$, there is $uv \in M$ such that $u \in S_0 \cup \ldots \cup S_r$ and $v \in A$. We replace uv by zv in M. Because $f(uv) = W > w(zv)$, we obtain a matching with a smaller weight. This contradicts the choice of M.

Next, we claim that

- there is $zv \in M$ such that $z \in Z$ and $v \in V(F_i)$. (2)

Indeed, this is because the vertices of $V(F_i)$ are adjacent to $|V(F_i)| - 1$ vertices of S_i and all other their neighbors are in Z.

Finally, we have that among all matching saturating A, M is a matching satisfying (1) and (2) such that for $M' = \{zv \in M \mid z \in Z\}$, $f(M')$ is minimum. To see it, observe that $f(uv) = W$ for $uv \in M \setminus M'$. Hence, $f(M \setminus M') = (|A| - |Z|)W$, because $|M \setminus M'| = |A| - |Z|$ by (1). Therefore, $f(M') = f(M) - f(M \setminus M') = f(M) - (|A| - |Z|)W$.

For every $z \in Z$, we define $\varphi(z) = v$, where $zv \in M'$ and $\varphi(x) = \psi(x)$ for $x \in X \cup Y$. Clearly, φ is an extension of ψ. By (1), φ is an injective mapping of $V(H)$ to $V(G)$. By (2) and the choice of X and Y, we obtain that $G \oplus_\varphi H$ is connected. We claim that φ is an extension of ψ such that $F = G \oplus_\varphi H$ is connected that has the minimum total weight $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y))$.

Recall that we try all possible choices of Y and for every choice of Y, we consider all possible choices of ψ. If we fail to find an injection $\varphi \colon V(H) \to V(G)$ such that φ is an extension of ψ and $F = G \oplus_\varphi H$ is connected we return the answer NO. Otherwise, we return φ that provides the minimum weight.

To complete the proof, observe that the total running time of the algorithm is $|V(G)|^{\mathcal{O}(t)} \cdot \log W$. ◀

Structured 2-Connectivity Augmentation. As it could be expected, the algorithm for Structured 2-Connectivity Augmentation is more technical. We start with a lemma, which is similar to Lemma 4. We show it by making use of Observations 1 and 3.

▶ **Lemma 6.** *Let G and H be graphs such that G is connected, and let $\varphi \colon V(H) \to V(G)$ be an injection such that $F = G \oplus_\varphi H$ is connected. Suppose that X is a vertex cover of H and $t = |X|$. Then there is a set $Y \subseteq V(H) \setminus X$ of size at most $2(t-1)$ such that for $H' = H[X \cup Y]$ and $\psi = \varphi|_{X \cup Y}$, the vertices of $\psi(X \cup Y)$ are in the same biconnected component of $F' = G \oplus_\psi H'$.*

▶ **Theorem 7.** *Let t be a positive integer and $\mathcal{C}$ be a graph class of vertex-cover number at most t. Then for any $H \in \mathcal{C}$,* Structured 2-Connectivity Augmentation *is solvable in time $|V(G)|^{\mathcal{O}(2^t)} \log W$.*

Sketch of the proof. Let G and H be graphs such that G is connected and $H \in \mathcal{C}$. Let $\omega \colon \binom{V(G)}{2} \to \mathbb{N}_0$ be a weight function. Similarly to the proof of Theorem 5 we show that we can find in time $|V(G)|^{\mathcal{O}(2^t)} \cdot \log W$ the minimum value of $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y))$

for an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is connected if such a mapping φ exists.

The first steps of our algorithm are the same as in the proof of Theorem 5. Again, we remind that $|V(H)| \leq |V(G)|$ and that H has no isolated vertices.

Next, we find a vertex cover X of minimum size in H of size at most t in time $|V(G)|^{\mathcal{O}(t)}$. If we fail to find X of size at most t, then $H \notin \mathcal{C}$. We return NO and stop. From now on we assume that X exists.

Suppose that there is an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is 2-connected and assume that for φ, $\omega(\varphi)$ is minimum. By Lemma 6, there is a set $Y \subseteq V(H) \setminus X$ of size at most $2(t-1)$ such that for $H' = H[X \cup Y]$ and $\psi = \varphi|_{X \cup Y}$, the vertices of $\psi(X \cup Y)$ are in the same biconnected component of $F' = G \oplus_\psi H'$. Considering all possibilities, we guess Y in time $|V(H)|^{\mathcal{O}(t)}$.

Now we consider all possible injective mapping $\psi\colon X \cup Y \to V(G)$ such that the vertices of $\psi(X \cup Y)$ are in the same biconnected component of $F' = G \oplus_\psi H'$ where $H' = H[X \cup Y]$. Notice that there at most $|V(G)|^{3t-2}$ such mappings that can be generated in time $|V(G)|^{\mathcal{O}(t)}$. If we fail to find ψ, we reject the current choice of Y. Otherwise, for every ψ, we try to extend it to an injection $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is 2-connected, and among all extensions we choose one that provides the minimum weight $\omega(\varphi)$.

Let $Z = V(H) \setminus (X \cup Y)$. The vertices of $\psi(X \cup Y)$ are in the same biconnected component of F'. Denote this biconnected component by F_0 and denote by $F_1, \ldots, F_r$ the pendant biconnected components of F' that are distinct from F_0. Recall that Z is an independent set of H and each vertex of Z has an incident edge with one endpoint in X. By Observation 1, we obtain the following crucial property.

For an injection $\varphi\colon V(H) \to V(G)$ such that $\psi = \varphi|_{X \cup Y}$, $F = G \oplus_\varphi H$ is 2-connected if and only if

- **(i)** for every $i \in \{1, \ldots, r\}$, there is $v \in V(F_i)$ such that $v \in \varphi(Z)$, and
- **(ii)** if v is the unique element of $V(F_i) \cap \varphi(Z)$ and v is incident to a bridge vu of G, then there is $x \in X$ such that $\varphi(x) \neq u$ and x is adjacent to $\varphi^{-1}(v)$ in H.

Similarly to the proof of Theorem 5, we solve auxiliary matching problems to find the minimum weight of φ but now, due the condition (ii), the algorithm becomes more complicated and we are using dynamic programming.

For $z \in Z$ and $v \in V(G) \setminus \psi(X \cup Y)$, we define the weight of mapping z to v as

$$w(z, v) = \sum_{u \in N_G(v) \cap \psi(N_H(z))} \omega(uv), \tag{3}$$

that is, $w(z, x)$ is the weight of edges that is added to the weight of mapping if we decide to extend ψ by mapping z to v. Our aim is to find the extension φ of ψ that satisfies (i) and (ii) such that the total weight of the mapping of the vertices of Z to verices of $V(G) \setminus \psi(X \cup Y)$ by φ is minimum.

Since X is a vertex cover of H of size t, the set Z can be partitioned into $s \leq 2^t$ classes of false twins $Z_1, \ldots, Z_s$. Let $p_i = |Z_i|$ for $i \in \{1, \ldots, s\}$. We exploit the following property of false twins in Z: if $x, y \in Z_i$, then $w(x, v) = w(y, v)$ for $v \in V(G) \setminus \psi(X \cup Y)$.

For each s-tuple of integers $(q_1, \ldots, q_s)$ such that $0 \leq q_i \leq p_i$, for $i \in \{1, \ldots, s\}$ and each $h \in \{0, \ldots, r\}$, we define

$$\alpha_h(q_1, \ldots, q_s) = \min_{\xi} \sum_{z \in Z'} w(z, \xi(z)), \tag{4}$$

where $Z' \subseteq Z$ such that $|Z' \cap Z_i| = q_i$ for $i \in \{1, \ldots, s\}$ and the minimum is taken over all

injective mappings $\xi\colon Z' \to (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_h)$ such that the following conditions are satisfied:

- **(a)** for every $i \in \{1, \ldots, h\}$, there is $v \in V(F_i)$ such that $v \in \xi(Z')$, and
- **(b)** if v is a unique element of $V(F_i) \cap \xi(Z')$ for some $i \in \{1, \ldots, h\}$ and v is incident to a bridge vu of G, then there is $x \in X$ such that $\psi(x) \neq u$ and x is adjacent to $\xi^{-1}(v)$ in H.

If such a mapping ξ does not exist, then we assume that $\alpha_h(q_1, \ldots, q_s) = +\infty$. Recall that if $x, y \in Z_i$, then $w(x, v) = w(y, v)$ for $v \in V(G) \setminus \psi(X \cup Y)$. It implies that the function $\alpha_h(q_1, \ldots, q_s)$ depends only on the values of $q_1, \ldots, q_s$.

We claim that computing $\alpha_r(p_1, \ldots, p_s)$ is equivalent to finding an extension φ of ψ of minimum weight such that $F = G \oplus_\varphi H$ is 2-connected.

Assume that $\alpha_r(p_1, \ldots, p_s) < +\infty$. Notice that $Z' = Z$ if $q_i = p_i$ for $i \in \{1, \ldots, s\}$. Let $\xi\colon Z \to (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_h)$ be an injection that provides the minimum in (4), that is, $\alpha_r(p_1, \ldots, p_s) = \sum_{z \in Z} w(z\xi(z))$. We define $\varphi(z) = \xi(z)$ for $z \in Z$ and $\varphi(x) = \psi(x)$ for $x \in X \cup Y$. Clearly, φ is an extension of ψ. Because ξ is an injection, we have that φ is an injective mapping. Since ξ satisfies (a) and (b), we obtain that φ satisfies (i) and (ii) and, therefore, $F = G \oplus_\varphi H$ is 2-connected. Let $R = \sum_{xy \in E(H),\ x,y \in X \cup Y} \omega(\psi(x)\psi(y))$. Then using (3), we have that

$$\begin{aligned}
\omega(\varphi) &= \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y)) \\
&= \sum_{xy \in E(H),\ x,y \in X \cup Y} \omega(\varphi(x)\varphi(y)) + \sum_{xz \in E(H),\ x \in X, z \in Z} \omega(\varphi(x)\varphi(y)) \\
&= R + \sum_{z \in Z} w(z, \varphi(z)) = R + \sum_{z \in Z} w(z, \xi(z)) = R + \alpha_r(p_1, \ldots, p_s). \qquad (5)
\end{aligned}$$

Let $\varphi'\colon V(H) \to V(G)$ be an injection that extends ψ such that $F' = G \oplus_{\varphi'} H$ is 2-connected. We define $\xi'\colon Z \to (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_h)$ by setting $\xi'(z) = \varphi'(z)$ for $z \in Z$. Since φ' is an injection, ξ' is also an injection. Because F' is 2-connected, φ satisfies (i) and (ii). This implies that ξ' satisfies (a) and (b). Therefore, $\sum_{z \in Z} w(z, \xi'(z)) \geq \alpha_r(p_1, \ldots, p_s)$. Similarly to (5), we have that $\omega(\varphi') = R + \sum_{z \in Z} w(z, \xi'(z)) \geq R + \alpha_r(p_1, \ldots, p_s)$. We conclude that φ is an extension φ of ψ of minimum weight such that $F = G \oplus_\varphi H$ is 2-connected.

Suppose that $\alpha_r(p_1, \ldots, p_s) = +\infty$. It implies that there is no injection $\xi\colon Z \to (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_h)$ satisfying (a) and (b). But this immediately implies that there is no injective extension φ of ψ satisfying (i) and (ii). This completes the proof of the claim.

We use dynamic programming to compute α_h consequently for $h = 0, 1, \ldots, r$.

We start with computing $\alpha_0(q_1, \ldots, q_s)$ for each s-tuple $(q_1, \ldots, q_s)$. Notice that the conditions (a) and (b) are irrelevant in this case, because they concern only $h \geq 1$. We construct the auxiliary complete bipartite graph $\mathcal{G}_0$ with the bipartition $(V(F_0) \setminus \psi(X \cup Y), Z')$ of its vertex set and define the weight of each edge zv for $z \in Z'$ and $v \in V(F_0) \setminus \psi(X \cup Y)$ as $w(z, v)$. We find a matching M in $\mathcal{G}_0$ that saturates every vertex of Z' and has the minimum weight using the Hungarian algorithm [7, 11] in time $\mathcal{O}(|V(G)|^3 \cdot \log W)$. If there is no matching saturating Z', we set $\alpha_0(q_1, \ldots, q_s) = +\infty$. Otherwise, $\alpha_0(q_1, \ldots, q_s) = w(M)$. It is straightforward to verify the correctness of computing $\alpha_0(q_1, \ldots, q_s)$ by the definition of this function.

Assume that $h \geq 1$ and we already computed the table of values of $\alpha_{h-1}(q_1, \ldots, q_s)$. We explain how to construct the table of values of $\alpha_{h-1}(q_1, \ldots, q_s)$. The the computation is based on

the observation that we can see an injective mapping $\xi\colon Z' \to (V(F_0) \setminus \psi(X \cup Y)) \cup V(F_1) \cup \ldots \cup V(F_h)$ as the union of two injections $\xi'\colon Z'' \to (V(F_0)\setminus\psi(X\cup Y))\cup V(F_1)\cup\ldots\cup V(F_{h-1})$ and $\lambda\colon Z''' \to V(F_h)$ for the appropriate partition (Z'', Z''') of Z'.

For each s-tuple of integers $(q_1, \ldots, q_s)$ such that $0 \leq q_i \leq p_i$ for $i \in \{1, \ldots, s\}$, we define

$$\alpha'_h(q_1, \ldots, q_s) = \min_{\lambda} \sum_{z \in Z'} w(z, \xi(z)), \tag{6}$$

where $Z' \subseteq Z$ such that $|Z' \cap Z_i| = q_i$ for $i \in \{1, \ldots, s\}$ and the minimum is taken over all injective mappings $\lambda\colon Z' \to V(F_h)$ such that the following conditions are fulfilled:

(a*) there is $v \in V(F_h)$ such that $v \in \lambda(Z')$, and
(b*) if v is the unique element of $V(F_h) \cap \lambda(Z')$ and v is incident to a bridge vu of G, then there is $x \in X$ such that $\psi(x) \neq u$ and x is adjacent to $\lambda^{-1}(v)$ in H.

If such a mapping λ does not exist, then we assume that $\alpha'_h(q_1, \ldots, q_s) = +\infty$. As for $\alpha_h(q_1, \ldots, q_s)$, $\alpha'_h(q_1, \ldots, q_s)$ depends only on the values of $q_1, \ldots, q_s$, because if $x, y \in Z_i$, then $w(x, v) = w(y, v)$ for $v \in V(G) \setminus \psi(X \cup Y)$.

Let uv be the unique bridge of G with $v \in V(F_h)$. Suppose that for an s-tuple $(q_1, \ldots, q_s)$, we obtain that $|Z'| = 1$ and for the unique vertex $z \in Z'$, z has a unique neighbor $x \in X$ in H and $\psi(x) = u$. Then we set $\alpha'_h(q_1, \ldots, q_s) = +\infty$ if $|V(F_h)| = 1$ and $\alpha'_h(q_1, \ldots, q_s) = \min\{w(zv') \mid v' \in V(F_h) \setminus \{v\}\}$ otherwise. For other s-tuples $(q_1, \ldots, q_s)$, we compute $\alpha'_h(q_1, \ldots, q_s)$ as follows. We construct the auxiliary complete bipartite graph $\mathcal{G}_h$ with the bipartition $(V(F_h), Z')$ of its vertex set and define the weigh of each edge zv for $z \in Z'$ and $v \in V(F_0) \setminus \psi(X \cup Y)$ as $w(zv)$. We find a matching M in $\mathcal{G}_h$ that saturates every vertex of Z' and has the minimum weight using the Hungarian algorithm [7, 11] in time $\mathcal{O}(|V(G)|^3 \cdot \log W)$. If there is no matching saturating Z', we set $\alpha'_h(q_1, \ldots, q_s) = +\infty$. Otherwise, $\alpha'_h(q_1, \ldots, q_s) = w(M)$. It is again straightforward to verify the correctness of computing $\alpha'_h(q_1, \ldots, q_s)$ using the definition of this function.

Now, to compute $\alpha_h(q_1, \ldots, q_s)$, we use the equation:

$$\alpha_h(q_1, \ldots, q_s) = \min\{\alpha_{h-1}(q'_1, \ldots, q'_s) + \alpha'_h(q''_1, \ldots, q''_s)\}, \tag{7}$$

where the minimum is taken over all s-tuples $(q'_1, \ldots, q'_s)$ and $(q''_1, \ldots, q''_s)$ such that $q_i = q'_i + q''_i$ for $i \in \{1, \ldots, s\}$.

To evaluate the running time, observe that there are at most $|V(G)|^s$ s-tuples $(q_1, \ldots, q_s)$. Since $s \leq 2^t$, it implies that the table of values of $\alpha_0(q_1, \ldots, q_s)$ can be computed in time $|V(G)|^{\mathcal{O}(2^t)} \cdot \log W$. Similarly, the table of values of $\alpha'_h(q_1, \ldots, q_s)$ for each $h \in \{1, \ldots, r\}$ can be computed in the same time. To compute $\alpha_h(q_1, \ldots, q_s)$ for a given s-tuple $(q_1, \ldots, q_s)$ using (7), we have to consider at most $|V(G)|^s$ pairs of s-tuples $(q'_1, \ldots, q'_s)$ and $(q''_1, \ldots, q''_s)$. Hence, we can compute the table of values $\alpha_h(q_1, \ldots, q_s)$ from the tables of values of $\alpha_{h-1}(q_1, \ldots, q_s)$ and $\alpha'_h(q_1, \ldots, q_s)$ in time $|V(G)|^{\mathcal{O}(2^t)} \cdot \log W$ for each $h \in \{1, \ldots, r\}$. We conclude that the total running time is $|V(G)|^{\mathcal{O}(2^t)} \cdot \log W$. ◀

3.2 Hardness of structured augmentation

In this section we show that Theorems 5 and 7 are tight in the sense that if the vertex-cover number of graphs in a hereditary graph class $\mathcal{C}$ is unbounded, then both structured augmentation problems are NP-complete. Our hardness proof actually holds for for any k-edge connectivity augmentation. For a positive integer k, we define the following problem:

STRUCTURED k-CONNECTIVITY AUGMENTATION

Input: Graphs G and H such that G is edge $(k-1)$-connected, a weight function $\omega\colon \binom{V(G)}{2} \to \mathbb{N}_0$ and a nonnegative integer W.

Task: Decide whether there is an injective $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is edge k-connected and the *weight* of the mapping $\omega(\varphi) = \sum_{xy \in E(H)} \omega(\varphi(x)\varphi(y)) \leq W$.

Let us note that for $k = 1$ this is STRUCTURED CONNECTIVITY AUGMENTATION and for $k = 2$ this is STRUCTURED 2-CONNECTIVITY AUGMENTATION.

▶ **Theorem 8.** *Let k be a positive integer. Let also $\mathcal{C}$ be a hereditary graph class. Then if the vertex-cover number of $\mathcal{C}$ is unbounded, then* STRUCTURED k-CONNECTIVITY AUGMENTATION *is* NP*-complete for $H \in \mathcal{C}$ in the strong sense.*

Also we observe that it is unlikely that we can avoid the dependency on t in the exponents of polynomial bounding the running time when solving STRUCTURED k-CONNECTIVITY AUGMENTATION for H with $\beta(H) \leq t$.

▶ **Proposition 9.** *For every positive integer k,* STRUCTURED k-CONNECTIVITY AUGMENTATION *is* W[1]*-hard when parameterized by $\beta(H)$ even if the weight of every pair of vertices of G is restricted to be ether 0 or 1.*

This proposition implies that unless FPT =W[1], we cannot solve STRUCTURED k-CONNECTIVITY AUGMENTATION for $k = 1, 2$ in time $f(\beta(H)) \cdot |V(G)|^{\mathcal{O}(1)}$. Hence the running time of the form $|V(G)|^{f(t)}$ of algorithms solving STRUCTURED k-CONNECTIVITY AUGMENTATION for graphs H with $\beta(H) \leq t$ is probably unavoidable.

4 Augmenting unweighted graphs

In this section we investigate unweighted STRUCTURED CONNECTIVITY AUGMENTATION and STRUCTURED 2-CONNECTIVITY AUGMENTATION. Let us remind that in the unweighted cases of the structured augmentation problems the task is to identify whether there is a superposition of graphs G and H of edge connectivity 1 or 2, correspondingly. In other words, we have the weight $\omega(uv) = 0$ for every pair of vertices of G and $W = 0$. We obtain structural characterizations of yes-instances for both problems.

For STRUCTURED CONNECTIVITY AUGMENTATION, we show the following theorem.

▶ **Theorem 10.** *Let G and H be graphs such that H has no isolated vertices and $|V(H)| \leq |V(G)|$. Then there is an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is connected if and only if $c(G) \leq |V(H)| - c(H) + 1$ and one of the following holds:*

(i) *H is connected,*

(ii) *H is disconnected graph and $i(G) \leq |V(H)| - c(H)$.*

Now we consider the case STRUCTURED 2-CONNECTIVITY AUGMENTATION.

▶ **Theorem 11.** *Let G and H be graphs such that G is connected, H has no isolated vertices and $|V(H)| \leq |V(G)|$. Then there is an injective mapping $\varphi\colon V(H) \to V(G)$ such that $F = G \oplus_\varphi H$ is 2-connected if and only if one of the following holds:*

(i) *G is 2-connected,*

(ii) *G is not 2-connected and $p(G) \leq |V(H)|$,*

unless G is a star $K_{1,n}$ where n is odd and H is a matching graph.

Theorems 10 and 11 immediately imply the next corollary.

▶ **Corollary 12.** *Unweighted* Structured 1-Connectivity Augmentation *and* Structured 2-Connectivity Augmentation *are solvable in time* $\mathcal{O}(|V(G)|+|E(G)|+|E(H)|)$.

5 Conclusion

We initiated the investigation of the structured connectivity augmentation problems where the aim is to increase the edge connectivity of the input graphs by adding edges when the added edges compose a given graph. In particular, we proved that Structured Connectivity Augmentation and Structured 2-Connectivity Augmentation are solvable in polynomial time when H is from a graph class $\mathcal{C}$ with bounded vertex-cover number. It is natural to ask about increasing connectivity of a $(k-1)$-connected graph to a k-connected graph for every positive integer k. For the "traditional" edge connectivity augmentation problem (see [6, 12]), the augmentation algorithms are based on the classic work of Dinits, Karzanov, and Lomonosov [1] about the structure of minimum edge separators. However, for the structural augmentation, the structure of the graph H is an obstacle for implementing this approach directly. Due to this, we could not push further our approach to establish the complexity of Structured k-Connectivity Augmentation for $k>2$ when H is of bounded vertex cover. This remains a natural open question. Recall that our hardness results showing that it is NP-hard to increase the connectivity of a $(k-1)$-connected graph to a k-connected graph when H belongs to a class with unbounded vertex cover number are proved for every k.

As the first step, it could be interesting to consider the variant of the problem for multigraphs. In this case, we allow parallel edges and assume that for a mapping $\phi\colon V(H)\to V(G)$, the multiplicity of $\phi(x)\phi(y)$ in $G\oplus_\phi H$ is the sum of the multiplicities of $\phi(x)\phi(y)$ in G and xy in H. Notice that all our algorithmic and hardness results can be restated for this variant of the problem. Actually, some of the proofs for this variant of the problem become even simpler.

The question of obtaining a k-connected graph for $k\geq 3$ is also open for the unweighted problem. Here we ask whether it is possible to derive structural necessary and sufficient conditions for a $(k-1)$-connected graph G and a graph H such that there exists an injective mapping $\phi\colon V(H)\to V(G)$ such that $G\oplus_\phi H$ is k-connected.

Another direction of the research is to consider vertex connectivity. As it is indicated by the existing results about vertex connectivity augmentation (see, e.g., [8, 9]), this variant of the problem could be more complicated.

Abstract

Unit square (grid) visibility graphs (USV and USGV, resp.) are described by axis-parallel visibility between unit squares placed (on integer grid coordinates) in the plane. We investigate combinatorial properties of these graph classes and the hardness of variants of the recognition problem, i. e., the problem of representing USGV with fixed visibilities within small area and, for USV, the general recognition problem.

1 Introduction

A visibility representation of a graph G is a set $\mathcal{R} = \{R_i \mid 1 \leq i \leq n\}$ of geometric objects (e. g., bars, rectangles, etc.) along with some kind of geometric visibility relation $\sim$ over $\mathcal{R}$ (e. g., axis-parallel visibility), such that $G = (\{v_i \mid 1 \leq i \leq n\}, \{\{v_i, v_j\} \mid R_i \sim R_j\})$. In this work, we focus on rectangle visibility graphs, which are represented by axis aligned rectangles in the plane and vertical and horizontal axis parallel visibility between them. In particular, we consider the more restricted variant of *unit square visibility graphs* (see [12]), and, in addition, we consider the case where the unit squares are placed on an integer grid (an alternative characterisation of the well-known class of graphs with rectilinear drawings).

The study of visibility representations is of interest, both for applications and for graph classes, and has remained an active research area[1] mainly because axis-aligned visibilities give rise to graph and network visualizations that satisfy good readability criteria: straight

[1] The 24th International Symposium on Graph Drawing and Network Visualization (GD 2016) featured an entire session on visibility representation (see [3, 10, 11, 24]), and the joint workshop day of the Symposium on Computational Geometry (SoCG) and the ACM Symposium on Theory of Computing (STOC) included a workshop on geometric representations of graphs in 2016.

edges, and edges that cross only at right angles. These properties are highly desirable in the design of layouts of circuits and communication paths. Indeed, the study of graphs arising from vertical visibilities among disjoint, horizontal line segments ("bars") in the plane originated during the 1980's in the context of VLSI design problems; see [16, 30, 29].

Because bar visibility graphs are necessarily planar, this model has been extended in various ways in order to represent larger classes of graphs. Such extensions include new definitions of visibility (e. g., sight lines that may penetrate up to k bars [13] or other geometric objects [4]), vertex representations by other objects (e. g., rectangles, L-shapes [18], and sets of up to t bars [23]), extensions to higher dimensional objects (see, e. g., [8] for visibility representation in 3D by axis aligned horizontal rectangles with vertical visibilities, or [19], which studies visibility representations by unit squares floating parallel to the x, y-plane and lines of sight that are parallel to the z axis). The desire for polysemy, that is, the expression of more than one graph by means of one underlying set of objects, has also provided impetus in the study of visibility representations (see for example [6] and [28]).

Rectangle visibility graphs have the attractive property, for visualization purposes, that they yield right angle crossing drawings (RAC graphs (see [15]), whose edges are drawn as sequences of horizontal and vertical segments forming a polyline with orthogonal bends), which have seen considerable interest in the graph drawing community. Unit square graphs form a subfamily of L-visibility graphs (see [18]) and their grid variant a subfamily of RACs with no bends (note that RAC recognition for 0-bends is NP-hard [2]).

Using visibilities among objects is but one example of the use of binary geometric relations for this purpose; other geometric relations include intersection relations (e.g., of strings or straight line segments in the plane, of boxes in arbitrary dimension), proximity relations (e.g., of points in the plane), and contact relations. In the literature, for the resulting graph classes, combinatorial aspects, relationships to other graph classes, as well as computational aspects are studied (see [20] for a survey focusing on contact representations of rectangles).

Finally, we note that visibility properties among sets of objects have been studied in a number of contexts, including motion planning and computer graphics. In [26] it is proposed to find shortest paths for mobile robots moving in a cluttered environment by looking for shortest paths in the visibility graph of the points located at the vertices of polygonal obstacles. This led to a search for fast algorithms to compute visibility graphs of polygons, as well as to a search for finding shortest paths without computing the entire visibility graph.

We extend the known combinatorial properties of unit square visibility graphs from [12], and proof their recognition problem to be NP-hard (this requires a reduction that is highly non-trivial on a technical level with the main difficulty to identify graph structures that can be shown to be representable by unit square layouts in a unique way to gain sufficient control for designing suitable gadgets). With respect to unit square *grid* visibility graphs, we extend known combinatorial properties and consider variants of its recognition problem.

Due to space constraints, we only provide proof sketches (details can be found in [9]).

2 Preliminaries

A *visibility layout*, or simply *layout*, is a set $\mathcal{R} = \{R_i \mid 1 \leq i \leq n\}$ with $n \in \mathbb{N}$, where R_i are closed and pairwise disjoint axis-parallel rectangles in the plane; the *position* of such a rectangle is the coordinate of its lower left corner. For every $R_i, R_j \in \mathcal{R}$, a closed non-degenerate axis-parallel rectangle S (i. e., a non-empty closed rectangle that is not a line segment) is a *visibility rectangle for R_i and R_j* if one side of S is contained in R_i and the opposite side in R_j. We define $R_i \rightarrow_{\mathcal{R}} R_j$ ($R_i \downarrow_{\mathcal{R}} R_j$), if there is a visibility rectangle S for R_i

and R_j, such that the left side (upper side) of S is contained in R_i, the right side (lower side) of S is contained in R_j and $S \cap R_k = \emptyset$, for every $R_k \in \mathcal{R} \setminus \{R_i, R_j\}$. Let $\leftrightarrow_\mathcal{R}$ and $\updownarrow_\mathcal{R}$ be the symmetric closures of $\rightarrow_\mathcal{R}$ and $\downarrow_\mathcal{R}$, respectively. Finally, $R_i \sim_\mathcal{R} R_j$ if $R_i \leftrightarrow_\mathcal{R} R_j$ or $R_i \updownarrow_\mathcal{R} R_j$ ($\sim_\mathcal{R}$ is the *visibility relation* (*with respect to* $\mathcal{R}$)). If the layout $\mathcal{R}$ is clear from the context or negligible, we drop the subscript $\mathcal{R}$. We denote $R_i \sim R_j$, $R_i \leftrightarrow R_j$ and $R_i \rightarrow R_j$ also as R_i *sees* R_j, R_i *horizontally sees* R_j and R_i *sees* R_j *from the left*, respectively, and analogous terminology applies to vertical visibilities. For $S, T \subseteq \mathcal{R}$, we use $S \rightarrow_\mathcal{R} T$ as shorthand form for $\bigwedge_{R \in S, R' \in T} R \rightarrow_\mathcal{R} R'$.

A layout $\mathcal{R} = \{R_i \mid 1 \leq i \leq n\}$ *represents* the undirected graph $\mathsf{G}(\mathcal{R}) = (\{v_i \mid 1 \leq i \leq n\}, \{\{v_i, v_j\} \mid 1 \leq i, j \leq n, R_i \sim R_j\})$, which is then called a *visibility graph*, and the class of visibility graphs is denoted by V. A graph is a *weak* visibility graph, if it can be obtained from a visibility graph by deleting some edges and the corresponding class of graphs is denoted by $\mathsf{V_w}$. As a convention, for a visibility graph $G = (V, E)$ and a layout representing it we denote by R_v the rectangle for $v \in V$ and define $R_{V'} = \{R_x \mid x \in V'\}$ for every $V' \subseteq V$. We call layouts $\mathcal{R}_1$ and $\mathcal{R}_2$ *isomorphic* if $\mathsf{G}(\mathcal{R}_1)$ and $\mathsf{G}(\mathcal{R}_2)$ are isomorphic. Furthermore, we call $\mathcal{R}_1$ and $\mathcal{R}_2$ *V-isomorphic* if, for some $x \in \{\rightarrow_{\mathcal{R}_1}, \rightarrow_{\mathcal{R}_1}^{-1}\}$ and $y \in \{\downarrow_{\mathcal{R}_1}, \downarrow_{\mathcal{R}_1}^{-1}\}$, the relational structure $(\mathcal{R}_1, \rightarrow_{\mathcal{R}_1}, \downarrow_{\mathcal{R}_1})$ is isomorphic to $(\mathcal{R}_2, x, y)$ or $(\mathcal{R}_2, y, x)$.[2]

Unit square visibility graphs (USV) and *unit square grid visibility graphs* (USGV) are represented by *unit square layouts*, where every $R \in \mathcal{R}$ is the unit square, and *unit square grid layouts*, where additionally the position of every R is from $\mathbb{N} \times \mathbb{N}$.[3] The weak classes $\mathsf{USV_w}$ and $\mathsf{USGV_w}$ are defined accordingly.

For a graph $G = (V, E)$, $N(v)$ is the *neighbourhood* of $v \in V$, $\vec{E}$ denotes an oriented version of E, i. e., $E = \{\{u, v\} \mid (u, v) \in \vec{E}\}$, and $f \colon \vec{E} \to E, (u, v) \mapsto \{u, v\}$ is a bijection. Let L, R and D, U be pairs of complementary values (for $X \in \{\mathsf{L}, \mathsf{R}, \mathsf{D}, \mathsf{U}\}$, $\overline{X}$ denotes its complement). An LRDU-*restriction* (for G) is a labeling $\sigma \colon \vec{E} \to \{\mathsf{L}, \mathsf{R}, \mathsf{D}, \mathsf{U}\}$ and it is *valid* if, for every $(u, v) \in \vec{E}$ with $\sigma((u, v)) = X$ and every $w \in V \setminus \{u, v\}$, $\sigma((u, w)) \neq X \neq \sigma((w, v))$ and $\sigma((v, w)) \neq \overline{X} \neq \sigma((w, u))$. Obviously, LRDU-restrictions only exist for graphs with maximum degree 4. A unit square grid visibility layout *satisfies* an LRDU-restriction σ if $\sigma((u, v)) = \mathsf{L}$ implies $R_v \rightarrow R_u$, $\sigma((u, v)) = \mathsf{R}$ implies $R_u \rightarrow R_v$, $\sigma((u, v)) = \mathsf{D}$ implies $R_u \downarrow R_v$ and $\sigma((u, v)) = \mathsf{U}$ implies $R_v \downarrow R_u$. An HV-*restriction* (for G) is a labeling $\sigma \colon E \to \{\mathsf{H}, \mathsf{V}\}$ and it is *valid* if, for every $u \in V$ at most two incident edges are labeled H and at most two incident edges are labeled V. A unit square grid visibility layout *satisfies* an HV-restriction σ if $\sigma(\{u, v\}) = \mathsf{H}$ implies $R_v \leftrightarrow R_u$ and $\sigma(\{u, v\}) = \mathsf{V}$ implies $R_v \updownarrow R_u$.

For a class $\mathfrak{G}$ of undirected graphs, the *recognition problem for* $\mathfrak{G}$ (denoted by $\textsc{Rec}(\mathfrak{G})$) for short) is the problem to decide, for a given undirected graph G, whether or not $G \in \mathfrak{G}$. In the following, we shall consider the problems $\textsc{Rec}(\mathsf{USGV})$ and $\textsc{Rec}(\mathsf{USV})$.

We briefly recall some established geometric graph representations relevant to this work. A *rectilinear drawing* (see [17, 25]) of a graph $G = (V, E)$ is a pair of mappings $x, y \colon V \to \mathbb{Z}$, where, for every $v \in V$, $x(v)$ and $y(v)$ represent the x- and y-coordinates of v on the grid and, for every edge $\{u, v\} \in E$, $(x(u), y(u))$ and $(x(v), y(v))$ are the endpoints of a horizontal or vertical line segment that does not contain any $(x(w), y(w))$ with $w \in V \setminus \{u, v\}$. A graph has *resolution* $\frac{2\pi}{d}$ if it has a drawing in which the degree of the angle between any two edges incident to a common vertex is at least $\frac{2\pi}{d}$. We call such graphs *resolution-*$\frac{2\pi}{d}$ *graphs* and are mainly interested in the case $d = 4$, see [21]. For planar graphs, resolution-$\frac{2\pi}{4}$ graphs are

[2] By $\preceq^{-1}$, we denote the inverse of a binary relation $\preceq$.

[3] Note that in the grid case, if a unit square is positioned at (x, y), then this is the only unit square on coordinates (x', y'), $x' \in \{x - 1, x, x + 1\}$, $y' \in \{y - 1, y, y + 1\}$.

just rectilinear graphs, see [7]. A *bendless right angle crossing* (BRAC) *drawing* of a graph is a straight-line drawing in which every crossing of two edges is at right angles.[4] Note that in a BRAC-drawing or a resolution-$\frac{2\pi}{4}$ drawing, edges are not necessarily axis-parallel (like it is the case for visibility layouts and rectilinear drawings). A graph is called *rectilinear* or *BRAC graph* if it has a rectilinear or BRAC-drawing, respectively.

3 Unit Square Grid Visibility Graphs

The readability of graph drawings is mainly affected by its *angular resolution* (angles formed by consecutive edges incident to a common node) and its *crossing resolution* (angles formed at edge crossings); see the discussion in [1]. In this regard, resolution-$\frac{\pi}{2}$ graphs and BRAC graphs have an angular resolution and crossing resolution of $\frac{\pi}{2}$, respectively, while rectilinear drawings and unit square grid visibility layouts force both resolutions to be $\frac{\pi}{2}$.

The question arises of how these classes relate to each other and in this regard, we first note that USGV and rectilinear graphs coincide. More precisely, a unit square grid layout can be transformed into a rectilinear drawing by replacing every unit square on position (x, y) by a vertex on position (x, y) and translate the former visibilities into straight-line segments. Transforming a rectilinear drawing into a unit square grid layout requires scaling it first by factor 2 and then replacing each vertex on position (x, y) by a unit square on position (x, y) (without scaling, sides or corners of unit squares may overlap). This only results in a *weak* layout, since visibilities may be created that do not correspond to edges in the rectilinear drawing. However, any weak unit square grid visibility graph can be transformed into a unit square grid visibility graph (as formally stated below in Theorem 7).

Since all these graphs except the BRAC graphs have maximum degree 4, we only consider degree-4 BRAC graphs. Obviously, resolution-$\frac{\pi}{2}$ graphs and degree-4 BRAC graphs are both superclasses of USGV (and rectilinear graphs). Witnessed by K_3, the inclusion in degree-4 BRAC graphs is proper, while the analogous question w. r. t. resolution-$\frac{\pi}{2}$ graphs is open. Moreover, K_3 is also an example of a degree-4 BRAC graph that is not a resolution-$\frac{\pi}{2}$ graph; whether there exist resolution-$\frac{\pi}{2}$ graphs without a BRAC-drawing is open.

Due to the equivalence of USGV and rectilinear graphs, results for the latter graph class carry over to the former. In this regard, we first mention that the NP-hardness proof of recognizing resolution-$\frac{\pi}{2}$ graphs from [21] actually produces drawings with axis-aligned edges; thus, it also applies to rectilinear graphs (a similar reduction (for rectilinear graphs and presented in more detail) is provided in [17]). As shown in [17], the recognition problem for rectilinear graphs can be solved in time $O(24^k \cdot k^{2k} \cdot n)$, where k is the number of vertices with degree at least 3. In [25], it is shown that recognition remains NP-hard if we ask whether a drawing exists that satisfies a given HV-restriction[5] or a drawing that satisfies a given circular order of incident edges. However, checking the existence of a rectilinear drawing satisfying a given LRDU-restriction can be done in time $O(|E| \cdot |V|)$. Consequently, by trying all such labellings, we can solve the recognition problem for rectilinear graphs in time $2^{O(n)}$. In this regard, it is worth noting that the hardness reduction from [17] can be easily modified, such that it also provides lower complexity bounds subject to the Exponential-Time Hypothesis (ETH), thereby demonstrating that the $2^{O(n)}$ algorithm is optimal subject to ETH.

[4] In the literature (e. g., [15]), the edges of a RAC-drawing are usually allowed to have bends; the investigated questions are on finding RAC-drawings that minimise the number of bends and crossings.
[5] The definition of HV- and LRDU-restriction given above naturally extends to rectilinear drawings.

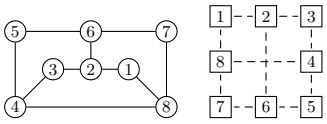

Figure 1 Necessarily non-planar visibility layout for a planar graph.

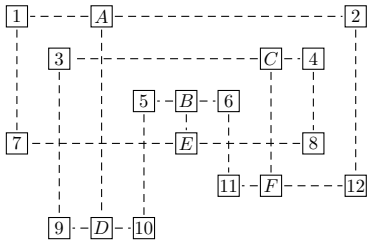

Figure 2 Subdivisions of $K_{3,3}$.

3.1 Combinatorial Properties of USGV

First, we shall see that the class USGV is downward closed w. r. t. the subgraph relation, i. e., if $G \in \mathsf{USGV}$, then all its subgraphs are in USGV (intuitively speaking, deletion of edges can be done by moving unit squares, while deletion of a vertex can be realised by deleting the corresponding unit square and then removing unwanted edges introduced by this operation). This observation will be a convenient tool for obtaining other combinatorial results.

▶ **Lemma 1.** *Let $G = (V, E) \in \mathsf{USGV}$, let $v \in V$ and $e \in E$. Then $(V, E \setminus \{e\}) \in \mathsf{USGV}$ and $(V \setminus \{v\}, E) \in \mathsf{USGV}$.*

It is straightforward to prove the following limitations of USGV.

▶ **Lemma 2.** *Let $G = (V, E) \in \mathsf{USGV}$. Then, (**1**) the maximum degree of G is 4, (**2**) for every $u, v \in V$, $|N(u) \cap N(v)| \leq 2$, and, (**3**) for every $\{u, v\} \in E$, $N(u) \cap N(v) = \emptyset$.*

A consequence of Lemma 2 is that no graph from USGV contains $K_{1,5}$, $K_{2,3}$ or K_3 as a subgraph, since they violate the first, second and third condition of Lemma 2, respectively. Obvious examples for graphs from USGV are subgraphs of a grid; as Lemma 1 shows, even non-induced subgraphs of a grid. In this context, notice that the problem of deciding if a given graph is such a *partial grid graph* is equivalent to deciding if it admits a unit-length VLSI layout, which, even restricted to trees, is an NP-hard problem; see [5] for details. Yet, USGV contains more, especially non-bipartite graphs, with the smallest example being C_5.

Next, we discuss planarity with a focus on the relationship between the planarity of graphs from USGV and planarity of their respective layouts (where a layout is called *planar* if it does not contain any crossing visibilities). In this regard, we first note that the planarity of a layout is obviously sufficient for the planarity of the represented graph. Moreover, it is trivial to construct non-planar layouts that nevertheless represent planar graphs. Figure 1(a) is an example of a planar unit square grid visibility graph, which can only be represented by non-planar layouts (e. g., the one of Figure 1(b)):

▶ **Proposition 3.** *There exists no planar unit square grid layout for the graph of Fig. 1(a).*

It is tempting to assume that graphs in USGV are necessarily planar, but, as demonstrated by Figure 2, USGV contains a subdivision of $K_{3,3}$. Hence, with Kuratowski's theorem, we conclude:

▶ **Theorem 4.** USGV *contains non-planar graphs.*

Next, we investigate possibilities to characterise USGV. In this regard, we first observe that a characterisation by forbidden induced subgraphs is not possible (note that under the assumption P ≠ NP, this also follows from the hardness of recognition).

▶ **Theorem 5.** USGV *does not admit a characterisation by a finite number of forbidden induced subgraphs.*

By Lemma 2, the classes of cycles, complete graphs and complete bipartite graphs within USGV are easily characterised: $C_i \in \mathsf{USGV}$ if and only if $i \geq 4$, $K_i \in \mathsf{USGV}$ if and only if $i \leq 2$, $K_{i,j} \in \mathsf{USGV}$ (with $i \leq j$) if and only if ($i = 1$ and $j \leq 4$) or ($i = 2$ and $j = 2$). Furthermore, the trees in USGV have a simple characterisation as well:

▶ **Theorem 6.** *A tree T is in* USGV *if and only if the maximum degree of T is at most four.*

By definition, $\mathsf{USGV} \subseteq \mathsf{USGV_w}$ and every $G' \in \mathsf{USGV_w}$ can be obtained from some $G \in \mathsf{USGV}$ by deleting some edges. Consequently, by Lemma 1, we conclude the following.

▶ **Theorem 7.** $\mathsf{USGV} = \mathsf{USGV_w}$.

3.2 Area-Minimisation

The *area-minimisation* version of the recognition problem is to decide whether a given graph has a drawing or layout of given width and height. The hardness of recognition for USGV and also for HV-restricted USGV carries over to the area-minimisation version, since an n-vertex graph has a layout if and only if it has a $(2n-1) \times (2n-1)$ layout. On the other hand, in the LRDU-restricted rectilinear (or unit square grid) case, recognition can be solved in polynomial time, so the authors of [25] provide a hardness reduction that proves the area-minimisation recognition problem NP-complete even for LRDU-restricted rectilinear graphs. However, this construction does not carry over to USGV, since the non-edges of a rectilinear drawing translate into non-visibilities, which require space as well;[6] moreover, it does not even work for the weak case of USGV, due to the necessary scaling by factor 2 to translate a rectilinear drawing into an equivalent weak unit square grid layout.

Next, we provide a reduction that shows the hardness of the area-minimisation version of Rec($\mathsf{USGV_w}$), which shall also imply several additional results. The problem 3-Partition (3Part) is defined as follows: Given $B \in \mathbb{N}$ and a multi-set $A = \{a_1, a_2, \ldots, a_{3m}\} \subseteq \mathbb{N}$ with $\frac{B}{4} < a_i < \frac{B}{2}$, $1 \leq i \leq 3m$, and $\sum_{i=1}^{3m} a_i = mB$, decide whether A can be partitioned into m multi-sets $A_1, \ldots, A_m$, such that $\sum_{a \in A_j} a = B$, $1 \leq j \leq m$ (note that the restriction $\frac{B}{4} < a_i < \frac{B}{2}$ enforces $|A_j| = 3$, $1 \leq j \leq m$). Given a 3Part instance, we construct a *frame graph* (see Figure 3) $G_f = (V_f, E_f)$ with:

$$
\begin{aligned}
V_f =& \{u_{i,j}, v_{i,j}, w_{i,1}, w_{i,2} \mid 1 \leq i \leq m, 0 \leq j \leq B\} \cup \{u_{m+1,0}, v_{m+1,0}, w_{m+1,1}, w_{m+1,2}\}, \\
E_f =& \{\{u_{i,j}, u_{i,j+1}\}, \{v_{i,j}, v_{i,j+1}\} \mid 1 \leq i \leq m, 0 \leq j \leq B-1\} \cup \\
& \{\{u_{i,B}, u_{i+1,0}\}, \{v_{i,B}, v_{i+1,0}\} \mid 1 \leq i \leq m\} \cup \{\{u_{i,j}, v_{i,j}\} \mid 1 \leq i \leq m, 1 \leq j \leq B\} \cup \\
& \{\{u_{i,0}, v_{i,0}\}, \{v_{i,0}, w_{i,1}\}, \{w_{i,1}, w_{i,2}\} \mid 1 \leq i \leq m+1\}.
\end{aligned}
$$

Next, we define a graph $G_A = (V_A, E_A)$ with $V_A = \{b_{i,j}, c_{i,j} \mid 1 \leq i \leq 3m, 1 \leq j \leq a_i\}$ and $E_A = \{\{b_{i,j}, b_{i,j+1}\}, \{c_{i,j}, c_{i,j+1}\} \mid 1 \leq i \leq 3m, 1 \leq j \leq a_i - 1\} \cup \{\{b_{i,j}, c_{i,j}\} \mid 1 \leq i \leq 3m, 1 \leq j \leq a_i\}$. Finally, we let $G = (V, E)$ with $V = V_f \cup V_A$ and $E = E_f \cup E_A$.

[6] In general, this space blow-up cannot be avoided, as witnessed by n isolated vertices which have a $1 \times n$ rectilinear drawing, but a smallest unit square grid layout of size $(2n-1) \times (2n-1)$

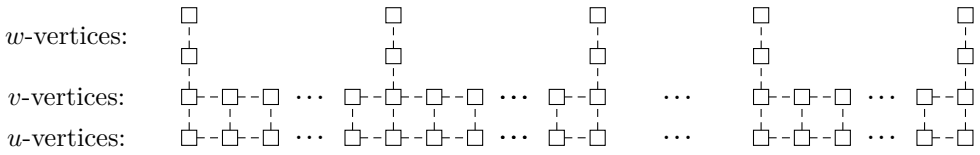

Figure 3 Unit square grid layout for the graph G_f.

The idea is that G_f forms m size-B compartments and the graphs on $b_{i,j}$, $c_{i,j}$ represent the a_i. In a layout respecting the size bounds, the way of allocating the graphs on $b_{i,j}$, $c_{i,j}$ to the compartments corresponds to a partition of A that is a solution for the 3Part-instance.

▶ **Lemma 8.** *(B, A) is a positive* 3Part*-instance if and only if G has a $(7\times(2(mB+m+1)-1))$ unit square grid layout.*

Since the reduction defined above is polynomial in m and B, and 3Part is strongly NP-complete (see [22, Theorem 4.4]), we can conclude the following:

▶ **Theorem 9.** *The area-minimisation variant of* Rec(USGV$_\mathsf{w}$) *is* NP*-complete.*

The area minimisation variant implicitly solves the general recognition problem, so the question arises whether it is also hard to decide if a graph from USGV$_\mathsf{w}$ (given as a layout) can be represented by a layout satisfying given size bounds. Since our reduction always produces a graph in USGV$_\mathsf{w}$ (with an obvious layout), independent of the 3Part-instance, it shows that the hardness remains if the input graph is given directly as a layout. Moreover, the problem is still NP-complete for the LRDU-restricted variant (the LRDU-restriction then simply enforces the structure shown in Figure 3).

The reduction also yields a (substantially simpler) alternative proof for the hardness of the area-minimisation recognition problem for LRDU-restricted rectilinear graphs [25] (more precisely, it can be shown that (B, A) is a positive 3Part-instance if and only if G has a $(4 \times (mB + m + 1))$ rectilinear drawing), and the hardness also carries over to the variant where the input graph is already given as a rectilinear drawing.

We conclude this section by pointing out that it is open whether the LRDU-restricted area-minimisation variant of Rec(USGV) can be solved in polynomial-time. Intuitively, reducing the size of a rectilinear drawing is difficult, since space can be saved by placing non-adjacent vertices on the same line, which is not possible for *non-weak* unit square grid layouts. However, computing a size-minimal unit square grid layout includes finding out to what extend the scaling by 2 is really necessary, which seems difficult as well.

4 Unit Square Visibility Graphs

Obviously, a larger class of graphs can be represented if the unit squares are not restricted to integer coordinates (see Figure 4 for some examples). In [12], cycles, complete graphs, complete bipartite graphs and trees in USV are characterised as follows: $C_i \in$ USV, for every $i \in \mathbb{N}$, $K_i \in$ USV if and only if $i \leq 4$, $K_{i,j} \in$ USV with $i \leq j$ if and only if $(1 \leq i \leq 2$ and $i \leq j \leq 6)$ or $(i = 3$ and $3 \leq j \leq 4)$,[7] and a tree T is in USV if and only if it is the union of two subdivided caterpillar forests with maximum degree 3 (note that [23] provides an algorithm that efficiently checks this property).

[7] For the more general question of representing bipartite graphs as rectangle visibility graphs, we refer to [14]. In particular, a linear upper bound on the number of edges, compared to the number of vertices, is known.

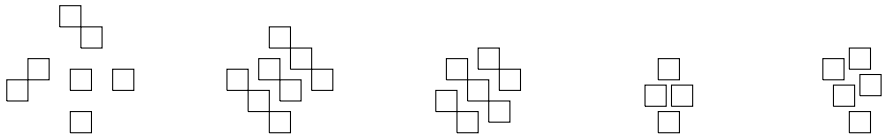

Figure 4 Visibility layouts for $K_{1,6}$, $K_{2,6}$, $K_{3,4}$, K_4 and a K_5 with one missing edge.

Next, we observe that every graph with at most 4 vertices is in USV, while K_5 is not (it is not hard to find layouts for graphs with at most 4 vertices; $K_5 \notin$ USV is shown in [12]).

▶ **Proposition 10.** *Every graph with at most* 4 *vertices is in* USV*.*

A crucial difference between USGV and USV is that for the latter, the degree is not bounded, as witnessed by layouts of the following form: □□□□□□□. However, if a unit square sees at least 7 other unit squares, then these must be placed in such a way that visibilities or "paths" between some of them are enforced (note that any $K_{1,n}$ may exist as induced subgraph, as can be demonstrated by modifying the above example layout such that between each two consecutive neighbours another "visibility-blocking" unit square is inserted). In [12], it is formally proven that in graphs from USV any vertex of degree at least 7 must lie on a cycle. In particular, these observations point out that an analogue of Lemma 1 is not possible for USV.

For the class of trees within USV, as long as we consider trees with maximum degree strictly less or larger than 6, a much simpler characterisation (compared to the one mentioned at the beginning of this section) applies:

▶ **Theorem 11.** *Let T be a tree with maximum degree k. If $k \leq 5$, then $T \in$* USV*, and if $k \geq 7$, then $T \notin$* USV*.*

Figure 5(a) shows an example of a tree from USV with maximum degree 6 and Figure 5(b) its representing layout. It can be easily verified that any node of degree 6 must be represented V-isomorphically to Figure 4(a) (note that this also holds for nodes A and B in Figures 5(a) and (b)). Figure 4(a) also demonstrates that not all trees with maximum degree 6 can be represented: let R denote the square below the central square in the layout, then it is impossible for R to see 5 additional unit squares that exclusively see R. On the other hand, USV contains trees with arbitrarily many degree-6 vertices, e. g., trees of the form depicted in Figure 5(c) (it is straightforward to see that they can be represented as the union of two forests of caterpillars with maximum degree 3). This reasoning shows that not all planar graphs are in USV, while it follows from [30] that all planar graphs are (non-unit square) rectangle visibility graphs (also see [29]).

Finally, we note that USV is a proper subset of $\mathsf{USV_w}$ (e. g., $K_{1,7}$ is a separating example):

▶ **Theorem 12.** $\mathsf{USV} \subsetneq \mathsf{USV_w}$.

4.1 The Recognition Problem

The recognition problem for USV consists in checking whether a given graph can be represented by a unit square layout. We first observe that this problem is in NP (note that this is not completely trivial, since we cannot naively guess a layout) and the main result of this section shall be its hardness (see Theorem 20).

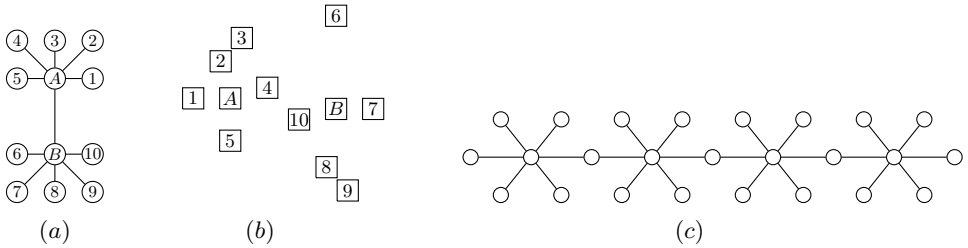

Figure 5 Illustration for trees from USV with maximum degree 6.

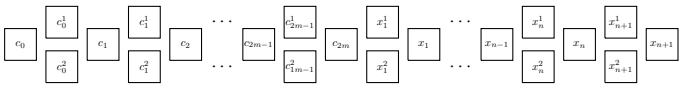

Figure 6 The backbone-gadget.

▶ **Theorem 13.** Rec(USV) ∈ NP.

We prove the NP-hardness by a reduction from NAE-3SAT, i. e., the not-all-equal 3-satisfiability problem [27]. To this end, let $F = \{c_1, \ldots, c_m\}$ be a 3-CNF formula over the variables $x_1, \ldots, x_n$, such that no variable occurs more than once in any clause, and, for the sake of convenience, let $c_i = \{y_{i,1}, y_{i,2}, y_{i,3}\}$, $1 \leq i \leq m$.

The general idea of the reduction is as follows: We identify graph structures that can be shown to have a (more or less) unique representation as a unit square layout. With these main building blocks, we construct a sequence of clause and variable gadgets, called *backbone* (see Figure 6), that can only be represented by a layout in a linear way, say horizontally. Furthermore, every clause gadget is vertically connected to its three literals, two of which are below and the other one above the backbone, or the other way around. The allocation of literal vertices to a variable x_i is done by a path of all literal vertices corresponding to x_i that is connected to the variable vertex for x_i. Such paths must lie either completely above or below the backbone. Interpreting the situation that a path lies above the backbone as assigning *true* to the corresponding literal, yields a not-all-equal satisfying assignment, as it is not possible that all the paths for a clause lie on the same side of the backbone.

We assume that each clause of F contains at most one negated variable, which is no restriction to not-all-equal satisfiability as a clause over literals l_1, l_2, l_3 is not-all-equal satisfied by an assignment if and only if a clause over literals $\bar{l}_1, \bar{l}_2, \bar{l}_3$ is. Furthermore, we also assume that every literal occurs at least three times in the formula. We first transform F into $F' = \{c_1, \ldots, c_{2m}\}$, where $c_{m+i} = c_i$ for $i = 1, \ldots, m$. Then, we transform F' into a graph $G = (V, E)$ as follows. The set of vertices is defined by $V = V_c \cup V_x \cup V_h$, where

$$V_c = \{c_j, c_j^1, c_j^2 \mid 0 \leq j \leq 2m-1\} \cup \{c_{2m}\} \cup \{l_j^1, l_j^2, l_j^3 \mid 1 \leq j \leq 2m\},$$
$$V_x = \{x_i, x_i^1, x_i^2 \mid 1 \leq i \leq n+1\} \cup \{t_i, \vec{t_i}, \overleftarrow{t_i}, f_i^1, \vec{f_i^1}, \overleftarrow{f_i^1}, f_i^2, \vec{f_i^2}, \overleftarrow{f_i^2} \mid 1 \leq i \leq n\},$$
$$V_h = \{h_{t_i}^r, h_{f_i^1}^r, h_{f_i^2}^r \mid 1 \leq i \leq n, 0 \leq r \leq 4\}.$$

Vertices c_j and x_i represent the corresponding clauses and variables and the vertices c_j^r, x_i^r, $r \in \{1, 2\}$ are used to enforce the *backbone* structure as described at the beginning of this section. The corresponding edges are implicitly defined, by requiring, for every $0 \leq i \leq 2m-1$ and $1 \leq i \leq n$, the following groups of 4 vertices to form a K_4: $\{c_j, c_j^1, c_j^2, c_{j+1}\}$, $\{x_i, x_{i+1}^1, x_{i+1}^2, x_{i+1}\}$, and $\{c_{2m}, x_1^1, x_1^2, x_1\}$. Also, for every $j \in \{1, 2\}$, the vertices $c_0^j, c_1^j, \ldots, c_{2m-1}^j, x_1^j, x_2^j, \ldots, x_{n+1}^j$ form a path in this order. Consequently, these

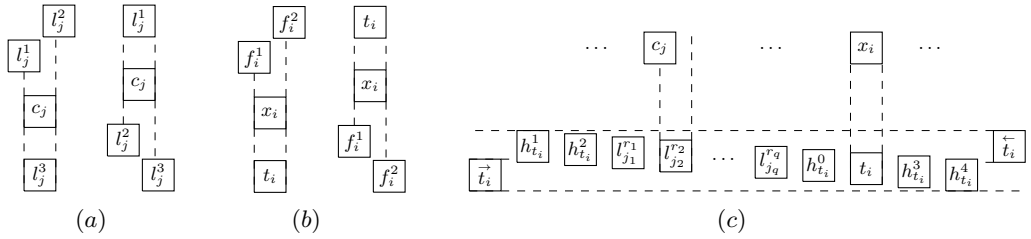

Figure 7 Possible placements of literal vertices, possible placements of assignment vertices, and the clause path for x_i.

vertices form the subgraph represented by the layout in Figure 6, which shall be the *backbone*. Vertices t_i, represent the literal x_i, f_i^1 represent the literal $\overline{x_i}$ in the first m clauses, and f_i^2 represent the literal $\overline{x_i}$ in the remaining clauses. Vertices l_j^1, l_j^2, l_j^3 represent the literals of clause c_j. These roles are reflected with edges $\{x_i, t_i\}$, $\{x_i, f_i^1\}$, $\{x_i, f_i^2\}$ for all $1 \leq i \leq n$ and $\{c_j, l_j^r\}$ for all $1 \leq j \leq 2m$ and $1 \leq r \leq 3$. The connection between literals and variable assignments is build by turning $l_{j,r}$ with $y_{j,r} = x_i$ into a path connected to t_i; analogously, $l_{j,r}$ with $y_{j,r} = \overline{x_i}$ in the first (the last, respectively) m clauses form a path connected to f_i^1 (f_i^2, respectively). More precisely, for every $1 \leq j \leq 2m$, $1 \leq i \leq n$ and $1 \leq r \leq 3$:

- if $y_{j,r} = x_i$, there are edges $\{l_j^r, \vec{t_i}\}$, $\{l_j^r, \overleftarrow{t_i}\}$,
- if $y_{j,r} = \overline{x_i}$ and $1 \leq j \leq m$, there are edges $\{l_j^r, \vec{f_i^1}\}$, $\{l_j^r, \overleftarrow{f_i^1}\}$ and $\{l_{j+m}^r, \vec{f_i^2}\}$, $\{l_{j+m}^r, \overleftarrow{f_i^2}\}$,
- there are edges $\{t_i, \vec{t_i}\}$, $\{t_i, \overleftarrow{t_i}\}$ and $\{\vec{t_i}, h_{t_i}^p\}$,$\{\overleftarrow{t_i}, h_{t_i}^p\}$ for all $0 \leq p \leq 4$,
- there are edges $\{f_i^s, \vec{f_i^s}\}$, $\{f_i, \overleftarrow{f_i^s}\}$ and $\{\vec{f_i^s}, h_{f_i^s}^p\}$,$\{\overleftarrow{f_i^s}, h_{f_i^s}^p\}$ for all $0 \leq p \leq 4$, $s \in \{1, 2\}$,

Moreover, for every i, $1 \leq i \leq n$,

- if $N(\vec{t_i}) = \{h_{t_i}^1, h_{t_i}^2, l_{j1}^{r_1}, l_{j2}^{r_2}, \ldots, l_{jq}^{r_q}, h_{t_i}^0, t_i, h_{t_i}^3, h_{t_i}^4\}$ with $j_1 < j_2 < \ldots < j_q$, then these vertices form a path in this order,
- if $N(\vec{f_i^s}) = \{h_{f_i^s}^1, h_{f_i^s}^2, l_{j1}^{r_1}, l_{j2}^{r_2}, \ldots, l_{jq}^{r_q}, h_{f_i^s}^0, f_i^s, h_{f_i^s}^3, h_{f_i^s}^4\}$ with $j_1 < j_2 < \ldots < j_q$ and $s \in \{1, 2\}$, then these vertices form a path in this order,

Next, we assume that the formula F' is not-all-equal satisfiable and show how a layout for G can be constructed. First, we represent the backbone as illustrated in Figure 6. If a variable x_i is assigned the value *true*, then we place the unit squares $R_{\{x_i, t_i, f_i^1, f_i^2\}}$ as illustrated on the left side of Figure 7(b), and otherwise as illustrated on the right side. The edges for the vertices $t_i, \vec{t_i}, \overleftarrow{t_i}, h_{t_i}^r$, $0 \leq r \leq 4$, and all l_j^r with $y_{j,r} = x_i$ can be realised as illustrated in Figure 7(c) (either placed above or below the backbone, according to the position of R_{t_i}). An analogous construction applies to the unit squares for l_j^r with $y_{j,r} = \overline{x_i}$, with the only difference that we have two such paths (one for the first m clauses and one for the remaining clauses) and that they both lie on the opposite side of the backbone with respect to R_{t_i}. Moreover, in these paths, the $R_{l_j^r}$ must be horizontally shifted such that they can see their corresponding R_{c_j} from above or from below, according to whether the path lies above or below the backbone (as indicated in Figure 7(c)). As long as not all paths for the three literals of the same clause lie all above or all below the backbone, this is possible by arranging the unit squares as illustrated in Figure 7(a). However, if for some clause all paths lie on the same side of the backbone, then the literals of the clause are either all set to *true* or all set to *false*, which is a contradiction to the assumption that the assignment is not-all-equal satisfiable. Consequently, we can represent G as described.

