Contributions. In this work our main contributions are faster algorithms to solve mean-payoff parity games. Previous and our results are summarized in Table 1.

1. *Threshold problem.* We present an $\mathcal{O}(n^{d-1} \cdot m \cdot W)$-time algorithm for the threshold problem for mean-payoff parity games, improving the previous $\mathcal{O}(n^{d+1} \cdot m \cdot W)$ bound. The important special case of parity objectives with two priorities correspond to Büchi and coBüchi objectives. Our bound for mean-payoff Büchi games and mean-payoff coBüchi games is $\mathcal{O}(n \cdot m \cdot W)$, which matches the best-known bound to solve the threshold problem for mean-payoff objectives [5], and improves the previous known $\mathcal{O}(n^3 \cdot m \cdot W)$ bound [4].
2. *Value problem.* We present an $\mathcal{O}(n^d \cdot m \cdot W \cdot \log(n \cdot W))$-time algorithm for the value problem for mean-payoff parity games, improving the previous $\mathcal{O}(n^{d+2} \cdot m \cdot W)$ bound. Our bound for mean-payoff Büchi games and mean-payoff coBüchi games is $\mathcal{O}(n^2 \cdot m \cdot W \cdot \log(n \cdot W))$, which matches the bound of [5] to solve the value problem for mean-payoff objectives, and improves the previous known $\mathcal{O}(n^4 \cdot m \cdot W)$ bound.

Technical contributions. Our main technical contributions are as follows:

1. First, for the threshold problem, we present a decremental algorithm for mean-payoff games that supports a sequence of vertex-set deletions along with their player-2 reachability set. We show that the total running time is $\mathcal{O}(n \cdot m \cdot W)$, which matches the best-known bound for the static algorithm to solve mean-payoff games. We show that using our decremental algorithm we can solve the threshold problem for mean-payoff Büchi games in time $\mathcal{O}(n \cdot m \cdot W)$.
2. Second, for mean-payoff coBüchi games, the decremental approach does not work. We present a new static algorithm for threshold mean-payoff games that identifies subsets X of the winning set for player 1, where the time complexity is $\mathcal{O}(|X| \cdot m \cdot W)$, i.e., it replaces n with the size of the set identified. We show that with our new static algorithm we can solve the threshold problem for mean-payoff coBüchi games in time $\mathcal{O}(n \cdot m \cdot W)$.
3. Finally, we show for all mean-payoff parity objectives, given an algorithm for the threshold problem, the value problem can be solved in time $n \cdot \log(n \cdot W)$ times the complexity of the threshold problem.

Related works. The problem of graph games with mean-payoff parity objectives was first studied in [11]. The NP $\cap$ coNP complexity bound was established in [9], and an improved algorithm for the problem was given in [4]. The mean-payoff parity objectives has also been considered in other stochastic setting such as Markov decision processes [10, 12] and stochastic games [13]. The algorithmic approaches for stochastic games build on the results for non-stochastic games. In this work, we present faster algorithms for mean-payoff parity games.

2 Preliminaries

Graphs. A graph $G = (V, E)$ consists of a finite set V of vertices and a finite set of edges $E \subseteq V \times V$. Given a graph $G = (V, E)$ and a subset $U \subseteq V$ we denote by $G \restriction U = (V', E')$ the subgraph of G induced by U, i.e., $V' = U$, $E' = (U \times U) \cap E$. For $v \in V$ we denote by $In(v)$ (resp., $Out(v)$) the set of incoming (resp., outgoing) vertices, i.e., $In(v) = \{v' \mid (v', v) \in E\}$, and $Out(v) = \{v' \mid (v, v') \in E\}$.

Table 1 Algorithmic bounds for mean-payoff (MP) and parity objectives, and special cases: threshold problem (left) and value problem (right).

	threshold problem		value problem	
	Previous	Our	Previous	Our
MP-Büchi	$\mathcal{O}(n^3 \cdot m \cdot W)$	$\mathcal{O}(n \cdot m \cdot W)$	$\mathcal{O}(n^4 \cdot m \cdot W)$	$\mathcal{O}(n^2 \cdot m \cdot W \cdot \log(nW))$
MP-coBüchi	$\mathcal{O}(n^3 \cdot m \cdot W)$	$\mathcal{O}(n \cdot m \cdot W)$	$\mathcal{O}(n^4 \cdot m \cdot W)$	$\mathcal{O}(n^2 \cdot m \cdot W \cdot \log(nW))$
MP-parity	$\mathcal{O}(n^{d+1} \cdot m \cdot W)$	$\mathcal{O}(n^{d-1} \cdot m \cdot W)$	$\mathcal{O}(n^{d+2} \cdot m \cdot W)$	$\mathcal{O}(n^d \cdot m \cdot W \cdot \log(nW))$

Game graphs. A game graph $\Gamma = (V, E, \langle V_1, V_2 \rangle)$ is a graph whose vertex set is partitioned into V_1 and V_2, (i.e., $V = V_1 \cup V_2$ and $V_1 \cap V_2 = \emptyset$). In a game graph every vertex $v \in V$ has a successor $v' \in V$, i.e., $Out(v) \neq \emptyset$ for all $v \in V$. Given a game graph Γ and a set U such that for all vertices u in U we have $Out(u) \cap U \neq \emptyset$, we denote by $\Gamma \restriction U$ the subgame induced by U.

Plays. Given a game graph Γ and a starting vertex v_0, the game proceeds in rounds. In each round, if the current vertex belongs to player 1, then player 1 chooses a successor vertex, and player 2 does likewise if the current vertex belongs to player 2. The result is a *play* ρ which is an infinite path from v_0, i.e., $\rho = v_0 v_1 \ldots$, where every $(v_i, v_{i+1}) \in E$ for all $i \geq 0$. We denote by $Plays(\Gamma)$ the set of all plays of the game graph.

Strategies. Strategies are recipes to extend prefixes of plays by choosing the next vertex. Formally, a strategy for player-1 is a function $\sigma_1 : V^* \cdot V_1 \mapsto V$ such that $(v, \sigma_1(\rho \cdot v)) \in E$ for all $v \in V_1$ and all $\rho \in V^*$. We define strategies σ_2 for player 2 analogously. We denote by Σ_1 and Σ_2 the set of all strategies for player 1 and player 2, respectively. Given strategies σ_1 and σ_2 for player 1 and player 2, and a starting vertex v_0, there is a unique play $\rho = v_0 v_1 \ldots$ such that for all $i \geq 0$, (a) if $v_i \in V_1$ then $v_{i+1} = \sigma_1(v_0 \ldots v_i)$; and (b) if $v_i \in V_2$ then $v_{i+1} = \sigma_2(v_0 \ldots v_i)$. We denote the unique play as $outcome(v_0, \sigma_1, \sigma_2)$. A strategy is *memoryless* if it is independent of the past and depends only on the current vertex, and hence can be defined as a function $\sigma_1 : V_1 \mapsto V$ and $\sigma_2 : V_2 \mapsto V$, respectively.

Objectives and parity objectives. An objective for a game graph Γ is a subset of the possible plays, i.e., $\phi \subseteq Plays(\Gamma)$. Given a play ρ we denote by $Inf(\rho)$ the set of vertices that appear infinitely often in ρ. A *parity* objective is defined with a priority function p that maps every vertex to a non-negative integer priority, and a play satisfies the parity objective for player 1 if the minimum priority vertex that appear infinitely often is even. Formally, the parity objective is $Parity_\Gamma(p) = \{\rho \in Plays(\Gamma) \mid \min\{p(v) \mid v \in Inf(\rho)\} \text{ is even}\}$. The Büchi and coBüchi objectives are special cases of parity objectives with two priorities only. We have $p : V \mapsto \{0, 1\}$ for Büchi objectives and $p : V \mapsto \{1, 2\}$ for the coBüchi objectives.

Payoff functions. Consider a game graph Γ, and a weight function $w : E \mapsto \mathbb{Z}$ that maps every edge to an integer. The mean-payoff function maps every play to a real-number and is defined as follows: For a play $\rho = v_0 v_1 \ldots$ in $Plays(\Gamma)$ we have $MP(w, \rho) = \liminf_{n \mapsto \infty} \frac{1}{n} \cdot \sum_{i=0}^{n-1} w(v_i, v_{i+1})$. The mean-payoff parity function also maps every play to a real-number or $-\infty$ as follows: if the parity objective is satisfied, then the value is the mean-payoff value, else it is $-\infty$. Formally, for a play ρ, we have

$$MPP_\Gamma(w, p, \rho) = \begin{cases} MP_\Gamma(w, \rho) & \text{if } \rho \in Parity_\Gamma(p); \\ -\infty & \text{if } \rho \notin Parity_\Gamma(p). \end{cases}$$

Threshold mean-payoff parity objectives. Given a threshold $\nu \in \mathbb{Q}$, the *threshold mean-payoff objective* $MeanPayoff_\Gamma(\nu) = \{\rho \in Plays(\Gamma) \mid MP(\rho) \geq \nu\}$ requires that the mean-payoff value is at least ν. The *threshold mean-payoff parity objective* is a conjunction of a parity objective and a threshold mean-payoff objective, i.e., $Parity_\Gamma(p) \cap MeanPayoff_\Gamma(\nu)$.

Winning strategies. Given an objective (such as parity, threshold mean-payoff, or threshold mean-payoff parity) ϕ, a vertex v is winning for player 1, if there is a strategy σ_1 such that for all strategies σ_2 of player 2, the play $outcome(v, \sigma_1, \sigma_2) \in \phi$ (i.e., the play satisfies the objective). We denote by $W_1(\phi)$ the set of winning vertices (or the winning region) for player 1 for the objective ϕ. The notation $W_2(\overline{\phi})$ for complementary objectives $\overline{\phi}$ for player 2 is similar.

Value functions. Given a payoff function f (such as the mean-payoff function, or the mean-payoff parity function), the value for player 1 is the maximal payoff that she can guarantee against all strategies of player 2. Formally,

$$val_\Gamma(f)(v) = \sup_{\sigma_1 \in \Sigma_1} \inf_{\sigma_2 \in \Sigma_2} f(outcome(v, \sigma_1, \sigma_2)).$$

Attractors. The player-1 attractor $Attr_1(S)$ of a given set $S \subseteq V$ is the set of vertices from which player-1 can force to reach a vertex in S. It is defined as the limit of the sequence $A_0 = S; A_{i+1} = A_i \cup \{v \in V_1 \mid Out(v) \cap A_i \neq \emptyset\} \cup \{v \in V_2 \mid Out(v) \subseteq A_i\}$ for all $i \geq 0$. Th Player-2 attractor $Attr_2(S)$ is defined analogously exchanging the roles of player 1 and player 2. The complement of an attractor induces a game graph, as in the complement every vertex has an outgoing edge in the complement set.

Relevant parameters. In this work we will consider computing the winning region for threshold mean-payoff parity objectives, and the value function for mean-payoff parity objectives. We will consider the following relevant parameters: n denotes the number of vertices, m denotes the number of edges, d denotes the number of priorities of the parity function p, and W is the maximum absolute value of the weight function w.

3 Decremental Algorithm for Threshold Mean-Payoff Games

In this section we present a decremental algorithm for threshold mean-payoff games that supports deleting a sequence of sets of vertices along with their player-2 attractors. The overall running time of the algorithm is $\mathcal{O}(n \cdot m \cdot W)$.

Key idea. A static algorithm based on the notion of progress measure for mean-payoff games was presented in [5]. We show that the progress measure is monotonic wrt to the deletion of vertices and their player-2 attractors. We use an amortized analysis to obtain the running time of our algorithm.

Mean-payoff progress measure. Let Γ be a mean-payoff game with threshold ν. Progress measure is a function f which maps every vertex in Γ to an element of the set $C_\Gamma = \{i \in \mathbb{N} \mid i \leq nW\} \cup \{\top\}$, i.e., $f : V \mapsto C_\Gamma$. Let $(\preceq, C_\Gamma)$ be a total order, where $x \preceq y$ for $x, y \in C_\Gamma$ holds iff $x \leq y \leq nW$ or $y = \top$. We define the operation $\ominus : C_\Gamma \times \mathbb{Z} \mapsto C_\Gamma$ for all $a \in C_\Gamma$ and $b \in \mathbb{Z}$ as follows:

$$a \ominus b = \begin{cases} \max(0, a - b) & \text{if } a \neq \top \text{ and } a - b \leq nW, \\ \top & \text{otherwise.} \end{cases}$$

A player-1 vertex v is *consistent* if $f(v) \succeq f(v') \ominus w(v,v')$ for *any* $v' \in Out(v)$. A player-2 vertex v is *consistent* if $f(v) \succeq f(v') \ominus w(v,v')$ for *all* $v' \in Out(v)$. Let $v \in V$ then $\mathit{lift}(\cdot, v) : [V \mapsto C_\Gamma] \mapsto [V \mapsto C_\Gamma]$ is defined by $\mathit{lift}(f, v) = g$ where:

$$g(u) = \begin{cases} f(u) & \text{if } u \neq v, \\ \min\{f(v') \ominus w(v,v') \mid (v,v') \in E\} & \text{if } u = v \in V_1, \\ \max\{f(v') \ominus w(v,v') \mid (v,v') \in E\} & \text{if } u = v \in V_2. \end{cases}$$

Static Algorithm The static algorithm in [5] is an iterative algorithm which maintains and returns a progress measure f and a list L of vertices which are not consistent. The initial progress measure of every vertex is set to zero. Also, $w(e)$ is set to $w(e) - \nu$ for all edges e in E. The list L is initialized with the vertices which are not consistent considering the initial progress measure. Then the following steps are executed in a while-loop:

1. Take out a vertex v of L.
2. Perform the *lift*-operation on the vertex, i.e., $f \leftarrow \mathit{lift}(f, v)$.
3. If a vertex v' in $In(v)$ is not consistent, put v' into L.
4. If L is empty, return f else proceed to the next iteration.

If every vertex is consistent, i.e., the list L is empty, the winning region of player 1 is the set of vertices which are not set to $\top$ in f, i.e., $W_1(\nu) = \{v \in V \mid f(v) \neq \top\}$.

Decremental input/output. Let Γ be a mean-payoff game with threshold ν. The *input* to the decremental algorithm is a sequence of sets $A_1, A_2, \ldots, A_k$, such that each A_i is a player-2 attractor of a set X_i in the game $\Gamma_i = \Gamma \restriction (V \setminus \bigcup_{j<i} A_j)$. The *output requirement* is the player-1 winning set after the deletion of $\bigcup_{j<i} A_j$ for $i = 1, \ldots, k$, i.e., the output requirement is the sequence $Z_1, Z_2, \ldots, Z_k$, where $Z_i = W_1(\phi)$ in $\Gamma_i = \Gamma \restriction (V \setminus \bigcup_{j<i} A_j)$, where $\phi = \mathit{MeanPayoff}_{\Gamma_i}(\nu)$ is the threshold mean-payoff objective. In other words, we repeatedly delete a vertex set X_i along with its player-2 attractor A_i from the current game graph Γ_i, and require the winning set for player 1 as an output after each deletion.

Decremental algorithm. We maintain a progress measure f_i, $1 \leq i \leq k$, during the whole sequence of deletions. The initial progress measure f_1 for the mean-payoff game Γ with threshold mean-payoff objective ϕ is calculated using the static algorithm. For all edges e in E, we set $w(e) = w(e) - \nu$. In iteration i with input A_i, in the game Γ_i with its corresponding vertex set V_i the following steps are executed:

1. If a vertex in the set $\{v \in V_i \setminus A_i \mid \exists v' : \ v' \in Out(v) \wedge v' \in A_i\}$ is not consistent in f_i without the set A_i, put it in a list L_i.
2. Delete the set A_i from Γ_i to receive Γ_{i+1} (and thus V_{i+1}).
3. Execute steps (1)-(4) of the above described iterative algorithm from [5] initialized with Γ_{i+1}, L_i and f_i restricted to the vertices in V_{i+1}.
4. Finally the winning region of player 1 can be extracted from the obtained progress measure f_{i+1}, i.e., $W_1(\phi) = \{v \in V_{i+1} \mid f(v) \neq \top\}$.

Correctness. Let Γ be a game graph, ϕ a threshold objective and $A_1, A_2, \ldots, A_k$ a sequence of sets, such that each A_i is a player-2 attractor in the game $\Gamma_i = \Gamma \restriction (V \setminus \bigcup_{j<i} A_j)$. To show the correctness of the decremental algorithm we need to show that the condition that the list L contains all vertices which are not consistent is an invariant of the decremental algorithm at line 3. This property was proved for the static algorithm in [5].

▶ **Lemma 1.** *The condition that L_i contains all vertices which are not consistent with the progress measure f_i restricted to V_{i+1} in Γ_{i+1} is an invariant of the static algorithm called in step 3 of the decremental algorithm for $1 \leq i \leq k-1$.*

Proof. The fact that the static algorithm correctly returns a progress measure with only consistent vertices when the invariant holds was shown in [5]. It was also shown in [5] that the invariant is maintained in the loop. It remains to show that the condition holds when we call the static algorithm at step 3. For the base case, let $i = 1$. In the initial progress measure f_1 and the initial game graph Γ_1, every vertex is consistent. By the definition of a player-2 attractor, deleting the set A_1 potentially removes edges (v, v') where v is a player-1 vertex in $V \setminus A_1$ and v' is in A_1. (Note that v cannot be a player-2 vertex.) All of the vertices not consistent anymore are added to L_i in step 1 of the decremental algorithm. For the inductive step let $i = j$. By induction hypothesis, all vertices which were not consistent with the progress measures f_{h-1} restricted to V_h for $2 \leq h \leq j$ were added to the corresponding lists. Thus by the correctness of the static algorithm, it correctly computes the new progress measure f_h for the game graph Γ_h where every vertex is consistent. Thus also every vertex in the progress measure f_j restricted to V_j is consistent. Again the player-2 attractor is removed and vertices which are not consistent with progress measure f_j restricted to V_{j+1} are put into L_j by step 1 of the algorithm. ◀

Thus we proved that the static algorithm always correctly updates to the new progress measure in each iteration. The winning region of player-1 is obtained by the returned progress measure (step 4). The decremental algorithm thus correctly computes the sequence $Z_1, Z_2, \ldots Z_k$, where $Z_i = W_1(\phi)$ in Γ_i.

Running Time. The calculation of the initial progress measure for the mean-payoff game Γ with threshold ν is in time $\mathcal{O}(n \cdot m \cdot W)$. The vertices which are not consistent anymore after the deletion of A_i can be found in time $\mathcal{O}(m)$ (step 1). As at most n such sets A_i exist, the running time is $\mathcal{O}(mn)$. In step 3 the static algorithm is executed with our current progress measure f_i: Every time a vertex v is picked from the list L_i it costs $\mathcal{O}(|Out(v) + In(v)|)$ time to use *lift* on it and to look for vertices in $In(v)$ which are not consistent anymore (steps 1-3 in the static algorithm). This cost is charged to its incident edges. Note that deleting a set of vertices and their corresponding player-2 attractor will only potentially *increase* the progress measure of some player-1 vertices. As we can increase the progress measure of every vertex only nW times before it is set to $\top$ where it is always consistent, we get the desired bound of $\mathcal{O}(m \cdot n \cdot W)$.
Thus our decremental algorithm for threshold mean-payoff games works as desired and we obtain the following result:

▶ **Theorem 2.** *Given a game graph Γ, a threshold mean-payoff objective ϕ and a sequence of sets $A_1, A_2, \ldots, A_k$ such that each A_i is a player-2 attractor of a set X_i in the game $\Gamma_i = \Gamma \restriction (V \setminus \bigcup_{j<i} A_j)$, the sequence $Z_1, Z_2, \ldots, Z_k$, where $Z_i = W_1(\phi)$ in Γ_i can be computed in $\mathcal{O}(n \cdot m \cdot W)$ time.*

▶ Remark. Note that the running time analysis of our decremental algorithm crucially depends on the monotonicity property of the progress measure. If edges are both added and deleted, then the monotonicity property does not hold. Hence obtaining a fully dynamic algorithm that supports both addition/deletion of vertices/edges with running time $\mathcal{O}(n \cdot m \cdot W)$ is an interesting open problem. However, we will show that for solving mean-payoff parity games, the decremental algorithm plays a crucial part.

4 Threshold Mean-Payoff Parity Games

In this section we present algorithms for threshold mean-payoff parity games. Our most interesting contributions are for the base case of mean-payoff Büchi- and mean-payoff coBüchi objectives, and the general case follows a standard recursive argument.

4.1 Threshold Mean-Payoff Büchi Games

In this section we consider threshold mean-payoff Büchi games.

Algorithm for threshold mean-payoff Büchi games. The basic algorithm is an iterative algorithm that deletes player-2 attractors. The algorithm proceeds in iterations. In iteration i, let D_i be the set of vertices already deleted. Consider the subgame $\Gamma_i = \Gamma \restriction (V \setminus D_i)$. Then the following steps are executed:

1. Let $V^i = V \setminus D_i$ and B_i denote the set of Büchi vertices (or vertices with priority 0) in Γ_i. Compute $Y_i = Attr_1(B_i)$ the player-1 attractor to B_i in Γ_i.
2. Let $X_i = V^i \setminus Y_i$. If X_i is non-empty, remove $A_i = Attr_2(X_i)$ from the game graph, and proceed to the next iteration.
3. Else $V^i = Y_i$. Let $U_i = W_1(\phi)$ in Γ_i, where $\phi = \mathit{MeanPayoff}(\nu)$, be the winning region for the threshold mean-payoff objective in Γ_i. Let $X_i = V^i \setminus U_i$. If X_i is non-empty, remove $A_i = Attr_2(X_i)$ from the game graph, and proceed to the next iteration. If X_i is empty, then the algorithm stops and all the remaining vertices are winning for player 1 for the threshold mean-payoff Büchi objective.

Correctness. Since the correctness argument has been used before [11], we only present a brief sketch: The basic correctness argument is to show that all vertices removed over all iterations do not belong to the winning set for player 1. In the end, for the remaining vertices, player 1 can ensure to reach the Büchi vertices, and ensures the threshold mean-payoff objectives. A strategy that plays for the threshold mean-payoff objectives longer and longer, and in between visits the Büchi vertices, ensures that the threshold mean-payoff Büchi objective is satisfied.

Running time analysis. We observe that the total running time to compute all attractors is at most $\mathcal{O}(n \cdot m)$, since the algorithm runs for $\mathcal{O}(n)$ iterations and each attractor computation is linear time. In step 3, the algorithm needs to compute the winning region for threshold mean-payoff objective. The algorithm always removes a set X_i and its player-2 attractor A_i, and requires the winning set for player 1. Thus we can use the decremental algorithm from Section 3, which precisely supports these operations. Hence using Theorem 2 in the algorithm for threshold mean-payoff Büchi games, we obtain the following result.

▶ **Theorem 3.** *Given a game graph Γ and a threshold mean-payoff Büchi objective ϕ, the winning set $W_1(\phi)$ can be computed in $\mathcal{O}(m \cdot n \cdot W)$ time.*

4.2 Threshold Mean-Payoff coBüchi Games

In this section we will present an $\mathcal{O}(n \cdot m \cdot W)$-time algorithm for threshold mean-payoff coBüchi games. We start with the description of the basic algorithm for threshold mean-payoff coBüchi games.

Algorithm for threshold mean-payoff coBüchi games. The basic algorithm is an iterative algorithm that deletes player-1 attractors. The algorithm proceeds in iteration. In iteration i, let D_i be the set of vertices already deleted. Consider the subgame $\Gamma_i = \Gamma \restriction (V \setminus D_i)$. Then the following steps are executed:

1. Let $V^i = V \setminus D_i$ and C_i denote the set of coBüchi vertices (or vertices with priority 1) in Γ_i. Compute $Y_i = Attr_2(C_i)$ the player-2 attractor to C_i in Γ_i.

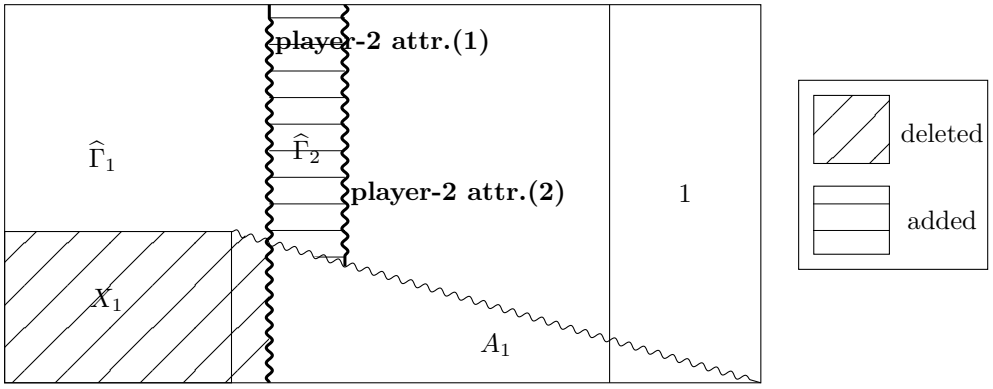

Figure 1 Pictorial illustration of threshold mean-payoff coBüchi games. The subgames $\widehat{\Gamma}_1$ and $\widehat{\Gamma}_2$ are shown. We observe that $\widehat{\Gamma}_2$ is obtained both by addition and deletion of game parts to $\widehat{\Gamma}_1$.

2. Let $X_i = V^i \setminus Y_i$. Consider the subgame $\widehat{\Gamma}_i = \Gamma_i \restriction X_i$. Compute the winning region $Z_i = W_1(\phi)$ for player 1 in $\widehat{\Gamma}_i$, where $\phi = \mathit{MeanPayoff}(\nu)$ is the threshold mean-payoff objective.
3. If Z_i is non-empty, remove $\mathit{Attr}_1(Z_i)$ from Γ_i, and proceed to the next iteration. Else if Z_i is empty, then all remaining vertices are winning for player 2.

Correctness argument. Consider the subgame Γ_i. In each subgame $\widehat{\Gamma}_i$ of Γ_i all edges of player 2 are intact, since it is obtained after removing a player-2 attractor Y_i. Moreover, there is no priority-1 vertex in $\widehat{\Gamma}_i$. Hence ensuring the threshold mean-payoff objective in $\widehat{\Gamma}_i$ for player 1 ensures satisfying the threshold mean-payoff coBüchi objective. Hence the set Z_i and its player-1 attractor belongs to the winning set of player 1 and can be removed. Thus all vertices removed are part of the winning region for player 1. Upon termination, in $\widehat{\Gamma}_i$, player 1 cannot satisfy the threshold mean-payoff condition from any vertex. Consider a player-2 strategy, where in $\widehat{\Gamma}_i$ player 2 falsifies the threshold mean-payoff condition, and in Y_i plays an attractor strategy to reach C_i (priority-1 vertices). Given such a strategy, either (a) Y_i is visited infinitely often, and then the coBüchi objective is violated; or (b) from some point on the play stays in $\widehat{\Gamma}_i$ forever, and then the threshold mean-payoff objective is violated. This shows the correctness of the algorithm. However, the running time of this algorithm is not $\mathcal{O}(n \cdot m \cdot W)$. We now present the key ideas to obtain an $\mathcal{O}(n \cdot m \cdot W)$-time algorithm.

First intuition. Our first intuition is as follows. In step 2 of the above algorithm, instead of obtaining the whole winning region $W_1(\phi)$ in $\widehat{\Gamma}_i$ it suffices to identify a subset X_i of the winning region (if it is non-empty) and remove its player-1 attractor. We call this the modified algorithm for threshold mean-payoff coBüchi games. We first describe why we cannot use the decremental approach in the following remark.

▶ Remark. Consider the subgames for which the threshold mean-payoff objective must be solved. Consider Figure 1. The first player-2 attractor removal induces subgame $\widehat{\Gamma}_1$. After identifying a winning region X_1 of $\widehat{\Gamma}_1$ we remove its player-1 attractor A_1. After removal of A_1, we consider the second player-2 attractor to the priority-1 vertices. The removal of this attractor induces $\widehat{\Gamma}_2$. We observe comparing $\widehat{\Gamma}_1$ and $\widehat{\Gamma}_2$ that certain vertices are removed, whereas other vertices are added. Thus the subgames to be solved for threshold mean-payoff objectives do not satisfy the condition of decremental or incremental algorithms (see Remark 3).

Second intuition. While we cannot use the decremental algorithm, we can solve the problem in $\mathcal{O}(n \cdot m \cdot W)$ time, if we have a modified static algorithm for threshold mean-payoff games, with the following property: (a) it identifies a subset of the winning region X for player 1, if the winning region is non-empty, in time $\mathcal{O}(|X| \cdot m \cdot W)$; (b) if the winning region is empty, it returns the empty set, and then it takes time $\mathcal{O}(n \cdot m \cdot W)$. With such an algorithm we analyze the running time of the above modified algorithm for threshold mean-payoff coBüchi games. The total time required for all attractor computations is again $\mathcal{O}(n \cdot m)$. Otherwise, we use the modified static algorithm to remove vertices of player-1 and to remove set of size X we take $\mathcal{O}(|X| \cdot m \cdot W)$ time, and thus we can charge each vertex $\mathcal{O}(m \cdot W)$ time. Hence the total time required is $\mathcal{O}(n \cdot m \cdot W)$. In the rest of the section we present this modified static algorithm for threshold mean-payoff games.

Problem Statement.

Input:	Mean-payoff game Γ with threshold ν.
Question:	If $W_1(\mathit{MeanPayoff}(\nu))$ is non-empty, return a nonempty set $X \subseteq W_1(\mathit{MeanPayoff}(\nu))$ in time $\mathcal{O}(\lvert X\rvert \cdot m \cdot W)$, else return $\emptyset$ in time $\mathcal{O}(n \cdot m \cdot W)$.

Modified static algorithm for threshold mean-payoff games. The basic algorithm for threshold mean-payoff games computes a progress measure, with a defined top element value $\top$. If the progress measure has the value $\top$ for a vertex, then the vertex is declared as winning for player 2. With value $\top = n \cdot W$, the correct winning region for both players can be identified. Moreover, for a given value α for $\top$, the progress measure algorithm requires $\mathcal{O}(\alpha \cdot m)$ time. Our modified static algorithm is based on the following idea:

1. Consider a value $\alpha \leq n \cdot W$ for the top element. With this reduced value for the top element, if a winning region is identified for player 1, then it is a subset of the whole winning region for player 1.
2. We will iteratively double the value for the top element.

Given the above ideas our algorithm is an iterative algorithm defined as follows: Initialize top value $\top_0 = W$. The i-th iteration is as follows:

1. Run the progress measure algorithm with top value $\top_i$.
2. If a winning region X for player is identified, return X.
3. Else $\top_{i+1} = 2 \cdot \top_i$ (i.e., the top value is doubled).
4. If $\top_{i+1} \geq 2 \cdot n \cdot W$, stop the algorithm and return $\emptyset$, else proceed to the next iteration.

Correctness and running time analysis. The key steps of the correctness argument and the running time analysis are as follows:

1. The above algorithm is correct, since if it returns a set X then it is a subset of the winning set for player 1.
2. If the algorithm returns a winning set with top value α, then the total running time till this iteration is $m \cdot (\alpha + \alpha/2 + \alpha/4 + \cdots)$, because the progress with top value α requires time $\mathcal{O}(\alpha \cdot m)$. Hence the total running time if a set X is returned with top value α is $\mathcal{O}(\alpha \cdot m)$.
3. Let Z be a set of vertices such that no player-2 vertex in Z has an edge out of Z, and the whole subgame $\Gamma \restriction Z$ is winning for player 1. Then a winning strategy in Z ensures that a progress measure with top value $|Z| \cdot W$ would identify the set Z as a winning set.
4. From above it follows that if the winning set X is identified at top value α, but no winning set was identified with top value $\alpha/2$, then the size of the winning set is at least $\alpha/(2W)$.

5. It follows from above that if a set X is identified, then the total running time to obtain set X is $\mathcal{O}(|X| \cdot m \cdot W)$.
6. Moreover, the total running time of the algorithm when no set X is identified is in $\mathcal{O}(n \cdot m \cdot W)$, and in this case, the winning region is empty.

Thus we solved the modified static algorithm for threshold mean-payoff games as desired and obtain the following result.

▶ **Theorem 4.** *Given a mean-payoff game Γ and a threshold ν, let $Z = W_1(MeanPayoff(\nu))$. If $Z \neq \emptyset$, then a non-empty set $X \subseteq Z$ can be computed in time $\mathcal{O}(|X| \cdot m \cdot W)$, else an empty set is returned if $Z = \emptyset$, which takes time $\mathcal{O}(n \cdot m \cdot W)$.*

Using the above algorithm to compute the winning set for player 1 in the subgames, we obtain an algorithm for threshold mean-payoff coBüchi games in time $\mathcal{O}(n \cdot m \cdot W)$.

▶ **Theorem 5.** *Given a game graph Γ and a threshold mean-payoff coBüchi objective ϕ, the winning set $W_1(\phi)$ can be computed in $\mathcal{O}(n \cdot m \cdot W)$ time.*

4.3 Threshold Mean-Payoff Parity Games

The algorithm for threshold mean-payoff parity games is the standard recursive algorithm [11] (classical parity game-style algorithm) that generalizes the Büchi and coBüchi cases (which are the base cases). The running time recurrence is as follows: $T(n, d, m, w) = n(T(n, d-1, m) + \mathcal{O}(m)) + \mathcal{O}(nmW)$. Using our approach we obtain the following result.

▶ **Theorem 6.** *Given a game graph Γ and a threshold mean-payoff parity objective ϕ, the winning set $W_1(\phi)$ can be computed in $\mathcal{O}(n^{d-1} \cdot m \cdot W)$ time.*

5 Optimal Values for Mean-payoff Parity Games

In this section we present an algorithm which computes the value function for mean-payoff parity games. For mean-payoff games a dichotomic search approach was presented in [5]. We show that such an approach can be generalized to mean-payoff parity games.

Range of Values for the Dichotomic Search. To describe the algorithm we recall a lemma about the possible range of optimal values of a mean-payoff parity game. The lemma is an easy consequence of the characterization of [11] that the mean-payoff parity value coincide with the mean-payoff value, and the possible range of value for mean-payoff games.

▶ **Lemma 7** ([11, 15, 16])**.** *Let Γ be a mean-payoff parity game. For each vertex $v \in V$, the optimal value $val_\Gamma(MPP)(v)$ is a rational number $\frac{y}{z}$ such that $1 \leq z \leq n$ and $|y| \leq z \cdot W$.*

By Lemma 7 the value of each vertex $v \in V$, is contained in the following set of rationals

$$S^\Gamma = \left\{ \frac{y}{z} \;\middle|\; y, z \in \mathbb{Z}, 1 \leq z \leq n \wedge -z \cdot W \leq y \leq z \cdot W \right\}.$$

▶ **Definition 8.** Let Γ be a mean-payoff parity game. We denote the set of vertices $v \in V$ such that $val_\Gamma(MPP)(v) \circ \mu$ where $\circ \in \{<, \leq, =, \geq, >\}$ with $V_\Gamma^{\circ\mu}$.

Key Observation. Let $\Gamma = (V, E, \langle V_1, V_2 \rangle, w, p)$ be a mean-payoff parity game. Let $\mu \in [-W, W]$. The sets $V_\Gamma^{>\mu}, V_\Gamma^{=\mu}$ and $V_\Gamma^{<\mu}$ can be computed using any algorithm for threshold mean-payoff parity games twice (for example using Theorem 6). To calculate $V_\Gamma^{\geq\mu}$ and $V_\Gamma^{<\mu}$ use the algorithm on Γ with the mean-payoff parity objective $\phi = Parity_\Gamma(p) \cap$

$\mathit{MeanPayoff}_\Gamma(\mu)$. Consider $\Gamma' = (V, E, \langle V_2, V_1\rangle, w', p)$, where $w'(e) = -w(e)$ for all edges $e \in E$ and player-1 and player-2 vertices are swapped. To calculate $V_\Gamma^{\leq\mu}$ and $V_\Gamma^{>\mu}$ use the algorithm on Γ' with mean-payoff parity objective $\phi = \mathit{Parity}_{\Gamma'}(p) \cap \mathit{MeanPayoff}_{\Gamma'}(-\mu)$. Given the sets $V_\Gamma^{\leq\mu}$, $V_\Gamma^{>\mu}, V_\Gamma^{\geq\mu}$ and $V_\Gamma^{<\mu}$ we can extract the sets $V_\Gamma^{>\mu}, V_\Gamma^{=\mu}$ and $V_\Gamma^{<\mu}$.
All values μ' in S^Γ are of the form $\frac{y}{z}$. For those values we can determine whether $v \in V_\Gamma^{\geq\mu'}$ by applying the algorithm for threshold mean-payoff parity games on $\Gamma' = (V, E, \langle V_2, V_1\rangle, w', p)$ where $w'(e) = w(e) \cdot z$ for all $e \in E$ with the mean-payoff parity objectives $\phi = \mathit{Parity}_\Gamma(p) \cap \mathit{MeanPayoff}_\Gamma(y)$. Note that in the worst case, the weight function w' of Γ' is in $\mathcal{O}(nW)$.

Dichotomic Search. Let Γ be a mean-payoff parity game. The dichotomic search algorithm is recursive algorithm initialized with $\Gamma_0 = \Gamma$ and $S_0 = S^\Gamma$. In recursive call i the following steps are executed:

1. Let $r_i = \min(S_i)$ and $s_i = max(S_i)$.
2. Determine a_1, the largest element in S_i less than or equal to $\frac{r_i+s_i}{2}$ and a_2, the smallest element in S_i greater than or equal to $\frac{r_i+s_i}{2}$.
3. Determine the partitions $V_{\Gamma_i}^{<a_1}$, $V_{\Gamma_i}^{=a_1}$, $V_{\Gamma_i}^{=a_2}$, $V_{\Gamma_i}^{>a_2}$ using the key observation.
4. For all $v \in V_{\Gamma_i}^{=a_1}$ set the value to a_1, for all $v \in V_{\Gamma_i}^{=a_2}$ set the value to a_2 and set the value to $-\infty$ for all vertices v which are not in any set calculated in step 3.
5. Recurse upon $\Gamma_i \restriction V_{\Gamma_i}^{<a_1}$ and $\Gamma_i \restriction V_{\Gamma_i}^{>a_2}$.

Correctness. Let Γ be a mean-payoff parity game. We prove that the dichotomic search algorithm correctly calculates $val_\Gamma(MPP)(v)$ for all $v \in V$. The algorithm is initialized with Γ and S^Γ. By Lemma 7 the values of the vertices $v \in V$ are in the set S^Γ. Because we perform a binary search over the set S^Γ we can guarantee the termination of the algorithm. Notice that we need to show that the values calculated in the subgames constructed in step 4 are identical to the values in the original game. Then correctness follows immediately by our key observation and because we perform a binary search over the set S^Γ.

▶ **Lemma 9.** *Given a mean-payoff parity game Γ and $\mu \in \mathbb{Q}$, let $\Gamma' = \Gamma \restriction V_\Gamma^{>\mu}$ and $\Gamma'' = \Gamma \restriction V_\Gamma^{<\mu}$. For all $v \in V_\Gamma^{>\mu}$, we have $val_{\Gamma'}(MPP)(v) = val_\Gamma(MPP)(v)$ and for all $v \in V_\Gamma^{<\mu}$, we have $val_{\Gamma''}(MPP)(v) = val_\Gamma(MPP)(v)$.*

Proof. Let $v \in V_\Gamma^{>\mu}$ be arbitrary. We will prove $val_{\Gamma'}(MPP)(v) = val_\Gamma(MPP)(v)$ by showing the following two cases:

- $val_{\Gamma'}(MPP)(v) \leq val_\Gamma(MPP)(v)$: Note that there can be no player-2 vertex in $V_\Gamma^{>\mu}$ with an edge to $V_\Gamma^{\leq\mu}$. Thus we cut away only edges of player-1 vertices in Γ'. Consequently player-1 has less choices in Γ' than in Γ at each of her vertices. Thus $val_{\Gamma'}(MPP)(v) \leq val_\Gamma(MPP)(v)$ holds.
- $val_{\Gamma'}(MPP)(v) \geq val_\Gamma(MPP)(v)$: Let σ_1 be an optimal strategy for player 1 and let σ_2 be an optimal strategy for player 2 which both exist by [11]. We will show that σ_1 produces plays with vertices in $V_\Gamma^{>\mu}$ only, if it starts from v. For the sake of contradiction assume that a play $\rho = \mathit{outcome}(v, \sigma_1, \sigma_2)$ contains a vertex $v^* \in V_\Gamma^{\leq\mu}$. Notice that there are no player-2 vertices in $V_\Gamma^{>\mu}$ with edges to $V_\Gamma^{\leq\mu}$. Thus σ_1 chose a successor vertex in $V_\Gamma^{\leq\mu}$. But when ρ ends up in $V_\Gamma^{\leq\mu}$ the optimal player-2 strategy σ_2 can guarantee that $MPP_\Gamma(w, p, \rho) \leq \mu$ by the definition of $V_\Gamma^{\leq\mu}$. There is a strategy to keep the value of the play starting at v greater than μ by the definition of $V_\Gamma^{>\mu}$. Thus any play ρ leading to $V_\Gamma^{\leq\mu}$ by σ_1 is not optimal which is a contradiction to our assumption. Consequently $val_{\Gamma'}(MPP)(v) \geq val_\Gamma(MPP)(v)$ follows.

The fact that for all $v \in V_\Gamma^{<\mu}$, we have $val_{\Gamma''}(MPP)(v) = val_\Gamma(MPP)(v)$ follows by a symmetric argument. ◀

Running Time. The running time of the dichotomic search is $\mathcal{O}(n \cdot \log(nW) \cdot \mathsf{TH})$ where TH is the running time of an algorithm for the threshold mean-payoff parity problem. The additional factor n comes from rescaling the weights of the mean-payoff parity game Γ which is described in the key observation. The factor $\mathcal{O}(\log(nW))$ is from using binary search on S as $|S| = \mathcal{O}(n^2 \cdot W)$.

▶ **Theorem 10.** *Given a game graph Γ and an algorithm that solves the threshold mean-payoff parity problem in $\mathcal{O}(\mathsf{TH})$, the value function of Γ can be computed in time $\mathcal{O}(n \cdot \log(nW) \cdot \mathsf{TH})$.*

As a corollary of the above theorem and Theorem 6, the value function for mean-payoff parity games can be computed in $\mathcal{O}(n^d \cdot m \cdot W \cdot \log(nW))$ time.

6 Conclusion

In this paper we present faster algorithms for mean-payoff parity games. Our most interesting results are for mean-payoff Büchi and mean-payoff coBüchi games, which are the base cases. For threshold mean-payoff Büchi and mean-payoff coBüchi games, our bound $\mathcal{O}(n \cdot m \cdot W)$ matches the current best-known bound for mean-payoff games. For the value problem, we show the dichotomic search approach of [5] for mean-payoff games can be generalized to mean-payoff parity games. This gives an additional multiplicative factor of $n \cdot \log(nW)$ as compared to the threshold problem. A recent work [14] shows that the value problem for mean-payoff objective can be solved with a multiplicative factor n compared to the threshold objective (i.e., it shaves of the log factor). An interesting question is whether the approach of [14] can be generalized to mean-payoff parity games.

Abstract

An automaton is synchronizing if there exists a word that sends all states of the automaton to a single state. The reset threshold is the length of the shortest such word. We study the set RT_n of attainable reset thresholds by automata with n states. Relying on constructions of digraphs with known local exponents we show that the intervals $\left[1,(n^2-3n+4)/2\right]$ and $[(p-1)(q-1),p(q-2)+n-q+1]$, where $2\le p<q\le n, p+q>n, \gcd(p,q)=1$, belong to RT_n, even if restrict our attention to strongly connected automata. Moreover, we prove that in this case the smallest value that does not belong to RT_n is at least $n^2-O(n^{1.7625}\log n/\log\log n)$. This value is increased further assuming certain conjectures about the gaps between consecutive prime numbers. We also show that any value smaller than $\frac{n(n-1)}{2}$ is attainable by an automaton with a sink state and any value smaller than $n^2-O(n^{1.5})$ is attainable in general case. Furthermore, we solve the problem of existence of slowly synchronizing automata over an arbitrarily large alphabet, by presenting for every fixed size of the alphabet an infinite series of irreducibly synchronizing automata with the reset threshold $n^2-O(n)$.

1 Introduction

Let $\mathscr{A} = (Q, \Sigma, \delta)$ be a *deterministic complete finite (semi)automaton* with the set of states Q, the alphabet Σ, and the transition function $\delta\colon Q \times \Sigma \to Q$. We denote the image of a state q under the action of a word w as $q \cdot w$. Automaton $\mathscr{A}$ is called *synchronizing* if there exist a word w and a state f such that for every state $q \in Q$ we have $q \cdot w = f$. Every such word w is called *synchronizing* (or *reset*) word for $\mathscr{A}$. The length of the shortest synchronizing word of $\mathscr{A}$ is called the *reset threshold* and is denoted by $\mathrm{rt}(\mathscr{A})$. This notion can be extended to subsets: for a subset $S \subseteq Q$, $\mathrm{rt}(\mathscr{A}, S)$ is the length of the shortest word w such that $|\delta(S, w)| = 1$.

Synchronizing automata constitute a well-studied class of automata with applications to group theory [4], coding theory [6, Chapter 10], industrial automation, matrix and control theories [7], etc. A brief survey of the theory of synchronizing automata can be found in [18, 33].

The reset threshold is one of the most important characteristics of a synchronizing automaton. One can compute a synchronizing word following a greedy strategy in polynomial-time, but finding the shortest such word is hard. The problem of deciding whether $\mathrm{rt}(\mathscr{A}) = k$ for a given automaton $\mathscr{A}$ and an integer k encoded in binary is DP-complete [23]. Moreover, unless P = NP, there is no polynomial-time algorithm computing the reset threshold with the approximation error $O(n^{1-\varepsilon})$ for a fixed $\varepsilon > 0$ [13]. Furthermore, widely used greedy algorithms have approximation error $\Omega(n)$, where n is the number of states in a given automaton [2].

One of the most famous open problems in automata theory is to determine general bounds on the reset thresholds of automata with n states. *The Černý conjecture* states that the reset threshold of an automaton is at most $(n-1)^2$ [10, 11]. Furthermore, this bound is reached by the Černý automaton $\mathscr{C}_n$ with n states, see [33, p. 18]. Despite intensive efforts of researchers and confirmation of this conjecture in various special classes of automata the best upper bound obtained so far is $(15617n^3 + 7500n^2 + 9375n - 31250)/93750$ [29].

The difficulty of the Černý conjecture led to a large number of attempts to disprove it by means of a counterexample obtained via computational experiments [31, 3, 20]. Although, no counterexample was ever found, several interesting observations were made. For example, it was noted that there are no synchronizing automata with n states and two letters with the reset threshold in the range $[n^2 - 3n + 5, (n-1)^2 - 1]$ for $n = 7, \ldots, 12$. Afterwards, a few more potential "gaps" were identified. It leads us in turn to the following general question that we address in our paper:

> What is the set RT_n of possible reset thresholds
> for synchronizing automata with n states?

Clearly, a complete answer to this question is out of reach for the state of the art techniques as the Černý conjecture is merely about an upper bound on RT_n. Nevertheless, it is possible to describe certain values belonging to RT_n by presenting synchronizing automata with known reset thresholds. This problem is also not trivial as one has to prove that a constructed automaton is not only synchronized by a word of the claimed length, but also demonstrate that any shorter word is not synchronizing.

Additional interest to results of this kind comes from the following reasons. Concrete examples of synchronizing automata with known reset thresholds shed light on the phenomenon of synchronization giving hints on potential proof of the Černý conjecture. Furthermore, the availability of hands on examples is important for the evaluation of new ideas and algorithms.

Synchronizing automata with the reset threshold close to $(n-1)^2$, so called slowly synchronizing automata, are especially important as they almost never appear in random samples of synchronizing automata. Moreover, the ideas used in construction of synchronizing automata with known reset thresholds could also lead to interesting connections between different fields. For example, a new line of research devoted to the interplay between synchronizing automata and primitive matrices was started in [3], see [14] for recent results. Part of our current work can be seen as a continuation of this line of research.

Over the years a large number of synchronizing automata with known reset thresholds were presented in the literature. It can be either sporadic examples possessing interesting properties [31, 33] or infinite series of automata designed to give a lower bound on the largest reset threshold among synchronizing automata belonging to a special class. For example, constructions of automata with the sink state are given in [1, 24, 26], Eulerian automata in [15, 30], automata with the reset threshold close to $(n-1)^2$ [3]. Multi-parametric series of automata with the aim of covering RT_n were presented in [16].

Our contributions. In the present paper we significantly expand the list of values known to belong to RT_n. Moreover, we present non-trivial lower bounds on the smallest value that does not belong to RT_n. Our approach can be summarized as follows. Recall that a subset of states $\mathcal{C}$ of the automaton $\mathscr{A}$ is a *sink* if $\delta(q,\ell) \in \mathcal{C}$ for every $q \in \mathcal{C}$ and $\ell \in \Sigma$. A classical observation states that a synchronizing automaton has the unique strongly connected sink component $\mathcal{C}$. Furthermore, the process of synchronization can be performed in the following manner: initially, one applies a word u such that $Q \cdot u \subseteq \mathcal{C}$, i.e. the automaton is brought to $\mathcal{C}$, afterwards, one applies v such that $|\mathcal{C} \cdot v| = 1$. Therefore, we consider three natural cases.

Case (i) strongly connected automata. In Section 2 we construct synchronizing automata belonging to this class with known reset thresholds based on examples of digraphs with known local exponents [28]. We show that the intervals $\left[1, (n^2-3n+4)/2\right]$ and $[(p-1)(q-1), p(q-2)+n-q+1]$, where $2 \leq p < q \leq n, p+q > n, \gcd(p,q) = 1$, belong to the set of attainable reset thresholds by n-state automata. The method that we use to convert digraphs into synchronizing automata is based on techniques recently introduced in [7, 14].

Let $\mathrm{gt}_{sc}(n)$ be the smallest value that does not serve as the reset threshold of a strongly connected automaton with n states. In Section 3 we show that $\mathrm{gt}_{sc}(n)$ is at least $n^2 - \tilde{O}(n^{1.7625})$, where $\tilde{O}(f(n))$ is the shorthand for $O(f(n)\log^k(f(n))$ for some k. Moreover, we strengthen this bound conditioning on the validity of classical conjectures related to the distribution of prime numbers. If the Riemann hypothesis is true, then $\mathrm{gt}_{sc}(n) \geq n^2 - \tilde{O}(n^{1.75})$. If the Cramer's conjecture is true, then $\mathrm{gt}_{sc}(n) \geq n^2 - \tilde{O}(n^{1.5})$. Our proofs are based on rigorous analysis of the overlaps of the aforementioned intervals. Similar intervals often appear in index set problems about digraphs and Boolean matrices, so our techniques can be applied to them as well [22].

Case (ii) automata with the sink state. The reset threshold of automata belonging to this class is bounded by $\frac{n(n-1)}{2}$, moreover, there exists a series of n-state automata reaching this bound [26]. In Section 4 we generalize this series to prove that for every $1 \leq \ell \leq \frac{n(n-1)}{2}$ there exists an n-state automaton with sink and the reset threshold equal to ℓ.

Case (iii) automata without restrictions. In Section 5 we utilize ideas of the previous cases to show that for every $1 \leq \ell \leq n^2 - O(n^{1.5})$ there exists an n-state synchronizing automaton with reset threshold equal to ℓ. This result does not depend on the number theoretic conjectures.

The number of letters of automata constructed in the previous cases grows with the number of states. In Section 6 we aim to get a better understanding on how the number of letters influences the set of possible reset thresholds. To avoid trivial cases we focus on *irreducibly synchronizing* automata, i.e. automata that become non-synchronizing after the removal of any letter. We resolve an open problem asking whether for each fixed size of the alphabet there is a series of irreducibly synchronizing n-state automata with the reset threshold $n^2 - O(n)$. Previously, such automata were known only over 2-letter and 3-letter alphabets [3, 21]. Namely, we construct infinite (in n and k) series of automata $\mathscr{M}_{n,k}$, $\mathscr{M}'_{n,k}$ with n states and k letters such that $rt(\mathscr{M}_{n,k}) = n^2 - (k+3)n + 2k + 3$ and $rt(\mathscr{M}'_{n,k}) = n^2 - (k+3)n + 2k + 4$. These examples can be also seen as a formal bound to the following common empirical statement: synchronizing automata with large number of letters have relatively small reset thresholds (due to a large number of possibilities at every step of synchronization).

2 Strongly connected automata

A digraph G is *primitive* if there exists a positive integer t such that for every pair of vertices u, v of G there exists a walk from u to v of length exactly t. The smallest such t is called the exponent of G and denoted by $\exp(G)$. A survey of results about this classical notion can be found in [9, Chapter 3.5].

The notion of local exponent was introduced in [8]. The *local exponent* of G at a vertex u, denoted by $\exp_G(u)$ or $\exp(u)$, is the smallest t such that for every vertex v of G there is a walk from u to v of length exactly t. Let $V = \{1, 2, \ldots, n\}$. We will always assume that the vertices are reordered so that $\exp_G(1) \leq \exp_G(2) \leq \ldots \leq \exp_G(n)$.

The behavior of the exponents and the local exponents of digraphs with n vertices gained a lot of attention in literature. Let $\mathrm{ES}_n(1)$ be the set of possible first local exponents of all digraphs with n vertices, i.e. $\mathrm{ES}_n(1) = \{\exp_G(1) \mid G = (V, E), |V| = n, G \text{ is primitive}\}$.

▶ **Theorem 1** ([28, Theorem 9])**.**

$$\mathrm{ES}_n(1) = \left[1, \frac{n^2 - 3n + 4}{2}\right] \bigcup \bigcup_{(p,q)\in L(n)} [(p-1)(q-1), p(q-2) + n - q + 1],$$

where $L(n) = \{(p, q) : 2 \leq p < q \leq n, p + q > n, \gcd(p, q) = 1\}$.

We will rely on Theorem 1 to construct synchronizing automata with known reset thresholds. The proof of the following proposition is based on the "determinization" procedure appearing in [7, 14, 17].

▶ **Proposition 2.** *Let $G(V, E)$ be a primitive n-vertex digraph. Then there exists a synchronizing n-state automaton $\mathscr{A}$ such that* $\mathrm{rt}(\mathscr{A}) = \exp_G(1)$.

Proof. The automaton $\mathscr{A}$ is constructed as follows. The set of states is equal to $V = \{1, 2, \ldots, n\}$. For every choice of states $s_1, s_2, \ldots, s_n \in V$ such that $(s_1, 1), (s_2, 2), \ldots, (s_n, n) \in E$ we add the letter $(s_1, \ldots, s_n)$ with the action $\delta(j, (s_1, \ldots, s_n)) = s_j$ for every $j \in V$.

We need to show that $\mathscr{A}$ is synchronizing and $\mathrm{rt}(\mathscr{A}) = \exp_G(1)$. Since G is primitive and every vertex is reachable from 1 in $\exp_G(1)$ steps there exists a sequence of n-tuples $(v_1^{(1)} = 1, v_2^{(1)} = 1, \ldots, v_n^{(1)} = 1), (v_1^{(2)}, v_2^{(2)}, \ldots, v_n^{(2)}), \ldots, (v_1^{(t)} = 1, v_2^{(t)} = 2, \ldots, v_n^{(t)} = n)$ of length $t = \exp_G(1)$ and such that for every $2 \leq i \leq t$, $1 \leq j \leq n$ we have $(v_j^{(i-1)}, v_j^{(i)}) \in E$. Furthermore, we can assume that if $v_j^{(i)} = v_k^{(i)}$ for some i, j, k then $v_j^{(\ell)} = v_k^{(\ell)}$ for all $\ell \leq i$.

Indeed, by substituting the value of $v_j^{(\ell)}$ to $v_k^{(\ell)}$ for all $\ell \leq i$ we will obtain a sequence satisfying all of the aforementioned properties.

Observe now that for every $i \geq 2$ there is a letter of $\mathscr{A}$ that maps the tuple $(v_1^{(i)}, v_2^{(i)}, \ldots, v_n^{(i)})$ to $(v_1^{(i-1)}, v_2^{(i-1)}, \ldots, v_n^{(i-1)})$, namely, any letter $(s_1, \ldots, s_n)$ satisfying $s_{v_j^{(i)}} = v_j^{(i-1)}$ for all $1 \leq j \leq n$. Thus, the sequence of tuples can be seen as an application of a word w mapping the set $\{1, 2, \ldots n\}$ to $\{1\}$. In other words, w is a synchronizing word of length $\exp_G(1)$.

It remains to note that $\mathrm{rt}(\mathscr{A}) \geq \exp_G(1)$. Indeed, every synchronizing word w mapping V to $\{f\}$ labels walks leading from every state to f; moreover, the edges of $\mathscr{A}$ are the inverted edges of G. Thus, every vertex of G is reachable from f in $|w|$ steps. Since $\exp_G(1)$ is the smallest number with this property, we have $|w| \geq \exp_G(1)$. ◀

By combining Theorem 1 and Proposition 2 we obtain the main result of this section:

▶ **Theorem 3.** *For every n, $\mathrm{ES}_n(1) \subset \mathrm{RT}_n$. Furthermore, it remains true even in the case of strongly connected automata.*

▶ **Remark 4.** *Clearly, $\mathrm{RT}_n \not\subset \mathrm{ES}_n(1)$, since the largest local 1-exponent is at most n^2-3n+3, by Theorem 1 (originally [27, Theorem 2.1]), while the Černý series of automata has the reset threshold equal to $(n-1)^2$.*

Proposition 2 is also tightly connected to the Hybrid Černý-Road Coloring conjecture [3, Conjecture 2]. Let G be a digraph with the set of edges E, and Σ be a finite alphabet. A *coloring* of G is an arbitrary deterministic finite state automaton obtained by distributing letters of Σ over the edges E. Note that G typically has a large number of colorings. The celebrated Road Coloring Theorem states that every primitive digraph with out-degree k has a synchronizing coloring with k letters [32]. The Hybrid Černý-Road Coloring conjecture states that such synchronizing coloring can always be found with the reset threshold at most $n^2 - 3n + 3$.

▶ **Corollary 5.** *Let G be a primitive digraph with n vertices. There exists an alphabet Σ and a coloring $\mathscr{A}$ of G with Σ such that $\mathscr{A}$ is a synchronizing automaton and $\mathrm{rt}(\mathscr{A}) \leq n^2 - 3n + 3$. In other words, the Hybrid Černý-Road Coloring conjecture holds true if we are allowed to use an alphabet of arbitrary size.*

Proof. The proof of Proposition 2 describes a procedure to derive a synchronizing coloring of $\overleftarrow{G}$ – the digraph obtained by reversing all the edges of G, with the reset threshold equal to $\exp_G(1)$. Since $\exp_G(1)$ is bounded by $n^2 - 3n + 3$ by Theorem 1, the corollary follows. ◀

3 Lower bounds on the smallest unattainable value

In this section we will derive a lower bound on the smallest value that is not a reset threshold of a strongly connected n-state automaton. The proof of main theorem is based on the following number theoretic result.

Let $g(x)$ be the maximal difference (*prime gap*) between any prime number $p \leq x$ and the next prime number. It is known that $g(x) \leq x^{0.525}$ when x is large enough [5].

Let $\omega(x)$ be the maximal number of distinct prime divisors of any number $i \leq x$. It is known that $\omega(x) \leq 1.38402 \log x / \log\log x$ for $x \geq 3$ [25].

▶ **Theorem 6.** *For n large enough, the function*

$$f(n) = 6n + 4n \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big)$$

satisfies the following equation:

$$\left[\left\lceil\frac{n^2}{3}\right\rceil, \lfloor n^2 - f(n)\rfloor\right] \subseteq \bigcup_{(p,q)\in L(n)} [(p-1)(q-1), (p-1)(q-1)+n-p],$$

where $L(n) = \{(p,q) \mid 2 \le p < q \le n, p+q > n, \gcd(p,q) = 1\}$.

▶ **Corollary 7.** *Using the known upper bound* $g(x) \le x^{0.525}$ [5] *we obtain*

$$f(n) = O(n^{1.7625}\log n/\log\log n).$$

Moreover, if we assume the Riemann hypothesis, which implies $g(x) \in O(\sqrt{x}\log x)$ [12]*, we get*

$$f(n) = O(n^{1.75}\log^2 n/\log\log n).$$

If we assume the Cramer's conjecture $g(x) \in O(\log^2 x)$ [12]*, we get*

$$f(n) = O(n^{1.5}\log^3 n/\log\log n).$$

Before proving Theorem 6 we will derive the main result of this section:

▶ **Theorem 8.** *Let* $\mathrm{gt}_{sc}(n) \ge 1$ *be the smallest unattainable value by the reset thresholds of* n*-state strongly connected synchronizing automata. Then* $\mathrm{gt}_{sc}(n)$ *grows at least as fast as* $n^2 - O(f(n))$*, where* $f(n)$ *is the function from Corollary 7. In particular,*

$$\lim_{n\to\infty} \mathrm{gt}_{sc}(n)/n^2 = 1.$$

Proof. By Theorems 1 and 3 and Proposition 2 we know that for every integer in $[1, (n^2-3n+4)/2]$ there exists an automaton with the reset threshold equal to it. Also, from Theorem 6 and Corollary 7 we obtain the same result for the interval $[\left\lceil\frac{n^2}{3}\right\rceil, n^2 - O(n^{1.7625}\log n/\log\log n)]$. In other words, $\mathrm{gt}_{sc}(n)$ is at least $n^2 - O(f(n))$. Since $O(n^{1.7625}\log n/\log\log n)$ grows strictly slower than n^2, we have $\mathrm{gt}_{sc}(n)/n^2$ tending to 1 when $n \to \infty$. ◀

▶ **Remark 9.** *Theorem 6 establishes a lower bound on the least value that does not belong to* ES_n *as well.*

Now we are going to prove Theorem 6. Let n be large enough. Let x be any integer from $[\lceil\frac{n^2}{3}\rceil, \lfloor n^2 - f(n)\rfloor]$. We will show that x falls in the interval $[(p-1)(q-1), (p-1)(q-1)+n-p]$ of some $(p,q) \in L(n)$. Let k be the smallest odd integer such that $x \le k^2$.

$$(k-2)^2 < x \le k^2.$$

We define

$$S = \{p \in [3, n-k-1] \mid (p \text{ is prime}) \wedge p \nmid (k+1)\}.$$

▶ **Lemma 10.** *For every* $s \in S$*, each pair* $(p,q) = (k+1-s, k+1+s)$ *is in* $L(n)$*.*

Proof. It is enough to check all conditions for (p,q) in $L(n)$. For the first condition $p = k+1-s \ge k+1-(n-k-1) = 2(k+1)-n \ge 2\sqrt{x}-n$. Because $3x \ge n^2$ (so $\sqrt{x} \ge n/\sqrt{3}$), we have $2\sqrt{x}-n \ge (2/\sqrt{3}-1)n$. So for $n \ge 13$, we have $p \ge 2$.

The condition $p < q$ is obvious, and $q = k+1+s \le k+1+n-k-1 = n$.

The next condition states that $p+q > n$ and it is clear, since $p+q = 2(k+1) \geq 2\sqrt{x} \geq 2n/\sqrt{3} > n$.

Now we show that p and q are coprime. Let d be a non-trivial common divisor of p and q. Then also d divides $q-p = 2s$. Since s is prime, d is either 2 or s. But $q = k+1+s$ is odd, since $k+1$ is even and s is odd. Also s cannot divide $q = k+1+s$, since by definition of s, s is not a divisor of $k+1$. Thus, p and q are coprime. ◀

Let $\text{next}_S(i)$ be the smallest number in S greater than i (if it exists). Let $\text{next}_P(i)$ be similarly defined for the set of prime numbers. For all i, we have $\text{next}_P(i) - i \leq g(i)$.

To simplify formulas we define:

$$b_k(s) = (k-s)(k+s) = k^2 - s^2$$
$$e_k(s) = (k-s)(k+s) + n - (k+1) + s = k^2 - s^2 + n - (k+1) + s$$
$$I_k(s) = [b_k(s), e_k(s)] = [k^2 - s^2, k^2 - s^2 + n - (k+1) + s]$$

Notice that $I_k(s)$ is the interval from Theorem 6 with $(p,q) = (k+1-s, k+1+s)$, which according to Lemma 10 is a pair from $L(n)$ for every $s \in S$.

Our plan is as follows. We will show the existence of $s_{max} \in S$ such that $b_k(s_{max}) \leq (k-2)^2$ and for every two consecutive elements $s, \text{next}_S(s) \in S \cap [3, s_{max}]$, the intervals $I_k(s)$ and $I_k(\text{next}_S(s))$ overlap. Since $b_k(s_{max}) \leq (k-2)^2$ and $k^2 \leq e_k(\text{next}_S(0))$, it will prove that the intervals

$$I_k(\text{next}_S(0)), \ldots, I_k(s), I_k(\text{next}_S(s)), \ldots, I_k(s_{max})$$

cover all integers from $[(k-2)^2, k^2]$. So in particular x will be covered.

▶ **Lemma 11.** *For every $\varepsilon \in [0,1)$, when n is large enough, there is $s_{max} \in S$ satisfying $b_k(s_{max}) \leq (k-2)^2$ and $2\sqrt{k-1} \leq s_{max} \leq (2+\varepsilon)\sqrt{k-1}$.*

Proof. Let s_{max} be the smallest prime number $\geq 2\sqrt{k-1}$ and such that $s_{max} \nmid k+1$.

We show that $s_{max} \in S$. Let p be the first prime number $\geq 2\sqrt{k-1}$. If $p \neq s_{max}$, then $p \mid k+1$. But since $p \geq 2\sqrt{k-1}$ there is no other prime number $p' > p$ such that $p' \mid (k+1)$, as otherwise $p' \cdot p \geq 4(k-1) > k+1$ (for $k \geq 2$). Hence, $s_{max} = \text{next}_P(p) > p$. So for both cases we get the upper bound:

$$\begin{aligned} s_{max} &\leq \text{next}_P(\text{next}_P(2\sqrt{k-1})) \\ &\leq 2\sqrt{k-1} + 2g(2\sqrt{k-1} + g(2\sqrt{k-1})). \end{aligned}$$

According to the bound $g(n) < n^\theta$ for $\theta = 0.525$ [5],

$$\begin{aligned} s_{max} &\leq 2\sqrt{k-1} + 2(4\sqrt{k-1})^\theta \\ &\leq 2\sqrt{k-1} + 2 \cdot 4^\theta \cdot (k-1)^{\theta/2} \\ &\leq 2\sqrt{k-1}(1 + 4^\theta \cdot (k-1)^{(\theta-1)/2}). \end{aligned}$$

Since $k \geq n/\sqrt{3}$, we have

$$0 \leq \lim_{k\to\infty} 4^\theta (k-1)^{0.5(\theta-1)} \leq \lim_{n\to\infty} 4^\theta (n/\sqrt{3} - 1)^{0.5(\theta-1)} = 0.$$

So for n large enough, we obtain the upper bound:

$$s_{max} \leq (2+\varepsilon)\sqrt{k-1}.$$

Observe that:

$$\begin{aligned} k^2 &= (k-2)^2 + 4k - 4 \\ &< x + 6k \\ &< n^2 - f(n) + 6n \\ &< n^2 - 24n\sqrt{n} \\ &< n^2 - 24n\sqrt{n} + (12\sqrt{n})^2, \end{aligned}$$

and so $k < n - 12\sqrt{n}$. From this we obtain:

$$\begin{aligned} s_{max} &\leq (2+\varepsilon)\sqrt{k-1} \\ &< 3\sqrt{n-1} \\ &< 12\sqrt{n} - 1 \\ &\leq n - (n - 12\sqrt{n}) - 1 \\ &\leq n - k - 1. \end{aligned}$$

Thus, $s_{max} \in [3, n-k-1]$ and therefore is in S.
Finally, we have:

$$\begin{aligned} s_{max} &\geq 2\sqrt{k-1} \\ s_{max}^2 &\geq 4(k-1) \\ k^2 - s_{max}^2 &\leq k^2 - 4k + 4 \\ b_k(s_{max}) &\leq (k-2)^2. \end{aligned}$$

◀

▶ **Lemma 12.** *For every $s \in S \cap [3, s_{max} - 1]$, the intervals $I_k(s)$ and $I_k(\mathrm{next}_S(s))$ overlap, that is, $b_k(s) \leq e_k(\mathrm{next}_S(s))$. Moreover $k^2 \leq e_k(\mathrm{next}_S(0))$.*

Proof. We have $\mathrm{next}_S(s) \leq s_{max}$, because $s_{max} \in S$. Notice that

$$\mathrm{next}_S(s) \leq s + g(s_{max}) \cdot \big(\omega(k+1) + 1\big), \tag{1}$$

because the number of distinct prime odd divisors of $k+1$ is at most $\omega(k+1)$, and the gap between every two consecutive of the prime divisors is bounded from above by $g(s_{max})$.

Observe that:

$$\begin{aligned} (k+1)^2 &< (k-2)^2 + 6k - 3 \\ &< x + 6k \\ &< n^2 - f(n) + 6n \\ &\leq n^2 - 4n \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big) \\ &< n^2 - 4n \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big) + \\ &\quad + \Big(2 \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big)\Big)^2, \end{aligned}$$

and so

$$k + 1 < n - 2 \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big). \tag{2}$$

Then we have:

$$\begin{aligned} e_k\big(\mathrm{next}_S(s)\big) - b_k(s) &= -\mathrm{next}_S(s)^2 + n - (k+1) + \mathrm{next}_S(s) + s^2 \\ &> n - (k+1) + s^2 - \mathrm{next}_S(s)^2. \end{aligned} \tag{3}$$

Using (1) we obtain:

$$\begin{aligned} e_k\big(\mathrm{next}_S(s)\big) - b_k(s) &> n - (k+1) + s^2 - \Big(s + \big(\omega(k+1)+1\big)g(s_{max})\Big)^2 \\ &= n - (k+1) - g(s_{max}) \cdot \big(\omega(k+1)+1\big)\Big(g(s_{max}) \cdot \big(\omega(k+1)+1\big) + 2s\Big) \end{aligned}$$

using (2) we obtain:

$$\begin{aligned} &\geq n - \Big(n - 2 \cdot g(3\sqrt{n}) \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \omega(n) + 6\sqrt{n}\big)\Big) \\ &\quad - g(s_{max}) \cdot \big(\omega(k+1)+1\big) \cdot \Big(g(s_{max}) \cdot \big(\omega(k+1)+1\big) + 2s\Big) \\ &\geq g(3\sqrt{n}) \cdot \sqrt{2} \cdot \omega(n) \cdot \big(g(3\sqrt{n}) \cdot \sqrt{2} \cdot \omega(n) + 6\sqrt{n}\big) \\ &\quad - g(s_{max}) \cdot \big(\omega(k+1)+1\big) \cdot \Big(g(s_{max}) \cdot \big(\omega(k+1)+1\big) + 2s\Big) \end{aligned} \tag{4}$$

Observe that $3\sqrt{n} > (2+\varepsilon)\sqrt{k-1} \geq s_{max}$ from Lemma 11. Also, since $n > k+1$ (by (2)), for $n \geq 30$ we have $\omega(n) \geq 3$ and so $\sqrt{2} \cdot \omega(n) \geq \omega(k+1)+1$. Because functions g and ω are monotonic, we finally obtain that (4) ≥ 0.

Consider $e_k\big(\mathrm{next}_S(0)\big) - k^2$. Then it is equal to (3) with $s = 0$. All the above inequalities remains unchanged and then $k^2 \leq e_k(\mathrm{next}_S(0))$. ◀

Summarizing, for each $x \in [n^2/3, n^2 - f(n)]$ we find some k such that $x \in [(k-2)^2, k^2]$. From Lemma 11 we know that there exists $s_{max} \in S$ such that $b_k(s_{max}) \leq (k-2)^2$. From Lemma 12 we also get $k^2 \leq e_k\big(\mathrm{next}_S(0)\big)$, and the intervals for consecutive values from S between $\mathrm{next}_S(0)$ and s_{max} overlap. Hence, in particular, x belongs to some interval $I_k(s_x)$ where $s_x \in S$, $\mathrm{next}_S(0) \leq s_x \leq s_{max}$. Lemma 10 ensures that the pair $(k+1-s_x, k+1+s_x)$ belongs to $L(n)$ from the Theorem 6, so x is covered.

4 Automata with a sink state

It is known that if a synchronizing automaton $\mathscr{A}_n$ has a sink state, then $\mathrm{rt}(\mathscr{A}_n) \leq \frac{(n-1)n}{2}$ [26]. We show that reset thresholds of automata with a sink state cover all values in $[1, \ldots, \frac{(n-1)n}{2}]$, at least if the size of the alphabet can be quadratic in n.

We construct a class of automata as follows. Let $T_n(V, E)$ be an undirected tree with $n = |V|$ vertices and the root r. We construct $\mathscr{A}(T_n) = (V, E, \delta)$, and the action of every letter $\{v_1, v_2\}$ is defined as follows:

$$\delta(v, \{v_1, v_2\}) = \begin{cases} v_1 & \text{if } v = v_2 \text{ and } r \notin \{v_1, v_2\}, \\ v_2 & \text{if } v = v_1 \text{ and } r \notin \{v_1, v_2\}, \\ r & \text{if } v, r \in \{v_1, v_2\}, \\ v & \text{otherwise.} \end{cases}$$

For $v \in V$ let $d(v)$ denote the distance in T_n from v to the root; hence $d(r) = 0$. For a subset $S \subseteq V$ we define:

$$U(T_n, S) = \sum_{q \in S} d(q).$$

▶ **Lemma 13.** *For every rooted tree $T_n(V, E)$ and every subset $S \subseteq V$ we have:* $\mathrm{rt}(\mathscr{A}(T_n), S) = U(T_n, S)$.

Proof. The proof follows easily by induction on $U(T_n, S)$. The case $U(T_n, S) = 0$ is trivial, since it must be that $S = \{r\}$. Let $U(T_n, S) \geq 1$ and assume that the claim holds for all S' such that $U(T_n, S') < U(T_n, S)$. Then observe that the action of any letter $\{v_1, v_2\} \in E$ increases the value of $U(T_n, S)$ by 1, decreases the $U(T_n, S)$ by 1, or does not change it. Moreover, we can always find such $\{v_1, v_2\}$ that decreases the value by 1, i.e. when $v_1 \in S$ and $v_2 \notin S$, or $v_1 = r$ and $v_2 \in S$. Thus the claim follows inductively and the automaton is synchronizing. ◀

▶ **Proposition 14.** *Given $n \geq 2$, for every $k \in [1, \ldots, \frac{(n-1)n}{2}]$ there exists an automaton $\mathscr{A}_n$ with a sink state and* $\mathrm{rt}(\mathscr{A}) = k$.

Proof. First, we consider the case of $k \geq n-1$. For each such k we construct a tree $T_n(V, E)$ with $U(T_n, V) = k$ and the claimed result follows by Lemma 13. We proceed by induction:

1. the *star* ($E = \{\{v, r\} \mid v \in V\}$) is suitable for the case of $n-1$;
2. let $T_n(V, E)$ be a tree such that $U(T_n, V) = k$. If the height of T_n is equal to $n-1$, then T_n is a *path* graph and $U(T_n, V) = \frac{(n-1)n}{2}$. Thus, we can assume that the height of T_n is smaller than $n-1$. We construct a new tree $T'_n(V', E)$ such that $U(T_n, V') = k+1$ in the following manner. Observe, that there exist two vertices v_1, v_2, both distinct from the root, that are leaves; without loss of generality let $d(v_1) \leq d(v_2)$. We will remove v_1, which does not change $d(v_2)$. Afterwards, we can find a vertex v_3 such that $d(v_3) = d(v_1)$, and attach v'_1 to v_3 as a leaf; thus $d(v'_1) = d(v_2) + 1$ and $U(T_n, V') = k+1$.

Hence, we can construct the tree for any k starting from $n-1$.

Finally, for $k \in \{1, \ldots, n-2\}$ let $\mathscr{A}_n(V, E, \delta)$ be the automaton with $V = \{r, v_1, \ldots, v_{n-1}\}$, $E = \{e_1, \ldots, e_k\}$ and the transitions defined by

$$\delta(v_i, e_j) = \begin{cases} r & \text{if } i = j \text{ or } i > k, \\ v_i & \text{otherwise.} \end{cases}$$

Obviously, to synchronize $\mathscr{A}_n$ it is sufficient and necessary to use a word with every letter from E. ◀

5 General case

Let $\mathscr{C}_m(Q, \Sigma, \delta_{\mathscr{C}})$ be the Černý automaton with m states [10]: $Q = \{q_0, \ldots, q_{m-1}\}$, $\Sigma = \{a, b\}$, $\delta_{\mathscr{C}}(q_{m-1}, a) = q_0$ and $\delta_{\mathscr{C}}(q_i, a) = q_i$ for $i \leq m-2$, and $\delta_{\mathscr{C}}(q_i, b) = (q_i + 1) \bmod m$.

Let $T_{m'}(V, E)$ be a tree with m' vertices and let $\mathscr{A}(T_{m'}) = (V, E, \delta_{\mathscr{A}})$ be the automaton from Section 4.

Given $\mathscr{C}_m$ and $\mathscr{A}(T_{m'})$ we construct the joint automaton $\mathscr{B}_n$ with $n = m + m' - 1$ states. This is done by union of both automata, while identifying the sink state r of $\mathscr{A}(T_{m'})$ with state q_0 of $\mathscr{C}_m$ and extending the actions of the letters for the states of the other automaton to identity.

Formally, assume that the alphabets Σ and E are disjoint, r is the sink state of $\mathscr{A}(T_{m'})$, and let $\mathscr{B}_n = (Q \cup V \setminus \{r\}, \Sigma \cup E, \delta)$, where δ is defined as follows:

$$\delta(q, a) = \begin{cases} \delta_{\mathscr{C}}(q, a) & \text{if } q \in Q \text{ and } a \in \Sigma, \\ \delta_{\mathscr{A}}(q, a) & \text{if } q \in V \setminus \{r\},\ a \in E, \text{ and } \delta_{\mathscr{A}}(q, a) \neq r, \\ q_0 & \text{if } q \in V \setminus \{r\},\ a \in E, \text{ and } \delta_{\mathscr{A}}(q, a) = r, \\ q & \text{if } q \in Q \text{ and } a \in E, \text{ or } q \in V \setminus \{r\} \text{ and } a \in \Sigma. \end{cases}$$

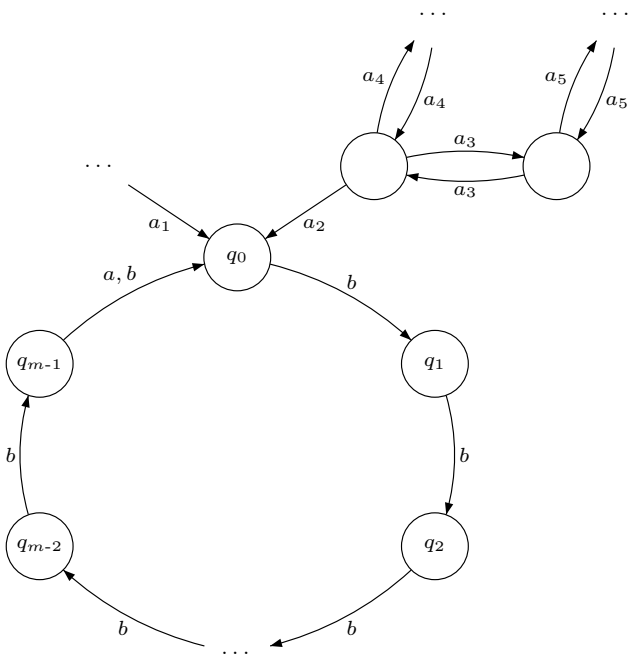

Figure 1 The automaton $\mathscr{B}_n$ from Section 5 formed from $\mathscr{C}_m$ and some $\mathscr{A}(T_{m'})$. The omitted transitions are self-loops.

The scheme of this construction is illustrated in Fig. 1.

▶ **Lemma 15.** *For all $m, m' \geq 1$ we have*

$$\mathrm{rt}(\mathscr{B}_n) = \mathrm{rt}(\mathscr{C}_m) + \mathrm{rt}(\mathscr{A}(T_{m'})).$$

Proof. Note that in the degenerated case $m' = 1$ this trivially holds, and suppose $m' \geq 2$.

To synchronize $\mathrm{rt}(\mathscr{B}_n)$ is it enough to apply the word $w'w$, where w' is a word synchronizing $\mathscr{A}(T_{m'})$ and w is a word synchronizing $\mathscr{C}_m$.

To show that this is a shortest possibility, let w be a synchronizing word for $\mathscr{B}_n$. Then w contain two disjoint subsequences of letters from Σ and from E, respectively. These subsequences synchronizes respectively $\mathscr{C}_m$ and $\mathscr{A}(T_{m'})$, which proves the lower bound. ◀

Arbitrary choice of m and m' with the constraint $n = m + m' - 1$ provides enough flexibility that finally leads to

▶ **Theorem 16.** *For every $k \leq n^2 - O(n^{3/2})$ there exists a synchronizing automaton with reset threshold k.*

Proof. Since $\mathrm{rt}(\mathscr{C}_m) = (m-1)^2$ and $\mathrm{rt}(\mathscr{A}(T_{m'})) \in \left[1, \ldots, \frac{(m'-1)m'}{2}\right]$ by Proposition 14, given m and m' we can construct an automaton with any value of reset threshold in $\left[(m-1)^2 + 1, (m-1)^2 + \frac{(m'-1)m'}{2}\right]$.

Since $n = m + m' - 1$ ($m' = n - m + 1$) we can cover all intervals

$$\left[(m-1)^2 + 1, (m-1)^2 + \frac{(n-m)(n-m+1)}{2}\right]$$

for all $1 \leq m \leq n$. Let g, $2 \leq g \leq (n-1)^2$, be the smallest number such that is not in the interval for some m. Consider the interval lying just before g ($g \geq 2$ so it exists), that is, let m

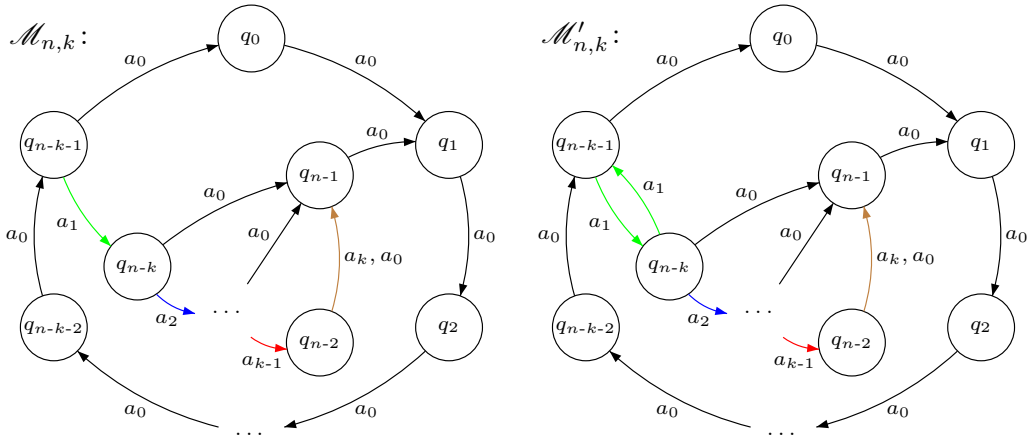

Figure 2 Automata $\mathscr{M}_{n,k}$ and $\mathscr{M}'_{n,k}$. The omitted transitions are self-loops.

be the largest number such that $g > (m-1)^2+((n-m)(n-m+1))/2$. Then the interval for $m+1$ must begin after g, so $g < m^2+1$. Hence $(m-1)^2+((n-m)(n-m+1))/2+1 \leq m^2$, which solved yields

$$m \geq \left(2n - \sqrt{16n+9} + 5\right)/2 = n - O(\sqrt{n}).$$

So $(m-1)^2 + (n-m)(n-m+1)/2 = n^2 - O(n^{3/2})$. ◀

6 Irreducibly synchronizing automata with large reset thresholds

Let $k \geq 1$ and $n \geq k+3$. Let $Q_n = q_0, \ldots, q_{n-1}$, and $\Sigma_k = a_0, \ldots, a_k$. We define the automaton $\mathscr{M}_{n,k} = (Q_n, \Sigma_k, \delta_{n,k})$, illustrated in Fig. 2 (left), with the transition function $\delta_{n,k}$ defined as follows:

$$\delta_{n,k}(q_i, a_0) = \begin{cases} q_{i+1} & \text{if } i \leq n-k-2 \\ q_0 & \text{if } i = n-k-1 \\ q_{n-1} & \text{if } n-k \leq i \leq n-2 \\ q_1 & \text{if } i = n-1, \end{cases}$$

and for $j \geq 1$

$$\delta_{n,k}(q_i, a_j) = \begin{cases} q_{i+1} & \text{if } i = n-k-2+j \\ q_i & \text{otherwise.} \end{cases}$$

We also define the variation $\mathscr{M}'_{n,k}(Q_n, \Sigma_k, \delta_{n,k})$, illustrated in Fig. 2 (right), of $\mathscr{M}_{n,k}$, where $\delta'_{n,k}$ is defined as follows:

$$\delta'_{n,k}(q_i, a_j) = \begin{cases} q_{n-k-1} & \text{if } i = n-k \text{ and } j = 1 \\ \delta_{n,k}(q_i, a_j) & \text{otherwise.} \end{cases}$$

▶ **Theorem 17.** *The automaton $\mathscr{M}_{n,k}$ is irreducibly synchronizing and has reset threshold*

$$n^2 - (k+3)n + 2k + 3.$$

Proof (sketch). The word $a_1 a_2 \cdots a_k (a_0^{n-k-1} a_1 \cdots a_k)^{n-k-2} a_0$ synchronizes $\mathscr{M}_{n,k}$ to the state q_1 and has length $n^2 - (k+3)n + 2k + 3$.

To show that this is the reset threshold, we use the backward tracing technique (cf. [19, Lemma 2], [21, 30]). The idea is to keep track, for $i = 1, 2, \ldots$, of families L_i of subsets of Q_n

that are preimages of a singleton under the action of a word of length i. Hence, L_i contains in particular all subsets that are compressible to a singleton by a word of length i. The smallest i such that $Q_n \in L_i$ is the length of the shortest reset words that synchronize to the singletons from L_0. Further, from each L_i we can exclude *visited* subsets, which are those being a proper subset of another subset from L_i or being a subset (non necessarily proper) of a subset from some $L_0, \ldots, L_{i-1}$ ([19, Lemma 2]). ◀

▶ **Theorem 18.** *The automaton $\mathscr{M}'_{n,k}$ is irreducibly synchronizing and has reset threshold*

$$n^2 - (k+3)n + 2k + 4.$$

Abstract

We investigate the power of *Non-commutative Arithmetic Circuits*, which compute polynomials over the free non-commutative polynomial ring $\mathbb{F}\langle x_1, \ldots, x_N \rangle$, where variables do not commute. We consider circuits that are restricted in the ways in which they can compute monomials: this can be seen as restricting the families of *parse trees* that appear in the circuit. Such restrictions capture essentially all non-commutative circuit models for which lower bounds are known. We prove several results about such circuits.

1. We show explicit exponential lower bounds for circuits with up to an exponential number of parse trees, strengthening the work of Lagarde, Malod, and Perifel (ECCC 2016), who prove such a result for *Unique Parse Tree* (UPT) circuits which have a single parse tree.
2. We show explicit exponential lower bounds for circuits whose parse trees are rotations of a single tree. This simultaneously generalizes recent lower bounds of Limaye, Malod, and Srinivasan (Theory of Computing 2016) and the above lower bounds of Lagarde et al., which are known to be incomparable.
3. We make progress on a question of Nisan (STOC 1991) regarding separating the power of Algebraic Branching Programs (ABPs) and Formulas in the non-commutative setting by showing a tight lower bound of $n^{\Omega(\log d)}$ for any UPT formula computing the product of d $n \times n$ matrices.

   When $d \leq \log n$, we can also prove superpolynomial lower bounds for formulas with up to $2^{o(d)}$ many parse trees (for computing the same polynomial). Improving this bound to allow for $2^{O(d)}$ trees would yield an unconditional separation between ABPs and Formulas.
4. We give deterministic white-box PIT algorithms for UPT circuits over any field (strengthening a result of Lagarde et al. (2016)) and also for sums of a constant number of UPT circuits with different parse trees.

1 Introduction

In this paper, we study questions related to Arithmetic Circuits, which are computational devices that use arithmetic operations (such as $+$ and $\times$) to compute multivariate polynomials over a field $\mathbb{F}$. While the more standard work in this area deals with the commutative polynomial ring $\mathbb{F}[x_1, \ldots, x_N]$, there is also a line of research, initiated by Hyafil [12] and Nisan [21], that studies the complexity of computing polynomials from the *non-commutative* polynomial ring $\mathbb{F}\langle x_1, \ldots, x_N \rangle$, where monomials are simply strings over the alphabet $X = \{x_1, \ldots, x_N\}$. The motivation for this is twofold: firstly, the study of polynomial computations over non-commutative algebras (e.g. the algebra of matrices over $\mathbb{F}$) naturally leads to such questions [7, 6], and secondly, computing, say, the Permanent non-commutatively[1] is at least as hard as computing it in the commutative setting, and thus the lower bound question should be easier to tackle in the non-commutative setting.

In an influential result, Nisan [21] justified this by proving exponential lower bounds for non-commutative *formulas*, and more generally *Algebraic Branching Programs* (ABPs), computing the Determinant and Permanent (and also other polynomials). The method used by Nisan to prove this lower bound can also be seen as a precursor to the method of Partial derivatives in Arithmetic circuit complexity (introduced by Nisan and Wigderson [22]), variants of which have been used to prove a large body of lower bound results in the area [22, 25, 9, 14, 16].

While lower bounds for general non-commutative circuits remain elusive, we do have other lower bounds that strengthen Nisan's result. Recently, Malod, along with two of the authors of this paper showed [19] that Nisan's method can be extended to prove lower bounds for *skew circuits*, which are circuits where every $\times$-gate has at most one non-variable input. Also, the first author, Malod and Perifel [18] proved lower bounds for another variant of non-commutative circuits that they defined to be *unambiguous* circuits (which we describe below). While these two results both strengthen Nisan's result, they are incomparable to each other, as shown in [18].

In this paper, we build on the above work to prove lower bounds that generalize these results significantly and also make progress on other problems related to non-commutative circuits. The circuits we consider are restricted in the ways they are allowed to compute monomials. We do this by restricting the "parse trees" that are allowed to appear in the circuits. Informally, the polynomial computed by any arithmetic circuit C can be written down as an exponentially-large sum of subcircuits, each of which contains only multiplication gates and hence computes a single monomial[2]; each such subcircuit gives rise to a tree, which we call a *parse tree of* C (see [18] and references therein for the background of parse trees), that tells us how the monomial was computed. For example, for the circuit C in Figure 1, the monomial $x_1x_2x_3x_4$ may be computed in C as $(x_1 \cdot x_2) \cdot (x_3 \cdot x_4)$ or as $(x_1 \cdot (x_2 \cdot x_3) \cdot x_4)$, each of which comes from a parse tree of C.

All the non-commutative circuit classes for which we know lower bounds can be defined by restrictions on the parse trees that appear in them. ABPs are circuits where all parse trees are left combs (i.e. a tree where every internal node has two children and the left child is always a leaf); skew circuits are equivalent in power to circuits where the parse trees are *twisted* combs (i.e. a tree where every internal node has two children and at least one of the

[1] We can define the Permanent in the non-commutative polynomial ring by ordering the variables in each monomial in the commutative permanent, say, in increasing order of the rows in which they appear.

[2] different subcircuits could compute the same monomial

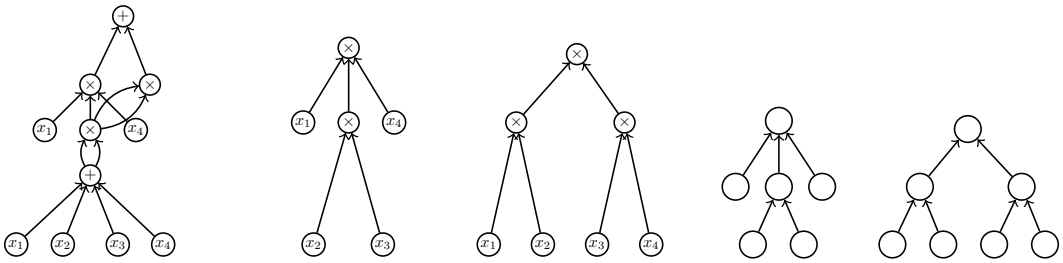

Figure 1 From left to right: a non-commutative arithmetic circuit C; two ways in which the monomial $x_1x_2x_3x_4$ is computed in the circuit; the corresponding parse trees.

two children is always a leaf); and unambiguous circuits (that we will call *Unique Parse Tree* (UPT) circuits below) are defined to be circuits that have only one parse tree. It is thus natural to consider other restrictions on the structure of the parse trees that appear in a circuit. We prove the following results about such circuits.

- We prove lower bounds for circuits that only contain a few different parse trees. The motivation for this is the lower bound of [18] for the case of circuits with a single parse tree and a construction in [19] that shows that poly(N, d)-sized circuits with $\exp(\Omega(d))$ many parse trees[3] evade all currently known techniques for proving lower bounds for non-commutative circuits. We show explicit exponential lower bound for circuits with up to $\exp(d^{\Omega(1)})$ parse trees (Theorem 13).
- We also consider structural restrictions on the collections of parse trees that appear in our circuits. As mentioned above, skew circuits are circuits where all parse trees are twisted combs, which can be seen as trees obtained by starting with a left comb (which defines an ABP) and successively applying rotations to the internal nodes that swap the children. We say that a circuit C is *rotation Unique Parse tree* (rotUPT) if there is a single tree T such that all the parse trees of C can be obtained as rotations of T.[4]
  We show an explicit exponential lower bound for rotUPT circuits (Theorem 17). Note that this result simultaneously generalizes the skew circuit lower bound of Limaye et al. [19] as well as the UPT circuit lower bound of Lagarde et al. [18].
- We consider the problem of separating ABPs from formulas, which was posed by Nisan [21] and is the non-commutative arithmetic analogue of separating NL from NC^1. Equivalently, this is the question of whether (an entry of) the product of d $n \times n$ matrices, all of whose entries are distinct variables, can be computed by a poly(n, d)-sized non-commutative formula. The standard divide-and-conquer approach yields, for every even Δ, a non-commutative formula of depth Δ and size $n^{O(\Delta d^{2/\Delta})}$ computing this polynomial and a size $n^{O(\log d)}$ formula in general. Further, these formulas can be seen to have a *unique* parse tree (i.e. they are UPT).
  We show that this upper bound is nearly tight for UPT formulas and every choice of Δ by showing a lower bound of $n^{\Omega(\Delta d^{1/\lfloor \Delta/2 \rfloor})}$.[5] (Theorem 18). In particular, our result implies that any UPT formula for this polynomial must have size $n^{\Omega(\log d)}$. We can extend this (Theorem 19) to prove a superpolynomial lower bound even in the case that the formula has at most k parse trees, where $k = 2^{o(d)}$ (however, for this result, we need the assumption that $d \leq \log n$).

[3] A close look at the circuits in [19] indicates that just about all parse trees of fan-in 2 appear in these circuits.
[4] There can be $\exp(\Omega(d))$ of these, as in the case of skew circuits.
[5] Our bounds are actually better stated in terms of the $\times$-*depth* of the formula.

- Finally, we consider the Polynomial Identity Testing (PIT) problem for non-commutative circuits with restricted parse trees. Lagarde et al. [18] show that deterministic PIT algorithms for UPT circuits can be obtained by adapting a PIT algorithm for ABPs due to Arvind, Joglekar and Srinivasan [3]. However, this technique only works over fields of characteristic zero. Here, we give a straightforward adaptation of an older PIT algorithm of Raz and Shpilka [24] (also for non-commutative ABPs) to show that PIT for UPT circuits can be solved in deterministic polynomial time over all fields (Theorem 20). We also consider circuits that are sums of UPT circuits (with possibly different parse trees). By using ideas from the work of Gurjar, Korwar, Saxena and Thierauf [10], we show that PIT for a sum of constant number of UPT circuits can be solved in deterministic polynomial time over any field (Theorem 21).

For lack of space, many of the proofs of the above statements have been omitted from this extended abstract. We refer the reader to the full version [17] for detailed proofs.

Related work. Hrubeš, Wigderson and Yehudayoff [11] initiated a study of the asymptotics of the classical *sum-of-squares* problem in mathematics and showed that a suitable result in this direction would yield strong lower bounds against general non-commutative circuits. While this line of work is currently the only feasible attack on the problem of general circuit lower bounds, we do not yet have any lower bounds using this technique.

Nisan and Wigderson [22] prove results that imply[6] some lower bounds for UPT formulas computing iterated matrix product. For depth-3 formulas, they prove an optimal n^d bound on computing the product of d $n \times n$ matrices. For depths $\Delta > 3$ though, the lower bound is only $\exp(\Theta(d^{1/\Delta}))$ and thus does not yield anything non-trivial when Δ approaches $\log d$. Indeed, the proof method of this result in [22] is not sensitive to the value of n and holds for any $n \geq 2$. Such a method cannot yield non-trivial lower bounds for general formulas since we do have $\mathrm{poly}(d)$-sized formulas in the setting when $n = O(1)$.

The results of Kayal, Saha, and Saptharishi [15] and Fournier, Limaye, Malod, and Srinivasan [8] together also prove a superpolynomial lower bound on the size of *regular* formulas (defined by [15]) computing the product of d $n \times n$ matrices in the commutative setting. While these formulas (in the non-commutative setting) are definitely UPT, the converse is not true.

Arvind, Mukhopadhyay and Raja [4] and Arvind, Joglekar, Mukhopadhyay and Raja [2] have some recent work on PIT algorithms for general non-commutative circuits that run in time *polylogarithmic* in the degree of the circuit and polynomial in the size of the circuit. Our results are incomparable with theirs, since our algorithms run in time polynomial in *both* degree and size but are deterministic, whereas the algorithms of [4, 2] are faster (especially in terms of degree) but *randomized*.

An earlier manuscript of Arvind and Raja [5] contains a claim that the PIT problem for non-commutative skew circuits has a deterministic polynomial time algorithm, but the proof is unfortunately flawed.[7]

Techniques. The techniques used to prove the lower bounds in this paper are generalizations of the techniques of Hyafil [12] and Nisan [21]. Given a homogeneous polynomial $f \in \mathbb{F}\langle X \rangle$ of degree d, we associate with it an $N^{d/2} \times N^{d/2}$ matrix whose rows and columns are labelled

[6] The results of [22] in fact hold in the stronger commutative *set-multilinear* setting.
[7] Private communication with the authors.

by monomials (i.e. strings over X) m of degree $d/2$ each. Nisan [21] considers the matrix $M[f]$ where the (m_1, m_2)th entry is the coefficient of the monomial $m_1 m_2$ in f. In [19, 18], along with our co-authors, we considered the more general family of matrices $M_Y[f]$ where $Y \subseteq [d]$ is of size $d/2$ and the (m_1, m_2)th entry of $M_Y[f]$ is the coefficient of the monomial m such that the projection of m to the locations in Y gives m_1 and the locations outside Y give m_2.

This is the general technique we use in this paper as well, though choosing the right Y requires some work. In the lower bound for circuits with few parse trees, it is chosen at random (in a similar spirit to a multilinear lower bound of Raz [23]). In the lower bound for rotUPT circuits, it is chosen in a way that depends on the structure of the parse trees in the circuit (combining the approaches of [19, 18]). In the separation of UPT formulas from ABPs, it is applied (after a suitable restriction) in a way that keeps the iterated matrix product polynomial high rank but reduces the rank of the UPT formula.

For the PIT algorithm for sums of UPT circuits, we use an observation of Gurjar et al. [10] (also see [21, 24]) that any polynomial P that has a small ABP has a small set of *characterizing identitites* such that $Q = P$ iff Q satisfies these identities. We are able to show (using a suitable decomposition lemma of [18]) that a similar fact is also true more generally in the case that P has a small UPT circuit. If Q also has a small UPT circuit, then checking these identities for Q reduces to a PIT circuit for a single UPT circuit, for which we already have algorithms. In this way, given two UPT circuits (with different parse trees) computing P, Q, we can check if $P - Q = 0$. Extending this idea exactly as in [10], we can efficiently check if the sum of any small number of UPT circuits is 0.

2 Preliminaries

We refer the reader to the survey [26] for standard definitions regarding arithmetic circuits.

2.1 Non-commutative polynomials

Throughout, we use $X = \{x_1, \ldots, x_N\}$ to denote the set of variables. We work over the *non-commutative* ring of polynomials $\mathbb{F}\langle X\rangle$ where monomials are *strings* over the alphabet X: for example, x_1x_2 and x_2x_1 are distinct monomials in this ring. For $d \in \mathbb{N}$, we use $\mathcal{M}_d(X)$ to denote the set of monomials (i.e. strings) over the variables in X of degree exactly d.

For $i, j \in \mathbb{N}$, we define $[i, j]$ to be the set $\{i, i+1, \ldots, j\}$ (the set is empty if $i > j$). We also use the standard notation $[i]$ to denote the set $[1, i]$.

Given homogeneous polynomials $g, h \in \mathbb{F}\langle X\rangle$ of degrees d_g and d_h respectively and an integer $j \in [0, d_h]$, we define the *j-product of g and h* – denoted $g \times_j h$ – as follows:

- When g and h are monomials, then we can factor h uniquely as a product of two monomials h_1h_2 such that $\deg(h_1) = j$ and $\deg(h_2) = d_h - j$. In this case, we define $g \times_j h$ to be $h_1 \cdot g \cdot h_2$.
- The map is extended bilinearly to general homogeneous polynomials g, h. Formally, let g, h be general homogeneous polynomials, where $g = \sum_\ell g_\ell$, $h = \sum_i h_i$ and g_ℓ, h_i are monomials of g, h respectively. For $j \in [0, d_h]$, each h_i can be factored uniquely into h_{i_1}, h_{i_2} such that $\deg(h_{i_1}) = j$ and $\deg(h_{i_2}) = d_h - j$. And $g \times_j h$ is defined to be $\sum_i \sum_\ell h_{i_1} g_\ell h_{i_2}$.

Note that $g \times_0 h$ and $g \times_{d_h} h$ are just the products $g \cdot h$ and $h \cdot g$ respectively.

2.2 The partial derivative matrix

Here we recall some definitions from [21] and [19]. Let Π denote a partition of $[d]$ given by an ordered pair (Y, Z), where $Y \subseteq [d]$ and $Z = [d] \setminus Y$. In what follows we only use ordered partitions of sets into two parts. We say that such a Π is *balanced* if $|Y| = |Z| = d/2$.

Given a monomial m of degree d and a set $W \subseteq [d]$, we use m_W to denote the monomial of degree $|W|$ obtained by keeping exactly the variables in the locations indexed by W.

▶ **Definition 1** (Partial Derivative matrix)**.** Let $f \in \mathbb{F}\langle X\rangle$ be a homogeneous polynomial of degree d. Given a partition $\Pi = (Y, Z)$ of $[d]$, we define an $N^{|Y|} \times N^{|Z|}$ matrix $M[f, \Pi]$ with entries from $\mathbb{F}$ as follows: the rows of $M[f, \Pi]$ are labelled by monomials from $\mathcal{M}_{|Y|}(X)$ and the columns by elements of $\mathcal{M}_{|Z|}(X)$. Let $m' \in \mathcal{M}_{|Y|}(X)$ and $m'' \in \mathcal{M}_{|Z|}(X)$; the (m', m'')th entry of $M[f, \Pi]$ is the coefficient in the polynomial f of the unique monomial m such that $m_Y = m'$ and $m_Z = m''$.

We will use the rank of the matrix $M[f, \Pi]$ – denoted $\text{rank}(f, \Pi)$ – as a measure of the complexity of f . Note that since the rank of the matrix is at most the number of rows, we have for any $f \in \mathbb{F}\langle X\rangle$ $\text{rank}(f, \Pi) \leq N^{|Y|}$.

▶ **Definition 2** (Relative Rank)**.** Let $f \in \mathbb{F}\langle X\rangle$ be a homogeneous polynomial of degree d. For any $Y \subseteq [d]$, we define the *relative rank of f w.r.t.* $\Pi = (Y, Z)$ – denoted $\text{rel-rank}(f, \Pi)$ – to be

$$\text{rel-rank}(f, \Pi) := \frac{\text{rank}(M[f, \Pi])}{N^{|Y|}}.$$

Fix a partition $\Pi = (Y, Z)$ of $[d]$ and two homogeneous polynomials g, h of degrees d_g and d_h respectively. Let $f = g \times_j h$ for some $j \in [0, d_h]$. This induces naturally defined partitions Π_g of $[d_g]$ and Π_h of $[d_h]$ respectively in the following way. Let $I_g = [j + 1, j + d_g]$ and $I_h = [d] \setminus I_g$. We define $\Pi_g = (Y_g, Z_g)$ such that $Y_g = \{j \in [d_g] \mid Y \text{ contains the } j\text{th smallest element of } I_g\}$; $\Pi_h = (Y_h, Z_h)$ is defined similarly with respect to I_h. Let $|Y_g|, |Z_g|, |Y_h|, |Z_h|$ be denoted d'_g, d''_g, d'_h, d''_h respectively.

In the above setting, we have a simple description of the matrix $M[f, \Pi]$ in terms of $M[g, \Pi_g]$ and $M[h, \Pi_h]$. We use the observation that monomials of degree $|Y| = d'_g + d'_h$ are in one-to-one correspondence with pairs (m'_g, m'_h) of degrees d'_g and d'_h respectively (and similarly for monomials of degree $|Z|$). The following appears in [19].

▶ **Lemma 3** (Tensor Lemma)**.** *Say $f = g \times_j h$ as above. Then, $M[f, \Pi] = M[g, \Pi_g] \otimes M[h, \Pi_h]$.*

▶ **Corollary 4.** *Say $f = g \times_j h$ as above. We have $\text{rank}(f, \Pi) = \text{rank}(g, \Pi_g) \cdot \text{rank}(h, \Pi_h)$. In the special case that one of Y_g, Z_g, Y_h, or Z_h is empty, the tensor product is an outer product of two vectors and hence $\text{rank}(f, \Pi) \leq 1$.*

We associate any partition $\Pi = (Y, Z)$ with the string in $\{-1, 1\}^d$ that contains a -1 in exactly the locations indexed by Y. Given partitions $\Pi_1, \Pi_2 \in \{-1, 1\}^d$, we now define $\Delta(\Pi_1, \Pi_2)$ to be the Hamming distance between the two strings or equivalently as $|Y_1 \Delta Y_2|$ where $\Pi_1 = (Y_1, Z_1)$ and $\Pi_2 = (Y_2, Z_2)$.

▶ **Proposition 5.** *Let $f \in \mathbb{F}\langle X\rangle$ be homogeneous of degree d and say $\Pi \in \{-1, 1\}^d$. Then, $\text{rank}(f, \Pi) = \text{rank}(f, -\Pi)$.*

Proof. Follows from the fact that $M[f, -\Pi]$ is the transpose of $M[f, \Pi]$. ◀

▶ **Lemma 6** (Distance lemma)**.** *Let $f \in \mathbb{F}\langle X\rangle$ be homogeneous of degree d and say $\Pi_1, \Pi_2 \in \{-1, 1\}^d$. Then, $\text{rank}(f, \Pi_2) \leq \text{rank}(f, \Pi_1) \cdot N^{\Delta(\Pi_1, \Pi_2)}$.*

Proof. See the full version [17]. ◀

2.3 Standard definitions related to non-commutative circuits

We consider noncommutative arithmetic circuits that compute polynomials over the ring $\mathbb{F}\langle X\rangle$. These are arithmetic circuits where the children of each $\times$ gate are ordered and the polynomial computed by a $\times$ gate is the product of the polynomials computed by its children, where the product is computed in the given order. Further, unless mentioned otherwise, we allow both $+$ and $\times$ gates to have unbounded fan-in and the $+$ gates to compute arbitrary linear combinations of its inputs (the input wires to the $+$ gate are labelled by the coefficients of the linear combination). A noncommutative formula is a circuit where the underlying directed acyclic graph is a rooted tree. The size of an arithmetic circuit or formula is the number of edges or wires in the circuit (which can be assumed to be at least the number of gates in the circuit).

We always assume that the output gate of the circuit is a $+$ gate (possibly of fan-in 1) and that input gates feed into $+$ gates. We also assume that $+$ and $\times$ gates alternate on any path from the output gate to an input gate (some of these gates can have fan-in 1). Any circuit can be converted to one of this form with at most a constant blow-up in size.

Throughout, our circuits and formulas will be *homogeneous* in the following sense. Define the formal degree of a gate as follows: the formal degree of an input gate is 1, the formal degree of a $+$ gate is the maximum of the formal degrees of its children, and that of a $\times$ gate is the sum of the formal degrees of its children. We say that a circuit is homogeneous if each gate computes a homogeneous polynomial and any gate computing a non-zero polynomial computes one of degree equal to the formal degree of the gate. Note, in particular, that every input node is labelled by a variable only (and not by constants from $\mathbb{F}$).

Homogeneity is *not* a strong assumption on the circuit: it is a standard fact that any homogeneous polynomial of degree d computed by a non-commutative circuit of size s can be computed by a homogeneous circuit of size $O(sd^2)$ [11].

We also consider homogeneous Algebraic Branching Programs (ABPs), defined by Nisan [21] in the non-commutative context. We give here a slightly different definition that is equivalent up to polynomial factors.

Assume that $N = n^2 \cdot d$ for positive $n, d \in \mathbb{N}$ and let $\mathrm{IMM}_{n,d}(X)$ denote the following polynomial in N variables (see, e.g. [22]). Assume X is partitioned into d sets of variables $X_1, \ldots, X_d$ of size n^2 each and let $M_1, \ldots, M_d$ be $n \times n$ matrices such that the entries of M_i ($i \in [d]$) are distinct variables in X_i. Let $M = M_1 \cdot M_2 \cdots M_d$; each entry of M is a homogeneous polynomial of degree d from $\mathbb{F}\langle X\rangle$. We define the polynomial $\mathrm{IMM}_{n,d}$ to be the sum of the diagonal entries of M.

A homogeneous ABP for a homogenous polynomial $f \in \mathbb{F}\langle X\rangle$ of degree d is a pair (n_1, ρ) where $n_1 \in \mathbb{N}$ and ρ is a map from $X' = \{x'_1, \ldots, x'_{n_1^2 d}\}$ to homogeneous linear functions from $\mathbb{F}\langle X\rangle$ such that f can be obtained by substituting $\rho(x'_i)$ for each x'_i in the polynomial $\mathrm{IMM}_{n_1,d}(X')$. The parameter n_1 is called the *width* of the ABP.

2.4 Non-commutative circuits with restricted parse trees

In this paper, we study restricted forms of non-commutative arithmetic circuits. The restrictions are defined by the way the circuits are allowed to multiply variables to compute a monomial. To make this precise we need the notion of a parse tree of a circuit, which has been considered in many previous works [13, 1, 20, 18].

Fix a homogeneous non-commutative circuit C. A *parse formula* of C is a *formula* C' obtained by making copies of gates in C as follows:

- Corresponding to the output $+$ gate of C, we add an output $+$ gate to C',

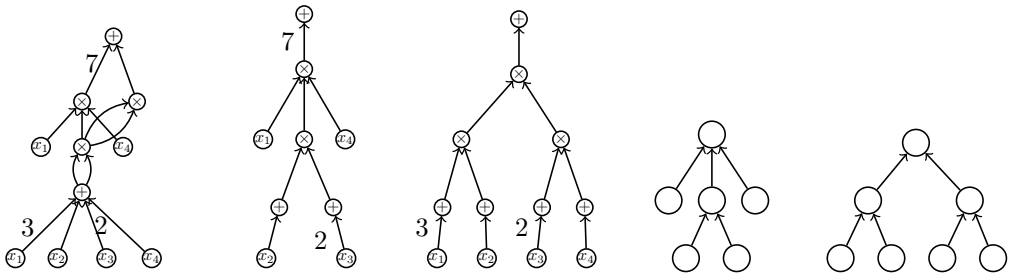

Figure 2 From left to right: a non-commutative arithmetic circuit; two parse formulas in the circuit; the corresponding parse trees. (To simplify the picture, we have not depicted the edges that carry the constant 1. Also we have not introduced + gates between the two layers of × gates; the reader should assume that the edges between the two layers carry + gates of fan-in 1.)

- For every + gate Φ' added to C' corresponding to a + gate Φ in C, we choose exactly one child Ψ of Φ in C and add a copy Ψ' to C' as a child of Φ'. The constant along the wire from Ψ' to Φ' remains the same as in C.
- For every × gate Φ' added to C' corresponding to a × gate Φ in C and *every wire* from a child Ψ to Φ in C, we make a copy of Ψ' to C' and make it a child of Φ.

Any such parse formula C' computes a *monomial* (with a suitable coefficient) and the polynomial computed by C is the sum of all monomials computed by parse formulas C' of C. We define $val(C')$ to be the monomial computed by C'.

A parse tree of C is a rooted, ordered tree obtained by taking a parse formula C' of C, "short circuiting" the + nodes (i.e. we remove the + nodes and connect the edges that were connected to it directly), and deleting all labels of the nodes and the edges of the tree. See Figure 2 for an example. Note that in a homogeneous circuit C, each such tree has exactly d leaves. We say that the tree T is the *shape* of the parse formula C'.

The process that converts the parse formula C' to T associates each internal node of T with a multiplication gate of C' and each leaf of T with an input gate of C'.

Let T be a parse tree of a homogeneous circuit C with d leaves. Given a node $v \in V(T)$, we define the $\deg(v)$ to be the number of leaves in the subtree rooted at v and $\mathrm{pos}(v) :=$ (1+the number of leaves preceding v in an in-order traversal of T). The type of v is defined to be $\mathrm{type}(v) := (\deg(v), \mathrm{pos}(v))$. (The reason for this definition is that in any parse formula C' of shape T, the monomial computed by the multiplication gate or input gate corresponding to v in C' computes a monomial of degree $\deg(v)$ which sits at position $\mathrm{pos}(v)$ w.r.t. the monomial computed by the circuit C'.) We also use $\mathcal{I}(T)$ to denote the set of internal nodes of T and $\mathcal{L}(T)$ to denote the set of leaves of T.

We use $\mathcal{T}(C)$ to denote the set of parse trees that can be obtained from parse formulas of C. We say that a homogeneous non-commutative arithmetic circuit is a *Unique Parse Tree circuit* (or *UPT circuit*) if $|\mathcal{T}(C)| = 1$. More generally if $|\mathcal{T}(C)| \leq k$, we say that C is *k-PT*. Finally, if $\mathcal{T}(C) \subseteq \mathcal{T}$ for some family $\mathcal{T}$ of trees, we say that C is *$\mathcal{T}$-PT*. Similarly, we also define UPT formulas, k-PT formulas and $\mathcal{T}$-PT formulas. If C be a UPT circuit with $\mathcal{T}(C) = \{T\}$, we say that T is the *shape* of the circuit C.

We say that a UPT circuit C is in *normal form* if we can associate with each gate Φ of the circuit a node $v(\Phi) \in V(T)$ such that the following holds: if Φ is an input gate, then $v(\Phi)$ is a leaf; if Φ is a × gate with children $\Psi_1, \ldots, \Psi_t$ (in that order), then the nodes $v(\Psi_1), \ldots, v(\Psi_t)$ are the children of $v(\Phi)$ (in that order); and finally, if Φ is a + gate with children $\Psi_1, \ldots, \Psi_t$ (which are all × or input gates since we assume that + and × gates are

alternating along each input to output path), then $v(\Phi) = v(\Psi_1) = \cdots = v(\Psi_t)$. (Intuitively, what this means is that in any unravelling of a parse formula containing a (multiplication or input) gate Φ to get the parse tree T, the gate Φ always takes the position of node $v(\Phi)$.)

We state below some simple structural facts about UPT circuits. (See [17] for proof.)

▶ **Proposition 7.**
1. *Let C be a UPT* formula. *Then C is in normal form.*
2. *For any UPT circuit C of size s and shape T, there is another UPT circuit C' of size $O(s^2)$ and shape T in normal form computing the same polynomial as C. Further, given C and T, such a C' can be constructed in time* $\mathrm{poly}(s)$.

Let C be either a UPT formula or a UPT circuit of shape T in normal form. We say that a $+$ gate Φ in C is a $(v, +)$ gate if $v(\Phi) = v$. Similarly, we refer to a $\times$ gate Φ in C as a $(v, \times)$ gate if $v(\Phi) = v$. For simplicity of notation, we also refer to an *input* gate Φ as a $(v, \times)$ gate if $v(\Phi) = v$. Note that the output gate is a $(v_0, +)$ gate where v_0 is the root of T.

We now observe that any UPT formula or circuit in normal form can be converted to another (of a possibly different shape) where each multiplication gate has fan-in at most 2.

▶ **Lemma 8.** *Let C be a normal form UPT circuit (resp. formula) of size s and shape T. Then there is a tree T' and normal form UPT circuit (resp. formula) C' of size $O(s)$ and shape T' such that C' computes the same polynomial as C and every multiplication gate in C' has fan-in at most 2. (This implies that every internal node of T' also has fan-in at most 2.) Further, there is a deterministic polynomial-time algorithm, which when given C, computes C' as above.*

Proof. See the full version [17]. ◀

Let C be a UPT circuit of shape T computing a homogeneous polynomial f of degree d. Given any node $u \in V(T)$, we define partition Π_u of $[d]$ so that $\Pi_u = (Y_u, Z_u)$ where $Y_u = \{\mathrm{pos}(v) \mid v \text{ a leaf and descendant of } u\}$.

We will need the following lemma of Lagarde et al. [18].

▶ **Lemma 9** ([18]). *Let C be a normal form UPT circuit of size s computing a homogeneous polynomial $f \in \mathbb{F}\langle X\rangle$ of degree d. Assume that the fan-in of each multiplication gate is bounded by 2. Then, for any $u \in V(T)$, $\mathrm{rank}(f, \Pi_u) \leq s$, where Π_u is as defined above.*

2.5 A polynomial that is full rank w.r.t. all partitions

The following was shown in [19].

▶ **Theorem 10.** *For any even d and any positive $N \in \mathbb{N}$, there is a $q_0(N, d)$ such that the following holds over any field of size at least $q_0(N, d)$. There is an explicit homogeneous polynomial $F_{N,d} \in \mathbb{F}\langle X\rangle$ of degree d such that for any balanced partition $\Pi = (Y, Z)$ of $[d]$, $\mathrm{rank}(f, \Pi) = N^{d/2}$ (equivalently, $\text{rel-rank}(f, \Pi) = 1$). Further, $F_{N,d}$ can be computed by an explicit homogeneous non-commutative arithmetic circuit of size* $\mathrm{poly}(N, d)$.

3 Lower bounds for k-PT circuits

In this section, we show that any k-PT circuit computing a polynomial of degree d where k is subexponential in d cannot compute the polynomial $F_{N,d}$ from Theorem 10. We will show that if both k and the size of the circuit are subexponential in d, then there is a Π such that $\text{rel-rank}(f, \Pi) < 1$.

Our proof is based on the following lemmas.

▶ **Lemma 11.** *Let C be a k-PT circuit (resp. formula) of size s with $\mathcal{T}(C) = \{T_1, \ldots, T_k\}$ computing $f \in \mathbb{F}\langle X\rangle$. Then there exist normal form UPT circuits (resp. formulas) $C_1, \ldots, C_k$ of size at most s^2 each such that $\mathcal{T}(C_i) = \{T_i\}$ and $f = \sum_{i=1}^{k} f_i$, where f_i the polynomial computed by C_i.*

Proof. See the full version [17]. ◀

▶ **Lemma 12.** *Let C be a UPT circuit in normal form over $\mathbb{F}\langle X\rangle$ of size $s = N^c$ and f a homogeneous polynomial of degree d computed by C. Let Π be a uniformly random partition of the variables of $[d]$ into two sets. Then for any parameter $b \in \mathbb{N}$,*

$$\Pr_{\Pi}\left[\operatorname{rank}(f,\Pi) \geq N^{d/2-b}\right] \leq \exp(-\Omega(d/(b+c)^2)).$$

Before proving Lemma 12, let us see that the above lemmas imply the following lower bound for homogeneous non-commutative circuits with few parse trees. Note that when the field $\mathbb{F}$ is large enough, this proves a lower bound for $F_{N,d}$ from Theorem 10.

▶ **Theorem 13.** *Assume that $N \geq 2$ is any constant and d an even integer parameter that is growing. Let $F \in \mathbb{F}\langle X\rangle$ be any polynomial such that for each balanced partition Π, $\operatorname{rank}(F,\Pi) = N^{d/2}$. Then, for any constant $\varepsilon \in (0,1)$, any circuit that computes F and satisfies $|\mathcal{T}(C)| = k \leq 2^{d^{\frac{1}{3}-\varepsilon}}$ must have size at least $2^{d^{\frac{1}{3}-\frac{\varepsilon}{2}}}$.*

Proof. Let C be any circuit of size $s \leq N^c$ for $c = d^{1/3-\varepsilon/2}$ with $|\mathcal{T}(C)| = k \leq 2^{d^{1/3-\varepsilon}}$ and computing $f \in \mathbb{F}\langle X\rangle$. We show that there is a balanced partition Π such that $\operatorname{rank}(f,\Pi) < N^{d/2}$. This will prove the theorem.

To show this, we proceed as follows. Using Lemma 11, we can write $f = \sum_{i\in[k]} f_i$ where each $f_i \in \mathbb{F}\langle X\rangle$ is computed by a normal form UPT circuit C_i of size at most $s^2 \leq N^{2c}$.

Fix any $i \in [k]$. By Lemma 12, the number of partitions Π for which $\operatorname{rank}(f_i,\Pi) \geq N^{\frac{d}{2}-c}$ is at most $2^d \cdot \exp(-\Omega(d/c^2))$. In particular, since the number of balanced partitions is $\binom{d}{d/2} = \Theta(\frac{2^d}{\sqrt{d}})$, we see that for a random *balanced* partition Π,

$$\Pr_{\Pi \text{ balanced}}\left[\operatorname{rank}(f_i,\Pi) \geq N^{d/2-c}\right] \leq \sqrt{d}\cdot\exp(-\Omega(d/c^2)) \leq \exp(-d^{1/3}).$$

Say f_i is good for Π if $\operatorname{rank}(f_i,\Pi) \geq N^{d/2-c}$. By the above, we have

$$\Pr_{\Pi \text{ balanced}}[\exists i \in [k] \text{ s.t. } f_i \text{ good for } \Pi] \leq k\cdot\exp(-d^{1/3}) \leq 2^{d^{1/3-\varepsilon}}\cdot\exp(-d^{1/3}) < 1.$$

In particular, there is a balanced Π such that no f_i is good for Π. Fix such a balanced partition Π. By the subadditivity of rank, we have

$$\begin{aligned}\operatorname{rank}(f,\Pi) &\leq \sum_{i\in[k]}\operatorname{rank}(f_i,\Pi) \leq k\cdot N^{d/2-c} \leq 2^{d^{1/3-\varepsilon}}\cdot N^{d/2-c}\\ &= N^{d/2}\cdot\exp(O(d^{1/3-\varepsilon}) - \Omega(d^{1/3-\varepsilon/2})) < N^{d/2}.\end{aligned}$$

This proves the theorem. ◀

Proof of Lemma 12 . Recall from Section 2.2 that we identify each partition Π with an element of $\{-1,1\}^d$. Given partitions $\Pi_1, \Pi_2 \in \{-1,1\}^d$ we use $\langle \Pi_1, \Pi_2\rangle$ to denote their inner product: i.e., $\langle \Pi_1, \Pi_2\rangle := \sum_{i\in[d]} \Pi_1(i)\Pi_2(i)$. Note that the Hamming distance $\Delta(\Pi_1,\Pi_2)$ is

$$\Delta(\Pi_1,\Pi_2) = \frac{d}{2} - \frac{1}{2}\langle \Pi_1, \Pi_2\rangle. \tag{1}$$

Let $\mathcal{T}(C) = \{T\}$. Recall that $|\mathcal{L}(T)| = d$ and by Lemma 8, we can assume that the fan-in of each internal node of T is bounded by 2. For any $u \in \mathcal{I}(T)$ (recall $\mathcal{I}(T)$ is the set of internal nodes of T), let $\mathcal{L}(u)$ denote the set of leaves of the subtree rooted at u. We identify each leaf $\ell \in V(T)$ with $\mathrm{pos}(\ell) \in [d]$. For each $u \in \mathcal{I}(T)$, we can define the partition Π_u from Section 2.4 by $\Pi_u(\ell) = -1$ iff $\ell \in \mathcal{L}(u)$.

For $\gamma > 0$, define a partition Π to be *γ-correlated to T* if for each $u \in \mathcal{I}(T)$, we have $\left|\sum_{\ell \in \mathcal{L}(u)} \Pi(\ell)\right| \leq \gamma$.

Lemma 12 immediately follows from Claims 14 and 15, stated below.

▶ **Claim 14.** *Let Π be any partition of $[d]$ such that $\mathrm{rank}(f, \Pi) \geq N^{d/2-b}$. Then Π is $O(b+c)$-correlated to T.*

Proof. We know from Lemma 9 and Proposition 5 that for each $u \in \mathcal{I}(T)$, $\mathrm{rank}(f, \Pi_u)$ and $\mathrm{rank}(f, -\Pi_u)$ are at most N^c. If Π is a partition such that either $\Delta(\Pi, \Pi_u)$ or $\Delta(\Pi, -\Pi_u)$ is strictly smaller than $\frac{d}{2} - (b+c)$ for *some* $u \in \mathcal{I}(T)$, then by Lemma 6 we would have $\mathrm{rank}(f, \Pi) < N^{d/2-b}$.

Thus, if $\mathrm{rank}(f, \Pi) \geq N^{d/2-b}$, we must have $\min\{\Delta(\Pi, \Pi_u), \Delta(\Pi, -\Pi_u)\} \geq \frac{d}{2} - (b+c)$ for each $u \in \mathcal{I}(T)$. By (1), this means that for each $u \in \mathcal{I}(T)$, $|\langle \Pi, \Pi_u \rangle| \leq \gamma$ for some $\gamma = O(b+c)$.

Let v be the root of T. Note that $\Pi_v \in \{-1, 1\}^d$ is the vector with all its entries being -1. Hence, we have for any $u \in \mathcal{I}(T)$,

$$\left|\sum_{\ell \in \mathcal{L}(u)} \Pi(\ell)\right| = \left|\langle \Pi, \frac{-(\Pi_u + \Pi_v)}{2} \rangle\right| \leq \frac{1}{2}(|\langle \Pi, \Pi_u \rangle| + |\langle \Pi, \Pi_v \rangle|) \leq O(\gamma).$$

This proves the claim. ◀

▶ **Claim 15.** *Say $\Pi \in \{-1, 1\}^d$ is chosen uniformly at random and $\gamma \leq \sqrt{d}$. Then $\Pr_\Pi[\Pi$ is γ-correlated to $T] \leq \exp(-\Omega(\frac{d}{\gamma^2}))$.*

The following technical subclaim is useful for proving Claim 15. (See [17] for proof.)

▶ **Subclaim 16.** *Assume that $r, t \in \mathbb{N}$ such that $rt \leq d/4$. Then we can find a sequence $u_1, \ldots, u_r \in \mathcal{I}(T)$ such that for each $i \in [r]$ we have $|\mathcal{L}(u_i) \setminus \bigcup_{j=1}^{i-1} \mathcal{L}(u_j)| \geq t$.*

Proof of Claim 15. We apply Subclaim 16 with $t = \Theta(\gamma^2)$ and $r = \Theta(d/\gamma^2)$ to get a sequence $u_1, \ldots, u_r \in \mathcal{I}(T)$ such that for each $i \in [r]$, we have $|\mathcal{L}(u_i) \setminus \bigcup_{j=1}^{i-1} \mathcal{L}(u_j)| \geq t$.

By the definition of γ-correlation, we have

$$\begin{aligned}\Pr_\Pi[\Pi \text{ } \gamma\text{-correlated to } T] &\leq \Pr_\Pi\left[\forall i \in [r], \left|\sum_{\ell \in \mathcal{L}(u_i)} \Pi(\ell)\right| \leq \gamma\right] \\ &\leq \prod_{i \in [r]} \Pr_\Pi\left[\left|\sum_{\ell \in \mathcal{L}(u_i)} \Pi(\ell)\right| \leq \gamma \;\middle|\; \{\Pi(\ell) \mid \ell \in \bigcup_{j<i} \mathcal{L}(u_j)\}\right] \qquad (2)\end{aligned}$$

Fix any $i \in [r]$ and $\Pi(\ell)$ for each $\ell \in \mathcal{L}_{<i} := \bigcup_{j<i} \mathcal{L}(u_j)$. The event $|\sum_{\ell \in \mathcal{L}(u_i)} \Pi(\ell)| \leq \gamma$ is equivalent to $\sum_{\ell \in \mathcal{L}(u_i) \setminus \mathcal{L}_{<i}} \Pi(\ell) \in I$ for some interval I of length $2\gamma = O(\sqrt{t})$. This is the probability that the sum of at least t $\{-1, 1\}$-valued random variables chosen i.u.a.r. lies in an interval of length $O(\sqrt{t})$. By the Central Limit theorem, this is at most $1 - \Omega(1)$. By (2), we get $\Pr_\Pi[\Pi$ γ-correlated to $T] \leq \exp\{-\Omega(r)\}$, which proves the claim. ◀

4 Other results

We refer the reader to the full version of the paper [17] for proofs of the results stated below.

Lower bounds for circuits with rotations of one parse tree. Given two parse trees T_1 and T_2 with the same number of leaves, we say that T_1 is a *rotation* of T_2, denoted $T_1 \sim T_2$, if T_1 can be obtained from T_2 by repeatedly reordering the children of various nodes in T_2. Clearly, $\sim$ is an equivalence relation. We use $[\![T]\!]$ to denote the equivalence class of tree T. We say that a homogeneous circuit C is *rotation UPT or rotUPT* if there is a tree T such that $\mathcal{T}(C) \subseteq [\![T]\!]$. We can show the following result.

▶ **Theorem 17.** *Let $N, d \in \mathbb{N}$ be parameters with d even. Let C be a rotUPT circuit of size s computing a polynomial $f \in \mathbb{F}\langle X\rangle$ of degree d over N variables, then there exists a partition $\Pi = \Pi_C$ s.t.* rel-rank(f, Π) *is at most* $\mathrm{poly}(s) \cdot N^{-\Omega(d)}$. *In particular, if $|\mathbb{F}| > q_0(N, d)$ where $q_0(N, d)$ is as in Theorem 10, any rotUPT circuit for $F_{N,d}$ has size $N^{\Omega(d)}$.*

Separation between Few PT formulas and ABPs. We now state two lower bounds for formulas against $\mathrm{IMM}_{n,d}$, yelding separations with ABPs.

We define the *$\times$-depth* of a formula to be the maximum number of $\times$-gates that one can meet on a path from the root to a leaf. Note that if a formula has alternating $+$ and $\times$ gates on each path and has depth Δ' and $\times$-depth Δ, then $\Delta' \geq \Delta \geq \lceil \frac{\Delta'}{2} \rceil$. We will state our first lower bound in terms of $\times$-depth.

▶ **Theorem 18.** *Let F be a UPT formula of $\times$-depth Δ, size s, computing* $\mathrm{IMM}_{n,d} \in \mathbb{F}\langle X\rangle$. *Then, $s \geq n^{\Omega(\Delta d^{1/\Delta})}$. In particular, any UPT formula for* $\mathrm{IMM}_{n,d}$ *must have size $n^{\Omega(\log d)}$.*

This lower bound is actually tight for every $\times$-depth Δ, since the standard divide and conquer approach to computing $\mathrm{IMM}_{n,d}$ gives in fact a UPT formula of size $n^{O(\Delta d^{1/\Delta})}$ and $\times$-depth Δ, for any $\Delta \leq \log d$.

We can also prove a lower bound on the size of k-PT formulas computing $\mathrm{IMM}_{n,d}$ as long as k is significantly smaller than 2^d and $d \leq \log n$.

▶ **Theorem 19.** *Let n, d be growing parameters with $d \leq \log n$. Then, any k-PT formula F computing* $\mathrm{IMM}_{n,d}$ *has size at least n^{ℓ} where $\ell = \Omega(\lg d - \lg\lg k)$. In particular, if $k = 2^{o(d)}$, the* $\mathrm{size}(F) \geq n^{\omega(1)}$ *and if $k = 2^{d^{1-\Omega(1)}}$, then* $\mathrm{size}(F) \geq n^{\Omega(\log d)}$.

Deterministic PIT for UPT and k-PT circuits. We now state two results regarding deterministic whitebox PIT algorithms for UPT and k-PT circuits. The first result was already known in characteristic 0 via the result of Lagarde et al. [18]. However, the algorithm we give, adapting the work of Raz and Shpilka [24], works over fields of any characteristic and runs in time polynomial in the size of the circuit. The second result uses additionally the ideas of Gurjar et al. [10] to extend the above algorithm to a deterministic PIT for sums of k UPT circuits; the algorithm runs in polynomial time as long as k is a constant.

▶ **Theorem 20** (PIT for UPT circuits)**.** *Let $N, s \in \mathbb{N}$ be parameters. There is a deterministic algorithm running in time* $\mathrm{poly}(s)$ *which, on input a UPT circuit C of size at most s over N variables, checks if C computes the zero polynomial or not.*

▶ **Theorem 21** (PIT for sums of k UPT circuits)**.** *Let $N, s, k \in \mathbb{N}$ be parameters. There is a deterministic algorithm running in time $s^{O(2^k)}$ which, on input k UPT circuits $C_1, \ldots, C_k$ (of possibly differing shapes) each of of size at most s over N variables, checks if $\sum_{i=0}^{k} C_i$ computes the zero polynomial or not.*

Abstract

Consider the Maximum Weight Independent Set problem for rectangles: given a family of weighted axis-parallel rectangles in the plane, find a maximum-weight subset of non-overlapping rectangles. The problem is notoriously hard both in the approximation and in the parameterized setting. The best known polynomial-time approximation algorithms achieve super-constant approximation ratios [5, 7], even though there is a $(1+\epsilon)$-approximation running in quasi-polynomial time [2, 8]. When parameterized by the target size of the solution, the problem is W[1]-hard even in the unweighted setting [12].

To achieve tractability, we study the following *shrinking model*: one is allowed to shrink each input rectangle by a multiplicative factor $1-\delta$ for some fixed $\delta > 0$, but the performance is still compared against the optimal solution for the original, non-shrunk instance. We prove that in this regime, the problem admits an EPTAS with running time $f(\epsilon,\delta)\cdot n^{\mathcal{O}(1)}$, and an FPT algorithm with running time $f(k,\delta)\cdot n^{\mathcal{O}(1)}$, in the setting where a maximum-weight solution of size at most k is to be computed. This improves and significantly simplifies a PTAS given earlier for this problem [1], and provides the first parameterized results for the shrinking model. Furthermore, we explore kernelization in the shrinking model, by giving efficient kernelization procedures for several variants of the problem when the input rectangles are squares.

1 Introduction

In Maximum (Weight) Independent Set, given a graph, the goal is to select a set of pairwise non-adjacent vertices with maximum cardinality or total weight. In its full generality, the problem is NP-hard and intractable both in the approximation and in the parameterized

setting: it is NP-hard to approximate within ratio $n^{1-\epsilon}$ for any $\epsilon > 0$ [16], and it is W[1]-hard when parameterized by the solution size [9]. Therefore, many restricted settings were studied.

One well-studied case is to consider a geometric setting where the input consists of a family of geometric objects, and the goal is to select a maximum-weight subfamily of pairwise non-overlapping objects. This case reduces to the graph setting by considering the intersection graph of the objects. These graphs are highly structured, which gives hope for better results than for general graphs.

This paper concentrates on the variant in which the input objects are axis-parallel rectangles in the two-dimensional plane. In this variant, Maximum Weight Independent Set admits much smaller approximation ratios than on general graphs. While no polynomial-time constant-factor approximation algorithm is known in general, there is an $\mathcal{O}(\log \log n)$-approximation algorithm for unweighted rectangles [5], an $\mathcal{O}(\log n / \log \log n)$-approximation algorithm for weighted rectangles [7], and a PTAS for squares [6, 10]. If one allows quasi-polynomial running time, then there is a $(1+\epsilon)$-approximation algorithm (a *QPTAS*) [3, 11]. It remains open whether this can be improved to a PTAS.

From the parameterized perspective, the problem remains W[1]-hard when parameterized by the size k of the solution, even for unweighted unit squares [12]. Therefore, the existence of an FPT algorithm with running time $f(k) \cdot n^{\mathcal{O}(1)}$ for a computable f is unlikely under standard assumptions from parameterized complexity; this also excludes the existence of an EPTAS for the problem [12]. However, the problem admits a faster-than-brute-force parameterized algorithm with running time $n^{\mathcal{O}(\sqrt{k})}$, which is optimal under the Exponential Time Hypothesis [13]. This algorithm works in the general setting of finding a maximum-weight independent set of size k in a family of polygons in the plane.

Shrinking model. In order to circumvent some of the many challenges that arise when designing approximation or parameterized algorithms for geometric Maximum Weight Independent Set, we investigate the *shrinking model* introduced by Adamaszek et al. [1]. In this model, one is allowed to shrink each input object by a multiplicative factor $1-\delta$ for some fixed $\delta > 0$, but the weight of the computed solution is still compared to the optimum for the original, non-shrunk instance; we give a formal definition later. It is known that the shrinking model allows for substantially better approximation algorithms than the general setting: Adamaszek et al. [1] gave a PTAS for axis-parallel rectangles, which was later generalized by Wiese to arbitrary convex polygons [15]. However, it has not been studied so far whether shrinking also helps to design parameterized algorithms. One concrete question would be whether Independent Set for axis-parallel rectangles remains W[1]-hard in the shrinking model.

Our results. This paper addresses the parameterized complexity of Maximum Weight Independent Set of Rectangles in the shrinking model, and answers the above questions. On the way to our two main parameterized contributions, we also improve the PTAS by Adamaszek et al. [1] to an EPTAS.

Our first main contribution is that Maximum Weight Independent Set of Rectangles is fixed-parameter tractable (FPT) in the shrinking model. Formally, for a shrinking parameter δ, we can decide in (deterministic) time $f(k,\delta) \cdot (nN)^{\mathcal{O}(1)}$ whether there is an independent set of k (shrunk) rectangles, or the original family has no independent subfamily of size k. Here, N is the total bit size of the input and f is some computable function. The algorithm also works in the weighted setting, where we look for a maximum-weight subset of at most k non-overlapping rectangles. The reason why we are able to circumvent

the W[1]-hardness for the standard model (i.e., without shrinking) is that the reduction of Marx [12] relies on tiny differences in the coordinates of the rectangles. However, as Adamaszek et al. [1] and this paper show, this aspect vanishes in the shrinking model.

The parameterized algorithm is actually a consequence of an EPTAS that we present for Maximum Weight Independent Set of Rectangles. That is, we give an algorithm with running time $f(\epsilon,\delta)\cdot(nN)^{\mathcal{O}(1)}$ that finds a subset of rectangles that do not overlap after shrinking by factor $1-\delta$, and whose total weight is at least $1-\epsilon$ times the optimum without shrinking. Recall that the standard model does not admit an EPTAS, unless FPT = W[1] [12].

Our EPTAS is based on the same principles as the PTAS of Adamaszek et al. [1]. The idea is to assemble an optimum solution using a bottom-up dynamic-programming approach pioneered by Erlebach et al. [10]. Each subproblem solved in the dynamic program corresponds to the maximum weight of an independent set contained in a "box", and the computation of the optimum for each such box boils down to enumerating a limited number of carefully chosen partitions of the box into smaller boxes. Intuitively, the ability to shrink is used to make sure that rectangles fit nicely into the different boxes. The main challenge is to ensure that these boxes can be assumed to be simple, and therefore only a limited number of subproblems is necessary to assemble a near-optimum solution.

The crucial contribution in our approximation algorithm is that we show that rectangular boxes suffice. In [1], most rectangles were shrunk in *only one direction* and therefore, the boxes were axis-parallel polygons with at most $g(\epsilon,\delta)$ sides each, for some function g. This makes the dynamic program very complex, and yields a running time of $(nN)^{g(\epsilon,\delta)}$ due to the sheer number of subproblems solved. In this paper, we fully exploit the properties of the shrinking model and shrink *each* rectangle in *two directions*. This changes the analysis, but the main advantage is that we only need to consider boxes that are rectangles (i.e., with only four sides) in our dynamic program. This greatly simplifies the dynamic program, and we show that we need to consider only $f(\epsilon,\delta)\cdot(nN)^{\mathcal{O}(1)}$ different subproblems. Hence, our EPTAS is both substantially faster and significantly simpler than previous work.

Our second main contribution is showing that several important subcases of Maximum Weight Independent Set of Rectangles with δ-shrinking admit polynomial kernels when parameterized by k and δ. Intuitively, such a kernel is a polynomial-time computable subfamily of the input rectangles of size bounded by a polynomial of k and δ that retains an optimum solution after δ-shrinking; a formal definition is given in Section 4. For unit squares of non-uniform weight, we construct a kernel of size $\mathcal{O}(k/\delta^2)$, while for squares of non-uniform size, but of uniform weight, we construct a kernel of size $\mathcal{O}(k^2\cdot\frac{\log(1/\delta)}{\delta^3})$. As a direct consequence, we obtain FPT algorithms for the considered variants with running time $(k/\delta)^{\mathcal{O}(\sqrt{k})}\cdot(nN)^{\mathcal{O}(1)}$ by applying the $n^{\mathcal{O}(\sqrt{k})}$-time algorithm of Marx and Pilipczuk [13] on the kernels. This *subexponential* running time is far better than the running time of our FPT algorithm for the general case.

Organization. In this extended abstract we sketch our EPTAS and present the main ideas behind the kernelization results. A much broader discussion, including complete proofs of all results, can be found in the full version available on the arXiv [14]. The proofs of claims marked with ♠ appear in the full version [14].

2 Preliminaries

We essentially adopt the notation of Adamaszek et al. [1]. Suppose that $\mathcal{R}=\{R_1,R_2,\ldots,R_n\}$ is a family of axis-parallel rectangles given in the input. Each rectangle R_i is described as $R_i=\{(a,b)\,:\,x_i^{(1)}<a<x_i^{(2)}$ and $y_i^{(1)}<b<y_i^{(2)}\}$, where $x_i^{(1)}<x_i^{(2)}$ and $y_i^{(1)}<y_i^{(2)}$

are integers. Thus, the input rectangles are assumed to be open, and their vertices are at integral points. We assume that the family $\mathcal{R}$ is given in the input with all the coordinates $x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)}$ encoded in binary; thus, the coordinates are at most exponential in the total bit size of the input, denoted by N. For a rectangle R_i, we define its *width* $g_i = x_i^{(2)} - x_i^{(1)}$ and *height* $h_i = y_i^{(2)} - y_i^{(1)}$. Moreover, each rectangle R_i has an associated *weight* w_i, which is a nonnegative real. For a subset $\mathcal{S} \subseteq \mathcal{R}$, we denote $w(\mathcal{S}) = \sum_{R_i \in \mathcal{S}} w_i$.

Fix a constant δ with $0 < \delta < 1$. For a rectangle R_i, its *δ-shrinking* $R_i^{-\delta}$ is the rectangle with x-coordinates $x_i^{(1)} + \frac{\delta}{2} g_i$ and $x_i^{(2)} - \frac{\delta}{2} g_i$, and y-coordinates $y_i^{(1)} + \frac{\delta}{2} h_i$ and $y_i^{(2)} - \frac{\delta}{2} h_i$. The δ-shrinking retains the weight w_i of the original rectangle. For a subset $\mathcal{S} \subseteq \mathcal{R}$, we denote $\mathcal{S}^{-\delta} = \{R_i^{-\delta} \colon R_i \in \mathcal{S}\}$ to be the family of δ-shrinkings of rectangles from $\mathcal{S}$.

A family of rectangles is *independent* (or is an *independent set*) if the rectangles are pairwise non-overlapping. In the Maximum Weight Independent Set of Rectangles problem (MWISR) we are given a family of axis-parallel rectangles $\mathcal{R} = \{R_1, R_2, \ldots, R_n\}$, and the goal is to find a subfamily of $\mathcal{R}$ that is independent and has maximum total weight. This maximum weight will be denoted by $\mathsf{OPT}(\mathcal{R})$. In the parameterized setting, we are additionally given an integer parameter k, and we look for a subfamily of $\mathcal{R}$ that has size at most k, is independent, and has maximum possible weight subject to these conditions. This maximum weight will be denoted by $\mathsf{OPT}_k(\mathcal{R})$.

In the δ-shrinking setting, we relax the requirement of independence to just requiring the disjointness of δ-shrinkings, but we still compare the weight of the output of our algorithm with $\mathsf{OPT}(\mathcal{R})$, respectively with $\mathsf{OPT}_k(\mathcal{R})$.

3 Main results

With the above definitions in mind, we can state formally our main results.

▶ **Theorem 1** (FPT for MWISR with δ-shrinking). *There is a deterministic algorithm that, given a weighted family $\mathcal{R}$ of n axis-parallel rectangles with total encoding size N and parameters k and δ, runs in time $f(k,\delta) \cdot (nN)^c$ for some computable function f and constant c, and outputs a subfamily $\mathcal{S} \subseteq \mathcal{R}$ such that $|\mathcal{S}| \leq k$, $\mathcal{S}^{-\delta}$ is independent, and $w(\mathcal{S}) \geq \mathsf{OPT}_k(\mathcal{R})$.*

▶ **Theorem 2** (EPTAS for MWISR with δ-shrinking). *There is a deterministic algorithm that, given a weighted family $\mathcal{R}$ of n axis-parallel rectangles with total encoding size N and parameters δ, ϵ, runs in time $f(\epsilon,\delta) \cdot (nN)^c$ for some computable function f and constant c, and outputs a subfamily $\mathcal{S} \subseteq \mathcal{R}$ such that $\mathcal{S}^{-\delta}$ is independent, and $w(\mathcal{S}) \geq (1-\epsilon)\mathsf{OPT}(\mathcal{R})$.*

In this section we sketch the proof of Theorem 2. Theorem 1 follows by a simple adjustment of the reasoning, as explained in the full version of the paper [14].

Throughout the proof we fix the input family $\mathcal{R} = \{R_1, \ldots, R_n\}$, and we denote $\mathsf{OPT}(\mathcal{R})$ by OPT. We also fix the constants δ and ϵ, and w.l.o.g. we assume that $1/\delta$ and $1/\epsilon$ are even integers larger than 4. For convenience, throughout the proof we aim at finding a solution $\mathcal{S}$ with $w(\mathcal{S}) \geq (1 - d \cdot \epsilon)\mathsf{OPT}$ for some constant d, for at the end we may rescale the parameter ϵ to ϵ/d. By shifting all the rectangles, we may assume without loss of generality that they all fit into the square $[1, L] \times [1, L]$, where $L = (1/\delta\epsilon)^\ell$ for some integer $\ell = \mathcal{O}(N)$. That is, all the coordinates $x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)}$ are between 1 and L, so in particular the width and the height of each rectangle is smaller than L.

We divide our reasoning into two steps. First, like in the PTAS of Adamaszek et al. [1], in Section 3.1 we describe how to remove some rectangles from $\mathcal{R}$ using standard shifting arguments so that OPT decreases only by an $\mathcal{O}(\epsilon)$-fraction, but the resulting family admits

some useful properties. Then, we shrink the rectangles in a similar way as in [1]; however, in contrast to [1] we will shrink *each* rectangle in both directions which will be important in our analysis. Second, we show that the properties of the obtained family enable us to compute an optimum solution using dynamic programming; this algorithm is presented in Section 3.2.

3.1 Sparsifying the family

Intuitively, we will apply shifting techniques to extract some structure in the input family $\mathcal{R}$ while losing only an $\mathcal{O}(\epsilon)$-fraction of OPT. The first goal is to classify the rectangles according to their widths (respectively, heights) such that rectangles in the same class have similar widths (respectively, heights), but between the classes the dimensions differ significantly.

▶ **Definition 3.** A subfamily $\mathcal{R}' \subseteq \mathcal{R}$ is *well-separated* if there exist two partitions $(\mathcal{R}^{\mathsf{V}}_1, \ldots, \mathcal{R}^{\mathsf{V}}_p)$ and $(\mathcal{R}^{\mathsf{H}}_1, \ldots, \mathcal{R}^{\mathsf{H}}_p)$ of $\mathcal{R}'$, with $p \leq \ell$, as well as reals ν_t, μ_t for $t = 1, 2, \ldots, p$, with the following properties satisfied for each $t \in \{1, 2, \ldots, p\}$:

- $\nu_t \leq g_i < \mu_t$ for each $R_i \in \mathcal{R}^{\mathsf{V}}_t$;
- $\nu_t \leq h_i < \mu_t$ for each $R_i \in \mathcal{R}^{\mathsf{H}}_t$;
- $\nu_t / \mu_{t-1} = 1/\delta\epsilon$ (except for $t = 1$) and $\mu_t / \nu_t = (1/\delta\epsilon)^{(1/\epsilon)-1}$; and
- $\nu_1 \leq 1$, $\mu_p \geq L$, and all numbers ν_t and μ_t apart from ν_1 are integers.

The partitions $(\mathcal{R}^{\mathsf{V}}_t)_{t=1,\ldots,p}$ and $(\mathcal{R}^{\mathsf{H}}_t)_{t=1,\ldots,p}$ are called the *vertical* and *horizontal levels*, respectively, whereas the parameters $(\nu_t)_{t=1,\ldots,p}$ and $(\mu_t)_{t=1,\ldots,p}$ are the *lower* and *upper limits* of the corresponding levels. Note that vertical levels partition $\mathcal{R}'$ by width, while the horizontal levels partition $\mathcal{R}'$ by height.

We now prove that we can find a well-separated subfamily that loses only an $\mathcal{O}(\epsilon)$-fraction of OPT using a standard shifting technique. Essentially the same step is used in the PTAS of Adamaszek et al. [1] (see Lemma 6 therein). Henceforth we will use the notation $[q] = \{0, 1, \ldots, q-1\}$ for any positive integer q.

▶ **Lemma 4.** *We can compute a collection of $1/\epsilon$ subfamilies $\mathcal{R}'_0, \ldots, \mathcal{R}'_{1/\epsilon-1} \subseteq \mathcal{R}$ in polynomial time such that each subfamily is well-separated, and there exists a $b^* \in [1/\epsilon]$ for which $\mathsf{OPT}(\mathcal{R}'_{b^*}) \geq (1 - 2\epsilon)\mathsf{OPT}$.*

Proof. Recall that the widths and heights of the rectangles from $\mathcal{R}$ are integers between 1 and $L-1$, where $L = (1/\delta\epsilon)^\ell$. First, create a partition of the rectangles into *vertical layers* $\mathcal{L}^{\mathsf{V}}_j$ for $j = 1, 2, \ldots, \ell$, where layer $\mathcal{L}^{\mathsf{V}}_j$ consists of rectangles R_i for which $(1/\delta\epsilon)^{j-1} \leq g_i < (1/\delta\epsilon)^j$. In a symmetric manner, partition $\mathcal{R}$ into *horizontal layers* $\mathcal{L}^{\mathsf{H}}_j$ for $j = 1, 2, \ldots, \ell$, where layer $\mathcal{L}^{\mathsf{H}}_j$ consists of rectangles R_i for which $(1/\delta\epsilon)^{j-1} \leq h_i < (1/\delta\epsilon)^j$.

For each offset $b \in [1/\epsilon]$ we construct a subfamily $\mathcal{R}'_b$ from $\mathcal{R}$ by removing all rectangles contained in those vertical layers $\mathcal{L}^{\mathsf{V}}_j$ and those horizontal layers $\mathcal{L}^{\mathsf{H}}_j$, for which $j \equiv b \mod (1/\epsilon)$. It is easy to see that each subfamily $\mathcal{R}'_b$ constructed in this manner is well-separated: each vertical level $\mathcal{R}^{\mathsf{V}}_t \subseteq \mathcal{R}'_b$ consists of $(1/\epsilon) - 1$ consecutive vertical layers between two removed ones, with the exception of the first and the last level, for which the start/end of the sequence of layers delimits the level. A symmetric analysis yields the partition into horizontal levels. It is straightforward to compute in polynomial time the partition into horizontal/vertical levels, as well as to choose their lower and upper limits.

Suppose that we choose b uniformly at random from the set $[1/\epsilon]$. Fix any optimum solution $\mathcal{S}$ in $\mathcal{R}$, that is, an independent set of rectangles such that $w(\mathcal{S}) = \mathsf{OPT}$. Observe that for any rectangle $R_i \in \mathcal{S}$, the probability that the vertical layer it belongs to is removed during the construction of $\mathcal{R}'_b$, is equal to ϵ. Similarly, the probability that the horizontal layer to which R_i belongs is removed when constructing $\mathcal{R}'_b$, is also ϵ. Hence, R_i is not

included in $\mathcal{R}'_b$ with probability at most 2ϵ. This means that the expected value of $w(\mathcal{S} \setminus \mathcal{R}'_b)$, the total weight of rectangles from $\mathcal{S}$ that did not survive in $\mathcal{R}'_b$, is at most $2\epsilon \cdot \mathsf{OPT}$. Hence, in expectation we have that $w(\mathcal{S} \setminus \mathcal{R}'_b) \leq 2\epsilon \cdot \mathsf{OPT}$. Therefore, there exists a subfamily $\mathcal{R}'_{b^*}$ with $b^* \in [1/\epsilon]$ such that $\mathsf{OPT}(\mathcal{R}'_{b^*}) \geq (1 - 2\epsilon)\mathsf{OPT}$. ◀

We now execute the rest of the algorithm on $\mathcal{R}'_b$ for each $b \in [1/\epsilon]$, and output the best solution obtained overall. This increases the running time of the algorithm by a factor $1/\epsilon$. From Lemma 4, however, we know that $\mathsf{OPT}(\mathcal{R}'_b) \geq (1 - 2\epsilon)\mathsf{OPT}$ for $b = b^*$, and thus we lose at most a factor $(1 - 2\epsilon)$ in this way. From now on, let $\mathcal{R}' = \mathcal{R}'_b$ for some $b \in [1/\epsilon]$.

Hierarchical grid structure. For any integer a, we describe a hierarchical grid structure and remove rectangles along it. We then execute the rest of the algorithm for a bounded number of values of a, losing at most an additional factor $(1 - 6\epsilon)$ in this way. Given a value of a, the grid structure is constructed as follows. We first divide the horizontal lines into p levels (p as in Definition 3) corresponding to the horizontal levels $\mathcal{R}^{\mathsf{H}}_t$. For level t, define the *level-t unit* as $u_t = \delta\nu_t/2$. Thus, for $t > 1$, we have $u_t = \mu_{t-1}/(2\epsilon)$, and hence u_t is an integer for $t > 1$, since $1/\epsilon$ is even. For each level $t \in \{1, 2, \ldots, p\}$ we define a set of horizontal grid lines G^{H}_t, consisting of the horizontal lines with y-coordinates from the set $\{a + b \cdot u_t \colon b \in \mathbb{Z}\}$. In other words, we take horizontal lines that are u_t apart from each other, and we shift them so that there is a line with y-coordinate a. We define vertical grid lines G^{V}_t of levels $t = 1, 2, \ldots, p$ in a symmetric manner, using the same shift parameter a and the same units for all levels. Define the *grid* of level t to be $G_t = G^{\mathsf{H}}_t \cup G^{\mathsf{V}}_t$. Note that any line of G_t is also a line of $G_{t'}$ for all $t' < t$. Thus, the grid of each level t' refines the grid of each larger level t.

Before we proceed, we describe the intuition of the next step; this step is also present in the PTAS of Adamaszek et al. [1] (see Lemma 7 therein). Rectangles belonging to $\mathcal{R}^{\mathsf{V}}_{t'}$ for $t' \geq t$ have width not smaller than ν_t. On the other hand, the lines of G^{V}_t are spaced at distance $u_t = \delta\nu_t/2$ apart, which means that there are $\Omega(1/\delta)$ vertical grid lines of G^{V}_t crossing each rectangle of vertical level t or larger. Intuitively, G^{V}_t provides a fine grid for those vertical levels, so that their rectangles can be snapped to the lines of G^{V}_t via shrinking by a multiplicative factor of at most $1 - \delta$. On the other hand, the rectangles of vertical levels $t - 1$ or smaller have widths not larger than $\mu_{t+1} = \nu_t \cdot (\delta\epsilon)$. Hence, the grid lines of G^{V}_t are at much larger distance to each other than the maximum possible width of such rectangles; more precisely, larger by a multiplicative factor at least $1/(2\epsilon)$. Consequently, if we were to choose $a \in [L]$ uniformly at random, then the probability that a rectangle R_i will be crossed by a vertical line of level larger than its vertical level, or a horizontal line of level larger than its horizontal level, will be $\mathcal{O}(\epsilon)$. If we exclude such rectangles, then we lose only an $\mathcal{O}(\epsilon)$-fraction of OPT in expectation. We now formalize the above intuition and use it to derive an existential statement and a deterministic algorithm.

We need the following definition. Let $R_i \in \mathcal{R}'$, and suppose that $R_i \in \mathcal{R}^{\mathsf{V}}_s \cap \mathcal{R}^{\mathsf{H}}_t$. We say that R_i is *abusive* if R_i is crossed by a vertical line of level larger than s, or R_i is crossed by a horizontal line of level larger than t; see Figure 1. A family of rectangles without abusive rectangles (with respect to the hierarchical grid structure for a) is called *well-behaved (for a)*.

▶ **Lemma 5.** *Let $U := \sum_{t=1}^{p} u_t$. We can compute a collection of $(1/\delta\epsilon)^{1/\epsilon}$ subfamilies $\mathcal{R}''_0, \ldots, \mathcal{R}''_{(1/\delta\epsilon)^{1/\epsilon}-1} \subseteq \mathcal{R}'$ in $(1/\delta\epsilon)^{1/\epsilon} \cdot (nN)^{\mathcal{O}(1)}$ time such that, for each $c \in [(1/\delta\epsilon)^{1/\epsilon}]$, the subfamily $\mathcal{R}''_c$ is well-separated and well-behaved for $c \cdot U$, and there exists a $c^* \in [(1/\delta\epsilon)^{1/\epsilon}]$ for which $\mathsf{OPT}(\mathcal{R}''_{c^*}) \geq (1 - 6\epsilon)\mathsf{OPT}(\mathcal{R}')$.*

Proof. For each $c \in [(1/\delta\epsilon)^{1/\epsilon}]$, the family $\mathcal{R}''_c$ is obtained from $\mathcal{R}'$ by removing all rectangles that are abusive with respect to the hierarchical grid structure for $a = c \cdot U$. Hence, $\mathcal{R}''_c$ is well-behaved for $c \cdot U$. Since we are only removing rectangles, $\mathcal{R}''_c$ is still well-separated.

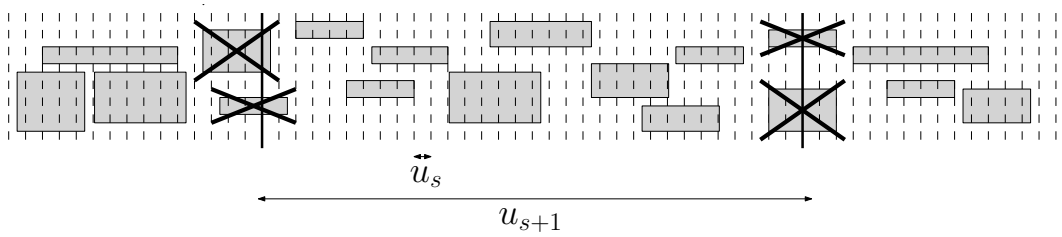

Figure 1 The vertical grid. The dashed vertical lines are the vertical grid lines of G_s^{V}, the bold vertical lines are the lines in the set G_{s+1}^{V}. All shown rectangles are from level $\mathcal{R}_s^{\mathsf{V}}$. The crossed out rectangles are abusive since they intersect lines from G_{s+1}^{V}.

It remains to show the existence of c^*. Let $R_i \in \mathcal{R}_s^{\mathsf{V}}$. As $R_i \in \mathcal{R}_s^{\mathsf{V}}$, we have that $g_i < \mu_s = \nu_{s+1} \cdot (\delta\epsilon) = u_{s+1} \cdot 2\epsilon$. Hence,

$$\frac{g_i}{\sum_{r=1}^{s} u_r} \leq \frac{g_i}{u_s} < \frac{u_{s+1} \cdot 2\epsilon}{u_s} = 2\epsilon \cdot (1/\delta\epsilon)^{1/\epsilon}. \tag{1}$$

Note that this inequality holds regardless of the choice of a for the construction of the hierarchical grid structure. Now consider the hierarchical grid structure for $a = c \cdot U$ for some $c \in [(1/\delta\epsilon)^{1/\epsilon}]$. Rectangle R_i is crossed by a vertical line of level larger than s if and only if it is crossed by a vertical line of level $s+1$. Lines of G_{s+1}^{V} are spaced at distance u_{s+1} from each other, which means that R_i is crossed by a line of G_{s+1}^{V} if and only if the remainder of $c \cdot U$ modulo u_{s+1} is among a set Γ_i of $g_i - 1$ consecutive remainders from $[u_{s+1}]$, being the remainders of the x-coordinates of vertical lines that cross R_i. By (1), Γ_i contains at most $2\epsilon \cdot (1/\delta\epsilon)^{1/\epsilon} + 2 \leq 3\epsilon \cdot (1/\delta\epsilon)^{1/\epsilon}$ multiples of $\sum_{r=1}^{s} u_r$. On the other hand, observe that $0 \leq c \cdot \sum_{r=1}^{s} u_r < u_{s+1}$ for all $c \in [(1/\delta\epsilon)^{1/\epsilon}]$, and that u_r divides u_{r+1} for each r. Hence, $c \cdot U$ gives remainder $c \cdot \sum_{r=1}^{s} u_r$ modulo u_{s+1}, which is always a multiple of $\sum_{r=1}^{s} u_r$. In particular, it follows that the multiples of $\sum_{r=1}^{s} u_r$ contained in Γ_i constitute at most a 3ϵ-fraction of all the remainders modulo u_{s+1} that $c \cdot U$ attains for $c \in [(1/\delta\epsilon)^{1/\epsilon}]$.

Suppose now that $c \in [(1/\delta\epsilon)^{1/\epsilon}]$ is chosen uniformly at random. Let $R_i \in \mathcal{R}_s^{\mathsf{V}} \cap \mathcal{R}_t^{\mathsf{H}}$. By the previous observation, R_i is crossed by a vertical line of level larger than s with probability at most 3ϵ. A similar analysis shows that R_i is crossed by a horizontal line of level larger than t with probability at most 3ϵ. Therefore, R_i is abusive with probability at most 6ϵ, and the total expected weight of the abusive rectangles in $\mathsf{OPT}(\mathcal{R}')$ with respect to $a = c \cdot U$ is bounded by $6\epsilon \cdot \mathsf{OPT}(\mathcal{R}')$. Hence, the value c^*, as claimed in the lemma statement, exists. ◀

We now execute the rest of the algorithm on $\mathcal{R}_c''$ for each $c \in [(1/\delta\epsilon)^{1/\epsilon}]$, and output the best solution obtained overall. This increases the running time of the algorithm by a factor $(1/\delta\epsilon)^{1/\epsilon}$. From Lemma 5, we know that $\mathsf{OPT}(\mathcal{R}_c'') \geq (1 - 6\epsilon)\mathsf{OPT}(\mathcal{R}')$ for $c = c^*$, and thus we lose at most a factor $(1 - 6\epsilon)$. From now on, let $\mathcal{R}'' = \mathcal{R}_c''$ for some $c \in [(1/\delta\epsilon)^{1/\epsilon}]$.

Snapping by shrinking. When considering $\mathcal{R}''$, the lines of G_t^{V} provide a fine division of every rectangle from vertical level t or larger, while no rectangle of smaller vertical level is crossed by them; symmetrically for horizontal grid lines. The idea now is to shrink each rectangle $R_i \in \mathcal{R}''$ so that its vertical sides are aligned with some vertical grid lines of the vertical level of R_i, while the horizontal sides are aligned with some horizontal grid lines of the horizontal level of R_i. This is formalized in the next lemma, which is also similar to Adamaszek et al. [1]. However, in this step there is a subtle but crucial difference. Consider a rectangle $R_i \in \mathcal{R}''$, and suppose $R_i \in \mathcal{R}_s^{\mathsf{V}} \cap \mathcal{R}_t^{\mathsf{H}}$. In [1], R_i is shrunk in the vertical dimension only if $s \geq t$ and in the horizontal dimension only if $t \geq s$. Here we always do both, which will be important for our dynamic programming.

▶ **Lemma 6.** *In polynomial time we can compute a well-behaved family of axis-parallel rectangles $\mathcal{Q}$ that contains one rectangle Q_i for each $R_i \in \mathcal{R}''$, of the same weight w_i as R_i and satisfying the following conditions:*

- *$R_i^{-\delta} \subseteq Q_i \subseteq R_i$ for each $R_i \in \mathcal{R}''$; and*
- *if $R_i \in \mathcal{R}_s^{\mathsf{V}} \cap \mathcal{R}_t^{\mathsf{H}}$, then both vertical sides of Q_i are contained in some vertical grid lines of G_s^{V}, and both horizontal sides of Q_i are contained in some horizontal grid lines of G_t^{H}.*

Proof. Take any $R_i \in \mathcal{R}''$, and suppose $R_i \in \mathcal{R}_s^{\mathsf{V}} \cap \mathcal{R}_t^{\mathsf{H}}$. We define Q_i as the rectangle cut from the plane by the following four lines:

- the left-most and the right-most vertical grid lines of G_s^{V} that cross R_i;
- the bottom-most and the top-most horizontal grid lines of G_t^{H} that cross R_i.

Clearly, we have that $Q_i \subseteq R_i$ and the second condition of the statement is satisfied. We are left with proving that $R_i^{-\delta} \subseteq Q_i$.

Consider first the left side of Q_i, which is contained in the left-most vertical grid line of G_s^{V} that crosses R_i. Since $R_i \in \mathcal{R}_s^{\mathsf{V}}$, we have that $g_i \geq \nu_s$, while the grid lines of G_s^{V} are spaced at distance $u_t = \delta\nu_s/2$ apart. This means that the left-most vertical grid line crossing R_i has the x-coordinate not larger than $x_i^{(1)} + \delta\nu_s/2$, which in turn is not larger than $x_i^{(1)} + \delta g_i/2$. This means that the left side of Q_i is either to the left or at the same x-coordinate as the left side of $R_i^{-\delta}$. An analogous reasoning can be applied to the other three sides of Q_i, thereby proving that $R_i^{-\delta} \subseteq Q_i$.

Note that since $\mathcal{Q}$ is obtained only by shrinking rectangles from $\mathcal{R}''$, it is still the case that no rectangle of $\mathcal{Q}$ is abusive. ◀

By Lemma 4 and Lemma 5, $\mathsf{OPT}(\mathcal{Q}) \geq \mathsf{OPT}(\mathcal{R}'') \geq (1-6\epsilon)\mathsf{OPT}(\mathcal{R}') \geq (1-8\epsilon)\mathsf{OPT}$ if $\mathcal{R}' = \mathcal{R}'_{b^*}$ and $\mathcal{R}'' = \mathcal{R}''_{c^*}$. Hence, the optimum solution for $\mathcal{Q}$ indeed has large enough weight. Moreover, by the first condition of Lemma 6, for any independent set of rectangles in $\mathcal{Q}$, the corresponding rectangles in $\mathcal{R}^{-\delta}$ are also independent. Hence, any solution for MWISR on $\mathcal{Q}$ projects to a solution of the same weight for MWISR with δ-shrinking on $\mathcal{R}$.

From now on we focus on the family $\mathcal{Q}$. For each $t \in \{1, 2, \ldots, p\}$, let $\mathcal{Q}_t^{\mathsf{V}} = \{Q_i \colon R_i \in \mathcal{R}_t^{\mathsf{V}}\}$ and $\mathcal{Q}_t^{\mathsf{H}} = \{Q_i \colon R_i \in \mathcal{R}_t^{\mathsf{H}}\}$.

3.2 Dynamic programming

We now present a dynamic programming algorithm that, given the family $\mathcal{Q}$ constructed in the previous section, computes the value $\mathsf{OPT}(\mathcal{Q})$. An optimum solution can be recovered from the run of the dynamic program using standard methods, and hence for simplicity we omit this aspect in the description.

We describe the algorithm as *backtracking with memoization*. That is, subproblems are solved by recursion, but once a subproblem has been solved once, the optimum value for it is stored in a map (is *memoized*), and further calls to solving this subproblem will only retrieve the memoized optimum value, rather than solve the subproblem again. Solving each subproblem (excluding recursive subcalls) takes time $f(\delta, \epsilon) \cdot n^{\mathcal{O}(1)}$ for some computable function f, and we argue that at most $g(\delta, \epsilon) \cdot (nN)^{\mathcal{O}(1)}$ subproblems are solved in total, for some other computable function g. This ensures the promised running time of the algorithm.

We first define subproblems. A *subproblem* is a tuple $I = (s, t, x_1, x_2, y_1, y_2)$, where the meaning of the entries is as follows. The pair $(s, t) \in \{1, \ldots, p\} \times \{1, \ldots, p\}$ is the *level* of the subproblem, which consists of the vertical level s and the horizontal level t. The numbers x_1, x_2, y_1, y_2 are integers satisfying $x_1 < x_2 \leq x_1 + (1/\delta\epsilon)^{1/\epsilon}$ and $y_1 < y_2 \leq y_1 + (1/\delta\epsilon)^{1/\epsilon}$. Integers x_1, x_2 are the lower and upper *vertical offsets*, respectively, while y_1, y_2 are the

lower and upper *horizontal offsets*, respectively. The *area covered* by subproblem $I = (s, t, x_1, x_2, y_1, y_2)$ is the rectangle

$$A_I = (a + x_1 \cdot u_s, a + x_2 \cdot u_s) \times (a + y_1 \cdot u_t, a + y_2 \cdot u_t).$$

In other words, (x_1, x_2, y_1, y_2) define the offsets of the four grid lines – two from G_s^{V} and two from G_t^{H} – that cut out A_I from the plane.

For a subproblem I, let $\mathcal{Q}_I$ be the family of all rectangles from $\mathcal{Q}$ that are contained in A_I. The next check follows from a simple calculation of parameters.

▶ **Lemma 7 (♠).** *If subproblem I has level (s, t), then $\mathcal{Q}_I \subseteq \bigcup_{s' \leq s,\, t' \leq t} \mathcal{Q}_{s'}^{\mathsf{V}} \cap \mathcal{Q}_{t'}^{\mathsf{H}}$.*

For a subproblem I, we define the *value* of I, denoted $\mathsf{Value}(I)$, as the maximum weight of a subfamily of $\mathcal{Q}_I$ that is independent. We show that there is a subproblem that encompasses the whole instance. Then, we show how to *solve* each subproblem I, that is, to compute $\mathsf{Value}(I)$, using recursion.

▶ **Lemma 8 (♠).** *There is a subproblem I_{all} of level (p, p), computable in constant time, such that $A_{I_{\mathsf{all}}} \supseteq (1, L) \times (1, L)$. Consequently, $\mathsf{OPT}(\mathcal{Q}) = \mathsf{Value}(I_{\mathsf{all}})$.*

Next comes the crucial point: we show how to *solve* each subproblem I, that is, to compute $\mathsf{Value}(I)$, using recursion.

▶ **Lemma 9 (♠).** *A subproblem I of level (s, t) can be solved using $f(\delta, \epsilon)$ calls to solving subproblems of levels $(s-1, t)$, $(s, t-1)$, and $(s-1, t-1)$, for some computable function f. Moreover, the time needed for this computation, excluding the time spent in the recursive calls, is at most $f(\delta, \epsilon) \cdot n$.*

Proof sketch. Consider all vertical lines of level s and all horizontal lines of level t that cross the rectangle A_I; their number is bounded by $(1/\delta\epsilon)^{1/\epsilon}$. These lines partition A_I into at most $(1/\delta\epsilon)^{2/\epsilon}$ smaller *cells* in a natural manner. Consider an independent set $\mathcal{S} \subseteq \mathcal{Q}_I$ such that $w(\mathcal{S}) = \mathsf{Value}(I)$. By obtaining a well-behaved family and applying the snapping procedure, we have the following structure; see Figure 2. Each rectangle from $\mathcal{S}$ of level (s, t) just occupies a rectangle of cells, each of them entirely. Whenever a rectangle from $\mathcal{S}$ is of level (s', t) for some $s' < s$, it is contained in a single column of cells, and its horizontal sides are aligned with some horizontal lines of the grid of cells. A symmetrical claim holds for rectangles from $\mathcal{S}$ of level (s, t') for any $t' < t$. Finally, any rectangle of $\mathcal{S}$ of level (s', t') for $s' < s$ and $t' < t$ is contained in a single cell.

It can be then easily seen that the whole grid of cells admits a partition into "boxes" such that each rectangle of $\mathcal{S}$ fits into a single box. Each box that is not contained in one column or in one row must be filled with a single rectangle of level (s, t), and we can greedily take the heaviest such rectangle. Each other box defines a subproblem of level (s', t') where $s' \leq s$, $t' \leq t$, and one of these inequalities is strict. Hence, an optimum solution for such a box can be computed using a recursive call. Therefore, the algorithm enumerates all partitions of the cells into boxes, and for each of them computes a candidate value using recursive subcalls; the value of I is the largest among the candidates. ◀

Finally, to bound the running time of the algorithm, we prove that there is only a small number of subproblems I for which $\mathcal{Q}_I$ is nonempty. Obviously, only such subproblems are necessary to solve, as the others have value 0.

▶ **Lemma 10 (♠).** *The number of subproblems I for which $\mathcal{Q}_I$ is nonempty is at most $81 \cdot (1/\delta\epsilon)^{4/\epsilon} \cdot |\mathcal{Q}| p^2$.*

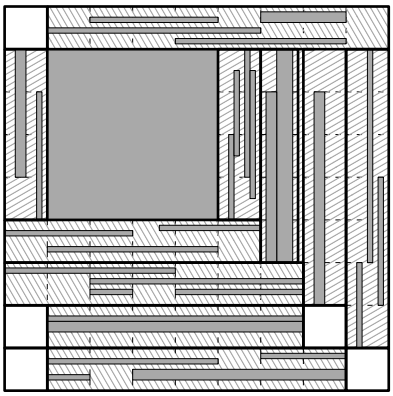

Figure 2 The partition of A_I into large, horizontal, vertical, and small cells. The figure is a slightly modified figure from [1].

Having gathered all the tools, we can describe the algorithm. To compute $\mathsf{OPT}(\mathcal{Q})$, it is sufficient to compute $\mathsf{Value}(I_{\mathsf{all}})$ for the subproblem I_{all} given by Lemma 8. For this we use backtracking with memoization. Starting from I_{all}, we recursively solve subproblems as explained in Lemma 9. Whenever $\mathsf{Value}(I)$ has been computed for some subproblem I, then this value is memoized in a map, and further calls to solving I will only return the value retrieved from the map, instead of recomputing the value again. Furthermore, whenever we attempt to compute $\mathsf{Value}(I)$ for a subproblem I for which $\mathcal{Q}_I$ is empty, we immediately return 0 instead of applying the procedure of Lemma 9. Therefore, the total running time of the algorithm is upper bounded by the number of subproblems I for which $\mathcal{Q}_I$ is nonempty, times the time spent on internal computations for each of them, including checking whether the respective family $\mathcal{Q}_I$ is empty and whether $\mathsf{Value}(I)$ has already been memoized. The first factor is bounded by $81 \cdot (1/\delta\epsilon)^{4/\epsilon} \cdot |\mathcal{Q}|p^2 \leq 81 \cdot (1/\delta\epsilon)^{4/\epsilon} \cdot nN^2$ due to Lemma 10. The second factor is bounded by $f(\delta,\epsilon) \cdot n^d$ for some constant d, due to Lemma 9. Hence, the running time of the whole algorithm is $f(\delta,\epsilon) \cdot (nN)^c$ for some computable function f and constant c. As mentioned before, the algorithm can be trivially adjusted to also compute an independent set of weight $\mathsf{Value}(I_{\mathsf{all}})$ by storing the value of each subproblem together with some independent set that certifies this value.

Summarizing, the dynamic programming described above computes an independent set in $\mathcal{Q}$ of weight $\mathsf{OPT}(\mathcal{Q})$ in time $f(\delta,\epsilon) \cdot (nN)^c$. As argued in the previous section, such an independent set projects to an independent set of the same weight in $\mathcal{R}^{-\delta}$, and $\mathsf{OPT}(\mathcal{Q}) \geq (1-8\epsilon)\mathsf{OPT}$ holds. This concludes the proof of Theorem 2.

4 Kernelization results

In this section we discuss kernelization for the case when the input family consists of squares. We first clarify the definition of a kernel, and then present the results.

Definition of kernel. The classic definition of kernelization is tailored to decision problems. Extending it to optimization problems in a weighted setting is often problematic, and making it compatible with the δ-shrinking model complicate it even more. Hence, we explicitly define kernelization for MWISR in the shrinking model, bearing in mind the main principle of kernelization: solving the kernel should project to a solution for the original instance.

▶ **Definition 11.** Let k be a non-negative integer, let $\delta \in (0,1)$, and let $\mathcal{R}$ be a family of axis-parallel rectangles. Then, a *kernel for* $(\mathcal{R}, k, \delta)$ is a polynomial-time computable subfamily $\mathcal{Q} \subseteq \mathcal{R}$ such that $|\mathcal{Q}| \leq f(k,\delta)$ for a computable function f, called the *size* of the kernel, and:

$$\mathsf{OPT}_k(\mathcal{Q}^{-\delta}) \geq \mathsf{OPT}_k(\mathcal{R}).$$

Thus, MWISR on $\mathcal{R}$ with the δ-shrinking relaxation may be solved by solving MWISR on $\mathcal{Q}^{-\delta}$ (without the δ-shrinking relaxation). If one wishes to use an algorithm for the shrinking relaxation on the kernel, then applying it to $\mathcal{Q}^{-\delta}$ with parameter δ will yield a subfamily $\mathcal{S}$ of size k such that $\mathcal{S}^{-2\delta}$ is independent and $w(\mathcal{S}) \geq \mathsf{OPT}_k(\mathcal{Q}^{-\delta}) \geq \mathsf{OPT}_k(\mathcal{R})$. Hence, this solves the original problem for 2δ-shrinking and we can rescale δ accordingly.

Definition 11 lacks one aspect of the classic notion of kernelization. Namely, the weights and the coordinates of the rectangles in the kernel are inherited from the original instance, so their bit encoding may not be bounded in terms of k and δ. We prefer to work with Definition 11, because it focuses our efforts on the core combinatorial aspects of our kernelization procedures. However, in the full version we argue that the sizes of the bit encodings of both the weights and the coordinates essentially can be reduced to polynomials in k and $1/\delta$ [14].

Results. The following theorem summarizes our kernelization results.

▶ **Theorem 12 (♠).** *Given a non-negative integer k, $\delta \in (0,1)$, and a family of axis-parallel squares $\mathcal{R}$, the following kernels for $(\mathcal{R}, k, \delta)$ can be computed in polynomial time:*

1. *If $\mathcal{R}$ consists of unit squares of uniform weight, then there is a kernel of size $\leq 16k/\delta^2$.*
2. *If $\mathcal{R}$ consists of unit squares of non-uniform weight, then there is a kernel of size $\leq 64k/\delta^2$.*
3. *If $\mathcal{R}$ consists of squares of non-uniform size, but of uniform weight, then there is a kernel of size $\mathcal{O}(k^2 \cdot \frac{\log(1/\delta)}{\delta^3})$.*

We now briefly sketch the main ideas. Consider first the simplest case of unit squares of uniform weight. Suppose two squares R_i and R_j are very close to each other: their centers are at distance less than $\delta/2$ in the ℓ_∞-metric (we will say that R_i and R_j are $(\delta/2)$-*close*). Then it is not hard to prove that $R_j^{-\delta} \subseteq R_i$, so intuitively, in the δ-shrinking model R_j is always a valid substitute for R_i. This allows for the following greedy strategy. Compute an inclusion-wise maximal subfamily $\mathcal{Q} \subseteq \mathcal{R}$ such that the centers of squares in $\mathcal{Q}$ are pairwise at distance at least $\delta/2$. By maximality, for every square $R_i \in \mathcal{R}$, there is a square $\phi(R_i) \in \mathcal{Q}$ that is $(\delta/2)$-close to R_i. By the observation above, the mapping ϕ maps every independent set in $\mathcal{R}$ to a subset of $\mathcal{Q}$ of the same size that is independent after δ-shrinking. Consequently, $\mathsf{OPT}_k(\mathcal{Q}^{-\delta}) \geq \mathsf{OPT}_k(\mathcal{R})$ and we may work with $\mathcal{Q}$ instead. However, the fact that squares of $\mathcal{Q}$ have centers pairwise far from each other immediately shows that the intersection graph of $\mathcal{Q}^{-\delta}$ has maximum degree bounded by a function of $1/\delta$ (similar to [4]). Then it is a standard exercise to give a linear kernel for Independent Set.

For unit squares of non-uniform weight, we follow the same strategy, but we construct $\mathcal{Q}$ greedily by iteratively taking the heaviest square and removing all squares that are $(\delta/2)$-close to it. This ensures that the substitute $\phi(R_i)$ is always at least as heavy as R_i. The maximum degree of the intersection graph of $\mathcal{Q}^{-\delta}$ can be bounded in the same manner. There is also a linear kernel for Maximum Weight Independent Set on bounded degree graphs, following the observation: Iterate k times the procedure of picking the heaviest vertex and removing all vertices at distance at most 2 from it. Then there is some maximum-weight independent set of size at most k that is contained in the removed vertices.

Finally, in the case of squares of non-uniform size and uniform weight, the following observation is crucial: if there are two squares R_i and R_j whose sizes differ by a multiplicative factor at least $2/\delta$, then either one is contained in the other, or they become disjoint after δ-shrinking. Observe that we may assume that the input does not contain any pair of squares where one is contained in the other, since the smaller one can be always selected instead of the larger. Hence, squares of very different sizes become disjoint after δ-shrinking. We partition the squares into levels according to the magnitude of their side lengths, and apply the following win-win approach. If many levels are non-empty, then we can find k of them so that picking one square from each yields an independent set of size k after δ-shrinking. Otherwise, only few levels are non-empty, and we can treat each level separately using essentially the same methods as for unit squares.

We conclude by discussing some applications. By composing our kernelization algorithms with the parameterized algorithm of Marx and Pilipczuk [13] for finding the heaviest k-independent set of polygons in the plane, we obtain algorithms with running time $(k/\delta)^{\mathcal{O}(\sqrt{k})} \cdot (nN)^{\mathcal{O}(1)}$ for all the problems encompassed by Theorem 12; this is much faster than the algorithm of Theorem 1. Also, some of our intermediate tools can be combined with the results of Alber and Fiala [4], yielding algorithms with running time $2^{\mathcal{O}_\delta(\sqrt{k})} \cdot (nN)^{\mathcal{O}(1)}$ for unit squares of non-uniform weight. We also obtain a faster EPTAS than Theorem 2 for squares of uniform size or uniform weight, for which the exponent depends only linearly on $1/\epsilon$. A precise description of these results can be found in the full version [14].

5 Conclusions

In this paper we have initiated the study of the shrinking model for parameterized geometric Independent Set, by giving FPT algorithms and polynomial kernels for the most basic variants. Most importantly, we have showcased that the shrinking model leads to robust tractability of problems that without this relaxation are hard from the parameterized perspective. We hope that this is the start of an interesting research direction, as our work raises several concrete open problems. Can our FPT algorithm and EPTAS for axis-parallel rectangles (Theorems 2 and 1) be generalized to arbitrary convex polygons, as is the case for the PTAS [15]? Recall that it was important for our algorithm that via shrinking we can align all edges of each rectangle with grid lines of suitable granularity. Then we could partition the plane recursively along these grid lines. Such an alignment is no longer possible for polygons, not even if each polygon is essentially a diagonal straight line segment. Instead, the PTAS in [15] crucially relies on guessing separators described via $\mathcal{O}_\epsilon(1)$ input polygons (and additionally $\mathcal{O}_\epsilon(1)$ grid lines). The total number of candidates for such separators is $n^{\mathcal{O}_\epsilon(1)}$, which leads to the running time of $n^{\mathcal{O}_\epsilon(1)}$ of the algorithm. Further, is it possible to improve the running time of our FPT algorithm to subexponential, that is, $2^{o(k)} \cdot (nN)^{\mathcal{O}(1)}$ for every fixed δ? What about polynomial kernels, i.e., kernelization procedures with polynomial output guarantees, for more complex objects than squares? Here, it seems that our arguments apply mutatis mutandis to e.g. (unit) disks instead of (unit) squares, but it is conceivable that even the general setting of convex polygons can be treated, for an appropriate definition of shrinking. Also, is there a polynomial kernel for squares of non-uniform size and non-uniform weight? This is not addressed in its full generality by our kernelization algorithms. Finally, can one give limits to tractability in the shrinking model, by showing W[1]-hardness or the nonexistence of polynomial kernels?

Abstract

Eilenberg-type correspondences, relating varieties of languages (e.g., of finite words, infinite words, or trees) to pseudovarieties of finite algebras, form the backbone of algebraic language theory. We show that they all arise from the same recipe: one models languages and the algebras recognizing them by monads on an algebraic category, and applies a Stone-type duality. Our main contribution is a variety theorem that covers e.g. Wilke's and Pin's work on ∞-languages, the variety theorem for cost functions of Daviaud, Kuperberg, and Pin, and unifies the two categorical approaches of Bojańczyk and of Adámek et al. In addition we derive new results, such as an extension of the local variety theorem of Gehrke, Grigorieff, and Pin from finite to infinite words.

1 Introduction

Algebraic language theory studies the behaviors of machines by relating them to algebraic structures. This has proved extremely fruitful. For example, regular languages can be described as the languages recognized by finite monoids, and the decidability of star-freeness rests on Schützenberger's theorem [30]: a regular language is star-free iff it is recognized by a finite aperiodic monoid. At the heart of algebraic language theory are results establishing generic correspondences of this kind. The prototype is Eilenberg's variety theorem [12], which states that *varieties of languages* (classes of regular languages closed under boolean operations, derivatives, and homomorphic preimages) correspond to *pseudovarieties of monoids* (classes of finite monoids closed under quotients, submonoids, and finite products). This together with Reiterman's theorem [25], stating that pseudovarieties of monoids can be specified by profinite equations, establishes a firm connection between automata, languages, and algebras.

Inspired by Eilenberg's work, over the past four decades numerous further variety theorems were discovered for regular languages [14,20,24,31], treating notions of varieties with modified closure properties, but also for machine behaviors beyond finite words, including weighted languages over a field [26], infinite words [21,35], words on linear orderings [5,6], ranked

† Supported by Deutsche Forschungsgemeinschaft (DFG) under project MI 717/5-1

trees [4], binary trees [29], and cost functions [11]. This plethora of structurally similar results has raised interest in category-theoretic approaches which allow to derive all the above results as special instances of only *one* general variety theorem. The first step in this direction was achieved in our previous work [1–3, 10]: there we replaced monoids by monoid objects in a category $\mathcal{D}$ of (ordered) algebras such as sets, posets, semilattices or vector spaces, and proved a variety theorem for $\mathcal{D}$-monoids that subsumes five different Eilenberg theorems for regular languages [12, 20, 24, 26, 31]. Subsequently, Bojańczyk [8] took an orthogonal approach: he keeps the category of sets but considers, in lieu of monoids, algebras for a *monad* on sorted sets as recognizing structures, improving earlier generic results from [4, 28].

In order to obtain the desired general variety theorem, a unification of the two approaches is required. On the one hand, one needs to take the step from sets to more general categories $\mathcal{D}$ to capture the proper notion of language recognition; for example, for the treatment of weighted languages [26] one needs to work over the category of vector spaces. On the other hand, to deal with machine behaviors beyond finite words, one has to replace monoids by other algebraic structures. The main contribution of this paper is a variety theorem that achieves the desired unification, and in addition directly encompasses many Eilenberg-type results captured by neither of the previous generic results, including the work [5, 6, 11, 21, 29, 35].

Traditionally, Eilenberg-like correspondences are proved in essentially the same four steps:

1. Identify an algebraic theory T such that the languages in mind are the ones recognized by finite T-algebras. For example, for regular languages one takes the theory of monoids.
2. Describe the syntactic T-algebras, i.e. the minimal algebraic recognizers of languages.
3. Infer the form of the derivatives under which varieties of languages are closed.
4. Establish the Eilenberg correspondence between varieties of languages and pseudovarieties of algebras by relating the languages of a variety to their corresponding syntactic algebras.

The key insight provided by our paper is that all steps can be simplified or even automated.

For Step 1, putting a common roof over Bojańczyk's and our own previous work, we consider an algebraic category $\mathcal{D}$ and algebras for a *monad* $\mathbf{T}$ on $\mathcal{D}^S$, the category of S-sorted $\mathcal{D}$-algebras for some finite set S of sorts. For example, to capture regular languages one takes the free-monoid monad $\mathbf{T}\Sigma = \Sigma^*$ on $\mathbf{Set}$. For regular ∞-languages one takes the monad $\mathbf{T}(\Sigma, \Gamma) = (\Sigma^+, \Sigma^\omega + \Sigma^* \times \Gamma)$ on $\mathbf{Set}^2$ representing ω-semigroups. For weighted languages over a finite field K, ones takes the free K-algebra monad $\mathbf{T}$ on the category of vector spaces.

For Steps 2 and 3, we develop our main technical tool, the concept of a *unary presentation* of a monad. A unary presentation expresses in categorical terms how to present $\mathbf{T}$-algebras by unary operations; for example, a monoid M is presented by the translations $x \mapsto yx$ and $x \mapsto xy$ for $y \in M$. It turns out that unary presentations are, in a precise sense, necessary and sufficient for constructing syntactic algebras (Theorem 4.7). This clarifies the role of syntactic algebras in earlier work on Eilenberg-type theorems, and the nature of derivatives appearing in varieties of languages. In our paper, syntactic algebras are *not* used for proving the variety theorem: we rely solely on the more elementary concept of a unary presentation.

We emphasize that, in general, nontrivial work lies in finding a good unary presentation for a monad $\mathbf{T}$. However, our work here shows that then Steps 3 and 4 are entirely generic: after choosing a unary presentation, we obtain a notion of *variety of* $\mathbf{T}$*-recognizable languages* (involving a notion of derivatives directly inferred from on the presentation) and the following

Variety Theorem. *Varieties of* $\mathbf{T}$*-recognizable languages are in bijective correspondence with pseudovarieties of* $\mathbf{T}$*-algebras.*

The proof has two main ingredients. The first one is duality: besides $\mathcal{D}$ we also consider a variety $\mathcal{C}$ that is dual to $\mathcal{D}$ on the level of finite algebras. Varieties of languages live in $\mathcal{C}$, while over $\mathcal{D}^S$ we form pseudovarieties of $\mathbf{T}$-algebras. This is much inspired by the work of Gehrke, Grigorieff, and Pin [14] who interpreted the original Eilenberg theorem [12] in terms of Stone duality ($\mathcal{C}$ = boolean algebras, $\mathcal{D}$ = sets). The second ingredient is the *profinite monad* of $\mathbf{T}$, introduced in [9]. It extends the classical construction of the free profinite monoid, and allows for the introduction of topological methods to our setting. The key to our approach is a categorical Reiterman theorem (Theorem 5.10) asserting that pseudovarieties of $\mathbf{T}$-algebras correspond to profinite equational theories. The Variety Theorem then boils down to the fact that (i) varieties of $\mathbf{T}$-recognizable languages dualize to profinite theories, and (ii) by the Reiterman theorem, profinite theories correspond to pseudovarieties of $\mathbf{T}$-algebras.

Our results establish a conceptual and highly parametric, yet easily applicable framework for algebraic language theory. In fact, to derive an Eilenberg correspondence in our framework, the traditional four steps indicated above are replaced by a simple three-step procedure:

1. Find a monad $\mathbf{T}$ whose finite algebras recognize the desired languages.
2. Choose a unary presentation for $\mathbf{T}$.
3. Spell out what a variety of $\mathbf{T}$-recognizable languages and a pseudovariety of $\mathbf{T}$-algebras is (by instantiating our general definitions), and invoke the Variety Theorem.

To illustrate the strength of this approach, we will show that roughly a dozen Eilenberg theorems in the literature emerge as special instances. In addition, we get several new results for free, e.g. an extension of the local variety theorem of [14] from finite to infinite words.

2 The Profinite Monad

We start by setting up our categorical framework for algebraic language theory. Recall that for a finitary one-sorted signature Γ, a *variety of algebras* is a class of Γ-algebras presented by equations between Γ-terms. A *variety of ordered algebras* is a class of ordered Γ-algebras (i.e. Γ-algebras on a poset with monotone Γ-operations) presented by inequations between Γ-terms. Morphisms of (ordered) Γ-algebras are (monotone) Γ-homomorphisms.

▶ **Assumptions 2.1.** Fix a variety $\mathcal{C}$ of algebras and a variety $\mathcal{D}$ of algebras/ordered algebras such that (i) $\mathcal{C}$ and $\mathcal{D}$ are *locally finite*, i.e. all finitely generated algebras are finite; (ii) the full subcategories $\mathcal{C}_f$ and $\mathcal{D}_f$ on finite algebras are dually equivalent; (iii) the signature of $\mathcal{C}$ contains a constant; (iv) epimorphisms in $\mathcal{D}$ are surjective. Further, fix a finite set S of sorts and a monad $\mathbf{T} = (T, \eta, \mu)$ on the product category $\mathcal{D}^S$ with T preserving epimorphisms.

▶ **Example 2.2.** The following categories $\mathcal{C}$ and $\mathcal{D}$ satisfy our assumptions:

1. $\mathcal{C} = \mathbf{BA}$ (boolean algebras) and $\mathcal{D} = \mathbf{Set}$: Stone duality [15] yields a dual equivalence $\mathbf{BA}_f^{op} \simeq \mathbf{Set}_f$, mapping a finite boolean algebra to the set of its atoms.
2. $\mathcal{C} = \mathbf{DL}_{01}$ (distributive lattices with $0, 1$) and $\mathcal{D} = \mathbf{Pos}$ (posets): Birkhoff duality [7] gives a dual equivalence $(\mathbf{DL}_{01})_f^{op} \simeq \mathbf{Pos}_f$, mapping a finite distributive lattice to the poset of its join-irreducible elements.
3. $\mathcal{C} = \mathcal{D} = \mathbf{JSL}_0$ (join-semilattices with 0): the self-duality $(\mathbf{JSL}_0)_f^{op} \simeq (\mathbf{JSL}_0)_f$ maps a finite semilattice $(X, \vee, 0)$ to its opposite semilattice $(X, \wedge, 1)$.
4. $\mathcal{C} = \mathcal{D} = \mathbf{Vec}_K$ (vector spaces over a finite field K): the familiar self-duality of $(\mathbf{Vec}_K)_f$ maps a finite (= finite-dimensional) vector space X to its dual space $X^* = \mathbf{Vec}_K(X, K)$.

▶ **Example 2.3.** Our focus is on monads $\mathbf{T}$ whose algebras represent formal languages.

1. Let $\mathbf{T}_*$ be the free-monoid monad on $\mathbf{Set}$. Languages of finite words correspond to subsets of $T_*\Sigma = \Sigma^*$. The category of $\mathbf{T}_*$-algebras is isomorphic to the category of monoids.
2. Languages of finite and infinite words (∞-*languages* for short) are represented by the monad $\mathbf{T}_\infty$ on $\mathbf{Set}^2$ associated to the algebraic theory of ω-semigroups. Recall that an ω-*semigroup* is a two-sorted set $A = (A_+, A_\omega)$ with a binary product $A_+ \times A_+ \xrightarrow{\cdot} A_+$, a mixed binary product $A_+ \times A_\omega \xrightarrow{\cdot} A_\omega$ and an ω-ary product $A_+^\omega \xrightarrow{\pi} A_\omega$ satisfying (mixed) associative laws [19]. The free ω-semigroup on a two-sorted set (Σ, Γ) is $(\Sigma^+, \Sigma^\omega + \Sigma^* \times \Gamma)$ with products given by concatenation of words. Thus $T_\infty(\Sigma, \Gamma) = (\Sigma^+, \Sigma^\omega + \Sigma^* \times \Gamma)$, and ∞-languages over the alphabet Σ are two-sorted subsets of $T_\infty(\Sigma, \emptyset) = (\Sigma^+, \Sigma^\omega)$.
3. Weighted languages $L\colon \Sigma^* \to K$ over a finite field K are represented by the free-K-algebra monad $\mathbf{T}_K$ on $\mathbf{Vec}_K$. Thus for the space K^Σ with finite basis Σ we have $T_K(K^\Sigma) = K\langle\Sigma\rangle$, the space of all polynomials $\sum_{i<n} k_i w_i$ ($k_i \in K$, $w_i \in \Sigma^*$) in non-commuting variables. Since $K\langle\Sigma\rangle$ has the basis Σ^*, weighted languages correspond to linear maps $T_K(K^\Sigma) \to K$.

▶ **Remark 2.4.** We denote by $\mathbf{Alg}_f\,\mathbf{T}$ and $\mathbf{Alg}\,\mathbf{T}$ the categories of (finite) $\mathbf{T}$-algebras. The category $\mathcal{D}^S$ has the factorization system of sortwise surjective morphisms and sortwise injective/order-reflecting morphisms. This lifts to $\mathbf{Alg}\,\mathbf{T}$ since T preserves surjections: every $\mathbf{T}$-homomorphism factors into a surjective $\mathbf{T}$-homomorphism followed by an injective/order-reflecting one. *Quotients* and *subalgebras* in $\mathbf{Alg}\,\mathbf{T}$ are taken in this factorization system.

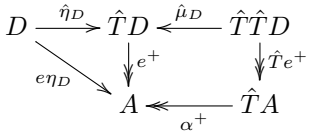
In the theory of regular languages, topology enters the stage via the Stone space $\widehat{\Sigma^*}$ of *profinite words*, formed as the inverse (a.k.a. cofiltered) limit of all finite quotient monoids of Σ^*. In [9] we generalized this construction from monoids to algebras for a monad as follows:

▶ **Notation 2.5.** For a variety $\mathcal{D}$ of algebras, let $\mathbf{Stone}(\mathcal{D})$ denote the category of *Stone-topological $\mathcal{D}$-algebras*; its objects are $\mathcal{D}$-algebras endowed with a Stone topology and continuous $\mathcal{D}$-operations, and its morphisms are continuous $\mathcal{D}$-morphisms. For a variety $\mathcal{D}$ of ordered algebras, let $\mathbf{Priest}(\mathcal{D})$ be the category of ordered topological $\mathcal{D}$-algebras with a Priestley topology, and monotone continuous $\mathcal{D}$-morphisms. Denote by $\widehat{\mathcal{D}}$ the full subcategory of $\mathbf{Stone}(\mathcal{D})/\mathbf{Priest}(\mathcal{D})$ on *profinite $\mathcal{D}$-algebras*, i.e. inverse limits of algebras in $\mathcal{D}_f$. Here we view $\mathcal{D}_f$ as a full subcategory of $\widehat{\mathcal{D}}$ by equipping objects of $\mathcal{D}_f$ with the discrete topology.

▶ **Example 2.6.** For the varieties $\mathcal{D}$ of Example 2.2, every algebra in $\mathbf{Stone}(\mathcal{D})/\mathbf{Priest}(\mathcal{D})$ is profinite: we have $\widehat{\mathbf{Set}} = \mathbf{Stone}$ (Stone spaces), $\widehat{\mathbf{Pos}} = \mathbf{Priest}$ (Priestley spaces), $\widehat{\mathbf{JSL}_0} = \mathbf{Stone}(\mathbf{JSL}_0)$ (Stone semilattices) and $\widehat{\mathbf{Vec}_K} = \mathbf{Stone}(\mathbf{Vec}_K)$ (Stone vector spaces); see [15].

▶ **Construction 2.7.** For any object $D \in \mathcal{D}_f^S$ form the poset $\mathsf{Quo}_f(\mathbf{T}D)$ of all finite quotient algebras $e\colon \mathbf{T}D \twoheadrightarrow (A, \alpha)$ of the free $\mathbf{T}$-algebra $\mathbf{T}D = (TD, \mu_D)$, ordered by $e \leq e'$ iff e factorizes through e'. Define the object $\hat{T}D$ in $\widehat{\mathcal{D}}^S$ to be the inverse limit of the diagram $\mathsf{Quo}_f(\mathbf{T}D) \to \widehat{\mathcal{D}}^S$ mapping $(e\colon \mathbf{T}D \twoheadrightarrow (A, \alpha))$ to A. We denote the limit projection associated to e by $e^+\colon \hat{T}D \twoheadrightarrow A$. In particular, for any finite $\mathbf{T}$-algebra (A, α) we have the projection $\alpha^+\colon \hat{T}A \to A$, since $\alpha\colon \mathbf{T}A \twoheadrightarrow (A, \alpha)$ is a surjective $\mathbf{T}$-homomorphism by the $\mathbf{T}$-algebra laws.

▶ **Theorem 2.8** (see [9])**.** *The object map $D \mapsto \hat{T}D$ from $\mathcal{D}_f^S$ to $\widehat{\mathcal{D}}^S$ extends (by taking inverse limits) to a functor $\hat{T}\colon \widehat{\mathcal{D}}^S \to \widehat{\mathcal{D}}^S$. Further, $\hat{T}$ can be equipped with the structure of a monad $\widehat{\mathbf{T}} = (\hat{T}, \hat{\eta}, \hat{\mu})$ called the* profinite monad *of $\mathbf{T}$. Its unit $\hat{\eta}_D$ and multiplication $\hat{\mu}_D$ for $D \in \mathcal{D}_f^S$ are uniquely determined by the commutativity of the diagrams*



for all $e\colon \mathbf{T}D \twoheadrightarrow (A, \alpha)$ in $\mathsf{Quo}_f(\mathbf{T}D)$. (1)

In categorical terms, $\widehat{\mathbf{T}}$ is the codensity monad of the functor $\mathbf{Alg}_f\,\mathbf{T} \to \widehat{\mathcal{D}}$, $(A,\alpha) \mapsto A$.

▶ **Example 2.9.** The monad $\widehat{\mathbf{T}_*}$ on **Stone** assigns to each finite set Σ the Stone space $\widehat{\Sigma^*}$ of profinite words. The monad $\widehat{\mathbf{T}_K}$ on $\mathbf{Stone}(\mathbf{Vec}_K)$ assigns to each finite vector space K^Σ the Stone vector space arising as the limit of all finite quotient spaces of $K[\Sigma]$.

▶ **Remark 2.10.**

1. If (A,α) is a finite $\mathbf{T}$-algebra, then (A,α^+) is a $\widehat{\mathbf{T}}$-algebra: putting $e=\alpha$ in (1) gives the unit and associative law. By [9, Prop. 3.10] this yields an isomorphism $\mathbf{Alg}_f\,\mathbf{T} \cong \mathbf{Alg}_f\,\widehat{\mathbf{T}}$ given by $(A,\alpha)\mapsto(A,\alpha^+)$ and $h\mapsto h$.
2. Let $V\colon \widehat{\mathcal{D}}^S \to \mathcal{D}^S$ denote the forgetful functor. If $D \in \widehat{\mathcal{D}}^S_f\ (=\mathcal{D}^S_f)$ we usually write D for VD. By [9, Rem. B.6] there is a natural transformation $\iota\colon TV \to V\hat{T}$ whose component $\iota_D\colon TVD \to V\hat{T}D$ for $D\in\mathcal{D}^S_f$ is determined by $Ve^+\cdot\iota_D = e$ for all $e\in \mathsf{Quo}_f(\mathbf{T}D)$.

▶ **Remark 2.11.**

1. $\widehat{\mathcal{D}}$ is the *pro-completion* (the free completion under inverse limits) of $\mathcal{D}_f$, see [15, Rem. VI.2.4]. Further, since the variety $\mathcal{C}$ is locally finite, $\mathcal{C}$ is the *ind-completion* (the free completion under filtered colimits) of $\mathcal{C}_f$. Therefore the dual equivalence between $\mathcal{C}_f$ and $\mathcal{D}_f$ extends to a dual equivalence between $\mathcal{C}$ and $\widehat{\mathcal{D}}$. We denote the equivalence functors by $P\colon \widehat{\mathcal{D}} \xrightarrow{\simeq} \mathcal{C}^{op}$ and $P^{-1}\colon \mathcal{C}^{op} \xrightarrow{\simeq} \widehat{\mathcal{D}}$. For example, for $\mathcal{C}/\mathcal{D} = \mathbf{BA}/\mathbf{Set}$ with $\widehat{\mathcal{D}} = \mathbf{Stone}$, this is the classical Stone duality [15]: P maps a Stone space to the boolean algebra of clopens, and P^{-1} maps a boolean algebra to the Stone space of all ultrafilters.
2. Denote by $|-|$ the forgetful functors of $\mathcal{C}$ and $\widehat{\mathcal{D}}$ into **Set** and by $\mathbb{1}_\mathcal{C}/\mathbb{1}_\mathcal{D}$ the free one-generated objects in $\mathcal{C}/\widehat{\mathcal{D}}$. The two finite objects $O_\mathcal{C} := P\mathbb{1}_\mathcal{D}$ and $O_\mathcal{D} := P^{-1}\mathbb{1}_\mathcal{C}$ play the role of a *dualizing object* [15] of $\mathcal{C}$ and $\widehat{\mathcal{D}}$. This means that there is a natural isomorphism between the functors $|-|\cdot P^{op}$ and $\widehat{\mathcal{D}}(-,O_\mathcal{D})\colon \widehat{\mathcal{D}}^{op}\to\mathbf{Set}$, given for any $D\in\widehat{\mathcal{D}}$ by
$$|PD| \cong \mathcal{C}(\mathbb{1}_\mathcal{C}, PD) \cong \widehat{\mathcal{D}}(P^{-1}PD, P^{-1}\mathbb{1}_\mathcal{C}) = \widehat{\mathcal{D}}(P^{-1}PD, O_\mathcal{D}) \cong \widehat{\mathcal{D}}(D, O_\mathcal{D}).$$
Similarly, $|-|\cdot P^{-1} \cong \mathcal{C}(-,O_\mathcal{C})$. Thus $O_\mathcal{C}$ and $O_\mathcal{D}$ have essentially the same underlying set, as $|O_\mathcal{D}| \cong \widehat{\mathcal{D}}(\mathbb{1}_\mathcal{D}, O_\mathcal{D}) \cong |P\mathbb{1}_\mathcal{D}| = |O_\mathcal{C}|$. For our pairs $\mathcal{C}/\mathcal{D}$ of Ex. 2.2, we get $O_{\mathbf{BA}} = \{0<1\}/O_{\mathbf{Set}} = \{0,1\}$, $O_{\mathbf{DL}_{01}} = \{0<1\} = O_{\mathbf{Pos}}$, $O_{\mathbf{JSL}_0} = \{0<1\}$, $O_{\mathbf{Vec}_K} = K$.
3. *Subobjects* in $\mathcal{C}$ are represented by monomorphisms, i.e. injective morphisms. Dually, *quotients* in $\widehat{\mathcal{D}}$ are represented by epimorphisms, which can be shown to be the surjective morphisms. Thus *quotients* of $\widehat{\mathbf{T}}$-algebras are represented by surjective $\widehat{\mathbf{T}}$-homomorphisms.

3 Recognizable Languages

A language $L\subseteq\Sigma^*$ of finite words may be identified with its characteristic function $L\colon\Sigma^*\to\{0,1\}$. To model languages in our categorical setting, we replace the one-sorted alphabet Σ by an S-sorted alphabet Σ in $\mathbf{Set}^S_f$, and represent it in $\mathcal{D}^S$ via the free object $\not\asymp\in\mathcal{D}^S_f$ generated by Σ (w.r.t. the forgetful functor $|-|\colon\mathcal{D}^S\to\mathbf{Set}^S$). Note that $\not\asymp$ is finite because $\mathcal{D}$ is locally finite. The output set $\{0,1\}$ is replaced by a finite "object of outputs" in $\mathcal{D}^S_f$, viz. the object with $O_\mathcal{D}\in\mathcal{D}_f$ in each sort. By abuse of notation, we denote this object of $\mathcal{D}^S_f$ also by $O_\mathcal{D}$. This leads to the following definition, unifying concepts from [2] and [8].

▶ **Definition 3.1.** A *language* over the alphabet $\Sigma\in\mathbf{Set}^S_f$ is a morphism $L\colon T\not\asymp\to O_\mathcal{D}$ in $\mathcal{D}^S$. It is called $\mathbf{T}$-*recognizable* if there exists a $\mathbf{T}$-homomorphism $h\colon\mathbf{T}\not\asymp\to(A,\alpha)$ with finite codomain and a morphism $p\colon A\to O_\mathcal{D}$ in $\mathcal{D}^S$ with $L=p\cdot h$. In this case, we say that L *is recognized by* h *(via* p*)*. We denote by $\mathsf{Rec}(\Sigma)$ the set of all $\mathbf{T}$-recognizable languages over Σ.

▶ **Example 3.2.**

1. $\mathbf{T} = \mathbf{T}_*$ on $\mathbf{Set}$ with $O_{\mathbf{Set}} = \{0,1\}$: a language $L\colon T_*\Sigma \to O_{\mathbf{Set}}$ corresponds to a language $L \subseteq \Sigma^*$ of finite words. It is recognized by a monoid morphism $h\colon \Sigma^* \to A$ iff $L = h^{-1}[Y]$ for some subset $Y \subseteq A$. Recognizable languages coincide with regular languages, i.e. languages accepted by finite automata; see e.g. [22].
2. $\mathbf{T} = \mathbf{T}_\infty$ on $\mathbf{Set}^2$ with $O_{\mathbf{Set}} = \{0,1\}$: since $T_\infty(\Sigma,\emptyset) = (\Sigma^+, \Sigma^\omega)$, a language $L\colon T_\infty(\Sigma,\emptyset) \to (\{0,1\},\{0,1\})$ corresponds to an ∞-language $L \subseteq (\Sigma^+,\Sigma^\omega)$. It is recognized by an ω-semigroup morphism $h\colon (\Sigma^+,\Sigma^\omega) \to A$ iff $L = h^{-1}[Y]$ for some two-sorted subset $Y \subseteq A$. Recognizable ∞-languages are the ones accepted by finite Büchi automata [19].

The topological perspective on regular languages rests on the important observation that regular languages over Σ correspond to the clopen subsets of the Stone space $\widehat{\Sigma^*}$ of profinite words, or equivalently to continuous maps from $\widehat{\Sigma^*}$ into the discrete space $\{0,1\}$; see e.g. [22, Prop. VI.3.12]. This generalizes from the monad $\mathbf{T}_*$ on $\mathbf{Set}$ to arbitrary monads $\mathbf{T}$:

▶ **Theorem 3.3.** *$\mathbf{T}$-recognizable languages over $\Sigma \in \mathbf{Set}_f^S$ correspond bijectively to morphisms from $\hat{T}\not\prec$ to $O_\mathcal{D}$ in $\widehat{\mathcal{D}}^S$. The bijection is given by $(\hat{T}\not\prec \xrightarrow{\hat{L}} O_\mathcal{D}) \mapsto (T\not\prec \xrightarrow{\iota\not\prec} V\hat{T}\not\prec \xrightarrow{V\hat{L}} O_\mathcal{D})$.*

▶ **Remark 3.4** (𝒞-algebraic structure on $\mathsf{Rec}(\Sigma)$)**.** By the above and Remark 2.11.2, we deduce

$$\mathsf{Rec}(\Sigma) \cong \widehat{\mathcal{D}}^S(\hat{T}\not\prec, O_\mathcal{D}) = \prod_s \widehat{\mathcal{D}}((\hat{T}\not\prec)_s, O_\mathcal{D}) \cong \prod_s |P(\hat{T}\not\prec)_s|. \tag{2}$$

Thus we can consider $\mathsf{Rec}(\Sigma)$ as an object of $\mathcal{C}$ isomorphic to $\prod_s P(\hat{T}\not\prec)_s$. One can show that $\mathsf{Rec}(\Sigma)$ is a subobject of the product $\prod_s O_\mathcal{C}^{|T\not\prec|_s}$ in $\mathcal{C}$: the embedding $\mathsf{Rec}(\Sigma) \rightarrowtail \prod_s O_\mathcal{C}^{|T\not\prec|_s}$ maps a language $L\colon T\not\prec \to O_\mathcal{D}$ to the S-tuple $(|T\not\prec|_s \xrightarrow{|L|_s} |O_\mathcal{D}| \xrightarrow{\cong} |O_\mathcal{C}|)_{s\in S}$, using the bijection $|O_\mathcal{D}| \cong |O_\mathcal{C}|$ of Remark 2.11.2. Consequently the $\mathcal{C}$-algebraic structure of $\mathsf{Rec}(\Sigma)$ is determined by $O_\mathcal{C}$. For example, for $\mathcal{C} = \mathbf{BA}$ with $O_{\mathbf{BA}} = \{0,1\}$, the boolean structure on $\mathsf{Rec}(\Sigma)$ is given by union, intersection and complement. Taking $\mathbf{T} = \mathbf{T}_*$ on $\mathbf{Set}$, we recover an important result of Pippenger [23]: the boolean algebra of regular languages over Σ is dual to the Stone space $\widehat{\Sigma^*}$ of profinite words. In fact, in this case (2) yields $\mathsf{Rec}(\Sigma) \cong P(\widehat{\Sigma^*})$.

4 Unary Presentations

In this section we introduce *unary presentations* of $\mathbf{T}$-algebras that later, in Section 6, will serve as our key tool for defining the derivatives of a language. For motivation, let A be an algebra over a finitary single-sorted signature Γ. By a standard result in universal algebra, an equivalence relation $\equiv$ on A is a Γ-congruence (i.e. stable under Γ-operations) iff it is stable under *elementary translations*, i.e. $a \equiv a'$ implies $u(a) \equiv u(a')$ for all maps $u\colon A \to A$ of the form $a \mapsto \gamma^A(a_0,\dots,a_i,a,a_{i+1},\dots a_n)$, where $\gamma \in \Gamma$ and $a_0,\dots a_n \in A$. (For the sorted case, see [17,18].) If Γ contains infinitary operations, this statement generally fails, but remains valid if $\equiv$ is refinable to a Γ-congruence of finite index; see Examples 4.3.3/5. Identifying equivalence relations with quotients, we first state the concept of refinement categorically:

▶ **Definition 4.1.** Let $(A,\alpha) \in \mathbf{Alg}\,\mathbf{T}$. A quotient $e\colon A \twoheadrightarrow B$ in $\mathcal{D}^S$ is $\mathbf{T}$-*refinable* if there is a finite quotient $\bar{e}\colon (A,\alpha) \twoheadrightarrow (C,\gamma)$ in $\mathbf{Alg}\,\mathbf{T}$ and a morphism $p\colon C \twoheadrightarrow B$ in $\mathcal{D}^S$ with $e = p\cdot\bar{e}$.

Then the description of congruences via translations has the following categorical formulation:

▶ **Definition 4.2.** A *unary operation* on $A \in \mathcal{D}^S$ is a morphism $u\colon A_s \to A_t$ in $\mathcal{D}$, where $s,t \in S$. A *unary presentation* of a $\mathbf{T}$-algebra (A,α) is a set $\mathbb{U}$ of unary operations on A such that, for any $\mathbf{T}$-refinable quotient $e\colon A \twoheadrightarrow B$ in $\mathcal{D}^S$, the following are equivalent:

(U1) e carries a quotient of (A,α) in $\mathbf{Alg}\,\mathbf{T}$, i.e. there exists a $\mathbf{T}$-algebra structure (B,β) on B for which $e\colon (A,\alpha) \twoheadrightarrow (B,\beta)$ is a $\mathbf{T}$-homomorphism.

(U2) Each unary operation $u\colon A_s \to A_t$ in $\mathbb{U}$ admits a lifting along e, i.e. a morphism $u_B\colon B_s \to B_t$ in $\mathcal{D}$ with $e_t \cdot u = u_B \cdot e_s$.

▶ **Example 4.3.**

1. $\mathbf{T} = \mathbf{T}_*$ on $\mathbf{Set}$: every monoid M has a unary presentation given by the unary operations $x \mapsto yx$ and $x \mapsto xy$ on M, where y ranges over all elements of M.
2. $\mathbf{T} = \mathbf{T}_\infty$ on $\mathbf{Set}^2$: every ω-semigroup $A = (A_+, A_\omega)$ has a unary presentation given by the operations (i) $x \mapsto yx$ and $x \mapsto xy$ on A_+, (ii) $x \mapsto xz$ and $x \mapsto x^\omega = \pi(x,x,x,\ldots)$ from A_+ to A_ω, and (iii) $z \mapsto yz$ on A_ω, where $y \in A_+ \cup \{1\}$ and $z \in A_\omega$. The proof uses Ramsey's theorem and appears implicitly in the work of Wilke [35]; see also [19].
3. Let $\mathbf{T}$ be a monad on $\mathbf{Set}^S$. Every $\mathbf{T}$-algebra (A,α) has a generic unary presentation given as follows. Let $1_s \in \mathbf{Set}^S$ be the S-sorted set with one element in sort s and otherwise empty; thus a morphism $1_s \to A$ in $\mathbf{Set}^S$ chooses an element of A_s. A *polynomial* over A is a morphism $p\colon 1_t \to T(A + 1_s)$ with $s,t \in S$, i.e. a "term" of output sort t in a variable of sort s. Denote by $A_s \xrightarrow{[p]} A_t$ the evaluation map that substitutes elements of A_s for the variable. The maps $[p]$ (where p ranges over polynomials over A) form a unary presentation of (A,α). The proof rests on the fact that $\mathbf{T}$-algebras can be viewed as algebras over a (possibly large and infinitary) signature [16]. Note that for monoids and ω-semigroups, the polynomial presentation is much larger than the one in Example 1/2; e.g., for a monoid M it contains all operations $x \mapsto y_0 x y_1 x \ldots x y_n$ with $y_0,\ldots,y_n \in M$. Polynomials appeared in [8] in the context of syntactic congruences; see Example 4.8.
4. In contrast to Example 4.3.3, in general not every $\mathbf{T}$-algebra admits a unary presentation if $\mathcal{D} \neq \mathbf{Set}$. Indeed, let $\mathcal{D} = \mathbf{Set}_{c,d}$ be the variety of sets with two constants c,d, and $\mathbf{Set}_{c\neq d}$ its full reflective subcategory on the terminal object 1 and all $X \in \mathcal{D}$ with $c^X \neq d^X$. The right adjoint $\mathbf{Set}_{c\neq d} \rightarrowtail \mathcal{D}$ induces a monad $\mathbf{T}$ on $\mathcal{D}$ with $\mathbf{Alg}\,\mathbf{T} \cong \mathbf{Set}_{c\neq d}$. One can show that the $\mathbf{T}$-algebra corresponding to $\{x,c,d\} \in \mathbf{Set}_{c\neq d}$ has no unary presentation.
5. If $\mathbf{T}$ represents algebras with finitary operations, the equivalence (U1)⇔(U2) often holds for arbitrary quotients e. However, the restriction to $\mathbf{T}$-*refinable* quotients is crucial in the presence of infinitary operations. For example, let $\mathbf{T}$ be the free Γ-algebra monad on $\mathbf{Set}$ for the signature Γ with one ω-ary operation. Thus TX is the set of well-founded Γ-trees (= ω-branching trees without infinite paths) with X-labeled leaves. Let $X \neq \emptyset$ and $e : TX \twoheadrightarrow \{0,1\}$ be the map sending a tree t to 0 iff t has finite height. Then for the polynomial presentation of $\mathbf{T}$, see Ex. 4.3.3, the direction (U2)⇒(U1) does not hold for e.

Digression: Syntactic T-algebras

Languages are often analyzed by means of *syntactic algebras*, i.e. their minimal recognizing algebras. This language-theoretic concept is closely related to our algebraic notion of a unary presentation, as we now explain. The results of this subsection serve to put our concepts into the context of classical algebraic language theory; they are, however, not used in the sequel and may be skipped by readers interested only in the variety theorem and its applications.

▶ **Definition 4.4.** Let $L\colon T\not\to \to O_{\mathcal{D}}$ be recognizable. A *syntactic* $\mathbf{T}$-*algebra for* L is a finite $\mathbf{T}$-algebra A_L together with a surjective $\mathbf{T}$-homomorphism $e_L\colon \mathbf{T}\not\to \twoheadrightarrow A_L$ (called a *syntactic morphism* for L) such that (i) e_L recognizes L, and (ii) e_L factors through any surjective $\mathbf{T}$-homomorphism $e\colon \mathbf{T}\not\to \twoheadrightarrow A$ recognizing L, i.e. $e_L = h \cdot e$ for some $h\colon A \twoheadrightarrow A_L$ in $\mathbf{Alg}\,\mathbf{T}$.

▶ **Example 4.5.** Let $\mathbf{T} = \mathbf{T}_*$ on $\mathbf{Set}$. The *syntactic monoid* [22] of a recognizable language $L\colon \Sigma^* \to \{0,1\}$ is the quotient monoid $e_L\colon \Sigma^* \twoheadrightarrow \Sigma^*/\equiv_L$, where $\equiv_L$ is the monoid congruence on Σ^* defined by $x \equiv_L x'$ iff $L(yxz) = L(yx'z)$ for all $y, z \in \Sigma^*$.

The above definition of $\equiv_L$ involves for each $y, z \in \Sigma^*$ the unary operation $x \mapsto yxz$ on Σ^*, which can be expressed as the composite of the operations $x \mapsto yx$ and $x \mapsto xz$ appearing in the unary presentation of Σ^* in Example 4.3.1. This is no coincidence: one can always derive a syntactic congruence from a unary presentation, and vice versa. For brevity, we discuss only the case where $\mathcal{D}$ is a variety of algebras; see the full paper [34] for the ordered case.

▶ **Notation 4.6.** Let $\mathbb{U}$ be a set of unary operations on $T\not\leftarrow$, and denote by $\overline{\mathbb{U}}$ its closure under composition and identity morphisms $id\colon (T\not\leftarrow)_s \to (T\not\leftarrow)_s$. Given a language $L\colon T\not\leftarrow \to O_{\mathcal{D}}$, the S-sorted equivalence relation $\equiv_{\mathbb{U},L}$ on $|T\not\leftarrow|$ is defined as follows: for $x, x' \in |T\not\leftarrow|_s$, put

$$x \equiv_{\mathbb{U},L} x' \quad \Leftrightarrow \quad L_t \cdot u(x) = L_t \cdot u(x') \text{ for all sorts } t \text{ and all } u\colon (T\not\leftarrow)_s \to (T\not\leftarrow)_t \text{ in } \overline{\mathbb{U}}.$$

One readily verifies that $\equiv_{\mathbb{U},L}$ is a congruence on $T\not\leftarrow$ in $\mathcal{D}^S$, i.e. sortwise stable under all $\mathcal{D}$-operations. We denote the induced quotient in $\mathcal{D}^S$ by $e_L\colon T\not\leftarrow \twoheadrightarrow T\not\leftarrow/\equiv_{\mathbb{U},L}$.

▶ **Theorem 4.7.** *For any set $\mathbb{U}$ of unary operations on $T\not\leftarrow$, the following are equivalent:*

(i) *$\mathbb{U}$ is a unary presentation of $\mathbf{T}\not\leftarrow$.*

(ii) *Every recognizable language $L\colon T\not\leftarrow \to O_{\mathcal{D}}$ has a syntactic $\mathbf{T}$-algebra, and $e_L\colon T\not\leftarrow \twoheadrightarrow T\not\leftarrow/\equiv_{\mathbb{U},L}$ carries a quotient of $\mathbf{T}\not\leftarrow$ in $\mathbf{Alg}\,\mathbf{T}$ that forms a syntactic morphism for L.*

▶ **Example 4.8.** Let $\mathbb{U}$ be the unary presentation of Σ^* in Example 4.3.1. Then $\equiv_{\mathbb{U},L}$ is precisely the congruence $\equiv_L$ of Example 4.5, and Theorem 4.7 shows that $\equiv_L$ is a syntactic congruence for L. Similarly, Example 4.3.2/3 and Theorem 4.7 give a description of the syntactic ω-semigroup for any recognizable ∞-language [19], and of the syntactic $\mathbf{T}$-algebra for any monad $\mathbf{T}$ on $\mathbf{Set}^S$ and any $\mathbf{T}$-recognizable language [8]. We omit the details.

Theorem 4.7 explains why syntactic algebras are presented as a key technique in earlier work on Eilenberg theorems: they implicitly contain unary presentations. However, the latter are the "heart of the matter", and it is easier to directly work with presentations in lieu of syntactic algebras to derive Eilenberg-type theorems. We will demonstrate this in Section 7.

5 Pseudovarieties of T-algebras and Profinite Theories

In this section we investigate pseudovarieties of $\mathbf{T}$-algebras and establish a categorical Reiterman theorem: pseudovarieties correspond to profinite equational theories. The results of the present section are largely independent of our Assumptions 2.1: they hold for any locally finite variety $\mathcal{D}$ of (ordered) algebras and any monad $\mathbf{T}$ on $\mathcal{D}^S$ that preserves surjections.

▶ **Definition 5.1.** A *Σ-generated $\mathbf{T}$-algebra* is a quotient $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow A$ of $\mathbf{T}\not\leftarrow$ in $\mathbf{Alg}\,\mathbf{T}$. The *subdirect product* of two quotients $e_i\colon \mathbf{T}\not\leftarrow \twoheadrightarrow A_i$ $(i = 0, 1)$ is the image $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow A$ of the $\mathbf{T}$-homomorphism $\langle e_0, e_1\rangle\colon \mathbf{T}\not\leftarrow \to A_0 \times A_1$. We say that e_1 is a *quotient* of e_0 if e_1 factors through e_0, i.e. $e_1 = q \cdot e_0$ for some q. A *local pseudovariety of Σ-generated $\mathbf{T}$-algebras* is a class of Σ-generated finite $\mathbf{T}$-algebras closed under subdirect products and quotients.

In order-theoretic terms, local pseudovarieties are precisely the ideals of the poset $\mathsf{Quo}_f(\mathbf{T}\not\leftarrow)$.

▶ **Definition 5.2.** A $\widehat{\mathbf{T}}$-algebra is *profinite* if it is an inverse limit of finite $\widehat{\mathbf{T}}$-algebras. By a *Σ-generated profinite $\widehat{\mathbf{T}}$-algebra* is meant a quotient $\varphi\colon \widehat{\mathbf{T}}\not\leftarrow \twoheadrightarrow P$ of $\widehat{\mathbf{T}}\not\leftarrow$ in $\mathbf{Alg}\,\widehat{\mathbf{T}}$ with P profinite. Σ-generated profinite $\widehat{\mathbf{T}}$-algebras are ordered by $\varphi \leq \varphi'$ iff φ factors through φ'.

▶ **Theorem 5.3** (Local Reiterman Theorem). *For each $\Sigma \in \mathbf{Set}_f^S$, the lattice of local pseudovarieties of Σ-generated $\mathbf{T}$-algebras (ordered by inclusion) is isomorphic to the lattice of Σ-generated profinite $\widehat{\mathbf{T}}$-algebras. The isomorphism maps a Σ-generated profinite $\widehat{\mathbf{T}}$-algebra $\varphi\colon \widehat{\mathbf{T}}\not\leftarrow \twoheadrightarrow P$ to the local pseudovariety of all finite quotients $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow A$ with $e^+ \leq \varphi$.*

▶ **Remark 5.4.** Theorem 5.3 can be interpreted in terms of profinite (in-)equations. If $\mathcal{D}$ is a variety of ordered algebras, a *profinite inequation* $u \leq v$ *over* Σ is a pair of elements $u, v \in |\hat{T}\not\leftarrow|_s$ in some sort s. We say that a Σ-generated finite $\mathbf{T}$-algebra $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow A$ *satisfies* $u \leq v$ if $e^+(u) \leq e^+(v)$. Using 5.3 one can show that local pseudovarieties are precisely the classes of Σ-generated finite $\mathbf{T}$-algebras presentable by profinite inequations over Σ. Similarly, if $\mathcal{D}$ is a variety of algebras, local pseudovarieties are presentable by *profinite equations*.

Eilenberg's theorem considers regular languages over arbitrary alphabets. In contrast, in a sorted setting one may need to make a *choice* of alphabets to capture the proper languages (e.g. alphabets of the form $(\Sigma, \emptyset)$ in 2.3.2). On the algebraic side, this requires us to restrict to $\mathbf{T}$-algebras with certain generators. From now on, let $\mathbb{A} \subseteq \mathbf{Set}_f^S$ be a fixed class of alphabets.

▶ **Definition 5.5.** A $\mathbf{T}$-algebra (A, α) is $\mathbb{A}$-*generated* if there is a surjective $\mathbf{T}$-homomorphism $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow (A, \alpha)$ with $\Sigma \in \mathbb{A}$. A *pseudovariety of* $\mathbf{T}$-*algebras* is a class $\mathcal{V}$ of $\mathbb{A}$-generated finite $\mathbf{T}$-algebras closed under $\mathbb{A}$-generated subalgebras of finite products (i.e. for $A_1, \ldots, A_n \in \mathcal{V}$ and any $\mathbb{A}$-generated subalgebra $A \rightarrowtail \prod_{i=1}^n A_i$, one has $A \in \mathcal{V}$) and quotients.

N.B. We emphasize that, in contrast to Definition 5.1, an $\mathbb{A}$-generated $\mathbf{T}$-algebra (A, α) is not equipped with a *fixed* quotient $e\colon \mathbf{T}\not\leftarrow \twoheadrightarrow (A, \alpha)$. Only the existence of e is required.

▶ **Example 5.6.**

1. Every finite $\mathbf{T}$-algebra (A, α) is $\mathbf{Set}_f^S$-generated: since $\mathcal{D}$ is locally finite, there is a surjective morphism $e\colon \not\leftarrow \twoheadrightarrow A$ with $\Sigma \in \mathbf{Set}_f^S$, so (A, α) is a quotient of $\mathbf{T}\not\leftarrow$ via $(\mathbf{T}\not\leftarrow \xrightarrow{Te} \mathbf{T}A \xrightarrow{\alpha} (A, \alpha))$. Consequently, for $\mathbb{A} = \mathbf{Set}_f^S$, a pseudovariety is a class of finite $\mathbf{T}$-algebras closed under quotients, subalgebras, and finite products. This concept was studied in [9]. For the monad $\mathbf{T}_*$ on $\mathbf{Set}$ we recover the original concept of Eilenberg [12]: a class of finite monoids closed under quotients, submonoids, and finite products.
2. Let $\mathbf{T} = \mathbf{T}_\infty$ on $\mathbf{Set}^2$. As suggested by Example 2.3.2, we choose $\mathbb{A} = \{\, (\Sigma, \emptyset) : \Sigma \in \mathbf{Set}_f \,\}$. A finite $\mathbf{T}_\infty$-algebra (= finite ω-semigroup) A is $\mathbb{A}$-generated iff it is *complete*, i.e. every element $a \in A_\omega$ can be expressed as an infinite product $a = \pi(a_0, a_1, \ldots)$ for some $a_i \in A_+$. Clearly complete ω-semigroups are closed under finite products. Thus a pseudovariety of $\mathbf{T}_\infty$-algebras is a class of finite complete ω-semigroups closed under quotients, complete ω-subsemigroups, and finite products. This concept is due to Wilke [35]; see also [19].

▶ **Remark 5.7.** Every $\mathbf{T}$-homomorphism $g\colon \mathbf{T}D' \to \mathbf{T}D$ with $D, D' \in \mathcal{D}_f^S$ extends uniquely to a $\widehat{\mathbf{T}}$-homomorphism $\hat{g}\colon \widehat{\mathbf{T}}D' \to \widehat{\mathbf{T}}D$ with $\iota_D \cdot g = V\hat{g} \cdot \iota_{D'}$ (for ι_D recall Remark 2.10.2).

▶ **Definition 5.8.** A *profinite theory* is a family $\varrho = (\, \varrho_\Sigma\colon \widehat{\mathbf{T}}\not\leftarrow \twoheadrightarrow P_\Sigma \,)_{\Sigma\in\mathbb{A}}$ such that (i) ϱ_Σ is a Σ-generated profinite $\widehat{\mathbf{T}}$-algebra for each $\Sigma \in \mathbb{A}$, and (ii) for every $\mathbf{T}$-homomorphism $g\colon \mathbf{T}\not\leftarrow \to \mathbf{T}\not\leftarrow$ with $\Sigma, \Delta \in \mathbb{A}$, there exists a $\widehat{\mathbf{T}}$-homomorphism $g_P\colon P_\Delta \to P_\Sigma$ with $\varrho_\Sigma \cdot \hat{g} = g_P \cdot \varrho_\Delta$. Profinite theories are ordered by $\varrho \leq \varrho'$ iff ϱ_Σ factors through ϱ'_Σ for each $\Sigma \in \mathbb{A}$.

▶ **Remark 5.9.** Profinite theories generalize the *varieties of filters of congruences* introduced by Almeida [4] for algebras over a finitary signature, and earlier by Thérien [32] for monoids.

▶ **Theorem 5.10** (Reiterman Theorem). *The lattice of pseudovarieties of* $\mathbf{T}$*-algebras (ordered by inclusion) is isomorphic to the lattice of profinite theories. The isomorphism maps a theory* $(\varrho_\Sigma\colon \widehat{\mathbf{T}}\not\prec \twoheadrightarrow P_\Sigma)_{\Sigma\in\mathbb{A}}$ *to the class of all finite* $\mathbf{T}$*-algebras arising as a quotient of some* P_Σ*.*

▶ **Remark 5.11.** Theorem 5.10 has again an interpretation in terms of profinite (in-)equations. If $\mathcal{D}$ is a variety of ordered algebras, we say that a finite $\mathbf{T}$-algebra (A,α) *satisfies* a profinite inequation $u \le v$ over $\Sigma \in \mathbb{A}$ if $h(u) \le h(v)$ for all $\widehat{\mathbf{T}}$-homomorphisms $h\colon \widehat{\mathbf{T}}\not\prec \to (A,\alpha^+)$. Using 5.10 one can show that pseudovarieties are precisely the classes of $\mathbb{A}$-generated finite $\mathbf{T}$-algebras presentable by profinite inequations over $\mathbb{A}$. In the unordered case, one takes profinite equations $u = v$. For $\mathbb{A} = \mathbf{Set}_f^S$, this was proved in [9, Thm. 4.12, Rem. 5.7].

6 The Variety Theorem

To investigate varieties of languages in our categorical setting, we need a notion of *language derivatives* extending the classical concept. To this end, we make use of our Assumption 2.1(iii) that the variety $\mathcal{C}$ has a constant in the signature. Choosing a constant gives a natural transformation from the constant functor $C_{\mathbb{1}_\mathcal{C}}$ on $\mathbb{1}_\mathcal{C}$ to the identity functor $\mathsf{Id}_\mathcal{C}$. It dualizes to a natural transformation $\bot\colon \mathsf{Id}_{\widehat{\mathcal{D}}} \to C_{O_\mathcal{D}}$. The purpose of $\bot$ is to model the empty set:

▶ **Example 6.1.** For our categories $\mathcal{D}$ of Example 2.2 and the corresponding objects $O_\mathcal{D}$ (see Remark 2.11.2) we choose $\bot\colon D \to O_\mathcal{D}$ for $D \in \widehat{\mathcal{D}}$ to be the constant morphism with value 0.

▶ **Definition 6.2.** Let $L\colon T\not\prec \to O_\mathcal{D}$ be a language. Then we define the following languages:

1. the *preimage* $g^{-1}L$ of L under a $\mathbf{T}$-homomorphism $g\colon \mathbf{T}\gtrdot \to \mathbf{T}\not\prec$ by $T\gtrdot \xrightarrow{g} T\not\prec \xrightarrow{L} O_\mathcal{D}$;
2. the *derivative* $u^{-1}L\colon T\not\prec \to O_\mathcal{D}$ of L w.r.t. a unary operation $u\colon (T\not\prec)_s \to (T\not\prec)_t$ by

$$(u^{-1}L)_s = (T\not\prec)_s \xrightarrow{u} (T\not\prec)_t \xrightarrow{L_t} O_\mathcal{D} \quad ; \quad (u^{-1}L)_r = (T\not\prec)_r \xrightarrow{\iota_\not\prec} (V\hat{T}\not\prec)_r \xrightarrow{V\bot} O_\mathcal{D} \ (r \neq s)$$

N.B. In the single-sorted case $S = 1$ the derivative $u^{-1}L$ is equal to $L \cdot u$ and the natural transformation $\bot$ is not used. Therefore Assumption 2.1(iii) can be dropped.

▶ **Example 6.3.**

1. $\mathbf{T} = \mathbf{T}_*$ on $\mathbf{Set}$: consider the unary operations of Example 4.3.1 presenting Σ^*. The induced derivatives of a language $L \subseteq \Sigma^*$ are exactly the classical ones, i.e. the languages $y^{-1}L = \{\, x \in \Sigma^* : yx \in L \,\}$ and $Ly^{-1} = \{\, x \in \Sigma^* : xy \in L \,\}$ for $y \in \Sigma^*$.
2. $\mathbf{T} = \mathbf{T}_\infty$ on $\mathbf{Set}^2$: consider the unary operations of Example 4.3.2 presenting $\mathbf{T}_\infty(\Sigma,\emptyset) = (\Sigma^+,\Sigma^\omega)$. The induced derivatives of $L \subseteq \Sigma^+ \cup \Sigma^\omega$ are $\{\, x \in \Sigma^+ : yx \in L \,\}$, $\{\, x \in \Sigma^+ : xy \in L \,\}$, $\{\, x \in \Sigma^+ : xz \in L \,\}$, $\{\, x \in \Sigma^+ : x^\omega \in L \,\}$, and $\{\, z \in \Sigma^\omega : yz \in L \,\}$, where $y \in \Sigma^*$ and $z \in \Sigma^\omega$. These are the derivatives for ∞-languages studied by Wilke [35].
3. Let $\mathbf{T}$ be any monad on $\mathbf{Set}^S$, and consider the unary operations $[p]$ of Example 4.3.3 presenting $\mathbf{T}\Sigma$. The induced derivatives of $L \subseteq T\Sigma$ are the languages $p^{-1}L \subseteq T\Sigma$ with $(p^{-1}L)_s = \{\, x \in (T\Sigma)_s : [p](x) \in L_t \,\}$ and $(p^{-1}L)_r = \emptyset$ for $r \neq s$, where $p\colon 1_t \to T(T\Sigma + 1_s)$ is a polynomial. These *polynomial derivatives* were studied by Bojańczyk [8].

▶ **Definition 6.4.** Given an S-indexed family $\mathcal{L} = (\, L^s\colon T\not\prec \to O_\mathcal{D} \,)_{s\in S}$ of languages over Σ, the *diagonal* of $\mathcal{L}$ is the language $\Delta\mathcal{L}$ over Σ with $(\Delta\mathcal{L})_s = L^s_s\colon (T\not\prec)_s \to O_\mathcal{D}$ for all $s \in S$.

▶ **Notation 6.5.** Recall that we work with a fixed class $\mathbb{A} \subseteq \mathbf{Set}_f^S$ of alphabets. Fix for each $\Sigma \in \mathbb{A}$ a unary presentation $\mathbb{U}_\Sigma$ of the free $\mathbf{T}$-algebra $\mathbf{T}\not\prec$.

▶ **Definition 6.6.**

1. A *local variety of languages* over $\Sigma \in \mathbb{A}$ is a subobject $W_\Sigma \subseteq \mathsf{Rec}(\Sigma)$ in $\mathcal{C}$ closed under $\mathbb{U}_\Sigma$-derivatives ($L \in W_\Sigma$ implies $u^{-1}L \in W_\Sigma$ for $u \in \mathbb{U}_\Sigma$) and diagonals.
2. A *variety of languages* is a family of local varieties $(\, W_\Sigma \subseteq \mathsf{Rec}(\Sigma)\,)_{\Sigma\in\mathbb{A}}$ closed under preimages, i.e. $L \in W_\Sigma$ implies $g^{-1}L \in W_\Delta$ for all $\Sigma, \Delta \in \mathbb{A}$ and $g\colon \mathbf{T}^{\geqslant}_{+} \to \mathbf{T}\not\leftarrow$ in $\mathbf{Alg}\,\mathbf{T}$.

▶ **Remark 6.7.**

1. Using the isomorphism $\mathsf{Rec}(\Sigma) \cong \prod_s P(\hat{T}\not\leftarrow)_s$ of Remark 3.4, one can show that a subobject $W_\Sigma \subseteq \mathsf{Rec}(\Sigma)$ is closed under diagonals iff it has the form $\prod_s m_s\colon \prod_s (W'_\Sigma)_s \rightarrowtail \prod_s P(\hat{T}\not\leftarrow)_s$ where $m_s\colon (W'_\Sigma)_s \rightarrowtail P(\hat{T}\not\leftarrow)_s$ is a monomorphism in $\mathcal{C}$.
2. There are two important cases where the closure under diagonals in Definition 6.6.1 is trivially satisfied and thus can be dropped. First, if $S = 1$, clearly every subobject of $\mathsf{Rec}(\Sigma)$ is closed under diagonals. Secondly, if $\mathcal{C}$ is one of the categories of Example 2.2 and $\mathbb{U}_\Sigma$ contains all identity morphisms, one can show that every subobject of $\mathsf{Rec}(\Sigma)$ closed under $\mathbb{U}_\Sigma$-derivatives is closed under diagonals. This will hold in all our applications.

We are ready to state the main result of our paper, which holds under the Assumptions 2.1.

▶ **Theorem 6.8** (Variety Theorem)**.**

1. *For each $\Sigma \in \mathbb{A}$, local varieties of languages over Σ and local pseudovarieties of Σ-generated $\mathbf{T}$-algebras form isomorphic lattices.*
2. *Varieties of languages and pseudovarieties of $\mathbf{T}$-algebras form isomorphic lattices. The isomorphism maps a pseudovariety $\mathcal{V}$ to the variety of all languages recognized by some algebra in $\mathcal{V}$.*

Proof sketch. Duality + Reiterman! For 1. one shows that a diagonal-closed subobject $W_\Sigma \subseteq \mathsf{Rec}(\Sigma)$, given by a monomorphism $(\, m_s\colon (W'_\Sigma)_s \rightarrowtail P(\hat{T}\not\leftarrow)_s \,)_{s\in S}$ in $\mathcal{C}^S$ by Rem. 6.7.1, is closed under derivatives iff the dual epimorphism $(\, P^{-1}m_s\colon (\hat{T}\not\leftarrow)_s \twoheadrightarrow P^{-1}(W'_\Sigma)_s \,)_{s\in S}$ in $\widehat{\mathcal{D}}^S$ carries a Σ-generated profinite $\widehat{\mathbf{T}}$-algebra. Then the Local Reiterman Theorem 5.3 gives the isomorphism. For 2. one shows that a family $(\, W_\Sigma \,)_{\Sigma\in\mathbb{A}}$ of local varieties is closed under preimages iff its dual family in $\widehat{\mathcal{D}}^S$ is a profinite theory, and uses the Reiterman Theorem. ◀

7 Applications

In this section, we derive some concrete variety theorems, including *new* results, as special instances of Theorem 6.8. In each case, we follow the three-step plan from the introduction.

Languages of finite words. Eilenberg's theorem [12] relates varieties of regular languages to pseudovarieties of monoids. It was later extended to ordered monoids [20], idempotent semirings [24] and K-algebras [26]. In [1, 3, 10] we unified all these results to an Eilenberg theorem for $\mathcal{D}$-monoids in a commutative variety $\mathcal{D}$, based on the dual view of automata as algebras and coalgebras. Recall that a variety $\mathcal{D}$ is *commutative* if for any $A, B \in \mathcal{D}$ the hom-set $\mathcal{D}(A, B)$ carries a subalgebra of $B^{|A|}$ in $\mathcal{D}$. A $\mathcal{D}$-*monoid* is an object $D \in \mathcal{D}$ with a monoid structure $(|D|, \bullet, 1)$ whose multiplication is a $\mathcal{D}$-*bimorphism*, i.e. for every $y \in |D|$ the maps $y \bullet -\colon |D| \to |D|$ and $- \bullet y\colon |D| \to |D|$ carry endomorphisms on D. Monoids in $\mathcal{D} = \mathbf{Set}$, $\mathbf{Pos}$, $\mathbf{JSL}_0$, $\mathbf{Vec}_K$ are classical monoids, ordered monoids, idempotent semirings and K-algebras, respectively. For any set Σ, the free $\mathcal{D}$-monoid $(\not\leftarrow^*, \bullet, \varepsilon)$ on $\not\leftarrow$ consists of the free $\mathcal{D}$-object $\not\leftarrow^*$ on Σ^*, the multiplication $\bullet$ extending the concatenation of words, and the empty word ε. The variety theorem for $\mathcal{D}$-monoids emerges from our three steps as follows:

1. Let $\mathbf{T}_M$ be the free-monoid monad on $\mathcal{D}$. Thus $T_M \not< = \not<^*$ and $\mathbf{Alg}\,\mathbf{T}_M$ is isomorphic to the category of $\mathcal{D}$-monoids. A language $L\colon \not<^* \to O_{\mathcal{D}}$ is $\mathbf{T}_M$-recognizable iff its restriction $L^{@}\colon \Sigma^* \to |O_{\mathcal{D}}|$ is a regular behavior, i.e. a function computed by some finite automaton with output set $|O_{\mathcal{D}}|$. If $|O_{\mathcal{D}}| \cong \{0,1\}$ (e.g., for $\mathcal{D} = \mathbf{Set}$, $\mathbf{Pos}$, $\mathbf{JSL}_0$), regular behaviors are exactly the characteristic functions of regular languages over Σ.
2. Generalizing Example 4.3.1, the free $\mathcal{D}$-monoid $\mathbf{T}_M \not< = \not<^*$ has the unary presentation $\mathbb{U}_\Sigma = \{\, \not<^* \xrightarrow{y\bullet -} \not<^*,\ \not<^* \xrightarrow{-\bullet y} \not<^* : y \in \Sigma^* \,\}$. Thus the $\mathbb{U}_\Sigma$-derivatives of a language $L\colon \not<^* \to O_{\mathcal{D}}$ are (after identifying L with $L^{@}$) the classical derivatives of Example 6.3.1.
3. Let $\mathbb{A} = \mathbf{Set}_f$. Instantiating Definition 6.6 gives the notion of a *variety of regular behaviors in* $\mathcal{C}$: a family $(W_\Sigma \subseteq \mathsf{Rec}(\Sigma))_{\Sigma\in\mathbb{A}}$ of regular behaviors closed under $\mathcal{C}$-algebraic operations (see Rem. 3.4), derivatives and preimages of $\mathcal{D}$-monoid morphisms, i.e. $g^{-1}L \in W_\Delta$ for any $L\colon \not<^* \to O_{\mathcal{D}}$ in W_Σ and any $\mathcal{D}$-monoid morphism $g\colon \gtrdot^* \to \not<^*$. Theorem 6.8 gives

▶ **Theorem 7.1** ([1,3,10]). *Let $\mathcal{C}$ and $\mathcal{D}$ be varieties satisfying the Assumptions 2.1(i),(ii),(iv), and suppose that the variety $\mathcal{D}$ is commutative. Then the lattice of (local) varieties of regular behaviors in $\mathcal{C}$ is isomorphic to the lattice of (local) pseudovarieties of $\mathcal{D}$-monoids.*

Four special instances are listed below. The third column describes the $\mathcal{C}$-algebraic operations under which (local) varieties are closed, and the fourth one states what $\mathcal{D}$-monoids are. All correspondences are known in the literature, and are uniformly covered by Theorem 7.1.

$\mathcal{C}$	$\mathcal{D}$	(local) var. of behav. closed under	$\cong$	(local) pseudovarieties of	proved in
$\mathbf{BA}$	$\mathbf{Set}$	boolean operations		monoids	[12, 14]
$\mathbf{DL}_{01}$	$\mathbf{Pos}$	finite union and finite intersection		ordered monoids	[14, 20]
$\mathbf{JSL}_0$	$\mathbf{JSL}_0$	finite union		idempotent semirings	[24]
$\mathbf{Vec}_K$	$\mathbf{Vec}_K$	addition of weighted languages		K-algebras	[26]

Polynomial varieties. Next, we derive Bojańczyk's polynomial variety theorem [8]. **1.** Let $\mathbf{T}$ be a monad on $\mathbf{Set}^S$. **2.** Choose the polynomial presentation of $\mathbf{T}\Sigma$. **3.** Let $\mathbb{A} = \mathbf{Set}_f^S$. Applying Def. 6.6, a *polynomial variety of languages* is a family of $\mathbf{T}$-recognizable languages closed under boolean operations, polynomial derivatives (see Ex. 6.2.3), and preimages of $\mathbf{T}$-homomorphisms. Thm. 6.8 gives Bojańczyk's variety theorem [8] and a new local version:

▶ **Theorem 7.2.** *The lattice of (local) polynomial varieties of $\mathbf{T}$-recognizable languages is isomorphic to the lattice of (local) pseudovarieties of $\mathbf{T}$-algebras.*

∞-languages. Finally, we derive two variety theorems for ∞-languages. For the first one, **1.** let $\mathbf{T} = \mathbf{T}_\infty$ on $\mathbf{Set}^2$. **2.** Choose $\mathbb{A} = \{\, (\Sigma, \emptyset) : \Sigma \in \mathbf{Set}_f \,\}$, and for each $\Sigma \in \mathbf{Set}_f$ the unary presentation of $\mathbf{T}_\infty(\Sigma,\emptyset) = (\Sigma^+, \Sigma^\omega)$ as in Example 4.3.2. **3.** Def. 6.6 yields the notion of a *variety of ∞-languages*: a family of ∞-regular languages closed under boolean operations, derivatives (see Example 6.3.2) and preimages of ω-semigroup morphisms. Theorem 6.8 gives

▶ **Theorem 7.3.** *The lattice of (local) varieties of ∞-languages is isomorphic to the lattice of (local) pseudovarieties of ω-semigroups.*

The non-local part is due to Wilke [19, 35] and the local part is a new result, extending the local variety theorem of [14] to infinite words. Similarly, we can obtain an ordered version of Theorem 7.3: **1.** take the monad $\mathbf{T}_{\infty,\leq}$ on $\mathbf{Pos}^2$ representing *ordered ω-semigroups* (i.e. ω-semigroups on a poset with monotone products). **2.** Choose $\mathbb{A}$ and the unary presentation

of $\mathbf{T}_{\infty,\leq}(\not<,\emptyset)$ as above. **3.** Since $\mathcal{C} = \mathbf{DL}_{01}$, Def. 6.6 gives *positive varieties of ∞-languages*, emerging from varieties by dropping closure under complement. Then Theorem 6.8 yields the theorem below. Its non-local part is due to Pin [21], and the local part is again a new result.

▶ **Theorem 7.4.** *The lattice of (local) positive varieties of ∞-languages is isomorphic to the lattice of (local) pseudovarieties of ordered ω-semigroups.*

The two above theorems do not follow from Theorem 7.1/7.2, which shows that our framework has a wider scope than the earlier work in [1, 3, 8, 10]. For many more applications, including variety theorems for tree languages [29] and cost functions [11], see the full paper [34].

8 Conclusions and Future Work

We presented a categorical framework for algebraic language theory that captures, as special instances, the bulk of the Eilenberg theorems in the literature for pseudovarieties of finite algebras and varieties of recognizable languages. Let us mention directions for future work.

First, we aim to investigate if it is possible to obtain a variety theorem for data languages based on nominal Stone duality [13]. On a similar note, it would also be interesting to see whether dualities modeling probabilistic phenomena (e.g. Gelfand or Kadison duality) lead to a meaningful algebraic language theory for probabilistic automata and languages.

Secondly, although *finite* structures are of most relevance from the automata-theoretic perspective, there has been some work on variety theorems with relaxed finiteness restrictions. One example is Reutenauer's theorem [26] for weighted languages over arbitrary fields K. To cover this in our setting the results of Section 5 should be presented for $(\mathcal{E},\mathcal{M})$-structured categories $\mathcal{D}$ in lieu of varieties. This has been worked out in [33] and, independently, in the recent preprint [27]. In the latter, also a formal "Eilenberg correspondence" is stated for dual $(\mathcal{E},\mathcal{M})$-categories. An important conceptual difference to our present work is that in loc. cit. one uses discrete dualities (e.g. complete atomic boolean algebras/sets instead of boolean algebras/Stone spaces) and that unary presentations do not appear. This makes the concept of a variety of languages (called a *coequational theory*) and the Eilenberg correspondence in [27] easy to state, but much harder to apply in practice. The results of [27] and of our paper do not entail each other, and we leave it for future work to find a common roof.

Membership Problem in $\mathrm{GL}(2,\mathbb{Z})$ Extended by Singular Matrices*

Abstract

We consider the membership problem for matrix semigroups, which is the problem to decide whether a matrix belongs to a given finitely generated matrix semigroup.

In general, the decidability and complexity of this problem for two-dimensional matrix semigroups remains open. Recently there was a significant progress with this open problem by showing that the membership is decidable for 2×2 nonsingular integer matrices. In this paper we focus on the membership for singular integer matrices and prove that this problem is decidable for 2×2 integer matrices whose determinants are equal to 0, 1, -1 (i.e. for matrices from $\mathrm{GL}(2,\mathbb{Z})$ and any singular matrices). Our algorithm relies on a translation of numerical problems on matrices into combinatorial problems on words and conversion of the membership problem into decision problem on regular languages.

1 Introduction

Matrices and matrix products play a crucial role in the representation and analysis of various computational processes such as linear recurrent sequences [13, 21, 22], arithmetic circuits [11], hybrid and dynamical systems [20, 2], probabilistic and quantum automata [7], stochastic games, broadcast protocols [10]. Many problems for matrices in dimension three and four are undecidable, but the decidability and complexity of problems for two-dimensional matrix semigroups remains open. One of such hard questions is the Membership problem.

Membership problem: Given a finite set of $m \times m$ matrices $\mathcal{F} = \{M_1, M_2, \ldots, M_n\}$ and a matrix M. Determine whether there exist an integer $k \geq 1$ and $i_1, i_2, \ldots, i_k \in \{1, \ldots, n\}$ such that

$$M_{i_1} \cdot M_{i_2} \cdots M_{i_k} = M.$$

In other words, determine whether a matrix M belongs to the semigroup generated by $\mathcal{F}$.

* This work was supported by EPSRC grant "Reachability problems for words, matrices and maps" (EP/M00077X/1).

There are only few known decidability results for the membership problem when the dimension is not bounded. In 1986 Kannan and Lipton [14] proved that the membership is decidable in polynomial time for a semigroup generated by a single $m \times m$ matrix (known as the *Orbit problem*). Later, in 1996 this decidability result was extended to a more general case of commutative matrices [1]. A generalization of this result to a special class of non-commutative matrices (a class of row-monomial matrices over a commutative semigroup satisfying some natural effectiveness conditions) was shown in 2004 in [16]. On the other hand, it is known that the membership is already undecidable for 3×3 integer matrices with determinant 0 (i.e. singular matrices), see [23]. As for the nonsingular case, it is known that the membership is undecidable for 4×4 integer matrices with determinant one, see [5]. A more recent survey of undecidable problems can be found in [8].

Due to a severe lack of methods and techniques the status of decision problems for 2×2 matrices (like membership, vector reachability, freeness) remains a long standing open problem. Recently, a new approach of translating numerical problems on 2×2 integer matrices into a variety of combinatorial and computational problems on words over group alphabet and studying their transformations as specific rewriting systems have led to new results on decidability and complexity. The main ingredient of the translation into combinatorial problems on words is the well-known result that the groups $\mathrm{SL}(2,\mathbb{Z})$ and $\mathrm{GL}(2,\mathbb{Z})$ are finitely generated. For example, $\mathrm{SL}(2,\mathbb{Z})$ can be generated by a pair of matrices

$$S = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \quad \text{and} \quad R = \begin{bmatrix} 0 & -1 \\ 1 & 1 \end{bmatrix}$$

with the following relations: $S^4 = I$, $R^6 = I$ and $S^2 = R^3$. So, we can represent a matrix $M \in \mathrm{SL}(2,\mathbb{Z})$ as a word in the alphabet $\{S, R\}$.

In particular, this symbolic representation was successfully used to show the decidability of the membership problem for the semigroups of $\mathrm{GL}(2,\mathbb{Z})$ [9] in 2005 and of the mortality problem for 2×2 integer matrices with determinants $0, \pm1$ [19] in 2008. It also found applications in the design of the polynomial time algorithm for the membership problem for the modular group [12] in 2007. Furthermore, it was used to show NP-hardness for most of the reachability problems in dimension two [6, 3] in 2012 and to prove decidability of the vector/scalar reachability problems in $\mathrm{SL}(2,\mathbb{Z})$ [24] in 2016.

In 2017 a significant progress was made towards decidability of the membership problem for 2×2 integer matrices extending previously known result on $\mathrm{GL}(2,\mathbb{Z})$ [9]. In [25] the first algorithm was discovered that can check the membership problem for a matrix semigroup generated by nonsingular 2×2 integer matrices. In this paper we show another extension of [9] and prove that the membership problem is decidable for 2×2 integer matrices whose determinants are equal to 0, 1, -1 (i.e. for matrices from $\mathrm{GL}(2,\mathbb{Z})$ and any singular matrices). As a first step we give an alternative proof of the decidability of the mortality problem (i.e. membership for the zero matrix) from [19], in which we will use the Smith normal forms of matrices. In contrast to [19], our new approach allows us to generalize this proof to show decidability of the membership problem for singular matrices. The algorithm is based on a nontrivial combination of algebraic properties of $\mathrm{GL}(2,\mathbb{Z})$, automata theory and properties of matrix products with singular matrices.

2 Preliminaries

The semigroup of 2×2 integer matrices is denoted by $\mathbb{Z}^{2\times2}$. Let $\mathrm{GL}(2,\mathbb{Z})$ be the general linear group of dimension 2 over $\mathbb{Z}$, that is, the group of 2×2 integer matrices whose determinant is equal to ±1. We will use $\mathbf{O}$ to denote the zero 2×2 matrix. A matrix is called *singular* if its determinant is equal to zero and *nonsingular* otherwise.

If $\mathcal{F}$ is a finite collection of matrices from $\mathbb{Z}^{2\times 2}$, then $\langle\mathcal{F}\rangle$ denotes the semigroup generated by $\mathcal{F}$ (including the identity matrix), that is, $M \in \langle\mathcal{F}\rangle$ if and only if $M = I$ or there are matrices $M_1, \ldots, M_n \in \mathcal{F}$ such that $M = M_1 \cdots M_n$.

Consider the following matrices from $\mathrm{GL}(2,\mathbb{Z})$:

$$N = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix},\ S = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix},\ R = \begin{bmatrix} 0 & -1 \\ 1 & 1 \end{bmatrix},\ X = -I = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}.$$

Every word in the alphabet $\Sigma = \{N, S, R, X\}$ corresponds to a matrix from $\mathrm{GL}(2,\mathbb{Z})$ in a natural way. Namely, the letters N, S, R, X correspond to the matrices defined by the above formulas, and a word $w \in \Sigma^*$ corresponds to the product of its letters. For example, the word SR corresponds to the matrix $\begin{bmatrix} -1 & -1 \\ 0 & -1 \end{bmatrix}$.

It is well-known that $\mathrm{GL}(2,\mathbb{Z})$ is generated by the above matrices. So any $M \in \mathrm{GL}(2,\mathbb{Z})$ can be presented by a word in the alphabet $\Sigma = \{N, S, R, X\}$. Such presentation is not unique because of the identities like $S^2 = R^3 = X$. However for every matrix $M \in \mathrm{GL}(2,\mathbb{Z})$, there is a unique canonical word that represents it, as described below.

▶ **Definition 1.** A word $w \in \Sigma^*$ is called a *canonical word* if it has the form

$$w = N^\delta X^\gamma S^\beta R^{\alpha_0} S R^{\alpha_1} S R^{\alpha_2} \ldots S R^{\alpha_{n-1}} S R^{\alpha_n},$$

where $\beta, \delta, \gamma \in \{0, 1\}$, $\alpha_0, \ldots, \alpha_{n-1} \in \{1, 2\}$, and $\alpha_n \in \{0, 1, 2\}$. In other words, w is *canonical* if it does not contain subwords SS or RRR. Moreover, letter N may appear only once in the first position, and letter X may appear only once either in the first position or after N.

▶ **Proposition 2** ([17, 18, 26, 25])**.** *For every $M \in \mathrm{GL}(2,\mathbb{Z})$, there is a unique canonical word w which represents M.*

We will also use two additional matrices $T = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$, $U = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}$ and the following identities: $R = ST$, $T = XSR$, $T^{-1} = XR^2S$, $U = XSR^2$ and $U^{-1} = XRS$.

▶ **Definition 3.** A subset $\mathcal{S} \subseteq \mathrm{GL}(2,\mathbb{Z})$ is called *regular* or *automatic* if there is a regular language L in alphabet Σ that describes $\mathcal{S}$. That is, every word $w \in L$ corresponds to a matrix M from $\mathcal{S}$, and for every matrix $M \in \mathcal{S}$, there is a word $w \in L$ that represents M.

▶ **Definition 4.** We call two words w_1 and w_2 from Σ^* *equivalent*, denoted $w_1 \sim w_2$, if they represent the same matrix. Two languages L_1 and L_2 in the alphabet Σ are *equivalent*, denoted $L_1 \sim L_2$, if
(i) for each $w_1 \in L_1$, there exists $w_2 \in L_2$ such that $w_1 \sim w_2$, and
(ii) for each $w_2 \in L_2$, there exists $w_1 \in L_1$ such that $w_2 \sim w_1$.
In other words, L_1 and L_2 are equivalent if and only if they describe the same language. Two finite automata $\mathcal{A}_1$ and $\mathcal{A}_2$ over alphabet Σ are *equivalent*, denoted $\mathcal{A}_1 \sim \mathcal{A}_2$, if $L(\mathcal{A}_1) \sim L(\mathcal{A}_2)$.

The next theorem will be a crucial ingredient of our decidability result.

▶ **Theorem 5.** *Given two regular subsets $\mathcal{S}_1$ and $\mathcal{S}_2$ of $\mathrm{GL}(2,\mathbb{Z})$, it is decidable whether the intersection $\mathcal{S}_1 \cap \mathcal{S}_2$ is empty or not.*

Proof. The proof is based on the following result: for every finite automaton $\mathcal{A}$ over alphabet Σ, there is an automaton $\mathrm{Can}(\mathcal{A})$ such that $\mathrm{Can}(\mathcal{A})$ accepts only canonical words and $\mathrm{Can}(\mathcal{A}) \sim \mathcal{A}$, that is, $\mathrm{Can}(\mathcal{A})$ and $\mathcal{A}$ describe the same subset of $\mathrm{GL}(2,\mathbb{Z})$. The construction of $\mathrm{Can}(\mathcal{A})$ can be found in [25], see also [9] for an alternative construction.

Now let L_1 and L_2 be regular languages that describe $\mathcal{S}_1$ and $\mathcal{S}_2$, respectively, and let $\mathcal{A}_1$ and $\mathcal{A}_2$ be finite automata such that $L(\mathcal{A}_1) = L_1$ and $L(\mathcal{A}_2) = L_2$. By Proposition 2, every matrix from $\mathrm{GL}(2,\mathbb{Z})$ corresponds to a unique canonical word. Therefore, we obtain the following equivalence: $\mathcal{S}_1 \cap \mathcal{S}_2 \neq \emptyset$ if and only if the languages of the automata $\mathrm{Can}(\mathcal{A}_1)$ and $\mathrm{Can}(\mathcal{A}_2)$ have nonempty intersection. Since the emptiness problem for regular languages is decidable, it is decidable whether $\mathcal{S}_1 \cap \mathcal{S}_2$ is empty or not. ◀

Another important ingredient of our proof is the existence and uniqueness of the Smith normal form of a matrix.

▶ **Theorem 6** (Smith normal form [15]). *For any matrix $A \in \mathbb{Z}^{2\times 2}$, there are matrices E, F from $\mathrm{GL}(2,\mathbb{Z})$ such that $A = E \begin{bmatrix} t_1 & 0 \\ 0 & t_2 \end{bmatrix} F$ for some nonnegative integers t_1 and t_2 such that $t_1 \mid t_2$. The diagonal matrix $\begin{bmatrix} t_1 & 0 \\ 0 & t_2 \end{bmatrix}$, which is unique, is called the* Smith normal form *of A. In fact, t_1 is equal to the gcd of the coefficients of A. Moreover, E, F, t_1, and t_2 can be computed in polynomial time.*

Remark. If $A \in \mathbb{Z}^{2\times 2}$ is nonzero matrix with $\det(A) = 0$, then the Smith normal form of A is equal to $\begin{bmatrix} t & 0 \\ 0 & 0 \end{bmatrix}$, where t is the gcd of the coefficients of A.

Using uniqueness of the Smith normal form we obtain the following corollary.

▶ **Corollary 7.** *If $E, F \in \mathrm{GL}(2,\mathbb{Z})$, then $E \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F$ is not a zero matrix.*

3 Main result

The main result of our paper is the following theorem.

▶ **Theorem 8.** *Let $M \in \mathbb{Z}^{2\times 2}$ and let $\mathcal{F} = \{A_1, \ldots, A_n, B_1, \ldots, B_m\}$ be a collection of matrices from $\mathbb{Z}^{2\times 2}$ such that $A_i \in \mathrm{GL}(2,\mathbb{Z})$ for $i = 1, \ldots, n$, and B_j is a singular matrix for $j = 1, \ldots, m$. Then it is decidable whether $M \in \langle \mathcal{F} \rangle$.*

Proof. First, note that if $M \in \langle \mathcal{F} \rangle$, then M is either singular or $M \in \mathrm{GL}(2,\mathbb{Z})$. Therefore, if $|\det(M)| > 1$, then we know that $M \notin \langle \mathcal{F} \rangle$. On the other hand, if $\det(M) = \pm 1$, i.e. if $M \in \mathrm{GL}(2,\mathbb{Z})$, then $M \in \langle \mathcal{F} \rangle$ if and only if $M \in \langle A_1, \ldots, A_n \rangle$. In other words, our problem reduces to the membership problem in $\mathrm{GL}(2,\mathbb{Z})$, and the decidability of the membership in $\mathrm{GL}(2,\mathbb{Z})$ was proven in [9].

Hence from now on we will assume that M is a singular matrix. First, we consider the case when M is the zero matrix and after that we consider the case when M is a nonzero singular matrix. The case when $M = \mathbf{O}$ is also called the *Mortality problem*. The decidability of the mortality problem for matrices with determinants 0 and ± 1 was shown in [19]. In Theorem 11 below we provide an alternative proof of this fact, which is based on the use of the Smith normal form of a matrix. Another reason why we include the proof of Theorem 11 is that it presents a simplified version of a more complicated construction for a nonzero M. Finally, in Theorem 13 we prove decidability of the membership problem for a nonzero singular matrix M. ◀

First, we prove Proposition 9 which will play an important role in the proofs of Theorems 11 and 13. Moreover, Proposition 9 and Corollary 10 reveal new structural properties of certain subsets of $\mathrm{GL}(2,\mathbb{Z})$ in symbolic presentation.

▶ **Proposition 9.** *For any fixed $a \in \mathbb{Z}$, let $M(a) = \left\{ \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ b,c,d \in \mathbb{Z} \right\}$. Then $M(a)$ is a regular subset of $\mathrm{GL}(2,\mathbb{Z})$.*

Proof. First, suppose that $a = 0$. Then

$$M(0) = \left\{ \begin{bmatrix} 0 & -1 \\ 1 & d \end{bmatrix} : d \in \mathbb{Z} \right\} \bigcup \left\{ \begin{bmatrix} 0 & 1 \\ -1 & d \end{bmatrix} : d \in \mathbb{Z} \right\} \bigcup \left\{ \begin{bmatrix} 0 & 1 \\ 1 & d \end{bmatrix} : d \in \mathbb{Z} \right\} \bigcup \left\{ \begin{bmatrix} 0 & -1 \\ -1 & d \end{bmatrix} : d \in \mathbb{Z} \right\}.$$

Note that $\begin{bmatrix} 0 & -1 \\ 1 & d \end{bmatrix} = ST^d$, $\begin{bmatrix} 0 & 1 \\ -1 & d \end{bmatrix} = -ST^{-d}$, $\begin{bmatrix} 0 & 1 \\ 1 & d \end{bmatrix} = SNT^d$, $\begin{bmatrix} 0 & -1 \\ -1 & d \end{bmatrix} = -SNT^{-d}$. Hence we can express $M(0)$ as

$$\begin{aligned} M(0) =& \{ST^d : d \in \mathbb{Z}\} \cup \{-ST^{-d} : d \in \mathbb{Z}\} \cup \{SNT^d : d \in \mathbb{Z}\} \cup \{-SNT^{-d} : d \in \mathbb{Z}\} = \\ & \{ST^d : d \geq 0\} \cup \{S(T^{-1})^d : d \geq 0\} \cup \{-S(T^{-1})^d : d \geq 0\} \cup \\ & \{-ST^d : d \geq 0\} \cup \{SNT^d : d \geq 0\} \cup \{SN(T^{-1})^d : d \geq 0\} \cup \\ & \{-SN(T^{-1})^d : d \geq 0\} \cup \{-SNT^d : d \geq 0\}. \end{aligned}$$

Therefore, $M(0)$ can be described by the following regular expression

$$\begin{aligned} & S(XSR)^* + S(XR^2S)^* + XS(XR^2S)^* + XS(XSR)^* + \\ & SN(XSR)^* + SN(XR^2S)^* + XSN(XR^2S)^* + XSN(XSR)^*. \end{aligned}$$

Now suppose that $a \neq 0$. Consider a matrix $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z})$ and let $b = b_0 + ma$ and $c = c_0 + na$, where $b_0, c_0 \in \{0, \ldots, |a| - 1\}$ and $m, n \in \mathbb{Z}$. Since $A \in \mathrm{GL}(2,\mathbb{Z})$, we have $ad - bc = \pm 1$ or

$$d = \frac{bc \pm 1}{a} = \frac{(b_0 + ma)(c_0 + na) \pm 1}{a} = \frac{b_0c_0 \pm 1}{a} + mc_0 + nb_0 + mna.$$

Since d is an integer, $\frac{b_0c_0 \pm 1}{a}$ must also be an integer. Note that

$$A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} = \begin{bmatrix} a & b_0 + ma \\ c_0 + na & \frac{b_0c_0 \pm 1}{a} + mc_0 + nb_0 + mna \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ n & 1 \end{bmatrix} \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0 \pm 1}{a} \end{bmatrix} \begin{bmatrix} 1 & m \\ 0 & 1 \end{bmatrix}.$$

So, $A = U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0 \pm 1}{a} \end{bmatrix} T^m$. Let $N^+(a)$ and $N^-(a)$ be the following finite sets

$$\begin{aligned} N^+(a) &= \{(b_0, c_0) \ : \ b_0, c_0 \in \{0, \ldots, |a| - 1\} \text{ and } \tfrac{b_0c_0 + 1}{a} \text{ is an integer}\}, \\ N^-(a) &= \{(b_0, c_0) \ : \ b_0, c_0 \in \{0, \ldots, |a| - 1\} \text{ and } \tfrac{b_0c_0 - 1}{a} \text{ is an integer}\}. \end{aligned}$$

Then

$$M(a) = \bigcup_{(b_0,c_0) \in N^+(a)} \left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} T^m \ : \ n,m \in \mathbb{Z} \right\} \bigcup \bigcup_{(b_0,c_0) \in N^-(a)} \left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0-1}{a} \end{bmatrix} T^m \ : \ n,m \in \mathbb{Z} \right\}.$$

For each $(b_0, c_0) \in N^+(a)$, let $w^+(b_0, c_0)$ be a word that represents the matrix $\begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix}$. Note that for every $(b_0, c_0) \in N^+(a)$, we can present $\left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} T^m : n, m \in \mathbb{Z} \right\}$ as a union of four sets

$$\left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} T^m : \ n, m \geq 0 \right\} \bigcup \left\{ (U^{-1})^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} T^m : \ n, m \geq 0 \right\} \bigcup$$
$$\left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} (T^{-1})^m : \ n, m \geq 0 \right\} \bigcup \left\{ (U^{-1})^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0+1}{a} \end{bmatrix} (T^{-1})^m : \ n, m \geq 0 \right\}.$$

Hence it can be described by the following regular expression

$$(XSR^2)^* w^+(b_0, c_0)(XSR)^* + (XRS)^* w^+(b_0, c_0)(XSR)^* +$$
$$(XSR^2)^* w^+(b_0, c_0)(XR^2S)^* + (XRS)^* w^+(b_0, c_0)(XR^2S)^*.$$

Similarly, we have that for every $(b_0, c_0) \in N^-(a)$, the set $\left\{ U^n \begin{bmatrix} a & b_0 \\ c_0 & \frac{b_0c_0-1}{a} \end{bmatrix} T^m : n, m \in \mathbb{Z} \right\}$ can be described by a regular expression. Since $M(a)$ is equal to a finite union of such sets, we conclude that it is also regular. ◀

▶ **Corollary 10.** *For every $i = 1, 2, 3, 4$ and any fixed $a \in \mathbb{Z}$, the following subset of $\mathrm{GL}(2,\mathbb{Z})$ is a regular set:* $M_i(a) = \left\{ \begin{bmatrix} a_1 & a_2 \\ a_3 & a_4 \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ a_i = a \text{ and } a_j \in \mathbb{Z} \text{ for } j \neq i \right\}$.

Proof. By definition, $M_1(a) = M(a)$, hence it is regular by Proposition 9. Now let $L(a)$ be a regular language that describes $M(a)$ and let $K = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$. It is not hard to see that $M_2(a) = M(a) \cdot K$, $M_3(a) = K \cdot M(a)$ and $M_4(a) = K \cdot M(a) \cdot K$. Note that matrix K corresponds to the word NXS. Therefore, $M_2(a)$, $M_3(a)$ and $M_4(a)$ can be described by the regular languages $L(a) \cdot \{NXS\}$, $\{NXS\} \cdot L(a)$ and $\{NXS\} \cdot L(a) \cdot \{NXS\}$, respectively. ◀

3.1 Mortality problem

In this section we will give an alternative proof of the decidability of the mortality problem from [19] which will be based on the use of the Smith normal form of a matrix.

▶ **Theorem 11.** *The mortality problem for 2×2 integer matrices with determinants $0, \pm 1$ is decidable.*

This theorem will be a consequence of Theorem 5 and Propositions 9 and 12.

▶ **Proposition 12.** *Let $\mathcal{F} = \{A_1, \ldots, A_n, B_1, \ldots, B_m\}$ be a collection of matrices from $\mathbb{Z}^{2\times 2}$ such that $A_i \in \mathrm{GL}(2,\mathbb{Z})$ for $i = 1, \ldots, n$, and $\det(B_j) = 0$ for $j = 1, \ldots, m$. Then $\mathbf{O} \in \langle \mathcal{F} \rangle$ if and only if $B_j = \mathbf{O}$ for some j or there are indices $i, j \in \{1, \ldots, m\}$ and a matrix $C \in \langle A_1, \ldots, A_n \rangle$ such that $B_i C B_j = \mathbf{O}$.*

Proof. Suppose that $B_j \neq \mathbf{O}$ for every j. Under this assumption, if $\mathbf{O} \in \langle \mathcal{F} \rangle$ then there are indices $i_1, \ldots, i_s \in \{1, \ldots, m\}$ and matrices $C_1, \ldots, C_{s+1} \in \langle A_1, \ldots, A_n \rangle$ such that

$$C_1 B_{i_1} C_2 B_{i_2} \cdots C_s B_{i_s} C_{s+1} = \mathbf{O}. \tag{1}$$

By Theorem 6, we can write each matrix B_{i_r}, for $i = 1, \ldots, s$, as $B_{i_r} = E_r \begin{bmatrix} t_r & 0 \\ 0 & 0 \end{bmatrix} F_r$, where $E_r, F_r \in \mathrm{GL}(2, \mathbb{Z})$ and $t_r > 0$. Then (1) is equivalent to

$$C_1 E_1 \begin{bmatrix} t_1 & 0 \\ 0 & 0 \end{bmatrix} F_1 C_2 E_2 \begin{bmatrix} t_2 & 0 \\ 0 & 0 \end{bmatrix} F_2 \cdots \\ \cdots C_{s-1} E_{s-1} \begin{bmatrix} t_{s-1} & 0 \\ 0 & 0 \end{bmatrix} F_{s-1} C_s E_s \begin{bmatrix} t_s & 0 \\ 0 & 0 \end{bmatrix} F_s C_{s+1} = \mathbf{O}. \quad (2)$$

Dividing (2) by the product $t_1 t_2 \cdots t_{s-1} t_s$, which is nonzero by our assumption, we obtain

$$C_1 E_1 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_1 C_2 E_2 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_2 \cdots C_{s-1} E_{s-1} \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_{s-1} C_s E_s \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_s C_{s+1} = \mathbf{O}. \quad (3)$$

Suppose for each $r = 2, \ldots, s$ the matrix $F_{r-1} C_r E_r$ have the form $F_{r-1} C_r E_r = \begin{bmatrix} a_r & b_r \\ c_r & d_r \end{bmatrix}$. Note that $\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} a & 0 \\ 0 & 0 \end{bmatrix}$. Therefore, (3) is equivalent to

$$C_1 E_1 \begin{bmatrix} a_2 a_3 \cdots a_s & 0 \\ 0 & 0 \end{bmatrix} F_s C_{s+1} = \mathbf{O}. \quad (4)$$

Suppose that $a_2 a_3 \cdots a_s \neq 0$. In this case (4) is equivalent to

$$C_1 E_1 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_s C_{s+1} = \mathbf{O},$$

where $C_1 E_1$ and $F_s C_{s+1}$ are matrices from $\mathrm{GL}(2, \mathbb{Z})$. This contradicts Corollary 7. Hence $a_2 a_3 \cdots a_s = 0$, and therefore there is $r \in \{2, \ldots, s\}$ such that $a_r = 0$. This implies that $B_{i_{r-1}} C_r B_{i_r} = \mathbf{O}$. Indeed,

$$B_{i_{r-1}} C_r B_{i_r} = E_{r-1} \begin{bmatrix} t_{r-1} & 0 \\ 0 & 0 \end{bmatrix} F_{r-1} C_r E_r \begin{bmatrix} t_r & 0 \\ 0 & 0 \end{bmatrix} F_r.$$

By assumption, $F_{r-1} C_r E_r = \begin{bmatrix} a_r & b_r \\ c_r & d_r \end{bmatrix}$. Thus

$$B_{i_{r-1}} C_r B_{i_r} = t_{r-1} t_r E_{r-1} \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} a_r & b_r \\ c_r & d_r \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_r = t_{r-1} t_r E_{r-1} \begin{bmatrix} a_r & 0 \\ 0 & 0 \end{bmatrix} F_r.$$

Since $a_r = 0$, we have $B_{i_{r-1}} C_r B_{i_r} = \mathbf{O}$.

The implication on the other direction is trivial. ◀

Proof of Theorem 11. Obviously, if $B_j = \mathbf{O}$ for some $j = 1, \ldots, m$, then $\mathbf{O} \in \langle \mathcal{F} \rangle$. Therefore, from now on we assume that all B_j's are nonzero singular matrices. In this case Proposition 12 implies that $\mathbf{O} \in \langle \mathcal{F} \rangle$ if and only if there are indices $i, j \in \{1, \ldots, m\}$ and a matrix $C \in \langle A_1, \ldots, A_n \rangle$ such that $B_i C B_j = \mathbf{O}$. We now show that the latter property is algorithmically decidable.

Let $B_i = E_i \begin{bmatrix} t_i & 0 \\ 0 & 0 \end{bmatrix} F_i$ and $B_j = E_j \begin{bmatrix} t_j & 0 \\ 0 & 0 \end{bmatrix} F_j$ be the Smith normal forms of B_i and B_j, respectively. Note that by our assumption $t_i, t_j > 0$. Let C be a matrix from $\langle A_1, \ldots, A_n \rangle$. We have $B_i C B_j = \mathbf{O}$ if and only if

$$E_i \begin{bmatrix} t_i & 0 \\ 0 & 0 \end{bmatrix} F_i C E_j \begin{bmatrix} t_j & 0 \\ 0 & 0 \end{bmatrix} F_j = \mathbf{O} \quad \text{or, equivalently,} \quad E_i \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_i C E_j \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_j = \mathbf{O}.$$

Let $F_iCE_j = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ for some $a, b, c, d \in \mathbb{Z}$. Then the above equation is equivalent to $E_i \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} F_j = \mathbf{O}$ or $E_i \begin{bmatrix} a & 0 \\ 0 & 0 \end{bmatrix} F_j = \mathbf{O}$. By Corollary 7, $E_i \begin{bmatrix} a & 0 \\ 0 & 0 \end{bmatrix} F_j = \mathbf{O}$ if and only if $a = 0$. So, we showed the following equivalence: $B_iCB_j = \mathbf{O}$ if and only if $F_iCE_j = \begin{bmatrix} 0 & b \\ c & d \end{bmatrix}$ for some $b, c, d \in \mathbb{Z}$.

Let $\mathcal{S}_1$ and $\mathcal{S}_2$ be the following subsets of $\mathrm{GL}(2,\mathbb{Z})$: $\mathcal{S}_1 = \{F_iCE_j : C \in \langle A_1, \ldots, A_n \rangle\}$ and $\mathcal{S}_2 = \left\{ \begin{bmatrix} 0 & b \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ b, c, d \in \mathbb{Z} \right\}$. In this notations the above equivalence can be written as follows: there is a matrix $C \in \langle A_1, \ldots, A_n \rangle$ such that $B_iCB_j = \mathbf{O}$ if and only if $\mathcal{S}_1 \cap \mathcal{S}_2 \neq \emptyset$.

It is easy to see that $\mathcal{S}_1$ is a regular subset of $\mathrm{GL}(2,\mathbb{Z})$ as it can be described by the regular expression $u_i(w_1 + \cdots + w_n)^* v_j$, where $w_1, \ldots, w_n$ are words representing the matrices $A_1, \ldots, A_n$ and u_i, v_j represent the matrices F_i, E_j, respectively. By Proposition 9, $\mathcal{S}_2$ is also a regular subset of $\mathrm{GL}(2,\mathbb{Z})$. Using Theorem 5, we can decide whether $\mathcal{S}_1 \cap \mathcal{S}_2 \neq \emptyset$ and hence decide whether there is a matrix $C \in \langle A_1, \ldots, A_n \rangle$ such that $B_iCB_j = \mathbf{O}$. This finishes the proof of Theorem 11. ◀

3.2 Membership problem

We are now ready to consider the case when M is a nonzero singular matrix.

▶ **Theorem 13.** *Let $\mathcal{F} = \{A_1, \ldots, A_n, B_1, \ldots, B_m\}$ be a finite collection of matrices such that $A_1, \ldots, A_n \in \mathrm{GL}(2,\mathbb{Z})$ and $B_1, \ldots, B_m$ are singular matrices from $\mathbb{Z}^{2\times 2}$. Also let $M \in \mathbb{Z}^{2\times 2}$ be a nonzero singular matrix. Then it is decidable whether $M \in \langle \mathcal{F} \rangle$.*

Proof. Let $M = E \begin{bmatrix} t & 0 \\ 0 & 0 \end{bmatrix} F$ be the Smith normal form of M, and for each $j = 1, \ldots, m$, let $B_j = E_j \begin{bmatrix} t_j & 0 \\ 0 & 0 \end{bmatrix} F_j$ be the Smith normal form of B_j. Since M is a nonzero matrix, we may assume that for each $j = 1, \ldots, m$, B_j is also a nonzero matrix. Hence without loss of generality we assume that $t, t_1, \ldots, t_m > 0$.

We will construct a graph $\mathcal{G}(M, \mathcal{F})$, depending on M and $\mathcal{F}$, which will have the following property: $M \in \langle \mathcal{F} \rangle$ if and only if there is a path in $\mathcal{G}(M, \mathcal{F})$ from an initial to a final node of weight t.

Description of $\mathcal{G}(M, \mathcal{F})$. Graph $\mathcal{G}(M, \mathcal{F})$ has m nodes labelled by singular matrices $B_1, \ldots, B_m$ and two special nodes **In** and **Fin**, where **In** is the only initial node and **Fin** is the only final node. The weights of the nodes are defined as follows.

▶ **Definition 14.** Recall that $E_j \begin{bmatrix} t_j & 0 \\ 0 & 0 \end{bmatrix} F_j$ is the Smith normal form of B_j. Then the weight of the node with label B_j is equal to t_j.

Furthermore, we add edges to this graph according to the following rules.

▶ **Definition 15.**

1. For every integer $u \neq 0$ such that $-t \leq u \leq t$ we add an edge from node B_i to node B_j of weight u if and only if there is a matrix $C \in \langle A_1, \ldots, A_n \rangle$ such that $F_iCE_j \in \left\{ \begin{bmatrix} u & b \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ b, c, d \in \mathbb{Z} \right\}$.

2. We also add an edge of weight u from the initial node **In** to a node with label B_j if there is a matrix $C \in \langle A_1, \dots, A_n \rangle$ such that $E^{-1}CE_j \in \left\{ \begin{bmatrix} u & b \\ 0 & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ b, d \in \mathbb{Z} \right\}$.
3. Finally, we add an edge of weight u from a node with label B_j to the final node **Fin** if there is a matrix $C \in \langle A_1, \dots, A_n \rangle$ such that $F_jCF^{-1} \in \left\{ \begin{bmatrix} u & 0 \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ c, d \in \mathbb{Z} \right\}$.

Note that the set $\{F_iCE_j : C \in \langle A_1, \dots, A_n \rangle\}$ is a regular subset of $\mathrm{GL}(2,\mathbb{Z})$ because it can be described by the regular expression $u_i(w_1 + \cdots + w_n)^* v_j$, where $w_1, \dots, w_n$ are words representing the matrices $A_1, \dots, A_n$ and u_i, v_j represent the matrices F_i, E_j, respectively. By Proposition 9, $\left\{ \begin{bmatrix} u & b \\ c & d \end{bmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ b, c, d \in \mathbb{Z} \right\}$ is also a regular subset of $\mathrm{GL}(2,\mathbb{Z})$. Therefore, by Theorem 5, we can algorithmically decide if there is an edge from node B_i to node B_j of weight u.

Moreover, the edges going out of **In** or ending in **Fin** can only have weights 1 or -1. Again, using Proposition 9, Corollary 10 and Theorem 5, we can algorithmically decide if there is an edge from **In** to B_j or from B_j to **Fin** of weight 1 or -1.

▶ **Definition 16.** The weight of a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** is equal to the product of the weights of nodes and edges that occur in it. That is, the weight of a path

$$\mathbf{In} \xrightarrow{u_0} B_{i_0} \xrightarrow{u_1} B_{i_1} \xrightarrow{u_2} B_{i_2} \quad \cdots \quad B_{i_{s-1}} \xrightarrow{u_s} B_{i_s} \xrightarrow{u_{s+1}} \mathbf{Fin}$$

is equal to $u_0 t_{i_0} u_1 t_{i_1} u_2 t_{i_2} \cdots t_{i_{s-1}} u_s t_{i_s} u_{s+1}$.

In the following proposition we will show that the membership problem is equivalent to the existence of a path in $\mathcal{G}(M, F)$ with a given weight.

▶ **Proposition 17.** *Let $M = E \begin{bmatrix} t & 0 \\ 0 & 0 \end{bmatrix} F$ be the Smith normal form of matrix M. Then $M \in \langle \mathcal{F} \rangle$ if and only if there is a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight t.*

Proof. Suppose

$$\mathbf{In} \xrightarrow{u_0} B_{i_0} \xrightarrow{u_1} B_{i_1} \xrightarrow{u_2} B_{i_2} \quad \cdots \quad B_{i_{s-1}} \xrightarrow{u_s} B_{i_s} \xrightarrow{u_{s+1}} \mathbf{Fin}$$

is a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight t. Recall that for every $r = 0, \dots, s$, we have $B_{i_r} = E_{i_r} \begin{bmatrix} t_{i_r} & 0 \\ 0 & 0 \end{bmatrix} F_{i_r}$. Hence $t = u_0 t_{i_0} u_1 t_{i_1} u_2 t_{i_2} \cdots t_{i_{s-1}} u_s t_{i_s} u_{s+1}$.

Since for every $r = 1, \dots, s$ we have an edge $B_{i_{r-1}} \xrightarrow{u_r} B_{i_r}$ of weight u_r, there is a matrix $C_r \in \langle A_1, \dots, A_n \rangle$ such that $F_{i_{r-1}} C_r E_{i_r} = \begin{bmatrix} u_r & b_r \\ c_r & d_r \end{bmatrix}$ for some $b_r, c_r, d_r \in \mathbb{Z}$. Since we have an edge $\mathbf{In} \xrightarrow{u_0} B_{i_0}$ of weight u_0, there is a matrix $C_0 \in \langle A_1, \dots, A_n \rangle$ such that $E^{-1} C_0 E_{i_0} = \begin{bmatrix} u_0 & b_0 \\ 0 & d_0 \end{bmatrix}$ for some $b_0, d_0 \in \mathbb{Z}$. And since we have an edge $B_{i_s} \xrightarrow{u_{s+1}} \mathbf{Fin}$ of weight u_{s+1}, there is a matrix $C_{s+1} \in \langle A_1, \dots, A_n \rangle$ such that $F_{i_s} C_{s+1} F^{-1} = \begin{bmatrix} u_{s+1} & 0 \\ c_{s+1} & d_{s+1} \end{bmatrix}$ for some $c_{s+1}, d_{s+1} \in \mathbb{Z}$.

Hence we obtain the following equation

$$
\begin{aligned}
&E^{-1}C_0B_{i_0}C_1B_{i_1}C_2B_{i_2}\cdots B_{i_{s-1}}C_sB_{i_s}C_{s+1}F^{-1} = \\
&E^{-1}C_0E_{i_0}\begin{bmatrix}t_{i_0} & 0\\ 0 & 0\end{bmatrix}F_{i_0}C_1E_{i_1}\begin{bmatrix}t_{i_1} & 0\\ 0 & 0\end{bmatrix}F_{i_1}C_2E_{i_2}\begin{bmatrix}t_{i_2} & 0\\ 0 & 0\end{bmatrix}F_{i_2}\cdots \\
&\qquad\cdots E_{i_{s-1}}\begin{bmatrix}t_{i_{s-1}} & 0\\ 0 & 0\end{bmatrix}F_{i_{s-1}}C_sE_{i_s}\begin{bmatrix}t_{i_s} & 0\\ 0 & 0\end{bmatrix}F_{i_s}C_{s+1}F^{-1} = \\
&t_{i_0}t_{i_1}t_{i_2}\cdots t_{i_{s-1}}t_{i_s}\begin{bmatrix}u_0 & b_0\\ 0 & d_0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_1 & b_1\\ c_1 & d_1\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_2 & b_2\\ c_2 & d_2\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\cdots \\
&\qquad\cdots\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_s & b_s\\ c_s & d_s\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_{s+1} & 0\\ c_{s+1} & d_{s+1}\end{bmatrix} = \\
&t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}\begin{bmatrix}u_0 & b_0\\ 0 & d_0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_{s+1} & 0\\ c_{s+1} & d_{s+1}\end{bmatrix} = \\
&t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}\begin{bmatrix}u_0u_{s+1} & 0\\ 0 & 0\end{bmatrix} = u_0t_{i_0}u_1t_{i_1}\cdots t_{i_{s-1}}u_st_{i_s}u_{s+1}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix} = \begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}.
\end{aligned}
$$

Therefore, $C_0B_{i_0}C_1B_{i_1}C_2B_{i_2}\cdots B_{i_{s-1}}C_sB_{i_s}C_{s+1} = E\begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}F = M$, and hence $M \in \langle\mathcal{F}\rangle$.

Now suppose that $M \in \langle\mathcal{F}\rangle$. It is not hard to see that there is a sequence of indices $i_0, i_1, \ldots, i_s \in \{1,\ldots,m\}$, and matrices $C_0, C_1, \ldots, C_{s+1} \in \langle A_1,\ldots,A_n\rangle$ such that

$$C_0B_{i_0}C_1B_{i_1}C_2B_{i_2}\cdots B_{i_{s-1}}C_sB_{i_s}C_{s+1} = M. \tag{5}$$

Recall that $E\begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}F$ is the Smith normal form of M, and $E_{i_r}\begin{bmatrix}t_{i_r} & 0\\ 0 & 0\end{bmatrix}F_{i_r}$ is the Smith normal form of B_{i_r}, for $r = 0,\ldots,s$. So we can rewrite (5) as follows

$$
\begin{aligned}
&E^{-1}C_0E_{i_0}\begin{bmatrix}t_{i_0} & 0\\ 0 & 0\end{bmatrix}F_{i_0}C_1E_{i_1}\begin{bmatrix}t_{i_1} & 0\\ 0 & 0\end{bmatrix}F_{i_1}C_2E_{i_2}\begin{bmatrix}t_{i_2} & 0\\ 0 & 0\end{bmatrix}F_{i_2}\cdots \\
&\qquad\cdots E_{i_{s-1}}\begin{bmatrix}t_{i_{s-1}} & 0\\ 0 & 0\end{bmatrix}F_{i_{s-1}}C_sE_{i_s}\begin{bmatrix}t_{i_s} & 0\\ 0 & 0\end{bmatrix}F_{i_s}C_{s+1}F^{-1} = \begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}.
\end{aligned}
\tag{6}
$$

For $r = 1,\ldots,s$, let $F_{i_{r-1}}C_rE_{i_r} = \begin{bmatrix}u_r & b_r\\ c_r & d_r\end{bmatrix}$. Then for every $r = 1,\ldots,s$, there is an edge $B_{i_{r-1}} \xrightarrow{u_r} B_{i_r}$ in $\mathcal{G}(M,\mathcal{F})$ of weight u_r. Furthermore, suppose that $E^{-1}C_0E_{i_0} = \begin{bmatrix}u_0 & b_0\\ c_0 & d_0\end{bmatrix}$ and $F_{i_s}C_{s+1}F^{-1} = \begin{bmatrix}u_{s+1} & b_{s+1}\\ c_{s+1} & d_{s+1}\end{bmatrix}$. Then we can rewrite (6) as

$$
\begin{aligned}
&\begin{bmatrix}u_0 & b_0\\ c_0 & d_0\end{bmatrix}\begin{bmatrix}t_{i_0} & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_1 & b_1\\ c_1 & d_1\end{bmatrix}\begin{bmatrix}t_{i_1} & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_2 & b_2\\ c_2 & d_2\end{bmatrix}\begin{bmatrix}t_{i_2} & 0\\ 0 & 0\end{bmatrix}\cdots \\
&\qquad\cdots\begin{bmatrix}t_{i_{s-1}} & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_s & b_s\\ c_s & d_s\end{bmatrix}\begin{bmatrix}t_{i_s} & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_{s+1} & b_{s+1}\\ c_{s+1} & d_{s+1}\end{bmatrix} = \begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}
\end{aligned}
$$

or equivalently

$$
\begin{aligned}
&t_{i_0}t_{i_1}t_{i_2}\cdots t_{i_{s-1}}t_{i_s}\begin{bmatrix}u_0 & b_0\\ c_0 & d_0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_1 & b_1\\ c_1 & d_1\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_2 & b_2\\ c_2 & d_2\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\cdots \\
&\qquad\cdots\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_s & b_s\\ c_s & d_s\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_{s+1} & b_{s+1}\\ c_{s+1} & d_{s+1}\end{bmatrix} = \begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}.
\end{aligned}
$$

From this equation we obtain

$$t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}\begin{bmatrix}u_0 & b_0\\ c_0 & d_0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{bmatrix}u_{s+1} & b_{s+1}\\ c_{s+1} & d_{s+1}\end{bmatrix}=\begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix} \quad \text{or}$$

$$t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}\begin{bmatrix}u_0u_{s+1} & u_0b_{s+1}\\ c_0u_{s+1} & c_0b_{s+1}\end{bmatrix}=\begin{bmatrix}t & 0\\ 0 & 0\end{bmatrix}.$$

Therefore, we have that $t = u_0t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}u_{s+1}$ and $u_0b_{s+1} = c_0u_{s+1} = 0$. By assumption $t \neq 0$, and so $u_0 \neq 0$ and $u_{s+1} \neq 0$. Therefore, $c_0 = 0$ and $b_{s+1} = 0$. Hence we have that $E^{-1}C_0E_{i_0} = \begin{bmatrix}u_0 & b_0\\ 0 & d_0\end{bmatrix}$ and $F_{i_s}C_{s+1}F^{-1} = \begin{bmatrix}u_{s+1} & 0\\ c_{s+1} & d_{s+1}\end{bmatrix}$, which means that there is an edge $\mathbf{In} \xrightarrow{u_0} B_{i_0}$ of weight u_0 and an edge $B_{i_s} \xrightarrow{u_{s+1}} \mathbf{Fin}$ of weight u_{s+1}. Thus we showed that there is path

$$\mathbf{In} \xrightarrow{u_0} B_{i_0} \xrightarrow{u_1} B_{i_1} \xrightarrow{u_2} B_{i_2} \quad \cdots \quad B_{i_{s-1}} \xrightarrow{u_s} B_{i_s} \xrightarrow{u_{s+1}} \mathbf{Fin}$$

in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight $u_0t_{i_0}u_1t_{i_1}u_2t_{i_2}\cdots t_{i_{s-1}}u_st_{i_s}u_{s+1} = t$. ◀

The next proposition provides a bound on the length of a path in $\mathcal{G}(M, \mathcal{F})$ with weight t.

▶ **Proposition 18.** *For any integer $t > 0$, if there is a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight t, then there is such path of length at most $2m\log_2 t + 2m + \log_2 t$.*

Proof. Suppose P is a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight t. Then the number of nodes and edges in P whose weight is greater than 1 or less than -1 is bounded by $\log_2 t$.

A *simple cycle* at node B_j is a closed path that starts and ends at B_j and in which no vertex appears twice except for B_j itself.

Note that if P contains a simple cycle of weight 1, then it can be removed from P without changing its weight. On the other hand, if P contains a simple cycle of weight -1, then removing such cycle will change the sign of the weight of P.

Let W_1 and W_2 be a successive pair of nodes or edges in P with weight different from ± 1. Then any node and edge that appears in P strictly between W_1 and W_2 has weight equal to ± 1. By the above observation we can remove all cycles of weight 1 that occur between W_1 and W_2 and leave at most one simple cycle of weight -1 between W_1 and W_2 in order to preserve the sign of the weight of P. So we can replace the original path from W_1 to W_2 by a new path with the same weight and length at most $2m$.

Recall there are at most $\log_2 t$ nodes and edges in P whose weight is different from ± 1. We now apply the above procedure to every pair W_1 and W_2 of successive nodes or edges in P whose weight is different from ± 1 including the cases when $W_1 = \mathbf{In}$ or $W_2 = \mathbf{Fin}$. There are at most $\log_2 t + 1$ such successive pairs. Therefore, we replace the whole path P with another path of the same weight and of length at most $2m(\log_2 t + 1) + \log_2 t$. Note that we added $\log_2 t$ in the end because every edge of weight different from ± 1 contributes 1 to the length of the path. ◀

Now we complete the proof of Theorem 13 using Propositions 17 and 18. Indeed, by Propositions 17 to decide whether $M \in \langle \mathcal{F} \rangle$, we need to check if there is a path in $\mathcal{G}(M, \mathcal{F})$ from **In** to **Fin** of weight t. By Propositions 18 the length of such path is bounded by $2m\log_2 t + 2m + \log_2 t$. Hence we can check all paths in $\mathcal{G}(M, \mathcal{F})$ of length up to $2m\log_2 t + 2m + \log_2 t$ to see if there is one with weight t. ◀

Conclusion and future work

The complexity of our algorithm is in EXPTIME. This is because a canonical word that represents a given matrix M has length exponential in the binary presentation of M. Hence the construction of regular languages in our proof takes exponential time. Moreover, the number of paths in $\mathcal{G}(M,\mathcal{F})$ of length up to $2m\log_2 t + 2m + \log_2 t$ is exponential in m.

In [4] it has been shown that the identity problem in $\mathrm{SL}(2,\mathbb{Z})$ is NP-complete. We would like to find out whether this construction can be combined with our result to show that the membership in $\mathrm{GL}(2,\mathbb{Z})$ extended by singular matrices is also NP-complete.

In our previous work [25] we proved that the membership problem is decidable for 2×2 nonsingular integer matrices. In this paper we considered matrices with determinants $0,\pm 1$. So, the next natural step will be to study the decidability of the membership problem for all 2×2 integer matrices, i.e. both singular and nonsingular ones.

Grammars for Indentation-Sensitive Parsing

Härmel Nestra

Institute of Computer Science, University of Tartu, Tartu, Estonia
harmel.nestra@ut.ee

Abstract

Adams' extension of parsing expression grammars enables specifying indentation sensitivity using two non-standard grammar constructs – indentation by a binary relation and alignment. This paper is a theoretical study of Adams' grammars. It proposes a step-by-step transformation of well-formed Adams' grammars for elimination of the alignment construct from the grammar. The idea that alignment could be avoided was suggested by Adams but no process for achieving this aim has been described before. This paper also establishes general conditions that binary relations used in indentation constructs must satisfy in order to enable efficient parsing.

1 Introduction

Parsing expression grammars (PEG) introduced by Ford [6] serve as a modern framework for specifying the syntax of programming languages and are an alternative to the classic context-free grammars (CFG). The core difference between CFG and PEG is that descriptions in CFG can be ambiguous while PEGs are inherently deterministic. A syntax specification written in PEG can in principle be interpreted as a top-down parser for that syntax; in the case of left recursion, this treatment is not straightforward but doable (see, e.g., [8]).

Formally, a PEG is a quadruple $G = (N, T, \delta, \mathsf{s})$ where:

- N is a finite set of *non-terminals*;
- T is a finite set of *terminals*;
- δ is a function mapping each non-terminal to its replacement (corresponding to the set of productions of CFG);
- s is the *start expression* (corresponding to the start symbol of CFG).

So $\delta : N \to \mathcal{E}_G$ and $\mathsf{s} \in \mathcal{E}_G$, where the set $\mathcal{E}_G$ of all *parsing expressions* writable in G is defined inductively as follows:

1. $\varepsilon \in \mathcal{E}_G$ (the empty string);
2. $a \in \mathcal{E}_G$ for every $a \in T$ (the terminals);
3. $X \in \mathcal{E}_G$ for every $X \in N$ (the non-terminals);
4. $\mathsf{pq} \in \mathcal{E}_G$ whenever $\mathsf{p} \in \mathcal{E}_G$, $\mathsf{q} \in \mathcal{E}_G$ (*concatenation*)
5. $\mathsf{p}/\mathsf{q} \in \mathcal{E}_G$ whenever $\mathsf{p} \in \mathcal{E}_G$, $\mathsf{q} \in \mathcal{E}_G$ (*choice*);
6. $!\mathsf{p} \in \mathcal{E}_G$ whenever $\mathsf{p} \in \mathcal{E}_G$ (*negation*, or *lookahead*);
7. $\mathsf{p}^* \in \mathcal{E}_G$ whenever $\mathsf{p} \in \mathcal{E}_G$ (*repetition*).

All constructs of PEG except for negation are direct analogues of constructs of the EBNF form of CFG, but their semantics is always deterministic. So p^* repeats parsing of p until failure, and p/q always tries to parse p first, q is parsed only if p fails. For example, the expression ab/a consumes the input string `ab` entirely while a/ab only consumes its first

character. The corresponding EBNF expressions $ab \mid a$ and $a \mid ab$ are equivalent, both can match either a or ab from the input string. Negation $!p$ tries to parse p and fails if p succeeds; if p fails then $!p$ succeeds with consuming no input. Other constructs of EBNF like non-null repetition p^+ and optional occurrence $[p]$ can be introduced to PEG as syntactic sugar.

Languages like Python and Haskell allow the syntactic structure of programs to be shown by indentation and alignment, instead of the more conventional braces and semicolons. Handling indentation and alignment in Python has been specified in terms of extra tokens INDENT and DEDENT that mark increasing and decreasing of indentation and must be generated by the lexer. In Haskell, rules for handling indentation and alignment are more sophisticated. Both these languages enable to locally use a different layout mode where indentation does not matter, which additionally complicates the task of formal syntax specification. Adams and Ağacan [3] proposed an extension of PEG notation for specifying indentation sensitivity and argued that it considerably simplifies this task for Python, Haskell and many other indentation-sensitive languages.

In this extension, expression $p^{>}$, for example, denotes parsing of p while assuming a greater indentation than that of the surrounding block. In general, parsing expressions may be equipped with binary relations (as was $>$ in the example) that must hold between the baselines of the local and the current indentation block. In addition, $\lfloor p \rfloor$ denotes parsing of p while assuming the first token of the input being aligned, i.e., positioned on the current indentation baseline. For example, the do expressions in Haskell can be specified by

$$\begin{array}{lcl} \langle doexp \rangle & ::= & \texttt{do}^{>}\ (\langle istmts \rangle / \langle stmts \rangle) \\ \langle istmts \rangle & ::= & (\lfloor \langle stmt \rangle \rfloor^{+})^{>} \\ \langle stmts \rangle & ::= & \texttt{\{}^{>} (\langle stmt \rangle (\texttt{;} \langle stmt \rangle)^{*} [\texttt{;}] \texttt{\}})^{\circledast} \end{array}$$

Here, $\langle istmts \rangle$ and $\langle stmts \rangle$ stand for statement lists in the indentation and relaxed mode, respectively. In the indentation mode, a statement list is indented (marked by $>$ in the second production) and all statements in it are aligned (marked by $\lfloor \cdot \rfloor$). In the relaxed mode, however, relation $\circledast$ is used to indicate that the indentation baseline of the contents can be anything. (Technically, $\circledast$ is the binary relation containing all pairs of natural numbers.) Terminals `do` and `{` are also equipped with $>$ to meet the Haskell requirement that subsequent tokens of aligned blocks must be indented more than the first token.

Alignment construct provides fulcra for disambiguating the often large variety of indentation baseline candidates. Besides simplicity of this grammar extension and its use, a strength of it lies in the fact that grammars can still serve as parsers.

The rest of the paper is organized as follows. Section 2 formally introduces additional constructs of PEG for specifying code layout, defines their semantics and studies their semantic properties. In Sect. 3, a semantics-preserving process of eliminating the alignment construct from grammars is described. General criteria for deciding if parsing can handle a relation efficiently are found in Sect. 4. Section 5 refers to related work and Sect. 6 concludes.

2 Indentation extension of PEG

Adams and Ağacan [3] extend PEGs with the indentation and alignment constructs. We propose a slightly different extension with three rather than two extra constructs. Our approach agrees with that implemented by Adams in his `indentation` package for Haskell [1], whence calling the grammars in our approach *Adams' grammars* is justified. All differences between the definitions in this paper and in [3] are listed and discussed in Subsect. 2.4.

Let $\mathbb{N}$ denote the set of all natural numbers, and let $\mathbb{B} = \{tt, ff\}$ (the Boolean domain). Denote by $\wp(X)$ the set of all subsets of set X, and let $\Re(X)$ denote the set of all binary

relations on set X, i.e., $\Re(X) = \wp(X \times X)$. Standard examples are $>\in \Re(\mathbb{N})$ (consisting of all pairs (n, m) of natural numbers such that $n > m$) and $\triangle \in \Re(\mathbb{N})$ (the identity relation consisting of all pairs of equal natural numbers); the indentation extension also makes use of $\circledast \in \Re(\mathbb{N})$ (the relation containing all pairs of natural numbers). Whenever $\rho \in \Re(X)$ and $Y \subseteq X$, denote $\rho(Y) = \{x \in X : \exists y \in Y.(y, x) \in \rho\}$ (the image of Y under relation ρ). The inverse relation of ρ is defined by $\rho^{-1} = \{(x, y) : (y, x) \in \rho\}$, and the composition of relations σ and ρ by $\sigma \circ \rho = \{(x, z) : \exists y.(x, y) \in \sigma \wedge (y, z) \in \rho\}$. Finally, denote $\Re^+(X) = \left\{\rho \in \Re(X) : \forall x \in X.\rho^{-1}(\{x\}) \neq \varnothing\right\} = \{\rho \in \Re(X) : \rho(X) = X\}$.

2.1 Adams' grammars

Extend the definition of $\mathcal{E}_G$ given in Sect. 1 with the following three additional clauses:

8. $p^\rho \in \mathcal{E}_G$ for every $p \in \mathcal{E}_G$ and $\rho \in \Re(\mathbb{N})$ (*indentation*);
9. $p_\sigma \in \mathcal{E}_G$ for every $p \in \mathcal{E}_G$ and $\sigma \in \Re(\mathbb{N})$ (*token position*);
10. $\lfloor p \rfloor \in \mathcal{E}_G$ for every $p \in \mathcal{E}_G$ (*alignment*).

Parsing of an expression p^ρ means parsing of p while assuming that the part of the input string corresponding to p forms a new indentation block whose baseline is in relation ρ to the baseline of the surrounding block. (Baselines are identified with column numbers.) The position construct p_σ, missing in [3], determines how tokens of the input can be situated w.r.t. the current indentation baseline. Finally, parsing an expression $\lfloor p \rfloor$ means parsing of p while assuming the first token of the input being positioned on the current indentation baseline (unlike the position operator, this construct does not affect processing the subsequent tokens).

Inspired by the `indentation` package [1], we call the relations that determine token positioning w.r.t. the indentation baseline *token modes*. In the token mode $>$ for example, tokens may appear only to the right of the indentation baseline. Applying the position operator with relation $>$ to parts of Haskell grammar to be parsed in the indentation mode avoids indenting every single terminal in the example in Sect. 1. Also, indenting terminals with $>$ is inadequate for do expressions occurring inside a block of relaxed mode but the position construct can be easily used to change the token mode for such blocks (e.g., to $\geq$).

We call a PEG extended with these three constructs a PEG$^>$. Recall from Sect. 1 that N and T denote the set of non-terminal and terminal symbols of the grammar, respectively, and $\delta : N \to \mathcal{E}_G$ is the production function. Concerning the semantics of PEG$^>$, each expression parses an input string of terminals ($w \in T^*$) in the context of a current set of indentation baseline candidates ($I \in \wp(\mathbb{N})$) and a current alignment flag indicating whether the next terminal should be aligned or not ($b \in \mathbb{B}$), assuming a certain token mode ($\tau \in \Re(\mathbb{N})$). Parsing may succeed, fail, or diverge. If parsing succeeds, it returns as a result a new triple containing the rest of the input w', a new set I' of baseline candidates updated according to the information gathered during parsing, and a new alignment flag b'. This result is denoted by $\top(w', I', b')$. If parsing fails, there is no result in a triple form; failure is denoted by $\bot$.

Triples of the form $(w, I, b) \in T^* \times \wp(\mathbb{N}) \times \mathbb{B}$ are behaving as *operation states* of parsing, as each parsing step may use these data and update them. We will write $State = T^* \times \wp(\mathbb{N}) \times \mathbb{B}$ (as we never deal with different terminal sets, dependence on T is not explicitly marked), and denote by $State + 1$ the set of possible results of parsing, i.e., $\{\top(s) : s \in State\} \cup \{\bot\}$.

The assertion that parsing expression e in grammar G with input string w in the context of I and b assuming token mode τ results in $o \in State + 1$ is denoted by $e, \tau \vdash_G (w, I, b) \to o$. The formal definition below must be interpreted inductively, i.e., an assertion of the form $G, \tau \vdash_e s \to o$ is valid iff it has a finite derivation by the following ten rules:

1. $\varepsilon, \tau \vdash_G s \to \top(s)$.
2. For every $a \in T$, $a, \tau \vdash_G (w, I, b) \to o$ holds in two cases:
   - If $o = \top(w', I', \mathit{ff})$ for w', I', i such that $w = a^i w'$ (a^i denotes a occurring at column i) and either $b = \mathit{ff}$ and $i \in \tau^{-1}(I)$, $I' = I \cap \tau(\{i\})$, or $b = \mathit{tt}$ and $i \in I$, $I' = \{i\}$;
   - If $o = \bot$, and there are no w' and i such that $w = a^i w'$ with either $b = \mathit{ff}$ and $i \in \tau^{-1}(I)$ or $b = \mathit{tt}$ and $i \in I$.
3. For every $X \in N$, $X, \tau \vdash_G s \to o$ holds if $\delta(X), \tau \vdash_G s \to o$ holds.
4. For every $\mathsf{p}, \mathsf{q} \in \mathcal{E}_G$, $\mathsf{pq}, \tau \vdash_G s \to o$ holds in two cases:
   - If there exists a triple s' such that $\mathsf{p}, \tau \vdash_G s \to \top(s')$ and $\mathsf{q}, \tau \vdash_G s' \to o$;
   - If $\mathsf{p}, \tau \vdash_G s \to \bot$ and $o = \bot$.
5. For every $\mathsf{p}, \mathsf{q} \in \mathcal{E}_G$, $\mathsf{p}/\mathsf{q}, \tau \vdash_G s \to o$ holds in two cases:
   - If there exists a triple s' such that $\mathsf{p}, \tau \vdash_G s \to \top(s')$ and $o = \top(s')$;
   - If $\mathsf{p}, \tau \vdash_G s \to \bot$ and $\mathsf{q}, \tau \vdash_G s \to o$.
6. For every $\mathsf{p} \in \mathcal{E}_G$, $!\mathsf{p}, \tau \vdash_G s \to o$ holds in two cases:
   - If $\mathsf{p}, \tau \vdash_G s \to \bot$ and $o = \top(s)$;
   - If there exists a triple s' such that $\mathsf{p}, \tau \vdash_G s \to \top(s')$ and $o = \bot$.
7. For every $\mathsf{p} \in \mathcal{E}_G$, $\mathsf{p}^*, \tau \vdash_G s \to o$ holds in two cases:
   - If $\mathsf{p}, \tau \vdash_G s \to \bot$ and $o = \top(s)$;
   - If there exists a triple s' such that $\mathsf{p}, \tau \vdash_G s \to \top(s')$ and $\mathsf{p}^*, \tau \vdash_G s' \to o$.
8. For every $\mathsf{p} \in \mathcal{E}_G$ and $\varrho \in \Re(\mathbb{N})$, $\mathsf{p}^{\varrho}, \tau \vdash_G (w, I, b) \to o$ holds in two cases:
   - If there exists a triple (w', I', b') such that $\mathsf{p}, \tau \vdash_G (w, \varrho^{-1}(I), b) \to \top(w', I', b')$ and $o = \top(w', I \cap \varrho(I'), b')$;
   - If $\mathsf{p}, \tau \vdash_G (w, \varrho^{-1}(I), b) \to \bot$ and $o = \bot$.
9. For every $\mathsf{p} \in \mathcal{E}_G$ and $\sigma \in \Re(\mathbb{N})$, $\mathsf{p}_{\sigma}, \tau \vdash_G s \to o$ holds if $\mathsf{p}, \sigma \vdash_G s \to o$ holds.
10. For every $\mathsf{p} \in \mathcal{E}_G$, $\lfloor \mathsf{p} \rfloor, \tau \vdash_G (w, I, b) \to o$ holds in two cases:
    - If there exists a triple (w', I', b') such that $\mathsf{p}, \tau \vdash_G (w, I, \mathit{tt}) \to \top(w', I', b')$ and $o = \top(w', I', b \wedge b')$;
    - If $\mathsf{p}, \tau \vdash_G (w, I, \mathit{tt}) \to \bot$ and $o = \bot$.

The idea behind the conditions $i \in \tau^{-1}(I)$ and $i \in I$ occurring in clause 2 is that any column i where a token may appear is in relation τ with the current indentation baseline (known to be in I) if the alignment flag is false, and coincides with the indentation baseline otherwise. For the same reason, consuming a token in column i restricts the set of allowed indentations to $\tau(\{i\})$ or $\{i\}$ depending on the alignment flag. In both cases, the alignment flag is set to ff. Similar principles lie behind the changes of the operation states in clauses 8 and 10.

For a toy example, consider parsing of $\lfloor ab \rfloor^{>}$ with the operation state $(a^2b^3, \mathbb{N}, \mathit{ff})$ assuming the token mode $\geq$. For that, we must parse $\lfloor ab \rfloor$ with $(a^2b^3, \mathbb{N} \setminus \{0\}, \mathit{ff})$ by clause 8 since $>^{-1}(\mathbb{N}) = \mathbb{N} \setminus \{0\}$. For that in turn, we must parse ab with $(a^2b^3, \mathbb{N} \setminus \{0\}, \mathit{tt})$ by clause 10. By clause 2, we have $a, \geq \vdash_G (a^2b^3, \mathbb{N} \setminus \{0\}, \mathit{tt}) \to \top(b^3, \{2\}, \mathit{ff})$ (as $2 \in \mathbb{N} \setminus \{0\}$) and $b, \geq \vdash_G (b^3, \{2\}, \mathit{ff}) \to \top(\varepsilon, \{2\}, \mathit{ff})$ (as $(2, 3) \in \geq^{-1}$). Therefore, by clause 4, $ab, \geq \vdash_G (a^2b^3, \mathbb{N} \setminus \{0\}, \mathit{tt}) \to \top(\varepsilon, \{2\}, \mathit{ff})$. Finally, $\lfloor ab \rfloor, \geq \vdash_G (a^2b^3, \mathbb{N} \setminus \{0\}, \mathit{ff}) \to \top(\varepsilon, \{2\}, \mathit{ff})$ and $\lfloor ab \rfloor^{>}, \geq \vdash_G (a^2b^3, \mathbb{N}, \mathit{ff}) \to \top(\varepsilon, \{0, 1\}, \mathit{ff})$ by clauses 10 and 8. The set $\{0, 1\}$ in the final state shows that only 0 and 1 are still candidates for the indentation baseline outside the parsed part of the input (before parsing, the candidate set was the whole $\mathbb{N}$).

Note that this definition involves circular dependencies. For instance, if $\delta(X) = X$ for some $X \in N$ then $X, \tau \vdash_G s \to o$ if $X, \tau \vdash_G s \to o$ by clause 3. There is no result of parsing in such cases (not even $\bot$). We call this behaviour *divergence*.

2.2 Properties of the semantics

Ford [6] proves that parsing in PEG is unambiguous, whereby the consumed part of an input string always is its prefix. Theorem 2.1 below is an analogous result for PEG$^>$. Besides the uniqueness of the result of parsing, it states that if we only consider relations in $\Re^+(\mathbb{N})$ then the whole operation state in our setting is in a certain sense decreasing during parsing.

Denote by $\geq$ the *suffix order* of strings (i.e., $w \geq w'$ iff $w = uw'$ for some $u \in T^*$) and by $\sqsupseteq$ the *implication order* of truth values (i.e., $tt \sqsupset ff$). Denote by $\geqslant$ the pointwise order on operation states, i.e., $(w, I, b) \geqslant (w', I', b')$ iff $w \geq w'$, $I \supseteq I'$ and $b \sqsupseteq b'$.

▶ **Theorem 2.1.** *Let $G = (N, T, \delta, \mathsf{s})$ be a PEG$^>$, $\mathsf{e} \in \mathcal{E}_G$, $\tau \in \Re^+(\mathbb{N})$ and $s \in State$. Then $\mathsf{e}, \tau \vdash_G s \to o$ for at most one o, whereby $o = \top(s')$ implies $s \geqslant s'$. Also if $s = (w, I, b)$ and $s' = (w', I', b')$ then $s \neq s'$ implies both $w > w'$ and $b' = ff$, and $I \neq \varnothing$ implies $I' \neq \varnothing$.*

Proof. By induction on the shape of the derivation tree of the assertion $\mathsf{e}, \tau \vdash_G s \to o$. ◀

Theorem 2.1 enables to observe a common pattern in the semantics of indentation and alignment. Denoting by $\kappa(\mathsf{p})$ either p° or $|\mathsf{p}|$, both clauses 8 and 10 have the following form, parametrized on two mappings $\alpha, \gamma : State \to State$:

For $\mathsf{p} \in \mathcal{E}_G$, $\kappa(\mathsf{p}), \tau \vdash_G s \to o$ holds in two cases:

- If there exists a state s' such that $\mathsf{p}, \tau \vdash_G \alpha(s) \to \top(s')$ and $o = \top(s \wedge \gamma(s'))$;
- If $\mathsf{p}, \tau \vdash_G \alpha(s) \to \bot$ and $o = \bot$.

The meanings of indentation and alignment constructs are distinguished solely by α and γ. For many properties, proofs that rely on this abstract common definition can be carried out, assuming that γ is monotone, preserves the largest element and follows together with α the axiom $x \wedge \gamma(y) \leq \gamma(\alpha(x) \wedge y)$. The class of all meet semilattices L with top element, equipped with mappings α, γ satisfying these three conditions, contains identities (i.e., semilattices L with $\alpha = \gamma = \mathrm{id}_L$) and is closed under compositions (of different α, γ defined on the same semilattice L) and under direct products. If $\rho \in \Re^+(\mathbb{N})$ then the conditions hold for $\alpha_1, \gamma_1 : \wp(\mathbb{N}) \to \wp(\mathbb{N})$ with $\alpha_1(I) = \rho^{-1}(I)$, $\gamma_1(I) = \rho(I)$, similarly in the case if $\alpha_2, \gamma_2 : \mathbb{B} \to \mathbb{B}$ with $\alpha_2(b) = tt$, $\gamma_2(b) = b$. Now the direct product of the identities of T^* and $\mathbb{B}$ with (α_1, γ_1) on $\wp(\mathbb{N})$ gives the indentation case, and the direct product of the identities of T^* and $\wp(\mathbb{N})$ and the Boolean lattice $\mathbb{B}$ with (α_2, γ_2) gives the alignment case.

If α, γ satisfy the conditions then $\gamma(\alpha(x)) \geq x$ since $x = x \wedge \top = x \wedge \gamma(\top) \leq \gamma(\alpha(x) \wedge \top) = \gamma(\alpha(x))$. Adding dual conditions (α monotone, $\alpha(\bot) = \bot$ and $\alpha(x) \vee y \geq \alpha(x \vee \gamma(y))$) would make (α, γ) a Galois' connection. In our cases, the dual axioms do not hold.

2.3 Semantic equivalence

▶ **Definition 2.2.** Let $G = (N, T, \delta, \mathsf{s})$ be a PEG$^>$ and $\mathsf{p}, \mathsf{q} \in \mathcal{E}_G$. We say that p and q are *semantically equivalent* in G and denote $\mathsf{p} \sim_G \mathsf{q}$ iff $\mathsf{p}, \tau \vdash_G s \to o \iff \mathsf{q}, \tau \vdash_G s \to o$ for every $\tau \in \Re^+(\mathbb{N})$, $s \in State$ and $o \in State + 1$.

For example, one can easily prove that $\mathsf{p}\varepsilon \sim_G \mathsf{p} \sim_G \varepsilon\mathsf{p}$, $\mathsf{p}(\mathsf{qr}) \sim_G (\mathsf{pq})\mathsf{r}$, $\mathsf{p}/(\mathsf{q}/\mathsf{r}) \sim_G (\mathsf{p}/\mathsf{q})/\mathsf{r}$, $\mathsf{p}(\mathsf{q}/\mathsf{r}) \sim_G \mathsf{pq}/\mathsf{pr}$, $\mathsf{p}/\mathsf{q} \sim_G \mathsf{p}/!\mathsf{pq}$ for all $\mathsf{p}, \mathsf{q}, \mathsf{r} \in \mathcal{E}_G$ [6]. We are particularly interested in equivalences involving the additional operators of PEG$^>$. In Sect. 3, they will be useful in eliminating alignment and position operators. The following Theorem 2.3 states distributivity laws of the three new operators of PEG$^>$ w.r.t. other constructs:

▶ **Theorem 2.3.** *Let $G = (N, T, \delta, s)$ be a PEG$^{>}$. Then:*

1. $\varepsilon_\sigma \sim_G \varepsilon$, $(pq)_\sigma \sim_G p_\sigma q_\sigma$, $(p/q)_\sigma \sim_G p_\sigma / q_\sigma$, $(!p)_\sigma \sim_G !p_\sigma$, $(p^*)_\sigma \sim_G (p_\sigma)^*$, $(p^\varrho)_\sigma \sim_G (p_\sigma)^\varrho$, $\lfloor p \rfloor_\sigma \sim_G \lfloor p_\sigma \rfloor$ *for all* $\sigma \in \Re^+(\mathbb{N})$;
2. $\varepsilon^\varrho \sim_G \varepsilon$, $(p/q)^\varrho \sim_G p^\varrho / q^\varrho$, $(!p)^\varrho \sim_G !p^\varrho$, $(p_\sigma)^\varrho \sim_G (p^\varrho)_\sigma$ *for all* $\varrho \in \Re^+(\mathbb{N})$;
3. $\lfloor \varepsilon \rfloor \sim_G \varepsilon$, $\lfloor p/q \rfloor \sim_G \lfloor p \rfloor / \lfloor q \rfloor$, $\lfloor !p \rfloor \sim_G ! \lfloor p \rfloor$, $\lfloor p_\sigma \rfloor \sim_G \lfloor p \rfloor_\sigma$.

Proof. The equivalences in claim 1 hold as the token mode steadily distributes to each case of the semantics definition. Those in claims 2 and 3 have straightforward proofs using the joint form of the semantics of indentation and alignment and the axioms of α, γ. ◀

Note that indentation does not distribute with concatenation, i.e., $(pq)^\varrho \not\sim_G p^\varrho q^\varrho$. This is because $(pq)^\varrho$ assumes one indentation block with a baseline common to p and q while $p^\varrho q^\varrho$ tolerates different baselines for p and q. For example, take $p = a \in T$, $q = b \in T$, let the token mode be $\triangle$ and the input state be $(a^1 b^2, \mathbb{N}, ff)$ (recall that a^i means terminal a occurring in column i). We have $a, \triangle \vdash_G (a^1 b^2, \mathbb{N} \setminus \{0\}, ff) \to \top(b^2, \{1\}, ff)$ and $b, \triangle \vdash_G (b^2, \{1\}, ff) \to \bot$ (since $(2,1) \notin \triangle$), therefore $ab, \triangle \vdash_G (a^1 b^2, \mathbb{N} \setminus \{0\}, ff) \to \bot$ and $(ab)^{>}, \triangle \vdash_G (a^1 b^2, \mathbb{N}, ff) \to \bot$. On the other hand, $a, \triangle \vdash_G (a^1 b^2, \mathbb{N} \setminus \{0\}, ff) \to \top(b^2, \{1\}, ff)$ implies $a^{>}, \triangle \vdash_G (a^1 b^2, \mathbb{N}, ff) \to \top(b^2, \{0\}, ff)$ (since $\mathbb{N} \cap (> (\{1\})) = \{0\}$) and, analogously, $b^{>}, \triangle \vdash_G (b^2, \{0\}, ff) \to \top(\varepsilon, \{0\}, ff)$ (since $>^{-1}(\{0\}) = \mathbb{N} \setminus \{0\} \ni 2$ and $\{0\} \cap (> (\{2\})) = \{0\}$). Consequently, $a^{>} b^{>}, \triangle \vdash_G (a^1 b^2, \mathbb{N}, ff) \to \top(\varepsilon, \{0\}, ff)$.

We can however prove the following facts:

▶ **Theorem 2.4.** *Let $G = (N, T, \delta, s)$ be a PEG$^{>}$.*

1. *Identity indentation law: For all $p \in \mathcal{E}_G$, $p^\triangle \sim_G p$.*
2. *Composition law of indentations: For all $p \in \mathcal{E}_G$ and $\varrho, \sigma \in \Re^+(\mathbb{N})$, $(p^\varrho)^\sigma \sim_G p^{\sigma \circ \varrho}$.*
3. *Distributivity of indentation and alignment: For all $p \in \mathcal{E}_G$ and $\varrho \in \Re^+(\mathbb{N})$, $\lfloor p \rfloor^\varrho \sim_G \lfloor p^\varrho \rfloor$.*
4. *Idempotence of alignment: For all $p \in \mathcal{E}_G$, $\lfloor \lfloor p \rfloor \rfloor \sim_G \lfloor p \rfloor$.*
5. *Cancellation of outer token modes: For all $p \in \mathcal{E}_G$ and $\sigma, \tau \in \Re(\mathbb{N})$, $(p_\sigma)_\tau \sim_G p_\sigma$.*
6. *Terminal alignment property: For all $a \in T$, $\lfloor a \rfloor \sim_G a_\triangle$.*

Proof. Claim 1 follows easily from the semantics of indentation. By the conditions imposed on α and γ, it follows that the composition of the effects of indentations or alignments with respective mapping pairs (α_1, γ_1) and (α_2, γ_2) coincides with the effect of a prospective construct of similar kind with mapping pair $(\alpha_2 \circ \alpha_1, \gamma_1 \circ \gamma_2)$. Claims 2–4 follow directly from this observation, as the composition of structures (α, γ) used for indentation and alignment is commutative and the structure (α, γ) used for alignment is idempotent. Claim 5 is trivial. Claim 6 follows from a straightforward case study. ◀

Theorems 2.3 and 2.4 enact bringing alignments through all syntactic constructs except concatenation. Alignment does not distribute with concatenation, because in parsing of an expression of the form $\lfloor pq \rfloor$, the terminal to be aligned can be in the part of the input consumed by p or (if parsing of p succeeds with consuming no input) by q. Alignment can nevertheless be moved through concatenation if any successful parsing of the first expression in the concatenation either never consumes any input or always consumes some input:

▶ **Theorem 2.5.** *Let $G = (N, T, \delta, s)$ be a PEG$^{>}$ and $p, q \in \mathcal{E}_G$.*

1. *If $p, \tau \vdash_G s \to \top(s')$ implies $s' = s$ for all $\tau \in \Re^+(\mathbb{N})$, $s, s' \in State$, then $\lfloor pq \rfloor \sim_G \lfloor p \rfloor \lfloor q \rfloor$.*
2. *If $p, \tau \vdash_G s \to \top(s')$ implies $s' \neq s$ for all $\tau \in \Re^+(\mathbb{N})$, $s, s' \in State$, then $\lfloor pq \rfloor \sim_G \lfloor p \rfloor q$.*

Proof. Straightforward case study. ◀

Theorem 2.5 (1) holds also for indentation (instead of alignment), the same proof in terms of α, γ is valid. Finally, the following theorem states that position and indentation of terminals are equivalent if the alignment flag is false and the token mode is the identity:

▶ **Theorem 2.6.** *Let* $G = (N, T, \delta, s)$ *be a PEG*$^{>}$. *Let* $a \in T$, $\sigma \in \Re^{+}(\mathbb{N})$ *and* $w \in T^{*}$, $I \in \wp(\mathbb{N})$, $o \in State + 1$. *Then* $a_{\sigma}, \triangle \vdash_{G} (w, I, \mathit{ff}) \to o \iff a^{\sigma}, \triangle \vdash_{G} (w, I, \mathit{ff}) \to o$.

Proof. Straightforward case study. ◀

2.4 Differences of our approach from previous work

Our specification of PEG$^{>}$differs from the definition used by Adams and Ağacan [3] by three essential aspects listed below. The last two discrepancies can be understood as bugs in the original description that have been corrected in the Haskell `indentation` package by Adams [1]. This package also provides means for locally changing the token mode. All in all, our modifications fully agree with the `indentation` package.

1. The position operator p_{σ} is missing in [3]. The treatment there assumes just one default token mode applying to the whole grammar, whence token positions deviating from the default must be specified using the indentation operator. The benefits of the position operator were shortly discussed in Subsect. 2.1.
2. According to the grammar semantics provided in [3], the alignment flag is never changed at the end of parsing of an expression of the form $\lfloor p \rfloor$. This is not appropriate if p succeeds without consuming any token, as the alignment flag would unexpectedly remain true during parsing of the next token that is out of scope of the alignment operator. The value the alignment flag had before starting parsing $\lfloor p \rfloor$ should be restored in this case. This is the purpose of conjunction in the alignment semantics described in this paper.
3. In [3], an alignment is interpreted w.r.t. the indentation baseline of the block that corresponds to the parsing expression to which the alignment operator is applied. Indentation operators occurring inside this expression and processed while the alignment flag is true are neglected. In the semantics described in our paper, raising the alignment flag does not suppress new indentations. Alignments are interpreted w.r.t. the indentation baseline in force at the aligned token site. This seems more appropriate than the former approach where the indentations cancelled because of an alignment do not apply even to the subsequent non-aligned tokens. Distributivity of indentation and alignment fails in the semantics of [3]. Note that alignment of a block nevertheless suppresses the influence of position operators whose scope extend over the first token of the block.