▶ **Lemma 14.** *If F is not-all-equal satisfiable, then $G \in$ USV.*

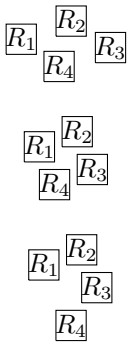

Figure 8 Re- presenting K_4.

Proving that a layout for G translates into a satisfying not-all-equal assignment for F, is much more involved. The general idea is to show that any layout for G must be V-isomorphic to the layout constructed above. However, this cannot be done separately for the individual gadgets, e. g., showing that the backbone must be represented as in Figure 6 (in fact, the structure of the backbone alone does not enforce such a layout) and the literal vertices must form a path as in Figure 7(c) and so on. Instead, the desired structure of the layout is only enforced by a rather complicated interplay of the different parts of G.

A main building stone is that a K_4 can only be represented in 3 different ways (up to V-isomorphism), which are illustrated in Figure 8. This observation is important, since the backbone is a sequence of K_4.

▶ **Lemma 15.** *Every layout for K_4 is V-isomorphic to one of the three layouts of Figure 8.*

We now assume that G can be represented by some layout $\mathcal{R}$. For every j, $1 \leq j \leq m$, we define $L_j = \{l_j^1, l_j^2, l_j^3\}$, for every i, $1 \leq i \leq n$, we define $A_i = \{t_i, f_i^1, f_i^2\}$, and, for every j, $1 \leq j \leq m-1$, we define $C_j^l = \{c_j, c_{j-1}, c_{j-1}^1, c_{j-1}^2\}$, $C_j^r = \{c_j, c_{j+1}, c_j^1, c_j^2\}$ and $C_j = C_j^l \cup C_j^r$.

We shall prove the desired structure of $\mathcal{R}$ by first considering the neighbourhood of c_j; once we have fixed the layout for this subgraph, the structure of the whole layout can be concluded inductively. The neighbourhood of c_j consists of C_j^l and C_j^r (two K_4 joined by c_j) and L_j, where all vertices of the two K_4 (except c_j) are not connected to any vertex of L_j. Intuitively speaking, this independence between L_j and the K_4 of the backbone will force the backbone to expand along one dimension, say horizontally (as depicted in Figure 6), while the visibilities between L_j and c_j must then be vertical (as depicted in Figure 7(a)). However, formally proving this turns out to be quite complicated.

The general proof idea is to somehow place the unit squares of R_{L_j} in such a way that they see R_{c_j} without creating unwanted visibilities. Then, the areas of visibility for the R_{L_j} are blocked for any unit squares from the backbone-neighbourhood R_{C_j}, since these are independent of R_{L_j}. For example, consider the situation depicted in Figure 9. Here, placing unit squares from R_{C_j} in the grey areas implies that they are within visibility of some unit squares from R_{L_j}. This leaves only few possibilities to place the unit squares from R_{C_j} and by applying arguments of this type, it can be concluded, by exhaustively searching all possibilities and under application of Lemma 15, that the only possible layouts have the above described form.

However, this argument is flawed: it is possible to place a unit square R_x within the grey areas, as long as the forbidden visibilities are blocked by other unit squares. This type of blocking would require a path between x and c_j or some vertex from L_j, respectively, which

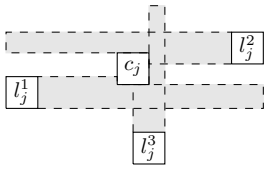

Figure 9 Possible placement of literal vertices for c_j.

does exist as structure in G. Consequently, in order to make the above described argument applicable, we first have to show that the existence of such visibility-blocking unit squares leads to a contradiction. This substantially increases the combinatorial depth of the already technical proof idea described above.

For the next lemma, which is the main tool in proving how the neighbourhood of c_j is represented, we need some notation. Let R_i, R_j, R_k be unit squares. If some (or every) visibility rectangle for R_i and R_k intersects R_j, then R_j is *strictly between* R_i and R_k (or R_j *blocks the view* between R_i and R_k, respectively).

▶ **Lemma 16.** *For all $1 \leq i \leq 2m$ and $r \in \{1,2,3\}$ and every $z \in N(c_i) \setminus \{l_i^r\}$ there exists no visibility rectangle for $R_{l_i^r}$ and R_z that is not intersected by R_{c_i}. In particular, this implies: R_z is not strictly between R_{c_i} and $R_{l_i^r}$, $R_{l_i^r}$ is not strictly between R_{c_i} and R_z, and, if R_{c_i} is strictly between $R_{l_i^r}$ and R_z, then R_{c_i} blocks the view between $R_{l_i^r}$ and R_z.*

By applying Lemma 16, we can now show that $R_{C_j^l}$ and $R_{C_j^r}$ cannot all see R_{c_j} from the same side, which can then be used in order to prove that either all R_{L_j} see R_{c_j} vertically or all of them see R_{c_j} horizontally:

▶ **Lemma 17.** *For every j, $1 \leq j \leq 2m-1$ and $y \in C_j \setminus \{c_j\}$, $R_{c_j} \to R_{C_j \setminus \{y, c_j\}}$ is not possible.*

▶ **Lemma 18.** *For every j, $1 \leq j \leq m$, either $R_{c_j} \leftrightarrow R_{L_j}$ or $R_{c_j} \updownarrow R_{L_j}$.*

We are now able to combine these lemmas in order to prove that a layout for G translates into a not-all-equal satisfying assignment for the formula F. To this end, we first note that the neighbourhood of a variable vertex x_i has an identical structure as the neighbourhood of the clause vertices, which implies that Lemmas 16, 17 and 18 also apply to this part of the graph. By combining Lemmas 16 and 18, we can show that for each clause c_j, either $R_{c_j} \leftrightarrow R_{C_j \setminus \{c_j\}}$ or $R_{c_j} \updownarrow R_{C_j \setminus \{c_j\}}$. By Lemma 15, this means that the two corresponding induced K_4 are represented as shown in Figure 6, and, furthermore, an inductive application of Lemma 17 forces them to form the shown horizontal or vertical backbone. Due to Lemma 18, the literal vertices and the assignment vertices corresponding to the same variable must all form a path on the same side of the backbone. We can now assign x_i the value *true* if and only if R_{t_i} is below the backbone. As long as, for the variables occurring in some clause c_j, $R_{f_i^1}$ is on the opposite side of R_{t_i}, clause c_j is not-all-equal satisfied, because then literals are set to *true* if and only if they are below the backbone and, due to Lemma 16, it is not possible that they all lie on the same side. However, if $R_{f_i^1}$ lies on the same side as R_{t_i}, which is possible, then $R_{f_i^2}$, again due to Lemma 16, must lie on the opposite side of R_{t_i} and, by the same argument, it follows that c_{j+m}, which is a copy of c_j, is not-all-equal satisfied (note that every clause has at most one negated variable).

▶ **Lemma 19.** *If $G \in$ USV, then F is not-all-equal satisfiable.*

▶ **Theorem 20.** Rec(USV) *is* NP*-complete.*

Since in our reduction the size of the graph is linear in the size of the formula, we can also conclude ETH-lower bounds for Rec(USV).

5 Conclusions

The hardness of Rec(USV_w) is still open (note that in our reduction, we heavily used the argument that certain constellations yield forbidden edges, which falls apart in the weak case) and we conjecture it to be NP-hard as well. Two open problems concerning graph classes related to USGV are mentioned in Section 3: (1) are USGV and the class of resolution-$\frac{\pi}{2}$ graphs identical, (2) are there resolution-$\frac{\pi}{2}$ graphs without BRAC-drawing? Note that a positive answer to (2) gives a negative answer to (1).

From a parameterised complexity point of view, our NP-completeness result shows that the number of different rectangle shapes (considered as a parameter) has no influence on the hardness of recognition. Another interesting parameter to explore would be the step size of the grid, i. e., for $k \in \mathbb{N}$, let USGV^k be defined like USGV, but for a $\{\frac{\ell}{k} \mid \ell \in \mathbb{N}\}^2$ grid. We note that these classes form an infinite hierarchy between $\mathsf{USGV} = \mathsf{USGV}^1$ and $\mathsf{USV} = \bigcup_k \mathsf{USGV}^k$, and it is hard to define them in terms of extensions of rectilinear graphs. Another interesting observation is that the hardness reduction for the recognition problem of rectilinear graphs from [17], if interpreted as reduction for Rec(USGV), does not work for USGV^2. The classes USGV^k might be practically more relevant, since placing objects in the plane with discrete distances is more realistic.

Abstract

In the last years renewed investigation of operator precedence languages (OPL) led to discover important properties thereof: OPL are closed with respect to all major operations, are characterized, besides the original grammar family, in terms of an automata family (OPA) and an MSO logic; furthermore they significantly generalize the well-known visibly pushdown languages (VPL). In another area of research, quantitative models of systems are also greatly in demand. In this paper, we lay the foundation to marry these two research fields. We introduce weighted operator precedence automata and show how they are both strict extensions of OPA and weighted visibly pushdown automata. We prove a Nivat-like result which shows that quantitative OPL can be described by unweighted OPA and very particular weighted OPA. In a Büchi-like theorem, we show that weighted OPA are expressively equivalent to a weighted MSO-logic for OPL.

1 Introduction

In the long history of formal languages the family of regular languages (RL) has always played a major role: thanks to its simplicity and naturalness, it enjoys many positive mathematical properties which have been thoroughly exploited in disparate practical applications; among them, those of main interest in this paper are the following:

- RL have been characterized in terms of various mathematical logics. Originally, Büchi, Elgot, and Trakhtenbrot [6, 18, 34] independently developed a monadic second order (MSO) logic defining exactly the RL family. This work has been followed by many further results; in particular those that exploited weaker but simpler logics such as first-order,

* This work was supported by Deutsche Forschungsgemeinschaft (DFG) Graduiertenkolleg 1763 (QuantLA).

propositional, and temporal ones culminated in the breakthrough of model checking to support automatic verification [28, 19, 7].

- Weighted RL have been introduced by Schützenberger in [32]: by assigning a weight in a suitable algebra to each language word, we may specify several attributes of the word, e.g., relevance, probability, etc. Much research then followed and extended Schützenberger's original work in various directions, cf. the books [4, 17, 23, 31, 13].

Unfortunately, all families with greater expressive power than RL – typically context-free languages (CFL), which are the most widely used family in practical applications – pay a price in terms of algebraic and logic properties and, consequently, of possible tools supporting their automatic analysis. For instance, for CFL, the containment problem is undecidable.

What was not possible for general CFL, however, has been possible for important subclasses of this family, which together we call *structured CFL*. Informally, by this term we denote those CFL where the syntactic tree-structure of their words is immediately "visible" in the words themselves. Two first equivalent examples of such families are parenthesis languages [27], which are generated by grammars whose right hand sides are enclosed within pairs of parentheses, and tree-automata [33], which generalize finite state machines (FSM) from the recognition of linear strings to tree-like structures. Among the many variations of parenthesis languages the recent family of *input-driven languages* [29, 35], alias *visibly pushdown languages (VPL)* [2], has received much attention in recent literature. For most of these structured CFL, including VPL, the relevant algebraic properties of RL still hold [2]. One of the most noticeable results has been a characterization of VPL in terms of a MSO logic that is a natural extension of Büchi's original one for RL [24, 2].

This fact has suggested to extend the investigation of weighted RL to various cases of structured languages. The result of such a fertile approach is a rich collection of *weighted logics*, first studied by Droste and Gastin [11], associated with *weighted tree automata* [16] and weighted extensions of VPA (the automata recognizing VPL) [26].

In an originally unrelated way *operator precedence languages (OPL)* have been defined and studied in two phases temporally separated by four decades. In his seminal work [20] Floyd was inspired by the precedence of multiplicative operations over additive ones in the execution of arithmetic expressions and extended such a relation to the whole input alphabet in such a way that it could drive a deterministic parsing algorithm that builds the syntax tree of any word that reflects the word's semantics; Fig. 1 and Section 2 give an intuition of how an OP grammar generates arithmetic expressions and assigns them a natural structure.

OPL do not cover all deterministic CFL, but they enjoy a distinguishing property, not possessed by general deterministic CFL, which we can intuitively describe as "*OPL are input driven but not visible*". They can be claimed as *input-driven* since the parsing actions on their words – whether to push or pop – depend exclusively on the input alphabet and on the relation defined thereon, but their structure is *not visible* in their words: e.g, they can include unparenthesized expressions where the precedence of multiplicative operators over additive ones is explicit in the syntax trees but hidden in their frontiers (see Fig. 1). Furthermore, unlike other structured CFL, OPL include deterministic CFL that are not real-time [25].

This recent remark suggested to resume their investigation systematically at the light of the recent technological advances and related challenges. Such a renewed investigation led to prove their closure under all major language operations [8] and to characterize them, besides Floyd's original grammars, in terms of an appropriate class of pushdown automata (OPA) and in terms of a MSO logic which is a fairly natural but not trivial extension of the previous ones defined to characterize RL and VPL [25]. Thus, OPL enjoy the same nice properties of RL and many structured CFL but considerably extend their applicability by breaking the barrier of visibility and real-time push-down recognition.

In this paper we join the two research fields above, namely we introduce *weighted OPL* and show that they are able to model system behaviors that cannot be specified by means of less powerful weighted formalisms such as weighted VPL. For instance, one might be interested in the behavior of a system which handles calls and returns but is subject to some emergency interrupts. Then it is important to evaluate how critically the occurrences of interrupts affect the normal system behavior, e.g., by counting the number of pending calls that have been preempted by an interrupt. As another example we consider a system logging all hierarchical calls and returns over words where this structural information is hidden. Depending on changing exterior factors like energy level, such a system could decide to log the above information in a selective way.

Our main contributions in this paper are the following.

- The model of *weighted OPA*, which have semiring weights at their transitions, significantly increases the descriptive power of previous weighted extensions of VPA, and has desired closure and robustness properties.
- For arbitrary semirings, there is a relevant difference in the expressive power of the model depending on whether it permits assigning weights to pop transitions or not. For commutative semirings, however, weights on pop transitions do not increase the expressive power of the automata. The difference in descriptive power between weighted OPA with arbitrary weights and without weights at pop transitions is due to the fact that OPL may be non-real-time and therefore OPA may execute several pop moves without advancing their reading heads.
- An extension of the classical result of Nivat [30] to weighted OPL. This robustness result shows that the behaviors of weighted OPA without weights at pop transitions are exactly those that can be constructed from weighted OPA with only one state, intersected with OPL, and applying projections which preserve the structural information.
- A weighted MSO logic and, for arbitrary semirings, a Büchi-Elgot-Trakhtenbrot-Theorem proving its expressive equivalence to weighted OPA without weights at pop transitions. As a corollary, for commutative semirings this weighted logic is equivalent to weighted OPA including weights at pop transitions.

Various possibilities arise for future research concerning theory and applications of our new model which will be discussed in the conclusion. The full version of this paper [10] provides all omitted technicalities and more explanatory comments and examples.

2 Preliminaries

Consider the CFG of Fig. 1 (left) and the syntax tree (center) which makes the structure of its frontier $n+n\times(n+n)$ visible. To drive a parsing algorithm in the deterministic construction of the tree associated with the string, Floyd introduced three *precedence relations*, $\lessdot$ (*yields precedence*), $\doteq$ (*equal in precedence*), $\gtrdot$ (*takes precedence*), (algorithmically derived from the grammar) between terminal symbols (Fig. 1 right). They do not satisfy any order axioms and are used to mark, respectively, the beginning, the internal elements, and the end of a grammar right hand side in the substitution rules of a shift-reduce parsing algorithm. For a complete description of Floyd's parsing algorithms driven by these relations, see, e.g, [21].

In this paper, instead, we exploit the more recent characterization of OPL in terms of recognizing automata [25], which are defined on a given alphabet *and* precedence matrix. We define an *OP alphabet* as a pair (Σ, M), where Σ is an alphabet and M, the *operator precedence matrix (OPM)*, is a $|\Sigma\cup\{\#\}|^2$ array describing for each ordered pair of symbols at most one (operator precedence) relation, that is, every entry of M is either $\lessdot$, $\doteq$, $\gtrdot$, or

$E \to E + T \mid T$
$T \to T \times F \mid F$
$F \to n \mid (E)$

	$+$	$\times$	$($	$)$	n
$+$	$\gtrdot$	$\lessdot$	$\lessdot$	$\gtrdot$	$\lessdot$
$\times$	$\gtrdot$	$\gtrdot$	$\lessdot$	$\gtrdot$	$\lessdot$
$($	$\lessdot$	$\lessdot$	$\lessdot$	$\doteq$	$\lessdot$
$)$	$\gtrdot$	$\gtrdot$		$\gtrdot$	
n	$\gtrdot$	$\gtrdot$		$\gtrdot$	

Figure 1 A grammar generating arithmetic expressions (left), an example derivation tree (center), and the precedence matrix (right). E.g. $M[1,2] = \lessdot$ means that $+$ yields precedence to $\times$.

empty (no relation). *We use the symbol # to mark the beginning and the end of a word and always let* $\# \lessdot a$ *and* $a \gtrdot \#$ *for all* $a \in \Sigma$.

Let $w = (a_1 ... a_n) \in \Sigma^+$ be a non-empty word. We say $a_0 = a_{n+1} = \#$ and define a new *chain* relation $\curvearrowright$ on the set of all positions of $\#w\#$, inductively, as follows. Let $0 \leq i < j \leq n+1$. We write $i \curvearrowright j$ if there exists a sequence of positions $i = k_1 < ... < k_m = j$, $m \geq 3$, such that $a_{k_1} \lessdot a_{k_2} \doteq ... \doteq a_{k_{m-1}} \gtrdot a_{k_m}$ and either $k_s + 1 = k_{s+1}$ or $k_s \curvearrowright k_{s+1}$ for each $s \in \{1, ..., m-1\}$. We say that w is *compatible* with M if for $\#w\#$, we have $0 \curvearrowright n+1$. We denote by (Σ^+, M) the set of all non-empty words over Σ which are compatible with M. For a *complete* OPM M, i.e. one without empty entries, this is Σ^+.

The chain relation can be compared with the *nesting* or *matching relation* of [2], which is also originating from additional information on the alphabet. However, instead of partitioning the alphabet into three disjoint parts (calls, internals, and returns), we add a *binary* relation for every pair of symbols denoting their precedence relation. Therefore, in contrast to the nesting relation, the same symbol can be either call or return depending on its context, and the same position can be part of multiple chain relations.

▶ **Definition 1.** A *(nondeterministic) operator precedence automaton (OPA)* $\mathcal{A}$ over an OP alphabet (Σ, M) is a tuple $\mathcal{A} = (Q, I, F, \delta)$, where $\delta = (\delta_{\text{shift}}, \delta_{\text{push}}, \delta_{\text{pop}})$, consisting of

- a finite set of states Q, the set of initial states $I \subseteq Q$, the set of final states $F \subseteq Q$, and
- the transition relations $\delta_{\text{shift}}, \delta_{\text{push}} \subseteq Q \times \Sigma \times Q$, and $\delta_{\text{pop}} \subseteq Q \times Q \times Q$.

Let $\Gamma = \Sigma \times Q$. A *configuration* of $\mathcal{A}$ is a triple $C = \langle \Pi, q, w\# \rangle$, where $\Pi \in \bot\Gamma^*$ represents a stack, $q \in Q$ the current state, and w the remaining input to read. A *run* of $\mathcal{A}$ on $w = a_1 ... a_n$ is a finite sequence of configurations $C_0 \vdash ... \vdash C_m$, such that every transition $C_i \vdash C_{i+1}$ has one of the following forms, where a is the first component of the topmost symbol of the stack Π, or $\#$ if the stack is $\bot$, and b is the next symbol of the input to read:

$$\begin{aligned}
&\textit{push move}: && \langle \Pi, q, bx \rangle && \vdash \langle \Pi[b, q], r, x \rangle && \text{if } a \lessdot b \text{ and } (q, b, r) \in \delta_{\text{push}},\\
&\textit{shift move}: && \langle \Pi[a, p], q, bx \rangle && \vdash \langle \Pi[b, p], r, x \rangle && \text{if } a \doteq b \text{ and } (q, b, r) \in \delta_{\text{shift}},\\
&\textit{pop move}: && \langle \Pi[a, p], q, bx \rangle && \vdash \langle \Pi, r, bx \rangle && \text{if } a \gtrdot b \text{ and } (q, p, r) \in \delta_{\text{pop}}.
\end{aligned}$$

An *accepting run* of $\mathcal{A}$ on w is a run from $\langle \bot, q_I, w\# \rangle$ to $\langle \bot, q_F, \# \rangle$, where $q_I \in I$ and $q_F \in F$. The *language accepted by* $\mathcal{A}$, denoted $L(\mathcal{A})$, consists of all words over (Σ^+, M) which have an accepting run on $\mathcal{A}$. We say $L \subseteq (\Sigma^+, M)$ is an *OPL* if L is accepted by an OPA over (Σ, M). As proven in [25], the deterministic variant of an OPA, using a single initial state and transition functions instead of relations, is as expressive as nondeterministic OPA.

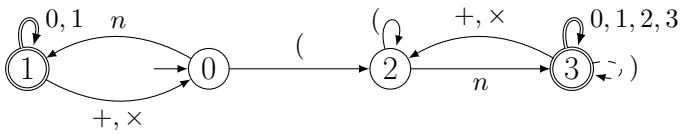

Figure 2 An OPA recognizing the language of the grammar of Fig. 1. The graphical notation is imported from [25]: pushes are normal arrows, shifts are dashed, pops are double arrows.

An example automaton is depicted in Fig. 2: with the OPM of Fig. 1 (right), it accepts the same language as the grammar of Fig. 1 (left).

▶ **Definition 2.** The logic MSO(Σ, M), short MSO, and its semantics is defined as in [25]

$$\beta ::= \mathrm{Lab}_a(x) \mid x \leq y \mid x \curvearrowright y \mid x \in X \mid \neg\beta \mid \beta \vee \beta \mid \exists x.\beta \mid \exists X.\beta$$

where $a \in \Sigma \cup \{\#\}$ and x, y, X are first resp. second order variables. The predicate $\mathrm{Lab}_a(x)$ asserts that position x is labeled a. The semantics of $\curvearrowright$ is defined by the chain relation.

▶ **Theorem 3** ([25]). *A language L over (Σ, M) is an OPL iff it is MSO-definable.*

3 Weighted OPL and Their Relation to Weighted VPL

In this section, we introduce a weighted extension of OPA. We show that weighted OPL include weighted visibly pushdown automata (VPL) and give examples showing how these weighted automata can express behaviors which were not expressible before.

Let $\mathbb{K} = (K, +, \cdot, 0, 1)$ be a *semiring*, i.e., $(K, +, 0)$ is a commutative monoid, $(K, \cdot, 1)$ is a monoid, $(x+y)\cdot z = x\cdot z + y\cdot z$, $x\cdot(y+z) = x\cdot y + x\cdot z$, and $0\cdot x = x\cdot 0 = 0$ for all $x, y, z \in K$. $\mathbb{K}$ is called *commutative* if $(K, \cdot, 1)$ is commutative. Important examples of commutative semirings include the Boolean semiring $\mathbb{B} = (\{0,1\}, \vee, \wedge, 0, 1)$, the semiring of the natural numbers $\mathbb{N} = (\mathbb{N}, +, \cdot, 0, 1)$, or the tropical semirings $\mathbb{R}_{\max} = (\mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0)$ and $\mathbb{R}_{\min} = (\mathbb{R} \cup \{\infty\}, \min, +, \infty, 0)$. Significant non-commutative semirings are $n \times n$-matrices over semirings $\mathbb{K}$ with matrix addition and multiplication as usual ($n \geq 2$), or the semiring $(\mathcal{P}(\Sigma^*), \cup, \cdot, \emptyset, \{\varepsilon\})$ of languages over Σ.

▶ **Definition 4.** A *weighted OPA (wOPA)* $\mathcal{A}$ over an OP alphabet (Σ, M) and a semiring $\mathbb{K}$ is a tuple $\mathcal{A} = (Q, I, F, \delta, \mathrm{wt})$, where $\mathrm{wt} = (\mathrm{wt}_{\mathrm{shift}}, \mathrm{wt}_{\mathrm{push}}, \mathrm{wt}_{\mathrm{pop}})$, consisting of

- an OPA $\mathcal{A}' = (Q, I, F, \delta)$ over (Σ, M) and
- the weight functions $\mathrm{wt}_{op} : \delta_{op} \to K$, $op \in \{\mathrm{shift}, \mathrm{push}, \mathrm{pop}\}$.

We call a wOPA *restricted*, denoted by *rwOPA*, if $\mathrm{wt}_{\mathrm{pop}}(q, p, r) = 1$ for each $(q, p, r) \in \delta_{\mathrm{pop}}$.

A *configuration* of a wOPA is a tuple $\langle \Pi, q, w\#, k\rangle$, where $(\Pi, q, w\#)$ is a configuration of the OPA $\mathcal{A}'$ and $k \in K$. A *run* of $\mathcal{A}$ is defined as for OPA, where, additionally, the weight k is updated by multiplying with the weight of the encountered transition, as follows.

$$\begin{aligned}
\langle \Pi, q, bx, k\rangle &\vdash \langle \Pi[b, q], r, x, k \cdot \mathrm{wt}_{\mathrm{push}}(q, b, r)\rangle && \text{if } a \lessdot b \text{ and } (q, b, r) \in \delta_{\mathrm{push}},\\
\langle \Pi[a, p], q, bx, k\rangle &\vdash \langle \Pi[b, p], r, x, k \cdot \mathrm{wt}_{\mathrm{shift}}(q, b, r)\rangle && \text{if } a \doteq b \text{ and } (q, b, r) \in \delta_{\mathrm{shift}},\\
\langle \Pi[a, p], q, bx, k\rangle &\vdash \langle \Pi, r, bx, k \cdot \mathrm{wt}_{\mathrm{pop}}(q, p, r)\rangle && \text{if } a \gtrdot b \text{ and } (q, p, r) \in \delta_{\mathrm{pop}}.
\end{aligned}$$

We call a run ρ *accepting* if it goes from $\langle \bot, q_I, w\#, 1\rangle$ to $\langle \bot, q_F, \#, k\rangle$, where $q_I \in I$ and $q_F \in F$. For such an accepting run, the *weight of* ρ is defined as $\mathrm{wt}(\rho) = k$. Finally, the *behavior of* $\mathcal{A}$ is a function $[\![\mathcal{A}]\!] : (\Sigma^+, M) \to K$, defined as

$$[\![\mathcal{A}]\!](w) = \sum_{\rho \text{ acc. run of } \mathcal{A} \text{ on } w} \mathrm{wt}(\rho) \ .$$

	call	ret	itr	$
call	⋖	≐	⋗	⋖
ret	⋗	⋗	⋗	⋖
itr	⋗		⋖	⋖
$	⋗	⋗	⋗	

Figure 3 The weighted OPA $\mathcal{A}_{\text{itr}}$ penalizing unmatched calls nondeterministically, and its precedence matrix (right). Weights are given in parentheses at transitions. The weight semiring is $\mathbb{Z}_{\max} = (\mathbb{Z} \cup \{-\infty\}, \max, +, -\infty, 0)$.

Every function $S : (\Sigma^+, M) \to K$ is called an *OP-series* (short: *series*, also *weighted language*). A wOPA $\mathcal{A}$ *accepts* a series S if $[\![\mathcal{A}]\!] = S$. A series S is called *recognizable* or a *wOPL* if there exists an wOPA $\mathcal{A}$ accepting it. S is *strictly recognizable* or an *rwOPL* if there exists an rwOPA $\mathcal{A}$ accepting it.

▶ **Example 5.** Consider a system that manages calls and returns (in VPL terminology) in a traditional LIFO policy but discards all pending calls if an interrupt (*itr*) occurs. Such a system can be naturally modeled by suitable OPA that can formalize various types of policies to manage interrupts [25][1]. We can use weights to , for instance, count the number of interrupted calls. A first simple wOPA could attach a negative weight to calls and a compensating one to corresponding returns so that the final weight assigned to the string would be "neutral" only if no call is discarded.

Consider now a more complex system where the penalties for unmatched calls may change nondeterministically. Here, we assume words to be separated into different intervals by the symbol \$, of which one nondeterministically chosen represents, e.g., a critical operating time, during which unmatched calls are penalized. The wOPA $\mathcal{A}_{\text{itr}}$ given in Fig. 3 formalizes such a system by assigning to an input sequence a global weight that is the maximal number of unmatched calls in one interval.

$\mathcal{A}_{\text{itr}}$ can be easily modified to formalize several variations of its policy: e.g., different policies could be associated with different intervals, different weights could be assigned to different types of calls and/or interrupts, different policies could also be defined by choosing different semirings, etc. Note that $\mathcal{A}_{\text{itr}}$ is restricted.

▶ **Example 6.** The automaton $\mathcal{A}_{\log}$, depicted in Fig. 4, chooses non-deterministically between logging everything and logging only 'important' information, e.g., only interrupts (this could be a system dependent on energy, WiFi, etc.). Notice that in this case assigning nontrivial weights to pop transitions is crucial. Let $\Sigma = \{\text{call}, \text{ret}, \text{itr}\}$, and define M as the obvious projection of $\mathcal{A}_{\text{itr}}$'s OPM. We employ the semiring $(\text{Fin}_{\Sigma'}, \cup, \circ, \emptyset, \{\varepsilon\})$ of all finite languages over $\Sigma' = \{c, r, p, i\}$. Then, $[\![\mathcal{A}_{\log}]\!](w)$ yields all possible logs on w.

The above example can be exploited to show by a pumping-like argument that wOPA are more expressive than rwOPA. This is due to the fact that a number of consecutive pops can attach to one position a product of size only bounded by the word-length and it is impossible to attach these weights at other positions without destroying their sequential order.

▶ **Proposition 7.** *There exist an OP alphabet (Σ, M), a semiring $\mathbb{K}$, and a weighted language $S : (\Sigma^+, M) \to K$ such that S is recognizable but not strictly recognizable.*

[1] A similar motivation inspired the recent extension of VPL as colored nested words by [1].

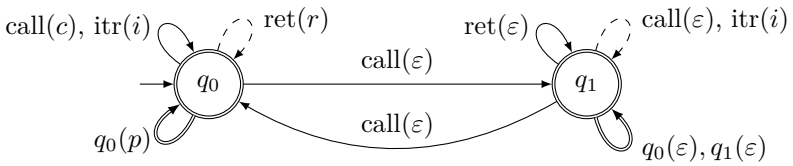

Figure 4 The wOPA $\mathcal{A}_{\text{log}}$ nondeterministically writes logs at different levels of detail.

	Σ_{call}	Σ_{ret}	Σ_{int}
Σ_{call}	$\lessdot$	$\doteq$	$\lessdot$
Σ_{ret}	$\gtrdot$	$\gtrdot$	$\gtrdot$
Σ_{int}	$\gtrdot$	$\gtrdot$	$\gtrdot$

E.g. $w = a\langle car\rangle$, over $\Sigma_{\text{int}} = \{a\}$, $\Sigma_{\text{call}} = \{\langle c\}$, $\Sigma_{\text{ret}} = \{r\rangle\}$

NWA: $q_0 \xrightarrow{a} q_1 \xrightarrow{\langle c} q_2 \xrightarrow{a} q_3 \xrightarrow{r\rangle} q_4$

OPA: $q_0 \xrightarrow{a} q_1' \Rightarrow q_1 \xrightarrow{\langle c} q_2 \xrightarrow{a} q_3' \Rightarrow q_3 \overset{r\rangle}{\dashrightarrow} q_4' \Rightarrow q_4$

Figure 5 The OPM M for VPL and an example of the translation of runs from NWA to OPA.

On the other hand, for commutative semirings rwOPA and wOPA are equally expressive.

▶ **Theorem 8.** *Let $\mathcal{A}$ be a wOPA over an OP alphabet (Σ, M) and a commutative semiring $\mathbb{K}$. Then, there exists an rwOPA $\mathcal{B}$ over (Σ, M) and $\mathbb{K}$ with $[\![\mathcal{A}]\!] = [\![\mathcal{B}]\!]$.*

Proof (Sketch). Let $\mathcal{A} = (Q, I, F, \delta, \text{wt})$ be a wOPA over (Σ, M) and $\mathbb{K}$. We construct an rwOPA $\mathcal{B}$ over (Σ, M) and $\mathbb{K}$ with the state set $Q' = Q \times Q \times Q$ and with the same behavior as $\mathcal{A}$ as follows. In the first state component $\mathcal{B}$ simulates $\mathcal{A}$. In the second and third state component of Q' the automaton $\mathcal{B}$ guesses the states q and r of the pop transition (q, p, r) of $\mathcal{A}$ which corresponds to the next push transition following after this configuration. This enables us to transfer the weight from the pop transition to the correct push transition. ◀

In the following, we show that rwOPL strictly include *weighted visibly pushdown languages* (wVPL). VPL is the class of languages corresponding to nested words [2] and recognized by *visibly pushdown automata* (VPA) or the expressively equivalent *nested word automata* (NWA). Let Σ be a *visibly pushdown alphabet* consisting of calls, internals, and returns. In [8], it was shown that for every VPA over Σ, there exists an equivalent OPA [25] over (Σ, M), where M is the OPM defined in Fig. 5.

In [26, 15], *weighted nested word automata* (wNWA) were introduced. These add semiring weights at every transition again depending on the information which symbols are calls, internals, or returns. Since every nested word has a unique representation over a visibly pushdown alphabet Σ, it can be interpreted as a compatible word of (Σ^+, M). In particular, we can interpret a wVPL, i.e., the language of a wNWA, as an OP-series $(\Sigma^+, M) \to \mathbb{K}$.

▶ **Theorem 9.** *Let $\mathbb{K}$ be a semiring and M be the OPM of Fig. 5. Then for every wNWA $\mathcal{A}$ as defined in [15], there exists an rwOPA $\mathcal{B}$ with $[\![\mathcal{A}]\!](w) = [\![\mathcal{B}]\!](w)$ for all $w \in (\Sigma^+, M)$.*

We give an intuition for this result as follows. Note that pushes, shifts, and pops significantly differ from calls, internals, and returns. Indeed, a return of a NWA reads and 'consumes' a symbol, while a pop of an OPA just pops the stack and leaves the next symbol untouched. Studying the OPM M and the example runs of Fig. 5, we see that every symbol of Σ_{ret} forces a shift transition of an OPA immediately followed by a pop. This suggests a fairly natural construction where we can simulate every weighted call by a weighted push, every

weighted internal by a weighted push together with a pop and every weighted return by a weighted shift together with a pop. Hence, we may omit weights at pop transitions.

Since OPA are strictly more expressive than VPA [8], this gives, together with Proposition 7, a complete picture of the expressive power of these three classes of weighted languages:

$$\text{wVPL} \subsetneq \text{rwOPL} \subsetneq \text{wOPL} \ .$$

Note that in the context of formal power series, wVPL strictly contain recognizable power series and wOPL form a proper subset of the class of algebraic power series, i.e., series recognized by weighted pushdown automata [23].

4 A Nivat Theorem

In this section, we show that strictly recognizable series are exactly those series which can be derived from a restricted weighted OPA with only one state, intersected with an unweighted OPL, and using an OPM-preserving projection of the alphabet.

In the following, we study closure properties of wOPL and rwOPL. As usual, we extend the operations $+$ and $\cdot$ to series by means of pointwise definitions.

▶ **Proposition 10.** *Let $S : (\Sigma^+, M) \to K$ be a recognizable (resp. strictly recognizable) series and $L \subseteq (\Sigma^+, M)$ an OPL. Then, the series $(S \cap L)(w) = \left\{ \begin{array}{ll} S(w) & , \text{ if } w \in L \\ 0 & , \text{ otherwise} \end{array} \right\}$ is recognizable (resp. strictly recognizable).*

Furthermore, if $\mathbb{K}$ is commutative, then the product of two recognizable (resp. strictly recognizable) series over (Σ^+, M) is again recognizable (resp. strictly recognizable).

Next, we show that recognizable series are closed under projections which preserve the OPM. For two OP alphabets (Σ, M), (Γ, M'), we write $h : (\Sigma, M) \to (\Gamma, M')$ for a mapping $h : \Sigma \to \Gamma$ such that for all $\bullet \in \{\lessdot, \doteq, \gtrdot\}$, we have $a \bullet b$ if and only if $h(a) \bullet h(b)$. We can extend h to a function $h : (\Sigma^+, M) \to (\Gamma^+, M')$ by setting $h(a_1 a_2 ... a_n) = h(a_1)h(a_2)...h(a_n)$. Let $S : (\Sigma^+, M) \to K$ be a series. We define $h(S) : (\Gamma^+, M') \to K$ for each $v \in (\Gamma^+, M')$ by

$$h(S)(v) = \sum_{w \in (\Sigma^+, M), h(w) = v} S(w) \ . \tag{1}$$

▶ **Proposition 11.** *Let $\mathbb{K}$ be a semiring, $S : (\Sigma^+, M) \to K$ recognizable (resp. strictly recognizable), and $h : (\Sigma, M) \to (\Gamma, M')$. Then, $h(S) : (\Gamma^+, M') \to K$ is recognizable (resp. strictly recognizable).*

Let h be a map between two alphabets. Given $h : \Gamma \to \Sigma$ and an OP alphabet (Σ, M), we define $h^{-1}(M)$ by setting $h^{-1}(M)_{a'b'} = M_{h(a')h(b')}$ for all $a', b' \in \Gamma$. As h is OPM-preserving, for every series $S : (\Sigma^+, M) \to K$, we get a series $h(S) : (\Gamma^+, h^{-1}(M)) \to K$, using the sum over all pre-images as in formula (1).

Let $\mathcal{N}(\Sigma, M, \mathbb{K})$ comprise all series $S : (\Sigma^+, M) \to K$ for which there exist an alphabet Γ, over $(\Gamma, h^{-1}(M))$ such that $S = h([\![\mathcal{B}]\!] \cap L)$.

Then, we can show that every rwOPL can be decomposed into the above introduced fragments. Using this decomposition and the closure properties of Prop. 10 and Prop. 11, we get the following Nivat-Theorem for weighted operator precedence automata.

▶ **Theorem 12.** *Let $\mathbb{K}$ be a semiring and $S : (\Sigma^+, M) \to K$ be a series. Then S is strictly recognizable if and only if $S \in \mathcal{N}(\Sigma, M, \mathbb{K})$.*

$$
\begin{aligned}
[\![\beta]\!]_{\mathcal{V}}(w,\sigma) &= \begin{cases} 1\,, & \text{if } (w,\sigma) \models \beta \\ 0\,, & \text{otherwise} \end{cases} & [\![\bigoplus_x \varphi]\!]_{\mathcal{V}}(w,\sigma) &= \sum_{i\in|w|} [\![\varphi]\!]_{\mathcal{V}\cup\{x\}}(w,\sigma[x\to i]) \\
[\![k]\!]_{\mathcal{V}}(w,\sigma) &= k \quad \text{for all } k\in\mathbb{K} & [\![\bigoplus_X \varphi]\!]_{\mathcal{V}}(w,\sigma) &= \sum_{I\subseteq|w|} [\![\varphi]\!]_{\mathcal{V}\cup\{X\}}(w,\sigma[X\to I]) \\
[\![\varphi\oplus\psi]\!]_{\mathcal{V}}(w,\sigma) &= [\![\varphi]\!]_{\mathcal{V}}(w,\sigma) + [\![\psi]\!]_{\mathcal{V}}(w,\sigma) & [\![\prod_x \varphi]\!]_{\mathcal{V}}(w,\sigma) &= \prod_{i\in|w|} [\![\varphi]\!]_{\mathcal{V}\cup\{x\}}(w,\sigma[x\to i]) \\
[\![\varphi\otimes\psi]\!]_{\mathcal{V}}(w,\sigma) &= [\![\varphi]\!]_{\mathcal{V}}(w,\sigma)\cdot[\![\psi]\!]_{\mathcal{V}}(w,\sigma)
\end{aligned}
$$

Figure 6 Semantics of weighted MSO logic for OPL.

5 Weighted MSO-Logic for OPL

We use modified ideas from Droste and Gastin [11], also incorporating the distinction into *boolean* formulas β and *weighted* formulas φ as in [5]. The boolean formulas model classical unweighted features, whereas weighted formulas may deal with quantitative aspects.

▶ **Definition 13.** We define the weighted logic MSO$(\mathbb{K},(\Sigma,M))$, short MSO$(\mathbb{K})$, as

$$
\begin{aligned}
&\beta ::= \mathrm{Lab}_a(x) \mid x\le y \mid x \curvearrowright y \mid x\in X \mid \neg\beta \mid \beta\vee\beta \mid \exists x.\beta \mid \exists X.\beta \\
&\varphi ::= \beta \mid k \mid \varphi\oplus\varphi \mid \varphi\otimes\varphi \mid \textstyle\bigoplus_x \varphi \mid \bigoplus_X \varphi \mid \prod_x \varphi
\end{aligned}
$$

where $a\in\Sigma\cup\{\#\}$, $k\in\mathbb{K}$; x,y are first order variables; and X is a second order variable.

Let $w\in(\Sigma^+,M)$ and $\varphi\in$ MSO$(\mathbb{K})$. As usual, let $[w]=\{1,...,|w|\}$ and $\mathcal{V}$ be a finite set of variables containing *free*(φ), all free variables of φ. A $(\mathcal{V},w)$-*assignment* σ is a function assigning to every first order variable of $\mathcal{V}$ an element of $[w]$ and to every second order variable a subset of $[w]$. We define $\sigma[x\to i]$ (and analogously $\sigma[X\to I]$) as the $(\mathcal{V}\cup\{x\},w)$-assignment mapping x to i and coinciding with σ on all variables different from x.

By following classical approaches, we consider the extended alphabet $\Sigma_{\mathcal{V}}=A\times\{0,1\}^{\mathcal{V}}$ together with its natural OPM $M_{\mathcal{V}}$ defined such that for all $(a,s),(b,t)\in\Sigma_{\mathcal{V}}$ and all $\bullet\in\{\lessdot,\doteq,\gtrdot\}$, we have $(a,s)\bullet(b,t)$ if and only if $a\bullet b$. We represent the word w together with the assignment σ as a word (w,σ) over $(\Sigma_{\mathcal{V}},M_{\mathcal{V}})$ such that 1 denotes every position where x resp. X holds. A word over $\Sigma_{\mathcal{V}}$ is called *valid*, if every first order variable is assigned to exactly one position. Being valid is a property which can be checked by an OPA.

We define the *semantics* of $\varphi\in$ MSO$(\mathbb{K})$ as a function $[\![\varphi]\!]_{\mathcal{V}}:(\Sigma_{\mathcal{V}}^+,M_{\mathcal{V}})\to K$ inductively for all valid $(w,\sigma)\in(\Sigma_{\mathcal{V}}^+,M_{\mathcal{V}})$ in Fig. 6. For not valid (w,σ), we set $[\![\varphi]\!]_{\mathcal{V}}(w,\sigma)=0$. We write $[\![\varphi]\!]$ for $[\![\varphi]\!]_{\mathrm{free}(\varphi)}$.

We can show that semantics $\varphi_{\mathcal{V}}$ for different $\mathcal{V}$ are consistent with each other as long as $\mathcal{V}$ contains all free variables of φ. If φ contains no free variables, φ is a *sentence* and $[\![\varphi]\!]:(\Sigma^+,M)\to K$.

▶ **Example 14.** Let us go back to the automaton $\mathcal{A}_{\mathrm{itr}}$ depicted in Fig. 3. The following boolean formula β defines three subsets of string positions, X_0,X_1,X_2, representing, respectively, the string portions where unmatched calls are not penalized, namely X_0,X_2, and the portion where they are, namely X_1:

$$
\begin{aligned}
\beta = \quad & x\in X_0 \leftrightarrow \exists y\exists z(y>x\wedge z>x\wedge \mathrm{Lab}_{\$}(y)\wedge\mathrm{Lab}_{\$}(z)) \\
& \wedge x\in X_1 \leftrightarrow \exists y\exists z(y\le x\le z\wedge \mathrm{Lab}_{\$}(y)\wedge\mathrm{Lab}_{\$}(z)\wedge(x\neq y\wedge x\neq z\to\neg\mathrm{Lab}_{\$}(x))) \\
& \wedge x\in X_2 \leftrightarrow \exists y\exists z(y<x\wedge z<x\wedge \mathrm{Lab}_{\$}(y)\wedge\mathrm{Lab}_{\$}(z))\ .
\end{aligned}
$$

Weight assignment is formalized by the formula φ which assigns weight 0 to calls, returns, and interrupts outside portion X_1; and weights $1, -1, 0$ to calls, returns, and interrupts, respectively, within portion X_1:

$$\begin{aligned}\varphi = \quad & (\neg((x \in X_0 \vee x \in X_2) \wedge (\mathrm{Lab}_{\mathrm{call}}(x) \vee \mathrm{Lab}_{\mathrm{ret}}(x) \vee \mathrm{Lab}_{\mathrm{itr}}(x))) \oplus 0) \\ & \otimes (\neg(x \in X_1 \wedge \mathrm{Lab}_{\mathrm{call}}(x)) \oplus 1) \otimes (\neg(x \in X_1 \wedge \mathrm{Lab}_{\mathrm{ret}}(x)) \oplus -1) \\ & \otimes (\neg(x \in X_1 \wedge \mathrm{Lab}_{\mathrm{itr}}(x)) \oplus 0) \otimes (\neg \mathrm{Lab}_{\$}(x) \oplus 0) \ .\end{aligned}$$

Then, the formula $\psi = \prod_x (\beta \otimes \varphi)$ defines the weight assigned by $\mathcal{A}_{\mathrm{itr}}$ to an input string through a single nondeterministic run and finally $\chi = \bigoplus_{X_0} \bigoplus_{X_1} \bigoplus_{X_2} \psi$ defines the global weight of every string in an equivalent way as the one defined by $\mathcal{A}_{\mathrm{itr}}$.

As shown by [11] in the case of words, the full weighted logic is strictly more powerful than weighted automata. A similar example also applies here. Therefore, in the following, we restrict our logic in an appropriate way.

▶ **Definition 15.** The *set of almost boolean formulas* is the smallest set of all formulas of MSO($\mathbb{K}$) containing all $k \in \mathbb{K}$ and all boolean formulas which is closed under $\oplus$ and $\otimes$.

Adapting ideas from [14], we can show by structural induction that almost boolean formulas describe precisely a certain form of wOPA's behaviors, called *OPL step functions*, which are all series S that can be written as $S = \sum_{i=1}^{n} k_i \mathbb{1}_{L_i}$, where L_i are OPL forming a partition of (Σ^+, M) and $k_i \in \mathbb{K}$ for each $i \in \{1, ..., n\}$. Furthermore, OPL step functions are recognizable by rwOPA and are closed under the natural extension of the semiring's $+$ and $\cdot$ to series.

▶ **Definition 16.** We call $\varphi \in \mathrm{MSO}(\mathbb{K})$ *restricted* if for all subformulas $\psi \otimes \theta$ of φ either ψ is almost boolean or all semiring weights occurring in ψ and θ commute elementwise, and additionally, for all subformulas $\prod_x \psi$ of φ, ψ is almost boolean.

In Example 14, the formula β is boolean, the formula φ is almost boolean, and ψ and χ are restricted. Notice that ψ and χ would be restricted even if $\mathbb{K}$ were not commutative.

▶ **Proposition 17.** *Let φ and ψ be two formulas of* MSO($\mathbb{K}$) *such that $[\![\varphi]\!]$ and $[\![\psi]\!]$ are recognizable (resp. strictly recognizable). Then we have*

- *$[\![\varphi \oplus \psi]\!]$, $[\![\sum_x \varphi]\!]$, and $[\![\sum_X \varphi]\!]$ are recognizable (resp. strictly recognizable).*
- *$[\![\varphi \otimes \psi]\!]$ is (resp. strictly) recognizable if $\varphi \otimes \psi$ is a subformula of a restricted formula.*
- *$[\![\prod_x \varphi]\!]$ is strictly recognizable if φ is an almost boolean formula of* MSO($\mathbb{K}$).

Proof (Sketch). Closure under $\oplus$ is dealt with by an usual disjoint union of two wOPA (resp. rwOPA). Closure under restricted $\otimes$ is dealt with by Proposition 10. For the sum quantification, we utilize Proposition 11. The closure under the restricted product quantification is non-trivial, but can be proved by adapting previous techniques to OPL step functions. ◀

Then, by induction on the structure of a weighted formula and using Proposition 17, we get

▶ **Proposition 18.** *For every restricted* MSO($\mathbb{K}$)*-sentence φ, there exists an rwOPA $\mathcal{A}$ with $[\![\mathcal{A}]\!] = [\![\varphi]\!]$.*

Now, we show that the converse of Proposition 18 holds as well.

▶ **Proposition 19.** *For every rwOPA $\mathcal{A}$, there exists a restricted* MSO($\mathbb{K}$)*-sentence φ with $[\![\mathcal{A}]\!] = [\![\varphi]\!]$. If $\mathbb{K}$ is commutative, then for every wOPA $\mathcal{A}$, there exists a restricted* MSO($\mathbb{K}$)*-sentence φ with $[\![\mathcal{A}]\!] = [\![\varphi]\!]$.*

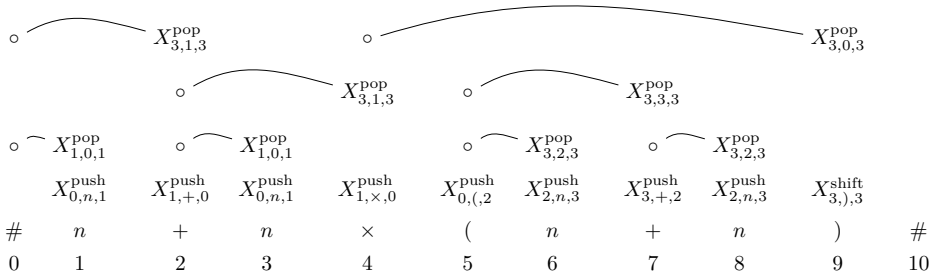

Figure 7 The string of Fig. 1 with the 2nd order variables evidenced for the automaton of Fig. 2.

Proof. The rationale adopted to build formula φ from $\mathcal{A}$ integrates the approach followed in [11, 15] with the one of [25]. On the one hand we need second order variables suitable to "carry" weights; on the other hand, unlike previous non-OP cases which are managed through real-time automata, an OPA can perform several transitions while remaining in the same position. Thus, we introduce the following second order variables: $X^{\text{push}}_{p,a,q}$ represents the set of positions where $\mathcal{A}$ performs a push move from state p, reading symbol a and reaching state q; $X^{\text{shift}}_{p,a,q}$ has the same meaning as $X^{\text{push}}_{p,a,q}$ for a shift operation; and $X^{\text{pop}}_{p,q,r}$ represents the set of positions of the symbol that is on top of the stack when $\mathcal{A}$ performs a pop transition from state p, with q on top of the stack, reaching r.

Let $\mathcal{V}$ consist of all $X^{\text{push}}_{p,a,q}$, $X^{\text{shift}}_{p,a,q}$, and $X^{\text{pop}}_{p,q,r}$ such that $a \in \Sigma$, $p, q, r \in Q$ and $(p, a, q) \in \delta_{\text{push}}$, resp. δ_{shift}, resp. $(p, q, r) \in \delta_{\text{pop}}$. We denote by $\bar{X}^{\text{push}}$, $\bar{X}^{\text{shift}}$, and $\bar{X}^{\text{pop}}$ enumerations over the respective set of second order variables. Using usual abbreviations for MSO-formulas and some adapted shortcuts from [25] and [11], we define the following unweighted formula ψ to characterize all accepted runs of $\mathcal{A}$

$$\psi = \mathit{Part}(\bar{X}^{\text{push}}, \bar{X}^{\text{shift}}) \wedge \mathit{Unique}(\bar{X}^{\text{pop}}) \wedge \mathit{InitFinal} \wedge \mathit{Tr}_{\text{push}} \wedge \mathit{Tr}_{\text{shift}} \wedge \mathit{Tr}_{\text{pop}} \ .$$

Here, the subformula *Part* will enforce the push and shift sets to be (together) a partition of all positions, while the *Unique* will make sure that we mark every position with at most one X^{pop}. *InitFinal* controls the initial and the acceptance condition and $\mathit{Tr}_{\text{push}}$, $\mathit{Tr}_{\text{shift}}$, and Tr_{pop} the respective transitions of the run according to their labels as follows.

$$\begin{aligned}
\mathit{Tr}_{\text{push}} &= \forall x. \textstyle\bigwedge_{p,q\in Q, a\in\Sigma} \left(x \in X^{\text{push}}_{p,a,q} \rightarrow \left[\text{Lab}_a(x) \wedge \exists z.(z \lessdot x \wedge (\text{Next}_p(z,x) \vee \text{Succ}_p(z,x)))\right]\right) \\
\mathit{Tr}_{\text{shift}} &= \forall x. \textstyle\bigwedge_{p,q\in Q, a\in\Sigma} \left(x \in X^{\text{shift}}_{p,a,q} \rightarrow \left[\text{Lab}_a(x) \wedge \exists z.(z \doteq x \wedge (\text{Next}_p(z,x) \vee \text{Succ}_p(z,x)))\right]\right) \\
\mathit{Tr}_{\text{pop}} &= \forall v. \textstyle\bigwedge_{p,q\in Q} \left(\left[\bigvee_{r\in Q} v \in X^{\text{pop}}_{p,q,r}\right] \leftrightarrow \left[\exists x \exists y \exists z.(\text{Tree}_{p,q}(x,z,v,y))\right]\right) \ .
\end{aligned}$$

The main idea is that for every $x \curvearrowright y$, we encode in $\text{Tree}(x, z, v, y)$ the two other 'critical' positions for this chain, namely z, which is the (either direct or hierarchical) successor of x in this chain and which is the position where we execute the push resulting from $x \lessdot z$; and v, which is the 'chain-predecessor' of y and the position we mark with the respective X^{pop} resulting from $v \gtrdot y$. E.g., with reference to Fig. 1 and Fig. 7, we have $\text{Tree}(4, 5, 9, 10)$.

Furthermore, $\text{Succ}_q(x, y)$ holds for two successive positions where the OPA reaches state q through a push or shift at position y, while $\text{Next}_q(x, y)$ holds when a pop move reaches state q while completing a chain $x \curvearrowright y$. Then $\text{Tree}_{p,q}$ explicitly controls the current state and the state on top of the stack when the pop move is executed as follows.

$$\begin{aligned}
\mathrm{Tree}(x,z,v,y) &:= x \curvearrowright y \wedge \begin{pmatrix} (x+1=z \ \vee \ x \curvearrowright z) \wedge \neg\exists t(z<t<y \wedge x \curvearrowright t) \wedge \\ (v+1=y \ \vee \ v \curvearrowright y) \wedge \neg\exists t(x<t<v \wedge t \curvearrowright y) \end{pmatrix} \\
\mathrm{Next}_r(x,y) &:= \exists z \exists v. \left(\mathrm{Tree}(x,z,v,y) \wedge \bigvee\nolimits_{p,q\in Q} v \in X^{\mathrm{pop}}_{p,q,r}\right) \\
\mathrm{Tree}_{i,j}(x,z,v,y) &:= \mathrm{Tree}(x,z,v,y) \wedge (\mathrm{Succ}_i(v,y) \vee \mathrm{Next}_i(v,y)) \wedge (\mathrm{Succ}_i(x,z) \vee \mathrm{Next}_i(x,z))
\end{aligned}$$

Notice that in the transition formulas, the partition (resp. uniqueness) axioms guarantee that in every run, the left side of the implication (resp. equivalence) is satisfied for only one triple (p,a,q), resp. (p,q,r). Thus, with arguments similar to [25], it can be shown that the sentences satisfying ψ are exactly those accepted by the unweighted OPA subjacent to $\mathcal{A}$.

Now, we add weights to ψ by defining the following restricted weighted formula

$$\begin{aligned}
\theta = \psi \otimes \prod_x \bigotimes_{p,q\in Q} \Big(& \bigotimes_{a\in\Sigma} (x \in X^{\mathrm{push}}_{p,a,q} \otimes \mathrm{wt}_{\mathrm{push}}(p,a,q)) \oplus (\neg(x \in X^{\mathrm{push}}_{p,a,q}) \otimes 1) \\
& \otimes \bigotimes_{a\in\Sigma} (x \in X^{\mathrm{shift}}_{p,a,q} \otimes \mathrm{wt}_{\mathrm{push}}(p,a,q)) \oplus (\neg(x \in X^{\mathrm{shift}}_{p,a,q}) \otimes 1) \\
& \otimes \bigotimes_{r\in Q} (x \in X^{\mathrm{pop}}_{p,q,r} \otimes \mathrm{wt}_{\mathrm{push}}(p,q,r)) \oplus (\neg(x \in X^{\mathrm{pop}}_{p,q,r}) \otimes 1)\Big) \ .
\end{aligned}$$

Here, the second part of θ multiplies up all weights of the encountered transitions. This is the crucial part where we either need that $\mathbb{K}$ is commutative or all pop weights are trivial because the product quantifier of θ assigns the pop weight at a different position than the occurrence of the respective pop transition in the automaton. Using only one product quantifier (weighted universal quantifier) this is unavoidable, since the number of pops at a given position is only bounded by the word length.

Since the subformulas $x \in X^{()}_{()} \otimes \mathrm{wt}(...)$ of θ are almost boolean, the subformula $\prod_x(...)$ of θ is $\prod$-restricted. Also, ψ is boolean and so θ is $\otimes$-restricted. Thus, θ is a restricted formula. Finally, we define $\varphi = \bigoplus_{X_1} \bigoplus_{X_2} ... \bigoplus_{X_m} \theta$. This implies $[\![\varphi]\!](w) = [\![\mathcal{A}]\!](w)$, for all $w \in (\Sigma^+, M)$. Therefore, φ is our required restricted sentence with $[\![\mathcal{A}]\!] = [\![\varphi]\!]$. ◀

By Proposition 18 and Proposition 19, we obtain the main result of this section.

▶ **Theorem 20.** *Let $\mathbb{K}$ be a semiring and $S : (\Sigma^+, M) \to K$ a series.*

1. *The following are equivalent:*
   - **(a)** *$S = [\![\mathcal{A}]\!]$ for some rwOPA.*
   - **(b)** *$S = [\![\varphi]\!]$ for some restricted sentence φ of* MSO($\mathbb{K}$).
2. *Let $\mathbb{K}$ be commutative. Then, the following are equivalent:*
   - **(a)** *$S = [\![\mathcal{A}]\!]$ for some wOPA.*
   - **(b)** *$S = [\![\varphi]\!]$ for some restricted sentence φ of* MSO($\mathbb{K}$).

Theorem 20 shows that the typical logical characterization of weighted languages does not generalize in the same way to the whole class wOPL: for non-rwOPL we need the extra hypothesis that $\mathbb{K}$ be commutative. Notice, however, that rwOPL may execute unbounded pop sequences; thus, they are powerful enough to include languages that are neither real-time nor visible. This remark naturally raises new intriguing questions which we will briefly address in the conclusion.

6 Conclusion

This paper moves a further step in the path of generalizing a series of results beyond the barrier of regular and structured – or visible – CFL [27, 33, 2, 25]. We introduced and

investigated weighted operator precedence automata and a corresponding weighted MSO logic. In our main results we show, for any semiring, that wOPA without pop weights and a restricted weighted MSO logic have the same expressive power. Furthermore, these behaviors can also be described as homomorphic images of the behaviors of particularly simple wOPA reduced to arbitrary unweighted OPA. If the semiring is commutative, these results apply also to wOPA with arbitrary pop weights.