Our grammar semantics has also two purely formal deviations from the semantics used by Adams and Ağacan [3] and Ford [6].

1. We keep track of the rest of the input in the operation state while both [3, 6] expose the consumed part of the input instead. This difference was introduced for simplicity and to achieve uniform decreasing of operation states in Theorem 2.1.
2. We do not have explicit step counts. They were used in [6] to compose proofs by induction. We provide analogous proofs by induction on the shape of derivation trees.

3 Elimination of alignment and position operators

Adams [2] describes alignment elimination in the context of CFGs. In [3], Adams and Ağacan claim that alignment elimination process for PEGs is more difficult due to the lookahead construct. To our knowledge, no concrete process of semantics-preserving alignment

elimination is described for PEGs before. We provide one below for well-formed grammars. We rely on the existence of position operators in the grammar; this is not an issue since we also show that position operators can be eliminated from alignment-free grammars.

We describe our process informally on an example; a general description together with correctness theorems can be found in our online paper [9].

As the repetition operator can always be eliminated (by adding a new non-terminal A_{p} with $\delta(A_{\mathsf{p}}) = \mathsf{p}A_{\mathsf{p}}/\varepsilon$ for each subexpression p that occurs under the star operator), we may assume that the input grammar G is repetition-free. The process also assumes that G is well-formed, all negations are applied to atomic expressions, and all choices are disjoint. A choice expression p/q is called *disjoint* if parsing of p and q cannot succeed in the same input state and token mode. *Well-formedness* is a decidable conservative approximation of the predicate that is true iff parsing in G never diverges (it definitely excludes grammars with left recursion but can exclude also some safe grammars). Well-formedness of PEGs was introduced by Ford [6]. Extending the notion to expressions containing the extra operators of PEG$^{>}$ is straightforward, details are provided in [9]. Achieving the other two preconditions can be considered as a preparatory and previously studied (e.g. in [6] as stage 1 of negation elimination) step of the process.

We will work on the example grammar $G = (N, T, \delta, \mathsf{s})$ where $N = \{A, B\}$, $T = \{a, b, c\}$, $\delta = \left\{A \mapsto !!c/a/B, B \mapsto b{\restriction}AA{\restriction}^{>}\right\}$ and $\mathsf{s} = A_{\geq}$. This grammar is well-formed and choices in the rule for A are disjoint ($!!c$, a and B can succeed only if the input string starts with c, a or b, respectively). Not all negations are in front of atoms; this can be fixed by introducing a new non-terminal C with rule $C \mapsto !c$ and replacing the rule for A with $A \mapsto !C/a/B$. Elimination of alignment and position operators from the grammar is done in 3 stages.

1. *Transform G to an equivalent grammar G_1 where for each expression of the form pq occurring in δ or s, parsing of p either never succeeds without consuming some input or can succeed only if consuming no input.*
   This "splitting" step enables to later bring alignments through concatenations (by Theorem 2.5). It only modifies rules and the start expression. The new set of rules and start expression could be

   $$\delta_1 = \left\{A \mapsto a/B \quad B \mapsto b{\restriction}AA/A!!c/!!cA/!!c!!c{\restriction}^{>}\right\}, \qquad \mathsf{s}_1 = (A/!!c)_{\geq}$$

   (in the version of the grammar with non-terminal C, there would be an additional rule for C that never succeeds). The formal process described in [9] would give a somewhat more complicated result but this simplified variant works fine and perfectly explains the ideas. The alternative with negation is removed from the rule of A to allow parsing of A succeed only if consuming some input (the same transformation would be performed on other non-terminals if it was necessary). The removed alternative (which happens to succeed only if consuming no input) is inserted into each concatenation of A, as well as into the start expression. Basically the same transformation was used by Ford [6] on stage 2 of his negation elimination process.
2. *Using the semantic equivalences of Subsect. 2.3, move all alignments down to atoms. Rewrite alignment of terminals in terms of the position operator and the identity relation. For each existing non-terminal X, introduce a new non-terminal with a rule whose right-hand side is obtained from ${\restriction}\delta_1(X){\restriction}$ by moving all alignments down to non-terminals, and replace all aligned non-terminals with the corresponding new non-terminals.*
   In our example, we have to introduce two new non-terminals A' and B' with right-hand sides obtained from ${\restriction}a/B{\restriction}$ and ${\restriction}b{\restriction}AA/A!!c/!!cA/!!c!!c{\restriction}^{>}{\restriction}$, respectively. Using that

$\lfloor AA\rfloor \sim \lfloor A\rfloor A$, $\lfloor A!!c\rfloor \sim \lfloor A\rfloor !!c$, $\lfloor !!cA\rfloor \sim !!c\lfloor\rfloor A\rfloor$ and $\lfloor !!c!!c\rfloor \sim !!c\lfloor\rfloor !!c\rfloor$, we end up with

$$\delta_2 = \left\{ \begin{array}{llll} A & \mapsto a/B & B & \mapsto b(A'A/A'!!c/!!c_\triangle A'/!!c_\triangle !!c_\triangle)^> \\ A' & \mapsto a_\triangle/B' & B' & \mapsto b_\triangle(A'A/A'!!c/!!c_\triangle A'/!!c_\triangle !!c_\triangle)^> \end{array} \right\}, \quad s_2 = (A/!!c)_\geq.$$

3. *Using the semantic equivalences of Subsect. 2.3, move all position operators down to atoms. For each non-terminal X and relation τ used by position operators, introduce a new non-terminal with a rule whose right-hand side is obtained from $(\delta_2(X))_\tau$ by moving position operators down to atoms, and replace all non-terminals under position operators with the corresponding new non-terminals. Replace position operators applied to terminals with indentation, omit identity indentations.*

   In our example, $\geq$ is the only relation used by position operators. Hence we must introduce one new non-terminal for each existing non-terminal. Denote them $\hat{A}$, $\hat{B}$, $\hat{A}'$, $\hat{B}'$. As the old non-terminals will never be used when parsing the new start expression, we can omit their rules. The rules of the new non-terminals and the start expression are

$$\delta_3 = \left\{ \begin{array}{llll} \hat{A} & \mapsto a^\geq/\hat{B} & \hat{B} & \mapsto b^\geq(\hat{A}'\hat{A}/\hat{A}'!!c^\geq/!!c\hat{A}'/!!c!!c)^> \\ \hat{A}' & \mapsto a/\hat{B}' & \hat{B}' & \mapsto b(\hat{A}'\hat{A}/\hat{A}'!!c^\geq/!!c\hat{A}'/!!c!!c)^> \end{array} \right\}, \quad s_3 = \hat{A}/!!c^\geq.$$

Note how terminals that do not have to be aligned have indentation $\geq$ while terminals to be aligned have no indentation. Parsings in the resulting grammar must run with the alignment flag unset and assume the identity token mode.

At step 1, the sizes of the right-hand sides of the rules can grow exponentially though the number of rules stays unchanged. Preprocessing the grammar via introducing new non-terminals in such a way that all concatenations were applied to atoms (similarly to Ford [6]) would hinder the growth, but the size in the worst case remains exponential. Steps 2 and 3 cause at most a linear growth of right-hand sides.

4 Which relations are good?

Speed of grammar-driven parsing of expressions that involve relations depends on the nature of the relations. The representation of the baseline candidate sets in operation states plays a particular role. Adams and Ağacan [3] prove that, during parsing of expressions that involve only relations $\triangle$, $>$, $\geq$ and $\circledast$, all intermediate sets I occurring in operation states have the form of a connected interval of natural numbers (possibly extending to infinity). This enables to represent any set I by its minimum $\min I$ and supremum $\sup I$ (supremum means maximum for finite sets and ∞ for infinite ones).

In practice, languages may require other indentation relations. Adams [2] mentions $\{(i+2, i) : i \in \mathbb{N}\}$ needed for occam, the `indentation` package [1] implements constant relations $\{(c, i) : i \in \mathbb{N}\}$. Here we generalize the result of [3] by finding a criterion for deciding which indentation relations preserve the interval form of the set of baseline candidates. The result also applies to the relations used by position operators since they matter only during parsing of terminals and the way they are used there is the same as in the case of indentation.

In this section, we denote $l_\rho(i) = \min(\rho(\{i\}))$ and $h_\rho(i) = \sup(\rho(\{i\}))$ for any $\rho \in \Re(\mathbb{N})$ and $i \in \mathbb{N}$. Functions l and h are undefined on i if $\rho(\{i\}) = \varnothing$. *Intervals* are sets of the form $\{j \in \mathbb{N} : n \leq j \leq o\}$ for any $n \in \mathbb{N}$, $o \in \mathbb{N} \cup \{\infty\}$. For uniform treatment, $\varnothing$ is also considered an interval (the case $n > o$ in the definition). This has no bad consequences as the set of baseline candidates is guaranteed to stay non-empty by Theorem 2.1.

4.1 Relations that keep indentation sets as intervals

When parsing of an expression of the form e^{ϱ} starts, it must create a new set $\varrho^{-1}(I)$ where I is the current set of indentation baseline candidates. There are two obvious conditions that must hold for $\varrho^{-1}(I)$ being an interval whenever I is:

1. For each $i \in \mathbb{N}$, $\varrho^{-1}(\{i\})$ must be an interval, as I can be a one-element set.
2. For any $i \in \mathbb{N}$, $\varrho^{-1}(\{i\}) \cup \varrho^{-1}(\{i+1\})$ must be an interval, as I can be $\{i, i+1\}$.

One can easily prove by induction on the size of I that if a relation ϱ satisfies conditions 1 and 2 then $\varrho^{-1}(I)$ is an interval for any interval I. Note that condition 2 holds iff for any two consecutive natural numbers i and j in any order, $l_{\varrho^{-1}}(i) \leq h_{\varrho^{-1}}(j) + 1$.

At the end of parsing of an expression of the form e^{ϱ}, a new set $I \cap \varrho(I')$ must be created to combine the information provided by the set I of baseline candidates for the surrounding indentation and the set I' of baseline candidates for the local indentation. Hence $I \cap \varrho(I')$ must be an interval whenever I and I' are. Taking $I = \mathbb{N}$ and $I' = \{i\}$ or $I' = \{i, i+1\}$, we see as before that $\varrho(\{i\})$ and $\varrho(\{i, i+1\})$ must be intervals for every $i \in \mathbb{N}$. Conversely, an easy induction on the number of elements in I' shows that if all sets $\varrho(\{i\})$ and $\varrho(\{i, i+1\})$ are intervals then $\varrho(I')$ is an interval for any interval I'. As the intersection of two intervals is an interval, this condition is also sufficient for $I \cap \varrho(I')$ being an interval.

To conclude, if for each used relation ϱ, all sets of the form $\varrho^{-1}(\{i\})$, $\varrho^{-1}(\{i, i+1\})$, $\varrho(\{i\})$ and $\varrho(\{i, i+1\})$ are intervals whereby $\varrho \in \Re^+(\mathbb{N})$, then all sets of baseline candidates occurring in the operation state are intervals during any parsing that starts with an interval as the baseline set. By Theorem 4.2 below, the set $\varrho(\{i, i+1\})$ can be omitted from this list, so three out of four conditions remain. For every relation $\varrho \in \Re^+(\mathbb{N})$ that fails to meet these three conditions, one can find a parsing expression e and an initial state such that a non-interval set appears during parsing. Indeed, the set $\varrho^{-1}(I)$ for an arbitrarily chosen finite interval $I = \{i, i+1, \ldots, i+k\}$ is evaluated during parsing of $\mathsf{e} = {}_{|}a(bc^{\varrho})^{\geq}{}_{|\geq}$ on an input string of the shape $a^i b^{i+k} w$, and for any $i \in \mathbb{N}$, if $\varrho(\{i\})$ is not an interval and hence contains some $n \in \mathbb{N}$ then $\varrho(\{i\})$ is evaluated during parsing of $\mathsf{e} = (ab^{\varrho})_{\triangle}$ on the input $a^n b^i$.

4.2 Implementation issues

By condition 1 at the beginning of Subsect. 4.1, any feasible relation ϱ is uniquely determined by the pair of functions $(l_{\varrho^{-1}}, h_{\varrho^{-1}})$. Similarly, ϱ is determined by $(l_{\varrho}, h_{\varrho})$ because of the analogous condition for $\varrho(\{i\})$. Functions $l_{\varrho^{-1}}$ and $h_{\varrho^{-1}}$ are total as we assume $\varrho \in \Re^+(\mathbb{N})$, while l_{ϱ} and h_{ϱ} can be partial. For the four relations considered in [3] for instance,

$$
\begin{array}{lcllcl}
(l_{\triangle^{-1}}(i), h_{\triangle^{-1}}(i)) & = & (i, i); & (l_{\triangle}(i), h_{\triangle}(i)) & = & (i, i); \\
(l_{>^{-1}}(i), h_{>^{-1}}(i)) & = & (i+1, \infty); & (l_{>}(i), h_{>}(i)) & = & (0, i-1) \text{ (provided } i > 0); \\
(l_{\geq^{-1}}(i), h_{\geq^{-1}}(i)) & = & (i, \infty); & (l_{\geq}(i), h_{\geq}(i)) & = & (0, i); \\
(l_{\circledast^{-1}}(i), h_{\circledast^{-1}}(i)) & = & (0, \infty); & (l_{\circledast}(i), h_{\circledast}(i)) & = & (0, \infty).
\end{array}
$$

We recall two well-known notions.

▶ **Definition 4.1.** 1. Call a function $f : \mathbb{N} \to \mathbb{Z} \cup \{\infty\}$ *non-decreasing* iff, for every $i, j \in \mathbb{N}$, $i \leq j$ implies $f(i) \leq f(j)$.

2. Call a function $f : \mathbb{N} \to \mathbb{Z} \cup \{\infty\}$ *weakly unimodal* iff there exists some $m \in \mathbb{N}$ such that, for every $i, j \in \mathbb{N}$, $i \leq j \leq m$ implies $f(i) \leq f(j)$ and $m \leq i \leq j$ implies $f(i) \geq f(j)$.

Unimodality of f means that the values of f are increasing until some argument m called *mode* and decreasing after that. Weakness specifies that increasing and decreasing can be non-strict (letting values at consecutive arguments equal). We will use also the corresponding

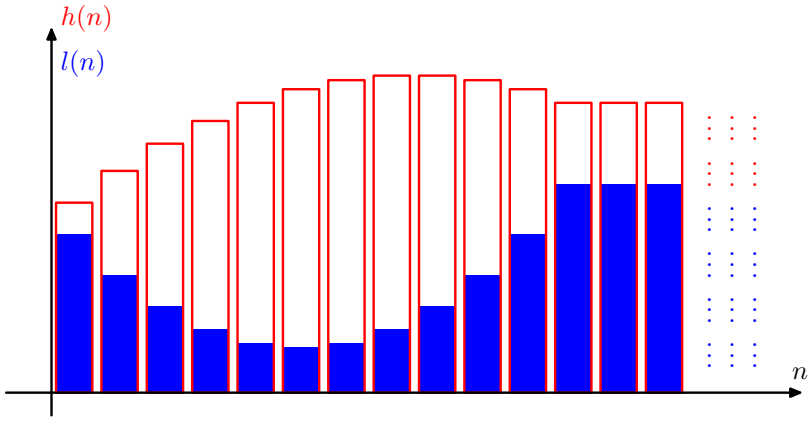

Figure 1 Functions h with the weak unimodality and l with the reverse unimodality property

reverse properties that hold for $f : \mathbb{N} \to \mathbb{Z}$ iff $-f$ has the original property. Thereby f is called *non-increasing* iff $-f$ is non-decreasing. Figure 1 depicts two functions l, h defined on $\mathbb{N}$ such that $l < h$ and both h and $-l$ are weakly unimodal (blue filled and red empty bars depict l and h, respectively).

▶ **Theorem 4.2.** *Let $\rho \in \Re^+(\mathbb{N})$ satisfy conditions 1 and 2 at the beginning of Subsect. 4.1. Then the following conditions are equivalent:*

(*) For every $i \in \mathbb{N}$, $\rho(\{i\})$ is an interval;

(**) Each of $h_{\rho^{-1}}$ and $-l_{\rho^{-1}}$ is either non-decreasing or weakly unimodal;

(***) For every $i \in \mathbb{N}$, both $\rho(\{i\})$ and $\rho(\{i, i+1\})$ are intervals.

Proof. Assume (*) and suppose that (**) does not hold. If $h_{\rho^{-1}}$ is neither non-decreasing nor weakly unimodal then there exist $i, j, j' \in \mathbb{N}$, $j + 1 < j'$ such that $i \le \min(h_{\rho^{-1}}(j), h_{\rho^{-1}}(j'))$ and, for every j'', if $j < j'' < j'$ then $h_{\rho^{-1}}(j'') < i$. By condition 2 assumed by the theorem, $l_{\rho^{-1}}(j) \le h_{\rho^{-1}}(j+1) + 1 \le i \le \min(h_{\rho^{-1}}(j), h_{\rho^{-1}}(j')) \le h_{\rho^{-1}}(j)$ and similarly $l_{\rho^{-1}}(j') \le h_{\rho^{-1}}(j'-1) + 1 \le i \le \min(h_{\rho^{-1}}(j), h_{\rho^{-1}}(j')) \le h_{\rho^{-1}}(j')$. Hence $\rho(\{i\})$ contains both j and j' but none of the numbers between j and j', which contradicts the fact that $\rho(\{i\})$ is an interval. The case with $-l_{\rho^{-1}}$ being neither non-decreasing nor weakly unimodal is handled analogously. Thus (*) implies (**).

Now assume (**). For every natural number i, denote $H_i = \{j \in \mathbb{N} : h_{\rho^{-1}}(j) \ge i\}$ and $L_i = \{j \in \mathbb{N} : l_{\rho^{-1}}(j) \le i\}$; then $\rho(\{i\}) = H_i \cap L_i$. By (**), H_i and L_i are intervals, hence $\rho(\{i\})$ is an interval for each i. Note that $i < i'$ implies $H_i \supseteq H_{i'}$ and $L_i \subseteq L_{i'}$. Moreover, $H_{i+1} \cup L_i = \mathbb{N}$: Indeed, $j \notin L_i$ implies $l_{\rho^{-1}}(j) > i$, meaning that $h_{\rho^{-1}}(j) \ge l_{\rho^{-1}}(j) \ge i + 1$ whence $j \in H_{i+1}$. Clearly $\rho(\{i, i+1\}) = \rho(\{i\}) \cup \rho(\{i+1\}) = (H_i \cap L_i) \cup (H_{i+1} \cap L_{i+1})$. To prove that $\rho(\{i, i+1\})$ is an interval, suppose that $j \in H_i \cap L_i$, $j' \in H_{i+1} \cap L_{i+1}$ and $j < j'' < j'$ (the case $j' < j'' < j$ is similar). As $H_{i+1} \subseteq H_i$, both j and j' belong to H_i. Similarly as $L_i \subseteq L_{i+1}$, both j and j' belong to L_{i+1}. Consequently, also $j'' \in H_i \cap L_{i+1}$ since both H_i and L_{i+1} are intervals. Now if $j'' \in H_{i+1}$ then $j'' \in H_{i+1} \cap L_{i+1} \subseteq \rho(\{i, i+1\})$, and if $j'' \in L_i$ then $j'' \in H_i \cap L_i \subseteq \rho(\{i, i+1\})$. Hence (**) implies (***).

Finally, (***) trivially implies (*). ◀

Knowing the modes of both $h_{\rho^{-1}}$ and $-l_{\rho^{-1}}$ (in the non-decreasing case with no upper bound, ∞ can be used as the mode), $\rho^{-1}(I)$ can be computed by $O(1)$ evaluations of $l_{\rho^{-1}}$ and $h_{\rho^{-1}}$ and $O(1)$ comparisons of natural numbers for any interval I. Indeed, $\sup(\rho^{-1}(I))$

equals the value of $h_{\varrho^{-1}}$ at one of the endpoints of I or at the mode (if the mode belongs to I), or is ∞ (if $h_{\varrho^{-1}}$ is non-decreasing and unbounded); $\min(\varrho^{-1}(I))$ can be found similarly.

The set of natural numbers where h_ϱ and l_ϱ are defined is an interval. An argument similar to the proof of part (*) $\Rightarrow$ (**) of Theorem 4.2 shows that each of h_ϱ and $-l_\varrho$ is either non-decreasing or weakly unimodal within its domain of definition. Hence by symmetry, it is possible to compute $\varrho(I')$ for any interval I' by $O(1)$ evaluations of l_ϱ and h_ϱ and $O(1)$ comparisons if the modes of both h_ϱ and $-l_\varrho$ are known. Partiality of h_ϱ and l_ϱ is not an issue since Theorem 2.1 guarantees that the set of indentation baseline candidates becomes never empty. Obviously the intersection of known intervals I and $\varrho(I')$ is computable by $O(1)$ comparisons.

Consequently, by representing relations ϱ with records that consist of functions l_ϱ, h_ϱ, $l_{\varrho^{-1}}$ and $h_{\varrho^{-1}}$ together with the modes of $-l_\varrho$, h_ϱ, $-l_{\varrho^{-1}}$ and $h_{\varrho^{-1}}$, every indentation causes only an $O(1)$ time overhead (if the values of the functions are computable in $O(1)$ time). It is reasonable to expect that the parser implementer provides the right representations for all the relations in use as the number of these relations is normally quite small.

For the four relations in [3], the modes can be defined as follows (they are not unique as the functions can increase or decrease non-strictly):

$$\begin{array}{llll} (m(-l_{\triangle^{-1}}), m(h_{\triangle^{-1}})) & = & (0,\infty); & (m(-l_{\triangle}), m(h_{\triangle})) = (0,\infty); \\ (m(-l_{>^{-1}}), m(h_{>^{-1}})) & = & (0,0); & (m(-l_{>}), m(h_{>})) = (1,\infty); \\ (m(-l_{\geq^{-1}}), m(h_{\geq^{-1}})) & = & (0,0); & (m(-l_{\geq}), m(h_{\geq})) = (0,\infty); \\ (m(-l_{\circledast^{-1}}), m(h_{\circledast^{-1}})) & = & (0,0); & (m(-l_{\circledast}), m(h_{\circledast})) = (0,0). \end{array}$$

5 Related work

PEGs were first introduced and studied by Ford [6] who also showed them to be closely related with the TS system [5] and TDPL [4], as well as to their generalized forms [5, 4].

Adams [2] and Adams and Ağacan [3] provide an excellent overview of previous approaches to describing indentation-sensitive languages and attempts of building indentation features into parser libraries. Our work is a theoretical study of the approach proposed in [3] while some details of the semantics used in our paper were "corrected" in the lines of Adams' `indentation` package for Haskell [1]. This package enables specifying indentation sensitivity within the Parsec and Trifecta parser combinator libraries. A process of alignment operator elimination is previously described for CFGs by Adams [2].

Matsumura and Kuramitsu [7] develop a very general extension of PEG that also enables to specify indentation. Their framework is powerful but complicated. The approach proposed in [3] and followed by us is in contrast with [7] by focusing on indentation and aiming to maximal simplicity and convenience of usage.

6 Conclusion

We studied the extension of PEG proposed by Adams and Ağacan [3] for indentation-sensitive parsing. This extension uses operators for marking indentation and alignment besides the classic ones. Having added one more operator (position) for convenience, we found a lot of useful semantic equivalences that are valid on expressions written in the extended grammars. We applied these equivalences subsequently for defining a process that algorithmically eliminates all alignment and position operators from well-formed grammars.

We analyzed practical limitations of the indentation extension of PEG from the aspect of efficient expressibility and computability of the relations and sets needed during parsing.

We found a wide class of relations that, provided the minimum and supremum of the set of numbers related to any given number is computable in $O(1)$ time, cause only $O(1)$ overhead at each parsing step.

Abstract

Finding maximum-cardinality matchings in undirected graphs is arguably one of the most central graph primitives. For m-edge and n-vertex graphs, it is well-known to be solvable in $O(m\sqrt{n})$ time; however, for several applications this running time is still too slow. We investigate how linear-time (and almost linear-time) data reduction (used as preprocessing) can alleviate the situation. More specifically, we focus on *linear-time kernelization*. We start a deeper and systematic study both for general graphs and for bipartite graphs. Our data reduction algorithms easily comply (in form of preprocessing) with every solution strategy (exact, approximate, heuristic), thus making them attractive in various settings.

1 Introduction

"Matching is a powerful piece of algorithmic magic" [22]. In the maximum matching problem, given an undirected graph, one has to compute a maximum set of nonoverlapping edges. Maximum matching is arguably among the most fundamental graph-algorithmic primitives allowing for a polynomial-time algorithm. More specifically, on an n-vertex and m-edge graph a maximum matching can be found in $O(m\sqrt{n})$ time [20]. Improving this upper time bound resisted decades of research. Recently, however, Duan and Pettie [9] presented a linear-time algorithm that computes a $(1-\epsilon)$-approximate maximum-weight matching, where the running time dependency on ϵ is $\epsilon^{-1}\log(\epsilon^{-1})$. For the unweighted case, the $O(m\sqrt{n})$ algorithm of Micali and Vazirani [20] implies a linear-time $(1-\epsilon)$-approximation, where in this case the running time dependency on ϵ is ϵ^{-1} [9]. We take a different route: First, we do not give up the quest for optimal solutions. Second, we focus on efficient – more specifically, linear-time executable – data reduction rules, that is, not solving an instance but significantly

shrinking its size before actually solving the problem. Doing so, however, we focus here on the unweighted case. In the context of decision problems and parameterized complexity analysis this approach is known as kernelization.

The spirit behind our approach is thus closer to the identification of efficiently solvable special cases of maximum matching. There is quite some body of work in this direction. For instance, since an augmenting path can be found in linear time [11], the standard augmenting path-based algorithm runs in $O(s(n+m))$ time, where s is the number of edges in the maximum matching. Yuster [25] developed an $O(rn^2 \log n)$-time algorithm, where r is the difference between maximum and minimum degree of the input graph. Moreover, there are linear-time algorithms for computing maximum matchings in special graph classes, including convex bipartite [23], strongly chordal [8], chordal bipartite [7], and cocomparability graphs [19].

All this and the more general spirit of "parameterization for polynomial-time solvable problems" [13] (also referred to as "FPT in P" or "FPTP" for short) forms the starting point of our research. Remarkably, Fomin et al. [10] recently developed an algorithm to compute a maximum matching in graphs of treewidth k in $O(k^4 n \log n)$ randomized time.

Following the paradigm of *kernelization*, that is, provably effective and efficient data reduction, we provide a systematic exploration of the power of not only polynomial-time but actually linear-time data reduction for maximum matching. Thus, our aim (fitting within FPTP) is to devise problem kernels that are computable in linear time. In other words, the fundamental question we pose is whether there is a very efficient preprocessing that provably shrinks the input instance, where the effectiveness is measured by employing some parameters. The philosophy behind this is that if we can design linear-time data reduction algorithms, then we may employ them for free before afterwards employing any super-linear-time solving algorithm. We believe that this sort of question deserves deeper investigation and we initiate it based on the matching problem.

As kernelization is defined for decision problems, we use in the remainder of the paper the *decision version* of maximum matching. In a nutshell, a kernelization of a decision problem instance is an algorithm that produces an equivalent instance whose size can solely be upper-bounded by a function in the parameter (preferably a polynomial). The focus on decision problems is justified by the fact that all our results, although formulated for the decision version, in a straightforward way extend to the corresponding optimization version.

(Maximum-Cardinality) Matching
Input: An undirected graph $G = (V, E)$ and a nonnegative integer s.
Question: Is there a size s subset $M_G \subseteq E$ of nonoverlapping (i.e. disjoint) edges?

Note that for any polynomial-time solvable problem solving the given instance and returning a trivial yes- or no-instance always produces a constant-size kernel in polynomial time. Hence, we are looking for kernelization algorithms that are *faster* than the algorithms solving the problem. The best we usually can hope for is linear time. For NP-hard problems, each polynomial-time kernelization algorithm is faster than any solution algorithm, unless P = NP. While the focus of classical kernelization for NP-hard problems is mostly on improving the *size* of the kernel, we particularly emphasize that for polynomially solvable problems it now becomes mandatory to also focus on the *running time* of the kernelization algorithm. Indeed, we consider linear-time kernelization as the holy grail and this drives our research when studying kernelization for Matching.

Our contributions. We present three kernels for Matching (see Table 1 for an overview). All our parameterizations can be categorized as "distance to triviality" [6, 14, 18, 24]. They are motivated as follows. First, note that it is important that the parameters we exploit can

Table 1 Our kernelization results.

Parameter k	running time	kernel size	
Results for Matching			
Feedback edge number	$O(n+m)$	$O(k)$ vertices and edges	(Theorem 3)
Feedback vertex number	$O(kn)$	$2^{O(k)}$ vertices and edges	(Theorem 11)
Results for Bipartite Matching			
Distance to chain graphs	$O(n+m)$	$O(k^3)$ vertices	(Theorem 15)

be computed, or well approximated (within constant factors), in linear time regardless of the parameter value. For instance, it is not known whether this is possible for treewidth. Next, note that maximum-cardinality matchings can be trivially found in linear time on trees (or forests). So we consider the edge deletion distance (feedback edge number) and vertex deletion distance (feedback vertex number) to forests. Notably, there is a trivial linear-time algorithm for computing the feedback edge number and there is a linear-time factor-4 approximation algorithm for the feedback vertex number [1]. We mention in passing that the parameter vertex cover number, which is lower-bounded by the feedback vertex number, has been frequently studied for kernelization [3, 4]. In particular, Gupta and Peng [15] and Giannopoulou et al. [13] provided a linear-time computable quadratic-size kernel for Matching with respect to the parameter solution size (or equivalently vertex cover number). Coming to bipartite graphs, we parameterize by the vertex deletion distance to chain graphs which is motivated as follows. First, chain graphs form one of the most obvious easy cases for bipartite graphs where Matching can be solved in linear time [23]. Second, we show that the vertex deletion distance of any bipartite graph to a chain graph can be 2-approximated in linear time. Moreover, vertex deletion distance to chain graphs lower-bounds the vertex cover number of a bipartite graph, and thus gives a stronger parameterization [18] than vertex cover number.

An overview of our main results is given in Table 1. We study kernelization for Matching parameterized by the feedback vertex number, that is, the vertex deletion distance to a forest (see Section 2). As a warm-up we first show that a subset of our data reduction rules for the "feedback vertex set kernel" also yields a linear-time computable linear-size kernel for the typically much larger parameter feedback edge number (see Section 2.1). As for Bipartite Matching no faster algorithm is known than on general graphs, we kernelize Bipartite Matching with respect to the vertex deletion distance to chain graphs (see Section 3).

Seen from a high level, our two technical main results (Theorems 11 and 15, see Table 1) employ the same algorithmic strategy, namely upper-bounding (as a function of the parameter) the number of neighbors in the appropriate vertex deletion set X; that is, X being the feedback vertex set or in the deletion set to chain graphs, respectively. To achieve this we develop new *"irrelevant edge techniques"* tailored to these two kernelization problems. More specifically, whenever a vertex v of the deletion set X has large degree, we efficiently detect edges incident to v whose removal does not change the size of the maximum matching. Then the remaining graph can be further shrunk by scenario-specific data reduction rules. While this approach of removing irrelevant edges is natural, the technical details and the proofs of correctness become quite technical and combinatorially challenging.

Note that there exists a trivial $O(km)$-time solving (not only kernelization) algorithm, where k is the feedback vertex number. Our kernel has size $2^{O(k)}$. Therefore, only if $k = o(\log n)$ our kernelization algorithm *provably* shrinks the initial instance. However, our result

is still relevant: First, our data reduction rules might assist in proving a polynomial upper bound on the kernel size – so our result is a first step in this direction. Second, the running time $O(kn)$ of our kernelization algorithm is a kind of "half way" between $O(km)$ (which could be as bad as $O(k^2n)$) and $O(n+m)$ (which is best possible). Finally, note that this work focuses on theoretical and worst-case analysis; in practice, our kernelization algorithm might achieve much better upper bounds on real-world input instances.

As a technical side remark, we emphasize that in order to achieve a linear-time kernelization algorithm, we often need to use suitable data structures and to carefully design the appropriate data reduction rules to be exhaustively applicable in linear time, making this form of "algorithm engineering" much more relevant than in the classical setting of mere polynomial-time data reduction rules.

Notation and Observations. We use standard notation from graph theory. Merging two vertices u and v means to first introduce a new vertex w with $N(w) = N(u) \cup N(v)$ and then delete u and v. A feedback vertex (edge) set of a graph G is a set X of vertices (edges) such that $G - X$ is a tree or a forest. The feedback vertex (edge) number denotes the size of a minimum feedback vertex (edge) set. All paths we consider are simple paths. Two paths in a graph are called *internally vertex-disjoint* if they are either completely vertex-disjoint or they overlap only in their endpoints. A *matching* in a graph is a set of pairwise disjoint edges. Let $G = (V, E)$ be a graph and let $M \subseteq E$ be a matching in G. The degree of a vertex is denoted by $\deg(v)$. A vertex $v \in V$ is called *matched* with respect to M if there is an edge in M containing v, otherwise v is called *free* with respect to M. If the matching M is clear from the context, then we omit "with respect to M". An *alternating path* with respect to M is a path in G such that every second edge of the path is in M. An *augmenting path* is an alternating path whose endpoints are free. It is well known that a matching M is maximum if and only if there is no augmenting path for it. Let $M \subseteq E$ and $M' \subseteq E$ be two matchings in G. We denote by $G(M, M') := (V, M \triangle M')$ the graph containing only the edges in the symmetric difference of M and M', that is, $M \triangle M' := M \cup M' \setminus (M \cap M')$. Observe that every vertex in $G(M, M')$ has degree at most two.

▶ **Observation 1.** *Let $G = (V, E)$ be a graph with a maximum matching M_G, let $X \subseteq V$ be a vertex subset of size k, and let M_{G-X} be a maximum matching for $G - X$. Then, $|M_{G-X}| \leq |M_G| \leq |M_{G-X}| + k$.*

Kernelization. A *parameterized problem* is a set of instances (I, k) where $I \in \Sigma^*$ for a finite alphabet Σ, and $k \in \mathbb{N}$ is the *parameter*. We say that two instances (I, k) and (I', k') of parameterized problems P and P' are *equivalent* if (I, k) is a yes-instance for P if and only if (I', k') is a yes-instance for P'. A *kernelization* is an algorithm that, given an instance (I, k) of a parameterized problem P, computes in polynomial time an equivalent instance (I', k') of P (the *kernel*) such that $|I'| + k' \leq f(k)$ for some computable function f. We say that f measures the *size* of the kernel, and if $f(k) \in k^{O(1)}$, we say that P admits a polynomial kernel. Often, a kernel is achieved by applying polynomial-time executable data reduction rules. We call a data reduction rule $\mathcal{R}$ *correct* if the new instance (I', k') that results from applying $\mathcal{R}$ to (I, k) is equivalent to (I, k). An instance is called *reduced* with respect to some data reduction rule if further application of this rule has no effect on the instance.

2 Kernelization for Matching on General Graphs

In this section we first present as a warm-up a simple, linear-size kernel for Matching with respect to the parameter feedback edge number (see Section 2.1). Exploiting the data reduction rules and ideas used for this kernel, we then present the main result of this section: an exponential-size kernel for the typically much smaller parameter feedback vertex number (see Section 2.2).

2.1 Warm-up: Parameter feedback edge number

We provide a linear-time computable linear-size kernel for Matching parameterized by the feedback edge number, that is, the size of a minimum feedback edge set. Observe that a minimum feedback edge set can be computed in linear time via a simple depth-first search or breadth-first search. The kernel is based on the next two simple data reduction rules due to Karp and Sipser [17]. They deal with vertices of degree at most two.

▶ **Reduction Rule 2.1.** *Let $v \in V$. If $\deg(v) = 0$, then delete v. If $\deg(v) = 1$, then delete v and its neighbor and decrease the solution size s by one (v is matched with its neighbor).*

▶ **Reduction Rule 2.2.** *Let v be a vertex of degree two and let u, w be its neighbors. Then remove v, merge u and w, and decrease the solution size s by one.*

Reduction Rules 2.1 and 2.2 are correct; however, it is not clear whether Reduction Rule 2.2 can be exhaustively applied in linear time. Fortunately, for our purpose it suffices to consider the following restricted version which we can exhaustively apply in linear time.

▶ **Reduction Rule 2.3.** *Let v be a vertex of degree two and u, w be its neighbors with u and w having degree at most two. Then remove v, merge u and w, and decrease s by one.*

▶ **Lemma 2.** *Reduction Rules 2.1 and 2.3 can be exhaustively applied in $O(n + m)$ time.*

▶ **Theorem 3.** Matching *admits a linear-time computable linear-size kernel with respect to the parameter feedback edge number k.*

Proof. Apply Reduction Rules 2.1 and 2.3 exhaustively in linear time (Lemma 2). We claim that the reduced graph $G = (V, E)$ has less than $12k$ vertices and less than $13k$ edges. Denote with $X \subseteq E$ a feedback edge set for G, $|X| \leq k$. Furthermore, denote with V^1_{G-X}, V^2_{G-X}, and $V^{\geq 3}_{G-X}$ the vertices that have degree one, two, and more than two in the $G - X$. Thus, $|V^1_{G-X}| \leq 2k$ as each leaf in $G - X$ has to be incident to an edge in X. Next, since $G - X$ is a forest (or tree), we have $|V^{\geq 3}_{G-X}| < |V^1_{G-X}|$ and thus $|V^{\geq 3}_{G-X}| < 2k$. Finally, each degree-two vertex in G needs at least one neighbor of degree at least three since G is reduced with respect to Reduction Rule 2.3. Thus, the vertices in V^2_{G-X} are either incident to an edge in X or adjacent to one of the at most $|V^{\geq 3}_{G-X}| + 2k$ vertices in G that have degree at least three. Since the sum over all degrees of vertices in $V^{\geq 3}_{G-X}$ is at most $\sum_{v \in V^{\geq 3}_{G-X}} \deg_{G-X}(v) \leq 2|V^{\geq 3}_{G-X}| + |V^1_{G-X}| < 6k$, it follows that $|V^2_{G-X}| \leq 8k$. Thus, the number of vertices in G is $|V^1_{G-X}| + |V^2_{G-X}| + |V^{\geq 3}_{G-X}| \leq 12k$. Since $G - X$ is a forest, it follows that G has at most $|V| + k \leq 13k$ edges. ◀

Applying the $O(m\sqrt{n})$-time algorithm for Matching [20] on the kernel yields:

▶ **Corollary 4.** Matching *can be solved in $O(n + m + k^{1.5})$ time, where k is the feedback edge number.*

2.2 Parameter feedback vertex number

We next provide for MATCHING a kernel of size $2^{O(k)}$ computable in $O(kn)$ time where k is the feedback vertex number. Using a known linear-time factor 4-approximation algorithm [1], we can approximate feedback vertex set and use it in our kernelization algorithm.

Roughly speaking, our kernelization algorithm extends the linear-time computable kernel with respect to the parameter feedback edge set. Thus, Reduction Rules 2.1 and 2.3 play an important role in the kernelization. Compared to the other kernels presented in this paper, the kernel presented here comes at the price of higher running time $O(kn)$ and bigger kernel size (exponential size). It remains open whether MATCHING parameterized by the feedback vertex number admits a linear-time computable kernel (possibly of exponential size), and whether it admits a polynomial kernel computable in $O(kn)$ time.

Subsequently, we describe our kernelization algorithm which keeps in the kernel all vertices in the given feedback vertex set X and shrinks the size of $G - X$. Before doing so, we need some further notation. In this section, we assume that each tree is rooted at some arbitrary (but fixed) vertex such that we can refer to the parent and children of a vertex. A leaf in $G - X$ is called a *bottommost leaf* either if it has no siblings or if all its siblings are also leaves. (Here, bottommost refers to the subtree with the root being the parent of the considered leaf.) The outline of the algorithm is as follows (we assume throughout that $k < \log n$ since otherwise the input instance is already a kernel of size $O(2^k)$):

1. Reduce G with respect to Reduction Rules 2.1 and 2.3.
2. Compute a maximum matching M_{G-X} in $G - X$.
3. Modify M_{G-X} in linear time such that only the leaves of $G - X$ are free.
4. Bound the number of free leaves in $G - X$ by k^2.
5. Bound the number of bottommost leaves in $G - X$ by $O(k^2 2^k)$.
6. Bound the degree of each vertex in X by $O(k^2 2^k)$. Then, use Reduction Rules 2.1 and 2.3 to provide the kernel of size $2^{O(k)}$.

Whenever we reduce the graph at some step, we also show that the applied data reduction is *correct*. That is, the given instance is a yes-instance if and only if the reduced one is a yes-instance. The correctness of our kernelization algorithm then follows by the correctness of each step. We discuss in the following some details of each step.

2.2.1 Steps 1 to 3

By Lemma 2 we can perform Step 1 in linear time. A maximum matching in Step 2 can be computed by repeatedly matching a free leaf to its neighbor and by removing both vertices from the graph (thus effectively applying Reduction Rule 2.1 to $G - X$). By Lemma 2, this can be done in linear time. Step 3 can be done in $O(n)$ time by traversing each tree in M_{G-X} in a BFS manner starting from the root: If a visited inner vertex v is free, then observe that all children are matched since M_{G-X} is maximum. Pick an arbitrary child u of v and match it with v. The vertex w that was previously matched to u is now free and since it is a child of u, it will be visited in the future. Observe that Steps 2 and 3 do not change the graph but only the auxiliary matching M_{G-X}, and thus these steps are correct.

2.2.2 Step 4

Recall that our goal is to upper-bound the number of edges between vertices of X and $V \setminus X$, since we can then use a simple analysis as for the parameter feedback edge set. Observe that if a vertex $x \in X$ has at least k neighbors in $V \setminus X$ that are free wrt. M_{G-X}, then there exists a maximum matching where x is matched to one of these k vertices since at most $k - 1$

can be "blocked" by other matching edges. This means that we can delete all other edges incident to x. Formalizing this idea, we obtain the following data reduction rule.

▶ **Reduction Rule 2.4.** *Let $G = (V, E)$ be a graph, let $X \subseteq V$ be a subset of size k, and let M_{G-X} be a maximum matching for $G - X$. If there is a vertex $x \in X$ with at least k free neighbors $V_x = \{v_1, \ldots, v_k\} \subseteq V \setminus X$, then delete all edges from x to vertices in $V \setminus V_x$.*

To finish Step 4, we exhaustively apply Reduction Rule 2.4 in linear time. Afterwards, there are at most k^2 free (wrt. to M_{G-X}) leaves in $G - X$ that have at least one neighbor in X since each of the k vertices in X is adjacent to at most k free leaves. Thus, applying Reduction Rule 2.1 we can remove the remaining free leaves that have no neighbor in X. However, since for each degree-one vertex also its neighbor is removed, we might create new free leaves and need to again apply Reduction Rule 2.4 and update the matching (see Step 3). This process of alternating application of Reduction Rules 2.1 and 2.4 stops after at most k rounds since the neighborhood of each vertex in X can be changed by Reduction Rule 2.4 at most once. This shows the running time $O(k(n+m))$. We next show how to improve this to $O(n+m)$ time and arrive at the final lemma of this subsection.

▶ **Lemma 5.** *Given a matching instance (G, s) and a feedback vertex set X, one can compute in linear time an instance (G', s') with feedback vertex set X and a maximum matching $M_{G'-X}$ in $G' - X$ such that the following holds.*

- *There is a matching of size s in G if and only if there is a matching of size s' in G'.*
- *Each vertex that is free wrt. $M_{G'-X}$ is a leaf in $G' - X$.*
- *There are at most k^2 free leaves in $G' - X$.*

2.2.3 Step 5

Step 5 reduces the graph in $O(kn)$ time so that at most $k^2(2^k + 1)$ bottommost leaves will remain in the forest $G - X$. We restrict ourselves to consider leaves that are matched with their parent vertex in M_{G-X} and that do not have a sibling. Any sibling of a bottommost leaf is by definition also a leaf. Thus, at most one of these leaves (the bottommost leaf or its siblings) is matched with respect to M_{G-X} and all other leaves are free. Recall that in the previous step we upper-bounded the number of free leaves with respect to M_{G-X} by k^2. Hence there are at most k^2 bottommost leaves with siblings.

Our general strategy for this step is to extend the idea behind Reduction Rule 2.4: We want to keep for each pair of vertices $x, y \in X$ at most k different internally vertex-disjoint augmenting paths from x to y. (For ease of notation we keep k paths although keeping $k/2$ is sufficient.) In this step, we only consider augmenting paths of the form x, u, v, y where v is a bottommost leaf and u is v's parent in $G - X$. Assume that the parent u of v is adjacent to some vertex $x \in X$. Observe that in this case any augmenting path starting with the two vertices x and u has to continue to v and end in a neighbor of v. Thus, the edge $\{x, u\}$ can be only used in augmenting paths of length three. Furthermore, all these length-three augmenting paths are clearly internally vertex-disjoint. If we do not need the edge $\{x, u\}$ because we kept k augmenting paths from x already, then we can delete $\{x, u\}$. Furthermore, if we deleted the last edge from u to X (or u had no neighbors in X in the beginning), then u is a degree-two vertex in G and can be removed by applying Reduction Rule 2.2. As the child v of u is a leaf in $G - X$, it follows that v has at most $k + 1$ neighbors in G. Thus, an application of Reduction Rule 2.2 to remove u takes $O(k)$ time.

Counting for each pair $x \in N(u) \cap X$ and $y \in N(v) \cap X$ one augmenting path gives in a simple worst-case analysis $O(k^2)$ time per edge; this is too slow for our purposes. Instead, we

count for each vertex $x \in N(u) \cap X$ and for each *set* $Y = N(v) \cap X$ one augmenting path. In this way, we know that for each $y \in Y$ there is one augmenting path from x to y, without iterating through all $y \in Y$. We get an exponential factor in the bound of the bottommost leaves since there are 2^k subsets of X, but we can perform this step in $O(kn)$ time as follows.

▶ **Lemma 6.** *Let $(G = (V, E), s)$ be a matching instance, let $X \subseteq V$ be a feedback vertex set, and let M_{G-X} be a maximum matching for $G - X$ with at most k^2 free vertices in $G - X$ that are all leaves. Then, can compute in $O(kn)$ time an instance (G', s') with feedback vertex set X and a maximum matching $M_{G'-X}$ in $G' - X$ such that the following holds.*

- *There is a matching of size s in G if and only if there is a matching of size s' in G'.*
- *There are at most $k^2(2^k + 1)$ bottommost leaves in $G' - X$.*
- *There are at most k^2 free vertices in $G' - X$ and they are all leaves.*

2.2.4 Step 6

In this subsection, we provide the final step of our kernelization algorithm. Recall that in the previous steps we have upper-bounded the number of bottommost leaves in $G - X$ by $O(k^2 2^k)$, we computed a maximum matching M_{G-X} for $G - X$ such that at most k^2 vertices are free wrt. M_{G-X} and all free vertices are leaves in $G - X$. Using this, we next show how to reduce G to a graph of size $O(k^3 2^k)$. To this end we need some further notation. A leaf in $G - X$ that is not bottommost is called a *pendant*. We define T to be the *pendant-free tree (forest) of* $G - X$, that is, the tree (forest) obtained from $G - X$ by removing all pendants. The next observation shows that $G - X$ is not much larger than T. Together with the second observation, this allows us to restrict ourselves in the following on giving an upper bound on the size of T.

▶ **Observation 7.** *Let $G - X$ be as described above with vertex set $V \setminus X$ and let T be the pendant-free tree (forest) of $G - X$ with vertex set V_T. Then, $|V \setminus X| \leq 2|V_T| + k^2$.*

▶ **Observation 8.** *Let F be a forest, let F' be the pendant-free forest of F, and let B be the set of all bottommost leaves in F. Then, the set of leaves in F' is exactly B.*

From Observation 8 it follows that the set B of bottommost leaves in $G - X$ is exactly the set of leaves in T. In the previous step we reduced the graph such that $|B| \leq k^2(2^k + 1)$. Thus, T has at most $k^2(2^k + 1)$ vertices of degree one and, since T is a tree (a forest), T also has at most $k^2(2^k + 1)$ vertices of degree at least three. Let V_T^2 be the vertices of degree two in T and let $V_T^{\neq 2}$ be the remaining vertices in T. From the above it follows that $|V_T^{\neq 2}| \leq 2k^2(2^k + 1)$. Hence, it remains to bound the size of V_T^2. To this end, we will upper-bound the degree of each vertex in X by $O(k^2 2^k)$ and then use Reduction Rules 2.1 and 2.3. We will check for each edge $\{x, v\} \in E$ with $x \in X$ and $V \setminus X$ whether we "need" it. This check will use the idea from the previous subsection where each vertex in X needs to reach each subset $Y \in X$ at most k times via an augmenting path. Similarly as in the previous section, we want to keep "enough" of these augmenting paths. However, this time the augmenting paths might be long, while different augmenting paths might overlap. To still use the basic approach, we use the following lemma stating that we can still somehow replace augmenting paths.

▶ **Lemma 9.** *Let M_{G-X} be a maximum matching in the forest $G - X$. Let P_{uv} be an augmenting path for M_{G-X} in G from u to v. Let P_{wx}, P_{wy}, and P_{wz} be three internally vertex-disjoint augmenting paths from w to x, y, and z, respectively, such that P_{uv} intersects all of them. Then, there exist two vertex-disjoint augmenting paths with endpoints u, v, w, and one of the three vertices x, y, and z.*

Proof. Label the vertices in P_{uv} alternating as *odd* or *even* with respect to P_{uv} so that no two consecutive vertices have the same label, u is *odd*, and v is *even*. Analogously, label the vertices in P_{wx}, P_{wy}, and P_{wz} as odd and even with respect to P_{wx}, P_{wy}, and P_{wz} respectively so that w is always odd. Since all these paths are augmenting, it follows that each edge from an even vertex to its succeeding odd vertex is in the matching M_{G-X} and each edge from an odd vertex to its succeeding even vertex is not in the matching. Observe that P_{uv} intersects each of the other paths at least at two consecutive vertices, since every second edge must be an edge in M_{G-X}. Since $G-X$ is a forest and all vertices in X are free with respect to M_{G-X}, it follows that the intersection of two augmenting paths is connected and thus a path. Since P_{uv} intersects the three augmenting paths from w, it follows that at least two of these paths, say P_{wx} and P_{wy}, have a "fitting parity", that is, in the intersections of P_{uv} with P_{wx} and with P_{wy} the even vertices with respect to P_{uv} are either even or odd with respect to *both* P_{wx} and P_{wy}.

Assume w.l.o.g. that in the intersections of the paths the vertices have the same label with respect to the three paths (if the labels differ, then revert the ordering of the vertices in P_{uv}, that is, exchange the names of u and v and change all labels on P_{uv} to its opposite). Denote with v_s^1 and v_t^1 the first and the last vertex in the intersection of P_{uv} and P_{wx}. Analogously, denote with v_s^2 and v_t^2 the first and the last vertex in the intersection of P_{uv} and P_{wy}. Assume w.l.o.g. that P_{uv} intersects first with P_{wx} and then with P_{wy}. Observe that v_s^1 and v_s^2 are even vertices and v_t^1 and v_t^2 are odd vertices since the intersections have to start and end with edges in M_{G-X}. For an arbitrary path P and for two arbitrary vertices p_1, p_2 of P, denote by $p_1 - P - p_2$ the subpath of P from p_1 to p_2. Observe that $u - P_{uv} - v_t^1 - P_{wx} - x$ and $w - P_{wy} - v_t^2 - P_{uv} - v$ are vertex-disjoint augmenting paths. ◀

Algorithm description. We now provide the algorithm for Step 6 (see Algorithm 1 for a pseudocode). Algorithm 1 uses a table Tab which has an entry for each vertex $x \in X$ and each set $Y \subseteq X$. The table is filled in such a way that the algorithm detected for each $y \in Y$ at least $\mathrm{Tab}[x, Y]$ internally vertex-disjoint augmenting paths from x to y. The main part of the algorithm is the boolean function 'Keep-Edge' in Lines 13 to 22 which makes the decision on whether to delete an edge $\{x, v\}$ for $v \in V \setminus X$ and $x \in X$. The function works as follows for edge $\{x, v\}$: Starting at v the graph will be explored along possible augmenting paths until a "reason" for keeping the edge $\{x, v\}$ is found or further exploration is possible.

If the vertex v is free wrt. M_{G-X}, then $\{x, v\}$ is an augmenting path and we keep $\{x, v\}$ (see Line 14). Observe that in Step 4 we upper-bounded the number of free vertices by k^2 and all these vertices are leaves. Thus, we keep a bounded number of edges incident to x because the corresponding augmenting paths can end at a free leaf. We provide the exact bound below when discussing the size of the graph returned by Algorithm 1. In Line 14, the algorithm stops exploring the graph and keeps the edge $\{x, v\}$ if v has degree at least three in T. The reason is to keep the graph exploration simple by following only paths in T. This ensures that the running time for exploring the graph from x does not exceed $O(n)$. Since the number of vertices in T with degree at least three is bounded (see discussion after Observation 8), it follows that only a bounded number of such edges $\{x, v\}$ are kept.

If v is not free wrt. M_{G-X}, then it is matched with some vertex w. If w is adjacent to some leaf u in $G-X$ that is free wrt. M_{G-X}, then the path x, v, w, u is an augmenting path. Thus, the algorithm keeps in this case the edge $\{x, v\}$, see Line 16. Again, since the number of free leaves is bounded, only a bounded number of edges incident to x will be kept. If w has degree at least three in T, then the algorithm stops the graph exploration here and keeps the edge $\{x, v\}$, see Line 16. Again, this is to keep the running time at $O(kn)$ overall.

Algorithm 1: Algorithm for Step 6 of our kernelization.

Input: A matching instance $(G = (V, E), s)$, a feedback vertex set $X \subseteq V$ of size k for G with $k < \log n$ and at most $k^2(2^k + 1)$ bottommost leaves in $G - X$, and a maximum matching M_{G-X} for $G - X$ with at most k^2 free vertices in $G - X$ that are all leaves.

Output: An equivalent matching instance (G', s') such that G' contains at most $O(k^3 2^k)$ vertices and edges.

1 Fix an arbitrary bijection $f\colon 2^X \to \{1, \dots, 2^k\}$
2 **foreach** $v \in V \setminus X$ **do**
3 Set $f_X(v) \leftarrow f(N(v) \cap X)$ // The number $f_X(v) < n$ can be read in constant time.
4 Initialize a table Tab of size $k \cdot 2^k$ with $\mathrm{Tab}[x, f(Y)] \leftarrow 0$ for $x \in X, \emptyset \subsetneq Y \subseteq X$
5 $T \leftarrow$ pendant-free tree (forest) of $G - X$
6 $V_T^{\geq 3} \leftarrow$ vertices in T with degree ≥ 3
7 **foreach** $x \in X$ **do**
8 **foreach** $v \in N(x) \setminus X$ **do**
9 **if** *Keep-Edge*$(x, v) =$ *false* **then** // Is $\{x, v\}$ needed for an augmenting path?
10 delete $\{x, v\}$
11 exhaustively apply Reduction Rules 2.1 and 2.3
12 **return** (G, s).
13 **Function** *Keep-Edge*$(x \in X, v \in V \setminus X)$
14 **if** *v is free wrt. M_{G-X} or $v \in V_T^{\geq 3}$* **then return** *true*
15 $w \leftarrow$ matched neighbor of v in M_{G-X}
16 **if** *$w \in V_T^{\geq 3}$ or w is adjacent to free leaf in $G - X$* **then return** *true*
17 **if** *w has at least one neighbor in X and* $\mathrm{Tab}[x, f_X(w)] < 6k^2$ **then**
18 $\mathrm{Tab}[x, f_X(w)] \leftarrow \mathrm{Tab}[x, f_X(w)] + 1$
19 **return** *true*
20 **foreach** *neighbor $u \neq v$ of w that is matched wrt. M_{G-X} and fulfills $\{u, x\} \notin E$* **do**
21 **if** *Keep-Edge*$(u, x) =$ *true* **then return** *true*
22 **return** *false*

Let $Y \subseteq X$ denote the neighborhood of w in X. The partial augmenting path x, v, w can be extended to each vertex in Y. Thus, if the algorithm did not yet find $6k^2$ paths from x to vertices whose neighborhood in X is also Y, then the table entry $\mathrm{Tab}[x, f_X(w)]$ (where $f_X(w)$ encodes the set $Y = N(w) \cap X$) is increased by one and the edge $\{x, v\}$ will be kept (see Lines 18 and 19). The proof that $6k^2$ paths suffice is based on an exchange argument using Lemma 9. If the algorithm already found $6k^2$ "augmenting paths" from x to Y, then the neighborhood of w in X is irrelevant for x and the algorithm continues.

In Line 20, all above discussed cases to keep the edge $\{x, v\}$ do not apply and the algorithm extends the partial augmenting part x, v, w by considering the neighbors of w except v. Since the algorithm dealt with possible extensions to vertices in X in Lines 17 to 19 and with extensions to free vertices in $G - X$ in Line 14, it follows that the next vertex on this path has to be a vertex u that is matched wrt. M_{G-X}. Furthermore, since we want to extend a partial augmenting path from x, we require that u is not adjacent to x as otherwise x, u would be another, shorter partial augmenting path from x to u and we do not need the currently stored partial augmenting path.

The next lemma shows that Algorithm 1 is correct and runs in $O(kn)$ time.

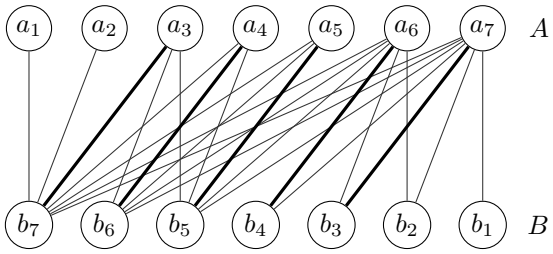

Figure 1 A chain graph. Note that the ordering of the vertices in A is going from left to right while the ordering of the vertices in B is going from right to left. The reason for these two orderings being drawn in different directions is that a maximum matching can be drawn as parallel edges, see e. g. the bold edges.

▶ **Lemma 10.** *Let $(G = (V, E), s)$ be a matching instance, let $X \subseteq V$ be a feedback vertex set of size k with $k < \log n$ and at most $k^2(2^k + 1)$ bottommost leaves in $G - X$, and let M_{G-X} be a maximum matching for $G - X$ with at most k^2 free vertices in $G - X$ that are all leaves. Then, Algorithm 1 computes in $O(kn)$ time an equivalent instance (G', s') of size $O(k^3 2^k)$.*

Simply performing Steps 1 to 6 yields the following kernel.

▶ **Theorem 11.** Matching *parameterized by the* feedback vertex number k *admits a kernel of size $2^{O(k)}$. It can be computed in $O(kn)$ time.*

Applying the $O(m\sqrt{n})$-time algorithm for Matching [20] on the kernel yields:

▶ **Corollary 12.** Matching *can be solved in $O(kn + 2^{O(k)})$ time, where k is the feedback vertex number.*

3 Kernelization for Matching on Bipartite Graphs

In this section, we investigate the possibility of efficient and effective preprocessing for Bipartite Matching. In particular, we show a linear-time computable polynomial-size kernel with respect to the parameter distance k to chain graphs. In the first part of this section, we provide the definition of chain graphs and describe how to compute the parameter. In the second part, we discuss the kernelization algorithm.

Definition and computation of the parameter. We first define chain graphs and we show that we can 4-approximate the parameter set in linear time.

▶ **Definition 13** ([5])**.** Let $G = (A, B, E)$ be a bipartite graph. Then G is a *chain graph* if each of its two color classes A, B admits a linear order w.r.t. neighborhood inclusion.

▶ **Lemma 14.** *There is a linear-time factor-4 approximation for the problem of deleting a minimum number of vertices in a bipartite graph in order to obtain a chain graph.*

Kernelization. Due to lack of space, we defer the details of our kernelization algorithm to the full version and provide in the following a high-level overview. In contrast to the kernelization in the previous section, here it is easy to bound the number of neighbors of each vertex in the deletion set X but complicated to shrink the remaining graph. Let $G = (A, B, E)$ be the given bipartite graph and let X a vertex subset such that $G - X$ is a chain graph. First compute a maximum matching M_{G-X} in $G - X$ where the edges in M_{G-X} are "parallel to each other", see Figure 1 for an illustration. Using Observation 1, we obtain the following.

▶ **Reduction Rule 3.1.** *If $|M_{G-X}| \geq s$, then return a trivial yes-instance; if $s > |M_{G-X}| + k$, then return a trivial no-instance.*

The next step of our kernelization algorithm is to bound the degree of each vertex in X. It suffices to keep for each $x \in X$ its k neighbors with smallest degree in A and in B, respectively. Due the small degree, such a vertex v is either free or matched to high-degree vertex u, see Figure 1. The correctness proof in the latter case uses the observation that there are a lot of possibilities to continue an augmenting path x, v, u as u has high degree. The reason for keeping k neighbors for each $x \in X$ is that at most $k-1$ neighbors might be "matched" (either directly or via an augmenting path) to other vertices in X.

After having bounded the degree of the vertices, we can show that for each vertex v in $G - X$ that is adjacent to a vertex in X we need to keep at most k neighbors right of v and k neighbors left of v (with respect to the linear ordering in each color class). Proving that this is indeed correct is the most technical part and relies heavily on the facts that $G - X$ is a chain graph and that the edges in M_{G-X} are "parallel".

Since for each of the k vertices in X we keep at most $2k$ neighbors in $G - X$, and for each of these neighbors, we keep $2k$ vertices, we arrive at the following.

▶ **Theorem 15.** Matching *on bipartite graphs admits a linear-time computable cubic-vertex kernel with respect to the vertex deletion distance to chain graphs.*

Applying the $O(n^{2.5})$-time algorithm for Bipartite Matching [16] on the kernel yields:

▶ **Corollary 16.** Matching *can be solved in $O(k^{7.5} + n + m)$ time, where k is the vertex deletion distance to chain graphs.*

Using the randomized $O(n^\omega)$-time bipartite matching algorithm based on matrix multiplication [21], one would obtain a randomized algorithm with running time $O(k^{3\omega} + n + m)$, where $\omega < 2.373$ is the matrix multiplication exponent.

4 Conclusion

We focused on kernelization results for Matching. In ongoing work, we are testing the practical relevance of our data reduction rules. There remain numerous challenges for future research as discussed in the second part of this concluding section. First, however, let us discuss the closely related issue of FPTP algorithms for Matching. There is a generic augmenting path-based approach to provide FPTP algorithms for Matching: One can find an augmenting path in linear time [2, 12, 20]. So the solving FPTP algorithm for Matching parameterized by some vertex deletion distance k works as follows:

1. Use a constant-factor linear-time (approximation) algorithm to compute a vertex set X such that $G - X$ is a "trivial" graph (where Matching is linear-time solvable).
2. Compute in linear time an initial maximum matching M in $G - X$.
3. Start with M as an *initial* matching in G and increase its size at most $|X| = k$ times to obtain in $O(k \cdot (n + m))$ time a *maximum* matching for G.

From this we can directly derive that Matching can be solved in $O(k(n+m))$ time, where k is one of the following parameters: feedback vertex number, feedback edge number, vertex cover number. Moreover, Bipartite Matching can be solved in $O(k(n+m))$ time, where k is the vertex deletion distance to chain graphs. Using our kernelization results, the multiplicative dependence of the running time on parameter k can now be made an additive one. For instance, in this way the running time for Bipartite Matching parameterized by vertex deletion distance to chain graphs "improves" from $O(k(n + m))$ to $O(k^{7.5} + n + m)$.

We conclude with listing some questions and tasks for future research. Can the running time of the kernelization with respect to feedback vertex set (see Section 2) be improved to linear time? Moreover, can the exponential upper bound on the kernel size be decreased to a polynomial upper bound? Is there a linear-time computable kernel for Matching parameterized by the treewidth t (assuming that t is given)? This would complement the recent randomized $O(t^4 n \log n)$ time algorithm [10]. Can one extend the kernel of Section 3 from Bipartite Matching to Matching parameterized by the distance to chain graphs?

Abstract

It is shown that every 2-planar graph is quasiplanar, that is, if a simple graph admits a drawing in the plane such that every edge is crossed at most twice, then it also admits a drawing in which no three edges pairwise cross. We further show that quasiplanarity is witnessed by a simple topological drawing, that is, any two edges cross at most once and adjacent edges do not cross.

1 Introduction

For $k \in \mathbb{N}$, a graph $G = (V, E)$ is called *k-planar* if it admits a drawing in the plane such that every edge is crossed at most k times (such a drawing is called a *k-plane* drawing of G). Similarly, G is called *k-quasiplanar* if it admits a drawing in which no k edges pairwise cross each other (a *k-quasiplane* drawing). A planar graph is 0-planar and 2-quasiplanar by definition. A 3-quasiplanar graph is also called *quasiplanar*, for short. The relation between k-planarity and ℓ-quasiplanarity has been studied only recently. Angelini et al. [6] proved that for $k \geq 3$, every k-planar graph is $(k+1)$-quasiplanar. However, the case $k = 2$ was left open. In this note, we show that the result extends to $k = 2$, and prove the following.

▶ **Theorem 1.** *Every 2-planar graph is quasiplanar.*

The inclusion is proper because there exists a family of (simple) quasiplanar graphs on n vertices with $6.5n - O(1)$ edges [3], whereas every 2-planar graph on $n \geq 3$ vertices has at most $5n - 10$ edges [21]. Our proof is constructive, and allows transforming a 2-plane drawing of an n-vertex graph into a quasiplane drawing in time polynomial in n.

Simple topological drawings. The concept of k-planarity and k-quasiplanarity assumes that the drawings are *topological graphs* where the edges are represented by Jordan arcs, edges may cross each other multiple times, and adjacent edges may cross. In a *simple topological graph*, any two edges cross at most once, and no two adjacent edges cross. Excluding the crossings between adjacent edges is a nontrivial condition [14]. For example, Brandenburg et al. [8] showed that every graph that admits a 1-plane simple topological drawing also admits a 1-plane *straight-line drawing* in which crossing edges meet at a right angle.

* Research by Tóth was supported in part by the NSF awards CFF-1422311 and CFF-1423615.

Angelini et al. [6] proved that for $k \geq 3$, every k-planar graph admits a $(k+1)$-quasiplane simple topological drawing. A careful analysis of our redrawing algorithm, which transforms a 2-plane drawing of a graph into a quasiplane drawing, reveals that it produces a quasiplane simple topological drawing. Thereby we obtain the following strengthening of Theorem 1.

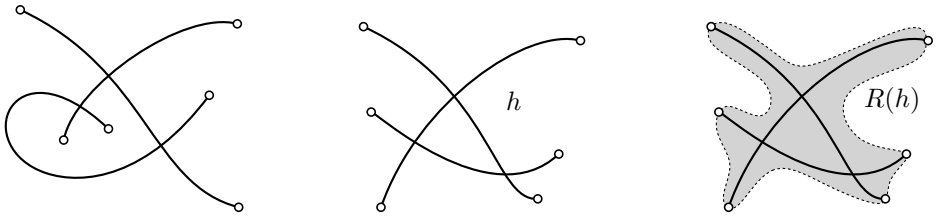
▶ **Theorem 2.** *Every 2-planar graph admits a quasiplane simple topological drawing.*

Related work. Graph planarity is a fundamental concept and a plethora of results has been obtained for planar graphs. The quest for generalizations has motivated the graph minor theory [17]. In the same vein, various notions of *near-planarity* have been studied [19]. The proximity of a graph to planarity may be measured by global parameters, such as the crossing number [22] or graph thickness and their variations [9, 10], or local parameters such as the minimum $k \in \mathbb{N}_0$ for which the graph is k-planar or k-quasiplanar. The concept of *k-planarity* plays a crucial role in proving the current best constants for the classic *Crossing Lemma* [2, 5, 18], and k-quasiplanarity is closely related to Ramsey-type properties of the intersection graph of Jordan arcs in the plane [4]. However, relations between the latter two graph classes have been studied only recently [6].

***k*-planarity.** Planar and 1-planar graphs are fairly well-understood [16]. The Crossing Lemma implies that a k-planar graph on n vertices has at most $4.1\sqrt{k} \cdot n$ edges, and this bound is the best possible apart from constant factors [21]. Tight upper bounds of $4n - 8$, $5n - 10$, and $5.5n - 11$ edges are known for $k = 1$, 2, and 3, respectively [18, 21], and an upper bound of $6n - 12$ edges is known for $k = 4$ [2]. For $k = 1, 2, 3$, so-called *optimal* k-planar graphs (which have the maximum number of edges on n vertices) have recently been completely characterized [7], however they have special properties that in general are not shared by edge-maximal k-planar graphs.

***k*-quasiplanarity.** Pach, Shahrokhi, and Szegedy [20] conjectured that for every $k \in \mathbb{N}$, an n-vertex k-quasiplanar graph has $O(n)$ edges, where the constant of proportionality depends on k. The conjecture has been verified for $k \leq 4$ [1]. The current best upper bound that holds for all $k \in \mathbb{N}$ is $n(\log n)^{O(\log k)}$ due to Fox and Pach [11]. Improvements are known in several important special cases. Suk and Walczak [23] prove that every n-vertex k-quasiplanar graph has $O(2^{\alpha(n)^c} n \log n)$ edges, where $\alpha(n)$ denotes the inverse Ackermann function and c depends only on k, if any two edges intersect in $O(1)$ points. They also show that every n-vertex k-quasiplanar graph has at most $O(n \log n)$ edges if every two edges intersect at most once. These bounds improve earlier work by Fox et al. [12, 13].

Organization. We prove Theorems 1 and 2 in Section 2: We describe a redrawing algorithm in Section 2.1, parameterized by two functions, f and g, that are defined on pairwise crossing triples of edges. In Section 2.3 we analyze local configurations that may produce a triple of pairwise crossing edges after redrawing. In Sections 2.4 and 2.5, we choose suitable functions f and g, and show that our rerouting algorithm with these parameters produces a quasiplane drawing for a 2-planar graph. In Section 2.6, we extend the analysis of our redrawing algorithm and show that it produces a simple topological quasiplane drawing. We conclude in Section 3 with a review of open problems. Due to space limitations, many proofs are omitted; they can be found in the full paper [15].



(a) tangled **(b)** untangled **(c)** region

Figure 1 Tangled and untangled 3-crossings and their associated regions.

2 Proof of Theorem 1

Let $G = (V, E)$ be a 2-planar graph. Assume without loss of generality that G is connected. We need to show that G admits a quasiplane drawing. Note that this quasiplane drawing to be constructed need not—and in general will not—be 2-plane. We may assume, without loss of generality, that G is edge-maximal, in the sense that no new edge can be added (to the abstract graph) without violating 2-planarity. Since G is 2-planar, it admits a 2-plane drawing. We show that it also admits a simple topological 2-plane drawing.

▶ **Lemma 3.** *Every 2-planar graph admits a 2-plane simple topological drawing. Specifically, a 2-plane drawing of a graph G with the minimum number of crossings (among all 2-plane drawings of G) is a simple topological graph.*

Note that a 2-plane drawing may contain a **3-crossing**, that is, a triple of pairwise crossing edges. A 3-crossing in a drawing is **untangled** if the six endpoints of the edges lie on the same face of the arrangement formed by the three edges; otherwise the 3-crossing is **tangled**, see Figure 1a and 1b for an example. Angelini et al. showed [6, Lemma 2] that every 2-planar graph admits a 2-plane drawing in which every 3-crossing is untangled. Their proof starts from a 2-plane drawing and rearranges tangled 3-crossings without introducing any new edge crossings. Therefore, in combination with our Lemma 3 we may start from a 2-plane drawing D of G with the following properties: (i) every 3-crossing is untangled, (ii) no two edges cross more than once, and (iii) no two adjacent edges cross.

If there is no 3-crossing in D, then G is quasiplanar by definition. Otherwise we construct a quasiplane drawing D' of G as described below.

Every 3-crossing in D spans a (topological) **hexagon** in the following sense. Let $\mathcal{H}$ be the set of unordered triples of edges in E that form a 3-crossing in D. In every triple $h \in \mathcal{H}$, each edge crosses both other edges of the triple, and so it cannot cross any edge in $E \setminus h$. Consequently, the triples in $\mathcal{H}$ are pairwise disjoint [6, Observation 1]. For each triple $h \in \mathcal{H}$, let $\mathrm{V}(h)$ denote the set that consists of the six endpoints of the three edges in h. Since h is untangled in D, all six vertices of $\mathrm{V}(h)$ lie on a face f_h of the arrangement induced by the edges of h as drawn in D. Any two vertices of $\mathrm{V}(h)$ that are consecutive along the boundary of f_h can be connected by a Jordan arc that closely follows the boundary of f_h and does not cross any edges in D; see Figure 1c. Together these arcs form a closed Jordan curve, which partitions the plane into two closed regions: let $R(h)$ denote the region that contains the edges of h, and let $\partial R(h)$ denote the boundary of $R(h)$. We think of $\partial R(h)$ as both a closed Jordan curve and as a graph that is a 6-cycle. As the triples in $\mathcal{H}$ are pairwise disjoint, we may assume that the regions $R(h)$, $h \in \mathcal{H}$, have pairwise disjoint interiors.

▶ **Observation 4.** *For every $h \in \mathcal{H}$, every pair of consecutive vertices of the 6-cycle $\partial R(h)$ are connected by an edge in G, and this edge is crossing-free in D.*

Proof. Let $u, v \in V$ be two consecutive vertices of a 6-cycle $\partial R(h)$ for some $h \in \mathcal{H}$.

We show that uv is an edge in G. Indeed, if uv is not an edge of G, then we can augment G with the edge $e = uv$, and insert it into the drawing D as a crossing-free Jordan arc along $\partial R(h)$ to obtain a 2-plane drawing D' of $G \cup \{e\}$. This contradicts our assumption that G is edge-maximal and no edge can be added to G without violating 2-planarity.

We then show that e is crossing free in D. Indeed, if e crosses any other edge in D, we can redraw e as a Jordan arc along $\partial R(h)$, which is crossing-free. The resulting drawing D' of G is 2-plane and has fewer crossings than D. This contradicts our assumption that D has a minimum number of crossings among all 2-plane drawings of G. ◀

By Observation 4 any two consecutive vertices along $\partial R(h)$ of a hexagon $h \in \mathcal{H}$ are connected by an edge e in G. Note that this does not necessarily imply that e is drawn along $\partial R(h)$ in D. It is possible that the cycle formed by the edge e in D and the copy of e drawn along $\partial R(h)$ (which is not part of D) contains other parts of the graph.

▶ **Observation 5.** *(a) Two distinct hexagons in $\mathcal{H}$ share at most five vertices; and (b) three distinct hexagons in $\mathcal{H}$ share at most two vertices.*

Angelini et al. proved [6, Lemma 3 and 4] that there exists an injective map $f : \mathcal{H} \to V$ that maps every hexagon $h \in \mathcal{H}$ to a vertex $v \in \mathrm{V}(h)$. For each hexagon $h \in \mathcal{H}$, exactly one edge in h is incident to the vertex $f(h)$. Let $g(h)$ be one of the two edges in h not incident to $f(h)$. Then for any such choice $g : \mathcal{H} \to E$ is an injective function (because the triples in $\mathcal{H}$ are pairwise disjoint). We complete the construction using a rerouting algorithm that for each hexagon $h \in \mathcal{H}$, reroutes the edge $g(h)$ "around" the vertex $f(h)$. The algorithm—described in detail below—is very similar to the one of Angelini et al., but with a few subtle changes to make it work for 2-planar graphs, rather than k-planar graphs, for $k \geq 3$.

2.1 Rerouting algorithm

We are given a 2-planar graph $G = (V, E)$, and a 2-plane drawing D of G with properties (i)–(iii), as described above. Let the functions $f : \mathcal{H} \to V$ and $g : \mathcal{H} \to E$ be given. (We will determine suitable choices for f and g later.) The algorithm consists of two phases.

Phase 1. For each hexagon $h \in \mathcal{H}$, we perform the following changes in D. Let $h = \{a, b, c\}$ such that the edge a is incident to $f(h)$ and $b = g(h) = uv$, where u is adjacent to $f(h)$ along $\partial R(h)$. Keep the original drawing of the edges a and c. Then arrange (possibly redraw) the edge b inside $R(h)$ so that the oriented Jordan arc uv crosses a before c. Finally, redraw the edge $b = g(h) = uv$ to go around vertex $f(h)$ as follows. See Figure 2.

1. Erase the portion of b in a small neighborhood of the crossing $a \cap b$ to split b into two Jordan arcs: an arc γ_v from v to a point x close to $a \cap b$, and another arc γ_u from x to u.
2. Keep γ_v as part of the new arc representing b, but discard γ_u and replace it by a new Jordan arc from x to u. This arc first closely follows the edge a towards $f(h)$, then goes around the endpoint $f(h)$ of a until it reaches the edge $f(h)u$ (which exists by Observation 4 and is crossing-free in D). The arc then closely follows the edge $f(h)u$ without crossing it to reach u.

As a result, edges a and b no longer cross and the 3-crossing induced by h is eliminated. However, the rerouting may create new crossings between $g(h)$ and edges incident to $f(h)$ (but not a and $uf(h)$). These new crossings are of no consequence, unless they create a 3-crossing. Hence we have to analyze under which circumstances 3-crossings can arise as a

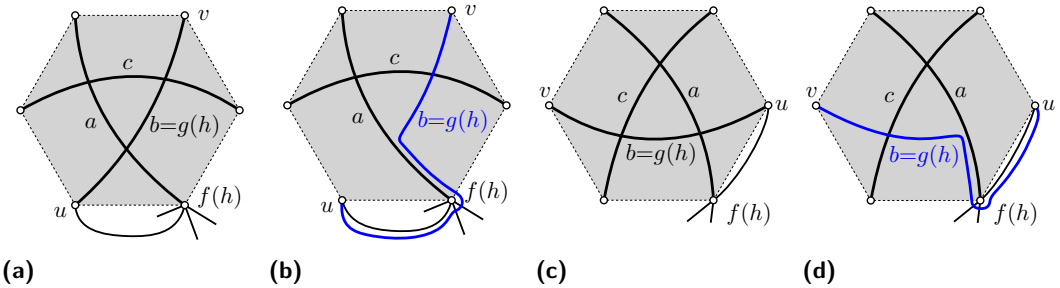


Figure 2 Rerouting $g(h)$ around $f(h)$; $g(h)$ can be either of the two edges not incident to $f(h)$.

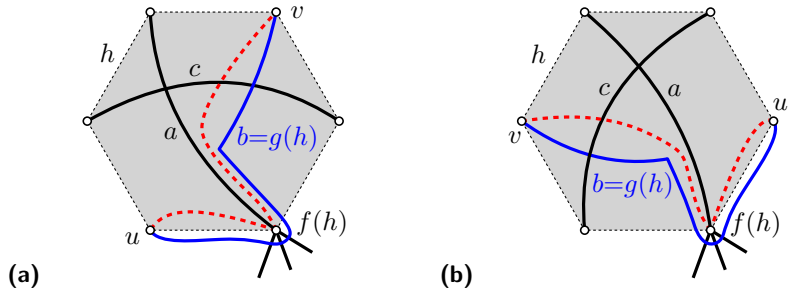

Figure 3 The hexagon h is a home for the two edges that are shown by a dashed red arc. These edges (if present in G) can be safely drawn inside $R(h)$.

result of the reroutings. But first we eliminate some potentially troublesome edge crossings in a second phase of the algorithm.

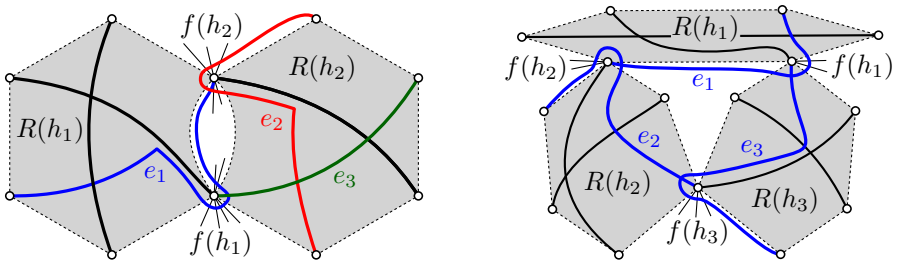
For an edge $e \in E$ a hexagon $h \in \mathcal{H}$ is a **home** for e if e is both incident to $f(h)$ and adjacent to $g(h)$. If h is a home for e, then e can be drawn inside $R(h)$ so that it has at most one crossing, with the edge $c \in h$ (see Figure 3).

Phase 2. As long as there exists an edge $e \in E$ so that (1) e has a home $h \in \mathcal{H}$, (2) there is no home $h' \in \mathcal{H} \setminus \{h\}$ of e so that e is drawn inside $R(h')$, and (3) e has at least one crossing in the current drawing, we reroute e to be drawn inside $R(h)$.

Note that each $h \in \mathcal{H}$ is a home for at most two edges and conversely an edge can have at most two homes (one for each endpoint because f is injective). Also note that an edge may be rerouted in both Phase 1 and Phase 2. This completes the description of the rerouting algorithm. Let $D(f, g)$ denote the drawing that results from applying both phases of the rerouting algorithm to the original drawing D of G.

2.2 Properties of $D(f, g)$

The edges of G fall into three groups, depending on how they are represented in $D(f, g)$ with respect to D: (1) **nonrerouted** edges have not been rerouted in either phase and remain the same as in D; (2) edges that have been rerouted in Phase 2 we call **safe** (regardless of whether or not they have also been rerouted in Phase 1); and (3) edges that have been rerouted in Phase 1 but not in Phase 2 we call **critical**. An edge is **rerouted** if it is either safe or critical. Let us start by classifying the *new* crossings that are introduced by the rerouting algorithm. Without loss of generality we may assume that in every hexagon $h \in \mathcal{H}$



(a) twin **(b)** fan

Figure 4 The redrawing may produce 3-crossings in form of twins or fans.

of D the edge $g(h)$ intersects the other two edges of h in the order described in the first paragraph of Phase 1 above. (If not, then redraw the edge $g(h)$ within $R(h)$ accordingly.)

▶ **Lemma 6.** *Consider a crossing c of two edges e_1 and e_2 in $D(f,g)$ that is not a crossing in D. After possibly exchanging the roles of e_1 and e_2, the crossing c is of exactly one of the following two types: (a) e_1 is safe and drawn in $R(h)$ for a home $h \in \mathcal{H}$ with $e_2 \in h$ nonrerouted; or (b) e_1 is critical and rerouted around an endpoint of e_2.*

▶ **Lemma 7.** *Consider a safe edge e in $D(f,g)$, and let $h \in \mathcal{H}$ denote the home of e so that $e = f(h)z$, for $z \in \mathrm{V}(h)$, is drawn inside $R(h)$. Then*

(i) *e is not part of a 3-crossing;*

(ii) *e does not cross any edge more than once; and*

(iii) *e crosses an adjacent edge e' only if e' is critical, incident to $f(h)$, and rerouted around $z = f(h')$, for some hexagon $h' \in \mathcal{H} \setminus \{h\}$, with $g(h') = e'$.*

▶ **Lemma 8.** *No two adjacent critical edges cross in $D(f,g)$.*

We are ready to completely characterize the 3-crossings in $D(f,g)$. The characterization allows us to then eliminate these 3-crossings by selecting the functions f and g suitably.

▶ **Definition 9.** Let $D(f,g)$ be a drawing of a graph $G = (V,E)$ with functions $f : \mathcal{H} \to V$ and $g : \mathcal{H} \to E$ as defined above. Three edges $e_1, e_2, e_3 \in E$ form a ...

- **twin** configuration in $D(f,g)$ if they are in two distinct hexagons $h_1, h_2 \in \mathcal{H}$, where $e_1 = g(h_1)$, $e_2 = g(h_2)$ and $e_3 \in h_2 \setminus \{e_2\}$, such that edge e_1 is incident to $f(h_2)$, edge e_3 is incident to $f(h_1)$ but not to $f(h_2)$, and e_3 is drawn inside $R(h_2)$. See Figure 4a.
- **fan** configuration in $D(f,g)$ if they are in three pairwise distinct hexagons $h_1, h_2, h_3 \in \mathcal{H}$, where $e_1 = g(h_1)$, $e_2 = g(h_2)$, and $e_3 = g(h_3)$, such that edge e_1 is incident to $f(h_2)$, edge e_2 is incident to $f(h_3)$, and edge e_3 is incident to $f(h_1)$. See Figure 4b.

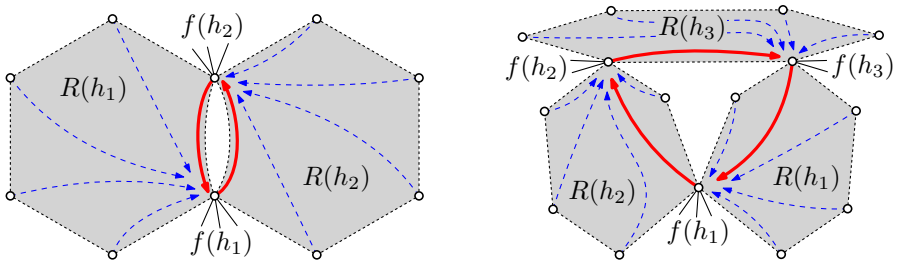
▶ **Lemma 10.** *Every 3-crossing in $D(f,g)$ forms a twin or a fan configuration.*

Theorem 1 is an immediate corollary of the following lemma, which we prove in Section 2.5.

▶ **Lemma 11.** *There exist functions $f : \mathcal{H} \to V$ and $g : \mathcal{H} \to E$ for which $D(f,g)$ is a quasiplane drawing of G.*

2.3 Conflict digraph

We define a plane digraph $K = (V,A)$ that represents the interactions between the hexagons in $\mathcal{H}$. The conflict graph depends on G, on the initial drawing D, and on the function



(a) twin **(b)** fan

Figure 5 Twin and fan configurations induce cycles in the conflict graph.

$f : \mathcal{H} \to V$, but it does not depend on the function g. For every hexagon $h \in \mathcal{H}$, we create five directed edges that are all directed towards $f(h)$ and drawn inside $R(h)$. These edges start from the five vertices on $\partial R(h)$ other than $f(h)$; see Figure 5. Note that two vertices in V may be connected by two edges with opposite orientations lying in two different hexagons (for instance, in a twin configuration as shown in Figure 5a). However, K contains neither loops nor parallel edges with the same orientation because f is injective and so every vertex can have incoming edges from at most one hexagon.

▶ **Observation 12.** *Let K be the conflict graph for $G = (V, E)$ and the drawing $D(f, g)$.*

(i) *K is a directed plane graph.*

(ii) *At every vertex $v \in V$, the incoming edges in K are consecutive in the rotation order of incident edges around v.*

(iii) *If $e_1 = v_1v_2$, $e_2 = v_2v_3$, and $e_3 = v_3v_1$ form a fan configuration in $D(f, g)$, then the conflict digraph contains a 3-cycle (v_1, v_2, v_3).*

(iv) *If $e_1 = g(h_1)$, $e_2 = g(h_2)$, and $e_3 \in h_2$ form a twin configuration in $D(f, g)$, then the conflict digraph contains a 2-cycle $(f(h_1), f(h_2))$.*

Proof. (i) The edges of K lie in the regions $R(h)$, $h \in \mathcal{H}$. Since these regions are interior-disjoint, edges from different regions do not cross. All edges in the same region $R(h)$, $h \in \mathcal{H}$, are incident to $f(h)$; so they do not cross, either. (ii) For each vertex $v \in V$, there is at most one $h \in \mathcal{H}$ such that $v = f(h)$. All incoming edges of v lie in the region $R(h)$, and all edges lying in $R(h)$ are directed towards $v = f(h)$ by construction. (iii–iv) Both claims follow directly from the definition of fan and twin configurations and the definition of K. ◀

Relations between cycles in K. We observed that K is a plane digraph, where every twin configuration induces a 2-cycle and every fan configuration induces a 3-cycle. So in order to control the appearance of twin and fan configurations in the drawing $D(f, g)$, we need to understand the structure of 2- and 3-cycles in the conflict digraph K. In the following paragraphs we introduce some terminology and prove some structural statements about cycles in K.

For a cycle c in K, let $\mathsf{int}(c)$ denote the **interior** of c, let $\mathsf{ext}(c)$ denote the **exterior** of c, let $R(c)$ denote the closed bounded **region** bounded by c, and let $\mathrm{V}(c)$ denote the **vertex set** of c. We use the notation $i \oplus 1 := 1 + (i \bmod k)$ and $i \ominus 1 := 1 + ((k + i - 2) \bmod k)$ to denote successors and predecessors, respectively, in a circular sequence of length k that is indexed $1, \ldots, k$. Let c_1 and c_2 be two cycles in the conflict graph K. We say that c_1 and c_2 are **interior-disjoint** if $\mathsf{int}(c_1) \cap \mathsf{int}(c_2) = \emptyset$. We say that c_1 **contains** c_2 if $R(c_2) \subseteq R(c_1)$. See Figure 6a for an example. In both cases, c_1 and c_2 may share vertices and edges, but they may also be vertex-disjoint.

(a) A smooth 3-cycle contains a smooth 2-cycle. **(b)** A nonsmooth 3-cycle.

Figure 6 Examples: smooth cycles and containment.

▶ **Lemma 13.** *If a vertex $v \in V$ is incident to two interior-disjoint cycles in K, then these cycles have opposite orientations (clockwise vs. counterclockwise). Consequently, every vertex $v \in V$ is incident to at most two interior-disjoint cycles in K.*

Ghosts. A cycle in the conflict digraph K is **short** if it has length two or three. We say that a 3-cycle in K is a **ghost** if two of its vertices induce a 2-cycle in K. Let $\mathcal{C}$ be the set of all short cycles in K that are not ghosts. Intuitively, we do not worry about a ghost cycle c so much. It will turn out later that by taking care of the 2-cycle c' that makes c a ghost, we also take care of c at the same time.

▶ **Lemma 14.** *A short cycle in K is uniquely determined by its vertex set.*

▶ **Lemma 15.** *Let $c_1, c_2 \in \mathcal{C}$. If $\mathrm{V}(c_1) \cap \mathsf{int}(c_2) \neq \emptyset$, then c_2 contains c_1.*

Proof. Suppose to the contrary that there exist short cycles $c_1, c_2 \in \mathcal{C}$ such that $v_1 \in \mathrm{V}(c_1) \cap \mathsf{int}(c_2)$ but c_2 does not contain c_1. Then some point along c_1 lies in $\mathsf{ext}(c_2)$. Since K is a plane graph, an entire edge of c_1 must lie in $\mathsf{ext}(c_2)$. Denote this edge by (v_2, v_3). Recall that c_1 is short (that is, it has at most three vertices), consequently, $c_1 = (v_1, v_2, v_3)$. Since c_1 has points in both $\mathsf{int}(c_2)$ and $\mathsf{ext}(c_2)$, the two cycles intersect in at least two points. In a plane graph, the intersection of two cycles consists of vertices and edges. Consequently $\mathrm{V}(c_1) \cap \mathrm{V}(c_2) = \{v_2, v_3\}$. Recall that c_2 is also short, and so it has a directed edge between any two of its vertices. However, (v_2, v_3) lies in $\mathsf{ext}(c_2)$, so the reverse edge (v_3, v_2) is present in c_2. That is, $\{v_2, v_3\}$ induces a 2-cycle in K. Hence both c_1 and c_2 are ghosts, contrary to our assumption. ◀

Smooth cycles. In order to avoid twin and fan configurations in $D(f, g)$, we would like to choose an injective function $f : \mathcal{H} \to V$, with $f(h) \in \mathrm{V}(h)$, that avoids short cycles in K, except for a special type of cycles (called *smooth*) to be defined next.

▶ **Definition 16.** Let $c = (v_1, \ldots, v_k)$ be a simple short cycle in the conflict graph K. Recall that every edge in K lies in a region $R(h)$, $h \in \mathcal{H}$, and is directed to $f(h)$. So the cycle c corresponds to a cycle of hexagons $(h_1, \ldots, h_k)$, such that the vertex $v_i = f(h_i)$ lies on the boundary of hexagons h_i and $h_{i\oplus 1}$, for $i = 1, \ldots, k$. We say that the hexagons $h_1, \ldots, h_k$ are **associated** with c. The cycle c is **smooth** if none of the associated hexagons has a vertex in $\mathsf{int}(c)$. (For example, the cycles in Figure 6a are smooth, but the 3-cycle in Figure 6b is not.)

Note that a smooth cycle in K may contain many vertices of various hexagons in its interior; the restrictions apply only to those (two or three) hexagons that are associated with the cycle. For instance, there could be several hexagons in the white regions between the hexagons in Figure 6. Let $\mathcal{C}_\mathrm{s}$ denote the set of all smooth cycles in $\mathcal{C}$, that is, the set of all short smooth nonghost cycles in K. In Section 2.4, we show how to choose f such that all cycles in $\mathcal{C}$ are smooth, that is, $\mathcal{C} = \mathcal{C}_\mathrm{s}$.

Properties of smooth cycles. The following three lemmata formulate some important properties of smooth cycles that hold for any injective function $f : \mathcal{H} \to V$, where $f(h) \in \mathrm{V}(h)$ for all $h \in \mathcal{H}$.

▶ **Lemma 17.** *Let $c \in \mathcal{C}_\mathrm{s}$ and let $u \in \mathsf{int}(c)$ be a vertex of G. Then there is no edge (u, v) in K for any $v \in \mathrm{V}(c)$.*

Proof. Suppose for the sake of a contradiction that (u, v) is an edge of K with $v \in \mathrm{V}(c)$. Let h be the hexagon with $f(h) = v$. All edges towards v are drawn inside h so that, in particular, $u \in \mathrm{V}(h)$. As h is associated with c, this contradicts the assumption that c is smooth. ◀

▶ **Lemma 18.** *Let $c_1, c_2 \in \mathcal{C}_\mathrm{s}$ so that $c_1 \neq c_2$ and c_2 contains c_1. Then $\mathrm{V}(c_1) \cap \mathrm{V}(c_2) = \emptyset$.*

Proof. Suppose to the contrary that there exists a vertex $u \in \mathrm{V}(c_1) \cap \mathrm{V}(c_2)$. We claim that $\mathrm{V}(c_1) \cap \mathsf{int}(c_2) = \emptyset$. To see this, consider a vertex $v \in \mathrm{V}(c_1) \cap \mathsf{int}(c_2)$. Then following c_1 from v to u we find an edge (x, y) of K so that $x \in \mathsf{int}(c_2)$ and $y \in \mathrm{V}(c_2)$. However, such an edge does not exist by Lemma 17. Hence there is no such vertex v and $\mathrm{V}(c_1) \cap \mathsf{int}(c_2) = \emptyset$. Given that c_2 contains c_1, it follows that $\mathrm{V}(c_1) \subseteq \mathrm{V}(c_2)$.

If c_1 is a 3-cycle, then so is c_2 and Lemma 14 contradicts our assumption $c_1 \neq c_2$. Hence c_1 is a 2-cycle and c_2 is a 3-cycle. But then c_2 is a ghost, in contradiction to $c_2 \in \mathcal{C}_\mathrm{s}$. ◀

▶ **Lemma 19.** *Any two cycles in $\mathcal{C}_\mathrm{s}$ are interior-disjoint or vertex disjoint.*

Proof. Let $c_1, c_2 \in \mathcal{C}_\mathrm{s}$ with $c_1 \neq c_2$. Suppose, to the contrary, that $\mathsf{int}(c_1) \cap \mathsf{int}(c_2) \neq \emptyset$ and $V(c_1) \cap V(c_2) \neq \emptyset$. Without loss of generality, an edge (u_1, u_2) of c_2 lies in the interior of c_1.

We may assume that u_1 and u_2 are common vertices of c_1 and c_2. Indeed, if u_1 and u_2 were not common vertices of the cycles, then a vertex of c_2 would lie in the interior of c_1. Then c_1 contains c_2 by Lemma 15, and $\mathrm{V}(c_1) \cap \mathrm{V}(c_2) = \emptyset$ by Lemma 18.

We may further assume that both c_1 and c_2 are 3-cycles. Indeed, if the vertex set of one of them contains that of the other, then one of them is a 3-cycle and the other is a 2-cycle. Since both c_1 and c_2 are present in $\mathcal{C}$, one of them would be a ghost cycle in $\mathcal{C}$, contradicting the definition of $\mathcal{C}$.

Since (u_1, u_2) is a directed edge of c_2 that lies in the interior of c_1, and c_1 is a 3-cycle that has an edge between any two of its vertices, the edge (u_2, u_1) is present in c_1. This implies that $c_3 = (u_1, u_2)$ is a 2-cycle in K. Therefore $c_3 \in \mathcal{C}$, and both c_1 and c_2 are ghost cycles in $\mathcal{C}$, contradicting the definition of $\mathcal{C}$, $\mathcal{C} \supseteq \mathcal{C}_\mathrm{s}$. This confirms that $c_1, c_2 \in \mathcal{C}_\mathrm{s}$, $c_1 \neq c_2$, are interior-disjoint or vertex disjoint, as claimed. ◀

2.4 Choosing the special vertices $f(h)$

As noted above, Angelini et al. proved [6, Lemmata 3 and 4] that there exists an injective map $f : \mathcal{H} \to V$ that maps every hexagon $h \in \mathcal{H}$ to a vertex $v \in \mathrm{V}(h)$. We review their argument (using Hall's matching theorem), and then strengthen the result to establish some additional properties of the function $f : \mathcal{H} \to V$.

Hall's condition. Let $\mathcal{A} \subseteq \mathcal{H}$ be a subset of hexagons, and let $\mathrm{V}(\mathcal{A}) \subseteq V$ be the set of vertices incident to the hexagons in $\mathcal{A}$. Following Angelini et al. [6, Lemma 4] we obtain Hall's condition via double counting.

▶ **Lemma 20.** *For every subset $\mathcal{A} \subseteq \mathcal{H}$, we have $|\mathrm{V}(\mathcal{A})| \geq 2|\mathcal{A}| + 2$.*

▶ **Corollary 21.** *There exists an injective map $f : \mathcal{H} \to V$ that maps every hexagon $h \in \mathcal{H}$ to a vertex $v \in \mathrm{V}(h)$.*

▶ **Corollary 22.** *For every nonempty subset $\mathcal{A} \subseteq \mathcal{H}$, we have $|\mathrm{V}(\mathcal{A})| \geq |\mathcal{A}| + 5$.*

Proof. If $|\mathcal{A}| = 1$, then $|\mathcal{A}| + 5 = 6$ and a single hexagon has 6 distinct vertices. If $|\mathcal{A}| = 2$, then $|\mathcal{A}|+5 = 7$; and two distinct hexagons have at least 7 distinct vertices by Observation 5a. Otherwise $|\mathcal{A}| \geq 3$, and Lemma 20 yields $|\mathrm{V}(\mathcal{A})| \geq 2|\mathcal{A}| + 2 \geq |\mathcal{A}| + 5$. ◀

▶ **Lemma 23.** *There exists an injective function $f : \mathcal{H} \to V$ such that $f(h) \in \mathrm{V}(h)$, for every $h \in \mathcal{H}$, and every cycle in $\mathcal{C}$ is smooth.*

2.5 Choosing the special edges $g(h)$

Let $f : \mathcal{H} \to V$ be a function as described in Lemma 23. That is, in the following we assume $\mathcal{C} = \mathcal{C}_{\mathrm{s}}$ (all short nonghost cycles in K are smooth). We use Hall's theorem to show that there is a matching of the cycles in $\mathcal{C}$ to the vertices in V such that each cycle is matched to an incident vertex. For a subset $\mathcal{B} \subseteq \mathcal{C}$, let $\mathrm{V}(\mathcal{B})$ denote the set of all vertices incident to some cycle in $\mathcal{B}$.

▶ **Lemma 24.** *For every set $\mathcal{B}_0 \subseteq \mathcal{C}$ of pairwise interior-disjoint cycles, $|\mathcal{B}_0| \leq |\mathrm{V}(\mathcal{B}_0)|$.*

Proof. We use double counting. Let I be the set of all pairs $(v, c) \in V \times \mathcal{B}_0$ such that v is incident to c. Every cycle is incident to ≥ 2 vertices, hence $|I| \geq 2|\mathcal{B}_0|$. By Lemma 13, every vertex is incident to at most two interior-disjoint cycles. Consequently, $|I| \leq 2|\mathrm{V}(\mathcal{B}_0)|$. The combination of the upper and lower bounds for $|I|$ yields $|\mathcal{B}_0| \leq |\mathrm{V}(\mathcal{B}_0)|$. ◀

▶ **Lemma 25.** *For every set $\mathcal{B} \subseteq \mathcal{C}$ of cycles, we have $|\mathcal{B}| \leq |\mathrm{V}(\mathcal{B})|$.*

▶ **Lemma 26.** *There exists an injective function $s : \mathcal{C} \to V$ that maps every cycle in $\mathcal{C}$ to one of its vertices.*

We are ready to define the function $g : \mathcal{H} \to E$, that maps every hexagon $h \in \mathcal{H}$ to one of its edges.

▶ **Lemma 27.** *There is a function $g : \mathcal{H} \to E$ such that*
- *for every $h \in \mathcal{H}$, $g(h) \in h$ and $g(h)$ is not incident to $f(h)$;*
- *for every 2-cycle $(f(h_1), f(h_2))$ in K, the edges $g(h_1)$ and $g(h_2)$ do not cross in $D(f, g)$;*
- *for every 3-cycle $(f(h_1), f(h_2), f(h_3))$ in K, at least two of the edges $g(h_1)$, $g(h_2)$, and $g(h_3)$ do not cross in $D(f, g)$.*

Proof. By Lemma 26, there is an injective function $s : \mathcal{C} \to V$ that maps every cycle $c \in \mathcal{C}$ to one of its vertices. For each cycle $c \in \mathcal{C}$, vertex $s(c)$ is the endpoint of some directed edge $(q(c), s(c))$ in the conflict graph. Consequently, there is a hexagon $h \in \mathcal{H}$ such that $s(c) = f(h)$ and $q(c) \in \mathrm{V}(h)$. We say that h is *assigned* to the cycle c. We distinguish two types of hexagons, depending on whether or not they are assigned to a 2-cycle of $\mathcal{C}$.

Hexagons that are not assigned to 2-cycles. For every hexagon h that is not assigned to any cycle, choose $g(h)$ to be an arbitrary edge in h that is not incident to the vertex $f(h)$. For every hexagon h that is assigned to a 3-cycle $c \in \mathcal{C}$, choose $g(h)$ to be the (unique) edge in h that is incident to neither $q(c)$ nor $s(c)$. If $c = (f(h_1), f(h_2), f(h_3))$ and without loss of generality $s(c) = f(h_2)$, then $g(h_2)$ is not incident to $f(h_1) = q(c)$, consequently $g(h_1)$ is disjoint from $g(h_2)$. (Note that $g(h_1)$ is not incident to $f(h_2) = s(c)$ because this would induce a 2-cycle in K, making c a ghost.)

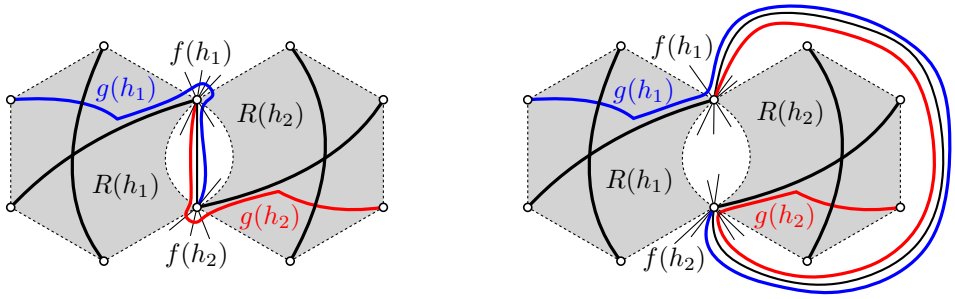


Figure 7 In Case 1 of Lemma 27, the edge $g(h_2)$ is incident to $f(h_1)$. We set $g(h_1)$ so that it is incident to $f(h_2)$. Regardless of how $f(h_1)f(h_2)$ is drawn, the edge separates $g(h_1)$ and $g(h_2)$ and ensures that they are disjoint.

Hexagons assigned to 2-cycles. Consider a 2-cycle $c \in \mathcal{C}$, and let h_1 and h_2 denote the associated hexagons so that without loss of generality $s(c) = f(h_1)$. Suppose without loss of generality that c is oriented clockwise. We distinguish three cases.

Case 1: $g(h_2)$ has already been selected and $g(h_2)$ is incident to $f(h_1)$. Then let $g(h_1)$ be the unique edge in h_1 incident to $f(h_2)$ (Figure 7). We claim that $g(h_1)$ and $g(h_2)$ do not cross in $D(f, g)$. As both edges are critical, by Lemma 6 they can only cross in the neighborhood of $f(h_1)$ or $f(h_2)$. Let a_i be the edge of h_i incident to $f(h_i)$, for $i \in \{1, 2\}$. The edge $g(h_i)$, for $i \in \{1, 2\}$, follows a_i towards the neighborhood of $f(h_i)$ and then crosses the edges incident to $f(h_i)$ following a_i in clockwise order (the orientation of c) until reaching the edge $f(h_1)f(h_2)$. Then $g(h_i)$ follows $f(h_1)f(h_2)$ to its other endpoint, without crossing the edge. Therefore, the path formed by the edges a_1, $f(h_1)f(h_2)$, and a_2 splits the neighborhoods of $f(h_1)$ and $f(h_2)$ into two components so that $g(h_1)$ and $g(h_2)$ are in different components. Thus $g(h_1)$ and $g(h_2)$ do not cross, as claimed.

Case 2: $g(h_2)$ has already been selected and $g(h_2)$ is not incident to $f(h_1)$. Then let $g(h_1)$ be the unique edge in h_1 incident to neither $f(h_1)$ nor $f(h_2)$ (Figure 8a). We claim that $g(h_1)$ and $g(h_2)$ do not cross in $D(f, g)$. As both edges are critical, by Lemma 6 they can only cross in the neighborhood of $f(h_1)$ or $f(h_2)$. But as $g(h_1)$ is not incident to $f(h_2)$, there is a neighborhood of $f(h_2)$ that is disjoint from $g(h_1)$, and so $g(h_1)$ and $g(h_2)$ do not cross there. Similarly, there is a neighborhood of $f(h_1)$ that is disjoint from $g(h_2)$, and so $g(h_1)$ and $g(h_2)$ do not cross there, either. Thus $g(h_1)$ and $g(h_2)$ do not cross in $D(f, g)$.

Case 3: no hexagon h_1 is assigned to a 2-cycle so that $g(h_2)$ has already been selected. Then we are left with hexagons that correspond to 2-cycles and form *cycles* $L = (h_1, \ldots, h_k)$ such that $(f(h_i), f(h_{i\oplus 1}))$ is a 2-cycle in $\mathcal{C}$, for $i = 1 \ldots, k$. These cycles are interior-disjoint by Lemma 19, and any two consecutive cycles in L have opposite orientations by Lemma 13. It follows that k is even.

Since every 2-cycle in L is smooth, the three vertices $f(h_{i\ominus 1})$, $f(h_i)$, and $f(v_{i\oplus 1})$ are consecutive along $\partial R(h_i)$. For every odd $i \in \{1, \ldots, k\}$, let $g(h_i)$ be the (unique) edge in h_i incident to $f(h_{i\ominus 1})$ (and incident to neither $f(h_i)$ nor $f(h_{i\oplus 1})$). Similarly, for every even $i \in \{1, \ldots, k\}$, let $g(h_i)$ be the edge in h_i incident to $f(h_{i\oplus 1})$ (and incident to neither $f(h_i)$ nor $f(h_{i\ominus 1})$). Refer to Figure 8b.

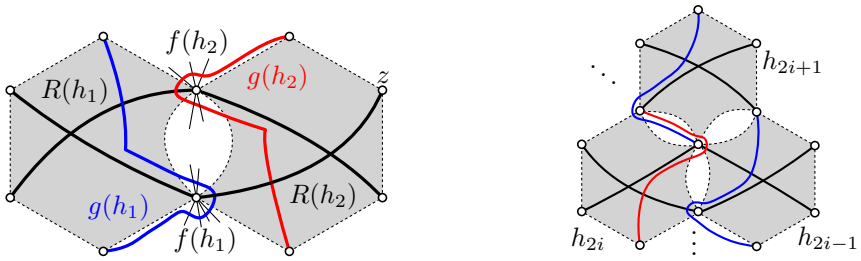

Figure 8 (a) In Case 2 of Lemma 27, the edge $g(h_2)$ is not incident to $f(h_1)$. We set $g(h_1)$ so that it is not incident to $f(h_2)$, to ensure that $g(h_1)$ and $g(h_2)$ are disjoint. (b) In Case 3 we face a cycle of 2-cycles. We consistently select edges to be rerouted in even (red edge) and odd (blue edge) hexagons so that they are pairwise disjoint.

For every odd index $i \in \{1, \ldots, k\}$, the rerouted edges $g(h_i)$ and $g(h_{i\oplus 1})$ are incident to neither $f(h_{i\oplus 1})$ nor $f(h_i)$. Similarly, for every even index $i \in \{1, \ldots, k\}$, the rerouted edges $g(h_i)$ and $g(h_{i\oplus 1})$ are incident to $f(h_{i\oplus 1})$ and $f(h_i)$, respectively. In both cases, the rerouted edges $g(h_i)$ and $g(h_{i\oplus 1})$ are disjoint.

Ghost cycles. It remains to consider ghost cycles. Let c_1 be a ghost cycle in K. Without loss of generality, assume that $c_1 = (v_1, v_2, v_3)$, where $v_1 = f(h_1)$, $v_2 = f(h_2)$, and $v_3 = f(h_3)$, and $c_2 = (v_1, v_2)$ is a 2-cycle in $\mathcal{C}$. Recall that c_2 is smooth (cf. Lemma 23). By construction, $g(h_1)$ and $g(h_2)$ do not cross in $D(f, g)$. Hence at least two of the edges in $\{g(h_1), g(h_2), g(h_3)\}$ do not cross in $D(f, g)$, as required. ◀

The combination of Lemma 10, Lemma 23, and Lemma 27 proves Lemma 11, which completes the proof of Theorem 1.

2.6 Quasiplane simple topological drawings

The redrawing algorithm in Section 2.1 transformed a 2-plane drawing D with properties (i)–(iii), and rerouted some of the edges in two phases to obtain a quasiplane drawing $D(f, g)$. In this section, we show that the algorithm produces a simple topological drawing, that is, any two edges cross at most once, and no two adjacent edges cross.

▶ **Theorem 2.** *Every 2-planar graph admits a quasiplane simple topological drawing.*

3 Conclusions

We have proved that every 2-planar graph is quasiplanar (Theorem 1) by showing that a 2-plane topological graph can be transformed into a quasiplane topological graph, in which no three edges pairwise cross. Theorem 2 strengthens the result to produce a quasiplane *simple* topological graph (any two edges cross at most once and adjacent edges do not cross).

In Section 2.4, we have shown that we can choose one vertex $f(h)$ for each hexagon $h \in \mathcal{H}$ such that all 2- and 3-cycles in the conflict graph K have some special properties. It is unclear, however, whether 2- and 3-cycles can be avoided altogether by a suitable choice of the function f. We formulate an open problem to this effect: Given a set $\mathcal{H}$ of interior-disjoint (topological) hexagons in the plane on a vertex set V, is there an injective function $f : \mathcal{H} \to V$

such that the conflict digraph K contains no 2-cycles (alternatively, neither 2- nor 3-cycles)? Several fundamental problems remain open for k-quasiplanar graphs:

- What is the computational complexity of recognizing k-quasiplanar graphs? Is there a polynomial-time algorithm that decides whether a given graph is quasiplanar (or k-quasiplanar for a given constant k)?
- Is there a constant c_k for every $k \in \mathbb{N}$ such that an n-vertex k-quasiplanar graph has at most $c_k n$ edges [20]? Affirmative answers are known for $k \leq 4$ only [1].
- By Theorem 1 and the main result in [6], every k-planar graph is $(k+1)$-quasiplanar, where $k \in \mathbb{N}$, $k \geq 2$. Angelini et al. [6] ask whether this result can be improved for large k: Denote by $\ell(k) \in \mathbb{N}$ the minimum integer such that every k-planar graph is ℓ-quasiplanar. Prove or disprove that $\ell(k) = o(k)$.

Abstract

Max-plus automata are quantitative extensions of automata designed to associate an integer with every non-empty word. A pair of distinct words is said to be an identity for a class of max-plus automata if each of the automata in the class computes the same value on the two words. We give the shortest identities holding for the class of max-plus automata with two states. For this, we exhibit an interesting list of necessary conditions for an identity to hold. Moreover, this result provides a counter-example of a conjecture of Izhakian, concerning the minimality of certain identities.

1 Introduction

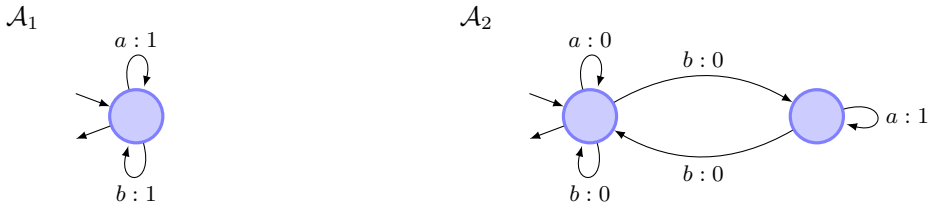
A natural question when dealing with computational models is to understand which pairs of inputs can be separated by the model, *i.e.* lead to different results. Or conversely, which pairs of distinct inputs will give the same computation. These pairs are called identities for the model. Regarding finite automata, two words are said to be separated by a given automaton if one is accepted and the other is rejected. When fixing an automaton, or even considering the class of automata with at most a certain number of states, we know that some pairs of distinct words are not separated. It is a simple argument of cardinality: the number of automata with a bounded number of states is finite and each of them computes a boolean value on a given word, while the number of words is infinite. However, when considering the full class, for every pair of distinct words, it is easy to construct an automaton accepting one and rejecting the other.

When dealing with quantitative extensions of automata, namely weighted automata, the situation is much more intricate. Weighted automata were introduced by Schützenberger in [12]. They compute functions from the set of words to the set of values of a semiring, allowing one to model quantities such as costs, gains or probabilities. The question of separating words (*i.e.* computing different values on the words) highly depends on the semiring. For probabilistic automata, or automata on the usual semiring $(\mathbb{R}, +, \times)$, it is known that there is an automaton (with two states) which separates every pair of distinct words.

* This work was partially supported by the LIPA project, funded by the European Research Council (ERC) under the European Unions Horizon 2020 research and innovation programme (grant agreement No 683080).

In this paper we are interested in max-plus automata, which are weighted automata over the tropical semiring that compute functions from the set of *non-empty* words to the values of the semiring $\mathbb{Z}_{\max} = (\mathbb{Z} \cup \{-\infty\}, \max, +)$. From now on, for simplicity, we may use the notation $\mathbb{Z}_{\max}$ to denote the semiring or the set of its values $\mathbb{Z} \cup \{-\infty\}$. We note that some authors prefer to work with min-plus automata, which compute values in the min-plus semiring $\mathbb{Z}_{\min} = (\mathbb{Z} \cup \{+\infty\}, \min, +)$. Since the two semirings ($\mathbb{Z}_{\max}$ and $\mathbb{Z}_{\min}$) are isomorphic, the results presented here can be easily translated to the min-plus case.

A *max-plus automaton* is a finite automaton whose transitions are weighted by integers. An easy way to think about these weights is to consider them as amounts of money that you win when you go through a transition. Along a run, you accumulate this money (you sum the amounts; this sum is called the *weight of the run*), and your purpose is, given a word w, to go from an initial state to a final state, by reading w and grabbing the maximal amount of money you can. The *value (or weight) associated with* w is the maximum possible amount that you could win by reading the word w. Max-plus automata are thus particularly suitable to model gain maximisation, study the worst-case complexity of a program [2] or evaluate performance of discrete event systems [4, 5]. Let us give two examples on the alphabet $\{a, b\}$ (where initial and final states are denoted by ingoing and outgoing arrows respectively):



The automaton $\mathcal{A}_1$ associates with each word its length. The function computed by the automaton $\mathcal{A}_2$ is more complicated and we begin by describing its behaviour in particular cases. Consider a word of the form $ba^{k_1}ba^{k_2}b\cdots ba^{k_\ell}b$ where all the k_i are positive integers. Then, the value computed by the automaton is the maximum of the sums $k_{i_1} + k_{i_2} + \cdots + k_{i_m}$ where no two i_j are consecutive, that is to say, $i_{j+1} \geqslant i_j + 2$ for all j.

Two distinct words u and v are separated by a class of max-plus automata if there is an automaton in the class that associates two different values on the two words, otherwise they form an identity for the class, usually denoted $u = v$. But this question is much more intricate than in the previous cases of boolean automata and automata weighted over the usual semiring. We can show that a single max-plus automaton cannot separate all pairs of distinct words. It is again a simple cardinality argument: if the weights of the transitions of an automaton are between $-m$ and m, then the value associated to a word of length n is between $-mn$ and mn, while the number of words of length n on a finite alphabet Σ is $|\Sigma|^n$. For n large enough, there must exist two distinct words having the same value. It is also clear that given two distinct words, one can construct a max-plus automaton (with an arbitrarily large number of states) separating them. A major open question is the following:

Given a bound d, does there exist an identity for the set of max-plus automata with at most d states?

In that case, a simple cardinality argument fails. This question was first considered in [9] where it was answered positively for $d = 2$. The known identity for two states consists of a pair of words of length 20, but the problem seems very difficult to tackle in the general case. Shitov [13] proposed an identity for $d = 3$ consisting of a pair of words of length 1795308.

Currently no generalisation of these results seems conceivable, the ultimate (very far) goal being to characterise the complete set of identities. This paper is motivated by the fact that a better understanding of the identities in the case $d = 2$ is already a first step for a better understanding of the general case.

Contribution. We focus on the class of max-plus automata with two states, denoted $\mathcal{C}$. It is easy to see that if $u = v$ is an identity which holds in $\mathcal{C}$ then u and v have the same length (see for example $\mathcal{A}_1$), defining the *length of the identity*. We give the unique two identities of minimal length (17) which hold in $\mathcal{C}$.

▶ **Theorem 1.** *There are two identities (up to a renaming of the letters) of minimal length which hold in the class of max-plus automata with two states:*

$$a^2b^3a^3babab^3a^2 = a^2b^3ababa^3b^3a^2 \quad \textit{and} \quad ab^3a^4baba^2b^3a = ab^3a^2baba^4b^3a$$

To achieve this goal, we give a rather short list of necessary conditions for an identity to hold which together eliminate all the other possible candidates of length shorter than 18 (Proposition 10, Section 3). This list is short enough that it can be tested by computer. We also prove that this list is minimal in the sense that each of the conditions eliminates at least one pair of words, that cannot be eliminated using the other conditions alone. However, this list is probably not complete, and future works will consist in trying to extend it to fully characterise the identities holding in $\mathcal{C}$. We then prove that the identities given in the statement of Theorem 1 hold in $\mathcal{C}$ (Proposition 11, Section 4).

Link with matrices. This topic is closely related with the question of identities on semigroups of matrices over the tropical semiring. We consider matrices with entries in $\mathbb{Z} \cup \{-\infty\}$ and the product AB for two matrices A, B (provided the number of columns of A and the number of rows of B coincide, denoted here d) is defined as $(AB)_{i,j} = \max_{1 \leqslant k \leqslant d}(A_{i,k} + B_{k,j})$.

An identity $u = v$ is said to be satisfied by a semigroup of matrices if for all substitutions of the letters by matrices in the semigroup, the equality holds.

A max-plus automaton with d states can equivalently be represented by a semigroup of matrices of dimension d: the states are numbered $\{1, \dots, d\}$ and for each letter, a square matrix $\mu(a)$ of dimension d is defined such that the (i, j)-coefficient contains the weight of the transition from state i to state j labelled by a or $-\infty$ if there is no such transition. Then μ extends to give a semigroup morphism $\mu : \Sigma^+ \to M_n(\mathbb{Z}_{\max})$. For a non-empty word w, it is straightforward to verify that $\mu(w)_{i,j}$ is the maximum of the weights of the runs from state i to state j, labelled by w. An initial vector I (*resp.* final vector F) with 1 row and d columns (*resp.* d rows and 1 column) and entries in $\{0, -\infty\}$ is defined by $I_i = 0$ (*resp.* $F_i = 0$) if and only if state i is initial (*resp.* final). The weight of a word w in $\mathcal{A}$ is exactly the value given by $I\mu(w)F \in \mathbb{Z}_{\max}$ (see for example [11] for more explanations). The max-plus automaton $\mathcal{A}_1$ illustrated on the previous page is represented by $\mu(a) = (1)$, $\mu(b) = (1)$ and $I = F = (0)$, while $\mathcal{A}_2$ is represented by:

$$\mu(a) = \begin{pmatrix} 0 & -\infty \\ -\infty & 1 \end{pmatrix} \qquad \mu(b) = \begin{pmatrix} 0 & 0 \\ 0 & -\infty \end{pmatrix} \qquad I = \begin{pmatrix} 0 & -\infty \end{pmatrix} \qquad F = \begin{pmatrix} 0 \\ -\infty \end{pmatrix}$$

Using this representation, it can be easily shown that $u = v$ is an identity which holds in $\mathcal{C}$ if and only if $u = v$ holds for the semigroup of square matrices of dimension 2. Then Theorem 1 implies the following theorem.

▶ **Theorem 2.** *There are two identities (up to a renaming of the letters) of minimal length which hold in the semigroup of tropical square matrices of dimension* 2*:*

$$a^2b^3a^3babab^3a^2 = a^2b^3ababa^3b^3a^2 \quad \textit{and} \quad ab^3a^4baba^2b^3a = ab^3a^2baba^4b^3a$$

Using the fact that the identities which hold in the semigroup of tropical square matrices of dimension 2 are the same as those which hold in the semigroup of tropical square matrices of dimension 2 with real entries (as explained in Section 2 below), Theorem 2 gives a counter-example to a conjecture of Izhakian concerning the structure of the identities of minimal length. Indeed, in [8, Conjecture 5.1] he provides a method of constructing identities satisfied by every subsemigroup of the semigroup of the tropical square matrices of dimension d consisting of matrices with maximal (tropical) rank (see [8] for detailed definitions), conjecturing that certain amongst these are of minimal length, but for $d = 2$, the shortest identities produced by this method have length greater than 17.

Organisation of the paper. In Section 2, we give first properties. In particular, we make some comments about working with weights in $\mathbb{Z}$ rather than $\mathbb{N}$, $\mathbb{Q}$ or $\mathbb{R}$, restricting the automata to have only one initial and one final state and considering only 2-letter alphabets. In Section 3, we give the list of conditions allowing us to eliminate all the pairs of words up to length 17 except two (up to renaming of the letters). In Section 4, we prove that these pairs do indeed form identities.

2 First properties

Given a word w and a letter a, we write $|w|$ to denote the length of w and $|w|_a$ to denote the number of occurrences of the letter a in w. If $w = w_0w_1\cdots w_\ell$ with $w_0, w_1, \ldots, w_\ell$ letters, the positions of w are $0, 1, \ldots \ell$ and w_i is said to be the letter at position i. In a max-plus automaton $\mathcal{A}$, a run labelled by w from a state p to a state q with weight α will be denoted $p \xrightarrow{w\,:\,\alpha} q$. We denote by $[\![\mathcal{A}]\!]$ the function (from the set of non-empty words over a finite alphabet Σ to $\mathbb{Z}_{\max}$) computed by $\mathcal{A}$. Let us recall that $\mathcal{C}$ denotes the class of all the max-plus automata with two states. More generally, for any positive integer d, we denote by $\mathcal{C}_d$ the class of all the max-plus automata with d states (so that $\mathcal{C}_2 = \mathcal{C}$). An identity over Σ, that is to say a pair of two distinct non-empty words over Σ, denoted $u = v$, holds in $\mathcal{C}_d$ if and only if for all $\mathcal{A} \in \mathcal{C}_d$, $[\![\mathcal{A}]\!](u) = [\![\mathcal{A}]\!](v)$. For now, we fix an integer $d \geqslant 2$.

Content. If $\Sigma = \{a_1, \ldots a_n\}$, the *content* of a word w is the n-tuple $(|w|_{a_1}, \ldots, |w|_{a_n})$ of the number of occurrences of each of the letters in w.

▶ **Lemma 3.** *If $u = v$ holds in $\mathcal{C}_d$, then u and v have the same content. In particular u and v have the same length.*

Proof. The number of occurrences of a letter a can be computed by a max-plus automaton with one state (both initial and final) with one transition for each letter of Σ, where the transition labelled by a has weight 1 and all other transitions have weight 0. (Note that this can be seen as a max-plus automaton with d states by simply adding states, and possibly transitions with weight 0). Thus, if the content of u and v differs then there exist an automaton in $\mathcal{C}_d$ computing two different values on these two words. ◀

Initial and final states. In the rest of the paper, we will freely use the following fact:

▶ **Lemma 4.** *An identity $u = v$ holds in $\mathcal{C}_d$ if and only if it holds in the class of max-plus automata with d states having exactly one initial and one final state.*

Proof. Denote by $\mathcal{C}'_d$ the class of max-plus automata with d states and exactly one initial and one final state. Clearly, if $u = v$ holds in $\mathcal{C}_d$, it must also hold in $\mathcal{C}'_d$. Conversely, suppose $u = v$ holds in $\mathcal{C}'_d$ and let $\mathcal{A} \in \mathcal{C}_d$. Consider now the set $\mathcal{S}$ of the max-plus automata in $\mathcal{C}'_d$ obtained from $\mathcal{A}$ with a unique initial state chosen from amongst the initial states of $\mathcal{A}$ and a unique final state chosen from amongst the final states of $\mathcal{A}$. Since $u = v$ holds in $\mathcal{C}'_d$, we get:

$$[\![\mathcal{A}]\!](u) = \max_{\mathcal{B}\in\mathcal{S}} ([\![\mathcal{B}]\!](u)) = \max_{\mathcal{B}\in\mathcal{S}} ([\![\mathcal{B}]\!](v)) = [\![\mathcal{A}]\!](v)$$

and thus $u = v$ holds in $\mathcal{C}_d$. ◀

Weights. The set of identities which hold in $\mathcal{C}_d$ does not change when restricting the weights to have values in $\mathbb{N}$ or when allowing them to take values in $\mathbb{Q}$ or $\mathbb{R}$. Some directions are clear by definitions. We give ideas for the others.

From $\mathbb{Z}$ to $\mathbb{N}$. Consider an identity $u = v$ which holds in the class of d-state max-plus automata with weights in $\mathbb{N}$. It follows from the proof of Lemma 3 that $|u| = |v|$. Now let $\mathcal{A} \in \mathcal{C}_d$ and consider the max-plus automaton $\mathcal{A}_k$ obtained from $\mathcal{A}$ by adding the same integer k to the weight of all transitions in $\mathcal{A}$. Since $\mathcal{A}$ has finitely many transitions it is clear that we can choose k large enough so that $\mathcal{A}_k$ has weights in $\mathbb{N}$. Then we get, $[\![\mathcal{A}]\!](u) = [\![\mathcal{A}_k]\!](u) - k|u| = [\![\mathcal{A}_k]\!](v) - k|v| = [\![\mathcal{A}]\!](v)$, from which it follows that $u = v$ holds for all $\mathcal{A} \in \mathcal{C}_d$.

From $\mathbb{Q}$ to $\mathbb{Z}$. Consider an identity $u = v$ that holds in $\mathcal{C}_d$ and let $\mathcal{A}$ be a d-state max-plus automaton with weights in $\mathbb{Q}$. By multiplying all the weights on the transitions of $\mathcal{A}$ by a suitable non-zero integer k (*e.g.* the *lcm* of the denominators), we get a max-plus automaton $\mathcal{A}_k$ with weights in $\mathbb{Z}$, such that $[\![\mathcal{A}]\!](u) = \frac{1}{k}[\![\mathcal{A}_k]\!](u) = \frac{1}{k}[\![\mathcal{A}_k]\!](v) = [\![\mathcal{A}]\!](v)$.

From $\mathbb{R}$ to $\mathbb{Q}$. Consider an identity $u = v$ that holds in the class of d-state max-plus automata with weights in $\mathbb{Q}$ and let $\mathcal{A}$ be a d-state max-plus automaton with weights in $\mathbb{R}$. Let $(\mathcal{A}_m)_{m\in\mathbb{N}}$ be a sequence of max-plus automata constructed from $\mathcal{A}$ by changing all the real weights to rational weights in such a way that for every transition of $\mathcal{A}$ weighted by α, the sequence of weights $\alpha_m \in \mathbb{Q}$ of the corresponding transitions in $\mathcal{A}_m$ tends to α. Since limits can be commuted with maximum and sum over finite sets, we have:

$$[\![\mathcal{A}]\!](u) = \lim_{m\to\infty} [\![\mathcal{A}_m]\!](u) = \lim_{m\to\infty} [\![\mathcal{A}_m]\!](v) = [\![\mathcal{A}]\!](v)$$

Finally, we show that we need only to consider *full automata*. An automaton is said to be full if for every pair of states p, q and every letter a, there is a transition from p to q labelled by a.

▶ **Lemma 5.** *An identity $u = v$ holds in $\mathcal{C}_d$ if and only if it holds in the subclass of $\mathcal{C}_d$ consisting of full automata.*

Proof. The if direction is clear by definition. For the converse direction, consider an identity $u = v$ which holds in the subclass of $\mathcal{C}_d$ consisting of full automata. Suppose for contradiction that $\mathcal{A} \in \mathcal{C}_d$ is an automaton falsifying the identity. For each integer k, construct the full automaton $\mathcal{A}_k$ from $\mathcal{A}$ by adding in any missing transitions and weighting these by k. If $[\![\mathcal{A}]\!](u) = -\infty$ (meaning that there is no accepting run on u) then for all k, the accepting runs on u in $\mathcal{A}_k$ necessarily take a transition weighted by k (we suppose that $\mathcal{A}$ has at least one

initial and one final state). By assumption, $[\![\mathcal{A}]\!](v)$ must be finite (otherwise $\mathcal{A}$ does not falsify the identity) and by construction, necessarily for all k, $[\![\mathcal{A}_k]\!](v) \geqslant [\![\mathcal{A}]\!](v)$ (since $\mathcal{A}$ is contained in $\mathcal{A}_k$). Let us denote by m the maximal weight on a transition of $\mathcal{A}$. Then, consider k less than $[\![\mathcal{A}]\!](v) - (|u| - 1)m$. We get $[\![\mathcal{A}_k]\!](v) = [\![\mathcal{A}_k]\!](u) \leqslant k + (|u| - 1)m < [\![\mathcal{A}]\!](v)$, which leads to a contradiction. The same reasoning holds if $[\![\mathcal{A}]\!](v) = -\infty$. Otherwise, if $[\![\mathcal{A}]\!](u)$ and $[\![\mathcal{A}]\!](v)$ are both finite, and by considering k large and negative enough, $[\![\mathcal{A}]\!](u) = [\![\mathcal{A}_k]\!](u) = [\![\mathcal{A}_k]\!](v) = [\![\mathcal{A}]\!](u)$, since each maximal accepting run will avoid the transitions weighted by k. ◀

Number of letters. An identity on a 2-letter alphabet can be seen as an identity over a larger alphabet and it is easy to see that for all $k \geqslant 2$ the identity holds in the class of d-state max-plus automata over two letters if and only if it holds in the class of d-state max-plus automata over k letters. Suppose now that $u = v$ is an identity holding in $\mathcal{C}_d$ over an alphabet Σ containing at least three letters. Since u and v are distinct, they must differ in some position, i say. Suppose then that $u_i \neq v_i$. Now, consider $\bar{u}$ and $\bar{v}$ obtained from u and v by replacing every letter, except v_i, by u_i. By construction $\bar{u}$ and $\bar{v}$ are distinct. We are going to prove that $\bar{u} = \bar{v}$ holds in the class of max-plus automata over Σ. Indeed, consider a d-state max-plus automaton $\mathcal{A}$ over Σ. Construct first an automaton $\mathcal{A}'$ obtained from $\mathcal{A}$ by removing all the transitions not labelled by u_i or v_i. Then construct an automaton $\mathcal{B}$ over Σ obtained from $\mathcal{A}'$, by adding copies of the transitions labelled by u_i for all the other letters, except v_i, *i.e.* for every transition $p \xrightarrow{u_i \,:\, \alpha} q$, and every letter $c \neq v_i$, add the transition $p \xrightarrow{c \,:\, \alpha} q$. Then,

$$
\begin{aligned}
[\![\mathcal{A}]\!](\bar{u}) &= [\![\mathcal{A}']\!](\bar{u}) && \text{since } \bar{u} \text{ contains only } u_i\text{'s and } v_i\text{'s} \\
&= [\![\mathcal{B}]\!](\bar{u}) && \text{since } \bar{u} \text{ contains only } u_i\text{'s and } v_i\text{'s} \\
&= [\![\mathcal{B}]\!](u) && \text{since every letter } c \neq v_i \text{ mimics } u_i \text{ in } \mathcal{B} \\
&= [\![\mathcal{B}]\!](v) && \text{since } u = v \text{ is an identity over } \Sigma \text{ holding in } \mathcal{C}_d \\
&= [\![\mathcal{B}]\!](\bar{v}) && \text{since every letter } c \neq v_i \text{ mimics } u_i \text{ in } \mathcal{B} \\
&= [\![\mathcal{A}]\!](\bar{v}) && \text{since } \bar{v} \text{ contains only } u_i\text{'s and } v_i\text{'s}
\end{aligned}
$$

Thus, if an identity over Σ holds in $\mathcal{C}_d$ then an identity of the same length using just two letters must also hold in $\mathcal{C}_d$. Since we are interested in minimal length identities, in the rest of the paper we will consider only 2-letter alphabets.

3 Minimality

As explained at the end of the previous section, from now on we fix a 2-letter alphabet $\Sigma = \{a, b\}$. In this section, we provide a list of conditions which must all be satisfied by the identities holding in $\mathcal{C}$. Thanks to this list and aided by a computer, we are left with exactly two pairs of words (up to exchanging a and b) of length shorter than 18 which are still candidates to be identities in $\mathcal{C}$. In the next section, we prove that they are indeed identities in $\mathcal{C}$.

3.1 Triangular identities

A max-plus automaton with two states p and q is said to be *triangular* if there is no transition either from p to q or from q to p. We denote by $\mathcal{C}_\mathcal{T}$ this class of automata. An identity holding in $\mathcal{C}$ must also hold in $\mathcal{C}_\mathcal{T}$. Identities holding in the class of triangular automata

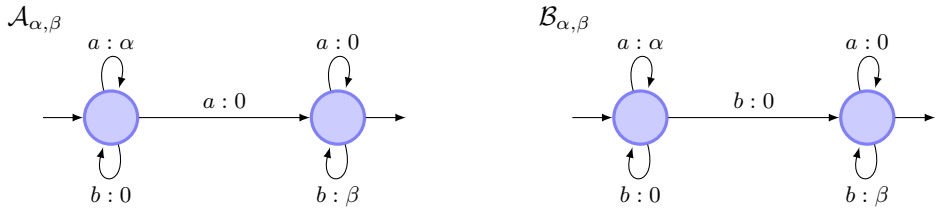
are much easier to study. They are fully characterised in [3], where it is proved that they are exactly the identities holding in the bicyclic monoid. More generally, several works [6, 7, 10, 1, 3] study identities holding in the class of triangular max-plus automata with d states, which correspond to the semigroup of upper-triangular matrices, where it has been proved that such an identity always exists.

Let us recall that if $u = v$ holds in $\mathcal{C}_\mathcal{T}$, then u and v have the same content (since the automata constructed in Lemma 3 are indeed triangular).

Beginning and end of a word. The *first* (*resp. second*, *last*, *penultimate*) *block* of a word w is the first (*resp.* second, last, penultimate) maximal block of the same consecutive letter of w. For example, for $w = a^3b^2a^6b^7a^4b$, these blocks are respectively a^3, b^2, b and a^4.

▶ **Lemma 6.** *If $u = v$ is an identity holding in $\mathcal{C}_\mathcal{T}$, then u and v have the same first, second, last and penultimate blocks respectively.*

Triangular identities. We give here a variant of a property in [3, Th 3.3 and Cor 3.4]. We show that the identities $u = v$ which hold in $\mathcal{C}_\mathcal{T}$ are exactly those such that u and v have the same content, the same first and last blocks, and which hold in the class of max-plus automata of one of the following shape, where α and β are integers either both positive or both negative:



If an identity holds for the class of all the max-plus automata of the form $\mathcal{A}_{\alpha,\beta}$ and $\mathcal{B}_{\alpha,\beta}$ for all integers α, β either both positive or both negative, the identity is said to be a *triangular identity*.

Checking triangular identities. Checking if a given identity $u = v$ is triangular can be done by symbolic computation using the shape of the automata above. More precisely, for any position i in a word w, we denote by $w_{<i}$ (*resp.* $w_{>i}$) the prefix of w strictly before position i (*resp.* the suffix of w strictly after position i). We get:

$$[\![\mathcal{A}_{\alpha,\beta}]\!](w) = \max_{w_i=a} (\alpha|w_{<i}|_a + \beta|w_{>i}|_b) \quad \text{and} \quad [\![\mathcal{B}_{\alpha,\beta}]\!](w) = \max_{w_i=b} (\alpha|w_{<i}|_a + \beta|w_{>i}|_b)$$

The identity $u = v$ is triangular if and only if for all integers α, β of the same sign, $[\![\mathcal{A}_{\alpha,\beta}]\!](u) = [\![\mathcal{A}_{\alpha,\beta}]\!](v)$ and $[\![\mathcal{B}_{\alpha,\beta}]\!](u) = [\![\mathcal{B}_{\alpha,\beta}]\!](v)$. It is proved in [3, Th 8.3] that it can be checked in polynomial time with respect to the sum of the lengths of u and v (even for a larger number of states). Another easy way to check a triangular identity in a reasonable time for identities of small length is to note that the parameters can be bounded:

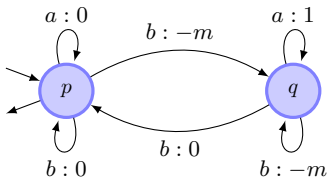
▶ **Lemma 7.** *Given two words u and v of the same length ℓ, $[\![\mathcal{A}_{\alpha,\beta}]\!](u) = [\![\mathcal{A}_{\alpha,\beta}]\!](v)$ (resp. $[\![\mathcal{B}_{\alpha,\beta}]\!](u) = [\![\mathcal{B}_{\alpha,\beta}]\!](v)$) holds for all integers α, β either both positive or both negative if and only if it holds for all such α, β with $|\alpha|$, $|\beta|$ bounded by $2\ell^2$.*

3.2 Block-permutation

Two words u and v are said to be *block-permuted* if u and v are composed of the same maximal blocks of the same consecutive letter but possibly in a different order. For example, $a^3b^2a^4b$ and $b^2a^3ba^4$ are block-permuted but $a^3b^2a^4b$ and a^2baba^4b are not.

▶ **Lemma 8.** *If $u = v$ is an identity which holds in $\mathcal{C}$, then u and v are block-permuted.*

Proof. Consider an identity $u = v$ which holds in $\mathcal{C}$. Suppose that u and v are not block-permuted, and that the maximal blocks of occurrences of the letter a are different (the proof for the letter b is similar). Let us write $n_1 \geqslant n_2 \geqslant \ldots \geqslant n_\ell$ for the lengths (with multiplicities) of the maximal blocks of consecutive a in u (*resp.* $m_1 \geqslant m_2 \geqslant \ldots \geqslant m_{\ell'}$ for v). By Lemma 3, u and v have the same content and so there must exist an index $i \in \{1, \ldots, \min(\ell, \ell')\}$ such that $n_j = m_j$ for all $j < i$, whilst $n_i \neq m_i$. Without loss of generality, suppose that $n_i > m_i$ and consider the following automaton where $m = n_i - 1$.



There are four options to read a word of the form ba^k (ignoring initial and final states for the moment): (1) around p with weight 0, (2) from p to q with weight $-m + k$, (3) around q with weight $-m + k$, or (4) from q to p with weight 0. Thus, if a maximal block of a is of length greater than m (except possibly the first or the last one), it should be read around q, otherwise, it should be read around p. By Lemma 6, u and v must have the same first and last blocks. For each $k = 1, \ldots, \ell$, let $N(k)$ be the set of indices from $1 \leqslant t \leqslant k$ such that a^{n_t} is not the first block of u and v, nor the last block of u and v. It is now easy to see that the weight of u must be greater than or equal to $\sum_{j \in N(i)}(n_j - m)$, while the weight of v is $\sum_{j \in N(i-1)}(n_j - m)$, which is smaller than the weight of u. Since this contradicts the fact that $u = v$ holds in $\mathcal{C}$, we conclude that $n_i = m_i$ for all i; or in other words, u and v are block-permuted. ◀

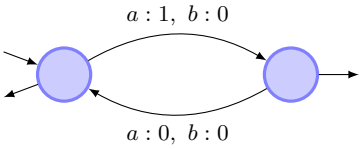
▶ **Corollary 9.** *If $u = v$ is an identity that holds in $\mathcal{C}$, then u and v each contain at least 7 maximal blocks of the same consecutive letter.*

Proof. Consider an identity $u = v$ with $u = a^{k_1}b^{k_2}a^{k_3}b^{k_4}a^{k_5}b^{k_6}$. If it holds in $\mathcal{C}$, then by Lemma 6, v must start with $a^{k_1}b^{k_2}$ and end with $a^{k_5}b^{k_6}$. Finally, by Lemma 8, necessarily u and v are the same word. ◀

3.3 Counting and parity conditions

Finally the last conditions we consider involve a finite number of max-plus automata with weights within $\{0, 1\}$ dealing in some sense with parity and counting conditions.

(C1). *The number of occurrences of the letter a in an even position.* This value is computed by the following automaton:



Note that, if two words have the same content, then the equality of this parameter for the two words implies the equality of all the other variants (number of b's in an odd position...). Indeed, the number of a's in an odd position is equal to the difference between the total number of a's and the number of a's in an even position. The number of b's in an even position is the difference between the total number of even positions and the number of a's in an even position.

(C2). *The number of occurrences of the letter a after an even number of b, and the number of occurrences of the letter b after an even number of a.* These values are computed respectively by the following automata:

As in the previous condition, providing two words have the same content, the equality on these parameters implies the equality on the other variants (number of a's after an odd number of b's, etc.). Indeed, the number of a's after an odd number of b's is equal to the difference between the total number of a's and the number of a's after an even number of b's...

The two last conditions are more difficult to explain.

(C3). We consider the following automata, and in each case the automata obtained such that exactly one of the states is both initial and final, as well as those obtained by exchanging a and b.

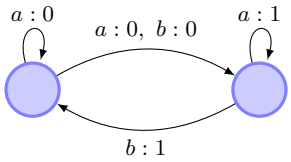
It can be checked that the words $ab^3ababa^3b^3a^2$ and $ab^3a^3babab^3a^2$ cannot be separated by any of the previously discussed conditions. However the automaton on the right, taking p to be both initial and final is able to do so, as we shall now show. The beginning of the two words are read deterministically until reaching the factor a^3. There, a non-deterministic choice is made to optimise the weight obtained by reading the end of the word. This choice is made at different positions in the two words leading to two different weights. More precisely, the maximal run for the word $ab^3ababa^3b^3a^2$ is as follows:

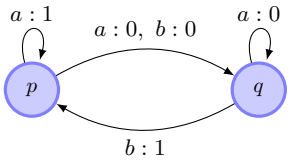
$$p \xrightarrow{ab^3\ :\ 1} p \xrightarrow{ababa\ :\ 0} \underbrace{q \xrightarrow{a^2\ :\ 0} p}_{\text{non-det choice}} \xrightarrow{b^3\ :\ 2} q \xrightarrow{a^2\ :\ 0} p$$

while the one for $ab^3a^3babab^3a^2$ is as follows:

$$p \xrightarrow{ab^3\,:\,1} \underbrace{p \xrightarrow{a^2\,:\,0} q}_{\text{non-det choice}} \xrightarrow{ababa\,:\,2} p \xrightarrow{b^3\,:\,2} q \xrightarrow{a^2\,:\,0} p$$

(C4). We consider the following automata, and in each case the automata obtained such that exactly one of the states is both initial and final, as well as those obtained by exchanging a and b.





The words $ab^2a^2ba^2ba^4b^3a$ and $ab^2a^4ba^2ba^2b^3a$ cannot be separated by any of the previously discussed conditions, whilst the automaton on the right, taking q to be both initial and final is able to do so. The beginning of the two words are read deterministically until reaching the factor a^2 in the middle of the two words. This determinism forces to read the two first blocks of a with weight 0, while the other ones will be read with weight 1. This leads to different results because of the commutation of the blocks a^2 and a^4 in the two words. More precisely, a maximal run for the word $ab^2a^2ba^2ba^4b^3a$ is as follows:

$$q \xrightarrow{ab^2a^2b\,:\,2} \underbrace{p \xrightarrow{a^2\,:\,1} q}_{\text{non-det choice}} \xrightarrow{b\,:\,1} p \xrightarrow{a^4\,:\,4} p \xrightarrow{b^3a\,:\,1} q$$

while the one for $ab^2a^4ba^2ba^2b^3a$ is as follows:

$$q \xrightarrow{ab^2a^4b\,:\,2} \underbrace{p \xrightarrow{a^2\,:\,1} q}_{\text{non-det choice}} \xrightarrow{b\,:\,1} p \xrightarrow{a^2\,:\,2} p \xrightarrow{b^3a\,:\,1} q$$

An identity $u = v$ is said to satisfy **(C1)**, **(C2)**, **(C3)** or **(C4)** if the same values is computed on u and v by the automata given above.

▶ **Proposition 10.** *There are exactly four triangular identities $u = v$ of length shorter than* 18 *satisfying* **(C1)**, **(C2)**, **(C3)** *and* **(C4)** *in which u and v are block-permuted and have the same first and last blocks.*

We have checked all these conditions assisted by a computer, with a program listing all the pairs of words not eliminated by one of these conditions.

Moreover, this list of conditions is in some sense minimal since for each of them, there are examples of pairs that are not eliminated when removing the condition from the list. These examples are also exhibited by our program.

We remark that if the block-permutation condition holds then the only automata we need to consider which involve weights not within $\{0, 1\}$ are the ones corresponding to the triangular conditions. This list of conditions is probably not sufficient to characterise fully the identities which hold in $\mathcal{C}$, however, one can ask if we can extend it and keep this distinction between the triangular conditions with arbitrary weights and the other conditions involving only weights in $\{0, 1\}$.

There are exactly four remaining candidates:

$$a^2b^3a^3babab^3a^2 = a^2b^3ababa^3b^3a^2, \quad ab^3a^4baba^2b^3a = ab^3a^2baba^4b^3a$$

and the ones obtained by exchanging the roles of a and b. In the next section, we prove that they indeed hold in $\mathcal{C}$.

4 The shortest identities

In this section, we conclude the proof of Theorem 1 by proving that the remaining candidate identities hold in $\mathcal{C}$. By exchanging the role of a and b, it is sufficient to prove the following proposition:

▶ **Proposition 11.** *The following two identities hold in $\mathcal{C}$:*

(I1) $a^2b^3a^3babab^3a^2 = a^2b^3ababa^3b^3a^2$ *and* **(I2)** $ab^3a^4baba^2b^3a = ab^3a^2baba^4b^3a$

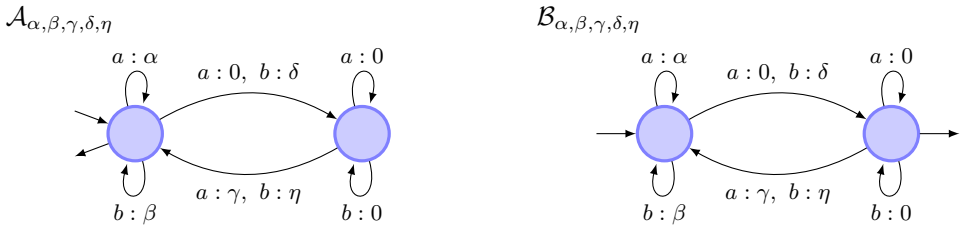
For a word $u = a_0 \cdots a_\ell$ of length $\ell + 1$, let us denote by $\tilde{u} = a_\ell \cdots a_0$ the *reverse* of u.

▶ **Lemma 12.** *Let $u \in \Sigma^+$. If $[\![\mathcal{A}]\!](u) \geqslant [\![\mathcal{A}]\!](\tilde{u})$ for all $\mathcal{A}$ in $\mathcal{C}$, then $u = \tilde{u}$ is an identity which holds in $\mathcal{C}$.*

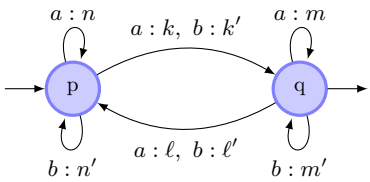
Proof. Consider an automaton $\mathcal{A}$ in $\mathcal{C}$. By hypothesis, $[\![\mathcal{A}]\!](u) \geqslant [\![\mathcal{A}]\!](\tilde{u})$. Construct now $\mathcal{B}$ obtained from $\mathcal{A}$ by reversing the transitions, *i.e.* there is a transition $p \xrightarrow{c\,:\,\alpha} q$ in $\mathcal{A}$ if and only if there is a transition $q \xrightarrow{c\,:\,\alpha} p$ in $\mathcal{B}$. Moreover the initial (*resp.* final) states of $\mathcal{B}$ are defined from the final (*resp.* initial) states of $\mathcal{A}$. By this construction, $[\![\mathcal{A}]\!](\tilde{u}) = [\![\mathcal{B}]\!](u) \geqslant [\![\mathcal{B}]\!](\tilde{u}) = [\![\mathcal{A}]\!](u)$. Thus $[\![\mathcal{A}]\!](\tilde{u}) = [\![\mathcal{A}]\!](u)$ for all $\mathcal{A}$ in $\mathcal{C}$ and hence $u = \tilde{u}$ holds in $\mathcal{C}$. ◀

Remark that the two identities **(I1)** and **(I2)** are of the form $u = \tilde{u}$.

▶ **Lemma 13.** *Given two words u and v of the same content, $[\![\mathcal{A}]\!](u) \geqslant [\![\mathcal{A}]\!](v)$ for all $\mathcal{A}$ in $\mathcal{C}$ if and only if $[\![\mathcal{B}]\!](u) \geqslant [\![\mathcal{B}]\!](v)$ for all $\mathcal{B}$ of one of the following two forms, where α, β, γ, δ, η are integers:*



Proof. The if direction is clear by definition. Conversely, denote by $\mathcal{C}'$ the class of automata described in the statement of the proposition. Suppose that $[\![\mathcal{B}]\!](u) \geqslant [\![\mathcal{B}]\!](v)$ for all $\mathcal{B} \in \mathcal{C}'$. Consider $\mathcal{A} \in \mathcal{C}$. First, by the proof of Lemma 5, we can suppose that $\mathcal{A}$ is full and by Lemma 4, that $\mathcal{A}$ has exactly one initial and one final state. Suppose that these two states are different. If not, a similar reasoning will hold, involving $\mathcal{A}_{\alpha,\beta,\gamma,\delta,\eta}$ instead of $\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}$. We represent $\mathcal{A}$ in the following picture:



First, construct $\mathcal{A}'$ from $\mathcal{A}$ by removing m (*resp.* m') from all the weights of the transitions labelled by a (*resp.* b). Then construct $\mathcal{B}$ from $\mathcal{A}'$ by removing $k - m$ from the weights of

the transitions labelled by a and b from p to q and adding $k-m$ from the weights of the transitions labelled by a and b from q to p. By construction, $\mathcal{B}$ is in $\mathcal{C}'$. We get:

$$\begin{aligned}
[\![\mathcal{A}]\!](u) &= [\![\mathcal{A}']\!](u) + m'|u|_b + m|u|_a && \text{by construction}\\
&= [\![\mathcal{B}]\!](u) + (k-m) + m'|u|_b + m|u|_a && \text{since } p \text{ is initial and } q \text{ final, thus on an}\\
&&& \text{accepting run, the transitions from}\\
&&& p \text{ to } q \text{ are taken (in total) exactly once}\\
&&& \text{more than the transitions from } q \text{ to } p\\
&\geqslant [\![\mathcal{B}]\!](v) + (k-m) + m'|v|_b + m|v|_a && \text{since } \mathcal{B} \text{ is in } \mathcal{C}' \text{ and}\\
&&& u \text{ and } v \text{ have the same content}\\
&\geqslant [\![\mathcal{A}']\!](v) + m'|v|_b + m|v|_a && \text{for the same reason as above}\\
&\geqslant [\![\mathcal{A}]\!](v) && \text{by construction}
\end{aligned}$$

◀

Let us consider **(I1)** and denote $u = a^2b^3a^3babab^3a^2$. By Lemmas 12 and 13, for proving that **(I1)** holds in $\mathcal{C}$, it is sufficient to prove that for all integers $\alpha, \beta, \gamma, \delta, \eta$, $[\![\mathcal{A}_{\alpha,\beta,\gamma,\delta,\eta}]\!](u) \geqslant [\![\mathcal{A}_{\alpha,\beta,\gamma,\delta,\eta}]\!](\tilde{u})$ and $[\![\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}]\!](u) \geqslant [\![\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}]\!](\tilde{u})$. Consider $\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}$. Aided by computer, we compute symbolically the values on u and on its reverse in $\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}$ as a tropical polynomial in α, β, γ, δ, η. Each monomial term corresponds to the weight of an accepting (but not necessarily maximal weight) run. For example, the monomial term $8\alpha + 8\beta$ corresponds to an accepting run on u (when reading u around the initial state and going to the final state on the last transition) and in fact on $\tilde{u}$ also. We denote by M_u, $M_{\tilde{u}}$ and M the set of monomials appearing only in the computation of u, only in the computation of $\tilde{u}$ or for both, respectively. We compute these three sets aided by a computer.

Finally, we prove that for each monomial in $M_{\tilde{u}}$ and each choice of parameters $\alpha, \beta, \gamma, \delta, \eta \in \mathbb{Z}$, there is a monomial in $M_u \cup M$ which is greater on the values $\alpha, \beta, \gamma, \delta, \eta$. This concludes the proof that $[\![\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}]\!](u) \geqslant [\![\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}]\!](\tilde{u})$ for all integers $\alpha, \beta, \gamma, \delta, \eta$. To do so, there is no need to consider the monomials in $M_{\tilde{u}}$ in which neither γ nor η appears. Indeed, we already checked in the previous section that **(I1)** satisfies the triangular conditions. Thus, $u = \tilde{u}$ holds for triangular automata. Consider $\mathcal{B}'_{\alpha,\beta,\delta}$ constructed from $\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}$ by removing the transitions from the final state to the initial state. A monomial in $M_{\tilde{u}}$ in which neither γ nor η appears corresponds to an accepting run in $\mathcal{B}'_{\alpha,\beta,\delta}$, and hence is bounded above by $\mathcal{B}'_{\alpha,\beta,\delta}(\tilde{u}) = \mathcal{B}'_{\alpha,\beta,\delta}(u)$, since this automaton is triangular. The latter is clearly bounded above by $\mathcal{B}_{\alpha,\beta,\gamma,\delta,\eta}(u)$. So for all monomials in $M_{\tilde{u}}$ in which neither γ nor η and each choice of parameters $\alpha, \beta, \gamma, \delta, \eta \in \mathbb{Z}$, there is necessarily a monomial in $M_u \cup M$ which is greater on the values $\alpha, \beta, \gamma, \delta, \eta$. Finally, the set $M_{\tilde{u}}$ without these monomials is of reasonable size and we are able to complete the computations by hand.

Similar computations hold for $\mathcal{A}_{\alpha,\beta,\gamma,\delta,\eta}$ and for **(I2)**.

5 Conclusion

In this paper, we give the shortest identities which hold in the class of max-plus automata with two states. We hope that a better understanding of this case is a first step towards a better understanding of the general case. In particular, we give an interesting list of conditions which are sufficient to achieve this goal. Future works will consist in trying to understand better these conditions and how to extend this list to fully characterise the sets of identities for max-plus automata with two states. In particular, we remark that under the

block-permutation condition, the only automata we need to consider which involve weights not within $\{0, 1\}$ are the ones corresponding to the triangular conditions. We ask if we can generalise this list of conditions to get the shortest identities for a larger number of states, and keep this distinction between the triangular conditions with arbitrary weights and the other conditions involving only weights in $\{0, 1\}$.

Abstract

We study the size and the complexity of computing finite state automata (FSA) representing and approximating the downward and the upward closure of Petri net languages with coverability as the acceptance condition. We show how to construct an FSA recognizing the upward closure of a Petri net language in doubly-exponential time, and therefore the size is at most doubly exponential. For downward closures, we prove that the size of the minimal automata can be non-primitive recursive. In the case of BPP nets, a well-known subclass of Petri nets, we show that an FSA accepting the downward/upward closure can be constructed in exponential time. Furthermore, we consider the problem of checking whether a simple regular language is included in the downward/upward closure of a Petri net/BPP net language. We show that this problem is EXPSPACE-complete (resp. NP-complete) in the case of Petri nets (resp. BPP nets). Finally, we show that it is decidable whether a Petri net language is upward/downward closed.

1 Introduction

Petri nets are a popular model of concurrent systems [14]. Petri net languages (with different acceptance conditions) have been extensively studied during the last years, including deciding their emptiness (which can be reduced to reachability) [31, 23, 25, 26], their regularity [39, 11], their context-freeness [38, 27], and many other decision problems (e.g. [17, 2, 15]). In this paper, we consider the class of Petri net languages with coverability as the acceptance condition (i.e. the set of sequences of transition labels occurring in a computation reaching a marking greater than or equal to a given final marking).

We address the problem of computing the *downward* and the *upward* closure of Petri net languages. The downward closure of a language L, denoted by $L{\downarrow}$, is the set of all subwords, all words that can be obtained from words in L by deleting letters. The upward closure of L, denoted by $L{\uparrow}$, is the set of all superwords, all words that can be obtained from words in

* The full version is available as technical report [7].
† A part of this work was carried out when the author was at Aalto University.

L by inserting letters. It is well-known that, for any language, the downward and upward closure are regular and can be described by a *simple regular expression (SRE)*. However, such an expression is in general not computable, e.g. for example, it is not possible to compute the downward closure of languages recognized by lossy channel systems [33].

In this paper, we first consider the problem of constructing a finite state automaton (FSA) accepting the upward/downward closure of a Petri net language. We give an algorithm that computes an FSA of doubly-exponential size for the upward closure in doubly-exponential time. This is done by showing that every minimal word results from a computation of length at most doubly exponential in the size of the input. Our algorithm is also optimal since we present a family of Petri net languages for which the minimal finite state automata representing their upward closure are of doubly-exponential size.

Our second contribution is a family of Petri net languages for which the size of the minimal finite state automata representing the downward closure is non-primitive recursive: The languages contain Ackermann many words. The downward closure of Petri net languages has been shown to be effectively computable [17]. The algorithm is based on the Karp-Miller tree [22], which has non-primitive recursive complexity.

Furthermore, we consider the SRE inclusion problem which asks whether the language of a simple regular expression is included in the downward/upward closure of a Petri net language. The idea behind SRE inclusion is to stratify the problem of computing the downward/upward closure: Rather than having an algorithm computing all information about the language, we imagine to have an oracle (e.g. an enumeration) making proposals for SREs that could be included in the downward/upward closure. The task of the algorithm is merely to check whether a proposed inclusion holds. We show that this problem is EXPSPACE-complete in both cases. In the case of upward closures, we prove that SRE inclusion boils down to checking whether the set of minimal words of the given SRE is included in the upward closure. In the case of downward closures, we reduce the problem to the simultaneous unboundedness problem for Petri nets, which is EXPSPACE-complete [11].

We also study the problem of checking whether a Petri net language actually is upward or downward closed. This is interesting as it means that an automaton for the closure, which we can compute with the aforementioned methods, is a precise representation of the system's behavior. We show that the problem of being upward/downward closed is decidable for Petri nets. The result is a consequence of a more general decidability that we believe is of independent interest. We show that checking whether a regular language is included in a Petri net language (with coverability as the acceptance condition) is decidable. Here, we rely on a decision procedure for trace inclusion due to Esparza et al. [21].

Finally, we consider *BPP*[1] *nets* [13], a subclass of Petri nets defined by a syntactic restriction: Every transition is allowed to consume at most one token in total. We show that we can compute finite state automata accepting the upward and the downward closure of a BPP net language in exponential time. The size of the FSA is also exponential. Our algorithms are optimal as we present a family of BPP net languages for which the minimal FSA representing their upward/downward closure have exponential size. Furthermore, we consider the SRE inclusion problem. We show that, in the case of BPP nets, it is NP-complete for both, inclusion in the upward and in the downward closure. To prove the upper bound, we reduce to the satisfiability problem for existential Presburger arithmetic (which is known to be NP-complete [37]). The hardness is by a reduction from SAT to the emptiness of BPP net languages, which in turn reduces to SRE inclusion.

[1] BPP stands for *basic parallel processes*, a notion from process algebra.

Related Work. Several constructions have been proposed in the literature to compute finite state automata recognizing the downward/upward closure. In the case of Petri net languages (with various acceptance conditions including reachability), it has been shown that the downward closure is effectively computable [17]. With the results in this paper, the computation and the state complexity have to be non-primitive recursive. For the languages generated by context-free grammars, effective computability of the downward closure is due to [40, 16, 10, 8]. For the languages recognized by one-counter automata, a strict subclass of the context-free languages, it has been shown how to compute in polynomial time a finite state automaton accepting the downward/upward closure of the language [6]. The effective computability of the downward closure has also been shown for stacked counter automata [43]. In [42], Zetzsche provides a characterization for a class of languages to have an effective downward closure. It has been used to prove the effective computability of downward closures of higher-order pushdown automata and higher-order recursion schemes [18, 9]. The downward closure of the languages of lossy channel systems is not computable [33].

The computability results discussed above have been used to prove the decidability of verification problems and to develop approximation-based program analysis methods (see e.g. [5, 4, 3, 24, 30, 44]). Throughout the paper, we will give hints to applications in verification.

2 Preliminaries

In this section, we fix some basic definitions and notations that will be used throughout the paper. For every $i, j \in \mathbb{N}$ with $i \leq j$, we use $[i..j]$ to denote the set $\{k \in \mathbb{N} \mid i \leq k \leq j\}$ (resp. $[i..j[$ for $\{k \in \mathbb{N} \mid i \leq k < j\}$). Let Σ be a finite alphabet. We use Σ_ε to denote $\Sigma \cup \{\varepsilon\}$. The length of a word u over Σ is denoted by $|u|$, where $|\varepsilon| = 0$. Let $k \in \mathbb{N}$ be a natural number, we use Σ^k (resp. $\Sigma^{\leq k}$) to denote the set of all words of length equal (resp. smaller or equal) to k. A language L over Σ is a (possibly infinite) set of finite words.

Let Γ be a subset of Σ. Given a word $u \in \Sigma^*$, we denote by $\pi_\Gamma(u)$ the projection of u over Γ, i.e. the word obtained from u by erasing all the letters that are not in Γ.

The *Parikh image* of a word [34] counts the number of occurrences of all letters while forgetting about their positioning. Formally, the function $\Psi : \Sigma^* \mapsto \mathbb{N}^\Sigma$ takes a word $w \in \Sigma^*$ and gives the function $\Psi(w) : \Sigma \to \mathbb{N}$ defined by $(\Psi(w))(a) = \left|\pi_{\{a\}}(w)\right|$ for all $a \in \Sigma$.

The *subword relation* $\preceq \subseteq \Sigma^* \times \Sigma^*$ [20] between words is defined as follows: A word $u = a_1 \dots a_n$ is a subword of v, denoted $u \preceq v$, if u can be obtained by deleting letters from v or, equivalently, if $v = v_0 a_1 v_1 \dots a_n v_n$ for some $v_0, \dots, v_n \in \Sigma^*$.

Let L be a language over Σ. The *upward closure* of L consists of all words that have a subword in the language, $L{\uparrow} = \{v \in \Sigma^* \mid \exists u \in L : u \preceq v\}$. The *downward closure* of L contains all words that are dominated by a word in the language, $L{\downarrow} = \{u \in \Sigma^* \mid \exists v \in L : u \preceq v\}$. Higman showed that the subword relation is a well-quasi ordering [20], which means that every set of words $S \subseteq \Sigma^*$ has a finite *basis* — a finite set of *minimal elements* $v \in S$ such that $\nexists u \in S : u \neq v, u \preceq v$. With finite bases, $L{\uparrow}$ and $L{\downarrow}$ are guaranteed to be regular for every language $L \subseteq \Sigma^*$ [19]. Indeed, they can be expressed using the subclass of simple regular languages defined by so-called *simple regular expressions* [1]. These SREs are choices among *products* p, $sre ::= p \mid sre + sre$. Products interleave single letters a or $(a + \varepsilon)$ with iterations over letters from subsets $\Gamma \subseteq \Sigma$ of the alphabet: $p ::= a \mid (a + \varepsilon) \mid \Gamma^* \mid p.p$. The syntactic size of an SRE sre is denoted by $|sre|$ and defined as expected.

Finite State Automata. A *finite state automaton (FSA)* A is a tuple $(Q, \to, q_0, Q_f, \Sigma)$ where Q is a finite non-empty set of states, Σ is the finite input alphabet, $\to \subseteq Q \times \Sigma_\varepsilon \times Q$ is the non-deterministic transition relation, $q_0 \in Q$ is the initial state, and $Q_f \subseteq Q$ is the set of

final states. We represent a transition $(q, a, q') \in \rightarrow$ by $q \xrightarrow{a}_A q'$ and generalize the relation to words in the expected way. The language of finite words accepted by A is denoted by $L(A)$. The size of A, denoted $|A|$, is defined by $|Q| + |\Sigma|$. An FSA is minimal for its language $L(A)$ if there is no FSA B with $L(A) = L(B)$ with a strictly smaller number of states.

Petri Nets. A *(labeled) Petri net* is a tuple $N = (\Sigma, P, T, F, \lambda)$ [36]. Here, Σ is a finite alphabet, P a finite set of *places*, T a finite set of *transitions*, $F : (P \times T) \cup (T \times P) \to \mathbb{N}$ a *flow function*, and $\lambda : T \mapsto \Sigma_\varepsilon$ a labelling function. When convenient, we will assume that the places are ordered, $P = [1..\ell]$ for some $\ell \in \mathbb{N}$. For a place or transition $x \in P \cup T$, we define the *preset* to consist of the elements that have an arc to x, ${}^\bullet x = \{y \in P \cup T \mid F(y, x) > 0\}$. The *postset* is defined similarly, $x^\bullet = \{y \in P \cup T \mid F(x, y) > 0\}$.

To define the semantics of Petri nets, we use *markings* $M : P \to \mathbb{N}$ that assign to each place a number of *tokens*. A marking M *enables* a transition t, denoted $M[t\rangle$, if $M(p) \geq F(p, t)$ for all $p \in P$. A transition t that is enabled may be *fired*, leading to the new marking M' defined by $M'(p) = M(p) - F(p, t) + F(t, p)$ for all $p \in P$, i.e. t consumes $F(p, t)$ many tokens and produces $F(t, p)$ many tokens in p. We write the firing relation as $M[t\rangle M'$. A *computation* $\pi = M_0[t_1\rangle M_1 \cdots [t_m\rangle M_m$ consists of markings and transitions. We extend the firing relation to transition sequences $\sigma \in T^*$ in the straightforward manner and also write $\pi = M_0[\sigma\rangle M_m$. A marking M is *reachable* from an initial marking M_0 if $M_0[\sigma\rangle M$ for some $\sigma \in T^*$. A marking M covers another marking M_f, denoted $M \geq M_f$, if $M(p) \geq M_f(p)$ for all $p \in P$. A marking M_f is *coverable* from M_0 if there is a marking M reachable from M_0 that covers M_f, $M_0[\sigma\rangle M \geq M_f$ for some $\sigma \in T^*$.

Given a Petri net N, an initial marking M_0, and a final marking M_f, the associated *covering language* is $L(N, M_0, M_f) = \{\lambda(\sigma) \mid \sigma \in T^*,\ M_0[\sigma\rangle M \geq M_f\}$, where the labeling function λ is extended to sequences of transitions in the straightforward manner. Given a natural number $k \in \mathbb{N}$, we define $L_k(N, M_0, M_f) = \left\{\lambda(\sigma) \;\middle|\; \sigma \in T^{\leq k},\ M_0[\sigma\rangle M \geq M_f\right\}$ to be the set of words accepted by computations of length at most k.

Let $max(F)$ denote the maximum of the range of F. The size of the Petri net N is $|N| = |\Sigma| + \cdot |P| \cdot |T| \cdot (1 + \lceil log_2(1 + max(F)) \rceil)$, i.e. we assume that the flow function is encoded in binary. Similarly, the size of a marking M is $|M| = |P| \cdot (1 + \lceil log_2(1 + max(M)) \rceil)$, where $max(M)$ denotes the maximum of the range of M. We define the *token count* $tc(M) = \Sigma_{p \in P} M(p)$ of a marking M to be the sum of all tokens assigned by M.

A Petri net N is said to be a *BPP net* if every transition consumes at most one token from one place (i.e. $\Sigma_{p \in P} F(p, t) \leq 1$ for every $t \in T$).

3 Upward Closures

We consider the problem of constructing a finite state automaton accepting the upward closure of a Petri net and a BPP net language, respectively. The upward closure offers an over-approximation of the system behavior that is useful for verification purposes [30].

Petri Nets. We prove a doubly-exponential upper bound on the size of the finite state automaton representing the upward closure of a Petri net language. Then, we present a family of Petri net languages for which the minimal finite state automata representing their upward closure have a size doubly exponential in the size of the input.

Upper Bound. Fix the Petri net $N = (\Sigma, P, T, F, \lambda)$ and let M_0 and M_f be the initial and the final marking of interest. Define $n = |N| + |M_0| + |M_f|$.

▶ **Theorem 1.** *One can construct an FSA of size* $O(2^{2^{\text{poly}(n)}})$ *for* $L(N, M_0, M_f)\uparrow$.

The remainder of the section is devoted to proving the theorem. We will show that every minimal word results from a computation of length at most $O(2^{2^{\text{poly}(n)}})$. Let us call such computations the minimal ones. Let k be a bound on the length of the minimal computations. This means the language $L_k(N, M_0, M_f)$ contains all minimal words of $L(N, M_0, M_f)$. Furthermore, $L_k(N, M_0, M_f) \subseteq L(N, M_0, M_f)$ and therefore the equality $L_k(N, M_0, M_f)\uparrow = L(N, M_0, M_f)\uparrow$ holds. Now we can use the following lemma to construct a finite automaton whose size is $O(2^{2^{\text{poly}(|n|)}})$ and that accepts $L_k(N, M_0, M_f)$. Without an increase in size, this automaton can be modified to accept $L_k(N, M_0, M_f)\uparrow$.

▶ **Lemma 2.** *Consider* N, M_0, *and* M_f. *For every* $k \in \mathbb{N}$, *we can construct an FSA of size* $O((k+2)^{\text{poly}(n)})$ *that accepts* $L_k(N, M_0, M_f)$, *where* $n = |N| + |M_0| + |M_f|$.

It remains to show that every minimal word results from a computation of length at most doubly exponential in the size of the input. This is the following proposition.

▶ **Proposition 3.** *For every computation* $M_0[\sigma\rangle M \geq M_f$, *there is* $M_0[\sigma'\rangle M' \geq M_f$ *with* $\lambda(\sigma') \preceq \lambda(\sigma)$ *and* $|\sigma'| \leq 2^{2^{cn \log n}}$, *where* c *is a constant.*

Our proof is an adaptation of Rackoff's technique to show that coverability can be solved in EXPSPACE [35]. Rackoff derives a bound (similar to ours) on the length of the shortest computations that cover a given marking. Rackoff's proof has been generalized to different settings, e.g. to BVAS in [12]. Lemma 5.3 in [28] claims that Rackoff's original proof already implies Proposition 3. This is not true as we provide a counterexample in the full version of this paper [7]. To handle labeled Petri nets, his proof needs two amendments. First, it is not sufficient to consider the shortest covering computations. Instead, we have to consider computations long enough to generate all minimal words. Second, Rackoff's proof splits a firing sequence into two parts and replaces the second part by a shorter one. In our case, we need that the shorter word is a subword of the original one.

We now elaborate on Rackoff's proof strategy and give the required definitions, then we explain in more detail our adaptation, and finally give the technical details.

We assume that the places are ordered, i.e. $P = [1..\ell]$. Rackoff's idea is to relax the definition of the firing relation and allow for negative token counts on the last $i+1$ to ℓ places. With a recurrence over the number of places, he then obtains a bound on the length of the computations that keep the first i places positive. Formally, an *unrestricted marking* of N is a function $M : P \to \mathbb{Z}$. An unrestricted marking M *i-enables* a transition $t \in T$ if $M(j) \geq F(j,t)$ for all $j \in [1..i]$. Firing t yields a new unrestricted marking M', denoted $M[t\rangle_i M'$, with $M'(p) = M(p) - F(p,t) + F(t,p)$ for all $p \in P$. A computation $\pi = M_0[t_1\rangle_i M_1 \dots [t_m\rangle_i M_m$ is *i-bounded* with $i \in [1..\ell]$ if for each marking M_k with $k \in [0..m]$ and each place $j \in [1..i]$, we have $M_k(j) \geq 0$. We assume a fixed marking M_f to be covered. The computation π is *i-covering* (wrt. M_f) if $M_m(j) \geq M_f(j)$ for all $j \in [1..i]$. Given two computations $\pi_1 = M_0[t_1\rangle_i \cdots [t_k\rangle_i M_k$ and $\pi_2 = M'_0[t'_1\rangle_i \cdots [t'_s\rangle_i M'_s$ such that $M_k(j) = M'_0(j)$ for all $j \in [1..i]$, we define their *i-concatenation* $\pi_1 \cdot_i \pi_2$ to be the computation $M_0[t_1\rangle_i \cdots [t_k\rangle_i M_k[t'_1\rangle_i M''_{k+1} \cdots [t'_s\rangle_i M''_{k+s}$.

Rackoff's result provides a bound on the length of the shortest i-covering computations. Since we have to generate all minimal words, we will specify precisely which computations to consider (not only the shortest ones). Moreover, Rackoff's bound holds independent of the initial marking. This is needed, because the proof of the main lemma splits a firing sequence into two parts and then considers the starting marking of the second part as the new initial

marking. The sets we define in the following will depend on some unrestricted initial marking M, but we then quantify over all possible markings to get rid of the dependency.

Let $\mathit{Paths}(M,i)$ be the set of all paths of all i-covering and i-bounded computations starting at M, i.e. $\mathit{Paths}(M,i) = \{\sigma \in T^* \mid \pi = M[\sigma\rangle_i M', \pi \text{ is } i\text{-bounded and } i\text{-covering}\}$. Let $\mathit{Words}(M,i) = \{\lambda(\sigma) \mid \sigma \in \mathit{Paths}(M,i)\}$ be the corresponding set of words, and let $\mathit{Basis}(M,i) = \{w \in \mathit{Words}(M,i) \mid w \text{ is } \preceq\text{-minimal}\}$ be its minimal elements. The central definitions is $\mathit{SPath}(M,i)$, the set of shortest paths yielding the minimal words in $\mathit{Basis}(M,i)$,

$$\mathit{SPath}(M,i) = \left\{ \sigma \in \mathit{Paths}(M,i) \;\middle|\; \begin{array}{l} \lambda(\sigma) \in \mathit{Basis}(M,i), \\ \nexists\, \sigma' \in \mathit{Paths}(M,i)\colon \quad |\sigma'| < |\sigma|, \lambda(\sigma') = \lambda(\sigma) \end{array} \right\} .$$

Define $m(M,i) = \max\{|\sigma| + 1 \mid \sigma \in \mathit{SPath}(M,i)\}$ to be the length (+1) of the longest path in $\mathit{SPath}(M,i)$, or $m(M,i) = 0$ if $\mathit{SPath}(M,i)$ is empty. Note that $\mathit{Basis}(M,i)$ is finite and therefore only finitely many different lengths occur for sequences in SPath, i.e. $m(M,i)$ is well-defined. To remove the dependency on M, define $f(i) = \max\{m(M,i) \mid M \in \mathbb{Z}^\ell\}$ to be the maximal length of an i-covering computation, where the maximum is taken over all unrestricted initial markings. The well-definedness of $f(i)$ is not clear yet and will be a consequence of the next lemma. A bound on $f(\ell)$ will give us a bound on the maximum length of a computation accepting a minimal word from $L(N, M_0, M_f)$. To derive the bound, we prove that $f(i+1) \leq (2^n f(i))^{i+1} + f(i)$ using Rackoff's famous case distinction [35].

▶ **Lemma 4.** *$f(0) = 1$ and $f(i+1) \leq (2^n f(i))^{i+1} + f(i)$ for all $i \in [0..\ell[$.*

Lower Bound. We present a family of Petri net languages for which the minimal finite state automata representing the upward closure are of size doubly exponential in the size of the input. We rely on a construction due to Lipton [29] that shows how to calculate in a precise way (including zero tests) with values up to 2^{2^n} in Petri nets.

▶ **Lemma 5.** *For every number $n \in N$, we can construct a Petri net $N(n) = (\{a\}, P, T, F, \lambda)$ and markings M_0, M_f of size polynomial in n such that $L(N(n), M_0, M_f) = \{a^{2^{2^n}}\}$.*

BPP Nets. We establish an exponential upper bound on the size of the finite automata representing the upward closure of BPP net languages. Then, we present a family of BPP net languages for which the minimal finite automata representing their upward closure are of size at least exponential in the size of the input.

Upper Bound. Fix the BPP net $N = (\Sigma, P, T, F, \lambda)$ and assume M_0 and M_f to be the initial and the final marking of interest. Let $n = |N| + |M_0| + |M_f|$.

▶ **Theorem 6.** *One can construct an FSA of size $O(2^{\mathrm{poly}(n)})$ for $L(N, M_0, M_f)\uparrow$.*

We will show that every minimal word results from a computation whose length is polynomially dependent on the number of transitions and on the number of tokens in the final marking (which may be exponential in the size of the input). Let k be a bound on the length of the minimal computations. With the same argument as before and using Lemma 2, we can construct a finite state automaton of size $O(2^{\mathrm{poly}(n)})$ that accepts $L_k(N, M_0, M_f)\uparrow$.

▶ **Proposition 7.** *Consider a BPP net N. For every computation $M_0[\sigma\rangle M \geq M_f$ there is $M_0[\sigma'\rangle M' \geq M_f$ with $\lambda(\sigma') \preceq \lambda(\sigma)$ and $|\sigma'| \leq tc(M_f)^2|T|$.*

The key to proving the lemma is to consider a structure that makes the concurrency among transitions in the BPP computation of interest explicit. Phrased differently, we give a true concurrency semantics (also called partial order semantics and similar to Mazurkiewicz traces) to BPP computations. Since BPPs do not synchronize, the computation yields a forest where different branches represent causally independent transitions. To obtain a subcomputation that covers the final marking, we select from the forest a set of leaves that corresponds exactly to the final marking. We then show that the number of transitions in the minimal forest that generates the selected set of leaves is polynomial in the number of tokens in the final marking and in the number of transitions.

Lower Bound. We present a family of BPP net languages for which the minimal finite state automata representing the upward closure are exponential in the size of the input. The idea is to rely on the final marking, which is encoded in binary and hence can require 2^n tokens.

▶ **Lemma 8.** *For all numbers $n \in \mathbb{N}$, we can construct a BPP net $N(n) = (\{a\}, P, T, F, \lambda)$ and markings M_0, M_f of size polynomial in n such that $L(N(n), M_0, M_f) = \{a^{2^n}\}$.*

4 Downward Closures

We consider the problem of constructing a finite state automaton accepting the downward closure of a Petri net and a BPP net language, respectively. The downward closure often has the property of being a precise description of the system behavior, namely as soon as asynchronous communication comes into play: If the components are not tightly coupled, they may overlook commands of the partner and see precisely the downward closure of the other's computation. As a result, having a representation of the downward closure gives the possibility to design exact or under-approximate verification algorithms.

Petri Nets. The downward closure of Petri net languages has been shown to be effectively computable in [17]. The algorithm is based on the Karp-Miller tree [22], which can be of non-primitive recursive size. We now present a family of Petri net languages that are already downward closed and for which the minimal finite automata have to be of non-primitive recursive size in the size of the input. Our result relies on a construction due to Mayr and Meyer [32]. It gives a family of Petri nets whose computations all terminate but, upon halting, may have produced Ackermann many tokens on a distinguished place.

▶ **Lemma 9.** *For all $n, x \in \mathbb{N}$, there is a Petri net $N(n) = (\{a\}, P, T, F, \lambda)$ and markings $M_0^{(x)}, M_f$ of size polynomial in $n + x$ such that $L(N(n), M_0^{(x)}, M_f) = \{a^k \mid k \leq Acker_n(x)\}$.*

Our lower bound is an immediate consequence of this lemma.

▶ **Theorem 10.** *There is a family of Petri net languages for which the minimal finite automata representing the downward closure are of non-primitive recursive size.*

This hardness result relies on a weak computation mechanism of very large numbers that is unlikely to show up in practical examples. The SRE inclusion problem studied in the following section can be understood as a refined analysis of the computation problem for downward closures.

BPP Nets. We prove an exponential upper bound on the size of the finite automata representing the downward closure of BPP languages. Then, we present a family of BPP languages for which the minimal finite automata representing their downward closure are exponential in the size of the input BPP nets.

Upper Bound. Fix the BPP net $N = (\Sigma, P, T, F, \lambda)$ and let M_0 and M_f be the initial and the final marking of interest. Let $n = |N| + |M_0| + |M_f|$.

▶ **Theorem 11.** *We can construct a finite automaton of size* $O(2^{\text{poly}(n)})$ *for* $L(N, M_0, M_f)\downarrow$.

The key insight for simulating N by a finite automaton is the following: If during a firing sequence a marking occurs that has more than c tokens (where c is specified below) in some place p, then there has to be a *pump*, a subsequence of the firing sequence that can be repeated to produce arbitrarily many tokens in p. The precise statement is this, where we use $m = max(F)$ to refer to the maximal multiplicity of an edge.

▶ **Lemma 12.** *Let* $M_0[\sigma\rangle M$ *such that for some place* $p \in P$*, we have* $M(p) > c$ *with* $c = tc(M_0)(|P| \cdot m)^{(|T|+1)}$ *Then for each* $j \in \mathbb{N}$*, there is* $M_0[\sigma_j\rangle M_j$ *such that (1)* $\sigma \preceq \sigma_j$*, (2)* $M \leq M_j$*, and (3)* $M_j(p) > j$*.*

The automaton for $L(N, M_0, M_f)\downarrow$ is the state space of N with token values beyond c set to ω. For every transition, we also have an ε-variant to obtain the downward closure. The language of this automaton is the downward closure of the language of the given BPP net.

Lower Bound. Consider the family of BPP net languages from the Lemma 8: $L(N(n), M_0, M_f) = \{a^{2^n}\}$, for all $n \in \mathbb{N}$. Its downward closure is $\{a^i \mid i \leq 2^n\}$. The minimal finite state automata recognising the downward closure have at least 2^n states.

5 SRE Inclusion in Downward Closure

The downward closure of a Petri net language is hard to compute. We therefore propose to under-approximate it by an SRE as follows. Assumev we have a heuristic coming up with a candidate SRE that is supposed to be an under-approximation in the sense that its language is included in the downward closure of interest. The problem we study is the algorithmic task of checking whether the inclusion indeed holds. If so, the SRE provides reliable (must) information about the system's behavior, behavior that is guaranteed to occur. This information is useful for finding bugs.

SRE Inclusion in Downward Closure (SRED)	
Given:	A Petri net (N, M_0, M_f), an SRE sre.
Question:	$L(sre) \subseteq L(N, M_0, M_f)\downarrow$?

Petri Nets.

▶ **Theorem 13.** SRED *is* EXPSPACE*-complete for Petri nets.*

Hardness is due to the hardness of coverability [29]. Indeed, marking M_f is coverable from M_0 in N iff $L(N, M_0, M_f) \neq \emptyset$ iff $\{\varepsilon\} \subseteq L(N, M_0, M_f)\downarrow$. Note that $\{\varepsilon\} = L(\emptyset^*)$ and therefore is a simple regular language.

For the upper bound, we take inspiration from a recent result of Zetzsche [42]. He has shown that, for a large class of models, computing the downward closure is equivalent to deciding an unboundedness problem. We use a variant of this problem that comes with a complexity result. The *simultaneous unboundedness problem for Petri nets* (SUPPN) is, given a Petri net N, an initial marking M_0, and a subset $X \subseteq P$ of places, decide whether for each $n \in \mathbb{N}$, there is a computation σ_n such that $M_0[\sigma_n\rangle M_{\sigma_n}$ with $M_{\sigma_n}(p) \geq n$ for all places $p \in X$. In [11], Demri has shown that this problem is EXPSPACE-complete.

▶ **Theorem 14** ([11]). SUPPN *is* EXPSPACE*-complete.*

We turn to the reduction of the inclusion problem SRED to the unboundedness problem SUPPN. Since SREs are choices among products, an inclusion $L(sre) \subseteq L(N, M_0, M_f)\downarrow$ holds iff $L(p) \subseteq L(N, M_0, M_f)\downarrow$ holds for all products p in *sre*. Since the Petri net language is downward closed, we can further simplify the products by removing choices. Fix a total ordering on the alphabet Σ. Such an ordering can be represented by a word w_Σ. We define the *linearization operation* that takes a product and returns a regular expression:

$$lin(a + \varepsilon) = a \qquad lin(a) = a$$
$$lin(\Gamma^*) = (\pi_\Gamma(w_\Sigma))^* \qquad lin(p_1 p_2) = lin(p_1)lin(p_2)\ .$$

For example, if $\Sigma = \{a, b, c\}$ and we take $w_\Sigma = abc$, then $p = (a + c)^*(a + \varepsilon)(b + c)^*$ is turned into $lin(p) = (ac)^* a (bc)^*$. The discussion justifies the following lemma.

▶ **Lemma 15.** *$L(sre) \subseteq L(N, M_0, M_f)\downarrow$ if and only if for all products p in sre we have $L(lin(p)) \subseteq L(N, M_0, M_f)\downarrow$.*

We will reduce $L(lin(p)) \subseteq L(N, M_0, M_f)\downarrow$ to SUPPN. To this end, we first understand $lin(p)$ as a Petri net $N_{lin(p)}$. We modify this Petri net by adding one place p_Γ for each block $(\pi_\Gamma(w_\Sigma))^* = a_i \dots a_j$. Each transition that repeats or leaves the block is modified to generate a token in p_Γ. As a result, p_Γ counts how often the word $\pi_\Gamma(w_\Sigma)$ has been executed.

The second step is to define an appropriate product of $N_{lin(p)}$ with the Petri net of interest. Intuitively, the product synchronizes with the downward closure of N.

▶ **Definition 16.** Consider two Petri nets $N_i = (\Sigma, P_i, T_i, F_i, \lambda)$, $i = 1, 2$, with $P_1 \cap P_2 = \emptyset$ and $T_1 \cap T_2 = \emptyset$. Their *right-synchronized product* $N_1 \rtimes N_2$ is the labeled Petri net $N_1 \rtimes N_2 = (\Sigma, P_1 \cup P_2, T_1 \cup T, F, \lambda)$, where for the transitions $t_1 \in T_1$, λ and F remain unchanged. The new transitions are $T = \{merge(t_1, t_2) \mid t_1 \in T_1, t_2 \in T_2, \lambda_1(t_1) = \lambda_2(t_2)\}$ with $\lambda(merge(t_1, t_2)) = \lambda_1(t_1) = \lambda_2(t_2)$ and similarly $F(p_i, merge(t_1, t_2)) = F_i(p_i, t_i)$, $F(merge(t_1, t_2), p_i) = F_i(t_i, p_i)$ for $p_i \in P_i$, $i = 1, 2$.

As indicated by the name *right-synchronized*, the transitions of N_1 can be fired without synchronization, while the transitions of N_2 can only be fired if a transition of N_1 with the same label is fired simultaneously.

Consider a Petri net N with initial marking M_0. We compute the right-synchronized product $N' = N \rtimes N_{lin(p)}$, take the initial marking M_0' that coincides with M_0 but puts a token on the initial place of $N_{lin(p)}$, and focus on the counting places $X = \{p_\Gamma \mid (\pi_\Gamma(w_\Sigma))^*\}$ is a block in p. The following correspondence holds.

▶ **Lemma 17.** *$L(lin(p)) \subseteq L(N, M_0, M_\emptyset)\downarrow$ if and only if the places in X are simultaneously unbounded in N' from M_0'. Here $M_\emptyset$ is the zero marking, i.e. $M_\emptyset(p) = 0$ for all p.*

The lemma does not yet involve the final marking M_f. We modify N' and X such that simultaneous unboundedness implies $L(lin(p)) \subseteq L(N, M_0, M_f)\downarrow$. The idea is to introduce a new place p_f that can become unbounded only after M_f has been covered. We furthermore add a transition t_f that consumes $M_f(p)$ tokens from each place p of N and produces one token in p_f. We add another transition t_{pump} that consumes one token in p_f and creates two tokens in p_f. Call the resulting net N''. The new initial marking M_0'' coincides with M_0' and assigns no token to p_f.

Note that we do not enforce that t_f is only fired after all the rest of the computation has taken place. We can rearrange the transitions in any valid firing sequence of N'' to obtain a sequence of the shape $\sigma.{t_f}^k.{t_{pump}}^{k'}$, where σ contains neither t_f nor t_{pump}.

▶ **Lemma 18.** *$L(lin(p)) \subseteq L(N, M_0, M_f)\downarrow$ iff the places in $X \cup \{p_f\}$ are simultaneously unbounded in N'' from M_0''.*

To conclude the proof of Theorem 13, it remains to argue that the generated instance for SUPPN is polynomial in the input, i.e. in N, M_0, M_f and p. The expression $lin(p)$ is certainly linear in p, and the net $N_{lin(p)}$ is polynomial in $lin(p)$. The blow-up caused by the right-synchronized product is at most quadratic, and adding the transitions and the places to deal with M_f is polynomial. The size of M_0'' is polynomial in the size of M_0 and p. Altogether, the size of N'', $X \cup \{p_f\}$, and M_0'' (which together form the generated instance for SUPPN) is polynomial in the size of the original input.

BPP Nets. We show that the problem of deciding whether the language of an SRE is included in the downward closure of a BPP net language is NP-complete.

▶ **Theorem 19.** SRED *for BPP nets is* NP*-complete.*

Hardness is by a reduction from SAT to BPP coverability, which in turn reduces to deciding whether the language of an SRE is included in the downward closure of a BPP language. For the reverse direction, we give a reduction to satisfiability of an existential formula in *Presburger arithmetic*, the first-order theory of the natural numbers with addition, subtraction, and order. An *existential* Presburger formula takes the form $\exists x_1 \dots \exists x_n . \varphi$ where φ is a quantifier-free formula. We shall also write positive Boolean combinations of existential formulas. By an appropriate renaming of the quantified variables, any such formula can be converted into an equivalent existential Presburger formula. We write $\varphi(\vec{x})$ to indicate that (at most) the variables $\vec{x} = x_1 \dots x_k$ occur free in φ. Given a function M from $\vec{x}$ to $\mathbb{N}$, the meaning of M *satisfies* φ is as usual and we write $M \models \varphi$ to denote this. We rely on the following complexity result:

▶ **Theorem 20** ([37])**.** *Satisfiability in existential Presburger arithmetic is* NP*-complete.*

Note that $L(sre) \subseteq L(N, M_0, M_f)\downarrow$ iff the inclusion holds for every product p in sre. Given such a product, we construct a new BPP net N' and an existential Presburger formula $\psi(P')$ such that $L(p) \subseteq L(N, M_0, M_f)\downarrow$ iff there is a marking M' reachable in N' from a modified initial marking M_0' with $M' \models \psi$. This concludes the proof with the help of the following characterization of reachability in BPP nets in terms of existential Presburger arithmetic.

▶ **Theorem 21** ([41, 13])**.** *Given a BPP net $N = (\Sigma, P, T, F, \lambda)$ and an initial marking M_0, one can compute in polynomial time an existential Presburger formula $\Psi(P)$ so that for all markings M: $M \models \Psi(P)$ if and only if $M_0[\sigma\rangle M$ for some $\sigma \in T^*$.*

Key to the construction of N' is a characterization of the computations that need to be present in the BPP net for the inclusion $L(p) \subseteq L(N, M_0, M_f)\downarrow$ to hold. Wlog., in the following we will assume that the product takes the shape

$$(a_1 + \varepsilon)\Sigma_1^*(a_2 + \varepsilon) \dots \Sigma_{n-1}^*(a_n + \varepsilon),$$

where $\Sigma_1, \dots, \Sigma_{n-1} \subseteq \Sigma$ and $a_1, \dots, a_n \in \Sigma$. For this language to be included in $L(N, M_0, M_f)\downarrow$, the BPP should have a computation with parts σ_i containing a_i and parts ρ_i between the σ_i that contain all letters in Σ_i and that can be repeated. To formalize the requirement, recall that we use w_Σ for a total order on the alphabet and $\pi_{\Sigma_i}(w_\Sigma)$ for the projection to $\Sigma_i \subseteq \Sigma$.

Moreover, we define $M \leq^c M'$, with c the constant defined in Lemma 12, if for all places $p \in P$ we have $M'(p) < c$ implies $M(p) \leq M'(p)$.

▶ **Definition 22.** Let p be a product. The BPP net N together with the markings M_0, M_f admits a *p-witness* if there are markings $M_1, M_1', \ldots, M_n, M_n'$ and computations σ_i, ρ_i that satisfy $M_i[\sigma_i\rangle M_i'$ for all $i \in [1..n]$, $M_i'[\rho_i\rangle M_{i+1}$ for all $i \in [1..n[$, and moreover: (1) $a_i \preceq \lambda(\sigma_i)$, for all $i \in [1..n]$, (2) $\pi_{\Sigma_i}(w_\Sigma) \preceq \lambda(\rho_i)$ and $M_i' \leq^c M_{i+1}$, for all $i \in [1..n-1]$, and (3) $M_1 = M_0$ and $M_f \leq^c M_n'$.

In a p-witness, (1) enforces that the a_i occur in the desired order, and the first part of (2) requires that $\pi_{\Sigma_i}(w_\Sigma)$ occurs in between. The second part of (2) means that each ρ_i (and thus $\pi_{\Sigma_i}(w_\Sigma)$) can be repeated. Property (3) enforces that the computation still starts in the initial marking and can be extended to cover the final marking.

The following proposition reduces the problem SRED for BPP nets to checking whether the BPP admits a p-witness.

▶ **Proposition 23.** *$L(p) \subseteq L(N, M_0, M_f)\downarrow$ holds iff (N, M_0, M_f) admits a p-witness.*

We now reduce the problem of finding such a p-witness to finding in another BPP net $N' = (\emptyset, P', T', F', \lambda')$ a reachable marking that satisfies a Presburger formula $\Psi_{M_f}^{M_0}(P')$. The task is to identify $2n$ markings that are related by $2n-1$ computations as required by a p-witness. The idea is to create $2n-1$ replicas of the BPP net and run them independently to guess the corresponding computations σ_i resp. ρ_i. The Presburger formula $\Psi_{M_f}^{M_0}$ will check that the target marking reached with σ_i coincides with the initial marking for ρ_i, and the target marking reached with ρ_i is the initial marking of σ_{i+1}. To this end, the net N' remembers the initial marking that each replica started from in a full copy (per replica) of the set of places of the BPP net. Furthermore $\Psi_{M_f}^{M_0}$ checks that each ρ^i can be repeated by ensuring that the final marking in the corresponding replica is larger than the initial marking. As initial marking for N', we consider the marking $M_\emptyset$ with $M_\emptyset(p) = 0$ for all p.

▶ **Proposition 24.** *There are σ' and M' so that $M_\emptyset[\sigma'\rangle M'$ in N' and $M' \models \Psi_{M_f}^{M_0}$ if and only if (N, M_0, M_f) admits a p-witness.*

6 SRE Inclusion in Upward Closure

Rather than computing the upward closure of a Petri net language we now check whether a given SRE under-approximates it. Formally, the problem is defined as follows.

SRE Inclusion in Upward Closure (SREU)	
Given:	A Petri net (N, M_0, M_f), SRE sre.
Question:	$L(sre) \subseteq L(N, M_0, M_f)\uparrow$?

▶ **Theorem 25.** SREU *is* EXPSPACE*-complete for Petri nets.*

The EXPSPACE lower bound is immediate by hardness of coverability for Petri nets [29]. The upper bound is due to the following fact: We only need to check whether the set of minimal words in the language of the given SRE is included in the upward closure of the Petri net language. Since the number of minimal words in the SRE language is less than the size of the SRE, and since checking whether a word is included in the upward closure of the language of the Petri net N can be reduced in polynomial time to coverability in Petri nets (which is well-known to be in EXPSPACE [35]), we obtain our EXPSPACE upper bound.

▶ **Theorem 26.** SREU *is* NP*-complete for BPP nets.*

The hardness is by a reduction of the coverability problem for BPP nets. For the upper bound, the algorithm is similar to the one for checking the inclusion of an SRE in the downward closure of a BPP language. Consider a product p of the given SRE. The inclusion $L(p) \subseteq L(N, M_0, M_f)\uparrow$ holds iff the minimal subwords $\min(p) = a_1 \dots a_n$ belong to $L(N, M_0, M_f)\uparrow$. Word $a_1 \dots a_n$ belongs to the upward closure iff one of its subwords is in $L(N, M_0, M_f)$. We reduce this check for an accepted subword to checking whether a reachable marking M in a different net N' satisfies a Presburger formula Ψ.

7 Being Upward/Downward Closed

We now study the problem to decide whether a Petri net language actually is upward or downward closed, i.e. whether the closure that we can compute is actually a precise representation of the system's behavior. Formally, the problem BUC is defined as follows:

Being upward closed (BUC)	
Given:	A Petri net (N, M_0, M_f).
Question:	$L(N, M_0, M_f) = L(N, M_0, M_f)\uparrow$?

The problem of being downward closed (BDC) replaces $\uparrow$ by $\downarrow$ in the above definition.

▶ **Theorem 27.** BUC *and* BDC *are decidable for Petri nets.*

Note that $L(N, M_0, M_f) \subseteq L(N, M_0, M_f)\uparrow$ trivially holds. It remains to decide the converse. First, we show how to decide $L(A) \subseteq L(N, M_0, M_f)$ for any given FSA A. This regular inclusion should be a problem of independent interest. Then, we can use the automaton for the upward closure constructed by Theorem 1 (resp. the automaton for the downward closure that can be constructed by [17]) to decide BUC (resp. BDC).

We rely on a result of Esparza et. al [21] that involves the *traces* of an FSA (resp. Petri net), labelings of computations that start from the initial state (resp. initial marking), regardless of whether they end in a final state (resp. covering marking). For a finite automaton A , we define $\mathcal{T}(A) = \{w \in \Sigma^* \mid q_{init} \xrightarrow{w} q \text{ for some } q \in Q\}$. Similarly, for a Petri net, we define $\mathcal{T}(N, M_0) = \{w \in \Sigma^* \mid \exists\, \sigma \in T^* \colon \lambda(\sigma) = w, M_0[\sigma\rangle M \text{ for some marking } M\}$.

▶ **Theorem 28** ([21]). *The inclusion $\mathcal{T}(A) \subseteq \mathcal{T}(N, M_0)$ is decidable.*

The algorithm constructs a computation tree of A and N. This tree determinizes N in that it tracks sets of incomparable markings reachable with the same trace. The construction terminates if either the set of markings becomes empty and the inclusion fails or (the automaton deadlocks or) we find a set of markings that covers a predecessor and the inclusion holds. The latter is guaranteed to happen due to the well-quasi ordering (wqo) of sets of markings. This dependence on wqos does not allow us to derive a complexity result.

We now show how to reduce checking the inclusion $L(A) \subseteq L(N, M_0, M_f)$ to deciding an inclusion among trace languages. Theorem 28 can be used to decide this inclusion. Let (N, M_0, M_f) be the Petri net of interest together with its initial and final marking, and let A be the given FSA. As language $L(N, M_0, M_f)$ is not prefix-closed in general, we consider the zero marking $M_\emptyset$ as the new final marking. This yields a prefix-closed language with $\mathcal{T}(N, M_0) = L(N, M_0, M_\emptyset)$, since now all valid firing sequences give a word in the language, and prefixes of valid firing sequences are again valid firing sequences. We still need to take the original final marking M_f into account. To do so, we modify the net by adding a new transition that can only be fired after M_f has been covered.

Let $a \notin \Sigma$ be a fresh letter. Let $N.a$ be the Petri net that is obtained from N and the given final marking M_f by adding a new transition t_{final} that consumes $M_f(p)$ many tokens from every place p of N and that is labeled by a. For the automaton, we use a similar trick. Let $A.a$ be an automaton for $L(A).a$ that is reduced so that the unique final state is reachable from every state.

▶ **Lemma 29.** *$L(A) \subseteq L(N, M_0, M_f)$ holds iff $\mathcal{T}(A.a) \subseteq \mathcal{T}(N.a, M_0)$ holds.*

The second inclusion is decidable using Theorem 28. This yields the desired result.

▶ **Theorem 30.** *$L(A) \subseteq L(N, M_0, M_f)$ is decidable.*

Abstract

The well-known k-SUM conjecture is that integer k-SUM requires time $\Omega(n^{\lceil k/2\rceil - o(1)})$. Recent work has studied multidimensional k-SUM in $\mathbb{F}_p^d$, where the best known algorithm takes time $\tilde{O}(n^{\lceil k/2\rceil})$. Bhattacharyya et al. [ICS 2011] proved a $\min(2^{\Omega(d)}, n^{\Omega(k)})$ lower bound for k-SUM in $\mathbb{F}_p^d$ under the Exponential Time Hypothesis. We give a more refined lower bound under the standard k-SUM conjecture: for sufficiently large p, k-SUM in $\mathbb{F}_p^d$ requires time $\Omega(n^{k/2-o(1)})$ if k is even, and $\Omega(n^{\lceil k/2\rceil - 2k\frac{\log k}{\log p} - o(1)})$ if k is odd.

For a special case of the multidimensional problem, *bounded monotone d-dimensional 3SUM*, Chan and Lewenstein [STOC 2015] gave a surprising $\tilde{O}(n^{2-2/(d+13)})$ algorithm using additive combinatorics. We show this algorithm is essentially optimal. To be more precise, bounded monotone d-dimensional 3SUM requires time $\Omega(n^{2-\frac{4}{d}-o(1)})$ under the standard 3SUM conjecture, and time $\Omega(n^{2-\frac{2}{d}-o(1)})$ under the so-called strong 3SUM conjecture. Thus, even though one might hope to further exploit the structural advantage of monotonicity, no substantial improvements beyond those obtained by Chan and Lewenstein are possible for bounded monotone d-dimensional 3SUM.

1 Introduction

The k-SUM problem and the k-SUM conjecture are related to a large number of problems in computational geometry [11], dynamic data structures, and graph theory. For example, Pătraşcu [17] showed lower bounds for dynamic problems under the 3SUM conjecture, and Kopelowitz, Pettie, and Porat [16] improved Pătraşcu's framework to give better reductions from 3SUM to SetIntersection, SetDisjointness, and triangle enumeration. Goldstein, Kopelowitz, Lewenstein, and Porat [13] showed several reporting problems are 3SUM-hard. Vassilevska and Williams [19], and Jafargholi and Viola [15] used 3SUM to study triangle problems. Abboud and Lewi [1] proved tight lower and upper bounds for the exact-weight subgraph finding problem under the k-SUM conjecture.

▶ **Definition 1** (k-SUM)**.** Given subsets $A_1, \ldots, A_k$ of size n of an abelian group G, the k-SUM problem asks whether there are $a_1 \in A_1, \ldots, a_k \in A_k$ such that $\sum_{i=1}^{k} a_i = 0$.

* Supported by NSF grant CCF-1423544 and a Simons Foundation Investigator grant.

A simple meet-in-the-middle algorithm can solve k-SUM in time $\tilde{O}(n^{\lceil k/2 \rceil})$,[1] and it is widely believed that this is the optimal time up to polylogarithmic factors. This is known as the k-SUM conjecture:

▶ **Conjecture 2** (k-SUM Conjecture). *For $k \geq 2$, k-SUM in $\mathbb{Z}$ requires randomized time $\Omega(n^{\lceil k/2 \rceil - o(1)})$.*

To support the k-SUM conjecture, Erickson [9] and Ailon and Chazelle [3] proved that k-linear decision trees cannot solve k-SUM with fewer than $n^{\lceil k/2 \rceil}$ queries. On the other hand, Freund [10], and Gold and Sharir [12] recently gave $O(n^2 \log\log n / \log n)$ algorithms for 3SUM. Hence, the standard 3SUM conjecture (Conjecture 7) is stated as an $\Omega(n^{2-o(1)})$ lower bound instead of $\Omega(n^2)$.

Intriguingly, in non-uniform models, substantially lower complexities are known: Grønlund and Pettie [14] showed that the decision tree complexity of 3SUM is $O(n^{3/2} \log n)$. Gold and Sharir [12] showed that the randomized $(2k-2)$-linear decision tree complexity of k-SUM is $O(n^{k/2})$ for any odd $k \geq 3$.

1.1 Multidimensional k-SUM in $\mathbb{F}_p^d$

One can also consider the k-SUM problem over domains other than $\mathbb{Z}$. The focus of this paper will be on the multidimensional case, where the domain is $\mathbb{F}_p^d$. The k-SUM problem in $\mathbb{F}_p^d$ is a problem of independent interest. For example, Jafargholi and Viola [15, 20] reduced listing triangles to 3SUM in $\mathbb{F}_2^d$. In coding theory, k-SUM in $\mathbb{F}_p^d$ is studied and known as WeightDistribution [8].

Bhattacharyya et. al. [6] recently gave a $\min(2^{\Omega(d)}, n^{\Omega(k)})$ lower bound for k-SUM in $\mathbb{F}_p^d$ under the Exponential Time Hypothesis. Pătraşcu and Williams [18] proved that the Exponential Time Hypothesis implies a weak version of the k-SUM conjecture - there is no $n^{o(k)}$ algorithm for k-SUM for all k. However, prior to this paper, no connection was known between integer k-SUM and k-SUM in $\mathbb{F}_p^d$. In this paper, we use the k-SUM conjecture to prove a more refined lower bound for k-SUM in $\mathbb{F}_p^d$:

▶ **Theorem 3.** *Under the k-SUM conjecture, for any $k \geq 2$, k-SUM in $\mathbb{F}_p^d$ requires time $\Omega(n^{k/2-o(1)})$ for even k, and time $\Omega(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - o(1)})$ for odd k, when p is sufficiently large.*

Like the one-dimensional case, the fastest known algorithm for k-SUM in $\mathbb{F}_p^d$ is the meet-in-the-middle algorithm in time $\tilde{O}(n^{\lceil k/2 \rceil})$, which matches with the above conditional lower bound for even k.

Our conditional lower bound is meaningful for each $k \geq 2$, which is a stronger statement than the asymptotic result by Bhattacharyya et. al.

1.2 Monotone d-dimensional 3SUM

Chan and Lewenstein [7] first studied bounded monotone d-dimensional 3SUM, motivated by bounded monotone $(\min, +)$-convolution and histogram indexing. Chan and Lewenstein gave a remarkable $\tilde{O}(n^{2-\frac{2}{d+13}})$ algorithm with techniques from additive combinatorics. One of our main result is to show this algorithm is essentially optimal under the 3SUM conjecture.

[1] $\tilde{O}(f(n))$ is a notation for $O(f(n)\text{polylog}(n))$.

▶ **Definition 4** (Bounded Monotone d-dimensional 3SUM). A set $A \subset \mathbb{Z}^d$ is monotone increasing if it can be sorted as $A = \{a_1, \ldots, a_n\}$ such that the j-th coordinates of $a_1, \ldots, a_n$ form a monotone increasing sequence for each $j = 1, \ldots, d$. Given monotone sets $A, B, S \subset [n]^d$, bounded monotone d-dimensional 3SUM asks if there exist $a \in A, b \in B, s \in S$ such that $a + b = s$.[2]

Chan and Lewenstein's subquadratic $\tilde{O}(n^{2-\frac{2}{d+13}})$ algorithm shows that bounded monotone d-dimensional 3SUM is easier than integer 3SUM, but how much easier? Since monotonicity is a strong restriction on the set structure, one may wonder whether further improvements are possible. We show, under the 3SUM conjecture, the answer is no:

▶ **Theorem 5.** *Under the standard 3SUM conjecture, bounded d-dimensional monotone 3SUM requires time $\Omega(n^{2-\frac{4}{d}-o(1)})$.*

One can also define a strong version of the 3SUM conjecture (see Conjecture 8) and this yields a slightly stronger result:

▶ **Theorem 6.** *Under the strong 3SUM conjecture, bounded d-dimensional monotone 3SUM requires time $\Omega(n^{2-\frac{2}{d}-o(1)})$.*

In Chan and Lewenstein's $\tilde{O}(n^{2-\frac{2}{d+13}})$ upper bound, the exponent $2 - 2/(d + 13)$ comes from solving a quadratic equation capturing a fairly involved recurrence; it is surprising to see essentially the same exponent arise for completely different reasons in our lower bound.

1.3 Standard vs Strong 3SUM Conjecture

In this section we discuss the so-called "strong" 3SUM conjecture. For clarity, we refer to the well-known 3SUM conjecture (a special case of Conjecture 2) as the "standard" 3SUM conjecture:

▶ **Conjecture 7** (Standard 3SUM Conjecture). *Integer 3SUM requires time $\Omega(n^{2-o(1)})$.*

It is known that 3SUM on a set of n integers can be reduced to the bounded domain of $\{-n^3, \ldots, n^3\}$ via a randomized reduction [5, 17]. The strong 3SUM conjecture further restricts the domain to $\{-n^2, \ldots, n^2\}$. It was first proposed by Amir, Chan, Lewenstein, and Lewenstein to obtain better conditional lower bounds for jumbled indexing [4]. [3]

▶ **Conjecture 8** (Strong 3SUM Conjecture). *3SUM on a set of n integers in the domain of $\{-n^2, \ldots, n^2\}$ requires time $\Omega(n^{2-o(1)})$.*

As a context for the strong 3SUM conjecture, 3SUM in the domain of $\{-n^{2-\delta}, \ldots, n^{2-\delta}\}$ can be solved in time $\tilde{O}(n^{2-\delta})$ by Fast Fourier Transform (FFT). However, it is a long-standing open problem whether there is a truly subquadratic algorithm for 3SUM in the domain of $\{-n^2, \ldots, n^2\}$.

It is an open problem whether the strong 3SUM conjecture is equivalent to the standard 3SUM conjecture. In this paper, we prove a partial result along these lines in Theorem 9. This result may be a folklore in some communities, but it seems that it has not been written down, so we include a formal analysis for completeness.

[2] $[m]$ is a notation for $\{0, 1, \ldots, m-1\}$.

[3] Recently, Goldstein, Kopelowitz, Lewenstein, and Porat [13] showed that the strong 3SUM conjecture is not necessary for the hardness of jumbled indexing, and improved the result by basing on the standard 3SUM conjecture.

▶ **Theorem 9.** *Under the standard 3SUM conjecture, 3SUM$^+$ in the domain of $\{-n^{2+\delta}, ..., n^{2+\delta}\}$ requires time $\Omega(n^{2-o(1)})$ for any $\delta > 0$.*

Here, 3SUM$^+$ is the extension of 3SUM that reports all $a_3 \in A_3$ such that $a_1 + a_2 + a_3 = 0$ for some $a_1 \in A_1, a_2 \in A_2$, i.e. it outputs $A_3 \cap -(A_1 + A_2)$. As noted by Chan and Lewenstein [7], all the known 3SUM algorithms actually solve 3SUM$^+$, including Fast Fourier Transfrom and Baren et al.'s slightly subquadratic $O((n^2/\log^2 n)(\log\log n)^2)$ algorithm [5].

If Theorem 9 still holds with $\delta = 0$ and 3SUM in place of 3SUM$^+$, then the strong 3SUM conjecture would be equivalent to the standard 3SUM conjecture.

1.4 Organization

The next three sections contain the technical proofs of the main theorems. In Section 2, we prove Theorem 3, the lower bound for k-SUM in $\mathbb{F}_p^d$ under the k-SUM conjecture. Section 3 contains the proofs for Theorem 5 and Theorem 6, which are lower bounds for bounded monotone 3SUM under the standard and strong 3SUM conjectures. In Section 4, we prove Theorem 9.

2 Reductions Used for the Lower Bound for k-SUM in $\mathbb{F}_p^d$

Underlying the lower bound for k-SUM in $\mathbb{F}_p^d$ is a pair of reductions: a reduction from integer k-SUM in $\mathbb{F}_p^d$ to integer $(k+1)$-SUM, and a reduction from integer k-SUM to $(k+1)$-SUM in $\mathbb{F}_p^d$. From the reductions, we deduce conditional lower bounds for k-SUM in $\mathbb{F}_p^d$, for bounded monotone d-dimensional 3SUM, and for 3SUM$^+$ in bounded domain $\{-n^{2+\delta}, ..., n^{2+\delta}\}$.

A natural idea for reduction is to use the bijection between $\mathbb{F}_p^d$ and $[p^d] \subset \mathbb{Z}$, seeing $\mathbb{F}_p^d$ as a base-p representation of integers. However, the bijection is not an abelian group homomorphism, due to the "carries" in integer addition and the mod p effect in $\mathbb{F}_p^d$-addition. The main challenge is to simulate the carries while preserving the k-SUM structure.

Lemma 10 is the reduction from k-SUM in $\mathbb{F}_p^d$ to integer $(k+1)$-SUM. This is the easier direction among the two reductions. We map $a = (a_0, ..., a_{d-1}) \in \mathbb{F}_p^d \mapsto \sum_{i=0}^{d-1} a_i (kp)^i \in \mathbb{Z}$, treating $\mathbb{F}_p^d$ coordinates as digits in a base-kp number. Since the digits are blown up by powers of kp, there are no "carries" in integer addition.

▶ **Lemma 10.** *Given a k-SUM instance in $\mathbb{F}_p^d$ on k sets $A^{(1)}, \cdots, A^{(k)}$ of size n, it can be reduced to an integer $(k+1)$-SUM instance on k sets of size n and an additional set of size k^d.*

Proof. Let $g : \mathbb{F}_p^d \to \mathbb{Z}$ be the injective map $a = (a_0, ..., a_{d-1}) \mapsto \sum_{i=0}^{d-1} a_i (kp)^i$.

For any $a^{(1)}, \ldots, a^{(k)} \in \mathbb{F}_p^d$, the sum $a^{(1)} + \cdots + a^{(k)}$ is zero in $\mathbb{F}_p^d$ if and only if the i-th coordinate sum $\sum_{j=1}^{k} a_i^{(j)}$ is a multiple of p for all $0 \le i < d$. Since $a_i^{(j)} < p$, we know $\sum_{j=1}^{k} a_i^{(j)} < kp$. The above condition can be rewritten as $\sum_{j=1}^{k} a_i^{(j)} = \lambda_i p$, where $\lambda_i \in \{0, ..., k-1\}$. This is further equivalent to

$$g(a^{(1)}) + \cdots + g(a^{(k)}) = \sum_{i=0}^{d-1} \lambda_i p (kp)^i \text{ for some } (\lambda_1, \ldots, \lambda_d) \in [k]^d.$$

Therefore, the original k-SUM instance in $\mathbb{F}_p^d$ can be reduced to the integer $(k+1)$-SUM instance on $g(A^{(1)}), \ldots, g(A^{(k)})$, and an additional set $\{-\sum_{i=0}^{d-1} \lambda_i p (kp)^i : (\lambda_i) \in [k]^d\}$. ◀

▶ **Corollary 11.** *Given a k-SUM instance in $\mathbb{F}_p^d$ on k sets of size n, it can be reduced to k^d instances of integer k-SUM.*

Proof. Using the reduction in Lemma 10, we can solve the $(k+1)$-SUM instance by enumerating the additional set of size k^d. For each element a in the additional set of size k^d, subtract a from the first set, and solve the k-SUM instance on the first k sets. ◀

Since the proof only uses the additive structure of $\mathbb{F}_p^d$, Lemma 10 also holds more generally for k-SUM instance in $\mathbb{Z}_q^d$, where q is not necessarily a prime number. In fact, all proofs in this section can be adapted to $\mathbb{Z}_q^d$ with some modification.

In the reverse direction, it is more challenging to design a reduction from integer to $\mathbb{F}_p^d$, since the reduction needs to simulate integer addition carries with $\mathbb{F}_p^d$.

In the proof of Lemma 12, we start with the bijection between $\mathbb{F}_p^d$ and $[p^d] \subset \mathbb{Z}$, viewing $\mathbb{F}_p^d$ as a base-p representation of integers. This provides a way to map integers to $\mathbb{F}_p^d$, but unfortunately the map does not preserve the additive structure in k-SUM. To fix this problem, the key observation is that the map does preserve the additive structure with respect to k-SUM when all coordinates are between 0 and $\lfloor \frac{p}{k} \rfloor$. Points in $\{0, \ldots, \lfloor \frac{p}{k} \rfloor\}^d \subset \mathbb{F}_p^d$ behaves nicely for our purpose. Therefore, we divide $\mathbb{F}_p$ into k chunks: $\{0, \ldots, \lfloor \frac{p}{k} \rfloor\}, \{\lceil \frac{p}{k} \rceil, \ldots, 2\lfloor \frac{p}{k} \rfloor\}$, $\ldots, \{\lambda \lceil \frac{p}{k} \rceil, \ldots, (\lambda+1)\lfloor \frac{p}{k} \rfloor\}$, and so on. Accordingly, $\mathbb{F}_p^d$ is divided into k^d cubes $\{S_\lambda : \lambda = (\lambda_1, \ldots, \lambda_d) \in [k]^d\}$. For each cube, we shift it to align with the nice cube $S_0 = \{0, \ldots, \lfloor \frac{p}{k} \rfloor\}^d$ where the reduction preserves the additive structure, perform the reduction, and then shift it back.

A similar technique was first used by Abboud, Lewi, and Williams [2] to reduce integer k-SUM to k-VECTOR-SUM.

▶ **Lemma 12.** *Assume $p > k^2$. Given an integer k-SUM instance on k sets $X^{(1)}, \ldots, X^{(k)}$ of size n in the bounded universe $[m]$, it can be reduced to a $(k+1)$-SUM instance in $\mathbb{F}_p^{2d}$ on k sets of size n and a set of size k^{2d}, where $d = \log_p m$.*

Proof. Let $f : \mathbb{F}_p^d \to \{0, \ldots, m\}$ be the bijection $a = (a_0, \ldots, a_{d-1}) \mapsto \sum_{i=1}^{d-1} a_i p^i$. Note this is a bijection but does not preserve the additive structure.

Define $\mu : \mathbb{F}_p^d \to [k]^d$ as the following index function. For any $a = (a_0, \ldots, a_{d-1}) \in \mathbb{F}_p^d$, $\mu(a) = (\mu_0, \ldots, \mu_{d-1})$, where μ_i is defined to be the integer such that $\mu_i \lceil \frac{p}{k} \rceil \le a_i < (\mu_i+1)\lfloor \frac{p}{k} \rfloor$.

For any $\lambda \in [k]^d$, define $S_\lambda := \{a \in \mathbb{F}_p^d : \mu(a) = \lambda\}$. Define $\overline{a} = a - \lfloor \frac{p}{k} \rfloor \cdot \mu(a)$, then we can write

$$a = \overline{a} + \left\lfloor \frac{p}{k} \right\rfloor \cdot \mu(a),$$

where $\overline{a} \in S_0$.

$$f(a) = f(\overline{a}) + \sum_{i=1}^{d-1} \mu_i(a) \left\lfloor \frac{p}{k} \right\rfloor p^i.$$

Observe that for any $\overline{a^{(1)}}, \ldots, \overline{a^{(k)}} \in S_0$, it is true that $\sum_{j=1}^{k} f(\overline{a^{(j)}}) = f(\sum_{j=1}^{k} \overline{a^{(j)}})$. This equality does not hold in general for elements outside S_0.

Thus, for any $a^{(1)}, \ldots, a^{(k)} \in \mathbb{F}_p^d$,

$$\sum_{j=1}^{k} f(a^{(j)}) = \sum_{j=1}^{k} f(\overline{a^{(j)}}) + \sum_{i=1}^{d} \left(\sum_{j=1}^{k} \mu_i(a^{(j)}) \right) \left\lfloor \frac{p}{k} \right\rfloor p^i.$$

Fix $\lambda^{(1)}, \ldots, \lambda^{(k)} \in [k]^d$. For any $(x^1, \ldots, x^{(k)})$ where $x^{(j)} \in X^{(j)} \cap S_{\lambda^{(j)}}$, if we denote $a^{(j)} = f^{-1}(x^{(j)})$, then

$$\sum_{j=1}^{k} x^{(j)} = \sum_{j=1}^{k} f(a^{(j)}) = \sum_{j=1}^{k} f(\overline{a^{(j)}}) + \sum_{i=1}^{d} \sum_{j=1}^{k} \lambda_i^{(j)} \left\lfloor \frac{p}{k} \right\rfloor p^i = f(\sum_{j=1}^{k} \overline{a^{(j)}}) + \sum_{i=1}^{d} \sum_{j=1}^{k} \lambda_i^{(j)} \left\lfloor \frac{p}{k} \right\rfloor p^i.$$

Thus,

$$\sum_{j=1}^{k} x^{(j)} = 0 \iff f(\sum_{j=1}^{k} \overline{a^{(j)}}) + \sum_{i=1}^{d}\sum_{j=1}^{k} \lambda_i^{(j)} \left\lfloor \frac{p}{k} \right\rfloor p^i = 0,$$

and

$$\sum_{j=1}^{k} x^{(j)} = 0 \iff \sum_{j=1}^{k} \overline{a^{(j)}} = f^{-1}\left(-\sum_{i=1}^{d}\sum_{j=1}^{k} \lambda_i^{(j)} \left\lfloor \frac{p}{k} \right\rfloor p^i \right). \tag{*}$$

Note that the right hand side only depends on $\lambda^{(1)}, ..., \lambda^{(k)}$, or more specifically $\sum_{j=1}^{k} \lambda_i^{(j)}$.

This gives a reduction from the integer k-SUM instance to a $(k+1)$-SUM instance on k sets of size n in $\mathbb{F}_p^d \times \mathbb{Z}^d$ of the form

$$A^{(j)} = \{(\overline{a}, \mu(a)) : f(a) \in X^{(j)}\},$$

and a set of size k^{2d} consisting of elements in the form of

$$-\left(f^{-1}(-\sum_{i=1}^{d} \sigma_i \left\lfloor \frac{p}{k} \right\rfloor p^i), \quad \sigma \right),$$

for all $\sigma \in [k^2]^d \subset \mathbb{Z}^d$. The range $[k^2]^d$ is determined by the fact that since $\lambda^{(j)} \in [k]^d$ for each j, the sum σ is bounded above by k^2 in each coordinate. The $\mathbb{Z}^d$ component in $\mathbb{F}_p^d \times \mathbb{Z}^d$ is always bounded in $[k^2]^d$, so $\mathbb{F}_p^d \times \mathbb{Z}^d$ can be viewed as $\mathbb{F}_p^{2d}$ when $p > k^2$. ◀

The assumption $p > k^2$ in Lemma 12 is adopted only to simplify some details at the end when turning $\mathbb{F}_p^d \times [k^2]^d$ into $\mathbb{F}_p^{2d}$. When $p \le k^2$, the same techniques apply with more care in dealing with the $[k^2]^d$ component. All previous parts before (*) in the proof hold for $p > k$, so the following corollary only requires $p > k$.

▶ **Corollary 13.** *Assume $p > k$. Given an integer k-SUM instance on k sets of size n in the bounded universe $[m]$, it can be reduced to k^{2d} instances of k-SUM in $\mathbb{F}_p^d$ on k sets of size n, where $d = \log_p m$.*

Proof. This follows from the reduction up to (*) in the proof of the previous theorem. ◀

2.1 Lower Bound for k-SUM in $\mathbb{F}_p^d$

The following lower bound under the k-SUM conjecture follows from Lemma 12. For even k, our result matches with the $\tilde{O}(n^{k/2})$ upper bound. For odd k, our lower bound is $\Omega(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - o(1)})$, while the best known upper bound is $\tilde{O}(n^{\lceil k/2 \rceil})$. The conditional lower bound converges to the upper bound as $p \to \infty$, which is expected since the group $\mathbb{F}_p$ behaves "more and more like $\mathbb{Z}$" as p increases.

The assumption that p is large enough such that $p \ge k^{2k}$ is still a meaningful assumption, because k^{2k} is a constant for fixed k.

▶ **Theorem 3.** (Restated) *For any $k \ge 2$, assume p is sufficiently large such that $p \ge k^{2k}$. Under the k-SUM conjecture, k-SUM in $\mathbb{F}_p^d$ requires time $\Omega(n^{k/2-o(1)})$ for even k, and $\Omega(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - o(1)})$ for odd k, for $d \ge 2k \log_p n$.*

Proof. Using a randomized reduction [5, 17], we can assume without loss of generality that a given integer k-SUM instance is in the bounded domain $[n^k] = \{0, \ldots, n^k - 1\}$.

Suppose k is even. By Lemma 12, any integer $(k-1)$-SUM instance can be reduced to a k-SUM instance in $\mathbb{F}_p^d$ on $k-1$ sets of size n and a set of size $(k-1)^d$, where $d = 2\log_p n^{(k-1)}$. (The d used here is $2d$ in Lemma 12.) Assuming $p > k^{2k}$, then the size of the last set can be bounded above by $(k-1)^d \leq k^d = n^{2k\frac{\log k}{\log p}} \leq n$. Hence, integer $(k-1)$-SUM can be reduced to k-SUM in $\mathbb{F}_p^d$ on k sets of size n. If k-SUM in $\mathbb{F}_p^d$ can be solved in time $O(n^{k/2-\epsilon})$, then integer $(k-1)$-SUM could be solved in time $O(n^{k/2-\epsilon}) = O(n^{\lceil \frac{k-1}{2} \rceil - \epsilon})$, violating the k-SUM conjecture.

Suppose k is odd. By Corollary 13, integer k-SUM can be reduced to k^d instances of k-SUM in $\mathbb{F}_p^d$. If k-SUM in $\mathbb{F}_p^d$ can be solved in time $O(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - \epsilon})$, then integer $(k-1)$-SUM could be solved in time $k^d \times O(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - \epsilon})$. Since $d = 2\log_p n^{(k-1)} \leq 2k\frac{\log n}{\log p}$, we can bound k^d by $k^d = n^{d\frac{\log k}{\log n}} \leq n^{2k\frac{\log k}{\log p}}$. Therefore, integer $(k-1)$-SUM could be solved in time $k^d \times O(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - \epsilon}) \leq O(n^{\lceil k/2 \rceil - \epsilon})$, violating the k-SUM conjecture. ◀

In particular, under the 3SUM conjecture, 3SUM in $\mathbb{F}_p^d$ requires time $\Omega(n^{2-\frac{6}{\log_3 p} - o(1)})$. This implies that there does not exist an $\epsilon > 0$ such that 3SUM in $\mathbb{F}_p^d$ can be solved in $O(n^{2-\epsilon})$ for all prime p, under the 3SUM conjecture. Combined with the reduction in Lemma 10, we obtain the following weak equivalence between integer k-SUM and k-SUM in $\mathbb{F}_p^d$.

▶ **Theorem 14.** *For any $k \geq 2$, integer k-SUM can be solved in $O(n^{\lceil k/2 \rceil - \delta})$ time for some $\delta > 0$ if and only if there exists an $\epsilon > 0$ such that k-SUM in $\mathbb{F}_p^d$ can be solved in $O(n^{\lceil k/2 \rceil - \epsilon})$ for all sufficiently large prime p.*

Proof. Suppose integer k-SUM can be solved in $O(n^{\lceil k/2 \rceil - \delta})$ time for some $0 < \delta < 1$. Take $\epsilon = \delta/2$, and take p large enough such that $k\frac{\log k}{\log p} < \delta/2$. Using a randomized reduction, we may assume without loss of generality that $d \leq k\log_p n$. By Corollary 11, k-SUM in $\mathbb{F}_p^d$ can be reduced to k^d instances of integer k-SUM, so k-SUM in $\mathbb{F}_p^d$ can be solved in time $k^d \cdot O(n^{\lceil k/2 \rceil - \delta}) \leq n^{k\frac{\log k}{\log p}} \cdot O(n^{\lceil k/2 \rceil - \delta}) = O(n^{\lceil k/2 \rceil - \delta/2})$.

Conversely, suppose there exists an $\epsilon > 0$ such that k-SUM in $\mathbb{F}_p^d$ can be solved in $O(n^{\lceil k/2 \rceil - \epsilon})$ for all sufficiently large prime p. Then, there exists some p large enough such that $\epsilon > 2k\frac{\log k}{\log p}$. By the proof of Theorem 3, integer k-SUM can be solved in time $O(n^{\lceil k/2 \rceil - \epsilon + 2k\frac{\log k}{\log p}})$. ◀

3 Proof of Lower Bound for Monotone 3SUM in $[n]^d$

In Definition 4, we defined bounded monotone d-dimensional 3SUM to be 3SUM on a monotone set in $[n]^d$, where n is the range of the coordinates. Alternatively, one could also define bounded monotone 3SUM to be on a monotone set of size n. Note that a monotone set in $[n]^d$ can have size at most dn, so the two definitions are equivalent up to a factor of d.

To prove the lower bound for bounded monotone 3SUM, we reduce from Convolution-3SUM to bounded monotone 3SUM. The Convolution-3SUM problem is a more restricted version of 3SUM:

▶ **Definition 15** (Convolution-3SUM)**.** Given an array $A[1 \ldots n]$, determine whether there exist $i \neq j$ with $A[i] + A[j] = A[i+j]$.

Pătraşcu [17] first proved that if 3SUM requires $\Omega(n^{2-o(1)})$ time, then so does Convolution-3SUM. Kopelowitz, Pettie, and Porat [16] showed that the randomized complexities of 3SUM and Convolution-3SUM differ by at most a logarithmic factor.

Note that the brute force algorithm for Convolution-3SUM runs in $O(n^2)$ time, as there are only $O(n^2)$ possible pairs to try. Amir, Chan, Lewenstein, and Lewenstein [4] pointed out a (randomized) reduction from Convolution-3SUM in any large domain to Convolution-3SUM in $\{-n^2, \ldots, n^2\}$.

The above results imply that the 3SUM conjecture is equivalent to the hardness of Convolution-3SUM in $\{-n^2, \ldots, n^2\}$, making Convolution-3SUM a useful tool for our purpose. Amir, Chan, Lewenstein, and Lewenstein [4] also restated the strong 3SUM conjecture as: Any algorithm for Convolution-3SUM in the domain of $\{-n, \ldots, n\}$ requires $\Omega(n^{2-o(1)})$ time.

Previously we defined k-SUM as determining whether there exists $a_1 + \cdots + a_k = 0$ for $a_i \in A_i$. In this section, for convenience we use an equivalent formulation of 3SUM: given sets A, B, S, determine whether there exist $a \in A, b \in B, s \in S$ such that $a + b = s$. The benefit is to avoid negative integer values. For 3SUM or Convolution-3SUM on A, B, S in $\{-u, \ldots, u\}$, add u to all values in A, B, and add $2u$ to all values in S. Therefore, it is sufficient to work with Convolution-3SUM in $[n^2]$ instead of $\{-n^2, \ldots, n^2\}$, and $[n]$ instead of $\{-n, \ldots, n\}$.

Convolution-3SUM in $[m]$ is a special case of 3SUM in $[n] \times [m]$, by mapping the array indices to the first coordinate, i.e. integer a_i in a Convolution-3SUM instance is mapped to the pair $(i, a_i) \in [n] \times [m]$. We will use this notation for simplicity. Since array indices are unique, no two values have the same first coordinate.

First, we reduce integer Convolution-3SUM to d-dimensional Convolution-3SUM, using the same techniques as in Lemma 12 (the reduction from integer 3SUM to d-dimensional 3SUM). Here we replace $\mathbb{F}_p^d$ with $[p]^d$, but the proof is nearly identical to Lemma 12, so we do not repeat it here.

▶ **Lemma 16.** *For any given dimension d, Convolution-3SUM in $[n^c]$ can be reduced to 4^d instances of Convolution-3SUM in $[n^{c/d}]^d$.*

Next we reduce from d-dimensional Convolution-3SUM to monotone d-dimensional Convolution-3SUM, by blowing up the bounded domain.

▶ **Lemma 17.** *Convolution-3SUM in $[m]^d$ can be reduced to Convolution-3SUM on monotone sets in $[nm]^d$.*

Proof. Let $f : [n] \times [m]^d \to [n] \times [nm]^d$ be the map $(a_0, a_1, ..., a_d) \mapsto (a_0, ma_0 + a_1, ..., ma_0 + a_d)$. Take $A' = f(A), B' = f(B), S' = f(S)$. Since f is linear in each coordinate, $a+b+s = 0$ implies $f(a) + f(b) + f(s) = 0$. Conversely, if $f(a) + f(b) + f(s) = 0$, the first coordinate guarantees $a_0 + b_0 + s_0 = 0$, and then it follows that $a_i + b_i + s_i = 0$ in each coordinate.

Since no two points in A (resp. B, S) share the same first coordinate, the new sets A' (resp. B', S') are monotone if we order them in increasing a_0 (resp. b_0, s_0), because the a_0 dominates in $ma_0 + a_i$. ◀

The following lemma is the main technical lemma from which Theorem 5 and Theorem 6 easily follow.

▶ **Lemma 18.** *Let c be a real constant between $1 \le c \le 2$, let $d > c$ be an integer, and let $\delta > 0$ be an arbitrarily small constant. Assume n is large enough such that $n > 2^{4d/\delta}$. If 3SUM for monotone sets in $[n]^d$ can be solved in time $O(n^{2-2c/d-\delta})$, then Convolution-3SUM in $[n^c]$ can be solved in time $O(n^{2-\delta/2})$.*

Proof. Let $\gamma = \frac{c}{d} < 1$. By Lemma 16 and Lemma 17, Convolution-3SUM in $[n^c]$ can be reduced to 4^d instances of Convolution-3SUM on monotone sets in $[n^{(1+\gamma)}]^d$. By writing the

array index as an additional dimension, i.e. mapping a_i in a Convolution-3SUM instance to (i, a_i), each of the 4^d Convolution-3SUM instances can be seen as $(d+1)$-dimensional monotone 3SUM in $[n^{(1+\gamma)}]^{(d+1)}$.

By assumption, 4^d instances of $(d+1)$-dimensional monotone 3SUM in $[n^{(1+\gamma)}]^{(d+1)}$ can be solved in time

$$4^d \cdot O(n^{(1+\gamma)(2-2c/d-\delta)}) = O(n^{\frac{d}{\log_4 n}+(1+\gamma)(2(1-c/d)-\delta)}).$$

The exponent can be simplified as follows. When $n > 2^{4d/\delta}$,

$$\frac{d}{\log_4 n} + (1+\gamma)(2(1-c/d)-\delta) = 2 - \delta - \gamma\delta - 2\gamma^2 + \frac{d}{\log_4 n} < 2 - \delta/2.$$

Thus, when n is sufficiently large, the 4^d instances of $(d+1)$-dimensional monotone 3SUM can be solved in time $O(n^{2-\delta/2})$. ◀

▶ **Theorem 5.** (Restated) *Under the standard 3SUM conjecture, bounded d-dimensional monotone 3SUM requires time $\Omega(n^{2-\frac{4}{d}-o(1)})$.*

Proof. This is a immediate corollary to Lemma 18 with $c = 2$. ◀

The lower bound can be improved to $\Omega(n^{2-\frac{4}{d+1}-o(1)})$ specifically for $c = 2$ with a little extra computation.

One can also define a strong version of the 3SUM conjecture (see Definition 8) and this yields a slightly stronger result:

▶ **Theorem 6.** (Restated) *Under the strong 3SUM conjecture, bounded d-dimensional monotone 3SUM requires time $\Omega(n^{2-\frac{2}{d}-o(1)})$.*

Proof. This is a immediate corollary to Lemma 18 with $c = 1$. ◀

4 Strong 3SUM Conjecture vs 3SUM Conjecture

The 3SUM conjecture states that integer 3SUM requires time $\Omega(n^{2-o(1)})$, while the strong 3SUM conjecture states that integer 3SUM in the bounded domain of $\{-n^2, \ldots, n^2\}$ requires time $\Omega(n^{2-o(1)})$. We would like to understand whether the 3SUM conjecture is equivalent to the strong 3SUM conjecture. To add evidence to this, we prove a partial result that 3SUM$^+$ in the domain of $\{-n^{2+\delta}, ..., n^{2+\delta}\}$ is as hard as unbounded integer 3SUM, using ideas about multidimensional 3SUM from previous sections.

▶ **Lemma 19** (Lemma 1, [5]). *Let A be a sorted list of n integers. For any fixed $c \in A$, we can decide whether c is a hit (i.e., whether there exist $a, b \in A$ such that $a + b = c$) in $O(n)$ time.*

The proof idea for Lemma 20 is similar to our reduction from multidimensional 3SUM to integer 3SUM in Lemma 10. Instead of $\mathbb{F}_p^3$, we consider 3SUM in the group $\mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$ for three different primes.

▶ **Lemma 20.** *Let $0 < \epsilon < 1$. If 3SUM$^+$ in $[M]$ can be solved in $O(n^{2-\epsilon})$ time, then for any primes p_1, p_2, p_3 such that $p_1 p_2 p_3 \leq \frac{M}{32}$, 3SUM$^+$ in $\mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$ can be solved in $O(n^{2-\epsilon})$ time.*

Proof. Let $S \subset \mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$ be a subset of size n. Let $\varphi : \mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3} \times \{0,1\}^3 \to [32p_1p_2p_3] \subset \mathbb{Z}$ be the injective map

$$\varphi : (a_1, a_2, a_3, t_1, t_2, t_3) \mapsto_\varphi (t_1p_1 + a_1) \cdot (16p_2p_3) + (t_2p_2 + a_2) \cdot (4p_3) + (t_3p_3 + a_3).$$

Let A be the image $A := \varphi(S \times \{0,1\}^3)$. The size of A is $8n$.

It is easy to check $\varphi(a_1, a_2, a_3, t_1, t_2, t_3) + \varphi(b_1, b_2, b_3, r_1, r_2, r_3) = \varphi(c_1, c_2, c_3, w_1, w_2, w_3)$ implies $(a_1, a_2, a_3) + (b_1, b_2, b_3) = (c_1, c_2, c_3)$ in $\mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$.

Conversely, suppose $(a_1, a_2, a_3) + (b_1, b_2, b_3) = (c_1, c_2, c_3)$ in $\mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$. For $i = 1, 2, 3$, since $a_i + b_i = c_i \pmod{p_i}$, either $a_i + b_i = c_i$ or $a_i + b_i = c_i + p_i$. Thus, there exists $w_1, w_2, w_3 \in \{0,1\}$ such that $\varphi(a_1, a_2, a_3, 0, 0, 0) + \varphi(b_1, b_2, b_3, 0, 0, 0) = \varphi(c_1, c_2, c_3, w_1, w_2, w_3)$.

To solve 3SUM$^+$ on S, first solve 3SUM$^+$ on A, which reports all $(A+A) \cap A$. The 3SUM$^+$ instance on S then outputs all $(c_1, c_2, c_3) \in S$ such that $\varphi(c_1, c_2, c_3, w_1, w_2, w_3) \in (A+A) \cap A$ for some $w_1, w_2, w_3 \in \{0,1\}$. The reduction takes $O(n)$ time. ◀

▶ **Lemma 21.** *Let $a_1, \ldots, a_k$ be k non-zero integers in the domain $\{-u, \ldots, u\}$. For any sufficiently large M,*

$$\Pr_{p_1,p_2,p_3 \in \mathcal{P}_M} \left[\#\{i : a_i \equiv 0 \pmod{p_1p_2p_3}\} < 24 \frac{\log^3(M) \log^3(u)}{M^3} k \right] \geq \frac{2}{3}.$$

Proof. Let $X_i = 1$ if $a_i \equiv 0 \pmod{p_1p_2p_3}$, and $X_i = 0$ otherwise. For each $i = 1, \ldots, k$, the number of distinct prime factors of a_i is at most $\log u$. By the Prime Number Theorem, $\pi(M) \sim \frac{M}{\log M}$, where $\pi(M)$ is the number of primes in $\{1, \ldots, M\}$. Hence, for M sufficiently large, $\pi(M) \geq \frac{1}{2} \frac{M}{\log M}$, and

$$\Pr_{p \in \mathcal{P}_M} [a_i \equiv 0 \pmod{p}] \leq \frac{\log u}{\frac{1}{2} \frac{M}{\log M}} = 2 \frac{\log M \log u}{M}.$$

Since p_1, p_2, p_3 are independently chosen primes,

$$E[X_i] = \Pr_{p_1,p_2,p_3 \in \mathcal{P}_M} [X_i = 1] = \prod_{j=1}^{3} \Pr_{p_j \in \mathcal{P}_M} [a_i \equiv 0 \pmod{p_j}] \leq \left(2 \frac{\log M \log u}{M} \right)^3.$$

Let $X = \sum_i X_i = \#\{i : a_i \equiv 0 \pmod{p_1p_2p_3}\}$. By linearity of expectation,

$$E[X] = \sum_i E[X_i] \leq k \cdot \left(2 \frac{\log M \log u}{M} \right)^3.$$

By Markov's Inequality, $\Pr[X \geq 3E[X]] \leq \frac{1}{3}$, as desired. ◀

▶ **Lemma 22.** *For any $0 < \delta < 1$, suppose 3SUM$^+$ in the bounded domain $[n^{2+\delta}]$ can be solved in $O(n^{2-\epsilon})$ time, then 3SUM can be solved in $O(n^{1+\delta} + n^{2-\epsilon} + n^{2-\delta} \log^6(n))$ time with probability $2/3$. (With probability $2/3$, the algorithm answers yes or no correctly, otherwise it outputs "Don't Know".)*

Proof. Using a randomized reduction [5, 17], assume without loss of generality the given 3SUM instance is in the domain of $[n^3]$. Also assume without loss of generality that the given 3SUM instance is on the same set A, asking whether there exist $a, b, c \in A$ such that $a + b = c$. Consider the following algorithm.

Step 1. Sort A. Choose $2n^\delta$ elements in A with uniform probability, and determine whether each of them is a hit. If a hit is found among the $2n^\delta$ elements, output yes and terminate. Otherwise, proceed to step 2. By Lemma 19, this step takes $O(n^{1+\delta})$ time.

Step 2. Choose three primes p_1, p_2, p_3 independently with uniform probability among all primes less than $n^{(2+\delta)/3}$. Map A to a set in A' in $\mathbb{F}_{p_1} \times \mathbb{F}_{p_2} \times \mathbb{F}_{p_3}$ by $a \mapsto (a \bmod p_1, a \bmod p_2, a \bmod p_3)$. By Lemma 20, under the given assumption, 3SUM$^+$ on A' can be solved in $O(n^{2-\epsilon})$ time.

Step 3. If the 3SUM$^+$ instance on A' reports more than $648\log^6(n)n^{1-\delta}$ hits, the algorithm fails and outputs "Don't Know".

Step 4. If the 3SUM$^+$ instance on A' reports no more than $648n^{1-\delta}\log^6(n)$ hits, for each pre-image of the hits, determine whether it is a hit in integer 3SUM. If a hit is found, output yes. Otherwise, output no. By Lemma 19, this step runs in time $O(n^{2-\delta}\log^6(n))$.

The total runtime of the algorithm is $O(n^{1+\delta} + n^{2-\epsilon} + n^{2-\delta}\log^6(n))$. To analyze the probability bound:

Suppose there are at least $n^{1-\delta}$ hits in A, then each randomly chosen element in Step 1 is a hit with probability at least $n^{-\delta}$. Let X be the total number of hits among the $2n^{\delta}$ randomly chosen elements in Step 1, and let $\mu = E[X]$. Since $\mu \geq 2$, by Multiplicative Chernoff Bound,

$$\Pr[X = 0] \leq \Pr[X < (1 - \frac{1}{2})\mu] < \left(\frac{e^{-\frac{1}{2}}}{(1-\frac{1}{2})^{1-\frac{1}{2}}}\right)^{\mu} = (2e)^{-\frac{\mu}{2}} \leq \frac{1}{2e}.$$

Thus, if the integer 3SUM instance on A has more than $n^{1-\delta}$ hits, the algorithm correctly outputs yes in Step 1 with probability at least $1 - \frac{1}{2e} \geq \frac{2}{3}$.

Suppose the 3SUM instance on A has fewer than $n^{1-\delta}$ hits. By applying Lemma 21 to all non-zero $a_i + b_j - c_k$ (at most n^3 triples), we know with probability at least $2/3$, the number of false positive triples is no more than

$$24n^3 \frac{\log^3(n^{(2+\delta)/3})\log^3(n^3)}{(n^{(2+\delta)/3})^3} \leq 24(2+\delta)^3\log^6(n)n^{1-\delta} \leq 648n^{1-\delta}\log^6(n).$$

Thus, the algorithm outputs yes/no correctly in Step 4 with probability at least $2/3$, and outputs "Don't Know" in Step 3 with probability at most $1/3$. ◀

▶ **Theorem 9.** (Restated) *Under the standard 3SUM conjecture, 3SUM$^+$ in the domain of $\{-n^{2+\delta}, ..., n^{2+\delta}\}$ requires time $\Omega(n^{2-o(1)})$ for any $\delta > 0$.*

Proof. This is an immediate corollary to Lemma 22. ◀

5 Conclusion and Open Problems

Under the standard k-SUM conjecture, we proved lower bounds for k-SUM in $\mathbb{F}_p^d$, for bounded monotone d-dimensional 3SUM, and for 3SUM$^+$ in the bounded domain of $\{-n^{2+\delta}, \ldots, n^{2+\delta}\}$ for arbitrarily small δ.

One open problem is whether there is a lower bound for 3XOR (3SUM in $\mathbb{F}_2^d$) under the 3SUM conjecture. Our result is only meaningful for p that are sufficiently large as a function of k. In particular, it does not assert anything for $p = 2$. 3XOR is related to other well known problems such as listing triangles [15]. Not much is known about the complexity of 3XOR. Even an $O(n^{1.99})$ algorithm or an $\Omega(n^{1.01})$ lower bound for 3XOR would be significant.

Another open problem is to obtain a faster k-SUM algorithm in $\mathbb{F}_p^d$ for odd k. Our conditional lower bound for k-SUM in $\mathbb{F}_p^d$ is tight for even k. However, for odd k, there is a gap between the best known $\tilde{O}(n^{\lceil k/2 \rceil})$ algorithm and our $\Omega(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p} - o(1)})$ lower bound. From an optimistic perspective, for odd k, our results suggest that there may be

an $O(n^{\lceil k/2 \rceil - 2k\frac{\log k}{\log p}})$ algorithm for k-SUM in $\mathbb{F}_p^d$ without violating the k-SUM conjecture. In particular, there may be an $O(n^{2-\frac{c}{\log p}})$ algorithm for 3SUM in $\mathbb{F}_p^d$, even under the 3SUM conjecture.

Abstract

Let G be a graph such that each vertex has its list of available colors, and assume that each list is a subset of the common set consisting of k colors. For two given list colorings of G, we study the problem of transforming one into the other by changing only one vertex color assignment at a time, while at all times maintaining a list coloring. This problem is known to be PSPACE-complete even for bounded bandwidth graphs and a fixed constant k. In this paper, we study the fixed-parameter tractability of the problem when parameterized by several graph parameters. We first give a fixed-parameter algorithm for the problem when parameterized by k and the modular-width of an input graph. We next give a fixed-parameter algorithm for the shortest variant which computes the length of a shortest transformation when parameterized by k and the size of a minimum vertex cover of an input graph. As corollaries, we show that the problem for cographs and the shortest variant for split graphs are fixed-parameter tractable even when only k is taken as a parameter. On the other hand, we prove that the problem is W[1]-hard when parameterized only by the size of a minimum vertex cover of an input graph.

1 Introduction

Recently, the framework of *reconfiguration* [14] has been extensively studied in the field of theoretical computer science. This framework models several situations where we wish to find a step-by-step transformation between two feasible solutions of a combinatorial (search) problem such that all intermediate solutions are also feasible and each step respects a fixed reconfiguration rule. This reconfiguration framework has been applied to several well-studied combinatorial problems. (See a survey [18].)

Figure 1 A reconfiguration sequence between two L-colorings f_0 and f_t of G.

1.1 Our problem

In this paper, we study a reconfiguration problem for list (vertex) colorings in a graph, which was introduced by Bonsma and Cereceda [3].

Let $C = \{c_1, c_2, \ldots, c_k\}$ be the set of k colors, called the *color set*. A (proper) *k-coloring* of a graph $G = (V, E)$ is a mapping $f\colon V \to C$ such that $f(v) \neq f(w)$ for every edge $vw \in E$. In *list coloring*, each vertex $v \in V$ has a set $L(v) \subseteq C$ of colors, called the *list of* v; sometimes, the list assignment $L\colon V \to 2^C$ itself is called a *list*. Then, a k-coloring f of G is called an *L-coloring* of G if $f(v) \in L(v)$ holds for every vertex $v \in V$. Therefore, a k-coloring of G is simply an L-coloring of G when $L(v) = C$ holds for every vertex v of G, and hence L-coloring is a generalization of k-coloring. Figure 1(b) illustrates four L-colorings of the same graph G in Figure 1(a); the color assigned to each vertex is attached to the vertex.

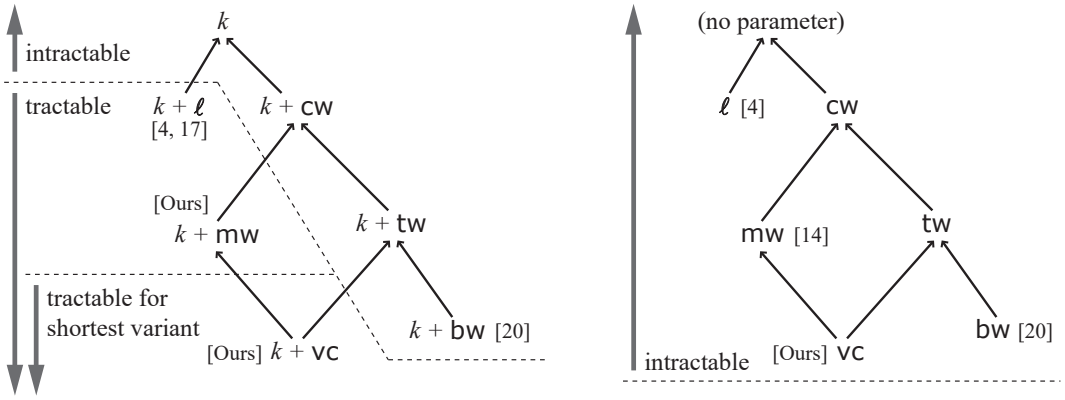
In the reconfiguration framework, two L-colorings f and f' of a graph $G = (V, E)$ are said to be *adjacent* if $|\{v \in V\colon f(v) \neq f'(v)\}| = 1$ holds, that is, f' can be obtained from f by recoloring exactly one vertex. A sequence $\langle f_0, f_1, \ldots, f_\ell \rangle$ of L-colorings of G is called a *reconfiguration sequence* between f_0 and f_ℓ (of *length* ℓ) if f_{i-1} and f_i are adjacent for each $i \in \{1, 2, \ldots, \ell\}$. Two L-colorings f and f' are *reconfigurable* if there exists a reconfiguration sequence between them. The LIST COLORING RECONFIGURATION problem is to determine whether two given L-colorings f_0 and f_t are reconfigurable, or not. Figure 1 shows an example of a yes-instance of LIST COLORING RECONFIGURATION, where the vertex whose color assignment was changed from the previous one is depicted by a black circle.

1.2 Known and related results

LIST COLORING RECONFIGURATION is one of the most well-studied reconfiguration problems, as well as COLORING RECONFIGURATION which is a special case of the problem such that $L(v) = \{c_1, c_2, \ldots, c_k\}$ holds for every vertex v. These problems have been studied intensively from various viewpoints [1, 2, 3, 4, 6, 7, 9, 13, 15, 19] including the generalizations [5, 20].

Bonsma and Cereceda [3] proved that COLORING RECONFIGURATION is PSPACE-complete even for bipartite graphs and any fixed constant $k \geq 4$. On the other hand, Cereceda et al. [7] gave a polynomial-time algorithm solving COLORING RECONFIGURATION for any graph and $k \leq 3$; the algorithm can be applied to LIST COLORING RECONFIGURATION, too. In particular, the former result implies that there is no fixed-parameter algorithm for COLORING RECONFIGURATION (and hence LIST COLORING RECONFIGURATION) when parameterized by only k under the assumption of P $\neq$ PSPACE.

Bonsma et al. [4] and Johnson et al. [15] independently developed a fixed-parameter algorithm to solve COLORING RECONFIGURATION when parameterized by $k + \ell$, where ℓ is the upper bound on the length of reconfiguration sequences, and again their algorithms can be applied to LIST COLORING RECONFIGURATION. In contrast, if COLORING RECONFIGURATION is parameterized only by ℓ, then it is W[1]-hard when k is an input [4] and does not admit a polynomial kernelization when k is fixed unless the polynomial hierarchy collapses [15].



(a) parameters with k (b) parameters without k

Figure 2 All results (including known ones) for LIST COLORING RECONFIGURATION from the viewpoint of parameterized complexity, where cw, tw, bw, mw, and vc are the upper bounds on the cliquewidth, treewidth, bandwidth, modular-width, and the size of a minimum vertex cover of an input graph, respectively.

Hatanaka et al. [13] proved that LIST COLORING RECONFIGURATION is PSPACE-complete even for complete split graphs, whose modular-width is zero. Wrochna [19] proved that LIST COLORING RECONFIGURATION is PSPACE-complete even when k and the bandwidth of an input graph are bounded by some constant; thus the treewidth and the cliquewidth of an input graph are also bounded.

1.3 Our contribution

To the best of our knowledge, known algorithmic results mostly employed the length ℓ of reconfiguration sequences as a parameter [4, 15], and no fixed-parameter algorithm is known when parameterized by graph parameters. Therefore, we study LIST COLORING RECONFIGURATION when parameterized by several graph parameters, and paint an interesting map of graph parameters which shows the boundary between fixed-parameter tractability and intractability. Our map is Figure 2 which shows both known and our results, where an arrow $\alpha \to \beta$ indicates that the parameter α is "stronger" than β, that is, β is bounded if α is bounded. (For relationships of parameters, see, e.g., [10, 16].)

More specifically, we first give a fixed-parameter algorithm solving LIST COLORING RECONFIGURATION when parameterized by k and the modular-width mw of an input graph. (The definition of modular-width will be given in Section 2.1.) Note that, according to the known results [3, 13], we cannot construct a fixed-parameter algorithm for general graphs when only one of k and mw is taken as a parameter under the assumption of P $\neq$ PSPACE. However, as later shown in Corollary 4, our algorithm implies that the problem is fixed-parameter tractable for cographs even when only k is taken as a parameter.

We then consider the shortest variant which computes the length of a shortest reconfiguration sequence (i.e., the minimum number of recoloring steps) for a yes-instance of LIST COLORING RECONFIGURATION, and show that it admits a fixed-parameter algorithm when parameterized by k and the size of a minimum vertex cover of an input graph. Moreover, as a corollary, we show that the shortest variant is fixed-parameter tractable for split graphs even when only k is taken as a parameter.

Finally, we prove that LIST COLORING RECONFIGURATION is $W[1]$-hard when parameterized only by the size of a minimum vertex cover of an input graph.

Due to the page limitation, several proofs are omitted from this extended abstract.

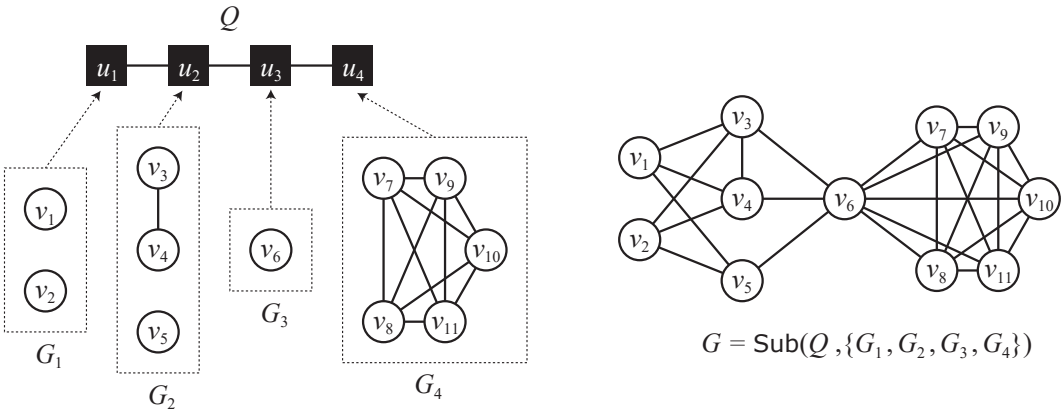

Figure 4 An example of substitution operation.

2 Preliminaries

We assume without loss of generality that graphs are simple and connected. Let $G = (V, E)$ be a graph with vertex set V and edge set E; we sometimes denote by $V(G)$ and $E(G)$ the vertex set and the edge set of G, respectively. For a vertex v in G, we denote by $N(G, v)$ the neighborhood $\{w \in V : vw \in E\}$ of v in G. For a vertex subset $V' \subseteq V$, we denote by $G[V']$ the subgraph of G induced by V', and denote $G \setminus V' = G[V(G) \setminus V']$. For a subgraph H of G, we denote $G \setminus H = G \setminus V(H)$. Let $\omega(G)$ be the size of a maximum clique of G. We have the following simple observation.

▶ **Observation 1.** *Let G be a graph with a list $L : V(G) \to 2^C$. If G has an L-coloring, then $\omega(G) \leq |C|$.*

A graph is *split* if its vertex set can be partitioned into a clique and an independent set. A graph is a *cograph* (or a P_4*-free* graph) if it contains no induced path with four vertices.

2.1 Modules and modular decomposition

A *module* of a graph $G = (V, E)$ is a vertex subset $M \subseteq V$ such that $N(G, v) \setminus M = N(G, w) \setminus M$ for every two vertices v and w in M. In other words, the module M is a set of vertices whose neighborhoods in $G \setminus M$ are the same. For example, the graph in Figure 3(a) has a module $M = \{v_3, v_4\}$ for which $N(G, v_3) \setminus M = N(G, v_4) \setminus M = \{v_1, v_2, v_6\}$ holds. Note that the vertex set V of G, the set consisting of only a single vertex, and the empty set $\emptyset$ are all modules of G; they are called *trivial*. A graph G is a *prime* if all of its modules are trivial; for an example, see Figure 3(b).

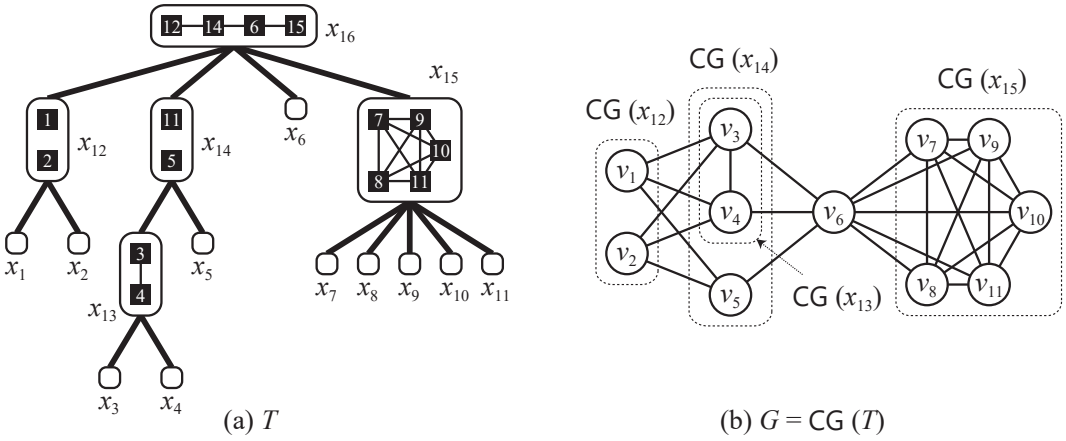

Figure 5 (a) A substitution tree T for (b) a graph G.

We now introduce the notion of modular decomposition, which was first presented by Gallai in 1967 as a graph decomposition technique [11]. For a survey, see, e.g., [12].

We first define the *substitution* operation, which constructs one graph from more than one graphs. Let Q be a graph, called a *quotient graph*, consisting of p (≥ 2) nodes $u_1, u_2, \ldots, u_p$, and let $\mathcal{F} = \{G_1, G_2, \ldots, G_p\}$ be a family of vertex-disjoint graphs such that G_i corresponds to u_i for every $i \in \{1, 2, \ldots, p\}$. The *$Q$-substitution* of $\mathcal{F}$, denoted by $\mathsf{Sub}(Q, \mathcal{F})$, is the graph which is obtained by taking a union of all graphs in $\mathcal{F}$ and then connecting every pair of vertices $v \in V(G_i)$ and $w \in V(G_j)$ by an edge if and only if u_i and u_j are adjacent in Q. That is, the vertex set of $\mathsf{Sub}(Q, \mathcal{F})$ is $\bigcup\{V(G_i) \colon G_i \in \mathcal{F}\}$, and the edge set of $\mathsf{Sub}(Q, \mathcal{F})$ is the union of $\bigcup\{E(G_i) \colon G_i \in \mathcal{F}\}$ and $\{vw \colon v \in V(G_i), w \in V(G_j), u_iu_j \in E(Q)\}$. (See Figure 4 as an example.)

A *substitution tree* is a rooted tree T such that each non-leaf node $x \in V(T)$ is associated with a quotient graph $\mathsf{Q}(x)$ and has $|V(\mathsf{Q}(x))|$ child nodes. For each node $x \in V(T)$, we can recursively define the *corresponding graph* $\mathsf{CG}(x)$ as follows: If x is a leaf, $\mathsf{CG}(x)$ consists of a single vertex. Otherwise, let $y_1, y_2, \ldots, y_p$ be $p = |V(\mathsf{Q}(x))|$ children of x, then $\mathsf{CG}(x) = \mathsf{Sub}(\mathsf{Q}(x), \{\mathsf{CG}(y_1), \mathsf{CG}(y_2), \ldots, \mathsf{CG}(y_p)\})$. For the root r of T, $\mathsf{CG}(r)$ is called the *corresponding graph of* T, and we denote $\mathsf{CG}(T) := \mathsf{CG}(r)$. We say that T is a substitution tree *for* a graph G if $\mathsf{CG}(T) = G$, and refer to a *node* in T in order to distinguish it from a vertex in G. Figure 5(a) illustrates a substitution tree for the graph G in Figure 5(b); each leaf x_i, $i \in \{1, 2, \ldots, 11\}$, corresponds to the subgraph of G consisting of a single vertex v_i. We note that the vertex set $V(\mathsf{CG}(x))$ of each corresponding graph $\mathsf{CG}(x)$, $x \in V(T)$, forms a module of $\mathsf{CG}(T)$.

A *modular decomposition tree* T (an *MD-tree* for short) for a graph G is a substitution tree for G which satisfies the following three conditions:

- Each node $x \in V(T)$ applies to one of the following three types:
  - a *series* node, whose quotient graph $\mathsf{Q}(x)$ is a complete graph;
  - a *parallel* node, whose quotient graph $\mathsf{Q}(x)$ is an edge-less graph; and
  - a *prime* node, whose quotient graph $\mathsf{Q}(x)$ is a prime with at least four vertices.
- No edge connects two series nodes.
- No edge connects two parallel nodes.

It is known that any graph G has a unique MD-tree with $O(|V(G)|)$ nodes, and it can be computed in time $O(|V(G)| + |E(G)|)$ [17]. We denote by $\mathsf{MD}(G)$ the unique MD-tree for a graph G. The *modular-width* $\mathsf{mw}(G)$ of a graph G is the maximum number of children of

a prime node in its MD-tree $\mathsf{MD}(G)$. The substitution tree T in Figure 5(a) is indeed the MD-tree for the graph G in Figure 5(b), and hence $\mathsf{mw}(G) = 4$; note that only x_{16} is a prime node in T.

We now define a variant of MD-trees, which will make our proofs and analyses simpler. A *pseudo modular decomposition tree* T (a *PMD-tree* for short) for a graph G is a substitution tree for G which satisfies the following two conditions:

- Each node $x \in V(T)$ applies to one of the following three types:
  - a 2-*join* node, whose quotient graph $\mathsf{Q}(x)$ is a complete graph with exactly two vertices;
  - a *parallel* node, whose quotient graph $\mathsf{Q}(x)$ is an edge-less graph; and
  - a *prime* node, whose quotient graph $\mathsf{Q}(x)$ is a prime with at least four vertices.
- No edge connects two parallel nodes.

▶ **Proposition 2.** *For any graph G, there exists a PMD-tree T with $O(|V(G)|)$ nodes such that each prime node $x \in V(T)$ has at most $\mathsf{mw}(G)$ children, and it can be constructed in polynomial time.*

We denote by $\mathsf{PMD}(G)$ a PMD-tree for G such that each prime node $x \in V(T)$ has at most $\mathsf{mw}(G)$ children. The *pseudo modular-width* $\mathsf{pmw}(G)$ of a graph G is the maximum number of children of a non-parallel node in its PMD-tree. Notice that $\mathsf{pmw}(G) = \max\{2, \mathsf{mw}(G)\}$ holds.

2.2 Other notation

Let $G = (V, E)$ be a graph, and let $L\colon V \to 2^C$ be a list. For two L-colorings f and f' of G, we define the *difference* $\mathsf{dif}(f, f')$ *between* f *and* f' as the set $\{v \in V\colon f(v) \neq f'(v)\}$. Notice that f and f' are adjacent if and only if $|\mathsf{dif}(f, f')| = 1$.

We express an instance $\mathcal{I}$ of LIST COLORING RECONFIGURATION by a 4-tuple (G, L, f_0, f_t) consisting of a graph G, a list L, and *initial* and *target* L-colorings f_0 and f_t of G.

Finally, we introduce a notion of "restriction" of mappings and instances. Consider an arbitrary mapping $\mu\colon V(G) \to S$, where G is a graph and S is any set. For a subgraph H of G, we denote by μ^H the *restriction* of μ on $V(H)$, that is, μ^H is a mapping from $V(H)$ to S such that $\mu^H(v) = \mu(v)$ for each vertex $v \in V(H)$. Let $\mathcal{I} = (G, L, f_0, f_t)$ be an instance of LIST COLORING RECONFIGURATION. For a subgraph H of G, we define the *restriction* $\mathcal{I}^H$ of $\mathcal{I}$ (on H) as the instance (H, L^H, f_0^H, f_t^H) of LIST COLORING RECONFIGURATION. Notice that f_0^H and f_t^H are proper L^H-colorings of H.

3 Fixed-Parameter Algorithm for Bounded Modular-Width Graphs

The following is our main theorem of this section.

▶ **Theorem 3.** LIST COLORING RECONFIGURATION *is fixed-parameter tractable when parameterized by $k + \mathsf{mw}$, where k and mw are the upper bounds on the size of the color set and the modular-width of an input graph, respectively.*

Because it is known that any cograph has modular-width zero, we have the following result as a corollary of Theorem 3.

▶ **Corollary 4.** LIST COLORING RECONFIGURATION *is fixed-parameter tractable for cographs when parameterized by the size k of the color set.*

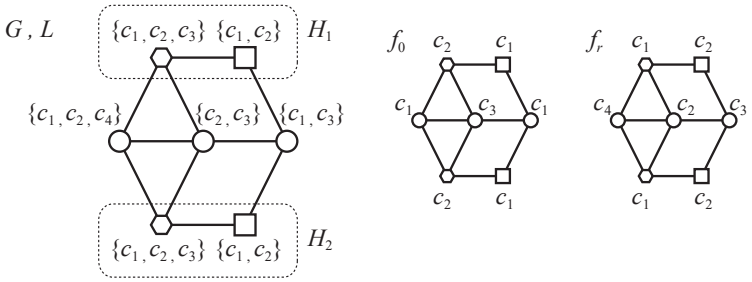

Figure 6 An instance $\mathcal{I} = (G, L, f_0, f_t)$ of LIST COLORING RECONFIGURATION, and two identical subgraphs H_1 and H_2.

Recall that $\mathsf{pmw}(G) = \max\{2, \mathsf{mw}(G)\}$, and hence $\mathsf{pmw}(G) \leq \mathsf{mw}(G) + 2$. Therefore, as a proof of Theorem 3, it suffices to give a fixed-parameter algorithm for LIST COLORING RECONFIGURATION with respect to $k + \mathsf{pmw}$, where pmw is an upper bound on $\mathsf{pmw}(G)$.

3.1 Reduction rule

In this subsection, we give a useful lemma, which compresses an input graph into a smaller graph with keeping the reconfigurability.

Let $\mathcal{I} = (G, L, f_0, f_t)$ be an instance of LIST COLORING RECONFIGURATION. For each vertex $v \in V(G)$, we define a *vertex assignment* $A(v)$ as a triple $(L(v), f_0(v), f_t(v))$ consisting of a list, and initial and target color assignments of v. Let H_1 and H_2 be two induced subgraphs of G such that $|V(H_1)| = |V(H_2)|$ and $V(H_1) \cap V(H_2) = \emptyset$. Then, H_1 and H_2 are *identical* (on $\mathcal{I}$) if there exists a bijective function $\phi\colon V(H_1) \to V(H_2)$ which satisfies the following two conditions:

1. H_1 and H_2 are isomorphic under ϕ, that is, $vw \in E(H_1)$ if and only if $\phi(v)\phi(w) \in E(H_2)$.
2. For all vertices $v \in V(H_1)$,
   a. $N(G, v) \setminus V(H_1) = N(G, \phi(v)) \setminus V(H_2)$; and
   b. $A(v) = A(\phi(v))$, that is, $L(v) = L(\phi(v))$, $f_0(v) = f_0(\phi(v))$ and $f_t(v) = f_t(\phi(v))$.

We note that the condition 2-a implies that there is no edge between H_1 and H_2. Figure 6 shows an example of identical subgraphs H_1 and H_2 on $\mathcal{I} = (G, L, f_0, f_t)$, where the bijective function maps each vertex in H_1 to a vertex in H_2 with the same shape.

We now prove the following key lemma, which holds for any graph.

▶ **Lemma 5.** (Reduction rule) *Let $\mathcal{I} = (G, L, f_0, f_t)$ be an instance of* LIST COLORING RECONFIGURATION*, and let H_1 and H_2 be two identical subgraphs of G. Then, $\mathcal{I}^{G \setminus H_2}$ is a yes-instance if and only if $\mathcal{I}$ is.*

3.2 Kernelization

Let $\mathcal{I} = (G, L, f_0, f_t)$ be an instance of LIST COLORING RECONFIGURATION. Suppose that the color set C has at most k colors, G is a connected graph with $\mathsf{pmw}(G) \leq \mathsf{pmw}$, and all vertices of G are totally ordered according to an arbitrary binary relation $\prec$.

3.2.1 Sufficient condition for identical subgraphs

We first give a sufficient condition for which two nodes in a PMD-tree $\mathsf{PMD}(G)$ for G correspond to identical subgraphs. Let $x \in V(\mathsf{PMD}(G))$ be a node, let $p := |V(\mathsf{CG}(x))|$, and assume that all vertices in $V(\mathsf{CG}(x))$ are labeled as $v_1, v_2, \ldots, v_p$ according to $\prec$; that is,

$v_i \prec v_j$ holds for each i, j with $1 \leq i < j \leq p$. Let $m \geq p$ be some integer which will be defined later. We now define an $(m+1) \times m$ matrix $\mathcal{M}_m(x)$ as follows:

$$(\mathcal{M}_m(x))_{i,j} = \begin{cases} 1 & \text{if } i,j \leq p \text{ and } v_iv_j \in E(\mathsf{CG}(x)); \\ 0 & \text{if } i,j \leq p \text{ and } v_iv_j \notin E(\mathsf{CG}(x)); \\ 0 & \text{if } p < i \leq m \text{ or } p < j \leq m; \\ A(v_j) & \text{if } i = m+1 \text{ and } j \leq p; \\ \emptyset & \text{otherwise,} \end{cases}$$

where $(\mathcal{M}_m(x))_{i,j}$ denotes an (i,j)-element of $\mathcal{M}_m(x)$. Notice that $\mathcal{M}_m(x)$ contains the adjacency matrix of $\mathsf{CG}(x)$ at its upper left $p \times p$ submatrix, and the bottommost row represents the vertex assignment of each vertex in $V(\mathsf{CG}(x))$. We call $\mathcal{M}_m(x)$ an *m-ID-matrix* of x. For example, consider the node x_{13} in Figure 5(a). Then, $p = 2$, and a 4-ID-matrix of x_{13} is as follows:

$$\mathcal{M}_4(x_{13}) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ A(x_3) & A(x_4) & \emptyset & \emptyset \end{bmatrix}$$

▶ **Lemma 6.** *Let y_1 and y_2 be two children of a parallel node x in $\mathsf{PMD}(G)$, and let m be an integer with $m \geq \max\{|V(\mathsf{CG}(y_1))|, |V(\mathsf{CG}(y_2))|\}$. If $\mathcal{M}_m(y_1) = \mathcal{M}_m(y_2)$ holds, then $\mathsf{CG}(y_1)$ and $\mathsf{CG}(y_2)$ are identical.*

3.2.2 Kernelization algorithm

We now describe how to kernelize an input instance. Our algorithm traverses a PMD-tree $\mathsf{PMD}(G)$ of G by a depth-first search in post-order starting from the root of $\mathsf{PMD}(G)$, that is, the algorithm processes a node of $\mathsf{PMD}(G)$ after its all children are processed.

Let $x \in V(\mathsf{PMD}(G))$ be a node which is currently visited. If x is a non-parallel node, we do nothing. Otherwise (i.e., if x is a parallel node,) let Y be the set of all children of x, and let $m := \max_{y \in Y} |V(\mathsf{CG}(y))|$. We first construct m-ID-matrices of all children of x. If there exist two nodes y_1 and y_2 such that $\mathcal{M}_m(y_1) = \mathcal{M}_m(y_2)$, then $\mathsf{CG}(y_1)$ and $\mathsf{CG}(y_2)$ are identical; and hence we remove $\mathsf{CG}(y_2)$ from G by Lemma 5. Then, we modify $\mathsf{PMD}(G)$ in order to keep it still being a PMD-tree for the resulting graph as follows. We remove a subtree rooted at y_2 from $\mathsf{PMD}(G)$, and delete a node corresponding to y_2 from a quotient graph $\mathsf{Q}(x)$ of x. If this removal makes x having only one child y in the PMD-tree, we contract the edge xy into a new node x' such that $\mathsf{Q}(x') = \mathsf{Q}(x)$.

The running time of this kernelization can be estimated as follows. For each node $x \in V(\mathsf{PMD}(G))$, the construction of m-ID-matrices can be done in time $O(|Y| \cdot m^2) = O(|V(G)|^3)$. We can check if $\mathcal{M}_m(y_1) = \mathcal{M}_m(y_2)$ for each pair of children y_1 and y_2 of x in time $O(m^2) = O(|V(G)|^2)$. Moreover, a modification of $\mathsf{PMD}(G)$, which follows an application of Lemma 5, can be done in polynomial time. Recall that the number of children of x and the size of a PMD-tree $\mathsf{PMD}(G)$ are both bounded linearly in $|V(G)|$, and hence our kernelization can be done in polynomial time.

3.2.3 Size of the kernelized instance

We finally prove that the size of the obtained instance $\mathcal{I}' = (G', L', f'_0, f'_t)$ depends only on $k + \mathsf{pmw}$; recall that pmw is the upper bound on $\mathsf{pmw}(G)$. By Observation 1, we can assume

that the maximum clique size $\omega(G')$ is at most k. In addition, G' is connected since G is connected and an application of Lemma 5 does not affect the connectivity of the graph. Therefore, it suffices to prove the following lemma.

▶ **Lemma 7.** *The graph G' has at most $h_{k,\mathsf{pmw}}(\omega(G'))$ vertices, where $h_{k,\mathsf{pmw}}(i)$ is recursively defined for an integer $i \geq 1$ as follows:*

$$h_{k,\mathsf{pmw}}(i) = \begin{cases} 1 & \text{if } i = 1; \\ \mathsf{pmw} \cdot h_{k,\mathsf{pmw}}(i-1) \cdot \sqrt{2}^{(h_{k,\mathsf{pmw}}(i-1))^2} \cdot (2^k \cdot k^2)^{h_{k,\mathsf{pmw}}(i-1)} & \text{otherwise.} \end{cases}$$

In particular, $h_{k,\mathsf{pmw}}(\omega(G'))$ depends only on $k + \mathsf{pmw}$.

Finally, we prove Theorem 3. By the above discussions, we can compute the kernelized instance $\mathcal{I}' = \mathcal{I}^{G'}$ of LIST COLORING RECONFIGURATION in polynomial time. Because the size of $\mathcal{I}'$ depends only on $k + \mathsf{pmw}$, we can solve $\mathcal{I}'$ by enumerating all $L^{G'}$-colorings. The running time for this enumeration depends only on $k + \mathsf{pmw}$, and hence we obtain a fixed-parameter algorithm for LIST COLORING RECONFIGURATION.

This completes the proof of Theorem 3.

4 Shortest Variant

In this section, we study the shortest variant, LIST COLORING SHORTEST RECONFIGURATION. We note that the shortest length can be expressed by a polynomial number of bits, because there are at most k^n colorings for a graph with n vertices and k colors. Therefore, the answer can be output in polynomial time. The following is our result.

▶ **Theorem 8.** LIST COLORING SHORTEST RECONFIGURATION *is fixed-parameter tractable when parameterized by $k + \mathsf{vc}$, where k and vc are the upper bounds on the sizes of the color set and a minimum vertex cover of an input graph, respectively.*

As a corollary, we have the following result.

▶ **Corollary 9.** LIST COLORING SHORTEST RECONFIGURATION *is fixed-parameter tractable for split graphs when parameterized by the size k of the color set.*

As a proof of Theorem 8, we give such a fixed-parameter algorithm. Our basic idea is the same as the fixed-parameter algorithm in Section 3. However, in order to compute the shortest length, we consider a more general "weighted" version of LIST COLORING SHORTEST RECONFIGURATION, which is defined as follows. Let $\mathcal{I} = (G, L, f_0, f_t)$ be an instance of LIST COLORING RECONFIGURATION, and assume that each vertex $v \in V(G)$ has a *weight* $w(v) \in \mathbb{N}$, where $\mathbb{N}$ is the set of all positive integers. For two adjacent L-colorings f and f' of a graph G, we define the *gap* $\mathsf{gap}_w(f, f')$ *between* f *and* f' as the weight $w(v)$ of v, where v is a unique vertex in $\mathsf{dif}(f, f')$. The *length* $\mathsf{len}_w(\mathcal{S})$ *of* a reconfiguration sequence $\mathcal{S} = \langle f_0, f_1, \ldots, f_\ell \rangle$ is defined as $\mathsf{len}_w(\mathcal{S}) = \sum_{i=1}^{\ell} \mathsf{gap}_w(f_{i-1}, f_i)$. We denote by $\mathsf{OPT}(\mathcal{I}, w)$ the minimum length of a reconfiguration sequence between f_0 and f_t; we define $\mathsf{OPT}(\mathcal{I}, w) = +\infty$ if $\mathcal{I}$ is a no-instance of LIST COLORING RECONFIGURATION. Then, LIST COLORING SHORTEST RECONFIGURATION can be seen as computing $\mathsf{OPT}(\mathcal{I}, w)$ for the case where every vertex has weight one. Thus, to prove Theorem 8, it suffices to construct a fixed-parameter algorithm for the weighted version when parameterized by $k + \mathsf{vc}$.

As with Section 3, we again use the concept of kernelization to prove Theorem 8. More precisely, for a given instance $(\mathcal{I}, w)$, we first construct an instance $(\mathcal{I}' = (G', L', f'_0, f'_t), w')$ in

polynomial time such that the size of $\mathcal{I}'$ depends only on $k+\mathsf{vc}$, and $\mathsf{OPT}(\mathcal{I}', w') = \mathsf{OPT}(\mathcal{I}, w)$ holds. Then, we can compute $\mathsf{OPT}(\mathcal{I}', w')$ by computing a (weighted) shortest path between f'_0 and f'_t in an edge-weighted graph defined as follows: the vertex set consists of all L'-colorings of G', and each pair of adjacent L'-colorings are connected by an edge with a weight corresponding to the gap between them.

4.1 Reduction rule for the weighted version

In this subsection, we give the counterpart of Lemma 5 for the weighted version.

Let $(\mathcal{I} = (G, L, f_0, f_t), w)$ be an instance of the weighted version, and assume that there exist two identical subgraphs H_1 and H_2 of G, both of which consist of single vertices, say, $V(H_1) = \{v_1\}$ and $V(H_2) = \{v_2\}$. We now define a new instance $(\mathcal{I}', w')$ as follows:

- $\mathcal{I}' = \mathcal{I}^{G \setminus H_2}$; and
- $w'(v_1) = w(v_1) + w(v_2)$ and $w'(v) = w(v)$ for any $v \in V(G) \setminus \{v_1, v_2\}$.

Intuitively, v_2 is merged into v_1 together with its weight. Then, we have the following lemma.

▶ **Lemma 10.** $\mathsf{OPT}(\mathcal{I}, w) = \mathsf{OPT}(\mathcal{I}', w')$.

4.2 Kernelization

Finally, we give a kernelization algorithm as follows.

Let $(\mathcal{I} = (G, L, f_0, f_t), w)$ be an instance of the weighted version such that G has a vertex cover of size at most vc. Because such a vertex cover can be computed in time $O(2^{\mathsf{vc}} \cdot |V(G)|)$ [8], we now assume that we are given a vertex cover V_C of size at most vc. Notice that $V_I := V \setminus V_C$ forms an independent set of G. Suppose that there exist two vertices $v_1, v_2 \in V_I$ such that $N(G, v_1) = N(G, v_2)$ and $A(v_1) = A(v_2)$ hold. Then, induced subgraphs $G[\{v_1\}]$ and $G[\{v_2\}]$ are identical. Therefore, we can apply Lemma 10 to remove v_2 from G, and modify a weight function without changing the optimality. As a kernelization, we repeatedly apply Lemma 10 for all such pairs of vertices in V_I, which can be done in polynomial time. Let G' be the resulting subgraph of G, and let $V'_I := V(G') \setminus V_C$. Since V_C is of size at most vc, it suffices to prove the following lemma.

▶ **Lemma 11.** $|V'_I| \leq 2^{\mathsf{vc}} \cdot 2^k \cdot k^2$.

This completes the proof of Theorem 8.

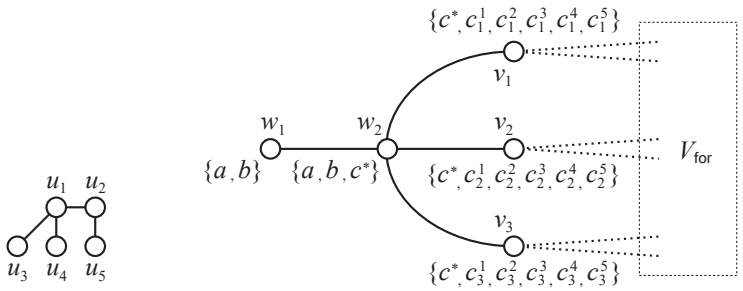
5 W[1]-Hardness

Because even the shortest variant is fixed-parameter tractable when parameterized by $k + \mathsf{vc}$, one may expect that vc is a strong parameter and the problem is fixed-parameter tractable with only vc. However, we prove the following theorem in this section.

▶ **Theorem 12.** List coloring reconfiguration *is W[1]-hard when parameterized by* vc*, where* vc *is the upper bound on the size of a minimum vertex cover of an input graph.*

Recall that list coloring reconfiguration is PSPACE-complete even for a fixed constant $k \geq 4$. Therefore, the problem is intractable if we take only one parameter, either k or vc.

In order to prove Theorem 12, we give an FPT-reduction from the independent set problem when parameterized by the solution size s, in which we are given a graph H and an integer $s \geq 0$, and asked whether H has an independent set of size at least s. This problem is known to be W[1]-hard [8].



(a) H , $s = 3$ (b) G , L

Figure 7 (a) An instance H of INDEPENDENT SET, and (b) the graph G and the list L. The set V_{for} contains vertices of $(i, j; p, q)$-forbidding gadgets for all $(i, j) \in \{(1, 2), (1, 3), (2, 3)\}$ and all $(p, q) \in \{(1, 1), (2, 2), (3, 3), (4, 4), (5, 5), (1, 2), (2, 1), (1, 3), (3, 1), (1, 4), (4, 1), (2, 5), (5, 2)\}$; thus $|V_{\mathsf{for}}| = 39$.

5.1 Construction

Let H be a graph with n vertices $u_1, u_2, \ldots, u_n$, and s be an integer as an input for INDEPENDENT SET. Then, we construct the corresponding instance (G, L, f_0, f_t) of LIST COLORING RECONFIGURATION as follows. (See also Figure 7.)

We first create s vertices $v_1, v_2, \ldots, v_s$, which are called *selection vertices*; let V_{sel} be the set of all selection vertices. For each $i \in \{1, 2, \ldots, s\}$, we set $L(v_i) = \{c^*, c_i^1, c_i^2, \ldots, c_i^n\}$. In our reduction, we will construct G and L so that assigning the color c_i^p, $p \in \{1, 2, \ldots, n\}$, to $v_i \in V_{\mathsf{sel}}$ corresponds to choosing the vertex $u_p \in V(H)$ as a vertex in an independent set of H. Then, in order to make a correspondence between a color assignment to V_{sel} and an independent set of size s in H, we need to construct the following properties:

- For each $p \in \{1, 2, \ldots, n\}$, we use at most one color from $\{c_1^p, c_2^p, \ldots, c_s^p\}$; this ensures that each vertex $u_p \in V(H)$ can be chosen at most once in an independent set.
- For each $p, q \in \{1, 2, \ldots, n\}$ with $u_p u_q \in E(H)$, we use at most one color from $\{c_1^p, c_2^p, \ldots, c_s^p, c_1^q, c_2^q, \ldots, c_s^q\}$; then, no two adjacent vertices in H are chosen in an independent set.

To do this, we define an $(i, j; p, q)$-forbidding gadget for $i, j \in \{1, 2, \ldots s\}$ and $p, q \in \{1, 2, \ldots, n\}$. The $(i, j; p, q)$-*forbidding gadget* is a vertex w which is adjacent to v_i and v_j and has a list $L(w) = \{c_i^q, c_j^p\}$. Observe that the vertex w forbids that v_i and v_j are simultaneously colored with c_i^p and c_j^q, respectively. In order to satisfy the desired properties above, we now add our gadgets as follows: for all $i, j \in \{1, 2, \ldots s\}$ with $i < j$,

- add an $(i, j; p, p)$-forbidding gadget for every vertex $u_p \in V(H)$; and
- add $(i, j; p, q)$- and $(i, j; q, p)$-forbidding gadgets for every edge $u_p u_q \in E(H)$.

We denote by V_{for} the set of all vertices in the forbidding gadgets. We finally create an edge consisting of two vertices w_1 and w_2 such that $L(w_1) = \{a, b\}$ and $L(w_2) = \{a, b, c^*\}$, and connect w_2 with all selection vertices in V_{sel}.

Finally, we construct two L-colorings f_0 and f_t of G as follows:

- for each $v_i \in V_{\mathsf{sel}}$, $f_0(v_i) = f_t(v_i) = c^*$;
- for each $w \in V_{\mathsf{for}}$, $f_0(w)$ and $f_t(w)$ are arbitrary chosen colors from $L(w)$; and
- $f_0(w_1) = f_t(w_2) = a$, and $f_t(w_1) = f_0(w_2) = b$.

Note that both f_0 and f_t are proper L-colorings of G. This completes the construction of (G, L, f_0, f_t).

5.2 Correctness of the reduction

In this subsection, we prove the following three statements:

- (G, L, f_0, f_t) can be constructed in time polynomial in the size of H.
- The upper bound vc on the size of a minimum vertex cover of G depends only on s.
- H is a yes-instance of INDEPENDENT SET if and only if (G, L, f_0, f_t) is a yes-instance of LIST COLORING RECONFIGURATION.

In order to prove the first statement, it suffices to show that the size of (G, L, f_0, f_t) is bounded polynomially in $n = |V(H)|$. From the construction, we have $|V(G)| = |V_{\mathsf{sel}}| + |V_{\mathsf{for}}| + |\{w_1, w_2\}| \leq s + s^2 \times (|V(H)| + 2|E(H)|) + 2 = O(n^4)$. In addition, each list contains $O(n)$ colors. Therefore, the construction can be done in time $O(n^{O(1)})$.

The second statement immediately follows from the fact that $\{w_2\} \cup V_{\mathsf{sel}}$ is a vertex cover in G of size $s + 1$; observe that $G \setminus (\{w_2\} \cup V_{\mathsf{sel}}) = G[\{w_1\} \cup V_{\mathsf{for}}]$ contains no edge.

Finally, we prove the third statement as follows.

▶ **Lemma 13.** *H is a yes-instance of* INDEPENDENT SET *if and only if (G, L, f_0, f_t) is a yes-instance of* LIST COLORING RECONFIGURATION.

This completes the proof of Theorem 12.

6 Conclusion

In this paper, we have studied LIST COLORING RECONFIGURATION from the viewpoint of parameterized complexity, in particular, with several graph parameters. We painted an interesting map of graph parameters in Figure 2 which shows the boundary between fixed-parameter tractability and intractability.

Abstract

In this paper we adopt a category-theoretic approach to the conception of automata classes enjoying minimization by design. The main instantiation of our construction is a new class of automata that are hybrid between deterministic automata and automata weighted over a field.

1 Introduction

In this paper we introduce a new automata model, *hybrid set-vector automata*, designed to accept weighted languages over a field in a more efficient way than Schützenberger's weighted automata [13]. The space of states for these automata is not a vector space, but rather a union of vector spaces "glued" together along subspaces. We call them hybrid automata, since they naturally embed both deterministic finite state automata and finite automata weighted over a field. In Section 2 we present at an informal level a motivating example and the intuitions behind this construction, avoiding as much as possible category-theoretical technicalities. We use this example to guide us throughout the rest of the paper.

A key property that the new automata model should satisfy is minimization. Since the morphisms of "glued" vector spaces are rather complicated to describe, proving the existence of minimal automata "by hand" is rather complicated. Therefore we opted for a more systematic approach and adopted a category-theoretic perspective for designing *new forms of automata* that enjoy *minimization by design*. In particular, we introduce the category of "glued" vector spaces in which these automata should live and we analyse its properties that render minimization possible.

Starting with the seminal papers of Arbib and Manes, see for example [3] and the references therein, and of Goguen [10], it became well established that category theory offers a neat understanding of several phenomena in automata theory. In particular, the key property of minimization in different contexts, such as for deterministic automata (over finite words)

and Schützenberger's automata weighted over fields [13], arises from the same categorical reasons (existence of some limits/colimits and an (epi,mono)-factorization system [3]).

There is a long tradition of seeing automata either as algebras or coalgebras for a functor. However, in the case of deterministic automata, the algebraic view does not capture the accepting states, while the coalgebraic view does not capture the initial state. In the coalgebraic setting one needs to consider the so-called pointed coalgebras, see for example [1], where minimal automata are modelled as well-pointed coalgebras. The dual perspective of automata seen as both algebras or coalgebras, as well as the duality between reachability and observability, has been explored more recently in papers such as [4, 5, 6].

Here we take yet another approach to defining automata in a category. The reader acquainted with category theory will recognise that we see automata as functors from an input category (that specifies the type of the machines under consideration, which in this paper is restricted to word automata) to a category of output values. We show that the next ingredients are sufficient to ensure minimization: the existence of an initial and of a final automaton for a language, and a factorization system on the category in which we interpret our automata.

For example, deterministic and weighted automata over a field are obtained by considering as output categories the categories Set of sets and functions and Vec of vector spaces and linear maps, respectively. Since Set and Vec have all limits and colimits, it is very easy to prove the existence of initial and final automata accepting a given language. In both cases, the minimal automaton for a language is obtained by taking an epi-mono factorization of the unique arrow from the initial to the final automaton.

Notice that the initial and the final automata have infinite (-dimensional) state sets (spaces). If the language at issue is regular, that is, if the unique map from the initial to the final automaton factors through a finite (-dimensional) automaton then, automatically, the minimal automaton will also be finite (-dimensional). However, this relies on very specific properties of the categories of sets and vector spaces, namely on the fact that the full subcategories $\mathsf{Set}_{\mathsf{fin}}$ of finite sets and $\mathsf{Vec}_{\mathsf{fin}}$ of finite dimensional vector spaces are closed in Set, respectively in Vec, under both quotients and subobjects.

Coming back to hybrid set-vector automata, we define them as word automata interpreted in an output category $\mathtt{Glue}(\mathsf{Vec})$ which we obtain as the completion of Vec under certain colimits, and can be described at an informal level as "glueings" of arbitrary vector spaces. The definition of this form of cocompletion $\mathtt{Glue}(\mathcal{C})$ of a category $\mathcal{C}$ is the subject of Section 4.

We are interested in those hybrid automata for which the state object admits a finitary description, which intuitively can be described as *finite* glueings of *finite dimensional* spaces. For this reason we will consider the subcategory $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$ of $\mathtt{Glue}(\mathsf{Vec})$. It turns out that $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$ is closed under quotients in $\mathtt{Glue}(\mathsf{Vec})$ but, crucially, *it is not closed under subobjects*. For example, a glueing of infinitely many one-dimensional spaces is a subobject of a two-dimensional space, but only the latter is an object of $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$.

This is the motivation for introducing a notion of *$(E_{\mathcal{S}},M_{\mathcal{S}})$-factorization of a category $\mathcal{C}$ through a subcategory $\mathcal{S}$*. This is a refinement of the classical notion of factorization system on $\mathcal{C}$ and is used for isolating the semantical computations (in $\mathcal{C}$) from the automata themselves (with an object from $\mathcal{S}$ as "set of configurations").[1] We show how it provides a minimization of "$\mathcal{S}$-automata for representing $\mathcal{C}$-languages". A concrete instance of this is a factorization system on $\mathtt{Glue}(\mathsf{Vec})$ through $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$, which plays a crucial role in proving the

[1] This distinction is usually not necessary, and we are not aware of its existence in the literature. It is crucial for us, thus we cannot use already existing results from the coalgebraic literature, e.g. [1].

existence of minimal $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automata for recognizing weighted languages.

The rest of the paper is organised as follows. We first develop a motivating example of a hybrid set-vector space automaton in Section 2. We then identify in Section 3 the category-theoretic ingredients that are sufficient for a class of automata to enjoy minimization. We then turn to our main contribution, namely the description and the study of the properties of (finite-)mono-diagrams in a category, in Section 4. We conclude in Section 5 with a discussion of some of the design choices we made in this paper.

2 The hybridisation of deterministic finite state and vector automata

In this section, we (rather informally) describe the motivating example of this paper: the construction of a family of automata that naturally extends both deterministic finite state automata and finite automata weighted over a field in the sense of Schützenberger (i.e., automata in the category of finite vector spaces). The intuition should then support the categorical constructions that we develop in the subsequent sections.

Set automata (deterministic automata). Let us fix ourselves an alphabet $\mathtt{A}$. A *deterministic automaton* (or *set automaton*) is a tuple

$$\mathcal{A} = (Q, i, f, (\delta_a)_{a\in\mathtt{A}})\,,$$

in which Q is a *set of states*, i is a map from a one element set $1 = \{0\}$ to Q (i.e. an *initial state*), f is a map from Q to a two elements set $2 = \{0, 1\}$ (i.e. a *set of accepting states*), and δ_a is a map from Q to itself for all letters $a \in \mathtt{A}$. Given a word $u = a_1 \dots a_n$, the automaton *accepts* the map $[\![\mathcal{A}]\!](u)\colon 1 \to 2$ defined as:

$$[\![\mathcal{A}]\!](u) = f \circ \delta_u \circ i \qquad \text{where} \quad \delta_{a_1\dots a_n} = \delta_{a_n} \circ \dots \circ \delta_{a_1}\,.$$

We recognize here the standard definition of a deterministic automaton, in which a word u is accepted if the map $[\![\mathcal{A}]\!](u)$ is the constant 1, and rejected if it is the constant 0.

Vector space automata (automata weighted over a field). Now, we can use the same definition of an automaton, this time with Q a vector space (over, say, the field $\mathbb{R}$), i a linear map from $\mathbb{R}$ to Q, f a linear map from Q to $\mathbb{R}$ (seen as a $\mathbb{R}$-vector space as usual), and δ_a a linear map from Q to itself. In other words, we have used the same definition, but this time in the category of vector spaces. Given a word u, a vector space automaton $\mathcal{A}$ computes $[\![\mathcal{A}]\!](u)\colon \mathbb{R} \to \mathbb{R}$ as the composite described above. Since a linear map from $\mathbb{R}$ to $\mathbb{R}$ is only determined by the image of 1, this automaton can be understood as associating to each input word u the real number $[\![\mathcal{A}]\!](u)(1)$. We will informally refer to such automata in this section as *vector space automata*. Let us provide an example.

Leading example. For a word $u \in \{a, b, c\}^*$ let $|u|_a$ denote the number of occurrences of the letter a in u. Let us compute the map F which, given a word $u \in \{a, b, c\}^*$, outputs $2^{|u|_a}$ if it contains an even number of b's and no c's, and 0 in all other cases. This is achieved with the vector space automaton $\mathcal{A}^{\mathsf{vec}} = (Q^{\mathsf{vec}} = \mathbb{R}^2, i^{\mathsf{vec}}, f^{\mathsf{vec}}, \delta^{\mathsf{vec}})$ where for all $x, y \in \mathbb{R}$,

$$i^{\mathsf{vec}}(x) = (x, 0)\,, \qquad \delta_a^{\mathsf{vec}}(x, y) = (2x, 2y)\,, \qquad \delta_b^{\mathsf{vec}}(x, y) = (y, x)\,,$$
$$f^{\mathsf{vec}}(x, y) = x\,, \qquad \delta_c^{\mathsf{vec}}(x, y) = (0, 0)\,.$$

One easily checks that indeed $[\![\mathcal{A}^{\mathsf{vec}}]\!](u)(1) = F(u)$ for all words $u \in \mathtt{A}^*$.

Can we do better? It is well known from Schützenberger's seminal work that the vector space automaton $\mathcal{A}^{\texttt{vec}}$ is minimal, both in an algebraic sense (to be described later) as well as at an intuitive level in the sense that no vector space automaton could recognize F with a dimension one vector space as configuration space: $\mathcal{A}^{\texttt{vec}}$ is "dimension minimal."

However, let us think for one moment on how one would "implement" the function F as an online device that would get letters as input, and would modify its internal state accordingly. Would we implement concretely $\mathcal{A}^{\texttt{vec}}$ directly? Probably not, since there is a more economic[2] way to obtain the same result: we can maintain 2^m where m is the number of a's seen so far, together with one bit for remembering whether the number of b's is even or odd. Such an automaton would start with 1 in its unique real valued register. Each time an a is met, the register is doubled, each time b is met, the bit is reversed, and when c is met, the register is set to 0. At the end of the input word, the automaton would output 0 or the value of the register depending on the current value of the bit. If we consider the configuration space that we use in this encoding, we use $\mathbb{R} \uplus \mathbb{R}$ instead of $\mathbb{R} \times \mathbb{R}$. Can we define an automata model that would faithfully implement this example?

A first generalization: disjoint unions of vector spaces. A way to achieve this is to interpret the generic notion of automata in the category of finite disjoint unions of vector spaces (*duvs*). One way to define such a *finite disjoint unions of vector spaces* is to use a finite set N of '*indices*' $p, q, r \ldots$, and to each index p associate a vector space V_p. The 'space' represented is then $\{(p, \vec{v}) \mid p \in N,\ \vec{v} \in V_p\}$. A 'map' between duvs represented by (N, V) and (N', V') is then a pair $h : N \to N'$ together with a linear map f_p from V_p to $V'_{h(p)}$ for all $p \in N$. It can be seen as mapping each $(p, \vec{v}) \in N \times V_p$ to $(h(p), f_p(\vec{v}))$. Call this a *duvs map*. Such duvs maps are composed in a natural way. This defines a category, and hence we can consider *duvs automata* which are automata with a duvs for its state space, and transitions implemented by duvs maps.

For instance, we can pursue with the computation of F and provide a duvs automaton $\mathcal{A}^{\texttt{duvs}} = (Q^{\texttt{duvs}}, i^{\texttt{duvs}}, f^{\texttt{duvs}}, \delta^{\texttt{duvs}})$ where $Q^{\texttt{duvs}} = \{(s, x) \mid s \in \{\texttt{even}, \texttt{odd}\},\ x \in \mathbb{R}\}$ (considered as a disjoint union of vector spaces with indices `even` and `odd` and all associated vector spaces $V_{\texttt{even}} = V_{\texttt{odd}} = \mathbb{R}$). The maps can be conveniently defined as follows:

$$
\begin{array}{lll}
i^{\texttt{duvs}}(x) = (\texttt{even}, x) & \delta_a^{\texttt{duvs}}(\texttt{even}, x) = (\texttt{even}, 2x) & \delta_a^{\texttt{duvs}}(\texttt{odd}, x) = (\texttt{odd}, 2x) \\
f^{\texttt{duvs}}(\texttt{even}, x) = x & \delta_b^{\texttt{duvs}}(\texttt{even}, x) = (\texttt{odd}, x) & \delta_b^{\texttt{duvs}}(\texttt{odd}, x) = (\texttt{even}, x) \\
f^{\texttt{duvs}}(\texttt{odd}, x) = 0 & \delta_c^{\texttt{duvs}}(\texttt{even}, x) = (\texttt{even}, 0) & \delta_c^{\texttt{duvs}}(\texttt{odd}, x) = (\texttt{odd}, 0)
\end{array}
$$

This automaton computes the expected F. It is also obvious that such automata over finite disjoint unions of vector spaces generalize both deterministic finite state automata (using only 0-dimensional vector spaces), and vector space automata (using only one index). However, is it the joint generalization that we hoped for? The answer is no...

Minimization of duvs automata. We could think that the above automaton $\mathcal{A}^{\texttt{duvs}}$ is minimal. However, it involved some arbitrary decisions when defining it. This can be seen in the fact that when $\delta_c^{\texttt{duvs}}$ is applied, we chose to not change the index (and set to null the real value): this is arbitrary, and we could have exchanged `even` and `odd`, or fixed it abitrarily to `even`, or to `odd`. All these *variants* would be equally valid for computing F.

[2] Under the reasonable assumption that maintaining a real is more costly than maintaining a bit.

It is a bit difficult at this stage to explain the non-minimality of these automata since we did not introduce the proper notions yet. Let us try at a high level, invoking some standard automata-theoretic concepts. The first remark is that every configuration in $Q^{\mathtt{duvs}}$ is 'reachable' in this automaton: indeed $(\mathtt{even}, x) = i^{\mathtt{duvs}}(x)$ and $(\mathtt{odd}, x) = \delta_b^{\mathtt{duvs}} \circ i^{\mathtt{duvs}}(x)$ for all $x \in \mathbb{R}$. Hence there is no hope to improve the automaton $\mathcal{A}^{\mathtt{duvs}}$ or one of its variants by some form of 'restriction to its reachable configurations'. Only 'quotienting of configurations' remains. However, one can show that none among $\mathcal{A}^{\mathtt{duvs}}$ and the variants mentioned above is the quotient of another. Keeping in mind the Myhill-Nerode equivalence, we should instead merge the configurations $(\mathtt{even}, 0)$ and $(\mathtt{odd}, 0)$ since these are observationally equivalent:

$$f^{\mathtt{duvs}} \circ \delta_u^{\mathtt{duvs}}(\mathtt{even}, 0) = 0 = f^{\mathtt{duvs}} \circ \delta_u^{\mathtt{duvs}}(\mathtt{odd}, 0) \qquad \text{for all words } u \in \mathtt{A}^*.$$

However, the quotient duvs obtained by merging $(\mathtt{even}, 0)$ and $(\mathtt{odd}, 0)$, albeit not very intuitive, consists of one index associated to a two dimensional vector space, which is essentially an indexed version of the vector space automaton $\mathcal{A}^{\mathtt{vec}}$ computed before. At this stage, we understand that minimising in the category of duvs is not very helpful, as we do not obtain the desired optimisation.

How to proceed from here. The only reasonable thing to do is indeed to merge $(\mathtt{even}, 0)$ and $(\mathtt{odd}, 0)$, but we have to be more careful about the precise meaning of 'quotient'. A possibility is to add explicitly equivalence classes in the definition of the automaton. However, category theory provides useful concepts and terminology for defining these objects: colimits, and more precisely the free co-completion of a category. In the previous paragraph, we have shown that the category of duvs – which is itself the free completion of Vec with respect to finite coproducts – is not a good ambient category for our purposes. We need more colimits, so that the notion of 'quotient' is further refined. At the other extreme, we could consider the free completion with respect to all colimits, which, informally, consists of objects obtained from the category using copying and gluing. We will explain later in Section 5 why we choose to not use this completion. Intuitively, by adding all colimits we glue the vector spaces "too much", and not only we loose a geometric intuition of the objects we are dealing with, but we may run into actual technical problems when it comes the existence of minimal automata.

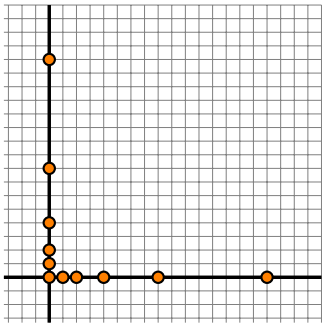
Instead, we restrict our attention to a class of colimits (which strictly contains coproducts) for which different spaces in the colimit can be "glued" together along subspaces, but which do not contain implicit self folding (i.e., such that an element of a vector space is not glued to a distinct element of the same vector space, directly or indirectly). E.g., we can describe 'two one-dimensional spaces, the 0-dimensional subspaces of which are identified through a linear bijection'. In this way we obtain the new category of *glued vector spaces* and *hybrid set-vector space automata*, corresponding to $\mathtt{Glue}(\mathsf{Vec})$-automata in the rest of the paper.

Generic arguments of colimits provide the language for describing these objects, but do not solve the question of minimality. In particular, we are interested in automata whose space of configurations is a *finite* colimit belonging to the class described above. The categorical development in this work addresses the minimization problem for hybrid automata.

An intuition in the case of gluing of vector spaces. In the case of gluing of vector spaces, it is possible to isolate a combinatorial statement that plays a crucial role in the existence of minimal hybrid set-vector automata:

> *(a)* Any subset of a finite-dimensional vector space admits a minimal cover as a finite union of subspaces. *(b)* Furthermore, there is a unique such cover which is a union of subspaces which are incomparable with respect to inclusion.

For instance, in the original vector space automaton $\mathcal{A}^{\mathsf{vec}}$, the states that are reachable in fact all belong to $\mathbb{R} \times \{0\} \cup \{0\} \times \mathbb{R}$, and this is the minimal cover as in (a) of these reachable configurations. This subset of $\mathbb{R}^2$ has the structure of two $\mathbb{R}$-spaces. These happen to intersect at $(0, 0)$, hence it is necessary to glue them at 0 to faithfully represent this set of reachable configurations. Thanks to (b) this decomposition is canonical, and hence can be used for describing the automaton.



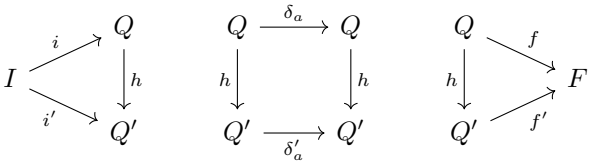
3 Automata in a category

In this section, we provide the general definition for a (finite word) automaton in a category. We also isolate properties guaranteeing the existence of minimal automata. Though presented differently, the material in the first subsection is essentially a slight variation around the work of Arbib and Manes [3], which introduced a notion of automaton in a category and, moreover, highlighted the connection between factorization systems of the ambient category, duality and minimization. In the remaining subsections we develop a refinement of this approach to minimization, and introduce a notion of factorization system through a subcategory.

3.1 Automata in a category, initial automaton, final automaton

▶ **Definition 3.1** (automata)**.** Let $\mathcal{C}$ be a locally small category, I and F be objects of $\mathcal{C}$, and $\mathtt{A}$ be some alphabet. An *automaton $\mathcal{A}$ in the category $\mathcal{C}$* (over the alphabet $\mathtt{A}$), for short a *$\mathcal{C}, I, F$-automaton* (or simply *$\mathcal{C}$-automaton* when I and F are obvious in the context), is a tuple (Q, i, f, δ), where Q is an object in $\mathcal{C}$ (called the *state object*), $i \colon I \to Q$ and $f \colon Q \to F$ are morphisms in $\mathcal{C}$ (called *initial* and *final morphisms*), and $\delta \colon \mathtt{A} \to \mathcal{C}(Q, Q)$ is a function associating to each letter $a \in \mathtt{A}$ a morphism $\delta_a \colon Q \to Q$ in $\mathcal{C}$. We extend the function δ to $\mathtt{A}^*$ as with δ_ϵ being the identity morphism on Q and $\delta_{wa} = \delta_a \circ \delta_w$ for all $a \in \mathtt{A}$ and $w \in \mathtt{A}^*$.

A *morphism of $\mathcal{C}, I, F$-automata* $h \colon \mathcal{A} \to \mathcal{A}'$ is a morphism $h \colon Q \to Q'$ in $\mathcal{C}$ between the state objects which commutes with the initial, final and transition morphisms:



(1)

▶ **Example 3.2.** The two guiding instantiation of this definition are as follows. When the category $\mathcal{C}$ is Set, $I = 1$ and $F = 2$, we recover the standard notion of a deterministic and complete automaton (over the alphabet $\mathtt{A}^*$). In the second case, when $\mathcal{C}$ is Vec over a base field $\mathbb{K}$, $I = \mathbb{K}$ and $F = \mathbb{K}$, we obtain $\mathbb{K}$-weighted automata. Indeed, if Q is isomorphic to $\mathbb{K}^n$ for some natural number n, then linear maps $i \colon \mathbb{K} \to Q$ are in one-to-one correspondence

with vectors $\mathbb{K}^n$. The same holds for linear maps $f\colon Q \to \mathbb{K}$, hence i and f are simply selecting an initial, respectively, a final vector.

▶ **Definition 3.3** (languages and language accepted). A $\mathcal{C}, I, F$-*language* (or $\mathcal{C}$-*language* when I and F are clear from the context) is a function $L\colon \mathtt{A}^* \to \mathcal{C}(I, F)$. We say that $\mathcal{A}$ *accepts the language* L if $L(w) = [\![\mathcal{A}]\!](w) := f \circ \delta_w \circ i$ for all $w \in \mathtt{A}^*$. Let $\mathsf{Auto}_{\mathcal{C}}(L)$ denote the *category of* $\mathcal{C}, I, F$*-automata for* L, that is, the category whose objects are $\mathcal{C}, I, F$-automata that accept the language L and whose arrows are morphisms of $\mathcal{C}, I, F$-automata[3].

▶ **Lemma 3.4.** *If the coproduct* $\coprod_{w\in\mathtt{A}^*} I$ *exists in* $\mathcal{C}$*, then* $\mathsf{Auto}_{\mathcal{C}}(L)$ *has an initial object* $\mathtt{init}_{\mathcal{C}}(L)$*. If the product* $\prod_{w\in\mathtt{A}^*} F$ *exists in* $\mathcal{C}$*, then* $\mathsf{Auto}_{\mathcal{C}}(L)$ *has a final object* $\mathtt{final}_{\mathcal{C}}(L)$*.*

In the case of Set, these automata are well known. The first one has as states $\mathtt{A}^*$, as initial state ε, and when it reads a letter a, its maps w to wa. Its final map sends the state w to $L(w)(0)$. There exists one and exactly one morphism from this automaton to each automata for the same language. The generalisation of this construction is that the state space is the coproduct of A^*-many copies of I. The final automaton is known as the automaton of 'residuals'. Its set of states are the maps from $\mathtt{A}^*$ to 2. The initial state is L itself, and when reading a letter a, the state S is mapped to $w \mapsto S(aw)$. The final map sends S to $S(\varepsilon)$. The generalisation of this construction is that the state space is the product of A^*-many copies of F.

3.2 Factorizations through a subcategory

It is important in the development of this paper to distinguish the category $\mathsf{Auto}_{\mathcal{C}}(L)$ in which the initial and final automata for a language L exist (recall Lemma 3.4) and which contains 'infinite automata', from the subcategory, named $\mathsf{Auto}_{\mathcal{S}}(L)$ that is used for the concrete automata (with state object in $\mathcal{S}$) which are intended to be algorithmically manageable. In this section, we provide the concept of factorizing through a subcategory, which articulates the relation between these two categories.

▶ **Definition 3.5** (factorization through a subcategory). Assume $\mathcal{S}$ is a subcategory of $\mathcal{C}$. An arrow $f\colon X \to Y$ in $\mathcal{C}$ is called $\mathcal{S}$-*small* if it factors through some object S of $\mathcal{S}$, that is, f is the composite $X \xrightarrow{u} S \xrightarrow{v} Y$ for some $u\colon X \to S$ and $v\colon S \to Y$.

A *factorization system through* $\mathcal{S}$ *on* $\mathcal{C}$ (or simply a *factorization system on* $\mathcal{C}$ if $\mathcal{C} = \mathcal{S}$) is a pair $(E_{\mathcal{S}}, M_{\mathcal{S}})$ where $E_{\mathcal{S}}$ and $M_{\mathcal{S}}$ are classes of arrows in $\mathcal{C}$ so that the codomains of all arrows in $E_{\mathcal{S}}$, the domains of all arrows in $M_{\mathcal{S}}$ are in $\mathcal{S}$, and the following conditions hold:

1. $E_{\mathcal{S}}$ and $M_{\mathcal{S}}$ are closed under composition with isomorphisms in $\mathcal{S}$, on the right, respectively left side.
2. All $\mathcal{S}$-small arrows in $\mathcal{C}$ have an $(E_{\mathcal{S}}, M_{\mathcal{S}})$-*factorization*, that is, if $f\colon X \to Y$ factors through an object of $\mathcal{S}$, then there exists $e \in E_{\mathcal{S}}$ and $m \in M_{\mathcal{S}}$, such that $f = m \circ e$.
3. The *unique* $(E_{\mathcal{S}}, M_{\mathcal{S}})$-*diagonalization property* holds: for each commutative diagram

$$\begin{array}{ccc} X & \xrightarrow{e} & T \\ {\scriptstyle f}\downarrow & \overset{u}{\swarrow} & \downarrow{\scriptstyle g} \\ S & \xrightarrow[m]{} & Y \end{array} \tag{2}$$

[3] If $\mathcal{A}$ accepts the language L and $h\colon \mathcal{A} \to \mathcal{A}'$ is a morphism of $\mathcal{C}, I, F$-automata, then $\mathcal{A}'$ also accepts the language L. Hence, $\mathsf{Auto}_{\mathcal{C}}(L)$ is a 'connected component' in the category of all $\mathcal{C}, I, F$-automata.

with $e \in E_{\mathcal{S}}$ and $m \in M_{\mathcal{S}}$, there exists a unique *diagonal*, that is, a unique morphism $u\colon T \to S$ such that $u \circ e = f$ and $m \circ u = g$.

Using standard techniques, we can prove that whenever $(E_{\mathcal{S}}, M_{\mathcal{S}})$ is a factorization system through $\mathcal{S}$ on $\mathcal{C}$, both classes $E_{\mathcal{S}}$ and $M_{\mathcal{S}}$ are closed under composition, their intersection consists of precisely the isomorphisms in $\mathcal{S}$, and, as expected, that $(E_{\mathcal{S}}, M_{\mathcal{S}})$-factorizations of $\mathcal{S}$-small morphisms are unique up to isomorphism.

▶ **Example 3.6.** Instantiating $(\mathcal{C}, \mathcal{S})$ to be $(\mathsf{Set}, \mathsf{Set}_{\mathsf{fin}})$ yields a natural factorization system through $\mathsf{Set}_{\mathsf{fin}}$ on Set (as the restriction of the standard (epi,mono)-factorization system on Set to $\mathsf{Set}_{\mathsf{fin}}$-small morphisms, i.e., the maps of finite image). Over these categories $\mathsf{Set}_{\mathsf{fin}}$-automata are deterministic finite state automata inside the more general category of Set-automata which are deterministic (potentially infinite) automata. The example $(\mathsf{Vec}, \mathsf{Vec}_{\mathsf{fin}})$ was already mentioned. In this case, being $\mathsf{Vec}_{\mathsf{fin}}$-small is equivalent to having finite rank.

Notice that for $(\mathcal{C}, \mathcal{S}) = (\mathsf{Set}, \mathsf{Set}_{\mathsf{fin}})$ or $(\mathsf{Vec}, \mathsf{Vec}_{\mathsf{fin}})$, the factorization systems through the subcategories are obtained simply by restricting the factorization systems on Set, respectively Vec. This is because, in these cases $\mathcal{S}$ is closed under quotients and subobjects in $\mathcal{C}$. The category $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$ used in this paper is closed under quotients, but in general not under subobjects (and this is the important reason for this extension of the standard notion of factorization). This is also a case in which there is a factorization system in the category $\mathcal{C}$, that coincide over $\mathcal{S}$ with factorizing through $\mathcal{S}$, but for which factorizing in $\mathcal{C}$ of an $\mathcal{S}$-small morphism and factorizing it through $\mathcal{S}$ yield different results.

A factorization system on $\mathcal{C}$ lifts naturally to categories of $\mathcal{C}$-valued functors. Automata being very close in definition to such a functor category, factorization systems also lift to them. Lemma 3.7 shows that this is also the case for factorization systems through $\mathcal{S}$, assuming of course that the input and output objects I and F belong to $\mathcal{S}$.

▶ **Lemma 3.7.** *Whenever $(E_{\mathcal{S}}, M_{\mathcal{S}})$ is a factorization system through a category $\mathcal{S}$ then $(E_{\mathsf{Auto}_{\mathcal{S}}(L)}, M_{\mathsf{Auto}_{\mathcal{S}}(L)})$ is a factorization system through $\mathsf{Auto}_{\mathcal{S}}(L)$ for the category $\mathsf{Auto}_{\mathcal{C}}(L)$, where $E_{\mathsf{Auto}_{\mathcal{S}}(L)}$ (resp. $M_{\mathsf{Auto}_{\mathcal{S}}(L)}$) contains these $\mathsf{Auto}_{\mathcal{C}}(L)$-morphisms that belong to $E_{\mathcal{S}}$ (resp. to $M_{\mathcal{S}}$) as $\mathcal{C}$-morphisms.*

3.3 Minimization through a subcategory

In this section, we show how the joint combination of having initial and final automata for a language, as given by Lemma 3.4, together with a factorization system through a subcategory $\mathcal{S}$ yields the existence of a minimal $\mathcal{S}$-automaton for small $\mathcal{C}$-languages.

We make the *following assumptions*: $(E_{\mathcal{S}}, M_{\mathcal{S}})$ is a factorization system through $\mathcal{S}$ on $\mathcal{C}$, and L is a $\mathcal{C}$-language accepted by some $\mathcal{S}$-automaton such that there exist an initial $\mathtt{init}_{\mathcal{C}}(L)$ $\mathcal{C}$-automaton and a final $\mathcal{C}$-automaton $\mathtt{final}_{\mathcal{C}}(L)$ for L.

▶ **Definition 3.8** (minimal automaton)**.** The *minimal $\mathcal{C}$-automaton for L*, denoted $\mathtt{min}_{\mathcal{S}}(L)$, is the[4] $\mathcal{S}$-automaton for L obtained by $(E_{\mathsf{Auto}_{\mathcal{S}}(L)}, M_{\mathsf{Auto}_{\mathcal{S}}(L)})$-factorization of the unique $\mathsf{Auto}_{\mathcal{S}}(L)$-small morphism from $\mathtt{init}_{\mathcal{C}}(L)$ to $\mathtt{final}_{\mathcal{C}}(L)$.

▶ **Theorem 3.9.** *For all $\mathcal{S}$-automata $\mathcal{A}$ for L satisfying the above assumptions, we have*

$$\mathtt{min}_{\mathcal{S}}(L) \cong \mathtt{obs}_{\mathcal{S}}(\mathtt{reach}_{\mathcal{S}}(\mathcal{A})) \cong \mathtt{reach}_{\mathcal{S}}(\mathtt{obs}_{\mathcal{S}}(\mathcal{A}))\,,$$

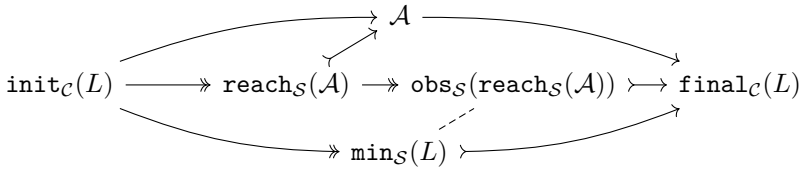
in which

[4] It is unique up to isomorphism according to the diagonal property.

- $\mathtt{reach}_{\mathcal{S}}(\mathcal{A})$ *is the result of applying an* $(E_{\mathsf{Auto}_{\mathcal{S}}(L)}, M_{\mathsf{Auto}_{\mathcal{S}}(L)})$*-factorization to the unique* $\mathsf{Auto}_{\mathcal{S}}(L)$*-morphism from* $\mathtt{init}_{\mathcal{C}}(L)$ *to* $\mathcal{A}$*, and*
- $\mathtt{obs}_{\mathcal{S}}(\mathcal{A})$ *is the result of applying an* $(E_{\mathsf{Auto}_{\mathcal{S}}(L)}, M_{\mathsf{Auto}_{\mathcal{S}}(L)})$*-factorization to the unique* $\mathsf{Auto}_{\mathcal{S}}(L)$*-morphism from* $\mathcal{A}$ *to* $\mathtt{final}_{\mathcal{C}}(L)$*.*

This theorem does not only state the existence of a minimal automaton, it also makes transparent how to make effective its construction: if one possesses both an implementation of $\mathtt{reach}_{\mathcal{S}}$ and $\mathtt{obs}_{\mathcal{S}}$, then their sequencing minimises an input automaton. From the above theorem it immediately follows that $\mathtt{min}_{\mathcal{S}}(L)$ is both an $E_{\mathsf{Auto}_{\mathcal{S}}(L)}$-quotient of a $M_{\mathsf{Auto}_{\mathcal{S}}(L)}$-subobject of $\mathcal{A}$ and a $M_{\mathsf{Auto}_{\mathcal{S}}(L)}$-subobject of an $E_{\mathsf{Auto}_{\mathcal{S}}(L)}$-quotient of $\mathcal{A}$: the minimal automaton divides every other automaton for the language.

Proof idea. The proof is contained in the following commutative diagram, in which $\twoheadrightarrow$ denotes $\mathsf{Auto}_{\mathcal{C}}(L)$-morphisms in $E_{\mathsf{Auto}_{\mathcal{S}}(L)}$, and $\rightarrowtail$ $\mathsf{Auto}_{\mathcal{C}}(L)$-morphisms in $M_{\mathsf{Auto}_{\mathcal{S}}(L)}$:



That $\mathtt{obs}_{\mathcal{S}}(\mathtt{reach}_{\mathcal{S}}(\mathcal{A}))$ is an $(E_{\mathsf{Auto}_{\mathcal{S}}(L)}, M_{\mathsf{Auto}_{\mathcal{S}}(L)})$-factorization of the unique $\mathsf{Auto}_{\mathcal{C}}(L)$-morphism from $\mathtt{init}_{\mathcal{C}}(L)$ to $\mathtt{final}_{\mathcal{C}}(L)$ follows since $E_{\mathsf{Auto}_{\mathcal{S}}(L)}$ is closed under composition. By the unique diagonal property, it is isomorphic to $\mathtt{min}_{\mathcal{S}}(L)$. The case $\mathtt{reach}_{\mathcal{S}}(\mathtt{obs}_{\mathcal{S}}(\mathcal{A}))$ is symmetric. ◀

3.4 A special case of factorization through

So far, the description of factorization and minimization of automata is very generic. Hereafter, the classes $E_{\mathcal{S}}$ and $M_{\mathcal{S}}$ are constructed along a particular principle which we describe now. In the next sections we will instantiate this construction when $\mathcal{S}$ is the subcategory $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$ of glued vector spaces.

In this section we fix an (E, M)-factorization system on $\mathcal{C}$ and a subcategory $\mathcal{S} \hookrightarrow \mathcal{C}$.

▶ **Definition 3.10.** An $\mathcal{S}$*-extremal epimorphism*[5] in $\mathcal{C}$ is an arrow $e\colon X \to S$ in $\mathcal{C}$, with S an object in $\mathcal{S}$, such that if $e = m \circ g$ where m is in M with domain in $\mathcal{S}$, then m is an isomorphism. We set $M_{\mathcal{S}}$ to be the class of arrows in M with domain in $\mathcal{S}$, and $E_{\mathcal{S}}$ to be the class of $\mathcal{S}$-extremal epimorphisms.

▶ **Definition 3.11.** An $M_{\mathcal{S}}$*-subobject in* $\mathcal{S}$ of an object X of $\mathcal{C}$ is an equivalence class up to isomorphism of a morphism $S \to X$ belonging to M, where S is an object of $\mathcal{S}$. The $M_{\mathcal{S}}$-subobject $S \to X$ is called *proper* if it is not an isomorphism.

▶ **Lemma 3.12.** *Assume the following conditions hold:*

1. *all arrows in* M *are monomorphisms in* $\mathcal{C}$*,*
2. $\mathcal{S}$ *is closed under* E*-quotients, i.e., if* $e\colon S \to T$ *is in* E *with* S *in* $\mathcal{S}$*, then* T *is isomorphic to an object of* $\mathcal{S}$*,*
3. *the intersection of a nonempty set of* $M_{\mathcal{S}}$*-subobjects of an object* X *of* $\mathcal{C}$ *exists and is an* $M_{\mathcal{S}}$*-subobject of* X*, and,*

[5] Note that $\mathcal{S}$-extremal epimorphisms need not be epimorphisms in $\mathcal{C}$.

4. *the pullback of an $M_{\mathcal{S}}$-subobject $m\colon S \to T$ of T along a morphism $T' \to T$ in $\mathcal{S}$ is an $M_{\mathcal{S}}$-subobject of T'.*

Then $(E_{\mathcal{S}}, M_{\mathcal{S}})$ is a factorization system through $\mathcal{S}$ on $\mathcal{C}$.

The next lemma ensures that condition 3 of Lemma 3.12 can be replaced with the weaker version involving only binary intersections of $M_{\mathcal{S}}$-subobjects, provided that any infinite descending chain of $M_{\mathcal{S}}$-subobjects eventually stabilises (of course, up to isomorphism).

▶ **Lemma 3.13.** *Assume that there are no infinite descending chains of proper $M_{\mathcal{S}}$-subobjects*

$$X \longleftarrow\!\!\prec S_1 \longleftarrow\!\!\prec S_2 \longleftarrow\!\!\prec \dots$$

and furthermore that the intersection of any two $M_{\mathcal{S}}$-subobjects of an object X of $\mathcal{C}$ exists and is an $M_{\mathcal{S}}$-subobject of X, then condition 3 in the hypothesis of Lemma 3.12 holds.

The proof simply uses finite partial intersections in order to create a strictly descending chain of $M_{\mathcal{S}}$-subobjects. By assumption, this construction has to stop, and the last element of the sequence happens to be the intersection of the entire family.[6]

4 Gluing of categories

We turn now to the central construction of this paper: given a category $\mathcal{C}$ and a subcategory $\mathcal{S}$, we construct a category $\mathtt{Glue}(\mathcal{C})$ of "gluings of objects in $\mathcal{C}$" that has both $\mathcal{C}$ and $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$ – the category of "finite gluings of objects in $\mathcal{S}$" – as subcategories. Under proper assumptions on $\mathcal{C}$ and $\mathcal{S}$, the resulting pair $(\mathtt{Glue}(\mathcal{C}), \mathtt{Glue}_{\mathsf{fin}}(\mathcal{S}))$ satisfies the assumption required for constructing minimisable automata for $\mathtt{Glue}(\mathcal{C})$-languages. Taking $\mathcal{C} = \mathsf{Vec}$ and $\mathcal{S} = \mathsf{Vec}_{\mathsf{fin}}$ we obtain the construction informally described in Section 2.

Throughout this section we assume that $\mathcal{C}$ is equipped with a (E, M)-factorization system consisting of strong epimorphisms and monomorphisms.

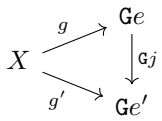
4.1 The free gluing of a category

When $\mathcal{C}$ is small, it is well known that the Yoneda embedding of $\mathcal{C}$ into the category of presheaves over $\mathcal{C}$ is a free completion of $\mathcal{C}$ under colimits of small diagrams. For a possibly large category, one has to consider instead the category of small presheaves, i.e. small colimits of representable ones, see for example [9]. For our purposes, we found more illuminating and direct to use a syntactic way of describing the colimit completion of a category.

The category of diagrams. Assume $\mathcal{C}$ is a locally small category. The *free colimit completion of* $\mathcal{C}$ is the category $\mathsf{Diag}(\mathcal{C})$ whose objects are *diagrams* $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$ and morphisms between two diagrams $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$ and $\mathtt{G}\colon \mathcal{E} \to \mathcal{C}$ will be given in Definition 4.1.

To this end we define an equivalence relation on arrows from an arbitrary object X of $\mathcal{C}$ to the objects in the image of $\mathtt{G}$. Assume e, e' are objects in $\mathcal{E}$. We consider the least equivalence relation $\sim_{\mathtt{G}}$ which contains all pairs (g, g'), where $g\colon X \to \mathtt{G}e$, $g'\colon X \to \mathtt{G}e'$ are such that there exists $j\colon e \to e'$ a map in $\mathcal{E}$ with $\mathtt{G}j \circ g = g'$, i.e., the diagram below commutes.

[6] The attentive reader will have recognised in this argument part of the reason why every subset of a finite-dimensional vector space admits a minimal cover as a finite union of subspaces.



We denote by $\widehat{\mathtt{G}}(X)$ the equivalence classes of the relation $\sim_{\mathtt{G}}$.

▶ **Definition 4.1.** A *morphism between diagrams* $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$ and $\mathtt{G}\colon \mathcal{E} \to \mathcal{C}$ is a map f which associates to each object d in $\mathcal{D}$ an equivalence class $f(d) \in \widehat{\mathtt{G}}(\mathtt{F}d)$, such that whenever $u\colon d \to d'$ is a morphism in $\mathcal{D}$ and $g\colon \mathtt{F}d' \to \mathtt{G}e$ is in the equivalence class $f(d')$, then $g \circ \mathtt{F}u$ is in the equivalence class $f(d)$.

The subcategory of gluings. We are now ready to define the category $\mathtt{Glue}(\mathcal{C})$, which is a restriction of $\mathsf{Diag}(\mathcal{C})$ to M-diagrams (see below), that is, to diagrams that intuitively 'do not quotient'. Recall that $\mathcal{C}$ has a factorization system (E, M) in which E are the strong epimorphisms and M are the monomorphisms.

▶ **Definition 4.2** (*glued category*)**.** An *M-cocone* over a diagram $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$ is a cocone $(u_d\colon \mathtt{F}d \to X)_{d\in\mathcal{D}}$ such that all the structural components of the cocone u_d are in M. An *M-diagram* is a diagram that has an M-cocone.

The *glued category* $\mathtt{Glue}(\mathcal{C})$ is the subcategory of $\mathsf{Diag}(\mathcal{C})$ over the M-diagrams $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$. Let $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{C})$ the subcategory of $\mathtt{Glue}(\mathcal{C})$ that has as objects the finite diagrams of $\mathtt{Glue}(\mathcal{C})$.

Notice that, if $\mathtt{F}$ is such a diagram, then we can show that for each morphism $v\colon d \to d'$ in $\mathcal{D}$, we have that $\mathtt{F}u\colon \mathtt{F}d \to \mathtt{F}d'$ is in M (however this is not a characterisation). Also, if there exists a universal cocone for an M-diagram, then this cocone is in particular an M-cocone.