Theorem 20 also raises the problems to find, for arbitrary semirings and for wOPA with pop weights, both an expressively equivalent weighted MSO logic and a Nivat-type result. In [16], very similar problems arose for weighted automata on unranked trees and weighted MSO logic. In [12], the authors showed that with another definition of the behavior of weighted unranked tree automata, an equivalence result for the restricted weighted MSO logic could be derived. Is there another definition of the behavior of wOPA (with pop weights) making them expressively equivalent to our restricted weighted MSO logic?

In [25], OPL of infinite words were investigated and shown to be practically important, so the problem arises to develop a theory of wOPA on infinite words. In order to define their quantitative behaviors, one could try to use valuation monoids as in [14, 9].

Finally, a new investigation field can be opened by exploiting the natural suitability of OPL towards parallel elaboration [3]. Computing weights, in fact, can be seen as a special case of semantic elaboration which can be performed hand-in-hand with parsing. In this case too, we can expect different challenges depending on whether the weight semiring is commutative or not and/or weights are attached to pop transitions too, which would be the natural way to follow the traditional semantic evaluation through synthesized attributes [22].

Abstract

Propositional and modal inclusion logic are formalisms that belong to the family of logics based on team semantics. This article investigates the model checking and validity problems of these logics. We identify complexity bounds for both problems, covering both lax and strict team semantics. By doing so, we come close to finalising the programme that ultimately aims to classify the complexities of the basic reasoning problems for modal and propositional dependence, independence, and inclusion logics.

1 Introduction

Team semantics is the mathematical framework of modern logics of dependence and independence, which, unlike Tarski semantics, is not based on singletons as satisfying elements (e.g., first-order assignments or points of a Kripke structure) but on sets of such elements. More precisely, a first-order team is a set of first-order assignments that have the same domain of variables. As a result, a team can be interpreted as a database table, where variables correspond to attributes and assignments to records. Team semantics originates from the work of Hodges [17], where it was shown that Hintikka's IF-logic can be based on a compositional (as opposed to game-theoretic) semantics. In 2007, Väänänen [24] proposed a fresh approach to logics of dependence and independence. Väänänen adopted team semantics as a core notion for his *dependence logic*. Dependence logic extends first-order logic by atomic statements such as *the value of variable x is determined by the value of y*. Such a statement is not meaningful under a single assignment, however, when evaluated over a team, such a statement corresponds precisely to functional dependence of database theory when the team is interpreted as a database table.

Besides functional dependence, there are many other important dependency notions used in fields like statistics and database theory, which give rise to interesting logics based on team semantics. The two most widely studied of these new logics are *independence logic* of Grädel and Väänänen [10], and *inclusion logic* of Galliani [5]. Inclusion logic extends first-order logic by atomic statements of the form $x \subseteq y$, which is satisfied in a team X if any value that appears as a value for x in X also appears as a value of y in X. Dependence and independence logics are equi-expressive with existential second-order logic and thus capture the complexity class NP [24, 10]. Surprisingly, inclusion logic has the same expressive power as *positive greatest fixed point logic* GFP^+ [7]. Since on finite structures, GFP^+ coincides with *least fixed point logic* LFP, it follows from the Immermann-Vardi-Theorem that inclusion logic captures the complexity class P on finite ordered structures. Interestingly under a semantical variant of inclusion logic called *strict semantics* the expressive power of inclusion logic rises to existential second-order logic [6]. Moreover, the fragment of inclusion logic (under strict semantics) in which only k universally quantified variables may occur captures the complexity class $\mathsf{NTIME}_{\mathsf{RAM}}(n^k)$ (i.e., structures that can be recognised by a nondeterministic random access machine in time $\mathcal{O}(n^k)$) [11]. The above characterisations exemplify that, indeed, inclusion logic and its fragments have very compelling descriptive complexity-theoretic properties.

In this paper, we study propositional and modal inclusion logic under both the standard semantics (i.e., *lax semantics*) and strict semantics. The research around propositional and modal logics with team semantics has concentrated on classifying the complexity and definability of the related logics. Due to very active research efforts, the complexity and definability landscape of these logics is understood rather well; see the survey of Durand et al. [4] and the references therein for an overview of the current state of the research. In the context of propositional logic (modal logic, resp.) a team is a set of propositional assignments with a common domain of variables (a subset of the domain a Kripke structure, resp.). *Extended propositional inclusion logic* (*extended modal inclusion logic*, resp.) extends propositional logic (modal logic, resp.) with *propositional inclusion atoms* $\varphi \subseteq \psi$, where φ and ψ are formulae of propositional logic (modal logic, resp.). Inclusion logics have fascinating properties also in the propositional setting. The following definability results hold for the standard lax semantics. A class of team pointed Kripke models is definable in extended modal inclusion logic iff $(\mathfrak{M}, \emptyset)$ is in the class for every model $\mathfrak{M}$, the class is closed under taking unions, and the class is closed under the so-called *team k-bisimulation*, for some finite k [16]. From this, a corresponding characterisation for extended propositional inclusion logic directly follows: a class of propositional teams is definable in extended propositional inclusion logic iff the empty team is in the class, and the class is closed under taking unions. In [21, 22] (global) model definability and frame definability of team based modal logics are studied. It is shown that surprisingly, in both cases, (extended) modal inclusion logic collapses to modal logic.

This paper investigates the complexity of the model checking and the validity problem for propositional and modal inclusion logic. The complexity of the satisfiability problem of modal inclusion logic was studied by Hella et al. [15]. The study on the validity problem of propositional inclusion logic was initiated by Hannula et al. [12], where the focus was on more expressive logics in the propositional setting. Consequently, the current paper directly extends the research effort initiated in these papers. It is important to note that since the logics studied in this paper are not closed under taking negations, the connection between the satisfiability problem and the validity problem fails. In [12] it was shown that, under lax semantics, the validity problem for propositional inclusion logic is coNP-complete. Here we obtain an identical result for the strict semantics. However, surprisingly, for model checking

the picture looks quite different. We establish that whereas the model checking problem for propositional inclusion logic is P-complete under lax semantics, the problem becomes NP-complete for the strict variant. Also surprisingly, for model checking in the modal setting, we obtain the identical results (as in the propositional setting): modal inclusion logic is P-complete under lax semantics and NP-complete under strict semantics. Nevertheless, for the validity problem, the modal variants are much more complex than the propositional ones; we establish coNEXP-hardness for both strict and lax semantics.

2 Propositional logics with team semantics

Let D be a finite, possibly empty set of proposition symbols. A function $s\colon D \to \{0,1\}$ is called an *assignment*. A set X of assignments $s\colon D \to \{0,1\}$ is called a *team*. The set D is the *domain* of X. We denote by 2^D the set of *all assignments* $s\colon D \to \{0,1\}$. If $\vec{p} = (p_1, \ldots, p_n)$ is a tuple of propositions and s is an assignment, we write $s(\vec{p})$ for $(s(p_1), \ldots, s(p_n))$.

Let Φ be a set of proposition symbols. The syntax of propositional logic $\mathsf{PL}(\Phi)$ is given by the following grammar: $\varphi ::= p \mid \neg p \mid (\varphi \wedge \varphi) \mid (\varphi \vee \varphi)$, where $p \in \Phi$.

We denote by $\models_{\mathsf{PL}}$ the ordinary satisfaction relation of propositional logic defined via assignments in the standard way. Next we give team semantics for propositional logic.

▶ **Definition 1** (Lax team semantics)**.** Let Φ be a set of atomic propositions and let X be a team. The satisfaction relation $X \models \varphi$ is defined as follows.

$$\begin{aligned} X \models p &\quad\Leftrightarrow\quad \forall s \in X : s(p) = 1, \\ X \models \neg p &\quad\Leftrightarrow\quad \forall s \in X : s(p) = 0. \\ X \models (\varphi \wedge \psi) &\quad\Leftrightarrow\quad X \models \varphi \text{ and } X \models \psi. \\ X \models (\varphi \vee \psi) &\quad\Leftrightarrow\quad Y \models \varphi \text{ and } Z \models \psi, \text{ for some } Y, Z \text{ such that } Y \cup Z = X. \end{aligned}$$

The lax team semantics is considered to be the standard semantics for team-based logics. In this paper, we also consider a variant of team semantics called the *strict team semantics*. In strict team semantics, the above clause for disjunction is redefined as follows:

$$X \models_{\mathsf{str}} (\varphi \vee \psi) \;\Leftrightarrow\; Y \models \varphi \text{ and } Z \models \psi, \text{ for some } Y, Z \text{ such that } Y \cap Z = \emptyset \text{ and } Y \cup Z = X.$$

When L denotes a team-based propositional logic, we let $\mathsf{L}_{\mathsf{str}}$ denote the variant of the logic with strict semantics. Moreover, in order to improve readability, for strict semantics we use $\models_{\mathsf{str}}$ instead of $\models$. As a result lax semantics is used unless otherwise specified. The next proposition shows that the team semantics and the ordinary semantics for propositional logic defined via assignments (denoted by $\models_{\mathsf{PL}}$) coincide.

▶ **Proposition 2** ([24])**.** *Let φ be a formula of propositional logic and let X be a propositional team. Then $X \models \varphi$ iff $\forall s \in X : s \models_{\mathsf{PL}} \varphi$.*

The syntax of *propositional inclusion logic* $\mathsf{PInc}(\Phi)$ is obtained by extending the syntax of $\mathsf{PL}(\Phi)$ by the grammar rule $\varphi ::= \vec{p} \subseteq \vec{q}$, where $\vec{p}$ and $\vec{q}$ are finite tuples of proposition variables with the same length. The semantics for propositional inclusion atoms is defined as follows:

$$X \models \vec{p} \subseteq \vec{q} \text{ iff } \forall s \in X \, \exists t \in X : s(\vec{p}) = t(\vec{q}).$$

▶ Remark. *Extended propositional inclusion logic* is the variant of PInc in which inclusion atoms of the form $\vec{\varphi} \subseteq \vec{\psi}$, where $\vec{\varphi}$ and $\vec{\psi}$ are tuples of PL-formulae, are allowed. Observe that this extension does not increase the complexity of the logic and on that account, in this paper, we only consider the non-extended variant.

	p	q	r
s_1	1	0	0
s_2	1	1	1
s_3	0	1	0

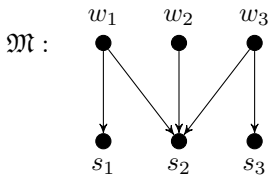

Figure 1 Assignments for teams in Example 4 and the Kripke model for Example 19.

Table 1 Complexity of the satisfiability, validity and model checking problems for propositional logics under both systems of semantics. The shown complexity classes refer to completeness results. † In [15] NEXP-completeness is claimed. However there is a mistake in the proof and the authors of [15] now have a proof for EXP-completeness.

	Satisfiability		Validity		Model checking	
	strict	lax	strict	lax	strict	lax
PL	— NP [3, 19] —		—— coNP [3, 19] ——		——— NC[1] [1] ———	
PInc	EXP†	EXP [15]	coNP [Th. 6]	coNP [12]	NP [Th. 14]	P [Th. 10]

Note that PInc is not a downward closed logic[1]. However, analogously to FO-inclusion-logic [5], satisfaction of PInc-formulas is closed under taking unions.

▶ **Proposition 3** (Closure under unions). *Let $\varphi \in \mathsf{PInc}$ and let X_i, for $i \in I$, be teams. Suppose that $X_i \models \varphi$ for each $i \in I$. Then $\bigcup_{i\in I} X_i \models \varphi$.*

Similarly as in first-order team semantics [5], also for propositional logic the strict and the lax semantics coincide; meaning that $X \models \varphi$ iff $X \models_{\mathsf{str}} \varphi$ for all X and φ. However this does not hold for propositional inclusion logic, for the following example shows that $\mathsf{PInc}_{\mathsf{str}}$ is not union closed. Moreover, we will show that the two different semantics lead to different complexities for the related model checking problems.

▶ **Example 4.** Let s_1, s_2, and s_3 be as in Figure 1 and define $\varphi := \big(p \wedge (p \subseteq r)\big) \vee \big(q \wedge (q \subseteq r)\big)$. Note that $\{s_1, s_2\} \models_{\mathsf{str}} \varphi$ and $\{s_2, s_3\} \models_{\mathsf{str}} \varphi$, but $\{s_1, s_2, s_3\} \not\models_{\mathsf{str}} \varphi$.

However, $\mathsf{PInc}_{\mathsf{str}}$ satisfies a useful weaker form of union closure: it is straightforward to prove by an induction on the formula structure that it is closed under unions of *singleton teams*.

▶ **Lemma 5.** *Let X be a team and $\varphi \in \mathsf{PInc}_{\mathsf{str}}$. If $\{s\} \models_{\mathsf{str}} \varphi$ for every $s \in X$, then $X \models_{\mathsf{str}} \varphi$.*

3 Complexity of propositional inclusion logic

We now define the model checking, satisfiability, and validity problems in the context of team semantics. Let L be a propositional logic with team semantics. A formula $\varphi \in \mathsf{L}$ is *satisfiable*, if there exists a non-empty team X such that $X \models \varphi$. A formula $\varphi \in \mathsf{L}$ is *valid* if $X \models \varphi$ holds for all teams X such that the propositions in φ are in the domain of X. The

[1] A logic L is downward closed if "$X \models \varphi$ and $Y \subseteq X$ implies $Y \models \varphi$" holds for every formula $\varphi \in \mathsf{L}$ and teams X and Y.

satisfiability problem SAT(L) and the validity problem VAL(L) are defined in an obvious way: Given a formula $\varphi \in \mathsf{L}$, decide whether the formula is satisfiable (valid, respectively). For the model checking problem MC(L) we consider combined complexity: Given a formula $\varphi \in \mathsf{L}$ and a team X, decide whether $X \models \varphi$. See Table 1 for known complexity results for PL and PInc, together with partial results of this paper.

It was shown by Hannula et al. [12] that the validity problem of PInc is coNP-complete. Here we establish that the corresponding problem for $\mathsf{PInc}_{\mathsf{str}}$ is also coNP-complete. Our proof is similar to theirs [12], except that instead of union closure we use Lemma 5.

▶ **Theorem 6.** *The validity problem for* $\mathsf{PInc}_{\mathsf{str}}$ *is* coNP*-complete w.r.t.* $\leq_m^{\log}$.

Proof Sketch. The coNP-hardness follows from the fact that PL is a sublogic of $\mathsf{PInc}_{\mathsf{str}}$ and since the validity problem of PL is coNP-hard. On the other hand, by Lemma 5, a formula $\varphi \in \mathsf{PInc}_{\mathsf{str}}$ is valid iff it is satisfied by all singleton teams $\{s\}$. It is easy to see that, over a singleton team $\{s\}$, any inclusion atom is equivalent to a short PL-formula. Consequently, there is a short PL-formula φ^* which is valid iff φ is valid. Since VAL(PL) is in coNP, the same holds for VAL($\mathsf{PInc}_{\mathsf{str}}$). ◀

3.1 Model checking in lax semantics is P-complete

In this section we construct a reduction from the monotone circuit value problem to the model checking problem of PInc. For a deep introduction to circuits see Vollmer [25].

▶ **Definition 7.** A *monotone Boolean circuit* with n input gates and one output gate is a 3-tuple $C = (V, E, \alpha)$, where (V, E) is a finite, simple, directed, acyclic graph, and $\alpha\colon V \to \{\vee, \wedge, x_1, \ldots, x_n\}$ is a function such that the following conditions hold:

1. Every $v \in V$ has in-degree 0 or 2.
2. There exists exactly one $w \in V$ with out-degree 0. We call this node w the *output gate* of C and denote it by g_{out}.
3. If $v \in V$ is a node with in-degree 0, then $\alpha(v) \in \{x_1, \ldots, x_n\}$.
4. If $v \in V$ has in-degree 2, then $\alpha(v) \in \{\vee, \wedge\}$.
5. For each $1 \leq i \leq n$, there exists exactly one $v \in V$ with $\alpha(v) = x_i$.

Let $C = (V, E, \alpha)$ be a monotone Boolean circuit with n input gates and one output gate. Any sequence $b_1, \ldots, b_n \in \{0, 1\}$ of bits of length n is called an *input* to the circuit C. A function $\beta\colon V \to \{0, 1\}$ defined such that

$$\beta(v) := \begin{cases} b_i & \text{if } \alpha(v) = x_i \\ \min\big(\beta(v_1), \beta(v_2)\big) & \text{if } \alpha(v) = \wedge, \text{ where } v_1 \neq v_2 \text{ and } (v_1, v), (v_2, v) \in E, \\ \max\big(\beta(v_1), \beta(v_2)\big) & \text{if } \alpha(v) = \vee, \text{ where } v_1 \neq v_2 \text{ and } (v_1, v), (v_2, v) \in E. \end{cases}$$

is called the *valuation of the circuit* C *under the input* $b_1, \ldots, b_n$. The *output of the circuit* C is then defined to be $\beta(g_{\text{out}})$.

The *monotone circuit value problem* (MCVP) is the following decision problem: Given a monotone circuit C and an input $b_1, \ldots, b_n \in \{0, 1\}$, is the output of the circuit 1?

▶ **Proposition 8** ([9])**.** MCVP *is* P*-complete w.r.t.* $\leq_m^{\log}$ *reductions.*

▶ **Lemma 9.** MC(PInc) *under lax semantics is* P*-hard w.r.t.* $\leq_m^{\log}$.

Proof. We will establish a $\leq_m^{\log}$-reduction from MCVP to the model checking problem of PInc under lax semantics. Since MCVP is P-complete, the claim follows. More precisely, we will show how to construct, for each monotone Boolean circuit C with n input gates and for each input $\vec{b}$ for C, a team $X_{C,\vec{b}}$ and a PInc-formula φ_C such that $X_{C,\vec{b}} \models \varphi_C$ iff the output of the circuit C with the input $\vec{b}$ is 1.

We use teams to encode valuations of the circuit. For each gate v_i of a given circuit, we identify an assignment s_i. The crude idea is that if s_i is in the team under consideration, the value of the gate v_i with respect to the given input is 1. The formula φ_C is used to quantify a truth value for each Boolean gate of the circuit, and then for checking that the truth values of the gates propagate correctly. We next define the construction formally.

Let $C = (V, E, \alpha)$ be a monotone Boolean circuit with n input gates and one output gate and let $\vec{b} = (b_1 \dots b_n) \in \{0,1\}^n$ be an input to the circuit C. We define that $V = \{v_0, \dots, v_m\}$ and that v_0 is the output gate of C. Define

$$\tau_C := \{p_0, \dots, p_m, p_\top, p_\bot\} \cup \{p_{k=i\vee j} \mid i < j, \alpha(v_k) = \vee, \text{ and } (v_i, v_k), (v_j, v_k) \in E\}.$$

For each $i \leq m$, we define the assignment $s_i \colon \tau_C \to \{0,1\}$ as follows:

$$s_i(p) := \begin{cases} 1 & \text{if } p = p_i \text{ or } p = p_\top, \\ 1 & \text{if } p = p_{k=i\vee j} \text{ or } p = p_{k=j\vee i} \text{ for some } j,k \leq m, \\ 0 & \text{otherwise.} \end{cases}$$

Furthermore, we define $s_\bot(p) = 1$ iff $p = p_\bot$ or $p = p_\top$. We note that the assignment $s_\bot$ will be the only assignment that maps $p_\bot$ to 1. We make use of the fact that for each gate v_i of C, it holds that $s_\bot(p_i) = 0$. We define

$$X_{C,\vec{b}} := \big\{s_i \mid \alpha(v_i) \in \{\wedge, \vee\}\big\} \cup \big\{s_i \mid \alpha(v_i) \in \{x_i \mid b_i = 1\}\big\} \cup \{s_\bot\},$$

that is, $X_{C,\vec{b}}$ consists of assignments for each of the Boolean gates, assignments for those input gates that are given 1 as an input, and of the auxiliary assignment $s_\bot$.

Let X be any nonempty subteam of $X_{C,\vec{b}}$ such that $s_\bot \in X$. We have

$$\begin{aligned} &X \models p_\top \subseteq p_0 && \text{iff } s_0 \in X \\ &X \models p_i \subseteq p_j && \text{iff } (s_i \in X \text{ implies } s_j \in X) \\ &X \models p_k \subseteq p_{k=i\vee j} && \text{iff } (i < j, (v_i, v_k), (v_j, v_k) \in E, \alpha(v_k) = \vee \\ & && \quad \text{and } s_k \in X \text{ implies that } s_i \in X \text{ or } s_j \in X) \end{aligned} \tag{1}$$

Recall the intuition that $s_i \in X$ should hold iff the value of the gate v_i is 1. Define

$$\begin{aligned} \psi_{\text{out}=1} &:= p_\top \subseteq p_0, \\ \psi_\wedge &:= \bigwedge\{p_i \subseteq p_j \mid (v_j, v_i) \in E \text{ and } \alpha(p_i) = \wedge\}, \\ \psi_\vee &:= \bigwedge\{p_k \subseteq p_{k=i\vee j} \mid i < j, (v_i, v_k) \in E, (v_j, v_k) \in E, \text{ and } \alpha(v_k) = \vee\}, \\ \varphi_C &:= \neg p_\bot \vee (\psi_{\text{out}=1} \wedge \psi_\wedge \wedge \psi_\vee). \end{aligned}$$

Now observe that $X_{C,\vec{b}} \models \varphi_C$ iff the output of C with the input $\vec{b}$ is 1.

The idea of the reduction is the following: The disjunction in ϕ_C is used to guess a team Y for the right disjunct that encodes the valuation β of the circuit C. The right disjunct is then evaluated with respect to the team Y with the intended meaning that $\beta(v_i) = 1$

whenever $s_i \in Y$. Note that Y is always as required in (1). The formula $\psi_{\text{out}=1}$ is used to state that $\beta(v_0) = 1$, whereas the formulae $\psi_\wedge$ and $\psi_\vee$ are used to propagate the truth value 1 down the circuit. The assignment $s_\bot$ and the proposition $p_\bot$ are used as an auxiliary to make sure that Y is nonempty and to deal with the propagation of the value 0 by the subformulae of the form $p_i \subseteq p_j$. Finally, it is easy to check that the reduction can be computed in logspace. ◀

For the proof of the above lemma it is not important that lax semantics is considered; the same proof works also for the strict semantics. However, as we will show in the next section, we can show a stronger result for the model checking problem of $\mathsf{PInc}_{\mathsf{str}}$; namely that it is NP-hard. In Section 5.1 we will show that the model checking problem for modal inclusion logic with lax semantics is in P (Lemma 21). Since PInc is essentially a fragment of this logic, by combining Lemmas 9 and 21, we obtain the following theorem.

▶ **Theorem 10.** MC(PInc) *under lax semantics is* P*-complete w.r.t.* $\leq_m^{\log}$.

3.2 Model checking in strict semantics is NP-complete

In this section we reduce the set splitting problem, a well-known NP-complete problem, to the model checking problem of $\mathsf{PInc}_{\mathsf{str}}$.

▶ **Definition 11.** The *set splitting* problem is the following decision problem:
Input: A family $\mathcal{F}$ of subsets of a finite set S.
Problem: Do there exist subsets S_1 and S_2 of S such that
1. S_1 and S_2 are a partition of S (i.e., $S_1 \cap S_2 = \emptyset$ and $S_1 \cup S_2 = S$),
2. for each $A \in \mathcal{F}$, there exist $a_1, a_2 \in A$ such that $a_1 \in S_1$ and $a_2 \in S_2$?

▶ **Proposition 12** ([8])**.** *The set splitting problem is* NP*-complete w.r.t.* $\leq_m^{\log}$.

The following proof relies on the fact that strict semantics is considered. It cannot hold for lax semantics unless P = NP.

▶ **Lemma 13.** MC($\mathsf{PInc}_{\mathsf{str}}$) *is* NP*-hard with respect to* $\leq_m^{\log}$.

Proof. We give a reduction from the set splitting problem to the model checking problem of PInc under strict semantics.

Let $\mathcal{F}$ be an instance of the set splitting problem. We stipulate that $\mathcal{F} = \{B_1, \ldots, B_n\}$ and that $\bigcup \mathcal{F} = \{a_1, \ldots, a_k\}$, where $n, k \in \mathbb{N}$. We will introduce fresh propositions p_i and q_j for each point $a_i \in \bigcup \mathcal{F}$ and set $B_j \in \mathcal{F}$. We will then encode the family of sets $\mathcal{F}$ by assignments over these propositions; each assignment s_i will correspond to a unique point a_i. Formally, let $\tau_{\mathcal{F}}$ denote the set $\{p_1, \ldots, p_k, q_1, \ldots, q_n, p_\top, p_c, p_d\}$ of propositions. For each $i \in \{1, \ldots, k, c, d\}$, we define the assignment $s_i \colon \tau_{\mathcal{F}} \to \{0, 1\}$ as follows:

$$s_i(p) := \begin{cases} 1 & \text{if } p = p_i \text{ or } p = p_\top, \\ 1 & \text{if, for some } j,\ p = q_j \text{ and } a_i \in B_j, \\ 0 & \text{otherwise.} \end{cases}$$

Define $X_{\mathcal{F}} := \{s_1, \ldots, s_k, s_c, s_d\}$, that is, $X_{\mathcal{F}}$ consists of assignments s_i corresponding to each of the points $a_i \in \bigcup \mathcal{F}$ and of two auxiliary assignments s_c and s_d. Note that the only assignment in $X_{\mathcal{F}}$ that maps p_c (p_d, resp.) to 1 is s_c (s_d, resp.) and that every assignment

maps $p_\top$ to 1. Moreover, note that for $1 \leq i \leq k$ and $1 \leq j \leq n$, $s_i(q_j) = 1$ iff $a_i \in B_j$. Now define

$$\varphi_{\mathcal{F}} := \big(\neg p_c \wedge \bigwedge_{i \leq n} p_\top \subseteq q_i\big) \vee \big(\neg p_d \wedge \bigwedge_{i \leq n} p_\top \subseteq q_i\big).$$

We claim that $X_{\mathcal{F}} \models_{\mathsf{str}} \varphi_{\mathcal{F}}$ iff the output of the set splitting problem with input $\mathcal{F}$ is "yes". ◀

In Section 5.1 we establish that the model checking problem of modal inclusion logic with strict semantics is in NP (Theorem 24). Since $\mathsf{PInc}_{\mathsf{str}}$ is essentially a fragment of this logic, together with Lemma 13, we obtain the following theorem.

▶ **Theorem 14.** $\mathrm{MC}(\mathsf{PInc}_{\mathsf{str}})$ *is* NP*-complete with respect to* $\leq_m^{\log}$.

4 Modal logics with team semantics

Let Φ be a set of proposition symbols. The syntax of modal logic $\mathsf{ML}(\Phi)$ is generated by the following grammar: $\varphi ::= p \mid \neg p \mid (\varphi \wedge \varphi) \mid (\varphi \vee \varphi) \mid \Diamond\varphi \mid \Box\varphi$, where $p \in \Phi$. By $\varphi^\perp$ we denote the formula that is obtained from $\neg\varphi$ by pushing all negation symbols to the atomic level using the standard duality between $\wedge$ ($\Box$) and $\vee$ ($\Diamond$). A (Kripke) Φ-*model* is a tuple $\mathfrak{M} = (W, R, V)$, where W, called the *domain* of $\mathfrak{M}$, is a non-empty set, $R \subseteq W \times W$ is a binary relation, and $V\colon \Phi \to \mathcal{P}(W)$ is a valuation of the proposition symbols. By $\models_{\mathsf{ML}}$ we denote the *satisfaction relation* of modal logic that is defined via pointed Φ-*models* in the standard way. Any subset T of the domain of a Kripke model $\mathfrak{M}$ is called *a team of* $\mathfrak{M}$. Before we define *team semantics* for ML, we introduce some auxiliary notation.

▶ **Definition 15.** Let $\mathfrak{M} = (W, R, V)$ be a model and T and S teams of $\mathfrak{M}$. Define that

$$R[T] := \{w \in W \mid \exists v \in T \text{ s.t. } vRw\} \text{ and } R^{-1}[T] := \{w \in W \mid \exists v \in T \text{ s.t. } wRv\}.$$

For teams T and S of $\mathfrak{M}$, we write $T[R]S$ if $S \subseteq R[T]$ and $T \subseteq R^{-1}[S]$.

Accordingly, $T[R]S$ holds if and only if for every $w \in T$, there exists some $v \in S$ such that wRv, and for every $v \in S$, there exists some $w \in T$ such that wRv. We are now ready to define team semantics for ML.

▶ **Definition 16** (Lax team semantics)**.** Let $\mathfrak{M}$ be a Kripke model and T a team of $\mathfrak{M}$. The satisfaction relation $\mathfrak{M}, T \models \varphi$ for $\mathsf{ML}(\Phi)$ is defined as follows.

$$\begin{aligned}
\mathfrak{M}, T \models p &\;\Leftrightarrow\; w \in V(p) \text{ for every } w \in T.\\
\mathfrak{M}, T \models \neg p &\;\Leftrightarrow\; w \notin V(p) \text{ for every } w \in T.\\
\mathfrak{M}, T \models (\varphi \wedge \psi) &\;\Leftrightarrow\; \mathfrak{M}, T \models \varphi \text{ and } \mathfrak{M}, T \models \psi.\\
\mathfrak{M}, T \models (\varphi \vee \psi) &\;\Leftrightarrow\; \mathfrak{M}, T_1 \models \varphi \text{ and } \mathfrak{M}, T_2 \models \psi \text{ for some } T_1 \text{ and } T_2 \text{ s.t. } T_1 \cup T_2 = T.\\
\mathfrak{M}, T \models \Diamond\varphi &\;\Leftrightarrow\; \mathfrak{M}, T' \models \varphi \text{ for some } T' \text{ s.t. } T[R]T'.\\
\mathfrak{M}, T \models \Box\varphi &\;\Leftrightarrow\; \mathfrak{M}, T' \models \varphi, \text{ where } T' = R[T].
\end{aligned}$$

Analogously to the propositional case, we also consider the *strict* variant of team semantics for modal logic. In the *strict* team semantics, we have the following alternative semantic definitions for the disjunction and diamond (where W denotes the domain of $\mathfrak{M}$).

$$\begin{aligned}
\mathfrak{M}, T \models_{\mathsf{str}} (\varphi \vee \psi) &\;\Leftrightarrow\; \mathfrak{M}, T_1 \models \varphi \text{ and } \mathfrak{M}, T_2 \models \psi\\
&\qquad \text{for some } T_1 \text{ and } T_2 \text{ such that } T_1 \cup T_2 = T \text{ and } T_1 \cap T_2 = \emptyset.\\
\mathfrak{M}, T \models_{\mathsf{str}} \Diamond\varphi &\;\Leftrightarrow\; \mathfrak{M}, f(T) \models \varphi \text{ for some } f\colon T \to W \text{ s.t. } \forall w \in T : wRf(w).
\end{aligned}$$

Table 2 Complexity of satisfiability, validity and model checking for modal logics under both strict and lax semantics. The given complexity classes refer to completeness results and "-h." denotes hardness. The complexities for Minc and EMinc coincide, see Theorems 23, 24, and 26.
† In [15] NEXP-completeness is claimed. However there is a mistake in the proof and the authors of [15] now have a proof for EXP-completeness.

	Satisfiability		Validity		Model checking	
	strict	lax	strict	lax	strict	lax
ML	- PSPACE [18] -		PSPACE [18]		P [2, 23]	
Minc	EXP†	EXP [15]	coNEXP-h. [Th. 25]	coNEXP-h. [Th. 25]	NP [Th. 24]	P [Th. 23]

When L is a team-based modal logic, we let $\mathsf{L}_{\mathsf{str}}$ to denote its variant with strict semantics. As in the propositional case, for strict semantics we use $\models_{\mathsf{str}}$ instead of $\models$. The formulae of ML have the following flatness property.

▶ **Proposition 17** (Flatness, see, e.g., [4]). *Let $\mathfrak{M}$ be a Kripke model and T be a team of $\mathfrak{M}$. Then, for every formula φ of $\mathsf{ML}(\Phi)$: $\mathfrak{M}, T \models \varphi \Leftrightarrow \forall w \in T : \mathfrak{M}, w \models_{\mathsf{ML}} \varphi$.*

The syntax of *modal inclusion logic* $\mathsf{Minc}(\Phi)$ and *extended modal inclusion logic* $\mathsf{EMinc}(\Phi)$ is obtained by extending the syntax of $\mathsf{ML}(\Phi)$ by the following grammar rule for each $n \in \mathbb{N}$:

$$\varphi ::= \varphi_1, \ldots, \varphi_n \subseteq \psi_1, \ldots, \psi_n,$$

where $\varphi_1, \psi_1, \ldots, \varphi_n, \psi_n \in \mathsf{ML}(\Phi)$. Additionally, for $\mathsf{Minc}(\Phi)$, we require that φ_1, ψ_1, …, φ_n, ψ_n are proposition symbols. The semantics for these inclusion atoms is defined as follows:

$$\mathfrak{M}, T \models \varphi_1, \ldots, \varphi_n \subseteq \psi_1, \ldots, \psi_n \Leftrightarrow \forall w \in T \exists v \in T : \bigwedge_{1 \leq i \leq n} (\mathfrak{M}, \{w\} \models \varphi_i \Leftrightarrow \mathfrak{M}, \{v\} \models \psi_i).$$

The following proposition is proven in the same way as the analogous results for first-order inclusion logic [5]. A modal logic L is union closed if $\mathfrak{M}, T \models \varphi$ and $\mathfrak{M}, S \models \varphi$ implies that $\mathfrak{M}, T \cup S \models \varphi$, for every $\varphi \in \mathsf{L}$.

▶ **Proposition 18** (Union Closure). *The logics* ML, Minc, EMinc *are union closed.*

Analogously to the propositional case, it is easy to establish that for ML the strict and the lax semantics coincide (for a proof in the first-order setting see [5]). Again, as in the propositional case, this does not hold for Minc or EMinc. Note that since $\mathsf{PInc}_{\mathsf{str}}$ is not union closed, neither is $\mathsf{Minc}_{\mathsf{str}}$, nor $\mathsf{EMinc}_{\mathsf{str}}$.

In contrary to the propositional case, Lemma 5 fails in the modal case as the following example illustrates.

▶ **Example 19.** Let $\mathfrak{M}$ be as depicted in the table of Figure 1 and let φ denote the $\mathsf{PInc}_{\mathsf{str}}$-formula of Example 4. Now $\mathfrak{M}, \{w_i\} \models_{\mathsf{str}} \Box\varphi$, for $i \in \{1, 2, 3\}$, but $\mathfrak{M}, \{w_1, w_2, w_3\} \not\models_{\mathsf{str}} \Box\varphi$.

5 Model checking and validity in modal team semantics

The model checking, satisfiability, and validity problems in the context of team semantics of modal logic are defined analogously to the propositional case. Let $\mathsf{L}(\Phi)$ be a modal logic with team semantics. A formula $\varphi \in \mathsf{L}(\Phi)$ is *satisfiable*, if there exists a Kripke Φ-model

$\mathfrak{M}$ and a non-empty team T of $\mathfrak{M}$ such that $\mathfrak{M}, T \models \varphi$. A formula $\varphi \in \mathsf{L}(\Phi)$ is *valid*, if $\mathfrak{M}, T \models \varphi$ holds for every Φ-model $\mathfrak{M}$ and every team T of $\mathfrak{M}$. The satisfiability problem SAT(L) and the validity problem VAL(L) are defined in the obvious way: Given a formula $\varphi \in \mathsf{L}$, decide whether the formula is satisfiable (valid, respectively). For model checking MC(L) we consider combined complexity: Given a formula $\varphi \in \mathsf{L}$, a Kripke model $\mathfrak{M}$, and a team T of $\mathfrak{M}$, decide whether $\mathfrak{M}, T \models \varphi$. See Table 2 for known complexity results on ML and Minc, together with partial results of this paper.

5.1 Complexity of model checking

Let $\mathfrak{M}$ be a Kripke model, T be a team of $\mathfrak{M}$, and φ be a formula of Minc. By $\mathrm{maxsub}(T, \varphi)$, we denote the maximum subteam T' of T such that $\mathfrak{M}, T' \models \varphi$. Since Minc is union closed (cf. Proposition 18), such a maximum subteam always exists.

For a proof of the following lemma, see the full version [14] of this article.

▶ **Lemma 20.** *If φ is a proposition symbol, its negation, or an inclusion atom, then $\mathrm{maxsub}(T, \varphi)$ can be computed in polynomial time with respect to $|T| + |\varphi|$.*

For the following lemma it is crucial that lax semantics is considered. The lemma cannot hold for strict semantics unless $\mathsf{P} = \mathsf{NP}$.

▶ **Lemma 21.** MC(Minc) *under lax semantics is in* P.

Proof. We will present a labelling algorithm for model checking $\mathfrak{M}, T \models \varphi$. Let $\mathrm{subOcc}(\varphi)$ denote the set of all *occurrences* of subformulae of φ. Below we denote occurrences as if they were formulae, but we actually refer to some particular occurrence of the formula.

A function $f \colon \mathrm{subOcc}(\varphi) \to \mathcal{P}(W)$ is called a labelling function of φ in $\mathfrak{M}$. We will next give an algorithm for computing a sequence $f_0, f_1, f_2, \ldots$, of such labelling functions.

- Define $f_0(\psi) = W$ for each $\psi \in \mathrm{subOcc}(\varphi)$.
- For odd $i \in \mathbb{N}$, define $f_i(\psi)$ bottom up as follows:
  1. For literal ψ, define $f_i(\psi) := \mathrm{maxsub}(f_{i-1}(\psi), \psi)$.
  2. $f_i(\psi \wedge \theta) := f_i(\psi) \cap f_i(\theta)$.
  3. $f_i(\psi \vee \theta) := f_i(\psi) \cup f_i(\theta)$.
  4. $f_i(\Diamond\psi) := \{w \in f_{i-1}(\Diamond\psi) \mid R[w] \cap f_i(\psi) \neq \emptyset\}$.
  5. $f_i(\Box\psi) := \{w \in f_{i-1}(\Box\psi) \mid R[w] \subseteq f_i(\psi)\}$.
- For even $i \in \mathbb{N}$ larger than 0, define $f_i(\psi)$ top to bottom as follows:
  1. Define $f_i(\varphi) := f_{i-1}(\varphi) \cap T$.
  2. If $\psi = \theta \wedge \gamma$, define $f_i(\theta) := f_i(\gamma) := f_i(\theta \wedge \gamma)$.
  3. If $\psi = \theta \vee \gamma$, define $f_i(\theta) := f_{i-1}(\theta) \cap f_i(\theta \vee \gamma)$ and $f_i(\gamma) := f_{i-1}(\gamma) \cap f_i(\theta \vee \gamma)$.
  4. If $\psi = \Diamond\theta$, define $f_i(\theta) := f_{i-1}(\theta) \cap R[f_i(\Diamond\theta)]$.
  5. If $\psi = \Box\theta$, define $f_i(\theta) := f_{i-1}(\theta) \cap R[f_i(\Box\theta)]$.

By a straightforward induction on i, we can prove that $f_{i+1}(\psi) \subseteq f_i(\psi)$ holds for every $\psi \in \mathrm{subOcc}(\varphi)$. The only nontrivial induction step is that for $f_{i+1}(\theta)$ and $f_{i+1}(\gamma)$, when $i+1$ is even and $\psi = \theta \wedge \gamma$. To deal with this step, observe that, by the definition of f_{i+1} and f_i, we have $f_{i+1}(\theta) = f_{i+1}(\gamma) = f_{i+1}(\psi)$ and $f_i(\psi) \subseteq f_i(\theta), f_i(\gamma)$, and by the induction hypothesis on ψ, we have $f_{i+1}(\psi) \subseteq f_i(\psi)$.

It follows that there is an integer $j \leq 2 \cdot |W| \cdot |\varphi|$ such that $f_{j+2} = f_{j+1} = f_j$. We denote this fixed point f_j of the sequence $f_0, f_1, f_2, \ldots$ by f_∞. By Lemma 20 the outcome of $\mathrm{maxsub}(\cdot, \cdot)$ is computable in polynomial time with respect to its input. That being, clearly f_{i+1} can be computed from f_i in polynomial time with respect to $|W| + |\varphi|$. On that account f_∞ is also computable in polynomial time with respect to $|W| + |\varphi|$.

We will next prove by induction on $\psi \in \mathrm{subOcc}(\varphi)$ that $\mathfrak{M}, f_\infty(\psi) \models \psi$. Note first that there is an odd integer i and an even integer j such that $f_\infty = f_i = f_j$.

1. If ψ is a literal, the claim is true since $f_\infty = f_i$ and $f_i(\psi) = \mathrm{maxsub}(f_{i-1}(\psi), \psi)$.
2. Assume next that $\psi = \theta \wedge \gamma$, and the claim holds for θ and γ. Since $f_\infty = f_j$, we have $f_\infty(\psi) = f_\infty(\theta) = f_\infty(\gamma)$, as a result, by induction hypothesis, $\mathfrak{M}, f_\infty(\psi) \models \theta \wedge \gamma$.
3. In the case $\psi = \theta \vee \gamma$, we obtain the claim $\mathfrak{M}, f_\infty(\psi) \models \psi$ by using the induction hypothesis, and the observation that $f_\infty(\psi) = f_i(\psi) = f_i(\theta) \cup f_i(\gamma) = f_\infty(\theta) \cup f_\infty(\gamma)$.
4. Assume then that $\psi = \Diamond\theta$. Since $f_\infty = f_i$, we have $f_\infty(\psi) = \{w \in f_{i-1}(\psi) \mid R[w] \cap f_\infty(\theta) \neq \emptyset\}$, as a consequence $f_\infty(\psi) \subseteq R^{-1}[f_\infty(\theta)]$. On the other hand, since $f_\infty = f_j$, we have $f_\infty(\theta) = f_{j-1}(\theta) \cap R[f_\infty(\psi)]$, for this reason $f_\infty(\theta) \subseteq R[f_\infty(\psi)]$. Thus $f_\infty(\psi)[R]f_\infty(\theta)$, and using the induction hypothesis, we see that $\mathfrak{M}, f_\infty(\psi) \models \psi$.
5. Assume finally that $\psi = \Box\theta$. Since $f_\infty = f_i$, we have $R[f_\infty(\psi)] \subseteq f_\infty(\theta)$. On the other hand, since $f_\infty = f_j$, we have $f_\infty(\theta) \subseteq R[f_\infty(\psi)]$. This shows that $f_\infty(\theta) = R[f_\infty(\psi)]$, that being the case by the induction hypothesis, $\mathfrak{M}, f_\infty(\psi) \models \psi$.

In particular, if $f_\infty(\varphi) = T$, then $\mathfrak{M}, T \models \varphi$. Consequently, to complete the proof of the lemma, it suffices to prove that the converse implication is true, as well. To prove this, assume that $\mathfrak{M}, T \models \varphi$. Then for each $\psi \in \mathrm{subOcc}(\varphi)$, there is a team T_ψ such that

1. $T_\varphi = T$.
2. If $\psi = \theta \wedge \gamma$, then $T_\psi = T_\theta = T_\gamma$.
3. If $\psi = \theta \vee \gamma$, then $T_\psi = T_\theta \cup T_\gamma$.
4. If $\psi = \Diamond\theta$, then $T_\psi[R]T_\theta$.
5. If $\psi = \Box\theta$, then $T_\theta = R[T_\psi]$.
6. If ψ is a literal, then $\mathfrak{M}, T_\psi \models \psi$.

We prove by induction on i that $T_\psi \subseteq f_i(\psi)$ for all $\psi \in \mathrm{subOcc}(\varphi)$. For $i = 0$, this is obvious, since $f_0(\psi) = W$ for all ψ. Assume next that $i+1$ is odd and the claim is true for i. We prove the claim $T_\psi \subseteq f_i(\psi)$ by induction on ψ.

1. If ψ is a literal, then $f_{i+1}(\psi) = \mathrm{maxsub}(f_i(\psi), \psi)$. Since $\mathfrak{M}, T_\psi \models \psi$, and by induction hypothesis, $T_\psi \subseteq f_i(\psi)$, the claim $T_\psi \subseteq f_{i+1}(\psi)$ is true.
2. Assume that $\psi = \theta \wedge \gamma$. By induction hypothesis on θ and γ, we have $T_\psi = T_\theta \subseteq f_{i+1}(\theta)$ and $T_\psi = T_\gamma \subseteq f_{i+1}(\gamma)$. For this reason, we get $T_\psi \subseteq f_{i+1}(\theta) \cap f_{i+1}(\gamma) = f_{i+1}(\psi)$.
3. The case $\psi = \theta \vee \gamma$ is similar to the previous one; we omit the details.
4. If $\psi = \Diamond\theta$, then $f_{i+1}(\psi) = \{w \in f_i(\psi) \mid R[w] \cap f_{i+1}(\theta) \neq \emptyset\}$. By the two induction hypotheses on i and θ, we have $\{w \in T_\psi \mid R[w] \cap T_\theta \neq \emptyset\} \subseteq f_{i+1}(\psi)$. The claim follows from this, since the condition $R[w] \cap T_\theta \neq \emptyset$ holds for all $w \in T_\psi$.
5. The case $\psi = \Box\theta$ is again similar to the previous one, so we omit the details.

Assume then that $i+1$ is even and the claim is true for i. This time we prove the claim $T_\psi \subseteq f_i(\psi)$ by top to bottom induction on ψ.

1. By assumption, $T_\varphi = T$, whence by induction hypothesis, $T_\varphi \subseteq f_i(\varphi) \cap T = f_{i+1}(\varphi)$.
2. Assume that $\psi = \theta \wedge \gamma$. By induction hypothesis on ψ, we have $T_\psi \subseteq f_{i+1}(\psi)$. Since $T_\psi = T_\theta = T_\gamma$ and $f_{i+1}(\psi) = f_{i+1}(\theta) = f_{i+1}(\gamma)$, this implies that $T_\theta \subseteq f_{i+1}(\theta)$ and $T_\gamma \subseteq f_{i+1}(\gamma)$.
3. Assume that $\psi = \theta \vee \gamma$. Using the fact that $T_\theta \subseteq T_\psi$, and the two induction hypotheses on i and ψ, we see that $T_\theta \subseteq f_i(\theta) \cap T_\psi \subseteq f_i(\theta) \cap f_{i+1}(\psi) = f_{i+1}(\theta)$. Similarly, we see that $T_\gamma \subseteq f_{i+1}(\gamma)$.

4. Assume that $\psi = \Diamond\theta$. By the induction hypothesis on i, we have $T_\theta \subseteq f_i(\theta)$, and by the induction hypothesis on ψ, we have $T_\theta \subseteq R[T_\psi] \subseteq R[f_{i+1}(\psi)]$. Accordingly, we see that $T_\theta \subseteq f_i(\theta) \cap R[f_{i+1}(\psi)] = f_{i+1}(\theta)$.
5. The case $\psi = \Box\theta$ is similar to the previous one; we omit the details.

It follows now that $T = T_\varphi \subseteq f_\infty(\varphi)$. Since $f_\infty(\varphi) \subseteq f_2(\varphi) \subseteq T$, we conclude that $f_\infty(\varphi) = T$. This completes the proof of the implication $\mathfrak{M}, T \models \varphi \;\Rightarrow\; f_\infty(\varphi) = T$. ◀

The following lemma then follows, since in the context of model checking, we may replace modal formulae that appear as parameters in inclusion atoms by fresh proposition symbols with the same extension.

▶ **Lemma 22.** MC(EMinc) *under lax semantics is in* P.

By combining Lemmas 9, 21, and 22, we obtain the following theorem.

▶ **Theorem 23.** MC(Minc) *and* MC(EMinc) *are* P*-complete w.r.t.* $\leq_m^{\log}$.

▶ **Theorem 24.** MC($\mathsf{Minc}_{\mathsf{str}}$) *and* MC($\mathsf{EMinc}_{\mathsf{str}}$) *are* NP*-complete w.r.t.* $\leq_m^{\log}$.

Proof. The NP-hardness follows from the propositional case, i.e., from Lemma 13.

In order to establish inclusion, we note that the obvious brute force algorithm for model checking for EMinc works in NP: For disjunctions and diamonds, we use nondeterminism to guess the correct partitions or successor teams, respectively. Conjunctions are dealt with sequentially and for boxes the unique successor team can be computed by brute force in quadratic time. Checking whether a team satisfies an inclusion atom or a (negated) proposition symbol can be computed by brute force in polynomial time (this also follows directly from Lemma 20). ◀

5.2 Complexity of validity

The following result involves a reduction from a complement problem of the validity problem of dependency quantified Boolean formulas [20]. The details can be found in the full version [14] of this article.

▶ **Theorem 25.** VAL(Minc) *and* VAL($\mathsf{Minc}_{\mathsf{str}}$) *are* coNEXP*-hard w.r.t.* $\leq_m^{\log}$.

While the exact complexities of the problems VAL(Minc) and VAL(EMinc) remain open, it is straightforward to establish that the complexities coincide. In the proof of the theorem below, we introduce fresh proposition symbols for each modal formula that appears as a parameter for an inclusion atom. We then replace these formulas by the fresh proposition symbols and separately force, by using ML, that the extensions of the proposition symbols and modal formulae are the same, respectively. See [14] for a detailed proof.

▶ **Theorem 26.** *Let* C *be a complexity class that is closed under polynomial time reductions. Then* VAL(Minc) *under lax (strict) semantics in complete for* C *if and only if* VAL(EMinc) *under lax (strict) semantics in complete for* C.

6 Conclusion

In this paper, we investigated the computational complexity of model checking and validity for propositional and modal inclusion logic to complete the complexity landscape of these problems in the mentioned logics. In particular, we gave emphasis to the subtle influence of

which semantics is considered: strict or lax. The model checking problem for these logics under strict semantics was shown to be NP-complete and under lax semantics P-complete. The validity problem was shown to be coNP-complete for the propositional strict semantics case, for the lax semantics coNP-completeness was established earlier by Hannula et al. [12]. For the modal case, we obtained a coNEXP lower bound under lax as well as strict semantics. The upper bound is left open for further research. We however established that, if closed under polynomial time reductions, the complexities of VAL(Minc) and VAL(EMinc), and VAL($\mathsf{Minc}_{\mathsf{str}}$) and VAL($\mathsf{EMinc}_{\mathsf{str}}$) coincide, respectively.

We conclude with an open problem. Let ML($\sim$) denote the extension of modal logic by the contradictory negation $\sim$ with the following semantics: $\mathfrak{M}, T \models \sim\varphi$ iff $\mathfrak{M}, T \not\models \varphi$. What is the complexity of VAL(ML($\sim$))? It is known that VAL(PL($\sim$)) is complete for *alternating exponential time with polynomially many alternations* [13]; this is the best known lower bound for VAL(ML($\sim$)). Decidability with non-elementary upper bound can be obtained, e.g., by using team-bisimulation and Hintikka-types; no better upper bound is known.

Abstract

We study the computational complexity of emptiness problems for circuits over sets of natural numbers with the operations union, intersection, complement, addition, and multiplication. For most settings of allowed operations we precisely characterize the complexity in terms of completeness for classes like NL, NP, and PSPACE. The case where intersection, addition, and multiplication is allowed turns out to be equivalent to the complement of polynomial identity testing (PIT).

Our results imply the following improvements and insights on problems studied in earlier papers. We improve the bounds for the membership problem $\mathrm{MC}(\cup, \cap, {}^{-}, +, \times)$ studied by McKenzie and Wagner 2007 and for the equivalence problem $\mathrm{EQ}(\cup, \cap, {}^{-}, +, \times)$ studied by Glaßer et al. 2010. Moreover, it turns out that the following problems are equivalent to PIT, which shows that the challenge to improve their bounds is just a reformulation of a major open problem in algebraic computing complexity:

- membership problem $\mathrm{MC}(\cap, +, \times)$ studied by McKenzie and Wagner 2007
- integer membership problems $\mathrm{MC}_{\mathbb{Z}}(+, \times)$ and $\mathrm{MC}_{\mathbb{Z}}(\cap, +, \times)$ studied by Travers 2006
- equivalence problem $\mathrm{EQ}(+, \times)$ studied by Glaßer et al. 2010

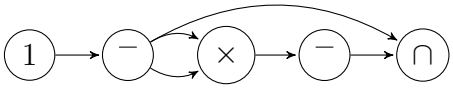
1 Introduction

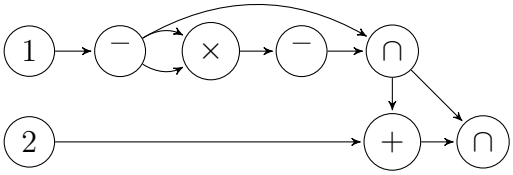
Stockmeyer and Meyer [31] investigated membership and equivalence problems for *integer expressions*, which are built up from single natural numbers using set operations $({}^{-}, \cup, \cap)$ and pairwise addition $(+)$. They also suggested to study expressions involving pairwise multiplication $(\times)$. For example, the expression $\overline{\overline{1} \times \overline{1} \cap 1}$ describes the set of primes $\mathbb{P}$.

The *membership problem for expressions* is the question of whether the set described by a given expression contains some given natural number. The *equivalence problem for expressions* asks whether two given expressions describe the same set. Restricting the set of allowed operations results in problems of different complexities.

Wagner [33] introduced *circuits over sets of natural numbers*. These circuits describe expressions in a succinct way. The input gates of such a circuit are labeled with natural numbers, the inner gates compute set operations $({}^{-}, \cup, \cap)$ and arithmetic operations $(+, \times)$. The following circuit has only 4 inner gates and describes the set of primes $\overline{\overline{1} \times \overline{1} \cap 1}$.



A slightly larger circuit describes the set $\{n \in \mathbb{P} \mid n-2 \in \mathbb{P}\}$, i.e., the set of those twin primes p for which $p-2$ is also prime. Hence the set described by this circuit is infinite if and only if the twin prime conjecture holds.



Wagner [33], Yang [34], and McKenzie and Wagner [22] studied the complexity of membership problems for circuits over natural numbers (MC): Here, for a given circuit C with numbers assigned to the input gates, one has to decide whether a given number b belongs to the set described by the circuit. Travers [32] and Breunig [6] considered membership problems for circuits over integers ($\mathrm{MC}_{\mathbb{Z}}$) and positive integers ($\mathrm{MC}_{\mathbb{N}^+}$), respectively. Glaßer et al [11] investigated *equivalence problems for circuits over sets of natural numbers* (EQ), i.e., the problem of deciding whether two given circuits compute the same set.

Satisfiability problems for circuits over sets of natural numbers, studied by Glaßer et al [13], are a generalization of the membership problems investigated by McKenzie and Wagner [22]: Here the circuits can have *unassigned input gates*. The question is, given a circuit C with gates from $\mathcal{O} \subseteq \{\cup, \cap, \bar{}, +, \times\}$, and given a natural number b, does there exist an assignment of natural numbers to the unassigned input gates such that b is contained in the set described by the circuit?

Apart from the mentioned research on circuit problems there has been work on related variants like functions computed by circuits [24] and constraint satisfaction problems over natural numbers [12, 8].

In the present paper, we study *emptiness problems for circuits over sets of natural numbers*. In contrast to membership and satisfiability problems, here the question is whether a given circuit C with gates from $\mathcal{O} \subseteq \{\cup, \cap, \bar{}, +, \times\}$ computes the empty set. We denote this problem with $\mathrm{EC}(\mathcal{O})$. In extension of that, we also consider circuits with unassigned input gates. For these we consider the problem $\Sigma_1\text{-EC}(\mathcal{O})$ (resp., $\Pi_1\text{-EC}(\mathcal{O})$), which asks whether the circuit computes the empty set for at least one assignment (resp., for all assignments).

Our contribution to emptiness problems. For most of the emptiness problems we precisely characterize the complexity in terms of completeness for classes like NL, P, NP, PSPACE, and coNEXP. In the remaining cases we obtain lower and upper bounds that do not match. Our results are summarized in Table 1 in Section 6.

The case of $\mathrm{EC}(\cap, +, \times)$ is particularly interesting. We show that it is logspace many-one equivalent to the complement of the polynomial identity testing (PIT), which asks whether a polynomial (given as a circuit) is identically zero. The problems are similar, still the proof of $\overline{\mathrm{PIT}} \leq_{\mathrm{m}}^{\log} \mathrm{EC}(\cap, +, \times)$ has to address two essential differences: First, PIT contains a universal quantifier (for all assignments the polynomial has to be zero), while $\mathrm{EC}(\cap, +, \times)$ does not. Second, PIT is defined over $\mathbb{Z}$, while $\mathrm{EC}(\cap, +, \times)$ is defined over $\mathbb{N}$.

In several cases we obtain upper bounds for $\Sigma_1\text{-EC}(\mathcal{O})$ and $\Pi_1\text{-EC}(\mathcal{O})$ by observing that if *some* assignment makes a circuit (non-)empty, then there exists a *small* such assignment.

Depending on $\mathcal{O}$ we obtain this observation by one of the following techniques: The first technique (e.g., used for Π_1-EC$(\cap,+) \in$ coNP in Theorem 6) uses specific systems of linear equations that consist of a large number of short equations. Such systems of equations have small solutions by the theory of integer programming. The second technique (e.g., used for EC$(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1$-EC$(\cap,+,\times)$ in Corollary 21) exploits the fact that the test of whether a multivariate polynomial is identically zero is possible by evaluating this polynomial for a fixed argument. The third technique (e.g., used for Σ_1-EC$(\cup,\cap,^-,+) \in$ 2EXPSPACE and Σ_1-EC$(\cup,\cap,^-,\times) \in$ 3EXPSPACE in Theorem 8) applies the decidability of Presburger and Skolem arithmetic.

Regarding the most general case EC$(\cup,\cap,^-,+,\times)$ we show that this problem is logspace many-one equivalent to MC$(\cup,\cap,^-,+,\times)$ and EQ$(\cup,\cap,^-,+,\times)$, belongs to $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$, and is $\leq_{\mathrm{m}}^{\log}$-hard for $\mathrm{L}^{\mathrm{NEXP}}$. We leave open whether EC$(\cup,\cap,^-,+,\times)$ is decidable and give evidence for the difficulty of finding a decision algorithm.

Our contribution to questions from previous work. By the equivalence mentioned above, our bounds for EC$(\cup,\cap,^-,+,\times)$ improve the bounds for the problems MC$(\cup,\cap,^-,+,\times)$ [22] and EQ$(\cup,\cap,^-,+,\times)$ [11] as follows. The lower bound is raised from NEXP to $\mathrm{L}^{\mathrm{NEXP}}$ and the upper bound is slightly reduced from $\mathcal{R}_{\mathrm{T}}(\Sigma_1)$ to $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.

We prove that PIT is logspace many-one equivalent to MC$(\cap,+,\times)$ studied in [22], MC$_{\mathbb{Z}}(+,\times)$, MC$_{\mathbb{Z}}(\cap,+,\times)$ studied in [32], and EQ$(+,\times)$ studied in [11]. This characterizes the complexity of these problems and shows that the question for improved bounds is equivalent to a well-studied, open problem in algebraic computing complexity.

Finally we show that EQ$(\cap,+,\times)$ is $\leq_{\mathrm{m}}^{\log}$-complete for the complement of the second level of the Boolean hierarchy over PIT. This characterizes the complexity of this equivalence problem and explains the difficulty of improving the known upper bound [11].

The intention of this article is to summarize results and to develop a feeling for the proofs. The emphasis is on sketching several ideas at the expense of details. A comprehensive presentation is provided in the technical report [4].

2 Preliminaries

Basic Notations. Let $\mathbb{N}$ (resp., $\mathbb{Z}$) denote the set of natural numbers (resp., integers). $\mathbb{N}^+$ is the set of positive integers. For $x \in \mathbb{Z}$ the absolute value of x is denoted by $\mathrm{abs}(x)$, and for a matrix of integers $A = (a_{i,j}) \in \mathbb{Z}^{m\times n}$ for positive natural numbers m and n we define $||A||_\infty = \max\{\mathrm{abs}(a_{i,j}) \mid 1 \leq i \leq m \text{ and } 1 \leq j \leq n\}$.

L, NL, P, RP, BPP, NP, PSPACE, and NEXP denote standard complexity classes [23]. For a nondeterministic machine M, let $\mathrm{acc}_M(x)$ be the number of accepting paths of M on input x. The class #L consists of all functions acc_M, where M is a nondeterministic logarithmic-space-bounded machine. C$_=$L is the class of problems A for which there exist $f, g \in$ #L such that for all inputs x it holds that $x \in A \Leftrightarrow f(x) = g(x)$. Further information on counting classes can be found in [2].

Let Σ_i and Π_i denote the levels of the arithmetical hierarchy. 2EXPSPACE, i.e., the class of problems decidable by a deterministic algorithm in double exponential space $2^{2^{n^k}}$ for some $k \in \mathbb{N}$, and 3EXPSPACE, which consists of the problems decidable in triple exponential space. For complexity classes $\mathcal{C}$ let co$\mathcal{C} = \{\overline{A} \mid A \in \mathcal{C}\}$. We denote by K the Σ_1-complete halting problem (for some fixed Gödelization).

Addition and multiplication are extended to sets of integers: Let $A, B \subseteq \mathbb{Z}$. Then $A + B = \{a + b \mid a \in A, b \in B\}$ and $A \times B = \{a \cdot b \mid a \in A, b \in B\}$.