▶ **Lemma 4.3.** *If $\mathcal{C}$ is cocomplete, then $\mathtt{Glue}(\mathcal{C})$ is a full reflective subcategory of $\mathsf{Diag}(\mathcal{C})$, and hence $\mathtt{Glue}(\mathcal{C})$ is a cocomplete category. If $\mathcal{C}$ is furthermore complete, then so is $\mathtt{Glue}(\mathcal{C})$.*

In the automata theoretic application we have in mind, we use this category in order to construct the initial and final automata for a language.

4.2 A factorization system through finite gluings

The category of most interest for us is the full subcategory $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$ of $\mathtt{Glue}(\mathcal{C})$ which consists of the finite M-diagrams over $\mathcal{S}$. In this section we construct in particular, under suitable assumptions, a factorization system through $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$ on $\mathtt{Glue}(\mathcal{C})$, making use of Lemma 3.12. For $\mathcal{S} = \mathsf{Vec}_{\mathsf{fin}}$, this is the category of 'finite gluings of finite vector spaces' that we longly introduced in Section 2.

We define the following classes of morphisms in $\mathtt{Glue}(\mathcal{C})$.

- $\mathit{Epi}_{\mathtt{Glue}(\mathcal{C})}$ consists of the morphisms $f\colon \mathtt{F} \to \mathtt{G}$, where $\mathtt{F}\colon \mathcal{D} \to \mathcal{C}$ and $\mathtt{F}\colon \mathcal{E} \to \mathcal{C}$, such that for all e in $\mathcal{E}$ there exists a representative $f_d\colon \mathtt{F}d \to \mathtt{G}e'$ in the equivalence class $f(d)$ and a morphism $u\colon \mathtt{G}e \to \mathtt{G}e'$, so that $u \sim_{\mathtt{G}} id_{\mathtt{G}e}$ and u factors through the image of f_d.
- $\mathit{Mono}_{\mathtt{Glue}(\mathcal{C})}$ consists of morphisms $f\colon \mathtt{F} \to \mathtt{G}$ such that for all morphisms $u\colon X \to \mathtt{F}d$ and $v\colon X \to \mathtt{F}d'$ such that $f_d \circ u \sim_{\mathtt{G}} f_{d'} \circ v$ (for f_d and $f_{d'}$ in the equivalence classes $f(d)$, respectively $f(d')$), we have that $u \sim_{\mathtt{F}} v$.

One can easily verify that the arrows in $\mathit{Mono}_{\mathtt{Glue}(\mathcal{C})}$ are exactly the monomorphisms in $\mathtt{Glue}(\mathcal{C})$.[7] The next lemma establishes that under mild conditions on $\mathcal{C}$ we have a (strong epi, mono) factorization system on $\mathtt{Glue}(\mathcal{C})$.

[7] As a side remark, we should mention that these classes of arrows correspond precisely to the natural transformations between the induced presheaves that are pointwise injective.

▶ **Lemma 4.4.** *Assume $\mathcal{C}$ has intersections. Then $(Epi_{\mathtt{Glue}(\mathcal{C})}, Mono_{\mathtt{Glue}(\mathcal{C})})$ is a (strong epi, mono) factorization system on $\mathtt{Glue}(\mathcal{C})$.*

In what follows we say that a subcategory $\mathcal{S}$ of $\mathcal{C}$ is *well-behaved* if it satisfies the hypothesis of Lemmas 3.12 and 3.13 with respect to the (strong epi, mono) factorization system on $\mathcal{C}$. (In fact condition 3 of Lemma 3.12 can be replaced by its binary version.)

▶ **Theorem 4.5.** *Assume $\mathcal{C}$ has intersections and pullbacks. If the subcategory $\mathcal{S}$ of $\mathcal{C}$ is well-behaved, then $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$ is a well-behaved subcategory of $\mathtt{Glue}(\mathcal{C})$.*

Some ideas about the proof. This result is an application of Lemmas 3.12 and 3.13. The central combinatorial aspect of this statement is that there exists no infinite strictly descending chains of $Mono_{\mathtt{Glue}(\mathcal{C})}$-subobjects in $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$. For the sake of contradiction, let us consider a descending sequence of diagrams from $\mathtt{Glue}_{\mathsf{fin}}(\mathcal{S})$:

$$\mathtt{F}_0 \xleftarrow{f_1} \mathtt{F}_1 \xleftarrow{f_2} \mathtt{F}_2 \xleftarrow{f_3} \dots$$

We have to prove that it is ultimately constant (up to isomorphism). Let the diagrams be $\mathtt{F}_i : \mathcal{D}_i \to \mathcal{S}$ for all i. The first step is to consider an *aggregation of mono-diagrams*, that is, we construct a big diagram that aggregates all the $\mathtt{F}_i$'s. At the level of objects this diagram contains the disjoint unions of the $\mathcal{D}_i$'s. We call the objects originating from $\mathcal{D}_i$ of *rank* i. Secondly, we prove a *global homogeneity* property of $\mathtt{F}$: given two arrows $g\colon X \to \mathtt{F}d$, $g'\colon X \to \mathtt{F}d'$ with d, d' at the same rank i, then $g \sim_{\mathtt{F}} g'$ if and only if $g \sim_{\mathtt{F}_i} g'$. Finally we prove the existence of an isomorphism g_j from $\mathtt{F}_{j-1}$ to $\mathtt{F}_j$ for some j by analysing the structure of $\mathtt{F}$ and using König's lemma. ◀

We come back to the leading example of $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automata. Applying Theorem 4.5 for $(\mathcal{C}, \mathcal{S}) = (\mathsf{Vec}, \mathsf{Vec}_{\mathsf{fin}})$ we obtain a factorization system through $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$ on $\mathtt{Glue}(\mathsf{Vec})$. Using Lemma 4.3 and Theorem 3.9 we derive that hybrid set-vector automata are minimisable.

▶ **Corollary 4.6.** *For any $\mathtt{Glue}(\mathsf{Vec})$-language accepted by some $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automaton there exists a minimal $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automaton. In particular, any Vec-language accepted by a $\mathsf{Vec}_{\mathsf{fin}}$-automaton has a minimal $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automaton.*

For the language described in Section 2, and for which the minimal vector automaton has a two-dimensional state space, we obtain a minimal $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automaton obtained by glueing two one-dimensional spaces at 0. Formally, this is an M-diagram $\mathtt{F}\colon \mathcal{D} \to \mathsf{Vec}_{\mathsf{fin}}$ where $\mathcal{D}$ is a three object poset $\{\bot, 0, 1\}$ with $\bot \leq 0$ and $\bot \leq 1$. The functor $\mathtt{F}$ maps $0, 1$ to one-dimensional spaces, $\bot$ to the zero-dimensional space and the morphisms $\bot \leq 0$ and $\bot \leq 1$ to its inclusions in the respective one-dimensional spaces.

For another example, consider the language which to a word $u \in a^*$ associates the value $\cos(\alpha|u|)$ for some α which is not a rational multiple of π, and whose minimal vector space automaton has a two-dimensional state space. If we used the factorization in $\mathtt{Glue}(\mathsf{Vec})$ we would obtain a glueing of infinitely many one-dimensional subspaces (obtained by rotations with angle α). Thus, it is crucial for our setting to use the *factorization system through* $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$. In this case, the minimal $\mathtt{Glue}_{\mathsf{fin}}(\mathsf{Vec}_{\mathsf{fin}})$-automaton also has just a two-dimensional vector space of states.

5 Conclusion

We have introduced a new way to construct automata which, thanks to category-theoretic insights, admits minimal automata 'by design'. The introductory example of hybrid set-vector

automata is a convincing instance of this approach, which has both algorithmic merits (in succinctness of the encoding of the state space) and theoretical merits (in that there exists minimal automata). The closest work to our knowledge is the work of Lombardy and Sakarovitch [12] which studies the sequentialisability of weighted automata; in the framework of this paper, this is answering the question whether a vector space automaton is equivalent to a hybrid set-vector automaton for which the state space consists of dimension 1 vector spaces only, glued at 0 (the problem remains open).

At the categorical level, we should say a few words regarding our design choices. First why not use more familiar co-completions such as the Ind-completion of the free co-completion? The answer is that if we did so, we would not obtain the desired behaviour when we restrict our attention to the 'finite' automata. For example finite filtered colimits are not very interesting, while the freely added finite colimits of vector spaces are not closed under quotients in the free co-completion, thus the work in the previous sections cannot be applied.

Another question one may ask is why we haven't used coalgebras, as in [2] or in the work of [1] on well-pointed coalgebras. First, the factorization through a subcategory, which plays a crucial role in our work, is not developed in that setting. Secondly, we believe that the functorial approach to automata, which neatly combines the dual narrative of automata seen as both algebras and coalgebras is worth saying. As we show in [8], we can employ this framework for minimizing subsequential transducers à la Choffrut [7] (by interpreting them as automata in a Kleisli category). This is also an example in which the conditions in Lemma 3.4 are not necessary. We believe, that at least in that situation the functorial approach works slightly smoother than the coalgebraic one [11]. Also, by changing the input category, we can further extend this work to capture tree automata or algebras (for instance monoids).

In the particular model of hybrid set-vector automata the problem of effectiveness remains: we have proved the existence of a minimal automaton for a language, but obtaining the reachable configurations in an effective way is the subject of ongoing work.

Abstract

We show that the equivalence, unambiguity and sequentiality problems are decidable for finitely ambiguous max-plus tree automata.

1 Introduction

A max-plus automaton is a finite automaton with transition weights in the real numbers. To each word, it assigns the maximum weight of all accepting paths on the word, where the weight of a path is the sum of the path's transition weights. Max-plus automata and their min-plus counterparts are weighted automata [19, 18, 13, 2, 4] over the max-plus or min-plus semiring. Under varying names, max-plus and min-plus automata have been studied and employed many times in the literature. They can be used to determine the star height of a language [7], to decide the finite power property [20, 21] and to model certain timed discrete event systems [5, 6]. Additionally, they appear in the context of natural language processing [14].

For practical applications, the decidable properties of an automaton model are usually of great interest. Typical problems considered include the emptiness, universality, inclusion, equivalence, sequentiality and unambiguity problems. We consider the last three of these problems for *finitely ambiguous* automata, which are automata in which the number of accepting paths for every word is bounded by a global constant. If there is at most one accepting path for every word, the automaton is called *unambiguous*. It is called *deterministic* or *sequential* if for each pair of a state and an input symbol, there is at most one valid transition into a next state. It is known [11] that finitely ambiguous max-plus automata are strictly more expressive than unambiguous max-plus automata, which in turn are strictly more expressive than deterministic max-plus automata.

Let us quickly recall the considered problems and the related results. The equivalence problem asks whether two automata are *equivalent*, which is the case if the weights assigned by them coincide on all words. In general, the equivalence problem is undecidable [12] for max-plus automata, but for finitely ambiguous max-plus automata it becomes decidable

* This work was supported by Deutsche Forschungsgemeinschaft (DFG), Graduiertenkolleg 1763 (QuantLA).

[22, 9]. The sequentiality problem asks whether for a given automaton, there exists an equivalent deterministic automaton. This was shown to be decidable by Mohri [14] for unambiguous max-plus automata. Finally, the unambiguity problem asks whether for a given automaton, there exists an equivalent unambiguous automaton. This problem is known to be decidable for finitely ambiguous and even *polynomially ambiguous* max-plus automata [11, 10]. In conjunction with Mohri's results, it follows that the sequentiality problem is decidable for these classes of automata as well.

In this paper, we show that these three problems are decidable for finitely ambiguous max-plus tree automata, which are max-plus automata that operate on trees instead of words. In the form of *probabilistic context-free grammars*, max-plus tree automata are commonly employed in natural language processing [17]. Our approach to the decidability of the equivalence problem uses ideas from [9]. We use a similar induction argument and also reduce the equivalence problem to the same decidable problem, namely the decidability of the existence of an integer solution for a system of linear inequalities [15]. On words, the proof relies on the decomposition of words into subwords of bounded length, of which one is removed in the induction step. This argument cannot be applied to trees as easily. A tree can be decomposed into *contexts* of bounded height, but this requires contexts with multiple variables. Removing such a context does usually not yield a tree. Consequently, our induction is much more involved. We also point out and correct an important oversight in the main theorem of [9].

The decidability of the unambiguity problem employs ideas from [11]. Here, we show how the *dominance property* can be generalized to max-plus tree automata. To show the decidability of the sequentiality problem, we first combine results from [3] and [14] to show the decidability of this problem for unambiguous max-plus tree automata, and then combine this result with the decidability of the unambiguity problem.

Our solution of the equivalence problem can be applied to weighted logics. In [16], a fragment of a weighted logic is shown to have the same expressive power as finitely ambiguous weighted tree automata. Over the max-plus semiring, equivalence is decidable for formulas of this fragment due to our results.

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$. By $\mathbb{N}^*$ we denote the set of all finite words over $\mathbb{N}$. The empty word is denoted by ε, and the length of a word $w \in \mathbb{N}^*$ by $|w|$. The set $\mathbb{N}^*$ is partially ordered by the prefix relation $\leq_p$ and totally ordered with respect to the lexicographic ordering $\leq_l$. A *ranked alphabet* is a pair $(\Gamma, \mathrm{rk}_\Gamma)$, often abbreviated by Γ, where Γ is a finite set and $\mathrm{rk}_\Gamma \colon \Gamma \to \mathbb{N}$. For every $m \geq 0$ we define $\Gamma^{(m)} = \mathrm{rk}_\Gamma^{-1}(m)$ as the set of all symbols of rank m. The rank $\mathrm{rk}(\Gamma)$ of Γ is defined as $\max\{\mathrm{rk}_\Gamma(a) \mid a \in \Gamma\}$.

The set of (*finite, labeled and ordered*) Γ-*trees*, denoted by T_Γ, is the set of all pairs $t = (\mathrm{pos}(t), \mathrm{label}_t)$, where $\mathrm{pos}(t) \subset \mathbb{N}^*$ is a finite non-empty prefix-closed set, $\mathrm{label}_t \colon \mathrm{pos}(t) \to \Gamma$ is a mapping and for every $w \in \mathrm{pos}(t)$ we have $wi \in \mathrm{pos}(t)$ iff $1 \leq i \leq \mathrm{rk}_\Gamma(\mathrm{label}_t(w))$. We write $t(w)$ for $\mathrm{label}_t(w)$. We also refer to the elements of $\mathrm{pos}(t)$ as *nodes*, to ε as the *root* of t and to prefix-maximal nodes as *leaves*.

Now let $s, t \in T_\Gamma$ and $w \in \mathrm{pos}(t)$. The *subtree of* t *at* w, denoted by $t|_w$, is a Γ-tree defined as follows. We let $\mathrm{pos}(t|_w) = \{v \in \mathbb{N}^* \mid wv \in \mathrm{pos}(t)\}$ and for $v \in \mathrm{pos}(t|_w)$, $\mathrm{label}_{t|_w}(v) = t(wv)$. The *substitution of* s *into* w *of* t, denoted by $t\langle s \to w\rangle$, is a Γ-tree defined as follows. We let $\mathrm{pos}(t\langle s \to w\rangle) = \{v \in \mathrm{pos}(t) \mid w \not\leq_p v\} \cup \{wv \mid v \in \mathrm{pos}(s)\}$. For $u \in \mathrm{pos}(t\langle s \to w\rangle)$, we let $\mathrm{label}_{t\langle s\to w\rangle}(u) = s(v)$ if $u = wv$, and otherwise $\mathrm{label}_{t\langle s\to w\rangle}(u) = t(u)$.

For $a \in \Gamma^{(m)}$ and trees $t_1, \dots, t_m \in T_\Gamma$, we also write $a(t_1, \dots, t_m)$ to denote the tree t with $\mathrm{pos}(t) = \{\varepsilon\} \cup \{iw \mid i \in \{1, \dots, m\}, w \in \mathrm{pos}(t_i)\}$, $\mathrm{label}_t(\varepsilon) = a$ and $\mathrm{label}_t(iw) = t_i(w)$.

A *commutative semiring* is a tuple $(K, \oplus, \odot, \mathbb{0}, \mathbb{1})$, abbreviated by K, with operations sum $\oplus$ and product $\odot$ and constants $\mathbb{0}$ and $\mathbb{1}$ such that $(K, \oplus, \mathbb{0})$ and $(K, \odot, \mathbb{1})$ are commutative monoids, multiplication distributes over addition, and $k \odot \mathbb{0} = \mathbb{0} \odot k = \mathbb{0}$ for every $k \in K$. In this paper, we only consider the following two semirings.

- The *boolean semiring* $\mathbb{B} = (\{0, 1\}, \vee, \wedge, 0, 1)$ with disjunction $\vee$ and conjunction $\wedge$.
- The *max-plus semiring* $\mathbb{R}_{\max} = (\mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0)$ where the sum and the product operations are max and $+$, respectively, extended to $\mathbb{R} \cup \{-\infty\}$ in the usual way.

A *(formal) tree series* is a mapping $S \colon T_\Gamma \to K$. The set of all tree series (over Γ and K) is denoted by $K\langle\langle T_\Gamma \rangle\rangle$. For two tree series $S, T \in K\langle\langle T_\Gamma \rangle\rangle$, the sum $S \oplus T$ and the *Hadamard product* $S \odot T$ are defined pointwise.

Let $(K, \oplus, \odot, \mathbb{0}, \mathbb{1})$ be a commutative semiring. A *weighted bottom-up finite state tree automaton (short: WTA) over K and Γ* is a tuple $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ where Q is a finite set (of states), Γ is a ranked alphabet (of input symbols), $\mu \colon \bigcup_{m=0}^{\mathrm{rk}(\Gamma)} Q^m \times \Gamma^{(m)} \times Q \to K$ (the weight function) and $\nu \colon Q \to K$ (the function of final weights). We set $\Delta_\mathcal{A} = \bigcup_{m=0}^{\mathrm{rk}(\Gamma)} Q^m \times \Gamma^{(m)} \times Q$. A tuple $(\vec{p}, a, q) \in \Delta_\mathcal{A}$ is called a *transition* and $(\vec{p}, a, q)$ is called *valid* if $\mu(\vec{p}, a, q) \neq \mathbb{0}$. A state $q \in Q$ is called *final* if $\nu(q) \neq \mathbb{0}$.

We call a WTA over the max-plus semiring a max-plus-WTA and a WTA over the boolean semiring a *finite tree automaton* (FTA). A WTA $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ over $\mathbb{B}$ is also written as a tuple $\mathcal{A}' = (Q, \Gamma, \delta, F)$ where $\delta = \{d \in \Delta_\mathcal{A} \mid \mu(d) = 1\}$ and $F = \{q \in Q \mid \nu(q) = 1\}$.

For $t \in T_\Gamma$, a mapping $r \colon \mathrm{pos}(t) \to Q$ is called a *quasi-run of $\mathcal{A}$ on t*. For a quasi-run r on t and $w \in \mathrm{pos}(t)$ with $t(w) = a \in \Gamma^{(m)}$, the tuple $\mathbb{t}(t, r, w) = (r(w1), \dots, r(wm), a, r(w))$ is called the *transition at w*. The quasi-run r is called a *(valid) run* if for every $w \in \mathrm{pos}(t)$ the transition $\mathbb{t}(t, r, w)$ is valid with respect to $\mathcal{A}$. We call a run r *accepting* if $r(\varepsilon)$ is final. By $\mathrm{Run}_\mathcal{A}(t)$ and $\mathrm{Acc}_\mathcal{A}(t)$ we denote the sets of all runs and all accepting runs of $\mathcal{A}$ on t, respectively. For $r \in \mathrm{Run}_\mathcal{A}(t)$ the *weight of r* is defined by $\mathrm{wt}_\mathcal{A}(t, r) = \bigodot_{w \in \mathrm{pos}(t)} \mu(\mathbb{t}(t, r, w))$. The *tree series accepted by $\mathcal{A}$*, denoted by $[\![\mathcal{A}]\!] \in K\langle\langle T_\Gamma \rangle\rangle$, is the tree series defined for every $t \in T_\Gamma$ by $[\![\mathcal{A}]\!](t) = \bigoplus_{r \in \mathrm{Acc}_\mathcal{A}(t)} \mathrm{wt}_\mathcal{A}(t, r) \odot \nu(r(\varepsilon))$ where the sum over the empty set is $\mathbb{0}$ by convention. The *support* of $\mathcal{A}$ is the set $\mathrm{supp}(\mathcal{A}) = \{t \in T_\Gamma \mid [\![\mathcal{A}]\!](t) \neq \mathbb{0}\}$.

The support of an FTA $\mathcal{A}$ is also called the *language accepted by $\mathcal{A}$* and denoted by $\mathcal{L}(\mathcal{A})$. A subset $L \subseteq T_\Gamma$ is called *recognizable* if there exists an FTA $\mathcal{A}$ with $L = \mathcal{L}(\mathcal{A})$.

A WTA $\mathcal{A}$ is called *deterministic* if for every $m \geq 0$, $a \in \Gamma^{(m)}$ and $\vec{p} \in Q^m$ there exists at most one $q \in Q$ with $\mu(\vec{p}, a, q) \neq \mathbb{0}$. We call $\mathcal{A}$ *finitely ambiguous* or *M-ambiguous* if $|\mathrm{Acc}_\mathcal{A}(t)| \leq M$ for some $M \geq 1$ and every $t \in T_\Gamma$. A 1-ambiguous WTA is also called *unambiguous*. We recall that for every recognizable language $L \subseteq T_\Gamma$, there exists a deterministic FTA $\mathcal{A}$ with $\mathcal{L}(\mathcal{A}) = L$.

An automaton $\mathcal{A}$ is called *trim* if (i) for every $q \in Q$ there exist $t \in T_\Gamma$, $r \in \mathrm{Acc}_\mathcal{A}(t)$ and $w \in \mathrm{pos}(t)$ such that $q = r(w)$ and (ii) for every valid $d \in \Delta_\mathcal{A}$ there exist $t \in T_\Gamma$, $r \in \mathrm{Acc}_\mathcal{A}(t)$ and $w \in \mathrm{pos}(t)$ such that $d = \mathbb{t}(t, r, w)$. The *trim part of $\mathcal{A}$* is the automaton obtained by removing all states $q \in Q$ which do not satisfy (i) and setting $\mu(d) = \mathbb{0}$ for all valid $d \in \Delta_\mathcal{A}$ which do not satisfy (ii). This process obviously has no influence on $[\![\mathcal{A}]\!]$.

3 The Equivalence Problem

For two max-plus-WTA $\mathcal{A}_1$ and $\mathcal{A}_2$ over an alphabet Γ, we say that $\mathcal{A}_1$ *dominates* $\mathcal{A}_2$, denoted by $\mathcal{A}_1 \geq \mathcal{A}_2$, if for all trees $t \in T_\Gamma$ we have $[\![\mathcal{A}_1]\!](t) \geq [\![\mathcal{A}_2]\!](t)$. We say that $\mathcal{A}_1$ and $\mathcal{A}_2$ are equivalent, denoted by $\mathcal{A}_1 = \mathcal{A}_2$, if for all $t \in T_\Gamma$ we have $[\![\mathcal{A}_1]\!](t) = [\![\mathcal{A}_2]\!](t)$.

The equivalence problem for max-plus (tree) automata asks whether for two given max-plus (tree) automata $\mathcal{A}_1$ and $\mathcal{A}_2$, it holds that $\mathcal{A}_1 = \mathcal{A}_2$. For words, this problem was shown to be undecidable in general [12], but it is decidable if both automata are finitely ambiguous [9]. In this section, we prove that the equivalence problem is decidable for finitely ambiguous max-plus-WTA. This section is based on ideas from [9].

▶ **Theorem 1.** *The equivalence problem for finitely ambiguous weighted tree automata over the max-plus semiring is decidable.*

In fact, we will show that if $\mathcal{A}_1$ is a finitely ambiguous max-plus-WTA and $\mathcal{A}_2$ any max-plus-WTA, then it is decidable whether $\mathcal{A}_1$ dominates $\mathcal{A}_2$.

▶ **Theorem 2.** *Let $\mathcal{A}_1$ be a finitely ambiguous max-plus-WTA and $\mathcal{A}_2$ any max-plus-WTA. It is decidable whether or not $\mathcal{A}_1 \geq \mathcal{A}_2$.*

If both automata in Theorem 2 are finitely ambiguous, we can reverse their roles. Consequently, Theorem 1 is a corollary of Theorem 2. The remainder of this section is dedicated to the proof of Theorem 2.

As a first step, we show in the following lemma that every finitely ambiguous max-plus-WTA $\mathcal{A}$ can be "normalized" such that all trees, which have an accepting run in $\mathcal{A}$, have the same number of accepting runs.

▶ **Lemma 3.** *Let $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ be an M-ambiguous max-plus-WTA. Then there exists a finitely ambiguous max-plus-WTA $\mathcal{A}'$ with $\mathcal{A} = \mathcal{A}'$ and $|\mathrm{Acc}_{\mathcal{A}'}(t)| \in \{0, M\}$ for all $t \in T_\Gamma$.*

For the rest of this section, fix an M-ambiguous max-plus-WTA $\mathcal{A}_1$ and a max-plus-WTA $\mathcal{A}_2$. By Lemma 3, we can assume that for all $t \in T_\Gamma$ we have $|\mathrm{Acc}_{\mathcal{A}_1}(t)| \in \{0, M\}$. Note that $\mathcal{A}_1 \geq \mathcal{A}_2$ can only hold if $\mathrm{supp}(\mathcal{A}_2) \subseteq \mathrm{supp}(\mathcal{A}_1)$, which is decidable since the supports of $\mathcal{A}_1$ and $\mathcal{A}_2$ are recognizable languages. Therefore, in the forthcoming considerations we will always assume that $\mathrm{supp}(\mathcal{A}_2) \subseteq \mathrm{supp}(\mathcal{A}_1)$ holds. We write $\mathcal{A}_i = (Q_i, \Gamma, \mu_i, \nu_i)$ for $i = 1, 2$.

For any tree in $\mathrm{supp}(\mathcal{A}_2)$, there are exactly M accepting runs of $\mathcal{A}_1$ on this tree. We want to apply pumping type arguments to all of these runs and a given accepting run of $\mathcal{A}_2$ simultaneously. For this, we encode the runs of $\mathcal{A}_1$ and the given run of $\mathcal{A}_2$ directly into the tree. Moreover, we want to decompose these trees, with all runs encoded, into smaller parts. Formally, such a decomposition will be a tree of trees. To mark where these smaller trees connect to each other, we use the new label $\diamond$.

▶ **Definition 4.** For a set X and an alphabet Σ, we define for $(a, x) \in \Sigma \times X$ the rank $\mathrm{rk}_{\Sigma \times X}(a, x) = \mathrm{rk}_\Sigma(a)$. We let $\Gamma_\diamond = (\Gamma \cup \{\diamond\}, \mathrm{rk}_\Gamma \cup \{\diamond \mapsto 0\})$, where $\diamond$ is a new symbol. Let $\mathfrak{Q} = Q_1^M \times Q_2$ and let $\pi_\mathfrak{Q}$, π_Γ and $\pi_{\Gamma_\diamond}$ be the projections of $\Gamma \times \mathfrak{Q}$ and $\Gamma_\diamond \times \mathfrak{Q}$ onto $\mathfrak{Q}$, Γ and $\Gamma_\diamond$, respectively.

For a tree $t \in T_{\Gamma_\diamond \times \mathfrak{Q}}$, we define $\mathrm{label}_t^{\Gamma_\diamond} = \pi_{\Gamma_\diamond} \circ \mathrm{label}_t$ and $\mathrm{label}_t^i = \pi_i \circ \pi_\mathfrak{Q} \circ \mathrm{label}_t$ where π_i is the i-th projection on $\mathfrak{Q}$. For $i \in \{1, \ldots, M+1\}$, we define

$$\mathrm{wt}_i(t) = \begin{cases} \sum\limits_{\substack{w \in \mathrm{pos}(t) \\ \mathrm{label}_t^{\Gamma_\diamond}(w) \neq \diamond}} \mu_1(\mathbb{t}((\mathrm{pos}(t), \mathrm{label}_t^{\Gamma_\diamond}), \mathrm{label}_t^i, w)) & \text{if } 1 \leq i \leq M \\ \sum\limits_{\substack{w \in \mathrm{pos}(t) \\ \mathrm{label}_t^{\Gamma_\diamond}(w) \neq \diamond}} \mu_2(\mathbb{t}((\mathrm{pos}(t), \mathrm{label}_t^{\Gamma_\diamond}), \mathrm{label}_t^i, w)) & \text{if } i = M+1. \end{cases}$$

A tree $t \in T_{\Gamma \times \mathfrak{Q}}$ is called *accepting* if $\mathrm{label}_t^1, \ldots, \mathrm{label}_t^M$ are pairwise distinct accepting runs of $\mathcal{A}_1$ on $(\mathrm{pos}(t), \mathrm{label}_t^{\Gamma_\diamond})$ and label_t^{M+1} is an accepting run of $\mathcal{A}_2$ on $(\mathrm{pos}(t), \mathrm{label}_t^{\Gamma_\diamond})$.

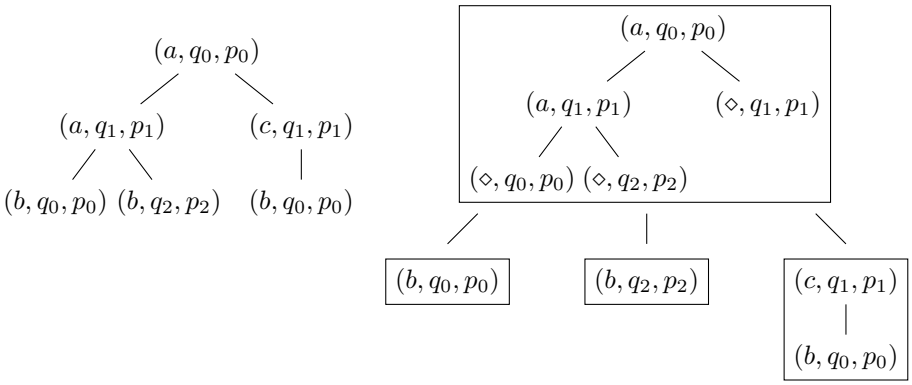

Figure 1 A tree in $T_{\Gamma\times\mathfrak{Q}}$ $(M = 1)$ and a possible cycle decomposition with f defined as $f(\varepsilon) = 1$ and $f(1) = f(2) = f(3) = 0$.

Let $t \in T_{\Gamma_\diamond\times\mathfrak{Q}}$, $n = |\{w \in \mathrm{pos}(t) \mid \mathrm{label}_t^{\Gamma_\diamond}(w) = \diamond\}|$ be the number of $\diamond$-leaves in t and $\{w_1, \dots, w_n\}$ a lexicographically ordered enumeration of these leaves, i.e. $w_1 \leq_l \dots \leq_l w_n$. For $1 \leq i \leq n$, we define $W_i(t) = w_i$. The set

$$\Xi = \{t \in T_{\Gamma_\diamond\times\mathfrak{Q}} \mid \forall w \in \mathrm{pos}(t) : |w| \leq |\mathfrak{Q}| \text{ and } \mathrm{label}_t^{\Gamma_\diamond}(\varepsilon) \neq \diamond\}$$

forms a ranked alphabet where for t as above we define $\mathrm{rk}_\Xi(t) = n$. We recall that $|w|$ denotes the length of w and $|\mathfrak{Q}|$ the cardinality of $\mathfrak{Q}$.

Every tree over Ξ corresponds to a unique tree over $\Gamma \times \mathfrak{Q}$. This inclusion $\mathcal{J} \colon T_\Xi \hookrightarrow T_{\Gamma\times\mathfrak{Q}}$ is formally given as follows. For $\mathfrak{t} \in T_\Xi$ with $\mathrm{pos}(\mathfrak{t}) = \{\varepsilon\}$ we let $\mathcal{J}(\mathfrak{t}) = \mathfrak{t}(\varepsilon)$. Otherwise let $m = \mathrm{rk}_\Xi(\mathfrak{t}(\varepsilon))$ and $\mathcal{J}(\mathfrak{t}) = \mathfrak{t}(\varepsilon)\langle\mathcal{J}(\mathfrak{t}|_1) \to W_1(\mathfrak{t}(\varepsilon))\rangle \dots \langle\mathcal{J}(\mathfrak{t}|_m) \to W_m(\mathfrak{t}(\varepsilon))\rangle$.

A tree $\mathfrak{t} \in T_\Xi$ is called *matching* if for all $w \in \mathrm{pos}(\mathfrak{t})$ and $i \in \{1, \dots, \mathrm{rk}_\Xi(\mathfrak{t}(w))\}$ we have $\pi_\mathfrak{Q}(\mathfrak{t}(w)(W_i(\mathfrak{t}(w)))) = \pi_\mathfrak{Q}(\mathfrak{t}(wi)(\varepsilon))$, i.e. the "state labels" of the $\diamond$-letters match with the state labels of the root at the corresponding child.

▶ **Definition 5.** Let $t \in T_{\Gamma\times\mathfrak{Q}}$. A *cycle decomposition of* t is a pair $\mathfrak{D} = (\mathfrak{t}, f)$, where $\mathfrak{t} \in T_\Xi$ and $f \colon \mathrm{pos}(\mathfrak{t}) \to \mathbb{N}$ is a mapping, satisfying the following.

1. We have $\mathcal{J}(\mathfrak{t}) = t$ and $\mathfrak{t}$ is matching.
2. For all $w \in \mathrm{pos}(\mathfrak{t})$ we have $f(w) \leq \mathrm{rk}_\Xi(\mathfrak{t}(w))$.
3. If $w \in \mathrm{pos}(\mathfrak{t})$ with $f(w) > 0$, then with $v = W_{f(w)}(\mathfrak{t}(w))$ we have $\pi_\mathfrak{Q}(\mathfrak{t}(w)(\varepsilon)) = \pi_\mathfrak{Q}(\mathfrak{t}(w)(v))$. In other words, the state labels of the root of $\mathfrak{t}(w)$ coincide with the state labels of the $f(w)$-th $\diamond$-leaf of $\mathfrak{t}(w)$.
4. If $f(w) = 0$ for some $w \in \mathrm{pos}(\mathfrak{t})$, then for all $i > 0$ with $wi \in \mathrm{pos}(\mathfrak{t})$, we have $f(wi) > 0$.

We call $w \in \mathrm{pos}(\mathfrak{t})$ a *cycle* if $f(w) > 0$ and otherwise a *link*. The set of all cycles of $\mathfrak{D}$ is denoted by $\mathrm{Cyc}(\mathfrak{D})$. By $\mathrm{Decomp}(t)$ we denote the set of all cycle decompositions of t. For $w \in \mathrm{pos}(\mathfrak{t})$ we call the set $\mathrm{Anc}_\mathfrak{D}(w) = \{v \in \mathrm{Cyc}(\mathfrak{D}) \mid vi \leq_p w \text{ for some } i \geq 1 \text{ with } i \neq f(v)\}$ the *ancestors* of w, see also Figure 2. We have the following lemma.

▶ **Lemma 6.** *For every $t \in T_{\Gamma\times\mathfrak{Q}}$, there exists a cycle decomposition $(\mathfrak{t}, f) \in \mathrm{Decomp}(t)$.*

For $w \in \mathrm{Cyc}(\mathfrak{D})$ we now define a new tree $\mathfrak{t}_\mathfrak{D}(w)$ over the alphabet $\Xi \cup \{\diamond\}$, where $\diamond$ has rank 0. Intuitively, $\mathfrak{t}_\mathfrak{D}(w)$ is the subtree of $\mathfrak{t}$ at w, with all cycles apart from w itself removed and the subtree at $wf(w)$ replaced by $\diamond$, see also Figure 2.

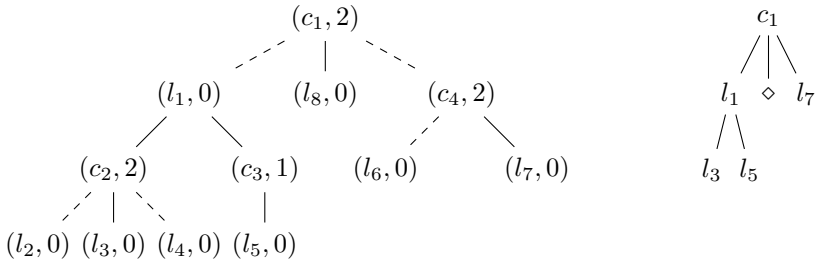

Figure 2 A cycle decomposition $\mathfrak{D}$ with f included in the labels and the tree $\mathfrak{t}_{\mathfrak{D}}(\varepsilon)$. A c denotes a cycle and an l a link. The position of l_8 has no ancestors, l_5 has only the ancestor c_1, and l_4 has ancestors c_1 and c_2.

Formally, we construct the tree as follows. We write f into the labels of $\mathfrak{t}$, i.e. we define $\mathfrak{t}' = (\mathrm{pos}(\mathfrak{t}), \mathrm{label}_{\mathfrak{t}} \times f)$. By π_1 and π_2 we denote the projections of $\Xi \times \mathbb{N}$ to the respective entries. We let $\mathfrak{s} = \mathfrak{t}'|_w$. Now, as long as there is $v \in \mathrm{pos}(\mathfrak{s})$ with $\pi_2(\mathfrak{s}(v)) > 0$ and $v \neq \varepsilon$, we redefine $\mathfrak{s} = \mathfrak{s}\langle \mathfrak{s}|_{v\pi_2(\mathfrak{s}(v))} \to v\rangle$. Finally, we let $\mathfrak{s}' = (\mathrm{pos}(\mathfrak{s}), \pi_1 \circ \mathrm{label}_{\mathfrak{s}})$ and $\mathfrak{t}_{\mathfrak{D}}(w) = \mathfrak{s}'\langle \diamond \to f(w)\rangle$. Note that $\mathfrak{t}_{\mathfrak{D}}(w)$ is matching.

For $i \in \{1, \ldots, M+1\}$ and $w \in \mathrm{Cyc}(\mathfrak{D})$ we define

$$\mathrm{wt}_i^{\mathfrak{D}}(w) = \sum_{\substack{v \in \mathrm{pos}(\mathfrak{t}_{\mathfrak{D}}(w)) \\ \mathrm{label}_{\mathfrak{t}_{\mathfrak{D}}(w)}(v) \neq \diamond}} \mathrm{wt}_i(\mathrm{label}_{\mathfrak{t}_{\mathfrak{D}}(w)}(v))$$

$$b_i^{\mathfrak{D}} = \sum_{\substack{v \in \mathrm{pos}(\mathfrak{t}) \\ v \notin \mathrm{Cyc}(\mathfrak{D}) \\ \mathrm{Anc}_{\mathfrak{D}}(v) = \emptyset}} \mathrm{wt}_i(\mathfrak{t}(v)) + \begin{cases} \nu_1(\mathrm{label}^i_{\mathfrak{t}(\varepsilon)}(\varepsilon)) & \text{if } 1 \leq i \leq M \\ \nu_2(\mathrm{label}^{M+1}_{\mathfrak{t}(\varepsilon)}(\varepsilon)) & \text{if } i = M+1. \end{cases}$$

We have the following lemma.

▶ **Lemma 7.** *Let $t \in T_{\Gamma \times \mathfrak{Q}}$, $s = (\mathrm{pos}(t), \mathrm{label}_t^{\Gamma_\diamond})$, $r_i = \mathrm{label}_t^i$ and $\mathfrak{D} = (\mathfrak{t}, f) \in \mathrm{Decomp}(t)$. Let $\{w_1, \ldots, w_n\}$ be a lexicographically ordered enumeration of $\mathrm{Cyc}(\mathfrak{D})$. Then*

$$\begin{aligned} \nu_1(r_i(\varepsilon)) \quad + \mathrm{wt}_{\mathcal{A}_1}(s, r_i) \quad &= b_i^{\mathfrak{D}} \quad + \mathrm{wt}_i^{\mathfrak{D}}(w_1) \quad + \ldots + \mathrm{wt}_i^{\mathfrak{D}}(w_n) \\ \nu_2(r_{M+1}(\varepsilon)) + \mathrm{wt}_{\mathcal{A}_2}(s, r_{M+1}) &= b_{M+1}^{\mathfrak{D}} + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_1) + \ldots + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_n) \end{aligned}$$

for $i \in \{1, \ldots, M\}$.

Let $\{w_1, \ldots, w_n\}$ be a lexicographically ordered enumeration of $\mathrm{Cyc}(\mathfrak{D})$. We consider the system of linear inequalities

$$b_i^{\mathfrak{D}} + \mathrm{wt}_i^{\mathfrak{D}}(w_1)X_1 + \ldots + \mathrm{wt}_i^{\mathfrak{D}}(w_n)X_n < b_{M+1}^{\mathfrak{D}} + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_1)X_1 + \ldots + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_n)X_n$$
$$0 < X_j$$

where i ranges over $1, \ldots, M$ and j over $1, \ldots n$. For a cycle decomposition $\mathfrak{D} \in \mathrm{Decomp}(t)$, the system above is denoted by $\mathrm{LIS}(\mathfrak{D})$.

▶ **Lemma 8.** *Let $t \in T_{\Gamma \times \mathfrak{Q}}$ be accepting and $\mathfrak{D} = (\mathfrak{t}, f) \in \mathrm{Decomp}(t)$. For every choice of $X_1, \ldots, X_n \in \mathbb{N}$, $X_i \geq 1$, there is an accepting tree $s \in T_{\Gamma \times \mathfrak{Q}}$ with*

$$\begin{aligned} \nu_1(\mathrm{label}_s^i(\varepsilon)) + \quad \mathrm{wt}_i(s) = \quad b_i^{\mathfrak{D}} + \quad \mathrm{wt}_i^{\mathfrak{D}}(w_1)X_1 + \ldots + \quad \mathrm{wt}_i^{\mathfrak{D}}(w_n)X_n \\ \nu_2(\mathrm{label}_s^{M+1}(\varepsilon)) + \mathrm{wt}_{M+1}(s) = b_{M+1}^{\mathfrak{D}} + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_1)X_1 + \ldots + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_n)X_n \end{aligned}$$

for every $i \in \{1, \ldots, M\}$.

Proof. For $X_1 = \ldots = X_n = 1$ we know by Lemma 7 that this is true for $s = t$. Otherwise let $w \in \mathrm{Cyc}(\mathfrak{D})$. We can "insert" the tree $\mathfrak{t}_{\mathfrak{D}}(w)$ into $\mathfrak{t}$ at w as follows. Let $\mathfrak{s} = \mathfrak{t}\langle \mathfrak{t}_{\mathfrak{D}}(w) \to wf(w)\rangle\langle \mathfrak{t}|_{wf(w)} \to wf(w)f(w)\rangle$. As w is a cycle, we know that $\mathfrak{s}$ is matching and with $s = \mathcal{J}(\mathfrak{s})$ we have

$$\begin{aligned}\nu_i(\mathrm{label}_s^i(\varepsilon)) + \mathrm{wt}_i(s) &= \nu_i(\mathrm{label}_t^i(\varepsilon)) + \mathrm{wt}_i(t) + \mathrm{wt}_i^{\mathfrak{D}}(w)\\ &= b_i^{\mathfrak{D}} + \mathrm{wt}_i^{\mathfrak{D}}(w_1) + \ldots + \mathrm{wt}_i^{\mathfrak{D}}(w_n) + \mathrm{wt}_i^{\mathfrak{D}}(w)\end{aligned}$$

where the last equality follows from Lemma 7. For every $j \in \{1, \ldots, n\}$ we apply this procedure $X_j - 1$ times to w_j to obtain s as needed. To see that s is indeed accepting, note that $\mathrm{label}_t^1, \ldots, \mathrm{label}_t^M$ are pairwise distinct. Since s is obtained from t by inserting subtrees, $\mathrm{label}_s^1, \ldots, \mathrm{label}_s^M$ must also be pairwise distinct. ◀

We are now ready to prove Theorem 2.

▶ **Lemma 9.** *Let* $N = \sum_{k=0}^{|\Omega|} \mathrm{rk}(\Gamma)^k$, $\Upsilon = \sum_{k=1}^{\mathrm{rk}(\Xi)+1}(|\Xi|+1)^k$, $\Omega = \sum_{k=1}^{\mathrm{rk}(\Xi)+2}(|\Xi|+1)^k$ *and* $\Theta = |\Xi|\Omega(2^\Omega + 2)$. *Then the following statements are equivalent.*

(i) $\mathcal{A}_1 \geq \mathcal{A}_2$.

(ii) *For all accepting* $t \in T_{\Gamma\times\mathfrak{Q}}$ *with* $|\mathrm{pos}(t)| \leq N\Upsilon^2\Theta(2+\mathrm{rk}(\Xi))$ *and all cycle decompositions* $\mathfrak{D} \in \mathrm{Decomp}(t)$, *the system of linear inequalities* $\mathrm{LIS}(\mathfrak{D})$ *does not possess an integer solution.*

(iii) *For all accepting* $t \in T_{\Gamma\times\mathfrak{Q}}$ *and all cycle decompositions* $\mathfrak{D} \in \mathrm{Decomp}(t)$, *the system of linear inequalities* $\mathrm{LIS}(\mathfrak{D})$ *does not possess an integer solution.*

Property (ii) is clearly decidable. There are only finitely many trees to check, each tree has only finitely many cycle decompositions, and the satisfiability of the corresponding linear inequality systems with integers is decidable due to [15]. In particular, Theorem 2 holds.

Proof (sketch).

(i) ⇒ (iii). We prove this by contradiction and assume that (iii) does not hold. Then there is an accepting $t \in T_{\Gamma\times\mathfrak{Q}}$ and a cycle decomposition $\mathfrak{D} \in \mathrm{Decomp}(t)$ such that the system of inequalities $\mathrm{LIS}(\mathfrak{D})$ has an integer solution. By Lemma 8 we can find an accepting tree $s \in T_{\Gamma\times\mathfrak{Q}}$ with

$$\begin{aligned}\nu_1(\mathrm{label}_s^i(\varepsilon)) + \quad \mathrm{wt}_i(s) = \quad b_i^{\mathfrak{D}} + \quad \mathrm{wt}_i^{\mathfrak{D}}(w_1)X_1 + \ldots + \quad \mathrm{wt}_i^{\mathfrak{D}}(w_n)X_n\\ \nu_2(\mathrm{label}_s^{M+1}(\varepsilon)) + \mathrm{wt}_{M+1}(s) = b_{M+1}^{\mathfrak{D}} + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_1)X_1 + \ldots + \mathrm{wt}_{M+1}^{\mathfrak{D}}(w_n)X_n\end{aligned}$$

for every $i \in \{1, \ldots, M\}$. Thus by Lemma 7 with $s' = (\mathrm{pos}(t), \mathrm{label}_s^{\Gamma_\diamond})$ and $r_i = \mathrm{label}_s^i$ for $i \in \{1, \ldots, M+1\}$ we have $\nu_1(r_i(\varepsilon)) + \mathrm{wt}_{\mathcal{A}_1}(s', r_i) < \nu_2(r_{M+1}(\varepsilon)) + \mathrm{wt}_{\mathcal{A}_2}(s', r_{M+1})$ for all $i \in \{1, \ldots, M\}$. Since $\mathcal{A}_1$ is M-ambiguous and $r_1, \ldots, r_M$ are pairwise distinct, this means $[\![\mathcal{A}_1]\!](s') < [\![\mathcal{A}_2]\!](s')$, i.e. (i) does not hold.

(iii) ⇒ (i). We show this by contradiction and assume that (i) does not hold. Then there is some tree $s \in \mathrm{supp}(\mathcal{A}_2)$ with $[\![\mathcal{A}_1]\!](s) < [\![\mathcal{A}_2]\!](s)$. Let $\mathrm{Acc}_{\mathcal{A}_1}(s) = \{r_1, \ldots, r_M\}$. Since $[\![\mathcal{A}_1]\!](s) < [\![\mathcal{A}_2]\!](s)$, there must be $r_{M+1} \in \mathrm{Acc}_{\mathcal{A}_2}(s)$ with $\nu_1(r_i(\varepsilon)) + \mathrm{wt}_{\mathcal{A}_1}(s, r_i) < \nu_2(r_{M+1}(\varepsilon)) + \mathrm{wt}_{\mathcal{A}_2}(s, r_{M+1})$ for all $i \in \{1, \ldots, M\}$. Consider the accepting tree $t = (\mathrm{pos}(s), (\mathrm{label}_s, r_1, \ldots, r_{M+1})) \in T_{\Gamma\times\mathfrak{Q}}$ and let $\mathfrak{D} = (\mathfrak{t}, f) \in \mathrm{Decomp}(t)$. Then according to Lemma 7, the system $\mathrm{LIS}(\mathfrak{D})$ clearly has the integer solution $X_1 = \ldots = X_n = 1$, i.e. (iii) does not hold.

(ii) ⇔ (iii). The direction (iii) ⇒ (ii) is clear. We prove (ii) ⇒ (iii) by induction on the size of the trees t. For "small" trees, it follows by assuming (ii) as true. For "large" trees t, we

show that if for a cycle decomposition $\mathfrak{D} = (\mathfrak{t}, f)$ the system $\mathrm{LIS}(\mathfrak{D})$ has an integer solution, then we can find a smaller tree and a cycle decomposition $\mathfrak{D}'$ of that tree for which $\mathrm{LIS}(\mathfrak{D}')$ also has an integer solution. This constitutes a contradiction to our induction hypothesis.

The main issue is how to construct this smaller tree. For words, it is easy. If a word is sufficiently long, there are two cycles with the same label. We remove one of these cycles from the word, thereby making the word shorter, and in $\mathrm{LIS}(\mathfrak{D})$ add the coefficient for this cycle to that of the other, identical cycle. It is clear that this is not possible for trees. By removing any cycle w, we also remove all other cycles v with $w \in \mathrm{Anc}_{\mathfrak{D}}(v)$.

Our solution for this is as follows. Using the concept of ancestors, we construct a tree hierarchy on the cycles of $\mathfrak{D}$. The "child cycles" of a given cycle w are all cycles for which w is the prefix-largest ancestor. We call this tree $\mathfrak{T}$ and consider two different cases. If $\mathfrak{T}$ has sufficiently many leaves, there are two different leaves pointing to the "same cycle". More precisely, we find $w_1 \neq w_2$ in $\mathrm{Cyc}(\mathfrak{D})$ with $\mathfrak{t}_{\mathfrak{D}}(w_1) = \mathfrak{t}_{\mathfrak{D}}(w_2)$ and for all $v \in \mathrm{Cyc}(\mathfrak{D})$ we have $w_1 \notin \mathrm{Anc}_{\mathfrak{D}}(v)$ and $w_2 \notin \mathrm{Anc}_{\mathfrak{D}}(v)$. The leaves of $\mathfrak{T}$ correspond to cycles which are save to remove as they are not ancestors of any other cycles. We can therefore remove w_2 and add this cycle's coefficient to that of w_1.

However, $\mathfrak{T}$ might not have sufficiently many leaves for this argumentation. But assuming that the number of leaves stays below the bound Υ, sufficiently large trees $\mathfrak{T}$ have arbitrarily long successions of nodes $w, w1, w1^2, \ldots, w1^n$ each having only one child. Now consider the cycles $v_0, \ldots, v_n \in \mathrm{Cyc}(\mathfrak{D})$ which correspond to such a succession $w, w1, \ldots, w1^n$. We can show that there is only a finite number of possible trees $\mathfrak{t}_{\mathfrak{D}}(v_i)$ for these cycles. If n is large enough, we can find $i_1 < i_2 < i_3 < i_4$ such that $\mathfrak{t}_{\mathfrak{D}}(v_{i_1}) = \mathfrak{t}_{\mathfrak{D}}(v_{i_2}) = \mathfrak{t}_{\mathfrak{D}}(v_{i_3}) = \mathfrak{t}_{\mathfrak{D}}(v_{i_4})$ and in addition $\{\mathfrak{t}_{\mathfrak{D}}(v_i) \mid i_1 \leq i \leq i_2\} = \{\mathfrak{t}_{\mathfrak{D}}(v_i) \mid i_3 \leq i \leq i_4\}$. We can then "remove" all cycles $v_{i_3}, \ldots, v_{i_4-1}$ by inserting the subtree of $\mathfrak{t}$ at v_{i_4} into the node v_{i_3}. The coefficients for the cycles removed in this way can then be added to the coefficients of the corresponding cycles in $v_{i_1}, \ldots, v_{i_2}$. ◀

On the Proof for the Word Case

For words, Theorem 1 was shown by Hashiguchi et al. There are two different versions of the paper, namely [8, 9]. In both papers, it is first shown that for deterministic max-plus word automata $\mathcal{A}_1, \ldots, \mathcal{A}_{M+1}$, it is decidable whether $\max_{i=1}^{M} [\![\mathcal{A}_i]\!] \geq [\![\mathcal{A}_{M+1}]\!]$. The approach for the generalization to finitely ambiguous automata is then different in both papers.

In [8], it is claimed that every finitely ambiguous max-plus word automaton can be written as a pointwise maximum of finitely many deterministic max-plus automata. This argumentation was withdrawn in [9] and the claim posed as an open problem. It does in fact not hold as shown in [1].

In [9], the argumentation is done directly on the runs of the finitely ambiguous max-plus automata. However, this causes problems when not all words have the same number of accepting runs. The two automata in Figure 3 over the one-letter alphabet $\{a\}$ constitute a counter example to Theorem 5.6 in [9], which is similar to our Lemma 9.

One easily checks that $\mathcal{A}_1 \geq \mathcal{A}_2$. There are two accepting runs of $\mathcal{A}_1$ on a^3, namely $q_1 a q_2 a q_3 a q_3$ and $q_4 a q_5 a q_6 a q_6$, and one of $\mathcal{A}_2$ on a^3, namely $p_1 a p_2 a p_3 a p_3$. The last a thus induces a cycle in the sense of [9]. From this, the linear inequality system

$$\begin{aligned} 2+ (-1) \cdot X &< 1+ 0 \cdot X \\ -2+ \quad 1 \cdot X &< 1+ 0 \cdot X \\ 0 &\leq X \end{aligned}$$

is derived. It clearly has the solution $X = 2$. However, it is stated that from the satisfiability

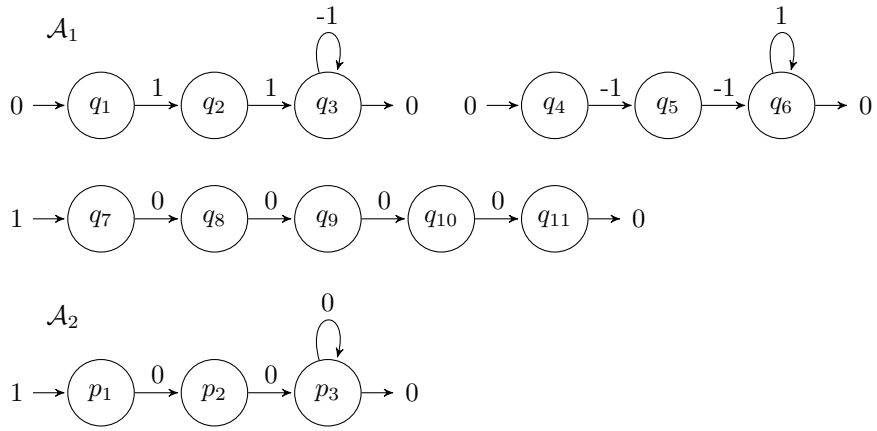

Figure 3 The automata $\mathcal{A}_1$ and $\mathcal{A}_2$ over the alphabet $\{a\}$ constitute a counter example to [9, Theorem 5.6]. The transition letters are omitted.

of this inequality system with an integer value it follows that $\mathcal{A}_1 \geq \mathcal{A}_2$ does not hold. The problem here is that the word a^4, which is supposed to "realize" the solution of the inequality system, in fact possesses a third accepting run $q_7aq_8aq_9aq_{10}aq_{11}$ which compensates the other two runs.

The proof of Theorem 5.6 in [9] can easily be fixed by normalizing the automaton $\mathcal{A}_1$ as we did in Lemma 3. If for some $M \geq 1$ we have $|\mathrm{Acc}_{\mathcal{A}_1}(w)| \in \{0, M\}$ for every word w, all arguments of the proof work as intended.

4 The Unambiguity Problem

The unambiguity problem asks whether for a given max-plus-WTA $\mathcal{A}$ there exists an unambiguous max-plus-WTA $\mathcal{A}'$ such that $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$. In this section, we show that the unambiguity problem is decidable for finitely ambiguous max-plus-WTA. We follow ideas from [11, Section 5], where the decidability of this problem was shown for finitely ambiguous max-plus word automata. The unambiguity problem is, in fact, even known to be decidable for polynomially ambiguous max-plus word automata [10]. We leave the question open as to whether the same holds true for polynomially ambiguous max-plus-WTA.

▶ **Theorem 10.** *For a finitely ambiguous max-plus-WTA $\mathcal{A}$ it is decidable whether there exists an unambiguous max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$. If $\mathcal{A}'$ exists, it can be effectively constructed.*

The rest of this section is dedicated to the proof of Theorem 10.

For an alphabet Γ, a tree over the alphabet $\Gamma_\diamond = (\Gamma \cup \{\diamond\}, \mathrm{rk}_\Gamma \cup \{\diamond \mapsto 0\})$ is called a Γ-*context*. For a max-plus-WTA $\mathcal{A} = (Q, \Gamma, \mu, \nu)$, a run of $\mathcal{A}$ on a Γ-context t is a run of the max-plus-WTA $\mathcal{A}' = (Q, \Gamma_\diamond, \mu', \nu)$ on t, where $\mu'(\diamond, q) = 0$ for all $q \in Q$ and $\mu'(d) = \mu(d)$ for $d \in \Delta_\mathcal{A}$. We denote $\mathrm{Run}^\diamond_\mathcal{A}(t) = \mathrm{Run}_{\mathcal{A}'}(t)$ and for $r \in \mathrm{Run}^\diamond_\mathcal{A}(t)$ write $\mathrm{wt}^\diamond_\mathcal{A}(t, r) = \mathrm{wt}_{\mathcal{A}'}(t, r)$.

For $s \in T_\Gamma$ with $|\{w \in \mathrm{pos}(s) \mid s(w) = \diamond\}| = 1$ and $r \in \mathrm{Run}^\diamond_\mathcal{A}(s)$ such that for $w_0 \in \mathrm{pos}(s)$ with $s(w_0) = \diamond$ we have $r(\varepsilon) = r(w_0)$ the pair (s, r) is called an $\mathcal{A}$-*circuit*. We call (s, r) *small* if $|w| \leq |Q|$ for all $w \in \mathrm{pos}(s)$.

Now let $\mathcal{A}$ be a finitely ambiguous max-plus-WTA. We decompose $\mathcal{A}$ into unambiguous max-plus-WTA as follows.

▶ **Lemma 11** ([16]). *Let $\mathcal{A}$ be a finitely ambiguous max-plus-WTA over Γ, then there exist finitely many unambiguous max-plus-WTA $\mathcal{A}_1, \dots, \mathcal{A}_M$ over Γ with $[\![\mathcal{A}]\!] = \max_{i=1}^{M} [\![\mathcal{A}_i]\!]$ and $\operatorname{supp}(\mathcal{A}_1) = \dots = \operatorname{supp}(\mathcal{A}_M)$.*

Let $\mathcal{A}_1, \dots, \mathcal{A}_M$ be unambiguous max-plus-WTA with $\operatorname{supp}(\mathcal{A}_1) = \dots = \operatorname{supp}(\mathcal{A}_M)$ and $[\![\mathcal{A}]\!] = \max_{i=1}^{M} [\![\mathcal{A}_i]\!]$. We write $\mathcal{A}_i = (Q_i, \Gamma, \mu_i, \nu_i)$ for $i \in \{1, \dots, M\}$. The *product automaton of $\mathcal{A}_1, \dots, \mathcal{A}_M$* is the trimmed automaton $\mathcal{B} = (Q, \Gamma, \mu, \nu)$ over the product semiring $(\mathbb{R}_{\max})^M$ defined as follows. We let $Q = Q_1 \times \dots \times Q_M$ and for $a \in \Gamma$ with $\operatorname{rk}_\Gamma(a) = m$ and $\mathbf{p}_0, \dots, \mathbf{p}_m \in Q$ with $\mathbf{p}_i = (p_{i1}, \dots, p_{iM})$ we define with $x_j = \mu_j(p_{1j}, \dots, p_{mj}, a, p_{0j})$ and $y_j = \nu_j(p_{0j})$

$$\mu(\mathbf{p}_1, \dots, \mathbf{p}_m, a, \mathbf{p}_0) = \begin{cases} (x_1, \dots, x_M) & \text{if } (x_1, \dots, x_M) \in \mathbb{R}^M \\ (-\infty, \dots, -\infty) & \text{otherwise} \end{cases}$$

$$\nu(\mathbf{p}_0) = \begin{cases} (y_1, \dots, y_M) & \text{if } (y_1, \dots, y_M) \in \mathbb{R}^M \\ (-\infty, \dots, -\infty) & \text{otherwise.} \end{cases}$$

Then $\mathcal{B}$ is unambiguous and for $t \in T_\Gamma$ we have $[\![\mathcal{B}]\!](t) = ([\![\mathcal{A}_1]\!](t), \dots, [\![\mathcal{A}_M]\!](t))$.

For $\mathbf{q}, \mathbf{p} \in Q$, we write $\mathbf{q} \preceq \mathbf{p}$ if there exists $t \in T_\Gamma$, $r \in \operatorname{Acc}_\mathcal{B}(t)$ and $w_1, w_2 \in \operatorname{pos}(t)$ with $w_1 \leq_p w_2$ such that $r(w_1) = \mathbf{q}$ and $r(w_2) = \mathbf{p}$. We write $\mathbf{q} \approx \mathbf{p}$ if $\mathbf{q} \preceq \mathbf{p}$ and $\mathbf{p} \preceq \mathbf{q}$. By $[\mathbf{q}]$ we denote the set of all $\mathbf{p} \in Q$ with $\mathbf{q} \approx \mathbf{p}$.

▶ **Definition 12.** Let $s \in T_{\Gamma_\diamond}$ be a Γ-context, $r \in \operatorname{Run}^\diamond_\mathcal{B}(s)$ and write $\operatorname{wt}^\diamond_\mathcal{B}(s, r) = (\theta_1, \dots, \theta_M)$. We define $\operatorname{wt}_i(s, r) = \theta_i$ and $\operatorname{wt}(s, r) = \max_{i=1}^{M} \operatorname{wt}_i(s, r)$.

A coordinate $i \in \{1, \dots, M\}$ is called *victorious* if $\operatorname{wt}_i(s, r) = \operatorname{wt}(s, r)$. The set of all victorious coordinates of (s, r) is denoted by $\operatorname{Vict}(s, r)$. For $\mathbf{q} \in Q$ we define

$$\operatorname{Vict}([\mathbf{q}]) = \bigcap_{\substack{(s,r) \text{ small } \mathcal{B}\text{-circuit} \\ r(\varepsilon) \in [\mathbf{q}]}} \operatorname{Vict}(s, r)$$

where the empty intersection is defined as $\{1, \dots, M\}$. For $P \subseteq Q$, we let $\operatorname{Vict}(P) = \bigcap_{\mathbf{p} \in P} \operatorname{Vict}([\mathbf{p}])$. We have the following lemma.

▶ **Lemma 13.** *There is an unambiguous max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$ if and only if for all $t \in T_\Gamma$ and all $r \in \operatorname{Acc}_\mathcal{B}(t)$ we have $\operatorname{Vict}(r(\operatorname{pos}(t))) \neq \emptyset$. The latter property is called the* dominance property *and is denoted by (**P**).*

(**P**) is decidable as follows. We can consider Q as an (unranked) alphabet and construct an FTA which accepts exactly the accepting runs of $\mathcal{B}$, i.e. all pairs $(\operatorname{pos}(t), r)$ for some $t \in T_\Gamma$ and $r \in \operatorname{Acc}_\mathcal{B}(t)$. Also, for $P \subseteq Q$ we can construct an FTA which accepts all trees in T_Q in which every $p \in P$ occurs at least once as a label. By taking the intersection of these two automata and checking for emptiness, we can decide for every $P \subseteq Q$ whether there is any $t \in T_\Gamma$ and $r \in \operatorname{Acc}_\mathcal{B}(t)$ with $P \subseteq r(\operatorname{pos}(t))$. Checking whether all P for which this is true satisfy $\operatorname{Vict}(P) \neq \emptyset$ is equivalent to checking (**P**).

▶ **Construction 14.** Let $N = \sum_{i=0}^{|Q|} \operatorname{rk}(\Gamma)^i$, $R = \bigcup_{i=1}^{M} (\mu_i(\Delta_{\mathcal{A}_i}) \cup \nu_i(Q_i))$ and $C = \max R - \min(R \setminus \{-\infty\})$. For $\mathbf{x} = (x_1, \dots, x_M) \in \mathbb{R}^M_{\max}$ we let $\check{\mathbf{x}} = \min\{x_i \mid 1 \leq i \leq M, x_i \neq -\infty\}$ and $\underline{\mathbf{x}} = \mathbf{x} - (\check{\mathbf{x}}, \dots, \check{\mathbf{x}})$.

Assume that $\mathcal{B}$ satisfies (**P**). We construct an unambiguous max-plus-WTA $\mathcal{A}' = (Q', \Gamma, \mu', \nu')$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$ and $Q' \subset \mathbb{R}^M_{\max} \times Q$ as follows.

Rule 1: For $(a, \mathbf{q}) \in \Delta_\mathcal{B} \cap (\Gamma \times Q)$ with $\mathbf{x} = \mu(a, \mathbf{q}) \in \mathbb{R}^M$, we let $(\underline{\mathbf{x}}, \mathbf{q}) \in Q'$ and $\mu'(a, (\underline{\mathbf{x}}, \mathbf{q})) = \check{\mathbf{x}}$.

Rule 2: Assume for $(\mathbf{z}_1, \mathbf{p}_1), \dots, (\mathbf{z}_m, \mathbf{p}_m) \in Q'$ that we have $d = (\mathbf{p}_1, \dots, \mathbf{p}_m, a, \mathbf{p}_0) \in \Delta_{\mathcal{B}}$ for some $a \in \Gamma$, $\mathbf{p}_0 \in Q$ and $\mathbf{x} = \mu(d) \in \mathbb{R}^M$. We let $\mathbf{t} = \sum_{i=1}^m \mathbf{z}_i + \mathbf{x}$ and define $\mathbf{y} \in \mathbb{R}^M_{\max}$ through

$$y_i = \begin{cases} -\infty & \text{if } t_i < \max\{t_j \mid 1 \le j \le M\} - (2N+1)C \\ t_i & \text{otherwise.} \end{cases}$$

We let $(\underline{\mathbf{y}}, \mathbf{p}_0) \in Q'$ and $\mu'((\mathbf{z}_1, \mathbf{p}_1), \dots, (\mathbf{z}_m, \mathbf{p}_m), a, (\underline{\mathbf{y}}, \mathbf{p}_0)) = \check{\mathbf{y}}$.

Finally, assume $(\mathbf{z}, \mathbf{p}) \in Q'$ and $\mathbf{x} = \nu(\mathbf{p}) \in \mathbb{R}^M$. Then we let $\nu'(\mathbf{z}, \mathbf{p}) = \max_{i=1}^M z_i + x_i$.

▶ **Lemma 15.** *$\mathcal{A}'$ is an unambiguous max-plus-WTA with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$.*

Proof (sketch). $\mathcal{A}'$ is unambiguous as there is a bijection between the accepting runs of $\mathcal{B}$ and $\mathcal{A}'$. The idea behind $\mathcal{A}'$ is as follows. From a bottom-up perspective, $\mathcal{A}'$ remembers in each coordinate of $\mathbf{z}$ the weight which $\mathcal{B}$ would have assigned to the run in this coordinate "so far". Since this can become unbounded, we normalize the smallest coordinate to 0 in each transition, make this coordinate's weight the transition weight, and remember only the difference to this weight in the remaining coordinates. Still, these differences can become unbounded. Therefore, once the difference exceeds the bound $(2N+1)C$, the coordinates with small weights are discarded by being set to $-\infty$.

We can show that the coordinate k which in $\mathcal{B}$ eventually yields the largest weight will not be discarded. First, we can show that a victorious coordinate of a run will never be smaller than the largest weight (over all coordinates) minus NC. Second, we can show that if l is victorious, then the weight of coordinate k will never be smaller than the weight of l minus $NC + C$. Our assumption is that (**P**) holds, so there exists some victorious coordinate in every accepting run. Therefore, the weight of k will never be smaller than the largest weight minus $(2N+1)C$ and is never discarded. ◀

We now prove that (**P**) is a necessary condition, i.e. that from the existence of an unambiguous automaton $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$ it follows that $\mathcal{B}$ satisfies (**P**).

▶ **Lemma 16.** *If there exists an unambiguous max-plus-WTA $\mathcal{A}' = (Q', \Gamma, \mu', \nu')$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$ then $\mathcal{B}$ satisfies (**P**).*

Proof. Let $t \in T_\Gamma$ and $r \in \mathrm{Run}_{\mathcal{B}}(t)$. Let $\mathcal{C} = \{(s, r_s) \text{ small } \mathcal{B}\text{-circuit} \mid [r_s(\varepsilon)] \cap r(\mathrm{pos}(t)) \neq \emptyset\}$. Let $\mathbf{p} \in r(\mathrm{pos}(t))$, $(s, r_s) \in \mathcal{C}$ and $\mathbf{q} = r_s(\varepsilon) \in [\mathbf{p}]$.

We can assume that $\mathbf{q} \in r(\mathrm{pos}(t))$ due to the following argument. Since to $\mathbf{p} \preceq \mathbf{q} \preceq \mathbf{p}$, we can find $t^{\mathbf{p}}_{\mathbf{q}}, t^{\mathbf{q}}_{\mathbf{p}} \in T_\Gamma$, $r^{\mathbf{p}}_{\mathbf{q}} \in \mathrm{Run}_{\mathcal{B}}(t^{\mathbf{p}}_{\mathbf{q}})$ and $r^{\mathbf{q}}_{\mathbf{p}} \in \mathrm{Run}_{\mathcal{B}}(t^{\mathbf{q}}_{\mathbf{p}})$ such that $r^{\mathbf{p}}_{\mathbf{q}}(\varepsilon) = \mathbf{p}$, $r^{\mathbf{q}}_{\mathbf{p}}(\varepsilon) = \mathbf{q}$ and for some $w_{\mathbf{q}} \in \mathrm{pos}(t^{\mathbf{p}}_{\mathbf{q}})$ and $w_{\mathbf{p}} \in \mathrm{pos}(t^{\mathbf{q}}_{\mathbf{p}})$ we have $r^{\mathbf{p}}_{\mathbf{q}}(w_{\mathbf{q}}) = \mathbf{q}$ and $r^{\mathbf{q}}_{\mathbf{p}}(w_{\mathbf{p}}) = \mathbf{p}$. Thus with $s' = t^{\mathbf{p}}_{\mathbf{q}}\langle t^{\mathbf{q}}_{\mathbf{p}}\langle \diamond \to w_{\mathbf{p}}\rangle \to w_{\mathbf{q}}\rangle$ we obtain a circuit $(s', r_{s'})$ with $r_{s'}(\varepsilon) = \mathbf{p}$ and $r_{s'}(w_{\mathbf{q}}) = \mathbf{q}$. We can insert $(s', r_{s'})$ into t and r to obtain a tree t' and a run $r' \in \mathrm{Acc}_{\mathcal{B}}(t')$ with $\mathbf{q} \in r'(\mathrm{pos}(t'))$.

Now let $w_{\mathbf{q}} \in \mathrm{pos}(t)$ with $r(w_{\mathbf{q}}) = \mathbf{q}$ and $w \in \mathrm{pos}(s)$ with $s(w) = \diamond$. We let $s^1 = s$ and for $n \ge 1$ define $s^{n+1} = s\langle s^n \to w\rangle$. Then from r_s we obtain a circuit $(s^{|Q'|}, r_s^{|Q'|})$ which we can insert at $w_{\mathbf{q}}$ to obtain a tree $t' \in T_\Gamma$ and a run $r' \in \mathrm{Acc}_{\mathcal{B}}(t')$. We do this for all small circuits in $\mathcal{C}$ simultaneously. We assume without loss of generality that after this the circuit $(s^{|Q'|}, r_s^{|Q'|})$ is still at position $w_{\mathbf{q}}$. Since $\mathrm{supp}\,\mathcal{B} = \mathrm{supp}\,\mathcal{A}'$, we find a run $r'' \in \mathrm{Acc}_{\mathcal{A}'}(t')$. By pigeon hole principle, we find $0 \le i_1 < i_2 \le |Q'|$ with $r''(w_{\mathbf{q}} w^{i_1}) = r''(w_{\mathbf{q}} w^{i_2})$. From this, we obtain an $\mathcal{A}'$-circuit $(s^{i_2 - i_1}, \hat{r})$ which corresponds to a $\mathcal{B}$-circuit $(s^{i_2-i_1}, r_s^{i_2-i_1})$. We can now insert $s^{i_2-i_1}$ at $w_{\mathbf{q}}$ repeatedly to create copies of these circuits. Clearly, this works for all small circuits in $\mathcal{C}$.

Let $c_1, \dots, c_n$ be an enumeration of $\mathcal{C}$. We write $c_i = (s_i, r_i)$. By $(\hat{s}_i, \hat{r}_i)$ and $(\hat{s}_i, \check{r}_i)$, we denote the circuits in $\mathcal{A}'$ and $\mathcal{B}$, respectively, we obtain from c_i in the way we obtained $(s^{i_2-i_1}, \hat{r})$ and $(s^{i_2-i_1}, r^{i_2-i_1})$ from (s, r_s). For $\mathbf{v} = (v_1, \dots, v_n) \in \mathbb{N}^n$, we denote by $t_\mathbf{v}$ the tree obtained by adding v_i copies of $\hat{s}_i$ to t for each $i \in \{1, \dots, n\}$. Since $\mathcal{B}$ and $\mathcal{A}'$ are both unambiguous, we can make the following observations.

For $i \in \{1, \dots, n\}$ we let $\rho_i = \mathrm{wt}_{\mathcal{A}'}(\hat{s}_i, \hat{r}_i)$. Then for some constant ρ_0 we have $[\![\mathcal{A}']\!](t_\mathbf{v}) = \rho_0 + v_1\rho_1 + \ldots + v_n\rho_n$. Due to the definition of victorious coordinates, for every $\mathbf{v}' = (v_2, \dots, v_n) \in \mathbb{N}^{n-1}$ there is $N^{(1)}_{\mathbf{v}'} \in \mathbb{N}$ such that for all $v_1 > N^{(1)}_{\mathbf{v}'}$ the tuple $[\![\mathcal{B}]\!](t_{(v_1,\dots,v_n)})$ has its maximum in entry j_1 for some $j_1 \in \mathrm{Vict}(\hat{s}_1, \check{r}_1)$. Then with $\rho^{(1)}_i = \mathrm{wt}_{j_1}(\hat{s}_i, \check{r}_i)$ for $i \in \{1, \dots, n\}$ and some constant $\rho^{(1)}_0$ we have for all $v_1 > N^{(1)}_{\mathbf{v}'}$ that $[\![\mathcal{B}]\!](t_\mathbf{v}) = \rho^{(1)}_0 + v_1\rho^{(1)}_1 + \ldots + v_n\rho^{(1)}_n$. By varying $\mathbf{v}$, we see that from $[\![\mathcal{A}']\!](t_\mathbf{v}) = [\![\mathcal{B}]\!](t_\mathbf{v})$ it follows that $\rho_i = \rho^{(1)}_i$ for all $i \in \{1, \dots, n\}$. We can do the same for the other circuits $(\hat{s}_2, \check{r}_2), \dots, (\hat{s}_n, \check{r}_n)$ and see that if $j_i \in \mathrm{Vict}(\hat{s}_i, \check{r}_i)$ for every $i \in \{1, \dots, n\}$ then $\mathrm{wt}_{j_1}(\hat{s}_i, \check{r}_i) = \ldots = \mathrm{wt}_{j_n}(\hat{s}_i, \check{r}_i)$ for every $i \in \{1, \dots, n\}$. In particular, $j_1 \in \mathrm{Vict}(\hat{s}_i, \check{r}_i)$ for all $i \in \{1, \dots, n\}$. This means $j_1 \in \mathrm{Vict}(r(\mathrm{pos}(t)))$ and $\mathcal{B}$ satisfies (**P**). ◀

5 The Sequentiality Problem

The sequentiality problem asks whether for a given max-plus-WTA $\mathcal{A}$ there exists a deterministic max-plus-WTA $\mathcal{A}'$ such that $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$. The term "sequentiality" stems from the fact that in the weighted setting, deterministic automata are also often called *sequential*. In this section, we show that the sequentiality problem is decidable for finitely ambiguous max-plus-WTA. For words, this is known due to [11].

Let $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ be a max-plus-WTA. We say that $\mathcal{A}$ satisfies the *twins property* [14, 3] if the following holds. Whenever for $q, q' \in Q$ there exist $t \in T_\Gamma$, $r, r' \in \mathrm{Run}_\mathcal{A}(t)$ with $r(\varepsilon) = q$, $r'(\varepsilon) = q'$ and $\mathcal{A}$-circuits $(s, r_1), (s, r_2)$ with $r_1(\varepsilon) = q$ and $r_2(\varepsilon) = q'$ then $\mathrm{wt}^\diamond_\mathcal{A}(s, r_1) = \mathrm{wt}^\diamond_\mathcal{A}(s, r_2)$.

▶ **Lemma 17.** *Let $\mathcal{A}$ be a trim unambiguous max-plus-WTA. There exists a deterministic max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$ if and only if $\mathcal{A}$ satisfies the twins property. If it exists, it can be effectively constructed.*

Proof (sketch). If $\mathcal{A}$ satisfies the twins property, we know due to [3, Lemma 5.10] that a deterministic max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}']\!] = [\![\mathcal{A}]\!]$ can be effectively constructed.

To show that the twins property is also a necessary condition, we can apply an idea similar to the proof of [14, Theorem 9]. ◀

▶ **Lemma 18** ([3, Theorem 5.17])**.** *For an unambiguous max-plus-WTA $\mathcal{A}$ it is decidable whether $\mathcal{A}$ satisfies the twins property.*

▶ **Theorem 19.** *For a finitely ambiguous max-plus-WTA $\mathcal{A}$ it is decidable whether there exists a deterministic max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$. If $\mathcal{A}'$ exists, it can be effectively constructed.*

Proof. Let $\mathcal{A}$ be a finitely ambiguous max-plus-WTA. Due to Theorem 10 we can decide whether there exists an equivalent unambiguous max-plus-WTA. If this is not the case, $\mathcal{A}$ can also not be determinizable. Otherwise we can effectively construct an unambiguous max-plus-WTA $\mathcal{A}'$ with $[\![\mathcal{A}]\!] = [\![\mathcal{A}']\!]$. Due to Lemma 18 we can decide whether $\mathcal{A}'$ satisfies the twins property, which according to Lemma 17 is equivalent to deciding whether $\mathcal{A}$ is determinizable. ◀

Abstract

The Minimum Circuit Size Problem (MCSP) and a related problem (MKTP) that deals with time-bounded Kolmogorov complexity are prominent candidates for NP-intermediate status. We show that, under very modest cryptographic assumptions (such as the existence of one-way functions), the problem of approximating the minimum circuit size (or time-bounded Kolmogorov complexity) within a factor of $n^{1-o(1)}$ is *indeed* NP-intermediate. To the best of our knowledge, these problems are the first natural NP-intermediate problems under the existence of an arbitrary one-way function.

We also prove that MKTP is hard for the complexity class DET under non-uniform NC^0 reductions. This is surprising, since prior work on MCSP and MKTP had highlighted weaknesses of "local" reductions such as $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$. We exploit this local reduction to obtain several new consequences:

- MKTP is not in $\mathsf{AC}^0[p]$.
- Circuit size lower bounds are equivalent to hardness of a relativized version MKTP^A of MKTP under a class of uniform AC^0 reductions, for a large class of sets A.
- Hardness of MCSP^A implies hardness of MKTP^A for a wide class of sets A. This is the first result directly relating the complexity of MCSP^A and MKTP^A, for any A.

1 Introduction

The Minimum Circuit Size Problem (MCSP) has attracted intense study over the years, because of its close connection with the natural proofs framework of Razborov and Rudich [23], and because it is a prominent candidate for NP-intermediate status. It has been known since [18] that NP-intermediate problems exist, if $\mathsf{P} \neq \mathsf{NP}$, but "natural" candidates for this status are rare. Problems such as factoring and Graph Isomorphism are sometimes put forward as candidates, but there are not strong complexity-theoretic arguments for why these problems should not lie in P. We prove that a very weak cryptographic assumption implies that a $n^{1-o(1)}$ approximation for MCSP is NP-intermediate.

* Supported by NSF grant CCF-1555409 (Allender) and JSPS KAKENHI Grant Numbers JP16J06743 (Hirahara). Proofs of some results have been omitted due to space limits; more details can be found at [6].

MCSP is hard for SZK [4] under BPP reductions, but the situation is quite different, when more restricted notions of reducibility are considered. Recent results [14, 19, 7] have suggested that MCSP might not even be hard for P under logspace reductions (although the evidence is still inconclusive).

The input to MCSP consists of a pair (T, s), where T is a bit string of length 2^m representing the truth-table of an m-variate Boolean function, and $s \in \mathbb{N}$; $(T, s) \in$ MCSP if there is a circuit computing T having size at most s. Note that, for different models of circuit (type of gates, allowable fan-in, etc.) and different measures of size (number of gates, number of wires, size of the description of the circuit, etc.) the resulting MCSP problems might have different complexity. No efficient reduction is known between different variants of the problem. However, all prior work on MCSP (such as [16, 3, 9, 19, 4, 25, 7, 14]) applies equally well to any of these variants. MCSP is also closely related to a type of time-bounded Kolmogorov complexity known as KT, which was defined in [3]. The problem of determining KT complexity, formalized as the language MKTP $= \{(x, s) : \mathrm{KT}(x) \leq s\}$ has often been viewed as just another equivalent "encoding" of MCSP in this prior work. (In particular, our results mentioned in the paragraphs above apply also to MKTP.) Recently, however, some reductions were presented that are not currently known to apply to MCSP [5].

In this section, we outline the ways in which this paper advances our understanding of MCSP and related problems, while reviewing some of the relevant prior work.

Hardness is equivalent to circuit size lower bounds. Significant effort (e.g. [16, 19, 7, 14])) has been made in order to explain why it is so difficult to show NP-hardness of MCSP or MKTP. Most of the results along this line showed implications from hardness of MCSP to circuit size lower bounds: If MCSP or MKTP is NP-hard under some restricted types of reductions, then a circuit size lower bound (which is quite difficult to obtain via current techniques of complexity theory) follows. For example, if MCSP or MKTP is hard for TC^0 under Dlogtime-uniform $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reductions, then NP $\not\subseteq$ P/poly and DSPACE$(n) \not\subseteq$ io-SIZE$(2^{\epsilon n})$ [19, 7].

Murray and Williams [19] asked if, in general, circuit lower bounds imply hardness of the circuit minimization problems. We answer their questions affirmatively in certain settings: A stronger lower bound DSPACE$(n) \not\subseteq$ io-SIZE$^{\mathsf{MKTP}}(2^{\epsilon n})$ implies that MKTP is hard for DET under logspace-uniform $\leq_{\mathrm{tt}}^{\mathsf{AC}^0}$ reductions (Theorem 11).

At this point, it is natural to ask if the circuit lower bounds are in fact *equivalent* to hardness of MKTP. We indeed show that this is the case, when we consider the minimum *oracle* circuit size problem. For an oracle A, MCSP^A is the set of pairs (T, s) such that T is computed by a size-s circuit that has "oracle gates" for A in addition to standard AND and OR gates. The related MKTP^A problem asks about the time-bounded Kolmogorov complexity of a string, when the universal Turing machine has access to the oracle A. For many oracles A that are hard for PH, we show that DSPACE$(n) \not\subseteq$ io-SIZE$^A(2^{\epsilon n})$ for some $\epsilon > 0$ *if and only if* MKTP^A is hard for DET under a certain class of reducibilities (Theorem 12).

That is, it is impossible to prove hardness of MKTP^A (under some reducibilities) without proving circuit lower bounds, and vice versa. Our results clearly connect the fact that it is difficult to obtain hardness of MKTP^A with the fact that circuit size lower bounds are difficult.

Hardness under local reductions, and unconditional lower bounds. Murray and Williams [19] showed that MCSP and MKTP are not hard for TC^0 under so-called *local* reductions computable in time less than $\sqrt{n}$ – and thus in particular they are not hard under NC^0

reductions that are very uniform (i.e., there is no routine computable in time $t(n) < n^{.5-\epsilon}$ that, on input (n, i) outputs the $O(1)$ queries upon which the i-th output bit of such an NC^0 circuit depends). Murray and Williams speculated that this might be a promising first step toward showing that MCSP is not hard for NP under Dlogtime-uniform AC^0 reductions, since it follows from [1] that any set that is hard for TC^0 under P-uniform AC^0 reductions is also hard for TC^0 under P-uniform NC^0 reductions. Indeed, the results of Murray and Williams led us to expect that MCSP and MKTP are not even hard for PARITY under non-uniform NC^0 reductions.

Contrary to these expectations, we show that MKTP is hard not only for TC^0 but even for the complexity class DET under non-uniform NC^0 reductions (Theorem 9). Consequently, MKTP is not in $\mathsf{AC}^0[p]$ for any prime p.[1] Note that it is still not known whether MCSP or $R_{\mathrm{KT}} = \{x : \mathrm{KT}(x) \geq |x|\}$ is in $\mathsf{AC}^0[p]$. It is known[2] [3] that neither of these problems is in AC^0. Under a plausible derandomization hypothesis, this non-uniform reduction can be converted into a logspace-uniform $\leq_{\mathrm{tt}}^{\mathsf{AC}^0}$ reduction that is an AND of NC^0-computable queries. Thus "local" reductions are more effective for reductions to MKTP than may have been suspected.

Implications among hardness conditions for MKTP and MCSP. No $\leq_{\mathrm{T}}^{\mathsf{P}}$ reductions are known between MKTP^A or MCSP^A for any A. Although most previous complexity results for one of the problems have applied immediately to the other, via essentially the same proof, there has not been any proven relationship among the problems. For the first time, we show that, for many oracles A, hardness for MCSP^A implies hardness for MKTP^A (Theorem 12).

A reduction that is not "oracle independent". Hirahara and Watanabe [14] observed that all of the then-known reductions to MCSP and MKTP were "oracle-independent", in the sense that, for any class $\mathcal{C}$ and reducibility $\leq_r$, all proofs that MCSP (or MKTP) is hard for $\mathcal{C}$ under $\leq_r$ also show that MCSP^A (MKTP^A) is also hard for $\mathcal{C}$. They showed that oracle-independent $\leq_{\mathrm{T}}^{\mathsf{P}}$-reductions cannot show hardness for any class larger than P.

This motivates the search for reductions that are *not* oracle-independent. We give a concrete example of a logspace-uniform $\leq_{\mathrm{ctt}}^{\mathsf{AC}^0}$ reduction that (under a plausible complexity assumption) reduces DET to MKTP. This is *not* an oracle independent reduction, since $\mathsf{MKTP}^{\mathsf{QBF}}$ is not hard for DET under this same class of reductions (Corollary 13).

A clearer picture of how hardness "evolves". It is instructive to contrast the evolution of the class of problems reducible to MKTP^A under different types of reductions, as A varies from very easy ($A = \emptyset$) to complex ($A = \mathsf{QBF}$). For this thought experiment, we assume the very plausible hypothesis that $\mathsf{DSPACE}(n) \not\subseteq \mathsf{io\text{-}SIZE}(2^{\epsilon n})$. Restrictions of QBF give a useful parameterization for the complexity of A. Consider A varying from being complete for each level of PH (that is, quantified Boolean formulas with $O(1)$ alternations between $\forall$ and $\exists$ quantifiers), to instances of QBF with $\log^* n$ alternations, then to $O(\log n)$ alternations etc.,

[1] Subsequent to our work, a stronger average-case lower bound against $\mathsf{AC}^0[p]$ was proved [13]. The techniques of [13] do not show how to reduce DET, or even smaller classes such as TC^0, to MKTP. Thus our work is incomparable to [13].

[2] Somewhat remarkably, Oliveira and Santhanam [20] have independently shown that MCSP and MKTP are hard for DET under non-uniform $\leq_{\mathrm{tt}}^{\mathsf{TC}^0}$ reductions. Their proof relies on self-reducibility properties of the determinant, whereas our proof relies on the fact that Graph Isomorphism is hard for DET [27]. Their results have the advantage that they apply to MCSP rather than merely to MKTP, but because it is not known whether $\mathsf{TC}^0 = \mathsf{P}$ they do not obtain unconditional lower bounds, as in Corollary 10.

through to $2^{\sqrt{\log n}}$ alternations, and until finally $A = \mathsf{QBF}$. Since $\mathsf{DSPACE}(n) \subseteq \mathsf{P}^A/\mathsf{poly}$, at some point in this evolution we have $\mathsf{DSPACE}(n) \subseteq \mathsf{io\text{-}SIZE}^A(2^{\epsilon n})$; it is plausible to assume that this doesn't happen until A has at least $\log n$ quantifier alternations, or more.

At all stages in this evolution $\mathsf{SZK} \subseteq \mathsf{BPP}^{\mathsf{MKTP}^A}$ [4], until at some point $\mathsf{BPP}^{\mathsf{MKTP}^A}$ expands to coincide with PSPACE [3]. Also, at all stages in this evolution $\mathsf{DET} \leq_{\mathrm{m}}^{\mathsf{NC}^0}$-reduces to MKTP^A (and even when $A = \mathsf{QBF}$ we do not know, for instance, if $\mathsf{NC}^3 \leq_{\mathrm{m}}^{\mathsf{NC}^0}$-reduces to MKTP^A). Thus these reductions behave "monotonically", in the sense that as the complexity of A increases, the class of problems reducible to MKTP^A does not shrink noticeably, and sometimes appears to grow markedly.

The situation is much more intriguing when we consider the *uniform* class of $\leq_{\mathrm{T}}^{\mathsf{AC}^0}$ reductions that arise from derandomizing the nonuniform $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reductions from DET. At the start, when $A = \emptyset$, we have DET reducing to MKTP^A, and this is maintained until A becomes complex enough so that $\mathsf{DSPACE}(n) \subseteq \mathsf{io\text{-}SIZE}^A(2^{\epsilon n})$. At this point, not only does DET not reduce to MKTP^A, but neither does PARITY! (See Theorem 12.)

This helps place the results of [7] in the proper context. In [7] strong evidence was presented against $\mathsf{MCSP}^{\mathsf{QBF}}$ being hard for, say, P under $\leq_{\mathrm{m}}^{\mathsf{L}}$ reductions, and this was taken as indirect evidence that MCSP itself should not be hard for P, since $\mathsf{MCSP} \in \mathsf{NP}$ and thus is much "easier" than the PSPACE-complete problem $\mathsf{MCSP}^{\mathsf{QBF}}$. However, we expect that MCSP^A and MKTP^A should behave somewhat similarly to each other, and it *can* happen that a class can reduce to MKTP (Theorem 11) and *not* reduce to MKTP^A for a more powerful oracle A (Corollary 13).

Hardness of the Gap problem. Our new hardness results for MKTP^A share with earlier reductions the property that they hold even for "Gap" versions of the problem. That is, for some $\epsilon > 0$, the reduction works correctly for any solution to the promise problem with "yes" instances $\{(x, s) : \mathrm{KT}^A(x) \leq s\}$ and "no" instances $\{(x, s) : \mathrm{KT}^A(x) > s + |x|^\epsilon\}$. However, we do not know if they carry over to instances with a wider "gap" between the Yes and No instances; earlier hardness results such as those of [3, 9, 4, 25] hold for a much wider gap (such as with the Yes instances having $\mathrm{KT}(x) < |x|^\epsilon$, and the no instances with $\mathrm{KT}(x) \geq |x|$), and this is one reason why they applied both to MKTP and to MCSP. Thus there is interest in whether it is possible to reduce MCSP with small "gap" to MCSP with large "gap". If this were possible, then MCSP and MKTP would be interreducible in some sense.

Earlier work [7] had presented unconditional results, showing that "gap" versions of MCSP could not be hard for TC^0 under $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reductions, unless those reductions had large "stretch" (mapping short inputs to long outputs). In [6], we show that BPP-Turing reductions among gap MCSP problems require large stretch, unless $\mathsf{MCSP} \in \mathsf{BPP}$.

Natural NP-intermediate Problems. In Section 3 we also consider gap MCSP problems where the "gap" is quite large (i.e., problems of approximating the minimum circuit size for a truth table of size n within a factor of $n^{1-o(1)}$). Problems of this sort are of interest, because of the role they play in the natural proofs framework of [23], if one is trying to prove circuit lower bounds of size $2^{o(n)}$. Our Theorem 6 shows that these problems are NP-intermediate in the sense that these do not lie in P/poly and are not NP-hard under P/poly reductions, under modest cryptographic assumptions (weaker than assuming that factoring or discrete log requires superpolynomial-size circuits, or assuming the existence of a one-way function). To the best of our knowledge, these problems are the first natural NP-intermediate problems under the existence of an arbitrary one-way function.

Our new insight on MCSP here is that, if the gap problems are NP-hard, then MCSP is

"strongly downward self-reducible": that is, any instance of MCSP of size n can be reduced to instances of size n^ϵ. In the past, many natural problems have been shown to be strongly downward self-reducible (see [8]); Our contribution is to show that MCSP also has such a property (under the assumption that the gap MCSP problems are NP-hard).

2 Preliminaries

We assume the reader is familiar with standard DTIME and DSPACE classes. We also occasionally refer to classes defined by time-bounded *alternating* Turing machines: $\mathsf{ATIME}(t(n))$, or by simultaneously bounding time and the number of alternations between existential and universal configurations: $\mathsf{ATIME\text{-}ALT}(t(n), a(n))$.

We refer the reader to the text by Vollmer [29] for background and more complete definitions of the standard circuit complexity complexity classes

$$\mathsf{NC}^0 \subsetneq \mathsf{AC}^0 \subsetneq \mathsf{AC}^0[p] \subsetneq \mathsf{TC}^0 \subseteq \mathsf{NC}^1 \subseteq \mathsf{P/poly},$$

as well as the standard complexity classes $\mathsf{L} \subseteq \mathsf{P} \subseteq \mathsf{NP} \subseteq \mathsf{PH} \subseteq \mathsf{PSPACE}$. Between L and P in this list, there is one more class that plays an important role for us: DET is the class of problems that are reducible to the problem of computing the determinant of integer matrices, by NC^1-Turing reductions.

This brings us to the topic of reducibility. Let $\mathcal{C}$ be either a class of functions or a class of circuits. We say that $A \leq_{\mathrm{m}}^{\mathcal{C}} B$ if there is a function $f \in \mathcal{C}$ (or f computed by a circuit family in $\mathcal{C}$, respectively) such that $x \in A$ iff $f(x) \in B$. We will make use of $\leq_{\mathrm{m}}^{\mathsf{L}}, \leq_{\mathrm{m}}^{\mathsf{TC}^0}, \leq_{\mathrm{m}}^{\mathsf{AC}^0}$ and $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reducibility. The more powerful notion of Turing reducibility also plays an important role in this work. Here, $\mathcal{C}$ is a complexity class that admits a characterization in terms of Turing machines or circuits, which can be augmented with an "oracle" mechanism, either by providing a "query tape" or "oracle gates". We say that $A \leq_{\mathrm{T}}^{\mathcal{C}} B$ if there is a oracle machine in $\mathcal{C}$ (or a family of oracle circuits in $\mathcal{C}$) accepting A, when given oracle B. We make use of $\leq_{\mathrm{T}}^{\mathsf{P/poly}}, \leq_{\mathrm{T}}^{\mathsf{BPP}}, \leq_{\mathrm{T}}^{\mathsf{P}}, \leq_{\mathrm{T}}^{\mathsf{L}}$ and $\leq_{\mathrm{T}}^{\mathsf{AC}^0}$ reducibility; instead of writing $A \leq_{\mathrm{T}}^{\mathsf{P/poly}} B$ or $A \leq_{\mathrm{T}}^{\mathsf{BPP}} B$, we will more frequently write $A \in \mathsf{P}^B/\mathsf{poly}$ or $A \in \mathsf{BPP}^B$. Turing reductions that are "nonadaptive" – in the sense that the list of queries that are posed on input x does not depend on the answers provided by the oracle – are called *truth-table reductions*. We make use of $\leq_{\mathrm{tt}}^{\mathsf{AC}^0}$ and $\leq_{\mathrm{tt}}^{\mathsf{TC}^0}$ reducibility.

Kabanets and Cai [16] sparked renewed interest in MCSP and highlighted connections between MCSP and more recent progress in derandomization. They introduced a class of reductions to MCSP, which they called *natural reductions*. Recall that instances of MCSP are of the form (T, s) where s is a "size parameter". A $\leq_{\mathrm{m}}^{\mathsf{P}}$ reduction f is called *natural* if $f(x)$ is of the form $f(x) = (f_1(x), f_2(|x|))$. That is, the "size parameter" is the same, for all inputs x of the same length.

Whenever circuit families are discussed (either when defining complexity classes, or reducibilities), one needs to deal with the issue of *uniformity*. For example, the class AC^0 (corresponding to families $\{C_n : n \in \mathbb{N}\}$ of unbounded fan-in AND, OR, and NOT gates having size $n^{O(1)}$ and depth $O(1)$) comes in various flavors, depending on the complexity of computing the mapping $1^n \mapsto C_n$. When this is computable in polynomial time (or logarithmic space), then one obtains P-uniform AC^0 (logspace-uniform AC^0, respectively). If no restriction at all is imposed, then one obtains non-uniform AC^0. As discussed in [29], the more restrictive notion of Dlogtime-uniform AC^0 is frequently considered to be the "right" notion of uniformity to use when discussing small complexity classes such as $\mathsf{AC}^0, \mathsf{AC}^0[p]$ and TC^0. If these classes are mentioned with no explicit mention of uniformity,

then Dlogtime-uniformity is intended. For uniform NC^1 the situation is somewhat more complicated, as discussed in [29]; there is wide agreement that the "correct" definition coincides with $\mathsf{ATIME}(O(\log n))$.

There are many ways to define time-bounded Kolmogorov complexity. The definition $\mathrm{KT}(x)$ was proposed in [3], and has the advantage that it is polynomially-related to circuit size (when a string x is viewed as the truth-table of a function). $\mathrm{KT}(x)$ is the minimum, over all d and t, of $|d| + t$, such that the universal Turing machine U, on input (d, i, b) can determine in time t if the i-th bit of x is b. (More formal definitions can be found in [3].)

A *promise problem* consists of a pair of disjoint subsets (Y, N). A language A is a *solution* to the promise problem (Y, N) if $Y \subseteq A \subseteq \overline{N}$. A language B reduces to a promise problem via a type of reducibility $\leq_r$ if $B \leq_r A$ for *every* set A that is a solution to the promise problem.

3 GapMCSP

In this section, we consider the "gap" versions of MCSP and MKTP. We focus primarily on MCSP, and for simplicity of exposition we consider the "size" of a circuit to be the number of AND and OR gates of fan-in two. (NOT gates are "free"). The arguments can be adjusted to consider other circuit models and other reasonable measures of "size" as well. Given a truth-table T, let $\mathrm{CC}(T)$ be the size of the smallest circuit computing T, using this notion of "size".

▶ **Definition 1.** For any function $\epsilon\colon \mathbb{N} \to (0,1)$, let $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ be the approximation problem that, given a truth-table T, asks for outputting a value $f(T) \in \mathbb{N}$ such that

$$\mathrm{CC}(T) \leq f(T) \leq |T|^{1-\epsilon(|T|)} \cdot \mathrm{CC}(T).$$

Note that this approximation problem can be formulated as the following promise problem. (See also [11] for similar comments.)

▶ **Fact 2.** $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ *is polynomial-time Turing equivalent to the following promise problem* (Y, N)*:*

$$Y := \{\, (T,s) \mid \mathrm{CC}(T) < s/|T|^{1-\epsilon(|T|)} \,\},$$
$$N := \{\, (T,s) \mid \mathrm{CC}(T) > s+1 \,\},$$

where T *is a truth-table and* $s \in \mathbb{N}$*.*

Note that $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ becomes easier when ϵ becomes smaller. If $\epsilon(n) = o(1)$, then (using the promise problem formulation) it is easy to see that $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ has a solution in $\mathsf{DTIME}(2^{n^{o(1)}})$, since the Yes instances have witnesses of length $|T|^{o(1)}$. However, it is worth emphasizing that, even when $\epsilon(n) = o(1)$, $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ is a canonical example of a combinatorial property that is useful in proving circuit size lower bounds of size $2^{o(n)}$, in the sense of [23]. Thus it is of interest that MCSP cannot reduce to $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ in this regime under very general notions of reducibility, unless MCSP itself is easy.

▶ **Theorem 3.** *For any polynomial-time-computable nonincreasing* $\epsilon(n) = o(1)$*, if* $\mathsf{MCSP} \in \mathsf{BPP}^{\mathrm{Gap}_\epsilon\mathrm{MCSP}}$ *then* $\mathsf{MCSP} \in \mathsf{BPP}$*.*

A new idea is that $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ is "strongly downward self-reducible." We will show that any $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ instance of length n is reducible to $n^{1-\epsilon}$ MCSP instances of length n^ϵ. To this end, we will exploit the following simple fact.

▶ **Lemma 4.** *For a function $f\colon \{0,1\}^n \to \{0,1\}$, a string $x \in \{0,1\}^k$ and $k \in \mathbb{N}$, let $f_x\colon \{0,1\}^{n-k} \to \{0,1\}$ be a function defined as $f_x(y) := f(x,y)$. Then, the following holds:*

$$\max_{x\in\{0,1\}^k} \mathrm{CC}(f_x) \leq \mathrm{CC}(f) \leq 2^k \cdot \left(\max_{x\in\{0,1\}^k} \mathrm{CC}(f_x) + 3 \right),$$

(In other words, $\max_{x\in\{0,1\}^k} \mathrm{CC}(f_x)$ gives an approximation of $\mathrm{CC}(f)$ within a factor of 2^k.)

Proof of Theorem 3. Let M be an oracle BPP Turing machine which reduces MCSP to Gap_ϵMCSP. Let $|T|^c$ be an upper bound for the running time of M, given a truth-table T, and let $|T| = 2^n$.

We recursively compute the circuit complexity of T by the following procedure: Run M on input T. If M makes a query S to the Gap_ϵMCSP oracle, then divide S into consecutive substrings $S_1, \cdots, S_{2^k}$ of length $|S| \cdot 2^{-k}$ such that $S_1 \cdot S_2 \cdots S_{2^k} = S$ (where k is a parameter, chosen later, that depends on $|S|$), and compute the circuit complexity of each S_i recursively for each $i \in [2^k]$. Then continue the simulation of M, using the value $2^k \cdot \left(\max_{i\in[2^k]} \mathrm{CC}(S_i) + 3\right)$ as an approximation to $\mathrm{CC}(S)$.

We claim that the procedure above gives the correct answer. For simplicity, let us first assume that the machine M has zero error probability. It suffices to claim that the simulation of M is correct in the sense that every query of M is answered with a value that satisfies the approximation criteria of Gap_ϵMCSP. Suppose that M makes a query S. By the assumption on the running time of M, we have $|S| \leq |T|^c = 2^{nc}$. By Lemma 4, we have

$$\mathrm{CC}(S) \leq 2^k \cdot \left(\max_{i\in[2^k]} \mathrm{CC}(S_i) + 3 \right) \leq 2^k \cdot (\mathrm{CC}(S) + 3).$$

In particular, the estimated value satisfies the promise of Gap_ϵMCSP if $2^k \cdot (\mathrm{CC}(S) + 3) \leq |S|^{1-\epsilon(|S|)} \cdot \mathrm{CC}(S)$. Since we may assume without loss of generality that $\mathrm{CC}(S) \geq 3$, it suffices to make sure that $2^{k+1} \cdot \mathrm{CC}(S) \leq |S|^{1-\epsilon(|S|)} \cdot \mathrm{CC}(S)$. Let $|S| = 2^m$. Then, in order to satisfy $k + 1 \leq (1 - \epsilon(|S|)) \cdot m$, let us define $k := (1 - \epsilon(|S|)) \cdot m - 1$. For this particular choice of k, the estimated value $2^k \cdot \left(\max_{i\in[2^k]} \mathrm{CC}(S_i) + 3\right)$ of the circuit complexity of S satisfies the promise of Gap_ϵMCSP, which implies that the reduction M computes the correct answer for MCSP.

Now we analyze the time complexity of the algorithm. Each recursive step makes at most 2^{2cn} many recursive calls, because there are potentially 2^{cn} many queries S of M, each of which may produce at most $2^k \leq 2^{cn}$ recursive calls. The length of each truth-table S_i that arises in one of the recursive calls is $|S_i| = |S| \cdot 2^{-k} = 2^{m-k} = 2^{\epsilon(|S|)\cdot m+1}$. We claim that $|S_i| \leq 2^{1+(n/2)}$ holds for sufficiently large n. Let us take n to be large enough so that $\epsilon(2^{n/2}) \leq 1/2c$. If $m \geq n/2$, then $|S_i| \leq 2^{\epsilon(2^m)\cdot m+1} \leq 2^{\epsilon(2^{n/2})\cdot cn+1} \leq 2^{1+(n/2)}$. Otherwise, since $m \leq n/2$ and $\epsilon(|S|) < 1$, we obtain $|S_i| \leq 2^{\epsilon(|S|)\cdot m+1} \leq 2^{1+(n/2)}$. Therefore, on inputs of length 2^n, each recursive call produces instances of length at most $2^{1+(n/2)}$. The overall time complexity can be estimated as $2^{c'n} \cdot 2^{c'n/2} \cdot 2^{c'n/4} \cdots = 2^{2c'n}$ for some constant c' (say, $c' = 3c$), which is a polynomial in the input length 2^n.

We note that the analysis above works even for *randomized* reductions that may err with exponentially small probability. Since we have proved that the algorithm runs in polynomial time, the probability that the algorithm makes an error is at most a polynomial times an exponentially small probability, which is still exponentially small probability (by the union bound). ◀

▶ Remark. If we drop the assumption that $\epsilon(n)$ be computable, then the proof of Theorem 3 still shows that if $\mathsf{MCSP} \in \mathsf{P}^{\mathrm{Gap}_\epsilon\mathrm{MCSP}}/\mathsf{poly}$ then $\mathsf{MCSP} \in \mathsf{P}/\mathsf{poly}$.

▶ **Corollary 5.** *Let* $\epsilon(n) = o(1)$. *If* $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ *has no solution in* $\mathsf{P/poly}$ *then* $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ *is not hard for* NP *(or even for* MCSP*) under* $\leq_{\mathrm{T}}^{\mathsf{P/poly}}$ *reductions, and is thus* NP*-intermediate.*

Proof. This is immediate from the preceding remark. If $\mathsf{MCSP} \in \mathsf{P}^{\mathrm{Gap}_\epsilon\mathsf{MCSP}}/\mathsf{poly}$ then $\mathsf{MCSP} \in \mathsf{P/poly}$, which in turn implies that $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ has a solution in $\mathsf{P/poly}$. ◀

In what follows, we show that the assumption of Corollary 5 is true under very modest cryptographic assumptions. It is known that, for any constant $\epsilon > 0$, $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ is SZK-hard under $\leq_{\mathrm{T}}^{\mathsf{P/poly}}$ reductions [4]. Here, we show that if SZK is not in $\mathsf{P/poly}$, then for some $\epsilon(n) = o(1)$, $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ has no solution in $\mathsf{P/poly}$. In fact, we can prove something *stronger*: If auxiliary-input one-way functions exist, then $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ is not in $\mathsf{P/poly}$. We now describe auxiliary-input one-way functions.

Usually, the existence of cryptographically-secure one-way functions is considered to be essential for meaningful cryptography. That is, one requires a function f computed in polynomial time such that, for any algorithm A computed by polynomial-sized circuits, $\Pr_x[f(A(f(x))) = f(x)] = 1/n^{\omega(1)}$ where x is chosen uniformly at random from $\{0,1\}^n$. A weaker notion that has been studied in connection with SZK goes by the name *auxiliary-input one-way functions*. This is an indexed family of functions $f_y(x) = F(y,x)$, where $|x| = p(|y|)$ for some polynomial p, and F is computable in time polynomial in $|y|$, such that for some infinite set I, for any algorithm[3] A computed by polynomial-sized circuits, for all $y \in I$, $\Pr_x[f_y(A(f_y(x))) = f_y(x)] = 1/n^{\omega(1)}$ where $n = |y|$ and x is chosen uniformly at random from $\{0,1\}^{p(n)}$. It is known that there are promise problems in SZK that have no solution in $\mathsf{P/poly}$ only if auxiliary-input one-way functions exist. (This is due to [22]; a good exposition can be found in [28, Theorems 7.1 & 7.5], based on earlier work of [21].)

▶ **Theorem 6.** *If auxiliary-input one-way functions exist, then there is a function* $\epsilon(n) = o(1)$ *such that* $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ *is* NP*-intermediate. (Namely,* $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ *has no solution in* $\mathsf{P/poly}$ *and* $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ *is not* NP*-hard under* $\leq_{\mathrm{T}}^{\mathsf{P/poly}}$ *reductions.)*

▶ Remark. In particular, either one of the following implies that some $\mathrm{Gap}_\epsilon\mathsf{MCSP}$ is NP-intermediate, since each implies the existence of auxiliary-input one-way functions:

1. the existence of cryptographically-secure one-way functions.
2. SZK is not in $\mathsf{P/poly}$.

4 Hardness for DET

In this section, we give some of our main contributions. We show that MKTP is hard for DET under $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reductions (Theorem 9); prior to this, no variant of MCSP was known to be hard for any complexity class under any type of many-one reducibility. The $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reduction that we present is nonuniform; we show that hardness under *uniform* reductions is related to lower bounds in circuit complexity, and in some cases we show that circuit lower bounds are *equivalent* to hardness results under uniform notions of reducibility (Theorem 12). These techniques yield the first results relating the complexity of MCSP^A and MKTP^A problems.

Here is the outline of this section. We will build on a randomized reduction of Allender, Grochow and Moore [5]: They showed that there is a ZPP reduction from the rigid[4] graph

[3] We have chosen to define one-way functions in terms of security against non-uniform adversaries. It is also common to use the weaker notion of security against probabilistic polynomial-time adversaries, as in [28].

[4] A graph is *rigid* if it has no nontrivial automorphisms.

isomorphism problem to MKTP. Here we show that the reduction is in fact an AC^0 reduction (Corollary 8). Combining Torán's AC^0 reduction [27] from DET to the rigid graph isomorphism as well as the Gap theorem [2], we will show $\mathsf{DET} \leq_{\mathrm{m}}^{\mathsf{NC}^0} \mathsf{MKTP}$ (Theorem 9).

To show that circuit size lower bounds are equivalent to hardness under uniform AC^0 reductions, we will derandomize the reduction of [5] (Theorem 11). To this end, we give an AC^0 reduction f from the rigid graph isomorphism problem to MKTP and an "encoder" e that encodes random binary strings into a random permutation in Lemma 7 below.

▶ **Lemma 7.** *Let A be any oracle. There is a function f computable in Dlogtime-uniform AC^0 and a function e computable in Dlogtime-uniform TC^0 such that, for any two rigid graphs G, H with n vertices:*

- $\Pr_r[f(G, H, e(r)) \notin \mathsf{MKTP}^A] > 1 - \frac{1}{2^{4n^2}}$ *if $G \not\equiv H$, and*
- $\Pr_r[f(G, H, e(r)) \in \mathsf{MKTP}^A] = 1$ *if $G \equiv H$.*

▶ **Corollary 8.** *Let A be any oracle. The rigid graph isomorphism problem is reducible to MKTP^A via a non-uniform $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reduction.*

Proof. A standard counting argument shows that there is a value of $e(r)$ that can be hardwired into the reduction of Lemma 7 that works correctly for all pairs (G, H) of n-vertex graphs. (Note that the input length is $2n^2$, and the error probability is at most $1/2^{4n^2}$.) ◀

▶ **Theorem 9.** *Let A be any oracle.* DET *is reducible to MKTP^A via a non-uniform $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reduction. Furthermore, this reduction is "natural" in the sense of [16].*

Proof. Since DET is closed under $\leq_{\mathrm{m}}^{\mathsf{TC}^0}$ reductions, it suffices to show that MKTP^A is hard under $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reductions, and then appeal to the "Gap" theorem of [2], to obtain hardness under $\leq_{\mathrm{m}}^{\mathsf{NC}^0}$ reducibility. Torán [27] shows that DET is AC^0-reducible to GI, and the proofs of Theorem 5.3 and Corollary 5.4 of [27] show that DET is AC^0-reducible to GI via a reduction that outputs only pairs of rigid graphs. Composing this reduction with the non-uniform AC^0 reduction given by Corollary 8 completes the argument. (Since DET is closed under complement, there is also a non-uniform $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reduction to the complement of MKTP^A.)

Since the same θ is used for all inputs of the same length, the reduction is "natural". ◀

The lower bounds of Razborov and Smolensky [24, 26] yield the following corollary:

▶ **Corollary 10.** *MKTP^A is not in $\mathsf{AC}^0[p]$ for any oracle A and any prime p.*

(An alternate proof of this circuit lower bound can be obtained by applying the pseudorandom generator of [10] that has sublinear stretch and is secure against $\mathsf{AC}^0[p]$. Neither argument seems easy to extend, to provide a lower bound for MCSP.)

One may wonder if the non-uniform reduction can be made uniform under a derandomization hypothesis. We do not know how to obtain a uniform $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reduction, but we can come close, if A is not too complex. Recall the definition of ctt-reductions: $B \leq_{\mathrm{ctt}}^{\mathcal{C}} C$ if there is a function $f \in \mathcal{C}$ with the property that $f(x)$ is a list $f(x) = (y_1, \ldots, y_m)$, and $x \in B$ if and only if $y_j \in C$ for all j. Furthermore, we say that f is a *natural* logspace-uniform $\leq_{\mathrm{ctt}}^{\mathsf{AC}^0}$-reduction to MKTP if each query y_j has the same length (and this length depends only on $|x|$), and also each y_j is of the form (z_j, θ) where the threshold θ depends only on $|x|$.

The following theorem can be viewed as a "partial converse" to results of [19, 7], which say that problems in $\mathsf{LTH} \subseteq \mathsf{E}$ require exponential size circuits if MCSP or MKTP is hard for TC^0 under Dlogtime-uniform $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ reductions. That is, the earlier results show that very uniform hardness results imply circuit lower bounds, whereas the next theorem shows that somewhat stronger circuit lower bounds imply uniform hardness results (for a less-restrictive

notion of uniformity, but hardness for a larger class). Later on, in Theorem 12, we present a related condition on reductions to MKTP^A that is *equivalent* to circuit lower bounds.

▶ **Theorem 11.** *Let A be any oracle. If there is some $\epsilon > 0$ such that $\mathsf{DSPACE}(n) \not\subseteq \mathsf{io\text{-}SIZE}^{\mathsf{MKTP}^A}(2^{\epsilon n})$, then every language in DET reduces to MKTP^A via a natural logspace-uniform $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$-reduction.*

Proof. Let $B \in \mathsf{DET}$. Thus there is an AC^0 reduction g reducing B to the Rigid Graph Isomorphism Problem [27]. Consider the following family of statistical tests $T_x(r)$, indexed by strings x:

> On input r:
> Compute $z = f(g(x), e(r))$, where $f(G, H, e(r))$ is the function from Lemma 7. Accept iff ($x \in B$ iff $z \in \mathsf{MKTP}^A$).

Since $B \in \mathsf{DET} \subseteq \mathsf{P}$, the test $T_x(r)$ has a polynomial-size circuit with one MKTP^A oracle gate. (In fact, the statistical test is an NC^2 circuit with one oracle gate.) If $x \in B$, then T_x accepts *every* string r, whereas if $x \notin B$, T_x accepts most strings r.

Klivans and van Melkebeek [17] (building on the work of Impagliazzo and Wigderson [15]) show that, if $\mathsf{DSPACE}(n)$ requires exponential-size circuits from a given class $\mathcal{C}$, then there is a hitting set generator computable in logspace that hits all large sets computable by circuits from $\mathcal{C}$ having size n^k. In particular, under the given assumption, there is a function h computable in logspace such that $h(0^n) = (r_1, r_2, \ldots, r_{n^c})$ with the property that, for all strings x of length n, there is an element of $h(0^n)$ that is accepted by T_x.

Now consider the logspace-uniform AC^0 oracle circuit family, where the circuit for inputs of length n has the strings $e(h(0^n)) = (e(r_1), e(r_2), \ldots, e(r_{n^c}))$ hardwired into it. The circuit computes the queries $f(g(x), e(r_i))$ for $1 \leq i \leq n^c$, and accepts if, for all i, $f(g(x), e(r_i)) \in \mathsf{MKTP}^A$. Note that if $x \notin B$, then one of the r_i is accepted by T_x, which means that $f(g(x), e(r_i)) \notin \mathsf{MKTP}^A$; if $x \in B$, then $f(g(x), e(r_i)) \in \mathsf{MKTP}^A$ for all i. This establishes that the reduction is correct. ◀

Theorem 11 deals with the oracle problem MKTP^A, but the most interesting case is the case where $A = \emptyset$. The hypothesis is false when $A = \mathsf{QBF}$, since the KT^A measure is essentially the same as the KS measure studied in [3], where it is shown that $\mathsf{PSPACE} = \mathsf{ZPP}^{R_{\mathrm{KS}}}$, and thus has polynomial-size $\mathsf{MKTP}^{\mathsf{QBF}}$-circuits. Strikingly, not only is the hypothesis false in this case – but the conclusion is false as well. (See Corollary 13.)

For certain oracles (and we discuss below how broad this class of oracles is), the existence of uniform reductions is *equivalent to* certain circuit lower bounds.

▶ **Theorem 12.** *Let $\mathsf{MKTP}^A \in \mathsf{P}^A/\mathsf{poly}$. Then the following are equivalent:*

- PARITY *reduces to* MKTP^A *via a natural logspace-uniform* $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$*-reduction.*
- *For some* $\epsilon > 0$, $\mathsf{DSPACE}(n) \not\subseteq \mathsf{io\text{-}SIZE}^A(2^{\epsilon n})$.
- *For some* $\epsilon > 0$, $\mathsf{DSPACE}(n) \not\subseteq \mathsf{io\text{-}SIZE}^{\mathsf{MKTP}^A}(2^{\epsilon n})$.
- DET *reduces to* MKTP^A *via a natural logspace-uniform* $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$*-reduction.*

Furthermore, if PARITY *reduces to* MCSP^A *via a natural logspace-uniform* $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$*-reduction, then all of the above hold.*

Proof. First, we show that the first condition implies the second.

Let $\{C_n : n \in \mathbb{N}\}$ be a logspace-uniform family of oracle circuits computing PARITY, consisting of AC^0 circuitry feeding into oracle gates, which in turn are connected to an AND gate as the output gate. Let the oracle gates in C_n be $g_1, g_2, \ldots, g_{n^c}$. On any input string x,

let the value fed into gate g_i on input x be $(q_i(x), \theta)$, and recall that, since the reduction is natural, the threshold θ depends only on n, and thus it is a constant in C_n.

Now, we appeal to [7, Claim 3.11], and conclude that each $\mathsf{MKTP}^{\mathsf{QBF}}$ oracle gate can be replaced by a DNF formula of size at most $n^{O(1)}2^{O(\theta^2 \log \theta)}$. Inserting these DNF formulae into C_n (in place of each oracle gate) results in a circuit of size $n^{O(1)}2^{O(\theta^2 \log \theta)}$ computing PARITY. Let the depth of this circuit be some constant d. It follows from [12] that $n^{O(1)}2^{O(\theta^2 \log \theta)} \geq 2^{\Omega(n^{1/(d-1)})}$, and hence that $\theta \geq n^{1/4d}$.

Note that all of the oracle gates g_i must output 1 on input $0^{n-1}1$, and one of the oracle gates g_{i_0} must output 0 on input 0^n. Thus we have $\mathrm{KT}^A(q_{i_0}(0^n)) \geq \theta \geq n^{1/4d}$. It follows from [3, Theorem 11] that the function with truth-table $q_{i_0}(0^n)$ has no circuit (with oracle gates for A) of size less than $(\mathrm{KT}^A(q_{i_0}(0^n)))^{1/3} \geq \theta^{1/3} \geq n^{1/12d}$.

Note that, in order to compute the j-th bit of some query $q_i(0^n)$, it suffices to evaluate a logspace-uniform AC^0 circuit where all of the input bits are 0. Since this computation can be done in logspace on input $(0^n 1^i 0^j)$, note that the language $H = \{(n, i, j) : \text{the } j\text{-th bit of query } q_i(0^n) \text{ is } 1\}$ is in linear space. Let $m = |(n, i, j)|$, and let $s(m)$ be the size of the smallest circuit D_m computing H for inputs of length m. Hardwire the bits for n and also set the bits for i to i_0. The resulting circuit on $|j| < m$ bits computes the function given by $q_{i_0}(0^n)$, and it was observed above that this circuit has size at least $n^{1/12d} \geq 2^{m/12d}$.

This establishes the first implication. (Note also that a similar argument yields the same conclusion from the assumption that PARITY reduces to MCSP^A via a natural logspace-uniform $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$-reduction.)

The assumption that $\mathsf{MKTP}^A \in \mathsf{P}^A/\mathsf{poly}$ suffices to show that the second condition implies the third. More formally, we'll consider the contrapositive. Assume that $\mathsf{DSPACE}(n) \subseteq \mathsf{io\text{-}SIZE}^{\mathsf{MKTP}^A}(2^{\epsilon n})$ for every $\epsilon > 0$. An oracle gate for MKTP^A on inputs of size m can be replaced by a circuit (with oracle gates for A) of size m^c for some constant c. Carrying out this substitution in a circuit (with oracle gates for MKTP^A) of size $2^{\epsilon n}$ yields a circuit of size at most $2^{\epsilon n} + 2^{\epsilon n}(2^{\epsilon n})^c$.

Let $\delta > 0$. Then we can pick ϵ so that $2^{\epsilon n} + 2^{\epsilon n}(2^{\epsilon n})^c < 2^{\delta n}$, thereby establishing that $\mathsf{DSPACE}(n) \subseteq \mathsf{io\text{-}SIZE}^A(2^{\delta n})$ for every $\delta > 0$. This establishes the second implication.

The 3rd condition implies the 4th by Theorem 11. The 4th obviously implies the 1st. ◀

To the best of our knowledge, this is the first theorem that has given conditions where the existence of a reduction to MCSP^A implies the existence of a reduction to MKTP^A. We know of no instance where the implication goes in the opposite direction.

At this point, we should consider the class of oracles for which Theorem 12 applies. That is, what is the set of oracles A for which $\mathsf{MKTP}^A \in \mathsf{P}^A/\mathsf{poly}$? First, we observe that this condition holds for any PSPACE-complete set, which yields the following corollary:

▶ **Corollary 13.** PARITY *does not reduce to either* $\mathsf{MKTP}^{\mathsf{QBF}}$ *or* $\mathsf{MCSP}^{\mathsf{QBF}}$ *via a natural logspace-uniform* $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$*-reduction.*

Another example is $A = \{(M, x, 1^m) : M$ is an alternating Turing machine that accepts x, and runs in time at most m and makes at most $\log m$ alternations$\}$. A is complete for the class $\mathsf{ATIME\text{-}ALT}(n^{O(1)}, O(\log n))$ under $\leq^{\mathsf{AC}^0}_{\mathrm{m}}$ reductions. Note that $\mathsf{MKTP}^A \in \mathsf{ATIME\text{-}ALT}(n^{O(1)}, O(\log n))$, and thus $\mathsf{MKTP}^A \in \mathsf{P}^A$. (Other examples can easily be created in this way, using an even smaller number of alternations. Note that, for this oracle A, it seems plausible that all four conditions in Theorem 12 hold.

Nonetheless, we grant that this seems to be a strong condition to place upon the oracle A – and it has even stronger consequences than are listed in Theorem 12. For instance, note that the proof that the first condition in Theorem 12 implies the second relies only on the

fact that PARITY requires large AC^0 circuits. Thus, an identical proof shows that these four conditions are also equivalent to the condition that PARITY is reducible to MKTP^A via a natural ctt-reduction where the queries are computed by logspace-uniform $\mathsf{AC}^0[7]$ circuits. (One can substitute any other problem and class of mod circuits, where an exponential lower bound follows from [24, 26].) In fact, as in [7, Lemma 3.10] we can apply random restrictions in a logspace-uniform way (as described in [1]) and obtain a reduction from PARITY to MKTP^A where the queries are computed by logspace-uniform NC^0 circuits! That is, for example, MAJORITY is reducible to MKTP^A via reductions of this sort computed by logspace-uniform $\mathsf{AC}^0[3]$ circuits iff PARITY is reducible to the same set via reductions where the queries are computed by logspace-uniform NC^0 circuits. We find these implications to be surprising. The "gap" phenomenon that was described in [2] (showing that completeness under one class of reductions is equivalent to completeness under a more restrictive class of reductions) had not previously been observed to apply to $\mathsf{AC}^0[p]$ reducibility.

We want to highlight some contrasts between Theorem 11 and Corollary 13. $\mathsf{MKTP}^{\mathsf{QBF}}$ is hard for PSPACE under ZPP-Turing reductions [3], whereas MKTP is in NP. Thus $\mathsf{MKTP}^{\mathsf{QBF}}$ appears to be much harder than MKTP. Yet, under a plausible hypothesis, MKTP is hard for a well-studied subclass of P under a type of reducibility, where the "harder" problem $\mathsf{MKTP}^{\mathsf{QBF}}$ cannot even be used as an oracle for PARITY under this same reducibility.

In other words, the (conditional) natural logspace-uniform $\leq^{\mathsf{AC}^0}_{\mathrm{ctt}}$ reductions from problems in DET to MKTP given in Theorem 11 are not "oracle independent" in the sense of [14]. Prior to this work, there had been no reduction to MCSP or MKTP that did not work for every MCSP^A or MKTP^A, respectively.

Prior to this work, it appears that there was no evidence for any variant of MCSP or MKTP being hard for a reasonable complexity class under $\leq^{\mathsf{L}}_{\mathrm{T}}$ reductions. All prior reductions (such as those in [4, 3, 5]) had been probabilistic and/or non-uniform, or (even under derandomization hypotheses) seemed difficult to implement in NC. We had viewed the results of [7] as providing evidence that none of these variants would be hard for P under, say, logspace reducibility. Now, we are no longer sure what to expect.

5 Conclusions and Open Questions

Conclusions. At a high level, we have advanced our understanding about MCSP and MKTP in the following two respects:

1. On one hand, under a very weak cryptographic assumption, the problem of approximating MCSP or MKTP is indeed NP-intermediate under *general* types of reductions when the approximation factor is quite *huge*. This complements the work of [19] for very *restricted* reductions.
2. On the other hand, if the gap is *small*, MKTP is DET-hard under nonuniform NC^0 reductions (contrary to previous expectations). This suggests that nonuniform reductions are crucial to understanding hardness of MCSP. While there are many results showing that NP-hardness of MCSP under *uniform* reductions is as difficult as proving circuit lower bounds, can one show that MCSP is NP-hard under P/poly reductions (without proving circuit lower bounds)?

Open Questions. It should be possible to prove unconditionally that MCSP is not in $\mathsf{AC}^0[2]$; we conjecture that the hardness results we give for MKTP hold also for MCSP.

We suspect that it should be possible to prove more general results of the form "If MCSP^A is hard for class $\mathcal{C}$, then so is MKTP^A". We view Theorem 12 to be just a first step in this

direction. One way to prove such a result would be to show that MCSP^A reduces to MKTP^A, but (with a few exceptions such as $A = \mathsf{QBF}$) no such reduction is known. Of course, the case $A = \emptyset$ is the most interesting case.

Is MKTP hard for P? Or for some class between DET and P? Is it more than a coincidence that DET arises both in this investigation of MKTP and in the work of [20] on MCSP?

Is there evidence that Gap_ϵMCSP has intermediate complexity when ϵ is a fixed constant, similar to the evidence that we present for the case when $\epsilon(n) = o(1)$?

Acknowledgments. We thank Ryan Williams, Rahul Santhanam, Salil Vadhan, Marina Knittel, and Prashant Nalini Vasudevan for helpful discussions.

Abstract

We consider two player, zero-sum, finite-state concurrent reachability games, played for an infinite number of rounds, where in every round, each player simultaneously and independently of the other players chooses an action, whereafter the successor state is determined by a probability distribution given by the current state and the chosen actions. Player 1 wins iff a designated goal state is eventually visited. We are interested in the complexity of stationary strategies measured by their *patience*, which is defined as the inverse of the smallest non-zero probability employed.

Our main results are as follows: We show that: (i) the optimal bound on the patience of optimal and ϵ-optimal strategies, for both players is doubly exponential; and (ii) even in games with a single non-absorbing state exponential (in the number of actions) patience is necessary.

1 Introduction

Concurrent reachability games

Concurrent reachability games[8] are played on finite-state graphs by 2 players for an infinite number of rounds. In every round, each player simultaneously and independently of the other player chooses moves (or actions). The current state and the chosen moves of the players determine a probability distribution over the successor state. The result of playing the game (or a *play*) is an infinite sequence of states and actions. The play starts in a designated *start state*. Player 1 wins the play iff the play ever enters a designated *goal state*. We say that player 1 is the *reachability player* and player 2 the *safety player*. These games were introduced in a seminal work by Shapley [23], and have been one of the most fundamental and well-studied game models in stochastic graph games. Matrix games (or normal form games) can model a wide range of problems with diverse applications, when there is a finite number of interactions [19, 26]. Concurrent reachability games can be viewed as a finite set of matrix games, such that the choices made in the current game determine which game is played next, and is the appropriate model for many applications [11]. Moreover, in analysis of reactive systems, concurrent games provide the appropriate model for reactive systems with components that interact synchronously [6, 7, 1].

* Some proofs are missing. See full version https://arxiv.org/abs/1506.02434, [4]

Relevance

Concurrent reachability games are relevant in many applications. For example, the synthesis problem in control theory (e.g., discrete-event systems as considered in [22]) corresponds to reactive synthesis of [21]. The synthesis problem for synchronous reactive systems is appropriately modeled as concurrent games [6, 7, 8]. Other than control theory, concurrent reachability games also provide the appropriate model to study several other interesting problems, such as two-player poker games [18].

Properties of strategies

Given a concurrent reachability games, the player-1 *value* $v_1(s)$ of the game at a state s is the limit probability with which he can guarantee that the play will eventually enter the goal state against all strategies of player 2. The player-2 *value* $v_2(s)$ is analogously the limit probability with which player 2 can ensure his own objective against all strategies of player 1. Concurrent reachability games are determined [10], i.e., for each state s we have $v_1(s) + v_2(s) = 1$. A *strategy* for a player, given a history (i.e., finite prefix of a play) specifies a probability distribution over the actions. A *stationary* strategy does not depend on the history, but only on the current state. For $\varepsilon \geq 0$, a strategy is ε-optimal for a state s for player i if it ensures his own objective with probability at least $v_i(s) - \varepsilon$ against all strategies of the opponent. A 0-optimal strategy is an *optimal* strategy. In concurrent reachability games, there exist stationary optimal strategies for the safety player [20, 14]; whereas in contrast, for the reachability player, optimal strategies do not exist in general, however, for every $\varepsilon > 0$ there exists stationary ε-optimal strategies [10].

The significance of patience and roundedness of strategies

The basic decision problem is as follows: given a concurrent reachability game and a rational threshold λ, decide whether $v_1(s) \geq \lambda$. The basic decision problem is in PSPACE and is *square-root sum* hard [9][1]. Given the hardness of the basic decision problem, the next most relevant computational problem is to compute an approximation of the value. The computational complexity of the approximation problem is closely related to the size of the description of ε-optimal strategies. Even for special cases of concurrent reachability game, namely *turn-based* reachability games, where in each state at most one player can choose between multiple moves, the best known complexity results are obtained by guessing an optimal strategy and computing the value in the game obtained after fixing the guessed strategy. A strategy has patience p if p is the inverse of the smallest non-zero probability used by a distribution describing the strategy. A rational valued strategy has roundedness q if q is the greatest denominator of the probabilities used by the distributions describing the strategy. Note that if a strategy has roundedness q, then it also has patience at most q. The description complexity of a stationary strategy can be bounded by the roundedness. A stationary strategy with exponential roundedness, can be described using polynomially many bits, whereas the explicit description of stationary strategies with doubly-exponential patience is not polynomial. Thus obtaining upper bounds on the roundedness and lower bounds on the patience is at the heart of the computational complexity analysis of concurrent reachability games. Also see [27, 28, 24] for the significance of computing strategies in concurrent stochastic games.

[1] The square-root sum problem is an important problem from computational geometry, where given a set of natural numbers $n_1, n_2, \ldots, n_k$, the question is whether the sum of the square roots exceed an integer b. The problem is not known to be in NP.

Previous results and our contributions

In this work we consider concurrent reachability games. We first describe the relevant previous results and then our contributions.

Previous results

For concurrent reachability game, the optimal bound on patience and roundedness for ε-optimal strategies for the reachability player, for $\varepsilon > 0$, is doubly exponential [13, 12]. The doubly-exponential lower bound is obtained by presenting a family of games (namely, Purgatory) where the reachability player requires doubly-exponential patience (however, in this game the patience of the safety player is 1) [13, 12]; whereas the doubly-exponential upper bound is obtained by expressing the values in the existential theory of reals [13, 12]. In contrast to the reachability player that in general do not have optimal strategies, similar to the safety player there are two related classes of concurrent stochastic games that admit optimal stationary strategies, namely, discounted-sum, and ergodic concurrent games. For both these classes the optimal bound on patience and roundedness for ε-optimal strategies, for $\varepsilon > 0$, is exponential [5, 15]. The optimal bound on patience and roundedness for optimal and ε-optimal strategies, for $\varepsilon > 0$, for the safety player has been an open problem.

Our contributions

Our main results are as follows:

1. *Lower bound: general.* We show that in concurrent reachability games, a lower bound on patience of optimal and ε-optimal strategies, for $\varepsilon > 0$, for the safety player is doubly exponential (in contrast to the above mentioned related classes of games that only require exponential patience). We present a family of games (namely, Purgatory Duel) where optimal and ε-optimal strategies, for $\varepsilon > 0$, for both players require doubly-exponential patience.
2. *Lower bound: three states.* We show that even in concurrent reachability games with three states of which two are absorbing (sink states with only self-loop transitions) the patience required for optimal and ε-optimal strategies, for $\varepsilon > 0$, is exponential (in the number of actions). An optimal (resp., ε-optimal, for $\varepsilon > 0$) strategy in a game with three states (with two absorbing states) is basically an optimal (resp., ε-optimal) strategy of a matrix game, where some entries of the matrix game depend on the value of the non-absorbing state (as some transitions of the non-absorbing state can lead to itself). In standard matrix games, the patience for ε-optimal strategies, for $\varepsilon > 0$, is only logarithmic [17]; and perhaps surprisingly in contrast we show that the patience for ε-optimal strategies in concurrent reachability games with only three states is exponential (i.e., there is a doubly-exponential increase from logarithmic to exponential).
3. *Upper bound.* We show that in concurrent reachability games, an upper bound on the patience of optimal strategies and an upper bound on the patience and roundedness of ε-optimal strategies, for $\varepsilon > 0$, is as follows: (a) doubly exponential in general; and (b) exponential for the safety player if the number of value classes (i.e., the number of different values in the game) is constant. Hence our upper bounds on roundedness match our lower bound results for patience. Our results also imply that if the number of value classes is constant, then the basic decision problem is in coNP.

In summary, we present a complete picture of the patience and roundedness required in concurrent reachability games.

Table 1 Strategy complexity (i.e., patience and roundedness of ε-optimal strategies, for $\varepsilon > 0$) of the reachability vs safety player depending on the number of value classes. Our results are bold faced, and LB (resp., UB) denotes lower (resp., upper) bound on patience (resp., roundedness).

# Value classes	Reachability	Safety
1	Linear	One
2	Double-exponential	One
3	Double-exponential	**Exponential LB, Theorem 13**
Constant	Double-exponential	**Exponential UB, Theorem 14**
General	Double-exponential	**Double-exponential LB, Theorem 12 UB, Theorem 14**

Distinguishing aspects of safety and reachability

While the optimal bound on patience and roundedness we establish in concurrent reachability games for the safety player matches that for the reachability player, there are many distinguishing aspects for safety as compared to reachability in terms of the number of value classes (as shown in Table 1). For the reachability player, if there is one value class, then the patience and roundedness required is linear: it follows from the results of [2] that if there is one value class then all the values must be either 1 or 0; and if all states have value 0, then any strategy is optimal, and if all states have value 1, then it follows from [8, 3] that there is an almost-sure winning strategy (that ensures the objective with probability 1) from all states and the optimal bound on patience and roundedness is linear. The family of game graphs defined by Purgatory has two value classes, and the reachability player requires doubly exponential patience and roundedness, even for two value classes. In contrast, if there are (at most) two value classes, then again the values are 1 and 0; and in value class 1, the safety player has an optimal strategy that is stationary and deterministic (i.e., a positional strategy) and has patience and roundedness 1 [8], and in value class 0 any strategy is optimal. While for two value classes, the patience and roundedness is 1 for the safety player, we show that for three value classes (even for three states) the patience and roundedness is exponential, and in general the patience and roundedness is doubly exponential (and such a finer characterization does not exist for the reachability player).

Our main ideas

Our most interesting results are the doubly-exponential and exponential lower bound on the patience and roundedness. We now present a brief overview about the lower bound example.

The game of *Purgatory* [13, 12] is a concurrent reachability game that was defined as an example showing that the *reachability* player must, in order to play near optimally, use a strategy with non-zero probabilities that are *doubly exponentially* small in the number of states of the game (i.e., the patience is doubly exponential).

In this paper we present another example of a reachability game where this is the case for the *safety* player as well. The game Purgatory consists of a (potentially infinite) sequence of *escape attempts*. In an escape attempt one player is given the role of the *escapee* and the other player is given the role as the *guard*. An escape attempt consists of at most N

rounds. In each round, the guard selects and hides a number between 1 and m, and the escapee must try to guess the number. If the escapee successfully guesses the number N times, the game ends with the escapee as the winner. If the escapee incorrectly guesses a number which is strictly larger than the hidden number, the game ends with the guard as the winner. Otherwise, if the escapee incorrectly guesses a number which is strictly smaller than the hidden number, the escape attempt is over and the game continues.

The game of Purgatory is such that the reachability player is always given the role of the escapee, and the safety player is always given the role of the guard. If neither player wins during an escape attempt (meaning there is an infinite number of escape attempts) the safety player wins. Purgatory may be modeled as a concurrent reachability game consisting of N non-absorbing positions in which each player has m actions. The value of each non-absorbing position is 1. This means that the reachability player has, for any $\varepsilon > 0$, a stationary strategy that wins from each non-absorbing position with probability at least $1 - \varepsilon$ [10], but such strategies must have doubly-exponential patience. In fact for N sufficiently large and $m \geq 2$, such strategies must have patience at least $2^{m^{N/3}}$ for $\varepsilon = 1 - 4m^{-N/2}$ [12]. For the safety player however, the situation is simple: *any* strategy is optimal.

We introduce a game we call the *Purgatory Duel* in which the safety player must also use strategies of doubly-exponential patience to play near optimally. The main idea of the game is that it forces the safety player to behave as a reachability player. We can describe the new game as a variation on the above description of the Purgatory game. The Purgatory Duel consists also of a (potentially infinite) sequence of escape attempts. But now, before each escape attempt the role of the escapee is given to each player with probability $\frac{1}{2}$, and in each escape attempt the rules are as described above. The game remains asymmetric in the sense that if neither player wins during an escape attempt, the safety player wins. The Purgatory Duel may be modeled as a concurrent reachability game consisting of $2N + 1$ non-absorbing positions, in which each player has m actions, except for a single position where the players each have just a single action.

Technical contributions

The key non-trivial aspects of our proof are as follows: first, is to come up with the family of games, namely, Purgatory Duel, where the ε-optimal strategies, for $\varepsilon \geq 0$, for the players are symmetric, even though the objectives are complementary; and then the precise analysis of the game needs to combine and extend several ideas, such as refined analysis of matrix games, and analysis of perturbed Markov decision processes (MDPs) which are one-player stochastic games.

Highlights

We highlight two features of our results, namely, the surprising aspects and the significance (see Section Discussion and Conclusion of the full version for further details).

1. *Surprising aspects.* The first surprising aspect of our result is the doubly-exponential lower bound for the safety player in concurrent reachability games. The properties of strategies for the safety player in concurrent reachability games resemble concurrent discounted games, as in both cases optimal stationary strategies exist, and locally optimal strategies are optimal. We show that in contrast to concurrent discounted games where exponential patience suffices for the safety player in concurrent reachability games doubly-exponential patience is necessary. The second surprising aspect is the lower bound example itself. The lower bound example is obtained as follows: (i) given Purgatory we first obtain

simplified Purgatory by changing the start state such that it deterministically goes to the next state; (ii) we then consider its dual where the roles of the players are exchanged; and (iii) Purgatory duel is obtained by merging the start states of simplified Purgatory and its dual. Both in simplified Purgatory and its dual, there are only two value classes, and positional optimal strategies exist for the safety player. Surprisingly we show that a simple merge operation gives a game with linear number of value classes and the patience increases from 1 to doubly-exponential. Finally, the properties of strategies for the reachability- and safety-player in concurrent reachability games differ substantially. An important aspect of our lower bound example is that we show how to modify an example for the reachability player to obtain the result for safety player.

2. *Significance.* Our most important results are the lower bounds, and the main significance is threefold. First, the most well-studied way to obtain computational complexity result in games is to explicitly guess strategies, and then verify the game obtained fixing the strategy. The lower bound for the reachability player by itself did not rule out that better complexity results can be obtained through better strategy complexity for the safety player (indeed, for constant number of value classes, we obtain a better complexity result than known before due to the exponential bound on roundedness). Our doubly-exponential lower bound shows that in general the method of explicitly guessing strategies would require exponential space, and would not yield NP or coNP upper bounds. Second, one of the most well-studied algorithm for games is the strategy-iteration algorithm. Our result implies that any natural variant of the strategy-iteration algorithm for the safety player that explicitly compute strategies require exponential space in the worst-case. Finally, in games, strategies that are witness to the values and specify how to play the game, are as important as values, and our results establish the precise strategy complexity (matching upper bound of roundedness with lower bounds of patience).

Full-version: Proofs and non-zero-sum games.

In the full version [4], we give full proofs of all our lemmas and also consider non-zero-sum and non-two-player concurrent games, but where each player has either a reachability or safety objective (concurrent reachability games is then the special case of 1 player with a reachability objective and 1 player with the complementary safety objective).

2 Definitions

Other number

Given a number $i \in \{1, 2\}$ let $\widehat{i}$ be the other number, i.e., if $i = 1$, then $\widehat{i} = 2$ and vice-versa.

Probability distributions

A *probability distribution* d over a finite set Z, is a map $d : Z \to [0, 1]$, such that $\sum_{z \in Z} d(z) = 1$. Fix a probability distribution d over a set Z. The distribution d is *pure (Dirac)* if $d(z) = 1$ for some $z \in Z$ and for convenience we overload the notation and let $d = z$. The *support* $\mathrm{Supp}(d)$ is the subset Z' of Z, such that $z \in Z'$ if and only if $d(z) > 0$. The distribution d is *totally mixed* if $\mathrm{Supp}(d) = Z$. The *patience* of d is $\max_{z \in \mathrm{Supp}(d)} \frac{1}{d(z)}$, i.e., the inverse of the minimum non-zero probability. The *roundedness* of d, if $d(z)$ is a rational number for all $z \in Z$, is the greatest denominator of $d(z)$. Note that roundness of d is always at least the patience of d. Given two elements $z, z' \in Z$, the probability distribution $d = \mathsf{U}(z, z')$ over Z is such that $d(z) = d(z') = \frac{1}{2}$. Let $\Delta(Z)$ be the set of all probability distributions over Z.

Concurrent reachability games

A concurrent reachability game, consists of (1) a finite set of *states* S, of size N; and (2) for each state $s \in S$ and each player i a set A^i_s of *actions* (and $A^i = \bigcup_s A^i_s$ is the set of all actions for player i, for each i; and $A = \bigcup_i A^i$ is the set of all actions) such that A^i_s consists of at most m actions; and (3) a stochastic *transition function* $\delta : S \times A^1 \times A^2 \to \Delta(S)$; and (4) a designated *goal state* $g \in S$. A state s is *deterministic* if $\delta(s, a_1, a_2)$ is pure (deterministic), for all $a_i \in A^i_s$ and for all i. A state s is called *absorbing* if $A^i_s = \{a\}$ for all i and $\delta(s, a, a) = s$. The number $\delta_{\min}$ is the smallest non-zero transition probability.

How to play a concurrent reachability game

The game G, starting in state s, is played as follows: initially a pebble is placed on $v_0 := s$. In each time step $T \geq 0$, the pebble is on some state v_T and each player selects (simultaneously and independently of the other players, like in the game rock-paper-scissors) an action $a^i_{T+1} \in A^i_{v_T}$. Then, the game selects v_{T+1} according to the probability distribution $\delta(v_T, a^1_{T+1}, a^2_{T+1})$ and moves the pebble onto v_{T+1}. The game then continues with time step $T + 1$ (i.e., the game consists of infinitely many time steps). For a round T, let a_{T+1} be the pair of choices of the actions for the players, i.e., $a_{T+1,i}$ is the choice of player i, for each i. Round 0 is identified by v_0 and round $T > 0$ is then identified by the pair (a_T, v_T). A *play* P_s, starting in state $v_0 = s$, is then a sequence of rounds $(v_0, (a_1, v_1), (a_2, v_2), \ldots, (a_T, v_T), \ldots)$, and for each ℓ a prefix of P^ℓ_s of length ℓ is then $(v_0, (a_1, v_1), (a_2, v_2), \ldots, (a_T, v_T), \ldots, (a_\ell, v_\ell))$, and we say that P^ℓ_s *ends in* v_ℓ. Player 1 wins a play P_s iff $v_T = g$ for some T. Similarly, player 2 wins a play P_s iff $v_T \neq g$ for *all* T We refer to player 1 as the reachability player and player 2 as the safety player.

Strategies

Fix a player i. A strategy is a recipe to choose a probability distribution over actions given a finite prefix of a play. Formally, a strategy σ_i for player i is a map from P^ℓ_s, for a play P_s of length ℓ starting at state s, to a distribution over $A^i_{v_\ell}$. Player i *follows* a strategy σ_i, if given the current prefix of a play is P^ℓ_s, he selects $a_{\ell+1}$ according to $\sigma_i(P^\ell_s)$, for all plays P_s starting at s and all lengths ℓ. A strategy σ_i for player i, is *stationary*, if for all ℓ and ℓ', and all pair of plays P_s and $P'_{s'}$, starting at states s and s' respectively, such that P^ℓ_s and $(P')^{\ell'}_{s'}$ ends in the same state t, we have that $\sigma_i(P^\ell_s) = \sigma_i((P')^{\ell'}_{s'})$; and we write $\sigma_i(t)$ for the unique distribution used for prefix of plays ending in t. The *patience* (resp., *roundedness*) of a strategy σ_i is the supremum of the patience (resp. roundedness) of the distribution $\sigma_i(P^\ell_s)$, over all plays P_s starting at state s, and all lengths ℓ. Also, a strategy σ_i is *pure* (resp., *totally mixed*) if $\sigma_i(P^\ell_s)$ is pure (resp., totally mixed), for all plays P_s starting at s and all lengths ℓ. A strategy is *positional* if it is pure and stationary. Let Σ^i be the set of all strategies for player i.

Strategy profiles

A *strategy profile* $\sigma = (\sigma_1, \sigma_2)$ is a pair of strategies, one for each player. A strategy profile σ defines a unique probability measure on plays, denoted $\Pr_\sigma$, when the players follow their respective strategies [25]. We say that a strategy profile has a property (e.g., is stationary) if each of the strategies in the profile has that property.

Values

Let $u(G, s, \sigma)$ be the probability that player 1 wins the game G when the players follow σ and the play starts in s (i.e., the utility or payoff for player 1). Also if the game G is clear from context we drop it from the notation. Given a concurrent reachability game G, the *upper value* $\overline{\mathrm{val}}(G, s)$ (resp., *lower value* $\underline{\mathrm{val}}(G, s)$) of G starting in s is

$$\overline{\mathrm{val}}(G, s) = \sup_{\sigma_1 \in \Sigma^1} \inf_{\sigma_2 \in \Sigma^2} u(G, s, \sigma_1, \sigma_2) \ ; \quad \underline{\mathrm{val}}(G, s) = \inf_{\sigma_2 \in \Sigma^2} \sup_{\sigma_1 \in \Sigma^1} u(G, s, \sigma_1, \sigma_2) \ .$$

As shown by [10] we have that $\mathrm{val}(G, s) := \overline{\mathrm{val}}(G, s) = \underline{\mathrm{val}}(G, s)$; which is called the *value* of s. We will sometimes write $\mathrm{val}(s)$ for $\mathrm{val}(G, s)$ if G is clear from the context. We will also write val for the vector where $\mathrm{val}_s = \mathrm{val}(s)$.

(ε-)optimal strategies for concurrent reachability games

For an $\varepsilon \geq 0$, a strategy σ_1 for player 1 (resp., σ_2 for player 2) is called *ε-optimal* if for each state s we have that $\mathrm{val}(s) - \varepsilon \leq \inf_{\sigma_2 \in \Sigma^2} u(s, \sigma_1, \sigma_2)$ (resp., $\mathrm{val}(s) + \varepsilon \geq \sup_{\sigma_1 \in \Sigma^1} u(s, \sigma_1, \sigma_2)$). For each i, a strategy σ_i for player i is called *optimal* if it is 0-optimal. There exist concurrent reachability games in which player 1 does not have optimal strategies, see [10] for an example. On the other hand in all concurrent reachability games G player 1 has a stationary ε-optimal strategy for each $\varepsilon > 0$. In all concurrent reachability games player 2 has an optimal stationary strategy (thus also an ε-optimal stationary strategy for all $\varepsilon > 0$) [20, 14]. Also, given a stationary strategy σ_1 for player 1 we have that there exists a positional strategy σ_2, such that $u(s, \sigma_1, \sigma_2) = \inf_{\sigma_2' \in \Sigma^2} u(s, \sigma_1, \sigma_2')$, i.e., we only need to consider positional strategies for player 2. Similarly, we only need to consider positional strategies for player 1, if we are given a stationary strategy for player 2.

Markov decision processes and Markov chains

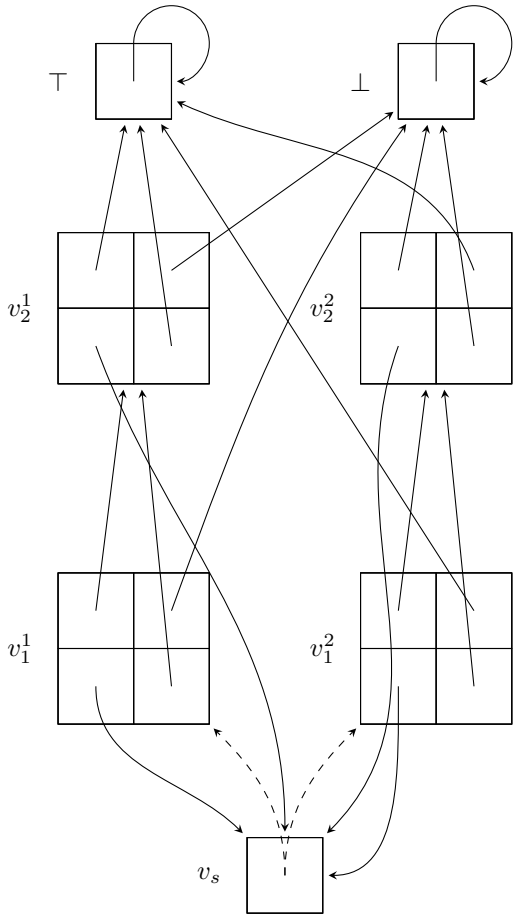
For each player i, a *Markov decision process (MDP) for player i* is a concurrent game where the size of A_s^j is 1 for all s and $j \neq i$. A *Markov chain* is an MDP for each player (that is the size of A_s^j is 1 for all s and j). A *closed recurrent set* of a Markov chain G is a maximal (i.e., no closed recurrent set is a subset of another) set $S' \subseteq S$ such that for all pairs of states $s, s' \in S$, the play starting at s reaches state s' eventually with probability 1 (note that it does not depend on the choices of the players as we have a Markov chain). For all starting states, eventually a closed recurrent set is reached with probability 1, and then plays stay in the closed reccurent set. Observe that fixing a stationary strategy for all but one player in a concurrent game, the resulting game is an MDP for the remaining player. Hence, fixing a stationary strategy for each player gives a Markov chain.

Game illustration

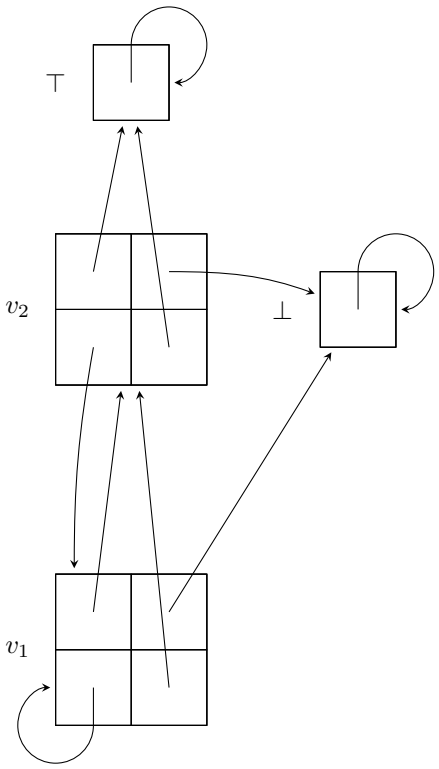
When we illustrate our games, we illustrate each state as a matrix, where the rows corresponds to the actions of the reachability player, the columns corresponds to the actions of the safety player. Thus, each entry e corresponds to an pair of actions (i, j) and a state s and we have an edge to $\delta(s, i, j)$ from e.

3 Patience Lower Bound

In this section we will establish the doubly-exponential lower bound on patience for concurrent reachability games. First we define the game family, namely, *Purgatory Duel* and we also recall the family *Purgatory*.



(a) Illustration of the Purgatory Duel with $m = n = 2$. The dashed edges have probability $\frac{1}{2}$ each.



(b) Illustration of Purgatory with $m = n = 2$.

Figure 1 Illustration of the games used for lower bounds.

The Purgatory Duel

In this paper we specifically focus on the following concurrent reachability game, the *Purgatory Duel*, defined on a pair of parameters (n, m). The game consists of $N = 2n+3$ states, namely $\{v_1^1, v_2^1, \ldots, v_n^1, v_1^2, v_2^2, \ldots, v_n^2, v_s, \top, \bot\}$ and all but v_s are deterministic. To simplify the definition of the game, let $v_0^1 = v_{n+1}^2 = \bot$ and $v_0^2 = v_{n+1}^1 = \top$. The states $\top$ and $\bot$ are absorbing. For each $i \in \{1, 2\}$ and $j \in \{1, \ldots, n\}$, the state v_j^i is such that $A^1_{v_j^i} = A^2_{v_j^i} = \{1, 2, \ldots, m\}$ and for each a_1, a_2 we have that $\delta(v_j, a_1, a_2)$ is (1) v_s if $a_1 > a_2$, (2) v_0^i if $a_1 < a_2$ and (3) v_{j+1}^i if $a_1 = a_2$. Finally, $A^1_{v_s} = A^2_{v_s} = \{a\}$ and $\delta(v_s, a, a) = \mathsf{U}(v_1^1, v_1^2)$. There is an illustration of the Purgatory Duel with $m = n = 2$ in Figure 1a.

The game Purgatory

We will also use the game *Purgatory* as defined by [12] (and also in [13] for the case of $m = 2$). Purgatory is similar to the Purgatory Duel and hence the similarity in names. Purgatory is also defined on a pair of parameters (n, m). The game consists of $N = n + 2$ states, namely, $\{v_1, v_2, \ldots, v_n, \top, \bot\}$ and each state is deterministic. To simplify the definition of the game,

let $v_{n+1} = \top$. For each $j \in \{1, \dots, n\}$, the state v_j is such that $A^1_{v_j} = A^2_{v_j} = \{1, 2, \dots, m\}$ and for each a_1, a_2 we have that $\delta(v_j, a_1, a_2)$ is (1) v_1 if $a_1 > a_2$, (2) $\bot$ if $a_1 < a_2$ and (3) v_{j+1} if $a_1 = a_2$. The states $\top$ and $\bot$ are absorbing. Furthermore, $S^1 = \{\top\}$. For an illustration of Purgatory with $m = n = 2$ see Figure 1b.

3.1 The patience of optimal strategies

In this section we present an approximation of the values of the states and the patience of the optimal strategies in the Purgatory Duel. We first show that the values of the states (besides $\top$ and $\bot$) are strictly between 0 and 1.

▶ **Lemma 1.** *Each state* $v \in \{v^1_1, v^1_2, \dots, v^1_n, v^2_1, v^2_2, \dots, v^1_2, v_s\}$ *is such that* $\mathrm{val}(v) \in [\frac{1}{m^{n+2}}, 1 - \frac{1}{m^{n+2}}]$

The proof of the above lemma is obtained by considering the strategy, for either player, that plays uniformly at random all available actions at every state. Next we show that every optimal stationary strategy for player 2 must be totally mixed.

▶ **Lemma 2.** *Let* σ_2 *be an optimal stationary strategy for player 2. The distribution* $\sigma_2(v^i_j)$ *is totally mixed and* $\mathrm{val}(v^1_j) > \mathrm{val}(v_s) > \mathrm{val}(v^2_j)$*, for all* i, j*.*

Next, we show that if either player follows a stationary strategy that is totally mixed on at least one side (that is, if there is an i', such that for each j the stationary strategy plays totally mixed in $v^{i'}_j$), then eventually either $\top$ or $\bot$ is reached with probability 1. The proof relies on the analysis of the Markov chain obtained given the strategies.

▶ **Lemma 3.** *For any* i *and* i'*, let* σ_i *be a stationary strategy for player* i*, such that* $\sigma_i(v^{i'}_j)$ *is totally mixed for all* j*. Let* $\sigma_{\widehat{i}}$ *be some stationary strategy for the other player. Then, each closed recurrent set in the Markov chain given by the game,* σ_i*, and* $\sigma_{\widehat{i}}$*, consists of only the state* $\top$ *or only the state* $\bot$*.*

The following definition basically *"mirrors"* a strategy σ_i for player i, for each i and gives it to the other player. We show (in Lemma 5) that if σ_2 is optimal for player 2, then the mirror strategy is optimal for player 1. We also show that if σ_2 is an ε-optimal strategy for player 2, for $0 < \varepsilon < \frac{1}{3}$, then so is the mirror strategy for player 1 (in Lemma 8).

▶ **Definition 4** (Mirror strategy)**.** Given a stationary strategy σ_i for player i, for either i, let the mirror strategy $\sigma^{\sigma_i}_{\widehat{i}}$ for player $\widehat{i}$ be the stationary strategy where $\sigma^{\sigma_i}_{\widehat{i}}(v^{\widehat{i'}}_j) = \sigma_i(v^{i'}_j)$ for each i' and j.

We next show that player 1 has optimal stationary strategies in the Purgatory Duel and give expressions for the values.

▶ **Lemma 5.** *Let* σ_2 *be some optimal stationary strategy for player 2. Then the mirror strategy* $\sigma_1^{\sigma_2}$ *is optimal for player 1. We have* $\mathrm{val}(v_s) = \frac{1}{2}$ *and* $\mathrm{val}(v^i_j) = 1 - \mathrm{val}(\widehat{v^i_j})$*, for all* i, j*.*

Finally, we give an approximation of the values of states in the Purgatory Duel and a lower bound on the patience of any optimal strategy of $2^{(m-1)^2 m^{n-2}}$.

▶ **Theorem 6.** *For each* j *in* $\{1, \dots, n\}$*, the value of state* v^1_j *in the Purgatory Duel is less than* $\frac{1}{2} + 2^{(1-m)\cdot m^{n-j}-1}$ *and for any optimal stationary strategy* σ_i *for either player* i*, the patience of* $\sigma_i(v^1_j)$ *is at least* $2^{(m-1)^2 m^{n-j-1}}$*.*

3.2 The patience of ε-optimal strategies

In this section we consider the patience of ε-optimal strategies for $0 < \varepsilon < \frac{1}{3}$. First we argue that each such strategy for player 2 is totally mixed on one side.

▶ **Lemma 7.** *For all $0 < \varepsilon < \frac{1}{2}$, each ε-optimal stationary strategy σ_2 for player 2 is such that $\sigma_2(v_j^2)$ is totally mixed, for all j.*

The idea is that against any strategy σ_2 that does not play totally mixed in some v_j^2, player 1 can ensure that if v_1^2 is entered, then $\perp$ is not reached before v_s is entered again (by playing 1 in $v_{j'}^2$, for $j' < j$ and some action not played by σ_2 in v_j^2). This allows player 1 to play a near optimal strategy from Purgatory in the states $v_{j'}^1$, ensuring that $\top$ is eventually reached with probability close to 1 from v_s and showing that σ_2 is far from optimal. We now show that if we mirror an ε-optimal strategy, then we get an ε-optimal strategy.

▶ **Lemma 8.** *For all $0 < \varepsilon < \frac{1}{3}$, each ε-optimal stationary strategy σ_2 for player 2 in the Purgatory Duel, is such that the mirror strategy $\sigma_1^{\sigma_2}$ is ε-optimal for player 1.*

Next we give a definition and a lemma, which is similar to Lemma 6 in [16]. The purpose of the lemma is to identify certain cases where one can change the transition function of an MDP in a specific way and obtain a new MDP with larger values.

▶ **Definition 9.** Let G be an MDP for a safety player. A *replacement set* is a set of triples of states, actions and distributions over the states $Q = \{(s_1, a_1, \delta_1), \ldots, (s_\ell, a_\ell, \delta_\ell)\}$. Given the replacement set Q, the MDP $G[Q]$ is an MDP over the same states as G, with the same set of safe states, and where the transition function δ' is similar to δ, except that $\delta'(s, a) = \delta_i$ if $s = s_i$ and $a = a_i$ for some i.

▶ **Lemma 10.** *Let G be an MDP with a safety player. Consider some replacement set $Q = \{(s_1, a_1, \delta_1), \ldots, (s_\ell, a_\ell, \delta_\ell)\}$, such that for all t and i we have that $\sum_{s \in S}(\delta(s_i, a_i)(s) \cdot \overline{v}_s^t) \leq \sum_{s \in S}(\delta_i(s) \cdot \overline{v}_s^t)$. Let $\overline{v'}^t$ be the value vector for $G[Q]$ with finite horizon t. (1) For all states s and time limits t we have that $\overline{v}_s^t \leq \overline{v'}_s^t$. (2) For all states s, we have that* $\mathrm{val}(G, s) \leq \mathrm{val}(G[Q], s)$.

The proof of the lemma is in the full version [4]. We next show that for player 1, the patience of ε-optimal strategies is high.

▶ **Lemma 11.** *For all $0 < \varepsilon < \frac{1}{3}$, each ε-optimal stationary strategy σ_1 for player 1 in the Purgatory Duel has patience at least $2^{m^{\Omega(n)}}$. For $N = 5$ the patience is $2^{\Omega(m)}$.*

The proof of the lemma is in the full version

We present the main theorem of this section. The proof follows easily from the previous lemmas (and is presented in details in the full version [4]).

▶ **Theorem 12.** *For all $0 < \varepsilon < \frac{1}{3}$, every ε-optimal stationary strategy, for either player, in the Purgatory Duel (that has $N = 2n + 3$ states and at most m actions for each player at all states) has patience $2^{m^{\Omega(n)}}$. For $N = 5$ the patience is $2^{\Omega(m)}$.*

3.3 The patience lower bound for three states

We show that the patience of all ε-optimal strategies, for all $0 < \varepsilon < \frac{1}{3}$, for both players in a concurrent reachability game G with three states of which two are absorbing, and the non-absorbing state has m actions for each player, can be as large as $2^{\Omega(m)}$. The key steps of

the proof are as follows: (1) First we consider the Purgatory duel with $n = 1$, and compress it down to 3 states by considering two steps of the Purgatory Duel in a single step. This gives us a game that has three states with one non-absorbing state (which we call 3-state Purgatory Duel) where ε-optimal strategies for the players require exponential patience in m. However, since two steps are simulated by a single step, this game increases the number of actions M from m to m^2. Hence, our patience bound for 3-state Purgatory Duel is only $2^{\Omega(\sqrt{M})}$. (2) We then show that we can restrict the above game to $2m - 1$ of the m^2 actions and still get the same patience as a function of m. We refer to this game as the restricted 3-state Purgatory Duel. Formally, we establish the following result.

▶ **Theorem 13.** *For all $0 < \varepsilon < \frac{1}{3}$, every ε-optimal stationary strategy, for either player, in the restricted 3-state Purgatory Duel (that has three states, two of which are absorbing, and the non-absorbing state has $O(m)$ actions for each player) has patience $2^{\Omega(m)}$.*

4 Patience Upper Bound

In this section we present the upper bounds. The values of concurrent reachability games can be expressed in the existential theory of reals. Using a refined analysis we present a formula where the number of variables depends only on the number of value classes, rather than the number of states. Using techniques similarly to [13] (such as quantifier elimination, sampling, and root separation for analysis of strategies in games), for concurrent reachability games with K value classes, we show that there is an optimal stationary strategy for the safety player where each probability is a real algebraic number, defined by a polynomial of degree $m^{O(K^2)}$ and the maximum coefficient bit-size is $\tau m^{O(K^2)}$, where τ is the bit-size of numbers in the input. We obtain the following theorem.

▶ **Theorem 14.** *For all concurrent reachability games with at most K different value-classes and probabilities that are rational numbers defined using at most τ bits, the following hold:*

1. *For all $\varepsilon > 0$, there exists an ε-optimal stationary strategy with roundedness at most $\frac{1}{\varepsilon} \lg \frac{1}{\varepsilon} 2^{N\tau m^{O(K^2)}}$.*
2. *For a fixed constant K, a state s and a number λ, given in binary, the problem of deciding whether $\mathrm{val}(s) \geq \lambda$ is in* coNP.