An oracle Turing machine is nonadaptive, if its queries are independent of the oracle (i.e., for all x and all oracles B and B', the computations $M^B(x)$ and $M^{B'}(x)$ have the same sequence of queries). For sets A and B we say that A is Turing reducible to B ($A \leq_{\mathrm{T}} B$), if there exists an oracle Turing machine M that accepts A with B as its oracle. If M is nonadaptive, then A is truth-table reducible to B ($A \leq_{\mathrm{tt}} B$). A is logspace Turing reducible to B ($A \leq_{\mathrm{T}}^{\log} B$), if there exists a logarithmic-space-bounded oracle Turing machine M (with one oracle tape) that accepts A with B as its oracle. If M's queries are nonadaptive (i.e., independent of the oracle), then A is logspace truth-table reducible to B ($A \leq_{\mathrm{tt}}^{\log} B$). A is logspace disjunctive-truth-table reducible to B ($A \leq_{\mathrm{dtt}}^{\log} B$), if there exists a logspace computable function f such that for all x, $f(x) = (y_1, y_2, \ldots, y_n)$ for some $n \geq 1$ and $\chi_A(x) = \max\{\chi_B(y_1), \chi_B(y_2), \ldots, \chi_B(y_n)\}$, where χ_S for a set S is the characteristic function of S. A set A is logspace (resp., polynomial time) many-one reducible to B, in notation $A \leq_{\mathrm{m}}^{\log} B$ (resp., $A \leq_{\mathrm{m}}^{\mathrm{p}} B$), if there exists a logarithmic-space-computable (resp., polynomial-time-computable) function f such that $\chi_A(x) = \chi_B(f(x))$. For a complexity class $\mathcal{C}$ we define $\mathcal{R}_{\mathrm{tt}}(\mathcal{C}) = \{A \mid \text{there is a } C \in \mathcal{C} \text{ with } A \leq_{\mathrm{tt}} C\}$.

Definition of circuits. A *circuit* $C = (V, E, g_C)$ is a finite, directed, acyclic graph with vertex set $V \subseteq \mathbb{N}$ and a designated vertex $g_C \in V$. Here, graphs are allowed to have multi-edges and are not required to be connected. We require that C is topologically ordered, that is, if $v, v' \in V$ are vertices with $v < v'$, then there is no edge from v' to v.

Let $\mathcal{O} \subseteq \{\cup, \cap, \overline{\ }, +, \times\}$. A *partially assigned $\mathcal{O}$-circuit* ($\mathcal{O}$-*circuit* for short) $C = (V, E, g_C, \alpha)$ is a circuit (V, E, g_C) whose nodes are labeled by the *labeling function* $\alpha : V \to \mathcal{O} \cup \mathbb{N} \cup \{\square\}$ such that each node has indegree ≤ 2, nodes with indegree 0 have labels from $\mathbb{N} \cup \{\square\}$, nodes with indegree 1 have label $\overline{\ }$, and nodes with indegree 2 have labels from $\mathcal{O} \setminus \{\overline{\ }\}$. In the context of circuits, nodes are also called *gates*. *Input gates* (i.e., gates with indegree 0) with labels from $\mathbb{N}$ are called *assigned* input gates. Input gates with label $\square$ are called *unassigned*. An $\mathcal{O}$-circuit whose input gates are all assigned is called *completely assigned $\mathcal{O}$-circuit*. We use the term *integer circuit* for both partially assigned $\mathcal{O}$-circuits and completely assigned $\mathcal{O}$-circuits.

There exists a deterministic logarithmic-space-bounded algorithm which on input of a graph decides whether the input is a partially assigned $\mathcal{O}$-circuit.

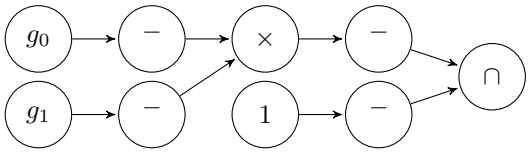
The set computed by a circuit. For an $\mathcal{O}$-circuit C with unassigned input gates $g_1 < \cdots < g_n$ and $x_1, \ldots, x_n \in \mathbb{N}$, let $C(x_1, \ldots, x_n)$ be the completely assigned $\mathcal{O}$-circuit that is obtained from C by modifying the labeling function α such that $\alpha(g_i) = x_i$ for $i = 1, \ldots, n$.

For a completely assigned $\mathcal{O}$-circuit $C = (V, E, g_C, \alpha)$ we inductively define the *set $I(g; C)$ computed by a gate $g \in V$* by

$$I(g;C) = \begin{cases} \{\alpha(g)\} \subseteq \mathbb{N} & \text{if } g \text{ has indegree } 0 \quad (g \text{ is an input gate}), \\ \mathbb{N} \setminus I(g';C) & \text{if } g = \overline{g'} \quad (g \text{ is a complement gate}), \\ I(g';C) \otimes I(g'';C) & \text{if } g = g' \otimes g'' \quad (g \text{ is a gate of type } \otimes \in \{\cup, \cap, +, \times\}). \end{cases}$$

The *set computed by C* is defined as $I(C) = I(g_C; C)$.

Example. For unassigned inputs g_0 and g_1, consider the circuit C:



We write $C = \overline{\overline{g_0} \times \overline{g_1}} \cap \overline{1}$ as an abbreviation. $C(1,1)$ computes the set of all primes, $C(x,y)$ for $x = y \in \mathbb{P} \cup \{0\}$ computes the set $\{x\}$, and $C(x,y)$ for all other (x,y) computes the empty set.

▶ **Definition 1.** Let $\mathcal{O} \subseteq \{\cup, \cap, \neg, +, \times\}$. We define *membership*, *emptiness*, *equivalence*, and *satisfiability* problems for circuits.

&\qquad \text{there exist } x_1,\ldots,x_n \in \mathbb{N} \text{ s.t. } b \in I(C(x_1,\ldots,x_n))\}\\
\mathrm{EQ}(\mathcal{O}) &\stackrel{df}{=} \{(C_1,C_2) \mid C_1, C_2 \text{ are completely assigned } \mathcal{O}\text{-circuits, } I(C_1) = I(C_2)\}^1\\
\mathrm{EC}(\mathcal{O}) &\stackrel{df}{=} \{C \mid C \text{ is a completely assigned } \mathcal{O}\text{-circuit and } I(C) = \emptyset\}\\
\Sigma_1\text{-EC}(\mathcal{O}) &\stackrel{df}{=} \{C \mid C \text{ is a partially assigned } \mathcal{O}\text{-circuit with } n \text{ unassigned inputs,}\\
&\qquad \text{there exist } x_1,\ldots,x_n \in \mathbb{N} \text{ s.t. } I(C(x_1,\ldots,x_n)) = \emptyset\}\\
\Pi_1\text{-EC}(\mathcal{O}) &\stackrel{df}{=} \{C \mid C \text{ is a partially assigned } \mathcal{O}\text{-circuit with } n \text{ unassigned inputs,}\\
&\qquad \text{for all } x_1,\ldots,x_n \in \mathbb{N} \text{ it holds } I(C(x_1,\ldots,x_n)) = \emptyset\}\\
\Sigma_1\text{-NEC}(\mathcal{O}) &\stackrel{df}{=} \overline{\Pi_1\text{-EC}(\mathcal{O})}
\end{aligned}$$

The integer variants $\mathrm{MC}_{\mathbb{Z}}(\mathcal{O})$, $\mathrm{EC}_{\mathbb{Z}}(\mathcal{O})$, and $\Sigma_1\text{-EC}_{\mathbb{Z}}(\mathcal{O})$ are defined analogously (assigned and unassigned inputs are from $\mathbb{Z}$, the complement is defined with respect to $\mathbb{Z}$). A systematic study of the membership problems $\mathrm{MC}_{\mathbb{Z}}(\mathcal{O})$ was done by Travers [32].

We use the following abbreviations: we write n for the singleton $\{n\}$; we write C for $I(C)$, where C is a circuit; we write $\mathrm{MC}(\cup, \cap, \neg, +, \times)$ for $\mathrm{MC}(\{\cup, \cap, \neg, +, \times\})$ and the like.

3 Basic Results

We start with easy reductions between $\mathrm{EC}(\mathcal{O})$, $\Sigma_1\text{-EC}(\mathcal{O})$, $\Pi_1\text{-EC}(\mathcal{O})$, and $\mathrm{MC}(\mathcal{O})$.

▶ **Lemma 2.** *Let $\mathcal{O} \subseteq \{\cup, \cap, \neg, +, \times\}$ and $\mathcal{E} \in \{\mathrm{EC}, \Sigma_1\text{-EC}, \Pi_1\text{-EC}\}$.*

1. *If $\cap \in \mathcal{O}$, then $\mathrm{MC}(\mathcal{O}) \leq_{\mathrm{m}}^{\log} \overline{\mathrm{EC}(\mathcal{O})}$ and $\Sigma_1\text{-MC}(\mathcal{O}) \leq_{\mathrm{m}}^{\log} \Sigma_1\text{-NEC}(\mathcal{O})$.*
2. *If $\times \in \mathcal{O}$, then $\overline{\mathrm{EC}(\mathcal{O})} \leq_{\mathrm{m}}^{\log} \mathrm{MC}(\mathcal{O})$ and $\Sigma_1\text{-NEC}(\mathcal{O}) \leq_{\mathrm{m}}^{\log} \Sigma_1\text{-MC}(\mathcal{O})$.*
3. *If $\mathcal{O} \subseteq \{\cup, +, \times\}$ or $\mathcal{O} \subseteq \{\neg\}$, then $\mathrm{EC}(\mathcal{O}) = \Sigma_1\text{-EC}(\mathcal{O}) = \Pi_1\text{-EC}(\mathcal{O}) = \emptyset$.*
4. *$\mathcal{E}(\{\cup, \neg\} \cup \mathcal{O}) \equiv_{\mathrm{m}}^{\log} \mathcal{E}(\{\cap, \neg\} \cup \mathcal{O}) \equiv_{\mathrm{m}}^{\log} \mathcal{E}(\{\cup, \cap, \neg\} \cup \mathcal{O})$ for $\mathcal{O} \subseteq \{+, \times\}$.*
5. *$\mathcal{E}(\mathcal{O}') \leq_{\mathrm{m}}^{\log} \mathcal{E}(\mathcal{O})$ for $\mathcal{O}' \subseteq \mathcal{O}$.*
6. *$\mathrm{EC}(\mathcal{O}) \leq_{\mathrm{m}}^{\log} \Sigma_1\text{-EC}(\mathcal{O})$ and $\mathrm{EC}(\mathcal{O}) \leq_{\mathrm{m}}^{\log} \Pi_1\text{-EC}(\mathcal{O})$.*

The following bounds are obtained with minor effort from known results and Lemma 2.

▶ **Theorem 3** ([22, 11, 13])**.**

1. *$\mathrm{EC}(\cup, \cap, +, \times)$ is $\leq_{\mathrm{m}}^{\log}$-complete for* coNEXP*.*
2. *$\mathrm{EC}(\cup, \cap, \neg, +), \mathrm{EC}(\cup, \cap, \neg, \times) \in$ PSPACE.*

[1] In [11], equivalence problems for circuits are denoted by $\mathrm{EC}(\mathcal{O})$, which is in conflict with our notation for emptiness problems. Therefore, we use the notation $\mathrm{EQ}(\mathcal{O})$ for equivalence problems.

3. $\mathrm{EC}(\cap,+)$ *and* $\mathrm{EC}(\cap,\times)$ *are* $\leq_{\mathrm{m}}^{\log}$*-hard for* $\mathrm{coC_{=}L}$.
4. $\Pi_1\text{-EC}(\cap,\times)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* coNP.

Circuits with solely set operations can express graph accessibility as well as evaluation and satisfiability of Boolean circuits. This leads to the following results.

▶ **Proposition 4.**
1. $\mathrm{EC}(\cap)$, $\Sigma_1\text{-EC}(\cap)$, *and* $\Pi_1\text{-EC}(\cap)$ *are* $\leq_{\mathrm{m}}^{\log}$*-complete for* NL.
2. $\mathrm{EC}(\cup,\cap,^{-})$, $\mathrm{EC}(\cup,\cap)$, $\Sigma_1\text{-EC}(\cup,\cap)$, *and* $\Pi_1\text{-EC}(\cup,\cap)$ *are* $\leq_{\mathrm{m}}^{\log}$*-complete for* P.
3. $\Sigma_1\text{-EC}(\cup,\cap,^{-})$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP *and* $\Pi_1\text{-EC}(\cup,\cap,^{-})$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* coNP.

4 Circuits with One Arithmetic Operation

4.1 Circuits without Complement

Here only those problems are relevant that admit intersection, since otherwise the circuits compute non-empty sets.

By an induction on the structure of the circuit we obtain: $C \in \Sigma_1\text{-EC}(\cap,+)$ if and only if at least one of the circuits $C(0,\ldots,0)$, $C(1,0,\ldots,0)$, $C(0,1,\ldots,0)$, $\ldots$, $C(0,0,\ldots,1)$ belongs to $\mathrm{EC}(\cap,+)$. Hence $\Sigma_1\text{-EC}(\cap,+) \leq_{\mathrm{dtt}}^{\log} \mathrm{EC}(\cap,+)$. It is known that $\mathrm{EC}(\cap,+) \in \mathrm{coC_{=}L}$ [11] and $\mathrm{coC_{=}L}$ is closed under $\leq_{\mathrm{dtt}}^{\log}$ [3]. This yields:

▶ **Theorem 5.** $\Sigma_1\text{-EC}(\cap,+) \in \mathrm{coC_{=}L}$.

We obtain several results that rely on an estimation by Schrijver [28] saying that systems of linear equations consisting of arbitrarily many equations have solutions whose greatest component is at most $(32k)^{12n^4}$, where k is the greatest constant in the system and n the number of variables. So there are "small solutions for huge systems of small equations".

It is straightforward to see that the question of whether an $\{\cap,+\}$-circuit C is in $\mathcal{E}(\cap,+)$ for $\mathcal{E} \in \{\mathrm{EC}, \Sigma_1\text{-EC}, \Pi_1\text{-EC}\}$ can be answered by solving a system of linear equations in which each unassigned input gate is represented by one variable and constants have polynomial length in the size of the circuit. We extend this idea such that also emptiness problems that allow unions can be reduced to similar problems regarding (sets of) equation systems. This leads to the following results.

▶ **Theorem 6.**
1. $\Pi_1\text{-EC}(\cap,+)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* coNP.
2. $\mathrm{EC}(\cup,\cap,+)$ *and* $\mathrm{EC}(\cup,\cap,\times)$ *are* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE.
3. $\Sigma_1\text{-EC}(\cup,\cap,+), \Pi_1\text{-EC}(\cup,\cap,+), \Pi_1\text{-EC}(\cup,\cap,\times) \in \mathrm{PSPACE}$.

The problems Σ_1-EC and EC for the sets of operations $\{\cap,\times\}$ and $\{\cup,\cap,\times\}$ will be solved by a general tool given in Theorems 19, 20, and Corollary 21.

4.2 Circuits with Complement

4.2.1 Upper Bounds

$\mathrm{Th}(\mathbb{N};+,=)$ denotes the Presburger arithmetic, i.e., the first-order theory of $\mathbb{N}$ with addition. $\mathrm{Th}(\mathbb{N};\times,=,\mathbb{P}\cup\{0,1\})$ denotes the Skolem arithmetic with constants, i.e., the first-order theory of $\mathbb{N}$ with multiplication and constants for 0, 1, and all primes.

▶ **Theorem 7** ([9, 10, 14, 5])**.**
1. $\mathrm{Th}(\mathbb{N};+,=) \in \mathrm{2EXPSPACE}$.
2. $\mathrm{Th}(\mathbb{N};\times,=,\mathbb{P}\cup\{0,1\}) \in \mathrm{3EXPSPACE}$.

The sets computed in the nodes of circuits over $\{\cup, \cap, \overline{\ }, +\}$ and $\{\cup, \cap, \overline{\ }, \times\}$ can be expressed by Presburger and Skolem formulas. These formulas can be constructed in polynomial time, which allows to transfer the upper bounds of Presburger and Skolem arithmetic.

▶ **Theorem 8.**
1. Σ_1-EC$(\cup, \cap, \overline{\ }, +), \Pi_1$-EC$(\cup, \cap, \overline{\ }, +) \in$ 2EXPSPACE.
2. Σ_1-EC$(\cup, \cap, \overline{\ }, \times), \Pi_1$-EC$(\cup, \cap, \overline{\ }, \times) \in$ 3EXPSPACE.

4.2.2 Lower Bounds

All emptiness problems covered by Section 4.2 – in particular EC$(\overline{\ }, +)$ and EC$(\overline{\ }, \times)$ – are $\leq_{\mathrm{m}}^{\log}$-hard for PSPACE. We show the same for MC$(\overline{\ }, +)$ and MC$(\overline{\ }, \times)$ improving unpublished results by Reinhardt, which were announced by McKenzie and Wagner [22] and which state that these problems are $\leq_{\mathrm{m}}^{\mathrm{p}}$-hard for PSPACE. This section mainly sketches our proof for the $\leq_{\mathrm{m}}^{\log}$-hardness of MC$(\overline{\ }, +)$ for PSPACE. For that we define a further problem.

▶ **Definition 9.** A $\{\overline{\ }, +\}$-circuit over $\mathbb{N}^k$ is a completely assigned $\{\overline{\ }, +\}$-circuit $C = ((V, E), g_C, \alpha)$ where all constants are elements of $\mathbb{N}^k$. The set $I(g; C) \subseteq \mathbb{N}^k$ computed by a node g is defined analogously to the one-dimensional case. Further let $I(C) = I(g_C; C)$ and

$$\mathrm{MC}^+(\overline{\ }, +) = \{(C, b) \mid C \text{ is a completely assigned } \{\overline{\ }, +\}\text{-circuit over } \mathbb{N}^k,$$
$$||c||_\infty \leq 1 \text{ for every input } c, \ ||b||_\infty \leq 3, \text{ and } b \in I(C)\}.$$

The PSPACE-hardness of this problem is obtained by reducing CNF-QBF, which is the problem of whether a given quantified Boolean formula F in conjunctive normal form is true. It is known that CNF-QBF is $\leq_{\mathrm{m}}^{\log}$-complete for PSPACE.

The proof of the following lemma is based on an unpublished proof by Reinhardt [25] showing the $\leq_{\mathrm{m}}^{\mathrm{p}}$-hardness of MC$(\overline{\ }, \times)$ for PSPACE.

▶ **Lemma 10.** MC$^+(\overline{\ }, +)$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE.

From now on our proof differs from Reinhardt's proof. Instead of showing directly $\mathrm{MC}^+(\overline{\ }, +) \leq_{\mathrm{m}}^{\mathrm{p}} \mathrm{MC}(\overline{\ }, \times)$ via a simple reduction, we first prove $\mathrm{MC}^+(\overline{\ }, +) \leq_{\mathrm{m}}^{\log} \mathrm{MC}(\overline{\ }, +)$ and then show $\overline{\mathrm{MC}(\overline{\ }, +)} \leq_{\mathrm{m}}^{\log} \mathrm{EC}(\overline{\ }, +) \leq_{\mathrm{m}}^{\log} \mathrm{EC}(\overline{\ }, \times) \leq_{\mathrm{m}}^{\log} \overline{\mathrm{MC}(\overline{\ }, \times)}$.

To show $\mathrm{MC}^+(\overline{\ }, +) \leq_{\mathrm{m}}^{\log} \mathrm{MC}(\overline{\ }, +)$ it is convenient to represent a vector of natural numbers $a = (a_0, \ldots, a_k)$ as a natural number $\mathrm{ad}_n(a) = \sum_{i=0}^{k} a_{k-i} n^i$ for $n \geq 2$. We denote the function mapping (C, b) onto $(C', \mathrm{ad}_n(b))$ by ad_{n}, where C' is the circuit obtained from C by replacing each input x with $\mathrm{ad}_n(x)$.

Indeed, ad_n for sufficiently large n works as reduction if for example union and intersection are allowed instead of complement. However, in our case we have $(0, 1, 0) \notin \overline{(0, 0, 0)} + (0, 0, 1)$, but $\mathrm{ad}_8(0, 1, 0) = \mathrm{ad}_8(0, 0, 7) + \mathrm{ad}_8(0, 0, 1) \in \overline{\mathrm{ad}_8(0, 0, 0)} + \mathrm{ad}_8(0, 0, 1)$. Such "overflows" are the reason why ad_n is not a reduction $\mathrm{MC}^+(\overline{\ }, +) \leq_{\mathrm{m}}^{\log} \mathrm{MC}(\overline{\ }, +)$ for any n.

To address this problem we implement an operation similar to the bitwise 'or' for characteristic sequences: for two finite sets A and B (note that for problems of the form "$(C, b) \in \mathrm{MC}^+(\overline{\ }, +)$?" it suffices to consider the first $b + 1$ bits of characteristic sequences of sets) let $m = \max(A \cup B)$ and consider $M = \overline{\overline{A + \{m-1\}} + 1 + \overline{B + \{m-1\}}} + 1 = ((A + \{m\}) \cup \{0\}) + ((B + \{m\}) \cup \{0\})$. Observe that $M \cap \{m, \ldots, 2m\} = \{m + x \mid x \in A \cup B\}$, which equals the union of A and B shifted by the offset m.

Now a circuit over $\mathbb{N}^k$ can be simulated by a circuit over $\mathbb{N}$: Roughly speaking, we use ad_8 and after computing the operation of some node g, the numbers x with $||\mathrm{ad}_8^{-1}(x)|| > 3$ can be deleted from $I(g)$ by adding them into $\overline{I(g)}$ via the 'or'-operation mentioned above. Every 'or'-operation yields an offset which has to be taken into account. This leads to:

▶ **Theorem 11.** $\mathrm{MC}(^{-},+)$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE.

The following theorem is essentially due to Sigmund [30]. He provided the proof of the second reduction and the main idea of the proof of the first one.

▶ **Theorem 12.** $\overline{\mathrm{MC}(^{-},+)} \leq_{\mathrm{m}}^{\log} \mathrm{EC}(^{-},+)$ *and* $\mathrm{EC}(^{-},+) \leq_{\mathrm{m}}^{\log} \mathrm{EC}(^{-},\times)$.

▶ **Corollary 13.** $\mathrm{EC}(^{-},+)$, $\mathrm{EC}(^{-},\times)$, *and* $\mathrm{MC}(^{-},\times)$ *are* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE.

5 Circuits with both Arithmetic Operations

Besides proving bounds for emptiness problems with $+$ and $\times$, we improve the known lower and upper bounds for $\mathrm{MC}(\cup,\cap,^{-},+,\times)$ [22] and $\mathrm{EQ}(\cup,\cap,^{-},+,\times)$ [11]. Then we provide arguments that suggest the difficulty of proving the decidability of $\mathrm{EC}(^{-},+,\times)$ and $\mathrm{EC}(\cup,\cap,^{-},+,\times,)$. Finally we draw connections to polynomial identity testing (PIT) and show that the open questions for the complexities of $\mathrm{MC}(\cap,+,\times)$ [22], $\mathrm{MC}_{\mathbb{Z}}(\cap,+,\times)$, $\mathrm{MC}_{\mathbb{Z}}(+,\times)$ [32], and $\mathrm{EQ}(+,\times)$ [11] are equivalent to the well-studied, open question for the complexity of PIT.

5.1 Upper and Lower Bounds for Possibly Undecidable Problems

We obtain upper bounds by improving a known decision algorithm [11] and lower bounds via the Matiyasevich-Robinson-Davis-Putnam theorem [21, 7].

▶ **Theorem 14.**
1. $\mathrm{EC}(\cup,\cap,^{-},+,\times) \in \mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.
2. $\Sigma_1\text{-}\mathrm{EC}(\cup,\cap,^{-},+,\times) \in \Sigma_2$ *and* $\Pi_1\text{-}\mathrm{EC}(\cup,\cap,^{-},+,\times) \in \Pi_2$.
3. $\Pi_1\text{-}\mathrm{EC}(\cap,+,\times)$ *and* $\Pi_1\text{-}\mathrm{EC}(\cup,\cap,+,\times)$ *are* $\leq_{\mathrm{m}}^{\log}$*-complete for* Π_1.
4. $\Sigma_1\text{-}\mathrm{MC}(^{-},+,\times)$ *and* $\Sigma_1\text{-}\mathrm{EC}(^{-},+,\times)$ *are* $\leq_{\mathrm{m}}^{\log}$*-hard for* Σ_1.
5. $\Pi_1\text{-}\mathrm{EC}(^{-},+,\times)$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* Π_1.

5.2 Connecting Emptiness with Membership and Equivalence Problems

We show that with the operations $^{-}$, $+$, and $\times$ one can express a Boolean combination of emptiness problems as a single emptiness problem. Therefore, truth-table reductions to certain emptiness problems can be transformed into many-one reductions. This allows us to show certain emptiness problems to be many-one equivalent to membership problems and equivalence problems. As a byproduct we improve the known lower and upper bounds of $\mathrm{MC}(\cup,\cap,^{-},+,\times)$ [22] and $\mathrm{EQ}(\cup,\cap,^{-},+,\times)$ [11].

▶ **Proposition 15.** *The following holds if* $\{^{-},+,\times\} \subseteq \mathcal{O}$.
1. *If* $A \leq_{\mathrm{tt}}^{\log} \mathrm{EC}(\mathcal{O})$, *then* $A \leq_{\mathrm{m}}^{\log} \mathrm{EC}(\mathcal{O})$. *If* $A \leq_{\mathrm{tt}} \mathrm{EC}(\mathcal{O})$, *then* $A \leq_{\mathrm{m}} \mathrm{EC}(\mathcal{O})$.
2. *If* $\mathrm{EC}(\mathcal{O})$ *is* $\leq_{\mathrm{m}}$*-hard for* Σ_1, *then it is* $\leq_{\mathrm{m}}$*-hard for* $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.
3. *If* $\mathrm{EC}(\mathcal{O}) \in \Sigma_1 \cup \Pi_1$, *then* $\mathrm{EC}(\mathcal{O}) \in \Sigma_0$.

▶ **Corollary 16.**
1. $\mathrm{MC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{EQ}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{EC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{EC}(\cup,\cap,^{-},+,\times)}$.
2. $\Sigma_1\text{-}\mathrm{MC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{NEC}(\cup,\cap,^{-},+,\times)$.
3. $\mathrm{EC}(\cup,\cap,^{-},+,\times), \mathrm{MC}(\cup,\cap,^{-},+,\times), \mathrm{EQ}(\cup,\cap,^{-},+,\times) \in \mathcal{R}_{\mathrm{tt}}(\Sigma_1)$ *and these problems are* $\leq_{\mathrm{m}}^{\log}$*-hard for* $\mathcal{R}_{\mathrm{T}}^{\log}(\mathrm{NEXP}) = \mathrm{L}^{\mathrm{NEXP}}$.
4. $\mathrm{EC}(^{-},+,\times)$ *is* $\leq_{\mathrm{m}}$*-hard for* Σ_1 *if and only if it is* $\leq_{\mathrm{m}}$*-complete for* $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.
5. $\mathrm{EC}(\cup,\cap,^{-},+,\times)$ *is* $\leq_{\mathrm{m}}$*-hard for* Σ_1 *if and only if it is* $\leq_{\mathrm{m}}$*-complete for* $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.

For $\{^{-}, +, \times\}$-circuits there are further equivalences between membership and emptiness problems.

▶ **Proposition 17.**
1. $\mathrm{MC}(^{-}, +, \times) \equiv_{\mathrm{m}}^{\log} \mathrm{EC}(^{-}, +, \times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{EC}(^{-}, +, \times)}$.
2. $\Sigma_1\text{-MC}(^{-}, +, \times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-EC}(^{-}, +, \times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-NEC}(^{-}, +, \times)$.

5.3 The Difficulty of $\mathrm{EC}(^{-}, +, \times)$ and $\mathrm{EC}(\cup, \cap, ^{-}, +, \times)$

In the Corollaries 13 and 16 we showed that $\mathrm{EC}(^{-}, +, \times)$ is $\leq_{\mathrm{m}}^{\log}$-hard for PSPACE and $\mathrm{EC}(\cup, \cap, ^{-}, +, \times,)$ is $\leq_{\mathrm{m}}^{\log}$-hard for $\mathrm{L}^{\mathrm{NEXP}}$. By Theorem 14, both problems belong to $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$. It is an open question whether these problems are decidable. This subsection explains the difficulty of finding decision algorithms for these problems.

Goldbach conjectured that every even integer greater than 2 is the sum of two primes. At the time the conjecture was made 1 was considered to be prime, but later the opposite view became accepted. Let $\mathbb{P}_1 = \mathbb{P} \cup \{1\}$. Below we formulate both variants, Goldbach's original conjecture (GC_1) and the one that nowadays is called *Goldbach's conjecture* (GC).

$$\begin{aligned} \mathrm{GC}_1 &= \forall n \geq 1\ \exists p, q \in \mathbb{P}_1\ \ [2n = p + q] \\ \mathrm{GC} &= \forall n \geq 2\ \exists p, q \in \mathbb{P}\ \ [2n = p + q] \end{aligned}$$

We define circuits that express the truth of these conjectures, where $\mathbb{P}_1$ stands for $\overline{\overline{1} \times \overline{1}}$, $\mathbb{P}$ for $\overline{\overline{1} \times \overline{1}} \cap \overline{1}$, and $\{0, 1\}$ for $\overline{\overline{0} + 1}$.

$$\begin{aligned} C_1 &= \overline{((\mathbb{P}_1 + \mathbb{P}_1) \times \{0, 1\}) + \{0, 1\}} \\ C &= \overline{\mathbb{P} + \mathbb{P}} \cap (2 \times \overline{\{0, 1\}}) \end{aligned}$$

GC_1 is true if any only if $C_1 \in \mathrm{EC}(^{-}, +, \times)$. GC is true if and only if $C \in \mathrm{EC}(\cup, \cap, ^{-}, +, \times,)$. This tells us: If one finds a decision algorithm for $\mathrm{EC}(^{-}, +, \times)$ or $\mathrm{EC}(\cup, \cap, ^{-}, +, \times)$ and proves its correctness, then in a sense this solves Goldbach's conjecture, since the computation of this algorithm is a proof or refutation. In particular, this would imply that Goldbach's conjecture is provable or refutable, which is unknown (cf. [17]). This underlines the difficulty of finding decision algorithms for $\mathrm{EC}(^{-}, +, \times)$ and $\mathrm{EC}(\cup, \cap, ^{-}, +, \times)$.

5.4 Connection between Emptiness and Σ_1-Emptiness

We show that several emptiness problems are equivalent to their Σ_1-emptiness variants. The proof exploits the fact that the test of whether a multivariate polynomial with coefficients bounded by some constant K is identically zero is possible by evaluating this polynomial for one fixed argument only dependent on K and the total degree of the polynomial. The following lemma shows that the test of whether multivariate polynomials are identically zero reduces to the univariate case.

▶ **Lemma 18** ([20]). *Given a polynomial $f(x_1, \ldots, x_n)$ over $\mathbb{R}$ with total degree at most d, the substitution $x_i \mapsto x^{(d+1)^{i-1}}$ has the property that f is identically zero on $\mathbb{R}^n$ if and only if the obtained univariate polynomial is identically zero on $\mathbb{R}$.*

The lemma allows a reduction from $\Sigma_1\text{-EC}(\cap, +, \times)$ to $\mathrm{EC}(\cap, +, \times)$: Consider a circuit $C \in \Sigma_1\text{-EC}(\cap, +, \times)$ with unassigned inputs $u_1, \ldots, u_n$ and let $z_1, \ldots, z_n \in \mathbb{N}$ such that $C(z_1, \ldots, z_n) = \emptyset$. So under this assignment there exists a $\cap$-gate g connected to the output and computing $\emptyset$ such that no ancestor of g computes $\emptyset$. The unique number computed in the left\right predecessor $g_l \backslash g_r$ of g (note that due to the absence of $^{-}$ and $\cup$ each gate

computes a set containing at most one element) can be written as a multivariate polynomial $p_l \backslash p_r$ with variables $u_1, \ldots, u_n$. It holds that $p_l \neq p_r$, since g computes $\emptyset$. By Lemma 18, the same holds for the univariate polynomials $p'_l \backslash p'_r$ obtained by the substitution. Note that $p'_l(x) \neq p'_r(x)$ for every large enough x. Moreover, there is a circuit computable in logarithmic space that generates such an x. So the substitution rule provides the assignment $x^{(d+1)^0}, x^{(d+1)^1}, \ldots, x^{(d+1)^{n-1}}$ under which g and hence also C computes $\emptyset$. This yields the following theorem.

▶ **Theorem 19.**
1. $\mathrm{EC}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cap,+,\times)$.
2. $\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$.
3. $\mathrm{EC}(\cap,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cap,\times)$.

We generalize this argument to $\{\cup,\cap,+,\times\}$-circuits by unfolding such circuits C to a tree D, which exponentially increases the size, but not the depth. Then we observe that $C(z_1,\ldots,z_n) = \emptyset$ if and only if for all possibilities to prune D to some D' such that each $\cup$-gate has exactly one predecessor it holds that $D'(z_1,\ldots,z_n) = \emptyset$. Since a $\cup$-gate with exactly one predecessor acts like a wire, the D' are $\{\cap,+,\times\}$-circuits. Hence $C \in \Sigma_1\text{-}\mathrm{EC}(\cup,\cap,+,\times)$ if and only if for all D' it holds that $D' \in \Sigma_1\text{-}\mathrm{EC}(\cap,+,\times)$. So we reached a situation similar to Theorem 19.1 with the difference that D' has exponential size and polynomial depth, which translates to polynomials with an exponential number of monomials and polynomially bounded degrees. Since the argument for Theorem 19 depends only on the polynomial's degree, but not on the number of monomials we obtain:

▶ **Theorem 20.**
1. $\mathrm{EC}(\cup,\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cup,\cap,+,\times)$.
2. $\mathrm{EC}(\cup,\cap,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cup,\cap,\times)$.

From known results on $\mathrm{MC}(\cap,+,\times)$ and $\mathrm{MC}(\cap,\times)$ [22] and Theorem 6 we obtain:

▶ **Corollary 21.**
1. $\mathrm{EC}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{MC}(\cap,+,\times)} \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{EQ}(+,\times)}$.
2. $\Sigma_1\text{-}\mathrm{EC}(\cap,+,\times) \in \mathrm{RP}$.
3. $\Sigma_1\text{-}\mathrm{EC}(\cup,\cap,+,\times)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* coNEXP.
4. $\Sigma_1\text{-}\mathrm{EC}(\cap,\times) \in \mathrm{P}$.
5. $\mathrm{EC}(\cap,\times) \equiv_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}(\cap,\times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{MC}(\cap,\times)}$.
6. $\Sigma_1\text{-}\mathrm{EC}(\cup,\cap,\times)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* PSPACE.

The 5th statement shows that improving the non-matching bounds for $\mathrm{EC}(\cap,\times)$ is as difficult as improving the bounds for $\mathrm{MC}(\cap,\times)$, which is an open problem from [22].

5.5 Connection to Polynomial Identity Testing

We extend the equivalence in statement 1 of Corollary 21 by $\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$, $\Sigma_1\text{-}\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$, $\overline{\mathrm{MC}_{\mathbb{Z}}(\cap,+,\times)}$, $\overline{\mathrm{MC}_{\mathbb{Z}}(+,\times)}$, and $\overline{\mathrm{PIT}}$. The connection to PIT is interesting as it explains the difficulty of several open questions, namely the non-matching lower and upper bounds of $\mathrm{MC}(\cap,+,\times)$ in [22], $\mathrm{MC}_{\mathbb{Z}}(\cap,+,\times)$ and $\mathrm{MC}_{\mathbb{Z}}(+,\times)$ in [32], and $\mathrm{EQ}(+,\times)$ in [11]. In addition, it settles the question for the complexity of $\mathrm{EC}(\cap,+,\times)$ and $\Sigma_1\text{-}\mathrm{EC}(\cap,+,\times)$.

PIT (polynomial identity testing) is the following problem: For a given integer circuit consisting of input gates associated with variables/constants from $\mathbb{Z}$ and internal gates for addition/multiplication over $\mathbb{Z}$, one has to decide whether the polynomial described by the

circuit is identically zero or not. The term *identically zero* means that the polynomial must be formally zero, i.e., if we write it as a linear combination of monomials with coefficients from $\mathbb{Z}$, then all coefficients are zero. For the ring $\mathbb{Z}$ this is equivalent to requiring that the polynomial is zero on $\mathbb{Z}^n$, where n is the number of unassigned input gates. (For other rings this makes a difference: for example over $\mathbb{F}_2$, the polynomial $x^2 + x$ is not identically zero, although it is zero on $\mathbb{F}_2$.) Formally, we can define PIT as the following problem concerning $\{+, \times\}$-circuits over $\mathbb{Z}$:

$$\text{PIT} \stackrel{df}{=} \{\, C \mid C \text{ is a } \{+,\times\}\text{-circuit with unassigned inputs } u_1 < \cdots < u_n \text{ such that the assigned inputs have labels from } \mathbb{Z} \text{ and for all } x_1,\ldots,x_n \in \mathbb{Z} \text{ it holds that } I(C(x_1,\ldots,x_n)) = \{0\} \,\}.$$

It is known that PIT $\in$ coRP [15], but proving the exact complexity of PIT is considered as one of the greatest challenges in algebraic computing complexity [26] and theoretical computer science in general [29]. This fundamental problem has many applications, e.g., a deterministic primality test [1]. For further background on PIT we refer to the articles [26, 29, 27, 19]. Let $\mathcal{PIT}$ denote the class of problems that are $\leq_{\mathrm{m}}^{\log}$-reducible to PIT.

▶ **Theorem 22.** $\mathrm{EC}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{MC}(\cap,+,\times)} \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{EQ}(+,\times)} \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{PIT}} \equiv_{\mathrm{m}}^{\log} \mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$.

We sketch the proof: By Corollary 21, $\mathrm{EC}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{MC}(\cap,+,\times)} \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{EQ}(+,\times)}$. Theorem 19 implies $\overline{\mathrm{EQ}(+,\times)} \leq_{\mathrm{m}}^{\log} \overline{\mathrm{PIT}} \leq_{\mathrm{m}}^{\log} \Sigma_1\text{-}\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times) \leq_{\mathrm{m}}^{\log} \mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$. It remains to show $\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times) \leq_{\mathrm{m}}^{\log} \mathrm{EC}(\cap,+,\times)$.

We simulate a $\{\cap,+,\times\}$-circuit C over $\mathbb{Z}$ by a $\{\cap,+,\times\}$-circuit C' over $\mathbb{N}$ such that the value $v \in \mathbb{Z}$ computed in gate i of C is represented in C' by two positive numbers $\widetilde{i} + v$ and $\widetilde{i} - v$, where $\widetilde{i} = 2^{3^i}$. This shift by $\widetilde{i}$ allows $\{\cap,+,\times\}$-circuits over $\mathbb{N}$ to represent numbers from $\mathbb{Z}$. A technical elaboration shows that the circuits can also *process* numbers represented in this way, i.e., there are subcircuits that simulate the operations $\cap$, $+$, and $\times$.

Together with the Theorems 19 and 22 we obtain:

▶ **Corollary 23.** *The following problems are* $\leq_{\mathrm{m}}^{\log}$*-equivalent to* $\overline{\mathrm{PIT}}$*:*
$\mathrm{EC}(\cap,+,\times)$, $\Sigma_1\text{-}\mathrm{EC}(\cap,+,\times)$, $\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$, $\Sigma_1\text{-}\mathrm{EC}_{\mathbb{Z}}(\cap,+,\times)$, $\overline{\mathrm{MC}_{\mathbb{Z}}(\cap,+,\times)}$, $\overline{\mathrm{MC}_{\mathbb{Z}}(+,\times)}$.

The equivalence to $\overline{\mathrm{PIT}}$ shows the difficulty of understanding the complexity of the problems $\mathrm{EC}(\cap,+,\times)$ and $\Sigma_1\text{-}\mathrm{EC}(\cap,+,\times)$ as well as the open problems from [22, 32, 11] mentioned above. Kabanets and Impagliazzo [16] substantiate the hardness of obtaining subexponential algorithms for PIT by showing that it implies that NEXP $\not\subset$ P/poly or the permanent is not computable by polynomial size arithmetic circuits over $\mathbb{Q}$ with divisions. Both statements are expected to be difficult to prove.

In view of Theorem 22 it seems unlikely that $\mathrm{EQ}(\cap,+,\times)$ is equivalent to PIT: A straightforward proof shows that $\mathrm{EQ}(\cap,+,\times)$ is $\leq_{\mathrm{m}}^{\log}$-complete for $\mathcal{PIT} \vee \mathrm{co}\mathcal{PIT} = \{L \cup L' \mid L \in \mathcal{PIT}, L' \in \mathrm{co}\mathcal{PIT}\}$, which is the complement of the second level of the Boolean hierarchy [18] over $\mathcal{PIT}$. If $\mathrm{EQ}(\cap,+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{PIT}$, then $\mathcal{PIT} = \mathcal{PIT} \vee \mathrm{co}\mathcal{PIT}$ and hence $\mathrm{PIT} \equiv_{\mathrm{m}}^{\log} \overline{\mathrm{PIT}} \in \mathrm{RP} \subseteq \mathrm{NP}$. Kabanets and Impagliazzo [16] show that PIT $\in$ NP is unlikely, since it implies NEXP$\cap$coNEXP $\not\subset$ P/poly or the permanent is not computable by polynomial-size arithmetic circuits over $\mathbb{Q}$ with divisions. This also explains the difficulty of improving the upper bound for $\mathrm{EQ}(\cap,+,\times)$ from BPP [11] to coRP, since this implies $\overline{\mathrm{PIT}} \leq_{\mathrm{m}}^{\log} \mathrm{EQ}(\cap,+,\times) \in \mathrm{coRP}$.

6 Conclusions and Open Questions

The results of this paper are summarized in Table 1. For most of the emptiness problems it was possible to precisely characterize their complexity.

Table 1 Upper bounds mean membership in the class, lower bounds stand for $\leq_{\mathrm{m}}^{\log}$-hardness for the class. Numbers refer to results in this paper. Gray cells do not contain references, since by statement 5 of Lemma 2 these results are obtained from white cells. Subsets $\mathcal{O}$ that are missing in the first column either correspond to trivial problems (statement 3 of Lemma 2) or can be transformed by De Morgan's law to an equivalent subset (statement 4 of Lemma 2). $\mathcal{PIT}$ is the class of problems that are logspace many-one reducible to polynomial identity testing, which is a well-studied problem in algebraic computing complexity. It is known that $\mathrm{P} \subseteq \mathcal{PIT} \subseteq \mathrm{coRP}$ and it is an open problem to improve these bounds.

$\mathcal{O}$	EC l.b.	EC u.b.	Σ_1-EC l.b.	Σ_1-EC u.b.	Π_1-EC l.b.	Π_1-EC u.b.
$\cap$	NL, 4	NL	NL	NL, 4	NL	NL, 4
$\cup\,\cap$	P, 4	P	P	P, 4	P	P, 4
$\cap\,+$	$\mathrm{coC_{=}L}$, 3	$\mathrm{coC_{=}L}$	$\mathrm{coC_{=}L}$	$\mathrm{coC_{=}L}$, 5	coNP, 6	coNP, 6
$\cap\,\times$	$\mathrm{coC_{=}L}$, 3	P	$\mathrm{coC_{=}L}$	P, 21	coNP, 3	coNP, 3
$^{-}\,+$	PSPACE, 13	PSPACE	PSPACE	2EXPSPACE	PSPACE	2EXPSPACE
$^{-}\,\times$	PSPACE, 13	PSPACE	PSPACE	3EXPSPACE	PSPACE	3EXPSPACE
$\cup\,\cap\,^{-}$	P	P, 4	NP, 4	NP, 4	coNP, 4	coNP, 4
$\cup\,\cap\,+$	PSPACE, 6	PSPACE	PSPACE	PSPACE, 6	PSPACE	PSPACE, 6
$\cup\,\cap\,\times$	PSPACE, 6	PSPACE	PSPACE	PSPACE, 21	PSPACE	PSPACE, 6
$\cap\,+\,\times$	co$\mathcal{PIT}$, 22	co$\mathcal{PIT}$	co$\mathcal{PIT}$	co$\mathcal{PIT}$, 23	Π_1, 14	Π_1
$^{-}\,+\,\times$	PSPACE	$\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$	Σ_1, 14	Σ_2	Π_1, 14	Π_2
$\cup\,\cap\,^{-}+$	PSPACE	PSPACE, 3	PSPACE	2EXPSPACE, 8	PSPACE	2EXPSPACE, 8
$\cup\,\cap\,^{-}\times$	PSPACE	PSPACE, 3	PSPACE	3EXPSPACE, 8	PSPACE	3EXPSPACE, 8
$\cup\,\cap\,+\times$	coNEXP, 3	coNEXP	coNEXP	coNEXP, 21	Π_1	Π_1, 14
$\cup\,\cap\,^{-}+\times$	$\mathrm{L}^{\mathrm{NEXP}}$, 16	$\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$, 14	Σ_1	Σ_2, 14	Π_1	Π_2, 14

The results provide insights and improved complexity bounds for the following problems: $\mathrm{MC}(\cup,\cap,^{-},+,\times)$, $\mathrm{MC}(\cap,+,\times)$ studied in [22], $\mathrm{MC}_{\mathbb{Z}}(+,\times)$, $\mathrm{MC}_{\mathbb{Z}}(\cap,+,\times)$ studied in [32], and $\mathrm{EQ}(\cup,\cap,^{-},+,\times)$, $\mathrm{EQ}(+,\times)$, $\mathrm{EQ}(\cap,+,\times)$ studied in [11].

A challenging open problem is to improve the bounds for the problems $\mathrm{EC}(^{-},+,\times)$ and $\mathrm{EC}(\cup,\cap,^{-},+,\times)$. Here the state of knowledge is as follows (cf. Propositions 15, 17, and Corollary 16):

1. Both problems are equivalent to problems investigated in [22, 11]: $\mathrm{EC}(^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{MC}(^{-},+,\times)$ and $\mathrm{EC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{MC}(\cup,\cap,^{-},+,\times) \equiv_{\mathrm{m}}^{\log} \mathrm{EQ}(\cup,\cap,^{-},+,\times)$.
2. Finding a decision algorithm and proving its correctness is at least as difficult as showing that Goldbach's conjecture is provable or refutable, which is an open problem.
3. The problems are either decidable or outside $\Sigma_1 \cup \Pi_1$.
4. The problems are $\leq_{\mathrm{m}}$-hard for Σ_1 if and only if they are $\leq_{\mathrm{m}}$-complete for $\mathcal{R}_{\mathrm{tt}}(\Sigma_1)$.

Another open problem is to improve the complexity bounds whenever we have one of the classes 2EXPSPACE and 3EXPSPACE as upper bound. The latter are consequences of the decidability of the Presburger and Skolem arithmetic. It is possible that more specific proof techniques can improve these bounds. By Lemma 2, Π_1-$\mathrm{EC}(\cup,\cap,^{-},\times)$ is equivalent to the complement of Σ_1-$\mathrm{MC}(\cup,\cap,^{-},\times)$, which has already been investigated in [13, 12].

A third open problem is to improve the bounds for $\mathrm{EC}(\cap,\times)$ and Σ_1-$\mathrm{EC}(\cap,\times)$. Both problems are equivalent to $\mathrm{MC}(\cap,\times)$, which has already been studied in [22].

Acknowledgements. We thank Klaus Reinhardt for sharing an unpublished proof for the $\leq_{\mathrm{m}}^{\mathrm{p}}$-hardness of $\mathrm{MC}(^{-},\times)$ for PSPACE, which we slightly adapted to show the $\leq_{\mathrm{m}}^{\log}$-hardness of $\mathrm{MC}^{+}(^{-},+)$ for PSPACE (Lemma 10), and for helpful discussions on the $\leq_{\mathrm{m}}^{\log}$-hardness

of MC($^-$, +) for PSPACE (Theorem 11). Moreover, we thank Jakob Sigmund for helpful discussions and contributions to the proof of Theorem 12.

Abstract

In algorithmic randomness, the class of K-trivial sets has proved itself to be remarkable, due to its numerous different characterizations. We pursue in this paper some work already initiated on K-trivials in the context of higher randomness. In particular we give here another characterization of the non hyperarithmetic higher K-trivial sets.

1998 ACM Subject Classification Computability theory

Keywords and phrases Algorithmic randomness, higher computability, K-triviality, effective descriptive set theory, Kolmogorov complexity

1 Introduction

Algorithmic randomness defines what it is for an infinite 0-1 valued sequence to be random. It takes its roots deeply in computability : lots of definition and techniques from pure computability are used in algorithmic randomness, as hierarchies, reducibilites and forcing constructions. The research in this field led to the identification of many different randomness notions, the most known being perhaps Martin-Löf randomness: a sequence is Martin-Löf random if it is in no Π^0_2 set $\bigcap_n \mathcal{U}_n$ where the Lebesgue measure of each $\mathcal{U}_n$ is smaller than 2^{-n}. The reader can refer to [21] and [8] for more details on algorithmic randomness. One of the main research area is to study how the different classes of random sequences relate. For a given such class of randoms, another important research area is to study the sets relative to which this class does not change. This is called *lowness for randomness*. For example, the class of K-trivials are exactly the low for Martin-Löf randomness. This class is defined as the set of infinite sequences having minimal (up to a constant) Kolmogorov complexity on their prefixes, that is the Kolmogorov complexity of a prefix should not be bigger than its length [1]. The class of K-trivials proved itself to be remarkable, due to its numerous very different characterizations [20], [12], [6], [1], [9].

Another field has a lot of interactions with computability theory : descriptive set theory. This field can be studied completely independently from recursion theory as in [14]. However, the study of descriptive set theory in close relation with computability appeared to be a fruitful approach. The mix of these two fields is called effective descriptive set theory and can be used to prove lots of results from the classical version of descriptive set theory. This is done mainly in [19]. Effective descriptive set theory also gave rise to higher computability.

* This work was partially supported by TARMAC.

[1] Here it is important that we use the so called *prefix-free Kolmogorov complexity*, as it is the case in general with algorithmic randomness.

The notion of computation for this field comes from a very logical point of view, far from any implementation. Nonetheless it is possible to give an intuition of higher computation which is closer to what computer scientists are used to: one can view a higher computation as a regular computation (by a Turing machine, say) where the steps of computation are carried through the computable ordinals. This new way of computing has several things in common with the classical one, and of course some differences (as the lack of continuity in a computation) that may cause trouble when trying to lift some computability theorems from the classical setting to the higher setting. The reader can refer to [22], [5] and [18] for more details on higher recursion theory. The reader can also see [11] for more information about what could be a Turing machine which keeps running over ordinal times of computation.

Algorithmic randomness naturally arises from mixing probability theory and computability. Following the same ideas, researchers defined notions of higher randomness, obtained analogously, but by considering higher computability instead of computability. After the founder paper of the field [13], a lots of advances were made by several researchers ([4], [3], [2], [10]). The reader can also refer to [5] and [18] for more details on higher randomness. One of the notion which has previously been studied and which is the core subject of the paper, is the notion of higher K-triviality, the direct higher analogue of K-triviality. In particular, we give in this paper a characterization of the non-Δ^1_1 higher K-trivials, by proving that they are exactly the sets that shrink the class $\mathrm{W}\Pi^1_1\mathrm{R}$ to the class Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$ when relativizing continuously. This characterization is specific to the higher setting: the randomness notions that are equivalent to $\mathrm{W}\Pi^1_1\mathrm{R}$ and Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$ in the lower setting, coincide.

2 Preliminaries

2.1 Notations

In this paper, we work in the space of infinite sequences of 0's and 1's, called the Cantor space, denoted by 2^ω. We call *strings* finite sequences of 0's and 1's and *sequences* or *sets* elements of the Cantor space. For a sequence A we write $A\upharpoonright_n$ to denote the string equal to the n first bits of A. The space of strings is denoted by $2^{<\omega}$ and the space of strings of length smaller than n is denoted by $2^{<n}$. For a string σ, we denote the set of sequences extending σ by $[\sigma]$.

The topology on Cantor space is generated by the basic intervals $[\sigma] = \{X \in 2^\omega \mid X \succ \sigma\}$ for any string σ. For a set of strings $W \subseteq 2^{<\omega}$, we let $[W] = \bigcup_{\sigma\in W}[\sigma]$. A set of string W is said to be prefix-free if no string in W is a prefix of another string in W.

For $\mathcal{A} \subseteq 2^\omega$ Lebesgue-measurable, $\lambda(\mathcal{A})$ denotes the Lebesgue measure of $\mathcal{A}$, which is the unique Borel measure such that $\lambda([\sigma]) = 2^{-|\sigma|}$ for all strings σ.

We assume that the reader is familiar with basic notions of computability. For $A, B \in 2^\omega$ we write $A \leq_T B$ if A is Turing reducible to B. We denote by $\emptyset'$ the halting problem. We also assume that the reader is familiar with the basics of effective descriptive set theory, in particular with the notations $\Sigma^0_1, \Pi^0_1, \Sigma^0_2, \Pi^0_2, etc...$

We finally also assume that the reader is familiar with the notion of Kolmogorov complexity. In this paper, we will only consider a prefix-free version of the Kolmogorov complexity (used in the definition of K-triviality): using compressors $M : 2^{<\omega} \to 2^{<\omega}$ such that the domain of M is prefix-free. It is an easy exercise to show that an optimal prefix-free compressor exists (optimal up to a constant of course).

2.2 Background on algorithmic randomness

In 1966, Martin-Löf gave in [16] a definition capturing elements of the Cantor space that can be considered 'random'. Many nice properties of the Martin-Löf random sequences make this notion of randomness one of the most interesting and one of the most studied.

Intuitively a random sequence should not have any atypical property. A property is here considered atypical if the set of sequences sharing this property is of measure 0. It also makes sense to consider only properties which can be described in some effective way (because any X has the property of being in the set $\{X\}$ and thus nothing would be random).

▶ **Definition 1.** An intersection of measurable sets $\bigcap_n \mathcal{A}_n$ is said to be *effectively of measure* 0 if the function which to n associates the measure of $\mathcal{A}_n$ is bounded by 2^{-n}. A *Martin-Löf test*, or an ML-test is a Π^0_2 set $\bigcap_n \mathcal{U}_n$ effectively of measure 0. We say that $X \in 2^\omega$ is *Martin-Löf random* if it is in no Martin-Löf test. The class of Martin-Löf randoms is also referred to as the class MLR.

The requirement for a Martin-Löf test to be effectively of measure 0 is important and leads to very nice properties. In particular there exists a universal Martin-Löf test, i.e. a test containing all the others (see [16]). This is not the case anymore if we drop the 'effectively of measure 0' condition. Instead we get a notion known as weak-2-randomness.

▶ **Definition 2.** A Π^0_2 nullset is called a *weak-2 test* or a W2 test. We say that $X \in 2^\omega$ is *weakly-2-random* if it is in no weak-2 test. The class of weakly-2-randoms is also referred to as the class W2R.

As a randomness notion, weak-2-randomness is a strictly stronger than 1-randomness: tests can capture more elements and thus there are fewer randoms. For any given randomness notion, it makes sense to relativize it to any oracle:

▶ **Definition 3.** Let $A \in 2^\omega$. An ML^A test is a $\Pi^0_2(A)$ set $\bigcap_n O_n$ effectively of measure 0. We say that $X \in 2^\omega$ is MLR^A if it is in no ML^A test. Similarly a $\mathrm{W2}^A$ test is a $\Pi^0_2(A)$ nullset, and we say that X is $\mathrm{W2R}^A$ if it is in no $\mathrm{W2}^A$ test.

A nice characterization of W2R has been given from restricting the relativization $\mathrm{MLR}^{\emptyset'}$: we can only use $\emptyset'$ to find the indices of the open sets in a test.

▶ **Definition 4.** Let $(W_e)_{e\in\omega}$ be an effective enumeration of the c.e. sets of strings. A $\mathrm{ML}\langle\emptyset'\rangle$ test is a set $\bigcap_n [W_{f(n)}]$ with $\lambda([W_{f(n)}]) \leq 2^{-n}$ were $f : \omega \to \omega$ is computable from $\emptyset'$. A set is $\mathrm{MLR}\langle\emptyset'\rangle$ if it is in no $\mathrm{ML}\langle\emptyset'\rangle$ test.

Note that with the full relativization of an ML test to A, the oracle A itself is not needed to find the index of the n-th $\Sigma^0_1(A)$ open set of the test: the use of A for that can be swallowed in the process of enumerating each $\Sigma^0_1(A)$ component of the test.

Going back to the previous definition, we have the following easy theorem:

▶ **Theorem 5** ([2], section 7)**.** $\mathrm{W2R} = \mathrm{ML}\langle\emptyset'\rangle$.

Proof. Let's start with $\mathrm{W2R} \subseteq \mathrm{ML}\langle\emptyset'\rangle$, given a $\mathrm{ML}\langle\emptyset'\rangle$ test $\bigcap_n \mathcal{U}_{f(n)}$, we will show that it is included in a W2R test. We define $V_{\langle m,t\rangle} = \bigcup_{s\geq t} \mathcal{U}_{f_s(m)}$. As $\bigcap_n V_n = \bigcap_n \mathcal{U}_{f(n)}$, we have that $\lambda(\bigcap_n \mathcal{V}_n) = 0$, so this is a W2R test.

Now, let $\bigcap_n \mathcal{U}_n$ be a Π^0_2 nullset, one can use $\emptyset'$ to find uniformly in n the first $m = f(n)$ such that $\lambda(\mathcal{U}_m) \leq 2^{-n}$. ◀

The sets relative to which $\mathrm{MLR}^A = \mathrm{MLR}$ have been extensively studied, and have been identified as the class of K-trivial sets.

▶ **Definition 6.** A set $A \in 2^\omega$ is K-trivial if for any n, the prefix-free Kolmogorov complexity of $A\restriction_n$ is smaller than the prefix-free Kolmogorov complexity of n (up to a constant).

The reader can refer to [21] for more details on the K-trivials. They are also the sets relative to which $\mathrm{W2R}^A = \mathrm{W2R}$:

▶ **Theorem 7** ([20], [15], [7])**.** *The following are equivalent for a set A:*
1. *A is K-trivial*
2. $\mathrm{W2R}^A = \mathrm{W2R}$
3. $\mathrm{MLR}^A = \mathrm{MLR}$

As we will see, this characterization fails in the higher setting, but it fails in a way that will help us provide another characterization of the higher K-trivials.

2.3 Background on higher computability

We assume that the reader is familiar with the concepts of Δ^1_1, Π^1_1 and Σ^1_1 subsets of ω and of 2^ω. A known result is that an open set $\mathcal{U}$ is Π^1_1 if and only if there exists a Π^1_1 set of strings W such that $\mathcal{U} = [W]^\prec$.

There is a strong analogy between classical concepts in computability (referred to as the *lower setting*) and their analogue in higher computability (referred to as the *higher setting*). For instance, Δ^1_1 can be seen as a higher analogue of computable, and Π^1_1 can be seen as a higher analogue of computably enumerable, with the difference that the times at which elements are enumerated are now computable ordinals.

We refer to the set of codes for computable ordinals (using whichever equivalent coding) as Kleene's $\mathcal{O}$. As usual, the smallest non-computable ordinal is denoted by ω_1^{CK}.

We recall here a few definitions about continuous higher Turing reductions. In [2] (Definition 1.1) higher Turing reductions are defined to compute elements of 2^ω. In [10] (section 3.2) this definition is extended in a straightforward way, to compute elements of $(\omega_1^{CK})^\omega$. We also extend this definition here in a straightforward way, to compute elements of $(\omega_1^{CK})^{\omega_1^{CK}}$.

An absolutely formal definition of computations of functions from ω_1^{CK} to ω_1^{CK} should either use the language of set theory and deals with actual ordinals, or use a unique notation system for computable ordinals. There exists such a Π^1_1 notation system $\mathcal{O}_1 \subseteq \omega$ (see [22] or [18], 3.6.1) and up to this notation system, one can view a function from ω_1^{CK} to ω_1^{CK} as a function from $\mathcal{O}_1$ to $\mathcal{O}_1$, and thus simply defined on integers.

▶ **Definition 8** ([10] [2])**.** We say that A higher Turing computes (or higher computes) $f : \omega_1^{CK} \mapsto \omega_1^{CK}$ (respectively $g : \omega \mapsto \omega_1^{CK}$) if there exists a Π^1_1 set $C \subseteq 2^{<\omega} \times \omega_1^{CK} \times \omega_1^{CK}$ (respectively $C \subseteq 2^{<\omega} \times \omega \times \omega_1^{CK}$) such that $f(o_1) = o_2$ iff $\exists \sigma \prec A\ (\sigma, o_1, o_2) \in C$ (respectively $g(n) = o$ iff $\exists \sigma \prec A\ (\sigma, n, o) \in C$). We say that A higher Turing computes $B \in 2^\omega$ if A higher Turing computes the characteristic function of B.

In [2] it is shown that Kleene's $\mathcal{O}$ higher Turing computes a set $A \in 2^\omega$ iff $\mathcal{O}$ Turing computes A.

2.4 Background on higher randomness

Higher randomness goes back to Martin-Löf who promoted the notion of Δ^1_1-randomness (already defined by Sacks [22]), defending the idea that it was the appropriate mathematical concept of randomness [17]. Even if his first definition undoubtedly became the most

successful over the years, this other definition recently got a second wind on the initiative of Hjorth and Nies who started to study the analogy between the usual notions of randomness and their higher counterparts. In order to do so they created in [13] a higher analogue of Martin-Löf randomness.

▶ **Definition 9** (Hjorth, Nies)**.** A Π^1_1-Martin-Löf test, or a Π^1_1-ML test, is given by an effectively null intersection of open sets $\bigcap_n \mathcal{U}_n$, each $\mathcal{U}_n$ being Π^1_1 uniformly in n. A sequence X is Π^1_1-Martin-Löf random if it is in no Π^1_1-Martin-Löf test. The class of Π^1_1-Martin-Löf randoms is also referred to as the class Π^1_1-MLR.

The higher analogue of weak-2-randomness has also been studied (see [4] [2]):

▶ **Definition 10.** We say that X is *weakly-Π^1_1-random* if it belongs to no $\bigcap_n \mathcal{U}_n$ with each $\mathcal{U}_n$ open set Π^1_1 uniformly in n and with $\lambda(\bigcap_n \mathcal{U}_n) = 0$. The class of weakly-$\Pi^1_1$-randoms is also referred to as the class $\mathrm{W}\Pi^1_1\mathrm{R}$.

It is also possible to define an analogue of $\mathrm{MLR}\langle\emptyset'\rangle$ in the higher setting, using Kleene's $\mathcal{O}$ in place of $\emptyset'$.

▶ **Definition 11.** Let $(W_e)_{e\in\omega}$ be an enumeration of the Π^1_1 sets of strings. A Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$ test is a set $\bigcap_n [W_{f(n)}]$ with $\lambda([W_{f(n)}]) \leq 2^{-n}$ were $f : \omega \to \omega$ is Turing computable from Kleene's $\mathcal{O}$. A set is Π^1_1-$\mathrm{MLR}\langle\mathcal{O}\rangle$ if it is in no Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$ test.

Theorem 5 does not lift to the higher setting. The proof in the lower setting uses what has been defined in [2] to be a 'time trick': we use the fact that time and space are the same objects: the natural numbers. In the higher setting, this is not anymore true as the time goes along the ordinals. It is in fact possible to show that the class Π^1_1-$\mathrm{MLR}\langle\mathcal{O}\rangle$ is strictly contained in the class $\mathrm{W}\Pi^1_1\mathrm{R}$. To be more specific, let us introduce maybe the most important notion of higher randomness, first given by Sacks, and made possible by a theorem of Lusin saying that even though Π^1_1 sets are not necessarily Borel, they remain all measurable.

▶ **Definition 12** (Sacks)**.** We say that $X \in 2^\omega$ is Π^1_1-Random if it is in no Π^1_1 nullset.

We have the following:

▶ **Theorem 13** ([2])**.** Π^1_1-$\mathrm{MLR}\langle\mathcal{O}\rangle \subsetneq \Pi^1_1$-Randoms $\subsetneq \mathrm{W}\Pi^1_1\mathrm{R} \subsetneq \Pi^1_1$-MLR

We finally give another characterization of Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$, that has no counterpart in the lower setting (with $\mathrm{ML}\langle\emptyset'\rangle$ in place of Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$), and which will be useful in the paper.

▶ **Property 14** ([2])**.** *The following are equivalent for a sequence $X \in 2^\omega$:*

1. *X is Π^1_1-$\mathrm{ML}\langle\mathcal{O}\rangle$ random*
2. *X does not belong to any test $(\mathcal{U}_s)_{s<\omega_1^{CK}}$ not necessarily nested where each $\mathcal{U}_s$ is a Π^1_1 open set uniformly in s, and such that $\lambda(\bigcap_{s<\omega_1^{CK}} \mathcal{U}_s) = 0$*

2.5 Continuous relativization of higher randomness

It is also possible to define an analogue of K-triviality in the higher setting. The higher K-trivials are defined analogously, but using a version of Kolmogorov complexity with Π^1_1-prefix-free compression machines.

▶ **Definition 15** ([13]). We define:

- The *higher prefix-free Kolmogorov complexity* is given by $K(y) = \min\{|\sigma| : U(\sigma) = y\}$ for U the universal prefix-free Π^1_1-machine given by $U(0^e1\tau) = M_e(\tau)$ and $(M_e)_{e\in\omega}$ a uniform enumeration of the Π^1_1 prefix-free machines.
- A is *higher K-trivial* if $\exists b\ \forall n\ K(A \upharpoonright n) \leq K(n) + b$.

However, for the higher K-trivials to also be low for Π^1_1-MLR, one has to be careful about the way things are relativized to oracles. In higher computability we don't have anymore the continuity aspect of the lower setting : if B is $\Delta^1_1(A)$, it does not mean that a finite quantity of A suffices to know a finite quantity of B. However, we can force this state of things, as done previously with the notion of higher Turing computations. We next define what it means to relativize the notion of Π^1_1 set, continuously to an oracle.

▶ **Definition 16** ([2]). An oracle-continuous Π^1_1 set of integers is given by a set $W \subseteq 2^{<\mathbb{N}} \times \mathbb{N}$. For a string σ we write W^σ to denote the set $\{n : \exists \tau \prec \sigma, (\tau, n) \in W\}$. For a sequence X we write W^X to denote the set $\{n : \exists \tau \prec X, (\tau, n) \in W\}$. The set W^X is then called an X-continuous Π^1_1 set of integers.

An open set $\mathcal{U}$ is X-continuously Π^1_1 if there is an X-continuously Π^1_1 set of strings W such that $\mathcal{U} = [W^X]$.

We are now ready to define continuous relativization of randomness notions :

▶ **Definition 17.** If A is a set, we say that X is $\mathrm{WII}^1_1\mathrm{R}^A$ if it is in no $\mathcal{U} = \bigcap_n \mathcal{U}_n$ where $(\mathcal{U}_n)_{n\in\omega}$ is a uniform family of A-continuous Π^1_1 open sets, such that $\lambda(\mathcal{U}) = 0$. We say that X is $\Pi^1_1\text{-MLR}^A$ if it is in no $\bigcap_n \mathcal{U}_n$ where $(\mathcal{U}_n)_{n\in\omega}$ is a uniform family of A-continuous Π^1_1 open sets, such that $\lambda(\mathcal{U}_n) \leq 2^{-n}$.

We now have the following:

▶ **Theorem 18** ([2]). *The higher K-trivials are exactly the low for* Π^1_1-MLR*, using continuous relativization.*

Unlike in the lower setting, the higher K-trivials are not anymore the low for $\mathrm{WII}^1_1\mathrm{R}$. For A Δ^1_1 (a special case of being higher K-trivial), it is still obviously the case that $\mathrm{WII}^1_1\mathrm{R}^A = \mathrm{WII}^1_1\mathrm{R}$. But if A is K-trivial and not Δ^1_1, we will actually see that $\mathrm{WII}^1_1\mathrm{R}^A = \Pi^1_1\text{-ML}\langle\mathcal{O}\rangle$.

3 Another characterization of the higher K-trivials

3.1 Collapsing approximations

When trying to lift the Δ^0_2 definitions from the lower to the higher setting, some new possibilities appear. In the lower setting, for an approximation of A the set $\{A_t : t < s\}$ is always finite as s ranges over the natural numbers. So in particular it is closed. At the contrary, when s is an ordinal, the set $\{A_t : t < s\}$ may not have this property, which leads us to define a different type of approximation, which depends on the topological properties of $\{A_t : t < s\}$.

▶ **Property/Definition 19** ([2]).

1. *A sequence A is higher Δ^0_2 if it satisfies the following equivalent properties :*
   - **(a)** $A \leq_T \mathcal{O}$
   - **(b)** *There is a higher computable sequence $(A_s)_{s<\omega_1^{CK}}$ with $\lim_{s\to\omega_1^{CK}} A_s = A$*
2. *A computable approximation $(A_s)_{s<\omega_1^{CK}}$ converging to A is said to be collapsing if for every stage s, the set A is not in the closure of $\{A_t : t < s\}$.*

Such approximations are called collapsing, because they can be used to "collapse" ω_1^{CK} to a computable ordinal in a strong way: such approximations can be used to compute an ω-sequence of computable ordinals, with ω_1^{CK} as a supremum:

▶ **Property 20** ([2]). *Every sequence A with a collapsing approximation, higher Turing computes a function $f : \omega \to \omega_1^{CK}$ which is cofinal in ω_1^{CK}.*

In classical computability, given an effectively open set $\mathcal{U}$, it is uniformly possible to obtain a c.e. and prefix-free set W such that $[W] = \mathcal{U}$. However, in the setting of higher computability, it can be proved that this is no more possible: there is a Π^1_1 open set $\mathcal{U}$ such that for every prefix-free Π^1_1 set of strings W, $\mathcal{U} \neq [W]$. But working relative to some sets that have a collapsing approximation allows us to use time tricks, and in a way brings us "closer" to classical computability.

▶ **Property 21** ([2],end of page 20). *If A has a collapsing approximation $(A_s)_{s<\omega_1^{CK}}$, and $\mathcal{U}$ is an oracle-continuous Π^1_1 open set, then there exists an oracle-continuous Π^1_1 set $W \subseteq 2^{<\omega} \times 2^{<\omega}$ such that $\mathcal{U}^A = [W^A]$ and for all B, the set W^B is prefix-free.*

Proof. We define an enumeration of a Π^1_1 oracle-continuous set W. The enumeration of W will compute throughout its stages a collapsing approximation $(A_s)_{s<\omega_1^{CK}}$ of A. At stage s, if A_s is not in the closure of $\{A_t\}_{t<s}$, then let $\tau \prec A_s$ be the smallest such that τ has never been a prefix of some A_t for $t < s$. Then enumerate into W^τ_{s+1} all strings σ of length smaller than or equal to $|\tau|$ such that $[\sigma] \subseteq \mathcal{U}^\tau_s$ but $[\sigma]$ is disjoint from $[W^\tau_s]$.

It is clear that $[W^A] \subseteq \mathcal{U}^A$. Let us argue that $\mathcal{U}^A \subseteq [W^A]$. Suppose $\sigma \in \mathcal{U}^A$. There are sequences $\{\tau_n\}_{n\in\omega}$ and $\{s_n\}_{n\in\omega}$ such that for every n, the ordinal s_n is the first for which we have $A_{s_n}\restriction_{|\tau_n|} = A\restriction_{|\tau_n|} = \tau_n$, and such that $\sup_n s_n = \omega_1^{CK}$.

Let n be the smallest such that $|\tau_n| > |\tau_{n-1}| \geq |\sigma|$ and such that $\sigma \in \mathcal{U}^{\tau_n}_{s_n}$. Then we have by construction that $\sigma \subseteq [W^{\tau_n}_{s_n+1}]$. Therefore $[W^A] = \mathcal{U}^A$. Also by construction W^B is prefix-free for every B. ◀

3.2 Properties of higher K-Trivials

One key property of the higher K-trivial sequences is that they have a collapsing approximation as long as they are not Δ^1_1.

▶ **Property 22** ([2]). *Every higher K-trivial, but not Δ^1_1, sequence has a collapsing approximation.*

▶ **Corollary 23.** *If A is higher K-trivial but not Δ^1_1, then:*

- *A higher Turing computes a function $f : \omega \to \omega_1^{CK}$ whose range is unbounded in ω_1^{CK} ;*
- *if $\mathcal{U}$ is an oracle-continuous Π^1_1 open set, one can uniformly find a Π^1_1 oracle-continuous set of strings W such that $\mathcal{U}^A = [W^A]$ and $\forall B \in 2^\omega$, W^B is prefix-free.*

Proof of the corollary. By property 22, together with property 20 and 21. ◀

The proof that the low for Martin-Löf randoms are exactly the K-trivials requires a big machinery. Using the fact that higher K-trivials have a collapsing approximation, it is possible to transpose this proof and to show that the continuously low for Π^1_1-MLR are the higher K-trivials. The machinery developed in this proof can also be used to show a slightly more general statement, known in the lower setting as the "Main Lemma". One can find a detailed proof and explanation of this result for the higher setting in [2]. We give here a version of the Main Lemma which is closer to our need than the one in [2] (using oracle-continuous open sets in place of oracle-continuous discrete semi-measures) :

▶ **Theorem 24** (Main Lemma). *If A is higher K-trivial, $(A_s)_{s<\omega_1^{CK}}$ is any collapsing approximation of A, and W is an oracle-continuous Π^1_1 set of strings such that there exists $c \in \omega$ such that for all X we have $\sum_{\sigma \in W^X} 2^{-|\sigma|} \leq c$, then there exists a higher computable function $q : \omega_1^{CK} \to \omega_1^{CK}$ such that:*

$$S = \sum_{r<\omega_1^{CK}} \sum_{\sigma \in E_r} 2^{-|\sigma|} \text{ is finite}$$

where

$$E_r = \left\{ \sigma : \begin{array}{l} \sigma \in W^A[q(r)] \text{ with use } u, \text{ and} \\ A[q(r)] \upharpoonright u \neq A[q(r+1)] \upharpoonright u \end{array} \right\}.$$

Intuitively, if A is higher K-trivial, we can slow down its approximations in such a way that not too much measure is added in the open set, with pieces of oracle that were believed at some point to be prefixes of A but in fact are not: the total sum of 'wrong' measure added this way over the times of computation can be made finite.

3.3 A higher K-trivial and not Δ^1_1 implies Π^1_1-ML$\langle\mathcal{O}\rangle = $ WΠ^1_1R^A

▶ **Theorem 25.** *If A is higher K-Trivial and not Δ^1_1, then* WΠ^1_1R$^A \subseteq \Pi^1_1$-MLR$\langle\mathcal{O}\rangle$.

Proof. Fix an A. By contrapositive, we prove that if X is captured by a Π^1_1-ML$\langle\mathcal{O}\rangle$ test, then it is also captured by a WΠ^1_1R^A test. We use the characterization 14 of Π^1_1-ML$\langle\mathcal{O}\rangle$ tests, so let $\mathcal{U} = \bigcap_{s<\omega_1^{CK}} \mathcal{U}_s$ be such a test.

We make use of the corollary 23 that A higher computes a function f with cofinality ω_1^{CK}. Let $g(\langle m, n\rangle)$ be the m-th element of $\mathcal{O}_{\leq f(n)} \subseteq \mathbb{N}$ (where $\mathcal{O}_{\leq \alpha}$ is the set of codes for computable ordinals smaller than α). Then g is also higher computable from A, and its range is all the computable ordinals. Now, we consider $\bigcap_n \mathcal{U}_{g(n)}$. As the range of g is ω_1^{CK}, the intersection is equal to $\mathcal{U}$, so its measure is 0 and as g is higher computable from A, this set is a WΠ^1_1R^A test. ◀

The other inclusion will be a corollary of a more general theorem, whose proof follows the same spirit than the proof in the lower setting that K-trivials are low for W2R.

▶ **Theorem 26.** *Let A be higher K-trivial. Let $G = \bigcap_n \mathcal{U}_n$ where $(\mathcal{U}_n)_{n\in\omega}$ is a uniform family of Π^1_1 open sets, continuously in A. Then there exists a set $S = \bigcap_{s<\omega_1^{CK}} \mathcal{V}_s$ where $(\mathcal{V}_s)_{s<\omega_1^{CK}}$ is a uniformly Π^1_1 family of open sets, such that $\lambda(S) = \lambda(G)$ and $S \supseteq G$.*

We will first prove the result for the simplest G, that is when the family is reduced to a single open set $\mathcal{U}$, and then extend this result to a uniform countable intersection of such open sets.

▶ **Lemma 27.** *Let A be higher K-trivial. Let G be a A-continuously Π^1_1 open set. Then there exists a set $S = \bigcap_{s<\omega_1^{CK}} \mathcal{V}_s$ where $(\mathcal{V}_s)_{s<\omega_1^{CK}}$ is a uniformly Π^1_1 family of open sets, such that $\lambda(S) = \lambda(G)$ and $S \supseteq G$.*

Proof. Using the property 21, there exists an oracle-continuous Π^1_1 set of strings W such that $G = [W^A]$, and such that W^B is prefix-free for all B.

If A is Δ^1_1 we are done. Otherwise, as it is higher K-trivial, it has a collapsing approximation, so we can try to use it to approximate G with Π^1_1 open sets $\mathcal{V}_s$. A first candidate for $\mathcal{V}_s$ could be $\bigcup_{s\leq r<\omega_1^{CK}} W^A[r]$, because every such $\mathcal{V}_s$ would contain G, but this approximation

is "too large", because W and approximations of A can be such that $W^A[s]$ enumerates the empty word for a family of s cofinal in ω_1^{CK}.

The trick to prevent the measure to increase is to restrain the computation of $W^A[s]$ only to some special stages and parts of the oracle, so that the weight of all errors is finite. These stages are given by the Main Lemma : let $q : \omega_1^{CK} \to \omega_1^{CK}$ be the function given by the Main Lemma, applied to W. We then have:

$$\sum_{r<\omega_1^{CK}} \sum_{\sigma\in E_r} 2^{-|\sigma|} \text{ is finite}$$

where

$$E_r = \left\{ \sigma : \begin{array}{l} \sigma \in W^A[q(r)] \text{ with use } u, \text{ and} \\ A[q(r)] \upharpoonright u \neq A[q(r+1)] \upharpoonright u \end{array} \right\}.$$

Now we define $\mathcal{V}_s$ by computing only over the special stages and prefixes, that is

$$\sigma \in \mathcal{V}_s \Leftrightarrow \exists r \geq s \text{ such that } \sigma \in W^A[q(r)].$$

Every $\mathcal{V}_s$ contains G as any string σ enumerated in W^A, with use u, will be in every $W^A[q(r)]$ for $r \geq t$ such that $A[q(t+1)]$ has settled on $A \upharpoonright u$.

Now consider the errors of the $\mathcal{V}_s$, that is the strings σ enumerated in $\mathcal{V}_s$ but such that $[\sigma] \not\subseteq G$. There must exists an $r \geq s$ such that $\sigma \in W^A[q(r)]$ with use u, and such that $A[q(r)] \upharpoonright u \neq A[q(r+1)] \upharpoonright u$. Then $\sigma \in E_r$ for some $r \geq s$. It follows that:

$$\lambda(\mathcal{V}_s \setminus G) \leq \sum_{s\leq r<\omega_1^{CK}} \sum_{\sigma\in E_r} 2^{-|\sigma|}.$$

But as the total sum is finite, the partial sum goes to zero as s increases:

$$\lim_{s\to\omega_1^{CK}} \lambda(\mathcal{V}_s \setminus G) = 0.$$

Finally with $S = \bigcap_{s<\omega_1^{CK}} \mathcal{V}_s$, we have $\lambda(S \setminus G) = 0$ and $S \supseteq G$, which concludes the proof of the lemma. ◀

proof of Theorem 26. It remains to prove using this lemma the more general case when $G = \bigcap_{n\in\omega} \mathcal{U}_n$. We can apply what we just proved to $R = \bigcup_{e\in\omega} 0^e 1[W_e]$ where $(W_e)_{e\in\omega}$ is an effective listing of the A-continuous Π^1_1 sets. We then find $T = \bigcap_{s<\omega_1^{CK}} T_s$ with $T \supseteq R$ and $\lambda(T) = \lambda(R)$.

Let f be a computable function such that $\mathcal{U}_n = [W_{f(n)}]$. Writing $A|w = \{X : wX \in A\}$, we let $S = \bigcap_{n\in\omega}(T \mid 0^{f(n)}1)$. Let us show that S works for our purpose. First S is a Π^1_1-ML$\langle\mathcal{O}\rangle$ test, by the characterization 14 of these tests, as

$$S = \bigcap_{n\in\omega} \left(\left(\bigcap_{s<\omega_1^{CK}} T_s \right) \mid 0^{f(n)}1 \right) = \bigcap_{\omega s+n<\omega_1^{CK}} T_s \mid 0^{f(n)}1.$$

Then $S \supseteq G$ as for every n, we have $T \mid 0^{f(n)}1 \supseteq R \mid 0^{f(n)}1 = [W_{f(n)}] = \mathcal{U}_n \supseteq G$. Finally, we show that $\lambda(S \setminus G) = 0$. We have:

$$S - G = \bigcap_{n\in\omega} S - [W_{f(n)}] \subseteq \bigcap_{n\in\omega} T \mid 0^{f(n)}1 - [W_{f(n)}].$$

But $\lambda(T \mid 0^{f(n)}1 - [W_{f(n)}]) \leq 2^{f(n)+1}\lambda(T - R) = 0$, so finally $\lambda(S - G) = 0$. ◀

▶ **Corollary 28.** *If A is higher K-Trivial and not Δ^1_1, then $\mathrm{W}\Pi^1_1\mathrm{R}^A \supseteq \Pi^1_1\text{-ML}\langle\mathcal{O}\rangle$.*

Proof. We proceed by contrapositive, and show that every $\mathrm{W}\Pi^1_1\mathrm{R}^A$ test G is included in a $\Pi^1_1\text{-ML}\langle\mathcal{O}\rangle$ test. Given a $\mathrm{W}\Pi^1_1\mathrm{R}^A$ test, we just apply the theorem to this test and get $S = \bigcap_{s<\omega_1^{CK}} \mathcal{V}_s$ such that $S \supseteq G$ and $\lambda(S) = \lambda(G) = 0$, that is S is a $\Pi^1_1\text{-ML}\langle\mathcal{O}\rangle$ test containing G. ◀

3.4 $\Pi^1_1\text{-ML}\langle\mathcal{O}\rangle = \mathrm{W}\Pi^1_1\mathrm{R}^A$ implies A higher K-trivial and not Δ^1_1

In this section, we will suppose that A is not higher K-trivial, and we will prove that under this assumption there exists a $\mathrm{W}\Pi^1_1\mathrm{R}^A$ sequence that is not $\Pi^1_1\text{-ML}\langle\mathcal{O}\rangle$ random. To do this we need the existence of a particular set, that will allow us to build a specific sequence by forcing.

This proof follows the lines of the proof of lowness for Π^1_1-randomness [10]: if A is not Δ^1_1 and not higher K-trivial, then there exists a Π^1_1-ML test relative to A, which captures a Π^1_1-random. In [10] the proof has been done using full relativization and not continuous relativization. Full relativization helps in particular to work with tests whose captured sequences are closed under suppression of prefixes. It is not necessarily obvious using continuous relativization that we can work with such tests. In particular, for some oracles A it might be the case that there is no universal Π^1_1-ML test continuously relativized to A. Thus we first need to show the following lemma:

▶ **Lemma 29.** *Let A be any set, and $\mathcal{U}$ a $\Pi^1_1\text{-ML}^A$ test. Then there exists an $\Pi^1_1\text{-ML}^A$ test $\mathcal{V}$ such that if $\sigma X \in \mathcal{U}$ then $X \in \mathcal{V}$.*

Proof. First we establish some notation. For $\mathcal{A} \subseteq 2^\omega$, we write $\mathcal{A}^{-n}$ for $\{X : \exists \sigma \in 2^n, \sigma X \in \mathcal{A}\}$ that is the set of strings of $\mathcal{A}$, for which we remove the first n bits. We remark that $\lambda(\mathcal{A}^{-n}) \leq 2^n\lambda(\mathcal{A})$. Now say $\mathcal{U} = \bigcap_n \mathcal{U}_n$ with $\lambda(\mathcal{U}_m) \leq 2^{-m}$ and $(\mathcal{U}_m)$ is uniformly Π^1_1-open, continuously in A. We define $\mathcal{V} = \bigcap_n \mathcal{V}_n$ by :

$$\mathcal{V}_n = \{X : \exists m > n, \exists \sigma \in 2^{<m}, \sigma X \in \mathcal{U}_{2m}\} = \bigcup_{m>n} \bigcup_{i<m} (\mathcal{U}_{2m})^{-i}.$$

We now only need to verify that this proves the theorem. We need this set to be a $\Pi^1_1\text{-ML}^A$ test. It is easily a uniform intersection of Π^1_1 open sets continuously in A, but we need to check that it is effectively of measure 0. We have

$$\lambda(\mathcal{V}_n) \leq \sum_{m>n} \sum_{i<m} \lambda(\mathcal{U}_{2m}^{-i}) \leq \sum_{m>n} \sum_{i<m} 2^i \lambda(\mathcal{U}_{2m})$$

by the remark after the definition of $\mathcal{A}^{-n}$, and then

$$\lambda(\mathcal{V}_n) \leq \sum_{m>n} \sum_{i<m} 2^i 2^{-2m} \leq \sum_{m>n} 2^m 2^{-2m} \leq \sum_{m>n} 2^{-m} \leq 2^{-n}.$$

So $\mathcal{V}$ is a test. ◀

▶ Remark. We did not proved that the test $\bigcap \mathcal{V}_n$ is closed under deletion of prefixes. It's own closure under deletion of prefixes may need to be bigger, but this state of things will be enough for our needs.

Recall we will suppose in this part that A is not higher K-trivial. The next lemma makes use of this fact to define a set that will be useful in our next construction.

▶ **Lemma 30.** *If A is not higher K-trivial, then there exists a Π^1_1-ML^A test $\bigcap_n \mathcal{U}_n$ such that for every n and every Π^1_1 open set $\mathcal{V}$ with $\lambda(\mathcal{V}) < 1$, we have $\mathcal{U}_n \cap \mathcal{V}^c \neq \emptyset$ (that is $\mathcal{U}_n \not\subseteq \mathcal{V}$).*

Proof. By contrapositive, we will show that if the conclusion of the theorem does not hold, then every Π^1_1-ML^A test is contained in a Π^1_1-ML test. As the sequences which are continuously low for Π^1_1-MLR are exactly the higher K-trivials (Theorem 18), we can conclude that A is higher K-trivial. Following this plan, our hypothesis becomes: "For every Π^1_1-ML^A test $\cap_n \mathcal{U}_n$ there exists n and a Π^1_1 open set $\mathcal{V}$ with $\lambda(\mathcal{V}) < 1$ and such that $\mathcal{U}_n \subseteq \mathcal{V}$."

Our goal is to show that A is low for Π^1_1-MLR. Let $\mathcal{U} = \bigcap \mathcal{U}_n$ be a Π^1_1-ML^A test. By the previous lemma, we find a test $\widetilde{\mathcal{U}} = \bigcap \widetilde{\mathcal{U}_n}$ containing all the suffixes of elements in $\mathcal{U}$. Then by the hypothesis, we find $\mathcal{V} \supseteq \bigcap \widetilde{\mathcal{U}_n} (\supseteq \bigcap \mathcal{U}_n)$ where $\mathcal{V}$ is Π^1_1 open and $\lambda(\mathcal{V}) < 1$. Let W be such that $\mathcal{V} = [W]$ and $\mathrm{wg}(W) = \sum_{\sigma \in W} 2^{-|\sigma|} < 1 - \varepsilon$ for some ε (we make W almost prefix-free , that is $\mathrm{wg}(W) \leq \lambda(\mathcal{V}) + \varepsilon'$ for ε' sufficiently small, as allowed by [18], Lemma 3.7.1). We define:

$$\mathcal{V}^n = [W^n] = [\{\sigma_1 \sigma_2 \cdots \sigma_n : \sigma_i \in W\}].$$

We show that $\bigcap \mathcal{V}^n \supseteq \bigcap \mathcal{U}_n$ and that it is a valid test. Let $X \in \bigcap \mathcal{U}_n - \bigcap \mathcal{V}^n$ toward a contradiction. There exists a n such that $X \in \mathcal{V}^n$ and $X \notin \mathcal{V}^{n+1}$ (we must have $X \in \mathcal{V}^1$ by definition of $\mathcal{V}^1$). As $X \in \mathcal{V}^n$, there exists $\sigma \in W^n$ such that $X = \sigma Y$. But as $X \in \bigcap \mathcal{U}_n$, $Y \in \bigcap \widetilde{\mathcal{U}_n} \subseteq \mathcal{V}$, and there exists $\tau \in W$ such that $Y = \tau Z$. But then, $\sigma\tau \in W^{n+1}$ and $X \in \mathcal{V}^{n+1}$, a contradiction.

It remains to prove that $\bigcap \mathcal{V}^n$ is a test which is the case if it is effectively of measure 0. To do so we can easily prove by induction that $\lambda(\mathcal{V}^n) \leq \mathrm{wg}(W)^n$. Indeed, $\lambda(\mathcal{V}^{n+1}) \leq \sum_{\sigma \in W^n} \sum_{\tau \in W} 2^{-|\sigma\tau|} \leq (\sum_{\sigma \in W^n} 2^{-|\sigma|})(\sum_{\tau \in W} 2^{-|\tau|}) = \mathrm{wg}(W)^n$. Then $\lambda(\mathcal{V}^{n+1}) \leq (1 - \varepsilon)^{n+1}$.

We covered every Π^1_1-ML^A test with a test without oracle, so A is low for Π^1_1-MLR, that is, higher K-trivial. ◀

▶ **Theorem 31.** *Suppose A is not higher K-trivial. Then, there is a Π^1_1-ML$\langle\mathcal{O}\rangle$-random which is not* WII$^1_1$R^A.

Proof. Let us denote by $\mathcal{R}_{\mathcal{O}}$ (respectively $\mathcal{R}_{\mathrm{W}}$) the set of Π^1_1-ML$\langle\mathcal{O}\rangle$ (respectively WII$^1_1$R^A) randoms. We are trying to prove that the set $\mathcal{R}_{\mathcal{O}} \cap \overline{\mathcal{R}_{\mathrm{W}}}$ is not empty. We will build an element inside this intersection by forcing. The main thing needed for the construction is to clarify how we will layer these two sets.

First we have $\mathcal{R}_{\mathcal{O}} = \bigcap_m \bigcup_n \mathcal{F}_{m,n}$ where the $\mathcal{F}_{m,n}$ are Σ^1_1 closed sets, increasing over n. Neither the intersection or the union need to be effective. Each union is in fact effective in Kleene's $\mathcal{O}$ (by definition of a Π^1_1-ML$\langle\mathcal{O}\rangle$ test) and each intersection is effective in the double jump of Kleene's $\mathcal{O}$ (to select the functions Turing computable from Kleene's $\mathcal{O}$ which are totals and which pick the right indices for a Π^1_1-ML$\langle\mathcal{O}\rangle$ test). Note that we can also require without loss of generality that each $\mathcal{F}_{m,n}$ contains only Π^1_1-ML randoms: to do so we simply replace each $\mathcal{F}_{m,n}$ by the uniform union of its intersection with each Σ^1_1 closed component in the complement of a universal Π^1_1-ML test.

Then $\overline{\mathcal{R}_{\mathrm{W}}}$ is the union of all the WII$^1_1$R^A tests. In particular, it contains the test $\bigcap_n \mathcal{U}_n$ given by the lemma 30: as A is not higher K-trivial, every $\mathcal{U}_n$ intersects every Σ^1_1 closed set of positive measure. Furthermore if this closed set contains only Π^1_1-ML randoms, this intersection must be of positive measure (it is a fact that no Π^1_1-ML random can be in a Σ^1_1 closed set of measure 0).

In conclusion, it is sufficient to construct a Z such that $Z \in \mathcal{U}_n$ for every n and $Z \in \bigcup_n \mathcal{F}_{m,n}$ for every m. It is now clear how to do so by forcing with a decreasing

sequence of Σ^1_1 closed sets of positive measure: We start with $\mathcal{F}_{0,0}$ which intersects with positive measure some $[\sigma_0] \subseteq \mathcal{U}_0$.

Suppose now by induction, that for some m we have closed sets $\mathcal{F}_{i,n_i}$ for $i \leq m$ and strings $\sigma_1 \prec \cdots \prec \sigma_m$, such that $\lambda(\bigcap_{i\leq m} \mathcal{F}_{i,n_i} \cap [\sigma_m]) > 0$ and such that $[\sigma_m] \subseteq \bigcap_{i\leq m} \mathcal{U}_i$. Let us find n_{m+1} and $\sigma_{m+1} \succ \sigma_m$ with $[\sigma_{m+1}] \subseteq \bigcap_{i\leq m+1} \mathcal{U}_i$ such that $\lambda(\bigcap_{i\leq m+1} \mathcal{F}_{i,n_i} \cap [\sigma_m]) > 0$.

As $\bigcap_{i\leq m} \mathcal{F}_{i,n_i} \cap [\sigma_m]$ is a Σ^1_1 closed set of positive measure, it intersects with positive measure the set $\mathcal{U}_{m+1}$. Thus there exists $\sigma_{m+1} \succ \sigma_m$ with $\sigma_{m+1} \subseteq \bigcap_{i\leq m+1} \mathcal{U}_i$ such that $\lambda(\bigcap_{i\leq m} \mathcal{F}_{i,n_i} \cap [\sigma_{m+1}]) > 0$. Now as $\lambda(\bigcup_n \mathcal{F}_{m+1,n}) = 1$, there is some n_{m+1} such that $\lambda(\bigcap_{i\leq m+1} \mathcal{F}_{i,n_i} \cap [\sigma_{m+1}]) > 0$.

By construction, the unique sequence $Z \in \bigcap_i [\sigma_i]$ is such that $Z \in \bigcap_m \bigcup_n \mathcal{F}_{m,n}$ and $Z \in \bigcap_n \mathcal{U}_n$ which concludes the proof. ◀

Abstract

Homomorphisms between relational structures play a central role in finite model theory, constraint satisfaction, and database theory. A central theme in quantum computation is to show how quantum resources can be used to gain advantage in information processing tasks. In particular, non-local games have been used to exhibit quantum advantage in boolean constraint satisfaction, and to obtain quantum versions of graph invariants such as the chromatic number. We show how quantum strategies for homomorphism games between relational structures can be viewed as Kleisli morphisms for a quantum monad on the (classical) category of relational structures and homomorphisms. We use these results to exhibit a wide range of examples of contextuality-powered quantum advantage, and to unify several apparently diverse strands of previous work.

1 Introduction

Finite relational structures and the homomorphisms between them form a mathematical core common to finite model theory [25], constraint satisfaction [14], and relational database theory [24]. Moreover, much of graph theory can be formulated in terms of the existence of graph homomorphisms, as expounded e.g. in the influential text [17]. Thus, implicitly at least, the mathematical setting for all these works is categories of σ-structures and homomorphisms, for relational vocabularies σ.

What could it mean to quantize these structures? More precisely, with the advent of quantum computing, we can now consider the consequences of using quantum resources for carrying out various information-processing tasks. A major theme of current research is to

* This work was carried out in part while the authors visited the Simons Institute for the Theory of Computing (supported by the Simons Foundation) at the University of California, Berkeley, as participants of the Logical Structures in Computation programme. Support from the following is also gratefully acknowledged: EPSRC – Engineering and Physical Sciences Research Council: EP/N018745/1 (SA, RSB) and EP/N017935/1 (NdS), 'Contextuality as a Resource in Quantum Computation'; CONACyT – Consejo Nacional de Ciencia y Tecnología (OZ); and Cambridge Quantum Computing Ltd. (OZ).

delineate the scope of the *quantum advantage* which can be gained by the use of quantum resources. How can this be related to these fundamental structures?

Our starting point is the notion of *quantum graph homomorphism* introduced in [27] as a generalization of the notion of quantum chromatic number [11]. Consider the following game, played by Alice and Bob cooperating against a Verifier. Their goal is to establish the existence of a homomorphism $G \to H$ for given graphs G and H. Verifier provides vertices $v_1, v_2 \in V(G)$ to Alice and Bob respectively. They produce outputs $w_1, w_2 \in V(H)$ in response. No communication between Alice and Bob is permitted during the game. They win if the following conditions hold: $v_1 = v_2 \;\Rightarrow\; w_1 = w_2$ and $v_1 \sim v_2 \;\Rightarrow\; w_1 \sim w_2$, where we write $\sim$ for the adjacency relation.

If only classical resources are permitted, then the existence of a *perfect strategy* for Alice and Bob — one in which they win with probability 1 — is equivalent to the existence of a graph homomorphism in the standard sense. However, using quantum resources, in the form of an entangled bipartite state where Alice and Bob can each perform measurements on their part, there are perfect strategies in cases where no classical homomorphism exists, thus exhibiting quantum advantage.

Alice–Bob games have also been studied for other tasks, notably for *constraint systems*. Consider the following system of linear equations over $\mathbb{Z}_2$:

$$\begin{array}{lll} A \oplus B \oplus C = 0 & D \oplus E \oplus F = 0 & G \oplus H \oplus I = 0 \\ A \oplus D \oplus G = 0 & B \oplus E \oplus H = 0 & C \oplus F \oplus I = 1 \end{array}$$

Of course, this system is not satisfiable in the standard sense, as we can see by summing over the left- and right-hand sides. Now consider the following Alice–Bob game. The Verifier sends Alice an equation, and Bob a variable. Alice returns an assignment to the variables in the equation, and Bob returns an assignment for his variable. They win if Bob's assignment agrees with Alice's, and moreover Alice's assignment satisfies the given equation. Classically, the existence of a perfect strategy is equivalent to the existence of a satisfying assignment for the whole system. Using quantum resources, there is a perfect strategy for the above system, which corresponds to Mermin's "magic square" construction [29]. This can be generalized to a notion of quantum perfect strategies for a broad class of constraint systems [13, 12], which have strong connections both to the study of contextuality in quantum mechanics, and to a number of challenging mathematical questions [36, 35]. Clearly, these games are analogous to those for graph homomorphisms. What is the precise relationship?

In [27], generalizing results in [11], the existence of a quantum perfect strategy for the homomorphism game from G to H is characterized in terms of the existence of a family $\{E_{vw}\}_{v \in V(G), w \in V(H)}$ of projectors in d-dimensional Hilbert space for some d, subject to certain conditions. Analogous results for constraint systems are proved in [13]. This characterization eliminates the two-person aspect of the game, and the shared state, leaving a "projector-valued relation" as the witness for existence of a quantum perfect strategy. We shall henceforth call these witnesses *quantum graph homomorphisms*. An important further step is taken in [27]. A construction $H \mapsto \mathsf{M}H$ on graphs is introduced, such that the existence of a quantum graph homomorphism from G to H is equivalent to the existence of a *standard* graph homomorphism $G \to \mathsf{M}H$.

Our contribution begins at this point. We describe a general notion of non-local game for witnessing homomorphisms between structures for any relational signature. We show that the use of quantum resources in these games can be characterized by a notion of *quantum homomorphism*. Moreover, quantum homomorphisms can in turn be characterized as the

Kleisli morphisms for a *quantum monad* on the (classical) category of relational structures and homomorphisms. This monad is *graded* [30] by the dimension of the Hilbert space.

Our account refines and generalizes the ideas from both [11, 27] and [13]. We characterize quantum solutions for general constraint satisfaction problems, showing as a special case that these subsume the binary constraint systems of [13]. We also show how quantum witnesses for strong contextuality in the sense of [4] are characterized by quantum homomorphisms.

The precise relationship with the quantum graph homomorphisms of [27] turns out to be more subtle. We show that their notion is characterized by a quantum solution in our sense for a related boolean constraint system. Overall, we show that a wide range of notions of quantum advantage is captured in a uniform way by the quantum monad, applied directly to the standard classical structures.

For reasons of limited space, some background material on linear algebra and quantum mechanics (e.g. the notions of POVM and PVM) and some proofs have been relegated to an Appendix.

2 From quantum perfect strategies to quantum homomorphisms

We write $[p] := \{1, \ldots, p\}$. We fix a finite relational vocabulary $\sigma = \{R_1, \ldots, R_p\}$, where R_a has arity k_a, $a \in [p]$. A σ-structure has the form $\mathcal{A} = (A, R_1^{\mathcal{A}}, \ldots, R_p^{\mathcal{A}})$, where A is a non-empty set, and $R_a^{\mathcal{A}} \subseteq A^{k_a}$, $a \in [p]$. A homomorphism of σ-structures $f : \mathcal{A} \to \mathcal{B}$ is a function $f : A \to B$ such that, for all $a \in [p]$ and $\mathbf{x} \in A^{k_a}$, $\mathbf{x} \in R_a^{\mathcal{A}} \;\Rightarrow\; f(\mathbf{x}) \in R_a^{\mathcal{B}}$. Here we use vector notation: $\mathbf{x} = (x_1, \ldots, x_{k_a})$ and $f(\mathbf{x}) = (f(x_1), \ldots, f(x_{k_a}))$. We denote the category of σ-structures and homomorphisms by $\mathcal{R}(\sigma)$, and the full subcategory of finite structures by $\mathcal{R}_f(\sigma)$.

We now consider the following game, played on finite structures $\mathcal{A}$ and $\mathcal{B}$, in which Alice and Bob cooperate to convince a Verifier that there is a homomorphism from $\mathcal{A}$ to $\mathcal{B}$:

- Alice and Bob are separated, and not allowed to communicate (exchange classical information) while the game is played.
- In a play of the game, the Verifier sends Alice an index a, and a tuple $\mathbf{x} \in R_a^{\mathcal{A}}$; and Bob an element $x \in A$.
- Alice returns a tuple $\mathbf{y} \in B^{k_a}$, and Bob returns an element $y \in B$.
- Alice and Bob win that play if
  - **(i)** $\mathbf{y} \in R_a^{\mathcal{B}}$
  - **(ii)** $x = \mathbf{x}_i \;\Rightarrow\; y = \mathbf{y}_i$, $i \in [k_a]$.

Alice and Bob may use probabilistic strategies. A *perfect strategy* is one in which they win with probability 1.

It is clear that if only classical resources are allowed, the existence of a perfect strategy is equivalent to the existence of a homomorphism from $\mathcal{A}$ to $\mathcal{B}$. The actual strategy played by Alice and Bob may be pure or mixed, in the latter case using some shared randomness.

We now consider the use of quantum resources in the homomorphism game. We shall only consider the case of finite-dimensional resources in this paper. Such resources have the following general form:

- There are finite-dimensional Hilbert spaces H and K, and a pure state ψ on $\mathsf{H} \otimes \mathsf{K}$. This state is shared between Alice and Bob. The separation between Alice and Bob is reflected in the fact that Alice can only perform operations on H, while Bob can only perform operations on K.
- For each $a \in [p]$ and tuple $\mathbf{x} \in R_a^{\mathcal{A}}$, Alice has a POVM $\mathcal{E}_{\mathbf{x}}^a = \{\mathcal{E}_{\mathbf{x},\mathbf{y}}^a\}_{\mathbf{y} \in B^{k_a}}$.
- For each $x \in A$, Bob has a POVM $\mathcal{F}_x = \{\mathcal{F}_{x,y}\}_{y \in B}$

These resources are used as follows:

- Given a and $\mathbf{x}$, Alice measures $\mathcal{E}^a_{\mathbf{x}}$ on her part of ψ.
- Given x, Bob measures $\mathcal{F}_x$ on his part of ψ.
- They obtain the joint outcome $(\mathbf{y}, y)$ with probability $\psi^*(\mathcal{E}^a_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}_{x,y})\psi$.

If with probability 1 the outcome $(\mathbf{y}, y)$ satisfies the winning conditions, then this is a quantum perfect strategy.

We can write the winning conditions explicitly in terms of the quantum operations:

$$\text{(QS1)} \quad \psi^*(\mathcal{E}^a_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}_{x,y})\psi = 0 \qquad \text{if } x = \mathbf{x}_i \text{ and } y \neq \mathbf{y}_i$$

$$\text{(QS2)} \quad \psi^*(\mathcal{E}^a_{\mathbf{x},\mathbf{y}} \otimes I)\psi = 0 \qquad \text{if } \mathbf{y} \notin R^{\mathcal{B}}_a.$$

A first remark is that our assumption of the bipartite structure of the state space does not in fact lose any generality. We could have asked simply that Bob's operators commute with those of Alice. However, since we are considering the finite-dimensional case, a result of Tsirelson [37, 35] implies that this is equivalent to the tensor product formulation we have used. Furthermore, using a pure state also does not lose any generality. Indeed, if we had a mixed state $\rho = \sum_i p_i \psi_i \psi_i^*$, with the trace replacing the inner products in (QS1) and (QS2), then the linearity of the trace implies that we could just as well have used any of the pure states ψ_i with the same measurements, and still satisfy the conditions.

We shall now show that in fact a quantum perfect strategy can without loss of generality be assumed to have a very special form, which will lead us to the equivalence with quantum homomorphisms. These results combine ingredients from [13] and [27, 11]. The proofs are closest to those in [34], but are considerably simpler as well as more general.

For notational convenience, we shall focus on the case where the relational signature has a single k-ary relation R. Thus a quantum perfect strategy for the homomorphism game from $\mathcal{A}$ to $\mathcal{B}$ has the form $(\psi, \{\mathcal{E}_{\mathbf{x}}\}_{\mathbf{x}\in R^{\mathcal{A}}}, \{\mathcal{F}_x\}_{x\in A})$, where $\mathcal{E}_{\mathbf{x}} = \{\mathcal{E}_{\mathbf{x},\mathbf{y}}\}_{\mathbf{y}\in B^k}$ and $\mathcal{F}_x = \{\mathcal{F}_{x,y}\}_{y\in B}$ are POVMs satisfying the conditions (QS1) and (QS2).

Our first step is to show that ψ can be taken to have full Schmidt rank.

▶ **Lemma 1.** *Given a quantum perfect strategy $(\psi', \{\mathcal{E}'_{\mathbf{x}}\}_{\mathbf{x}\in R^{\mathcal{A}}}, \{\mathcal{F}'_x\}_{x\in A})$, we can find a strategy $(\psi, \{\mathcal{E}_{\mathbf{x}}\}_{\mathbf{x}\in R^{\mathcal{A}}}, \{\mathcal{F}_x\}_{x\in A})$ where $\psi \in \mathbb{C}^d \otimes \mathbb{C}^d$ has the form $\sum_{i=1}^d \lambda_i e_i \otimes e_i$ with $\lambda_i > 0$ for all i.*

Proof. Our proof will follow closely the first part of the proof of Theorem 6.5.1 in [34], so we omit detailed calculations. We write the Schmidt decomposition of ψ' as $\sum_{i=1}^d \lambda_i \alpha_i \otimes \beta_i \in \mathbb{C}^{d_A} \otimes \mathbb{C}^{d_B}$, where $\{\alpha_i\}$, $\{\beta_i\}$ are orthonormal families of vectors, and $\lambda_i > 0$.

We define $P_A := \sum_{i=1}^d e_i \alpha_i^*$, $P_B := \sum_{i=1}^d e_i \beta_i^*$. Thus $P_A : \mathbb{C}^{d_A} \to \mathbb{C}^d$, and $P_B : \mathbb{C}^{d_B} \to \mathbb{C}^d$. It is straightforward to verify that $P_A P_A^* = I_d = P_B P_B^*$. We have $\psi := (P_A \otimes P_B)\psi'$, and $\psi' = (P_A^* \otimes P_B^*)\psi$.

Similarly, we define $\mathcal{E}_{\mathbf{x},\mathbf{y}} := P_A \mathcal{E}'_{\mathbf{x},\mathbf{y}} P_A^*$, and $\mathcal{F}_{x,y} := P_A \mathcal{F}'_{x,y} P_B^*$. Again, it is straightforward to verify that this yields well-defined POVMs, and moreover that the probabilities are preserved: $\psi^*(\mathcal{E}_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}_{x,y})\psi = \psi'^*(\mathcal{E}'_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}'_{x,y})\psi'$. Thus $(\psi, \{\mathcal{E}_{\mathbf{x}}\}_{\mathbf{x}\in R^{\mathcal{A}}}, \{\mathcal{F}_x\}_{x\in A})$ is a quantum perfect strategy. ◀

The following simple general result will be useful.

▶ **Lemma 2.** *Let $\mathcal{A}$ be a $*$-algebra, and a, b, d be self-adjoint elements of $\mathcal{A}$, where d is also invertible. Suppose that $ad = adb = db$. Then a and b are projectors, and they both commute with d^2. If $\mathcal{A}$ is a C^*-algebra, then $a = b$.*

Proof. First, $a^2d = adb = ad$. Since d is invertible, this implies that $a^2 = a$, so a is a projector. Similarly, $b^2 = b$. Moreover, since a, b and d are self-adjoint, $db = ad \iff bd = da$. Hence $ad^2 = dbd = d^2a$.

If $\mathcal{A}$ is a C*-algebra, then it is standard that d commutes with every element which commutes with d^2 [9, 32], so $da = ad = db$, and since d is invertible, this yields $a = b$. ◀

We shall now show that under the assumption of full Schmidt rank, the measurements are already remarkably constrained. We define $\mathcal{E}^i_{\mathbf{x},y} := \sum_{\mathbf{y}_i=y} \mathcal{E}_{\mathbf{x},\mathbf{y}}$.

▶ **Lemma 3.** *Let $(\psi, \{\mathcal{E}_\mathbf{x}\}, \{\mathcal{F}_x\})$ be a quantum perfect strategy in which ψ has full Schmidt rank. Then for all $\mathbf{x}$, i, y, $\mathcal{E}^i_{\mathbf{x},y}$ and $\mathcal{F}_{x,y}$ are projectors, and $\mathcal{E}^i_{\mathbf{x},y} = \mathcal{F}^T_{x,y}$ whenever $x = \mathbf{x}_i$.*

Proof. We write ψ as $\sum_{i=1}^d \lambda_i e_i \otimes e_i$, where $\lambda_i > 0$. The corresponding $d \times d$ diagonal matrix $D = \mathsf{diag}\{\lambda_i\}$ is full rank, and hence invertible, and $D^* = D$. Note that $\psi = \mathsf{vec}(D)$, the vectorization of D. Using the standard equations $(A \otimes B)\mathsf{vec}(D) = \mathsf{vec}(ADB^T)$ and $\mathsf{vec}(A)^*\mathsf{vec}(B) = \mathsf{Tr}(AB)$, we have

$$\psi^*(\mathcal{E}_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}_{x,y})\psi = 0 \iff \mathsf{Tr}(D\mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y}) = 0 \iff \mathsf{Tr}(\mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y}D) = 0.$$

By Proposition 17, $\mathsf{Tr}(\mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y}D) = 0 \iff \mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y}D = \mathbf{0}$, and since D is invertible, this is equivalent to $\mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y} = \mathbf{0}$. By condition (QS1), $\mathcal{E}_{\mathbf{x},\mathbf{y}}D\mathcal{F}^T_{x,y} = \mathbf{0}$ when $x = \mathbf{x}_i$ and $y \neq \mathbf{y}_i$. This in turn implies that $\mathcal{E}^i_{\mathbf{x},y}D\mathcal{F}^T_{x,y'} = \mathbf{0}$ when $x = \mathbf{x}_i$ and $y \neq y'$.

Now fix $\mathbf{x}$ and $x = \mathbf{x}_i$. Let $A_y := \mathcal{E}^i_{\mathbf{x},y}$, and $B_y := \mathcal{F}^T_{x,y}$. We have $\sum_y A_y = I = \sum_y B_y$, and $A_yDB_{y'} = \mathbf{0}$ when $y \neq y'$. Hence $A_yD = \sum_{y'} A_yDB_{y'} = A_yDB_y = \sum_{y'} A_{y'}DB_y = DB_y$. We can now apply Lemma 2, taking $a = A_y$, $d = D$, and $b = B_y$, to conclude that $\mathcal{E}^i_{\mathbf{x},y}$ and $\mathcal{F}_{x,y}$ are projectors, and moreover that they commute with D^2. We can use the last part of Lemma 2 to conclude that $\mathcal{E}^i_{\mathbf{x},y} = \mathcal{F}^T_{x,y}$ whenever $x = \mathbf{x}_i$. ◀

Finally, we show that the state can be chosen to be maximally entangled.

▶ **Lemma 4.** *Let $(\psi', \{\mathcal{E}_\mathbf{x}\}, \{\mathcal{F}_x\})$ be a quantum perfect strategy where $\psi' = \sum_{i=1}^d \lambda_i e_i \otimes e_i$ with $\lambda_i > 0$ for all i. Then $(\psi, \{\mathcal{E}_\mathbf{x}\}, \{\mathcal{F}_x\})$ is a quantum perfect strategy, where $\psi = 1/\sqrt{d}\sum_{i=1}^d e_i \otimes e_i$ is the maximally entangled state.*

Proof. Let D' be the diagonal matrix associated with ψ'. Using Lemma 3,

$$\psi'^*(\mathcal{E}_{\mathbf{x},\mathbf{y}} \otimes \mathcal{F}_{x,y})\psi' = 0 \iff \mathcal{E}_{\mathbf{x},\mathbf{y}}D'\mathcal{F}^T_{x,y} = \mathbf{0} \iff \mathcal{E}_{\mathbf{x},\mathbf{y}}\mathcal{F}^T_{x,y}D' = \mathbf{0} \iff \mathcal{E}_{\mathbf{x},\mathbf{y}}\mathcal{F}^T_{x,y} = \mathbf{0},$$

since D' commutes with $\mathcal{F}^T_{x,y}$ and is invertible. Similarly,

$$\psi'^*(\mathcal{E}_{\mathbf{x},\mathbf{y}} \otimes I)\psi' = 0 \iff \mathcal{E}_{\mathbf{x},\mathbf{y}}D' = \mathbf{0} \iff \mathcal{E}_{\mathbf{x},\mathbf{y}} = \mathbf{0}.$$

These conditions will be preserved by any state ψ whose diagonal matrix is full rank and commutes with the matrices $\mathcal{F}_{x,y}$. This holds in particular for the maximally entangled state, whose diagonal matrix has the form $\frac{1}{\sqrt{d}}I_d$. ◀

We can now combine Lemmas 1, 3 and 4 to obtain the following result:

▶ **Theorem 5.** *The existence of a quantum perfect strategy implies the existence of a strategy $(\psi, \{\mathcal{E}_\mathbf{x}\}, \{\mathcal{F}_x\})$ with the following properties:*

- *The POVMs $\mathcal{E}^i_\mathbf{x}$ and $\mathcal{F}_x$ are projective.*
- *The state ψ is a maximally entangled state $\psi = 1/\sqrt{d}\sum_{i=1}^d e_i \otimes e_i$.*
- *If $x = \mathbf{x}_i$ then $\mathcal{E}^i_{\mathbf{x},y} = \mathcal{F}^T_{x,y}$.*
- *If $\mathbf{x} \in R^\mathcal{A}$ and $\mathbf{y} \notin R^\mathcal{B}$, then $\mathcal{E}_{\mathbf{x},\mathbf{y}} = \mathbf{0}$.*

It is worth noting that the procedure for obtaining the strategy in this special form has three steps:

- In Step 1, the state and strategies are projected down to the subspace corresponding to the support of the Schmidt decomposition of the state. This step reduces the dimension of the Hilbert space, and preserves the probabilities for the strategy exactly.
- Step 2 does not change the strategy at all, but shows that it must already have strong properties.
- Step 3 changes the state but not the measurements. In general, the probabilities for the strategy will be changed, but the possibilities are preserved exactly.

Thus in passing to the special form, the dimension is reduced; the process by which we obtain projective measurements is not at all akin to dilation.

This theorem shows that all the information determining the strategy is in Alice's operators. Moreover, Alice's operators must be chosen non-contextually, so that $\mathcal{E}^i_{\mathbf{x},y}$ is independent of the context $\mathbf{x}$. This means that we can define projectors $P_{x,y} := \mathcal{E}^i_{\mathbf{x},y}$ whenever $x = \mathbf{x}_i$. If $\mathbf{x}_i = x = \mathbf{x}'_j$, then we have $\mathcal{E}^i_{\mathbf{x},y} = \mathcal{F}^T_{x,y} = \mathcal{E}^j_{\mathbf{x}',y}$, so $P_{x,y}$ is well-defined.

Now, recall the notion of joint measurability: a family of POVMs $\{A^1_y\}_{y\in Y_1}, \ldots, \{A^k_y\}_{y\in Y_k}$ is said to be jointly measurable if there is a POVM $\{B_{\mathbf{y}}\}_{\mathbf{y}\in Y_1\times\cdots\times Y_k}$ such that for all i, $A^i_y = \sum_{\mathbf{y}_i=y} B_{\mathbf{y}}$. The following result is standard [16].

▶ Proposition 6. A family of projective measurements is jointly measurable by a POVM if and only if they pairwise commute, and in this case the POVM is the product of the family, and hence projective.

For each $\mathbf{x} \in R^{\mathcal{A}}$, the projective measurements $P_{\mathbf{x}_i} = \{P_{\mathbf{x}_i,y}\}$ defined above are jointly measured by $\mathcal{E}_{\mathbf{x}}$. Thus $\mathcal{E}_{\mathbf{x}}$ is the projective measurement $P_{\mathbf{x}} = \{P_{\mathbf{x},\mathbf{y}}\}_{\mathbf{y}}$ given by $P_{\mathbf{x},\mathbf{y}} := P_{\mathbf{x}_1,\mathbf{y}_1} \cdots P_{\mathbf{x}_k,\mathbf{y}_k}$.

We shall now introduce the notion of *quantum homomorphism* between relational structures $\mathcal{A}$ and $\mathcal{B}$. A quantum homomorphism is a family of projectors $\{P_{x,y}\}_{x\in A,y\in B}$ in $\mathsf{Proj}(d)$ for some d, satisfying the following conditions:

- (QH1) For all $x \in A$, $\sum_{y\in B} P_{x,y} = I$.
- (QH2) For all $\mathbf{x} \in R^{\mathcal{A}}$, $x = \mathbf{x}_i$, $x' = \mathbf{x}_j$, and $y, y' \in B$, $[P_{x,y}, P_{x',y'}] = \mathbf{0}$. Thus we can define a projective measurement $P_{\mathbf{x}} = \{P_{\mathbf{x},\mathbf{y}}\}_{\mathbf{y}}$, where $P_{\mathbf{x},\mathbf{y}} := P_{\mathbf{x}_1,\mathbf{y}_1} \cdots P_{\mathbf{x}_k,\mathbf{y}_k}$.
- (QH3) If $\mathbf{x} \in R^{\mathcal{A}}$ and $\mathbf{y} \notin R^{\mathcal{B}}$, then $P_{\mathbf{x},\mathbf{y}} = \mathbf{0}$.

Note that (QH1) implies that for any x, $P_{x,y}P_{x,y'} = \mathbf{0}$ whenever $y \neq y'$.

We write $\mathcal{A} \xrightarrow{q} \mathcal{B}$ for the existence of a quantum homomorphism from $\mathcal{A}$ to $\mathcal{B}$.

▶ **Theorem 7.** *For finite structures $\mathcal{A}$, $\mathcal{B}$, the following are equivalent:*

1. *There is a quantum perfect strategy for the homomorphism game from $\mathcal{A}$ to $\mathcal{B}$.*
2. *$\mathcal{A} \xrightarrow{q} \mathcal{B}$.*

Proof. The implication from (1) to (2) follows directly from Theorem 5 and the subsequent discussion. For the converse, given a quantum homomorphism $\{P_{x,y}\}_{x\in A,y\in B}$, we can define $\mathcal{E}_{\mathbf{x},\mathbf{y}} := P_{\mathbf{x},\mathbf{y}}$, $\mathcal{F}_{x,y} := P^T_{x,y}$, and use the maximally entangled state to obtain a quantum perfect strategy. It is straightforward to verify that the homomorphism conditions (QH1)–(QH3) imply the strategy conditions (QS1) and (QS2). ◀

As a final remark, although we have focussed on a single relation to simplify the notation, our results go through for arbitrary relational signatures. Note that the general form of condition (QH2) is that $P_{x,y}$ and $P_{x',y'}$ must commute whenever x and x' are adjacent in the Gaifman graph of $\mathcal{A}$ – that is, they both occur in some tuple of some relation.

3 From quantum homomorphisms to the quantum monad

We now show how to characterize quantum homomorphisms as the Kleisli morphisms of a monad $\mathcal{Q}_d$ on the category of relational structures. This monad is *graded* [30] by the dimension of the Hilbert space used as the quantum resource.

The monad will be defined on the category $\mathcal{R}(\sigma)$ of all σ-structures, since $\mathcal{Q}_d\mathcal{A}$ will always be infinite, even if $\mathcal{A}$ is finite. For the underlying universes of the structures, the construction can be seen as a quantum variant of the discrete distribution monad [20], widely used in coalgebra and semantics. It is well known that the distribution monad can be defined over any commutative semiring, with the non-negative reals being used for the standard case of probabilities [20, 4]. Here we shall use the projectors $\mathsf{Proj}(d)$ with d ranging over the positive integers. For each d, $\mathsf{Proj}(d)$ is a partial commutative semiring, since we can only add projectors if they are orthogonal, and only multiply them if they commute. We also have the graded multiplication given by the tensor product: if $P \in \mathsf{Proj}(d)$ and $Q \in \mathsf{Proj}(d')$, then $P \otimes Q \in \mathsf{Proj}(dd')$.

We fix a relational signature σ. For each positive integer d and σ-structure $\mathcal{A}$, we define a σ-structure $\mathcal{Q}_d\mathcal{A}$. The universe of this structure $\mathcal{Q}_dA$ is the set of all functions $p : A \to \mathsf{Proj}(d)$ satisfying the normalization condition: $\sum_{x\in A} p(x) = I$. Note that normalization implies that the projectors $\{p(x)\}_{x\in A}$ are pairwise orthogonal. Since we are in finite dimension d, this in turn implies that p has finite support: $p(x) = \mathbf{0}$ for all but finitely many x. We can think of $\mathcal{Q}_dA$ as the projector-valued distributions on A in dimension d. For each relation R of arity k in σ, we define $R^{\mathcal{Q}_d\mathcal{A}}$ to be the set of all tuples $(p_1, \ldots, p_k)$ such that:

- (QR1) For all $i, j \in [k]$, $x, x' \in A$: $[p_i(x), p_j(x')] = \mathbf{0}$.
- (QR2) For all $\mathbf{x} \in A^k$, if $\mathbf{x} \notin R^{\mathcal{A}}$, then $\mathbf{p}(\mathbf{x}) = \mathbf{0}$, where $\mathbf{p}(\mathbf{x}) := p_1(x_1) \cdots p_k(x_k)$.

Note that the first condition implies that the product of projectors in the second is a well-defined projector.

▶ Proposition 8. Let $\mathcal{A}$ and $\mathcal{B}$ be finite σ-structures. There is a bijective correspondence between quantum homomorphisms $\{P_{x,y}\}_{x\in A,y\in B}$ from $\mathcal{A}$ to $\mathcal{B}$ in dimension d and standard homomorphisms $h : \mathcal{A} \to \mathcal{Q}_d\mathcal{B}$.