Abstract

We show an algorithm that for a given regular tree language L decides if $L \in \mathbf{\Pi}^0_2$, that is if L belongs to the second level of Borel Hierarchy. Moreover, if $L \in \mathbf{\Pi}^0_2$, then we construct a weak alternating automaton of index $(0, 2)$ which recognises L. We also prove that for a given language L, L is definable by a weak alternating $(1, 3)$-automaton if and only if it is definable by a weak non-deterministic $(1, 3)$-automaton.

1 Introduction

Automata on infinite trees and the corresponding Monadic Second Order Logic provide a rich framework for expressing properties of regular languages of trees. Characterising natural subclasses of regular tree languages can be considered one of the fundamental problems related to automata on infinite trees. When we additionally require that the characterisation should be of an algorithmic nature, the problem usually turns to be very difficult and so far solved only in few instances.

▶ **Problem 1** (The Characterisation Problem). *For a given class of sets of trees $\mathcal{C}$ design an algorithm which decides if a given regular tree language L belongs to $\mathcal{C}$.*

Let us consider the problem for the following classes of tree languages: 1) languages definable in First Order Logic, 2) languages definable in Weak Monadic Second Order Logic, or 3) Borel languages. Providing an effective characterisation for any of the above classes among all regular languages of trees seems to be beyond the reach of currently available methods. In all the above instances it would be desirable to prove a dichotomy *simple* versus *difficult* languages; with *difficult* languages being characterised by existence of an embedding of a standard difficult language. In this work we resolve the **Characterisation Problem**

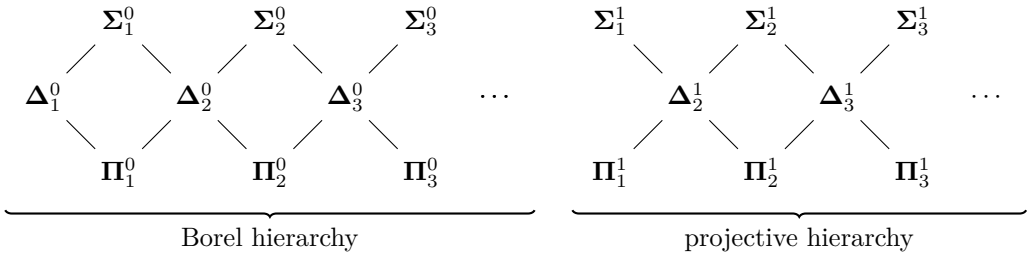

Figure 1 Borel and projective hierarchies.

for the case of $\mathcal{C} = \mathbf{\Pi}^0_2$, i.e. for the set of languages that belong to the second level of the Borel hierarchy. A posteriori, it turns out that $\mathcal{C}$ is the class of languages recognisable by weak alternating automata of *index* $(0, 2)$, that is the class of parity automata that involve priorities 0, 1, and 2; such that the transitions of the automaton are monotone wrt. priorities.

▶ **Theorem 2.** *If L is a regular tree language then either:*

- *L can be recognised by a weak alternating $(0, 2)$-automaton and so $L \in \mathbf{\Pi}^0_2$,*
- *L cannot be recognised by a weak alternating $(0, 2)$-automaton, $L \notin \mathbf{\Pi}^0_2$, and L is $\mathbf{\Sigma}^0_2$-hard.*

Moreover, it can be effectively decided which of the cases holds. If $L \in \mathbf{\Pi}^0_2$ then a weak alternating $(0, 2)$-automaton can effectively be constructed for L.

All regular languages of trees are $\mathbf{\Sigma}^1_2$ sets and from Rabin's Complementation Theorem [20] follows that every regular language of trees is in the class $\mathbf{\Delta}^1_2$. In the case of weak alternating automata (see e.g. [13]) one can provide a much more precise upper bound for the complexity:

▶ **Lemma 3** (See e.g. [6])**.** *If L is a language recognised by a weak alternating $(0, n)$-automaton then $L \in \mathbf{\Pi}^0_n$.*

Combining [24] and [6] we obtain that this is the optimal upper bound for the languages definable in Weak Monadic Second Order Logic.

The **Characterisation Problem** seems to be settled only for few families $\mathcal{C}$. The following list summarises all the cases which according to authors' knowledge have been considered in the literature so far, with the unrestricted input of general regular tree languages:

1. The simple case of clopen sets considered a mathematical folklore.
2. The case of open and closed sets, see [1, page 1] or [14, page 83-84]
3. The case of Boolean combinations of open sets settled in [1] using sophisticated algebraic methods.
4. The techniques of [1] were further reused in [7] to provide an effective characterisation of the class $\mathbf{\Delta}^0_2$. However, as it turned out, the application of the tools of [1] presented in that paper was not correct and the proofs contain some missing arguments[1]; as a corollary of the present article we also obtain another algorithm solving Problem 1 for the case $\mathcal{C} = \mathbf{\Delta}^0_2$. Additionally, this paper provides a new automata theoretic observation: regular languages in $\mathbf{\Delta}^0_2$ belong to the respective delta class of the weak alternating index hierarchy: for any regular language L in $\mathbf{\Delta}^0_2$ there exist a weak alternating $(0, 2)$-automaton and a weak alternating $(1, 3)$-automaton that recognise L.

[1] The statement of Theorem 1 in [7] is correct but a critical combinatorial Proposition 5 requires a different and a more sophisticated argument which will be presented in a journal version of that work.

5. From [9] we know that regular tree languages occupy the first ω–levels of Kolmogorov's $\mathcal{R}$-hierarchy.

The following problem that can be seen as a reversed version of Lemma 3 requires a fine-grained analysis of $\mathbf{\Pi}^0_n$ regular languages of trees:

▶ **Problem 4.** *Given a regular tree language that belongs to $\mathbf{\Pi}^0_n$, does there exist a weak alternating $(0,n)$-automaton that recognises it?*

In the case of $n = 1$ the positive answer is considered folklore (it also follows from [1]), however for every $n > 1$ the problem was open. Our article gives the positive answer for the specific case when $n = 2$.

Related work

Characterising WMSO among Büchi automata. The proof presented in this paper is inspired by a characterisation [23] of Borel languages (as well as recognisable by all weak alternating automata) among the languages recognisable by Büchi automata. Although the similar structure of the proof and the idea behind the characterisation game $\mathcal{F}$, there are certain differences between the two proofs. Firstly, the structure of the game $\mathcal{F}$ is much simpler here than in [23]. Moreover, the construction of the automata $\mathcal{G}_K$ from Section 6 requires certain new ideas because we deal with arbitrary parity automata (in [23] the input is restricted to Büchi automata and the construction is just an unravelling of the respective game $\mathcal{G}$). In particular, in this work we introduce the concept of K-acceptance.

Deterministic and other special classes of languages. In absence of a method solving Problem 1 for all regular languages, a number of attempts was made for special families of regular languages [18, 17, 16, 8] that are recognised by automata with restricted forms of non-determinism.

Cost-MSO and counter automata. Another take on characterising various classes of languages via games can be found in [5, 4, 3]. The authors of this paper are not aware of results directly applicable to weak alternating parity automata of index $(1,3)$. However, as shown in this paper, weak non-deterministic parity automata of index $(1,3)$ are equivalent with weak alternating parity automata of the same index. Therefore, it seems feasible to obtain the automata-theoretic part (without the correspondence to topological classes) of Theorem 2 using the tools presented in [5, 12, 4].

2 Basic notions

Trees. Let us fix a finite alphabet A, that is just a finite non-empty set of symbols (e.g. $A = \{a, b\}$). We work on the space of labelled complete infinite binary trees over A. An *A-labelled tree* t (shortly *tree*) is a function $t\colon \{\mathtt{L},\mathtt{R}\}^* \to A$ where the symbols $\mathtt{L}$, $\mathtt{R}$ are called *directions*. The set of all A-labelled trees is denoted by Tr_A.

Elements $u \in \{\mathtt{L},\mathtt{R}\}^*$ are called *nodes* of a tree. The elements $u\mathtt{L}$, $u\mathtt{R}$ are called *children* of u. The empty sequence ϵ is called the root of a tree. A *branch* of a tree is just an infinite sequence of directions $\beta \in \{\mathtt{L},\mathtt{R}\}^\omega$. A node u is on a branch α if it is a prefix of α, i.e. $u \prec \alpha$. In that case $u = \alpha\restriction_{|u|}$. If u is a node of a tree then by $t\restriction_u$ we indicate the tree t truncated in u in the usual sense: $t\restriction_u(w) \stackrel{\text{def}}{=} t(uw)$.

Topological complexity. In this work we use the standard topological notions for the space of infinite trees, see [11, 26] . The relevant topological notions in the context of infinite trees are described in Sections 1.6.1 and 1.6.2 of [22].

The space Tr_A with the standard product topology is known to be an uncountable Polish space (homeomorphic with the Cantor set). Thus, all the standard notions of Descriptive Set Theory naturally apply to trees.

Assume that $\mathcal{X}$ is a topological space known from the context. By $\mathbf{\Sigma}^0_1$ (resp. $\mathbf{\Pi}^0_1$) we denote the set of open (resp. closed) sets in $\mathcal{X}$. The classes $\mathbf{\Sigma}^0_{n+1}$ and $\mathbf{\Pi}^0_{n+1}$ are defined inductively: $\mathbf{\Sigma}^0_{n+1}$ contains countable unions of sets in $\mathbf{\Pi}^0_n$; $\mathbf{\Pi}^0_{n+1}$ contains countable intersections of sets in $\mathbf{\Sigma}^0_n$. In particular $\mathbf{\Sigma}^0_2$ are countable unions of closed sets; this class is often denoted F_σ. Similarly, $\mathbf{\Pi}^0_2$ are countable intersections of open sets; often denoted G_δ.

For a class Γ of sets (e.g. $\mathbf{\Pi}^0_2$), we say that a set $Y \subseteq \mathcal{X}$ is Γ-*hard* if for every set $Y' \in \mathcal{X}'$ that is in Γ there exists a continuous reduction $f\colon \mathcal{X}' \to \mathcal{X}$ such that $Y' = f^{-1}[Y]$. A set Y is Γ-complete if Y is Γ-hard and belongs to Γ.

Automata Theory. In this work we use both notions of *non-deterministic* and *alternating* parity tree automata. Again, we refer the reader to [19, 25]. The notation we use comes from Sections 1.3 and 1.4 of [22].

A *parity tree automaton* $\mathcal{A}$ is a tuple $\mathcal{A} = \langle A^{\mathcal{A}}, Q^{\mathcal{A}}, q_{\mathrm{I}}^{\mathcal{A}}, \Delta^{\mathcal{A}}, \Omega^{\mathcal{A}} \rangle$, where: $A^{\mathcal{A}}$ is the alphabet we are working on; $Q^{\mathcal{A}}$ is the set of *states* of the automaton $\mathcal{A}$; $q_{\mathrm{I}}^{\mathcal{A}}$ is a particular element of $Q^{\mathcal{A}}$ and it is called the *initial state*; $\Delta^{\mathcal{A}}$ will be defined in a moment; and $\Omega^{\mathcal{A}}$ is a function $\Omega^{\mathcal{A}}\colon Q^{\mathcal{A}} \to \omega$ that assigns a *priority* to every state of the automaton. If the automaton is known from the context then we omit the superscript $\mathcal{A}$.

An automaton $\mathcal{A}$ is *non-deterministic* if $\Delta \subseteq Q \times A \times Q \times Q$ contains *transitions* of the form $(q, a, q_{\mathtt{L}}, q_{\mathtt{R}})$. A non-deterministic automaton $\mathcal{A}$ *accepts* a tree $t \in \mathrm{Tr}_A$ if there exists an *accepting run* ρ, i.e. a $Q^{\mathcal{A}}$-labelled tree that is consistent with the transitions of $\mathcal{A}$ and the parity condition is satisfied on every branch β of t: $\limsup_{n\to\infty} \Omega\big(\rho(\beta\restriction_n)\big)$ is even.

An automaton $\mathcal{A}$ is *alternating* if Δ is a function that assigns to each pair $q \in Q$, $a \in A$ a finite positive Boolean combination of pairs (d, q') where $d \in \{\mathtt{L}, \mathtt{R}\}$ is a direction and $q' \in Q$ is the consecutive state. For instance $\Delta(q, a)$ can be of the form $\big((\mathtt{L}, q'_{\mathtt{L}}) \wedge (\mathtt{L}, q''_{\mathtt{L}})\big) \vee (\mathtt{R}, q''_{\mathtt{R}})$.

An alternating automaton $\mathcal{A}$ induces, for every tree $t \in \mathrm{Tr}_A$, a parity game $\mathcal{A}(t)$ called the *acceptance game* of $\mathcal{A}$ on t. $\mathcal{A}$ *accepts* t if $\exists$ has a winning strategy in the game $\mathcal{A}(t)$.

We require our automata to be *complete*, meaning that for every state $q \in Q$ and letter $a \in A$ there needs to be some transition.

For both non-deterministic and alternating tree automata $\mathcal{A}$ we define the *language* of $\mathcal{A}$ (denoted $\mathrm{L}(\mathcal{A})$) as the set of all trees accepted by $\mathcal{A}$. It is known that the expressive power of non-deterministic and alternating automata is the same:

▶ **Theorem 5** ([10]). *Let $L \subseteq \mathrm{Tr}_A$. There exists an alternating parity tree automaton $\mathcal{A}$ such that $\mathrm{L}(\mathcal{A}) = L$ if and only if there exists a non-deterministic parity tree automaton $\mathcal{B}$ such that $\mathrm{L}(\mathcal{B}) = L$. Moreover, both translations are effective.*

If for $L \subseteq \mathrm{Tr}_A$ there exists a non-deterministic (equivalently alternating) automaton $\mathcal{A}$ such that $L = \mathrm{L}(\mathcal{A})$ then we say that L is *regular*. A parity automaton is *weak* if the values of Ω are non-decreasing along transitions. The *index* of an automaton is the pair (i, j) where i is the minimal and j is the maximal value of Ω on Q.

3 Overview of the proof of Theorem 2

Let L be a regular language and let us fix once and for all two non-deterministic parity tree automata $\mathcal{A}$ and $\mathcal{B}$ that recognise respectively: $\mathrm{L}(\mathcal{B}) = L$ is the given language and $\mathrm{L}(\mathcal{A}) = L^{\mathrm{c}}$ is its complement. The proof will consist of the following steps:

- First we define a game $\mathcal{F}$ of infinite duration and perfect information. The game $\mathcal{F}$ is played by two players: Eve ($\exists$) and Adam ($\forall$). Player $\exists$ constructs a tree t together with three runs: one of the automaton $\mathcal{A}$ and two of the automaton $\mathcal{B}$. The second of them is influenced by $\forall$ who can ask $\exists$ to *restart* whenever he wants. The crucial property of the game $\mathcal{F}$ is that it is played over a finite arena and the winning condition is ω-regular.
- If $\exists$ wins $\mathcal{F}$ then her winning strategy can be used to prove that the language $\mathrm{L}(\mathcal{B})$ is actually $\mathbf{\Sigma}^0_2$-hard. In particular it cannot be recognised by a weak alternating automaton of index $(0, 2)$. To prove this topological hardness we test the winning strategy of $\exists$ against a well-designed family of strategies of $\forall$. In terms of Descriptive Set Theory it can be seen as finding an embedding of the Cantor set 2^ω that intersects $\mathrm{L}(\mathcal{B})$ on rationals.
- If $\forall$ wins $\mathcal{F}$ then we use his finite-memory winning strategy to construct a finite approximation of the automaton $\mathcal{B}$ that is denoted $\mathcal{G}_{K_0}$. The construction ensures that $\mathcal{G}_{K_0}$ is a weak alternating automaton of index $(0, 2)$ that recognises $\mathrm{L}(\mathcal{B})$.

4 The game $\mathcal{F}$

We start by defining a game $\mathcal{F}$ of infinite duration that is based on the non-deterministic parity tree automata $\mathcal{A} = \langle A, Q^{\mathcal{A}}, q_{\mathrm{I}}^{\mathcal{A}}, \Delta^{\mathcal{A}}, \Omega^{\mathcal{A}} \rangle$ and $\mathcal{B} = \langle A, Q^{\mathcal{B}}, q_{\mathrm{I}}^{\mathcal{B}}, \Delta^{\mathcal{B}}, \Omega^{\mathcal{B}} \rangle$ for L^{c} and L respectively. The purpose of $\mathcal{F}$ is to satisfy the following two propositions.

▶ **Proposition 6.** *If $\exists$ wins $\mathcal{F}$ then $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^0_2$-hard.*

▶ **Proposition 7.** *If $\forall$ wins $\mathcal{F}$ then $\mathrm{L}(\mathcal{B})$ is recognised by a weak alternating $(0, 2)$-automaton.*

The above propositions together with Lemma 3 give a complete characterisation of the topological complexity and the weak index of $\mathrm{L}(\mathcal{B})$.

Positions of $\mathcal{F}$. The positions of $\mathcal{F}$ are of the form $(p, q, s) \in Q^{\mathcal{A}} \times Q^{\mathcal{B}} \times Q^{\mathcal{B}}$ where: $p \in Q^{\mathcal{A}}$ is called an *$\mathcal{A}$-state*, $q \in Q^{\mathcal{B}}$ is called a *$\mathcal{B}$-state*, $s \in Q^{\mathcal{B}}$ is called an *active state*. The initial position of $\mathcal{F}$ is $(q_{\mathrm{I}}^{\mathcal{A}}, q_{\mathrm{I}}^{\mathcal{B}}, q_{\mathrm{I}}^{\mathcal{B}})$.

Rounds of $\mathcal{F}$. Assume that a round of $\mathcal{F}$ starts in a position (p, q, s). The choices done by the players are as follows:

1. $\forall$ can choose to *restart* by letting $s' = q$ or to *stay* by keeping $s' = s$.
2. $\exists$ declares: (i) a letter $a \in A$; (ii) a transition $(p, a, p_{\mathtt{L}}, p_{\mathtt{R}}) \in \Delta^{\mathcal{A}}$ of $\mathcal{A}$; (iii) a transition $(q, a, q_{\mathtt{L}}, q_{\mathtt{R}}) \in \Delta^{\mathcal{B}}$ of $\mathcal{B}$; (iv) another transition $(s', a, s'_{\mathtt{L}}, s'_{\mathtt{R}}) \in \Delta^{\mathcal{B}}$ of $\mathcal{B}$.
3. $\forall$ responds by selecting a direction $d \in \{\mathtt{L}, \mathtt{R}\}$.

After such a round the game proceeds to the position (p_d, q_d, s'_d). Four example rounds of $\mathcal{F}$ are presented in Figure 2.

If π is a finite or infinite play of $\mathcal{F}$, a *trace* is a finite or infinite sequence of active states s in consecutive rounds in which $\forall$ has not *restarted*. Thus, those active states come from successive transitions of the automaton $\mathcal{B}$.

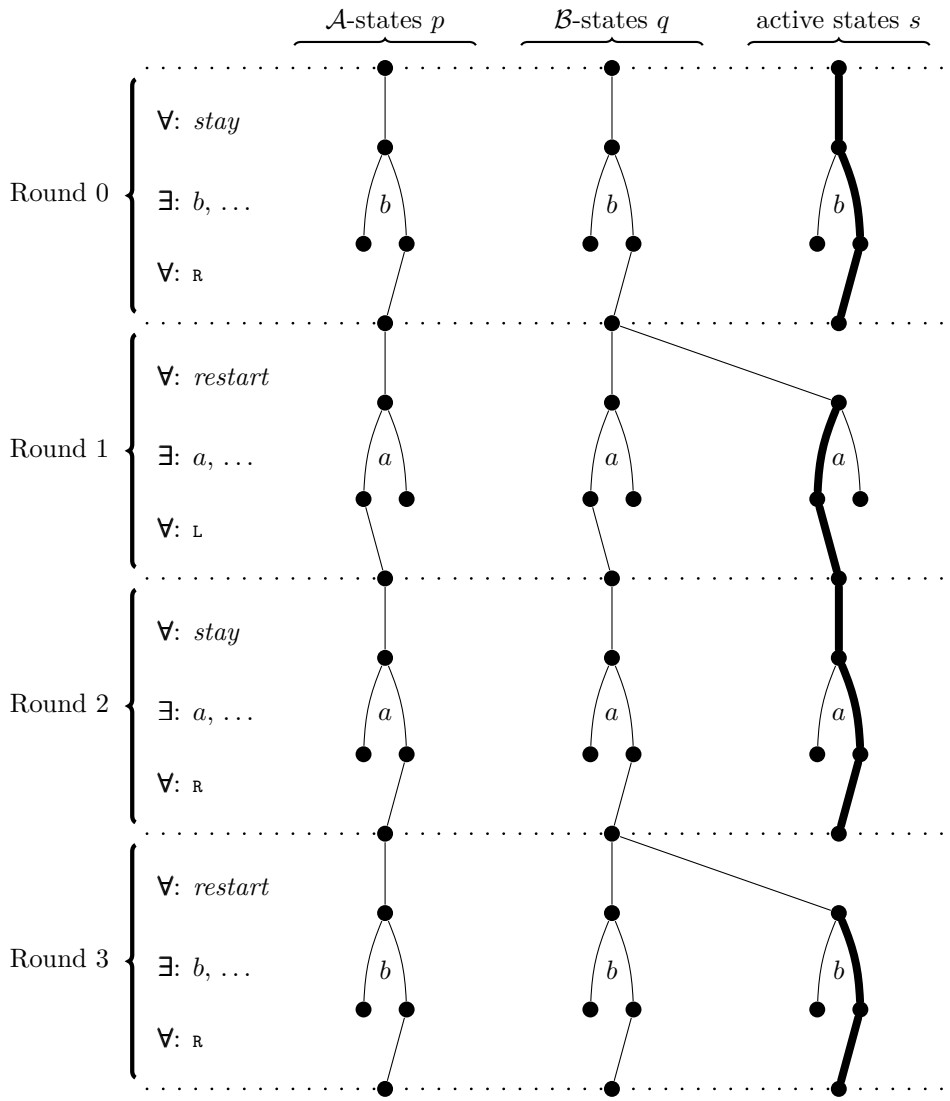

Figure 2 Four consecutive rounds of the game $\mathcal{F}$. The black dots are the states of the automata $\mathcal{A}$ and $\mathcal{B}$. Each round consists of three choices: first ∀ either *restarts* or *stays*, then ∃ provides a letter and three transitions (depicted by those Λ-shaped gadgets), finally ∀ chooses a direction. The three boldfaced paths are three traces formed by the active states: the first one lasts in Round 0; the second one in Rounds 1 and 2; the third one starts in Round 3.

Winning condition of $\mathcal{F}$. Now we will define the winning condition for ∃ in $\mathcal{F}$. It will depend on a Boolean combination of the following three properties, speaking about the sequence of rounds that were played:

(WR) ∀ has *restarted* infinitely many times.

(WA) The sequence of $\mathcal{A}$-states p is accepting in $\mathcal{A}$.

(WB) The sequence of active states s is accepting in $\mathcal{B}$ (i.e. it satisfies the parity condition).

A play of $\mathcal{F}$ is winning for ∃ if it satisfies

$$\big((\mathrm{WR}) \wedge (\mathrm{WA})\big) \ \vee \ \big(\neg(\mathrm{WR}) \wedge (\mathrm{WB})\big). \tag{1}$$

In other words, there are two cases: If ∀ has restarted infinitely many times then ∃ wins iff the sequence of visited $\mathcal{A}$-states satisfies the parity condition. If ∀ has restarted only finitely many times then ∃ wins iff the sequence of visited active states satisfies the parity condition. Notice that a priori both (WA) and (WB) can happen simultaneously, because for example there may exist two runs $\rho_{\mathcal{A}}$ and $\rho_{\mathcal{B}}$ of the automata $\mathcal{A}$ and $\mathcal{B}$ that both satisfy the parity condition on some particular branch.

By the definition, the winning condition of $\mathcal{F}$ is an ω-regular property of sequences of rounds. Additionally, there are only finitely many positions of $\mathcal{F}$ and each round allows finitely many possible choices by the players. Therefore, we obtain the following fact.

▶ **Fact 8** ([2]). *The winner of $\mathcal{F}$ can be effectively found and he/she can win using a finite memory winning strategy.*

5 Proof of Proposition 6

In this section we prove that if ∃ wins $\mathcal{F}$ then $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^0_2$-hard. Let $\sigma_\exists$ be her winning strategy. Let $C \subseteq \{0,1\}^\omega$ be the set of sequences containing only finitely many 1s.

It is known that C is $\mathbf{\Sigma}^0_2$-complete [26]. We will construct a continuous reduction from C to $\mathrm{L}(\mathcal{B})$ and so we obtain that $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^0_2$-hard.

We will say that σ is a *quasi-strategy* of ∀ in $\mathcal{F}$ if σ specifies when to *restart* and leaves undecided the choice of directions d. Notice that if σ is a quasi-strategy of ∀ then we can construct a tree t consisting of the letters a played by $\sigma_\exists$ against σ: the letter $t(u)$ is the $(|u|+1)$th letter played by $\sigma_\exists$ against ∀ playing accordingly to σ and choosing successive directions of u.

To each sequence $\alpha \in \{0,1\}^\omega$ we will assign a quasi-strategy σ_α of ∀ in $\mathcal{F}$. Consider $\alpha \in \{0,1\}^\omega$ and an Mth round of $\mathcal{F}$ for $M = 0, 1, \ldots$

- If $\alpha(M) = 0$ then σ_α *stays* by keeping $s' = s$.
- If $\alpha(M) = 1$ then σ_α *restarts* by putting $s' = q$.

Let the tree t_α be the effect of confronting the strategy $\sigma_\exists$ against the quasi-strategy σ_α. Since the behaviour of the strategy σ_α in an Mth round of $\mathcal{F}$ depends only on the first M bits of α, the function $\alpha \mapsto t_\alpha$ is continuous. A routine verification (see below) shows that

$$\alpha \in C \iff t_\alpha \in \mathrm{L}(\mathcal{B}). \tag{2}$$

When $\alpha \in C$. First assume that $\alpha \in C$, i.e. that there are only finitely many 1s in α. Let M be the maximal number such that $\alpha(M-1) = 1$ (or $M = 0$ if there is no such M). Let $\rho^{\mathcal{B}}$ be the run of $\mathcal{B}$ defined as follows:

- For $|u| \leq M$ let $\rho^{\mathcal{B}}(u)$ be the $\mathcal{B}$-state q from the beginning of the $|u|$th round of the play consistent with $\sigma_\exists$ and σ_α in which the sequence of directions chosen by ∀ was u.
- For $|u| > M$ let $\rho^{\mathcal{B}}(u)$ be the active state s from the beginning of the $|u|$th round of the play consistent with $\sigma_\exists$ and σ_α in which the sequence of directions chosen by ∀ was u.

It is easy to see that $\rho^{\mathcal{B}}$ is in fact a run of $\mathcal{B}$ over t_α. It remains to see that it is accepting. Consider an infinite branch of t_α. This branch corresponds to an infinite play of $\mathcal{F}$ consistent with $\sigma_\exists$ and the quasi-strategy σ_α. Since in all the rounds after the Mth one, ∀ has *stayed* by putting $s' = s$, the states of $\rho^{\mathcal{B}}$ form an infinite trace in that play. Therefore, the condition ¬(WR) holds. As the play is won by ∃, also (WB) must hold. It means that the trace must be accepting in $\mathcal{B}$, thus the run $\rho^{\mathcal{B}}$ is accepting on our branch. This way we have proved that $\rho^{\mathcal{B}}$ is accepting and $t_\alpha \in \mathrm{L}(\mathcal{B})$.

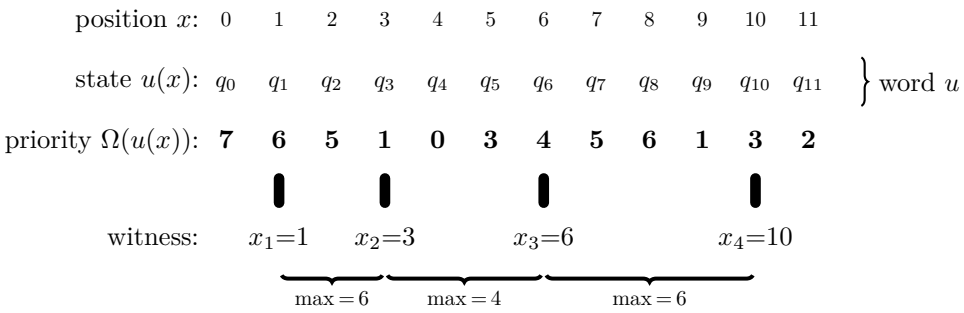

Figure 3 A word u that is 4-accepting. The sequence x_1, x_2, x_3, x_4 witnesses that. If we loop u between the positions 1 and 6, we get the sequence $q_0, q_1, \ldots, q_6, q_1, q_2, \ldots, q_6, q_1 \ldots$ that satisfies the parity condition.

When $\alpha \notin C$. Now assume that $\alpha \notin C$, i.e. that there are infinitely many 1s in α. Our aim is to prove that the run $\rho^{\mathcal{A}}$ formed by the $\mathcal{A}$-states p played by $\exists$ in all the plays consistent with $\sigma_\exists$ and σ_α is accepting. Consider an infinite branch of t_α and the corresponding play π of $\mathcal{F}$. Since infinitely many times $\forall$ has *restarted*, this play satisfies (WR). As the play is won by $\exists$, also (WA) must hold. It means that the sequence of $\mathcal{A}$-states p must be accepting in $\mathcal{A}$. Thus, we have proved that $t_\alpha \in \mathrm{L}(\mathcal{A})$ and therefore $t_\alpha \notin \mathrm{L}(\mathcal{B})$. This concludes the proof of $\mathbf{\Sigma}_2^0$-hardness of $\mathrm{L}(\mathcal{B})$.

6 Proof of Proposition 7

In this section we prove that if $\forall$ wins $\mathcal{F}$ then $\mathrm{L}(\mathcal{B})$ can be recognised by a weak alternating parity automaton of index $(0, 2)$. Since the winning condition of $\mathcal{F}$ is ω-regular, we can assume that $\forall$ wins using a strategy $\sigma_\forall$ based on a finite-memory structure M. Our aim is to construct an automaton recognising $\mathrm{L}(\mathcal{B})$.

***K*-accepting runs.** We start by defining a notion of K-accepting sequences — sequences of states of $\mathcal{B}$ that are similar to accepting ones. We will show that the strategy $\sigma_\forall$ must avoid such sequences.

Let u be a finite or infinite sequence of states of $\mathcal{B}$. Consider a number $K \in \omega$. We say that u is *K-accepting* if there exists a sequence of positions $0 \leq x_1 < x_2 < \ldots < x_K < |u|$ such that for every $n = 1, 2, \ldots, K-1$ we have:

$$\max\left\{\Omega^{\mathcal{B}}\big(u(x)\big) \;\middle|\; x_n \leq x \leq x_{n+1}\right\} \text{ is even.} \tag{3}$$

In other words, for $n = 1, \ldots, K-1$, the maximal priority of states between positions x_n and x_{n+1} of u must be even. We call such a sequence of positions $(x_1, \ldots, x_K)$ a *witness* of K-acceptance, see Figure 3.

The above definition is constructed in such a way to guarantee the following properties:

(P1) If u is K-accepting then it contains K positions such that each cycle built using an interval between two of them gives us a sequence of states satisfying the parity condition.

(P2) For every K, the set of all finite words that are K-accepting is regular. It is not obvious how a regular expression for this language should look like, however, the definition of the property of being K-accepting is clearly MSO-definable, thus by the results of Rabin, Scott [21], and Trakhtenbrot [27] (cf. e.g. [19]), we know that this language is regular.

(P3) If u is K-accepting then every word of the form uw is also K-accepting.
(P4) If $\alpha \in \left(Q^{\mathcal{B}}\right)^{\omega}$ satisfies the parity condition then for every $K \in \omega$ there exists a finite prefix of α that is K-accepting.

▶ **Lemma 9.** *There exists a value $K_0 \in \omega$ such that if π is an infinite play of $\mathcal{F}$ consistent with $\sigma_{\forall}$ then no trace of π is K_0-accepting.*

Proof. Let $K_0 \stackrel{\text{def}}{=} \left(\left|Q^{\mathcal{A}}\right| \times \left|Q^{\mathcal{B}}\right| \times \left|Q^{\mathcal{B}}\right|\right) \times \left|M\right| + 1$ where inside the brackets is the number of positions of $\mathcal{F}$ and M is the memory structure of $\sigma_{\forall}$.

Assume for the sake of contradiction that there exists a play π that is consistent with $\sigma_{\forall}$ and contains a K_0-accepting trace. For a round number $x \in \omega$ during π let (v_x, m_x) be the configuration of the game at the moment when x rounds were played: $v_x = (p_x, q_x, s_x)$ for an $\mathcal{A}$-state p_x, $\mathcal{B}$-state q_x, and active state s_x; and m_x is the current memory value of $\sigma_{\forall}$.

By the assumption we know that for some $x < y < \omega$ the sequence of active states s_x, s_{x+1}, …, s_y is a trace (i.e. there is no *restart* during these rounds) and it is K_0-accepting. Let $x \leq x_1, \ldots, x_{K_0} \leq y$ be a sequence of numbers of rounds that is a witness for the K_0-acceptance of this trace, see Equation (3).

Figure 4 provides an illustration for this construction. The upper picture presents a play π seen in the product of the game $\mathcal{F}$ and the memory structure M used by $\sigma_{\forall}$. Small dots mark positions before successive rounds of this play. The lower picture presents the play π in a chronological way. The boldfaced vertical snake-like shape is a trace that is 5-accepting; the rounded shapes indicate a witness of this fact: $x_1 = 2$, $x_2 = 3$, $x_3 = 6$, $x_4 = 8$, and $x_5 = 10$. Since 5 is bigger than the number of available pairs (v, m) we have a repetition: $(v_3, m_3) = (v_8, m_8)$. This allows us to construct a new play π', by staying forever on the loop between the rounds 3 and 8. The play π' obtained this way contains an infinite trace that satisfies the parity condition.

By the choice of K_0 we know that for some $1 \leq n < n' \leq K_0$ we have: $v_{x_n} = v_{x_{n'}}$ and $m_{x_n} = m_{x_{n'}}$; i.e. there must be a repetition of the position of $\mathcal{F}$ and the memory of $\sigma_{\forall}$ among the positions witnessing K_0-acceptance of the trace.

Consider a play π' of $\mathcal{F}$ which starts as π for the first x_n rounds. Then π' follows the loop between the rounds $x_n + 1$ and $x_{n'}$. Notice that π' is in fact a play because $v_{x_n} = v_{x_{n'}}$. Since we have chosen the positions x_n, $x_{n'}$ from a trace, this loop does not contain a *restart*. Clearly π' is consistent with $\sigma_{\forall}$ because the memory values m_{x_n} and $m_{x_{n'}}$ are equal.

Because x_n and $x_{n'}$ are chosen from a witness of K_0-acceptance of the trace, Property (P1) implies that π' contains an infinite accepting trace. Therefore, the play π' satisfies $\big(\neg(\mathrm{WR}) \wedge (\mathrm{WB})\big)$ and thus is winning for $\exists$ in $\mathcal{F}$, what contradicts the assumption that $\sigma_{\forall}$ was a winning strategy of $\forall$. ◀

Construction of automata $\mathcal{G}_K$. Take a number $K \in \omega$. We will now define a weak alternating parity automaton $\mathcal{G}_K$ of index $(0, 2)$. The language $\mathrm{L}(\mathcal{G}_K)$ will be an over-approximation of $\mathrm{L}(\mathcal{B})$. Later on we will prove that the strategy $\sigma_{\forall}$ witnesses the fact that $\mathrm{L}(\mathcal{B})$ actually equals $\mathrm{L}(\mathcal{G}_K)$ for some $K \in \omega$ (in fact for $K = K_0$ from Lemma 9).

The idea behind the automaton $\mathcal{G}_K$ is the following: $\mathcal{G}_K$ accepts a tree t if there exists a run $\rho_0^{\mathcal{B}}$ of $\mathcal{B}$ over t such that for every node u of the tree, it is possible to find another run of $\mathcal{B}$ over the subtree $t\restriction_u$ starting from the state $\rho_0^{\mathcal{B}}(u)$ that is K-accepting on every branch of this subtree.

Assume that $\mathcal{D}(K) = \langle Q^{\mathcal{B}}, Q^{\mathcal{D}}, q_1^{\mathcal{D}}, \Delta^{\mathcal{D}}, F^{\mathcal{D}} \rangle$ is a deterministic automaton over finite words (DFA) with the alphabet $Q^{\mathcal{B}}$ that recognises the language of K-accepting sequences of states of $\mathcal{B}$, see Property (P2).

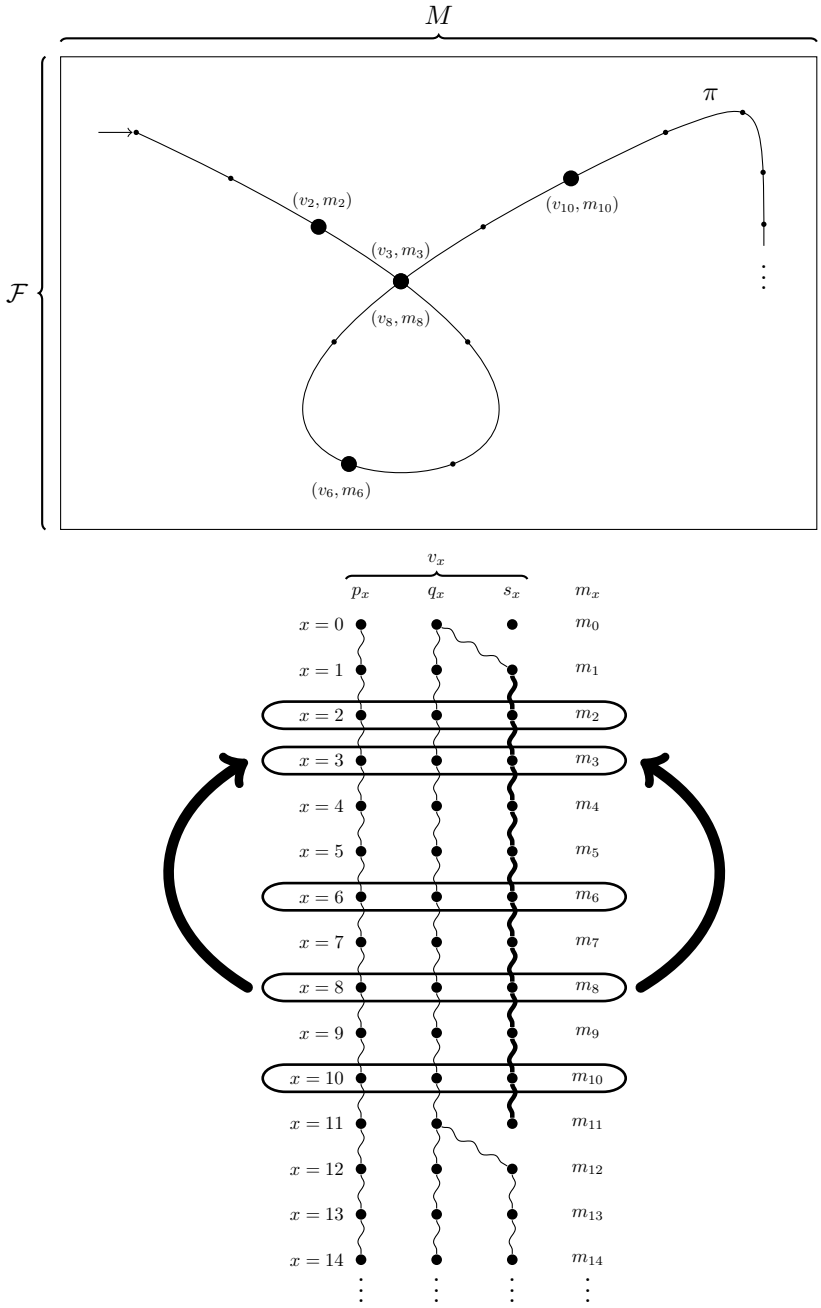

Figure 4 An illustration to the proof of Lemma 9.

The states of $\mathcal{G}_K$ are of the form (q, τ) where $q \in Q^{\mathcal{B}}$ is a state of $\mathcal{B}$ and $\tau \in \{?\} \sqcup Q^{\mathcal{D}}$ is either $?$ or a state of $\mathcal{D}(K)$.

The initial state of $\mathcal{G}_K$ is $(q_{\mathrm{I}}^{\mathcal{B}}, ?)$. The transitions of $\mathcal{G}_K$ are built by the following rules. Given a state (q, τ) and a letter a, the successive state and direction are constructed in the following way (formally the following choices should be encoded as a finite positive Boolean combination of the consecutive directions and states).

1. If $\tau = ?$ then $\forall$ can choose to *start* by letting $\tau' = q_{\mathrm{I}}^{\mathcal{D}}$ or to *skip* by keeping $\tau' = ?$. If $\tau \in Q^{\mathcal{D}}$ then $\forall$ has no choice and in that case $\tau' = \tau$.

2. If $\tau' \in Q^{\mathcal{D}}$ then we let[2] $\tau'' = \Delta^{\mathcal{D}}(\tau, q)$, otherwise $\tau'' = \tau' = \mathbf{?}$ is unchanged.
3. $\exists$ proposes a transition of $\mathcal{B}$ of the form $\big(q, a, q_{\mathtt{L}}, q_{\mathtt{R}}\big)$.
4. $\forall$ chooses a direction $d \in \{\mathtt{L}, \mathtt{R}\}$.

After these choices are done, the automaton moves in the direction d to the state (q_d, τ''). Let the priority of a state (q, τ) of $\mathcal{G}_K$ be: (i) If $\tau = \mathbf{?}$ then the priority is 0. (ii) If $\tau \in Q^{\mathcal{D}} \setminus F^{\mathcal{D}}$ then the priority is 1. (iii) If $\tau \in F^{\mathcal{D}}$ then the priority is 2.

Notice that because of the structure of the transitions of $\mathcal{G}_K$, the above defined condition is a weak parity condition of index $(0, 2)$. It is important to notice that Property (P3) implies that once a state of priority 2 is reached then we never move to a state of priority 1.

▶ **Lemma 10.** *For every $K \in \omega$ we have* $\mathrm{L}(\mathcal{B}) \subseteq \mathrm{L}(\mathcal{G}_K)$.

Proof. Take a tree $t \in \mathrm{L}(\mathcal{B})$ and let $\rho^{\mathcal{B}}$ be an accepting run of $\mathcal{B}$ on t. Then clearly $\exists$ can win the acceptance game $\mathcal{G}_K(t)$ by just playing consecutive transitions of $\rho^{\mathcal{B}}$. When $\forall$ chooses at some point to *start*, ultimately a state with $\tau \in F^{\mathcal{D}}$ will be reached because of Property (P4). Therefore, every play will be won by $\exists$. ◀

Equivalence. We will now conclude the proof of Proposition 7 using the following lemma.

▶ **Lemma 11.** *For K_0 from Lemma 9 we have* $\mathrm{L}(\mathcal{G}_{K_0}) = \mathrm{L}(\mathcal{B})$.

Proof. Assume contrarily that $\mathrm{L}(\mathcal{G}_{K_0}) \neq \mathrm{L}(\mathcal{B})$. Lemma 10 says that $\mathrm{L}(\mathcal{B}) \subseteq \mathrm{L}(\mathcal{G}_{K_0})$, so there must exists a tree $t \in \mathrm{L}(\mathcal{G}_{K_0}) \setminus \mathrm{L}(\mathcal{B})$. From that assumption we know that:

- there exists an accepting run $\rho^{\mathcal{A}}$ of $\mathcal{A}$ over t,
- $\exists$ has a winning strategy $\delta_{\exists}$ in the acceptance game $\mathcal{G}_{K_0}(t)$.

Our aim is to prove that $\exists$ can win in $\mathcal{F}$ against $\sigma_{\forall}$ by using a strategy $\sigma_{\exists}$ that is based on $\rho^{\mathcal{A}}$ and $\delta_{\exists}$. Let us define the strategy $\sigma_{\exists}$.

First, $\sigma_{\exists}$ plays the letters a and the transitions of $\mathcal{A}$ from the $\mathcal{A}$-states p according to the tree t and the run $\rho^{\mathcal{A}}$. This way we guarantee that every play of this strategy will satisfy (WA). Additionally $\sigma_{\exists}$ chooses the transitions of $\mathcal{B}$ from the $\mathcal{B}$-states q according to the strategy $\delta_{\exists}$ simulating the situation that $\forall$ has never *started*. Thus, at every moment of a play consistent with $\sigma_{\exists}$, there is a unique play of $\delta_{\exists}$ ending in a node u and a state of $\mathcal{G}_{K_0}$ of the form $(q, \mathbf{?})$ with u being the sequence of directions played so-far by $\forall$ in $\mathcal{F}$ and q being the current $\mathcal{B}$-state. What remains is the choice of transitions of $\mathcal{B}$ from the active states s. For that, $\exists$ will keep track of a play of the acceptance game $\mathcal{G}_{K_0}(t)$ with $\tau \in Q^{\mathcal{D}}$. At the initial position of $\mathcal{F}$ the play is the one which begins by $\forall$ *starting* (i.e. $\tau = q_{\mathrm{I}}^{\mathcal{D}}$). Whenever $\forall$ *restarts* in $\mathcal{F}$, $\exists$ forgets about the previously tracked play of $\mathcal{G}_{K_0}(t)$ and begins to track the play that comes with the current $\mathcal{B}$-state q by simulating the situation in which $\forall$ has just *started* in $\mathcal{G}_{K_0}(t)$.

Consider the play π that is consistent with both $\sigma_{\exists}$ and $\sigma_{\forall}$. We need to prove that π is winning for $\exists$. As we have already observed, such a play satisfies (WA). We will prove that it also satisfies (WR) by proving the following claim. This concludes the proof of Lemma 11 by giving a contradiction: $\sigma_{\forall}$ is a winning strategy of $\forall$ but π is a play consistent with $\sigma_{\forall}$ that is winning for $\exists$.

▶ **Claim 12.** *In the play π Player $\forall$ must have* restarted *infinitely many times.*

[2] We follow the transition of $\mathcal{D}$ from τ over q: $\tau \in Q^{\mathcal{D}}$ is a state of $\mathcal{D}$ and $q \in Q^{\mathcal{B}}$ is a letter read by $\mathcal{D}$.

Assume contrarily that from some point on $\forall$ has not *restarted*. Thus, π contains an infinite trace on which $\exists$ has played successive transitions of $\mathcal{B}$ in the active states s according to her strategy $\delta_\exists$ in $\mathcal{G}_{K_0}(t)$. Since the strategy $\delta_\exists$ is winning, some prefix of the considered trace must be K_0-accepting. This gives a contradiction with Lemma 9. ◀

7 Weak non-deterministic $(1,3)$-automata

In this section we prove the following additional result that may be considered folklore, although we have not found it in the literature. The construction is based on the standard de-alternation techniques together with the idea from [15].

▶ **Theorem 13.** *If L is a language that can be recognised by a weak alternating parity automaton $\mathcal{A}$ of index $(1,3)$ then L can be recognised by a weak non-deterministic parity automaton $\mathcal{B}$ of index $(1,3)$.*

This observation was important to properly define the game $\mathcal{F}$. However, somehow surprisingly, it does not play any role in the final proof of Theorem 2.

The idea of the proof is as follows. Given a tree $t \in \mathrm{Tr}_A$ the automaton $\mathcal{B}$ will guess a positional strategy of $\exists$ in the acceptance game $\mathcal{A}(t)$. Then it will verify that the guessed strategy is in fact winning. Therefore, it will track all the possible choices performed by $\forall$ along all the branches of the tree t. Thus, the set of states of $\mathcal{B}$ is the power set $\mathsf{P}(Q^{\mathcal{A}})$. Notice that the guessed strategy of $\exists$ is winning if for every branch of t the following conditions are satisfied: (i) no state of $\mathcal{A}$ of priority 3 is ever reached, (ii) every play ultimately reaches a state of priority 2.

An easy application of König's lemma shows that the second condition above actually implies that at some point no state of priority 1 can belong to the set of reachable states of $\mathcal{A}$. This way, the automaton $\mathcal{B}$ can be seen as a naïve power set construction over $\mathcal{A}$. Such a construction can be performed for any alternating automaton (even not weak), however, in most of the cases the assignment of priorities to the states of the power set automaton is not correct. The crucial ingredient of this construction relies on the fact that the weak parity condition of index $(1,3)$ admits a correct priority assignment for the power set automaton.

8 Conclusions and further work

This work provides a relatively simple effective characterisation of the class of regular languages in $\mathbf{\Pi}^0_2$. Additionally, it proves that the considered class of languages coincides with the respective level of the alternating index hierarchy (i.e. weak alternating $(0,2)$-automata).

The simplicity of involved techniques comes from certain specific properties of the considered classes. Firstly, there are ω-regular languages that are complete for the class $\mathbf{\Pi}^0_2$. In our case the examples are: the language C of infinite binary sequences containing infinitely many 1s; and the property (WR) used in the winning condition of the game $\mathcal{F}$. Secondly, similarly to the case of Büchi languages, the class of weak alternating $(1,3)$-automata admits a dealternation technique, see Theorem 13. Although this dealternation result does not play any role in the proof of Theorem 2, it was used in the design of the game $\mathcal{F}$ and stays behind the fact that the game actually characterises the class of languages recognisable by weak alternating $(0,2)$-automata.

We plan to investigate generalisations of Theorem 2 to $\mathbf{\Pi}^0_n$ for $n \geq 3$. Since decidability results related to the **Characterisation Problem** are not that easy to obtain, we propose for further investigation the topological problems related to the **Characterisation Problem** and Problem 4 formulated in Introduction.

Moreover, our work gives a quite clear situation up to the second level of Borel Hierarchy in terms of decidability and correspondence between the Borel index and the weak index, but there are still some "holes" that have to be filled regarding e.g. *Wadge Hierarchy*:

▶ **Problem 14.** *Find all Wadge degrees inhabited by regular* $\mathbf{\Delta}^0_2$ *languages of trees.*

From [6] it follows that every Wadge degree less than ω^ω is inhabited by a regular language. We believe that this is the maximum regular languages can get:

▶ **Conjecture 15.** *There is no regular tree language in* $\mathbf{\Delta}^0_2$ *with Wadge degree above* ω^ω.

On the Exact Amount of Missing Information That Makes Finding Possible Winners Hard

Palash Dey[1] and Neeldhara Misra*[2]

Abstract

We consider election scenarios with incomplete information, a situation that arises often in practice. There are several models of incomplete information and accordingly, different notions of outcomes of such elections. In one well-studied model of incompleteness, the votes are given by partial orders over the candidates. In this context we can frame the problem of finding a *possible winner*, which involves determining whether a given candidate wins in at least one completion of a given set of partial votes for a specific voting rule.

The Possible Winner problem is well-known to be NP-complete in general, and it is in fact known to be NP-complete for several voting rules where the number of undetermined pairs in every vote is bounded only by some constant. In this paper, we address the question of determining precisely the smallest number of undetermined pairs for which the Possible Winner problem remains NP-complete. In particular, we find the exact values of t for which the Possible Winner problem transitions to being NP-complete from being in P, where t is the maximum number of undetermined pairs in every vote. We demonstrate tight results for a broad subclass of scoring rules which includes all the commonly used scoring rules (such as plurality, veto, Borda, and k-approval), Copeland$^{\alpha}$ for every $\alpha \in [0, 1]$, maximin, and Bucklin voting rules. A somewhat surprising aspect of our results is that for many of these rules, the Possible Winner problem turns out to be hard even if every vote has at most one undetermined pair of candidates.

1 Introduction

In many real life situations including multiagent systems, agents often need to aggregate their preferences and agree upon a common decision (candidate). Voting is an immediate natural tool in these situations. Common and classic applications of voting in multiagent systems include collaborative filtering and recommender systems [26], spam detection [9], computational biology [20], winner determination in sports competition [5] etc. We refer the readers to [25] for an elaborate treatment of computational voting theory.

Usually, in a voting setting, it is assumed that the votes are complete orders over the candidates. However, due to many reasons, for example, lack of knowledge of voters about

* The second author acknowledges support from the DST-INSPIRE faculty grant (IFA12-ENG-31).

some candidates, a voter may be indifferent between some pairs of candidates. Hence, it is both natural and important to consider scenarios where votes are partial orders over the candidates. When votes are only partial orders over the candidates, the winner cannot be determined with certainty since it depends on how these partial orders are extended to linear orders. This leads to a natural computational problem called the Possible Winner problem [21]: given a set of partial votes $\mathcal{P}$ and a distinguished candidate c, is there a way to extend the partial votes to complete votes where c wins? The Possible Winner problem has been studied extensively in the literature [23, 27, 28, 29, 7, 8, 4, 1, 22, 18] following its definition in [21]. Betzler et al. [6] and Baumeister et al. [2] show that the Possible Winner winner problem is NP-complete for all scoring rules except for the plurality and veto voting rules; the Possible Winner winner problem is in P for the plurality and veto voting rules. The Possible Winner problem is known to be NP-complete for many common voting rules, for example, a class of scoring rules, maximin, Copeland, Bucklin etc. even when the maximum number of undetermined pairs of candidates in every vote is bounded above by small constants [29]. Walsh showed that the Possible Winner problem can be solved in polynomial time for all the voting rules mentioned above when we have a constant number of candidates [28].

1.1 Our Contribution

Our main contribution lies in pinning down exactly the minimum number of undetermined pairs allowed per vote so that the Possible Winner winner problem continues to be NP-complete for a large class of scoring rules, Copeland$^\alpha$, maximin, and Bucklin voting rules. To begin with, we describe our results for scoring rules. We work with a class of scoring rules that we call smooth, which are essentially scoring rules where the score vector for $(m+1)$ candidates can be obtained by either duplicating an already duplicated score in the score vector for m candidates, or by extending the score vector for m candidates at one of the endpoints with an arbitrary new value. The smooth rules account for all commonly used scoring rules (such as Borda, plurality, veto, k-approval). Using t to denote the maximum number of undetermined pairs of candidates in every vote, we show the following (note that the Possible Winner problem is in P for all scoring rules when $t = 0$):

- The Possible Winner problem is NP-complete even when $t = 1$ for scoring rules which have two distinct nonzero differences between consecutive coordinates in the score vector (we call them differentiating) and in P when $t = 1$ for other scoring rules [Theorem 7].
- Else the Possible Winner problem is NP-complete when $t \geqslant 2$ and in P when $t \leqslant 1$ for scoring rules that contain $(\alpha+1, \alpha+1, \alpha)$ for any $\alpha \in \mathbb{N}$ [Theorem 8].
- Else the Possible Winner problem is NP-complete when $t \geqslant 3$ and in P when $t \leqslant 2$ for scoring rules which contain $(\alpha+2, \alpha+1, \alpha+1, \alpha)$ for any $\alpha \in \mathbb{N}$ [Theorem 9].
- The Possible Winner problem is NP-complete when $t \geqslant 4$ and in P when $t \leqslant 3$ for k-approval and k-veto voting rules for any $k > 1$ [Theorem 10].
- The Possible Winner problem is NP-complete when $t \geqslant m-1$ and in P when $t \leqslant m-2$ for the scoring rule $(2, 1, 1, \ldots, 1, 0)$ [Theorem 10].

We summarize our results for the Copeland$^\alpha$, maximin, and Bucklin voting rules in Table 1. We observe that the Possible Winner problem for the Copeland$^\alpha$ voting rule is NP-complete even when every vote has at most 2 undetermined pairs of candidates for $\alpha \in \{0, 1\}$. However, for $\alpha \in (0, 1)$, the Possible Winner problem for the Copeland$^\alpha$ voting rule is NP-complete even when every vote has at most 1 undetermined pairs of candidates. Our results show that the Possible Winner winner problem continues to be NP-complete

Table 1 Summary and comparison of results from the literature for Copeland$^{\alpha}$, maximin, and Bucklin voting rules. *The result was proved for the simplified Bucklin voting rule but the proof can be modified easily for the Bucklin voting rule.

Voting rules	NP-complete	Poly time	Known from literature [29]
Copeland^{0,1}	$t \geqslant 2$ [Theorem 11]	$t \leqslant 1$ [Theorem 12]	NP-complete for $t \geqslant 8$
Copeland$^{\alpha}$ $\alpha \in (0,1)$	$t \geqslant 1$ [Theorem 15]	–	
Maximin	$t \geqslant 2$ [Theorem 17]	$t \leqslant 1$ [Theorem 18]	NP-complete for $t \geqslant 4$
Bucklin	$t \geqslant 2$ [Theorem 19]	$t \leqslant 1$ [Theorem 19]	NP-complete for $t \geqslant 16^{\star}$

for all the common voting rules studied here (except k-approval) even when the number of undetermined pairs of candidates per vote is at most 2. Other than finding the exact number of undetermined pairs needed per vote to make the Possible Winner problem NP-complete for common voting rules, we also note that all our proofs are much simpler and shorter than most of the corresponding proofs from the literature subsuming the work in [29, 6, 2].

2 Preliminaries

Let us denote the set $\{1, 2, \ldots, n\}$ by $[n]$ for any positive integer n. Let $\mathcal{C} = \{c_1, c_2, \ldots, c_m\}$ be a set of candidates or alternatives and $\mathcal{V} = \{v_1, v_2, \ldots, v_n\}$ a set of voters. If not mentioned otherwise, we denote the set of candidates by $\mathcal{C}$, the set of voters by $\mathcal{V}$, the number of candidates by m, and the number of voters by n. Every voter v_i has a preference or vote $\succ_i$ which is a complete order over $\mathcal{C}$. We denote the set of complete orders over $\mathcal{C}$ by $\mathcal{L}(\mathcal{C})$. We call a tuple of n preferences $(\succ_1, \succ_2, \cdots, \succ_n) \in \mathcal{L}(\mathcal{C})^n$ an n-voter preference profile. An election is defined as a set of candidates together with a voting profile. It is often convenient to view a preference as a subset of $\mathcal{C} \times \mathcal{C}$ — a preference $\succ$ corresponds to the subset $\mathcal{A} = \{(x, y) \in \mathcal{C} \times \mathcal{C} : x \succ y\}$. For a preference $\succ$ and a subset $\mathcal{A} \subseteq \mathcal{C}$ of candidates, we define $\succ(\mathcal{A})$ be the preference $\succ$ restricted to $\mathcal{A}$, that is $\succ(\mathcal{A}) = \succ \cap (\mathcal{A} \times \mathcal{A})$. Let $\uplus$ denote the disjoint union of sets. A map $r : \uplus_{n, |\mathcal{C}| \in \mathbb{N}^+} \mathcal{L}(\mathcal{C})^n \longrightarrow 2^{\mathcal{C}} \setminus \{\emptyset\}$ is called a *voting rule*. For a voting rule r and a preference profile $\succ = (\succ_1, \ldots, \succ_n)$, we say a candidate x wins uniquely if $r(\succ) = \{x\}$ and x co-wins if $x \in r(\succ)$. For a vote $\succ \in \mathcal{L}(\mathcal{C})$ and two candidates $x, y \in \mathcal{C}$, we say x is placed before y in $\succ$ if $x \succ y$; otherwise we say x is placed after y in $\succ$. A candidate is said to be at the i^{th} position from the top (bottom) if there are $(i-1)$ candidates after (before) it. For any two candidates $x, y \in \mathcal{C}$ with $x \neq y$ in an election $\mathcal{E}$, let us define the margin $\mathcal{D}_{\mathcal{E}}(x, y)$ of x from y to be $|\{i : x \succ_i y\}| - |\{i : y \succ_i x\}|$. Examples of some common voting rules are as follows.

Positional scoring rules. A collection $(\overrightarrow{s_m})_{m \in \mathbb{N}^+}$ of m-dimensional vectors $\overrightarrow{s_m} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_1) \in \mathbb{N}^m$ with $\alpha_m \geqslant \alpha_{m-1} \geqslant \ldots \geqslant \alpha_1$ and $\alpha_m > \alpha_1$ for every $m \in \mathbb{N}^+$ naturally defines a voting rule — a candidate gets score α_i from a vote if it is placed at the i^{th} position from the bottom, and the score of a candidate is the sum of the scores it receives from all the votes. The winners are the candidates with maximum score. Scoring rules remain unchanged if we multiply every α_i by any constant $\lambda > 0$ and/or add any constant μ. Hence, we assume without loss of generality that for any score vector $\overrightarrow{s_m}$, there exists a j such that $\alpha_k = 0$ for all $k < j$ and the greatest common divisor of $\alpha_1, \ldots, \alpha_m$ is one. Such a $\overrightarrow{s_m}$ is called a normalized score vector. Without loss of generality, we will work with

normalized scoring rules only in this work. If α_i is 0 for $i \in [m-k]$ and 1 otherwise, then we get the k-approval voting rule. For the k-veto voting rule, α_i is 0 for $i \in [k]$ and 1 otherwise. 1-approval is called the plurality voting rule and 1-veto is called the veto voting rule. We note that our notation is slightly unconventional, this is in the interest of convenience in some of the computations that we will encounter with score vectors.

Copeland$^\alpha$. Given $\alpha \in [0,1]$, the Copeland$^\alpha$ score of a candidate x is $|\{y \neq x : \mathcal{D}_\mathcal{E}(x,y) > 0\}| + \alpha|\{y \neq x : \mathcal{D}_\mathcal{E}(x,y) = 0\}|$. The winners are the candidates with maximum Copeland$^\alpha$ score. If not mentioned otherwise, we will assume α to be zero.

Maximin. The maximin score of a candidate x in an election E is $\min_{y \neq x} \mathcal{D}_\mathcal{E}(x,y)$. The winners are the candidates with maximum maximin score.

Bucklin. Let ℓ be the minimum integer such that there exists at least one candidate $x \in \mathcal{C}$ whom more than half of the voters place in their top ℓ positions. Then the Bucklin winner is the candidate who is placed most number of times within top ℓ positions of the votes.

Elections with Incomplete Information A more general setting is an *election* where the votes are only *partial orders* over candidates. A *partial order* is a relation that is *reflexive, antisymmetric*, and *transitive*. A partial vote can be extended to possibly more than one linear vote depending on how we fix the order for the unspecified pairs of candidates. Given a partial vote $\succ$, we say that an extension $\succ'$ of $\succ$ *places the candidate c as high as possible* if $a \succ' c$ implies $a \succ'' c$ for every extension $\succ''$ of $\succ$.

▶ **Definition 1** (r–Possible Winner)**.** Given a set of partial votes $\mathcal{P}$ over a set of candidates $\mathcal{C}$ and a candidate $c \in \mathcal{C}$, does there exist an extension $\mathcal{P}'$ of $\mathcal{P}$ such that $c \in r(\mathcal{P}')$?

3 Results

For ease of exposition, we present all our results for the co-winner case. All our proofs extend easily to the unique winner case too. We begin with our results for the scoring rules.

3.1 Scoring Rules

In this section, we establish a dichotomous result describing the status of the Possible Winner problem for a large class of scoring rules when the number of undetermined pairs in every vote is at most one, two, three, or four. We begin by introducing some terminology. Instead of working directly with score vectors, it will sometimes be convenient for us to refer to the "vector of differences", which, for a score vector s with m coordinates, is a vector $d(s)$ with $m-1$ coordinates with each entry being the difference between adjacent scores corresponding to that location and the location left to it. This is formally stated below.

▶ **Definition 2.** Given a normalized score vector $\overrightarrow{s_m} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_1 = 0) \in \mathbb{N}^m$, the associated difference vector $d(\overrightarrow{s_m})$ is given by $(\alpha_m - \alpha_{m-1}, \alpha_{m-1} - \alpha_{m-2}, \ldots, \alpha_2 - \alpha_1) \in \mathbb{N}^{m-1}$. We also employ the following notation to refer to the smallest score difference among all non-zero differences, and the largest score difference, respectively:

- $\delta(\overrightarrow{s_m}) = \min(\{\alpha_i - \alpha_{i-1} \mid 2 \leqslant i \leqslant m \text{ and } \alpha_i - \alpha_{i-1} > 0\})$
- $\Delta(\overrightarrow{s_m}) = \max(\{\alpha_i - \alpha_{i-1} \mid 2 \leqslant i \leqslant m\})$

Note that for every non-trivial normalized score vector $\overrightarrow{s_m}$, $\Delta(\overrightarrow{s_m})$ is always non-zero. We now proceed to defining the notion of smooth scoring rules. Consider a score vector $\overrightarrow{s_m} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_1)$. For $0 \leqslant i \leqslant m$, we say that $\overrightarrow{s_{m+1}}$ is obtained from s_m by inserting α just before position i from the right if:

$$\overrightarrow{s_{m+1}} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_{i+1}, \alpha, \alpha_i, \ldots, \alpha_2, \alpha_1)\,.$$

Note that if $i = 0$, we have $\overrightarrow{s_{m+1}} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_1, \alpha)$, and if $i = m$, then we have $\overrightarrow{s_{m+1}} = (\alpha, \alpha_m, \alpha_{m-1}, \ldots, \alpha_1)$. For $0 \leqslant i \leqslant m$, we say that the position i is *admissible* if $i = 0$, or $i = m$, or $\alpha_{i+1} = \alpha_i$.

▶ **Definition 3** (Smooth scoring rules)**.** We say that a scoring rule s is smooth if there exists some constant $m_0 \in \mathbb{N}^+$ such that for all $m \geqslant m_0$, the score vector $\overrightarrow{s_m}$ can be obtained from $\overrightarrow{s_{m-1}}$ by inserting an additional score value at any position i that is admissible.

Observe that the additional score value is forced to be equal to an existing score value unless it is inserted at one of the endpoints. Intuitively speaking, a smooth scoring rule is one where the score vector for m candidates can be obtained by either extending the one for $(m-1)$ candidates at one of the ends, or by inserting a score between an adjacent pair of ambivalent locations (i.e, consecutive scores in the score vector with the same value). Although at a first glance it may seem that the class of smooth scoring rules involves an evolution from a limited set of operations, we note that all of the common scoring rules, such as plurality, veto, k-approval, Borda, and scoring rules of the form $(2, 1, \ldots, 1, 0)$, are smooth. We now turn to some definitions that will help describe the cases that appear in our classification result.

▶ **Definition 4.** Let $s = (\overrightarrow{s_m})_{m \in \mathbb{N}^+}$ be a scoring rule.

- We say that s is a *Borda-like scoring rule* if there exists some $m_0 \in \mathbb{N}^+$ for which we have that $\Delta(\overrightarrow{s_m}) = \delta(\overrightarrow{s_m})$ for every $m > m_0$.
- Any rule that is not Borda-like is called a *differentiating scoring rule*.
- For any vector t with ℓ coordinates, we say that s is t-difference-free if there exists some $n_0 \in \mathbb{N}^+$ such that for every $m \geqslant n_0$, the vector t does not occur in $d(\overrightarrow{s_m})$. In other words, the vector $\langle d(\overrightarrow{s_m})[i], \ldots, d(\overrightarrow{s_m})[i+\ell-1]\rangle \neq t$ for any $1 \leqslant i \leqslant m - \ell$.
- For any vector t, we say that s is t-contaminated if it is not t-difference-free. We also say that s is t-contaminated at m if the vector t occurs in $d(\overrightarrow{s_m})$.

We will frequently be dealing with Borda-like score vectors. To this end, the following easy observation will be useful.

▶ **Observation 5.** *If $s = (\overrightarrow{s_m})_{m \in \mathbb{N}^+}$ is a Borda-like scoring rule in its normalized form, then there exists $n_0 \in \mathbb{N}^+$ such that all the coordinates of $d(\overrightarrow{s_m})$ are either zero or one for all $m > n_0$.*

It turns out that if a scoring rule is smooth, then its behavior with respect to some of the properties above is fairly monotone. For instance, we have the following easy proposition. For the interest of space, we omit proofs of some of our results including all our polynomial time algorithms. For a few proofs, we only provide a sketch of the proof deferring the complete proof to the appendix. We mark these results with $\star$. All our polynomial time algorithms are based on reduction to the maximum flow problem in a graph. All the complete proofs can be found here [12].

[$\star$] Let $s = (\overrightarrow{s_m})_{m \in \mathbb{N}^+}$ be a smooth scoring rule that is not Borda-like. Then there exists some $n_0 \in \mathbb{N}^+$ such that $\Delta(\overrightarrow{s_m}) \neq \delta(\overrightarrow{s_m})$ for every $m > n_0$.

We are now ready to state the first classification result of this section, for the scenario where every vote has at most one missing pair. We use $(3, B2)$–SAT to prove some of our hardness results. The $(3, B2)$–SAT problem is the 3-SAT problem restricted to formulas in which each clause contains exactly three literals, and each variable occurs exactly twice positively and twice negatively. We know that $(3, B2)$–SAT is NP-complete [3]. Let us first present a structural result for scoring rules which we will use subsequently.

Suppose we have a set $\mathcal{C} = \{c_1, \ldots, c_{m-1}, g\}$ of m candidates including a "dummy" candidate g. Then it is well known [1, 16, 14, 13, 15, 17, 11], that for a score vector $(\alpha_m, \ldots, \alpha_1)$ and integers $\{k_i^j\}_{i\in[m-1],j\in[m-1]}$, we can add votes polynomially many in $\sum_{i\in[m-1],j\in[m-1]} k_i^j$ so that the score of the candidate c_i is $\lambda + \sum_{j\in[m-1]} k_i^j(\alpha_j - \alpha_{j+1})$ for some λ and the score of g is less than λ. Since the greatest common divisor of non-zero differences of the consecutive entries in a normalized score vector is one, we have the following.

▶ **Lemma 6.** *Let $\mathcal{C} = \{c_1, \ldots, c_m\} \cup D, (|D| > 0)$ be a set of candidates, and $\vec{\alpha}$ a normalized score vector of length $|\mathcal{C}|$. Then for every $\mathbf{X} = (X_1, \ldots, X_m) \in \mathbb{Z}^m$, there exists $\lambda \in \mathbb{N}$ and a voting profile $\mathcal{V}$ such that the $\vec{\alpha}$-score of c_i is $\lambda + X_i$ for all $1 \leqslant i \leqslant m$, and the score of candidates $d \in D$ is less than λ. Moreover, the number of votes in $\mathcal{V}$ is $O(poly(|\mathcal{C}| \cdot \sum_{i=1}^{m} |X_i|))$.*

▶ **Theorem 7.** *[⋆] Let s be a smooth scoring rule. If s is differentiating, then the* Possible Winner *problem is* NP*-complete, even if every vote has at most one undetermined pair of candidates. Otherwise, that is, when s is Borda-like, the* Possible Winner *problem for s is in* P *if every vote has at most one undetermined pair of candidates.*

Proof. *(Outline.)* For the hardness result, we reduce from an instance of $(3, B2)$-SAT. Let $\mathcal{I}$ be an instance of $(3, B2)$-SAT, over the variables $\mathcal{V} = \{x_1, \ldots, x_n\}$ and with clauses $\mathcal{T} = \{c_1, \ldots, c_t\}$. To construct the reduced instance $\mathcal{I}'$, we introduce two candidates for every variable, and one candidate for every clause, one special candidate w, and a dummy candidate g to achieve desirable score differences. Notationally, we will use b_i (corresponding to x_i) and b_i' (corresponding to $\bar{x}_i$) to refer to the candidates based on the variable x_i and e_j to refer to the candidate based on the clause c_j. To recap, the set of candidates are given by:

$$\mathcal{C} = \{b_i, b_i' \mid x_i \in \mathcal{V}\} \cup \{e_j \mid c_j \in \mathcal{T}\} \cup \{w, g\}.$$

Consider an arbitrary but fixed ordering over $\mathcal{C}$, such as the lexicographic order. In this proof, the notation $\overrightarrow{\mathcal{C}'}$ for any $\mathcal{C}' \subseteq \mathcal{C}$ will be used to denote the lexicographic ordering restricted to the subset $\mathcal{C}'$. Let m denote $|\mathcal{C}| = 2n + t + 2$, and let $\overrightarrow{s_m} = (\alpha_m, \alpha_{m-1}, \ldots, \alpha_1) \in \mathbb{N}^m$. Since s is a smooth differentiating scoring rule, we have that there exist $1 \leqslant p, q \leqslant m$ such that $|p - q| > 1$ and $\alpha_p - \alpha_{p-1} > \alpha_q - \alpha_{q-1} \geqslant 1$.

We use D to refer to the larger of the two differences above, namely $\alpha_p - \alpha_{p-1}$ and d to refer to $\alpha_q - \alpha_{q-1}$. We now turn to a description of the votes. Fix an arbitrary subset $\mathcal{C}_1$ of $(m - p)$ candidates. For every variable $x_i \in \mathcal{V}$, we introduce the following complete and partial votes.

$$\mathfrak{p}_i := \overrightarrow{\mathcal{C}_1} \succ b_i \succ b_i' \succ \overrightarrow{\mathcal{C} \setminus \mathcal{C}_1} \text{ and } \mathfrak{p}_i' := \mathfrak{p}_i \setminus \{(b_i, b_i')\}$$

We next fix an arbitrary subset $\mathcal{C}_2 \subset \mathcal{C}$ of $(m - q)$ candidates. Consider a literal ℓ corresponding to the variable x_i. We use $\ell^\star$ to refer to the candidate b_j if the literal is positive and to refer to the candidate b_j' if the literal is negated. For every clause $c_j \in \mathcal{T}$ given by $c_j = \{\ell_1, \ell_2, \ell_3\}$, we introduce the following complete and partial votes.

$$\mathfrak{q}_{j,1} := \overrightarrow{\mathcal{C}_2} \succ e_j \succ \ell_1^\star \succ \overrightarrow{\mathcal{C} \setminus \mathcal{C}_2} \text{ and } \mathfrak{q}_{j,1}' := \mathfrak{q}_{j,1} \setminus \{(e_j, \ell_1^\star)\}$$

Table 2 Score of candidates from $\mathcal{P} \cup \mathcal{W}$.

$s^+(e_j) = s^+(w) + d \; \forall \; 1 \leqslant j \leqslant t$ $s^+(b'_i) = s^+(w) + 1 - d - D \; \forall \; 1 \leqslant i \leqslant n$	$s^+(b_i) = s^+(w) + 1 - d \; \forall \; 1 \leqslant i \leqslant n$ $s^+(g) < s^+(w)$

$\mathfrak{q}_{j,2} := \overrightarrow{\mathcal{C}_2} \succ e_j \succ \ell_2^\star \succ \overrightarrow{\mathcal{C} \setminus \mathcal{C}_2}$ and $\mathfrak{q}'_{j,2} := \mathfrak{q}_{j,2} \setminus \{(e_j, \ell_2^\star)\}$

$\mathfrak{q}_{j,3} := \overrightarrow{\mathcal{C}_2} \succ e_j \succ \ell_3^\star \succ \overrightarrow{\mathcal{C} \setminus \mathcal{C}_2}$ and $\mathfrak{q}'_{j,3} := \mathfrak{q}_{j,3} \setminus \{(e_j, \ell_3^\star)\}$

Let us define the following sets of votes:

$$\mathcal{P} = \left(\bigcup_{i=1}^{n} \mathfrak{p}_i\right) \cup \left(\bigcup_{1 \leqslant j \leqslant t, 1 \leqslant b \leqslant 3} \mathfrak{q}_{j,b}\right) \text{ and } \mathcal{P}' = \left(\bigcup_{i=1}^{n} \mathfrak{p}'_i\right) \cup \left(\bigcup_{1 \leqslant j \leqslant t, 1 \leqslant b \leqslant 3} \mathfrak{q}'_{j,b}\right)$$

There exists a set of complete votes $\mathcal{W}$ of size polynomial in m with the following properties due to Lemma 6. Let $s^+ : \mathcal{C} \longrightarrow \mathbb{N}$ be a function mapping candidates to their scores from the set of votes $\mathcal{P} \cup \mathcal{W}$. Then $\mathcal{W}$ can be constructed to ensure the scores as in Table 2. We now define the instance $\mathcal{I}'$ of Possible Winner to be $(\mathcal{C}, \mathcal{P}' \cup \mathcal{W}, w)$. This completes the description of the reduction. We now turn to a proof of the equivalence. Before we begin making our arguments, observe that since w does not participate in any undetermined pairs of the votes in $\mathcal{P}'$, it follows that the score of w continues to be $s^+(w)$ in any completion of $\mathcal{P}'$. The intuition for the construction, described informally, is as follows. The score of every "clause candidate" needs to decrease by d, which can be achieved by pushing it down against its literal partner in the $\mathfrak{q}_j$-votes. However, this comes at the cost of increasing the score of the literals by $2d$ (since every literal appears in at most two clauses). It turns out that this can be compensated appropriately by ensuring that the candidate corresponding to the literal appears in the $(p-1)^{th}$ position among the $\mathfrak{p}$-votes, which will adjust for this increase. Therefore, the setting of the (b'_i, b_i) pairs in a successful completion of $\mathfrak{p}_i$ can be read off as a signal for how the corresponding variable should be set by a satisfying assignment. We defer the formal proof of equivalence of the two instances and the polynomial time solvable case to the appendix. ◀

We make a couple of quick remarks before moving on to our next result. Observe that any hardness result that holds for instances where every vote has at most k undetermined pairs also holds for instances where every vote has at most k' undetermined pairs with $k' > k$, by a standard special case argument. Therefore, the next question for us to address is that of whether the Possible Winner problem is in P for all Borda-like scoring rules when the number of undetermined pairs in every vote is at most two. We show that the complexity of the Possible Winner problem for the Borda-like scoring rules crucially depends on the presence (or absence) some particular patterns in the score vector. We begin by stating a hardness result which uses a reduction from the well-known Three Dimensional Matching problem [19].

To help us deal with the nature of the score vectors considered, we will use the following proposition, which again reflects the monotonicity property alluded to earlier.

[⋆] Let s be a normalized smooth scoring rule that is not $\langle 1, 1 \rangle$-difference-free. Then there exists some $n_0 \in \mathbb{N}^+$ such that for every $m \geqslant n_0$, s is $\langle 1, 1 \rangle$-contaminated at m.

We are now ready to state our next result, which shows that if there are at most 2 undetermined pairs of candidates in every vote, and we are dealing with a smooth Borda-like scoring rule s, then the Possible Winner problem is NP-complete if s is $\langle 1, 1 \rangle$-contaminated, and solvable in polynomial time otherwise.

▶ **Theorem 8.** *[⋆] Let s be a smooth, Borda-like scoring rule. If s is $\langle 1,1\rangle$-contaminated, the* Possible Winner *problem is* NP*-complete, even if every vote has at most* 2 *undetermined pairs of candidates. On the other hand, if s is $\langle 1,1\rangle$-difference-free, then the* Possible Winner *problem for s is in* P *if every vote has at most* 2 *undetermined pairs of candidates.*

We now address the case involving at most three undetermined pairs in every vote. The interesting scoring rules here are smooth Borda-like scoring rules that are $\langle 1,1\rangle$-difference-free. It turns out that here, if the scoring rule is further $\langle 1,0,1\rangle$-difference-free, then the problem again admits a maxflow formulation. On the other hand, s is $\langle 1,0,1\rangle$-contaminated at $m \geqslant N_0$ for some constant N_0, then the Possible Winner problem is NP-complete even with 3 undetermined pairs of candidates per vote.

▶ **Theorem 9.** *[⋆] Let s be a smooth, Borda-like, $\langle 1,1\rangle$-difference-free scoring rule. If there exists a constant $N_0 \in \mathbb{N}^+$ such that s is $\langle 1,0,1\rangle$-contaminated for all $m \geqslant n_0$, then the* Possible Winner *problem is* NP*-complete, even if every vote has at most* 3 *undetermined pairs. On the other hand, if s is $\langle 1,0,1\rangle$-difference-free, then the* Possible Winner *problem for s is in* P *if every vote has at most* 3 *undetermined pairs.*

▶ Remark. Note that unlike the previous two results, this statement is not a complete classification, because we don't have an appropriate analog of Propositions 3.1 and 3.1. Having said that, our result holds for a more general class of scoring rules: those where s is $\langle 1,0,1\rangle$-contaminated at m "sufficiently" often, that is to say that if $\overrightarrow{s_m}$ is $\langle 1,0,1\rangle$-contaminated and $m' > m$ is the smallest natural number for which $\overrightarrow{s_m}$ is $\langle 1,0,1\rangle$-contaminated, then $m' - m$ is bounded by some polynomial function of m, by inserting appropriately many dummy candidates using standard techniques.

We now turn to our final result for scoring rules. Let s be a smooth, Borda-like scoring rule that is $\langle 1,1\rangle$-difference-free. Then we have the following. If s is $\langle 0,1,0\rangle$-contaminated, then the Possible Winner problem for s is NP-complete even when every vote has at most 4 undetermined pairs of candidates. If s is $\langle 0,1,0\rangle$-difference-free, then notice that $d(\overrightarrow{s_m})$ for any suitably large $m \in \mathbb{N}^+$ can contain at most two ones (since s is also $\langle 1,1\rangle$-difference-free). If the number of ones in $d(\overrightarrow{s_m})$ is one, then $d(\overrightarrow{s_m})$ either has a one on the first or the last coordinate (recall that s is $\langle 0,1,0\rangle$-difference-free), corresponding to the plurality and veto voting rules, respectively. On the other hand, if the number of ones is two, $d(\overrightarrow{s_m}) = \langle 1,0,\ldots,0,1\rangle$, which is equivalent (in normal form) to the scoring rule $(2,1,\ldots,1,0)$. The Possible Winner problem is polynomial time solvable for plurality and veto voting rules, and we show here that it is also polynomially solvable for the scoring rule $(2,1,\ldots,1,0)$ as long as the number of undetermined pairs of candidates in any vote is at most $m-1$. We note that the status for the Possible Winner problem for this rule was left unresolved in [6] and was later resolved in [2]. If we allow for m or more undetermined pairs of candidates in every vote, then we show that the Possible Winner problem is NP-complete. As before, we will need the following property of $\langle 1,0,1\rangle$-contaminated vectors.

[⋆] Let s be a normalized smooth scoring rule that is not $\langle 1,0,1\rangle$-difference-free. Then there exists some $n_0 \in \mathbb{N}^+$ such that s is $\langle 0,1,0\rangle$-contaminated at m for every $m > n_0$.

We now state the final result in this section. It is easily checked that the result accounts for all smooth, Borda-like scoring rules that are $\langle 1,1\rangle$-difference-free.

▶ **Theorem 10.** *[⋆] Let s be a smooth, Borda-like scoring rule that is $\langle 1,1\rangle$-difference-free. Then we have the following.*

1. *If s is $\langle 0,1,0\rangle$-contaminated, then the* Possible Winner *problem for s is* NP*-complete even when every vote has at most* 4 *undetermined pairs of candidates.*

2. *If s is equivalent to $(2,1,\ldots,1,0)$, then* Possible Winner *is* NP*-complete even when the number of undetermined pairs of candidates in every vote is at most $m-1$.*
3. *If s is equivalent to $(2,1,\ldots,1,0)$ and the number of undetermined pairs of candidates is strictly less than $m-1$, then* Possible Winner *is in* P*.*

3.2 Copeland$^\alpha$ Voting Rule

We now turn to the Copeland$^\alpha$ voting rule. We show in Theorem 11 below that the Possible Winner problem is NP-complete for the Copeland$^\alpha$ voting rule even when every vote has at most 2 undetermined pairs of candidates for every $\alpha \in [0,1]$.

▶ **Theorem 11.** *[⋆] The* Possible Winner *problem is* NP*-complete for the Copeland$^\alpha$ voting rule even if the number of undetermined pairs of candidates in every vote is at most* 2 *for every $\alpha \in [0,1]$.*

We prove in Theorem 12 that the number of undetermined pairs of candidates in Theorem 11 is tight for the Copeland^0 and Copeland^1 voting rules.

▶ **Theorem 12.** *[⋆] The* Possible Winner *problem is in* P *for the Copeland^0 and Copeland^1 voting rules if the number of undetermined pairs of candidates in every vote is at most* 1*.*

We show next that the Possible Winner problem is NP-complete for the Copeland$^\alpha$ voting rule even if the number of undetermined pairs of candidates in every vote is at most 1 for $\alpha \in (0,1)$. We break the proof into two parts — Lemma 13 proves the result for every $\alpha \in (0, 1/2]$ and Lemma 14 proves for every $\alpha \in [1/2, 1)$.

▶ **Lemma 13.** *[⋆] The* Possible Winner *problem is* NP*-complete for the Copeland$^\alpha$ voting rule even if the number of undetermined pairs in every vote is at most* 1 *for every $\alpha \in (0, 1/2]$.*

Proof. The Possible Winner problem for the Copeland$^\alpha$ voting rule is clearly in NP. To prove NP-hardness of Possible Winner, we reduce Possible Winner from $(3,B2)$–SAT. Let $\mathcal{I}$ be an instance of $(3,B2)$–SAT, over the variables $\mathcal{V} = \{x_1,\ldots,x_n\}$ and with clauses $\mathcal{T} = \{c_1,\ldots,c_m\}$. We construct an instance $\mathcal{I}'$ of Possible Winner from $\mathcal{I}$ as follows.

Set of candidates: $\mathcal{C} = \{x_i, \bar{x}_i, d_i : i \in [n]\} \cup \{c_i : i \in [m]\} \cup \{c\} \cup \mathcal{G}$, where $\mathcal{G} = \{g_1,\ldots,g_{mn}\}$.

For every $i \in [n]$, let us define $\mathfrak{p}^1_{x_i}, \mathfrak{p}^2_{x_i} : x_i \succ d_i \succ$ others and $\mathfrak{p}^1_{\bar{x}_i}, \mathfrak{p}^2_{\bar{x}_i} : \bar{x}_i \succ d_i \succ$ others. Using $\mathfrak{p}^1_{x_i}, \mathfrak{p}^2_{x_i}, \mathfrak{p}^1_{\bar{x}_i}, \mathfrak{p}^2_{\bar{x}_i}$, we define the partial votes $\mathfrak{p}^{1\prime}_{x_i}, \mathfrak{p}^{2\prime}_{x_i}, \mathfrak{p}^{1\prime}_{\bar{x}_i}, \mathfrak{p}^{2\prime}_{\bar{x}_i}$ as follows.

$$\mathfrak{p}^{1\prime}_{x_i}, \mathfrak{p}^{2\prime}_{x_i} : \mathfrak{p}^1_{x_i} \setminus \{(x_i, d_i)\} \ , \ \mathfrak{p}^{1\prime}_{\bar{x}_i}, \mathfrak{p}^{2\prime}_{\bar{x}_i} : \mathfrak{p}^1_{\bar{x}_i} \setminus \{(\bar{x}_i, d_i)\}$$

Let a clause c_j involves the literals $\ell^1_j, \ell^2_j, \ell^3_j$. For every $j \in [m]$, let us consider the following votes $\mathfrak{q}_j(\ell^1_j), \mathfrak{q}_j(\ell^2_j), \mathfrak{q}_j(\ell^3_j)$.

$$\mathfrak{q}_j(\ell^k_j) : c_j \succ \ell^k_j \succ \text{others}, \forall k \in \{1,2,3\}$$

Using $\mathfrak{q}_j(\ell^1_j), \mathfrak{q}_j(\ell^2_j), \mathfrak{q}_j(\ell^3_j)$, we define the partial votes $\mathfrak{q}'_j(\ell^1_j), \mathfrak{q}'_j(\ell^2_j), \mathfrak{q}'_j(\ell^3_j)$ as follows.

$$\mathfrak{q}'_j(\ell^k_j) : \mathfrak{q}_j(\ell^k_j) \setminus \{(c_j, \ell^k_j)\}, \forall k \in \{1,2,3\}$$

Let us define

$$\mathcal{P} = \cup_{i\in[n]} \{\mathfrak{p}^1_{x_i}, \mathfrak{p}^2_{x_i}, \mathfrak{p}^1_{\bar{x}_i}, \mathfrak{p}^2_{\bar{x}_i}\} \cup_{j\in[m]} \{\mathfrak{q}_j(\ell^1_j), \mathfrak{q}_j(\ell^2_j), \mathfrak{q}_j(\ell^3_j)\}$$

Table 3 Summary of Copeland$^\alpha$ scores of the candidates from $\mathcal{P} \cup \mathcal{Q}$. All the wins and defeats in the table are by a margin of 2.

Candidates	Copeland$^\alpha$ score	Winning against	Losing against	Tie with
c	$(2n+m)\alpha$ $+n+{}^{3mn}/_{4}$	$G' \subset \mathcal{G}, \lvert G'\rvert = n+{}^{3mn}/_{4}$	$\mathcal{G} \setminus G', \lvert G'\rvert = n+{}^{3mn}/_{4}$ $d_i, \forall i \in [n]$	$x_i, \bar{x}_i \forall i \in [n]$ $c_j \forall j \in [m]$
$x_i, \forall i \in [n]$	$(2n+m)\alpha$ $+n+{}^{3mn}/_{4}$	$G'' \subset \mathcal{G}, \lvert G''\rvert = {}^{3mn}/_{4}$ $d_i \forall i \in [n]$	$\mathcal{G} \setminus (G' \cup G'')$	$c, G' \subset \mathcal{G}, \lvert G'\rvert = m$ $x_j, \forall j \in [n] \setminus \{i\}$ $\bar{x}_j \forall j \in [n]$
$\bar{x}_i, \forall i \in [n]$	$(2n+m)\alpha$ $+n+{}^{3mn}/_{4}$	$G'' \subset \mathcal{G}, \lvert G''\rvert = {}^{3mn}/_{4}$ $d_i \forall i \in [n]$	$\mathcal{G} \setminus (G' \cup G'')$	$c, G' \subset \mathcal{G}, \lvert G'\rvert = m$ $\bar{x}_j, \forall j \in [n] \setminus \{i\}$ $x_j \forall j \in [n]$
$c_j, \forall j \in [m]$	$(2n+m-1)\alpha$ $+n+{}^{3mn}/_{4}+1$	$x_i, \bar{x}_i \forall i \in [n]$ $G' \subset \mathcal{G}, \lvert G'\rvert = {}^{3mn}/_{4}-n+1$	$\mathcal{G} \setminus (G' \cup G'')$ $d_i, \forall i \in [n]$	c $c_j \forall j \in [m] \setminus \{i\}$ $G'' \subset \mathcal{G}, \lvert G''\rvert = 2n-1$
$d_i, i \in [n]$	$(2n+m)\alpha$ $+n+{}^{3mn}/_{4}-1$	$c, c_j, \forall j \in [m]$ $G'' \subset \mathcal{G}, \lvert G''\rvert = {}^{3mn}/_{4}-m+n-2$	$x_i, \bar{x}_i \forall i \in [n]$ $\mathcal{G} \setminus (G' \cup G'')$	$G' \subset \mathcal{G}, \lvert G'\rvert = 2n+m$
$g_i, \forall i \in [mn]$	$< {}^{3mn}/_{4}$		$\forall j \in \{i+k : k \in [\lfloor {}^{(mn-1)}/_{2} \rfloor]$	

and

$$\mathcal{P}' = \cup_{i\in[n]}\{\mathfrak{p}^{1\prime}_{x_i}, \mathfrak{p}^{2\prime}_{x_i}, \mathfrak{p}^{1\prime}_{\bar{x}_i}, \mathfrak{p}^{2\prime}_{\bar{x}_i}\} \cup_{j\in[m]} \{\mathfrak{q}'_j(\ell^1_j), \mathfrak{q}'_j(\ell^2_j), \mathfrak{q}'_j(\ell^3_j)\}.$$

There exists a set of complete votes $\mathcal{Q}$ of size polynomial in n and m which realizes Table 3 [24]. All the wins and defeats in Table 3 are by a margin of 2. We now define the instance $\mathcal{I}'$ of Possible Winner to be $(\mathcal{C}, \mathcal{P}' \cup \mathcal{Q}, c)$. Notice that the number of undetermined pairs of candidates in every vote in $\mathcal{I}'$ is at most 1. This finishes the description of the Possible Winner instance. We defer the formal proof of equivalence of the two instances and the polynomial time solvable case to the appendix. ◀

Next we present Lemma 14 which resolves the complexity of the Possible Winner problem for the Copeland$^\alpha$ voting rule for every $\alpha \in [1/2, 1)$ when every partial vote has at most one undetermined pair of candidates.

▶ **Lemma 14.** *[⋆] The* Possible Winner *problem is* NP*-complete for the Copeland$^\alpha$ voting rule even if the number of undetermined pairs in every vote is at most* 1 *for every* $\alpha \in [1/2, 1)$.

We get the following result for the Copeland$^\alpha$ voting rule from Theorem 13 and 14.

▶ **Theorem 15.** *The* Possible Winner *problem is* NP*-complete for the Copeland$^\alpha$ voting rule even if the number of undetermined pairs of candidates in every vote is at most* 1 *for every* $\alpha \in (0, 1)$.

3.3 Maximin and Bucklin Voting Rules

To prove our hardness result for the maximin voting rule, we reduce the Possible Winner problem from the d–Multicolored Independent Set problem which is defined as below. d–Multicolored Independent Set is known to be NP-complete (for example, see this [10]). We denote arbitrary instance of d–Multicolored Independent Set by $\left(\mathcal{V} = \uplus_{i=1}^{k} \mathcal{V}_k, \mathcal{E}\right)$.

▶ **Definition 16** (d–Multicolored Independent Set)**.** Given a d-regular graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, an integer k, and a partition of the set of vertices $\mathcal{V}$ into k independent sets $\mathcal{V}_1, \ldots, \mathcal{V}_k$, that is $\mathcal{V} = \cup_{i\in[k]}\mathcal{V}_i$ and $\mathcal{V}_i$ is an independent set for every $i \in [k]$, does there exists an independent set $\mathcal{S} \subset \mathcal{V}$ in $\mathcal{G}$ such that $|\mathcal{S} \cap \mathcal{V}_i| = 1$ for every $i \in [k]$.

Table 4 Pairwise margins of candidates from $\mathcal{P} \cup \mathcal{Q}$.

$\forall e \in \mathcal{E}, \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(e, c) = \lambda$	$\forall i \in [k], \forall u \in \mathcal{V}_i, \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(u, g_i) = \lambda - 2d$
$\forall i \in [k], \forall u \in \mathcal{V}_i, \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(g'_i, u) = \lambda + 2d$	$\forall i \in [k], e \in \mathcal{E}, \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(e, g'_i) = \lambda$
$\forall e = (u_i, u_j) \in \mathcal{E}, \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(u_i, e) = \mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(u_j, e) = \lambda - 2$	

Table 5 Summary of initial Copeland scores of the candidates.

Candidate	maximin score	worst against	Candidate	maximin score	worst against
c	$-\lambda$	$e \in \mathcal{E}$	$(u_i, u_j) \in \mathcal{E}$	$-(\lambda - 2)$	u_i, u_j
$u \in \mathcal{V}_i$	$-(\lambda + 2d)$	g'_i	g_i	$-(\lambda - 2d)$	$u \in \mathcal{V}_i$
g'_i	$-\lambda$	$e \in \mathcal{E}$			

Now we prove our hardness result for the Possible Winner problem for the maximin voting rule in Theorem 17.

▶ **Theorem 17.** *The* Possible Winner *problem is* NP*-complete for the maximin voting rule even if the number of undetermined pairs of candidates in every vote is at most* 2*.*

Proof. The Possible Winner problem for the maximin voting rule is clearly in NP. To prove NP-hardness of Possible Winner, we reduce Possible Winner from d–Multicolored Independent Set. Let $\mathcal{I} = \left(\mathcal{V} = \cup_{i=1}^{k} \mathcal{V}_k, \mathcal{E}\right)$ be an arbitrary instance of d–Multicolored Independent Set. We construct an instance $\mathcal{I}'$ of Possible Winner from $\mathcal{I}$ as follows.

Set of candidates: $\mathcal{C} = \mathcal{V} \cup \mathcal{E} \cup \{c\} \cup \{g_i, g'_i : i \in [k]\}$

For every $u \in \mathcal{V}_i$ and $\ell \in [d]$, let us consider the following vote $\mathfrak{p}_u$.

$\mathfrak{p}_u^\ell = \overrightarrow{(\mathcal{C} \setminus \{u, g_i, g'_i\})}_u \succ g_i \succ g'_i \succ u$, where $\overrightarrow{(\mathcal{C} \setminus \{u, g_i, g'_i\})}_u$ is any fixed ordering of $\mathcal{C} \setminus \{u, g_i, g'_i\}$

Using $\mathfrak{p}_u^\ell$, we define a partial vote $\mathfrak{p}_u'^\ell$ as $\mathfrak{p}_u'^\ell = \mathfrak{p}_u^\ell \setminus \{(g_i, u), (g'_i, u)\}$. For every edge $e = (u_i, u_j)$ where $u_i \in \mathcal{V}_i$ and $u_j \in \mathcal{V}_j$, let us consider the following votes $\mathfrak{p}_{e,u_i}$ and $\mathfrak{p}_{e,u_j}$.

$$\mathfrak{p}_{e,u_i} = \overrightarrow{(\mathcal{C} \setminus \{u_i, g'_i, e\})} \succ e \succ g'_i \succ u_i \ , \ \mathfrak{p}_{e,u_j} = \overrightarrow{(\mathcal{C} \setminus \{u_j, g'_j, e\})} \succ e \succ g'_j \succ u_j$$

Using $\mathfrak{p}_{e,u_i}$ and $\mathfrak{p}_{e,u_j}$, we define the partial votes $\mathfrak{p}'_{e,u_i}$ and $\mathfrak{p}'_{e,u_j}$ as follows.

$$\mathfrak{p}'_{e,u_i} = \mathfrak{p}_{e,u_i} \setminus \{(e, u_i), (g'_i, u_i)\} \ , \ \mathfrak{p}'_{e,u_j} = \mathfrak{p}_{e,u_j} \setminus \{(e, u_j), (g'_j, u_j)\}$$

Let us call $\mathfrak{p}_e = \{\mathfrak{p}_{e,u_i}, \mathfrak{p}_{e,u_j}\}$ and $\mathfrak{p}'_e = \{\mathfrak{p}'_{e,u_i}, \mathfrak{p}'_{e,u_j}\}$. Let us define $\mathcal{P} = \cup_{u\in\mathcal{V},\ell\in[d]} \mathfrak{p}_u^\ell \cup_{e\in\mathcal{E}} \mathfrak{p}_e$ and $\mathcal{P}' = \cup_{u\in\mathcal{V},\ell\in[d]} \mathfrak{p}_u'^\ell \cup_{e\in\mathcal{E}} \mathfrak{p}'_e$. There exists a set of complete votes $\mathcal{Q}$ of size polynomial in $|\mathcal{V}|$ and $|\mathcal{E}|$ with the pairwise margins as in Table 4 [24]. Let $\lambda > 3d$ be any positive even integer.

For every pair of candidates $(c_i, c_j) \in \mathcal{C} \times \mathcal{C}$ whose pairwise margin is not defined above, we define $\mathcal{D}_{\mathcal{P}\cup\mathcal{Q}}(c_i, c_j) = 0$. We summarize the maximin score of every candidate in $\mathcal{P} \cup \mathcal{Q}$ in Table 5. We now define the instance $\mathcal{I}'$ of Possible Winner to be $(\mathcal{C}, \mathcal{P}' \cup \mathcal{Q}, c)$. Notice that the number of undetermined pairs of candidates in every vote in $\mathcal{I}'$ is at most 2. This finishes the description of the Possible Winner instance. We claim that $\mathcal{I}$ and $\mathcal{I}'$ are equivalent.

In the forward direction, suppose that $\mathcal{I}$ be a YES instance of d–MULTICOLORED INDEPENDENT SET. Then there exists $u_i \in \mathcal{V}_i$ for every $i \in [k]$ such that $\mathcal{U} = \{u_i : i \in [k]\}$ forms an independent set. We extend the partial vote $\mathfrak{p}'^{\ell}_u$ for every $u \in \mathcal{V}_i, i \in [k], \ell \in [d]$ to $\bar{\mathfrak{p}}^{\ell}_u$ as follows.

$$\bar{\mathfrak{p}}^{\ell}_u = \begin{cases} \overrightarrow{(\mathcal{C} \setminus \{u, g_i, g'_i\})}_u \succ u \succ g_i \succ g'_i & u \in \mathcal{U} \\ \overrightarrow{(\mathcal{C} \setminus \{u, g_i, g'_i\})}_u \succ g_i \succ g'_i \succ u & u \notin \mathcal{U} \end{cases}$$

For every $e = (u_i, u_j)$, we extend $\mathfrak{p}'_{e,u_i}$ and $\mathfrak{p}'_{e,u_j}$ to $\bar{\mathfrak{p}}_{e,u_i}$ and $\bar{\mathfrak{p}}_{e,u_j}$. Since $\mathcal{U}$ is an independent set, at least one of u_i and u_j does not belong to $\mathcal{U}$. Without loss of generality, let us assume $u_i \notin \mathcal{U}$.

$$\bar{\mathfrak{p}}_{e,u_i} = \overrightarrow{(\mathcal{C} \setminus \{u_i, g'_i, e\})} \succ u_i \succ e \succ g'_i \ , \ \bar{\mathfrak{p}}_{e,u_j} = \overrightarrow{(\mathcal{C} \setminus \{u_j, g'_j, e\})} \succ e \succ g'_j \succ u_j$$

Let us call $\bar{\mathfrak{p}}_e = \{\bar{\mathfrak{p}}_{e,u_i}, \bar{\mathfrak{p}}_{e,u_j}\}$. We consider the extension of $\mathcal{P}$ to $\bar{\mathcal{P}} = \cup_{u \in \mathcal{V}, \ell \in [d]} \bar{\mathfrak{p}}^{\ell}_u \cup_{e \in \mathcal{E}} \bar{\mathfrak{p}}_e$. We claim that c is a co-winner in the profile $\bar{\mathcal{P}} \cup \mathcal{Q}$ since the maximin score of c, g_i, g'_i for every $i \in [k]$, $u \in \mathcal{V}$, and $e \in \mathcal{E}$ in $\bar{\mathcal{P}} \cup \mathcal{Q}$ is $-\lambda$.

In the reverse direction suppose the POSSIBLE WINNER instance $\mathcal{I}'$ be a YES instance. Then there exists an extension of the set of partial votes $\mathcal{P}'$ to a set of complete votes $\bar{\mathcal{P}}$ such that c is a co-winner in $\bar{\mathcal{P}} \cup \mathcal{Q}$. Let us call the extension of $\mathfrak{p}'^{\ell}_u$ in $\bar{\mathcal{P}}$ $\bar{\mathfrak{p}}^{\ell}_u$, $\mathfrak{p}'_{e,u_i}$ and $\mathfrak{p}'_{e,u_j}$ in $\bar{\mathcal{P}}$ $\bar{\mathfrak{p}}_{e,u_i}$ and $\bar{\mathfrak{p}}_{e,u_j}$ respectively. First we notice that the maximin score of c in $\bar{\mathcal{P}} \cup \mathcal{Q}$ is $-\lambda$ since the relative ordering of c with respect to every other candidate is already fixed in $\mathcal{P}' \cup \mathcal{Q}$. Now we observe that, in $\mathcal{P} \cup \mathcal{Q}$, the maximin score of g_i for every $i \in [k]$ is $-(\lambda - 2d)$. Hence, for c to co-win, there must exists at least one $u^*_i \in \mathcal{V}_i$ for every $i \in [k]$ such that $u^*_i \succ g_i \succ g'_i$ in $\bar{\mathfrak{p}}^{\ell}_{u^*_i}$ for every $\ell \in [d]$. We claim that $\mathcal{U} = \{u^*_i : i \in [k]\}$ is an independent set in $\mathcal{I}$. If not, then suppose there exists an edge e between u^*_i and u^*_j for some $i, j \in [k]$. Now notice that, for c to co-win either $u^*_i \succ e \succ g'_i$ in $\bar{\mathfrak{p}}_{e,u^*_i}$ or $u^*_j \succ e \succ g'_j$ in $\bar{\mathfrak{p}}_{e,u^*_j}$. However, this makes the maximin score of either u^*_i or u^*_j strictly more than $-\lambda$ contradicting our assumption that c co-wins the election. Hence, $\mathcal{U}$ forms an independent set in $\mathcal{I}$. ◀

We next prove in Theorem 18 that the maximum number of undetermined pairs of candidates in Theorem 17 is tight.

▶ **Theorem 18.** *[⋆] The* POSSIBLE WINNER *problem is in* P *for the maximin voting rule if the number of undetermined pairs of candidates in every vote is at most* 1.

Finally, we state our results for the Bucklin voting rule.

▶ **Theorem 19.** *[⋆] The* POSSIBLE WINNER *problem is* NP*-complete for the Bucklin voting rule even if the number of undetermined pairs of candidates in every vote is at most* 2*, and is in* P *if the number of undetermined pairs of candidates in every vote is at most* 1.

4 Conclusion

We have demonstrated the exact minimum number of undetermined pairs allowed per vote which keeps the POSSIBLE WINNER winner problem NP-complete, and we were able to address a large class of scoring rules, Copeland$^{\alpha}$, maximin, and Bucklin voting rules. Our results generalize many of the known hardness results in the literature, and show that for many voting rules, we need a surprisingly small number of undetermined pairs (often just one or two) for the POSSIBLE WINNER problem to be NP-complete. In the context of scoring rules, it would be interesting to extend these tight results to the class of pure scoring rules, and to extend Theorem 9 to account for all smooth scoring rules.

Fractal Intersections and Products via Algorithmic Dimension

Neil Lutz*

Department of Computer and Information Science, University of Pennsylvania, Philadelphia, PA, USA
neillutz@gmail.com

Abstract

Algorithmic dimensions quantify the algorithmic information density of individual points and may be defined in terms of Kolmogorov complexity. This work uses these dimensions to bound the classical Hausdorff and packing dimensions of intersections and Cartesian products of fractals in Euclidean spaces. This approach shows that a known intersection formula for Borel sets holds for arbitrary sets, and it significantly simplifies the proof of a known product formula. Both of these formulas are prominent, fundamental results in fractal geometry that are taught in typical undergraduate courses on the subject.

1 Introduction

Classical fractal dimensions, among which *Hausdorff dimension* [12] is the most important, refine notions of measure to quantitatively classify sets of measure 0. In 2000, J. Lutz [15] showed that Hausdorff dimension can be simply characterized using betting strategies called *gales*, and that this characterization can be *effectivized* in order to quantitatively classify non-random infinite data objects. This *effective Hausdorff dimension* and other, related *algorithmic dimensions* have been applied to multiple areas of computer science and have proven especially useful in algorithmic information theory [25].

The connection between algorithmic and classical dimensions has more recently been exploited in the other direction, i.e., to apply algorithmic information theoretic methods and intuition to classical fractal geometry (e.g., [29, 2]). A *point-to-set principle* of J. Lutz and N. Lutz [16], stated here as Theorem 6, characterizes the classical Hausdorff dimension of any set in $\mathbb{R}^n$ in terms of the algorithmic dimensions of its individual points.

In the same work, J. Lutz and N. Lutz showed that the point-to-set principle gives rise to a new, pointwise technique for dimensional lower bounds, and, as a proof of concept, used this technique to give an algorithmic information theoretic proof of Davies's 1971 [7] theorem stating that every Kakeya set in $\mathbb{R}^2$ has Hausdorff dimension 2. This bounding technique has since been used by N. Lutz and Stull [18] to make new progress on a problem in classical fractal geometry by deriving an improved lower bound on the Hausdorff dimension of generalized Furstenberg sets, as defined by Molter and Rela [26].

* This research was done at Rutgers University and supported in part by National Science Foundation Grant 1445755.

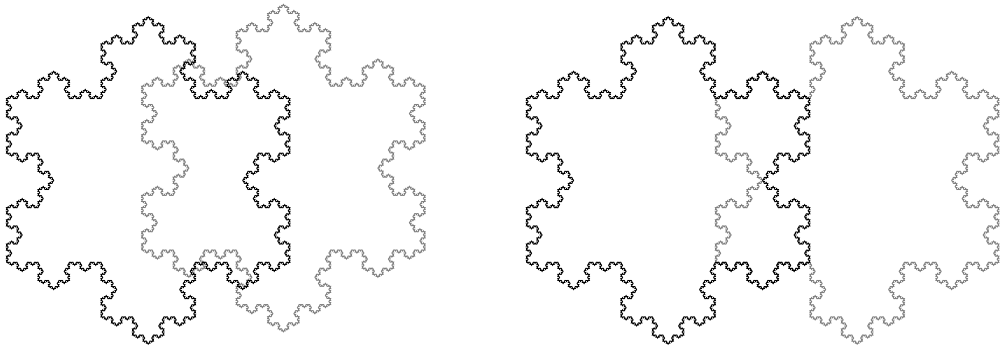

Figure 1 Let E and F both be Koch snowflakes, which have Hausdorff dimension $\log_3 4 \approx 1.26$. *Left:* Theorem 1 states that, for almost all translation parameters $z \in \mathbb{R}^2$, the Hausdorff dimension of the intersection $E \cap (F + z)$ is at most $2 \log_3 4 - 2 \approx 0.52$. *Right:* For a measure zero set of translations, the intersection may have Hausdorff dimension as large as that of the original sets. Note that Koch curves are Borel sets, so the new generality introduced by Theorem 1 is not required for this example.

The same algorithmic dimensional technique is applied here to bound the dimensions of intersections and products of fractals. Most significantly, we extend the following intersection formula, previously shown to hold when E and F are Borel sets [11], to arbitrary sets E and F.[1] This formula is illustrated in Figure 1.

▶ **Theorem 1.** *For all $E, F \subseteq \mathbb{R}^n$, and for (Lebesgue) almost all $z \in \mathbb{R}^n$,*

$$\dim_H(E \cap (F + z)) \leq \max\{0, \dim_H(E \times F) - n\},$$

where $F + z = \{x + z : x \in F\}$.

Our approach also yields a simplified proof of the following known product formula for general sets.

▶ **Theorem 2** (Marstrand [19])**.** *For all $E \subseteq \mathbb{R}^m$ and $F \subseteq \mathbb{R}^n$,*

$$\dim_H(E) + \dim_H(F) \leq \dim_H(E \times F).$$

We use symmetric arguments to derive the known corresponding statements about *packing dimension* [37, 10], a formulation of fractal dimension that was developed independently by Tricot [37] and Sullivan [36] and is dual to Hausdorff dimension. These results are included here to showcase the versatility of this technique and its ability to capture the exact duality between Hausdorff and packing dimensions.

2 Classical Fractal Dimensions

We begin by stating classical, measure-theoretic definitions of the two most well-studied notions of fractal dimension, Hausdorff dimension and packing dimension. These definitions are included here for completeness but are not used directly in the remainder of this work; we will instead apply equivalent characterizations in terms of algorithmic information, as described in Section 3.

[1] This result is closely related to the Marstrand Slicing Theorem, as stated in the excellent recent book by Bishop and Peres [4]. The proof given there assumes that a set is Borel, but this assumption was inadvertently omitted from the theorem statement [3].

▶ **Definition 2.1** (Hausdorff [12]). For $E \subseteq \mathbb{R}^n$, let $\mathcal{U}_\delta(E)$ be the collection of all countable covers of E by sets of positive diameter at most δ, where the *diameter* of any set $U \subseteq \mathbb{R}^n$ is given by

$$\operatorname{diam}(U) = \sup_{x,y \in U} |x - y| .$$

For all $s \geq 0$, let

$$H^s_\delta(E) = \inf \left\{ \sum_{i \in \mathbb{N}} \operatorname{diam}(U_i)^s \ : \ \{U_i\}_{i \in \mathbb{N}} \in \mathcal{U}_\delta(E) \right\} .$$

The *s-dimensional Hausdorff (outer) measure of* E is

$$H^s(E) = \lim_{\delta \to 0^+} H^s_\delta(E) ,$$

and the *Hausdorff dimension of* E is

$$\dim_H(E) = \inf \{s > 0 : H^s(E) = 0\} = \sup \{s : H^s(E) = \infty\} .$$

Three desirable properties have made $\dim_H$ the most standard notion of fractal dimension since it was introduction by Hausdorff in 1919. First, it is defined on every set in $\mathbb{R}^n$. Second, it is *monotone*: if $E \subseteq F$, then $\dim_H(E) \leq \dim_H(F)$. Third, it is *countably stable*: if $E = \bigcup_{i \in \mathbb{N}} E_i$, then $\dim_H(E) = \sup_{i \in \mathbb{N}} \dim_H(E_i)$. These three properties also hold for packing dimension, which was defined much later, independently by Tricot [37] and by Sullivan [36].

▶ **Definition 2.2** (Tricot [37], Sullivan [36]). For all $x \in \mathbb{R}^n$ and $\rho > 0$, let $B_\rho(x)$ denote the open ball of radius ρ and center x. For all $E \subseteq \mathbb{R}^n$, let $\mathcal{V}_\delta(E)$ be the class of all countable collections of pairwise disjoint open balls with centers in E and diameters at most δ. That is, for every $i \in \mathbb{N}$, we have $V_i = B_{\rho_i}(x_i)$ for some $x_i \in E$ and $\rho_i \in [0, \delta/2]$, and for every $j \neq i$, $V_i \cap V_j = \emptyset$. For all $s \geq 0$, define

$$P^s_\delta(E) = \sup \left\{ \sum_{i \in \mathbb{N}} \operatorname{diam}(V_i)^s \ : \ \{V_i\}_{i \in \mathbb{N}} \in \mathcal{V}_\delta(E) \right\} ,$$

and let

$$P^s_0(E) = \lim_{\delta \to 0^+} P^s_\delta(E) .$$

The *s-dimensional packing (outer) measure of* E is

$$P^s(E) = \inf \left\{ \sum_{i \in \mathbb{N}} P^s_0(E_i) \ : \ E \subseteq \bigcup_{i \in \mathbb{N}} E_i \right\} ,$$

and the *packing dimension of* E is

$$\dim_P(E) = \inf \{s : P^s(E) = 0\} = \sup \{s > 0 : P^s(E) = \infty\} .$$

Notice that defining packing dimension in this way requires an extra step of optimization compared to Hausdorff dimension. More properties and details about classical fractal dimensions may be found in standard references such as [23, 11, 35].

3 Algorithmic Fractal Dimensions

This section defines the effective Hausdorff and packing dimensions in terms of algorithmic information, i.e., Kolmogorov complexity. We also define conditional dimensions and discuss some properties of these dimensions, including their relationships to classical Hausdorff and packing dimensions.

3.1 Kolmogorov Complexity

Kolmogorov complexity quantifies the *incompressibility* of finite data objects. It is most often defined in the space $\{0,1\}^*$ of binary strings, but it is readily extended to other discrete domains. For the purposes of this work, the complexity of rational points is most relevant. Hence, fix some standard binary encoding for n-tuples of rationals. The *Kolmogorov complexity of* p is the length of the shortest binary program that outputs p. Formally, it is

$$K(p) = \min_{\pi\in\{0,1\}^*} \{|\pi| : U(\pi) = p\},$$

where U is a fixed universal prefix-free Turing machine and $|\pi|$ is the length of π. This quantity is also called the *algorithmic information content* of p. The *conditional Kolmogorov complexity of* p *given* $q \in \mathbb{Q}^n$ is the length of the shortest binary program that outputs p when given q as an input:

$$K(p|q) = \min_{\pi\in\{0,1\}^*} \{|\pi| : U(\pi, q) = p\}.$$

The *algorithmic mutual information between* $p \in \mathbb{Q}^m$ *and* $q \in \mathbb{Q}^n$ measures, informally, the amount that knowledge of q helps in the task of compressing p. Formally, it is

$$I(p : q) = K(p) - K(p|q).$$

The quantities $K(p)$, $K(p|q)$, and $I(p : q)$ may be considered algorithmic versions of *entropy* $H(X)$, *conditional entropy* $H(X|Y)$, and *mutual information* $I(X;Y)$, from classical (Shannon) information theory. See references [14, 27, 8] for more details on algorithmic information and the connections between algorithmic and classical theories of information.

3.2 Effective Dimensions

Using approximation by rationals, Kolmogorov complexity may be further extended to Euclidean spaces [17]. For every $E \subseteq \mathbb{R}^n$, define

$$K(E) = \min\{K(p) : p \in E \cap \mathbb{Q}^n\},$$

where the minimum is understood to be infinite if $E \cap \mathbb{Q}^n$ is empty. This is the length of the shortest program that outputs some rational point in E. The *Kolmogorov complexity of* $x \in \mathbb{R}^n$ *at precision* $r \in \mathbb{N}$ is given by

$$K_r(x) = K(B_{2^{-r}}(x)),$$

the length of the shortest program that outputs any *precision-r* rational approximation of x. $K_r(x)$ may also be described as the *algorithmic information content* of x at precision r, and similarly, $K_r(x)/r$ is the *algorithmic information density* of x at precision r. This ratio does not necessarily converge as $r \to \infty$, but it does have limiting bounds in $[0, n]$. These limits are used to define effective dimensions.

▶ **Definition 3.1** ([15, 24, 1, 17]). Let $x \in \mathbb{R}^n$.

1. The *effective Hausdorff dimension of* x is
$$\dim(x) = \liminf_{r\to\infty} \frac{K_r(x)}{r}\,.$$
2. The *effective packing dimension of* x is
$$\mathrm{Dim}(x) = \limsup_{r\to\infty} \frac{K_r(x)}{r}\,.$$

These dimensions were originally defined by J. Lutz [15] and Athreya, Hitchcock, J. Lutz, and Mayordomo [1], respectively. The original definitions were in Cantor space and used *gales*, which are betting strategies that generalize martingales, emphasizing the *unpredictability* of a sequence instead of its incompressibility. The Kolmogorov complexity characterizations and translation to Euclidean spaces are due to Mayordomo [24] and J. Lutz and Mayordomo [17]. Relationships between Hausdorff dimension and Kolmogorov complexity were also studied earlier by Ryabko [30, 31, 32], Staiger [33, 34], and Cai and Hartmanis [5]; see Section 6 of [15] for a detailed discussion of this history.

We will use the fact that these dimensions are preserved by sufficiently well-behaved functions, namely bi-Lipschitz computable bijections.

▶ **Lemma 3** (Reimann [28], Case and J. Lutz [6]). *If* $f : \mathbb{R}^m \to \mathbb{R}^n$ *is computable and bi-Lipschitz, then* $\dim(x) = \dim(f(x))$ *and* $\mathrm{Dim}(x) = \mathrm{Dim}(f(x))$ *for all* $x \in \mathbb{R}^m$.

3.3 Conditional Dimensions

The information theoretic nature of Definition 3.1 has led to the development of algorithmic dimensional quantities corresponding to the other algorithmic information theoretic quantities defined above. As analogues to mutual information and conditional information, Case and J. Lutz defined *mutual dimensions* [6], and J. Lutz and N. Lutz defined *conditional dimensions*. This work will use the latter, which we now describe.

Given $E \subseteq \mathbb{R}^m$ and $F \subseteq \mathbb{R}^n$, define
$$K(E|F) = \max\left\{\min\{K(p|q) : p \in E \cap \mathbb{Q}^m\} : q \in F \cap \mathbb{Q}^n\right\}.$$
Then the *conditional Kolmogorov complexity of* $x \in \mathbb{R}^m$ *at precision* $r \in \mathbb{N}$ *given* $y \in \mathbb{R}^n$ *at precision* $s \in \mathbb{N}$ is given by
$$K_{r,s}(x|y) = K(B_{2^{-r}}(x)|B_{2^{-s}}(y))\,.$$

▶ **Definition 3.2** (J. Lutz and N. Lutz [16]). Let $x \in \mathbb{R}^m$ and $y \in \mathbb{R}^n$.

1. The *lower conditional dimension of* x *given* y is
$$\dim(x : y) = \liminf_{r\to\infty} \frac{K_{r,r}(x|y)}{r}\,.$$
2. The *upper conditional dimension of* x *given* y is
$$\mathrm{Dim}(x : y) = \limsup_{r\to\infty} \frac{K_{r,r}(x|y)}{r}\,.$$

That work also showed that the *symmetry of algorithmic information* holds in Euclidean space, in the form
$$K_r(x, y) = K_r(x) + K_{r,r}(y|x) + o(r)\,.$$
This fact and elementary properties of limits inferior and superior immediately imply the following *chain rule for effective dimensions*.

▶ **Theorem 4** (J. Lutz and N. Lutz [16]). *For all $x \in \mathbb{R}^m$ and $y \in \mathbb{R}^n$,*

$$\begin{aligned}\dim(x) + \dim(y|x) &\leq \dim(x,y)\\ &\leq \dim(x) + \mathrm{Dim}(y|x)\\ &\leq \mathrm{Dim}(x,y)\\ &\leq \mathrm{Dim}(x) + \mathrm{Dim}(y|x)\,.\end{aligned}$$

3.4 Oracles and Relative Dimensions

By making the fixed universal machine U an oracle machine, the algorithmic information quantities above may be defined relative to any oracle $A \subseteq \mathbb{N}$. The definitions of $K^A(\sigma|\tau)$, $K^A(\sigma)$, $K^A_r(x)$, $K^A_r(x|y)$, $\dim^A(x)$, $\mathrm{Dim}^A(x)$, $\dim^A(x|y)$ and $\mathrm{Dim}^A(x|y)$ all exactly mirror their unrelativized versions, except that U is permitted to query membership in A as a computational step.

For $y \in \mathbb{R}^n$, we write $\dim^y(x)$ as shorthand for $\dim^{A_y}(x)$, where $A_y \subseteq \mathbb{N}$ encodes the binary expansions of y's coordinates in some standard way, and similarly for $\mathrm{Dim}^y(x)$. Since this kind of oracle access to y is at least as informative as any finite-precision estimate for y (ignoring the small amount of information given by the precision parameter itself), these relative dimensions are bounded above by conditional dimensions.

▶ **Lemma 5** (J. Lutz and N. Lutz [16]). *For all $x \in \mathbb{R}^m$ and $y \in \mathbb{R}^n$,*

1. $\dim^y(x) \leq \dim(x|y)$,
2. $\mathrm{Dim}^y(x) \leq \mathrm{Dim}(x|y)$.

3.5 Point-to-Set Principle

Effective Hausdorff dimension and effective packing dimension were conceived as constructive versions of classical Hausdorff dimension and packing dimension [15, 1]. The following *point-to-set principle* uses relativization to precisely characterize their relationships to their non-algorithmic precursors.

▶ **Theorem 6** (J. Lutz and N. Lutz [16]). *For every $E \subseteq \mathbb{R}^n$, the Hausdorff dimension and packing dimension of E are*

1. $\dim_H(E) = \min_{A \subseteq \mathbb{N}} \sup_{x \in E} \dim^A(x)\,,$
2. $\dim_P(E) = \min_{A \subseteq \mathbb{N}} \sup_{x \in E} \mathrm{Dim}^A(x)\,.$

Notice that, unlike the definitions of $\dim_H(E)$ and $\dim_P(E)$ given in Section 2, the above characterizations are completely symmetrical.

Theorem 6 allows us to prove lower bounds on classical dimensions in a pointwise way. To show a statement of the form $\dim_H(E) \geq \alpha$, it suffices to show, for a given oracle A and every $\varepsilon > 0$, that there exists an $x \in E$ satisfying $\dim^A(x) \geq \alpha - \varepsilon$. Unlike previous applications of this bounding technique [16, 18], the proofs in Sections 4 and 5 do not directly invoke Kolmogorov complexity; the only tools needed are Lemma 3, Theorem 4, Lemma 5, and Theorem 6.

4 Intersections of Fractals

In this section we prove Theorem 1. We then use a symmetric argument to prove the corresponding statement for packing dimension, which is known [10]. For the case where

$E, F \subseteq \mathbb{R}^n$ are Borel sets, Theorem 1 was shown in its present form by Falconer [11]. Closely related results, which also place restrictions on E and F, were proven earlier by Mattila [21, 22] and Kahane [13].

▶ **Theorem 1.** *For all $E, F \subseteq \mathbb{R}^n$, and for (Lebesgue) almost all $z \in \mathbb{R}^n$,*

$$\dim_H(E \cap (F + z)) \leq \max\{0, \dim_H(E \times F) - n\}\,, \tag{1}$$

where $F + z = \{x + z : x \in F\}$.

Proof. Let $E, F \subseteq \mathbb{R}^n$ and $z \in \mathbb{R}^n$. If $E \cap (F + z) = \emptyset$, then (1) holds trivially, so assume that the intersection is nonempty. Theorem 6 guarantees that there is some oracle set $A \subseteq \mathbb{N}$ satisfying

$$\dim_H(E \times F) = \sup_{(x,y) \in E \times F} \dim^A(x, y)\,. \tag{2}$$

It also guarantees, given any $\varepsilon > 0$, that there is an $x \in E \cap (F + z)$ such that

$$\dim^{A,z}(x) \geq \dim_H(E \cap (F + z)) - \varepsilon\,. \tag{3}$$

Since $(x, x - z) \in E \times F$, we have

$$\begin{aligned}
\dim_H(E \times F) &\geq \dim^A(x, x - z) \\
&= \dim^A(x, z) \\
&\geq \dim^A(z) + \dim^A(x|z) \\
&\geq \dim^A(z) + \dim^{A,z}(x) \\
&\geq \dim^A(z) + \dim_H(E \cap (F + z)) - \varepsilon\,.
\end{aligned}$$

The above lines follow from (2), Lemma 3, Theorem 4, Lemma 5, and (3), respectively. Letting $\varepsilon \to 0$, we have

$$\dim_H(E \cap (F + z)) \leq \dim_H(E \times F) - \dim^A(z)\,.$$

Thus, (a) holds whenever $\dim^A(z) = n$. In particular, it holds when z is Martin-Löf random relative to A, i.e., for Lebesgue almost all $z \in \mathbb{R}^n$ [14, 20]. ◀

For the case that E and F are Borel sets, Falconer [11] notes that the intersection formula is readily extended to rigid motions and similarities. The same argument applies in the general case, so Theorem 1 has the following corollary.

▶ **Corollary 7.** *Let $E, F \subseteq \mathbb{R}^n$. Let G be the group of rigid motions or the group of similarities on $\mathbb{R}^n$. Then, for almost all $\sigma \in G$,*

$$\dim_H(E \cap \sigma(F)) \leq \max\{0, \dim_H(E \times F) - n\}\,. \tag{4}$$

Proof (Following Falconer [11]). For all rotations (and all scalings) of F, Theorem 1 tells us that (4) holds for almost all translations. Thus, (4) holds for almost all rigid motions and almost all similarities. ◀

A corresponding intersection formula for packing dimension has been shown for arbitrary $E, F \subseteq \mathbb{R}^n$ by Falconer [10]. That proof is not difficult or long, but an algorithmic dimensional proof is presented here as an instance where this technique applies symmetrically to both Hausdorff and packing dimension.

▶ **Theorem 8** (Falconer [10]). *For all $E, F \subseteq \mathbb{R}^n$, and for (Lebesgue) almost all $z \in \mathbb{R}^n$,*

$$\dim_P(E \cap (F+z)) \leq \max\{0, \dim_P(E \times F) - n\}\,.$$

Proof. As in Theorem 1, we may assume that the intersection is nonempty. Apply Theorem 6 to choose an oracle set $B \subseteq \mathbb{N}$ such that

$$\dim_P(E \times F) = \sup_{(x,y)\in E\times F} \mathrm{Dim}^B(x,y) \tag{5}$$

and, given $\varepsilon > 0$, a point $y \in E \cap (F+z)$ satisfying

$$\mathrm{Dim}^{B,z}(y) \geq \dim_P(E \cap (F+z)) - \varepsilon\,. \tag{6}$$

Then $(y, y-z) \in E \times F$, and we may proceed much as before:

$$\begin{aligned}
\dim_P(E \times F) &\geq \mathrm{Dim}^B(y, y-z) \\
&= \mathrm{Dim}^B(y,z) \\
&\geq \dim^B(z) + \mathrm{Dim}^B(y|z) \\
&\geq \dim^B(z) + \mathrm{Dim}^{B,z}(y) \\
&\geq \dim^B(z) + \dim_P(E \cap (F+z)) - \varepsilon\,.
\end{aligned}$$

These lines follow from (5), Lemma 3, Theorem 4, Lemma 5, and (6). Again, $\dim^B(z) = n$ for almost every $z \in \mathbb{R}^n$, so this completes the proof. ◀

5 Products of Fractals

In this section we prove four known product inequalities for fractal dimensions. Inequality (7), which was stated in the introduction as Theorem 2, is due to Marstrand [19]. When E and F are Borel sets, it is simple to prove (7) by using Frostman's Lemma, but the argument for general sets using net measures is considerably more difficult [23, 9]. The other three inequalities are due to Tricot [37]. Reference [23] gives a more detailed account of this history.

▶ **Theorem 9** (Marstrand [19], Tricot [37]). *For all $E \subseteq \mathbb{R}^m$ and $F \subseteq \mathbb{R}^n$,*

$$\begin{aligned}
\dim_H(E) + \dim_H(F) &\leq \dim_H(E \times F) && (7)\\
&\leq \dim_H(E) + \dim_P(F) && (8)\\
&\leq \dim_P(E \times F) && (9)\\
&\leq \dim_P(E) + \dim_P(F)\,. && (10)
\end{aligned}$$

Notice the superficial resemblance of this theorem to Theorem 4. This similarity is not a coincidence; each inequality in Theorem 9 follows from the corresponding line in Theorem 4. The arguments given here for (7–10) are each similar in length to the proof of (7) for Borel sets. That is, they are quite short.

Proof. Theorem 6 guarantees, for every $\varepsilon > 0$, that there exist an oracle set $A \subseteq \mathbb{N}$ and points $x \in E$ and $y \in F$ such that

$$\begin{aligned}
\dim_H(E \times F) &= \sup_{z\in E\times F} \dim^A(z)\,, && (11)\\
\dim^A(x) &\geq \dim_H(E) - \varepsilon\,,\\
\dim^{A,x}(y) &\geq \dim_H(F) - \varepsilon\,.
\end{aligned}$$

Then by (11), Theorem 4 relative to A, and Lemma 5 relative to A, we have

$$\begin{aligned}\dim_H(E \times F) &\geq \dim^A(x, y) \\ &\geq \dim^A(x) + \dim^A(y|x) \\ &\geq \dim^A(x) + \dim^{A,x}(y) \\ &\geq \dim_H(E) + \dim_H(F) - 2\varepsilon\,,\end{aligned}$$

by our choice of x and y. Since $\varepsilon > 0$ was arbitrary, we conclude that (7) holds.

For (8), let $\varepsilon > 0$ and use both parts of Theorem 6 to find $B, C \subseteq \mathbb{N}$, $u \in E$, and $v \in F$ such that

$$\begin{aligned}\dim_H(E) &= \sup_{x \in E} \dim^B(x)\,, \\ \dim_P(F) &= \sup_{y \in E} \mathrm{Dim}^C(y)\,, \\ \dim^{B,C}(u, v) &\geq \dim_H(E \times F) - \varepsilon\,.\end{aligned}$$

Since B and C minimize their respective expressions, we also have

$$\begin{aligned}\dim_H(E) &= \sup_{x \in E} \dim^{B,C}(x)\,, \\ \dim_P(F) &= \sup_{y \in E} \mathrm{Dim}^{B,C}(y)\,.\end{aligned}$$

Thus, we can apply Theorem 4 relative to B, C, after first noticing that conditioning on another point never increases dimension.

$$\begin{aligned}\dim_H(E) + \dim_P(F) &\geq \dim^{B,C}(u) + \mathrm{Dim}^{B,C}(v) \\ &\geq \dim^{B,C}(u|v) + \mathrm{Dim}^{B,C}(v) \\ &\geq \dim^{B,C}(u, v) \\ &\geq \dim_H(E \times F) - \varepsilon\,.\end{aligned}$$

Again, ε was arbitrary, so (8) holds.

For (9) and (10), we use essentially the same arguments as above. By Theorem 6, there are $A', B' \subseteq \mathbb{N}$, $x', u' \in E$, $y', v' \in F$, and $\varepsilon > 0$ that satisfy

$$\begin{aligned}\dim_P(E \times F) &= \sup_{z \in E \times F} \mathrm{Dim}^{A'}(z)\,, \\ \dim_H(E) &= \sup_{z \in E} \mathrm{Dim}^{B'}(z)\,, \\ \dim^{A'}(x') &\geq \dim_H(E) - \varepsilon\,, \\ \mathrm{Dim}^{A',x'}(y') &\geq \dim_P(F) - \varepsilon\,, \\ \mathrm{Dim}^{B',C}(u', v') &\geq \dim_P(E \times F) - \varepsilon\,,\end{aligned}$$

where x and C are as above. We once again apply relativized versions of Theorem 4 and

Lemma 5:

$$\begin{aligned}
\dim_P(E) + \dim_P(F) &\geq \mathrm{Dim}^{B',C}(u') + \mathrm{Dim}^{B',C}(v') \\
&\geq \mathrm{Dim}^{B',C}(u'|v') + \mathrm{Dim}^{B',C}(v') \\
&\geq \mathrm{Dim}^{B',C}(u', v') \\
&\geq \dim_P(E \times F) - \varepsilon \\
&\geq \mathrm{Dim}^{A'}(x', y') - \varepsilon \\
&\geq \dim^{A'}(x') + \mathrm{Dim}^{A'}(y'|x') - \varepsilon \\
&\geq \dim^{A'}(x') + \mathrm{Dim}^{A',x'}(y') - \varepsilon \\
&\geq \dim_H(E) + \dim_P(F) - 3\varepsilon\,.
\end{aligned}$$

Letting $\varepsilon \to 0$ completes the proof. ◀

6 Conclusion

The applications of theoretical computer science to pure mathematics in this paper yielded a significant extension to a basic theorem on Hausdorff dimension, as well as a much simpler argument for another such theorem. Understanding classical fractal dimensions as pointwise, algorithmic information theoretic quantities enables reasoning about them in a way that is both fine-grained and intuitive, and the proofs in this work are further evidence of the power and versatility of bounding techniques using Theorem 6. In particular, Theorem 1 demonstrates that this approach can be used to strengthen the foundations of fractal geometry. Therefore, in addition to further applications of these techniques, developing more refined results on the relationship between classical geometric measure theory and Kolmogorov complexity is an appealing direction for future investigations.

Abstract

We study two-player inclusion games played over word-generating higher-order recursion schemes. While inclusion checks are known to capture verification problems, two-player games generalize this relationship to program synthesis. In such games, non-terminals of the grammar are controlled by opposing players. The goal of the existential player is to avoid producing a word that lies outside of a regular language of safe words.

We contribute a new domain that provides a representation of the winning region of such games. Our domain is based on (functions over) potentially infinite Boolean formulas with words as atomic propositions. We develop an abstract interpretation framework that we instantiate to abstract this domain into a domain where the propositions are replaced by states of a finite automaton. This second domain is therefore finite and we obtain, via standard fixed-point techniques, a direct algorithm for the analysis of two-player inclusion games. We show, via a second instantiation of the framework, that our finite domain can be optimized, leading to a $(k+1)$EXP algorithm for order-k recursion schemes. We give a matching lower bound, showing that our approach is optimal. Since our approach is based on standard Kleene iteration, existing techniques and tools for fixed-point computations can be applied.

1 Introduction

Inclusion checking has recently received considerable attention [53, 22, 1, 2, 36]. One of the reasons is a new verification loop, which invokes inclusion as a subroutine in an iterative fashion. The loop has been proposed by Podelski et al. for the safety verification of recursive programs [32], and then been generalized to parallel and parameterized programs [42, 20, 18] and to liveness [19]. The idea of Podelski's loop is to iteratively approximate unsound data flow in the program of interest, and add the approximations to the specification. Consider a program with control-flow language CF that is supposed to satisfy a safety specification

* The full version is available as technical report [28].
† This work was supported by the Engineering and Physical Sciences Research Council [EP/K009907/1]. The work instigated while some of the authors were visiting the Institute for Mathematical Sciences, National University of Singapore in 2016. The visit was partially supported by the Institute.
‡ A part of the work was carried out when the author was at Aalto University.

given by a regular language R. If the check $CF \subseteq R$ succeeds, then the program is correct as the data flow only restricts the set of computations. If a computation $w \in CF$ is found that lies outside R, then it depends on the data flow whether the program is correct. If data is handled correctly, w is a counterexample to R. Otherwise, w is generalized to a regular language S of infeasible computations. We set $R = R \cup S$ and repeat the procedure.

Podelski's loop has also been generalized to synthesis [35, 44]. In that setting, the program is assumed to have two kinds of non-determinism. Some of the non-deterministic transitions are understood to be controlled by the environment. They provide inputs that the system has to react to, and are also referred to as demonic non-determinism. In contrast, the so-called angelic non-determinism are the alternatives of the system to react to an input. The synthesis problem is to devise a controller that resolves the angelic non-determinism in a way that a given safety specification is met. Technically, the synthesis problem corresponds to a two-player perfect information game, and the controller implements a winning strategy for the system player. When generalizing Podelski's loop to the synthesis problem, the inclusion check thus amounts to solving a strategy-synthesis problem.

Our motivation is to synthesize functional programs with Podelski's loop. We assume the program to be given as a non-deterministic higher-order recursion scheme where the non-terminals are assigned to two players. One player is the system player who tries to enforce the derivation of words that belong to a given regular language. The other player is the environment, trying to derive a word outside the language. The use of the corresponding strategy-synthesis algorithm in Podelski's loop comes with three characteristics: (1) The algorithm is invoked iteratively, (2) the program is large and the specification is small, and (3) the specification is non-deterministic. The first point means that the strategy synthesis should not rely on costly precomputation. Moreover, it should have the chance to terminate early. The second says that the cost of the computation should depend on the size of the specification, not on the size of the program. Computations on the program, in particular iterative ones, should be avoided. Together with the third characteristic, these two consequences rule out reductions to reachability games. The required determinization would mean a costly precomputation, and the reduction to reachability would mean a product with the program. This discussion in particular forbids a reduction of the strategy-synthesis problem to higher-order model checking [45], which indeed can be achieved (see the full version [28] for a comparison to intersection types [41]). Instead, we need a strategy synthesis that can directly deal with non-deterministic specifications.

We show that the winning region of a higher-order inclusion game wrt. a non-deterministic right-hand side can be computed with a standard fixed-point iteration. Our contribution is a domain suitable for this computation. The key idea is to use Boolean formulas whose atomic propositions are the states of the targeted finite automaton. While a formula-based domain has recently been proposed for context-free inclusion games [35] (and generalized to infinite words [44]), the generalization to higher-order is new. Consider a non-terminal that is ground and for which we have computed a formula. The Boolean structure reflects the alternation among the players in the plays that start from this non-terminal. The words generated along the plays are abstracted to sets of states from which these words can be accepted. Determining the winner of the game is done by evaluating the formula when sets of states containing the initial state are assigned the value true. To our surprise, the above domain did not give the optimal complexity. Instead, it was possible to further optimize it by resolving the determinization information. Intuitively, the existential player can also resolve the non-determinism captured by a set. Crucially, our approach handles the non-determinism of the specification inside the analysis, without preprocessing.

Besides offering the characteristics that are needed for Podelski's loop, our development also contributes to the research program of *effective denotational semantics*, as recently proposed by Salvati and Walukiewicz [51] as well as Grellois and Melliès [24, 24], with [5, 48] being early works in this field. The idea is to solve verification problems by computing the semantics of a program in a suitable domain. Salvati and Walukiewicz studied the expressiveness of greatest fixed-point semantics and their correspondence to automata [51], and constructions of enriched Scott models for parity conditions [50, 49]. A similar line of investigation has been followed in recent work by Grellois and Melliès [25, 26]. Hofmann and Chen considered the verification of more restricted ω-path properties with a focus on the domain [33]. They show that explicit automata constructions can be avoided and give a domain that directly captures subsets (so-called patches) of the ω-language. The work has been generalized to higher order [34]. Our contribution is related in that we focus on the domain (suitable for capturing plays).

Besides the domain, the correctness proof may be of interest. We employ an exact fixed-point transfer result as known from abstract interpretation. First, we give a semantic characterization showing that the winning region can be captured by an infinite model (a greatest fixed point). This domain has as elements (potentially infinite) sets of (finite) Boolean formulas. The formulas capture plays (up to a certain depth) and the atomic propositions are terminal words. The infinite set structure is to avoid infinite syntax. Then we employ the exact fixed-point transfer result to replace the terminals by states and get rid of the sets. The final step is another exact fixed-point transfer that justifies the optimization. We give a matching lower bound. The problem is $(k+1)\mathsf{EXP}$-complete for order-k schemes.

Related Work. The relationship between recursion schemes and extensions of pushdown automata has been well studied [16, 17, 37, 29]. This means algorithms for recursion schemes can be transferred to extensions of pushdown automata and vice versa. In the sequel, we will use *pushdown automata* to refer to pushdown automata and their family of extensions.

The decidability of Monadic Second Order Logic (MSO) over trees generated by recursion schemes was first settled in the restricted case of *safe* schemes by Knapik *et al.* [37] and independently by Caucal [14]. This result was generalized to all schemes by Ong [45]. Both of these results consider *deterministic* schemes only.

Related results have also been obtained in the consideration of games played over the configuration graphs of pushdown automata [52, 13, 38, 29]. Of particular interest are *saturation* methods for pushdown games [7, 21, 12, 8, 30, 31, 9]. In these works, automata representing sets of winning configurations are constructed using fixed-point computations.

A related approach pioneered by Kobayashi et al. operating directly on schemes is that of *intersection types* [40, 41], where types embedding a property automaton are assigned to terms of a scheme. Recently, saturation techniques were transferred to intersection types by Broadbent and Kobayashi [10]. The typing algorithm is then a least fixed-point computation analogous to an optimized version of our Kleene iteration, restricted to deterministic schemes. This has led to one of the most competitive model-checking tools for schemes [39].

One may reduce our language inclusion problems to many of the above works. E.g. from an inclusion game for schemes, we may build a game over an equivalent kind of pushdown automaton and take the product with a determinization of the NFA. This obtains a reachability game over a pushdown automaton that can be solved by any of the above methods. However, such constructions are undesirable for iterative invocations as in Podelski's loop.

We already discussed the relationship to model-theoretic verification algorithms. Abstract interpretation has also been used by Ramsay [47], Salvati and Walukiewicz [50, 49], and

Grellois and Melliès [24, 23] for verification. The former used a Galois connection between safety properties (concrete) and equivalence classes of intersection types (abstract) to recreate decidability results known in the literature. The latter two strands gives a semantics capable of computing properties expressed in MSO. Indeed, abstract interpretation has long been used for static analysis of higher-order programs [4].

2 Preliminaries

Complete Partial Orders. Let $(D, \leq)$ be a *partial order* with set D and (partial) ordering $\leq$ on D. We call $(D, \leq)$ *pointed* if there is a greatest element, called the *top element* and denoted by $\top \in D$. A *descending chain* in D is a sequence $(d_i)_{i\in\mathbb{N}}$ of elements in D with $d_i \geq d_{i+1}$. We call $(D, \leq)$ *ω-complete* if every descending chain has a greatest lower bound, called the *meet* or the *infimum*, and denoted by $\bigsqcap_{i\in\mathbb{N}} d_i$. If $(D, \leq)$ is pointed and ω-complete, we call it a *pointed ω-complete partial order (cppo)*. In the following, we will only consider partial orders that are cppos. Note, cppo is usually used to refer to the dual concept, i.e. partial orders with a least element and least upper bounds for ascending chains.

A function $f : D \to D$ is *$\sqcap$-continuous* if for all descending chains $(d_i)_{i\in\mathbb{N}}$ we have $f(\bigsqcap_{i\in\mathbb{N}} d_i) = \bigsqcap_{i\in\mathbb{N}} f(d_i)$. We call a function $f : D \to D$ *monotonic* if for all $d, d' \in D$, $d \leq d'$ implies $f(d) \leq f(d')$. Any function that is $\sqcap$-continuous is also monotonic. For a monotonic function, $\top \geq f(\top) \geq f^2(\top) = f(f(\top)) \geq f^3(\top) \geq \dots$ is a descending chain.

If the function is $\sqcap$-continuous, then $\bigsqcap_{i\in\mathbb{N}} f^i(\top)$ is by Kleene's theorem the greatest fixed point of f, i.e. $f(\bigsqcap_{i\in\mathbb{N}} f^i(\top)) = \bigsqcap_{i\in\mathbb{N}} f^i(\top)$ and $\bigsqcap_{i\in\mathbb{N}} f^i(\top)$ is larger than any other element d with $f(d) = d$. We also say $\bigsqcap_{i\in\mathbb{N}} f^i(\top)$ is the greatest solution to the equation $x = f(x)$.

A lattice satisfies the *descending chain condition (DCC)* if every descending chain has to be stationary at some point. In this case $\bigsqcap_{i\in\mathbb{N}} f^i(\top) = \bigsqcap_{i=0}^{i_0} f^i(\top)$ for some index i_0 in $\mathbb{N}$. With this, we can compute the greatest fixed point: Starting with $\top$, we iteratively apply f until the result does not change. This process is called *Kleene iteration*. Note that finite cppos, i.e. with finitely many elements in D, trivially satisfy the descending chain condition.

Finite Automata. A *non-deterministic finite automaton (NFA)* is a tuple $A = (Q_{NFA}, \Gamma, \delta, q_0, Q_f)$ where Q_{NFA} is a finite set of states, Γ is a finite alphabet, $\delta \subseteq Q_{NFA} \times \Gamma \times Q_{NFA}$ is a (non-deterministic) transition relation, $q_0 \in Q_{NFA}$ is the initial state, and $Q_f \subseteq Q_{NFA}$ is a set of final states. We write $q \xrightarrow{a} q'$ to denote $(q, a, q') \in \delta$. Moreover, given a word $w = a_1 \cdots a_\ell$, we write $q \xrightarrow{w} q'$ whenever there is a sequence of transitions, also called *run*, $q_1 \xrightarrow{a_1} q_2 \xrightarrow{a_2} \cdots \xrightarrow{a_\ell} q_{\ell+1}$ with $q_1 = q$ and $q_{\ell+1} = q'$. The run is accepting if $q = q_0$ and $q' \in Q_f$. The language of A is $\mathcal{L}(A) = \{w \mid q_0 \xrightarrow{w} q \in Q_f\}$.

3 Higher-Order Recursion Schemes

We introduce higher-order recursion schemes, *schemes* for short, following the presentation in [27]. Schemes can be understood as grammars generating the computation trees of programs in a functional language. As is common in functional languages, we need a typing discipline. To avoid confusion with type-based approaches to higher-order model checking [40, 46, 41], we refer to types as *kinds*. Kinds define the functionality of terms, without specifying the data domain. Technically, the only data domain is the ground kind o, from which (potentially higher-order) function kinds are derived by composition:

$$\kappa \ ::= \ o \ \mid \ (\kappa_1 \to \kappa_2) \ .$$

We usually omit the brackets and assume that the arrow associates to the right. The number of arguments to a kind is called the *arity*. The *order* defines the functionality of the arguments: A first-order kind defines functions that act on values, a second-order kind functions that expect functions as parameters. Formally, we have

$$\mathsf{arity}(o) = 0, \qquad \mathsf{order}(o) = 0,$$
$$\mathsf{arity}(\kappa_1 \to \kappa_2) = \mathsf{arity}(\kappa_2) + 1, \qquad \mathsf{order}(\kappa_1 \to \kappa_2) = \max(\mathsf{order}(\kappa_1) + 1, \mathsf{order}(\kappa_2)) \ .$$

Let K be the set of all kinds. Higher-order recursion schemes assign kinds to symbols from different alphabets, namely non-terminals, terminals, and variables. Let Γ be a set of such *kinded symbols*. For each kind κ, we denote by Γ^κ the restriction of Γ to the symbols with kind κ. The *terms* $\mathcal{T}^\kappa(\Gamma)$ of kind κ over Γ are defined by simultaneous induction over all kinds. They form the smallest set satisfying

1. $\Gamma^\kappa \subseteq \mathcal{T}^\kappa(\Gamma)$,
2. $\bigcup_{\kappa_1} \{t\ v \mid t \in \mathcal{T}^{\kappa_1 \to \kappa_2}(\Gamma), v \in \mathcal{T}^{\kappa_1}(\Gamma)\} \subseteq \mathcal{T}^{\kappa_2}(\Gamma)$, and
3. $\{\lambda x.t \mid x \in \mathcal{T}^{\kappa_1}(\Gamma), t \in \mathcal{T}^{\kappa_2}(\Gamma)\} \subseteq \mathcal{T}^{\kappa_1 \to \kappa_2}(\Gamma)$.

If term t is of kind κ, we also write $t\colon \kappa$. We use $\mathcal{T}(\Gamma)$ for the set of all terms over Γ. We say a term is λ-*free* if it contains no sub-term of the form $\lambda x.t$. A term is *variable-closed* if all occurring variables are bound by a preceding λ-expression.

▶ **Definition 1.** A *higher-order recursion scheme*, (*scheme* for short), is a tuple $G = (V, N, T, R, S)$, where V is a finite set of kinded symbols called *variables*, T is a finite set of kinded symbols called *terminals*, and N is a finite set of kinded symbols called *non-terminals* with $S \in N$ the *initial symbol*. The sets V, T, and N are pairwise disjoint. The finite set R consists of *rewriting rules* of the form $F = \lambda x_1 \dots \lambda x_n.e$, where $F \in N$ is a non-terminal of kind $\kappa_1 \to \dots \kappa_n \to o$, $x_1, \dots, x_n \in V$ are variables of the required kinds, and e is a λ-free, variable-closed term of ground kind from $\mathcal{T}^o(T \uplus N \uplus \{x_1\colon \kappa_1, \dots, x_n\colon \kappa_n\})$.

The semantics of G is defined by rewriting subterms according to the rules in R. A *context* is a term $C[\bullet] \in \mathcal{T}(\Gamma \uplus \{\bullet\colon o\})$ in which $\bullet$ occurs exactly once. Given a context $C[\bullet]$ and a term $t : o$, we obtain $C[t]$ by replacing the unique occurrence of $\bullet$ in $C[\bullet]$ by t. With this, $t \Rightarrow_G t'$ if there is a context $C[\bullet]$, a rule $F = \lambda x_1 \dots \lambda x_n.e$, and a term $F\ t_1\ \dots\ t_n : o$ such that $t = C[F\ t_1\ \dots\ t_n]$ and $t' = C[e[x_1 \mapsto t_1, \dots, x_n \mapsto t_n]]$. In other words, we replace one occurrence of F in t by a right-hand side of a rewriting rule, while properly instantiating the variables. We call such a replaceable $F\ t_1\ \dots\ t_n$ a *reducible expression (redex)*. The rewriting step is *outermost to innermost (OI)* if there is no redex that contains the rewritten one as a proper subterm. The OI-language $\mathcal{L}(G)$ of G is the set of all (finite, ranked, labeled) trees T over the terminal symbols that can be created from the initial symbol S via OI-rewriting steps. We will restrict the rewriting relation to OI-rewritings in the rest of this paper. Note, all words derivable by IO-rewriting are also derivable with OI-rewriting.

Word-Generating Schemes. We consider *word-generating schemes*, i.e. schemes with terminals $T \uplus \{\$: o\}$ where exactly one terminal symbol \$ has kind o and all others are of kind $o \to o$. The generated trees have the shape $a_1\ (a_2\ (\cdots\ (a_k\ \$)))$, which we understand as the finite word $a_1 a_2 \dots a_k \in T^*$. We also see $\mathcal{L}(G)$ as a language of finite words.

Determinism. The above schemes are non-deterministic in that several rules may rewrite a non-terminal. We associate with a non-deterministic scheme $G = (V, N, T, R, S)$ a deterministic scheme G^{det} with exactly one rule per non-terminal. Intuitively, G^{det} makes the non-determinism explicit with new terminal symbols.

Formally, let $F : \kappa$ be a non-terminal with rules $F = t_1$ to $F = t_\ell$. We may assume each $t_i = \lambda x_1 \dots \lambda x_k . e_i$, where e_i is λ-free. We introduce a new terminal symbol $op_F : o \to o \to \dots \to o$ of arity ℓ. Let the set of all these terminals be $T^{det} = \{ op_F \mid F \in N \}$. The set of rules R^{det} now consists of a single rule for each non-terminal, namely $F = \lambda x_1 \dots \lambda x_k . op_F\ e_1 \cdots e_\ell$. The original rules in R are removed. This yields $G^{det} = (V, N, T \cup T^{det}, R^{det}, S)$. The advantage of resolving the non-determinism explicitly is that we can give a semantics to non-deterministic choices that depends on the non-terminal instead of having to treat non-determinism uniformly.

Semantics. Let $G = (V, N, T, R, S)$ be a deterministic scheme. A *model* of G is a pair $\mathcal{M} = (\mathcal{D}, \mathcal{I})$, where $\mathcal{D}$ is a family of domains $(\mathcal{D}(\kappa))_{\kappa \in K}$ that satisfies the following: $\mathcal{D}(o)$ is a cppo and $\mathcal{D}(\kappa_1 \to \kappa_2) = \mathit{Cont}(\mathcal{D}(\kappa_1), \mathcal{D}(\kappa_2))$. Here, $\mathit{Cont}(A, B)$ is the set of all $\sqcap$-continuous functions from domain A to B. We comment on this cppo in a moment. The interpretation $\mathcal{I} : T \to \mathcal{D}$ assigns to each terminal $s : \kappa$ an element $\mathcal{I}(s) \in \mathcal{D}(\kappa)$.

The ordering on functions is defined component-wise, $f \leq_{\kappa_1 \to \kappa_2} g$ if $(f\ x) \leq_{\kappa_2} (g\ x)$ for all $x \in \mathcal{D}(\kappa_1)$. For each κ, we denote the top element of $\mathcal{D}(\kappa)$ by $\top_\kappa$. For the ground kind, $\top_o$ exists since $\mathcal{D}(\kappa)$ is a cppo, and $\top_{\kappa_1 \to \kappa_2}$ is the function that maps every argument to $\top_{\kappa_2}$. The meet of a descending chain of functions $(f_i)_{i \in \mathbb{N}}$ is the function defined by $(\bigsqcap_{\kappa_1 \to \kappa_2} (f_i)_{i \in \mathbb{N}})\ x = \bigsqcap_{\kappa_2} (f_i\ x)_{i \in \mathbb{N}}$. Note that the sequence on the right-hand side is a descending chain.

The *semantics of terms* defined by a model is a function

$$\mathcal{M}[\![-]\!] : \mathcal{T} \to (N \cup V \nrightarrow \mathcal{D}) \to \mathcal{D} \ .$$

that assigns to each term built over the non-terminals and terminals again a function. This function expects a valuation $\nu : N \cup V \nrightarrow \mathcal{D}$ and returns an element from the domain. A valuation is a partial function that is defined on all non-terminals and the free variables. We lift $\sqcap$ to descending chains of valuations with $(\bigsqcap_{i \in \mathbb{N}} \nu_i)(y) = \bigsqcap_{i \in \mathbb{N}} (\nu_i(y))$ for $y \in N \cup V$. We obtain that the set of such valuations is a cppo where the greatest elements are those valuations which assign the greatest elements of the appropriate domain to all arguments.

Since the right-hand sides of the rules in the scheme are variable-closed, we do not need a variable valuation for them. We need the variable valuation, however, whenever we proceed by induction on the structure of terms. The semantics is defined by such an induction:

$$\mathcal{M}[\![s]\!]\ \nu = \mathcal{I}(s) \qquad \mathcal{M}[\![F]\!]\ \nu = \nu(F) \qquad \mathcal{M}[\![t_1\ t_2]\!]\ \nu = (\mathcal{M}[\![t_1]\!]\ \nu)\ (\mathcal{M}[\![t_2]\!]\ \nu)$$
$$\mathcal{M}[\![x]\!]\ \nu = \nu(x) \qquad \mathcal{M}[\![\lambda x : \kappa . t_1]\!]\ \nu = d \in \mathcal{D}(\kappa) \mapsto \mathcal{M}[\![t_1]\!]\ \nu[x \mapsto d] \ .$$

We show that $\mathcal{M}[\![t]\!]$ is $\sqcap$-continuous for all terms t. This follows from continuity of the functions in the domain, but requires some care when handling application.

▶ **Proposition 2.** *For all t, $\mathcal{M}[\![t]\!]$ is $\sqcap$-continuous (in ν) over the respective lattice.*

Given $\mathcal{M}$, the rules $F_1 = t_1, \dots, F_k = t_k$ of the (deterministic) scheme give a function

$$\mathit{rhs}_\mathcal{M} : (N \to \mathcal{D}) \to (N \to \mathcal{D}) \ , \quad \text{where} \quad \mathit{rhs}_\mathcal{M}(\nu)(F_j) = \mathcal{M}[\![t_j]\!]\ \nu \ .$$

Since the right-hand sides are variable-closed, the $\mathcal{M}[\![t_j]\!]$ are functions in the non-terminals. Provided $\mathcal{M}[\![t_1]\!]$ to $\mathcal{M}[\![t_k]\!]$ are $\sqcap$-continuous (in the valuation of the non-terminals), the function $\mathit{rhs}_\mathcal{M}$ will be $\sqcap$-continuous. This allows us to apply Kleene iteration as follows. The initial value is the greatest element $\sigma^0_\mathcal{M}$ where $\sigma^0_\mathcal{M}(F_j) = \top_j$ with $\top_j$ the top element of $\mathcal{D}(\kappa_j)$. The $(i+1)^{\text{th}}$ approximant is computed by evaluating the right-hand side at the i^{th}

solution, $\sigma_{\mathcal{M}}^{i+1} = rhs_{\mathcal{M}}(\sigma_{\mathcal{M}}^{i})$. The greatest fixed point is the tuple $\sigma_{\mathcal{M}}$ defined below. It can be understood as the greatest solution to the equation $\nu = rhs_{\mathcal{M}}(\nu)$. We call this greatest solution $\sigma_{\mathcal{M}}$ the *semantics of the scheme* in the model.

$$\sigma_{\mathcal{M}} = \bigsqcap_{i \in \mathbb{N}} \sigma_{\mathcal{M}}^{i} = \bigsqcap_{i \in \mathbb{N}} rhs_{\mathcal{M}}^{i}(\sigma_{\mathcal{M}}^{0})$$

4 Higher-Order Inclusion Games

Our goal is to solve higher-order games, whose arena is defined by a scheme. We assume that the derivation process is controlled by two players. To this end, we divide the non-terminals of a word-generating scheme into those owned by the existential player $\Diamond$ and those owned by the universal player $\Box$. Whenever a non-terminal is to be replaced during the derivation, it is the owner who chooses which rule to apply. The winning condition is given by an automaton A, Player $\Diamond$ attempts to produce a word that is in $\mathcal{L}(A)$, while Player $\Box$ attempts to produce a word outside of $\mathcal{L}(A)$.

▶ **Definition 3.** A *higher-order game* is a triple $\mathcal{G} = (G, A, O)$ where G is a word-generating scheme, A is an NFA, $O : N \to \{\Diamond, \Box\}$ is a partitioning of the non-terminals of G.

A play of the game is a sequence of OI-rewriting steps. Since terms generate words, it is unambiguous which term forms the next redex to be rewritten. In particular, all terms are of the form $a_1(a_2(\cdots(a_k(t))))$, where t is either \$ or a redex $F\ t_1\ \cdots\ t_m$. If $O(F) = \Diamond$ then Player $\Diamond$ chooses a rule $F = \lambda x_1 \ldots \lambda x_m.e$ to apply, else Player $\Box$ chooses the rule. This moves the play to $a_1\ (a_2\ (\cdots\ (a_k\ e[x_1 \mapsto t_1, \ldots, x_m \mapsto t_m])))$.

Each play begins at the initial non-terminal S, and continues either ad infinitum or until a term $a_1\ (a_2\ (\cdots\ (a_k\ \$)))$, understood as the word $w = a_1 \ldots a_k$, is produced. Infinite plays do not produce a word and are won by Player $\Diamond$. Finite maximal plays produce such a word w. Player $\Diamond$ wins whenever $w \in \mathcal{L}(A)$, Player $\Box$ wins if $w \in \overline{\mathcal{L}(A)}$. Since the winning condition is Borel, either Player $\Diamond$ or Player $\Box$ has a winning strategy [43].

The Winner of a Higher-Order Game (HOG)	
Input:	A higher-order game $\mathcal{G}$.
Question:	Does Player $\Diamond$ win $\mathcal{G}$? If so, effectively represent Player $\Diamond$'s strategy.

Our contribution is a fixed-point algorithm to decide HOG. We derive it in three steps. First, we develop a concrete model for higher-order games whose semantics captures the above winning condition. Second, we introduce a framework that for two models and a mapping between them guarantees that the mapping of the greatest fixed point with respect to the one model is the greatest fixed point with respect to the other model. Finally, we introduce an abstract model that uses a finite ground domain. The solution of HOG can be read off from the semantics in the abstract model, which in turn can be computed via Kleene iteration. Moreover, this semantics can be used to define Player $\Diamond$'s winning strategy. We instantiate the framework for the concrete and abstract model to prove the soundness of the algorithm.

Concrete Semantics

Consider a HOG instance $\mathcal{G} = (G, A, O)$. Let G^{det} be the determinized version of G. Our goal is to define a model $\mathcal{M}^C = (\mathcal{D}^C, \mathcal{I}^C)$ such that the semantics of G^{det} in this model allows us to decide HOG. Recall that we only have to define the ground domain. For composed kinds, we use the functional lifting discussed in Section 3.

Our idea is to associate to kind o the set of positive Boolean formulas where the atomic propositions are words in T^*. To be able to reuse the definition, we define formula domains in more generality as follows.

Domains of Boolean Formulas. Given a (potentially infinite) set P of atomic propositions, the *positive Boolean formulas* $\mathsf{PBool}(P)$ over P are defined to contain true, every p from P, and compositions of formulas via conjunction and disjunction. We work up to logical equivalence, which means we treat ϕ_1 and ϕ_2 as equal as long as they are logically equivalent.

Unfortunately, if the set P is infinite, $\mathsf{PBool}(P)$ is not a cppo, because the meet of a descending chain of formulas might not be a finite formula. The idea of our domain is to have conjunctions of infinitely many formulas. As is common in logic, we represent them as infinite sets. Therefore, we consider the set of all sets of (finite) positive Boolean formulas $\mathcal{P}(\mathsf{PBool}(T^*)) \setminus \{\emptyset\}$ factorized modulo logical equivalence, denoted $(\mathcal{P}(\mathsf{PBool}(T^*)) \setminus \{\emptyset\})/_{\Leftrightarrow}$. To be precise, the sets may be finite or infinite, but they must be non-empty.

To define the factorization, let an assignment to the atomic propositions be given by a subset of $P' \subseteq P$. The atomic proposition p is true if $p \in P'$. An assignment satisfies a Boolean formula, if the formula evaluates to true in that assignment. It satisfies a set of Boolean formulas, if it satisfies all elements. Given two sets of formulas Φ_1 and Φ_2, we write $\Phi_1 \Rightarrow \Phi_2$, if every assignment that satisfies Φ_1 also satisfies Φ_2. Two sets of formulas are equivalent, denoted $\Phi_1 \Leftrightarrow \Phi_2$, if $\Phi_1 \Rightarrow \Phi_2$ and $\Phi_2 \Rightarrow \Phi_1$ holds.

The ordering on these factorized sets is implication (which by transitivity is independent of the representative). The top element is the set $\{\mathsf{true}\}$, which is implied by every set. The conjunction of two sets is union. Note that it forms the meet in the partial order, and moreover note that meets over arbitrary sets exist, in particular the domain is a cppo. We will also need an operation of disjunction, which is defined by $\Phi_1 \vee \Phi_2 = \{\phi_1 \vee \phi_2 \mid \phi_1 \in \Phi_1, \phi_2 \in \Phi_2\}$. We will also use disjunctions of higher (but finite) arity where convenient. Note that the disjunction on finite formulas is guaranteed to result in a finite formula. Therefore, the above is well-defined.

In our case, the assignment $P' \subseteq T^*$ of interest is the language of the automaton A. Player $\Diamond$ will win the game iff the concrete semantics assigns a set of formulas to S that is satisfied by $\mathcal{L}(A)$.

The Concrete Domains and Interpretation of Terminals. From a ground domain, higher-order domains are defined as continuous functions as in Section 3. Thus we only need

$$\mathcal{D}^C(o) = (\mathcal{P}(\mathsf{PBool}(T^*)) \setminus \{\emptyset\})/_{\Leftrightarrow} \ .$$

The endmarker \$ yields the set of formulas $\{\varepsilon\}$, i.e. $\mathcal{I}^C(\$) = \{\varepsilon\}$. A terminal $a : o \to o$ prepends a to a given word w. That is $\mathcal{I}^C(a) = \mathsf{prepend}_a$, where $\mathsf{prepend}_a$ distributes over conjunction and disjunction:

$$\mathsf{prepend}_a(\phi) = \begin{cases} aw & \phi = w \ , \\ \mathsf{prepend}_a(\phi_1)\ op\ \mathsf{prepend}_a(\phi_2) & \phi = \phi_1\ op\ \phi_2 \text{ and } \ op \in \{\wedge, \vee\} \ , \\ \phi & \phi = \mathsf{true} \ . \end{cases}$$

We apply $\mathsf{prepend}_a$ to sets of formulas by applying it to every element. Finally, $\mathcal{I}^C(op_F)$ where op_F has arity ℓ is an ℓ-ary conjunction (resp. disjunction) if Player $\Box$ (resp. $\Diamond$) owns F.

For $\mathcal{M}^C = (\mathcal{D}^C, \mathcal{I}^C)$ to be a model, we need our interpretation of terminals to be $\sqcap$-continuous. This follows largely by the distributivity of our definitions.

▶ **Lemma 4.** *For all non-ground terminals s, $\mathcal{I}^C(s)$ is $\sqcap$-continuous.*

▶ **Example 5.** Consider the higher-order game defined by the scheme $S = H\ a\ \$ \mid b\ \$$ and $H = \lambda f.\lambda x.f\ (f\ x) \mid \lambda f.\lambda x.H\ (H\ f)\ x$. Assume S is owned by Player $\Diamond$ and H is owned by Player $\Box$. Let the automaton accept the language $\{b\}$. Player $\Diamond$ can choose to rewrite S to $b\ \$$ and therefore has a strategy to produce a word in the language. To derive this information from the concrete semantics, we compute $\sigma_{\mathcal{M}^C}(H)$. It is the function mapping $f \in \mathit{Cont}(\mathcal{D}^C(o), \mathcal{D}^C(o))$ and $d \in \mathcal{D}^C(o)$ to $\bigcup_{k>0} f^{2k}(d)$. Note that the union is the conjunction of sets of formulas, which is the interpretation of op_H for the universal player. Moreover, note that due to non-determinism we obtain all even numbers of applications of f, not only the powers of 2. With this, the semantics of the initial symbol is

$$\sigma_{\mathcal{M}^C}(S) = \bigcup_{k>0} \mathsf{prepend}_a^{2k}(\{\varepsilon\}) \vee \mathsf{prepend}_b(\{\varepsilon\}) = \{a^{2k} \vee b \mid k > 0\}.$$

The assignment $\{b\}$ given by the language of the NFA satisfies $\{a^{2k} \vee b \mid k > 0\}$. Indeed, since b evaluates to true, every formula in the set evaluates to true.