Proof. Given a quantum homomorphism $\{P_{x,y}\}$, define $h : \mathcal{A} \to \mathcal{Q}_d\mathcal{B}$ by $h(x) = p$, where $p(y) := P_{x,y}$. (QH1) implies normalization. Given $\mathbf{x} \in R^{\mathcal{A}}$, we have to show that $\mathbf{p} = h(\mathbf{x}) \in R^{\mathcal{Q}_d\mathcal{A}}$. (QH2) implies that (QR1) is satisfied for $p_i(y)$, $p_j(y')$, where $p_i = h(x_i)$, $p_j = h(x_j)$. Similarly, (QH3) implies (QR2).

For the converse, given $h : \mathcal{A} \to \mathcal{Q}_dB$, define $P_{x,y} := h(x)(y)$. Again, normalization implies (QH1), (QR1) implies (QH2), and (QR2) implies (QH3). ◀

This correspondence is analogous to the familiar one between relations and set-valued functions, which shows that the category of relations is the Kleisli category of the powerset monad on **Set**.

Now we show that $\mathcal{Q}_d$ extends to a functor on $\mathcal{R}(\sigma)$. Given a homomorphism $h : \mathcal{A} \to \mathcal{B}$, we define $\mathcal{Q}_dh : \mathcal{Q}_d\mathcal{A} \to \mathcal{Q}_d\mathcal{B}$ by $\mathcal{Q}_dh(p)(y) := \sum_{h(x)=y} p(x)$.

▶ Proposition 9. $\mathcal{Q}_dh$ is a well-defined homomorphism. Moreover, $\mathcal{Q}_d$ is functorial: $\mathcal{Q}_dg \circ \mathcal{Q}_dh = \mathcal{Q}_d(g \circ h)$ and $\mathcal{Q}_d\mathsf{id}_A = \mathsf{id}_{\mathcal{Q}_dA}$.

Proof. The finite support and normalization conditions ensure that $\mathcal{Q}_dh$ is well-defined. Functoriality is proved exactly as for the distribution monad. We verify that $\mathcal{Q}_dh$ is a homomorphism. Suppose that $(p_1, \ldots, p_k) \in R^{\mathcal{Q}_d\mathcal{A}}$. By (QR1), this implies that $[p_i(x), p_j(x')] = \mathbf{0}$

for all $i, j \in [k]$, $x, x' \in A$. This implies that

$$[\mathcal{Q}_d h(p_i)(y), \mathcal{Q}_d h(p_j)(y')] \;=\; [\sum_{h(x)=y} p_i(x), \sum_{h(x')=y'} p_j(x')] \;=\; \mathbf{0}$$

so $\mathcal{Q}_d h(\mathbf{p})$ satisfies (QR1). For (QR2), if $\mathbf{y} \notin R^{\mathcal{B}}$,

$$\mathcal{Q}_d h(\mathbf{p})(\mathbf{y}) \;=\; \prod_{j=1}^{k} \sum_{h(\mathbf{x}_j)\,=\,\mathbf{y}_j} p_j(\mathbf{x}_j) \;=\; \sum_{h(\mathbf{x})\,=\,\mathbf{y}} \mathbf{p}(\mathbf{x}) \;=\; \mathbf{0},$$

by (QR2) for $\mathbf{p} \in R^{\mathcal{Q}_d\mathcal{A}}$, since $\mathbf{y} \notin R^{\mathcal{B}}$ and $h(\mathbf{x}) = \mathbf{y}$ implies $\mathbf{x} \notin R^{\mathcal{A}}$. Thus $\mathcal{Q}_d h(\mathbf{p}) \in R^{\mathcal{Q}_d\mathcal{B}}$. ◀

The unit of the monad $\eta_{\mathcal{A}} : \mathcal{A} \to \mathcal{Q}_1\mathcal{A}$ sends $x \in A$ to the "delta distribution" $\delta_x \in \mathcal{Q}_1 A$, where $\delta_x(x) = I_1$, $\delta_x(x') = \mathbf{0}$ if $x \neq x'$. Verification that this is well-defined and yields a natural transformation is straightforward.

We also have the graded monad multiplication: $\mu_{\mathcal{A}}^{d,d'} : \mathcal{Q}_d\mathcal{Q}_{d'}\mathcal{A} \to \mathcal{Q}_{dd'}\mathcal{A}$. This is defined as follows: $\mu_{\mathcal{A}}^{d,d'}(P)(x) := \sum_{p \in \mathcal{Q}_{d'}\mathcal{A}} P(p) \otimes p(x)$. We prove that this gives a well-defined natural transformation in the Appendix. Thinking of $\otimes$ as the graded semiring multiplication on projectors, we can see the correspondence to the distribution monad.

We recall that given a category $\mathcal{C}$, the endofunctor category $[\mathcal{C}, \mathcal{C}]$ is monoidal; a monad on $\mathcal{C}$ is a monoid in this category [26]. Now let $(M, \cdot, 1)$ be a monoid, which we can view as a discrete category with a strict monoidal structure. An *M-graded monad* [30] on $\mathcal{C}$ is a lax monoidal functor from M into $[\mathcal{C}, \mathcal{C}]$. Such a functor is given by the following data: an assignment $m \mapsto T_m$ of an endofunctor on $\mathcal{C}$ to each element of M; a natural transformation $\eta : \mathsf{Id} \xrightarrow{\cdot} T_1$ (the graded unit); and a natural transformation $\mu^{m,m'} : T_m T_{m'} \xrightarrow{\cdot} T_{m \cdot m'}$ for all m, m' (the graded multiplication). These are subject to coherence conditions, which generalize the usual monad equations. We refer to [30] for details.

In our case, we use the monoid $\mathbb{N}^+$ of positive integers under multiplication.

▶ **Theorem 10.** *The triple $(\{\mathcal{Q}_d\}_d, \eta, \{\mu^{d,d'}\}_{d,d'})$ is a $\mathbb{N}^+$-graded monad on $\mathcal{R}(\sigma)$.*

The proof of this result involves verifying a number of equations, and is fairly lengthy but straightforward. We provide details in the Appendix.

We are particularly interested in the Kleisli category for this graded monad. The objects of this category are the same as those of $\mathcal{R}(\sigma)$. A morphism from $\mathcal{A}$ to $\mathcal{B}$ is a homomorphism $h : \mathcal{A} \to \mathcal{Q}_d\mathcal{B}$. By Proposition 8, we know that Kleisli morphisms correspond exactly to quantum homomorphisms.

The graded composition of Kleisli arrows $h : \mathcal{A} \to \mathcal{Q}_d\mathcal{B}$ and $k : \mathcal{B} \to \mathcal{Q}_{d'}\mathcal{C}$ is the arrow $k \bullet h : \mathcal{A} \to \mathcal{Q}_{dd'}\mathcal{C}$ given by $k \bullet h := \mu_{\mathcal{B}}^{d,d'} \circ \mathcal{Q}_d k \circ h$. An explicit description can be calculated from the graded monad structure given above: $(k \bullet h)(x)(z) \;=\; \sum_{y \in B} h(x)(y) \otimes k(y)(z)$. If we write this in terms of the corresponding quantum homomorphisms $\{P_{x,y}\}_{x \in A, y \in B}$, $\{Q_{y,z}\}_{y \in B, z \in C}$, we obtain $\{R_{x,z}\}_{x \in A, z \in C}$ given by the formula $R_{x,z} = \sum_{y \in B} P_{x,y} \otimes Q_{y,z}$. This recovers the concrete definition given for quantum graph homomorphisms in [27].

4 Quantum advantage via the quantum monad

We shall now show how the quantum monad provides a unified framework for expressing quantum advantage in a wide range of information processing tasks. We shall show equivalences between:

- state-independent strong contextuality arguments
- quantum advantage in constraint satisfaction
- existence of quantum (but not classical) homomorphisms between relational structures.

4.1 Classical correspondences

We begin with the standard classical correspondence between constraint satisfaction problems and the existence of homomorphisms. A CSP instance has the form $\mathcal{K} = (V, D, C)$ where V is a set of variables, D is a domain of values[1], and C is a set of constraints of the form $(\mathbf{x}, r)$, where for some k, $\mathbf{x} \in V^k$, and $r \subseteq D^k$. We say that $c = (\mathbf{x}, r)$ is a k-ary constraint. A *solution* of the CSP is a function $s : V \to D$ such that, for all $(\mathbf{x}, r) \in C$, $s(\mathbf{x}) \in r$, where $s(\mathbf{x}) := (s(x_1), \ldots, s(x_k))$.

Given $\mathcal{K} = (V, D, C)$ we define two structures over the signature with a k-ary relation symbol R_c for each k-ary constraint c. First, $\mathcal{B}_\mathcal{K}$ has as universe D, and for each $c = (\mathbf{x}, r) \in C$, $R_c^{\mathcal{B}_\mathcal{K}} = r$. Secondly, $\mathcal{A}_\mathcal{K}$ has universe V, and for each $c = (\mathbf{x}, r) \in C$, $R_c^{\mathcal{A}_\mathcal{K}} = \{\mathbf{x}\}$. The following is immediate:

▶ Proposition 11. There is a one-to-one correspondence between solutions for $\mathcal{K}$ and homomorphisms $\mathcal{A}_\mathcal{K} \to \mathcal{B}_\mathcal{K}$.

There is also a converse to this result. Given σ-structures $\mathcal{A}$ and $\mathcal{B}$, we can define the CSP $\mathcal{K}_{AB} = (V, D, C)$, where $V = A$, $D = B$, and $C = \{(\mathbf{a}, R^\mathcal{B}) \mid R \in \sigma,\ \mathbf{a} \in R^\mathcal{A}\}$.

▶ Proposition 12. There is a one-to-one correspondence between homomorphisms $\mathcal{A} \to \mathcal{B}$ and solutions for $\mathcal{K}_{AB}$.

We will now look at *empirical models over measurement scenarios*, introduced in [4] as a general setting for studying contextuality, in quantum mechanics and beyond, with non-locality as a special case.

A measurement scenario is a triple $(X, \mathcal{M}, O)$, where X is a set of measurement labels; $\mathcal{M}$ is a family of subsets of X, where we think of $C \in \mathcal{M}$ as a set of compatible measurements, or a context; and O is a set of measurement outcomes. An empirical model $e : (X, \mathcal{M}, O)$ for a scenario is a family $e = \{e_C\}_{C \in \mathcal{M}}$ of probability distributions $e_C \in \mathsf{Prob}(O^C)$ on the joint outcomes of measuring all the variables in a context C. Such empirical models can arise from observational data (hence the name), or be generated by measuring a quantum state in contexts comprising jointly measurable observables. A hierarchy of notions of contextuality can be defined in this general setting [4, 2]. We shall be concerned with *strong contextuality*. We say that $e : (X, \mathcal{M}, O)$ is strongly contextual if there is no global assignment $g : X \to O$ such that, for all $C \in \mathcal{M}$, $e_C(g|_C) > 0$. That is, there is no global assignment consistent with the model in the sense of yielding *possible* outcomes (non-zero probability) in all contexts. This form of contextuality is witnessed by the GHZ construction [15, 28], as well as by Kochen–Specker paradoxes [22], and post-quantum devices such as the PR box [33].

Given $e : (X, \mathcal{M}, O)$, we fix an ordering on X, and define a CSP $\mathcal{K}_e = (X, O, C)$, where C is the set of constraints $((x_1, \ldots, x_k), r)$ such that $x_1 < \cdots < x_k$, $\{x_1, \ldots, x_k\} \in C$ and $r = \{s(\mathbf{x}) \mid e_C(s) > 0\}$.

▶ Proposition 13. There is a one-to-one correspondence between consistent global assignments for e and solutions of $\mathcal{K}_e$. Thus e is strongly contextual iff $\mathcal{K}_e$ has no (classical) solution.

[1] One could have different domains associated with different variables. However, this is an inessential generalization, which we omit to keep notation simple.

We thus have a three-way correspondence between CSPs, empirical models, and homomorphisms between relational structures.

4.2 Quantum solutions

We now consider how quantum resources enter the picture. Since we already have a notion of quantum homomorphism for general relational structures, the correspondences established in the previous subsection give us ready-made notions of quantum solutions for CSPs and empirical models. We define a *quantum solution* for a CSP $\mathcal{K} = (V, D, C)$ to be a quantum homomorphism $\mathcal{A}_{\mathcal{K}} \xrightarrow{q} \mathcal{B}_{\mathcal{K}}$, i.e. a Kleisli morphism $\mathcal{A}_{\mathcal{K}} \to \mathcal{Q}_d\mathcal{B}_{\mathcal{K}}$ for some d. Similarly, we define a quantum solution for an empirical model $e : (X, \mathcal{M}, O)$ to be a quantum homomorphism $\mathcal{A}_{\mathcal{K}_e} \xrightarrow{q} \mathcal{B}_{\mathcal{K}_e}$.

We shall now compare these notions to existing ones for empirical models and constraints. These will turn out to be special cases.

Note first that given an empirical model e, the corresponding CSP $\mathcal{K}_e$ is determined purely by the *supports* of the probability distributions e_C, i.e. the possibilistic content of the model. It is only this information which is relevant to strong contextuality. We can consider a fine-grained notion of realization of a probabilistic empirical model, as in [4]. However, if our focus is strong contextuality, it is natural to consider the notion of *quantum witness* for an empirical model $e : (X, \mathcal{M}, O)$, given by a state ψ, and a PVM $P_x = \{P_{x,o}\}_{o \in O}$ for each $x \in X$, such that $[P_{x,o}, P_{x',o'}] = \mathbf{0}$ whenever x and x' both occur in some $C \in \mathcal{M}$. These must then satisfy, for all $C \in \mathcal{M}$ and $s \in O^C$, $e_C(s) = 0 \Rightarrow \psi^* P_{\mathbf{x},s(\mathbf{x})}\psi = 0$, where $P_{\mathbf{x},s(\mathbf{x})} = P_{x_1,s(x_1)} \cdots P_{x_k,s(x_k)}$. This provides a quantum witness for strong contextuality if e is a strongly contextual empirical model. An example is provided by the GHZ state, using X and Y measurements for each party [4]. An infinite family of such examples using three-qubit states is described in [1].

We can also consider a stronger notion. A *state-independent* quantum witness for $e : (X, \mathcal{M}, O)$ is given by a family of PVMs $\{P_x\}_{x \in X}$ which, for *any* state ψ, yield a quantum witness for e. The Mermin magic square and pentagram [29], and Kochen–Specker constructions [22, 10], provide examples of state-independent quantum realizations of strong contextuality. Note that in the state-independent case, we have the condition: $e_C(s) = 0 \Rightarrow P_{\mathbf{x},\mathbf{o}} = \mathbf{0}$. Comparison with the definition of quantum homomorphism $\mathcal{A}_{\mathcal{K}_e} \xrightarrow{q} \mathcal{B}_{\mathcal{K}_e}$ immediately yields the following result:

▶ Proposition 14. For an empirical model $e : (X, \mathcal{M}, O)$ there is a one-to-one correspondence between state-independent quantum witnesses for e and quantum solutions for $\mathcal{K}_e$.

An interesting point arising from this result, taken together with the results from Section 2, is that state-independent strong contextuality proofs can always be underwritten by non-locality arguments. This can be seen as a general form of constructions for turning Kochen–Specker contextuality proofs into Bell non-locality arguments [19]. Indeed, the role of the entangled state and of Bob in the non-local game is to provide an operational or physical underpinning for the compatibility or generalized no-signalling assumption which is made for empirical models [4]. Can we find a similar underpinning in the state-dependent case? We shall return to this point in the final section.

We now consider *binary constraint systems* (BCS), which have been extensively studied [13, 12, 36, 21]. We shall follow the account in [13]. A BCS (V, C) is simply a boolean CSP $(V, \{0,1\}, C)$. In this case, constraints can be written in the form $c = (\mathbf{x}, b_c)$, where $b_c : \{0,1\}^k \to \{0,1\}$ is a boolean function. Our general notion of quantum solution yields in this case a family of PVMs $P_x = \{P_{x,o}\}_{o \in \{0,1\}}$ for $x \in V$, such that $[P_{x,o}, P_{x',o'}] = \mathbf{0}$ whenever x and x' both occur in some constraint, and $P_{\mathbf{x},\mathbf{o}} = \mathbf{0}$ for $c = (\mathbf{x}, b_c)$ with $b_c(\mathbf{o}) = 0$.

In [13], a notion of *operator solution* for a BCS is defined. This is an assignment of a self-adjoint operator (aka observable) A_x to each variable x, such that: (1) each A_x is binary, i.e. $A_x^2 = I$; (2) $[A_x, A_{x'}] = \mathbf{0}$ when x and x' both occur in the same constraint. To express constraints, the representation of boolean values $b \mapsto (-1)^b$, $b \in \{0,1\}$, is used. It is standard that each boolean function $\{-1,+1\}^k \to \{-1,+1\}$ can be uniquely represented by a real multilinear polynomial $p(X_1, \ldots, X_k)$ [31]. Moreover, if the corresponding boolean function in the $\{0,1\}$-representation is $b : \{0,1\}^k \to \{0,1\}$, then for $\mathbf{o} \in \{0,1\}^k$: $(-1)^{b(\mathbf{o})} = p((-1)^{\mathbf{o}_1}, \ldots, (-1)^{\mathbf{o}_k})$. It is also standard that if we substitute pairwise commuting self-adjoint operators $A_1, \ldots, A_k$ for the variables $X_1, \ldots, X_k$, we obtain a self-adjoint operator $p(A_1, \ldots, A_k)$. The condition for an operator solution to satisfy the constraints is then expressed as follows: for each constraint $c = (\mathbf{x}, b_c)$, where b_c is represented by the polynomial $p_c(X_1, \ldots, X_k)$, we must have $p_c(A_1, \ldots, A_k) = -I$.

To relate this notion of operator solution to our quantum solution, note that a binary observable A_x with $A_x^2 = I$ has a spectral decomposition $A_x = P_{x,0} - P_{x,1}$, where $P_{x,0}$, $P_{x,1}$ are projectors. Commutation of the observables for variables occurring in the same context is equivalent to commutation of the corresponding projectors. Given a constraint $c = ((x_1, \ldots, x_k), p_c)$, since the observables $A_{x_1}, \ldots, A_{x_k}$ pairwise commute, we obtain a resolution of the identity $\sum_{\mathbf{o} \in \{0,1\}^k} P_{\mathbf{x},\mathbf{o}} = I$. Multiplying $p_c(A_1, \ldots, A_k)$ by this expression yields

$$p_c(A_1, \ldots, A_k) \;=\; \sum_{\mathbf{o} \in \{0,1\}^k} p_c((-1)^{\mathbf{o}_1}, \ldots, (-1)^{\mathbf{o}_k}) P_{\mathbf{x},\mathbf{o}}.$$

It follows that $p_c(A_1, \ldots, A_k) = -I$ iff for all $\mathbf{o}$ with $b_c(\mathbf{o}) = 0$, $P_{\mathbf{x},\mathbf{o}} = \mathbf{0}$. As an immediate consequence, we have:

▶ Proposition 15. Given a BCS (V, C), there is a one-to-one correspondence between operator solutions of the BCS and quantum solutions of the corresponding CSP.

4.3 Graphs

The results we have seen thus far show that our notion of quantum homomorphism subsumes a number of existing notions in contextuality and non-local games. However, as we shall now see, the situation in the setting which provided the original motivation for our approach, namely graph homomorphisms, is somewhat more subtle.

Graphs arise as structures for the signature with a single binary relation. Simple graphs are those where the relation is symmetric and irreflexive. If we specialize our definition of quantum homomorphism to the case $G \xrightarrow{q} H$ between graphs G and H, this gives a family $\{P_{x,y}\}_{x \in V(G), y \in V(H)}$ of projectors satisfying the following conditions:

- for all $x, x' \in V(G)$ and $y, y' \in V(H)$ with $x \sim x'$, $[P_{x,y}, P_{x',y'}] = 0$;
- for all $x, x' \in V(G)$ and $y, y' \in V(H)$ with $x \sim x'$ and $y \not\sim y'$, $P_{x,y} P_{x',y'} = 0$.

This definition differs from that introduced by Mančinska and Roberson [27] as a generalization of quantum graph colouring [11], in that the latter does *not* impose the first condition forcing commutativity between the PVMs corresponding to adjacent vertices of G. We refer to that as an *MR quantum graph homomorphism* in order to distinguish it from our notion.[2]

This reflects a difference in the Alice–Bob game used to motivate each definition. In the game we consider, Alice receives an ordered edge of G as an input and Bob a vertex of G,

[2] See also the locally commuting graph homomorphisms from [18], which require the commutativity condition, but differ from ours by not restricting to finite-dimensional quantum resources.

and we require that Alice answers with an edge of H and Bob with a vertex of H in a fashion consistent with Alice's choice. By contrast, Mančinska and Roberson consider a symmetric Alice–Bob game, where each player receives a vertex of G as input and outputs a vertex of H, and their outputs are required to be the same when they receive the same vertex, and required to form an edge of H whenever their inputs form an edge of G.

It is clear that a quantum homomorphism between graphs in the sense of this paper is also an MR quantum graph homomorphism. But the precise relationship between the two notions is yet to be understood in general: in particular, whether the existence of an MR quantum graph homomorphism implies the existence of a quantum homomorphism in our sense. However, by adapting a construction due to Ji [21], we can capture the existence of MR quantum graph homomorphisms in terms of quantum homomorphisms of relational structures, via a BCS.

Given graphs G and H, we define $V = \{r_{xy} \mid x \in V(G), y \in V(H)\}$. For each $x \in V(G)$, we have a boolean constraint $\bigvee_y r_{xy}$; a constraint $\neg(r_{xy} \wedge r_{xy'})$ when $y \neq y'$; and a constraint $\neg(r_{xy} \wedge r_{x'y'})$ whenever $x \sim x'$ and $y \not\sim y'$. This defines a BCS (V, C).

▶ **Theorem 16.** *Given graphs G and H, there is a one-to-one correspondence between MR quantum graph homomorphisms from G to H and quantum homomorphisms $\mathcal{A}_\mathcal{K} \xrightarrow{q} \mathcal{B}_\mathcal{K}$ for the associated CSP $\mathcal{K} = (V, \{0,1\}, C)$.*

Proof. We recall that an MR quantum graph homomorphism is given by a family of projectors $\{P_{x,y}\}_{x \in V(G), y \in V(H)}$ such that (MR1) $\sum_y P_{x,y} = I$, and (MR2) $P_{x,y}P_{x',y'} = \mathbf{0}$ whenever $x \sim x'$ and $y \not\sim y'$. A quantum homomorphism $\mathcal{A}_\mathcal{K} \xrightarrow{q} \mathcal{B}_\mathcal{K}$ is given by a family of projectors $\{Q_{xy,o}\}$, $x \in V(G)$, $y \in V(H)$, $o \in \{0,1\}$, such that the following conditions hold: (QH1) $Q_{xy,0} + Q_{xy,1} = I$; (QH2) $Q_{xy,1}Q_{xy',1} = \mathbf{0}$, $(y \neq y')$; (QH3) $Q_{xy,1}Q_{x'y',1} = \mathbf{0}$, $(x \sim x' \wedge y \not\sim y')$; (QH4) $Q_{xy_1,0} \cdots Q_{xy_k,0} = \mathbf{0}$, $V(H) = \{y_1, \ldots, y_k\}$. The commutativity conditions which are additionally required are implied by the orthogonality conditions (QH2) and (QH3).

Given an MR homomorphism $\{P_{x,y}\}$, we define $Q_{xy,1} := P_{x,y}$, $Q_{xy,0} := I - P_{x,y}$. Clearly (QH1) is satisfied. (MR1) implies (QH2), while (MR2) implies (QH3). Finally, using (QH2), $(I - P_{x,y_1}) \cdots (I - P_{x,y_k}) = I - \sum_y P_{x,y}$, and by (MR1), (QH4) holds.

Conversely, given a quantum homomorphism $\{Q_{xy,o}\}$, we define $P_{x,y} := Q_{xy,1}$. (MR2) follows from (QH3), while using (QH1), we can reverse the reasoning in the previous paragraph to show that (QH4) implies (MR1). These passages are clearly mutually inverse, so the result follows. ◀

It is noteworthy that our approach allows us to avoid *ad hoc* coding of constraints by polynomials, as in [13, 21]. Instead, we quantize the standard classical notions in a uniform way, using the quantum monad.

5 Outlook

This work suggests a number of directions for further study. We list a few:

- A notion of quantum graph isomorphism, with an equivalent characterization via an Alice–Bob game, has been studied in [8]. This can be generalized to relational structures. How does this fit in our quantum monad framework?
- Our approach captures quantum advantage provided by state-independent strong contextuality. Does state-dependent contextuality admit a similar treatment?
- Any strategy for an Alice–Bob game has a winning probability, which is related to the contextual fraction [3]. Can our approach be adapted to deal with quantitative aspects?

- Homomorphisms are intimately related with the existential positive fragment. Can this be extended to provide a notion of quantum validity for first-order formulae?
- Can other concepts from finite model theory, such as pebble games, which admit a comonadic formulation [7], be similarly quantized?
- The algebras of the quantum monad can be described as convex structures with mixing weighted by projectors rather than just numbers in $[0, 1]$. Is this viewpoint useful?

A Review of linear algebra and quantum mechanics background

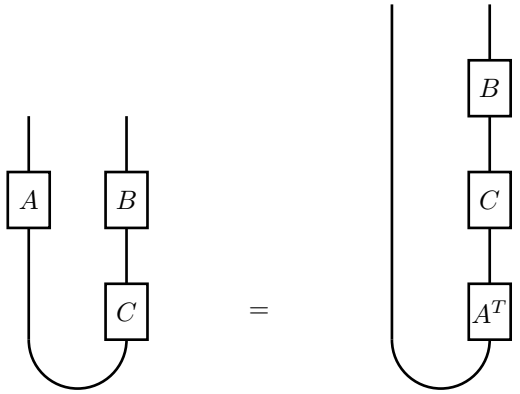
Since we are working in finite dimensions, we will use standard matrix notation. Thus we are dealing with $d \times d'$ complex matrices. We write matrix transpose as A^T. Apart from the usual operations of matrix addition and multiplication, there is the adjoint A^*, which is the conjugate transpose of A. Thus $[a_{i,j}]^* = [\overline{a_{j,i}}]$. The zero matrix is $\mathbf{0}$, the identity matrix in dimension d is $I = I_d$.[3] We view $d' \times d$ complex matrices interchangably as linear maps $\mathbb{C}^d \to \mathbb{C}^{d'}$, acting on "column vectors", i.e. $d \times 1$ matrices. We identify 1×1 matrices with scalars, i.e. complex numbers. The inner product of vectors $\mathbf{x}, \mathbf{y} \in \mathbb{C}^d$ is given by the matrix product $\mathbf{x}^*\mathbf{y}$. The norm of a vector $\mathbf{x}$ is $\|\mathbf{x}\| := \sqrt{\mathbf{x}^*\mathbf{x}}$. The standard basis vectors in dimension d are $e_1, \ldots, e_d$, where e_i has i'th component 1, and all other components 0.

A square matrix A is self-adjoint (aka Hermitian) if $A^* = A$. It is positive semidefinite if it self-adjoint, and $\mathbf{x}^*A\mathbf{x} \geq 0$ for all vectors $\mathbf{x}$. If A is positive semidefinite, so is C^*AC for any C. We have the order $A \leq B$ if $B - A$ is positive semidefinite. The condition $A \geq \mathbf{0}$ says exactly that A is positive semidefinite. The matrices $A \geq \mathbf{0}$ form a convex cone. A is a projector if $A^* = A = A^2$. We write $\mathsf{Proj}(d)$ for the set of $d \times d$ projectors. A fact we shall use frequently is that for any family of projectors $\{P_i\}$ in $\mathsf{Proj}(d)$, $\sum_i P_i \leq I$ iff $P_iP_j = \mathbf{0}$ whenever $i \neq j$.

If $A = [a_{i,j}]$ is a $m \times n$ matrix and B a $p \times q$ matrix, then the Kronecker product $A \otimes B := [a_{i,j}B]$ is an $mp \times nq$ matrix, which represents the tensor product of the corresponding linear maps. This operation is strictly associative, with unit $\mathbf{1} := [1]$. The key equation is the interchange law with matrix multiplication: $(A \otimes B)(C \otimes D) = AC \otimes BD$. This is functoriality. The category of complex matrices is a strict monoidal category with respect to this operation. Indeed, the category of complex matrices is equivalent to the category of finite-dimensional Hilbert spaces at the level of dagger compact closed categories, the basic setting for categorical quantum mechanics [5, 6]. The final operation we consider is vectorization of a matrix: $\mathsf{vec}(A)$ turns a $d \times d'$ matrix into a dd'-vector by stacking the columns of A on top of each other. In terms of the closed structure on the category of matrices, it is the name of the morphism A. The "cup" or unit of the compact closed

[3] We will omit dimensional subscripts whenever we can get away with it.

structure is $\mathsf{vec}(I)$. We have the equation $\mathsf{vec}(A) = (I \otimes A)\mathsf{vec}(I)$, and the "sliding rule": $(A \otimes I)\mathsf{vec}(I) = (I \otimes A^T)\mathsf{vec}(I)$, from which we can derive the key equation for vectorization: $(A \otimes B)\mathsf{vec}(C) = \mathsf{vec}(BCA^T)$. Diagrammatically, this is



A vector $\psi \in \mathbb{C}^{d_A} \otimes \mathbb{C}^{d_B}$ has a *Schmidt decomposition* $\psi = \sum_{i=1}^{d} \lambda_i \alpha_i \otimes \beta_i$, where $d \leq \min(d_a, d_b)$, $\{\alpha_i\}$ and $\{\beta_i\}$ are orthonormal sets of vectors in $\mathbb{C}^{d_A}$ and $\mathbb{C}^{d_B}$ respectively, and $\lambda_i > 0$ for all i. This follows directly from Singular Value Decomposition. We refer to d as the *Schmidt rank* of ψ.

The following result is standard, but we did not find an explicit reference so we include a proof.

▶ Proposition 17. Let A and B be positive semidefinite matrices. Then $\mathsf{Tr}(AB) = 0 \iff AB = \mathbf{0}$.

Proof. Since A and B are positive semidefinite, they have positive semidefinite square roots $\sqrt{A}$, $\sqrt{B}$, and $\mathsf{Tr}(AB) = \mathsf{Tr}(\sqrt{A}\sqrt{A}\sqrt{B}\sqrt{B}) = \mathsf{Tr}(\sqrt{B}\sqrt{A}\sqrt{A}\sqrt{B}) = \mathsf{Tr}(C^*C)$, where $C := \sqrt{A}\sqrt{B}$. Since C^*C is positive semidefinite, $\mathsf{Tr}(C^*C) = 0 \iff C^*C = \mathbf{0} \iff C = \mathbf{0}$. But $C = \mathbf{0}$ implies $AB = \sqrt{A}C\sqrt{B} = \mathbf{0}$. ◀

Now we briefly review the needed notions from quantum mechanics. A (pure) state in dimension d is a vector of unit norm in $\mathbb{C}^d$. A POVM (positive operator-valued measure) is a family $\{A_i\}_i$ with $A_i \geq \mathbf{0}$ for all i, and $\sum_i A_i = I$. The indices i label the measurement outcomes. Measuring a POVM $\{A_i\}_i$ on a state ψ yields outcome i with probability $\psi^* A_i \psi$. A POVM is projective (or a PVM) if A_i is a projector for all i. This implies that $A_i A_j = \mathbf{0}$ for all $i \neq j$, i.e. the projectors are mutually orthogonal. The product of projectors is a projector if and only if they commute, which is usually written as $[P, Q] = \mathbf{0}$, where $[P, Q] := PQ - QP$.

B Quantum monad

▶ Proposition 18. For each $\mathcal{A}$, $\mu_{\mathcal{A}}^{d,d'}$ is a well-defined homomorphism, and yields a natural transformation.

Proof. First, $\mu_{\mathcal{A}}^{d,d'}$ is a well-defined function, by finiteness of support. To show that it is a homomorphism, consider $(P_1, ..., P_k) \in R^{\mathcal{Q}_d \mathcal{Q}_{d'} \mathcal{A}}$. We must first show that for all $z, z' \in C$, and i, j, $[p_i(z), p_j(z')] = \mathbf{0}$, where $p_i := \mu_{\mathcal{A}}^{d,d'}(P_i)$, $p_j := \mu_{\mathcal{A}}^{d,d'}(P_j)$. Using linearity, this reduces to showing that $P_i(p) \otimes p(z)$ commutes with $P_j(p') \otimes p'(z')$ for all $p, p' \in \mathcal{Q}_{d'}$. Applying (QR1) to P_i and P_j, we have that $P_i(p)$ commutes with $P_j(p')$. If $p(z)$ commutes with $p'(z')$, we are done. If not, then we know that p cannot be adjacent to p' in the Gaifman graph of $\mathcal{Q}_{d'}$. Hence for any expansion $\mathbf{p} = (p_1, \ldots, p_k)$ with $p_i = p$, $p_j = p'$,

$\mathbf{p} \notin R^{\mathcal{Q}_{d'}\mathcal{A}}$, so by (QR2) we must have $P_1(p_1)\cdots P_k(p_k) = \mathbf{0}$. Using normalization, we have $P_i(p)P_j(p') = \sum_{\mathbf{p}_i=p,\mathbf{p}_j=p'} P_1(p_1)\cdots P_k(p_k) = \mathbf{0}$, and so

$$(P_i(p)\otimes p(z))(P_j(p')\otimes p'(z')) = \mathbf{0} = (P_j(p')\otimes p(z'))(P_i(p)\otimes p(z)).$$

Now let $q_i = \mu_{\mathcal{A}}^{d,d'}(P_i)$, $i = 1,\ldots,k$. To show that (QR2) holds for $(q_1,\ldots,q_k)$ reduces similarly to showing that, if $\mathbf{x} \notin R^{\mathcal{A}}$, then $P_1(p_1)\cdots P_k(p_k)\otimes p_1(x_1)\cdots p_k(x_k) = \mathbf{0}$ for all $p_1,\ldots,p_k$. If $p_1(x_1)\cdots p_k(x_k) = \mathbf{0}$ we are done; otherwise, since $\mathbf{x} \notin R^{\mathcal{A}}$, we must have $\mathbf{p} \notin R^{\mathcal{Q}_{d'}\mathcal{A}}$, and applying (QR2) to $(P_1,...,P_k)$, we must have $P_1(p_1)\cdots P_k(p_k) = \mathbf{0}$.

Naturality is commutativity of the following square.

$$\begin{array}{ccc} \mathcal{Q}_d\mathcal{Q}_{d'}\mathcal{A} & \xrightarrow{\mu_{\mathcal{A}}^{d,d'}} & \mathcal{Q}_{dd'}\mathcal{A} \\ \downarrow{\scriptstyle \mathcal{Q}_d\mathcal{Q}_{d'}f} & & \downarrow{\scriptstyle \mathcal{Q}_{dd'}f} \\ \mathcal{Q}_d\mathcal{Q}_{d'}\mathcal{B} & \xrightarrow[\mu_{\mathcal{B}}^{d,d'}]{} & \mathcal{Q}_{dd'}\mathcal{B} \end{array}$$

This is the following calculation:

$$\begin{aligned} \mathcal{Q}_{dd'}f\circ\mu_{\mathcal{A}}^{d,d'}(P)(y) &= \sum_{f(x)=y}\sum_{p} P(p)\otimes p(x) \\ &= \sum_{q}\sum_{\mathcal{Q}_{d'}f(p)=q} P(p)\otimes q(y) \\ &= \sum_{q}\mathcal{Q}_d\mathcal{Q}_{d'}(f)(P)(q)\otimes q(y) \\ &= \mu_{\mathcal{B}}^{d,d'}\circ\mathcal{Q}_d\mathcal{Q}_{d'}f(P)(y). \end{aligned}$$

The second step uses the fact that $\mathcal{Q}_{d'}f(p) = q \iff q(y) = \sum_{f(x)=y} p(x)$. ◀

The unit $\eta : \mathsf{Id} \xrightarrow{\cdot} T_1$ and graded multiplication $\mu^{m,m'} : T_mT_{m'} \xrightarrow{\cdot} T_{m\cdot m'}$ of a graded M-monad are required to satisfy the following coherence conditions:

$$\begin{array}{ccc} T_mX & \xrightarrow{\eta_{T_mX}} & T_1T_mX \\ \downarrow{\scriptstyle T_m\eta_X} & \searrow & \downarrow{\scriptstyle \mu_X^{1,m}} \\ T_mT_1X & \xrightarrow[\mu_X^{m,1}]{} & T_mX \end{array} \qquad \begin{array}{ccc} T_mT_{m'}T_{m''}X & \xrightarrow{T_m\mu_X^{m',m''}} & T_mT_{m'\cdot m''}X \\ \downarrow{\scriptstyle \mu^{m,m'}_{T_{m''}X}} & & \downarrow{\scriptstyle \mu_X^{m,m'\cdot m''}} \\ T_{m\cdot m'}T_{m''}X & \xrightarrow[\mu_X^{m\cdot m',m''}]{} & T_{m\cdot m'\cdot m''}X. \end{array}$$

We verify these for the quantum monad.

▶ **Lemma 19.** *Let $\mathcal{A}$ be a structure and $d \in \mathbb{N}^+$. Then, the following diagram commutes:*

$$\begin{array}{ccc} \mathcal{Q}_d\mathcal{A} & \xrightarrow{\eta_{\mathcal{Q}_d\mathcal{A}}} & \mathcal{Q}_1\mathcal{Q}_d\mathcal{A} \\ \downarrow{\scriptstyle \mathcal{Q}_d\eta_{\mathcal{A}}} & \searrow & \downarrow{\scriptstyle \mu_{\mathcal{A}}^{1,d}} \\ \mathcal{Q}_d\mathcal{Q}_1\mathcal{A} & \xrightarrow[\mu_{\mathcal{A}}^{d,1}]{} & \mathcal{Q}_d\mathcal{A} \end{array}$$

Proof. Let $p \in \mathcal{Q}_d\mathcal{A}$ and $x \in A$. The claim is that $(\mu_{\mathcal{A}}^{1,d} \circ \eta_{\mathcal{Q}_d\mathcal{A}})(p)(x) = p(x) = (\mu_{\mathcal{A}}^{d,1} \circ \mathcal{Q}_d\eta_{\mathcal{A}})(p)(x)$. The left-hand side of this equation expands to

$$\mu_{\mathcal{A}}^{1,d}(\eta_{\mathcal{Q}_d\mathcal{A}}(p))(x) = \sum_{p' \in \mathcal{Q}_d\mathcal{A}} \eta_{\mathcal{Q}_d\mathcal{A}}(p)(p') \otimes p'(x) = p(x),$$

and the right-hand side to

$$\begin{aligned} \mu_{\mathcal{A}}^{d,1}(\mathcal{Q}_d\eta_{\mathcal{A}}(p))(x) &= \sum_{p' \in \mathcal{Q}_1\mathcal{A}} \mathcal{Q}_d\eta_{\mathcal{A}}(p)(p') \otimes p'(x) \\ &= \mathcal{Q}_d\eta_{\mathcal{A}}(p)(\delta_x) \\ &= \sum_{\eta_{\mathcal{A}}(x')=\delta_x} \eta_{\mathcal{A}}(p)(x') \\ &= p(x), \end{aligned}$$

where $\delta_x : A \to \{0,1\}$ is defined by $\delta_x(x') := \delta_{x,x'}$ for all $x' \in A$. ◀

▶ **Lemma 20.** *Let $\mathcal{A}$ be a structure and $a, b, c \in \mathbb{N}^+$. Then, the following diagram commutes:*

$$\begin{array}{ccc} \mathcal{Q}_a\mathcal{Q}_b\mathcal{Q}_c\mathcal{A} & \xrightarrow{\mathcal{Q}_a\mu_{\mathcal{A}}^{b,c}} & \mathcal{Q}_a\mathcal{Q}_{bc}\mathcal{A} \\ \downarrow{\scriptstyle \mu_{\mathcal{Q}_c\mathcal{A}}^{a,b}} & & \downarrow{\scriptstyle \mu_{\mathcal{A}}^{a,bc}} \\ \mathcal{Q}_{ab}\mathcal{Q}_c\mathcal{A} & \xrightarrow[\mu_{\mathcal{A}}^{ab,c}]{} & \mathcal{Q}_{abc}\mathcal{A} \end{array}$$

Proof. Let $P \in \mathcal{Q}_a\mathcal{Q}_b\mathcal{Q}_c\mathcal{A}$ and $x \in A$. The claim is that $(\mu_{\mathcal{A}}^{a,bc} \circ \mathcal{Q}_a\mu_{\mathcal{A}}^{b,c})(P)(x) = (\mu_{\mathcal{A}}^{ab,c} \circ$

$\mu^{a,b}_{\mathcal{Q}_c\mathcal{A}})(P)(x)$. We have:

$$
\begin{aligned}
& \mu^{a,bc}_{\mathcal{A}}(\mathcal{Q}_a\mu^{b,c}_{\mathcal{A}}(P))(x) \\
= & \sum_{q\in\mathcal{Q}_{bc}\mathcal{A}} \mathcal{Q}_a\mu^{b,c}_{\mathcal{A}}(P)(q)\otimes q(x) \\
= & \sum_{q\in\mathcal{Q}_{bc}\mathcal{A}} \left(\sum_{\mu^{b,c}_{\mathcal{A}}(p')=q} P(p')\right)\otimes q(x) \\
= & \sum_{q\in\mathcal{Q}_{bc}\mathcal{A}} \sum_{\mu^{b,c}_{\mathcal{A}}(p')=q} P(p')\otimes \mu^{b,c}_{\mathcal{A}}(p')(x) \\
= & \sum_{q\in\mathcal{Q}_{bc}\mathcal{A}} \sum_{\mu^{b,c}_{\mathcal{A}}(p')=q} P(p')\otimes \left(\sum_{p\in\mathcal{Q}_c\mathcal{A}} p'(p)\otimes p(x)\right) \\
= & \sum_{q\in\mathcal{Q}_{bc}\mathcal{A}} \sum_{\mu^{b,c}_{\mathcal{A}}(p')=q} \sum_{p\in\mathcal{Q}_c\mathcal{A}} P(p')\otimes p'(p)\otimes p(x) \\
= & \sum_{p'\in\mathcal{Q}_b(\mathcal{Q}_c\mathcal{A})} \sum_{p\in\mathcal{Q}_c\mathcal{A}} P(p')\otimes p'(p)\otimes p(x) \\
= & \sum_{p\in\mathcal{Q}_c\mathcal{A}} \left(\sum_{p'\in\mathcal{Q}_b(\mathcal{Q}_c\mathcal{A})} P(p')\otimes p'(p)\right)\otimes p(x) \\
= & \sum_{p\in\mathcal{Q}_c\mathcal{A}} \mu^{a,b}_{\mathcal{Q}_c\mathcal{A}}(P)(p)\otimes p(x) \\
= & \ \mu^{ab,c}_{\mathcal{A}}(\mu^{a,b}_{\mathcal{Q}_c\mathcal{A}}(P))(x)
\end{aligned}
$$

◀

Additional material on the quantum monad

We shall now show that the quantum monad is monoidal (or commutative) and affine [23]. This continues the analogy with the distribution monad, which is well known to have these properties [20].

The category $\mathcal{R}(\sigma)$ has finite products, given by the usual cartesian product of structures. The terminal object $\top$ is the one-element structure, with each relation interpreted as the universal relation. Because of normalization, the following is immediate:

▶ Proposition 21. For all d, $\mathcal{Q}_d\top \cong \top$. Thus the quantum monad is affine.

Now given structures $\mathcal{A}$ and $\mathcal{B}$, we define a map $m^{d,d'}_{\mathcal{A},\mathcal{B}} : \mathcal{Q}_d\mathcal{A}\times\mathcal{Q}_{d'}\mathcal{B}\to\mathcal{Q}_{dd'}(A\times B)$ by $m^{d,d'}_{\mathcal{A},\mathcal{B}}(p,q)(x,y) := p(x)\otimes q(y)$.

▶ Proposition 22. This is a well-defined homomorphism, and the family $\{m^{d,d'}_{\mathcal{A},\mathcal{B}}\}$ defines a graded natural transformation satisfying the monoidal coherence conditions, thus witnessing a commutative strength.

Towards a Polynomial Kernel for Directed Feedback Vertex Set*

Abstract

In the Directed Feedback Vertex Set (DFVS) problem, the input is a directed graph D and an integer k. The objective is to determine whether there exists a set of at most k vertices intersecting every directed cycle of D. DFVS was shown to be fixed-parameter tractable when parameterized by solution size by Chen, Liu, Lu, O'Sullivan and Razgon [JACM 2008]; since then, the existence of a polynomial kernel for this problem has become one of the largest open problems in the area of parameterized algorithmics.

In this paper, we study DFVS parameterized by the feedback vertex set number of the underlying *undirected graph*. We provide two main contributions: a polynomial kernel for this problem on general instances, and a linear kernel for the case where the input digraph is embeddable on a surface of bounded genus.

1 Introduction

Feedback Set problems are fundamental combinatorial optimization problems. Typically, in these problems, we are given a graph G (directed or undirected) and a positive integer k, and the objective is to select at most k vertices, edges or arcs to hit all cycles of the input graph. Feedback Set problems are among Karp's 21 NP-complete problems [27] and have been a topic of active research from algorithmic [1, 2, 3, 6, 7, 8, 9, 10, 13, 14, 20, 23, 28, 25, 30, 32, 37] as well as structural points of view [19, 26, 29, 31, 33, 34, 35]. In particular, such problems constitute one of the most important topics of research in parameterized algorithms [6, 8, 9, 10, 13, 14, 28, 25, 30, 32, 37], spearheading the development of several

new techniques. In this paper, we study the DFVS problem, where the objective is to find a set of k vertices that intersects all directed cycles in a given digraph.

For over a decade resolving the fixed-parameter tractability of DFVS (whether there is an algorithm running in time $f(k)\cdot n^{\mathcal{O}(1)}$ for some computable function f) was considered the most important open problem in parameterized complexity. In fact, this problem was posed as an open problem in the first few papers on fixed-parameter tractability (FPT) [16, 17]. The problem can be formally stated as follows.

Directed Feedback Vertex Set (DFVS)	
Instance:	A digraph D and a positive integer k.
Parameter:	k
Question:	Does there exist a vertex subset of size at most k that intersects every cycle in D?

DFVS was shown to be fixed-parameter tractable in a breakthrough paper by Chen, Liu, Lu, O'Sullivan and Razgon [9] in 2008.

One of the most natural follow-up questions once a problem has been classified as fixed-parameter tractable is 'does it admit a polynomial kernel?'. A *polynomial kernel* is essentially a polynomial-time preprocessing algorithm that transforms the given instance of the problem into an equivalent one whose size is bounded polynomially in the parameter. Following the resolution of the fixed-parameter tractability of DFVS, the question of whether the problem admits a polynomial kernel was raised and has since become one of the main open problems in the area of parameterized complexity.

The most frequently used way of parameterizing problems, like in the case of DFVS, is taking the solution size as the parameter. An alternate method of parameterization is choosing a parameter that never exceeds the solution size but can potentially be much smaller. A classical example of this approach is parameterizing the Vertex Cover problem by the feedback vertex set (FVS) number. Clearly, the number of vertices required to make a graph acyclic never exceeds the number of vertices needed to make the graph edgeless. On the other hand, the feedback vertex set number could be arbitrarily smaller than the size of the smallest vertex cover. This problem was first studied by Bodlaender and Jansen [24], who showed that Vertex Cover parameterized by the feedback vertex number has a polynomial kernel. This was later extended by Cygan et al. [12] who systematically studied several generalizations of this problem and obtained several positive as well as negative results with respect to the existence of polynomial kernels.

While this kind of an alternate parameterization is interesting for problems which are known to have polynomial kernels when parameterized by the solution size, it is the *exact opposite* approach which is useful when dealing with problems for which this question has been answered negatively or remains open. This paper deals with such a parameterization for DFVS as an intermediate step towards answering the main question, that of a polynomial kernel for DFVS. To this end, we chose a natural parameter which is never less than the solution size, in particular the feedback vertex set number of the undirected graph underlying the given digraph. The problem we are interested in can formally be stated as follows.

Directed Feedback Vertex Set parameterized by FVS (DFVS[FVS])	
Instance:	A digraph D, an integer p, and a set F such that F is an UFVS of D.
Parameter:	$\lvert F\rvert$
Question:	Does there exist a vertex subset of size at most p that intersects every cycle in D?

Since every UFVS (undirected feedback vertex set) of D is also a DFVS (directed feedback vertex set) of D, we may assume without loss of generality that $p \leq |F|$ for every instance of DFVS[FVS]. Furthermore, we use k to denote the size of F. Our first result is a polynomial kernel for DFVS[FVS], formally stated below.

▶ **Theorem 1.** *There is a kernel with $\mathcal{O}(k^4)$ vertices for* DFVS[FVS].

The overall approach for proving Theorem 1 is inspired by the result of Bodlaender and Dijk [5] on kernelizing the undirected feedback vertex set problem. However, several obstacles needed to be overcome for the techniques to be applicable in the directed setting.

Interestingly, the existence of a polynomial kernel for DFVS parameterized by the solution size remains open even in the restricted setting of planar graphs. While our Theorem 1 naturally also provides a polynomial kernel for DFVS[FVS] on planar graphs, as our second main contribution we show that one can in fact obtain a significantly stronger result not only on planar graphs, but on all graphs embeddable on orientable surfaces.

▶ **Theorem 2.** *There is a kernel with $\mathcal{O}(k)$ vertices for* DFVS[FVS] *when the input digraph is embeddable on a surface of constant genus.*

We note that the existence of such a linear kernel can also be obtained from the Meta-Kernelization framework [4] by observing that DFVS[FVS] has finite integer index. However, the framework is non-constructive; unlike our Theorem 2, it does not provide a concrete kernelization algorithm for the problem.

Some proofs have been omitted due to space limitation.

2 Preliminaries

Graphs and Digraphs. We consider undirected and directed graphs that may contain self-loops and multiple edges and mostly use standard notation that can be found, for instance, in the textbook by Diestel [15]. For an undirected or directed graph D we denote by $V(D)$ its vertex set and by $E(D)$ its edgeset (or arcset). For a set of vertices $A \subseteq V(D)$, we denote by $D \setminus A$ the (di-)graph obtained from D after deleting all vertices in A as well as all arcs/edges incident to some vertex in V. Moreover, $D[A]$ denotes the graph $D \setminus (V(D) \setminus A)$. We say that a vertex u is a *neighbor* of a vertex v in D if $\{u, v\} \in E(D)$ (in the case that D is undirected) or at least one of $(u, v) \in E(D)$ or $(v, u) \in E(D)$ holds (in the case that D is directed). We denote by $N_D(v)$ (or by $N(D)$ if D is clear from the context) the set of all neighbors of v in D and refer to $|N_D(v)|$ as the *degree* of v in D (if D is undirected) or as the *total degree* of v in D (if D is directed). For a set of vertices A, we denote by $N_D(A)$ the set $(\bigcup_{a \in A} N_D(a)) \setminus A$.

In addition to the above, we also use standard notions such as *in-neighbors* and *out-neighbors*, *paths* and *directed paths* as well as *endpoints* and *internal vertices* of such paths, *contractions*, minors and others. We denote by $N^-_D(u)$ and $N^+_D(u)$ the set of all in-neighbors and out-neighbors of v in D, respectively; once again, we drop the subscript D if it can be inferred from the context and for a vertex set $A \subseteq V(D)$ we write $N^-_D(A)$ and $N^+_D(A)$ to denote the sets $(\bigcup_{a \in A} N^-_D(a)) \setminus A$ and $(\bigcup_{a \in A} N^+_D(a)) \setminus A$, respectively. We denote by $\overline{D}$ the undirected graph obtained from D after replacing every arc $(u, v) \in E(D)$ with an edge $\{u, v\}$; if there are arcs in both directions between u and v, then we say that there is a *bidirectional arc* between u and v and $\overline{D}$ will contain two parallel u-v edges.

▶ **Proposition 3** ([22]). The orientable and nonorientable genus, denoted by γ and $\tilde{\gamma}$, of complete bipartite graphs is given by the following formulae:

$$\gamma(K_{m,n}) = \left\lceil \frac{(m-2)(n-2)}{4} \right\rceil, m,n \geq 2; \qquad \tilde{\gamma}(K_{m,n}) = \left\lceil \frac{(m-2)(n-2)}{2} \right\rceil, m,n \geq 2.$$

▶ **Corollary 4.** If G is a graph such that $\gamma(G) \leq g$ and $\tilde{\gamma}(G) \leq h$ for some constants g and h, then G does not contain $K_{3,4g+3}$ nor $K_{3,2h+3}$ as a minor.

For a more detailed treatment of topological graph theory the reader is referred to [22].

Parameterized Algorithms and Kernelization. For a detailed illustration of the following facts the reader is referred to [11, 18]. A *parameterized problem* is a language $\Pi \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a finite alphabet; the second component k of instances $(I,k) \in \Sigma^* \times \mathbb{N}$ is called the *parameter*. A parameterized problem Π is *fixed-parameter tractable* if it admits a *fixed-parameter algorithm*, which decides instances (I,k) of Π in time $f(k) \cdot |I|^{\mathcal{O}(1)}$ for some computable function f.

A *kernelization* for a parameterized problem Π is a polynomial-time algorithm that given any instance (I,k) returns an instance (I',k') such that $(I,k) \in \Pi$ if and only if $(I',k') \in \Pi$ and such that $|I'| + k' \leq f(k)$ for some computable function f. The function f is called the *size* of the kernelization, and we have a polynomial kernelization if $f(k)$ is polynomially bounded in k. It is known that a parameterized problem is fixed-parameter tractable if and only if it is decidable and has a kernelization. However, the kernels implied by this fact are usually of superpolynomial size.

A *reduction rule* is an algorithm that takes as input an instance $I = (D,p,F)$ of DFVS[FVS] and outputs an instance $I' = (D',p',F')$ of the same problem. We say that the reduction rule is *sound* if I is a *yes*-instance if and only if I' is a *yes*-instance. In order to describe our kernelization algorithm, we present a series of reduction rules. We prove the soundness of each reduction rule immediately after presenting its description, unless the soundness is obvious. The reduction rules we present will be executed in the order in which they appear. That is, if at any point we may apply Reduction Rule i as well as Reduction Rule j where $i < j$, we will execute Reduction Rule i.

3 A Polynomial Kernel for DFVS[FVS]

Note that every FVS of $\overline{D}$ is also a DFVS of D. Given an instance D of DFVS, our kernelization algorithm for DFVS parameterized by FVS first computes a 2-approximate FVS S of $\overline{D}$ (using for instance the algorithm given in [1]) and then uses S to reduce the instance in polynomial-time into an equivalent instance with at most $\mathcal{O}(|S|^4)$ vertices.

Hence in the following we will assume that D is a directed graph and S is a FVS of $\overline{D}$ of size k. Our first two reduction rules are sound because (a) neither sinks nor sources can appear on a directed cycle and (b) if a vertex v has exactly one in-neighbor u in D then every directed cycle containing v has to use the arc (u,v) (a symmetric statement holds for vertices with exactly one out-neighbor).

▶ **Reduction Rule 5.** Delete all sources and sinks from D.

▶ **Reduction Rule 6.** Let l be an arbitrary vertex in D.

- If $N^+(l) = \{p\}$, then we contract the arc (l,p) into a new vertex l^*.
- If $N^-(l) = \{p\}$, then we contract the arc (p,l) into a new vertex l^*.

After the exhaustive application of these two rules, we may assume without loss of generality that the digraph D has no sinks or sources, and that every vertex has at least 2 in-neighbors and at least 2 out-neighbors. We now state one of our main reduction rules.

▶ **Reduction Rule 7.** Let u and v be two (not necessarily distinct) vertices in S such that there are at least $k+1$ internally vertex-disjoint directed u-v paths in D. Then,

- if $u \neq v$ and $(u,v) \notin E(D)$, we add an arc from u to v to D, or
- if $u = v$, we remove u from D and decrease the parameter k by one.

Proof of soundness. Let $u, v \in S$ be as above and let D' be the digraph obtained from D after applying the reduction rule. If $u = v$ then clearly every DFVS for D of size at most k contains u, which shows the soundness of the reduction rule.

If on the other hand $u \neq v$, we will show that a set $S' \subseteq V(D) = V(D')$ of size at most k is a DFVS for D if and only if it is also a DFVS for D'. The backward direction is trivial because D is a subgraph of D'. For the forward direction let S' be a DFVS for D of size at most k and assume for a contradiction that S' is not a DFVS for D'. Then $D' \setminus S'$ contains a directed cycle C that contains the arc (u,v). Hence $D' \setminus S'$ and thus also $D \setminus S'$ contains a directed v-u path P. Moreover, since S' has size at most k and there are at least $k+1$ vertex-disjoint directed u-v paths in D, we conclude that there is a u-v path P' in $D \setminus S'$. But then $P \cup P'$ must contain a directed cycle, which is also a directed cycle in $D \setminus S'$, a contradiction to our assumption that S' is a DFVS of D. ◀

We will use Reduction Rule 7 to reduce the number of vertices in $D \setminus S$ that 'directly contribute' to (pairs of) vertices in S. We formalize this idea in the following definition.

▶ **Definition 8.** Let (u,v) be an ordered pair of vertices in S. If $u \neq v$, then we refer to (u,v) as a *potential arc* in $D[S]$ and if additionally $(u,v) \notin D$ then we refer to (u,v) as a *non-arc*. If on the other hand $u = v$, then we refer to (u,v) as a *self-loop*. We say that a vertex $v \in V(D) \setminus S$ *contributes* to a potential arc or self-loop (u,w), if $(u,v) \in E(D)$ and $(v,w) \in E(D)$.

After the exhaustive application of Reduction Rule 7, we have the following structural observation regarding the input.

▶ **Observation 9.** For every $u \in S$ there are at most k internally vertex-disjoint u-u paths in D; moreover for every two distinct vertices u and v in S with $(u,v) \notin E(D)$, there are at most k vertex disjoint u-v paths in D. As a result, for every non-arc or self-loop (u,v), there are at most k vertices that contribute to (u,v).

Since S has at most k vertices and at most $k(k-1)$ ordered pairs of vertices, Observation 9 implies the following.

▶ **Observation 10.** There are at most $k^2(k-1)$ vertices in $D \setminus S$ that contribute to some non-arc of $D[S]$. Moreover, there are at most k^2 vertices in $D \setminus S$ that contribute to some self-loop of $D[S]$.

Our next aim is to bound the number of vertices in $A = D \setminus S$ in terms of k. Towards achieving this we will distinguish these vertices in terms of their degree in $D \setminus S$. We therefore denote by A_0, A_1, A_2, and $A_{\geq 3}$ the sets of all vertices in A that have total degree 0, 1, 2, and at least 3, respectively, in $D \setminus S$.

3.1 Bounding A_0, A_1 and $A_{\geq 3}$.

Note that Observation 10 already provides a bound for the number of vertices in A_0 that contribute to some self-loop of $D[S]$. Hence, in order to bound A_0, it is sufficient to provide a bound for the remaining vertices, in the following denoted by A'_0, in A_0. In the following let v be a vertex in A'_0. Because of Rule 5 v must have at least one in-neighbor and one out-neighbor in S. Consequently, v contributes to at least one potential arc of $D[S]$.

▶ **Reduction Rule 11.** If v does not contribute to a non-arc of $D[S]$, then we remove v from D.

Proof of soundness. Let v be as above and let D' be the directed graph obtained from D after deleting v. We show that a set $S' \subseteq V(D)$ is a DFVS for D if and only if S' is a DFVS for D'. The forward direction of this claim is trivial because D' is a subgraph of D. Towards showing the backward direction let S' be a DFVS for D' and assume for a contradiction that S' is not a DFVS for D. Then there must exist a directed cycle C in $D \setminus S'$ that contains v as well as two arcs (s, v) and (v, s') for some $s, s' \in S$. Because v does not contribute to a self-loop of $D[S]$, we have that $s \neq s'$. Because v does not contribute to a non-arc of $D[S]$, it follows that $(s, s') \in E(D)$. Hence the arc (s, s') together with the directed path from s' to s contained in C forms a directed cycle in $D' \setminus S'$, a contradiction to our assumption that S' is a DFVS for D'. ◀

After the exhaustive application of the above rule, we obtain that v contributes to some non-arc of $D[S]$ and hence together with Observation 10, we obtain the following.

▶ **Observation 12.** There are at most $k^2(k-1)$ vertices in A'_0.

Bounding A_1. We now present the reduction rules we use to bound the size of A_1, i.e., the number of leaves in A. Again it is sufficient to bound the number of vertices in A_1 that do not contribute to some self-loop of $D[S]$, in the following denoted by A'_1. Namely, we will introduce reduction rule that ensure that every vertex in A'_1 contributes to at least one non-arc in $D[S]$. Together with Observation 10 this then bounds the size of A'_1. Recall that at this point every vertex in D has at least two in-neighbors and at least two out-neighbors and since moreover every vertex in A'_1 does not contribute to a self-loop, we obtain that every vertex in A'_1 has at least one in-neighbor and at least one out-neighbor in S that are distinct. Hence we obtain:

▶ **Observation 13.** Every vertex in A'_1 has at least one in-neighbor and at least one out-neighbor in S and hence every vertex in A'_1 contributes to a potential arc of $D[S]$.

The next reduction rule reduces leaves that do not contribute to a non-arc of $D[S]$.

▶ **Reduction Rule 14.** If $l \in A'_1$ does not contribute to a non-arc of $D[S]$, then:
- if l is a source in $D \setminus S$, then we delete all arcs from l to vertices in S,
- if l is a sink in $D \setminus S$, then we delete all arcs from vertices in S to l.