Correctness of Semantics and Winning Strategies. We need to show that the concrete semantics matches the original semantics of the game.

▶ **Theorem 6.** *$\sigma_{\mathcal{M}^C}(S)$ is satisfied by $\mathcal{L}(A)$ iff there is a winning strategy for Player $\Diamond$.*

When $\sigma_{\mathcal{M}^C}(S)$ is satisfied by $\mathcal{L}(A)$ the concrete semantics gives a winning strategy for $\Diamond$: From a term t such that $\mathcal{M}^C[\![t]\!]\ \sigma_{\mathcal{M}^C}$ is satisfied by $\mathcal{L}(A)$, Player $\Diamond$, when able to choose, picks a rewrite rule that transforms t to t', where $\mathcal{M}^C[\![t']\!]\ \sigma_{\mathcal{M}^C}$ remains satisfied. The proof of Theorem 6 shows this is always possible, and, moreover, Player $\Box$ is unable to reach a term for which satisfaction does not hold. This does not yet give an effective strategy since we cannot compute $\mathcal{M}^C[\![t]\!]\ \sigma_{\mathcal{M}^C}$. However, the abstract semantics will be computable, and can be used in place of the concrete semantics by Player $\Diamond$ to implement the winning strategy.

The proof that $\sigma_{\mathcal{M}^C}(S)$ being unsatisfied implies a winning strategy for Player $\Box$ is more involved and requires the definition of a correctness relation between semantics and terms that is lifted to the level of functions, and shown to hold inductively.

5 Framework for Exact Fixed-Point Transfer

The concrete model $\mathcal{M}^C$ does not lead to an algorithm for solving HOG since its domains are infinite. Here, we consider an abstract model $\mathcal{M}^A$ with finite domains. The soundness of the resulting Kleene iteration relies on the two semantics being related by a precise abstraction α. Since both semantics are defined by fixed points, this requires us to prove $\alpha(\sigma_{\mathcal{M}^C}) = \sigma_{\mathcal{M}^A}$. In this section, we provide a general framework to this end.

Consider the deterministic scheme G together with two models (left and right) $\mathcal{M}_l = (\mathcal{D}_l, \mathcal{I}_l)$ and $\mathcal{M}_r = (\mathcal{D}_r, \mathcal{I}_r)$. Our goal is to relate the semantics in these models in the sense that $\sigma_{\mathcal{M}_r} = \alpha(\sigma_{\mathcal{M}_l})$. Such exact fixed-point transfer results are well-known in abstract interpretation. To generalize them to higher-order we give easy to instantiate conditions on α, $\mathcal{M}_l$, and $\mathcal{M}_r$ that yield the above equality. Interestingly, exact fixed-point transfer results seem to be rare for higher-order (e.g. [46]). Our development is inspired by Abramsky's lifting of abstraction functions to logical relations [3], which generalizes [11, 4]. These works focus on approximation and the compatibility we need for exactness is missing. Our framework is easier to apply than [15, 6], which are again concerned with approximation and do not offer (but may lead to) exact fixed-point transfer results.

For the terminology, an *abstraction* is a function $\alpha : \mathcal{D}_l(o) \to \mathcal{D}_r(o)$. To lift the abstraction to function domains, we define the notion of *being compatible with* α. Compatibility intuitively states that the function on the concrete domain is not more precise than what the abstraction function distinguishes. This allows us to define the abstraction of a function by applying the function and abstracting the result, $\alpha(f)\ \alpha(v_l) = \alpha(f\ v_l)$. Compatibility ensures the independence of the choice of v_l.

By definition, all ground elements $v_l \in \mathcal{D}_l(o)$ are compatible with α. For function domains, compatibility and the abstraction are defined as follows.

▶ **Definition 7.** Assume α and the notion of compatibility are defined on $\mathcal{D}_l(\kappa_1)$ and $\mathcal{D}_l(\kappa_2)$. Let $\top^l_\kappa$ (resp. $\top^r_\kappa$) be the greatest element of $\mathcal{D}_l(\kappa)$ (resp. $\mathcal{D}_r(\kappa)$) for each κ.

1. Function $f \in \mathcal{D}_l(\kappa_1 \to \kappa_2)$ is compatible with α, if
   a. for all compatible $v_l, v_l' \in \mathcal{D}_l(\kappa_1)$ with $\alpha(v_l) = \alpha(v_l')$ we have $\alpha(f\ v_l) = \alpha(f\ v_l')$, and
   b. for all compatible $v_l \in \mathcal{D}_l(\kappa_1)$ we have that $f\ v_l$ is compatible.
2. We define $\alpha(f) \in \mathcal{D}_r(\kappa_1 \to \kappa_2)$ as follows.
   a. If f is compatible, we set $\alpha(f)\ v_r = \alpha(f\ v_l)$, provided there is a compatible $v_l \in \mathcal{D}_l(\kappa_1)$ with $v_r = \alpha(v_l)$, and $\alpha(f)\ v_r = \top^r_{\kappa_2}$ otherwise.
   b. If f is not compatible, $\alpha(f) = \top^r_{\kappa_1 \to \kappa_2}$.

We lift α to valuations $\nu : N \uplus V \nrightarrow \mathcal{D}_l$ by $\alpha(\nu)(F) = \alpha(\nu(F))$ and similar for x. We also lift compatibility to valuations $\nu : N \uplus V \nrightarrow \mathcal{D}_l$ by requiring $\nu(F)$ to be compatible for all $F \in N$ and similar for $x \in V$.

The conditions needed for the exact fixed-point transfer are the following.

▶ **Definition 8.** Function α is *precise* for $\mathcal{M}_l$ and $\mathcal{M}_r$, if

(P1) $\alpha(\mathcal{D}_l(o)) = \mathcal{D}_r(o)$,

(P2) $\alpha : \mathcal{D}_l(o) \to \mathcal{D}_r(o)$ is $\sqcap$-continuous,

(P3) $\alpha(\top^l_o) = \top^r_o$,

(P4) $\alpha(\mathcal{I}_l(s)) = \mathcal{I}_r(s)$ for all terminals $s\colon o$, and similarly $\alpha(\mathcal{I}_l(s)\ v_l) = \mathcal{I}_r(s)\ \alpha(v_l)$ for all terminals $s : \kappa_1 \to \kappa_2$ and all compatible $v_l \in \mathcal{D}_l(\kappa_1)$,

(P5) $\mathcal{I}_l(s)\ v_l$ is compatible for all terminals $s : \kappa_1 \to \kappa_2$, and all compatible $v_l \in \mathcal{D}_l(\kappa_1)$.

(P1) is surjectivity of α. (P2) states that α is well-behaved wrt. $\sqcap$. (P3) says that the greatest element is mapped as expected. Note that (P1)-(P3) are only posed for the ground domain. One can prove that they generalize to function domains by the definition of function abstraction. (P4) is that the interpretations of terminals in $\mathcal{M}^C$ and $\mathcal{M}^A$ are suitably related. Finally (P5) is compatibility. (P4) and (P5) are generalized to terms in Lemma 9.

To prove $\alpha(\sigma_{\mathcal{M}_l}) = \sigma_{\mathcal{M}_r}$, we need that $rhs_{\mathcal{M}_r}$ is an exact abstract transformer of $rhs_{\mathcal{M}_l}$. The following lemma states this for all terms t, in particular those that occur in the equations. The generalization to product domains is immediate. Note that the result is limited to compatible valuations, but this will be sufficient for our purposes. The proof proceeds by induction on the structure of terms, while simultaneously proving $\mathcal{M}_l[\![t]\!]$ compatible with α. With this result, we obtain the required exact fixed-point transfer for precise abstractions.

▶ **Lemma 9.** *Assume* (P1)*,* (P4)*, and* (P5) *hold. For all terms t and all compatible ν, we have $\mathcal{M}_l[\![t]\!]\ \nu$ compatible and $\alpha(\mathcal{M}_l[\![t]\!]\ \nu) = \mathcal{M}_r[\![t]\!]\ \alpha(\nu)$.*

▶ **Theorem 10** (Exact Fixed-Point Transfer)**.** *Let G be a scheme with models $\mathcal{M}_l$ and $\mathcal{M}_r$. Let σ_l and σ_r be the corresponding semantics. If $\alpha : \mathcal{D}_l \to \mathcal{D}_r$ is precise, we have $\sigma_r = \alpha(\sigma_l)$.*

6 Domains for Higher-Order Games

We propose two domains, *abstract* and *optimized*, that allow us to solve HOG. The computation is a standard fixed-point iteration, and, in the optimized domain, this iteration has optimal complexity. Correctness follows by instantiating the previous framework.

Abstract Semantics. Our goal is to define an abstract model for games that (1) suitably relates to the concrete model from Section 4 and (2) is computable. By a suitable relation, we mean the two models should relate via an abstraction function. Provided the conditions on precision hold, correctness of the abstraction then follows from Theorem 10. Combined with Theorem 6, this will allow us to solve HOG. Computable in particular means the domain should be finite and the operations should be efficiently computable.

We define the $\mathcal{M}^A = (\mathcal{D}^A, \mathcal{I}^A)$ as follows. Again, we resolve the non-determinism into Boolean formulas. But rather than tracking the precise words generated by the scheme, we only track the current set of states of the automaton. To achieve the surjectivity required by precision, we restrict the powerset to those sets of states from which a word is accepted. Let $\mathsf{acc}(w) = \{q \mid q \xrightarrow{w} q_f \in Q_f\}$. For a language L we have $\mathsf{acc}(L) = \{\mathsf{acc}(w) \mid w \in L\}$. The abstract domain for terms of ground kind is $\mathcal{D}^A(o) = \mathsf{PBool}(\mathsf{acc}(T^*))$. The lifting to functions is as explained in Section 3. Satisfaction is now defined relative to a set Ω of elements of $\mathcal{P}(Q_{NFA})$ (cf. Section 4). With finitely many atomic propositions, there are only finitely many formulas (up to logical equivalence). This means we no longer need sets of formulas to represent infinite conjunctions, but can work with plain formulas. The ordering is thus the ordinary implication with the meet being conjunction and top being true.

The interpretation of ground terms is $\mathcal{I}^A(\$) = Q_f$ and $\mathcal{I}^A(a) = \mathsf{pre}_a$. Here pre_a is the predecessor computation under label a, $\mathsf{pre}_a(Q) = \{q' \in Q_{NFA} \mid q' \xrightarrow{a} q \in Q\}$. It is lifted to formulas by distributing it over conjunction and disjunction. The composition operators are again interpreted as conjunctions and disjunctions, depending on the owner of the non-terminal. Since we restrict the atomic propositions to $\mathsf{acc}(T^*)$, we have to show that the interpretations use only this restricted set. Proving $\mathcal{I}^A(s)$ is $\sqcap$-continuous is standard.

▶ **Lemma 11.** *The interpretations are defined on the abstract domain.*

▶ **Lemma 12.** *For all terminals s, $\mathcal{I}^A(s)$ is $\sqcap$-continuous over the respective lattices.*

Recall our concrete model is $\mathcal{M}^C = (\mathcal{D}^C, \mathcal{I}^C)$, where $\mathcal{D}^C = \mathcal{P}(\mathsf{PBool}(T^*))$. To relate this model to $\mathcal{M}^A$, we define the abstraction function $\alpha : \mathcal{D}^C(o) \to \mathcal{D}^A(o)$. It leaves the Boolean structure of a formula unchanged but maps every word (which is an atomic proposition) to the set of states from which this word is accepted. For a set of formulas, we take the conjunction of the abstraction of the elements. This conjunction is finite as we work over a finite domain, so there is no need to worry about infinite syntax. Technically, we define α on $\mathsf{PBool}(T^*)$ by $\alpha(\Phi) = \bigwedge_{\phi \in \Phi} \alpha(\phi)$ for a set of formulas $\Phi \in \mathcal{P}(\mathsf{PBool}(T^*))$, and

$$\alpha(\phi) = \begin{cases} \mathsf{acc}(w) & \text{if } \phi = w, \\ \alpha(\phi_1)\ op\ \alpha(\phi_2) & \text{if } \phi = \phi_1\ op\ \phi_2 \text{ and } op \in \{\wedge, \vee\}, \\ \phi & \text{if } \phi = \mathsf{true}\ . \end{cases}$$

This definition is suitable in that $\alpha(\sigma_{\mathcal{M}^C}) = \sigma_{\mathcal{M}^A}$ entails the following.

▶ **Theorem 13.** *$\sigma_{\mathcal{M}^A}(S)$ is satisfied by $\{Q \in \mathsf{acc}(T^*) \mid q_0 \in Q\}$ iff Player $\Diamond$ wins $\mathcal{G}$.*

To see that the theorem is a consequence of the exact fixed-point transfer, observe that $\{Q \in \mathsf{acc}(T^*) \mid q_0 \in Q\} = \mathsf{acc}(\mathcal{L}(A))$. Then, by $\sigma_{\mathcal{M}^A} = \alpha(\sigma_{\mathcal{M}^C})$ we have $\mathsf{acc}(\mathcal{L}(A))$ satisfies

$\sigma_{\mathcal{M}^A}(S)$ iff it also satisfies $\alpha(\sigma_{\mathcal{M}^C}(S))$. This holds iff $\mathcal{L}(A)$ satisfies $\sigma_{\mathcal{M}^C}(S)$ (a simple induction over formulas). By Theorem 6, this occurs iff Player $\Diamond$ wins the game.

It remains to establish $\alpha(\sigma_{\mathcal{M}^C}) = \sigma_{\mathcal{M}^A}$. With the framework, the exact fixed-point transfer follows from precision, Theorem 10. The proof of the following is routine.

▶ **Proposition 14.** *α is precise. Hence, $\alpha(\sigma_{\mathcal{M}^C}) = \sigma_{\mathcal{M}^A}$.*

Optimized Semantics. The above model yields a decision procedure for HOG via Kleene iteration. Unfortunately, the complexity is one exponential too high: The height of the domain for a symbol of order k in the abstract model is $(k+2)$-times exponential, where the height is the length of the longest strictly descending chain in the domain. This gives the maximum number of steps of Kleene iteration needed to reach the fixed point.

We present an optimized version of our model that is able to close the gap: In this model, the domain for an order-k symbol is only $(k+1)$-times exponentially high. The idea is to resolve the atomic propositions in $\mathcal{M}^A$, which are sets of states, into disjunctions among the states. The reader familiar with inclusion algorithms will find this decomposition surprising.

We first define $\alpha : \mathsf{PBool}(\mathsf{acc}(T^*)) \to \mathsf{PBool}(Q_{NFA})$. The optimized domain will then be based on the image of α. This guarantees surjectivity. For a set of states Q, we define $\alpha(Q) = \bigvee Q = \bigvee_{q \in Q} q$. For a formula, the abstraction function is defined to distribute over conjunction and disjunction. The optimized model is $\mathcal{M}^O = (\mathcal{D}^O, \mathcal{I}^O)$ with ground domain $\alpha(\mathsf{PBool}(\mathsf{acc}(T^*)))$. The interpretation is $\mathcal{I}^O(\$) = \bigvee Q_f$. For a, we resolve the set of predecessors into a disjunction, $\mathcal{I}^O(a)\ q = \bigvee \mathsf{pre}_a(\{q\})$. The function distributes over conjunction and disjunction. Finally, $\mathcal{I}^O(op_F)$ is conjunction or disjunction of formulas, depending on the owner of the non-terminal. Since we use a restricted domain, we have to argue that the operations do not leave the domain. It is also straightforward to prove our interpretation is $\sqcap$-continuous as required.

▶ **Lemma 15.** *The interpretations are defined on the optimized domain.*

▶ **Lemma 16.** *For all terminals s, $\mathcal{I}^O(s)$ is $\sqcap$-continuous over the respective lattices.*

We again show precision, enabling the required exact fixed-point transfer.

▶ **Proposition 17.** *α is precise. Hence, $\alpha(\sigma_{\mathcal{M}^A}) = \sigma_{\mathcal{M}^O}$.*

▶ **Theorem 18.** *$\sigma_{\mathcal{M}^O}(S)$ is satisfied by $\{q_0\}$ iff Player $\Diamond$ wins $\mathcal{G}$.*

It is sufficient to show $\sigma_{\mathcal{M}^A}(S)$ is satisfied by $\{Q \in \mathsf{acc}(T^*) \mid q_0 \in Q\}$ iff $\sigma_{\mathcal{M}^O}(S)$ is satisfied by $\{q_0\}$. Theorem 13 then yields the statement. Propositions Q in $\sigma_{\mathcal{M}^A}(S)$ are resolved into disjunctions $\bigvee Q$ in $\sigma_{\mathcal{M}^O}(S)$. For such a proposition, we have $Q \in \{Q \in \mathsf{acc}(T^*) \mid q_0 \in Q\}$ iff $\bigvee Q$ is satisfied by $\{q_0\}$. This equivalence propagates to the formulas $\sigma_{\mathcal{M}^A}(S)$ and $\sigma_{\mathcal{M}^O}(S)$ as the Boolean structure coincides. The latter follows from $\alpha(\sigma_{\mathcal{M}^A}(S)) = \sigma_{\mathcal{M}^O}(S)$.

Complexity. To solve HOG, we compute the semantics $\sigma_{\mathcal{M}^O}$ and then evaluate $\sigma_{\mathcal{M}^O}(S)$ at the assignment $\{q_0\}$. For the complexity, assume that the highest order of any non-terminal in $\mathcal{G}$ is k. We show the number of iterations needed to compute the greatest fixed point is at most $(k+1)$-times exponential. We do this via a suitable upper bound on the length of strictly descending chains in the domains assigned by $\mathcal{D}^O$.

▶ **Proposition 19.** *The semantics $\sigma_{\mathcal{M}^O}$ can be computed in $(k+1)\mathsf{EXP}$, where k is the highest order of any non-terminal in the input scheme.*

The lower bound is via a reduction from the word membership problem for alternating k-iterated pushdown automata with polynomially-bounded auxiliary work-tape. This problem was shown by Engelfriet to be $(k+1)$EXP-hard. We can reduce this problem to HOG via well-known translations between iterated stack automata and recursion schemes, using the regular language specifying the winning condition to help simulate the work-tape.

▶ **Proposition 20.** *Determining whether Player $\Diamond$ wins $\mathcal{G}$ is $(k+1)$EXP-hard for $k > 0$.*

Together, these results show the following corollary and final result.

▶ **Corollary 21.** HOG *is $(k+1)$EXP-complete for order-k schemes and $k > 0$.*

Fine-Grained Complexity of Rainbow Coloring and Its Variants*

Akanksha Agrawal

University of Bergen, Norway
akanksha.agrawal@uib.no

Abstract

Consider a graph G and an edge-coloring $c_R : E(G) \to [k]$. A rainbow path between $u, v \in V(G)$ is a path P from u to v such that for all $e, e' \in E(P)$, where $e \neq e'$ we have $c_R(e) \neq c_R(e')$. In the Rainbow k-Coloring problem we are given a graph G, and the objective is to decide if there exists $c_R : E(G) \to [k]$ such that for all $u, v \in V(G)$ there is a rainbow path between u and v in G. Several variants of Rainbow k-Coloring have been studied, two of which are defined as follows. The Subset Rainbow k-Coloring takes as an input a graph G and a set $S \subseteq V(G) \times V(G)$, and the objective is to decide if there exists $c_R : E(G) \to [k]$ such that for all $(u, v) \in S$ there is a rainbow path between u and v in G. The problem Steiner Rainbow k-Coloring takes as an input a graph G and a set $S \subseteq V(G)$, and the objective is to decide if there exists $c_R : E(G) \to [k]$ such that for all $u, v \in S$ there is a rainbow path between u and v in G. In an attempt to resolve open problems posed by Kowalik et al. (ESA 2016), we obtain the following results.

- For every $k \geq 3$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, unless ETH fails.
- For every $k \geq 3$, Steiner Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|S|^2)}n^{\mathcal{O}(1)}$, unless ETH fails.
- Subset Rainbow k-Coloring admits an algorithm running in time $2^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$. This also implies an algorithm running in time $2^{o(|S|^2)}n^{\mathcal{O}(1)}$ for Steiner Rainbow k-Coloring, which matches the lower bound we obtain.

1 Introduction

Graph connectivity is one of the fundamental properties in graph theory. Several connectivity measures like k-vertex connectivity, k-edge connectivity, hamiltonicity, etc. have been studied for graphs. Chartrand et al. [8] defined an interesting connectivity measure, called rainbow connectivity, which is defined as follows. Let G be a graph and $c_R : E(G) \to [k]$ be an edge-coloring of G. A *rainbow path* between $u, v \in V(G)$ is a path P from u to v such that for all $e, e' \in E(P)$, where $e \neq e'$ we have $c_R(e) \neq c_R(e')$. A graph with an edge-coloring is *rainbow-connected* if for every pair of vertices there is a rainbow path between them. In the Rainbow k-Coloring problem we are given a graph G, and the objective is to decide if there exists an edge-coloring $c_R : E(G) \to [k]$ such that for all $u, v \in V(G)$, there is a rainbow

* Due to space limitations most proofs have been omitted.
The research leading to these results received funding from the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013)/ ERC Grant Agreements no. 306992.

path between u and v in G. The problem has received attention both from graph theoretic and algorithmic point of view, the details of which can be found, for instance in [9, 23, 24].

Rainbow k-Coloring problem is notoriously hard. It was conjectured by Caro et al. [4] to be NP-complete already for $k = 2$. Indeed, by giving a polynomial time reduction from 3-SAT, this was confirmed by Chakraborty et al. [5]. Building on their results, Ananth et al. [3] later showed that Rainbow k-Coloring remains NP-complete for every $k \geq 2$. An alternate hardness proof was also given by Le and Tuza [21]. For the complexity of the problem on restricted graph classes, see e.g., [5, 6, 7, 8].

Impagliazzo et al. [16] introduced the Exponential time hypothesis (ETH), which has been used as a basis for proving qualitative lower bounds for computational problems. The ETH states that 3-SAT does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$, where n is the number of variables in the input 3-CNF formula. It has been shown that assuming ETH, several NP-hard problems like Independent Set, Hitting set, and Chromatic Number do not admit subexponential time algorithms (see the survey [25]).

Kowalik et al. [20] studied the fine-grained complexity of Rainbow k-Coloring and some of its variants. In particular, they showed that Rainbow k-Coloring admits neither an algorithm running in time $2^{o(|V(G)|^{3/2})}|V(G)|^{\mathcal{O}(1)}$, nor an algorithm running in time $2^{o(|E(G)|/\log|E(G)|)}|V(G)|^{\mathcal{O}(1)}$, unless ETH fails. They also studied a variant of Rainbow k-Coloring, called Subset Rainbow k-Coloring (to be defined shortly), which was introduced by Chakraborty et al. [5]. They showed that Subset Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}|V(G)|^{\mathcal{O}(1)}$ assuming ETH. In contrast, they designed an FPT algorithm for the problem running in time $|S|^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$, where S is a part of the input. For $k = 2$, they obtained a faster algorithm running in time $2^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$. Finally, they proposed yet another (parametric) variant of Rainbow k-Coloring, which they called Steiner Rainbow k-Coloring. Their lower bound result for Rainbow k-Coloring implies that Steiner Rainbow k-Coloring does not admit an algorithm running in time $2^{o|S|^{3/2}}n^{\mathcal{O}(1)}$. Moreover, their algorithm for Subset Rainbow k-Coloring gives an algorithm for Steiner Rainbow k-Coloring running in time $2^{\mathcal{O}(|S|^2\log|S|)}n^{\mathcal{O}(1)}$.

Our results. We attempt to tighten the gaps in the study of fine-grained complexity of Rainbow k-Coloring and some of its variants, initiated by Kowalik et al. [20]. We now describe our results in detail.

The first problem that we study is Steiner Rainbow k-Coloring, which is formally defined below.

Steiner Rainbow k-Coloring	**Parameter:** $\|S\|$
Input: A graph G and a vertex subset $S \subseteq V(G)$.	
Question: Does there exist an edge-coloring $c_R : E(G) \to [k]$ such that for every $u, v \in S$, there is a rainbow path between u and v in G?	

In Section 3, we show that for every $k \geq 3$, Steiner Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|S|^2)}n^{\mathcal{O}(1)}$, under ETH. This resolves an open problem posed by Kowalik et al. [20]. To prove the result, we give a reduction from k-Coloring on graphs of maximum degree $2(k-1)$ which does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$, assuming ETH. Our reduction starts by computing a harmonious coloring of the (bounded degree) input instance of k-Coloring, which forms an essential step in the construction of S for the instance of Steiner Rainbow k-Coloring that we create. The idea of using harmonious coloring for proving lower bounds of the form $2^{o(\ell^2)}n^{\mathcal{O}(1)}$ was used by Agrawal et al. [1] to prove a lower bound for Split Contraction, when parameterized by the vertex cover number ℓ, of the input graph. Also, the idea of partitioning vertices

of the input graph based on some coloring scheme was used by Cygan et al. [10] to prove ETH-based lower bounds for Graph Homomorphism and Subgraph Isomorphism.

The next problem we study is Rainbow k-Coloring, which is formally defined below.

Rainbow k-Coloring
Input: A graph G.
Question: Does there exist an edge-coloring $c_R : E(G) \to [k]$ such that for every $u, v \in V(G)$, there is a rainbow path between u and v in G?

Kowalik et al. [20] conjectured that for every $k \geq 2$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, unless ETH fails. In Section 4, we resolve this conjecture for every $k \geq 3$. Again, we proceed with a reduction from k-Coloring on bounded degree graphs. Although, the general scheme of reduction is the same as the one we five for Steiner Rainbow k-Coloring, in this case the reduction is more involved. Furthermore, we require to distinguish between the cases for k being odd and even in the gadget construction. Also, to keep our gadgets simpler, we separate the case for $k = 3$ and $k > 3$.

Finally, we study the complexity of Subset Rainbow k-Coloring, which is formally defined below.

Subset Rainbow k-Coloring **Parameter:** $|S|$
Input: A graph G and a subset $S \subseteq V(G) \times V(G)$.
Output: An edge-coloring $c_R : E(G) \to [k]$ such that for every $(u, v) \in S$, there is a rainbow path between u and v in G, if it exists. Otherwise, return *no*.

In Section 5 we design an FPT algorithm running in time $2^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$ for Subset Rainbow k-Coloring, for every fixed k. This resolves the conjecture of Kowalik et al. [20] regarding the existence of an algorithm running in time $2^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$ for Subset Rainbow k-Coloring, and is an improvement over their algorithm, which runs in time $|S|^{\mathcal{O}(|S|)}n^{\mathcal{O}(1)}$, for $k \geq 3$. Our algorithm is based on the technique of color coding, which was introduced by Alon et al. [2]. Observe that Steiner Rainbow k-Coloring is a special case of Subset Rainbow k-Coloring. Hence, as a corollary we obtain an algorithm running in time $2^{\mathcal{O}(|S|^2)}n^{\mathcal{O}(1)}$ for Steiner Rainbow k-Coloring, which matches the lower bound we prove in Section 3.

2 Preliminaries

In this section, we state some basic definitions and introduce terminology from graph theory and algorithms. We also establish some of the notation that will be used throughout.

We denote the set of natural numbers by $\mathbb{N}$. For $k \in \mathbb{N}$, by $[k]$ we denote the set $\{1, 2, \ldots, k\}$. We use standard terminology from the book of Diestel [13] for the graph related terminologies which are not explicitly defined here. We consider finite simple graphs. For a graph G, by $V(G)$ and $E(G)$ we denote the vertex and edge sets of the graph G, respectively. For $v \in V(G)$, by $N_G(v)$ we denote the set $\{u \in V(G) \mid (v, u) \in E(G)\}$. We drop the subscript G from $N_G(v)$ when the context is clear. For $C, C' \subseteq V(G)$, we say that there is an edge between C and C' in G if there exists $u \in C$ and $v \in C'$ such that $(u, v) \in E(G)$. A *path* $P = (v_1, v_2, \ldots, v_\ell)$ is a graph with vertex and edge sets as $\{v_1, v_2, \ldots, v_\ell\}$ and $\{(v_i, v_{i+1}) \mid i \in [l-1]\}$, respectively.

A *harmonious coloring* of a graph G is a vertex coloring $\varphi : V(G) \to [k]$, with color classes $C_1, C_2, \ldots, C_k$ such that for each $i \in [k]$, C_i is an independent set in G and for all $i, j \in [k]$, where $i \neq j$ there is at most one edge between C_i and C_j in G. We use the following result

for computing a harmonious coloring on bounded degree graphs.

▶ **Proposition 1** ([11, 14, 22, 26]). *Given a G with the degree of each vertex bounded by d, where d is a fixed constant. A harmonious coloring of G can be computed in time $\mathcal{O}(n^{\mathcal{O}(1)})$ using $\mathcal{O}(\sqrt{n})$ colors with each color class having at most $\mathcal{O}(\sqrt{n})$ vertices.*

3 Lower bound for Steiner Rainbow k-Coloring

In this section, we show that for every $k \geq 3$, Steiner Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|S|^2)}n^{\mathcal{O}(1)}$, unless ETH fails. Towards this we give an appropriate reduction from k-Coloring on graphs of maximum degree $2(k-1)$. We note that k-Coloring does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$ unless ETH fails [17]. Moreover, assuming ETH, 3-Coloring does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$ on graphs of maximum degree 4 [18, 11]. This follows from the fact that 3-Coloring does not admit such an algorithm, and a reduction from an instance G of 3-Coloring to an equivalent instance G' of 3-Coloring, where G' is a graph with maximum degree 4 with $|V(G')| \in \mathcal{O}(|V(G)|)$ (see [15, Theorem 4.1]). In fact, we can show that k-Coloring does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$ on graphs of maximum degree $2(k-1)$ (folklore). This result can be obtained (inductively) by giving a reduction from an instance G of $(k-1)$-Coloring on graphs of degree at most $2(k-2)$ to an instance of k-Coloring on a graphs of bounded average degree (by adding global vertex), and then using an approach similar to that in Theorem 4.1 in [15] we can obtain an (equivalent) instance of k-Coloring where the degree of the graph is bounded by $2(k-1)$.

Given an instance G of k-Coloring on n vertices and degree bounded by $2(k-1)$, we start by computing a harmonious coloring φ of G with $t \in \mathcal{O}(\sqrt{n})$ color classes such that each color class contains at most $\mathcal{O}(\sqrt{n})$ vertices using Proposition 1. Let $C_1, C_2, \ldots, C_t$ be the color classes of φ. Recall that for $i, j \in [t]$ with $i \neq j$ there is at most one edge between C_i and C_j in G. Moreover, C_i is an independent set in G, where $i \in [t]$. We create an instance G' of k-Coloring which has a harmonious coloring φ' with color classes $C'_1, C'_2, \ldots, C'_t$ such that for all $i, j \in [t]$, $i \neq j$ we have exactly one edge between C_i and C_j. Initially, we have $G = G'$ and $C'_i = C_i$, for all $i \in [t]$. For each $i, j \in [t]$, $i \neq j$ such that there is no edge between C_i and C_j in G we add two new vertices a_{ij} and a_{ji} to $V(G')$ and add the edge (a_{ij}, a_{ji}) to $E(G')$. Furthermore, we add a_{ij} to C'_i and a_{ji} to C'_{ji}. Observe that $|V(G')| \in \mathcal{O}(n)$, $|E(G')| \in \mathcal{O}(n)$, and for each $i \in [t]$, $|C'_i| \in \mathcal{O}(\sqrt{n})$. Also, for each $i, j \in [t]$, $i \neq j$ there is exactly one edge between C'_i and C'_j in G'. It is easy to see that G is a *yes* instance of k-Coloring if and only if G' is a *yes* instance of k-Coloring.

Hereafter, we will be working with the instance G' of k-Coloring, together with its harmonious coloring φ' with color classes $C'_1, C'_2, \ldots, C'_t$. Moreover, for $i, j \in [t]$, $i \neq j$ there is exactly one edge between C'_i and C'_j in G'.

We now move to the description of creating an equivalent instance $(\tilde{G}, S)$ of Steiner Rainbow k-Coloring, where $k \geq 3$. Initially, we have $V(\tilde{G}) = V(G')$. For $(u, v) \in E(G')$ we add $k-3$ new vertices $x^{uv}_1, x^{uv}_2, \ldots, x^{uv}_{k-3}$ to $\tilde{G}$ and add all the edges in the path $(u, x^{uv}_1, \ldots, x^{uv}_{k-3}, v)$ to $E(\tilde{G})$. Note that for $k = 3$ we do not any new vertex and directly add the edge (u, v) to $\tilde{G}$. For each $i \in [t]$ we add a vertex c_i to $\tilde{G}$ and add all the edges in $\{(c_i, v) \mid v \in C'_i\}$ to $E(\tilde{G})$. Finally, we set $S = \{c_i \mid i \in [t]\}$. Notice that $|S| \in \mathcal{O}(\sqrt{n})$. In the following lemma we establish that G' is a *yes* instance of k-Coloring if and only if $(\tilde{G}, S)$ is a *yes* instance of Steiner Rainbow k-Coloring.

▶ **Lemma 2.** *G' is a* yes *instance of k-Coloring if and only if $(\tilde{G}, S)$ is a* yes *instance of* Steiner Rainbow k-Coloring.

Proof. In the forward direction, let G' be a *yes* instance of k-Coloring, and $c : V(G') \to [k]$ be one of its solution. We create a coloring $c_R : E(\tilde{G}) \to [k]$ as follows. For $i \in [t]$ and $v \in C'_i$ we set $c_R(c_i, v) = c(v)$. For $i, j \in [t]$, $i \neq j$ let u, v be the (unique) vertices in C'_i and C'_j such that $(u, v) \in E(G')$. We now describe the value of c_R for edges in the path $P = (u, x_1^{uv}, \ldots, x_{k-3}^{uv}, v)$. Notice that $|E(P)| = k - 2$, and we arbitrarily assign distinct integers in $[k] \setminus \{c_R(c_i, u), c_R(c_j, v)\}$ to $c_R(e)$, where $e \in E(P)$. Since c is a proper coloring of G', $c_R(c_i, u) = c(u) \neq c(v) = c_R(c_j, v)$. This together with the definition of c_R for edges in P implies that there is a rainbow path, namely $(c_i, u, x_1^{uv}, \ldots, x_{k-3}^{uv}, v, c_j)$ in $\tilde{G}$ between c_i and c_j. This concludes the proof in the forward direction.

In the reverse direction, let $(\tilde{G}, S)$ be a *yes* instance of Steiner Rainbow k-Coloring, and $c_R : E(\tilde{G}) \to [k]$ be one of its solution. We create a coloring $c : V(G') \to [k]$ as follows. For $i \in [t]$ and $v \in C'_i$, we let $c(v) = c_R(c_i, v)$. We show that c is a solution to k-Coloring in G'. Consider $(u, v) \in E(G')$, and let $u \in C'_i$ and $v \in C'_j$. Note that we have $i \neq j$. Let P be a rainbow path between c_i and c_j in $\tilde{G}$. By the construction of $\tilde{G}$, we have $N_{\tilde{G}}[c_i] \cap N_{\tilde{G}}[c_j] = \emptyset$. Moreover, since P is a rainbow path, it can contain at most k edges. Recall that $N_{\tilde{G}}(c_i) = C'_i$, $N_{\tilde{G}}(c_j) = C'_j$, and there is exactly one path with at most $k - 2$ edges between a vertex in C'_i and a vertex in C'_j, namely $(c_i, u, x_1^{uv}, \ldots, x_{k-3}^{uv}, v, c_j)$. This together with the construction of c implies that $c(u) \neq c(v)$. This concludes the proof. ◀

▶ **Theorem 3.** Steiner Rainbow k-Coloring *does not admit an algorithm running in time* $2^{o(|S|^2)}n^{\mathcal{O}(1)}$*, unless* ETH *fails. Here,* n *is the number of vertices in the input graph.*

4 Lower bound for Rainbow k-Coloring

In this section, we show that for every $k \geq 3$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, unless ETH fails. We give different reductions for the case when $k = 3$ (Section 4.1), k is an even number greater than 3 (Section 4.2), and k is an odd number greater than 4 (Section 4.3). We note that although the approach used for the proving lower bound for Rainbow 3-Coloring is extensible to Rainbow k-Coloring when k is odd, it unnecessarily adds to complexity of the reduction. Moreover, the approach we follow for showing the lower bound result for $k > 3$, where k is an odd number, introduces some technical issues when we try to extend it for $k = 3$.

Towards proving our lower bound result, we give an appropriate reduction from k-Coloring on graphs of maximum degree $2(k - 1)$, which does not admit an algorithm running in time $2^{o(n)}n^{\mathcal{O}(1)}$ unless ETH fails. The key idea behind the reduction is the same as that presented in Section 3, but for this case it is more involved. Before moving on to the description of the reductions we define a graph that will be useful in our reductions.

A *clique sequence* $\mathbb{Z}_{n,t} = (Z_1, Z_2, \ldots Z_t)$ of order (n, t) is a graph defined as follows. We have $V(\mathbb{Z}_{k,t}) = \uplus_{i \in [t]} Z_i$, where $|Z_i| = n$ for all $i \in [t]$. For each $i \in [t]$, all the edges in $\{(z, z') \mid z, z' \in Z_i\}$ are present in $E(\mathbb{Z}_{n,t})$, *i.e.* Z_i is a clique. Furthermore, for all $i \in [t - 1]$ all the edges in $\{(z, z') \mid z, \in Z_i, x' \in Z_{i+1}\}$ are present in $E(\mathbb{Z}_{n,t})$.

4.1 Lower bound for Rainbow 3-Coloring

In this section, we show that Rainbow 3-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, where n is the number of vertices in the input graph G.

Let G be an instance of 3-Coloring on n vertices with maximum degree bounded by 4. We start by computing (in polynomial time) a harmonious coloring φ of G with $t \in \mathcal{O}(\sqrt{n})$ color classes such that each color class contains at most $\mathcal{O}(\sqrt{n})$ vertices using Proposition 1.

Let $C_1, C_2, \ldots, C_t$ be the color classes of φ. From the discussion in Section 3, we assume that for $i, j \in [t]$, $i \neq j$ there is exactly one edge between C_i and C_j in G. We construct an instance G' of Rainbow 3-Coloring as follows.

- *Color class gadget.* Consider $i \in [t]$. The color class gadget $\mathcal{C}_i$ comprises of the set C_i, two vertices c_i, b_i, and a clique U_i on 3 vertices with vertex set $\{u_1^i, u_2^i, u_3^i\}$. We add all the edges in $\{(v, c_i), (v, b_i), (v, u_1^i), (v, u_2^i), (v, u_3^i) \mid v \in C_i\}$ to $E(\mathcal{C}_i)$. Also, we add the edge (b_i, c_i) to $E(\mathcal{C}_i)$.
- *Connection between color class gadgets.* Consider $i, j \in [t]$ such that $i \neq j$. We add all the edges in $\{(b_i, u_\ell^j) \mid \ell \in [3]\}$ to $E(G')$. Furthermore, we add all the edges $\{(u_\ell^i, u_{\ell'}^j) \mid \ell, \ell' \in [3]\}$ to $E(G')$. Note that $\{u_\ell^{i'} \mid i' \in [t], \ell \in [3]\}$ induces a clique in G'.
- *Encoding edges.* For $i, j \in [t]$, $i \neq j$ we add the unique edge (u, v) between C_i and C_j with $u \in C_i$ and $v \in C_j$ to G'. Note that this is same as adding all the edges in $E(G)$ to $E(G')$.

This finishes the description of the instance G' of Rainbow 3-Coloring. We note that some of the edges in G' are not necessary for the correctness of the reduction. However, they are added to reduce the number of pairs for which we need to argue about the existence of a rainbow path. Before moving on to the proof of equivalence between these instances, we create an edge-coloring $c_R : E(G') \to [3]$. Here, we create c_R based on a solution c to 3-Coloring in G, assuming that G is a *yes* instance of 3-Coloring. We will follow computation modulo k, and therefore color 0 is same as color k.

▶ **Definition 4.** Given a solution c to 3-Coloring in G, we construct $c_R : E(G') \to [3]$ as follows.

1. For $i \in [t]$, and $v \in C_i$ set $c_R(v, c_i) = c(v)$, $c_R(v, b_i) = c(v)$, and for $\ell \in [3]$, $c_R(v, u_\ell^i) = \ell$.
2. For $i, j \in [t]$, $i \neq j$ let (u, v) be the unique edge between C_i and C_j. We set $c_R(u, v)$ to be the unique integer in $[3] \setminus \{c(u), c(v)\}$. Here, the uniqueness is guaranteed by the fact that c is a proper 3-coloring of G, promising that $c(u) \neq c(v)$.
3. For $i \in [t]$ set $c_R(b_i, c_i) = 3$, $c_R(u_1^i, u_2^i) = 3$, $c_R(u_2^i, u_3^i) = 2$, and $c_R(u_3^i, u_1^i) = 1$.
4. For $i, j \in [t]$, $i \neq j$ and $\ell \in [3]$ set $c_R(b_i, u_\ell^j) = \ell - 1$.
5. For $i, j \in [t]$, $i \neq j$ and $\ell \in [3]$ set $c_R(u_\ell^i, u_\ell^j) = \ell$. Furthermore, for $\ell' \in [3] \setminus \{\ell\}$ we set $c_R(u_\ell^i, u_{\ell'}^j) = \hat{\ell}$, where $\hat{\ell}$ is the unique integer in $[3] \setminus \{\ell, \ell'\}$.

Next, we prove some lemmata that will be useful in establishing the equivalence between the instance G of 3-Coloring and the instance G' of Rainbow 3-Coloring.

▶ **Lemma 5.** *For $i, j \in [t]$, where $i \neq j$, let (u^*, v^*) be the unique edge between C_i and C_j with $u^* \in C_i$ and $v^* \in C_j$. There is exactly one path, namely (c_i, u^*, v^*, c_j) in G', between c_i and c_j that has at most 3 edges.*

▶ **Lemma 6.** *Let G be a yes instance of 3-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [3]$ be the coloring given by Definition 4 for the coloring c of G. Then for all $i \in [t]$, and $u, v \in \mathcal{C}_i$ there is a rainbow path between u and v in G'.*

▶ **Lemma 7.** *Let G be a yes instance of 3-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [3]$ be the coloring given by Definition 4 for the coloring c of G. Then for all $i, j \in [t]$, $i \neq j$ for all $u \in \mathcal{C}_i$ and $v \in \mathcal{C}_j$ there is a rainbow path between u and v in G'.*

We now establish equivalence between the instance G of 3-Coloring and the instance G' of Rainbow 3-Coloring.

▶ **Lemma 8.** *G is a yes instance of* 3-Coloring *if and only if G' is a yes instance of* Rainbow 3-Coloring.

Proof. In the forward direction, let G be a *yes* instance of 3-Coloring, and $c : V(G) \to [3]$ be one of its solution. Let $c_R : E(G') \to [3]$ be the coloring given by Definition 4 for the given coloring c of G. From Lemma 6 and 7 it follows that c_R is a solution to Rainbow 3-Coloring in G'.

In the reverse direction, let G' be a *yes* instance of Rainbow 3-Coloring, and $c_R : E(G') \to [3]$ be one of its solution. We create a coloring $c : V(G) \to [3]$ as follows. For $i \in [t]$ and $v \in C_i$, we let $c(v) = c_R(c_i, v)$. We show that c is a valid solution to 3-Coloring in G. Consider $(u, v) \in E(G)$, and let $u \in C_i$ and $v \in C_j$. Note that we have $i \neq j$. Let P be a rainbow path between c_i and c_j in G'. Note that P can have at most 3 edges. By Lemma 5 we know that $P = (c_i, u, v, c_j)$, therefore by construction of c, we have $c_R(c_i, u) = c(u) \neq c(v) = c_R(c_i, v)$. This concludes the proof. ◀

▶ **Theorem 9.** Rainbow 3-Coloring *does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, unless* ETH *fails. Here, n is the number of vertices in the input graph.*

4.2 Lower Bound for Rainbow k-Coloring, $k > 3$ and even

In this section, we show that Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, for every even k where $k > 3$. Here, n is the number of vertices in the input graph.

Let G be an instance of k-Coloring on n vertices with maximum degree bounded by $2(k-1)$. Here, $k > 3$ and k is an even number. We start by computing (in polynomial time) a harmonious coloring φ of G with $t \in \mathcal{O}(\sqrt{n})$ color classes such that each color class contains at most $\mathcal{O}(\sqrt{n})$ vertices using Proposition 1. Let $C_1, C_2, \ldots, C_t$ be the color classes of φ with exactly one edge between C_i and C_j in G, where $i, j \in [t]$. We modify the graph G and its harmonious coloring φ, to obtain a more structured instance, which will be useful later. For each $i \in [t]$, we add k new vertices $v^*_{i1}, v^*_{i2}, \ldots, v^*_{ik}$ to $V(G)$, and add them to C_i. We continue to call the modified graph as G and its harmonious coloring as φ with color classes $C_1, C_2, \ldots, C_t$. We note that $\{v^*_{ij} \mid i \in [t], j \in [k]\}$ induce an independent set in G. The purpose of adding these k new vertices is to ensure that if G is a *yes* instance of k-Coloring then there is a k-coloring c of G, such that for each $i \in [t]$ and $j \in [k]$, we have $c^{-1}(j) \cap C_i \neq \emptyset$. This will be helpful in simplifying some of the arguments later. Observe that the original instance is a *yes* instance of a k-Coloring is and only if the modified instance is a *yes* instance of k-Coloring. Moreover, given a k-coloring of G (modified graph), in polynomial time we can obtain another k-coloring c' of G such that for all $i \in [t], j \in [k]$ we have $c(v^*_{ij}) = j$. Also, we have $|V(G)| \in \mathcal{O}(n)$, and $|E(G)| \in \mathcal{O}(n)$, where n is the number of vertices in the original instance. Hereafter, whenever we talk about a solution c to k-Coloring in G (if it exists) we will assume (without explicitly mentioning) that for all $i \in [t]$ and $p \in [k]$ we have $C_i \cap c^{-1}(p) \neq \emptyset$. We now move to the description of the reduction.

We proceed by describing color class gadget $\mathcal{C}_i$, corresponding to the color class C_i, where $i \in [t]$, and gadgets to encode edges in G. Then we state the connection between various color class gadgets and edge gadgets. We let $k = 2\ell$, where $\ell \in \mathbb{N}$ and $\ell > 1$. We create an instance G' of Rainbow k-Coloring as described below.

- *Color class gadget.* Consider $i \in [t]$. The color class gadget $\mathcal{C}_i$ comprises of the set C_i, a vertex c_i, and a clique sequence $\mathbb{Z}_i = (U^i_1 \cup D^i_1, \ldots, U^i_{\ell-1} \cup D^i_{\ell-1})$ of order $(2k, \ell - 1)$. Here, for each $i \in [\ell - 1]$ we have $|U_i| = |D_i| = k$. For $r \in [\ell - 1]$ we let $U^i_r = \{u^i_{rp} \mid p \in [k]\}$,

and $D^i_r = \{d^i_{rp} \mid p \in [k]\}$. We add all the edges in $\{(c_i, v) \mid v \in C_i\}$ to $E(\mathcal{C}_i)$. Also, we add all the edges in $\{(v, w) \mid v \in C_i, w \in U^i_1 \cup D^i_1\}$ to $E(\mathcal{C}_i)$.

- *Connection between color class gadgets.* For each $i, j \in [t]$ where $i \neq j$, we add all the edges in $\{(w, w') \mid w \in U^i_{\ell-1} \cup D^i_{\ell-1}, w' \in U^j_{\ell-1} \cup D^j_{\ell-1}\}$ to $E(G')$.
- *Edge gadget.* Consider $i, j \in [t]$ with $i < j$. Recall that there is exactly one edge between C_i and C_j. Corresponding to this edge we create a path $P = (x^{ij}_1, \ldots, x^{ij}_{\ell-2}, z_{ij}, x^{ji}_{\ell-2}, \ldots, x^{ji}_1)$ on $k-3$ vertices, and add it to G'. We note that whenever we say vertex z_{ji} it refers to the vertex z_{ij} *i.e.* z_{ij} and z_{ji} denotes the same vertex.
- *Connection between color class gadgets and edge gadgets.* Consider $i, j \in [t]$, where $i < j$. Let (u^*_i, v^*_j) be the unique edge between C_i and C_j with $u^*_i \in C_i$ and $v^*_j \in C_i$. We add the edges $(u^*_i, x^{ij}_1), (x^{ji}_1, v^*_j)$ to $E(G')$. Notice that when $\ell = 2$ x^{ij}_1 does not exists. In this case, we add the edges $(u^*_i, z), (z, v^*_j)$ to $E(G')$. For each $r \in [\ell - 2]$ we add all the edges in $\{(x^{ij}_r, w) \mid w \in U^i_r \cup D^i_r\}$ to $E(G')$. Similarly, we add all the edges in $\{(x^{ji}_r, w) \mid w \in U^j_r \cup D^j_r\}$ to $E(G')$. Also, we add all the edges in $\{(z_{ij}, u) \mid u \in U^i_{\ell-1} \cup D^i_{\ell-1} \cup U^j_{\ell-1} \cup D^j_{\ell-1}\}$ to $E(G')$.

This finishes the construction of instance G' of Rainbow k-Coloring for the given instance G of k-Coloring. Before moving on to proving the equivalence between these instances, we create an edge-coloring $c_R : E(G') \to [k]$. Here, we create c_R based on a solution c to k-Coloring in G, assuming that is G a *yes* instance of k-Coloring. We will follow computation modulo k (color 0 is same as color k).

▶ **Definition 10.** Given a solution c to k-Coloring in G, we construct $c_R : E(G') \to [k]$ as follows.

1. For $i \in [t]$, and $v \in C_i$ we set $c_R(v, c_i) = c(v)$.
2. For $i, j \in [t]$, $i < j$ let (u^*_i, v^*_j) be the unique edge between C_i and C_j. Consider the path $P = (u^*_i, x^{ij}_1, \ldots x^{ij}_{\ell-2}, z_{ij}, x^{ji}_{\ell-2}, \ldots x^{ji}_1, v^*_j)$. We arbitrarily assign unique integers in $[k] \setminus \{c(u^*_i), c(v^*_j)\}$ to $c_R(e)$, for each $e \in E(P)$.
3. For $i \in [t]$, a vertex $v \in C_i$, and $p \in [k]$ we set $c_R(v, u^i_{1p}) = p - 1$, and $c_R(v, d^i_{1p}) = p$.
4. For $i \in [t]$, $r \in [\ell - 1]$, and $p, q \in [k]$ we set $c_R(d^i_{rp}, u^i_{rq}) = p$.
5. For $i, j \in [t]$, where $i \neq j$, $r \in [\ell - 1]$, and $p \in [k]$ we set $c_R(x^{ij}_r, u^i_{rp}) = p$, and $c_R(x^{ij}_r, d^i_{rp}) = p + 1$.
6. For $i \in [t]$, $r \in [\ell - 2]$, $p, q \in [k]$ we set $c_R(d^i_{(r+1)p}, d^i_{rq}) = p$, and $c_R(u^i_{rp}, u^i_{(r+1)q}) = p$.
7. For $i, j \in [t]$ where $i \neq j$, $p, q \in [k]$ we set $c_R(u^i_{(\ell-1)p}, d^j_{(\ell-1)q}) = p$, $c_R(u^i_{(\ell-1)p}, z_{ij}) = p$, and $c_R(d^i_{(\ell-1)p}, z_{ij}) = p + 1$.
8. For $i \in [t]$, $r \in [\ell - 2]$, $p, q \in [k]$ we set $c_R(u^i_{rp}, d^i_{(r+1)q}) = q$ and $c_R(u^i_{(r+1)p}, d^i_{rq}) = p$.
9. For all $i \in [t]$, $r \in [\ell - 1]$, $p, q \in [k]$, where $p \neq q$ we set $c_R(u^i_{rp}, u^i_{rq}) = k$.
10. For all the remaining edges in $E(G')$, c_R assigns it an integer in $[k]$ arbitrarily.

Next, we prove some lemmata that will be useful in establishing equivalence between the instance G of k-Coloring and the instance G' of Rainbow k-Coloring.

▶ **Lemma 11.** *For $i, j \in [t]$, where $i \neq j$, let P be a path between c_i and c_j with at most k edges in G'. If $\ell > 2$ then P contains the edge $(x^{ij}_{\ell-2}, z_{ij})$. Otherwise, P contains the edge (u, z_{ij}), where u is the unique vertex in C_i that in adjacent to a vertex in C_j.*

▶ **Lemma 12.** *For $i, j \in [t]$, where $i \neq j$ let (u^*, v^*) be the unique edge between C_i and C_j with $u^* \in C_i$ and $v^* \in C_j$. There is exactly one path, namely $(c_i, u^*, x^{ij}_1, \ldots, x^{ij}_{\ell-2}, z_{ij}, x^{ji}_{\ell-2}, \ldots, x^{ji}_1, v^*, c_j)$ in G' between c_i and c_j that has at most k edges.*

▶ **Lemma 13.** *Let G be a yes instance of k-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [k]$ be the coloring given by Definition 10 for the coloring c of G. For all $i \in [t]$, and $u, v \in V(\mathcal{C}_i) \cup \{z_{ij} \mid j \in [k] \setminus \{i\}\} \cup \{x_r^{ij} \mid j \in [t] \setminus \{i\}, r \in [\ell - 2]\}$ there is a rainbow path between u and v in G'.*

▶ **Lemma 14.** *Let G be a yes instance of k-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [k]$ be the coloring given by Definition 10 for the coloring c of G. For all $i, j \in [t]$ where $i \neq j$, $u \in V(\mathcal{C}_i) \cup \{z_{ij'} \mid j' \in [k] \setminus \{i\}\} \cup \{x_r^{ij'} \mid j' \in [t] \setminus \{i\}, r \in [\ell - 2]\}$ and $v \in V(\mathcal{C}_j) \cup \{z_{ji'} \mid i' \in [k] \setminus \{j\}\} \cup \{x_r^{ji'} \mid i' \in [t] \setminus \{j\}, r \in [\ell - 2]\}$ there is a rainbow path between u and v in G'.*

We now establish equivalence between the instance G of k-Coloring and the instance G' of Rainbow k-Coloring.

▶ **Lemma 15.** *G' is a yes instance of k-Coloring if and only if G' is a yes instance of* Rainbow k-Coloring.

▶ **Theorem 16.** Rainbow k-Coloring *does not admit an algorithm running in time $2^{o(|E(G)|)} n^{\mathcal{O}(1)}$, unless* ETH *fails. Here, n is the number of vertices in the input graph, and k is an even number greater than 3.*

4.3 Lower Bound for Rainbow k-Coloring, $k > 3$ and odd

In this section, we show that Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)} n^{\mathcal{O}(1)}$, for every odd k where $k > 3$. Here, n is the number of vertices in the input graph.

Let G be an instance of k-Coloring on n vertices with maximum degree bounded by $2(k-1)$. Here, $k > 3$ and k is an odd number. We start by computing (in polynomial time) a harmonious coloring φ of G with $t \in \mathcal{O}(\sqrt{n})$ color classes such that each color class contains at most $\mathcal{O}(\sqrt{n})$ vertices using Proposition refprop:compute-harmonious-coloring. Let $C_1, C_2, \ldots, C_t$ be the color classes of φ. From the discussion in Section 3, we assume that for $i, j \in [t]$, $i \neq j$ there is exactly one edge between C_i and C_j in G. As discussed in Section 4.2, we modify the graph G and its harmonious coloring φ, to obtain a more structured (equivalent) instance of k-Coloring. This is achieved by adding k new vertices $v_{i1}^*, v_{i2}^*, \ldots, v_{ik}^*$ to C_i (and G) for each $i \in [t]$. The purpose of adding these k new vertices is to ensure that if G is a *yes* instance of k-Coloring then there is a k-coloring c of G, such that for each $i \in [t]$ and $j \in [k]$, we have $c^{-1}(j) \cap C_i \neq \emptyset$. Hereafter, whenever we talk about a solution c to k-Coloring in G (if it exists) we will assume (without explicitly mentioning) that for all $i \in [t]$ and $p \in [k]$ we have $C_i \cap c^{-1}(p) \neq \emptyset$.

We move to the description of the reduction. We first describe the color class gadget $\mathcal{C}_i$, corresponding to each color class C_i, where $i \in [t]$, and gadgets to encode edges in G. We also have a link vertex which is connected to all color class gadgets (but not all vertices). After this, we state connections between color class gadgets and edge gadgets. We let $k = 2\ell + 1$, where $\ell \in \mathbb{N}$ and $\ell \geq 2$. We create an instance G' of Rainbow k-Coloring as follows.

- *Color class gadget.* Consider $i \in [t]$. The color class gadget $\mathcal{C}_i$ comprises of the set C_i, a vertex c_i, and a clique sequence $\mathbb{Z}_i = (U_1^i \cup D_1^i, \ldots, U_{\ell-1}^i \cup D_{\ell-1}^i)$ of order $(2k, \ell - 1)$. Here, for each $i \in [\ell - 1]$ we have $|U_i| = |D_i| = k$. For $r \in [\ell - 1]$ we let $U_r^i = \{u_{rp}^i \mid p \in [k]\}$ and $D_r^i = \{d_{rp}^i \mid p \in [k]\}$. We add all the edges in $\{(c_i, v) \mid v \in C_i\}$ to $E(\mathcal{C}_i)$. Also, we add all the edges in $\{(v, w) \mid v \in C_i, w \in U_1^i \cup D_1^i\}$ to $E(\mathcal{C}_i)$.
- *Link vertex and its connection to color class gadgets.* We add a vertex z to G'. For each $i \in [t]$, we add all the edges in $\{(z, w) \mid w \in U_{\ell-1}^i \cup D_{\ell-1}^i\}$ to $E(G')$.

- *Edge gadget.* Consider $i, j \in [t]$ with $i \neq j$. Recall that there is exactly one edge between C_i and C_j. Corresponding to this edge we create a path $P = (x_1^{ij}, \ldots, x_{\ell-1}^{ij}, x_{\ell-1}^{ji}, \ldots, x_1^{ji})$ on $k-3$ vertices, and add it to G'.
- *Connection between color class gadgets and edge gadgets.* Consider $i, j \in [t]$, where $i \neq j$. Let (u_i^*, v_j^*) be the unique edge between C_i and C_j with $u_i^* \in C_i$ and $v_j^* \in C_i$. We add the edges $(u_i^*, x_1^{ij}), (x_1^{ji}, v_j^*)$ to $E(G')$. For each $r \in [\ell - 1]$ we add all the edges in $\{(x_r^{ij}, w) \mid w \in U_r^i \cup D_r^i\}$ to $E(G')$. Similarly, we add all the edges in $\{(x_r^{ji}, w) \mid w \in U_r^j \cup D_r^j\}$ to $E(G')$.

This finishes the construction of the instance G' of Rainbow k-Coloring for the given instance G of k-Coloring. Before moving on to proving the equivalence between these instances, we create an edge-coloring $c_R : E(G') \to [k]$. Here, we create c_R based on a solution c to k-Coloring in G, assuming that is G a *yes* instance of k-Coloring. We will follow computation modulo k (color 0 is same as color k).

▶ **Definition 17.** Given a solution c to k-Coloring in G, we construct $c_R : E(G') \to [k]$ as follows.

1. For $i \in [t]$, and $v \in C_i$ we set $c_R(v, c_i) = c(v)$.
2. For $i, j \in [t]$, $i \neq j$ let (u_i^*, v_j^*) be the unique edge between C_i and C_j. Consider the path $P = (u_i^*, x_1^{ij}, \ldots x_{\ell-1}^{ij}, x_{\ell-1}^{ji}, \ldots x_1^{ji}, v_j^*)$. We arbitrarily assign unique integers in $[k] \setminus \{c(u_i^*), c(v_j^*)\}$ to $c_R(e)$, for each $e \in E(P)$.
3. For $i \in [t]$, a vertex $v \in C_i \cup \{x_1^{ij} \mid j \in [t] \setminus \{i\}\}$, and $p \in [k]$ we set $c_R(v, u_{1p}^i) = p - 1$, and $c_R(v, d_{1p}^i) = p$.
4. For $i \in [t]$, $r \in [\ell - 1]$, and $p, q \in [k]$ we set $c_R(d_{rp}^i, u_{rq}^i) = p$.
5. For $i, j \in [t]$, where $i \neq j$, $r \in [\ell - 1]$, and $p \in [k]$ we set $c_R(x_r^{ij}, u_{rp}^i) = p$, and $c_R(x_r^{ij}, d_{rp}^i) = p + 1$.
6. For $i \in [t]$, $r \in [\ell - 2]$, $p, q \in [k]$ we set $c_R(d_{(r+1)p}^i, d_{rq}^i) = p$, and $c_R(u_{rp}^i, u_{(r+1)q}^i) = p$.
7. For $i \in [t]$, $p \in [k]$ we set $c_R(u_{(\ell-1)p}^i, z) = p$, and $c_R(d_{(\ell-1)p}^i, z) = p - 1$.
8. For $i \in [t]$, $r \in [\ell - 2]$, $p, q \in [k]$ we set $c_R(u_{rp}^i, d_{(r+1)q}^i) = q$ and $c_R(u_{(r+1)p}^i, d_{rq}^i) = p$.
9. For all $i \in [t]$, $r \in [\ell]$, $p, q \in [k]$, where $p \neq q$ we set $c_R(u_{rp}^i, u_{rq}^i) = k$.
10. For all the remaining edges in $E(G')$, c_R assigns it an integer in $[k]$ arbitrarily.

Next, we prove some lemmata that will be useful in establishing the equivalence between the instance G of k-Coloring and the instance G' of Rainbow k-Coloring.

▶ **Lemma 18.** *For $i, j \in [t]$, where $i \neq j$, let P be a path between c_i and c_j with at most k edges in G'. Then $(x_{\ell-1}^{ij}, x_{\ell-1}^{ij}) \in E(P)$.*

▶ **Lemma 19.** *For $i, j \in [t]$, where $i \neq j$ let (u_i^*, v_j^*) be the unique edge between C_i and C_j with $u_i^* \in C_i$ and $v_j^* \in C_j$. There is exactly one path, namely $(c_i, u_i^*, x_1^{ij}, \ldots, x_{\ell-1}^{ij}, x_{\ell-1}^{ji}, \ldots, x_1^{ji}, v_j^*, c_j)$ in G' between c_i and c_j that has at most k edges.*

▶ **Lemma 20.** *Let G be a yes instance of k-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [k]$ be the coloring given by Definition 17 for the coloring c of G. For all $i \in [t]$, and $u, v \in V(\mathcal{C}_i) \cup \{x_r^{ij} \mid j \in [t] \setminus \{i\}, r \in [\ell - 1]\} \cup \{z\}$ there is a rainbow path between u and v in G'.*

▶ **Lemma 21.** *Let G be a yes instance of k-Coloring, and c be one of its solution. Furthermore, let $c_R : E(G') \to [k]$ be the coloring given by Definition 17 for the coloring c of G. For all $i, j \in [t]$ where $i \neq j$, $u \in V(\mathcal{C}_i) \cup \{x_r^{ij'} \mid j' \in [t] \setminus \{i\}, r \in [\ell - 1]\}$ and $v \in \mathcal{C}_j \cup \{x_r^{ji'} \mid i' \in [t] \setminus \{j\}, r \in [\ell - 1]\}$ there is a rainbow path between u and v in G'.*

▶ **Lemma 22.** *G' is a yes instance of k-Coloring if and only if G' is a yes instance of* Rainbow k-Coloring.

▶ **Theorem 23.** Rainbow k-Coloring *does not admit an algorithm running in time $2^{o(|E(G)|)}n^{\mathcal{O}(1)}$, unless* ETH *fails. Here, n is the number of vertices in the input graph, and k is an odd number greater than 3.*

5 FPT Algorithm for Subset Rainbow k-Coloring

In this section, we design an FPT algorithm running in time $\mathcal{O}(2^{|S|}n^{\mathcal{O}(1)})$ for Subset Rainbow k-Coloring, when parameterized by $|S|$. Our algorithm is based on the technique of color coding, which was first introduced by Alon et al. [2]. We first describe a randomized algorithm for Subset Rainbow k-Coloring, which we derandomize using splitters.

The intuition behind the algorithm is as follows. Let (G, S) be an instance of Subset Rainbow k-Coloring on n vertices and m edges. For a solution $c_R : E(G) \to [k]$, to Subset Rainbow k-Coloring in (G, S) the following holds. For each $(u, v) \in S$, there exist a path P from u to v in G with at most k edges such that for all $e, e' \in E(P)$, where $e \neq e'$ we have $c_R(e) \neq c_R(e')$. Therefore, at most $k|S|$ edges in G seems to be "important" for us, *i.e.* if we color at most $k|S|$ edges "nicely" then we would obtain the desired soultion. To capture this, we start by randomly coloring edges in G, hoping that with sufficiently high probability we obtain a coloring that colors the desired set of edges "nicely". Once we have obtained such a "nice" coloring, we employ the algorithm of Kowalik and Lauri [19] to check if there is a rainbow path for each $(u, v) \in S$. We note that we use the algorithm given by [19] instead of the one in [28] because the latter requires exponential space.

Algorithm Rand-SRC. Let $c : E(G) \to [k]$ be a coloring of $E(G)$, where each edge is colored with one of the colors in $[k]$ uniformly and independently at random. If for each $(u, v) \in S$, there is rainbow path between u and v in G' with edge-coloring c then the algorithm return c as a solution to Subset Rainbow k-Coloring in (G, S). Otherwise, it returns *no*. We note that for a given graph G with edge-coloring c, and vertices u and v, in time $2^k n^{\mathcal{O}(1)}$ time we can check if there is a rainbow path between u and v in G' by using the algorithm given by Corollary 5 in [19]. This completes the description of the algorithm.

We now proceed to show how we can obtain an algorithm with constant success probability.

▶ **Theorem 24.** *There is an algorithm that, given an instance (G, S) of* Subset Rainbow k-Coloring*, in time $2^{\mathcal{O}(|S|k\log k)}n^{\mathcal{O}(1)}$ either returns no or outputs a solution to* Subset Rainbow k-Coloring *in (G, S). Moreover, if the input is a yes instance of* Subset Rainbow k-Coloring*, then it returns a solution with positive constant probability.*

We start by defining some terminologies which will be useful in derandomization of our algorithm (see [12, 27]). An (n, p, ℓ)-*splitter* $\mathcal{F}$, is a family of functions from $[n]$ to ℓ such that for every $S \subseteq [n]$ of size at most p there is a function $f \in \mathcal{F}$ such that f splits S evenly. That is, for all $i, j \in [\ell]$, $|f^{-1}(i)|$ and $|f^{-1}(j)|$ differs by at most 1. Observe that when $\ell \geq p$ then for any $S \subseteq [n]$ of size at most p and a function $f \in \mathcal{F}$ that splits S, we have $|f^{-1}(i) \cap S| \leq 1$, for all $i \in [\ell]$. An (n, ℓ, ℓ)-splitter is called as an (n, ℓ)-*perfect hash family*. Moreover, for any $\ell \geq 1$, we can construct an (n, ℓ)-perfect hash family of size $e^{\ell}\ell^{\mathcal{O}(\log \ell)} \log n$ in time $e^{\ell}\ell^{\mathcal{O}(\log \ell)} n \log n$ [27].

We next move to the description of derandomization of the algorithm presented in Theorem 24. For the sake of simplicity in explanation, we associate each $e \in E(G)$ with a unique integer, say i_e in $[m]$, and whenever we refer to e as an integer, we actually refer to the integer

i_e. We start by computing an $(m, k|S|)$-perfect hash family $\mathcal{F}$ of size $e^{k|S|}(k|S|)^{\mathcal{O}(\log k|S|)} \log m$ in time $e^{k|S|}(k|S|)^{\mathcal{O}(\log k|S|)} m \log m$ using the algorithm of Naor et al. [27]. We will create a family of function $\mathcal{F}'$ from $[m]$ to $[k]$ of size $e^{k|S|}(k|S|)^{\mathcal{O}(\log k|S|)} k^{k|S|} \log m$. Towards this, consider an $f \in \mathcal{F}$ and a partition $\mathcal{P} = \{P_1, P_2, \ldots, P_{k'}\}$ of $[k|S|]$ into k' sets, where $k' \leq k$. We let $f_{\mathcal{P}}$ to be the function obtained from f as follows. For each $i \in [k']$ we have $f_{\mathcal{P}}^{-1}(i) = \cup_{x \in P_i} f^{-1}(x)$. For every such pair f and $\mathcal{P}$, we add the function $f_{\mathcal{P}}$ to the set $\mathcal{F}'$. We will call such an $\mathcal{F}'$ as $(m, k|S|, k)$-*unified perfect hash* family. Observe that $\mathcal{F}'$ has size at most $e^{k|S|}(k|S|)^{\mathcal{O}(\log k|S|)} k^{k|S|} \log m$. We now describe the derandomized algorithm SRC, which is a result of derandomization of Rand-SRC.

Algorithm SRC. Given an instance (G, S) of Subset Rainbow k-Coloring, the algorithm start by computing an $(m, k|S|, k)$-unified perfect hash family $\mathcal{F}'$. If there exists $c : E(G) \to [k]$, where $c \in \mathcal{F}'$ such that for each $(u, v) \in S$, there is rainbow path between u and v in G' with the edge-coloring c then we return c as a solution to Subset Rainbow k-Coloring in (G, S). Otherwise, we return that (G, S) is a *no* instance of Subset Rainbow k-Coloring. We note that for a given graph G with edge-coloring c, and vertices u and v, in time $2^k n^{\mathcal{O}(1)}$ time we can check if there is a rainbow path between u and v in G' by using the algorithm given by Corollary 5 in [19]. This completes the description of the algorithm.

▶ **Theorem 25.** *Given an instance (G, k) of* Subset Rainbow k-Coloring*, the algorithm* SRC *either correctly reports that (G, k) is a no instance of* Subset Rainbow k-Coloring *or returns a solution to* Subset Rainbow k-Coloring *in (G, S). Moreover,* SRC *runs in time $2^{\mathcal{O}(|S|)} n^{\mathcal{O}(1)}$, for every fixed k. Here, $n = |V(G)|$.*

▶ **Corollary 26.** Steiner Rainbow k-Coloring *admits an algorithm running in time $2^{\mathcal{O}(|S|^2)} n^{\mathcal{O}(1)}$.*

6 Conclusion

In this paper, we proved that for all $k \geq 3$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)} n^{\mathcal{O}(1)}$, unless ETH fails. This (partially) resolves the conjecture of Kowalik et al. [20], which states that for every $k \geq 2$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(|E(G)|)} n^{\mathcal{O}(1)}$. It would be an interesting direction to study whether or not Rainbow k-Coloring admits an algorithm running in time $2^{o(|E(G)|)} n^{\mathcal{O}(1)}$, for $k = 2$. We also studied the problem Steiner Rainbow k-Coloring, and proved that for every $k \geq 3$ the problem does not admit an algorithm running in time $2^{o(|S|^2)} n^{\mathcal{O}(1)}$, unless ETH fails. We complemented this by designing an algorithm for Subset Rainbow k-Coloring running in time $2^{\mathcal{O}(|S|)} n^{\mathcal{O}(1)}$, which implies an algorithm running in time $2^{\mathcal{O}(|S|^2)} n^{\mathcal{O}(1)}$ for Steiner Rainbow k-Coloring. It would be interesting to study whether or not Steiner Rainbow k-Coloring admits an algorithm running in time $2^{o(|S|^2)} n^{\mathcal{O}(1)}$, for $k = 2$. Kowalik et al. [20] also conjectured that for every $k \geq 2$, Rainbow k-Coloring does not admit an algorithm running in time $2^{o(n^2)} n^{\mathcal{O}(1)}$, which is another interesting direction of research.

Abstract

Evolutionary graph theory studies the evolutionary dynamics in a population structure given as a connected graph. Each node of the graph represents an individual of the population, and edges determine how offspring are placed. We consider the classical birth-death Moran process where there are two types of individuals, namely, the residents with fitness 1 and mutants with fitness r. The fitness indicates the reproductive strength. The evolutionary dynamics happens as follows: in the initial step, in a population of all resident individuals a mutant is introduced, and then at each step, an individual is chosen proportional to the fitness of its type to reproduce, and the offspring replaces a neighbor uniformly at random. The process stops when all individuals are either residents or mutants. The probability that all individuals in the end are mutants is called the fixation probability, which is a key factor in the rate of evolution. We consider the problem of approximating the fixation probability.

The class of algorithms that is extremely relevant for approximation of the fixation probabilities is the Monte-Carlo simulation of the process. Previous results present a polynomial-time Monte-Carlo algorithm for undirected graphs when r is given in unary. First, we present a simple modification: instead of simulating each step, we discard *ineffective* steps, where no node changes type (i.e., either residents replace residents, or mutants replace mutants). Using the above simple modification and our result that the number of effective steps is concentrated around the expected number of effective steps, we present faster polynomial-time Monte-Carlo algorithms for undirected graphs. Our algorithms are always at least a factor $O(n^2/\log n)$ faster as compared to the previous algorithms, where n is the number of nodes, and is polynomial even if r is given in binary. We also present lower bounds showing that the upper bound on the expected number of effective steps we present is asymptotically tight for undirected graphs.

1 Introduction

In this work we present faster Monte-Carlo algorithms for approximation of the fixation probability of the fundamental Moran process on population structures with symmetric interactions. We start with the description of the problem.

Evolutionary dynamics. Evolutionary dynamics act on populations, where the composition of the population changes over time due to mutation and selection. Mutation generates new types and selection changes the relative abundance of different types. A fundamental concept in evolutionary dynamics is the fixation probability of a new mutant [7, 11, 13, 14]: Consider a population of n *resident* individuals, each with a fitness value 1. A single *mutant* with non-negative fitness value r is introduced in the population as the initialization step. Intuitively, the fitness represents the reproductive strength. In the classical Moran process the following *birth-death* stochastic steps are repeated: At each time step, one individual is chosen at random proportional to the fitness to reproduce and one other individual is chosen uniformly at random for death. The offspring of the reproduced individual replaces the dead individual. This stochastic process continues until either all individuals are mutants or all individuals are residents. The *fixation probability* is the probability that the mutants take over the population, which means all individuals are mutants. A standard calculation shows that the fixation probability is given by $(1-(1/r))/(1-(1/r^n))$. The correlation between the relative fitness r of the mutant and the fixation probability is a measure of the effect of natural selection. The rate of evolution, which is the rate at which subsequent mutations accumulate in the population, is proportional to the fixation probability, the mutation rate, and the population size n. Hence fixation probability is a fundamental concept in evolution.

Evolutionary graph theory. While the basic Moran process happens in well-mixed population (all individuals interact uniformly with all others), a fundamental extension is to study the process on population structures. Evolutionary graph theory studies this phenomenon. The individuals of the population occupy the nodes of a connected graph. The links (edges) determine who interacts with whom. Basically, in the birth-death step, for the death for replacement, a neighbor of the reproducing individual is chosen uniformly at random. Evolutionary graph theory describes evolutionary dynamics in spatially structured population where most interactions and competitions occur mainly among neighbors in physical space [12, 3, 8, 15]. Undirected graphs represent population structures where the interactions are symmetric, whereas directed graphs allow for asymmetric interactions. The fixation probability depends on the population structure [12, 1, 9, 4]. Thus, the fundamental computational problem in evolutionary graph theory is as follows: given a population structure (i.e., a graph), the relative fitness r, and $\epsilon > 0$, compute an ϵ-approximation of the fixation probability.

Monte-Carlo algorithms. A particularly important class of algorithms for biologists is the Monte-Carlo algorithms, because it is simple and easy to interpret. The Monte-Carlo algorithm for the Moran process basically requires to simulate the process, and from the statistics obtain an approximation of the fixation probability. Hence, the basic question we address in this work is simple Monte-Carlo algorithms for approximating the fixation probability. It was shown in [6] that simple simulation can take exponential time on directed graphs and thus we focus on undirected graphs. The main previous algorithmic result in this area [5] presents a polynomial-time Monte-Carlo algorithm for undirected graphs when r is given in unary. The main result of [5] shows that for undirected graphs it suffices to run each simulation for polynomially many steps.

Table 1 Comparison with previous work, for constant $r > 1$. We denote by n, Δ, τ, and ϵ, the number of nodes, the maximum degree, the random variable for the fixation time, and the approximation factor, respectively. The results in the column "All steps" is from [5], except that we present the dependency on Δ, which was considered as n in [5]. The results of the column "Effective steps" is the results of this paper

	All steps	Effective steps
#steps in expectation	$O(n^2\Delta^2)$	$O(n\Delta)$
Concentration bounds	$\Pr[\tau \geq \frac{n^2\Delta^2 rx}{r-1}] \leq 1/x$	$\Pr[\tau \geq \frac{6n\Delta x}{\min(r-1,1)}] \leq 2^{-x}$
Sampling a step	$O(1)$	$O(\Delta)$
Fixation algo	$O(n^6\Delta^2\epsilon^{-4})$	$O(n^2\Delta^2\epsilon^{-2}(\log n + \log \epsilon^{-1}))$

Our contributions. In this work our main contributions are as follows:

1. *Faster algorithm for undirected graphs* First, we present a simple modification: instead of simulating each step, we discard *ineffective* steps, where no node changes type (i.e., either residents replace residents, or mutants replace mutants). We then show that the number of effective steps is concentrated around the expected number of effective steps. The sampling of each effective step is more complicated though than sampling of each step. We then present an efficient algorithm for sampling of the effective steps, which requires $O(m)$ preprocessing and then $O(\Delta)$ time for sampling, where m is the number of edges and Δ is the maximum degree. Combining all our results we obtain faster polynomial-time Monte-Carlo algorithms: Our algorithms are always at least a factor $n^2/\log n$ times a constant (in most cases $n^3/\log n$ times a constant) faster as compared to the previous algorithm, and is polynomial even if r is given in binary. We present a comparison in Table 1, for constant $r > 1$ (since the previous algorithm is not in polynomial time for r in binary). For a detailed comparison see the full version [2].
2. *Lower bounds* We also present lower bounds showing that the upper bound on the expected number of effective steps we present is asymptotically tight for undirected graphs.

Related complexity result. While in this work we consider evolutionary graph theory, a related problem is evolutionary games on graphs (which studies the problem of frequency dependent selection). The approximation problem for evolutionary games on graphs is considerably harder (e.g., PSPACE-completeness results have been established) [10].

Technical contributions. Note that for the problem we consider the goal is not to design complicated efficient algorithms, but simple algorithms that are efficient. By simple, we mean something that is related to the process itself, as biologists understand and interpret the Moran process well. Our main technical contribution is a simple idea to discard ineffective steps, which is intuitive, and we show that the simple modification leads to significantly faster algorithms. We show a gain of factor $O(n\Delta)$ due to the effective steps, then lose a factor of $O(\Delta)$ due to sampling, and our other improvements are due to better concentration results. We also present an interesting family of graphs for the lower bound examples. Technical proofs omitted due to lack of space are in the full version [2].

2 Moran process on graphs

Connected graph and type function. We consider the population structure represented as a connected graph. There is a connected *graph* $G = (V, E)$, of n nodes and m edges, and two types $T = \{t_1, t_2\}$. The two types represent residents and mutants, and in the technical

exposition we refer to them as t_1 and t_2 for elegant notation. We say that a node v is a *successor* of a node u if $(u, v) \in E$. The graph is *undirected* if for all $(u, v) \in E$ we also have $(v, u) \in E$, otherwise it is *directed*. There is a *type function* f mapping each node v to a type $t \in T$. Each type t is in turn associated with a positive integer $w(t)$, the type's fitness denoting the corresponding reproductive strength. Without loss of generality, we will assume that $r = w(t_1) \geq w(t_2) = 1$, for some number r (the process we consider does not change under scaling, and r denotes relative fitness). Let $W(f) = \sum_{u \in V} w(f(u))$ be the total fitness. For a node v let $\deg v$ be the degree of v in G. Also, let $\Delta = \max_{v \in V} \deg v$ be the maximum degree of a node. For a type t and type function f, let $V_{t,f}$ be the nodes mapped to t by f. Given a type t and a node v, let $f[v \to t]$ denote the following function: $f[v \to t](u) = t$ if $u = v$ and $f(u)$ otherwise.

Moran process on graphs. We consider the following classical Moran birth-death process where a *dynamic evolution step* of the process changes a type function from f to f' as follows:

1. First a node v is picked at random with probability proportional to $w(f(v))$, i.e. each node v has probability of being picked equal to $\frac{w(f(v))}{W(f)}$.
2. Next, a successor u of v is picked uniformly at random.
3. The type of u is then changed to $f(v)$. In other words, $f' = f[u \to f(v)]$.

Fixation. A type t *fixates* in a type function f if f maps all nodes to t. Given a type function f, repeated applications of the dynamic evolution step generate a sequence of type functions $f = f_1, f_2, \ldots, f_\infty$. Note that if a type has fixated (for some type t) in f_i then it has also fixated in f_j for $i < j$. We say that a process has *fixation time* i if f_i has fixated but f_{i-1} has not. We say that an initial type function f has fixation probability p for a type t, if the probability that t eventually fixates (over the probability measure on sequences generated by repeated applications of the dynamic evolution step f)

Basic questions. We consider the following basic questions:

1. *Fixation problem* Given a type t, what is the fixation probability of t averaged over the n initial type functions with a single node mapping to t?
2. *Extinction problem* Given a type t, what is the fixation probability of t averaged over the n initial type functions with a single node *not* mapping to t?
3. *Generalized fixation problem* Given a graph, a type t and an type function f what is the fixation probability of t in G, when the initial type function is f?

▶ Remark. Note that in the *neutral* case when $r = 1$, the fixation problem has answer $1/n$ and extinction problem has answer $1 - 1/n$. Hence, in the rest of the paper we will consider $r > 1$. Also, to keep the presentation focused, in the main article, we will consider fixation and extinction of type t_1. In the full version [2] we also present another algorithm for the extinction of t_2.

Results. We will focus on undirected graphs. For undirected graphs, we will give new FPRAS (fully polynomial, randomized approximation scheme) for the fixation and the extinction problem, and a polynomial-time algorithm for an additive approximation of the generalized fixation problem. There exists previous FPRAS for the fixation and extinction problems [5]. Our upper bounds are at least a factor of $O(\frac{n^2}{\log n})$ (most cases $O(\frac{n^3}{\log n})$) better and always in $\mathrm{Poly}(n, 1/\epsilon)$, whereas the previous algorithms are not in polynomial time for r given in binary.

3 Discarding ineffective steps

We consider undirected graphs. Previous work by Diaz et al. [5] showed that the expected number of dynamic evolution steps till fixation is polynomial, and then used it to give a polynomial-time Monte-Carlo algorithm. Our goal is to improve the quite high polynomial-time complexity, while giving a Monte-Carlo algorithm. To achieve this we define the notion of effective steps.

Effective steps. A dynamic evolution step, which changes the type function from f to f', is *effective* if $f \neq f'$ (and *ineffective* otherwise). The idea is that steps in which no node changes type (because the two nodes selected in the dynamic evolution step already had the same type) can be discarded, without changing which type fixates/gets eliminated.

Two challenges. The two challenges are as follows:

1. *Number of steps* The first challenge is to establish that the expected number of effective steps is asymptotically smaller than the expected number of all steps. We will establish a factor $O(n\Delta)$ improvement (recall Δ is the maximum degree).
2. *Sampling* Sampling an effective step is harder than sampling a normal step. Thus it is not clear that considering effective steps leads to a faster algorithm. We consider the problem of efficiently sampling an effective step in a later section, see Section 5. We show that sampling an effective step can be done in $O(\Delta)$ time (after $O(m)$ preprocessing).

Notation. For a type function f, let $\Gamma_v(f)$ be the subset of successors of v, such that $u \in \Gamma_v(f)$ iff $f(v) \neq f(u)$. Also, let $W'(f) = \sum_u w(f(u)) \cdot \frac{|\Gamma_u(f)|}{\deg u}$.

Modified dynamic evolution step. Formally, we consider the following *modified dynamic evolution step* (that changes the type function from f to f' and assumes that f does not map all nodes to the same type):

1. First a node v is picked at random with probability proportional to $p(v) = w(f(v)) \cdot \frac{|\Gamma_v(f)|}{\deg v}$ i.e. each node v has probability of being picked equal to $\frac{p(v)}{W'(f)}$.
2. Next, a successor u of v is picked uniformly at random among $\Gamma_v(f)$.
3. The type of u is then changed to $f(v)$, i.e., $f' = f[u \to f(v)]$.

In the following lemma we show that the modified dynamic evolution step corresponds to the dynamic evolution step except for discarding steps in which no change was made.

▶ **Lemma 1.** *Fix any type function f such that neither type has fixated. Let f_d (resp., f_m) be the next type function under dynamic evolution step (resp., modified dynamic evolution step). Then, $\Pr[f \neq f_d] > 0$ and for all type functions f' we have: $\Pr[f' = f_d \mid f \neq f_d] = \Pr[f' = f_m]$.*

Potential function ψ. Similar to [5] we consider the *potential function* $\psi = \sum_{v \in V_{t_1,f}} \frac{1}{\deg v}$ (recall that $V_{t_1,f}$ is the set of nodes of type t_1). We now lower bound the expected difference in potential per modified evolutionary step.

▶ **Lemma 2.** *Let f be a type function such that neither type has fixated. Apply a modified dynamic evolution step on f to obtain f'. Then,*

$$\mathbb{E}[\psi(f') - \psi(f)] \geq \frac{r-1}{\Delta \cdot (r+1)} \quad .$$

Proof. Observe that f differs from f' for exactly one node u. More precisely, let v be the node picked in line 1 of the modified dynamic evolution step and let u be the node picked in line 2. Then, $f' = f[u \to f(v)]$. The probability to select v is $\frac{p(v)}{W'(f)}$. The probability to then pick u is $\frac{1}{|\Gamma_v(f)|}$.

We have that

- If $f(u) = t_2$ (and thus, since it got picked $f(v) = t_1$), then $\psi(f') - \psi(f) = \frac{1}{\deg u}$.
- If $f(u) = t_1$ (and thus, since it got picked $f(v) = t_2$), then $\psi(f') - \psi(f) = -\frac{1}{\deg u}$.

Below we use the following notations:

$$E_{12} = \{(v,u) \in E \mid f(v) = t_1 \text{ and } f(u) = t_2\}; E_{21} = \{(v,u) \in E \mid f(v) = t_2 \text{ and } f(u) = t_1\}.$$

Thus,

$$\begin{aligned}
&\mathbb{E}[\psi(f') - \psi(f)] = \\
&\sum_{(v,u)\in E_{12}} \left(\frac{p(v)}{W'(f)} \cdot \frac{1}{|\Gamma_v(f)|} \cdot \frac{1}{\deg u}\right) - \sum_{(v,u)\in E_{21}} \left(\frac{p(v)}{W'(f)} \cdot \frac{1}{|\Gamma_v(f)|} \cdot \frac{1}{\deg u}\right) \\
&= \sum_{(v,u)\in E_{12}} \left(\frac{w(f(v))}{W'(f) \cdot (\deg u) \cdot (\deg v)}\right) - \sum_{(v,u)\in E_{21}} \left(\frac{w(f(v))}{W'(f) \cdot (\deg u) \cdot (\deg v)}\right) \ .
\end{aligned}$$

Using that the graph is undirected we get,

$$\begin{aligned}
\mathbb{E}[\psi(f) - \psi(f')] &= \sum_{(v,u)\in E_{12}} \left(\frac{w(f(v)) - w(f(u))}{W'(f) \cdot (\deg u) \cdot (\deg v)}\right) \\
&= \frac{1}{W'(f)} \sum_{(v,u)\in E_{12}} \left(\frac{r-1}{\min(\deg u, \deg v) \cdot \max(\deg u, \deg v)}\right) \\
&\geq \frac{r-1}{\Delta \cdot W'(f)} \sum_{(v,u)\in E_{12}} \frac{1}{\min(\deg u, \deg v)} = \frac{r-1}{\Delta \cdot W'(f)} \cdot S \ ,
\end{aligned}$$

where $S = \sum_{(v,u)\in E_{12}} \frac{1}{\min(\deg u, \deg v)}$. Note that in the second equality we use that for two numbers a, b, their product is equal to $\min(a,b) \cdot \max(a,b)$. By definition of $W'(f)$, we have

$$\begin{aligned}
W'(f) &= \sum_u w(f(u)) \cdot \frac{|\Gamma_u(f)|}{\deg u} = \sum_u \sum_{v\in\Gamma_u(f)} \frac{w(f(u))}{\deg u} = \sum_{\substack{(v,u)\in E \\ f(u)\neq f(v)}} \frac{w(f(u))}{\deg u} \\
&= \sum_{(v,u)\in E_{12}} \left(\frac{w(f(u))}{\deg u} + \frac{w(f(v))}{\deg v}\right) \leq \sum_{(v,u)\in E_{12}} \frac{w(f(u)) + w(f(v))}{\min(\deg u, \deg v)} = (r+1) \cdot S \ .
\end{aligned}$$

Thus, we see that $\mathbb{E}[\psi(f') - \psi(f)] \geq \frac{r-1}{\Delta\cdot(r+1)}$, as desired. This completes the proof. ◀

▶ **Lemma 3.** *Let $r = x\Delta$ for some number $x > 0$. Let f be a type function such that neither type has fixated. Apply a modified dynamic evolution step on f to obtain f'. The probability that $|V_{t_1,f'}| = |V_{t_1,f}| + 1$ is at least $\frac{x}{x+1}$ (otherwise, $|V_{t_1,f'}| = |V_{t_1,f}| - 1$).*

▶ **Lemma 4.** *Consider an upper bound ℓ, for each starting type function, on the expected number of (effective) steps to fixation. Then for any starting type function the probability that fixation requires more than $2 \cdot \ell \cdot x$ (effective) steps is at most 2^{-x}.*

We now present the main theorem of this section, which we obtain using the above lemmas, and techniques from [5].

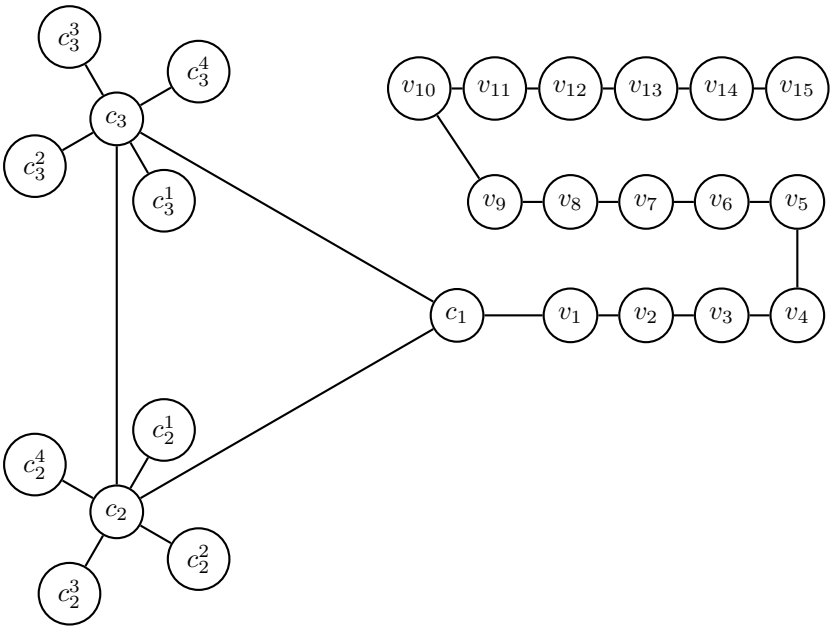

Figure 1 Example of a member of the family that attains the lower bound for undirected graphs. (Specifically, it is $G^{6,31}$)

▶ **Theorem 5.** *Let t_1 and t_2 be the two types, such that $r = w(t_1) > w(t_2) = 1$. Let Δ be the maximum degree. Let k be the number of nodes of type t_2 in the initial type function. The following assertions hold:*

- Bounds dependent on r
  1. Expected steps *The process requires at most $3k\Delta/\min(r-1,1)$ effective steps in expectation, before fixation is reached.*
  2. Probability *For any integer $x \geq 1$, after $6xn\Delta/\min(r-1,1)$ effective steps, the probability that the process has not fixated is at most 2^{-x}, irrespective of the initial type function.*
- Bounds independent on r
  1. Expected steps *The process requires at most $2nk\Delta^2$ effective steps in expectation, before fixation is reached.*
  2. Probability *For any integer $x \geq 1$, after $4xn^2\Delta^2$ effective steps, the probability that the process has not fixated is at most 2^{-x}, irrespective of the initial type function.*
- Bounds for $r \geq 2\Delta$
  1. Expected steps *The process requires at most $3k$ effective steps in expectation, before fixation is reached.*
  2. Probability *For any integer $x \geq 1$, after $6xn$ effective steps, the probability that the process has not fixated is at most 2^{-x}, irrespective of the initial type function.*

4 Lower bound for undirected graphs

In this section, we will argue that our bound on the expected number of effective steps is essentially tight, for fixed r.

We construct our lower bound graph $G^{\Delta,n}$, for given Δ, n (sufficiently large), but fixed $r > 1$, as follows. We will argue that fixation of $G^{\Delta,n}$ takes $\Omega(k\Delta)$ effective steps, if there are initially exactly k members of type t_2. For simplicity, we consider $\Delta > 2$ and $n > 4\Delta$ (it is

easy to see using similar techniques that for lines, where $\Delta = 2$, the expected fixation time is $\Omega(k)$ - basically because t_1 is going to fixate with pr. $\approx 1 - 1/r$, using a proof like Lemma 6, and converting the k nodes of type t_2 takes at least k efficient steps). There are two parts to the graph: A line of $\approx n/2$ nodes and a stars-on-a-cycle graph of $\approx n/2$. There is 1 edge from the one of the stars in the stars-on-a-cycle graph to the line. More formally, the graph is as follows: Let $x := \lfloor n/(2\Delta - 2) \rfloor$. There are nodes $V_C = \{c_1, \ldots, c_x\}$, such that c_i is connected to c_{i-1} and c_{i+1} for $1 < i < x$. Also, c_1 is connected to c_x. The nodes V_C are the centers of the stars in the stars-on-a-cycle graph. For each i, such that $2 \leq i \leq x$, the node c_i is connected to a set of leaves $V_C^i = \{c_i^1, \ldots, c_i^{\Delta-2}\}$. The set $V_C \cup \bigcup_{i=2}^{x} V_C^i$ forms the stars-on-a-cycle graph. Note that c_1 is only connected to c_2 and c_x in the stars-on-a-cycle graph. We have that the stars-on-a-cycle graph consists of $s = (x-1) \cdot (\Delta - 1) + 1 \approx n/2$ nodes. There are also nodes $V_L = \{\ell_1, \ldots, \ell_{n-s}\}$, such that node ℓ_i is connected to ℓ_{i-1} and ℓ_{i+1} for $1 < i < n/2$. The nodes V_L forms the line and consists of $n - s \geq n/2$ nodes. The node c_1 is connected to ℓ_1. There is an illustration of $G^{6,31}$ in Figure 1.

We first argue that if at least one of $V_L' = \{\ell_{\lceil n/4 \rceil}, \ldots, \ell_{n-s}\}$ is initially of type t_1, then with pr. lower bounded by a number depending only on r, type t_1 fixates (note that $|V_L'| \geq n/4$ and thus, even if there is only a single node of type t_1 initially placed uniformly at random, it is in V_L' with pr. $\geq 1/4$).

▶ **Lemma 6.** *With pr. above $\frac{1-1/r}{2}$ if at least one of V_L' is initially of type t_1, then t_1 fixates.*

The proof is based on applying the gambler's ruin twice. Once to find out that the pr. that V_L eventually becomes all t_1 is above $\frac{1-1/r}{2}$ (it is nearly $1 - 1/r$ in fact) and once to find out that if V_L is at some point all t_1, then the pr. that t_2 fixates is exponentially small with base r and exponent $n - s$. See the full version [2] for the proof.

Whenever a node of V_C^i, for some i, changes type, we say that a *leaf-step* occurred. We will next consider the pr. that an effective step is a leaf-step.

▶ **Lemma 7.** *The pr. that an effective step is a leaf-step is at most $\frac{r}{\Delta}$.*

The proof is quite direct and considers that the probability that a leaf gets selected for reproduction over a center node in the stars-on-a-cycle graph. See the full version [2] for the proof.

We are now ready for the theorem.

▶ **Theorem 8.** *Let $r > 1$ be some fixed constant. Consider $\Delta > 2$ (the maximum degree of the graph), $n > 4\Delta$ (sufficiently big), and some k such that $0 < k < n$. Then, if there are initially k members of type t_2 placed uniformly at random, the expected fixation time of $G^{\Delta,n}$ is above $\frac{k\Delta(1-1/r)}{32r}$ effective steps.*

Proof. Even if $k = n - 1$, we have that with pr. at least $\frac{1}{4}$, the lone node of type t_1 is initially in V_L'. If so, by Lemma 6, type t_1 is going to fixate with pr. at least $\frac{1-1/r}{2}$. Note that even for $\Delta = 3$, at least $\frac{n}{4}$ nodes of the graphs are in $V' := \bigcup_{i=2}^{x} V_C^i$ (i.e. the leaves of the stars-on-a-cycle graph). In expectation $\frac{k}{4}$ nodes of V' are thus initially of type t_2. For fixation for t_1 to occur, we must thus make that many leaf-steps. Any effective step is a leaf-step with pr. at most $\frac{r}{\Delta}$ by Lemma 7. Hence, with pr. $\frac{1}{4} \cdot \frac{1-1/r}{2}$ ($\frac{1}{4}$ is the probability that at least one node of type t_1 is in V_L' and $\frac{1-1/r}{2}$ is a lower bound on the fixation probability if a node of V_L' is of type t_1) we must make $\frac{k\Delta}{4r}$ effective steps before fixation in expectation, implying that the expected fixation time is at least $\frac{k\Delta(1-1/r)}{32r}$ effective steps. ◀

5 Sampling an effective step

In this section, we consider the problem of sampling an effective step. It is quite straightforward to do so in $O(m)$ time. We will present a data-structure that after $O(m)$ preprocessing can sample and update the distribution in $O(\Delta)$ time. For this result we assume that a uniformly random number can be selected between 0 and x for any number $x \leq n \cdot w(t)$ in constant time, a model that was also implicitly assumed in previous works [5][1].

▶ Remark. If we consider a weaker model, that requires constant time for each random bit, then we need $O(\log n)$ random bits in expectation and additional $O(\Delta)$ amortized time, using a similar data-structure (i.e., a total of $O(\Delta + \log n)$ amortized time in expectation). The argument for the weaker model is presented in the full version [2]. In this more restrictive model [5] would use $O(\log n)$ time per step for sampling.

Sketch of data-structure. We first sketch a list data-structure that supports (1) inserting elements; (2) removing elements; and (3) finding a random element; such that each operation takes (amortized or expected) $O(1)$ time. The idea based on dynamic arrays is as follows:

1. **Insertion** Inserting elements takes $O(1)$ amortized time in a dynamic array, using the standard construction.
2. **Deletion** Deleting elements is handled by changing the corresponding element to a null-value and then rebuilding the array, without the null-values, if more than half the elements have been deleted since the last rebuild. Again, this takes $O(1)$ amortized time.
3. **Find random element** Repeatedly pick a uniformly random entry. If it is not null, then output it. Since the array is at least half full, this takes in expectation at most 2 attempts and thus expected $O(1)$ time.

At all times we keep a doubly linked list of empty slots, to find a slot for insertion in $O(1)$ time.

Data-structure. The idea is then as follows. We have 2Δ such list data-structures, one for each pair of type and degree. We also have a weight associated to each list, which is the sum of the weight of all nodes in the list, according to the modified dynamic evolution step. When the current type function is f, we represent each node v as follows: The corresponding list data-structure contains $|\Gamma_v(f)|$ copies of v (and v keeps track of the locations in a doubly linked list). Each node v also keeps track of $\Gamma_v(f)$, using another list data-structure. It is easy to construct the initial data-structure in $O(m)$ time (note: $\sum_v |\Gamma_v(f)| \leq 2m$).

Updating the data-structure. We can then update the data-structure when the current type function f changes to $f[u \to t]$ (all updates have that form for some t and u), by removing u from the list data-structure $(f(u), \deg u)$ containing it and adding it to $(t, \deg u)$. Note that if we removed x' copies of u from $(f(u), \deg u)$ we add $\deg u - x'$ to $(t, \deg u)$. Also, we update each neighbor v of u (by deleting or adding a copy to $(f(v), \deg v)$, depending on whether $f(v) = t$). We also keep the weight corresponding to each list updated and $\Gamma_v(f)$ for all nodes v. This takes at most 4Δ data-structure insertions or deletions, and thus $O(\Delta)$ amortized time in total.

[1] The construction of [5] was to store a list for t_1 and a list for t_2 and then first decide if a t_1 or t_2 node would be selected in this step (based on r and the number of nodes of the different types) and then pick a random such node. This works when all nodes of a type has the same weight but does not generalize to the case when each node can have a distinct weight based on the nodes successors like here

Sampling an effective step. Let f be the current type function. First, pick a random list L among the 2Δ lists, proportional to their weight. Then pick a random node v from L. Then pick a node at random in $\Gamma_v(f)$. This takes $O(\Delta)$ time in expectation.

▶ Remark. Observe that picking a random list among the 2Δ lists, proportional to their weight takes $O(\Delta)$ time to do naively: E.g. consider some ordering of the lists and let w_i be the total weight of list i (we keep this updated so it can be found in constant time). Pick a random number x between 1 and the total weight of all the lists (assumed to be doable in constant time). Iterate over the lists in order and when looking at list i, check if $x < \sum_{j=1}^{i} w_j$. If so, pick list i, otherwise continue to list $i+1$. By making a binary, balanced tree over the lists (similar to what is used for the more restrictive model, see the full version [2]), the time can be brought down to $O(\log \Delta)$ for this step - however the naive approach suffices for our application, because updates requires $O(\Delta)$ time.

This leads to the following theorem.

▶ **Theorem 9.** *An effective step can be sampled in (amortized and expected) $O(\Delta)$ time after $O(m)$ preprocessing, if a uniformly random integer between 0 and x, for any $0 < x \leq n \cdot w(t)$, can be found in constant time.*

6 Algorithms for approximating fixation probability

We present the algorithms for solving the fixation, extinction, and generalized fixation problems.

The Meta-simulation algorithm. Similar to [5], the algorithms are instantiating the following meta-simulation algorithm, that takes a distribution over initial type functions $\mathcal{D}$, type t and natural numbers u and z as input:

Function MetaSimulation(t,z,u,$\mathcal{D}$)

```
Let y ← 0;
for (i ∈ {1, ..., z}) do
    Initialize a new simulation I with initial type function f picked according to D;
    Let j ← 0;
    while (I has not fixated) do
        if (j ≥ u) then
            return Simulation took too long;
        Set j ← j + 1;
        Simulate an effective step in I;
    if (t fixated in I) then
        Set y ← y + 1;
return y/z;
```

Basic principle of simulation. Note that the meta-simulation algorithm uses $O(uz\Delta)$ time (by Theorem 9). In essence, the algorithm runs z simulations of the process and terminates with "Simulation took too long" iff some simulation took over u steps. Hence, whenever the algorithm returns a number it is the mean of z binary random variables, each equal to 1 with

probability $\Pr[\mathcal{F}_t \mid \mathcal{E}_u]$, where $\mathcal{F}_t$ is the event that t fixates and $\mathcal{E}_u$ is the event that fixation happens before u effective steps, when the initial type function is picked according to $\mathcal{D}$ (we note that the conditional part was overlooked in [5], moreover, instead of steps we consider only effective steps). By ensuring that u is high enough and that the approximation is tight enough (basically, that z is high enough), we can use $\Pr[\mathcal{F}_t \mid \mathcal{E}_u]$ as an approximation of $\Pr[\mathcal{F}_t]$, as shown in the following lemma.

▶ **Lemma 10.** *Let $0 < \epsilon < 1$ be given. Let $\mathcal{X}, \mathcal{E}$ be a pair of events and x a number, such that $\Pr[\mathcal{E}] \geq 1 - \frac{\epsilon \cdot \Pr[\mathcal{X}]}{4}$ and that $x \in [(1-\epsilon/2)\Pr[\mathcal{X} \mid \mathcal{E}], (1+\epsilon/2)\Pr[\mathcal{X} \mid \mathcal{E}]]$. Then*

$$x \in [(1-\epsilon)\cdot \Pr[\mathcal{X}], (1+\epsilon)\cdot \Pr[\mathcal{X}]] \ .$$

The value of u: $u_{z,r}$. Consider some fixed value of z. The value of u is basically just picked so high that $\Pr[\mathcal{E}_u] \geq 1 - \frac{\epsilon \cdot \Pr[\mathcal{F}_t]}{4}$ (so that we can apply Lemma 10) and such that after taking union bound over the z trials, we have less than some constant probability of stopping. The right value of u is thus sensitive to r, but in all cases at most $O(n^2\Delta^2 \max(\log z, \log \epsilon^{-1}))$, because of Theorem 5. More precisely, we let

$$u_{z,r} = \begin{cases} 30n \cdot \max(\log z, \log \epsilon^{-1}) & \text{if } r \geq 2\Delta \\ \frac{30n\Delta}{\min(r-1,1)} \cdot \max(\log z, \log \epsilon^{-1}) & \text{if } 1 + \frac{1}{n\cdot\Delta} \leq r < 2\Delta \\ 20n^2\Delta^2 \cdot \max(\log z, \log \epsilon^{-1}) & \text{if } r < 1 + \frac{1}{n\cdot\Delta} \end{cases} .$$

Algorithm Algo1. We consider the fixation problem for t_1. Algorithm Algo1 is as follows:
1. Let $\mathcal{D}$ be the uniform distribution over the n type functions where exactly one node is t_1.
2. Return MetaSimulation(t_1,z,$u_{z,r}$,$\mathcal{D}$), for $z = 48 \cdot \frac{n}{\epsilon^2}$.

Algorithm Algo2. We consider the extinction problem for t_1. Algorithm Algo2 is as follows:
1. Let $\mathcal{D}$ be the uniform distribution over the n type functions where exactly one node is t_2.
2. Return MetaSimulation(t_1,z,$u_{z,r}$,$\mathcal{D}$), for $z = 24/\epsilon^2$.

Algorithm Algo3. We consider the problem of (additively) approximating the fixation probability given some type function f and type t. Algorithm Algo3 is as follows:
1. Let $\mathcal{D}$ be the distribution that assigns 1 to f.
2. Return MetaSimulation(t,z,$u_{z,r}$,$\mathcal{D}$), for $z = 6/\epsilon^2$.

▶ **Theorem 11.** *Let G be a connected undirected graph of n nodes with the highest degree Δ, divided into two types of nodes t_1, t_2, such that $r = w(t_1) > w(t_2) = 1$. Given $\frac{1}{2} > \epsilon > 0$, let $\alpha = n^2 \cdot \Delta \cdot \epsilon^{-2} \cdot \max(\log n, \log \epsilon^{-1})$ and $\beta = n \cdot \Delta \cdot \epsilon^{-2} \cdot \log \epsilon^{-1}$. Consider the running times:*

$$T(x) = \begin{cases} O(x) & \text{if } r \geq 2\Delta \\ O(\frac{x\cdot\Delta}{\min(r-1,1)}) & \text{if } 1 + \frac{1}{n\cdot\Delta} \leq r < 2\Delta \\ O(n \cdot \Delta^2 \cdot x) & \text{if } 1 < r < 1 + \frac{1}{n\cdot\Delta} \end{cases} .$$

- **Fixation (resp. Extinction) problem for t_1** *Algorithm* Algo1 *(resp.* Algo2*) is an FPRAS algorithm, with running time $T(\alpha)$ (resp. $T(\beta)$), that with probability at least $\frac{3}{4}$ outputs a number in $[(1-\epsilon)\cdot\rho, (1+\epsilon)\cdot\rho]$, where ρ is the solution of the fixation (resp. extinction) problem for t_1.*

- **Generalized fixation problem** *Given an initial type function f and a type t, there is an (additive approximation) algorithm,* Algo3*, with running time $T(\beta)$, that with probability at least $\frac{3}{4}$ outputs a number in $[\rho - \epsilon, \rho + \epsilon]$, where ρ is the solution of the generalized fixation problem given f and t.*

▶ Remark. There exists no known FPRAS for the generalized fixation problem and since the fixation probability might be exponentially small such an algorithm might not exist. (It is exponentially small for fixation of t_2, even in the Moran process (that is, when the graph is complete) when there initially is 1 node of type t_2)

Alternative algorithm for extinction for t_2. We also present an alternative algorithm for extinction for t_2 when r is big. This is completely different from the techniques of [5]. The alternative algorithm is based on the following result where we show for big r that $1/r$ is a good approximation of the extinction probability for t_2, and thus the algorithm is polynomial even for big r in binary.

▶ **Theorem 12.** *Consider an undirected graph G and consider the extinction problem for t_2 on G. If $r \geq \max(\Delta^2, n)/\epsilon$, then $\frac{1}{r} \in [(1-\epsilon)\cdot\rho, (1+\epsilon)\cdot\rho]$, where ρ is the solution of the extinction problem for t_2.*

Proof sketch. We present a proof sketch, and details are in the full version [2]. We have two cases:

- By [5, Lemma 4], we have $\rho \geq \frac{1}{n+r}$. Thus, $(1+\epsilon)\cdot\rho \geq \frac{1}{r}$, as desired, since $n/\epsilon \leq r$.
- On the other hand, the probability of fixation for t_2 in the first effective step is at most $\frac{1}{r+1} < \frac{1}{r}$ (we show this in the full version [2]). The probability that fixation happens for t_2 after the first effective step is at most ϵ/r because of the following reason: By Lemma 3, the probability of increasing the number of members of t_2 is at most $p := \frac{1}{r/\Delta+1}$ and otherwise it decrements. We then model the problem as a Markov chain M with state space corresponding to the number of members of t_1, using p as the probability to decrease the current state. In M the starting state is state 2 (after the first effective step, if fixation did not happen, then the number of members of t_1 is 2). Using that $\Delta^2/\epsilon \leq r$, we see that the probability of absorption in state 0 of M from state 2 is less than ϵ/r. Hence, ρ is at most $(1+\epsilon)/r$ and $(1-\epsilon)\rho$ is thus less than $1/r$. ◀

▶ Remark. While Theorem 12 is for undirected graphs, a variant (with larger r and which requires the computation of the pr. that t_1 goes extinct in the first step) can be established even for directed graphs, see the full version [2].

Concluding remarks. In this work we present faster Monte-Carlo algorithms for approximating fixation probability for undirected graphs (see the full version [2] for detailed comparison). An interesting open question is whether the fixation probability can be approximated in polynomial time for directed graphs.

The 2CNF Boolean Formula Satisfiability Problem and the Linear Space Hypothesis*

Tomoyuki Yamakami

Faculty of Engineering, University of Fukui, Japan
TomoyukiYamakami@gmail.com

Abstract

We aim at investigating the solvability/insolvability of nondeterministic logarithmic-space (NL) decision, search, and optimization problems parameterized by size parameters using simultaneously polynomial time and sub-linear space on multi-tape deterministic Turing machines. We are particularly focused on a special NL-complete problem, 2SAT – the 2CNF Boolean formula satisfiability problem – parameterized by the number of Boolean variables. It is shown that 2SAT with n variables and m clauses can be solved simultaneously polynomial time and $(n/2^{c\sqrt{\log n}})\,polylog(m+n)$ space for an absolute constant $c > 0$. This fact inspires us to propose a new, practical working hypothesis, called the linear space hypothesis (LSH), which states that $2SAT_3$ – a restricted variant of 2SAT in which each variable of a given 2CNF formula appears as literals in at most 3 clauses – cannot be solved simultaneously in polynomial time using strictly "sub-linear" (i.e., $n^{\varepsilon}\,polylog(n)$ for a certain constant $\varepsilon \in (0,1)$) space. An immediate consequence of this working hypothesis is $\mathrm{L} \neq \mathrm{NL}$. Moreover, we use our hypothesis as a plausible basis to lead to the insolvability of various NL search problems as well as the nonapproximability of NL optimization problems. For our investigation, since standard logarithmic-space reductions may no longer preserve polynomial-time sub-linear-space complexity, we need to introduce a new, practical notion of "short reduction." It turns out that $\overline{2SAT_3}$ is complete for a restricted version of NL, called Syntactic NL or simply SNL, under such short reductions. This fact supports the legitimacy of our working hypothesis.

1 Background and Main Contributions

1.1 Motivational Discussion: Space Complexity of Parameterized 2SAT

Since Cook [4] demonstrated its NP-completeness, the Boolean formula satisfiability problem (SAT) of determining whether a given Boolean formula is satisfied by a suitably-chosen variable assignment has been studied extensively for more than 50 years. As its restricted variant, the *kCNF Boolean formula satisfiability problem* (kSAT), for an integer index $k \geq 3$, whose input formulas are of k-conjunctive normal form (kCNF) has also been a centerpiece of computational complexity theory. Since kSAT is complete for NP (nondeterministic

* This work was done in part at the University of Toronto between August 1, 2016 and March 30, 2017 and was supported by the Natural Sciences and Engineering Research Council of Canada.

polynomial time) [4], its solvability is linked to the computational complexity of all other NP problems; for instance, if kSAT is solved in polynomial time, then so are all NP problems. A recent study has been focused on the solvability of kSAT with n Boolean variables and m clauses within "sub-exponential" (which means $2^{\varepsilon n}poly(n+m)$ for an absolute constant $\varepsilon \in (0,1)$ and a suitable polynomial $poly(\cdot)$) runtime. In this line of study, Impagliazzo, Paturi, and Zane [10] took a new approach toward kSAT and its search version, Search-kSAT, parameterized by the number $m_{vbl}(x)$ of Boolean variables and the number $m_{cls}(x)$ of clauses in a given kCNF formula x as natural "size parameters" (which were called "complexity parameters" in [10]). To discuss such sub-exponential-time solvability for a wide range of NP-complete problems, Impagliazzo et al. further devised a crucial notion of *sub-exponential-time reduction family (or SERF-reduction)*, which preserves the sub-exponential-time complexity, and they cleverly demonstrated that the two size parameters, $m_{vbl}(x)$ and $m_{cls}(x)$, make Search-kSAT SERF-equivalent (that is, the both are SERF-reducible to each other). As a working hypothesis, Impagliazzo and Paturi [9] formally proposed the *exponential time hypothesis* (ETH), which asserts the insolvability of kSAT parameterized by $m_{vbl}(x)$ (succinctly denoted by $(k\mathrm{SAT}, m_{vbl})$) in sub-exponential time for all indices $k \geq 3$. Their hypothesis is obviously a stronger assertion than P $\neq$ NP and it has then led to intriguing consequences, including finer lower bounds on the solvability of various parameterized NP problems (see, e.g., a survey [14]).

Whereas ETH concerns with kSAT for $k \geq 3$, we are focused on the remaining case of $k = 2$. The decision problem 2SAT is known to be complete* for NL (nondeterministic logarithmic space) under log-space reductions. Since 2SAT already enjoys a polynomial-time algorithm (because NL $\subseteq$ P), we are more concerned with how much memory space such an algorithm requires to run. An elaborate algorithm solves 2SAT with n variables and m clauses using simultaneously polynomial time and $(n/2^{c\sqrt{\log n}})\,polylog(m+n)$ space (Theorem 4.2), where $c > 0$ is a constant and $polylog(\cdot)$ is a suitable polylogarithmic function. This space bound is slightly below n; however, it is not yet known that 2SAT parameterized by $m_{vbl}(x)$ (or $m_{cls}(x)$) can be solved in polynomial time using strictly "sub-linear" space. Here, the informal term "sub-linear" for a size parameter $m(x)$ refers to a function of the form $m(x)^{\varepsilon}\ell(|x|)$ on input instances x for a certain absolute constant $\varepsilon \in (0,1)$ and an appropriately-chosen polylogarithmic function $\ell(n)$. Of course, this multiplicative factor $\ell(|x|)$ becomes redundant if $m(x)$ is relatively large (for example, $m(x) \geq \log^k |x|$ for any constant $k > 0$) and thus "sub-linear" turns out to be simply $m(x)^{\varepsilon}$.

In parallel to a restriction of SAT to kSAT, for polynomial-time sub-linear-space solvability, we further limit 2SAT to $2\mathrm{SAT}_k$, which consists of all satisfiable formulas in which each variable appears as literals in at most k clauses. Notice that $2\mathrm{SAT}_k$ for each $k \geq 3$ is also NL-complete (Proposition 4.1) as 2SAT is; in contrast, $k\mathrm{SAT}_2$ already falls into L for any index $k \geq 2$.

1.2 Sub-Linear Space and Short Reductions

All (parameterized) decision problems solvable in polynomial time using sub-linear space form a new complexity class PsubLIN (whose prefix "P" refers to "polynomial time"), which is located between L and P. This class PsubLIN naturally includes, for example, DCFL (deterministic context-free) because Cook [5] earlier showed that every language in DCFL is

* This is because Jones, Lien, and Laaser [13] demonstrated the NL-completeness of the complement of SAT (called UNSAT_2 in [13]) and Immerman [8] and Szelepcsényi [18] proved the closure of NL under complementation.

recognized in polynomial time using $O(\log^2 n)$-space, where n is input size. Unfortunately, there is no separation known among L, NL, PsubLIN, and P.

It turns out that PsubLIN does not seem to be closed under standard log-space reductions; thus, those reductions are no longer suitable tools to discuss the solvability of NL-complete problems in polynomial time using sub-linear space. Therefore, we need to introduce a much weaker form of reductions, called *short reductions*, which preserve polynomial-time, sub-linear-space complexity. Intuitively speaking, a short reduction is a reduction between two (parameterized) decision problems computed by a reduction machine (or a reduction function) that can generate strings of size parameter proportional to or less than size parameter of its input string. In particular, we will define three types of such short reductions in Section 3: short L-m-reducibility ($\leq_m^{\mathrm{sL}}$), short L-T-reducibility ($\leq_T^{\mathrm{sL}}$), and short sub-linear-space-T-reducibility ($\leq_T^{\mathrm{sSLRF}}$).

As noted earlier, Impagliazzo et al. demonstrated in [10, Corollary 2] that $(k\mathrm{SAT}, m_{vbl})$ is SERF-equivalent to $(k\mathrm{SAT}, m_{cls})$. Similarly, we can give a short reduction from $2\mathrm{SAT}_3$ with m_{vbl} to $2\mathrm{SAT}_3$ with m_{cls}, and vice verse; in other words, $(2\mathrm{SAT}_3, m_{vbl})$ and $(2\mathrm{SAT}_3, m_{cls})$ are equivalent under short L-T-reductions (Lemma 4.3(2)). On the contrary, such equivalence is not known for 2SAT and this circumstance signifies the importance of $2\mathrm{SAT}_3$.

Another importance of $2\mathrm{SAT}_3$ can be demonstrated by showing that $2\mathrm{SAT}_3$ is actually one of the hardest problems in a natural subclass of NL, which we call *Syntactic NL* or simply *SNL*. An *SNL formula* $\Psi \equiv \Psi(x)$ is of the form $\exists T \forall i_1 \cdots \forall i_r \forall y_1 \cdots \forall y_s \exists z_1 \cdots \exists z_t\ \psi$, starting with a second-order existential quantifier, followed by first-order quantifiers, with a supporting *semantic model*. From this model, we define a *certificate size* $m_{cert}(x)$. Their precise definitions will be given in Section 4. We say that Ψ *syntactically expresses* A if, for every x, $x \in A$ exactly when $\Psi(x)$ is true. The notation SNL stands for the collection of all (A, m), each of which is expressed syntactically by an appropriate SNL-formula Ψ and satisfies $m(x) = cm_{cert}(x)$ for a certain constant $c > 0$.

▶ **Theorem 1.1.** $(\overline{2\mathrm{SAT}_3}, m_{vbl})$ *is complete for* SNL *under short SLRF-T-reductions.*

1.3 A New, Practical Working Hypothesis for $2\mathrm{SAT}_3$

Since its introduction in 2001, ETH for kSAT ($k \geq 3$) has served as a driving force to obtain finer lower bounds on the sub-exponential-time computability of various parameterized NP problems, since those bounds do not seem to be obtained directly from the popular assumption of P $\neq$ NP. In a similar vein, we wish to propose a new working hypothesis, called the *linear space hypothesis* (LSH) for $2\mathrm{SAT}_3$, in which no deterministic algorithm solves $(2\mathrm{SAT}_3, m_{vbl})$ simultaneously in polynomial time using sub-linear space. More precisely:

> The Linear Space Hypothesis (LSH) for $2\mathrm{SAT}_3$: For any choice of $\varepsilon \in (0, 1)$ and any polylogarithmic function ℓ, no deterministic Turing machine solves $2\mathrm{SAT}_3$ parameterized by m_{vbl} simultaneously in polynomial time using $m_{vbl}(x)^{\varepsilon}\ell(|x|)$ space, where x refers to an input instance to $2\mathrm{SAT}_3$.

We can replace m_{vbl} in the above definition by m_{cls} (see Section 4), and thus we often omit it. Consider the case of L = NL. Since $2\mathrm{SAT}_3$ belongs to L, it is also in PsubLIN. This consequence contradicts LSH for $2\mathrm{SAT}_3$. Therefore, we immediately obtain:

▶ **Theorem 1.2.** *If LSH for* $2\mathrm{SAT}_3$ *is true, then* L $\neq$ NL.

From Theorem 1.2, our working hypothesis LSH for $2\mathrm{SAT}_3$ is expected to lead to finer, better consequences than what the assumption L $\neq$ NL can lead to.

Let δ_3 denote the infimum of a real number $\varepsilon \in [0,1]$ for which there is a deterministic Turing machine solving $2\mathrm{SAT}_3$ simultaneously in polynomial time using at most $m_{vbl}(x)^{\varepsilon}\ell(|x|)$ space on instances x for a certain fixed polylogarithmic function ℓ. Here, we acknowledge three possible cases: (i) $\delta_3 = 0$, (ii) $0 < \delta_3 < 1$, and (iii) $\delta_3 = 1$, and one of them must be true after all. The hypothesis LSH for $2\mathrm{SAT}_3$ exactly matches (iii).

▶ **Proposition 1.3.** *The working hypothesis LSH for* $2\mathrm{SAT}_3$ *is true iff* $\delta_3 = 1$ *holds.*

For any $\leq_r$-reduction, the notation $\leq_r(\mathrm{SNL})$ refers to the collection of all (parameterized) decision problems that can be reduced by $\leq_r$-reductions to certain problems in SNL.

▶ **Proposition 1.4.** *The following statements are all logically equivalent. (1)* $(2\mathrm{SAT}_3, m_{vbl}) \in \mathrm{PsubLIN}$. *(2)* $\mathrm{SNL} \subseteq \mathrm{PsubLIN}$. *(3)* $\leq_T^{\mathrm{sLRF}}(\mathrm{SNL}) \subseteq \mathrm{PsubLIN}$.

Proposition 1.4(3) can be compared to the fact that $\leq_m^{\mathrm{L}}(\mathrm{SNL}) = \mathrm{NL}$.

Furthermore, we seek two other characterizations of the hypothesis LSH for $2\mathrm{SAT}_3$. The first problem is a variant of a well-known NP-complete problem, called the $\{0,1\}$-*linear programming problem* (LP_2). In what follows, a vector of dimension n means an $n \times 1$ matrix and a rational number is treated as a pair of appropriate integers.

$(2,k)$-Entry $\{0,1\}$-Linear Programming Problem ($\mathrm{LP}_{2,k}$):

- Instance: a rational $m \times n$ matrix A and a rational vector b of dimension n, where $m, n \geq 1$ and each row of A has at most two nonzero entries and each column of A has at most k non-zero entries.
- Question: is there any $\{0,1\}$-vector x satisfying $Ax \geq b$?

As natural size parameters $m_{col}(x)$ and $m_{row}(x)$, we take the numbers of columns and of rows of A for instance $x = (A, b)$ given to $\mathrm{LP}_{2,k}$, respectively.

Another problem to consider is a variant of the *directed s-t connectivity problem*[†] (DSTCON) of asking whether a path between two given vertices exists in a directed graph.

Degree-k Directed s-t Connectivity Problem (kDSTCON):

- Instance: a directed graph $G = (V, E)$ of degree (i.e., indegree plus outdegree) at most k, and two designated vertices s and t.
- Question: is there any path from s to t in G?

For any instance $x = (G, s, t)$ to kDSTCON, $m_{ver}(x)$ and $m_{edg}(x)$ respectively denote the number of vertices and that of edges in G.

▶ **Theorem 1.5.** *The following statements are logically equivalent: (1) LSH for* $2\mathrm{SAT}_3$*, (2) LSH for* $\mathrm{LP}_{2,3}$ *(with* m_{row} *or* m_{col}*), and (3) LSH for* 3DSTCON *(with* m_{ver} *or* m_{edg}*).*

This theorem allows us to use $\mathrm{LP}_{2,3}$ and 3DSTCON for LSH as substitutes for $2\mathrm{SAT}_3$.

1.4 Four Examples of How to Apply the Working Hypothesis

To demonstrate the usefulness of LSH for $2\mathrm{SAT}_3$, we will seek four applications of LSH in the fields of search problems and optimization problems. Although many NL decision problems have been turned into *NL search problems* (whose precise definition is given in Section 6), not all NL problems can be "straightforwardly" converted into a framework of NL search problems. For example, 2SAT is NL-complete but the problem of finding a truth assignment (when

[†] This is also known as the graph accessibility problem and the graph reachability problem in the literature.

variables are ordered in an arbitrarily fixed way) that satisfies a given 2CNF formula does not look like a legitimate form of NL search problem. In addition, its optimization version, Max2SAT, is already complete for APX (polynomial-time approximable NP optimization) instead of NLO (NL optimization class) under polynomial-time approximation-preserving reductions (see [1]).

First, we will see two simple applications of LSH for $2SAT_3$ in the area of NL search problems. Earlier, Jones et al. [13] discussed the NL-completeness of a decision problem concerning *one-way nondeterministic finite automata* (or 1nfa's). We modify this problem into an associated search problem, called Search-1NFA, as given below.

1NFA Membership Search Problem (Search-1NFA):
- Instance: a 1nfa $M = (Q, \Sigma, \delta, q_0, F)$ with no λ-moves, and a parameter 1^n, where λ is the empty string for $n \in \mathbb{N}$.
- Solution: an input string x of length n accepted by M (i.e., when x is written on M's read-only input tape, M eventually enters a final state in F before or on reading the last symbol of x).

As a meaningful size parameter m_{nfa}, we set $m_{nfa}(x) = |Q||\Sigma|n$ for instance $x = (M, 1^n)$.

▶ **Theorem 1.6.** *Assuming that LSH for* $2SAT_3$*, for every fixed value* $\varepsilon \in (0, 1/2)$*, there is no polynomial-time* $O(n^{1/2-\varepsilon})$*-space algorithm for* (Search-1NFA, m_{nfa}).

Jenner [11] presented a few variants of the well-known *knapsack problem* and showed their NL-completeness. Here, we choose one of them that fit into the NL-search framework by a small modification. Given a string x, a substring z of x is called *unique* if there exists a unique pair u, v satisfying $x = uzv$. Write $[n]$ for the set $\{1, 2, \ldots, n\}$.

Unique Ordered Concatenation Knapsack Search Problem (Search-UOCK):
- Instance: a string w and a sequence $(w_1, w_2, \ldots, w_n)$ of strings over a certain fixed alphabet Σ such that, for every $i \in [n]$, if w_i is a substring of w, then w_i is unique.
- Solution: a sequence $(i_1, i_2, \ldots, i_k)$ of indices with $k \geq 1$ such that $1 \leq i_1 < i_2 < \cdots < i_k \leq n$ and $w = w_{i_1} w_{i_2} \cdots w_{i_k}$.

Our size parameter m_{elm} for Search-UOCK is the number of elements $w_1, w_2, \ldots, w_n$ in the above definition (namely, $m_{elm}(x) = n$ for instance x).

▶ **Theorem 1.7.** *If LSH for* $2SAT_3$ *holds, then, for any* $\varepsilon > 0$*, there is no polynomial-time* $O(n^{1/2-\varepsilon})$*-space algorithm for* (Search-UOCK, m_{elm}).

We then turn to the area of *NL optimization problems* (or *NLO problems*, in short) [19, 20]. See Section 6 for their formal definition. We will consider a problem that belongs to $LSAS_{NLO}$ but does not seem to be solvable using log space. Here, $LSAS_{NLO}$ is the collection of NLO problems that have log-space approximation schemes, where a *log-space approximation scheme* for an NLO problem P is a deterministic Turing machine M that takes any input of the form (x, k) and outputs a solution y of P using space at most $f(k) \log |x|$ for a certain log-space computable function $f : \mathbb{N} \to \mathbb{N}$ for which the performance ratio R satisfies $R(x, y) \leq 1 + \frac{1}{k}$. Such a solution y is called a $(1 + \frac{1}{k})$*-approximate solution*. Notice that the *performance ratio* is a ratio between the value of an optimal solution and that of M's output.

In 2007, Tantau [19] presented an NL maximization problem, called Max-HPP, which falls into $LSAS_{NLO}$. This problem was later rephrased in [20, arXiv version] in terms of complete graphs and it was shown to be computationally hard for LO_{NLO} (log-space computable NL optimization) under *approximation-preserving exact* NC^1*-reduction*.

Maximum Hot Potato Problem (Max-HPP):

- Instance: an $n \times n$ matrix A whose entries are drawn from $[n]$, a number $d \in [n]$, and a start index $i_1 \in [n]$, where $n \in \mathbb{N}^+$.
- Solution: an index sequence $\mathcal{S} = (i_1, i_2, \ldots, i_d)$ of length d with $i_j \in [n]$ for any $j \in [d]$.
- Measure: total weight $w(\mathcal{S}) = \sum_{j=1}^{d-1} A_{i_j i_{j+1}}$.

We use the number n of columns in a given matrix as size parameter $m_{col}(A, d, i_1)$. We can show that, under the assumption of LSH for $2\mathrm{SAT}_3$, (Max-HPP, m_{col}) cannot have polynomial-time $O(k^{1/3} \log m_{col}(x))$-space approximation schemes of finding $(1 + \frac{1}{k})$-approximate solutions for instances x.

▶ **Theorem 1.8.** *If LSH for* $2\mathrm{SAT}_3$ *is true, then, for any* $\varepsilon > 0$*, there is no polynomial-time* $O(k^{1/3} \log m_{col}(x))$*-space algorithm finding* $(1+\frac{1}{k})$*-approximate solutions of* (Max-HPP, m_{col})*, where* x *is any instance and* k *is an approximation parameter.*

The fourth example concerns with the computational complexity of transforming one type of finite automata into another type. It is known that we can convert a 1nfa M to an "equivalent" *one-way deterministic finite automaton* (or 1dfa) M' in the sense that both M and M' recognize exactly the same language. In particular, we consider the case of transforming an n-state *unary* 1nfa into its equivalent *unary* 1dfa, where a unary finite automaton takes a single-letter input alphabet. A standard procedure of such transformation requires polynomial-time and $O(n)$ space (cf. [7]). Under LSH for $2\mathrm{SAT}_3$, we can demonstrate that this space bound cannot be made significantly smaller.

▶ **Theorem 1.9.** *If LSH for* $2\mathrm{SAT}_3$ *is true, then, for any constant* $\varepsilon \in (0, 1)$*, there is no polynomial-time* $O(n^{\varepsilon})$*-space algorithm that takes an* n*-state unary 1nfa as input and produces an equivalent unary 1dfa of* $O(n \log n)$ *states.*

2 Basic Notions and Notation

Let $\mathbb{N}$ be the set of *natural numbers* (i.e., nonnegative integers) and set $\mathbb{N}^+ = \mathbb{N} - \{0\}$. Two notations $\mathbb{R}$ and $\mathbb{R}^{\geq 0}$ denote respectively the set of all *real numbers* and that of all *nonnegative real numbers*. For any two integers m and n with $m \leq n$, the notation $[m, n]_{\mathbb{Z}}$ denotes the set $\{m, m+1, m+2, \ldots, n\}$, which is an *integer interval* between m and n. For simplicity, when $n \geq 1$, we write $[n]$ for $[1, n]_{\mathbb{Z}}$.

In this paper, all *polynomials* are assumed to have nonnegative integer coefficients. All *logarithms* are to base 2. A *polylogarithmic (or polylog) function* ℓ is a function mapping $\mathbb{N}$ to $\mathbb{R}^{\geq 0}$ such that there exists a polynomial p for which $\ell(n) = p(\log n)$ holds for all $n \in \mathbb{N}$, provided that "$\log 0$" is conventionally set to be 0.

In a course of our study on polynomial-time sub-linear-space computability, it is convenient to expand the standard framework of decision problems to problems *parameterized* by properly chosen "size parameters" (called "complexity parameters" in [10]), which serve as a basis unit of the time/space complexity of an algorithm. In this respect, we follow a framework of Impagliazzo et al. [10] to work with a flexible choice of size parameter. A standard size parameter is the total length $|x|$ of the binary representation of an input instance x and it is often denoted by $||$. More generally, a *(log-space) size parameter* $m(x)$ for a problem P is a function mapping Σ^* (where Σ is an input alphabet) to $\mathbb{N}$ such that (1) m must be computed using log space (that is, by a certain Turing machine that takes input x and outputs $m(x)$ in unary on an output tape using at most $c \log |x| + d$ space for certain constants $c, d > 0$) and (2) there exists a polynomial p satisfying $m(x) \leq p(|x|)$ for all instances x of P.

As key examples, for any graph-related problem (such as 3DSTCON), $m_{edg}(x)$ and $m_{ver}(x)$ denote respectively the total number of edges and that of vertices in a given graph instance x. Clearly, m_{ver} and m_{edg} are log-space computable. To emphasize the use of size parameter m, we often write (P, m) in place of P. We say that a multi-tape Turing machine M uses *logarithmic space* (or *log space*, in short) with respect to size parameter m if there exist two absolute constants $c, d \geq 0$ such that each of the work tapes (not including input and output tapes) used by M on x are upper-bounded by $c \log m(x) + d$ on every input x.

Two specific notations L and NL respectively stand for the classes of all decision problems solvable on multi-tape deterministic and nondeterministic Turing machines using log space. It is known that the additional requirement of "polynomial runtime" does not change these classes. More generally, PTIME,SPACE($s(n)$) expresses a class composed of all (parameterized) decision problems (P, m) solvable deterministically in polynomial time (in $|x|$) using space at most $s(m(x))$ on any instance x given to P.

To define NL search and optimization problems in Section 6, it is convenient for us to use a practical notion of "auxiliary Turing machine" (see, e.g., [20]). An *auxiliary Turing machine* is a multi-tape deterministic Turing machine equipped with an extra read-only *auxiliary input tape*, in which a tape head scans each auxiliary input symbol only once by moving from the left to the right. Given two alphabets Σ and Γ, a (parameterized) decision problem (P, m) with $P \subseteq \Sigma^* \times \Gamma^*$ is in auxL if there exist a polynomial p and an auxiliary Turing machine M that takes a standard input x and an auxiliary input y of length $p(|x|)$ and decides whether M accepts (x, y) or not in time polynomial in $|x|$ using space logarithmic in $m(x)$. Its functional version is denoted by auxFL, provided that each underlying Turing machine is equipped with an extra *write-only* output tape (in which a tape head moves to the right whenever it writes a non-blank output symbol) and that the machine produces output strings of at most polynomial length.

3 Sub-Linear Space and Short Reductions

Recall from [9, 10] that the term "sub-exponential" means $2^{\varepsilon m(x)}\, poly(|x|)$ for a certain constant $\varepsilon \in (0, 1)$. In contrast, our main subject is polynomial-time, sub-linear-space computability, where the term "sub-linear" refers to functions of the form $m(x)^{\varepsilon}\, polylog(|x|)$ on input instances x for a certain constant $\varepsilon \in (0, 1)$ and a certain polylogarithmic function $polylog(n)$. As noted in Section 1.2, the multiplicative factor $polylog(|x|)$ can be eliminated whenever $m(x)$ is relatively large.

First, we will provide basic definitions for (parameterized) decision problems. A decision problem P parameterized by size parameter m is said to be *solvable in polynomial time using sub-linear space* if, for a certain choice of constant $\varepsilon \in (0, 1)$, there exist a deterministic Turing machine M_ε, a polynomial p_ε, and a polylogarithmic function ℓ_ε for which M solves P simultaneously in at most $p_\varepsilon(|x|)$ steps using space at most $m(x)^{\varepsilon}\ell_\varepsilon(|x|)$ for all instances x given to P.

The notation PsubLIN expresses the collection of all (parameterized) decision problems (P, m) that are solvable in polynomial time using sub-linear space. In other words, PsubLIN $= \bigcup_{\varepsilon\in(0,1)}$ PTIME,SPACE($m(x)^{\varepsilon}\ell(|x|)$) for input instances x, where m refers to an arbitrary (log-space) size parameter and ℓ refers to any polylogarithmic function. It thus follows that L $\subseteq$ PsubLIN $\subseteq$ P but none of these inclusions is known to be proper.

The notion of reducibility among decision problems is quite useful in measuring the relative complexity of the problems. For the class PsubLIN, in particular, we need a restricted form of reducibility, which we call "short" reducibility, satisfying a special property that any

outcome of the reduction is linearly upper-bounded in size by an input of the reduction. We will define such restricted reductions for (parameterized) decision problems of our interest.

We begin with a description of *L-m-reducibility* for (parameterized) decision problems. Given two (parameterized) decision problems (P_1, m_1) and (P_2, m_2), we say that (P_1, m_1) is *L-m-reducible to* (P_2, m_2), denoted by $(P_1, m_1) \leq_m^{\mathrm{L}} (P_2, m_2)$, if there is a function $(f, ||) \in \mathrm{FL}$ (where $||$ refers to the bit length) and two constants $k_1, k_2 > 0$ such that, for any input string x, (i) $x \in P_1$ iff $f(x) \in P_2$ and (iii) $m_2(f(x)) \leq m_1(x)^{k_1} + k_1$. Notice that all functions in FL are, by their definition, polynomially bounded.

Concerning polynomial-time sub-linear-space solvability, we introduce a restricted variant of this L-m-reducibility, which we call the *short L-m-reducibility* (or sL-m-reducibility, in short), obtained by replacing the equality $m_2(f(x)) \leq m_1(x)^{k_1} + k_1$ in the above definition of $\leq_m^{\mathrm{L}}$ with $m_2(f(x)) \leq k_1 m_1(x) + k_1$. To express this new reducibility, we use a new notation of $\leq_m^{\mathrm{sL}}$.

Since many-one reducibility is too restrictive to use, we need a stronger notion of Turing reduction, which fits into a framework of polynomial-time, sub-linear-space computability. Our reduction is actually a *polynomial-time sub-linear-space reduction family* (SLRF, in short), performed by oracle Turing machines. A (parameterized) decision problem (P_1, m_1) is *SLRF-T-reducible to* another one (P_2, m_2), denoted by $(P_1, m_1) \leq_T^{\mathrm{SLRF}} (P_2, m_2)$, if, for every fixed value $\varepsilon > 0$, there exist an oracle Turing machine M_ε equipped with an extra write-only query tape, a polynomial p_ε, a polylog function ℓ_ε, and three constants $k_1, k_2 \geq 1$ such that, for every instance x to P_1, (1) $M_\varepsilon^{P_2}$ runs in at most $p_\varepsilon(|x|)$ time using at most $m_1(x)^\varepsilon \ell_\varepsilon(|x|)$ space, provided that its query tape is not subject to this space bound, (2) if $M_\varepsilon^{P_2}(x)$ makes a query to P_2 with query word z written on the query tape, then z satisfies both $m_2(z) \leq m_1(x)^{k_1} + k_1$ and $|z| \leq |x|^{k_2} + k_2$, and (3) after M_ε makes a query, in a single step, it automatically erases its query tape, it returns its tape head back to the initial cell, and oracle P_2 informs the machine of its answer by changing the machine's inner state.

The *short SLRF-T-reducibility* (or sSLRF-T-reducibility, in short) is obtained from the SLRF-reducibility by substituting $m_2(z) \leq k_1 m_1(x) + k_1$ for the above inequality $m_2(z) \leq m_1(x)^{k_1} + k_1$. The notation $\leq_T^{\mathrm{sSLRF}}$ denotes this restricted reducibility. In the case where M_ε is limited to log-space usage, we use a different notation of $\leq_T^{\mathrm{sL}}$. Note that any $\leq_T^{\mathrm{sSLRF}}$-reduction is an $\leq_T^{\mathrm{SLRF}}$-reduction but the converse is not true because there is a pair of problems reducible by $\leq_T^{\mathrm{SLRF}}$-reductions but not by $\leq_T^{\mathrm{sSLRF}}$-reductions.

For any reduction $\leq_r$, a decision problem P is said to be *$\leq_r$-complete* for a given class $\mathcal{C}$ of problems if (1) $P \in \mathcal{C}$ and (2) every problem Q in $\mathcal{C}$ is $\leq_r$-reducible to P. We use the notation $\leq_r(\mathcal{C})$ to express the collection of all problems that are $\leq_r$-reducible to certain problems in $\mathcal{C}$. When $\mathcal{C}$ is a singleton, say, $\mathcal{C} = \{A\}$, we write $\leq_r(A)$ instead of $\leq_r(\{A\})$.

It follows that $(P_1, m_1) \leq_m^{\mathrm{L}} (P_2, m_2)$ implies $(P_1, m_1) \leq_T^{\mathrm{L}} (P_2, m_2)$, which further implies $(P_1, m_1) \leq_T^{\mathrm{SLRF}} (P_2, m_2)$. The same statement holds for $\leq_m^{\mathrm{sL}}$, $\leq_T^{\mathrm{sL}}$, and $\leq_T^{\mathrm{sSLRF}}$. Moreover, $(P_1, m_1) \leq_m^{\mathrm{sL}} (P_2, m_2)$ implies $(P_1, m_1) \leq_m^{\mathrm{L}} (P_2, m_2)$. The same holds for $\leq_T^{\mathrm{sSLRF}}$ and $\leq_T^{\mathrm{SLRF}}$.

Here are other basic properties of SLRF-T- and sSLRF-T-reductions.

▶ **Lemma 3.1.**

1. *The reducibilities $\leq_T^{\mathrm{SLRF}}$ and $\leq_T^{\mathrm{sSLRF}}$ are reflexive and transitive.*
2. *The class* PsubLIN *is closed under $\leq_T^{\mathrm{sSLRF}}$-reductions.*
3. *There exist recursive decision problems X and Y such that $X \leq_T^{\mathrm{SLRF}} Y$ but $X \not\leq_T^{\mathrm{sSLRF}} Y$. A similar statement holds also for $\leq_m^{\mathrm{L}}$ and $\leq_m^{\mathrm{sL}}$.*

4 The 2CNF Boolean Formula Satisfiability Problem and SNL

We will make a brief discussion on 2SAT (2CNF Boolean formulas satisfiability problem) and the complexity class SNL. As noted in Section 1.1, 2SAT is NL-complete under L-m-reductions.

In what follows, we are focused on two specific size parameters: $m_{vbl}(x)$ and $m_{cls}(x)$, which respectively denote the numbers of propositional variables and clauses appearing in formula-related instance x (not necessarily limited to instances of 2SAT).

We further restrict 2SAT by limiting the number of literals appearing in an input Boolean formula as follows. Let $k \in \mathbb{N}^+$. We denote by $2\mathrm{SAT}_k$ the collection of all formulas ϕ in 2SAT such that, for each variable v in ϕ, the number of occurrences of v and $\overline{v}$ is at most k. Since $2\mathrm{SAT}_1$ and $2\mathrm{SAT}_2$ are solvable using only log space, we force our attention on the case of $k \geq 3$. From $(2\mathrm{SAT}, ||) \leq_m^{\mathrm{L}} (2\mathrm{SAT}_3, ||)$ with a help of the fact that 2SAT is NL-complete, we can immediately obtain the following.

▶ **Proposition 4.1.** *For each index $k \geq 3$, $2\mathrm{SAT}_k$ is* NL*-complete.*

To solve 2SAT in polynomial time, we need slightly larger than sub-linear space.

▶ **Theorem 4.2.** *For a certain constant $c > 0$ and a polylog function $\ell(n)$, 2SAT with n variables and m clauses can be solved in polynomial time using $n^{1-c/\sqrt{\log n}}\ell(m+n)$ space.*

For any reduction $\leq_r$ defined in Section 3, we write $(P_1, m_1) \equiv_r (P_2, m_2)$ if both $(P_1, m_1) \leq_r (P_2, m_2)$ and $(P_2, m_2) \leq_r (P_1, m_1)$ hold.

▶ **Lemma 4.3.** *Let $m \in \{m_{vbl}, m_{cls}\}$ and $k \geq 3$. (1) $(2\mathrm{SAT}_k, m) \equiv_m^{\mathrm{sL}} (2\mathrm{SAT}_3, m)$ and (2) $(2\mathrm{SAT}_3, m_{vbl}) \equiv_m^{\mathrm{sL}} (2\mathrm{SAT}_3, m_{cls})$.*

Contrary to Lemma 4.3(2), it is still unknown whether $(2\mathrm{SAT}, m_{vbl}) \equiv_T^{\mathrm{sL}} (2\mathrm{SAT}, m_{cls})$.

Hereafter, we will define the notion of SNL formulas, which induce the complexity class SNL. Let $x = (S_1, \ldots, S_a, x_1, \ldots, x_b)$ be any instance, including "sets" S_i and "objects" x_j. An *SNL formula* Ψ is of the form $\exists T \forall i_1 \cdots \forall i_r \forall y_1 \cdots \forall y_s \exists z_1 \cdots \exists z_t\ \psi$, where ψ is a quantifier-free formula, which is a Boolean combination of *atomic formulas* of the following forms: $T(i, v)$, $(u_1, \ldots, u_k) \in S_j$, $u = v$, $i \leq j$, and $symb(v, i) = a$ (i.e., a is the ith symbol of v), where T is a second-order predicate symbol, and $i_1, \ldots, i_r, y_1, \ldots, y_s, z_1 \ldots, z_t$ are first-order variables, having the following *semantic model* for Ψ. In this model, T ranges over a subset of $[p(|x|)] \times U_x$ (where U_x is a universe) with $|U_x| \leq cm(x)$, each i_j ranges a number in $[p_j(|x|)]$, each y_j takes an element in another universe $U_{x,j}$ with $|U_{x,j}| \leq c_j m(x)$, and each z_j ranges over a set $Z_{x,j}$ of at most e elements (i.e., $|Z_{x_j}| \leq e$) for absolute constants $c, c_j, e \geq 1$ and polynomials p, p_j, not depending on the choice of x. A *certificate size* $m_{cert}(x)$ is defined to be $|U_x|$ as our basis size parameter.

As a quick example, let us consider a (parameterized) decision problem (A, m) such that there are a polynomial p, a constant $c > 0$, and a deterministic Turing machine M recognizing A simultaneously in time at most $p(|x|)$ using space at most $\log_{|\Gamma|} m(x) + c$ for every instance x to A, where Γ is a work-tape alphabet. We assume that M terminates in a configuration in which the work tape is blank and all tape heads return to the initial position. For our convenience, δ is extended to include a special transition from an accepting configuration to itself. To express (A, m), we define an SNL-formula $\Psi \equiv \Psi(x)$ as: $\exists T[Func(T) \wedge \exists v_0 \exists v_1 [T(1, v_0) \wedge T(last(T), v_1) \wedge v_1 \in ACC_x \wedge \forall i \forall v \exists w [T(i, v) \rightarrow (v, w) \in Tran_\delta \wedge T(i+1, w)]]]$ with a semantic model supporting $T \subseteq [p(|x|)] \times U_x$, $i \in [p(|x|)]$, $v_0, x_1, v, w, \in U_x$, where $U_x = \Gamma^{\log_{|\Gamma|} m(x)+c}$, ACC_x is the set of a unique accepting configuration, $last(T)$ indicates

the largest index i that ensures $\exists v[T(i,v)]$, $Trans_\delta$ expresses a δ-transition between two configurations, and $Func(T)$ asserts that T represents a function $f(i)=z$ satisfying $T(i,z)$. Note that $|U_x| \leq |\Gamma|^{c+1}m(x)$. Hence, (A,m) belongs to SNL.

5 The Working Hypothesis LSH for $2SAT_3$

The exponential time hypothesis (ETH) has served as a driving force to obtain better lower bounds on the computational complexity of various important problems (see, e.g., [14]).

In Theorem 4.2, we have seen that 2SAT with n variables and m clauses can be solved in polynomial time using $n^{1-c/\sqrt{\log n}}polylog(m+n)$ space for a certain constant $c>0$; however, it is not yet known to be solved in polynomial time using sub-linear space. This circumstance encourages us to propose (in Section 1.3) a practical working hypothesis – the *linear space hypothesis* (LSH) for $2SAT_3$ – which asserts the insolvability of $(2SAT_3, m_{ver})$ in polynomial time using sub-linear space. The choice of m_{vbl} does not matter; as shown in Lemma 4.3(2) with a help of Lemma 3.1(2), we can replace m_{vbl} in the definition of LSH by m_{cls}. Theorem 1.5 has further given two alternative definitions to LSH in terms of $LP_{2,3}$ and 3DSTCON.

As noted in Section 1.3, Theorem 1.2 states that the above working hypothesis leads to $L \neq NL$. Moreover, Proposition 1.3 asserts that LSH for $2SAT_3$ is equivalent to $\delta_3 = 1$.

The working hypothesis LSH concerns with $2SAT_3$ but it also carries over to 2SAT.

▶ **Lemma 5.1.** *Assuming that LSH for* $2SAT_3$ *is true, each of the following statements holds: (1)* $\leq_T^{sSLRF}(2SAT_3, m_{vbl}) \not\subseteq PsubLIN$ *and (2)* $(2SAT, m_{vbl}) \notin PsubLIN$.

As another consequence of LSH for $2SAT_3$, we can show the existence of a pair of problems in the class $\leq_T^{sSLRF}(2SAT_3, m_{vbl})$, which are incomparable with respect to $\leq_T^{sSLRF}$-reductions. This indicates that the class $\leq_T^{sSLRF}(2SAT_3, m_{vbl})$ has a fine, complex structure with respect to sSLRF-T-reducibility.

▶ **Theorem 5.2.** *Assuming LSH for* $2SAT_3$*, there are two decision problems* (A, m_A) *and* (B, m_B) *in* $\leq_T^{sSLRF}(2SAT_3, m_{vbl})$ *such that* $(A, m_A) \not\leq_T^{sSLRF} (B, m_B)$ *and* $(B, m_B) \not\leq_T^{sSLRF} (A, m_A)$.

6 Proofs of the Four Examples of LSH Applications

In Section 1.4, we have described four examples of how to apply our working hypothesis LSH for $2SAT_3$. Here, we will give three of their proofs.

First, we will briefly describe *(parameterized) NL search problems*. In general, a search problem parameterized by (log-space) size parameter m is expressed as (I, SOL, m), where I consists of (admissible) instances and SOL is a function from I to a set of strings (called a *solution space*) such that, for any $(x,y) \in I \circ SOL$, $y \in SOL(x)$ implies $|y| \leq am(x)+b$ for certain constants $a, b > 0$, where $I \circ SOL$ stands for $\{(x,y) \mid x \in I, y \in SOL(x)\}$. In particular, when we use the standard "bit length" of instances, we omit "||" and write (I, SOL) instead of $(I, SOL, ||)$. Of all search problems, *(parameterized) NL search problems* are (parameterized) search problems (I, SOL, m) for which $I \in L$ and $I \circ SOL \in$ auxL. Finally, we denote by Search-NL the collection of all (parameterized) NL search problems.

We say that a deterministic Turing machine M *solves* (I, SOL, m) if, for any instance $x \in I$, M takes x as input and produces a solution in $SOL(x)$ if $SOL(x) \neq \emptyset$, and produces a designated symbol $\perp$ ("no solution") otherwise. Now, we recall from Section 1.4 a special

NL search problem, called Search-1NFA, in which we are asked to find an input of length n accepted by a given λ-free 1nfa M. Theorem 1.6 states that no polynomial-time $O(n^{1/2-\varepsilon})$-space algorithm solves $(\text{Search-1NFA}, m_{nfa})$.

Proof of Theorem 1.6. Toward a contradiction, we assume that $(\text{Search-1NFA}, m_{nfa})$ is solved by a deterministic Turing machine M in time polynomial in $|y|$ using space at most $cm_{nfa}(y)^{1/2-\varepsilon}$ on instances y, where $c, \varepsilon > 0$ are constants. Our aim is to show that $(\text{3DSTCON}, m_{ver})$ can be solved in polynomial time using sub-linear space, because this contradicts LSH for 3DSTCON, which is equivalent to LSH for 2SAT_3 by Theorem 1.5(3).

Let $x = (G, s, t)$ be any instance to 3DSTCON with $G = (V, E)$ and $s, t \in V$. Let $n = |V|$. Associated with this x, we define a 1nfa $N = (Q, \Sigma, \delta, q_0, F)$ as follows. First, let $Q = V$ and $\Sigma = [0, 3]_{\mathbb{Z}}$. Define $q_0 = s$ and $F = \{t\}$. For each $v \in V$, consider its neighbor $out(v) = \{w \in V \mid (v, w) \in E\}$. We assume that all elements in $out(v)$ are enumerated in a fixed linear order as $out(v) = \{w_1, w_2, \ldots, w_k\}$ with $0 \leq k \leq 3$. The transition function δ is defined as $\delta(v, i) = \{w_i\}$ if $0 \leq i \leq k$.

Supposedly, $\gamma = (v_1, v_2, \ldots, v_d)$ is a path from $s = v_1$ to $t = v_d$ in G. For each index $i \in [d]$, we choose an index $\ell(v_i)$ satisfying $v_{i+1} = w_{\ell(v_i)} \in out(v_i)$ and we then set $z = \ell(v_1)\ell(v_2)\cdots\ell(v_{d-1})0^{n-d+1}$. When N reads z, it eventually enters v_d, which is a halting state, and therefore N accepts z. On the contrary, in the case where there is no path from s to t in G, N never accepts any input. Therefore, it follows that (*) 3DSTCON has a path from s to t iff N accepts z.

Finally, we set $y = (N, 1^n)$ as an instance to Search-1NFA parameterized by m_{nfa}. Note that $m_{nfa}(y) = |Q||\Sigma|n \leq 4|V|^2 = 4m_{ver}(z)^2$. By (*), 3DSTCON can be solved by running M on y in polynomial time; moreover, the space required for this computation is upper-bounded by $cm_{nfa}(y)^{1/2-\varepsilon} \leq 2cm_{ver}(x)^{1-2\varepsilon}$, which is obviously sub-linear. ◀

Another NL search problem, Search-UOCK, asks to find, for a given string w, an index sequence $(i_1, \ldots, i_k)$ in increasing order that makes the concatenation $w_{i_1} \cdots w_{i_k}$ equal to w among $\{w_1, w_2, \ldots, w_n\}$. Here, we present the proof of Theorem 1.7.

Proof of Theorem 1.7. Let us assume that there is a polynomial-time $cm_{elm}(x)^{1/2-\varepsilon}$-space algorithm A for $(\text{Search-UOCK}, m_{elm})$ on instances x for certain constants $\varepsilon, c > 0$. We will use this A to solve $(\text{3DSTCON}, m_{ver})$ in polynomial time using sub-linear space.

Let $x = (G, s, t)$ be any instance to 3DSTCON with $G = (V, E)$. For simplicity of our argument, let $V = \{1, 2, \ldots, n\}$, $s = 1$, and $t = n$. Now, we define $\langle i, j\rangle = (i-1)n + j$ for each pair $i, j \in [n]$. First, we modify G into another graph $G' = (V', E')$, where $V' = \{\langle i, j\rangle \mid i, j \in [n]\}$ and $E' = \{(\langle i, j\rangle, \langle i', j'\rangle) \in V' \times V' \mid i' = i + 1, (j, j') \in E\}$. Note that $|V'| = n^2$ and $|E'| = |V||E| \leq 3|V|^2 = 3n^2$ since $|E| \leq 3|V|$. Moreover, let $s' = \langle 1, s\rangle$ and $t' = \langle n, t\rangle$. This new graph G' satisfies the following property, called the *topological order*: for any pair $i, j \in V'$, $(i, j) \in E'$ implies $i < j$.

From (G', s', t'), we want to define $w = bin(1)\#bin(2)\#\cdots\#bin(n)\#$, where $bin(i)$ indicates the binary representation of a natural number i and $\#$ is a designated separator not in $\{0, 1\}$. Moreover, for each edge $(i, j) \in E'$, we define $w_{ij} = bin(i+1)\#bin(i+2)\#\cdots\#bin(j)\#$. It follows that, for each w_{ij}, if w_{ij} is a substring of w, then w_{ij} must be unique. Note that $z = (w, w_{ij})_{(i,j)\in E'}$ is an instance to Search-1NFA with $m_{elm}(z) = |E'| \leq 3n^2 = 3m_{ver}(x)^2$.

By running A on input z, we can solve $(\text{3DSTCON}, m_{edg})$ for instance x in time polynomial in $|x|$ using space at most $cm_{elm}(z)^{1/2-\varepsilon}$, which equals $3cm_{ver}(x)^{1-2\varepsilon}$. This contradicts LSH for 3DSTCON, which implies LSH for 2SAT_3 by Theorem 1.5(3). ◀

The next practical application of the working hypothesis LSH for $2SAT_3$ targets the area of combinatorial NL optimization. An *NL optimization problem* (or an NLO problem) P is a tuple $(I, SOL, mes, goal)$ with $I \in \mathrm{L}$, $I \circ SOL \in \mathrm{auxL}$, $mes : I \circ SOL \to \mathbb{N}^+$ in auxFL, and $goal \in \{\textsc{max}, \textsc{min}\}$. See [19, 20] for its precise definition. Let NLO stand for the class of all NLO problems. An *optimal solution* y for instance x must satisfy $mes(x, y) = mes^*(x)$, where $mes^*(x) = goal_{y \in SOL(x)}\{mes(x, y)\}$. The *performance ratio* R of a solution y on an instance x is $R(x, y) = \max\{\frac{mes^*(x)}{mes(x,y)}, \frac{mes(x,y)}{mes^*(x)}\}$.

We say that an NLO problem $P = (I, SOL, mes, goal)$ parameterized by size parameter m is *solvable using log space* if there is a deterministic Turing machine that takes any instance $x \in I$ and outputs an optimal solution in $SOL(x)$ using logarithmically many tape cells in terms of size parameter $m(x)$. We write $\mathrm{LO}_{\mathrm{NLO}}$ to denote the class of all NLO problems solvable in polynomial time.

An NPO problem P is said to be *log-space γ-approximable* if there is a log-space Turing machine such that, for any instance x, if $SOL(x) \neq \emptyset$, then M outputs a solution in $SOL(x)$ with $R(x, M(x)) \leq \gamma$; otherwise, M outputs $\perp$ ("no solution"). The notation $\mathrm{LSAS}_{\mathrm{NLO}}$ denotes the class of NLO problems P for which there exists a log-space approximation scheme for P, where a *log-space approximation scheme* for P is a deterministic Turing machine M that takes inputs of the form (x, k) and outputs a solution y of P using space at most $f(k) \log |x|$ for a certain log-space computable function $f : \mathbb{N} \to \mathbb{N}$ such that the performance ratio R satisfies $R(x, y) \leq 1 + 1/k$. It follows that $\mathrm{LO}_{\mathrm{NLO}} \subseteq \mathrm{LSAS}_{\mathrm{NLO}} \subseteq \mathrm{NLO}$. Here, we are focused on problems in $\mathrm{LSAS}_{\mathrm{NLO}}$, that is, NLO problems having log-space approximation schemes.

Let us recall an NLO problem, called Max-HPP, from Section 1.4. Theorem 1.8 states that no polynomial-time $O(k^{1/3} \log m_{col}(x))$-space algorithm that finds $(1 + \frac{1}{k})$-approximate solutions solves $(\text{Max-HPP}, m_{col})$. To prove this theorem, we state a useful supporting lemma. An optimization problem $(I, SOL, mes, goal)$ parameterized by m is said to be *$g(m(x))$-bounded* if $mes(x, y) \leq g(m(x))$ holds for any $(x, y) \in I \circ SOL$.

▶ **Lemma 6.1.** *Let $c \geq 1$. Every $O(m(x)^c)$-bounded maximization problem in $\mathrm{LSAS}_{\mathrm{NLO}}$, parameterized by log-space size parameter $m(x)$, whose $(1 + \frac{1}{k})$-approximate solutions are found using $O(k^{\frac{1}{2c+1}} \log m(x))$ space can be solved in polynomial time using $O(m(x)^{1/2-\varepsilon})$ space on instances x for a certain constant $\varepsilon \in (0, 1/2)$.*

Proof of Theorem 1.8. Let $\varepsilon > 0$. Note that $(\text{Max-HPP}, m_{col})$ is $m_{col}(z)$-bounded for any instance z. Assume that there is a polynomial-time $O(k^{1/3} \log m_{col}(z))$-space algorithm of finding $(1 + \frac{1}{k})$-approximate solutions of Max-HPP on instances z. Lemma 6.1 then implies that $(\text{Max-HPP}, m_{col})$ is solved by a certain deterministic Turing machine M in polynomial time using space at most $cm_{col}(z)^{1/2-\varepsilon}$ on instances z for a certain constant $c > 0$. We want to use this machine M to solve $(\text{3DSTCON}, m_{ver})$ in polynomial time using sub-linear space.

Let $x = (G, s, t)$ be any instance given to 3DSTCON with $G = (V, E)$ and $n = |V| \geq 2$. We define another graph $G' = (V', E')$, where $V' = \{(i, v) \mid i \in [n], v \in V\}$ and $E' = \{((i, u), (i + 1, v)) \mid i \in [n - 1], (u, v) \in E\}$. Note that $|V'| = n^2$. We set $s' = (1, s)$ and $t' = (n, t)$. From this graph G', we want to construct an instance $z = (A, n, s')$ to Max-HPP, where A is a $|V'| \times |V'|$ matrix. By identifying vertices in V' with numbers in $[n^2]$, we set $A_{s't'} = A_{t's'} = A_{vv} = 1$ for any $v \in V' - \{t\}$ and $A_{t'v} = A_{vs'} = 1$ for all $v \in V'$. For any other pair $(u, v) \in V' \times V'$, if $(u, v) \in E'$, then we define $A_{vw} = n$; otherwise, define $A_{uv} = 1$. Note that $m_{col}(z) = n^2 = m_{ver}(x)^2$.

If there is a path $(v_1, v_2, \ldots, v_k)$ from s' to t' in G', then we define $v_{k+j} = v_k$ for all indices $j \in [n^2 - k]$. It then follows that $\sum_{i=1}^{n^2-1} A_{v_i v_{i+1}} = (n^2 - 1)n$ and clearly this is

optimal. On the contrary, let $\gamma = (v_1, v_2, \ldots, v_{n^2})$ be an optimal solution with an optimal value $(n^2-1)n$. By the requirement of Max-HPP, v_1 must be s'. Moreover, $A_{v_i v_{i+1}} = n$ holds for each $i \in [n^2-1]$. Hence, if we allow a self-loop at vertex t' in G', then γ forms a path from s'. Since $|V'| = n^2$, γ must include t'. Hence, γ contains a subpath from s' to t' in G'.

We then run M on the input z to obtain an optimal index sequence γ. By the above argument, if $w(\gamma) = (n^2-1)n$, then a path from s to t exists; otherwise, there is no path from s to t. Since M uses at most $cm_{col}(z)^{1/2-\varepsilon}$ space, the space usage of the whole procedure is at most $cm_{col}(z)^{1/2-\varepsilon}$, which turns out to be $cm_{ver}(x)^{1-2\varepsilon}$ by $m_{col}(z) = m_{ver}(x)^2$. Therefore, 3DSTCON is solvable in polynomial time using sub-linear space. This contradicts LSH for 3DSTCON, which is equivalent to LSH for $2SAT_3$ by Theorem 1.5(3). ◀

Abstract

Dybjer and Setzer introduced the definitional principle of inductive-recursively defined families – i.e. of families $(\mathsf{U} : \mathsf{Set}, \mathsf{T} : \mathsf{U} \to D)$ such that the inductive definition of U may depend on the recursively defined T – by defining a type $\mathsf{DS}\ D\ E$ of codes. Each $c : \mathsf{DS}\ D\ E$ defines a functor $[\![\ c\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$, and $(\mathsf{U}, \mathsf{T}) = \mu[\![\ c\ ]\!] : \mathsf{Fam}\ D$ is exhibited as the initial algebra of $[\![\ c\ ]\!]$.

This paper considers the composition of DS-definable functors: Given $F : \mathsf{Fam}\ C \to \mathsf{Fam}\ D$ and $G : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$, is $G \circ F : \mathsf{Fam}\ C \to \mathsf{Fam}\ E$ DS-definable, if F and G are? We show that this is the case if and only if powers of families are DS-definable, which seems unlikely. To construct composition, we present two new systems UF and PN of codes for inductive-recursive definitions, with $\mathsf{UF} \hookrightarrow \mathsf{DS} \hookrightarrow \mathsf{PN}$. Both UF and PN are closed under composition. Since PN defines a potentially larger class of functors, we show that there is a model where initial algebras of PN-functors exist by adapting Dybjer-Setzer's proof for DS.

1 Introduction

Codes for inductive-recursive definitions were introduced in a series of papers by Dybjer and Setzer [6, 7, 8]. An initial motivation [5] was to give generic rules that can be specialised to define most types occurring in Martin-Löf Type Theory [13], including inductive families [4] and Tarski-style universes [14]. An inductive-recursive definition defines not only a type, but more generally a family $(\mathsf{U} : \mathsf{Set}, \mathsf{T} : \mathsf{U} \to D)$ of types for some $D : \mathsf{Set}_1$, where the inductive definition of U may depend on the recursively defined T; examples can be found in Section 2. To represent such definitions, Dybjer and Setzer introduced a type $\mathsf{DS}\ D\ E$ of codes representing functors $\mathsf{Fam}\ D \to \mathsf{Fam}\ E$. The family $(\mathsf{U}, \mathsf{T}) = \mu[\![\ c\ ]\!] : \mathsf{Fam}\ D$ arises as the initial algebra of a functor $[\![\ c\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ D$ represented by a code $c : \mathsf{DS}\ D\ D$.