Note that after application of Rule 14, l will only have either in-neighbors or out-neighbors in S and can hence be reduced further using Rule 6. Consequently, after the exhaustive application of the above rules, we conclude that every vertex in A'_1 contributes to at least one non-arc of $D[S]$. Due to Observation 10 we conclude that there are at most $k^2(k-1)$ vertices in A'_1. Finally, since $\overline{D \setminus S}$ is a forest and the number of vertices of degree at least 3 in a forest is at most equal to the number of leaves minus two, we get the following.

▶ **Observation 15.** There are at most $k^3 - 2$ vertices in $A_{\geq 3}$.

Note that at this point, we have bounded the size of the sets A_0, A_1 and $A_{\geq 3}$ and the only set that remains is A_2.

3.2 Bounding A_2

Our next aim is to bound the number of vertices in A_2.

▶ **Definition 16.** Let v be a vertex in A_2. We say that v is a *sink-vertex* or a *source-vertex* if the two arcs of $D \setminus S$ incident on it are both incoming arcs or outgoing arcs respectively. Otherwise we say that v is a *balanced-vertex*.

Note that due to Reduction Rule 6, there are no balanced vertices in $D \setminus S$ which have *no* neighbors in S. This is because otherwise, we would have already contracted one of the two arcs incident to v in $D \setminus S$.

Therefore, at this point, we infer the following.

▶ **Observation 17.** Every vertex in A_2 has at least one neighbor in S.

▶ **Definition 18.** Let $P = (v_1, \ldots, v_r)$ be a directed path of maximum length in $D \setminus S$ whose internal vertices are in A_2. Then we say that P is a path segment in $D \setminus S$. We say that P is an *outer path segment* if at least one of its endpoints is not in A_2, otherwise we say that P is an *inner path segment*.

Note that path segments are by definition *directed paths*. Our strategy now is to obtain a bound on the total number of path segments and then proceed to bound the length of each path segment. We first bound the number of outer path segments in $D \setminus S$ as follows. Let G be the undirected graph obtained from $\overline{D} \setminus S$ after contracting all edges which are incident to at least one vertex of degree 2 . Then the number of outer path segments in $D \setminus S$ is equal to two times the number of edges of G. Because G is a forest without degree two vertices it holds that the number of edges of G is equal to the number of leaves plus the number of non-leaves in G minus one. Hence the number of outer path segments is at most $2(|A'_1 \cup A_{\geq 3}| - 1)$, which together with the already obtained bound on these sets and Observation 15 allows us to infer the following.

▶ **Observation 19.** The number of outer path segments in $D \setminus S$ is at most $4k^2(k-1)+2k^2-6$.

In order to bound the number of inner path segments, we need to introduce a new reduction rule. We begin by defining the notion of a path segment 'contributing' to a potential arc.

▶ **Definition 20.** We say that a path segment $P = (v_1, \ldots, v_r)$ *contributes* to a potential arc (s, s') of $D[S]$ if there are i and j with $1 \leq i \leq j \leq r$ such that $(s, v_i) \in E(D)$ and $(v_j, s') \in E(D)$. Moreover, we say that P contributes to a self-loop if there are i and j with $1 \leq i \leq j \leq r$ such that $(s, v_i) \in E(D)$ and $(v_j, s) \in E(D)$ for some $s \in S$.

▶ **Reduction Rule 21.** If an inner path segment does not contribute to a non-arc or to a self-loop of $D[S]$, then we remove all internal vertices of P.

After the exhaustive application of the above rule, we obtain:

▶ **Observation 22.** Every inner path segment contributes to at least one non-arc or self-loop of $D[S]$.

Because every pair of inner path segments that contribute to some non-arc or self-loop (s, s') of $D[S]$ increase the number of disjoint paths between s and s' in D by at least one, Observation 9 implies that for every non-arc or self-loop (s, s') of $D[S]$ there are at most $2k$ inner path segments that contribute to (s, s'). Finally, because S has at most k vertices and at most $k(k-1)$ ordered pairs of vertices, we conclude that there are at most $2k^2(k-1) + 2k^2$ inner path segments in $D \setminus S$. Having obtained a bound on the number of inner path segments too, we conclude the following.

▶ **Observation 23.** The number of path segments in $D \setminus S$ is at most $6k^2(k-1) + 4k^2 - 6$.

Our next aim is to provide a bound on the overall length of path segments and use it to bound the size of A_2. Towards this aim we introduce reduction rules that allow us to bound the in-degree and the out-degree w.r.t. S of any vertex occurring internally in path segments.

▶ **Definition 24.** Let $s \in S$ and let $P = (v_1, \ldots, v_r)$ be an induced directed path in $D \setminus S$, whose internal vertices are in A_2 and that satisfies:

- $(s, v_1) \in E(D)$ and $(s, v_r) \in E(D)$ and v_1 is a balanced vertex in A_2,
- for every i with $1 < i < r$, it holds that $(s, v_i) \notin E(D)$.

If P satisfies the above properties we call P an *out-segment* for s. We say that P *contributes* to a potential arc or self-loop (s, s') in $D[S]$ if there is an index i with $1 \leq i < r$ such that $(v_i, s') \in E(D)$ for some $s' \in S$.

We now introduce a reduction rule that allows us to preprocess and reduce certain out-segments.

▶ **Reduction Rule 25.** Let $s \in S$ and let $P = (v_1, \ldots, v_r)$ be an out-segment for s. If P does not contribute to any non-arc or self-loop of $D[S]$, then we remove the arc (s, v_1).

After the exhaustive application of the above rule, we obtain the following.

▶ **Observation 26.** For each $s \in S$, there are at most k^2 out-segments for s.

Proof. Since Rule 25 does not apply, every out-segment for s contributes to at least one non-arc or self-loop of $D[S]$. Furthermore, every out-segment for s that contributes to some non-arc or self-loop (s, s') of $D[S]$ increases the number of internally vertex-disjoint paths s-s' paths in D by one. Observation 9 implies that for every non-arc or self-loop (s, s') of $D[S]$, there are at most k out-segments for s in $D \setminus (S \cup B)$ that contribute to (s, s').

Finally, because every vertex s is contained in at most a single self-loop and in at most $k-1$ non-arcs of $D[S]$, we infer that there are at most $k(k-1) + k$ out-segments for s. This completes the proof of the observation. ◀

We are now ready to bound the size of the set A_2.

▶ **Observation 27.** The number of vertices in A_2 is at most $12k^4 - 2k^3 - 12k$.

Proof. We begin by arguing that for every $s \in S$, s has at most $2k \cdot (6k^2(k-1) + 4k^2 - 6 + k(k-1) + k)$ neighbors in A_2. Since the number of out-neighbors of s in A_2 is at most the number of path segments (bounded by Observation 23) plus the number of out-segments for s (bounded by Observation 26), we obtain an upper bound of $6k^2(k-1) + 4k^2 - 6 + k^2$ on the size of the out-neighborhood (and by symmetry, the in-neighborhood) of s in A_2.

Consequently, the total number of neighbors of vertices in S to vertices in A_2 and thus (because of Observation 17) the total number of vertices in A_2 is at most $2k \cdot (6k^2(k-1) + 4k^2 - 6 + k^2)$. Finally, since the size of S is bounded by k, the observation follows. ◀

We are now ready to prove a bound on the size of the kernel. Recall that thus far we have obtained the following bounds:

- there are at most k^2 vertices in $D \setminus S$ contributing to a self-loop in $D[S]$ (Observation 10),
- $|A'_0| \leq k^2(k-1)$ (Observation 12),
- $|A'_1| \leq k^2(k-1)$ (see paragraph before Observation 15),
- $|A_2| \leq 12k^4 - 2k^3 - 12k$ (Observation 27),
- $|A_{\geq 3}| \leq k^3 - 2$ (Observation 15),

It follows that the total number of vertices in the reduced graph is at most $k^2 + |A'_0 \cup A'_1 \cup A_2 \cup A_{\geq 3} \cup S|$ which is at most $k^2 + 2k^2(k-1) + k^3 - 2 + 12k^4 - 2k^3 - 12k + k$, thus proving Theorem 1. This completes the description of our kernel for general instances of the problem; we now proceed to the linear kernel on graphs of bounded genus.

4 A Linear Kernel for DFVS[FVS] on Bounded Genus graphs

Throughout this section we will use D to denote a directed graph of genus at most some fixed bound g. We let S be a feedback vertex set of $\overline{D}$ and let c be a constant such that $\overline{D}$ is a $K_{3,c}$-minor-free graph, where c depends only on g as per Corollary 4. We begin with the following lemma, which follows directly from [21, Lemma 4.3].

▶ **Lemma 28.** *Let $G = (X, Y, E)$ be a bipartite graph and c a constant such that G is $K_{3,c}$-minor-free. Then,*

- *there are $\mathcal{O}(|X|)$ subsets $X' \subseteq X$ such that $X' = N(u)$ for some $u \in Y$ and*
- *for any subset $X' \subseteq X$ such that $|X'| \geq 3$, the set $Y' = \{y \in Y : N(y) \supseteq X'\}$ has size at most $c - 1$.*

We mainly use this lemma to bound the number of connected components of $\overline{D} \setminus S$, it gives directly a bound on the number of connected components with at least 3 neighbors in S, for the connected components with at most 2 neighbors in S, we need to introduce some new reduction rules. We will need a few additional notions to provide a concise presentation of the results in this section. A digraph H is called a *road* iff $\overline{H}$ is a path; the first and last vertex on a road are called its *endpoints*, and all other vertices on a road are called *internal* vertices. Moreover, for a directed graph G consider a connected component of $\overline{G}$ with vertex set A such that $G[A]$ is acyclic. Then $G[A]$ (and, equivalently, the set A) is called an *acyclic component* of G. Observe that there is a one-to-one correspondence between connected components of $\overline{D} \setminus S$ and acyclic components of $D \setminus S$.

For each distinct $x, y \in S$, we denote by $\mathcal{C}_{x,y}$ the set of all acyclic components C of $D \setminus S$ with $N(C) = \{x, y\}$. Finally, we use $\mathcal{C}^{\rightarrow}_{x,y}$ to denote the subset of $\mathcal{C}_{x,y}$ of components C with the property that $D[C \cup \{x, y\}]$:

- contains a directed path from x to y, but
- contains neither an x-x directed path nor a y-y directed path intersecting C.

Observe that any road within D that is disjoint from a feedback vertex set of $\overline{D}$ may contain exactly one arc between two adjacent vertices. Furthermore, in any instance where Reduction Rule 5 is not applicable, the input digraph D itself does not contain an acyclic component. That is, every connected component of $\overline{D}$ contains a directed cycle.

▶ **Observation 29.** If Reduction Rule 5 is not applicable and C is an acyclic component of $D \setminus S$, then there is a directed $N(C)$-$N(C)$ path in $D[C \cup N(C)]$ containing at least one vertex of C.

Crucially, Observation 29 implies that for each component C in $\mathcal{C}_{x,y}$, either $D[C \cup \{x\}]$ (or $D[C \cup \{y\}]$ by symmetry) contains a cycle, or $C \in \mathcal{C}^{\rightarrow}_{x,y} \cup \mathcal{C}^{\rightarrow}_{y,x}$.

▶ **Reduction Rule 30.** If C is an acyclic component of $D \setminus S$ where $N_{\overline{D}}(C) = \{x\}$ for some $x \in S$ and $C \cup \{x\}$ contains a cycle, then we remove $D[C \cup \{x\}]$ from D and reduce k by 1.

The soundness of the above rule follows from the fact that any DFVS which does not contain x must necessarily intersect C, and hence there also exists a DFVS of at most the same size which contains x but does not intersect C.

By expanding the above argument, we observe that if there exists a DFVS T containing at least two vertices from $\mathcal{C}_{x,y} \cup \{x, y\}$, then the set $T' = (T \setminus \mathcal{C}_{x,y}) \cup \{x, y\}$ is also clearly a solution of at most the same size as T. Hence every minimum DFVS contains at most two vertices from $\mathcal{C}_{x,y} \cup \{x, y\}$. Consequently, if we have a minimum DFVS T and $C_1, C_2, C_3 \in \mathcal{C}_{x,y}$, then at least one of C_1, C_2 or C_3 has an empty intersection with T. The soundness of the following three Reduction Rules follows.

▶ **Reduction Rule 31.** If $\mathcal{C}_{x,y}$ contains at least 3 acyclic components C_1, C_2, C_3 such that $D[C_1 \cup x]$, $D[C_2 \cup x]$ and $D[C_3 \cup x]$ each contains a cycle, we remove x and decrease k by 1.

▶ **Reduction Rule 32.** If $\mathcal{C}^{\rightarrow}_{x,y} \cap \mathcal{C}^{\rightarrow}_{y,x}$ contains at least 4 components, then we remove all components of $\mathcal{C}^{\rightarrow}_{x,y} \cup \mathcal{C}^{\rightarrow}_{y,x}$ from D and add the arcs (x, y) and (y, x) to D.

▶ **Reduction Rule 33.** If $\mathcal{C}^{\rightarrow}_{x,y}$ contains at least 3 components and $\mathcal{C}^{\rightarrow}_{x,y} \setminus \mathcal{C}^{\rightarrow}_{y,x}$ is not empty, then we remove all components of $\mathcal{C}^{\rightarrow}_{x,y} \setminus \mathcal{C}^{\rightarrow}_{y,x}$ from D and add the arc (x, y) to D.

▶ **Lemma 34.** *After applying Reduction Rules 5 to 6 and Reduction Rules 30 to 33, the resulting digraph is also $K_{3,c}$-minor-free.*

Proof. Since Reduction Rule 5, 30 and 31 only remove vertices, it clearly does not affect the fact that D is $K_{3,c}$-minor-free. Furthermore, the operations in Reduction Rule 6, 32 and 33 result in a graph D' such that $\overline{D'}$ is a minor of $\overline{D}$. Hence, the graph resulting from these reduction rules is also $K_{3,c}$-minor-free. ◀

We now argue the main structural consequence of applying these reduction rules.

▶ **Lemma 35.** *Suppose that Reduction Rule 5 and Reduction Rules 30 to 33 do not apply. Then $D \setminus S$ has $\mathcal{O}(|S|)$ acyclic components.*

▶ **Lemma 36.** *Let C be a connected component of $\overline{D} \setminus S$, and ℓ be the number of neighbors of C in S. If Reduction Rules 5 and 6 are not applicable, then $\overline{D}[C]$ has $\mathcal{O}(\ell)$ leaves.*

Proof. Recall that when the first two reduction rules do not apply, every vertex in D is incident to at least 4 arcs and thus every leaf of C is incident to at least 3 arcs with endpoints in S. However, since there can be bidirectional arcs between C and S, every leaf of C has at least 2 neighbors in S. From Lemma 28 it follows that there are only $\mathcal{O}(\ell)$ vertices in C with at least 3 neighbors in S. Hence it suffices to obtain an $\mathcal{O}(\ell)$ bound on the leaves of C with exactly two neighbors in S.

Recalling Lemma 28, we observe that each of the leaves of C has one of $\mathcal{O}(\ell)$ possible neighborhoods in S. Let us fix two distinct vertices x and y in $N(C)$. We will show that there are at most $c - 1$ leaves of C with both x and y as neighbors. Suppose for a contradiction that there is a set L of at least c leaves of $\overline{D}[C]$ which are adjacent to x and y. Since $\overline{D}[C]$ is a tree and L is a subset of its leaves, the graph $\overline{D}[C \setminus L]$ is also a tree. If we contract $\overline{D}[C \setminus L]$ into a single vertex, say z, then the subgraph induced on the vertices in $L \cup \{x, y, z\}$ would be isomorphic to $K_{3,c}$, contradicting the fact that $\overline{D}$ is $K_{3,c}$-minor-free. We conclude that C can have at most $c - 1$ leaves with neighbors x and y, completing the proof. ◀

▶ **Lemma 37.** *If none of Reduction Rules 5, 6, 30-33 apply, then $\overline{D} \setminus S$ has at most $\mathcal{O}(|S|)$ vertices of degree at least 3.*

Proof. Let $\mathcal{C}$ be the set of all components of $D \setminus S$. Since none of the aforementioned reduction rules apply, we can invoke Lemma 35 and Lemma 36. That is, we conclude that there are only $\mathcal{O}(|S|)$ components in $\mathcal{C}$ and that the number of leaves in a component $C \in \mathcal{C}$ is $\mathcal{O}(|N(C)|)$.

Since the number of leaves in a tree gives an upper bound on the number of vertices of degree at least 3, this implies that the number of vertices of degree at least 3 in $\overline{D}[C]$ is also bounded by $\mathcal{O}(|N(C)|)$. Thus it suffices to show that $\sum_{C \in \mathcal{C}} |N(C)| = \mathcal{O}(|S|)$. However, $\sum_{C \in \mathcal{C}} |N(C)|$ is the same as the number of edges in the graph G which we obtain from $\overline{D}$ by contracting each component of $\mathcal{C}$ to a single vertex and removing all edges between vertices in S. Since G is clearly a minor of $\overline{D}$, it is also $K_{3,c}$-minor-free and hence $|E(G)|$ is at most $\mathcal{O}(|V(G)|) = \mathcal{O}(|S| + |\mathcal{C}|) = \mathcal{O}(|S|)$, which concludes the proof. ◀

The main consequence of the above lemma is that we can now add all the vertices of degree at least 3 to the set S in order to get a set S' which is also a feedback vertex set of $\overline{D}$ of size $\mathcal{O}(|S|) = \mathcal{O}(k)$. At the same time, the graph $\overline{D} \setminus S'$ is significantly more structured: every connected component of this graph is in fact a path and this will play a crucial role in the rest of this section. Since $|S'| \in \mathcal{O}(|S|)$, it suffices to obtain a reduced instance of size linear in $|S'|$, and so for ease of presentation we will hereinafter set $S := S'$.

▶ **Reduction Rule 38.** If none of the Reduction Rules 5-6, 30-33 apply, then we add all vertices of total degree three in $D \setminus S$ to S.

Observe that after applying Reduction Rule 38, $D \setminus S$ is a set of roads. Furthermore, once we ensure that $D \setminus S$ is a set of roads, none of the reduction rules in this section will ever create a new degree 3 vertex in $D \setminus S$. Hence we can exhaustively apply all the reduction rules in this section once again to ensure that the number of roads in $D \setminus S$ is $\mathcal{O}(|S|)$. In the rest of the section, we present reduction rules to handle the roads in $D \setminus S$.

4.1 Dealing with roads

Our first step will be to transform our instance so that all roads in $D \setminus S$ are even more structured with respect to their adjacencies with S.

▶ **Definition 39.** A road P in $D \setminus S$ is *nice* if $|N(P') \cap S| \leq 2$, where P' are the internal vertices of P.

In other words, nice roads are roads whose internal vertices are *all* adjacent to at most two specific vertices from S (other than the endpoints of the road); observe that this is equivalent to requiring that $|N(P')| \leq 4$, where P' is the set of internal vertices of the nice road P.

In order to achieve this transformation, we will iteratively construct an auxiliary vertex set Q to store certain vertices that form separators between nice road segments in $D - S$. In the course of this procedure, we will also construct an injective mapping δ from Q to the connected components of $D \setminus (S \cup Q)$. We initialize by setting $\delta = Q = \emptyset$.

▶ **Reduction Rule 40.** Let A be a connected component which is a road in $D \setminus (S \cup Q)$ that is not nice. Moreover, let A' be a maximal nice subroad of A which contains a leaf in $\overline{D} \setminus (S \cup Q)$ and let a' be the unique neighbor of A' in A. Then add a' to Q and add $a' \mapsto A'$ to δ.

For each vertex $q \in Q$, let $R_q = \{q\} \cup \delta(q)$. Observe that R_q is a road which contains at least 3 neighbors in S. Furthermore, for any $q, q' \in Q$ our construction of δ ensures that R_q and $R_{q'}$ are vertex-disjoint since $\delta(q)$ is a nice road in $D \setminus (S \cup Q)$, for all $q \in Q$.

▶ **Lemma 41.** *After the exhaustive application of Reduction Rule 40, we have* $|Q| = \mathcal{O}(|S|)$.

The next rule is only applied *once* after the exhaustive application of Reduction Rule 40. Note that it does not increase the parameter by more than a linear factor due to Lemma 41.

▶ **Reduction Rule 42.** Set $S := S \cup Q$.

Observe that after the exhaustive application of Reduction Rule 40 and the application of Reduction Rule 42, each road in $D - S$ is nice. Furthermore, the number of roads in $D - S$ is still linear in S, since removing $|Q|$ vertices from a set of roads only increases the number of roads in the set by at most $|Q|$. Our next task is to deal with nice roads, but we first state a useful observation about general roads.

▶ **Observation 43.** Let P be a road in $D \setminus S$ and let P' be the internal vertices of P. For any DFVS T of D, the set $(T \setminus P') \cup N(P')$ is also a DFVS of D. In particular, every minimum DFVS contains at most $|N(P')|$ vertices of $P \cup N(P')$.

▶ **Reduction Rule 44.** Let P be a nice road in $D \setminus S$, P' internal vertices of P, and x a vertex in $N(P') \setminus V(P)$. If $D[P' \cup \{x\}]$ contains at least $|N(P')|$ directed cycles intersecting only in x, then we remove x from D and set $k = k - 1$.

For internal vertices of a road P, we define an equivalence relation $\sim_P$ such as $a \sim_P b$ if and only if $N^+(a) \setminus V(P) = N^+(b) \setminus V(P)$ and $N^-(a) \setminus V(P) = N^-(b) \setminus V(P)$ (i.e., a and b have same out- and in- neighborhoods outside of P). We are now ready to state our final reduction rule, which will later allow us to bound the length of each nice road by a constant.

▶ **Reduction Rule 45.** Let P be a nice road in $D \setminus S$, and let P' be internal vertices of P with $\ell = |N(P')|$. If P' contains a directed subpath $Q = (q_1, \ldots, q_{\ell+2})$, such that $q_i \sim_P q_j$ for all $1 \leq i, j \leq \ell + 1$, then we remove q_ℓ from D and add the arc $(q_{\ell-1}, q_{\ell+1})$.

We are now ready to complete the proof of our linear kernelization by bounding the size of an instance after the exhaustive application of our reduction rules.

▶ **Lemma 46.** *If none of Reduction Rules 5, 6 and 30-45 apply, then* $|D| = \mathcal{O}(|S|)$.

Proof Sketch. Let $\mathcal{P}$ be the set of all acyclic component of $D \setminus S$. Recall that since Reduction Rules 5, 6 and 30-42 do not apply, every acyclic component in $\mathcal{P}$ is a nice road in D and there are at most $|\mathcal{P}| = \mathcal{O}(|S|)$ such nice roads. Therefore, it suffices to show that there is a constant d which bounds the size of any nice road P in $\mathcal{P}$. This is achieved by the following three-step process: (a) we bound the number of vertices with bidirectional arcs to (from) a vertex from S, (b) we bound the number of sinks and sources on P, and (c) we bound the number of remaining vertices in P, i.e., vertices on directed path segments between vertices covered under points (a) and (b).

It is not difficult to show that points (a) and (b) follow from the exhaustive application of Reduction Rule 44. For point (c), we first observe that each vertex on a directed path must have precisely one in- and one out-neighbor in S, which means that there are only 2 'types' of vertices on these directed path segments. Then Reduction Rule 44 allows us to bound the number of alternations of types on a directed path, while Reduction Rule 45 provides a bound on the number of consecutive types on such paths. ◀

5 Conclusions and Future Work

Our results provide a stepping stone towards resolving the existence of a polynomial kernel for DFVS, and to the best of our knowledge also represent the first explicit kernelization results for DFVS with respect to any natural parameter. They also open up several new directions for future research. For instance, can we find reasonable parameters that lie "between" DFVS number and FVS number, and would it be possible to generalize our polynomial kernel to these? What about parameters which are incomparable to the FVS number but also upper-bound the DFVS number? Can our linear kernel be lifted to graph classes of bounded expansion or nowhere dense graphs? Can Theorem 1 be improved to a cubic or quadratic kernel, for instance by using techniques similar to the improvement obtained for the undirected setting by Thomasse [36]? Another related problem of interest is whether DFVS can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$, which remains open even on planar graphs.

Abstract

Network games are widely used as a model for selfish resource-allocation problems. In the classical model, each player selects a path connecting her source and target vertex. The cost of traversing an edge depends on the number of players that traverse it. Thus, it abstracts the fact that different users may use a resource at different times and for different durations, which plays an important role in defining the costs of the users in reality. For example, when transmitting packets in a communication network, routing traffic in a road network, or processing a task in a production system, the traversal of the network involves an inherent delay, and so sharing and congestion of resources crucially depends on time.

We study *timed network games*, which add a time component to network games. Each vertex v in the network is associated with a cost function, mapping the load on v to the price that a player pays for staying in v for one time unit with this load. In addition, each edge has a guard, describing time intervals in which the edge can be traversed, forcing the players to spend time on vertices. Unlike earlier work that add a time component to network games, the time in our model is continuous and cannot be discretized. In particular, players have uncountably many strategies, and a game may have uncountably many pure Nash equilibria. We study properties of timed network games with cost-sharing or congestion cost functions: their stability, equilibrium inefficiency, and complexity. In particular, we show that the answer to the question whether we can restrict attention to boundary strategies, namely ones in which edges are traversed only at the boundaries of guards, is mixed.

1 Introduction

Network games (NGs, for short) [9, 37, 38] constitute a well studied model of non-cooperative games. The game is played among selfish players on a network, which is a directed graph. Each player has a source and a target vertex, and a strategy is a choice of a path that connects these two vertices. The cost of a player is the sum of costs of the edges her path traverses, where a cost of an edge depends on the *load* on it, namely the number of players using the edge. We distinguish between two types of costs. In *cost-sharing* games (a.k.a. network

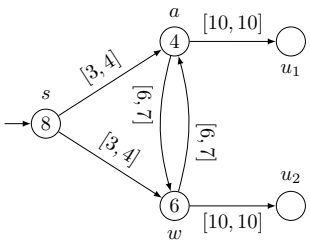
* The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013, ERC grant no 278410) and the Austrian Science Fund (FWF) under grants S11402-N23 (RiSE/SHiNE) and Z211-N23 (Wittgenstein Award).

formation games), each edge has a cost and the players that use it split the cost among them, thus the load has a positive effect on cost. For example, when the costs correspond to prices, users that share a resource also share its price. Then, in *congestion* games, the load has a negative effect on cost: each edge has a non-decreasing *latency function* that maps the load on the edge to its cost given this load. For example, when the network models a road system and costs correspond to the traversal time, an increased load on an edge corresponds to a traffic jam, increasing the cost of the players that use it.

One limitation of NGs is that the cost of using a resource abstracts the fact that different users may use the resource at different times and for different durations. This is a real limitation, as time plays an important role in many real-life settings. For example, in a road or communication systems, congestion only affects cars or messages that use a road or a channel simultaneously. We are interested in settings in which congestion affects the QoS or the way a price is shared (rather than the travel time). For example, discomfort increases in a crowded train or price is shared by the passengers in a taxi without affecting the travel time. Similarly, in mobile networks, the call quality depends on the number of subscribers using the network simultaneously. As a third example, when processing a task in a production system, jobs move from one station to another. The way the cost of running the stations is shared by the jobs that use it depends on the time spent in the stations and on the synchronization among the jobs.

We introduce and study *timed network games* (TNGs, for short) – a new model that adds a time component on NGs. Similar to NGs, the game is played on a network and the players need to find a path from their source to target vertices. Rather than paying for the traversal of edges, in TNGs the players pay for spending time in vertices. Each edge in the network has a *guard*, which is a disjunction of time intervals that specifies when an edge can be traversed. Traversing an edge is done instantaneously. So, a strategy for a player is a *timed path*: a sequence of pairs $\langle v, t\rangle$ of a vertex v and the time t spent on v. When the path traverses an edge in the network, the guard of the edge must be satisfied. For an integer $k \in \mathbb{N}$, let $[k] = \{1, \ldots, k\}$. Each vertex v has a cost function $r_v : [k] \to \mathbb{R}_{\geq 0}$ that assigns the cost of using v for one time unit, given the load in v. A *profile* in a TNG is then a vector of timed paths, namely the strategies of all players. Given a profile P, the cost of each player is induced by the cost functions of the vertices visited in her timed path, the time spent at each vertex, and the load on the vertices during these visits.

▶ **Example 1.** Consider an automobile service center with three stations: (s) tuning engine, (a) tire and air check, and (w) dry and wet wash. The costs for operating the stations per one time unit are 8, 4 and 6 respectively, and they are independent of the number of cars served. Accordingly, cost is shared by the users. There are two billing counters, u_1 and u_2, for dropped-in and registered cars. The setting is modeled by the TNG below. As described in the TNG, after spending some time in s, the cars can alternate between stations w and a. Assume that there are two players, and consider the profile P in which the first player chooses the timed path $(s, 3), (a, 7), u_1$ and the second player chooses the timed path $(s, 3), (a, 4), (w, 3), u_2$. Player 1's cost in P is $8/2 \cdot 3 + 4/2 \cdot 4 + 4 \cdot 3 = 32$ and Player 2's cost is $8/2 \cdot 3 + 4/2 \cdot 4 + 6 \cdot 3 = 38$. Another possible profile in this game is P', in which the strategies of the two players are $(s, 3), (w, 4), (a, 3), u_1$ and $(s, 3), (w, 7), u_2$. Now, the costs are 36 and 42, respectively.



There has been reference to *time* already in early work on *flow networks* [26]. Research spans from pioneering and theoretical work on flow networks in which congestion leads to queues (c.f., [41, 42]) to nowadays practical research on traffic engineering in software defined networks [2]. These works, however, do not address the problem from a game-theoretic perspective. To the best of our knowledge, the first works to consider network games with a time component are [36] and [28]. In [36], the focus is still on flow networks, and it enriches [41, 42] by viewing infinitesimal flow particles as selfish agents (see also [14]). Closer to our work, network games with time components where studied in [28, 31, 35]. These models differ from our model in two main aspects. First, the cost a player pays in these models is the time it takes to reach its destination, and our cost represents the QoS. Second, time is discrete in these models so the set of strategies the players choose is finite, whereas the source of the difficulty of our model is the real-time and the fact that the players have uncountably many strategies. The closest to our model is a model studied in [28], which studies a QoS pricing but using discrete time.

Our model of TNGs is the first to add real-time considerations to the strategies of the players. Indeed, a strategy for a player is not just the path of edges she is going to traverse, but also the time spent in vertices, which can be any number in $\mathbb{R}_{\geq 0}$. Thus, even if we restrict attention to simple paths, each player has uncountably many strategies. This continuous time and the richness of strategies that it brings with it is also a key difference between TNGs and NGs. Our model is inspired by *timed automata* [5]. There too, time is continuous, transitions between states are guarded by time constraints, and so is the time spent in a state. There are typically uncountably many runs of a timed automaton, corresponding to the uncountably many strategies a player typically has in our TNGs. The fact timed automata handle continuous time makes them the prominent formalism for specifying real-time on-going behaviors, and they are way more useful than formalisms in which time has been discretized (c.f., temporal logic with discrete clocks [23], or the fictitious-clock approach of [27]). We note that our TNGs correspond to a restricted class of timed automata, as our guards refer to the global time and cannot express, for example, a bound on the time spent in a vertex. In Section 7 we discuss the extension of our model to a richer one.

Note that, as in the *time-dependent cost* model of [28], load does not affect travel time and only affects the cost. Unlike [28], in TNGs time is continuous, which enables TNGs to model richer settings in practice. Note also that the cost function may model various applications. Consider, for example, a communication network with servers that encode or decode messages. A typical cost function for a server is the inverse of the quality of the signal, which is related to the number of bits needed to encode a message. Assuming that a server can handle a certain amount of data per unit time, this cost is the reciprocal of the number of bits used to encode a message. If the server allows a 16-bit encoding of a message when it serves less than 128 users simultaneously, and allows an 8-bit encoding when it serves between 128 and 256 users simultaneously, then the cost function maps x to $\frac{1}{16}$, for $x \leq 128$, and to $\frac{1}{8}$, for $129 \leq x \leq 256$, reflecting a better quality of the received message when load goes below 128 [33].

The first question that arises in the context of games is the existence of *stable outcomes* of the game. In the context of NGs, the most prominent stability concept is that of a (pure) *Nash equilibrium* (NE, for short) – a profile such that no player can decrease her cost by unilaterally deviating from her current strategy[1]. Decentralized decision-making may lead to solutions that are sub-optimal from the point of view of society as a whole. The standard measures to quantify the inefficiency incurred due to selfish behavior is the *price of stability* (PoS) [9] and the *price of anarchy* (PoA) [30]. In both measures we compare against a *social optimum* (SO, for short), namely a profile that minimizes the sum of costs of all players. The PoS (PoA, respectively) is the best-case (worst-case) inefficiency of an NE; that is, the ratio between the cost of a best (worst) NE and an SO. In Example 1, profile P is an SO, and is also a (best) NE, while profile P' is a worst NE. Note that there can be uncountably many NEs in the TNG in Example 1. Indeed, for all $t \in [3,4]$, the profile P_t with the strategies $(s,3),(a,t),(w,4-t)(a,3)u_1$ and $(s,3),(a,t),(w,7-t)u_2$, is an NE with costs $8/2\cdot 3+4/2\cdot t+6/2\cdot(4-t)+4\cdot 3 = 36-t$ and $8/2\cdot 3+4/2\cdot t+6/2\cdot(4-t)+6\cdot 3 = 42-t$.

The picture of stability and equilibrium inefficiency for standard NGs is well understood. Every NG has an NE, and in fact these games are *potential games* [37], thus every sequence of *best response* moves, namely moves that the players perform in order to reduce their costs, converges to an NE. For k-player cost-sharing NGs, the PoS and PoA are $\log k$ and k, respectively [9]. For congestion games with affine cost functions, PoS ≈ 1.577 [21, 3] and PoA $= \frac{5}{2}$ [22].

The fact a TNG has uncountably many profiles makes the adoption of results known for NGs questionable. Let us elaborate on this point. Consider a TNG $\mathcal{T}$, and a finite set $T \subseteq \mathbb{R}_{\geq 0}$ of time points. Note that there are only finitely many T-profiles in $\mathcal{T}$ (that is, profiles with T-strategies, in which all edges are taken at some time point in T). We show that once we restrict attention to T-profiles, we can construct an NG that is isomorphic to $\mathcal{T}$, in the sense that there is a cost-preserving bijection between profiles in the NG and T-profiles in the TNG $\mathcal{T}$. While this enables us to reduce questions about T-profiles in the TNG to questions on NGs, it is not clear to which finite set T we can restrict attention. In the setting of timed automata, much work has been done on obtaining decidability by partitioning $\mathbb{R}_{\geq 0}$ into finitely many *regions*. Essentially, all time points within a region are bisimilar, in the sense that the actions the automaton may take inside all time points in a region, coincide [5]. Our challenge here is similar: searching for a finite set of time points that partitions $\mathbb{R}_{\geq 0}$ to finitely many intervals.

Recall that the source for delays in TNGs are time guards on the edges, where each guard is a disjunction of intervals $[a,b]$, for $a \leq b \in \mathbb{Q}_{\geq 0}$. We refer to the two end points of all guards as *boundaries*. One can suspect that we can restrict attention to *boundary strategies*, namely timed paths that traverse edges only at boundary time points, and *boundary profiles* in which all the players choose boundary strategies. We show that the situation is mixed. The good news follows from choosing T above to be the boundaries, thus we show that a boundary NE and SO exist and an NE can be found by performing best-response moves that use only boundary strategies. Unfortunately, however, one cannot restrict attention to boundary profiles, as the best and worst NEs need not be boundary. We show a best and worst NE is attained in TNGs, which is not a-priori guaranteed.

In terms of inefficiency, the reduction from TNGs to isomorphic NGs enables us to extend upper bounds on the PoS and PoA from NGs to TNGs. The adoption of lower bounds

[1] Throughout this paper, we consider *pure* strategies, as is the case for the vast literature on cost-sharing games.

requires a reduction in the other direction – from NGs to TNGs, which we can show only for acyclic NGs. Consequently, we can apply only lower bounds known for acyclic NGs, which forces us to either prove direct bounds or to tighten lower bounds known for NGs to acyclic NGs. All in all, we are able to show that the PoS and PoA coincide for NGs and TNGs, except for the lower bound on the PoS of congestion TNGs, which we leave open. Finally, in terms of computational complexity, we prove that the problem of finding an NE is PLS-complete [29] for TNGs, which coincides with the complexity bounds for NGs [24, 40]. Proving membership in PLS follows easily from the reduction from TNGs to NGs. Proving hardness is more complex. For congestion TNGs, we are able to rely on known hardness results for congestion NGs, as they apply already for acyclic congestion NGs [1]. For cost-sharing TNGs we need a similar reduction from acyclic cost-sharing NGs, whose precise complexity is an open problem. Accordingly, we first settle the latter problem and prove that finding an NE in acyclic cost-sharing NG is PLS-hard, which allows us to prove the hardness result for cost-sharing TNGs.

Due to lack of space, some proofs appear in the full version, which can be found in the authors' homepages.

2 Preliminaries

We describe a *(closed) time interval* by $[m_1, m_2]$, for $m_1, m_2 \in \mathbb{R}_{\geq 0}$. We refer to m_1 and m_2 as the *start* and the *end interval boundaries*, respectively. A *guard* is the constant *true* or a disjunction of time intervals. A point in time $t \in \mathbb{R}_{\geq 0}$ *satisfies* a guard g if g is *true* or g includes a disjunct $[m_1, m_2]$ such that $m_1 \leq t \leq m_2$.

A *timed network* (TN) is a tuple $\langle V, E, \{g_e\}_{e \in E}\rangle$, where V is a set of vertices, $E \subseteq V \times V$ is a set of directed edges, and for each edge $e \in E$, the guard g_e specifies the time intervals during which e may be traversed. A *timed network game* (TNG) is $\mathcal{T} = \langle k, V, E, \{g_e\}_{e \in E}, \{r_v\}_{v \in V}, \langle s_i, u_i\rangle_{i \in [k]}\rangle$, where k is the number of players; $\langle V, E, \{g_e\}_{e \in E}\rangle$ is a timed network; for $v \in V$, the cost function $r_v : [k] \to \mathbb{R}_{\geq 0}$ maps the load on vertex v, namely the number of players that simultaneously visit vertex v, to the cost each of them pays for staying in v for one time unit with this load; and for $i \in [k]$, the pair $\langle s_i, u_i\rangle \in V \times V$ describes the objective of Player i: choosing a timed path from s_i to u_i. A timed network game is *symmetric* if all the players have the same objective, i.e. the same source and target pair. We use $B(\mathcal{T})$ to denote the set of interval boundaries appearing in the guards of $\mathcal{T}$.

In order to satisfy her objective, Player i has to choose a path in $\mathcal{T}$ from s_i to u_i as well as the duration spent in each vertex in the path. Indeed, while edges are traversed instantaneously, the guards on the edges force the players to spend time on vertices. Each player then aims to minimize the cost of these stays. In order to formally define the strategies of the players and their costs, we first need some definitions.

A *timed path* in the TNG $\mathcal{T}$ is a sequence $\pi = \langle v_0, t_0\rangle, \ldots, \langle v_{n-1}, t_{n-1}\rangle, v_n \in (V \times \mathbb{R}_{\geq 0})^* \cdot V$, such that for all $0 \leq i < n$, we have that $\langle v_j, v_{j+1}\rangle \in E$; that is, $v_0, \ldots, v_n$ is a path in the graph $\langle V, E\rangle$. Intuitively, for all $0 \leq i < n$, we have that t_j describes the time spent in the vertex v_j before the path continues to v_{j+1}. Let $\tau_0 = t_0$ and $\tau_j = \tau_{j-1} + t_j$, for $0 < j < n$. Note that $\tau_j = \sum_{l=0}^{j} t_l$. Thus, τ_j is the time that has elapsed since the traversal of π starts and until π leaves the vertex v_j. We sometimes refer to π also as the sequence $\langle \tau_0, e_1\rangle, \ldots, \langle \tau_{n-1}, e_n\rangle \in (\mathbb{R}_{\geq 0} \times E)^*$, where for all $1 \leq j \leq n$, we have that $e_j = \langle v_{j-1}, v_j\rangle$ is the j-th edge in π and is taken at time τ_{j-1}. We say that the timed path π is *legal* if for all $0 \leq j < n$, we have that τ_j satisfies the guard $g_{e_{j+1}}$.

A *strategy* for a player with an objective $\langle s, u\rangle$ is a legal timed path $\pi = \langle v_0, t_0\rangle, \ldots, \langle v_{n-1}, t_{n-1}\rangle, v_n$ such that $v_0 = s$ and $v_n = u$. Consider a finite set $T \subseteq \mathbb{R}_{\geq 0}$

of time points. We say that the strategy π is a *T-strategy* if all edges in π are taken at times in T. Formally, for all $0 \leq j < n$, we have that $\tau_j \in T$. A *profile* is a tuple $P = \langle \pi_1, \ldots, \pi_k \rangle$ of strategies for the players. That is, for $1 \leq i \leq k$, we have that π_i is a strategy for Player i. A profile is a T-profile if all its strategies are T-strategies. Of special interest are *boundary* strategies and profiles, namely T-strategies and T-profiles for $T = B(\mathcal{T})$. Note that each profile P has a finite minimal set $T \subseteq \mathbb{R}_{\geq 0}$ such that P is a T-profile. We denote this set by T_P.

Given $T \subseteq \mathbb{R}_{\geq 0}$, let $t_{\max} = \max(T)$. Also, for $t \in T$ such that $t \neq t_{\max}$, let $next_T(t)$ be the time point $t' \in T$ such that $t < t'$ and there is no $t'' \in T$ such that $t < t'' < t'$. That is, $next_T(t)$ is the time point successor to t in T. We can partition the interval $[0, t_{\max}]$ to a set Υ of sub-intervals $[m_1, m_2]$ such that m_1 and m_2 are in $T \cup \{0\}$, and $m_2 = next_T(m_1)$. We refer to the sub-intervals in Υ as *periods*. When T is T_P for some profile P, then the set Υ is the coarsest partition of $[0, t_{\max}]$ into periods such that no player crosses an edge within each period. We denote this partition by Υ_P.

Consider a T-profile P. For a player $i \in [k]$ and a period $\gamma \in \Upsilon_P$, let $visits_P(i, \gamma)$ be the vertex that Player i visits during period γ. That is, if $\pi_i = \langle v_0^i, t_0^i \rangle, \ldots, \langle v_{n_i-1}^i, t_{n_i-1}^i \rangle, v_{n_i}^i$ is the legal timed path that is the strategy for Player i and $\gamma = [m_1, m_2]$, then $visits_P(i, \gamma)$ is the vertex v_j^i for the index $1 \leq j < n_i$ such that $\tau_{j-1}^i \leq m_1 \leq m_2 \leq \tau_j^i$. Note that since P is a T-profile, then for each period $\gamma = [m_1, m_2] \in \Upsilon_P$, the number of players that stay in each vertex v during γ is fixed. Let $load_P(v, \gamma)$ denote this number. Formally $load_P(v, \gamma) = |\{i : visits_P(i, \gamma) = v\}|$. Finally, for a period $\gamma = [m_1, m_2]$, let $|\gamma| = m_2 - m_1$ be the duration of γ.

Recall that the cost function $r_v : [k] \longrightarrow \mathbb{R}_{\geq 0}$ maps the load of v to the cost of v per time unit. Accordingly, if $visits_P(i, \gamma) = v$, then the cost of Player i in P over the period γ is $cost_{\gamma,i}(P) = r_v(load_P(v, \gamma)) \cdot |\gamma|$. We distinguish between two types of cost functions. We say that in *uniform cost-sharing games* (CS-TNGs, for short), the players that visit a vertex share its cost equally. Formally, each vertex v is associated with a rate $b_v \in \mathbb{R}_{\geq 0}$, and for all $l \geq 1$, we have $r_v(l) = \frac{b_v}{l}$. Note that increasing the load in uniform cost-sharing games decreases the cost of the players. On the other hand, in *congestion games* (CON-TNGs, for short), the cost functions are non-decreasing, thus increasing the load also increases the cost for each player. The total cost of Player i in profile P is then $cost_i(P) = \sum_{\gamma \in \Upsilon_P} cost_{\gamma,i}(P)$. The cost of the profile P, denoted $cost(P)$, is the total cost incurred by all the players, i.e., $cost(P) = \sum_{i=1}^{k} cost_i(P)$.

Consider a TNG $\mathcal{T}$. For a profile P and a strategy π of player $i \in [k]$, let $P[i \leftarrow \pi]$ denote the profile obtained from P by replacing the strategy for Player i by π. A profile P is said to be a *(pure) Nash equilibrium* (NE) if none of the players in $[k]$ can benefit from a unilateral deviation from her strategy in P to another strategy. In other words, for every player i and every strategy π that Player i can deviate to from her current strategy in P, it holds that $cost_i(P[i \leftarrow \pi]) \geq cost_i(P)$. The set of NEs of the game $\mathcal{T}$ is denoted by $NE(\mathcal{T})$.

A *social optimum* (SO) of a game $\mathcal{T}$ is a profile that attains the infimum cost over all profiles. We denote by $SO(\mathcal{T})$ the cost of an SO profile; i.e., $SO(\mathcal{T}) = \inf_P cost(P)$. Note that since a TNG may have infinitely many profiles, we should indeed take the infimum (rather than minimum) over all profiles, and thus, an SO profile may not exist. As we shall show, however, all TNGs have boundary SO profiles. An SO profile may be achieved by a centralized authority and need not be an NE. The following parameters measure the inefficiency caused as a result of the selfish interests of the players. First, the *price of stability* (PoS) [8] of a timed network game $\mathcal{T}$ is the ratio between the infimum cost of an NE and the cost of a social optimum of $\mathcal{T}$. That is, $\text{PoS}(\mathcal{T}) = inf_{P \in NE(\mathcal{T})} cost(P)/SO(\mathcal{T})$. Then, the

price of anarchy (PoA) [34] of $\mathcal{T}$ is the ratio between the supremum cost of an NE and the cost of a social optimum of $\mathcal{T}$. That is, $\text{PoA}(\mathcal{T}) = sup_{P \in NE(\mathcal{T})} cost(P)/SO(\mathcal{T})$. Note that here too, we have to use infimum and supremum rather than minimum and maximum, yet we are going to show that best and worst NEs are always attained. For a family $\mathcal{F}$ of games, we say that the PoA of $\mathcal{F}$ is *at most* x if for all games F in $\mathcal{F}$, we have $PoA(F) \leq x$ and is *at least* x, if there exists a game F in $\mathcal{F}$ such that $PoA(F) = x$, and similarly for PoS.

3 Reduction to and from Network Games

A *network game* (NG) is $\mathcal{N} = \langle k, V, E, \{l_e\}_{e \in E}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$, and has a similar structure to a TNG. A strategy of a player $i \in [k]$ is a path from s_i to u_i. The cost function $l_e : [k] \to \mathbb{R}_{\geq 0}$ maps the load on edge e to the cost each player pays for using e. As is the case with TNGs, one can consider both cost-sharing (CS-NGs) and congestion (CON-NGs) network games. Consider a profile $P = \langle \sigma_1, \sigma_2, \ldots, \sigma_k \rangle$ in the game. Since all the costs are positive, we can restrict attention to strategies in which the paths chosen by the players are simple. Then, we can also ignore the order between the edges in the paths and assume that for all $i \in [k]$, we have that $\sigma_i \subseteq E$ is a set of edges that composes a path from s_i to u_i.[2] For an edge $e \in E$, we denote by $load_P(e)$, the number of players that use the edge e in P. Each player that uses e then pays $l_e(load_P(e))$, and the cost of Player i in P is $\sum_{e \in \sigma_i} l_e(load_P(e))$.

Given an NG $\mathcal{N}$, a TNG $\mathcal{T}$ and a finite set $T \subset \mathbb{R}_{\geq 0}$, we say that $\mathcal{N}$ and $\mathcal{T}$ are *isomorphic with respect to* T if $\mathcal{N}$ and $\mathcal{T}$ have the same number of players and there exists a 1-to-1 cost-preserving correspondence between the profiles in $\mathcal{N}$ and the T-profiles in $\mathcal{T}$. Formally, there exists a bijection f from the set of T-profiles in $\mathcal{T}$ and the profiles in $\mathcal{N}$ such that for every T-profile P in $\mathcal{T}$ and $i \in [k]$, the costs of Player i in P and $f(P)$ coincide.

NGs have been extensively studied. In this section, we show that once we fix a set $T \subseteq \mathbb{R}_{\geq 0}$ of time points, we can reduce a TNG $\mathcal{T}$ with edges taken only at time points in T to an NG. Formally, we have the following.

▶ **Theorem 2.** *Given a TNG $\mathcal{T}$ and a finite set $T \subseteq \mathbb{R}_{\geq 0}$, we can construct an NG $\mathcal{N}$ such that $\mathcal{N}$ and $\mathcal{T}$ are isomorphic with respect to T. The size of $\mathcal{N}$ is polynomial in the size of $\mathcal{T}$ and T, and it is constructed in polynomial time.*

Proof. In TNGs, cost is associated with vertices and the time is spent in them, whereas in NGs, cost is associated with the edges and there is no reference to time. Thus, the construction translates the cost of staying in vertices during time intervals induced by T to the cost of traversing edges.

Consider a TNG $\mathcal{T} = \langle k, V, E, \{r_v\}_{v \in V}, \{g_e\}_{e \in E}, (s_i, u_i)_{i \in [k]} \rangle$ and the given set T. We assume that $0 \in T$. We construct an NG $\mathcal{N} = \langle k, V', E', \{l_e\}_{e \in E'}, (\langle s_i, 0 \rangle, u_i)_{i \in [k]} \rangle$, where $V' \subseteq (V \times T) \cup \{u_i\}_{i \in [k]}$ and $E' \subseteq V' \times V'$ is defined as follows (See an example in the full version. For every vertex $v \in V$, we have the following edges in E'. Let $\tau_{\max} = \max(T)$.

1. For every $\tau \neq \tau_{\max} \in T$, let $\tau' = next_T(\tau)$. Then, the edge $e = ((v, \tau), (v, \tau'))$ is in E', corresponding to players staying in vertex v during the interval $[\tau, \tau']$. Accordingly, the cost of e is such that for every $m \in [k]$, we have $l_e(m) = r_v(m)(\tau' - \tau)$.
2. For every $v' \neq v$ with $(v, v') \in E$ and $\tau \in T$ such that τ satisfies $g_{\langle v, v' \rangle}$, we have an edge $e = ((v, \tau), (v', \tau))$ in E'. This edge corresponds to the edge (v, v') in E. Recall that the

[2] Note that the assumptions on each edge being visited at most once in strategies in NGs does not apply to TNGs. Indeed, there, a player may benefit from visiting a vertex multiple times (see Example 1).

cost of crossing an edge in a TNG is 0. Accordingly, the cost of e is such that for every $m \in [k]$, we have $l_e(m) = 0$.

3. If $v = u_i$ for some $i \in [k]$, then for all $\tau \in T$, we have an edge $e = ((v, \tau), v)$ in E', with $l_{e'}(m) = 0$ for every $m \geq 1$. In $\mathcal{N}$, the target vertex for Player i is u_i.

It is easy to see that the size of $\mathcal{N}$ is polynomial in $\mathcal{T}$ and T. In the full version, we prove that $\mathcal{N}$ and $\mathcal{T}$ are indeed isomorphic with respect to T. That is, we show a bijection f from the set of T-profiles in $\mathcal{T}$ and the profiles in $\mathcal{N}$ such that for every T-profile P in $\mathcal{T}$ and $i \in [k]$, the costs of Player i in P and $f(P)$ coincide. ◀

A reduction in the other direction, namely of NGs to TNGs, is not obvious, as the dynamic of TNGs requires a synchronization among all the traversals in each of the edges. We illustrate this in the full version of the paper. When, however, the NG is acyclic, we can use a topological ordering on the edges and synchronize the traversals. Intuitively, each edge in the NG induces a vertex in the TNG, and the guards are defined so that the vertex associated with the j-th edge in the topological order is visited during the period $[j-1, j]$. This can be easily forced by guarding the edges entering the vertex by $[j-1, j-1]$ and guarding these that leave it by $[j, j]$. See the full version for the proof.

▶ **Theorem 3.** *Given an acyclic NG $\mathcal{N}$, we can construct in polynomial time a TNG $\mathcal{T}$ that is isomorphic to $\mathcal{N}$ with respect to $B(\mathcal{T}) \cup \{0\}$. The size of $\mathcal{T}$ is polynomial in the size of $\mathcal{N}$.*

4 On Boundary Strategies and Profiles

Since a strategy for a player in a TNG is a timed path with time points in $\mathbb{R}_{\geq 0}$, then each player has uncountably many possible strategies, and hence it is possible to have uncountably many profiles. In NGs, a strategy is a non-timed path from the source to the target. Even there, in the non-timed setting, there may be infinitely many paths from the source to the target. It is easy to see, however, that every strategy that is a non-simple path is dominated by the strategy obtained by removing cycles, and thus one can restrict attention to the finitely many profiles that consist of strategies that are simple paths. Our goal in this section is to examine whether some similar restriction can be made in TNGs. Indeed, being able to restrict attention to finitely many profiles would simplify our understanding of TNGs and their analysis. A natural candidate is a restriction to boundary strategies, namely these in which all edges are taken at interval boundaries. We show that while a boundary NE exists in all TNGs, and that all TNGs have a boundary SO, there may be uncountably many NEs that are not boundary. Moreover, there are TNGs in which the best and worst NEs are not boundary.

We first need the following lemma.

▶ **Lemma 4.** *Consider a TNG $\mathcal{T}$ and a finite set $T \subset \mathbb{R}_{\geq 0}$ such that $B(\mathcal{T}) \subseteq T$. Let $\pi_1, \ldots, \pi_{k-1}$ be T-strategies of players $1, \ldots, k-1$ respectively. There exists a T-strategy π_k of Player k such that for every strategy π'_k of Player k that is not a T-strategy, we have $cost_k(\langle \pi_1, \ldots, \pi_{k-1}, \pi_k \rangle) \leq cost_k(\langle \pi_1, \ldots, \pi_{k-1}, \pi'_k \rangle)$.*

Intuitively, Lemma 4 states that if all players but one use boundary strategies, then a best strategy for the k-th player can also be a boundary one. It implies that when we want to prove that a certain boundary profile is an NE, we can restrict attention to deviations that use boundary strategies.

▶ **Theorem 5.** *All TNGs have a boundary NE. Moreover, from every profile P, there is a sequence of best-response moves that converges to an NE. When P is boundary, so is the obtained NE.*

Proof. Given a TNG $\mathcal{T}$, let $\mathcal{N}$ be an NG that is isomorphic to $\mathcal{T}$ with respect to $B(\mathcal{T})$. Let f be the bijection from the set of profiles in $\mathcal{N}$ to the set of $B(\mathcal{T})$-profiles in $\mathcal{T}$ such that for every profile P in $\mathcal{N}$ and $i \in [k]$, the costs of Player i in P and $f(P)$ coincide. By Theorem 2, such an NG and bijection f exist. By [8, 24, 37], all NGs have an NE. Consider an NE $P_{\mathcal{N}}$ in $\mathcal{N}$. In the full version we prove that $f(P_{\mathcal{N}})$ is an NE in $\mathcal{T}$.

For the second claim, the above considerations also imply that starting from a profile P, we can restrict attention to best-response moves in which edges are taken in time points in $T_P \cup B(\mathcal{T})$, and reach the desired NE. In particular, when P is boundary, so is the obtained NE. ◀

Recall that an SO profile attains the infimum cost over all profiles. We now show that an SO profile always exists, and in fact there always exists a boundary SO. We show that a boundary SO profile always exists. The idea is that if, in a profile P, an edge e is taken at a non-boundary time τ, then it is possible to obtain a profile P' in which e is taken at a boundary time and $cost(P') \leq cost(P)$. We formalize this intuition in the full version.

▶ **Theorem 6.** *All TNGs have a boundary SO.*

We proceed to show that there are non-trivial TNGs that have uncountably many NEs, which implies they also have uncountably many non-boundary NEs.

▶ **Theorem 7.** *There exist CS-TNGs and CON-TNGs that have uncountably many NEs.*

Proof. The CS-TNG from Example 1 has uncountably many NEs. In the full version, we present and analyze in detail a different CS-TNG with uncountably many NEs.

We continue to CON-TNGs. Consider the TNG appearing in Figure 1. The objectives of Players 1 and 2 is $\langle a, d\rangle$ and the objectives of Players 3 and 4 is $\langle b, d\rangle$. The cost functions are written in the vertices. For $y \in [0, 0.5]$, let P_y be the profile in which Players 1 and 2 traverse the edge (a, b), and Players 3 and 4 traverse the edge (b, c), all at time y. In the full version, we prove that for every $y \in [0, 0.5]$, the profile P_y is an NE. Since y can have any value in $[0, 0.5]$, we are done. ◀

Theorem 7 suggests that the values of a best and worst NEs should be defined by means of infimum and supremum, and may not be attained. In the full version we prove that best and worst NEs do exist. Essentially, it follows from the fact that our guards are closed intervals, implying that the time points in an NE should satisfy a system of inequalities with no strict inequalities. As bad news, we now show that while a boundary NE alway exists, the best and worst NEs need not be boundary.

▶ **Theorem 8.** *There exists a CS-TNG in which the best NE is not a boundary profile.*

Proof. Consider the two-player TNG $\mathcal{N}$ that is played on the network depicted in Figure 2. The objective of Player i is $\langle s, u_i\rangle$. Player 1 has two boundary strategies: A, in which she traverses the edge $\langle s, a\rangle$ at time 0, and B, in which she takes it at time 2. Note that the suffixes of the strategies are fixed, as Player 1 must traverse the edge $\langle a, u_1\rangle$ at time 3. Player 2 has three boundary strategies: Strategies A and B, in which she traverses edge $\langle s, a\rangle$ at time 0 and 2, respectively, and Strategy C, in which she traverses the edge $\langle s, b\rangle$ at time 2. Again, the suffixes of the strategies A and B are fixed. In the full version,

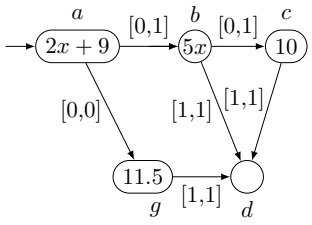


Figure 1 A CON-TNG in which the worst NE is not boundary.

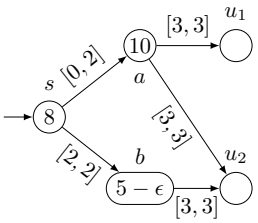

Figure 2 A CS-TNG in which the best NE is not boundary.

we prove that $\langle A, A\rangle$ and $\langle B, C\rangle$ are the only boundary NEs with $cost(\langle A, A\rangle) = 30$ and $cost(\langle B, C\rangle) = 31 - \epsilon$.

For $x \in (0, 2)$, let P_x be the profile in which both players traverse the edge $\langle s, a\rangle$ at time $2 - x$. In the full version, we show that we can define ϵ and x so that P_x is an NE with $cost(P_x) < \min\{cost(\langle A, A\rangle), cost(\langle B, C\rangle)\}$. For example, by taking $x = 0.25$ and $\epsilon = 0.5$ we get an NE with $cost(P_x) = 26.5$ ◀

▶ **Theorem 9.** *There exists a CS-TNG in which the worst NE is not a boundary profile.*

Proof. Consider the two-player TNG $\mathcal{N}$ that is played on the network depicted in Figure 3. The objective of Player i is $\langle s, u_i\rangle$. Player 1 has three boundary strategies: A, in which she traverses the edge (v_1, v_2) at time 0; B, in which she takes it at time 2; and D, in which she traverses the edge (v_1, v_5) at time 2.

Player 2 has four boundary strategies: A, in which she traverses edge (v_1, v_2) at time 0; B, where she takes (v_1, v_2) at time 2; C, where she traverses the edge (v_1, v_4) at time 2; and E, where she traverses the edge (s, v_3). Note that strategy E has a fixed cost of 13.2.

In the full version, we prove that the only boundary profile that is an NE is the profile $\langle D, C\rangle$, whose cost is 26.3, and that the non-boundary profile $P_{0.2}$ in which Players 1 and 2 traverse the edge (v_1, v_2) together at time 1.8 is an NE with cost 26.4, which is higher than $cost(\langle D, C\rangle)$. ◀

▶ **Theorem 10.** *There exists a CON-TNG in which the worst NE is not a boundary profile.*

Proof. Recall the CON-TNG presented in Figure 1. In the proof of Theorem 7, we proved that for all $0 \leq y \leq 0.5$, the profile P_y, in which Players 1 and 2 traverse the edge (a, b) and Players 3 and 4 traverse the edge (b, c), all at time y, is an NE. We have $cost_1(P_y) = cost_2(P_y) = 13y + 10 \cdot (1 - y) = 3y + 10$, whereas $cost_3(P_y) = cost_4(P_y) = 10y + 10 \cdot (1 - y) = 10$. Thus $cost(P_y) = 6y + 40$.

Players 1 and 2 have three boundary strategies: A, in which they traverse the edge (a, b) at time 0; B, in which they traverse the edge (a, b) at time 1; and C, in which they traverse the edge (a, g) at time 0. Players 3 and 4 have three boundary strategies: D, in which they

traverse the edge (b, c) at time 0, and E, in which they traverse the edge (b, c) at time 1, and F, in which they traverse the edge (b, d) at time 1.

In the full version, we show that the boundary NEs with the highest cost are $\langle C, B, E, E\rangle$ and $\langle C, B, F, F\rangle$ having a cost of 42.5. The cost of the profile $P_{0.5}$ is $6 \cdot 0.5 + 40 = 43$. This implies that the worst NE in the CON-TNG in Figure 1 is a non-boundary profile. ◀

We note that it might appear that whenever there exists a non-boundary NE in a TNG $\mathcal{T}$, there exist uncountably many NEs in $\mathcal{T}$. This, however, is not the case as can be seen in the TNG in Figure 3. As argued in the proof of Theorem 9, this TNG has only one non-boundary NE. We also note that while we showed that the best and worst NEs in a CS-TNG need not be boundary, for congestion games we only showed that the worst NE need not be boundary. Thus, the problem of whether there is a CON-TNG in which the best NE is not boundary is left open.

5 Equilibrium Inefficiency

As discussed in Section 1, decentralized decision-making often leads to solutions that are sub-optimal from the point of view of the society as a whole. Recall that the measures PoS and PoA measure the inefficiency caused by the selfish behavior of the players. It refers to the ratio between the best (PoS) and worst (PoA) NEs and the SO. In this section we discuss these measures for TNGs. For NGs, the PoS and PoA are well understood. In order to use Theorem 2 and apply the results known for NGs to TNGs, we need to find a set of time points with respect to which the models are isomorphic. As discussed in Section 4, the natural candidate for this is the set of interval boundaries. While, however, we can restrict attention to boundary strategies when we consider the SO, such a restriction is not sound when we consider the infimum and supremum values of NEs. We show that our results in Theorem 2 and Section 4 do imply the required upper bounds, and that the lower bounds known for NGs can be extended to TNGs by carefully revising the examples known there.

▶ **Theorem 11.** *The PoS and PoA for TNGs are upper-bounded by these for NGs. Thus, for CS-TNGs with k players, the PoS is at most $\log k$ and the PoA is at most k. For CON-TNGs with affine cost functions, the PoS is at most 1.577 and the PoA is at most $\frac{5}{2}$.*

Proof. Consider a TNG $\mathcal{T}$. Let P be an NE in $\mathcal{T}$ and let $\mathcal{N}_P$ be the NG isomorphic to $\mathcal{T}$ with respect to $B(\mathcal{T}) \cup T_P$. Let f be a cost preserving bijection from the $(B(\mathcal{T}) \cup T_P)$-profiles of $\mathcal{T}$ and these of $\mathcal{N}_P$. As argued in the proof of Theorem 5, the profile $f(P)$ is an NE in $\mathcal{N}_P$. It follows that the cost of an NE in $\mathcal{T}$ is upper and lower bounded by the cost of an NE in an NG. Also, by Theorem 6, there exists a boundary SO in $\mathcal{T}$, which, by Theorem 2, corresponds to an SO in $\mathcal{N}$. Thus, the ratio between an NE in $\mathcal{T}$ and the cost of its SO is upper and lower bounded by this ratio in an NG. Since the above holds for all TNGs, we are done. ◀

Adopting the lower bounds on PoS and PoA from NGs to TNGs is more difficult, as the reduction from NGs to TNGs can be applied only to acyclic NGs. Fortunately, for CS-NGs, matching lower bounds have been proven for acyclic networks. Hence, using considerations that are similar to these in the proof of Theorem 11 (in fact, simpler ones, as there is no need to refer to T_P), we can use the reduction described in Theorem 3 in order to conclude the following.

▶ **Theorem 12.** *The PoS and PoA for TNGs are lower-bounded by these for acyclic NGs. Thus, for CS-TNGs with k players, the PoS is at least $\log k$ and the PoA is at least k.*

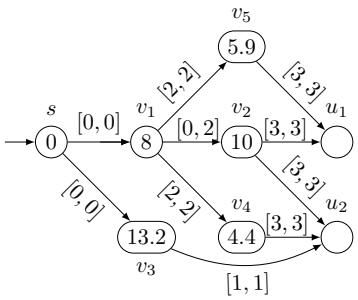

Figure 3 A CS-TNG in which the worst NE is not boundary.

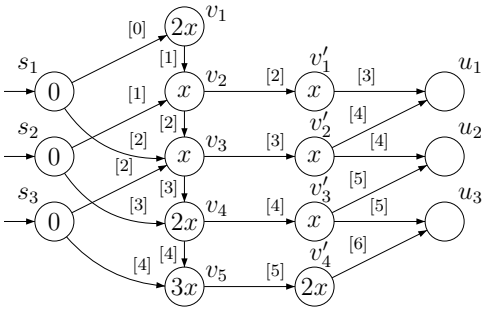

Figure 4 A lower bound of PoA $= \frac{5 \cdot k}{2(k-2)+3+5}$ for CON-TNGs.

For CON-TNG, the adoption of results from CON-NGs is more challenging, as known lower bounds use cyclic network. We are still able to prove a lower bound for the PoA. A bound for CON-NGs with linear cost function has been shown in [21]. In our case, we show that the upper bound is matched asymptotically

▶ **Theorem 13.** *There are CON-TNGs with linear cost functions such that for k=3 or more players, the PoA is* $\frac{5 \cdot k}{2(k-2)+3+5}$. *Hence as* $k \to \infty$, *the PoA approaches* $\frac{5}{2}$.

Proof. Consider the three-player CON-TNG appearing in Figure 4. The sources and targets of the three players are s_1, s_2, s_3 and u_1, u_2, u_3, respectively. The cost of staying in the source vertices is 0. For the rest of the vertices, the cost functions are as follows: $r_{v_1}(x) = r_{v_4}(x) = 2x$, $r_{v_2}(x) = r_{v_3}(x) = x$, $r_{v_5}(x) = 3x$, $r_{v'_1}(x) = r_{v'_2}(x) = r_{v'_3}(x) = x$, and $r_{v'_4}(x) = 2x$.

Consider the profile P in which Player i, for all $i \in \{1, 2, 3\}$, visits the vertices v_i, v_{i+1}, v'_i. The profile P is an NE in which each player pays 5, so $cost(P) = 15$. However, an SO is obtained when each Player i moves from her source to target through vertices v_{i+2}, v'_{i+1}. In this profile, the costs of the players are $2, 3$, and 5. Thus PoA $= \frac{15}{2+3+5} = \frac{3}{2}$.

If there are k players, we consider the game with vertices $v_1, \ldots, v_{k+2}$ and vertices $v'_1, \ldots, v'_{k+1}$. The cost functions are $r_{v_1}(x) = r_{v_{k+1}}(x) = r_{v'_{k+1}}(x) = 2x$, $r_{v_{k+2}}(x) = 3x$, while for the remaining vertices v apart from the source and the target vertices, $r_v(x) = x$. The PoA is $\frac{5 \cdot k}{2(k-2)+3+5}$. Hence, PoA asymptotically reaches its upper bound as k tends to ∞. ◀

6 The Complexity of Finding an NE

The complexity class PLS contains local search problems with polynomial time searchable neighborhoods [29]. Essentially, a problem is in PLS if there is a set of feasible solutions for it such that it is possible to find, in polynomial time, an initial feasible solution and then

iteratively improve it, with each improvement being performed in polynomial time, until a local optimum is reached. See the full version for the formal definition.

In this section we prove that the problem of finding an NE is PLS-complete for TNGs, which coincides with the complexity bounds for NGs [24, 40]. Proving membership in PLS would follow easily from the reduction to NGs. Proving hardness is more involved: While for CON-TNGs we are able to rely on previous results, corresponding to CS-TNGs, we first solve the problem for acyclic CS-NGs. We start with the upper bound.

▶ **Theorem 14.** *The problem of finding an NE in CS-TNGs and CON-TNGs is in PLS. For symmetric TNGs, the problem can be solved in polynomial time.*

Proof. For membership in PLS, we describe an algorithm to find an NE. Consider a TNG $\mathcal{T}$, and let $\mathcal{N}$ be the isomorphic NG with respect to $B(\mathcal{T})$. Recall that the size of $\mathcal{N}$ is polynomial in the size of $\mathcal{T}$. We run the PLS algorithm for finding an NE P in $\mathcal{N}$. As in Theorem 5, the profile $f^{-1}(P)$ is an NE in $\mathcal{T}$, thus we are done. When $\mathcal{T}$ is symmetric, so is $\mathcal{N}$. Since finding an NE in a symmetric NG can be done in polynomial time [24], the claim follows. ◀

For PLS-hardness, we describe a reduction from the problem of finding a local MAX CUT in a weighted network (LMC, for short) which is known to be PLS-complete [39]. In [1], a polynomial-time reduction is shown from the LMC problem to the problem of finding an NE in CON-NGs. The reduction involves two steps: from the LMC problem to the problem of finding an NE in a class of games called *quadratic threshold games*, which in turn is reduced to the problem of finding an NE in a CON-NG. The reduction in [1] always produces an acyclic CON-NG. By Theorem 3, the latter can be reduced to an isomorphic CON-TNG. In order to use a similar technique for CS-TNGs, we first establish PLS-hardness for acyclic CS-NGs, which is an open problem. The proof uses a non-trivial reduction from the LMC problem and can be found in the full version.

▶ **Theorem 15.** *The problem of finding an NE in acyclic CS-NGs is PLS-hard.*

We thus have a matching lower bound also for CS-TNGs leading to the following theorem.

▶ **Theorem 16.** *The problems of finding an NE in CS-TNGs and CON-TNGs are PLS-complete.*

7 Discussion and Directions for Future Research

We introduced and studied timed network games, which are an extension of network games with real-time considerations. TNGs are inspired by *timed automata* [5], which are automata extended by a finite set of *clocks*. A clock is a variable that takes values in $\mathbb{R}_{\geq 0}$ and whose values increase as time passes. In the full version we study *TNGs with clocks*, in which, as in timed automata, transitions are labeled by constraints on the clocks and clocks may be *reset* when traversing a transition. For example, if we reset a clock x when we enter a vertex v, then a guard $x \leq 5$ in a transition that leaves v, bounds the time spent in v to be at most 5 time units. The TNGs we study here are equivalent to a model with clocks that are never reset. Indeed, then, all clocks maintain the time that has passed since the start of the game, and guards impose bounds on this time. TNGs with clocks are already interesting in the degenerate case when there is only one player, a.k.a. *priced timed automata* (PTA, for short) [7, 13].

We describe here briefly our results for TNGs with clocks. Clearly, the negative results we obtain here for TNGs without clocks follow to the general setting. Recall that a main tool for obtaining positive results is a reduction between TNGs and NGs. The key to such a reduction is a partition of $\mathbb{R}_{\geq 0}$ into finitely many intervals, which involves two questions: about the granularity to which we have to partition $\mathbb{R}_{\geq 0}$, and about the maximal point in time that is of interest. While the answer to the first question is not difficult also for TNGs with clocks, the answer to the second question is difficult and interesting in its own right. Our positive results are not obtained using such a reduction. In order to prove the existence of an NE in every TNG with clocks, we show that such games are potential games and we also find a lower bound on the decrease in potential in a best response. Note that only showing that TNGs with clocks are potential games does not suffice to prove existence of an NE as there are infinitely many profiles. We then turn to study computational-complexity problems and show that the best-response problem is PSPACE-complete, which matches the complexity of *cost optimal reachability* in PTAs [15]. Finally, we address the question above; namely, we find bounds on the minimal time at which the players reach their destinations in an NE and an SO.

This work belongs to a line of works that transfer concepts and ideas between the areas of formal verification and algorithmic game theory: logics for specifying multi-agent systems [6, 19], studies of equilibria in games related to synthesis and repair problems [18, 17, 25, 4], and of non-zero-sum games in formal verification [20, 16]. This line of work also includes an extension of NGs to objectives that are richer than reachability [12], NGs in which the players select their paths dynamically [11], and efficient reasoning about NGs with huge networks [32, 10].

Additional extensions of TNGs that we plan to study are the following: (1) Richer objectives, where the vertices of the TNG are labeled by letters from an alphabet, allowing objectives that describe on-going behaviors [12]. For example, an objective may require each visit to vertex labeled *send* to be preceded by a vertex labeled *encode*. (2) A *dynamic* choice of paths, where strategies do not specify the full path but rather map prefixes of paths of all players to the next move [11]. For example, when the network models a network of roads and the players are drivers, it makes sense to allow drivers to observe the congestion in the network when reaching a junction (vertex) before choosing the next road (edge) in their path. (3) A *global-cost* mechanism, in which the load on a resource refers to the total time for which it is used, rather than to particular time instants.

Abstract

In this paper we study arithmetic computations in the nonassociative, and noncommutative free polynomial ring $\mathbb{F}\{x_1, x_2, \ldots, x_n\}$. Prior to this work, nonassociative arithmetic computation was considered by Hrubes, Wigderson, and Yehudayoff [7], and they showed lower bounds and proved completeness results. We consider Polynomial Identity Testing (PIT) and polynomial factorization over $\mathbb{F}\{x_1, x_2, \ldots, x_n\}$ and show the following results.

1. Given an arithmetic circuit C of size s computing a polynomial $f \in \mathbb{F}\{x_1, x_2, \ldots, x_n\}$ of degree d, we give a deterministic $\text{poly}(n, s, d)$ algorithm to decide if f is identically zero polynomial or not. Our result is obtained by a suitable adaptation of the PIT algorithm of Raz-Shpilka[13] for noncommutative ABPs.
2. Given an arithmetic circuit C of size s computing a polynomial $f \in \mathbb{F}\{x_1, x_2, \ldots, x_n\}$ of degree d, we give an efficient deterministic algorithm to compute circuits for the irreducible factors of f in time $\text{poly}(n, s, d)$ when $\mathbb{F} = \mathbb{Q}$. Over finite fields of characteristic p, our algorithm runs in time $\text{poly}(n, s, d, p)$.

1 Introduction

Noncommutative computation, introduced in complexity theory by Hyafil [8] and Nisan [12], is an important subfield of algebraic complexity theory. The main algebraic structure of interest is the free noncommutative ring $\mathbb{F}\langle X\rangle$ over a field $\mathbb{F}$, where $X = \{x_1, x_2, \cdots, x_n\}$ is a set of free noncommuting variables. A central problem is Polynomial Identity Testing which may be stated as follows:

Let $f \in \mathbb{F}\langle X\rangle$ be a polynomial represented by a noncommutative arithmetic circuit C. The circuit C can either be given by a black box (using which we can evaluate C on matrices with entries from $\mathbb{F}$ or an extension field), or the circuit may be explicitly given. The algorithmic problem is to check if the polynomial computed by C is identically zero. We recall the formal definition of a noncommutative arithmetic circuit.

▶ **Definition 1.** An *arithmetic circuit* C over a field $\mathbb{F}$ and indeterminates $X = \{x_1, x_2, \cdots, x_n\}$ is a directed acyclic graph (DAG) with each node of indegree zero labeled by a variable or a scalar constant from $\mathbb{F}$: the indegree 0 nodes are the input nodes of the circuit. Each internal node of the DAG is of indegree two and is labeled by either a $+$ or a $\times$ (indicating that it is a plus gate or multiply gate, respectively). Furthermore, the two inputs to each $\times$ gate are designated as left and right inputs which prescribes the order of multiplication at that gate. A gate of C is designated as *output*. Each internal gate computes a polynomial (by adding or multiplying its input polynomials), where the polynomial computed at an input node is just its label. The *polynomial computed* by the circuit is the polynomial computed at its output gate.

When the multiplication operation of the circuit in Definition 1 is *noncommutative*, it is called a *noncommutative arithmetic circuit* and it computes a polynomial in the free noncommutative ring $\mathbb{F}\langle X\rangle$. Since cancellation of terms is restricted by noncommutativity, intuitively it appears noncommutative polynomial identity testing would be easier than polynomial identity testing in the commutative case. This intuition is supported by fact that there is a deterministic polynomial-time white-box PIT algorithm for noncommutative ABP [13]. In the commutative setting a deterministic polynomial-time PIT for ABPs would be a major breakthrough.[1] However, there is little progress towards obtaining an efficient deterministic PIT for general noncommutative arithmetic circuits. For example, the problem is open even for noncommutative *skew* circuits.

If *associativity* is also dropped then it turns out that PIT becomes easy, as we show in this work. More precisely, we consider the free noncommutative and nonassociative ring of polynomials $\mathbb{F}\{X\}$, $X = \{x_1, x_2, \ldots, x_n\}$, where a polynomial is an $\mathbb{F}$-linear combination of monomials, and each monomial comes with a bracketing order of multiplication. For example, in the nonassociative ring $\mathbb{F}\{X\}$ the monomial $(x_1(x_2x_1))$ is different from monomial $((x_1x_2)x_1)$, although in the associative ring $\mathbb{F}\langle X\rangle$ they clearly coincide.

When the multiplication operation is both noncommutative and nonassociative, it is called a *nonassociative noncommutative circuit* and it computes a polynomial in the free nonassociative noncommutative ring $\mathbb{F}\{X\}$. Previously, the nonassociative arithmetic model of computation was considered by Hrubes, Wigderson, and Yehudayoff [7]. They showed completeness and explicit lower bound results for this model. We show the following result about PIT.

- Let $f(x_1, x_2, \ldots, x_n) \in \mathbb{F}\{X\}$ be a degree d polynomial given by an arithmetic circuit of size s. Then in deterministic $\mathrm{poly}(s, n, d)$ time we can test if f is an identically zero polynomial in $\mathbb{F}\{X\}$.

▶ Remark. We note that our algorithm in the above result does not depend on the choice of the field $\mathbb{F}$. A recent result of Lagarde et al. [11] shows an exponential lower bound, and a deterministic polynomial-time PIT algorithm over $\mathbb{R}$ for noncommutative circuits where all parse trees in the circuit are isomorphic. We also note that in [4] an exponential lower bound is shown for set-multilinear arithmetic circuits with the additional semantic constraint that each monomial has a unique parse tree in the circuit (but different monomials can have different parse trees).

Next, we consider polynomial factorization in the ring $\mathbb{F}\{\mathrm{X}\}$. Polynomial factorization is very well-studied in the commutative ring $\mathbb{F}[X]$: Given an arithmetic circuit C computing a multivariate polynomial $f \in \mathbb{F}[\mathrm{X}]$ of degree d, the problem is to efficiently compute circuits

[1] The situation is similar even in the lower bound case where Nisan proved that noncommutative determinant or permanent polynomial would require exponential-size algebraic branching program [12].

for the irreducible factors of f. A celebrated result of Kaltofen [9] solves the problem in randomized $\text{poly}(n, s, d)$ time. Whether there is a polynomial-time deterministic algorithm is an outstanding open problem. Recently, it is shown (for fields of small characteristic and characteristic zero) that the complexity of deterministic polynomial factorization problem and the PIT problem are polynomially equivalent [10]. A natural question is to determine the complexity of polynomial factorization in the noncommutative ring $\mathbb{F}\langle X\rangle$. The free noncommutative ring $\mathbb{F}\langle X\rangle$ is not even a *unique factorization domain* [6]. However, unique factorization holds for homogeneous polynomials in $\mathbb{F}\langle X\rangle$, and it is shown in [2] that for homogeneous polynomials given by noncommutative circuits, the unique factorization into irreducible factors can be computed in randomized polynomial time (essentially, by reduction to the noncommutative PIT problem).

In this paper, we note that the ring $\mathbb{F}\{X\}$ is a *unique factorization domain*, and given a polynomial in $\mathbb{F}\{X\}$ by a circuit, we show that circuits for all its irreducible factors can be computed in deterministic polynomial time.

- Let $f(x_1, x_2, \ldots, x_n) \in \mathbb{F}\{X\}$ be a degree d polynomial given by an arithmetic circuit of size s. Then if $\mathbb{F} = \mathbb{Q}$, in deterministic $\text{poly}(s, n, d)$ time we can output the circuits for the irreducible factors of f. If $\mathbb{F}$ is a finite field such that $char(\mathbb{F}) = p$, we obtain a deterministic $\text{poly}(s, n, d, p)$ time algorithm for computing circuits for the irreducible factors of f.

1.1 Outline of the proofs

Identity Testing Result. The main ideas for our algorithm are based on the white-box Raz-Shpilka PIT algorithm for noncommutative ABPs [13]. As in the Raz-Shpilka algorithm [13], if the circuit computes a nonzero polynomial $f \in \mathbb{F}\{X\}$, then our algorithm output a *certificate monomial* m such that coefficient of m in f is nonzero.

We first sketch the main steps of the Raz-Shpilka algorithm. The Raz-Shpilka algorithm processes the input ABP (assumed homogeneous) layer by layer. Suppose layer i of the ABP has w nodes. The algorithm maintains a spanning set $\mathbb{B}_i$ of at most w many linearly independent w-dimensional vectors of monomial coefficients. More precisely, each vector $v_m \in \mathbb{B}_i$ is the vector of coefficients of monomial m computed at each of the w nodes in layer i. Furthermore, the coefficient vector at layer i of any monomial is in the span of $\mathbb{B}_i$. The construction of $\mathbb{B}_{i+1}$ from $\mathbb{B}_i$ can be done efficiently. Clearly the identity testing problem can be solved by checking if there is a nonzero vector in $\mathbb{B}_d$, where d is the total number of layers.

Now we sketch our PIT algorithm for polynomials over $\mathbb{F}\{\mathrm{X}\}$ given by circuits. Let f be the input polynomial given by the circuit C.

We encode monomials in the free nonassociative noncommutative ring $\mathbb{F}\{\mathrm{X}\}$ as monomials in the free noncommutative ring $\mathbb{F}\langle \mathrm{X}, (,)\rangle$, such that the encoding preserves the multiplication structure of $\mathbb{F}\{\mathrm{X}\}$ (Observation 2). For $1 \leq j \leq d$, we can efficiently find from C a homogeneous circuit C_j that computes the degree j homogeneous part of C. Thus, it suffices to test if $C_j \equiv 0$ for each j. Hence, it suffices to consider the case when $f \in \mathbb{F}\{\mathrm{X}\}$ is homogeneous and C is a homogeneous circuit computing f.

For $j \leq d$ let G_j denote the set of degree j gates of C. The algorithm maintains a set $\mathbb{B}_j$ of $|G_j$-dimensional linearly independent vectors of monomial coefficients such that any degree j monomial's coefficient vector is in the linear span of $\mathbb{B}_j$. Clearly, $|\mathbb{B}_j| \leq |G_j|$. We compute $\mathbb{B}_{j+1}$ from the sets $\{\mathbb{B}_i : 1 \leq i \leq j\}$. For each vector in $\mathbb{B}_j$ we also keep the corresponding monomial. In the nonassociative model a degree d monomial $m = (m_1 m_2)$ is generated in a *unique way*. To check if the coefficient vector of m is in the span of $\mathbb{B}_d$ it suffices to consider

vectors in the spans of $\mathbb{B}_{d_1}$ and $\mathbb{B}_{d_2}$, where $d_1 = \deg(m_1)$ and $d_2 = \deg(m_2)$. This is a crucial difference from a general noncommutative circuit and using this property we can compute $\mathbb{B}_{j+1}$.

Polynomial Factorization in $\mathbb{F}\{X\}$. For a polynomial $f \in \mathbb{F}\{\mathrm{X}\}$, let f_j denote the homogeneous degree j part of f. For a monomial m, let $c_m(f)$ denote the coefficient of m in f. We will use the PIT algorithm as subroutine for the factoring algorithm. Arvind et al. [2] have shown that given a monomial m and a homogeneous noncommutative circuit C, in deterministic polynomial time circuits for the formal left and right derivatives of C with respect to m can be efficiently computed. This result is another ingredient in our algorithm.

We sketch the easy case, when the given polynomial f of degree d has no constant term. Applying our PIT algorithm to the homogeneous circuit C_d (computing f_d) we find a nonzero monomial $m = (m_1\ m_2)$ of degree d in f_d along with its coefficient $c_m(f)$. Notice that for any nontrivial factorization $f = gh$, m_1 is a nonzero monomial in g and m_2 is a nonzero monomial in h. Suppose $|m_1| = d_1$ and $|m_2| = d_2$. Then the left derivative of C_d with respect to m_1 gives $c_{m_1}(g)\ h_{d_2}$ and the right derivative of C_d with respect to m_2 gives $c_{m_2}(h)\ g_{d_1}$. We now use the circuits for these derivatives and the nonassociative structure, to find circuits for different homogeneous parts of g and h. The details, including the general case when f has a nonzero constant term, is in Section 4.

1.2 Organization

In Section 2 we describe some useful properties of nonassociative and noncommutative polynomials. In Section 3 we give the PIT algorithm for $\mathbb{F}\{X\}$. In Section 4 we describe the factorization algorithm for $\mathbb{F}\{X\}$. Finally, we list some open problems in Section 5.

2 Preliminaries

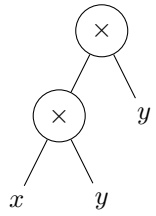
For an arithmetic circuit C, a *parse tree* for a monomial m is a multiplicative sub-circuit of C rooted at the output gate defined by the following process starting from the output gate:

- At each $+$ gate retain exactly one of its input gates.
- At each $\times$ gate retain both its input gates.
- Retain all inputs that are reached by this process.
- The resulting subcircuit is multiplicative and computes a monomial m (with some coefficient).

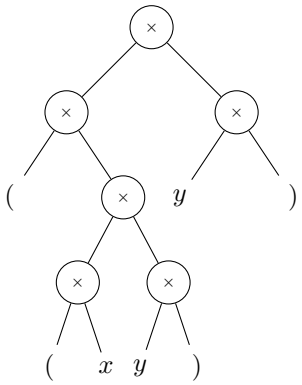
For arithmetic circuits C computing polynomials in the free nonassociative noncommutative ring $\mathbb{F}\{X\}$, the same definition for the parse tree of a monomial applies. As explained in the introduction, in this case each parse tree (generating some monomial) comes with a bracketed structure for the multiplication. It is convenient to consider a polynomial in $\mathbb{F}\{x_1, \ldots, x_n\}$ as an element in the noncommutative ring $\mathbb{F}\langle x_1, \ldots, x_n, (,)\rangle$ where we introduce two auxiliary variables (and) (for left and right bracketing) to encode the parse tree structure of any monomial. We illustrate the encoding by the following example.

Consider the monomial (which is essentially a binary tree with leaves labeled by variables) in the nonassociative ring $\mathbb{F}\{x, y\}$ shown in Figure 1a. Its encoding as a bracketed string in the free noncommutative ring $\mathbb{F}\langle x, y, (,)\rangle$ is ((x y) y) and its parse tree shown in Figure 1b.

Consider an arithmetic circuit C computing a polynomial $f \in \mathbb{F}\{X\}$. The circuit C can be efficiently transformed to a circuit $\tilde{C}$ that computes the corresponding polynomial $\tilde{f} \in \mathbb{F}\langle X, (,)\rangle$ by simply introducing the bracketing structure for each multiplication gate



(a) A nonassociative and noncommutative monomial xyy.



(b) Corresponding monomial $((xy)\ y) \in \mathbb{F}\langle X\rangle$.

Figure 1 Nonassociative & noncommutative monomial and its corresponding noncommutative bracketed monomial.

Figure 2 Nonassociative circuit and its corresponding noncommutative bracketed circuit.

of C in a bottom-up manner as indicated in the following example figures. Consider the circuits described in Figures 2a and 2b where f_i, g_i, h_i's are polynomials computed by subcircuits. Clearly the bracket variables preserve the parse tree structure. The following fact is immediate.

▶ **Observation 2.** *A nonassociative noncommutative circuit C computes a nonzero polynomial $f \in \mathbb{F}\{X\}$ if and only if the corresponding noncommutative circuit $\tilde{C}$ computes a nonzero polynomial $\tilde{f} \in \mathbb{F}\langle X, (,)\rangle$.*

We recall that the free noncommutative ring $\mathbb{F}\langle \mathrm{X}\rangle$ is not a unique factorization domain (UFD) [6] as shown by the following standard example : $xyx + x = x(yx + 1) = (xy + 1)x$. In contrast, the nonassociative free ring $\mathbb{F}\{\mathrm{X}\}$ is a UFD.

▶ **Proposition 3.** *Over any field $\mathbb{F}$, the ring $\mathbb{F}\{\mathrm{X}\}$ is a unique factorization domain. More precisely, any polynomial $f \in \mathbb{F}\{X\}$ can be expressed a product $f = g_1 g_2 \cdots g_r$ of irreducible polynomials $g_i \in \mathbb{F}\{X\}$. The factorization is unique upto constant factors and reordering.*

▶ Remark. Usually, even the ordering of the irreducible factors in the factorization is unique.

Exceptions arise because of the equality $(g+\alpha)(g+\beta) = (g+\beta)(g+\alpha)$ for any polynomial $g \in \mathbb{F}\{X\}$ and $\alpha, \beta \in \mathbb{F}$.

We shall indirectly see a proof of this proposition in Section 4 where we describe the algorithm for computing all irreducible factors.

Given a noncommutative circuit C computing a homogeneous polynomial in $\mathbb{F}\langle \mathrm{X} \rangle$ and a monomial m over X, one can talk of the left and right derivatives of C w.r.t m [2]. Let $f = \sum_{m'} c_{m'}(f)m'$ for some $f \in \mathbb{F}\langle \mathrm{X} \rangle$ and A be the subset of monomials m' of f that have m as prefix. Then the left derivative of f w.r.t. m is

$$\frac{\partial^{\ell} f}{\partial m} = \sum_{m' \in A} c_{m'}(f)m'',$$

where $m' = m \cdot m''$ for $m' \in A$. Similarly we can define the right derivative $\frac{\partial^{r} f}{\partial m}$. As shown in [2], if f is given by a circuit C then in deterministic polynomial time we can compute circuits for $\frac{\partial^{\ell} f}{\partial m}$ and $\frac{\partial^{r} f}{\partial m}$. We briefly discuss this in the following lemma.

▶ **Lemma 4.** [2] *Given a noncommutative circuit C of size s computing a homogeneous polynomial f of degree d in $\mathbb{F}\langle \mathrm{X} \rangle$ and monomial m, there is a deterministic* $\mathrm{poly}(n, d, s)$ *time algorithm that computes circuits $C_{m,\ell}$ and $C_{m,r}$ for the left and right derivatives $\frac{\partial^{\ell} C}{\partial m}$ and $\frac{\partial^{r} C}{\partial m}$, respectively.*

Proof. We explain only the left partial derivative case. Let m be a degree d' monomial and $f \in \mathbb{F}\langle X \rangle$ be a homogeneous degree d polynomial f computed by circuit C. In [2],a small substitution deterministic finite automaton A with $d'+2$ states is constructed that recognizes all length d strings with prefix m and substitutes 1 for prefix m. The transition matrices of this automaton can be represented by $(d'+2) \times (d'+2)$ matrices. From the evaluation of circuit C on these transition matrices will recover the circuit for $\frac{\partial^{\ell} C}{\partial m}$ in the $(1, d^{'}+1)^{th}$ entry of the output matrix. ◀

The left and right partial derivatives of inhomogeneous polynomials are similarly defined. The same matrix substitution works for non-homogeneous polynomials as well [2]. As discussed above, given a nonassociative arithmetic circuit C computing a polynomial $f \in \mathbb{F}\{\mathrm{X}\}$, we can transform C into a noncommutative circuit $\tilde{C}$ that computes a polynomial $\tilde{f} \in \mathbb{F}\langle X, (,) \rangle$. Suppose we want to compute the left partial derivative of f w.r.t. a monomial $m \in \mathbb{F}\{X\}$. Using the tree structure of m we transform it into a monomial $\tilde{m} \in \mathbb{F}\langle X, (,) \rangle$ and then we can apply Lemma 4 to $\tilde{C}$ and $\tilde{m}$ to compute the required left partial derivative. We can similarly compute the right partial derivative. We use this in Section 4.

We also note the following simple fact that the homogeneous parts of a polynomial $f \in \mathbb{F}\{X\}$ given by a circuit C can be computed efficiently. We can apply the above transformation to obtain circuit $\tilde{C}$ and use a standard lemma (see e.g., [14]) to compute the homogeneous parts of $\tilde{C}$.

▶ **Lemma 5.** *Given a noncommutative circuit C of size s computing a noncommutative polynomial f of degree d in $\mathbb{F}\langle \mathrm{X}, (,) \rangle$, one can compute homogeneous circuits C_j (where each gate computes a homogeneous polynomial) for j^{th} homogeneous part f_j of f, where $0 \leq j \leq d$, deterministically in time* $\mathrm{poly}(n, d, s)$.

3 Identity Testing in $\mathbb{F}\{X\}$

In this section we describe our identity testing algorithm.

▶ **Theorem 6.** *Let $f(x_1, x_2, \ldots, x_n) \in \mathbb{F}\{X\}$ be a degree d polynomial given by an arithmetic circuit of size s. Then in deterministic* $\mathrm{poly}(s, n, d)$ *time we can test if f is an identically zero polynomial in $\mathbb{F}\{X\}$.*

Proof. By Lemma 5 we can assume that the input is a homogeneous nonassociative circuit C computing some homogeneous degree d polynomial in $\mathbb{F}\{X\}$ (i.e. every gate in C computes a homogeneous polynomial). Also, all the $\times$ gates in C have fanin 2 and $+$ gates have unbounded fanin. We can assume the output gate is a $+$ gate. We can also assume w.l.o.g. that the $+$ and $\times$ gates alternate in each input gate to output gate path in the circuit (otherwise we introduce sum gates with fan-in 1).

The j^{th}-layer of circuit C to be the set of all $+$ gates in computing degree j homogeneous polynomials. Let s^+ be the total number of $+$ gates in C. To each monomial m we can associate a vector $v_m \in \mathbb{F}^{s^+}$ of coefficients, where v_m is indexed by the $+$ gates in C, and $v_m[g]$ is the coefficient of monomial m in the polynomial computed at the $+$ gate g. We can also write

$$v_m[g] = c_m(p_g),$$

where p_g is the polynomial computed at the sum gate g.

For the j^{th} layer of $+$ gates, we will maintain a maximal linearly independent set $\mathbb{B}_j$ of vectors v_m of monomials. These vectors correspond to degree j monomials. Although $v_m \in \mathbb{F}^{s^+}$, notice that $v_m[g] = 0$ at all $+$ gates that do not compute a degree j polynomial. Thus, $|\mathbb{B}_j|$ is bounded by the number of $+$ gates in the j^{th} layer. Hence, $|\mathbb{B}_j| \leq s$.

The sets $\mathbb{B}_j$ are computed inductively for increasing values of j. For the base case, the set $\mathbb{B}_1$ can be easily constructed by direct computation. Inductively, suppose the sets $\mathbb{B}_i : 1 \leq i \leq j-1$ are already constructed. We describe the construction of $\mathbb{B}_j$. Computing $\mathbb{B}_d$ and checking if there is a nonzero vector in it yields the identity testing algorithm.

We now describe the construction for the j^{th} layer assuming we have basis $\mathbb{B}_{j'}$ for every $j' < j$. Consider a $\times$ gate with its children computing homogeneous polynomials of degree d_1 and d_2 respectively. Notice that $j = d_1 + d_2$ and $0 < d_1, d_2 < j$. Consider the monomial[2] set

$$M = \{m_1 m_2 \mid v_{m_1} \in \mathbb{B}_{d_1} \text{ and } v_{m_2} \in \mathbb{B}_{d_2}\}.$$

We construct vectors $\{v_m \mid m \in M\}$ as follows.

$$v_{m_1 m_2}[g] = \sum_{(g_{d_1}, g_{d_2})} v_{m_1}[g_{d_1}] v_{m_2}[g_{d_2}],$$

where g is a $+$ gate in the j^{th} layer, g_{d_1} is a $+$ gate in the d_1^{th} layer, g_{d_2} is a $+$ gate in the d_2^{th} layer, and there is a $\times$ gate which is input to g and computes the product of g_{d_1} and g_{d_2}.

Let $\mathbb{B}_{d_1,d_2}$ denote a maximal linearly independent subset of $\{v_m \mid m \in M\}$. Then we let $\mathbb{B}_d$ be a maximal linearly independent subset of

$$\bigcup_{d_1+d_2=d} \mathbb{B}_{d_1,d_2}.$$

[2] We note that the nonassociative monomial $m_1 m_2$ is a binary tree with the root having two children: the left child is the root of the binary tree for m_1 and the right child is the root of the binary tree for m_2.

▶ **Claim 7.** *For every monomial m of degree j, v_m is in the span of $\mathbb{B}_j$.*

Proof of Claim. Let $m = m_1 m_2$ and the degree of m_1 is d_1 and the degree of m_2 is d_2 [3]. By *Induction Hypothesis* vectors v_{m_1} and v_{m_2} are in the span of $\mathbb{B}_{d_1}$ and $\mathbb{B}_{d_2}$ respectively. Hence, we can write

$$v_{m_1} = \sum_{i=1}^{D_1} \alpha_i v_{m_i} \quad v_{m_i} \in \mathbb{B}_{d_1} \quad \text{and} \quad v_{m_2} = \sum_{j=1}^{D_2} \beta_j v_{m'_j} \quad v_{m'_j} \in \mathbb{B}_{d_2},$$

where $|\mathbb{B}_{d_j}| = D_j$. Now, for a gate g in the j^{th} layer, By Induction Hypothesis and by construction we have

$$\begin{aligned} v_m[g] &= \sum_{(g_{d_1}, g_{d_2})} v_{m_1}[g_{d_1}] v_{m_2}[g_{d_2}] = \sum_{g_{d_1}, g_{d_2}} (\sum_{i=1}^{D_1} \alpha_i v_{m_i}[g_{d_1}])(\sum_{j=1}^{D_2} \beta_j v_{m'_j}[g_{d_2}]) \\ &= \sum_{i=1}^{D_1} \sum_{j=1}^{D_2} \alpha_i \beta_j \sum_{g_{d_1}, g_{d_2}} v_{m_i}[g_{d_1}] v_{m'_j}[g_{d_2}] = \sum_{i=1}^{D_1} \sum_{j=1}^{D_2} \alpha_i \beta_j v_{m_i m'_j}[g]. \end{aligned}$$

Thus v_m is in the span of $\mathbb{B}_{d_1,d_2}$ and hence in the span of $\mathbb{B}_j$. This proves the claim.
The PIT algorithm only has to check if $\mathbb{B}_d$ has a nonzero vector. This proves the claim. ◀

Suppose the input nonassociative circuit C computing some degree d polynomial $f \in \mathbb{F}\{X\}$ is inhomogeneous. Then, using Lemma 5 we can first compute in polynomial time homogeneous circuits $C_j \ : \ 0 \leq j \leq d$, where C_j computes the degree-j homogeneous part f_j. Then we run the above algorithm on each C_j to check whether f is identically zero. This completes the proof of the theorem. ◀

4 Polynomial Factorization in $\mathbb{F}\{X\}$

In this section we describe our polynomial-time white-box factorization algorithm for polynomials in $\mathbb{F}\{X\}$. More precisely, given as input a nonassociative circuit C computing a polynomial $f \in \mathbb{F}\{X\}$, the algorithm outputs circuits for all irreducible factors of f. The algorithm uses as subroutine the PIT algorithm for polynomial in $\mathbb{F}\{X\}$ described in Section 3.

To facilitate exposition, we completely describe a deterministic polynomial-time algorithm that computes a nontrivial factorization $f = g \cdot h$ of f, by giving circuits for g and h, unless f is irreducible. We will briefly outline how this extends to finding all irreducible factors efficiently.

We start with a special case.

▶ **Lemma 8.** *Let $f \in \mathbb{F}\{X\}$ be a degree d polynomial given by a circuit C of size s such that the constant term in f is zero. Furthermore, suppose there is a factorization $f = g \cdot h$ such that the constant terms in g and h are also zero. Then in deterministic* $\mathrm{poly}(n, d, s)$ *time we can compute the circuits for polynomials g and h.*

Proof. We first consider the even more restricted case when C computes a homogeneous degree d polynomial $f \in \mathbb{F}\{X\}$. For the purpose of computing partial derivatives, it is convenient to transform C into the noncommutative circuit $\tilde{C}$, as explained in Section 2,

[3] Here a crucial point is that for a nonassociative monomial of degree d, such a choice for d_1 and d_2 is *unique*. This is a place where a general noncommutative circuit behaves very differently.

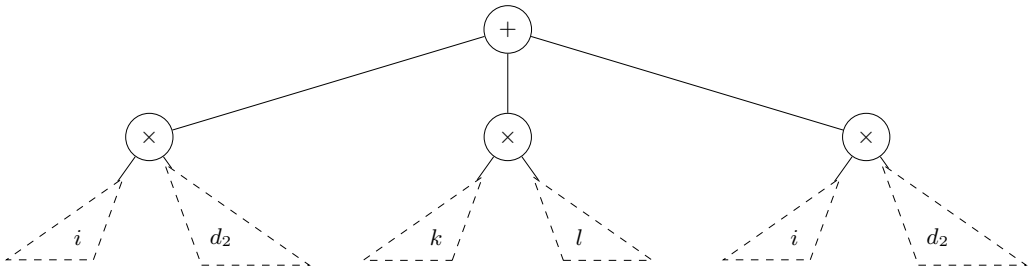

Figure 3 Circuit C_{i+d_2} for f_{i+d_2}.

which computes the fully bracketed polynomial $\tilde{f} \in \mathbb{F}\langle X, (,)\rangle$. Using Theorem 6 we compute a monomial $m = (m_1 m_2)$ where m_1 and m_2 are also fully bracketed. We can transform $\tilde{C}$ to drop the outermost opening and closing brackets. Now, using Lemma 4, we compute the resulting circuits left partial derivative w.r.t. m_1 and right partial derivative w.r.t. m_2. Call these $\tilde{f}_1$ and $\tilde{f}_2$. We can check if $\tilde{f} = (\tilde{f}_1 \tilde{f}_2)$: we first recover the corresponding nonassociative circuits for f_1 and f_2 from the circuits for $\tilde{f}_1$ and $\tilde{f}_2$. Then we can apply the PIT algorithm of Theorem 6 to check if $f = f_1 f_2$. Clearly, f is irreducible iff $f \neq f_1 f_2$. Continuing thus, we can fully factorize f into its irreducible factors.

Now we prove the actual statement. Applying Lemma 5, we compute homogeneous circuits $C_j : 1 \leq j \leq d$ for the homogeneous degree j component f_j of the polynomial f. Clearly $f_d = g_{d_1} h_{d_2}$. We run the PIT algorithm of Theorem 6 on the circuit C_d to extract a monomial m of degree d along with its coefficient $c_m(f_d)$ in f_d. Notice that the monomial m is of the form $m = (m_1\ m_2)$. If g and h are nontrivial factors of f then m_1 and m_2 are monomials in g and h respectively. Compute the circuits for the left and right derivatives with respect to m_1 and m_2.

$$\frac{\partial^{\ell} C_d}{\partial m_1} = c_{m_1}(g_{d_1}) \cdot h_{d_2} \quad \text{and} \quad \frac{\partial^{r} C_d}{\partial m_2} = c_{m_2}(h_{d_2}) \cdot g_{d_1}.$$

In general the $(i + d_2)^{th} : i \leq d - d_2$ homogeneous part of f can be expressed as

$$f_{i+d_2} = g_i h_{d_2} + \sum_{t=i+1}^{i+d_2-1} g_t h_{d_2\ -\ (t-i)}.$$

We depict the circuit C_{i+d_2} for the polynomial f_{i+d_2} in Figure 3. The top gate of the circuit is a + gate. From C_{i+d_2}, we construct another circuit C'_{i+d_2} keeping only those × gates as children whose left degree is i and right degree is d_2. The resulting circuit is shown in Figure 4. The circuit C'_{i+d_2} must compute $g_i h_{d_2}$. By taking the right partial of C'_{i+d_2} with respect to m_2, we obtain the circuit for $c_{m_2}(h_{d_2})\ g_i$.

We repeat the above construction for each $i \in [d_1]$ to obtain circuits for $c_{m_2}(h_{d_2}) g_i$ for $1 \leq i \leq d_1$. Similarly we can get the circuits for $c_{m_1}(g_{d_1}) h_i$ for each $i \in [d_2]$ using the left derivatives with respect to the monomial m_1.

By adding the above circuits we get the circuits C_g and C_h for $c_{m_2}(h_{d_2}) g$ and $c_{m_1}(g_{d_1}) h$ respectively. We set $C_g = \frac{c_{m_2}(h_{d_2})}{c_m(f)} g$ so that $C_g C_h = f$. Using PIT algorithm one can easily check whether g and h are nontrivial factors. In that case we further recurse on g and h to obtain their irreducible factors. ◀

Now we consider the general case when f and its factors g, h have arbitrary constant terms. In the subsequent proofs we assume, for convenience, that $\deg(g) \geq \deg(h)$. The case when $\deg(g) < \deg(h)$ can be handled analogously. We first consider the case $\deg(g) = \deg(h)$.

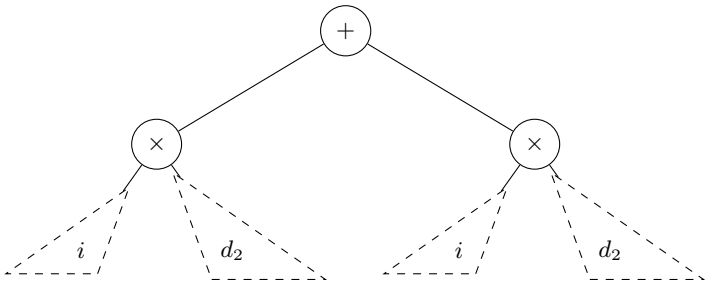

Figure 4 C'_{i+d_2} keeps only degree (i, d_2) type $\times$ gates.

▶ **Lemma 9.** *For a degree d polynomial $f \in \mathbb{F}\{X\}$ given by a circuit C suppose $f = (g+\alpha)(h+\beta)$, where $g, h \in \mathbb{F}\{X\}$ such that $\deg(g) = \deg(h)$, and $\alpha, \beta \in \mathbb{F}$. Suppose $m = (m_1 m_2)$ is a nonzero degree d monomial. Then, in deterministic polynomial time we can compute circuits for the polynomials $c_{m_1}(g) \cdot h$ and $c_{m_2}(h) \cdot g$, where $c_{m_1}(g)$ and $c_{m_2}(h)$ are coefficient of m_1 and m_2 in g and h respectively.*

Proof. We can write $f = (g+\alpha)(h+\beta) = g \cdot h + \beta \cdot g + \alpha \cdot h + \alpha \cdot \beta$. Applying the PIT algorithm of Theorem 6 on f, we compute a maximum degree monomial $m = (m_1 m_2)$. Computing the left derivative of circuit C w.r.t. monomial m_1, after removing the outermost brackets, we obtain a circuit computing $c_{m_1}(g)h + \beta c_{m_1}(g) + \alpha c_{m_1}(h)$. Dropping the constant term, we obtain a circuit computing polynomial $c_{m_1}(g)h$. Similarly, computing the right derivative w.r.t m_2 yields a circuit for $c_{m_2}(h)g + \beta c_{m_2}(g) + \alpha c_{m_2}(h)$. Removing the constant term we get a circuit for $c_{m_2}(h)g$. ◀

When $\deg(g) > \deg(h)$ we can recover $h + \beta$ entirely (upto a scalar factor) and we need to obtain the homogeneous parts of g separately.

▶ **Lemma 10.** *Let $f = (g+\alpha) \cdot (h+\beta)$ be a polynomial of degree d in $\mathbb{F}\{X\}$ given by a circuit C. Suppose $\deg(g) > \deg(h)$. Then, in deterministic polynomial time we can compute the circuit C' for $c_{m_1}(g)(h+\beta)$.*

Proof. Again, applying the PIT algorithm to f we obtain a nonzero degree d monomial $m = (m_1\ m_2)$ of f. If $f = (g+\alpha)(h+\beta)$ then $f = g \cdot h + \alpha h + \beta g + \alpha\beta$. As $\deg(g) > \deg(h)$, the left partial derivative of C with respect to m_1 yields a circuit C' for $c_{m_1}(g)\ (h+\beta)$. ◀

Extracting the homogeneous components from the circuit C' given by Lemma 10, yields circuits for $\{c_{m_1}(g)h_i \ : \ i \in [d_2]\}$. We also get the constant term $c_{m_1}(g)\beta$. Now we obtain the homogeneous components of g as follows.

▶ **Lemma 11.** *Suppose circuit C computes f, where $f = (g+\alpha)\ (h+\beta)$ of degree d, $\alpha, \beta \in \mathbb{F}$, $\deg(g) = d_1$ and $\deg(h) = d_2$ such that $d_1 > d_2$.*

- *Let m be a nonzero degree d monomial of f such that $m = (m_1\ m_2)$. Then circuits for $\{c_{m_2}(h)g_i : i \in [d_1 - d_2 + 1, d_1]\}$ can be computed in deterministic polynomial time.*
- *The $(d_2+i)^{th}$ homogeneous part of f is given by $f_{d_2+i} = \sum_{j=0}^{d_2-1} g_{d_2+i-j}\ h_j + g_i\ h_{d_2}$ for $1 \le i \le d_1 - d_2$. From the circuit C_{d_2+i} of f_{d_2+i}, we can efficiently compute circuits for $\{c_{m_2}(h_{d_2})g_i : 1 \le i \le d_1 - d_2\}$.*

Proof. For the first part, fix any $i \in [d_1 - d_2 + 1, d_1]$, and compute the homogeneous $(i+d_2)^{th}$ part f_{i+d_2} of f by a circuit C_{i+d_2}. Similar to Lemma 8, we focus on the sub-circuits of C_{i+d_2} formed by $\times$ gate of the degree type (i, d_2). Since i is at least $d_1 - d_2 + 1$, such gates can

compute the multiplication of a degree i polynomial with a degree d_2 polynomial. Then, by taking the right partial derivative with respect to m_2 we recover the circuits for $c_{m_2}(h_{d_2})\ g_i$ for any $i \in [d_1 - d_2 + 1, d_1]$.

Next, the goal is to recover the circuits for g_i (upto a scalar multiple), where $1 \leq i \leq d_1 - d_2$, and also recover the constant terms α and β. When $i \leq d_1 - d_2$ a product gate of type (i, d_2) can entirely come from g which requires a different handling.

We explain only the case when $i = d_1 - d_2$ (the others are similar). For $i = d_1 - d_2$, we have $f_{d_1} = \beta g_{d_1} + \sum_{j=1}^{d_2-1} g_{d_1-j}\ h_j + g_{d_1-d_2}\ h_{d_2}$. By Lemma 10, we can compute a circuit C' for $c_{m_1}(g)(h + \beta)$. Extracting the constant term yields $c_{m_1}(g)\beta$. From Lemma 11 we have a circuit C'' for $c_{m_2}(h)g_{d_1}$. Multiplying these circuits, we obtain a circuit C^* for $c_{m_2}(h)c_{m_1}(g)\beta g_{d_1}$. Since $c_{m_2}(h)c_{m_1}(g) = c_m(f)$, dividing C^* by $c_m(f)$ yields a circuit for βg_{d_1}. Note that, by the first part of this lemma, we already have circuits for every term g_{d_1-j} appearing in the above sum. Subtracting $\beta g_{d_1} + \sum_{j=1}^{d_2-1} g_{d_1-j}\ h_j$ from the circuit C_{d_1} for f_{d_1}, yields a circuit for polynomial $g_{d_1-d_2}h_{d_2}$. Computing the right derivative of the resulting circuit w.r.t m_2 (Lemma 4) yields a circuit for $c_{m_2}(h)g_{d_1-d_2}$.

For general $i \leq d_1 - d_2$, when we need to compute g_i, again we will have already computed circuits for all $g_j, j > i$. A suitable right derivative computation will yield a circuit for $c_{m_2}(h)g_i$. ◀

Lemmas 8, 9, 10, and 11 yield an efficient algorithm for computing circuits for the two factors $c_{m_2}(h)(\sum_{i=1}^{d_1} g_i)$ and $c_{m_1}(g)(\sum_{i=1}^{d_2} h_i)$ when $\deg(g) \geq \deg(h)$. The case when $\deg(g) < \deg(h)$ is similarly handled using left partial derivatives in the above lemmas.

Now we explain how to compute the constant terms of the individual factors. We discuss the case when $\alpha \neq 0$. The other case is similar.

First we recall that given a monomial m and a noncommutative circuit C, the coefficient of m in C can be computed in deterministic polynomial time [3]. We know that $f_0 = \alpha \cdot \beta$. We compute the coefficient of the monomial m_1 in the circuits for polynomials $c_{m_2}(h)c_{m_1}(g)gh$, $c_{m_2}(h)g$, and $c_{m_1}(g)h$. Let these coefficients be a, b and c, respectively. Moreover, we know that $c_{m_2}(h)c_{m_1}(g)$ is the coefficient of monomial $m = (m_1\ m_2)$ in f. Let the coefficient of m_1 in f be γ. Let $\gamma_1 = c_{m_1}(g)$ and $\gamma_2 = c_{m_2}(h)$ and $\delta = c_{m_1}(g)c_{m_2}(h)$.

Now equating the coefficient of m_1 from both side of the equation $f = (g + \alpha)(h + \beta)$ and substituting $\beta = \frac{f_0}{\alpha}$, we get

$$\gamma = \frac{a}{\gamma_1\gamma_2} + \frac{\alpha c}{\gamma_1} + \frac{f_0 b}{\alpha\gamma_2} = \frac{a}{\delta} + \frac{\alpha c}{\gamma_1} + \frac{f_0 b}{\alpha\gamma_2}.$$

Letting $\xi = \alpha\gamma_2$, this gives a quadratic equation in the unknown ξ.

$$c\xi^2 + (a - \gamma\delta)\xi + f_0 b\delta = 0.$$

By solving the above quadratic equation we get two solutions A_1 and A_2 for $\xi = \alpha\gamma_2$. Notice that $\beta\gamma_1 = \frac{\delta f_0}{\xi}$. As we have circuits for $c_{m_2}(h)g = \gamma_2 g$ and for $c_{m_1}(g)h = \gamma_1 h$, we obtain circuits for $\gamma_2(g + \alpha)$ and $\gamma_1(h + \beta)$ (two solutions, corresponding to A_1 and A_2). To pick the right solution, we can run the PIT algorithm to check if $\gamma_1\gamma_2 f$ equals the product of these two circuits that purportedly compute $\gamma_2(g + \alpha)$ and $\gamma_1(h + \beta)$.

Over $\mathbb{Q}$ we can just solve the quadratic equation in deterministic polynomial time using standard method. If $\mathbb{F} = \mathbb{F}_q$ for $q = p^r$, we can factorize the quadratic equation in deterministic time $\text{poly}(p, r)$ [15]. Using randomness, one can solve this problem in time $\text{poly}(\log p, r)$ using Berlekamp's factoring algorithm [5]. This also completes the proof of the following.

▶ **Theorem 12.** *Let $f \in \mathbb{F}\{X\}$ be a degree d polynomial given by a circuit of size s. If $\mathbb{F} = \mathbb{Q}$, in deterministic $\mathrm{poly}(s, n, d)$ time we can compute a nontrivial factorization of f or reports f is irreducible. If $\mathbb{F}$ is a finite field such that $char(\mathbb{F}) = p$, we obtain a deterministic $\mathrm{poly}(s, n, d, p)$ time algorithm that computes a nontrivial factorization of f or reports f is irreducible.*

Finally, we state the main result of this paper.

▶ **Theorem 13.** *Let $f \in \mathbb{F}\{X\}$ be a degree d polynomial given by a circuit of size s. Then if $\mathbb{F} = \mathbb{Q}$, in deterministic $\mathrm{poly}(s, n, d)$ time we can output the circuits for the irreducible factors of f. If $\mathbb{F}$ is a finite field such that $char(\mathbb{F}) = p$, we obtain a deterministic $\mathrm{poly}(s, n, d, p)$ time algorithm for computing circuits for the irreducible factors of f.*

▶ Remark. We could apply Theorem 12 repeatedly to find all irreducible factors of the input $f \in \mathbb{F}\{X\}$. However, the problem with that approach is that the circuits for g and h we computed in the proof of Theorem 12, where $f = gh$ is the factorization, is larger than the input circuit C for f by a polynomial factor. Thus, repeated application would incur a superpolynomial blow-up in circuit size. We can avoid that by computing the required partial derivative of g as a suitable partial derivative of the circuit C directly. This will keep the circuits polynomially bounded. This idea is from [2] where it is used for homogeneous noncommutative polynomial factorization. Combined with Theorem 12 this gives the polynomial-time algorithm of Theorem 13.

5 Conclusion

Motivated by the nonassociative circuit lower bound result shown in [7], we study PIT and polynomial factorization in the free nonassociative noncommutative ring $\mathbb{F}\{X\}$ and obtain efficient white-box algorithms for the problems.

Hrubes, Wigderson, and Yehudayoff [7] have also shown exponential circuit-size lower bounds for nonassociative, commutative circuits. It would be interesting to obtain an efficient polynomial identity testing algorithm for that circuit model too. Even a randomized polynomial-time algorithm is not known.

Obtaining an efficient *black-box* PIT in the ring $\mathbb{F}\{X\}$ is also an interesting problem. Of course, for such an algorithm the black-box can be evaluated on a suitable nonassociative algebra. To the best of our knowledge, there seems to be no algorithmically useful analogue of the Amitsur-Levitzki theorem [1].

Abstract

Graph games provide the foundation for modeling and synthesis of reactive processes. Such games are played over graphs where the vertices are controlled by two adversarial players. We consider graph games where the objective of the first player is the conjunction of a qualitative objective (specified as a parity condition) and a quantitative objective (specified as a mean-payoff condition). There are two variants of the problem, namely, the *threshold* problem where the quantitative goal is to ensure that the mean-payoff value is above a threshold, and the *value* problem where the quantitative goal is to ensure the optimal mean-payoff value; in both cases ensuring the qualitative parity objective. The previous best-known algorithms for game graphs with n vertices, m edges, parity objectives with d priorities, and maximal absolute reward value W for mean-payoff objectives, are as follows: $\mathcal{O}(n^{d+1} \cdot m \cdot W)$ for the threshold problem, and $\mathcal{O}(n^{d+2} \cdot m \cdot W)$ for the value problem. Our main contributions are faster algorithms, and the running times of our algorithms are as follows: $\mathcal{O}(n^{d-1} \cdot m \cdot W)$ for the threshold problem, and $\mathcal{O}(n^d \cdot m \cdot W \cdot \log(n \cdot W))$ for the value problem. For mean-payoff parity objectives with two priorities, our algorithms match the best-known bounds of the algorithms for mean-payoff games (without conjunction with parity objectives). Our results are relevant in synthesis of reactive systems with both functional requirement (given as a qualitative objective) and performance requirement (given as a quantitative objective).

1 Introduction

Graph games. A graph game is played on a finite directed graph with two players, namely, player 1 and player 2 (the adversary of player 1). The vertex set is partitioned into player-1

and player-2 vertices. At player-1 vertices, player 1 chooses a successor vertex; and at player-2 vertices, player 2 does likewise. The result of playing the game forever is an infinite path through the graph. There has been a long history of using graph games for modeling and synthesizing reactive processes [6, 17, 18]: a reactive system and its environment represent the two players, whose states and transitions are specified by the vertices and edges of a game graph. Consequently, graph games provide the theoretical foundation for modeling and synthesizing reactive processes.

Qualitative and quantitative objectives. For reactive systems, the objective is given as a set of desired paths (such as ω-regular specifications), or as a quantitative optimization objective with a payoff function on the paths. The class of ω-regular specifications provide a robust framework to express all commonly used specifications for reactive systems in verification and synthesis. Parity objectives are a canonical way to express ω-regular objectives [19], where an integer priority is assigned to every vertex, and a path satisfies the parity objective for player 1 if the minimum priority visited infinitely often is even. One of the classical and most well-studied quantitative objectives is the mean-payoff objective, where a reward is associated with every edge, and the payoff of a path is the long-run average of the rewards of the path.

Mean-payoff parity objectives. Traditionally the verification and the synthesis problems were considered with qualitative objectives. However, recently combinations of qualitative and quantitative objectives have received a lot of attention. Qualitative objectives such as ω-regular objectives specify the functional requirements of reactive systems, whereas the quantitative objectives specify resource consumption requirements (such as for embedded systems or power-limited systems). Combining quantitative and qualitative objectives is crucial in the design of reactive systems with both resource constraints and functional requirements [8, 11, 3, 1]. For example, mean-payoff parity objectives are relevant in synthesis of optimal performance lock-synchronization for programs [7], where one player is the synchronizer, the opponent is the environment; the performance criteria is specified as mean-payoff objective; and the functional requirement (e.g., data-race freedom or liveness) as an ω-regular objective. Mean-payoff parity objectives have been used in several other applications, e.g., define permissivity for parity games [4] and robustness in synthesis [2].

Threshold and value problems. For graph games with mean-payoff and parity objectives there are two variants of the problem. First, the *threshold* problem, where a threshold ν is given for the mean-payoff objective, and player 1 must ensure the parity objective and that the mean-payoff is at least ν. Second, the *value* problem, where player 1 maximizes the mean-payoff value while ensuring the parity objective. In the sequel of this section, we will refer to graph games with mean-payoff and parity objectives as mean-payoff parity games.

Previous results. Mean-payoff parity games were first studied in [11], and algorithms for the value problem were presented. It was shown in [9] that the decision problem for mean-payoff parity games lies in NP $\cap$ coNP (similar to the status of mean-payoff games and parity games). For game graphs with n vertices, m edges, parity objectives with d priorities, and maximal absolute reward value W for the mean-payoff objective, the previous known algorithmic bounds for mean-payoff parity games are as follows: For the threshold problem the results of [9] give an $\mathcal{O}(n^{d+4} \cdot m \cdot d \cdot W)$-time algorithm. This algorithmic bound was improved in [4] where an $\mathcal{O}(n^{d+2} \cdot m \cdot W)$-time algorithm was presented for the value problem. The result of [4] does not explicitly present any other better bound for the threshold problem. However, the recursive algorithm of [4] uses value mean-payoff games as a sub-routine, and replacing

value mean-payoff games with threshold mean-payoff games gives an $\mathcal{O}(n)$-factor saving, and yields an $\mathcal{O}(n^{d+1} \cdot m \cdot W)$-time algorithm for the threshold problem for mean-payoff parity games.