Induction-recursion is important as it is the strongest form of inductive definition we have, surpassing, for example, inductive definitions [10] and inductive families [2]. This paper asks the following fundamental and significant question:

Is the theory of inductive-recursive definitions, as currently understood, optimal?

We still believe that conceiving of inductive-recursive definitions as initial algebras in the category $\mathsf{Fam}\ D$ is the right thing to do. However, the current type of codes for generating such functors may not actually be optimal for this purpose. We come to this conclusion by considering the question of composition of codes. Given $[\![\ c\ ]\!] : \mathsf{Fam}\ C \to \mathsf{Fam}\ D$ and

$[\![\ d\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$ represented by Dybjer-Setzer codes $c : \mathsf{DS}\ C\ D$ and $d : \mathsf{DS}\ D\ E$ respectively, is $[\![\ d\ ]\!] \circ [\![\ c\ ]\!] : \mathsf{Fam}\ C \to \mathsf{Fam}\ E$ DS-definable, i.e. is there a code $d \bullet c : \mathsf{DS}\ C\ E$ such that $[\![\ d \bullet c\ ]\!] = [\![\ d\ ]\!] \circ [\![\ c\ ]\!]$? A positive answer would allow modularity in datatype definitions, as one can then replace all inductive arguments (U, T) in a datatype by $F(U, T)$ for any DS-definable functor F by composing with the code for F. For instance, a code for an inductive definition of multiway trees, where each node has a list of subtrees, can be constructed by composing a code for lists with itself. Other classes of data types such as inductive definitions or inductive families are closed under composition [10] – it is a property naturally to be expected from the viewpoint of initial algebra semantics.

It is currently unknown whether DS is closed under composition, although we suspect that it is not. In support of this claim, we show that DS is closed under composition *if and only if* powers $A \to [\![\ c\ ]\!]$ of codes are definable (Section 2, where we also recall Dybjer and Setzer's codes). Since such a power operation is unlikely to exist, we are led to investigate alternative systems of inductive-recursive definitions that *are* closed under composition.

We first introduce a system UF of *uniform* codes for inductive-recursive definitions, and their decoding (Section 3). This system can be regarded as a subsystem of DS, and as such, it is clear that UF-functors have initial algebras since DS-functors do. The novum is that uniformity of codes can be exploited to define powers, which in turn means that a composition operator for uniform codes is obtainable, i.e. we have isolated a subclass of DS-functors that is closed under composition. Next we introduce another system PN of *polynomial* codes, and their decoding (Section 4). Notably, PN contains a constructor for the dependent product of codes which ensures that PN is closed under composition. PN is a supersystem of DS and hence we cannot inherit initial algebras for PN from DS, but must prove their existence directly: we do so by adapting Dybjer-Setzer's proof to our more general setting. The introduction of new alternative formulations of induction-recursion has the potential to have significant impact if they – as we believe to be the case – have better properties than the current one and hence come to supplant the current formulation.

Type-theoretic notation and assumptions. We work informally in a standard type theory with dependent function spaces $\big(x : A\big) \to B(x)$ (written $A \to B$ if x does not occur in B), dependent pair types $\big(\Sigma x : A\big)B(x)$ (written $A \times B$ if x does not occur in B), coproducts $A + B$ with injections inl and inr, and an identity type which we shall simply write as $a = b$. Finite enumerations are denoted by $\{a_1, a_2, \ldots, a_m\}$; instances include $0 = \{\}$, $1 = \{\star\}$ and $2 = \{\mathsf{ff}, \mathsf{tt}\}$. We write anonymous functions as $(a \mapsto b)$, or $(\_ \mapsto b)$ when the argument is not used by the function. We assume two universes à la Russell $\mathsf{Set} : \mathsf{Set}_1$, with $A : \mathsf{Set}$ implying $A : \mathsf{Set}_1$. We assume function extensionality, i.e. that pointwise equal functions are equal. This is essential in our development. For simplicity, we also assume uniqueness of identity proofs, i.e. that if $p : a = b$ and $q : a = b$, then $p = q$, but this assumption should be avoidable with a little more work. In any case, both of these assumptions are valid in extensional Type Theory [14], which readily has a set-theoretic interpretation. The content of this paper (except for the set-theoretical model of PN) has been formalised in Agda[1].

2 Dybjer-Setzer Codes DS for Inductive-Recursive Definitions

We recall the system of Dybjer-Setzer codes DS, how codes represent inductive-recursive definitions, and finally prove powers to be necessary and sufficient for DS to be closed under composition.

[1] Available at `http://personal.cis.strath.ac.uk/fredrik.nordvall-forsberg/variantsIR/`.

2.1 Definition of DS and its Decoding

For $D,\ E : \mathsf{Set}_1$, the type $\mathsf{DS}\ D\ E$ consists of codes that represent functors $\mathsf{Fam}\ D \to \mathsf{Fam}\ E$ describing the constructors of inductive-recursive definitions.

▶ **Definition 1.** Given $D, E : \mathsf{Set}_1$, the large type $\mathsf{DS}\ D\ E : \mathsf{Set}_1$ of *Dybjer-Setzer codes* is inductively defined by the following generators:

$$\iota : E \to \mathsf{DS}\ D\ E$$
$$\sigma : \big(A : \mathsf{Set}\big) \to (A \to \mathsf{DS}\ D\ E) \to \mathsf{DS}\ D\ E$$
$$\delta : \big(A : \mathsf{Set}\big) \to ((A \to D) \to \mathsf{DS}\ D\ E) \to \mathsf{DS}\ D\ E$$

Here ι shall represent trivial functors, σ sums of functors, and δ dependent sums. See Dybjer and Setzer [7] for a more in-depth explanation, and the examples below for intuition. Note that Dybjer and Setzer only considered systems of the form $\mathsf{DS}\ D\ D$, i.e. where $E = D$. For our purposes the more general formulation will be clearer; it also accounts for the fact that $\mathsf{DS}\ D\ E$ is functorial covariantly in E and contravariantly in D.

▶ **Example 2** (W-types)**.** By choosing $D = E = 1$, we can use $\mathsf{DS}\ 1\ 1$ to represent inductive definitions. Let us encode Martin-Löf's type $\mathsf{W}\ S\ P : \mathsf{Set}$ of wellfounded trees, where $S : \mathsf{Set}$ encodes the possible shapes of the tree, and $P : S \to \mathsf{Set}$ maps each shape to its branching degree. This type is inductively defined by the constructor

$$\mathsf{sup} : \big(s : S\big) \to (P(s) \to \mathsf{W}\ S\ P) \to \mathsf{W}\ S\ P$$

Here we see that sup takes one non-inductive argument $s : S$, followed by an inductive argument $P(s) \to \mathsf{W}\ S\ P$, which depends on the first non-inductive one. We will see shortly in Example 5 that $\mathsf{W}\ S\ P$ can be represented by the code $c_{\mathsf{W}\ S\ P} : \mathsf{DS}\ 1\ 1$ with $c_{\mathsf{W}\ S\ P} = \sigma\, S\, (s \mapsto \delta\, P(s)\, (\_ \mapsto \iota\star))$ where σ is used for the non-inductive argument and δ for the inductive one, finally finishing off with a trivial ι.

▶ **Example 3** (A universe closed under W-types)**.** We get considerably more power by choosing $D = E = \mathsf{Set}$. Now we can represent a universe containing 2 that is *closed under* W*-types* by the code $c_{2\mathsf{W}} : \mathsf{DS}\ \mathsf{Set}\ \mathsf{Set}$, where

$$c_{2\mathsf{W}} = \sigma\ \{\mathsf{two}, \mathsf{w}\}\ (\mathsf{two} \mapsto \iota\ 2; \mathsf{w} \mapsto \delta\ 1\ (X \mapsto (\delta\ (X\star)\ (Y \mapsto \iota\ (\mathsf{W}\ (X\star)\ Y)))))$$

First we offer a choice between two constructors: two and w using σ. In the two case, we use an ι code to ensure the name two decodes to 2; in the w case, we ask for a name s for the shapes of the W-type using $\delta\ 1$, and for every element in the decoding of that name, we ask for a name for the branching degrees using $\delta\ (X\star)$ – here $X : 1 \to \mathsf{Set}$ represents the decoding of the name s. The rest of the code gets to depend on the decoding $Y : X\star \to \mathsf{Set}$ of this family, and we finish by declaring that this constructor decodes to $\mathsf{W}\ (X\star)\ Y$. Note that this code can be written as a coproduct of codes $c_2\ +_{\mathsf{DS}}\ c_{\mathsf{W}}$: generally for $c\ d : \mathsf{DS}\ D\ E$, we define their coproduct $c +_{\mathsf{DS}} d = \sigma\ 2\ (\mathsf{ff} \mapsto c\,;\ \mathsf{tt} \mapsto d)$. We will return to this in Example 11.

Decoding of Dybjer-Setzer codes as functors on families make the above intuitions precise. For $D : \mathsf{Set}_1$, $\mathsf{Fam}\ D$ is the category where objects are families of Ds, i.e. pairs (A, P) where $A : \mathsf{Set}$ and $P : A \to D$; a morphism $(A, P) \to (B, Q)$ consists of a function $f : A \to B$ together with a proof that $Q(f(a)) = P(a)$ for each $a : A$. For future reference, we note that Fam is a functor with action on morphisms $\mathsf{Fam}(h)\,(A, P) = (A, h \circ P)$ and moreover a monad with unit $\eta_{\mathsf{Fam}}(e) = (1, \_ \mapsto e)$ and multiplication $\mu_{\mathsf{Fam}} : \mathsf{Fam}\ (\mathsf{Fam}\ D) \to \mathsf{Fam}\ D$ given by $\mu_{\mathsf{Fam}}(A, P) = \big((\Sigma x : A)(P(x)_0), (x, y) \mapsto (P(x))_1\ y\big)$ where we have written $P(x)_0$ and $P(x)_1$ for the components of the family $P(x) = (P(x)_0, P(x)_1)$.

▶ **Definition 4.** Let $D, E : \mathsf{Set}_1$ and $c : \mathsf{DS}\ D\ E$. We define the *decoding* of c as the functor $[\![\ c\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$ given by $[\![\ c\ ]\!](A,P) = ([\![\ c\ ]\!]_0(A,P), [\![\ c\ ]\!]_1(A,P))$, where $[\![\ \_\ ]\!]_0 : \mathsf{DS}\ D\ E \to \mathsf{Fam}\ D \to \mathsf{Set}$ and $[\![\ \_\ ]\!]_1 : \big(c : \mathsf{DS}\ D\ E\big) \to \big(Z : \mathsf{Fam}\ D\big) \to [\![\ c\ ]\!]_0\ Z \to E$ are defined by

$$
\begin{aligned}
&[\![\ \iota\ e\ ]\!]_0\ (U,T) = 1 && [\![\ \iota\ e\ ]\!]_1\ (U,T)\ \star = e\\
&[\![\ \sigma\ A\ f\ ]\!]_0\ (U,T) = \big(\Sigma a : A\big)([\![\ f\ a\ ]\!]_0\ (U,T)) && [\![\ \sigma\ A\ f\ ]\!]_1\ (U,T)\ (a,x) = [\![\ f\ a\ ]\!]_1\ (U,T)\ x\\
&[\![\ \delta\ A\ F\ ]\!]_0\ (U,T) = && [\![\ \delta\ A\ F\ ]\!]_1\ (U,T)\ (g,x) =\\
&\quad \big(\Sigma g : A \to U\big)([\![\ F\ (T \circ g)\ ]\!]_0\ (U,T)) && \qquad [\![\ F\ (T \circ g)\ ]\!]_1\ (U,T)\ x
\end{aligned}
$$

▶ **Example 5.** For decoding Example 2, note that $\mathsf{Fam}\ 1 \cong \mathsf{Set}$ since the second component of such a family is trivial. Thus, if $(W,T) : \mathsf{Fam}\ 1$, then

$$[\![\ c_{\mathsf{W}\ S\ P}\ ]\!]_0(W,T) = \big(\Sigma s : S\big)\big((P(s) \to W) \times 1\big) \tag{1}$$

such that indeed $\mathsf{sup} : [\![\ c_{\mathsf{W}\ S\ P}\ ]\!]_0(\mathsf{W}\ S\ P, \_) \to \mathsf{W}\ S\ P$ (up to isomorphism), and initial algebras of $[\![\ c_{\mathsf{W}\ S\ P}\ ]\!] : \mathsf{Fam}\ 1 \to \mathsf{Fam}\ 1$ are W-types. Instead of leaving the fibres of the family trivial, we can "upgrade" the given code to do something interesting in the whole family. For instance, if we redefine $c_{\mathsf{W}\ S\ P} : \mathsf{DS}\ \mathsf{Set}\ \mathsf{Set}$ by

$$c_{\mathsf{W}\ S\ P} = \sigma\ S\ (s \mapsto \delta\ P(s)\ (Y \mapsto \iota\ \Big(\big(x : P(s)\big) \to Y\ x\Big)))$$

the index type decoding (1) stays the same, but the decoding $[\![\ c_{\mathsf{W}\ S\ P}\ ]\!]_1(W,T)$ applies T everywhere in the given structure. In particular, if we choose $S = \mathbb{N}$ and $P = \mathsf{Fin}$, where $\mathsf{Fin}\ n$ is a finite type with n elements, then $[\![\ c_{\mathsf{W}\ \mathbb{N}\ \mathsf{Fin}}\ ]\!](W,T) \cong (\mathsf{List}\, W,\ [w_1, \ldots, w_n] \mapsto T\, w_1 \times \ldots \times T\, w_n)$. We will see a use of this upgraded code later in Example 21.

▶ **Example 6.** Similarly, the decoding of the code $c_{2\mathsf{W}} : \mathsf{DS}\ \mathsf{Set}\ \mathsf{Set}$ from Example 3 satisfies $[\![\ c_{2\mathsf{W}}\ ]\!]_0(U,T) \cong 1 + \big(\Sigma s : U\big)(T(s) \to U)$ with $[\![\ c_{2\mathsf{W}}\ ]\!]_1(U,T)\ (\mathsf{inl}\star) = 2$ and $[\![\ c_{2\mathsf{W}}\ ]\!]_1(U,T)\ (\mathsf{inr}\,(s,p)) = \mathsf{W}\ (T\,s)\ (T \circ p)$ which are the equations for a universe closed under W-types.

Dybjer and Setzer [7] also give rules ensuring that $[\![\ c\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ D$ has an initial algebra $(\mathsf{U}_{[\![\ c\ ]\!]}, \mathsf{T}_{[\![\ c\ ]\!]})$ for every $c : \mathsf{DS}\ D\ D$. We omit them here.

2.2 Composition of DS codes

We are now approaching the actual topic of the paper. Given DS-codes $c : \mathsf{DS}\ C\ D$ and $d : \mathsf{DS}\ D\ E$, is there a code $d \bullet c : \mathsf{DS}\ C\ E$ such that $[\![\ d \bullet c\ ]\!](U,T) \cong [\![\ d\ ]\!]([\![\ c\ ]\!](U,T))$? We immediately notice that it is easy to define postcomposition of any code by a ι or a σ code: the functor $[\![\ \iota\ e\ ]\!]$ ignores its argument, hence so must $[\![\ (\iota\ e) \bullet c\ ]\!]$, and for σ codes, we can just proceed structurally. The δ case, however, requires more thought. Again, looking first at the action on index types of the families, we find for the right hand side of the above equation

$$
\begin{aligned}
[\![\ \delta\ A\ F\ ]\!]_0([\![\ c\ ]\!]_0 Z) &= \big(\Sigma g : A \to [\![\ c\ ]\!]_0 Z\big)\big([\![\ F\big([\![\ c\ ]\!]_1(Z) \circ g\big)\ ]\!]_0([\![\ c\ ]\!]Z)\big)\\
&= \Big(\big(A \longrightarrow_{\mathsf{Fam}} [\![\ c\ ]\!]Z\big) \gg\!=_{\mathsf{Fam}} \big(g \mapsto [\![\ F\big([\![\ c\ ]\!]_1(Z) \circ g\big)\ ]\!]_0([\![\ c\ ]\!]Z)\big)\Big)_0
\end{aligned}
$$

where $\_ \gg\!=_{\mathsf{Fam}} \_ : \mathsf{Fam}\ D \to (D \to \mathsf{Fam}\ E) \to \mathsf{Fam}\ E$ is the bind of the Fam monad defined by $Z \gg\!=_{\mathsf{Fam}} h = \mu_{\mathsf{Fam}}\,(\mathsf{Fam}(h)\,Z)$, and

$$
\begin{aligned}
&\_ \longrightarrow_{\mathsf{Fam}} \_ : \big(S : \mathsf{Set}\big) \to \mathsf{Fam}\ D \to \mathsf{Fam}\ (S \to D)\\
&S \longrightarrow_{\mathsf{Fam}} (A,P) = (S \to A, g \mapsto P \circ g)
\end{aligned}
$$

is a power in the category of elements $\big(\Sigma D : \mathsf{Set}_1\big)(\mathsf{Fam}\ D)$ of the functor Fam. This suggests that to define $(\delta\ A\ F) \bullet c$, we need to internalise $\gg\!=_{\mathsf{Fam}}$ and $\longrightarrow_{\mathsf{Fam}}$ in the system DS. The first is readily achievable, because $\mathsf{DS}\ C$ is also a monad [11]:

▶ **Proposition 7.** *There is an operation* $\_ \gg\!= \_ : \mathsf{DS}\ C\ D \to (D \to \mathsf{DS}\ C\ E) \to \mathsf{DS}\ C\ E$ *such that* $[\![\ c \gg\!= g\ ]\!]\ Z \cong [\![\ c\ ]\!]\ Z \gg\!=_{\mathsf{Fam}} (e \mapsto [\![\ g\, e\ ]\!]\ Z)$ *for every* $Z : \mathsf{Fam}\ C$, $c : \mathsf{DS}\ C\ D$ *and* $g : D \to \mathsf{DS}\ C\ E$.

Thus it remains to define powers of codes. Here, however, we hit a wall trying to define $S \longrightarrow c$ by induction on c: to apply the inductive hypothesis on $f\ a$ in the following S-fold power of a σ code

$$S \to [\![\ \sigma\ A\ f\ ]\!]_0\ Z = S \to \big(\Sigma a : A\big)([\![\ f\ a\ ]\!]_0\ Z) \cong \big(\Sigma g : S \to A\big)\big((x : S) \to [\![\ f\ (g\ x)\ ]\!]_0\ Z\big)$$

we would need to generalise our construction to *dependent products* $\big(x : S\big) \to c(x)$ where $c : S \to \mathsf{DS}\ D\ E$. But, if we do so, we can no longer do an induction on c, and we are stuck. Even worse, any definition of composition necessarily involves powers:

▶ **Theorem 8.** *There is a composition operator for* DS *if and only if there is a power operator for* DS. *Here, by composition and power operators we mean terms*

$$\_ \bullet \_ : \mathsf{DS}\ D\ E \to \mathsf{DS}\ C\ D \to \mathsf{DS}\ C\ E$$
$$\_ \longrightarrow \_ : \big(S : \mathsf{Set}\big) \to \mathsf{DS}\ D\ E \to \mathsf{DS}\ D\ (S \to E)$$

respectively such that $[\![\ c \bullet d\ ]\!]\ Z \cong [\![\ c\ ]\!]([\![\ d\ ]\!]\ Z)$ *and* $[\![\ S \longrightarrow c\ ]\!]\ Z \cong (S \longrightarrow_{\mathsf{Fam}} [\![\ c\ ]\!]\ Z)$.

Proof. Given $\_ \longrightarrow \_$, we can define $\_ \bullet \_$ by

$$\begin{aligned}(\iota\ e) \bullet d &= \iota\ e\\ (\sigma\ A\ f) \bullet d &= \sigma\ A\ (a \mapsto (f\ a) \bullet d)\\ (\delta\ A\ F) \bullet d &= (A \longrightarrow d) \gg\!= (g \mapsto (F\ g) \bullet d)\end{aligned}$$

using Proposition 7. Conversely, $A \longrightarrow c \coloneqq (\delta\ A\ (h \mapsto \iota\ h)) \bullet c$ is a power operator. ◀

Two natural options suggest themselves as solutions: (i) restrict codes to ensure that no dependency arises in the definition of powers; (ii) devise a system with dependent products of codes. In the next two sections, we investigate new systems of codes for both of these solutions.

3 Uniform Codes UF for Inductive-Recursive Definitions

This section presents our first new system for induction-recursion with a native composition operation. The system UF of *uniform codes* is a subsystem of DS (Proposition 14). Informally, a uniform code is a DS code where, for every constructor in a term, all immediate subterms have the same root-constructor. Thus (the shape of) $\sigma\ A\ (a \mapsto \delta\ B(a)\ (h \mapsto \iota\ \phi(a, h)))$ is uniform, whereas $\sigma\ A\ f +_{\mathsf{DS}} \delta\ B\ G = \sigma\ 2\ (\mathsf{tt} \mapsto \sigma\ A\ f; \mathsf{ff} \mapsto \delta\ B\ G)$ is not since one subcode is a σ code while the other is a δ one. Uniform codes originated with Peter Hancock [12].

3.1 Definition of UF and its Decoding

Formally, we define a type of codes $\mathsf{Uni}\ D : \mathsf{Set}_1$ determining the code shapes, simultaneously with a function $\mathsf{Info} : \mathsf{Uni}\ D \to \mathsf{Set}_1$, which assigns to each code the information available for indexing codes depending on it, in a uniform way.

▶ **Definition 9.** Let $D, E : \mathsf{Set}_1$. The large type $\mathsf{UF}\ D\ E : \mathsf{Set}_1$ of *uniform codes for induction-recursion* is defined by $\mathsf{UF}\ D\ E \coloneqq \big(\Sigma c : \mathsf{Uni}\ D\big)(\mathsf{Info}\ c \to E)$, where $\mathsf{Uni}\ D : \mathsf{Set}_1$ and $\mathsf{Info} : \mathsf{Uni}\ D \to \mathsf{Set}_1$ are mutually defined by

$$\begin{aligned}
&\iota_{\mathsf{UF}} : \mathsf{Uni}\ D && \mathsf{Info}\ \iota_{\mathsf{UF}} = 1\\
&\sigma_{\mathsf{UF}} : \big(c : \mathsf{Uni}\ D\big) \to (\mathsf{Info}\ c \to \mathsf{Set}) \to \mathsf{Uni}\ D && \mathsf{Info}\ (\sigma_{\mathsf{UF}}\ c\ A) = \big(\Sigma\gamma : \mathsf{Info}\ c\big)(A\ \gamma)\\
&\delta_{\mathsf{UF}} : \big(c : \mathsf{Uni}\ D\big) \to (\mathsf{Info}\ c \to \mathsf{Set}) \to \mathsf{Uni}\ D && \mathsf{Info}\ (\delta_{\mathsf{UF}}\ c\ A) = \big(\Sigma\gamma : \mathsf{Info}\ c\big)(A\ \gamma \to D)
\end{aligned}$$

It is easy to see that $\mathsf{UF}\ D\ \_$ is functorial by function composition (alternatively, it is defined as the action of a container [1], and hence automatically functorial). This two-level presentation of codes $(\mathsf{Uni}, \mathsf{Info})$ has similarities with the $(\mathsf{SP}, \mathsf{Arg})$ presentation of Dybjer-Setzer codes in the original paper [6], where however SP was merely inductively defined, whereas here $(\mathsf{Uni}, \mathsf{Info})$ is itself an inductive-recursive definition. A further difference is that the definition of Uni is left-nested while SP as well as DS are right-nested in the sense of Pollack [15]. This can be seen as the source of uniformity in the definition.

▶ **Example 10** (W-types, again)**.** In order to get a feel for uniform codes, we return to the W-types of Example 2. A uniform code in $\mathsf{UF}\ 1\ 1$ representing the W-type $\mathsf{W}\ S\ P$ is $c_{\mathsf{W}\ S\ P,\mathsf{UF}} = \delta_{\mathsf{UF}}\ \big(\sigma_{\mathsf{UF}}\ \iota_{\mathsf{UF}}\ (\_ \mapsto S)\big)\ ((\_, s) \mapsto P(s)) : \mathsf{Uni}\ 1$, together with the terminal map $\mathsf{Info}\ c_{\mathsf{W}\ S\ P,\mathsf{UF}} \to 1$. If we compare this to the Dybjer-Setzer code from Example 2, we see that the order of the (non-base-case) constructors is reversed:

$$\begin{aligned}
(\delta_{\mathsf{UF}}\ \big(\sigma_{\mathsf{UF}}\ \iota_{\mathsf{UF}}\ (_ \mapsto S)\big)\ ((_, s) \mapsto P(s))\ ,\ _ \mapsto \star) &: \mathsf{UF}\ 1\ 1\\
\sigma\ S\ (s \mapsto \delta\ P(s)\ (_ \mapsto \iota\star)) &: \mathsf{DS}\ 1\ 1
\end{aligned}$$

Also this code can be "upgraded" to a more interesting $\mathsf{UF}\ \mathsf{Set}\ \mathsf{Set}$ code applying a given T everywhere. We get the same decoding as in Example 5 if we replace the trivial map $(\_ \mapsto \star) : \mathsf{Info}\ c_{\mathsf{W}\ S\ P,\mathsf{UF}} \to 1$ by the map $(s, Y, \star) \mapsto \big(x : P(s)\big) \to Y\ x$.

▶ **Example 11** (A universe closed under W-types, again)**.** Example 3 uses coproducts of DS codes. Coproducts of uniform codes a priori do not always exist as the different summands may have different shapes. However, we will prove coproducts of uniform codes to exist in Section 3.3. Assuming, for now, the coproduct $\_ +_{\mathsf{UF}} \_ : \mathsf{UF}\ D\ E \to \mathsf{UF}\ D\ E \to \mathsf{UF}\ D\ E$, we construct the code $c_{2,\mathsf{UF}} +_{\mathsf{UF}} c_{\mathsf{W},\mathsf{UF}} : \mathsf{UF}\ \mathsf{Set}\ \mathsf{Set}$ from the following summands – again note that the nesting is the other way around compared to the DS code in Example 3:

$$\begin{aligned}
c_{2,\mathsf{UF}} &= (\iota_{\mathsf{UF}}, \star \mapsto 2) : \mathsf{UF}\ \mathsf{Set}\ \mathsf{Set}\\
c_{\mathsf{W},\mathsf{UF}} &= \big(\delta_{\mathsf{UF}}\ \big(\delta_{\mathsf{UF}}\ \iota_{\mathsf{UF}}\ (\star \mapsto 1)\big)\ ((\star, S) \mapsto S\star), ((\star, S), P) \mapsto \mathsf{W}\ (S\star)\ P\big) : \mathsf{UF}\ \mathsf{Set}\ \mathsf{Set}
\end{aligned}$$

Decoding of uniform codes $\mathsf{UF}\ D\ E$ is again given by functors $\mathsf{Fam}\ D \to \mathsf{Fam}\ E$. The definition is very similar to the decoding of DS codes except that UF codes have two components. We use the same notation $[\![-]\!]$ for decoding a uniform code as for decoding a DS code; this convention is reasonable since we will give a semantics-preserving translation from UF to DS in Section 3.2.

▶ **Definition 12.** Let $c : \mathsf{Uni}\ D$ and $\alpha : \mathsf{Info}\ c \to E$. The uniform code $(c, \alpha) : \mathsf{UF}\ D\ E$ induces a functor $[\![\ c, \alpha\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$ by $[\![\ c, \alpha\ ]\!]\ Z = \mathsf{Fam}(\alpha)\ ([\![\ c\ ]\!]_{\mathsf{Uni}}\ Z, [\![\ c\ ]\!]_{\mathsf{Info}}\ Z)$ where $[\![\ \_\ ]\!]_{\mathsf{Uni}} : \mathsf{Uni}\ D \to \mathsf{Fam}\ D \to \mathsf{Set}$ and $[\![\ \_\ ]\!]_{\mathsf{Info}} : \big(c : \mathsf{Uni}\ D\big) \to \big(Z : \mathsf{Fam}\ D\big) \to [\![\ c\ ]\!]_{\mathsf{Uni}}\ Z \to \mathsf{Info}\ c$ are simultaneously defined by induction on c:

$$\begin{aligned}
&[\![\ \iota_{\mathsf{UF}}\ ]\!]_{\mathsf{Uni}}\ (U,T) = 1 && [\![\ \iota_{\mathsf{UF}}\ ]\!]_{\mathsf{Info}}\ (U,T)\ \star = \star \\
&[\![\ \sigma_{\mathsf{UF}}\ c\ A\ ]\!]_{\mathsf{Uni}}\ (U,T) = && [\![\ \sigma_{\mathsf{UF}}\ c\ A\ ]\!]_{\mathsf{Info}}\ (U,T)\ (x,a) = \\
&\quad \big(\Sigma x : [\![\ c\ ]\!]_{\mathsf{Uni}}\ (U,T)\big)(A([\![\ c\ ]\!]_{\mathsf{Info}}\ (U,T)\ x)) && \quad ([\![\ c\ ]\!]_{\mathsf{Info}}\ (U,T)\ x, a) \\
&[\![\ \delta_{\mathsf{UF}}\ c\ A\ ]\!]_{\mathsf{Uni}}\ (U,T) = && [\![\ \delta_{\mathsf{UF}}\ c\ A\ ]\!]_{\mathsf{Info}}\ (U,T)\ (x,g) = \\
&\quad \big(\Sigma x : [\![\ c\ ]\!]_{\mathsf{Uni}}\ (U,T)\big)(A([\![\ c\ ]\!]_{\mathsf{Info}}\ (U,T)\ x) \to U) && \quad ([\![\ c\ ]\!]_{\mathsf{Info}}\ (U,T)\ x, T \circ g)
\end{aligned}$$

▶ **Example 13.** Decoding $c_{\mathsf{W}\ S\ P,\mathsf{UF}}$ from Example 10, we see that

$$[\![\ c_{\mathsf{W}\ S\ P,\mathsf{UF}}\ ]\!]_{\mathsf{Uni}}\ (U,T) = \big(\Sigma(\star, s) : 1 \times S\big)(P(s) \to U)$$

which is isomorphic to the domain of the W-type constructor sup, but this time nested the other way compared to the decoding of $c_{\mathsf{W}\ S\ P}$ in Example 5. By Theorem 18, we will have $[\![\ c +_{\mathsf{UF}} d\ ]\!]\ Z \cong [\![\ c\ ]\!]\ Z\ + [\![\ d\ ]\!]\ Z$, where the right hand side uses the coproduct of families. Hence $c_{2,\mathsf{UF}} +_{\mathsf{UF}} c_{\mathsf{W},\mathsf{UF}}$ from Example 11 decodes correctly.

3.2 Embedding of UF into DS

We embed UF into DS, i.e. we give a translation of codes which is *semantics-preserving* in that the decoding of a code is isomorphic to the decoding of its translation. Since UF codes are "backwards" compared to DS codes, this embedding resembles the well-known accumulator based algorithm for reversing a list. Define $\mathsf{accUFtoDS} : \big(c : \mathsf{Uni}\ D\big) \to (\mathsf{Info}\ c \to \mathsf{DS}\ D\ E) \to \mathsf{DS}\ D\ E$ (the second argument is the accumulator) by

$$\begin{aligned}
\mathsf{accUFtoDS}\ \iota_{\mathsf{UF}}\ F &= F\ \star \\
\mathsf{accUFtoDS}\ (\sigma_{\mathsf{UF}}\ c\ A)\ F &= \mathsf{accUFtoDS}\ c\ (\gamma \mapsto \sigma\ (A\ \gamma)\ (a \mapsto F\ (\gamma, a))) \\
\mathsf{accUFtoDS}\ (\delta_{\mathsf{UF}}\ c\ A)\ F &= \mathsf{accUFtoDS}\ c\ (\gamma \mapsto \delta\ (A\ \gamma)\ (h \mapsto F\ (\gamma, h)))
\end{aligned}$$

and define $\mathsf{UFtoDS} : \mathsf{UF}\ D\ E \to \mathsf{DS}\ D\ E$ by kicking things off with a ι:

$$\mathsf{UFtoDS}\ (c, \alpha) = \mathsf{accUFtoDS}\ c\ (\iota \circ \alpha)\ .$$

▶ **Proposition 14.** *The translation* UFtoDS *is an embedding, i.e. for every* $c : \mathsf{UF}\ D\ E$ *and* $Z : \mathsf{Fam}\ D$*, we have* $[\![\ \mathsf{UFtoDS}\ c\ ]\!]\ Z \cong [\![\ c\ ]\!]\ Z$*.*

3.3 Coproducts of Uniform Codes

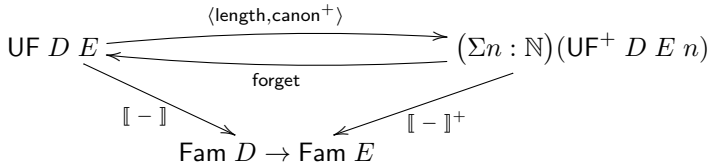
The coproduct $c +_{\mathsf{DS}} d := \sigma\ 2\ (\mathsf{tt} \mapsto c; \mathsf{ff} \mapsto d)$ of two DS codes is not in general the embedding of a uniform code, even if c and d are, as c and d may still have different shapes. Hence we cannot immediately use the same construction to define coproducts of uniform codes, but we note that whenever c and d do have the same shape, this construction still works. Our plan for constructing coproducts of uniform codes is then to find equivalent replacements of the summands, such that the new pair has a common shape, and then using the standard coproduct. To this end, we introduce an $\mathbb{N}$-indexed variant $\mathsf{UF}^+\ D\ E\ n = \big(\Sigma c : \mathsf{Uni}^+\ D\ n\big)(\mathsf{Info}^+\ c \to E)$ of UF for this section only. There are two differences between UF^+ and UF: firstly, UF^+ is indexed by the length n of its codes, and secondly in UF^+ the δ_{UF} and σ_{UF} codes are replaced by a combined code

$$\begin{aligned}
\delta\sigma : \big(c : \mathsf{Uni}^+\ D\ n\big) \to \big(A : \mathsf{Info}^+\ c \to \mathsf{Set}\big) \to \\
\big((\gamma : \mathsf{Info}^+\ c) \to A\ \gamma \to \mathsf{Set}\big) \to \mathsf{Uni}^+\ D\ (\mathsf{suc}\ n)
\end{aligned}$$

with $\mathsf{Info}^+\ (\delta\sigma\ c\ A\ B) = \big(\Sigma\gamma : \mathsf{Info}^+\ c\big)\big(\Sigma x : A\ \gamma\big)(B\ \gamma\ x \to D)$. The code $\delta\sigma$ should be thought of as a δ_{UF} code followed by a σ_{UF} code. We can recover "ordinary" σ_{UF} and δ_{UF} by $\sigma_+\ c\ A \coloneqq \delta\sigma\ c\ A\ (\_,\_ \mapsto 0)$ and $\delta_+\ c\ B \coloneqq \delta\sigma\ c\ (\_ \mapsto 1)(\gamma,\_ \mapsto B\,\gamma)$. We have just informally described translations $\mathsf{forget} : \mathsf{UF}^+\ D\ E\ n \to \mathsf{UF}\ D\ E$ and $\mathsf{canon}^+ : \big(c : \mathsf{UF}\ D\ E\big) \to \mathsf{UF}^+\ D\ E\ (\mathsf{length}\,c)$, where length counts the depth of the code c. A decoding $[\![-]\!]^+$ can be defined for UF^+ along the lines for the one for UF (alternatively, Proposition 15(ii) below can be used as a definition).

▶ **Proposition 15.** *Let $D, E : \mathsf{Set}_1$ and $Z : \mathsf{Fam}\ D$. If $c : \mathsf{UF}\ D\ E$ and $d : \mathsf{UF}^+\ D\ E\ n$, then (i) $[\![\ \mathsf{canon}^+\ c\ ]\!]^+\ Z \cong [\![\ c\ ]\!]\ Z$; and (ii) $[\![\ \mathsf{forget}\ d\ ]\!]\ Z \cong [\![\ d\ ]\!]^+\ Z$.*

This proposition can be summed up in the following commuting diagram:



Next, note $[\![\ \delta\sigma\ c\ 1\ (\_ \mapsto 0)\ ]\!]^+\ Z \cong [\![\ c\ ]\!]^+\ Z$. Thus we can pad out $c : \mathsf{UF}^+\ D\ E\ n$ to $\mathsf{pad}_k\ c : \mathsf{UF}^+\ D\ E\ (n + k + 1)$ without changing the meaning of the code:

▶ **Lemma 16.** *Let $k : \mathbb{N}$. There is an operation $\mathsf{pad}_k : \mathsf{UF}^+\ D\ E\ n \to \mathsf{UF}^+\ D\ E\ (n + k + 1)$ such that $[\![\ \mathsf{pad}_k\ c\ ]\!]^+\ Z \cong [\![\ c\ ]\!]^+\ Z$ for every $Z : \mathsf{Fam}\ D$.*

Since all UF^+ codes of the same length also are of the same shape, it is now easy to form coproducts of such codes. Define $\_ +_+ \_ : \mathsf{UF}^+\ D\ E\ n \to \mathsf{UF}^+\ D\ E\ n \to \mathsf{UF}^+\ D\ E\ (\mathsf{suc}\,n)$ by $(c, \alpha) +_+ (d, \beta) = (c +_{\mathsf{Uni}} d, [\alpha, \beta] \circ (c +_{\mathsf{Info}} d))$ where $\_ +_{\mathsf{Uni}} \_$ is defined by

$$\iota_+ +_{\mathsf{Uni}} \iota_+ = \sigma_+\ \iota_+\ (\_ \mapsto 2)$$
$$(\delta\sigma\ c\ A\ B) +_{\mathsf{Uni}} (\delta\sigma\ d\ A'\ B') = \delta\sigma\ (c +_{\mathsf{Uni}} d)\ ([A, A'] \circ (c +_{\mathsf{Info}} d))\ ([B, B'] \circ (c +_{\mathsf{Info}} d))$$

simultaneously with a map $(c +_{\mathsf{Info}} d) : \mathsf{Info}^+\ (c +_{\mathsf{Uni}} d) \to \mathsf{Info}^+\ c + \mathsf{Info}^+\ d$, whose definition is similar. Note that we did not need to consider the definition of e.g. $\iota_+ +_{\mathsf{Uni}} (\delta\sigma\ c\ A\ B)$ as these summands cannot possibly have the same length.

▶ **Lemma 17.** *For all $c, d : \mathsf{UF}^+\ D\ E\ n$ and $Z : \mathsf{Fam}\ D$ we have $[\![\ c +_+ d\ ]\!]^+\ Z \cong [\![\ c\ ]\!]^+\ Z + [\![\ d\ ]\!]^+\ Z$, where the right hand side is a coproduct of families.*

Putting everything together, we have:

▶ **Theorem 18.** *Let $D, E : \mathsf{Set}_1$. Define $\_ +_{\mathsf{UF}} \_ : \mathsf{UF}\ D\ E \to \mathsf{UF}\ D\ E \to \mathsf{UF}\ D\ E$ by $c +_{\mathsf{UF}} d = \mathsf{forget}\ (\mathsf{canon}^+\ c +_+ \mathsf{canon}^+\ d)$. Then $[\![\ c +_{\mathsf{UF}} d\ ]\!]\ Z \cong [\![\ c\ ]\!]\ Z + [\![\ d\ ]\!]\ Z$.*

3.4 Composition of uniform Codes

Recall Section 2.2, where composition of DS codes followed from a power operation which – because of the dependency arising in its attempted construction – we could not define. Fortunately, in UF, a power operator is definable! Composition is here – as for DS – facilitated by a conjunction of the power operation and a bind operator. A full bind operation for UF is not definable since the grafting of uniform trees into a uniform tree may not be uniform since the trees may differ in height (i.e. UF is not a monad). However, for composition, it suffices to graft trees of the *same* height. Define $- \gg\!=[- \longrightarrow -] : \big(c : \mathsf{Uni}\ D\big) \to (\mathsf{Info}\ c \to$

$\mathsf{Set}) \to \mathsf{Uni}\ D \to \mathsf{Uni}\ D$, together with $(c \gg\!=\![E \longrightarrow d])_{\mathsf{Info}} : \mathsf{Info}\ (c \gg\!=\![E \longrightarrow d]) \to \big(\Sigma x : \mathsf{Info}\ c\big)(E\,x \to \mathsf{Info}\ d)$, which explains the meaning of $c \gg\!=\![E \longrightarrow d]$ at the level of Info. We write $\gg\!=_{\mathsf{Info},0}$ and $\gg\!=_{\mathsf{Info},1}$ for the first and second projection of $(c \gg\!=\![E \longrightarrow d])_{\mathsf{Info}}$ respectively, inferring the other arguments from context:

$$
\begin{aligned}
&c \gg\!=\![E \longrightarrow \iota_{\mathsf{UF}}] = c\\
&c \gg\!=\![E \longrightarrow \sigma_{\mathsf{UF}}\ d\ A]\\
&\qquad = \sigma_{\mathsf{UF}}\ (c \gg\!=\![E \longrightarrow d])(\gamma \mapsto \big(e : E(\gg\!=_{\mathsf{Info},0}\ \gamma)\big) \to A(\gg\!=_{\mathsf{Info},1}\ \gamma\, e))\\
&c \gg\!=\![E \longrightarrow \delta_{\mathsf{UF}}\ d\ A] =\\
&\qquad = \delta_{\mathsf{UF}}\ (c \gg\!=\![E \longrightarrow d])(\gamma \mapsto \big(\Sigma e : E(\gg\!=_{\mathsf{Info},0}\ \gamma)\big)A(\gg\!=_{\mathsf{Info},1}\ \gamma\, e))
\end{aligned}
$$

$$
\begin{aligned}
&(c \gg\!=\![E \longrightarrow \iota_{\mathsf{UF}}])_{\mathsf{Info}}\ x = (x, (\_ \mapsto \star))\\
&(c \gg\!=\![E \longrightarrow \sigma_{\mathsf{UF}}\ d\ A])_{\mathsf{Info}}\ (x, g) = (\gg\!=_{\mathsf{Info},0}\ \ x, e \mapsto (\gg\!=_{\mathsf{Info},0}\ \ x\ e, g\ e))\\
&(c \gg\!=\![E \longrightarrow \delta_{\mathsf{UF}}\ d\ A])_{\mathsf{Info}}\ (x, g) = (\gg\!=_{\mathsf{Info},0}\ \ x, e \mapsto (\gg\!=_{\mathsf{Info},0}\ \ x\ e, (a \mapsto g\ (e, a)))
\end{aligned}
$$

This definition is validated by the following proposition:

▶ **Proposition 19.** *There is an equivalence*

$$[\![\ c \gg\!=\![E \longrightarrow d], (d \gg\!=\![E \longrightarrow d])_{\mathsf{Info}}\ ]\!] \cong ([\![\ c, \mathsf{id}\ ]\!]) \gg\!=_{\mathsf{Fam}} (e \mapsto ((E\ e) \longrightarrow_{\mathsf{Fam}} [\![\ d, \mathsf{id}\ ]\!]))$$

▶ Remark. While is not possible to derive a bind operator from $\_ \gg\!=\![\_ \longrightarrow \_]$, we do obtain a power operator with the right universal property by

$$A \longrightarrow (c, f) \coloneqq (\iota_{\mathsf{UF}} \gg\!=\![(\_ \mapsto A) \longrightarrow c], (\gamma \mapsto f \circ \gg\!=_{\mathsf{Info},1}))\ .$$

(This fact will not be needed in the proof of composition in Theorem 20.)

We can now define composition for UF codes in a fashion similar to Theorem 8, except that we separate the action of the first component of a code and take care of the second component in a second step:

▶ **Theorem 20.** *The operations*

$$
\begin{aligned}
&\_ \bullet_{\mathsf{Uni}} \_ : \mathsf{Uni}\ D \to \mathsf{UF}\ C\ D \to \mathsf{Uni}\ C\\
&(\_ \bullet_{\mathsf{Info}} \_) : \big(c : \mathsf{Uni}\ D\big) \to \big(R : \mathsf{UF}\ C\ D\big) \to \mathsf{Info}\ (c \bullet_{\mathsf{Uni}} R) \to \mathsf{Info}\ c
\end{aligned}
$$

simultaneously defined by

$$
\begin{aligned}
\iota_{\mathsf{UF}} \bullet_{\mathsf{Uni}} R &= \iota_{\mathsf{UF}}\\
(\sigma_{\mathsf{UF}}\ c\ A) \bullet_{\mathsf{Uni}} R &= \sigma_{\mathsf{UF}}\ (c \bullet_{\mathsf{Uni}} R)\ (A \circ (c \bullet_{\mathsf{Info}} R))\\
(\delta_{\mathsf{UF}}\ c\ A) \bullet_{\mathsf{Uni}} (d, \beta) &= (c \bullet_{\mathsf{Uni}} (d, \beta)) \gg\!=\![(A \circ (c \bullet_{\mathsf{Info}} (d, \beta))) \longrightarrow d]\\
(\iota_{\mathsf{UF}} \bullet_{\mathsf{Info}} R)\ x &= x\\
((\sigma_{\mathsf{UF}}\ c\ A) \bullet_{\mathsf{Info}} R)\ (x, y) &= ((c \bullet_{\mathsf{Info}} R)\ x, y)\\
((\delta_{\mathsf{UF}}\ c\ A) \bullet_{\mathsf{Info}} (d, \beta))\ x &= ((c \bullet_{\mathsf{Info}} (d, \beta))\ (\gg\!=_{\mathsf{Info},0}\ \ x, \beta \circ (\gg\!=_{\mathsf{Info},1}\ \ x)))
\end{aligned}
$$

make $\_ \bullet \_ : \mathsf{UF}\ D\ E \to \mathsf{UF}\ C\ D \to \mathsf{UF}\ C\ E$ *a composition operation for* UF *codes, where*

$$(c, \alpha) \bullet (d, \beta) = (c \bullet_{\mathsf{Uni}} (d, \beta), \alpha \circ (c \bullet_{\mathsf{Info}} (d, \beta)))\ .$$

▶ **Example 21.** If we compose c_{2W} from Example 11 with the "upgraded" code $c_{\mathsf{W}\,\mathbb{N}\,\mathsf{Fin}}$ from Example 10, we get a code for a universe where each constructor now takes a list of inductive arguments, with decoding the product of the decodings. Up to an isomorphism relating coproducts of compositions with compositions of coproducts, the resulting code is $c_{\mathsf{2W}} \bullet c_{\mathsf{W}\,\mathbb{N}\,\mathsf{Fin}} \cong c_{2,\mathsf{UF}} +_{\mathsf{UF}} c'_{W,\mathsf{UF}}$, where $c_{2,\mathsf{UF}}$ is as before, and

$$\begin{aligned} c'_{W,\mathsf{UF}} = (\delta_{\mathsf{UF}}\ (\sigma_{\mathsf{UF}}\ c_{\mathsf{W}\,\mathbb{N}\,\mathsf{Fin}}\ ((\star, n, Y) &\mapsto ((x : \mathsf{Fin}\,n) \to Y\,x) \to \mathbb{N})) \\ ((\star, n, Y, e) &\mapsto (\Sigma y : (x : \mathsf{Fin}\,n) \to Y\,x)\mathsf{Fin}\,(e\,y)), \\ ((\star, n, Y, e, B) &\mapsto (\Sigma y : (x : \mathsf{Fin}\,n) \to Y\,x)(w : \mathsf{Fin}\,(e\,y)) \to B\,(y, w))) \ . \end{aligned}$$

4 Polynomial Codes PN for Inductive-Recursive Definitions

We saw in Section 2.2 that composition for Dybjer-Setzer codes requires a power operator. However, simply adding a code for powers means that $\mathsf{DS}\ D\ \_$ is no longer a monad, and the bind operation was crucial for constructing composition. Hence, further adjustments are required. Following this line of thought results in a system including sums and type-indexed products. For this reason, we call it *polynomial inductive-recursive definitions*, and denote it by PN. It was originally invented by the second author in order to make induction-recursion resemble the descriptions of datatypes in Chapman et al. [3]. Just like uniform codes, polynomial codes are presented as a two-level definition which itself is an inductive-recursive definition:

▶ **Definition 22.** Let $D, E : \mathsf{Set}_1$. The large type $\mathsf{PN}\ D\ E : \mathsf{Set}_1$ of *polynomial codes for induction-recursion* is defined by $\mathsf{PN}\ D\ E \coloneqq (\Sigma c : \mathsf{Poly}\,\mathsf{D})(\mathsf{Info}\,\mathsf{c} \to E)$, where $\mathsf{Poly}\,\mathsf{D} : \mathsf{Set}_1$ and $\mathsf{Info} : \mathsf{Poly}\,\mathsf{D} \to \mathsf{Set}_1$ are mutually defined by

$$\begin{array}{rll} \mathsf{id}_{\mathsf{PN}} : \mathsf{Poly}\,\mathsf{D} & & \mathsf{Info}\,\mathsf{id}_{\mathsf{PN}} = D \\ \mathsf{con} : (A : \mathsf{Set}) \to \mathsf{Poly}\,\mathsf{D} & & \mathsf{Info}\,(\mathsf{con}\,\mathsf{A}) = A \\ \mathsf{sig} : (S : \mathsf{Poly}\,\mathsf{D}) \to (\mathsf{Info}\,\mathsf{S} \to \mathsf{Poly}\,\mathsf{D}) \to \mathsf{Poly}\,\mathsf{D} & & \mathsf{Info}\,(\mathsf{sig}\,\mathsf{S}\,\mathsf{F}) = (\Sigma x : \mathsf{Info}\,\mathsf{S})(\mathsf{Info}\,(\mathsf{F}\,\mathsf{x})) \\ \mathsf{pi} : (A : \mathsf{Set}) \to (A \to \mathsf{Poly}\,\mathsf{D}) \to \mathsf{Poly}\,\mathsf{D} & & \mathsf{Info}\,(\mathsf{pi}\,\mathsf{A}\,\mathsf{F}) = (x : A) \to \mathsf{Info}\,(\mathsf{F}\,\mathsf{x}) \end{array}$$

Warning: polynomial codes should not be confused with polynomial functors [9, 10]! We use the same name Info as in uniform codes for the function computing the information represented by a code. The code $\mathsf{id}_{\mathsf{PN}}$ represents the identity functor, $\mathsf{con}\ A$ the functor constantly returning index type A, $\mathsf{sig}\ S\ F$ represents a dependent coproduct of functors, and $\mathsf{pi}\ A\ F$ represents an A-indexed dependent product of functors. Observe that $\mathsf{PN}\ D\ \_$ is again, like $\mathsf{UF}\ D\ \_$, functorial by function composition.

▶ **Example 23** (W-types, again)**.** We revisit Examples 2 and 10. For $S : \mathsf{Set}$, $P : S \to \mathsf{Set}$ the polynomial code for the W-type $\mathsf{W}\ S\ P$ is $(c_{\mathsf{W}\ S\ P,\mathsf{PN}}, \_ \mapsto \star) : \mathsf{PN}\ 1\ 1$ where $c_{\mathsf{W}\ S\ P,\mathsf{PN}} = \mathsf{sig}\ (\mathsf{con}\ S)(s \mapsto\ \ \mathsf{pi}\ (P\ s)\ (\_ \mapsto \mathsf{id}_{\mathsf{PN}}))$. Again this can be upgraded to a PN Set Set code, applying $T : U \to \mathsf{Set}$ everywhere in the structure, by replacing the trivial map $(\_ \mapsto \star) : \mathsf{Info}\,\mathsf{c}_{\mathsf{W}\ \mathsf{S}\ \mathsf{P},\mathsf{PN}} \to 1$ by the map $((s, Y) \mapsto (c : P(s)) \to Y\,x) : \mathsf{Info}\,\mathsf{c}_{\mathsf{W}\ \mathsf{S}\ \mathsf{P},\mathsf{PN}} \to \mathsf{Set}$.

▶ **Example 24** (A universe closed under W-types, again)**.** We also revisit Example 3 again. A polynomial code $(c_{\mathsf{2W},\mathsf{PN}}, \alpha) : \mathsf{PN}\ \mathsf{Set}\ \mathsf{Set}$ for a universe containing 2, closed under W-types is given by $c_{\mathsf{2W},\mathsf{PN}} : \mathsf{Poly}\ \mathsf{Set}$ and $\alpha_{\mathsf{2W},\mathsf{PN}} : \mathsf{Info}\,\mathsf{c}_{\mathsf{2W},\mathsf{PN}} \to \mathsf{Set}$ where

$$c_{\mathsf{2W},\mathsf{PN}} = \mathsf{sig}\ (\mathsf{con}\ \{\mathsf{two}, \mathsf{w}\})(\mathsf{two} \mapsto \mathsf{con}\ 1; \mathsf{w} \mapsto \mathsf{sig}\ \mathsf{id}_{\mathsf{PN}}\ (X \mapsto \mathsf{pi}\ X\ (\_ \mapsto \mathsf{id}_{\mathsf{PN}})))$$

and $\alpha_{\mathsf{2W},\mathsf{PN}}$ is defined by $\alpha_{\mathsf{2W},\mathsf{PN}}(\mathsf{two}, x) = 2$ and $\alpha_{\mathsf{2W},\mathsf{PN}}(\mathsf{w}, (A, B)) = \mathsf{W}\ S\ P$.

▶ Remark. One obtains a weaker system by replacing the pi code by a code $\mathsf{pow} : \mathsf{Set} \to \mathsf{Poly}\ D \to \mathsf{Poly}\ D$ with $\mathsf{Info}\,(\mathsf{pow}\,\mathsf{A}\,\mathsf{c}) = A \to \mathsf{Info}\,\mathsf{c}$. In the full system, such a code can be defined by $\mathsf{pow}\ A\ c \coloneqq \mathsf{pi}\ A\ (\_ \mapsto c)$. The weaker system also enjoys composition, and the embedding of Dybjer-Setzer codes in Section 4.1 factors through the system with powers only. Semantically, the stronger system is just as easy to handle (see Theorem 27 below).

Polynomial codes in $\mathsf{PN}\ D\ E$ decode to functors $\mathsf{Fam}\ D \to \mathsf{Fam}\ E$ in the following way:

▶ **Definition 25.** Let $c : \mathsf{Poly}\ D$ and $\alpha : \mathsf{Info}\,\mathsf{c} \to E$. The polynomial code $(c, \alpha) : \mathsf{PN}\ D\ E$ induces a functor $[\![\ c, \alpha\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ E$ by $[\![\ c, \alpha\ ]\!]\ Z = \mathsf{Fam}(\alpha)\ ([\![\ c\ ]\!]_0\ Z, [\![\ c\ ]\!]_{\mathsf{info}}\ Z)$ where $[\![\ c\ ]\!]_0 : \mathsf{Fam}\ D \to \mathsf{Set}$ and $[\![\ c\ ]\!]_{\mathsf{info}} : (X : \mathsf{Fam}\ D) \to [\![\ c\ ]\!]_0\ X \to \mathsf{Info}\,\mathsf{c}$ are simultaneously defined by induction on c:

$$[\![\ \mathsf{id_{PN}}\ ]\!]_0\ (U,T) = U \qquad [\![\ \mathsf{id_{PN}}\ ]\!]_{\mathsf{info}}\ (U,T)\ x = T\,x$$
$$[\![\ \mathsf{con}\ A\ ]\!]_0\ X = A \qquad [\![\ \mathsf{con}\ A\ ]\!]_{\mathsf{info}}\ X\ a = a$$
$$[\![\ \mathsf{sig}\ S\ F\ ]\!]_0\ (U,T) = \big(\Sigma s : [\![\ S\ ]\!]_0\ (U,T)\big)([\![\ F([\![\ S\ ]\!]_{\mathsf{info}}\ (U,T)\ s)\ ]\!]_0\ (U,T))$$
$$[\![\ \mathsf{sig}\ S\ F\ ]\!]_{\mathsf{info}}\ (U,T)\ (s,x) = ([\![\ S\ ]\!]_{\mathsf{info}}\ (U,T)\ s, [\![\ F\ ([\![\ S\ ]\!]_{\mathsf{info}}\ (U,T)\ s)\ ]\!]_{\mathsf{info}}\ (U,T)\ x)$$
$$[\![\ \mathsf{pi}\ A\ F\ ]\!]_0\ X = \big(x : A\big) \to [\![\ Fx\ ]\!]_0\ X \qquad [\![\ \mathsf{pi}\ A\ F\ ]\!]_{\mathsf{info}}\ X\ g = (a \mapsto [\![\ (Fa)\ ]\!]_{\mathsf{info}}\ X\ (g\ a))$$

▶ **Example 26.** Decoding $c_{\mathsf{W}\ S\ P,\mathsf{PN}}$ from Example 23, we get

$$[\![\ c_{\mathsf{W}\ S\ P,\mathsf{PN}}\ ]\!]_0\ (U,T) = \big(\Sigma s : S\big)(P(s) \to U)$$

this time matching the domain of the W-type constructor sup strictly. Similarly decoding $(c_{\mathsf{2W},\mathsf{PN}}, \alpha_{\mathsf{2W},\mathsf{PN}})$ from Example 24 we again get the same result as in Example 6.

Since we did not exhibit PN as a subsystem of DS, we cannot rely on Dybjer and Setzer's proof of soundness, i.e. that initial algebras of the corresponding functors exist in their model. We can, however, extend their proof to polynomial codes[2]:

▶ **Theorem 27.** *Working in ZFC, assume the existence of a Mahlo cardinal* M *and a 1-inaccessible cardinal* I *above it. Then there is a set-theoretic model of Martin-Löf Type Theory +* PN *where types* $A : \mathsf{Set}$ *are interpreted as sets in* V_{M} *and large types* $D : \mathsf{Set}_1$ *are interpreted as sets in* V_{I} *(here* V_α *is the cumulative hierarchy). In this model, all functors* $[\![\ c\ ]\!] : \mathsf{Fam}\ D \to \mathsf{Fam}\ D$ *arising from polynomial codes* $c : \mathsf{PN}\ D\ D$ *have initial algebras.*

Note that the existence of large cardinals is only needed for the soundness proof, and not for working within the theory itself. The same situation applies to Dybjer and Setzer's DS.

4.1 Embedding of DS into PN

▶ **Proposition 28.** *The map* $\mathsf{DStoPN} : \mathsf{DS}\ D\ E \to \mathsf{PN}\ D\ E$ *given by* $\mathsf{DStoPN}\,c = (\mathsf{toP}\,c, \mathsf{tol}\,c)$ *where* $\mathsf{toP} : \mathsf{DS}\ D\ E \to \mathsf{Poly}\,\mathsf{D}$ *and* $\mathsf{tol} : \big(c : \mathsf{DS}\ D\ E\big) \to \mathsf{Info}\,(\mathsf{toP}\,\mathsf{c}) \to E$ *are defined by*

$$\mathsf{toP}(\iota\ e) = \mathsf{con}\,1 \qquad \mathsf{tol}(\iota\ e)\star = e$$
$$\mathsf{toP}(\sigma\ A\ f) = \mathsf{sig}\,(\mathsf{con}A)\,(\mathsf{toP} \circ f) \qquad \mathsf{tol}(\sigma\ A\ f)\,(a,x) = \mathsf{tol}\,(f\ a)\,x$$
$$\mathsf{toP}(\delta\ A\ F) = \mathsf{sig}\,(\mathsf{pi}\,A\,(\_ \mapsto \mathsf{id_{PN}}))\,(\mathsf{toP} \circ F) \qquad \mathsf{tol}(\delta\ A\ F)\,(g,x) = \mathsf{tol}\,(F\ g)\,x$$

is semantics-preserving.

We conjecture that this embedding is strict, i.e. that there is a code $c : \mathsf{PN}\ D\ E$ with $[\![\ c\ ]\!] \not\simeq [\![\ \mathsf{DStoPN}\ d\ ]\!]$ for every $d : \mathsf{DS}\ D\ E$ for some $D, E : \mathsf{Set}_1$.

[2] We require a little bit more from the metatheory: Dybjer and Setzer [8] require I to be 0-inaccessible only. But existence of I is a mild assumption compared to the existence of M.

4.2 Composition of Polynomial Codes

Composition for PN codes can be defined following the same pattern as in Proposition 8, where we constructed composition for DS codes using the assumption of a power operation, and the fact that DS is a monad. The system PN has a power operation using the pi constructor, and is a monad thanks to the sig constructor:

▶ **Proposition 29.** *For each* $D : \mathsf{Set}_1$, $\mathsf{PN}\ D$ *is a monad, i.e. there are terms* $\eta_{\mathsf{PN}} : E \to \mathsf{PN}\ D\ E$ *and* $\mu_{\mathsf{PN}} : \mathsf{PN}\ D\ (\mathsf{PN}\ D\ E) \to \mathsf{PN}\ D\ E$ *satisfying the monad laws. Furthermore, let* $(U,T) : \mathsf{Fam}\ D$. *Then* $[\![\ \eta_{\mathsf{PN}}(e)\ ]\!](U,T) = \eta_{\mathsf{Fam}}(e)$ *for every* $e : E$ *and , and* $[\![\ \mu_{\mathsf{PN}}(c)\ ]\!](U,T) = \mu_{\mathsf{Fam}}(\mathsf{Fam}([\![\ -\ ]\!](U,T))([\![\ c\ ]\!](U,T)))$ *for every* $c : \mathsf{PN}\ D\ (\mathsf{PN}\ D\ E)$.

Proof. We define $\eta_{\mathsf{PN}}(e) = (\mathsf{con}\ 1, \_ \mapsto e)$ and $\mu_{\mathsf{PN}}(c,\alpha) = (\mathsf{sig}\ c\ (\mathsf{fst} \circ \alpha), (x,y) \mapsto \mathsf{snd}\ (\alpha\ x)\ y)$. The equations in terms of the monad structure on Fam holds on the nose. ◀

Using the monad structure, we can define a "dependent bind" operation

$$\begin{aligned} \_ \gg\!=_{\mathsf{PN}} \_ &: \mathsf{PN}\ C\ D \to ((x : D) \to \mathsf{PN}\ C\ (E\,x)) \to \mathsf{PN}\ C\ ((\Sigma x : D)(E\,x)) \\ c \gg\!=_{\mathsf{PN}} h &= \mu_{\mathsf{PN}}(\mathsf{PN}(x \mapsto \mathsf{PN}(y \mapsto (x,y)))\ (h\,x)\ c) \end{aligned}$$

We also note that the pi constructor can be packaged up into the following "dependent power" operation for $S : \mathsf{Set}$ and $E : A \to \mathsf{Set}_1$:

$$\begin{aligned} \pi_{\mathsf{PN}} A &: (a : A) \to \mathsf{PN}\ D\ (E\,a) \to \mathsf{PN}\ D\ ((a : A) \to (E\,a)) \\ \pi_{\mathsf{PN}}\ A\ f &= (\mathsf{pi}\ A\ (\mathsf{fst} \circ f), (g \mapsto (a \mapsto \mathsf{snd}\,(f a)\ (g a)))) \end{aligned}$$

Using these ingredients, we can now define composition of PN codes:

▶ **Theorem 30.** *For* $c : \mathsf{Poly}\ D$ *and* $\alpha : \mathsf{Info}\,c \to E$ *and* $R : \mathsf{PN}\ C\ D$, *define* $(c,\alpha) \bullet R = \mathsf{PN}(\alpha)\,(c/R) : \mathsf{PN}\ C\ E$, *where* $\_/\_ : (c : \mathsf{Poly}\ E) \to \mathsf{PN}\ D\ E \to \mathsf{PN}\ D(\mathsf{Info}\,c)$ *is defined by*

$$\begin{aligned} \mathsf{id}_{\mathsf{PN}}/R &= R & (\mathsf{sig}\ c\ f)/R &= (c/R) \gg\!=_{\mathsf{PN}} (p \mapsto (f\,p)/R) \\ (\mathsf{con}\ A)/R &= (\mathsf{con} A, \mathsf{id}) & (\mathsf{pi}\ A\ f)/R &= \pi_{\mathsf{PN}}\ A\ (a \mapsto (f a)/R) \end{aligned}$$

Then $[\![\ R \bullet Q\ ]\!]\,(U,T) \cong [\![\ R\ ]\!]\,([\![\ Q\ ]\!]\,(U,T))$.

▶ **Example 31.** Let us compose $c_{\mathsf{2W,PN}}$ from Example 24 with the "upgraded" code $c_{\mathsf{W}\ \mathbb{N}\ \mathsf{Fin,PN}}$ from Example 23. This time we get the code $\mathsf{sig}\ (\mathsf{con}\ \{\mathsf{two}, \mathsf{w}\})\ f$, where $f\ \mathsf{two} = \mathsf{con}\ 1$ and $f\ \mathsf{w} = \mathsf{sig}\ c_{\mathsf{W}\ \mathbb{N}\ \mathsf{Fin,PN}}\ ((n,Y) \mapsto \mathsf{pi}\ ((x : \mathsf{Fin}\,n) \to (Y\,x))\ (\_ \mapsto c_{\mathsf{W}\ \mathbb{N}\ \mathsf{Fin,PN}}))$.

5 Conclusions

Inductive-recursive definitions arise as initial algebras of endofunctors on Fam D, but the question of exactly which functors does not have a canonical answer. Dybjer and Setzer [7] gave one axiomatisation DS, which was adequate in the sense that it covered all examples "in the wild", and all functors represented in it could be shown to have initial algebras (in a sufficiently strong metatheory). We have presented two alternative axiomatisations UF and PN that retain these properties, but in addition are closed under composition. This opens up the field to find the *optimal* axiomatisation of inductive-recursive definitions. As a start, we hope to show in future work that both inclusions $\mathsf{UF} \hookrightarrow \mathsf{DS} \hookrightarrow \mathsf{PN}$ are strict.

Abstract

A one-dimensional fragment of first-order logic is obtained by restricting quantification to blocks of existential quantifiers that leave at most one variable free. This fragment contains two-variable logic, and it is known that over words both formalisms have the same complexity and expressive power. Here we investigate the one-dimensional fragment over trees. We consider unranked unordered trees accessible by one or both of the descendant and child relations, as well as ordered trees equipped additionally with sibling relations. We show that over unordered trees the satisfiability problem is ExpSpace-complete when only the descendant relation is available and 2-ExpTime-complete with both the descendant and child or with only the child relation. Over ordered trees the problem remains 2-ExpTime-complete. Regarding expressivity, we show that over ordered trees and over unordered trees accessible by both the descendant and child the one-dimensional fragment is equivalent to the two-variable fragment with counting quantifiers.

1 Introduction

One-dimensional fragment of first-order logic, F_1, is obtained by restricting quantification to blocks of existential quantifiers that leave at most one variable free (as the logic is closed under negation and boolean operations one may also use blocks of universal quantifiers). It is not difficult to show that over general relational structures the satisfiability problem for F_1 is undecidable [8]. In such situations, there are two standard ways of regaining decidability. One can either try to impose some additional restrictions on the syntax of the considered logic or to restrict attention to some specific classes of structures. Both approaches have been tried in the context of F_1.

A nice syntactic restriction of F_1 which turns out to be decidable over general structures is called a *uniform* one-dimensional fragment, UF_1. It was introduced in [8] as a generalization of the two-variable fragment of first-order logic, FO^2, to contexts with relations of arity higher than two, e.g., databases. The readers interested in this variant are referred to [8], [11], [12] and a survey [14] which also reveals some connections with description logics.

Let us turn to the restricted classes of structures. There are two important first-choice options, well motivated in various areas of computer science, namely the class of words and the class of trees. F_1 over words and ω-words is investigated in [10]. The satisfiability

* E.K. was supported by the Polish National Science Centre grant No. 2016/21/B/ST6/01444. A.K. was supported by the ERC grant 647289 CODA.

problem is shown to be NExpTime-complete, exactly as in the case of FO^2 [7]. Moreover, over words F_1 and FO^2 turn out to share the same expressive power. The advantage of F_1 over FO^2 is that the former allows us to express some properties in a more natural way (and seems to be more succinct, which is however not formally proved). There are a few other related formalisms over words, worth mentioning here. In [7] it is shown that FO^2 is expressively equivalent to unary temporal logic, UTL, i.e., temporal logic with four navigational operators: *next state*, *somewhere in the future*, *previous state*, *somewhere in the past*. FO^2, however, is exponentially more succinct than UTL. The satisfiability problem for UTL is PSpace-complete. An extension of FO^2 by counting quantifiers, C^2, is shown to be NExpTime-complete over words in [5]. In fact, it is not difficult to observe that over words C^2 has the same expressive power as plain FO^2 (but, again, the former is more succinct). Another interesting extension of FO^2 over words, this time significantly increasing its expressive power, is an extension by the *between* predicate recently studied by in [13]. Its satisfiability problem is ExpSpace-complete.

Turning now to the class of trees, both FO^2 and C^2 retain a reasonable complexity, namely their satisfiability problems over trees are ExpSpace-complete. See [2] for the analysis of FO^2 over trees and [1] for its extension covering C^2. Regarding the expressive power, the situation depends on the type of the trees considered. In the case of *unordered* trees FO^2 cannot count and is less expressive than C^2. Over *ordered* trees both formalisms are equally expressive [1] and share the expressiveness with the navigational core of XPath temporal logic (cf. [15]). The importance of FO^2 and C^2 over trees is also justified by the fact that they are located close to the border between elementary and non-elementary, e.g., adding the third variable makes the satisfiability problem very hard: still decidable, but as shown in [18] necessarily with a non-elementary complexity.

In this paper we investigate the computational complexity and the expressive power of F_1 over trees. We consider finite unranked trees accessible by a few navigational signatures: just the descendant relation; just the child relation; both the descendant and the child relations; and, finally, the descendant relation, the child relation plus the next-sibling and following-sibling relations. Concerning the complexity of satisfiability, it depends on whether the child relation is present or not. With the child relation the satisfiability problem is 2-ExpTime-complete, and without it is ExpSpace-complete. To show the complexity results we perform some surgery on models leading to small model properties, and then design algorithms searching for such appropriate small models. Technically, we extend the approach from [4] used there in the context of FO^2. Roughly speaking we appropriately abstract the information about a node by its *profile* (an analogous notion is called *a full type* in [4]) and then we either contract nodes with the same profiles, or delete some nodes whose sufficiently many profiles are realized in a (fragment) of a model. Worth mentioning is that an orthogonal extension of the method from [4] is used in [1] in the context of C^2. In both cases the challenge is to carefully tune the notion of a profile (full type) in order to get the optimal complexity. Regarding expressivity, we argue that over ordered trees with all of the four navigational relations we consider, F_1 is expressively equivalent to C^2 and FO^2. We also show that over unordered trees equipped with both the descendant and the child relation F_1 is still equivalent to C^2 (but this time the latter is known to be more expressive than FO^2). While the former equivalence is rather easy to see (though slightly awkward to formally show), the latter is less obvious and more difficult to prove. In our expressivity studies we do not consider the cases of unordered trees accessible by only one of the descendant and the child relations. However, we conjecture that also under these scenarios F_1 is equivalent to C^2. We leave the related investigations for the full version of this paper.

In the case of trees, as in the case of F_1 over words, the advantage of F_1 over FO^2 and C^2 is that it allows to specify some properties in a more natural and elegant way. If we want to say that a tree contains some (especially not fully specified) pattern, consisting of more than two elements, we can just quantify an appropriate number of positions, and say how they should be labelled and related to each other. Expressing the same in FO^2 (if possible), and usually also in C^2, will very likely require some heavy recycling of the two available variables and a careful navigation over trees. Let us just recall a simple example from [10], which in fact does not even use the navigational relations. The formula $\exists xyz \bigwedge_{i=1}^{n}(P_i(x) \vee P_i(y) \wedge P_i(z))$ says that there are three points which together ensure that each unary properties $P_1, \ldots, P_n$ appears in a model. A reader is asked to check that complicated and long formulas arise when we try to express the same in FO^2 or even in C^2 over (ordered or unordered) trees.

The rest of the paper is organized as follows. In Section 2 we define the logic and structures we are interested in and introduce some tools which will be then used in the following sections. In Section 3 we perform some surgery on trees, which then, in Section 4, allows us to establish the exact complexity bounds under all the considered navigational scenarios. In Section 5 we consider expressivity issues, relating F_1 over trees with C^2, FO^2 and GF^2, and finally in Section 6 we conclude the paper.

2 Preliminaries

2.1 Trees and logics

We work with signatures of the form $\tau = \tau_0 \cup \tau_{bin}$, where τ_0 is a set of unary symbols and $\tau_{bin} \subseteq \{\downarrow, \downarrow_+, \rightarrow, \rightarrow^+\}$ is a set of *navigational* binary symbols. Over such signatures we consider the *one-dimensional* fragment of first-order logic F_1, that is the relational fragment in which quantification is restricted to blocks of existential quantifiers that leave at most one variable free. Formally, F_1 over relational signature τ and some countably infinite set of variables Var is the smallest set such that:

- $R\bar{x} \in \mathrm{F}_1$ for all $R \in \tau$ and all tuples $\bar{x}$ of variables from Var of the appropriate length,
- $x = y \in \mathrm{F}_1$ for all variables $x, y \in Var$,
- F_1 is closed under $\vee$ and $\neg$,
- if φ is an F_1 formula with free variables $x_0, \ldots, x_k$ then formulas $\exists x_0, \ldots, x_k \varphi$ and $\exists x_1, \ldots, x_k \varphi$ belong to F_1.

As usually, we can use standard abbreviations for other Boolean operations, like $\wedge, \rightarrow, \top$, etc., as well as for universal quantification. The length of a formula φ is measured in a natural way, and denoted $\|\varphi\|$. The *width* of a formula is the maximum of the numbers of free variables in its subformulas.

For a given formula φ we denote by $\tau_0(\varphi)$ the set of unary symbols that appear in φ. We write $\mathrm{F}_1[\tau_{bin}]$ to denote that the only binary symbols that are allowed are those from τ_{bin}.

We are interested in finite unranked tree structures, in which the interpretation of symbols from τ_{bin} is fixed: if available in the signature, $\downarrow$ is interpreted as the child relation, $\rightarrow$ as the right sibling relation, and $\downarrow_+$ and $\rightarrow^+$ as their respective transitive closures. If at least one of $\rightarrow$, $\rightarrow^+$ is interpreted in a tree then we say that this tree is *ordered*; in the opposite case we say that the tree is *unordered*. In this paper we investigate the four navigational signatures, namely, in the case of unordered trees, we consider accessing them only by the descendant relation ($\mathrm{F}_1[\downarrow_+]$), only by the child relation ($\mathrm{F}_1[\downarrow]$), and by both of them ($\mathrm{F}_1[\downarrow_+, \downarrow]$); in the case of ordered trees we consider just the full signature ($\mathrm{F}_1[\downarrow, \downarrow_+, \rightarrow, \rightarrow^+]$).

We use symbol $\mathfrak{T}$ (possibly with sub- or superscripts) to denote tree structures. For a given tree $\mathfrak{T}$ we denote by T its universe. If a is a node of $\mathfrak{T}$ then we denote by $\mathfrak{T}_a^{\downarrow}$ the subtree

of $\mathfrak{T}$ rooted at a, by $\mathfrak{T}_a^{\uparrow}$ the tree obtained from $\mathfrak{T}$ by removing all subtrees rooted at the children of a. Additionally, in the case of ordered trees we denote by $\mathfrak{T}_a^{\leftarrow}$ the substructure (which usually is not a tree) of $\mathfrak{T}$ generated by the nodes of subtrees rooted at a and all its left siblings (nodes a' such that $\mathfrak{T} \models a' \rightarrow^+ a$), and, symmetrically, we denote by $\mathfrak{T}_a^{\rightarrow}$ the substructure of $\mathfrak{T}$ generated by the nodes of subtrees rooted at a and all its right siblings.

2.2 Normal form

We adapt here the well known Scott normal form for FO^2 [16] to our purposes. We say that an $\mathrm{F}_1[\tau_{bin}]$ formula φ is in *normal form* if φ has the following shape:

$$\bigwedge_{1 \leq i \leq m_\exists} \forall y_0 \exists y_1 \dots y_{k_i} \varphi_i^\exists \wedge \bigwedge_{1 \leq i \leq m_\forall} \forall x_1 \dots x_{l_i} \varphi_i^\forall, \tag{1}$$

where $\varphi_i^\exists = \varphi_i^\exists(y_0, y_1, \dots, y_{k_i})$ and $\varphi_i^\forall = \varphi_i^\forall(x_1, \dots, x_{l_i})$ are quantifier-free. Please note that the width of φ is the maximum of the set $\{k_i + 1\}_{1 \leq i \leq m_\exists} \cup \{l_j\}_{1 \leq j \leq m_\forall}$. The following fact can be proved in a standard fashion, see, e.g., [6] for a more detailed exposition of the technique.

▶ **Lemma 1.** *For every $\mathrm{F}_1[\tau_{bin}]$ formula φ, one can compute in polynomial time an $\mathrm{F}_1[\tau_{bin}]$ formula φ' in normal form (over the signature extended by some fresh unary symbols) such that for trees of size (number of nodes) equal at least to the width of φ: (i) any model of φ can be expanded to a model of φ' by appropriately interpreting fresh unary symbols; (ii) any model of φ' restricted to the signature of φ is a model of φ.*

Proof. (Sketch) We successively replace innermost subformulas ψ of φ of the form $\exists y_1, \dots, y_k$ $\varphi(y_0, y_1, \dots, y_k)$ by atoms $P_\psi(y_0)$, where P_ψ is a fresh unary symbol, and axiomatize P_ψ using two normal form conjuncts: $\forall y_0 \exists y_1, \dots, y_k (P_\psi(y_0) \rightarrow \varphi(y_0, y_1, \dots, y_k))$ and $\forall y_0, y_1, \dots, y_k$ $(\neg\varphi(y_0, y_1, \dots, y_k) \vee P_\psi(y_0))$. ◀

Lemma 1 allows us, when dealing with satisfiability or when analysing the size and shape of models, to restrict attention to normal form formulas (models of size smaller than the width of the considered formula can be easily treated separately).

2.3 Types and profiles

In this subsection we prepare some notions useful in the rest of this paper.

2.3.1 Types

For $k \in \mathbb{N} \setminus \{0\}$ a *k-type* (or a *type of size k*) π over a signature $\tau = \tau_0 \cup \tau_{bin}$ is a set of literals over variables $x_1, \dots, x_k$ (often identified with a conjunction of its elements) such that

- for each $P \in \tau_0$ and $1 \leq i \leq k$ either Px_i or $\neg Px_i$ belongs to π
- for each $\rightleftharpoons \in \tau_{bin}$ and $1 \leq i, j, \leq k$, $i \neq j$ either $x_i \rightleftharpoons x_j$ or $\neg x_i \rightleftharpoons x_j$ belongs to π
- for each $1 \leq i < j \leq k$ the inequality $x_i \neq x_j$ belongs to π
- π is satisfiable in a tree, i.e., there exists a tree $\mathfrak{T}$ containing nodes $a_1, \dots, a_k$ such that $\mathfrak{T} \models \pi(a_1, \dots, a_k)$

In this paper we will only be interested in k-types over signatures containing $\downarrow_+$. If for some variable x_i and all $j \neq i$ we have that $x_i \downarrow_+ x_j \in \pi$ then we call x_i the *root* of π. If for some variable x_i and all $j \neq i$ either $x_j \downarrow_+ x_i \in \pi$ or $x_i \downarrow_+ x_j \notin \pi$ and $x_j \downarrow_+ x_i \notin \pi$ then we call x_i a *leaf* of π. Additionally for signatures containing horizontal relations: If for some variable x_i

and all $j \neq i$ either $x_i \rightarrow^+ x_j \in \pi$ or there is h such that $x_i \rightarrow^+ x_h, x_h \downarrow_+ x_j \in \pi$ then we call x_i the *leftmost element* of π. Analogously we define the *rightmost element* of π.

Note that a k-type may have at most one root, one leftmost element and one rightmost element, but many leaves. A *type* is a k-type for some $k \geq 1$.

We say that a tuple of distinct nodes $a_1 \ldots, a_k$ of a tree $\mathfrak{T}$ *realizes* a k-type π if $\mathfrak{T} \models \pi[a_1, \ldots, a_k]$. In this case we write $\text{type}^{\mathfrak{T}}(a_1, \ldots, a_k) = \pi$.

For a given k-type π and a sequence of variables $x_{i_1}, \ldots, x_{i_k}$ we denote by $\pi(x_{i_1}, \ldots, x_{x_k})$ the result of the simultaneous substitution $x_j \leftarrow x_{i_j}$ in π. Note that in this operation $i_1, \ldots, i_k$ is not required to be a permutation of $1, \ldots, k$.

2.3.2 Subtypes

Observe that a 1-type is completely determined by a subset of τ_0. We denote by $\pi \restriction x_i$ the 1-type obtained by restricting π to literals over x_i and then replacing in them x_i by x_1. More generally, for distinct indices $i_1, \ldots, i_l \in \{1, \ldots, k\}$ we denote by $\pi \restriction [x_{i_1} \ldots x_{i_l}]$ the l-type obtained by restricting π to literals over $x_{i_1}, \ldots, x_{i_l}$, and then replacing in them x_{i_j} by x_j (for $j = 1, \ldots, l$). We say that $\pi \restriction [x_{i_1} \ldots x_{i_l}]$ is a *subtype* of π; if $i_1 = 1$ then such a subtype is called an *initial subtype* of π. Initial subtypes may be formed with $l = k$ and are called *rearrangement* of π in this case. We say that a set $\mathcal{C}$ of types is *closed under initial subtypes* if for any k-type $\pi \in \mathcal{C}$ and any distinct $i_2, \ldots, i_l \in \{2, \ldots, k\}$, we have $\pi \restriction [x_1, x_{i_2}, \ldots, x_{i_l}] \in \mathcal{C}$.

2.3.3 Profiles

Profiles are intended to abstract the information about a node in a tree. Namely, they say what are the types of tuples (of some bounded size) containing the given element. For convenience we will separately store the types of tuples built of the nodes *above* and *below* the given element.

A *k-profile* over a signature τ (containing $\downarrow_+$) is a tuple $(\alpha, \mathcal{A}, \mathcal{B})$ such that:

- α is a 1-type,
- $\mathcal{A}$ is a set of types closed under initial subtypes, such that for all $\pi \in \mathcal{A}$: (i) π is of size at most k; (ii) $\pi \restriction x_1 = \alpha$ and (iii) x_1 is a leaf of π,
- $\mathcal{B}$ is a set of types closed under initial subtypes, such that for all $\pi \in \mathcal{B}$: (i) π is of size at most k; (ii) $\pi \restriction x_1 = \alpha$ and (iii) x_1 is the root of π.

Given a profile θ we will sometimes refer to its components as $\theta.\alpha$, $\theta.\mathcal{A}$ and $\theta.\mathcal{B}$.

In the case of the signature $\{\downarrow, \downarrow_+, \rightarrow, \rightarrow^+\}$ we also consider *horizontal* k-profiles, i.e., tuples of the form $(\alpha, \mathcal{A}, \mathcal{B}, \mathcal{A}_L, \mathcal{A}_R)$, extending k-profiles in such a way that:

- $\mathcal{A}_L$ is a set of types closed under the initial subtypes, such that for all $\pi \in \mathcal{A}_L$: (i) π is of size at most k, (ii) $\pi \restriction x_1 = \alpha$ and (iii) x_1 is the leftmost element of π,
- $\mathcal{A}_R$ is a set of types closed under the initial subtypes, such that for all $\pi \in \mathcal{A}_L$: (i) π is of size at most k, (ii) $\pi \restriction x_1 = \alpha$ and (iii) x_1 is the rightmost element of π,

By simple calculations we get:

▶ **Claim 2.** *For any navigational signature τ_{bin} we have:*

(i) *The number of k-types over $\tau = \tau_0 \cup \tau_{bin}$ is bounded exponentially in $|\tau_0|$ and k. In particular, there are $2^{|\tau_0|}$ 1-types.*

(ii) *The number of k-profiles and horizontal k-profiles over $\tau_0 \cup \tau_{bin}$ are bounded doubly exponentially in $|\tau_0|$ and k.*

We denote by $\mathrm{prof}_k^{\mathfrak{T}}(a)$ the k-profile *realized* by a in $\mathfrak{T}$, i.e., the profile $(\alpha, \mathcal{A}, \mathcal{B})$ such that:

- α is the 1-type of a,
- $\mathcal{A}$ is the set of types of size at most k realized by tuples $a_1, a_2, \ldots, a_l \in T_a^{\uparrow}$ such that $a_1 = a$,
- $\mathcal{B}$ is the set of types of size at most k realized by tuples $a_1, a_2, \ldots, a_l \in T_a^{\downarrow}$ such that $a_1 = a$.

An element $a \in T$ *realizes* a horizontal k-profile $(\alpha, \mathcal{A}, \mathcal{B}, \mathcal{A}_L, \mathcal{A}_R)$ if it realizes $(\alpha, \mathcal{A}, \mathcal{B})$ and

- $\mathcal{A}_L$ is the set of types of size at most k realized by tuples $a_1, a_2, \ldots, a_l \in T_a^{\leftarrow}$ such that $a_1 = a$,
- $\mathcal{A}_R$ is the set of types of size at most k realized by tuples $a_1, a_2, \ldots, a_l \in T_a^{\rightarrow}$ such that $a_1 = a$.

Note that in realized horizontal profiles it is also the case that both $\mathcal{A}_L$ and $\mathcal{A}_R$ are subsets of $\mathcal{A}$. Also all of $\mathcal{A}, \mathcal{B}, \mathcal{A}_L, \mathcal{A}_R$ are closed under initial subsets.

In the sequel, whenever a formula $\varphi \in \mathrm{F}_1[\tau_{bin}]$ is fixed we silently assume that all k-types, k-profiles, horizontal-k-profiles and all structures considered are over the signature $\tau_{bin} \cup \tau_0(\varphi)$.

Let us consider a k-profile $\theta = (\alpha, \mathcal{A}, \mathcal{B})$. We say that an l-type π $(1 \leq l \leq k)$ is *implicit* in θ if π is a member of $\mathcal{A}$ or $\mathcal{B}$ or if there are l_1-type $\pi_1 \in \mathcal{A}$, l_2-type $\pi_2 \in \mathcal{B}$, $l_1 + l_2 - 1 = k$, such that π is the unique l-type containing $\pi_1 \cup \pi_2(x_1, x_{l_1+1}, x_{l_1+2}, \ldots, x_{l_1+l_2-1})$, Note that if for some $2 \leq i \leq l_1$ we have $x_i{\downarrow_+}x_1 \in \pi_1$ then $x_i{\downarrow_+}x_j \in \pi$ for all $j \geq l_1$ and if $x_i{\downarrow_+}x_1 \notin \pi$ then also $x_j{\downarrow_+}x_1 \notin \pi$ for all $j \geq l_1$. Intuitively, an l-type π is implicit in θ if in any tree in which θ is realized by a node a there is a tuple of nodes starting with a realizing π.

Let φ be a normal form formula of width n. Given an n-profile θ one can easily see if its any realization in any tree $\mathfrak{T}$ have all the witnesses required by $\forall\exists...\exists$ conjuncts of φ, and if each tuple of nodes of $\mathfrak{T}$ containing a cannot violate any universal conjunct of φ. Formally, we say that an n-profile θ is *φ-admissible* if

1. for every conjunct of φ of the form $\forall y_0 \exists y_1 \ldots y_{k_i} \varphi_i^{\exists}(y_0, \ldots, y_{k_i})$ there is a k-type π $(k \leq k_i)$ implicit in θ and a function $h : \{y_1, \ldots, y_{k_i}\} \to \{x_1, \ldots, x_{l_i}\}$, such that $\pi \models \varphi_i^{\exists}[y_0/x_1, y_1/h(y_1), \ldots, y_{l_i}/h(y_{k_i})]$.
2. for every conjunct of φ of the form $\forall y_1 \ldots y_{l_i} \varphi_i^{\forall}(y_1, \ldots, y_{l_i})$ any k-type $(k \leq l_i)$ implicit in θ and any function $h : \{y_1, \ldots, y_{l_i}\} \to \{x_1, \ldots, x_k\}$ having x_1 in its image we have $\pi \models \varphi_i^{\forall}[y_1/h(y_1), \ldots, y_1/h(y_1), \ldots, y_{l_i}/h(y_{k_i})]$

It is then straightforward to see the following.

▶ **Lemma 3.** *Let φ be a normal form formula of width n. Then $\mathfrak{T} \models \varphi$ iff all n-profiles realized in $\mathfrak{T}$ are φ-admissible.*

In our decision procedures we will sometimes check admissibility of profiles. Since the number of types implicit in a profile is bounded polynomially this can be done (relatively) easily.

▶ **Claim 4.** *Given a normal form F_1 formula φ of width n and an n-profile θ it can be checked in nondeterministic polynomial time (in $\|\varphi\|$ and $|\theta|$) whether θ is φ-admissible.*

In the next section we perform some surgery on models of a normal form formula φ. Namely, we remove some nodes and sometimes change the connections among the remaining nodes. Observing that the n-profiles of the surviving nodes are not changed we will then be able to conclude (thanks to Lemma 3) that the resulting trees are still models of φ.

3 Pruning trees

We now show that when looking for models of a formula φ one can restrict attention to models with bounded depth and degree. We obtain an exponential bound on the depth in the case of signatures not containing $\downarrow$, and a doubly exponential bound when $\downarrow$ is present. The bound on the degree is exponential for unordered trees and doubly exponential for ordered trees. We remark that all the above bounds are essentially optimal.

3.1 Bounded paths

The crucial observation here is that one can remove the fragment of a model between two nodes having the same profile.

▶ **Lemma 5.** *Let τ_{bin} be any of the navigational signatures $\{\downarrow\}$, $\{\downarrow_+\}$, $\{\downarrow,\downarrow_+\}$, $\{\downarrow,\downarrow_+,\rightarrow,\rightarrow^+\}$. Let φ be a normal form $\mathrm{F}_1[\tau_{bin}]$ formula of width n. Let $\mathfrak{T} \models \varphi$ and let $a, b \in T$ be two nodes such that $\mathfrak{T} \models a\downarrow_+ b$ and $\mathrm{prof}_n^{\mathfrak{T}}(a) = \mathrm{prof}_n^{\mathfrak{T}}(b)$. Let $\mathfrak{T}'$ be the tree obtained from $\mathfrak{T}$ by replacing the subtree rooted at a by the subtree rooted at b. Then for any $c \in T'$ we have that $\mathrm{prof}_n^{\mathfrak{T}'}(c) = \mathrm{prof}_n^{\mathfrak{T}}(c)$. In consequence $\mathfrak{T}' \models \varphi$.*

Proof. Consider the case when c belongs to $\mathfrak{T}'^{\downarrow}_b$ (possibly $c = b$). Since $\mathfrak{T}'^{\downarrow}_b = \mathfrak{T}^{\downarrow}_b$ then in particular $\mathfrak{T}'^{\downarrow}_c = \mathfrak{T}^{\downarrow}_c$ and it is clear that $\mathrm{prof}_n^{\mathfrak{T}'}(c).\mathcal{B} = \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{B}$.

To see that $\mathrm{prof}_n^{\mathfrak{T}'}(c).\mathcal{A} \subseteq \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$ consider any $\pi \in \mathrm{prof}_n^{\mathfrak{T}'}(c).\mathcal{A}$. Take a realization of π in $\mathfrak{T}'$ starting with c. Let $c, b_1, \ldots, b_k, a_1, \ldots, a_l$ be a list of all nodes of this realization, such that $b_1, \ldots, b_k \in T'^{\downarrow}_b$ and $a_1, \ldots, a_l \notin T'^{\downarrow}_b$. Let $\pi_0 = \mathrm{type}^{\mathfrak{T}'}(c, b_1, \ldots, b_k, a_1, \ldots, a_l)$. Note that π_0 is a rearrangement of π. Let $\pi'_0 = \mathrm{type}^{\mathfrak{T}'}(b, a_1, \ldots, a_l)$. Note that $\pi'_0 = \mathrm{type}^{\mathfrak{T}}(a, a_1, \ldots, a_l)$ and thus $\pi'_0 \in \mathrm{prof}_n^{\mathfrak{T}}(a).\mathcal{A} = \mathrm{prof}_n^{\mathfrak{T}}(b).\mathcal{A}$. It follows that π'_0 is realized in $\mathfrak{T}$ by $b, a'_1, \ldots, a'_l$ for some $a'_1, \ldots, a'_l \in T^{\uparrow}_b$. Observe that $\mathrm{type}^{\mathfrak{T}}(c, b_1, \ldots, b_k, a'_1, \ldots, a'_l) = \pi_0$ and thus $\pi_0 \in \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$. As $\mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$ is closed under initial subtypes (and thus also rearrangements) it follows that $\pi \in \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$

For the opposite direction, consider now any $\pi \in \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$. Take a realization of π in $\mathfrak{T}$ starting with c. Let $c, b_1, \ldots, b_k, a_1, \ldots, a_l$ be a list of all nodes of this realization such that $b_1, \ldots, b_k \in T^{\downarrow}_b$ and $a_1, \ldots, a_l \notin T^{\downarrow}_b$. Let $\pi_0 = \mathrm{type}^{\mathfrak{T}}(c, b_1, \ldots, b_k, a_1, \ldots, a_l)$ Let $\pi'_0 = \mathrm{type}^{\mathfrak{T}}(b, a_1, \ldots, a_l)$. Note that $\pi'_0 \in \mathrm{prof}_n^{\mathfrak{T}}(b).\mathcal{A} = \mathrm{prof}_n^{\mathfrak{T}}(a).\mathcal{A}$ and thus $a, a'_1, \ldots, a'_l$ realize π'_0 in $\mathfrak{T}'$ for some $a'_1, \ldots, a'_l$. Now $\mathrm{type}^{\mathfrak{T}'}(b, a'_1, \ldots, a'_l) = \pi'_0$ and $\mathrm{type}^{\mathfrak{T}'}(c, b_1, \ldots, b_k, a'_1, \ldots, a'_l) = \pi_0$. Thus $\pi_0 \in \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$ and since π is a rearrangement of π_0 then also $\pi \in \mathrm{prof}_n^{\mathfrak{T}}(c).\mathcal{A}$.

The case when $c \in T'^{\uparrow}_b$ can be analysed analogously. Since we have shown that all profiles of nodes in $\mathfrak{T}'$ are realized in $\mathfrak{T}$ it follows by Lemma 3 that $\mathfrak{T}' \models \varphi$. ◀

Having proved Lemma 5 we can now obtain the desired bounds.

▶ **Corollary 6.**

(i) *Every satisfiable $\mathrm{F}_1[\downarrow]$, $\mathrm{F}_1[\downarrow,\downarrow_+]$ or $\mathrm{F}_1[\downarrow,\downarrow_+,\rightarrow,\rightarrow^+]$ normal form formula φ has a model whose vertical root-to-leaf paths are bounded doubly exponentially in $\|\varphi\|$ by a fixed function $\mathfrak{f}_d$.*

(ii) *Every satisfiable $\mathrm{F}_1[\downarrow_+]$ normal form formula φ has a model whose vertical root-to-leaf paths are bounded exponentially in $\|\varphi\|$ by a fixed function $\mathfrak{f}_s$.*

Proof. Take a model $\mathfrak{T} \models \varphi$. If there are nodes a, b meeting conditions of Lemma 5 then replace the subtree rooted at a by the subtree rooted at b. Repeat this operation until all root-to-leaf paths realize only distinct n-profiles. Let $\mathfrak{T}^*$ be the eventually obtained tree. By Lemma 5 we have $\mathfrak{T}^* \models \varphi$. To see (i) just recall that by Claim 2 (ii) the number of distinct

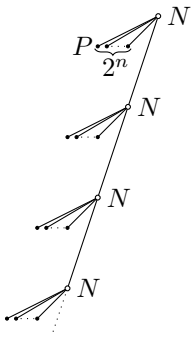

Figure 1 Enforcing doubly exponential path in $\mathrm{F}_1[\downarrow]$.

n-profiles over $\{\downarrow\}$, $\{\downarrow, \downarrow_+\}$ or $\{\downarrow, \downarrow_+, \rightarrow, \rightarrow^+\}$ is bounded doubly exponentially in $\tau_0(\varphi)$ and n and thus also in $\|\varphi\|$. For (ii) take any vertical root-to-leaf path p of $\mathfrak{T}^*$ and consider any 1-type α realized on this path. Let $a_1, \ldots, a_k$ be the list of all nodes of p realizing α, $\mathfrak{T}^* \models a_i \downarrow_+ a_j$ for $i < j$. Let $(\alpha, \mathcal{A}_i, \mathcal{B}_i)$ be the n-profile (over $\{\downarrow_+\}$) of a_i for $1 \leq i \leq k$. We observe that for $i < j$ we have $\mathcal{A}_i \subseteq \mathcal{A}_j$ and, $\mathcal{B}_i \supseteq \mathcal{B}_j$. Let us explain the former of these two inclusions. Take any k-type $\pi \in \mathcal{A}_i$ and let $a_i, b_2, \ldots, b_k$ be its realization. Note that the nodes $b_2, \ldots, b_k$ are related by $\downarrow_+$ to a_j precisely as to a_i. Thus $a_j, b_2, \ldots, b_k$ realizes π and thus $\pi \in \mathcal{A}_j$. The latter inclusion can be shown analogously. Recall that by Claim 2 (i) $|\mathcal{A}_i|$ and $|\mathcal{B}_i|$ are bounded exponentially. Thus when moving along $a_1, \ldots, a_k$ each of the components $\mathcal{A}_i$ and $\mathcal{B}_i$ can change at most exponentially many times, and in consequence, k is bounded exponentially. Finally, noting that the number of 1-types is also bounded exponentially we get the desired bound. ◀

The bounds in the both parts of the above corollary are essentially optimal. Exponentially long paths over $\{\downarrow_+\}$ can be easily enforced even in FO^2 by organizing, by means of unary predicates $P_0, \ldots, P_{n-1}$, a binary counter counting from 0 to $2^n - 1$ and requiring each node storing a value smaller than $2^n - 1$ to have a descendant storing the value greater by one. Let us see that the presence of $\downarrow$ allows to simply enforce doubly-exponential paths. We use unary predicates $N, P, P_0, \ldots, P_{n-1}, Q$. See Fig. 1. The intended long path is the path of elements in N. Every element in N is going to have 2^n children marked by P, each of which has a *local position* in the range $[0, 2^n - 1]$ encoded by means of $P_0, \ldots, P_{n-1}$. Reading the truth-values of Q as binary digits we can assume that the collection of the P-children of a node in N encodes its *global position* in the tree in the range $[0, 2^{2^n} - 1]$ (the i-th bit of this global position is 1 iff at the element at local position i the value of Q is true). It is then possible to say that each node in n whose global position is smaller than $2^{2^n} - 1$ has a child in N with the global position greater by 1. We skip here the details.

3.2 Bounded degree

Our next aim is to show that also the degree of nodes can be bounded.

▶ **Lemma 7.**

(i) *Let φ be a normal form $\mathrm{F}_1[\downarrow, \downarrow_+, \rightarrow, \rightarrow^+]$ formula. Let $\mathfrak{T} \models \varphi$. Then there exists a tree $\mathfrak{T}^* \models \varphi$ obtained by removing some subtrees from $\mathfrak{T}$ (and appropriately repairing the sibling relations), in which the degree of every node is bounded doubly exponentially in $\|\varphi\|$ by a fixed function $\mathfrak{f}'_d$.*

(ii) *Let φ be a normal form $\mathrm{F}_1[\downarrow]$, $\mathrm{F}_1[\downarrow_+]$ or $\mathrm{F}_1[\downarrow, \downarrow_+]$. Let $\mathfrak{T} \models \varphi$. Then there exists a tree $\mathfrak{T}^* \models \varphi$ obtained by removing some subtrees from $\mathfrak{T}$, in which the degree of every node is bounded exponentially in $\|\varphi\|$ by a fixed function $\mathfrak{f}'_s$.*

Proof. Let n be the width of φ.

(i) Consider any node $a \in T$. Let $a_1, \ldots, a_k$ be all the the children of a, listed from left to right. If for some $i < j$ the horizontal n-profiles of a_i and a_j are equal (note that $i > 1$ in this case) then we remove all the subtrees rooted at $a_i, \ldots, a_{j-1}$ and join a_{i-1} with a_j by $\rightarrow$. By arguments similar to those from the proof of Lemma 5 we can show that the profiles of the surviving elements of T do not change. Repeating this process as long as possible we eventually obtain a tree in which the number of children of a is bounded doubly exponentially (by the number of distinct horizontal n-profiles). We then repeat the process successively for all the nodes of $\mathfrak{T}$.

(ii) The $\mathcal{B}$ components of profiles do not behave monotonically along horizontal paths (as they do along vertical paths), thus we cannot use horizontal k-profiles to get the desired exponential bound on their length. We proceed in a slightly different manner. Consider any node $a \in T$. Let $\bar{a} = a_1, \ldots, a_k$ be the list of the children of a. For $1 \leq i \leq k$ let $types(a_i)$ be the set of types of size at most n realized in $\mathfrak{T}^{\downarrow}_{a_i}$ by tuples whose first element is a_i. For each type $\pi \in \bigcup_{i=1}^{k} types(a_i)$ mark n nodes in $\bar{a}$ such that $\pi \in types(a_i)$ (or all such nodes if there are less than n of them). This way we mark at most exponentially many children of a. Let us remove all the subtrees rooted at unmarked nodes from $\bar{a}$ and denote the obtained tree $\mathfrak{T}'$. We claim the the n-profiles of all the elements surviving the surgery do not change. Consider any $c \in T'$. Noting that the elements of $\mathfrak{T}'$ are related to each other by the navigational predicates $\downarrow_+, \downarrow$ exactly as they are related in $\mathfrak{T}$ we see that $\mathrm{prof}^{\mathfrak{T}'}_n(c).\mathcal{A} \subseteq \mathrm{prof}^{\mathfrak{T}}_n(c).\mathcal{A}$ and $\mathrm{prof}^{\mathfrak{T}'}_n(c).\mathcal{B} \subseteq \mathrm{prof}^{\mathfrak{T}}_n(c).\mathcal{B}$.

For $\supseteq$ we distinguish two case: the one in which c is in $\mathfrak{T}'^{\uparrow}_a$, and the other in which it is not. Let us sketch the arguments for the latter (the former is similar). Since c retains its subtree from $\mathfrak{T}$ it is clear that $\mathrm{prof}^{\mathfrak{T}}_n(c).\mathcal{B} \subseteq \mathrm{prof}^{\mathfrak{T}'}_n(c).\mathcal{B}$. To see that $\mathrm{prof}^{\mathfrak{T}}_n(c).\mathcal{A} \subseteq \mathrm{prof}^{\mathfrak{T}'}_n(c).\mathcal{A}$ take any $\pi \in \mathrm{prof}^{\mathfrak{T}}_n(c).\mathcal{A}$ and its any realization $c, b_1, \ldots, b_l \in T$. Split $b_1, \ldots, b_l$ into the disjoint tuples of nodes: let the first tuple $\bar{b}_0$ contain the nodes from $\mathfrak{T}^{\uparrow}_a$ and the other tuples $\bar{b}_1, \ldots, \bar{b}_s$ the nodes from the subtrees rooted at distinct nodes from $\bar{a}$ (note that $s < n$). The tuple $\bar{b}_0$ is retained in $\mathfrak{T}'$; the other tuples may be deleted, but due to our strategy of marking important nodes in $\bar{a}$ there exists a $1{-}1$ function returning for a tuple $\bar{b}_i$ a node in $\bar{a}$ surviving the surgery in whose subtree a tuple $\bar{b}'_i$ of type equal to the type of $\bar{b}_i$ exists. Using the elements $c, \bar{b}_0, \bar{b}'_1, \ldots, \bar{b}'_s$ we can now form a realization of π in $\mathfrak{T}'$ (starting from c). Thus $\pi \in \mathrm{prof}^{\mathfrak{T}'}_n(c).\mathcal{A}$, which finishes the argument.

Again, repeating the described process for all nodes we eventually obtain a tree $\mathfrak{T}^*$ in which the degree of every node is bounded exponentially and the n-profiles of all nodes remain as in $\mathfrak{T}$, and thus are φ-admissible. In effect $\mathfrak{T}^* \models \varphi$. ◀

The bounds on the degree of nodes in Lemma 7 are essentially optimal. In particular a doubly exponential chain of siblings can be enforced by means of $\rightarrow$ and $\downarrow$ (or $\rightarrow$ and $\downarrow_+$) similarly to a doubly exponential vertical root-to-leaf path: every element of the chain is required to have 2^n children storing the binary digits of a doubly exponential counter; the next sibling of a node a is forced to store the counter value greater by one than the value stored at a.

4 Complexity of satisfiability

In this section, using the results from Section 3 we establish the precise complexity of the satisfiability problem in all of the scenarios we consider.

4.1 Only descendant relation

Let us start with the observation that in the case when only the descendant relation is present in the navigational signature the complexity of F_1 is equal to the complexity of FO^2 and C^2.

▶ **Theorem 8.** *The satisfiability problem for* $\mathrm{F}_1[\downarrow_+]$ *is* ExpSpace*-complete.*

The lower bound is inherited from $\mathrm{FO}^2[\downarrow_+]$, [2], which in turn refers to ExpSpace-hardness of the so-called one-way two-variable guarded fragment, [9]. For the upper bound we design an alternating exponential time procedure. The result then follows from the well known fact that AExpTime=ExpSpace, [3]. The procedure first guesses the profile of the root and then guesses the profiles of its children, checking if the information recorded in the profiles is locally consistent, and if each guessed profile is φ-admissible. Further, it works in a loop, universally moving to one of the children, guessing profiles of its children and proceeding similarly.

Algorithm 1: Procedure F_1`[↓+]-sat-test`

Input: an $\mathrm{F}_1[\downarrow_+]$ normal form formula φ
- let n be the width of φ
- let $maxdepth := \mathfrak{f}_s(\|\varphi\|)$; let $maxdegree := \mathfrak{f}'_s(\|\varphi\|)$; % *cf. Cor. 6 and Lem. 7*
- let $level := 0$;
- **guess** an n-profile θ such that $\theta.\mathcal{A} = \{\alpha\}$; % *root*
- **while** $level < maxdepth$ **do**
  - if θ is not φ-admissible then **reject**
  - **guess** an integer $0 \leq k \leq maxdegree$; % *the number of children*
  - for $1 \leq i \leq k$ **guess** a profile θ_i;
  - if not *locally-consistent*$(\theta, \theta_1, \ldots, \theta_k)$ then **reject**;
  - if $\theta.\mathcal{B} = \{\alpha\}$ then **accept** % *a leaf reached; it must be* $k = 0$
  - $level := level + 1$;
  - **universally choose** $1 \leq i \leq k$; let $\theta := \theta_i$;
- **endwhile**
- **reject**
- **endprocedure**

The function *locally-consistent* checks whether, from a local point of view, a tree may have a node realizing an n-profile θ whose children realize n-profiles $\theta_1, \ldots, \theta_k$. It checks if $\theta.\mathcal{B}$ is the set of types which can be obtained, informally speaking, by putting $\theta.\alpha$ on top of a disjoint union of types taken from distinct $\theta_i.\mathcal{B}$ (possibly with their roots removed); and, analogously, verifies some natural conditions on the $\mathcal{A}$-components of θ and θ_i-s. We skip the details of this function.

▶ **Lemma 9.** *Procedure* F_1`[↓+]-sat-test` *accepts its input* φ *iff* φ *is satisfiable.*

Proof. Assume that φ is satisfiable. By Corollary 6 (ii) and Lemma 7 (ii) there exists a small model $\mathfrak{T} \models \varphi$. The procedure accepts φ by making all its guesses in accordance to $\mathfrak{T}$, i.e., in the first step it sets θ to be equal to the n-profile of the root of $\mathfrak{T}$ and then in each step it sets θ_i to be the n-profile of the i-th child of the previously considered element.

In the opposite direction, from an accepting (tree-)run t of the procedure we can naturally construct a tree structure $\mathfrak{T}_t$, with 1-types of elements as guessed during the execution. Our procedure guesses actually not only 1-types but full n-profiles of nodes. The function *locally-consistent* guarantees that the n-profiles of nodes $\mathfrak{T}_t$ are indeed as guessed. To see this, we first prove by induction on the height of nodes that the $\mathcal{B}$ components of profiles are

as required: the base step for leaves holds due to the acceptance condition of the procedure; then we move towards the root using the conditions of the function *locally-consistent*. For the $\mathcal{A}$-components we proceed by induction on the depth of nodes: the base case holds for the root by the requirement on the first profile from the procedure; then we move down the tree using the conditions of the function *locally-consistent* and the already proved fact that the $\mathcal{B}$-component are as required.

Since the procedure checks if each of the guessed n-profiles is φ-admissible, then by Lemma 3 we have that $\mathfrak{T}_t \models \varphi$. ◀

To finish the proof of Thm. 8 it remains to note that the values of *maxdepth* and *maxdegree* ensure that the algorithm works indeed in (alternating) exponential time.

4.2 Descendant and child

We first note that when the child relation $\downarrow$ is available in the signature then, in contrast to the case of FO^2 and C^2 the satisfiability problem becomes 2-ExpTime-hard. This can be shown by a simple adaptation of the 2-ExpTime-hardness proof for the unary negation fragment, UNFO, [17], which works in particular for UNFO[$\downarrow$] over trees. Actually some two-dimensional formulas appear in that proof, but their usage is not crucial and can be easily avoided.

▶ **Theorem 10.** *The satisfiability problem for* $\mathrm{F}_1[\downarrow]$ *is 2-*ExpTime*-hard.*

A matching upper bound for $\mathrm{F}_1[\downarrow, \downarrow_+]$ is easy to obtain using the tools we have already developed.

▶ **Theorem 11.** *The satisfiability problem for* $\mathrm{F}_1[\downarrow, \downarrow_+]$ *is 2-*ExpTime*-complete.*

Proof. The lower bound follows from Thm. 10. For the upper bound we just modify the procedure F_1`[`$\downarrow_+$`]-sat-test` from Section 4.1 in a natural way. By Corollary 6 (i) and Lemma 7 (i) we know that satisfiable formulas have models with doubly exponentially bounded paths and exponentially bounded degree of nodes. Thus we just change the initial value of *maxdepth* to $\mathfrak{f}_d(\|\varphi\|)$ and adjust the function *locally-consistent* by taking into account the presence of $\downarrow$ relation. The obtained procedure works in alternating exponential space. Since AExpSpace = 2-ExpTime [3] we get the desired result. ◀

4.3 Ordered trees

We conclude this section observing that the satisfiability problem of F_1 over ordered trees remains in 2-ExpTime.

▶ **Theorem 12.** *The satisfiability problem for* $\mathrm{F}_1[\downarrow, \downarrow_+, \rightarrow, \rightarrow^+]$ *is 2-*ExpTime*-complete.*

Proof. The lower bound follows from Thm. 10. For the upper bound we need another modification of the procedure F_1`[`$\downarrow_+$`]-sat-test`. As we want to fit in alternating exponential space we cannot this time allow ourselves for guessing at once all the children of a node (as there may be doubly exponentially many of them). Instead we start by guessing the leftmost one, and then move to the right until we reach the rightmost one. During this horizontal walk, at each node a we actually make a universal choice between continuing the walk to the right and moving down to the first child of a. Further, instead of n-profiles of nodes we guess horizontal-n-profiles of the form $(\alpha, \mathcal{A}, \mathcal{B}, \mathcal{A}_L, \mathcal{A}_R)$. The function `locally-consistent` takes this into account; it can be naturally designed to ensure that the the nodes guessed in an

accepting tree-run of the procedure indeed have the declared horizontal profiles. Note in particular that knowing the components $\mathcal{A}_L$, $\mathcal{A}_R$ and $\mathcal{B}$ of the horizontal profile of any child of a one can compute the $\mathcal{B}$ component of the profile of a. We leave the technical details of the required adaptation for the full version of the paper. ◀

5 Expressivity

We show that the expressive power of $\mathrm{F}_1[\tau_{bin}]$ is equal to the expressive power of $\mathrm{C}^2[\tau_{bin}]$ in the case of ordered trees, $\tau_{bin} = \{\downarrow, \downarrow_+, \rightarrow, \rightarrow^+\}$, and in the case of unordered trees accessible by both the descendant and the child relations, $\tau_{bin} = \{\downarrow, \downarrow_+\}$. Translation from C^2 to F_1 is easy. Consider, e.g., a subformula of the form $\exists^{\geq k} y \psi(x, y)$ and note that it can be written as $\exists y_1, \ldots, y_k(\bigwedge_{i \neq j} y_i \neq y_j \wedge \bigwedge_i \psi(x, y_i))$. Regarding the opposite direction, in the case of the ordered trees the equivalence is not very surprising: the power of the full navigational signature allows scanning trees in an ordered way and express the existence of patterns described by F_1 subformulas by a reuse of two variables. Actually, one can even directly translate F_1 to FO^2 without counting in this case. The equivalence over unordered trees is slightly harder and less obvious. The proof of the following theorem will be given in the full version of this paper.

▶ **Theorem 13.** *For any* $\mathrm{F}_1[\downarrow, \downarrow_+]$ *(*$\mathrm{F}_1[\downarrow, \downarrow_+, \rightarrow, \rightarrow^+]$*) sentence* φ *there is a* $\mathrm{C}^2[\downarrow, \downarrow_+]$ *(*$\mathrm{C}^2[\downarrow, \downarrow_+, \rightarrow, \rightarrow^+]$*) sentence* φ^* *such that for any tree* $\mathfrak{T}$ *we have* $\mathfrak{T} \models \varphi$ *iff* $\mathfrak{T} \models \varphi^*$*, and vice versa.*

Let us also collect here the results comparing the expressive power over trees of F_1, C^2 and two other two-variable logics: the two-variable guarded fragment, GF^2, and plain FO^2. By $A \prec B$ we denote that A is strictly less expressive than B (on the level of sentences), and by $A \equiv B$ we denote that A and B have the same expressive power.

▶ **Corollary 14.**
(i) *Over* $\tau = \{\downarrow, \downarrow_+, \rightarrow, \rightarrow^+\}$ *we have* $\mathrm{GF}^2[\tau] \equiv \mathrm{FO}^2[\tau] \equiv \mathrm{C}^2[\tau] \equiv \mathrm{F}_1[\tau]$.
(ii) *If* $\tau = \{\downarrow, \downarrow_+\}$ *then* $\mathrm{GF}^2[\tau] \prec \mathrm{FO}^2[\tau] \prec \mathrm{C}^2[\tau] \equiv \mathrm{F}_1[\tau]$.

Regarding (i): the translation of FO^2 to GF^2 can be done similarly to the translation of FO^2 to a variant of Core XPath in [15], equivalence of C^2 and FO^2 is shown in [1] and of C^2 and F_1 in Thm. 13. Regarding (ii): Let us assume that the signature contains no unary predicates and for $i \in \mathbb{N}$ let $\mathfrak{T}_i$ denote the tree consisting just of a root and its i children. The C^2 formula $\exists x \exists^{\geq 3} y\ x \downarrow_+ y$ distinguishes $\mathfrak{T}_3$ and $\mathfrak{T}_2$, while the FO^2 formula $\exists xy(\neg x \downarrow_+ y \wedge \neg y \downarrow_+ x \wedge x \neq y)$ distinguishes $\mathfrak{T}_2$ and $\mathfrak{T}_1$. It is not difficult to see that FO^2 cannot distinguish between $\mathfrak{T}_3$ and $\mathfrak{T}_2$ (use a simple 2-pebble game argument, cf. [1]) and that GF^2 cannot distinguish between $\mathfrak{T}_2$ and $\mathfrak{T}_1$ (use bisimulations).

6 Conclusion

We established the computational complexity of F_1 over unordered trees, showing its ExpSpace-completeness over trees accessible only by the descendant relation and 2-ExpTime-completeness in the presence of the child relation. The 2-ExpTime-upper bound holds also for ordered trees equipped additionally with the next-sibling and following-sibling relations. Deriving the complexities for the remaining combinations of the considered navigational symbols (e.g., $\mathrm{F}_1[\downarrow_+, \rightarrow]$) is not difficult, and we will do it in the full version of this paper.

We also proved that under two of the considered navigational scenarios F_1 is expressively equivalent to C^2. Extending the expressive power comparison between F_1 and C^2 (and other logics) to the signatures containing just one of $\downarrow$, $\downarrow_+$ is left as a future work.

Another interesting open problem is to formally compare the succinctness of F_1 versus FO^2 and C^2 over trees (and over words).

We worked with unranked trees, but it is not difficult to adapt all the results for the case of ranked trees. In particular the counters in the 2-ExpTime-lower bound proof (Thm. 10) can be organized as binary subtrees instead of horizontal chains of siblings.

Abstract

Given a set $\mathcal{P}$ of points in the Euclidean plane and two triangulations of $\mathcal{P}$, the flip distance between these two triangulations is the minimum number of flips required to transform one triangulation into the other. The Parameterized Flip Distance problem is to decide if the flip distance between two given triangulations is equal to a given integer k. The previous best FPT algorithm runs in time $O^*(k \cdot c^k)$ ($c \leq 2 \times 14^{11}$), where each step has fourteen possible choices, and the length of the action sequence is bounded by $11k$. By applying the backtracking strategy and analyzing the underlying property of the flip sequence, each step of our algorithm has only five possible choices. Based on an auxiliary graph G, we prove that the length of the action sequence for our algorithm is bounded by $2|G|$. As a result, we present an FPT algorithm running in time $O^*(k \cdot 32^k)$.

1 Introduction

Given a set $\mathcal{P}$ of n points in the Euclidean plane, a *triangulation* of $\mathcal{P}$ is a maximal planar subdivision whose vertex set is $\mathcal{P}$ [10]. A *flip* operation to one diagonal e of a convex quadrilateral in a triangulation is to remove e and insert the other diagonal into this quadrilateral. Note that if the quadrilateral associated with e is not convex, the flip operation is not allowed. The *flip distance* between two triangulations is the minimum number of flips required to transform one triangulation into the other.

Triangulations play an important role in computational geometry, which are applied in areas such as computer-aided geometric design and numerical analysis [11, 13, 21].

Given a point set $\mathcal{P}$ in the Euclidean plane, we can construct a graph $G_T(\mathcal{P})$ in which every triangulation of $\mathcal{P}$ is represented by a vertex, and two vertices are adjacent if their

* This work is supported in part by the National Natural Science Foundation of China under Grants (61420106009, 61232001, 61472449, 61672536, 61572414).

corresponding triangulations can be transformed into each other through one flip operation. $G_T(\mathcal{P})$ is called the *triangulations graph* of $\mathcal{P}$. Properties of the triangulations graph are studied in the literature. Aichholzer et al. [1] showed that the lower bound of the number of vertices of $G_T(\mathcal{P})$ is $\Omega(2.33^n)$. Lawson and Charles [17] showed that the diameter of $G_T(\mathcal{P})$ is $O(n^2)$. Hurtado et al. [14] proved that the bound is tight. Since $G_T(\mathcal{P})$ is connected [17], any two triangulations of $\mathcal{P}$ can be transformed into each other through a certain number of flips.

The Flip Distance problem consists in computing the flip distance between two triangulations of $\mathcal{P}$, which was proved to be NP-complete by Lubiw and Pathak [18]. Pilz [20] showed that the Flip Distance problem is APX-hard. Aichholzer et al. [2] proved that the Flip Distance problem is NP-complete on triangulations of simple polygons. However, the complexity of the Flip Distance problem on triangulations of convex polygons has been open for many years, which is equivalent to the problem of computing the rotation distance between two rooted binary trees [23].

The Parameterized Flip Distance problem is: given two triangulations of a set of points in the plane and an integer k, deciding if the flip distance between these two triangulations is equal to k. For the Parameterized Flip Distance problem on triangulations of a convex polygon, Lucas [19] gave a kernel of size $2k$ and an $O^*(k^k)$-time algorithm. Kanj and Xia [15] studied the Parameterized Flip Distance problem on triangulations of a set of points in the plane, and presented an $O^*(k \cdot c^k)$-time algorithm ($c \leq 2 \cdot 14^{11}$), which applies to triangulations of general polygonal regions (even with holes or points inside it).

In this paper, we exploit the structure of the Parameterized Flip Distance problem further. At first, we give a nondeterministic construction process to illustrate our idea. The nondeterministic construction process contains only two types of actions, which are the *moving action* as well as the *flipping and backing action*. There are 4 choices for the moving action and one choice for the flipping and backing action. Given two triangulations and a parameter k, we prove that either there exists a sequence of actions of length at most $2k$, following which we can transform one triangulation into the other, or we can reject this instance. Thus we get an improved $O^*(k \cdot 32^k)$-time FPT algorithm, which also applies to triangulations of general polygonal regions (even with holes or points inside it).

2 Preliminaries

In a triangulation T, a flip operation f to an edge e that is the diagonal of a convex quadrilateral $\mathcal{Q}$ is to delete e and insert the other diagonal e' into $\mathcal{Q}$. We define e as the *underlying edge* of f, denoted by $\varepsilon(f)$, and e' as the *resulting edge* of f, denoted by $\varphi(f)$. (For consistency and clarity, we continue to use some symbols and definitions from [15]). Note that if e is not a diagonal of any convex quadrilateral in the triangulation, flipping e is not allowed. Suppose that we perform a flip operation f on a triangulation T_1 and get a new triangulation T_2. We say f transforms T_1 into T_2. T_1 is called an *underlying triangulation* of f, and T_2 is called a *resulting triangulation* of f. Given a set $\mathcal{P}$ of n points in the Euclidean plane, let T_{start} and T_{end} be two triangulations of $\mathcal{P}$, in which T_{start} is the initial triangulation and T_{end} is the objective triangulation. Let $F = \langle f_1, f_2, ..., f_r \rangle$ be a sequence of flips, and $\langle T_0, T_1, ..., T_r \rangle$ be a sequence of triangulations of $\mathcal{P}$ in which $T_0 = T_{start}$ and $T_r = T_{end}$. If T_{i-1} is an underlying triangulation of f_i, and T_i is a resulting triangulation of f_i for each $i = 1, 2, ..., r$, we say F transforms T_{start} into T_{end}, or F is a *valid sequence*, denoted by $T_{start} \xrightarrow{F} T_{end}$. The flip distance between T_{start} and T_{end} is the length of a shortest valid flip sequence.

Now we give the formal definition of the Parameterized Flip Distance problem.

Parameterized Flip Distance
Input: Two triangulations T_{start} and T_{end} of $\mathcal{P}$ and an integer k.
Question: Decide if the flip distance between T_{start} and T_{end} is equal to k.

The triangulation on which we are performing a flip operation is called the *current triangulation*. An edge e which belongs to the current triangulation but does not belong to T_{end} is called a *necessary edge* in the current triangulation. It is easy to see that for any necessary edge e, there must exist a flip operation f in a valid sequence such that $e = \varepsilon(f)$. Otherwise, we cannot get the objective triangulation T_{end}.

For a directed graph D, a maximal connected component of its underlying graph is called a *weakly connected component* of D. We define the size of an undirected tree as the number of its vertices.

A *parameterized problem* is a decision problem for which every instance is of the form (x, k), where x is the input instance and $k \in \mathbb{N}$ is the parameter. A parameterized problem is *fixed-parameter tractable* (FPT) if it can be solved by an algorithm (*FPT algorithm*) in $O(f(k)|x|^{O(1)})$ time, where $f(k)$ is a computable function of k. In addition to computational geometry, parameterized problems in other areas such as graph theory [8, 9, 12], computational biology [3, 22] and MAX-SAT [6] are also studied extensively. For a further introduction to parameterized algorithms, readers could refer to [4, 7].

3 The Improved Algorithm for the Parameterized Flip Distance Problem

Given T_{start} and T_{end}, let $F = \langle f_1, f_2, ..., f_r \rangle$ be a valid sequence, that is, $T_{start} \xrightarrow{F} T_{end}$. Definition 1 defines the adjacency of two flips in F.

▶ **Definition 1.** [15] Let f_i and f_j be two flips in F $(1 \leq i < j \leq r)$. We define that flip f_j is adjacent to flip f_i, denoted by $f_i \to f_j$, if the following two conditions are satisfied:
(1) either $\varphi(f_i) = \varepsilon(f_j)$, or $\varphi(f_i)$ and $\varepsilon(f_j)$ share a triangle in triangulation T_{j-1};
(2) $\varphi(f_i)$ is not flipped between f_i and f_j, that is, there does not exist a flip f_p in F, where $i < p < j$, such that $\varphi(f_i) = \varepsilon(f_p)$.

By Definition 1, we can construct a directed acyclic graph (DAG), denoted by D_F. Every node in D_F represents a flip operation of F, and there is an arc from f_i to f_j if f_j is adjacent to f_i. For convenience, we label the nodes in D_F using labels of the corresponding flip operations. In other words, we can see a node in D_F as a flip operation and vice versa.

The following lemma shows that any topological sorting of D_F is a valid sequence.

▶ **Lemma 2.** *[15] Let T_0 and T_r be two triangulations and $F = \langle f_1, f_2, ..., f_r \rangle$ be a sequence of flips such that $T_0 \xrightarrow{F} T_r$. Let $\pi(F)$ be a permutation of the flips in F such that $\pi(F)$ is a topological sorting of D_F. Then $\pi(F)$ is a valid sequence of flips such that $T_0 \xrightarrow{\pi(F)} T_r$.*

Lemma 2 ensures that if we repeatedly remove a source node from D_F and flip the underlying edge of this node until D_F becomes empty, we can get a valid sequence and the objective triangulation T_{end}.

Here we introduce the definition of a walk.

▶ **Definition 3.** [16] A *walk* in a triangulation T (starting from an edge $e \in T$) is a sequence of edges of T beginning with e in which any two consecutive edges share a triangle in T.

According to Lemma 2, if there is a valid sequence F for the input instance, any topological sorting of D_F is also a valid sequence for the given instance. The difficulty is that F is unknown. In order to find the topological sorting of D_F, the algorithm in [15] takes a nondeterministic walk to find an edge e which is the underlying edge of a source node, flips this edge (removing the corresponding node from D_F), nondeterministically walks to an edge which shares a triangle with e and recursively searches for an edge corresponding to a source node. They deal with weakly connected components of D_F one after one (refer to Corollary 4 in [15]), that is, their algorithm tries to find a solution F in which all flips belonging to the same weakly connected component of D_F appear consecutively. In order to keep searching procedure within the current weakly connected component, they use a stack to preserve the nodes (defined as *connecting point* in [15]) whose removal separates the current weakly connected component into small weakly connected components. When removing all nodes of a small component, their algorithm jumps to the connecting point at the top of the stack and moves to deal with another small component.

We observe that it is not necessary to remove all nodes of a weakly connected component before dealing with other weakly connected components, that is, our algorithm may find a solution F in which the nodes belonging to the same weakly connected components appear dispersedly. Thus we do not need a stack to preserve connecting points. Instead of five types of actions in [15], we only need two types, that is, moving action as well as flipping and backtracking action (see Section 3.2). Moreover, every time we find a source node, we remove the node, flip the underlying edge and backtrack instead of searching for the next node in four directions, thus reducing the number of choices for the actions. Another contribution of this paper is that we construct an auxiliary graph G and prove that G is a forest. Since there is a bijection between nondeterministic actions and nodes as well as edges of G, we prove that there exists a sequence of actions of length at most $2|D_F|$, which is smaller than $11|D_F|$ in [15]. In addition, we make some optimization on the strategy of finding the objective sequence. As a result, we improve the running time of the algorithm from $O^*(k \cdot c^k)$ where $c \leq 2 \cdot 14^{11}$ to $O^*(k \cdot 32^k)$.

3.1 Nondeterministic construction process

Now we give a description of our nondeterministic construction process **NDTRV** (see Fig. 1). The construction is nondeterministic as it always guesses the optimal choice correctly when running. The actual deterministic algorithm enumerates all possible choices to simulate the nondeterministic actions (see Fig. 3). Readers could refer to [5] as an example of nondeterministic algorithm. We present this construction process in order to depict the idea behind our deterministic algorithm clearly and vividly.

Let T_{start} be the initial triangulation, and T_{end} be the objective triangulation. Suppose that F is a shortest valid sequence, that is, F has the shortest length among all valid sequences. Let D_F be the DAG constructed after F according to Definition 1. **NDTRV** traverses D_F, removes the vertices of D_F in a topologically-sorted order and transforms T_{start} into T_{end}. Although D_F is unknown, for further analysis, we assume that **NDTRV** can remove and copy nodes in D_F so that it can construct an auxiliary undirected graph G and a list L based on D_F during the traversal. In later analysis we show that G is a forest, and there is a bijection between actions of **NDTRV** and nodes as well as edges of G. Obviously G and L are unknown as well. We just show that if a shortest valid sequence F exists, then D_F exists. So do G, L and Q. We can see D_F and G as conceptual or dummy graphs. We construct G instead of analysing a subgraph of D_F because one move action (see Section 3.2) of **NDTRV** may correspond to one or two edges in D_F (see Fig. 2), while there is a one-to-one correspondence between move actions and edges in G .

At the beginning of an iteration, **NDTRV** picks a necessary edge $e = \varepsilon(f_h)$ arbitrarily and nondeterministically guesses a walk W to find the underlying edge of a source node f_s. Lemma 5 shows that there exists such a walk W whose length is bounded by the length of a directed path B from f_s to f_h, and every edge e' in W is the underlying edge of some flip f' on B. **NDTRV** uses L to preserve a sequence of nodes $\Gamma = \langle f_s = v_1, ..., f_h = v_\ell \rangle$ on B, whose underlying edges are in W. Simultaneously **NDTRV** constructs a path S by copying all nodes in Γ as well as adding an undirected edge between the copy of v_i and v_{i+1} for $i = 1, ..., \ell$. S is defined as a *searching path*. The node f_h is called a *starting node*. If a starting node is precisely a source node in D_F, the searching path consists only of the copy of this starting node. When finding $\varepsilon(f_s)$, **NDTRV** removes f_s from D_F, flips $\varepsilon(f_s)$ and moves back to the previous edge $\varepsilon(v_2)$ of $\varepsilon(f_s)$ in W. If v_2 becomes a source node of D_F, **NDTRV** removes v_2 from D_F, flips $\varepsilon(v_2)$ and moves back to the previous edge $\varepsilon(v_3)$. **NDTRV** repeats the above operations until finding a node v_i in Γ which is not a source node in D_F. Then **NDTRV** uses v_i as a new starting node, and recursively guesses a walk nondeterministically from $\varepsilon(v_i)$ to find another edge which is the underlying edge of a source node as above. **NDTRV** performs these operations until the initial starting node f_h becomes a source node in D_F. Finally **NDTRV** removes f_h and flips $\varepsilon(f_h)$, terminating this iteration. **NDTRV** repeats the above iteration until T_{start} is transformed into T_{end}. We give the formal presentation of **NDTRV** in Fig. 1 and an example in Fig. 2.

3.2 Actions of the construction

Our construction process contains two types of actions operating on triangulations. The edge which the algorithm is operating on is called *the current edge*. The current triangulation is denoted by $T_{current}$.

- **(i)** Move to one edge that shares a triangle with the current edge in $T_{current}$. We formalize it as $(move, e_1 \mapsto e_2)$, where e_1 is the current edge and e_2 shares a triangle with e_1.
- **(ii)** Flip the current edge and move back to the previous edge of the current edge in W. We formalize it as $(f, e_4 \mapsto e_3)$, where f is the flip performed on the current edge, e_4 equals $\varphi(f)$ and e_3 is the previous edge of $\varepsilon(f)$ in the current walk W.

Since there are four edges that share a triangle with the current edge, there are at most four directions for an action of type (i). However, there is only one choice for an action of type (ii).

3.3 The sequence of actions

The following theorem is the main theorem for the deterministic algorithm **FLIPDT**, which bounds the length of the sequence of actions by $2|V(D_F)|$.

▶ **Theorem 4.** *There exists a sequence of actions of length at most $2|V(D_F)|$ following which we can perform a sequence of flips F' of length $|V(D_F)|$, starting from a necessary edge in T_{start}, such that F' is a topological sorting of D_F.*

In order to prove theorem 4, we need to introduce some lemmas. We will give the proof for Theorem 4 at the end of Section 3.3.

Lemma 5 shows the existence of a length-bounded walk to find an edge which is the underlying edge of a source node.

▶ **Lemma 5.** *[16] Suppose that a sequence of flips F^- is performed such that every time we flip an edge, we delete the corresponding source node in the DAG resulting from preceding*

NDTRV(T_{start}, T_{end}; D_F)

deleting operations. Let f_h be a node in the remaining DAG such that $\varepsilon(f_h)$ is an edge in the triangulation T resulting from performing the sequence of flips F^-. There is a source node f_s in the remaining DAG satisfying:

(1) *There is a walk W in T from $\varepsilon(f_h)$ to $\varepsilon(f_s)$.*

(2) *There is a directed path B from f_s to f_h in the remaining DAG that we refer to as the backbone of the DAG.*

(3) *The length of W is at most that of B.*

(4) *Any edge in W is the underlying edge of a flip in B, that is, $W = \langle \varepsilon(v_1), ..., \varepsilon(v_\ell) \rangle$, where $v_1 = f_s, ..., v_\ell = f_h$ are nodes in B and there is a directed path B_i from v_i to v_{i+1} for $i = 1, ..., \ell - 1$ such that $B_i \subset B$. A searching path is an undirected path constructed by copying $v_1, ..., v_\ell$ and connecting the copies of $v_1, ..., v_\ell$ into a path.*

▶ **Lemma 6.** ***NDTRV*** *transforms T_{start} into T_{end} with the minimum number of flips and stops in polynomial time if it correctly guesses every moving and flipping action.*

Proof. Suppose that F is a shortest valid sequence. According to Lemma 5, every edge

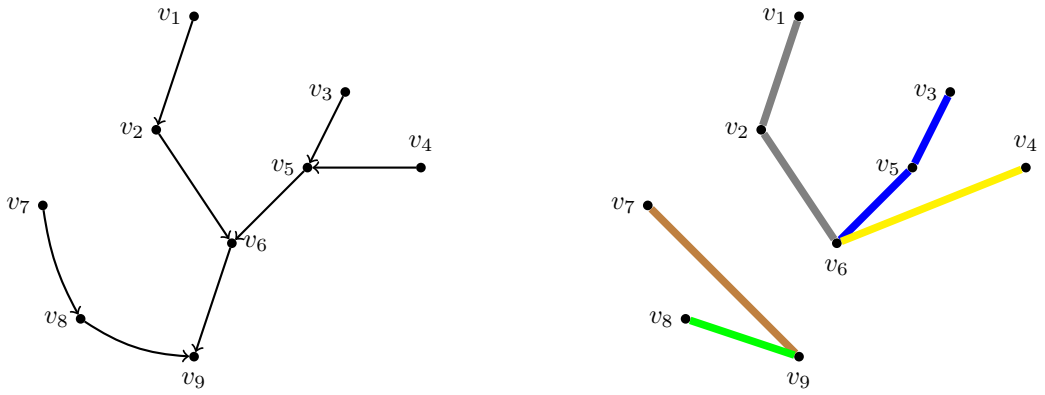

Figure 2 An example for constructing G. The graph on the left is the DAG. The graph on the right is the auxiliary graph G constructed by **NDTRV**. $\varepsilon(v_6)$ is the first chosen necessary edge, and $\varepsilon(v_9)$ is the second one. Edges with the same color belong to the same searching path. Searching paths in the same connected component are constructed in the same iteration.

flipped in **NDTRV** is the underlying edge of a source node in the remaining graph of D_F, and every node removed from the remaining graph of D_F in **NDTRV** is a source node. If $T_{current}$ is equal to T_{end} but D_F is not empty, then there exists a valid sequence F' which is shorter than F, contradicting that F is a shortest valid sequence. Thus **NDTRV** traverses D_F, removes all nodes of D_F in a topologically-sorted order and transforms T_{start} into T_{end} with the minimum number of flips by Lemma 2. Since the diameter of a transformations graph $G_T(\mathcal{P})$ is $O(n^2)$ [17], **NDTRV** stops in polynomial time. ◀

NDTRV constructs G, Q and L during its execution. Lemma 7, Lemma 8 and Lemma 9 show some properties of G, Q, L and D_F.

▶ **Lemma 7.** *At the end of **NDTRV**, the graph G consists of all searching paths constructed during the execution of **NDTRV**. Moreover, the list Q contains a sequence of nondeterministic actions starting from a necessary edge in T_{start} following which we can perform a sequence of flips F' of length $|V(D_F)|$ such that F' is a topological sorting of D_F.*

Proof. From the construction of G, we see that one node is added into G when it is in some searching path. Moreover, we add an edge between two nodes in G if and only if they are adjacent in a searching path. It follows that G consists of all searching paths constructed during the execution of **NDTRV**.

By the proof of Lemma 6, **NDTRV** removes the nodes of D_F in a topologically-sorted order. Since Q records every action of **NDTRV**, if we perform the actions in Q, we get a valid sequence F'. This completes the proof. ◀

▶ **Lemma 8.** *The following statements are true:*

(1) *At the end of any iteration of **NDTRV**, all nodes whose copies are in the searching paths constructed in this iteration are removed from D_F, and L becomes empty.*

(2) *During every step of **NDTRV**, there exists a directed path in the remaining graph of D_F passing through every node in L from the last node of L to the first node of L.*

(3) *All searching paths in G are edge-disjoint. Any two searching paths which belong to two different iterations respectively are node-disjoint. Searching paths constructed in each iteration form a tree respectively, namely a track tree. Moreover, G is a forest.*

Proof. Suppose we are in the first iteration. We name the searching paths in this iteration $S_1, ..., S_m$ by the order they are constructed. Suppose now we have constructed searching paths $S_1, ..., S_i$ and $i < m$. We prove that statements (2) and (3) hold for the first iteration by induction on i. When $i = 1$, the statement is true because there is only one searching path S_1 forming a tree, and there is a directed path in the remaining graph of D_F passing through every node in L from the last to the first according to Lemma 5. Assume that the statements are true for any $i < m$, that is, $S_1, ..., S_i$ are edge-disjoint, and they form a tree. Moreover, there exists a directed path P in the remaining graph of D_F passing through every node in L from the last to the first (inductive hypothesis). The next searching path we will construct is S_{i+1}. Note that before constructing S_{i+1}, we may remove the last node of L repeatedly from the remaining graph of D_F and L if it is a source node in the remaining graph of D_F. Since every node we removed was the beginning node of the directed path P, there was still a directed path passing through every node in L from the last to the first. Let $f_{start,i+1}$ be the starting node whose copy is in S_{i+1}, which means that $f_{start,i+1}$ is the last node in L, and $f_{start,i+1}$ is not a source node in the remaining graph of D_F. By the inductive hypothesis and the analysis above, there is a directed path P_1 from $f_{start,i+1}$ to f_h which is the first node of L. Let f'_s be a source node in the remaining graph of D_F such that the copy of f'_s is in S_{i+1}. By Lemma 5, there is a directed path P_2 in the remaining graph of D_F passing through the nodes whose copies are in S_{i+1} from f'_s to $f_{start,i+1}$. We argue that P_1 has only one common node with P_2, which is exactly $f_{start,i+1}$. Otherwise, there is a directed cycle induced by some of the nodes on P_1 and P_2 in the remaining graph of D_F, contradicting the acyclicity of D_F. It follows that there is a directed path in the remaining graph of D_F passing through every node in L from the last node of L to the first node of L. Since S_{i+1} cannot contain any copies of the nodes that have been removed from the remaining graph of D_F and L, S_{i+1} has only one common node with the searching paths S_1,...,S_i, namely the copy of $f_{start,i+1}$. It is implied that a node of D_F cannot be added to L more than once for the same reason. As a result, S_1,...,S_i and S_{i+1} are edge-disjoint, and S_1,...,S_{i+1} form a tree. The tree formed by S_1,...,S_m is a track tree. This completes the inductive proof.

We prove statement (1) in the first iteration by contradiction. Suppose that there exists one or several nodes left in L at the end of an iteration, and w is the last one in L. Suppose w was added to L when searching path S_p was constructed and **TrackTree**(v_p) was called. Let u be the node appended to L on its heel. Such a node u existed since w was not a source node then. Otherwise w was removed, resulting in a contradiction as one node of D_F cannot be added to L more than once (according to the proof in the above paragraph). Since w is the last one in L at the end of this iteration, u was removed, and **NDTRV** moved back to $\varepsilon(w)$. According to **NDTRV**, w has never become a source node in D_F. Otherwise, w has been removed from L, leading to a contradiction since one node of D_F cannot be added to L more than once. Thus **TrackTree**(w) was called. The terminal condition of **TrackTree**(w) is that w becomes a source node in D_F, and w is removed from L and D_F. This implies that this iteration does not end, a contradiction. It follows that L becomes empty at the end of the first iteration. According to **NDTRV**, all nodes whose copies are in the searching paths constructed in the first iteration are removed from D_F.

We prove that statements (1), (2) and (3) hold for the whole procedure by induction. We have proved that they are true for the first iteration. Suppose that there are t iterations in the procedure, and statements (1), (2) and (3) hold for the first j iterations for any $1 \leq j < t$. By the inductive hypothesis, at the end of the j-th iteration, L is empty. A node x whose copy is in the searching paths constructed in the first j iterations can never appear in L in the

$(j+1)$-th iteration because it has been removed from D_F. It follows that the searching paths constructed in the $(j+1)$-th iteration are node-disjoint with the searching paths constructed in the first j iterations. Thus they are edge-disjoint. Since L is empty, it is not difficult to see that the proof for the first iteration also holds for the $(j+1)$-th iteration. It follows that the searching paths constructed in the $(j+1)$-th iteration form a tree that is node disjoint with other j trees belonging to the first j iterations respectively, that is, these trees form a forest all together. By Lemma 7, G consists of all searching paths constructed during the execution of **NDTRV**. It follows that G is a forest. This completes the inductive proof for the whole procedure. ◀

▶ **Lemma 9.** *$|V(G)|$ is equal to $|V(D_F)|$.*

Proof. According to **NDTRV**, a node v is added to L if and only if its copy is added to G, and v is removed from L if and only if v is removed from D_F. By the proof in Lemma 8, no node in D_F can be added to L more than once. By the proof of Lemma 6, all nodes of D_F are removed by **NDTRV**. It follows that all nodes in D_F have exactly one copy in G. Thus $|V(G)| = |V(D_F)|$. ◀

We give the proof of Theorem 4 below.

Proof. (Theorem 4) In the procedure of constructing G in Fig. 1, we construct a list Q which consists of actions of type (i) and (ii). We claim that Q is exactly the sequence satisfying the requirement of this theorem. By Lemma 7, the number of actions of type (ii) in Q is exactly $|V(D_F)| = |V(G)|$. **NDTRV** adds an action of type (i) to Q if and only if it adds an an edge to $E(G)$. Moreover, Q and $E(G)$ are both empty at the beginning of **NDTRV**. It follows that there is a one-to-one correspondence between actions of type (i) in Q and edges in G. By Lemma 8, G is a forest. As a result, $|E(G)| \leq |V(G)|$, and the length of Q is bounded by $|E(G)| + |V(G)| \leq 2|V(G)| = 2|V(D_F)|$. ◀

3.4 The deterministic algorithm

Now we are ready to give the deterministic algorithm **FLIPDT** for the Parameterized Flip Distance problem. The specific algorithm is presented in Fig. 3. As mentioned above, we assume that **NDTRV** is always able to guess the optimal choice correctly. In fact, **FLIPDT** achieves this by trying all possible sequences of actions and partitions of k. At the top level, **FLIPDT** branches into all partitions of k, namely $(k_1, ..., k_t)$ satisfying $k_1 + ... + k_t = k$ and $k_1, ..., k_t \geq 1$, in which k_i $(i = 1, ..., t)$ equals the size of the track tree A_i constructed during the i-th iteration.

Suppose that **FLIPDT** is under some partition $(k_1, ..., k_t)$. Let $T^0_{iteration} = T_{start}$. **FLIPDT** permutates all necessary edges in T_{start} in the lexicographical order, and the ordering is denoted by O_{lex}. Here we number the given points of $\mathcal{P}$ in the Euclidean plane from 1 to n arbitrarily and label one edge by a tuple consisting of two numbers of its endpoints (the smaller number is ahead of the other one). Thus we can order the edges lexicographically. **FLIPDT** performs t iterations. At the beginning of the i-th iteration, $i = 1, ..., t$, we denote the current triangulation by $T^{i-1}_{iteration}$. For $i = 1, ..., t$, $T^i_{iteration}$ is also the triangulation resulting from the execution of the i-th iteration. At the beginning of the i-th iteration $(i = 1, ..., t)$, **FLIPDT** repeatedly picks the next edge in O_{lex} until finding a necessary edge e belonging to $T^{i-1}_{iteration}$ (just pick the first edge in O_{lex} in the first iteration). Note that one edge in O_{lex} may not be a necessary edge anymore with respect to $T^{i-1}_{iteration}$. Moreover, if **FLIPDT** reaches the end of O_{lex} but does not find a necessary edge belonging

FLIPDT(T_{start}, T_{end}, k)
Input: two triangulations T_{start} and T_{end} of a point set $\mathcal{P}$ in the Euclidean plane and an integer k.
Output: return YES if there exists a sequence of flips of length k that transforms T_{start} into T_{end}; otherwise return NO.

1. **For** each partition $(k_1, ..., k_t)$ of k satisfying $k_1 + k_2 + ... + k_t = k$ and $k_1, ..., k_t \geq 1$ **do**
1.1 Order all necessary edges in T_{start} lexicographically and denote this ordering by O_{lex};
1.2 **FDSearch**(T_{start},1,$(k_1, ..., k_t)$); /*iteration 1 *distributed with* k_1 */
2. **Return** NO;

FDSearch(T,i,$(k_1, ..., k_t)$) /*the concrete branching procedure*/
Input: a triangulation T, an integer i denoting that the algorithm is at the i-th iteration and a partition $(k_1, ..., k_t)$ of k.
Output: return YES if the instance is accepted.

1. Repeatedly pick the next edge in O_{lex} until finding a necessary edge e with respect to T and T_{end};
2. **If** it reaches the end of O_{lex} but finds no necessary edge in T **then**
2.1 Update O_{lex} by permutating all necessary edges in $T^{i-1}_{iteration}$ in lexicographical order, and pick the first edge e in O_{lex};
3. **For** each possible sequence of actions seq_i of length $2k_i - 1$ **do**
3.1 T' = **Transform**(T,seq_i,e);
3.2 **If** $i < t$ **then** /*continue to the next iteration distributed with* k_{i+1} */
3.2.1 **FDSearch**(T',$i + 1$,$(k_1, ..., k_t)$);
3.3 **Else if** $i = t$ and $T' = T_{end}$ **then** /*compare* T' *with* T_{end} */
3.3.1 **Return** YES;

Transform(T,s,e) /*subprocess for transforming triangulations*/
Input: a triangulation T, a sequence of actions s and a starting edges e.
Output: a new triangulation T'.

1. Perform a sequence of actions s starting from e in T, getting a new triangulation T';
2. **Return** T';

Figure 3 The deterministic algorithm for the Flip Distance problem

to $T^{i-1}_{iteration}$, it needs to update O_{lex} by clearing O_{lex} and permutating all necessary edges in $T^{i-1}_{iteration}$ lexicographically, and choose the first edge in the updated ordering O_{lex}. Then **FLIPDT** branches into every possible sequence of actions seq_i of length $2k_i - 1$. For each enumeration of seq_i, **FLIPDT** performs the actions of seq_i on $T^{i-1}_{iteration}$ starting from e and gets a new triangulation $T^{i}_{iteration}$. For every triangulation $T^{i}_{iteration}$ resulting from seq_i, **FLIPDT** performs the $(i + 1)$-th iteration on $T^{i}_{iteration}$. **FLIPDT** proceeds as above from the first iteration to the last iteration. When **FLIPDT** finishes the last iteration, it judges if the resulting triangulation $T^{t}_{iteration}$ is equal to T_{end}. If they are equal, the input instance is a yes-instance. Otherwise, **FLIPDT** rejects this case and proceeds.

Now we analyse how to enumerate all possible sequences of length $2k_i - 1$. By the proof of Lemma 8 and Theorem 4, the searching paths constructed during each iteration form a track tree in which a node corresponds to an action of type (ii) while an edge corresponds to an action of type (i). It follows that the number of actions of type (ii) is k_i, and the number of actions of type (i) is $k_i - 1$ since the number of nodes equals the number of edges plus one in a tree. According to **NDTRV**, the last action γ in seq_i must be of type (ii), and in any prefix of $seq_i - \gamma$ the number of actions of type (i) must not be less than that of type (ii). Thus **FLIPDT** only needs to enumerate all sequences of length $2k_i - 1$ satisfying the above constraints.

The following theorem proves the correctness of the algorithm **FLIPDT**.

▶ **Theorem 10.** *Let* (T_{start}, T_{end}, k) *be an input instance.* ***FLIPDT*** *is correct and runs in time* $O^*(k \cdot 32^k)$.

Proof. Suppose that (T_{start}, T_{end}, k) is a yes-instance. There must exist a sequence of flips F of length k such that $T_{start} \xrightarrow{F} T_{end}$. Thus D_F exists according to Definition 1. By **NDTRV**, Lemma 7 and Lemma 8, there exists an undirected graph G consisting of a set of node-disjoint track trees $A_1, ..., A_t$. Moreover, Theorem 4 shows that there exists a sequence of actions Q following which we can perform all flips of D_F in a topologically-sorted order. Due to **NDTRV**, Q consists of several subsequences $seq_1, ..., seq_t$, in which seq_i is constructed in the i-th iteration and corresponds to the track tree A_i for $i = 1, ..., t$. Supposing the size of A_i is λ_i for $i = 1, ..., t$ satisfying $\lambda_1 + ... + \lambda_t = k$, seq_i contains λ_i actions of type (ii) corresponding to the nodes of A_i as well as $\lambda_i - 1$ actions of type (i) corresponding to the edges of A_i. **FLIPDT** guesses the size of every track tree by enumerating all possible partitions of k into $(k_1, ..., k_t)$ such that $k_1 + ... + k_t = k$ and $k_1, ..., k_t \geq 1$. We say that k_i is distributed to the i-th iteration or the distribution for the i-th iteration is k_i for $i = 1, ..., t$.

We claim that **FLIPDT** is able to perform a sequence Σ of actions which correctly guesses every subsequence $seq_1, ..., seq_t$ of the objective sequence Q, that is, Σ is a concatenation of $seq_1, ..., seq_t$. Suppose that **FLIPDT** has completed i iterations. We prove this claim by induction on i. At the first iteration, **FLIPDT** starts by picking the first necessary edge e_1 in list O_{lex}. In the first iteration of constructing Q, **NDTRV** starts by picking an arbitrary necessary edge. Without loss of generality, it chooses e_1 and construct seq_1 starting from e_1. The length of seq_1 is $2\lambda_1 - 1$. Since **FLIPDT** tries every distribution in $\{1, ..., k\}$ for the first iteration and $1 \leq \lambda_1 \leq k$, there is a correct guess of the distribution equal to λ_1 for this iteration. Under this correct guess, **FLIPDT** tries all possible sequences of actions of length $2\lambda_1 - 1$ starting from e_1. It follows that **FLIPDT** is able to perform a sequence that is equals to seq_1 in the first iteration resulting in a triangulation T_1.

Suppose that the claim is true for any first i iterations $(1 \leq i < t)$. That is, under some guess for the partition of k, $\lambda_1, ..., \lambda_i$ are distributed to the first i iterations respectively. Moreover, **FLIPDT** has completed i iterations and performed a sequence of actions $seq_{concat,i}$, which is equal to the concatenation of $seq_1, ..., seq_i$, resulting in a triangulation T_i. Based on T_i and $seq_{concat,i}$, **FLIPDT** is ready to perform the $(i+1)$-th iteration. Suppose that **FLIPDT** picks e_{i+1} from O_{lex}. Let us see the construction of Q in **NDTRV**. Suppose **NDTRV** has constructed the first i track trees $A_1, ..., A_i$, and it is ready to begin a new iteration by arbitrarily picking a necessary edge in the current triangulation. Since **FLIPDT** correctly guessed and performed the first i subsequences of Q, T_i is exactly equal to the current triangulation in **NDTRV**. Thus e_{i+1} is a candidate edge belonging to the set of all selectable necessary edges for **NDTRV** in this iteration. Without loss of generality, it chooses e_{i+1} and constructs seq_{i+1} of length $2\lambda_{i+1} - 1$ starting from e_{i+1}. Since the sizes of $A_1, ..., A_i$ are $\lambda_1, ..., \lambda_i$ respectively, we get that $1 \leq \lambda_{i+1} \leq k - (\lambda_1 + ... + \lambda_i)$. We argue that **FLIPDT** is able to perform a sequence that is equal to the concatenation of $seq_1, ..., seq_{i+1}$. Since the edges in O_{lex} are ordered lexicographically and **FLIPDT** chooses necessary edges in a fixed manner, **FLIPDT** is sure to choose e_{i+1} to begin the $(i+1)$-th iteration for every guessed sequence in which the first i subsequences are equal to seq_1,...,seq_i respectively. Thus **FLIPDT** actually tries every distribution in $\{1, ..., k - (\lambda_1 + ... + \lambda_i)\}$ for the $(i+1)$-th iteration starting from e_{i+1} based on T_i and $seq_{concat,i}$. It follows that there is a correct guess of distribution for the $(i+1)$-th iteration which is equal to λ_{i+1}. Under this correct guess of distribution, **FLIPDT** tries all possible sequences of length $2\lambda_{i+1} - 1$ starting from e_{i+1} on T_i based on $seq_{concat,i}$, ensuring that one of them is equal to seq_{i+1}. It follows that the claim is true for the first $i+1$ iterations. This completes the inductive proof for the claim.

If (T_{start}, T_{end}, k) is a yes-instance, the action sequence Q of length at most $2k$ exists and the deterministic algorithm can find such a sequence. Otherwise, there is no valid sequence F of length k. Thus there is no such action sequence Q. As a result, **FLIPDT** returns NO. It is proved that **FLIPDT** decides the given instance (T_{start}, T_{end}, k) correctly.

Finding and ordering all necessary edges in T_{start} takes $O(n+k\log k)$ time, and **FLIPDT** may update the ordering O_{lex} at the beginning of each iteration. The number of partitions of k is known as the composition number of k, which is 2^{k-1}. Under each partition $(k_1, ..., k_t)$ of k and for each k_i, $i = 1, ..., t$, we enumerate all possible subsequences of actions in which there are k_i actions of type (ii) and $k_i - 1$ actions of type (i). It follows that the number of all possible subsequences is bounded by $\binom{2(k_i-1)}{k_i-1} \times 4^{k_i-1} = O^*(16^{k_i})$ since there are four choices for action (i) and one choice for action (ii). Here we use Stirling's approximation $n! \approx \sqrt{2\pi n}(n/e)^n$ and get that $\binom{2(k_i-1)}{k_i-1} = O^*(4^{k_i})$. It follows that there are $O^*(16^{k_1}) \times O^*(16^{k_2}) \times ... \times O^*(16^{k_t}) = O^*(16^k)$ cases under each partition. Since for each case we can perform the sequence of actions in $O(k)$ time, and the resulting triangulation can be compared to T_{end} in $O(k)$ time, the running time of the whole algorithm is bounded by $O^*(k \cdot 2^{k-1} \cdot (n + k\log k) + k \cdot 2^{k-1} \cdot 16^k) = O^*(k \cdot 32^k)$.

According to the definition of the Flip Distance problem, we need to decide if we can find a shorter valid flip sequence for the given triangulations T_{start} and T_{end}. This is achieved by calling **FLIPDT** on each instance (T_{start}, T_{end}, k') for $k' = 0, ..., k$. The running time is bounded by $\sum_{k'=0}^{k} O^*(k' \cdot 32^{k'}) = O^*(k \cdot 32^k)$. ◀

4 Conclusion

In this paper we presented an FPT algorithm running in time $O^*(k \cdot 32^k)$ for the Parameterized Flip Distance problem, improving the previous $O^*(k \cdot c^k)$-time ($c \leq 2 \times 14^{11}$) FPT algorithm by Kanj and Xia [15]. An important related problem is computing the flip distance between triangulations of a convex polygon, whose traditional complexity is still unknown. Although our algorithm can be applied to the case of convex polygon, it seems that an $O(c^k)$ algorithm with smaller c for this case probably exists due to its more restrictive geometric property. In addition, whether there exists a polynomial kernel for the Parameterized Flip Distance problem is also an attractive problem.

Reversible Kleene Lattices*

Paul Brunet

University College London, United Kingdom
paul@brunet-zamansky.fr

Abstract

We investigate the equational theory of reversible Kleene lattices, that is algebras of languages with the regular operations (union, composition and Kleene star), together with the intersection and mirror image. Building on results by Andréka, Mikulás and Németi from 2011, we construct the free representation of this algebra. We then provide an automaton model to compare representations. These automata are adapted from Petri automata, which we introduced with Pous in 2015 to tackle a similar problem for algebras of binary relations. This allows us to show that testing the validity of equations in this algebra is decidable, and in fact ExpSpace-complete.

1 Introduction

We are interested in algebras of languages, equipped with the constants empty language (0), unit language (1, the language containing only the empty word), the binary operations of union (+), intersection (∩), and concatenation (·), and the unary operations of Kleene star ($\_^\star$) and mirror image, also called converse, ($\_^\smile$). We call these algebras *reversible Kleene lattices*. Given a finite set of variables X, and two terms e, f built from variables and the above operations, we say that the equation $e = f$ (respectively inequation $e \leq f$) is *valid* if the corresponding equality (resp. containment) holds universally. A *free representation* is a set $\mathcal{M}$ together with a map h from terms to elements of $\mathcal{M}$ such that $e = f$ is valid if and only if h maps e and f to the same element of $\mathcal{M}$.

It is well known that to any term over this syntax, one can associate a regular language, and that comparing regular languages is decidable. In fact, the problem of comparing regular expressions with intersection with respect to regular language equivalence is ExpSpace-complete [12]. The difference with the work presented here is that we are considering equations which are stable under substitution. Formally, this means that we do not interpret the letter a as the singleton language $\{a\}$, but rather as a universally quantified variable ranging over all languages. What is remarkable however is that testing the validity of equations in reversible Kleene lattices is still an ExpSpace-complete problem, as we show in this paper. Several fragments of this algebra have been studied:

Kleene algebra (KA) [9]: if we restricts ourselves to the operators of regular expressions (0, 1, +, ·, and $\_^\star$), then the free representation is the set of regular languages, with the usual definition of the language of an expression. Testing the validity of equations in KA is thus a PSpace-complete problem [19, 14].

Kleene algebra with converse (KAC) [3]: if we add to KA the converse operation, then the free representation consists of regular expressions over a duplicated alphabet, with a letter a' denoting the converse of the letter a. The associated decision problem is still in PSpace.

Identity-free Kleene lattices (KL^-) [1]: this algebra stems from the operators 0, +, $\cdot$, $\cap$ and $\_^+$, where the latter is the non-zero iteration. Andréka Mikulás and Németi studied this fragment, and showed that the free representation of this algebra consists of languages of series-parallel graphs, downward closed with respect to some graph preorder. We reformulated their results with Pous [6], and introduced a new class of automata, called Petri automata, able to recognise these languages of graphs. In [6] we provided a decision procedure to compare these automata, thus yielding an ExpSpace decision procedure for the equational theory of this algebra. It is in fact ExpSpace-complete, thanks to some simple adaptation of a result by Fürer [12].

The present work is then an extension of identity-free Kleene lattices, by adding unit and mirror image. The addition of mirror image is fairly simple, relying mainly on ideas from [3]. However, the seemingly small addition of 1 yields some complications. In fact, in [1, 6] there is a free representation of Kleene allegories, an algebra over the same signature as reversible Kleene lattices, but whose intended model is binary relations rather than languages. In this context, adding 1 means moving from *series-parallel* graphs to graphs of tree-width 2, which might have cycles. This is a significant problem for automata based decision procedures.

In the context of languages, adding 1 yields other problems. However, the free representation we get for reversible Kleene lattices remains more tractable than that of Kleene allegories. In particular we do not create cycles in series parallel graphs, but rather have to collect additional information. Let us illustrate the kind of reasoning we develop to study these algebras with the following inequation: $c \cdot (1 \cap a) \leq a \cdot c$. On the left hand side (LHS), the term $1 \cap a$ appears. This term is either equal to 1 if the empty word belongs to language a, or 0 otherwise. In the first case, the LHS is equal to c and we have $1 \leq a$, meaning that $c = 1 \cdot c \leq a \cdot c$. In the second case the LHS is equal to 0, which is contained in $a \cdot c$ as well. The key observation here is that the second case does not really matter: in a term build out of concatenations, intersections, converse, variables and units, if 0 appears somewhere then the term will always evaluate to 0 and thus be contained in any other term. The free representations we develop for union-free terms consist of pairs of a representation of a 1-free term and a set of language variables which are assumed to contain the empty word. This allows us to make the reasoning we used above automatic.

Following an approach similar to [6], we construct in Section 2 the free representation of reversible Kleene lattices, and introducing a new Petri net-based automata model we show in Section 3 that testing the validity of equations is a decidable problem, and in fact an ExpSpace-complete one. We conclude and list some perspectives in Section 4.

Basic definitions and notations

For a pair $p = \langle x, y \rangle$, we denote by $\pi_1(p) = x$ the first projection, and by $\pi_2(p) = y$ the second projection. The set of functions from a set A to a set B is written $A \to B$, and the set of partial functions from A to B is written $A \rightharpoonup B$. The number of elements of a finite set A is written $|A|$. The empty word is denoted by ε, and the set of words over the alphabet Σ is $\Sigma^\star$. If $w = x_1 \dots x_n$ is a word of length n, $w[i, j]$ is the word $x_i \dots x_j$ if $i \leqslant j$, and undefined otherwise. If f is a function from some set X to $\{0, \dots, n\}$, x, y are elements of X, and if $f(x) \leqslant f(y)$, we use the notation $w^f[x, y]$ for the word $w[f(x), f(y)]$.

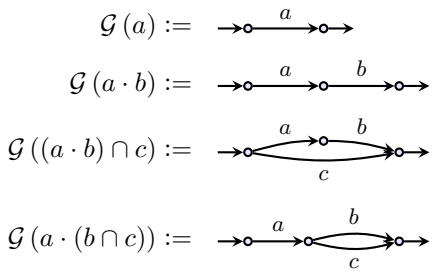

Figure 1 Graphs associated to terms.

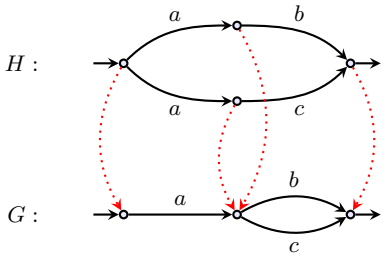

Figure 2 Graph homomorphism.

Let X be a finite set of variables, we define $\dot{A} := A \cup \{a^\smile \mid a \in A\}$ for every subset $A \subseteq X$. The set $\dot{X}$ is called the duplicated alphabet, we let α, β range over $\dot{X}$. Expressions over X are given by the following grammar:

$$e, f ::= 0 \mid 1 \mid x \mid e^\smile \mid e + f \mid e \cdot f \mid e \cap f \mid e^\star. \qquad (x \in X)$$

The set of expressions over X is written $\mathcal{E}\langle X \rangle$. The size of an expression e, written $|e|$, is its number of symbols, *i.e.* the number of vertices in its syntax tree. Most of the time, we will implicitly assume that the converse operator only appears as $x^\smile$, with $x \in X$. This is not restrictive, as every expression can be transformed linearly such that this property holds. Given a second alphabet Σ, an interpretation is a map $\sigma : X \to \mathcal{P}(\Sigma^\star)$ which associates to every variable a a language $\sigma(a)$. This map can be uniquely extended to a homomorphism $\widehat{\sigma} : \mathcal{E}\langle X \rangle \to \mathcal{P}(\Sigma^\star)$ defined inductively:

$$\widehat{\sigma}(0) = \emptyset \qquad \widehat{\sigma}(1) = \{\varepsilon\} \qquad \widehat{\sigma}(a) = \sigma(a) \qquad \widehat{\sigma}(e^\smile) = \widehat{\sigma}(e)^\smile = \{x_n \dots x_1 \mid x_1 \dots x_n \in \widehat{\sigma}(e)\}$$

$$\widehat{\sigma}(e + f) = \widehat{\sigma}(e) \cup \widehat{\sigma}(f) \qquad \widehat{\sigma}(e \cdot f) = \widehat{\sigma}(e) \cdot \widehat{\sigma}(f) \qquad \widehat{\sigma}(e \cap f) = \widehat{\sigma}(e) \cap \widehat{\sigma}(f)$$

$$\widehat{\sigma}(e^\star) = \widehat{\sigma}(e)^\star = \{w_1 \dots w_n \mid w_i \in \widehat{\sigma}(e)\}.$$

We say that $e = f$ (respectively $e \leq f$) is valid, and write $\mathrm{Lang} \models e = f$ (resp. $\mathrm{Lang} \models e \leq f$), when for every interpretation σ, we have $\widehat{\sigma}(e) = \widehat{\sigma}(f)$ (resp. $\widehat{\sigma}(e) \subseteq \widehat{\sigma}(f)$).

It is interesting to note that as decision problems, the validity of equations and that of inequations are equivalent. Indeed, the following equivalences hold:

$$\mathrm{Lang} \models e = f \Leftrightarrow \mathrm{Lang} \models e \leq f \wedge \mathrm{Lang} \models f \leq e \qquad \mathrm{Lang} \models e \leq f \Leftrightarrow \mathrm{Lang} \models e + f = f.$$

2 The free representation of reversible Kleene lattices

2.1 Intuitions

First introduced in the context of relation algebra [2, 11], directed labelled 2-pointed graphs can be used to describe the algebra of languages over the signature $\langle \cdot, \cap \rangle$. First, we associate to every term u over this signature such a graph $\mathcal{G}(u)$. See Figure 1 for examples. The set of such graphs is equipped with a preorder: G is smaller than H if there is a graph homomorphism from H to G. Such a homomorphism is illustrated in Figure 2.

Already, this gives us a clue as to the (in)equational theory: the inequation $u \leq v$ is valid if and only if $\mathcal{G}(u)$ is smaller than $\mathcal{G}(v)$. Moving to identity-free Kleene lattices, *i.e.* to

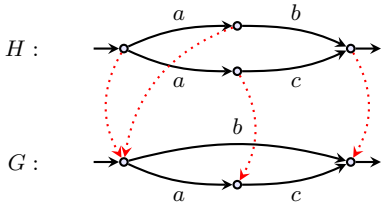

Figure 3 Weak graph morphism: $\langle G, \{a\}\rangle \blacktriangleleft \langle H, \emptyset\rangle$

the signature $\langle 0, +, \cdot, \cap, \_^+\rangle$, we associate to every term e a set $\mathcal{G}(e)$ of such graphs, and then take its downward closure $\mathcal{G}(e)\downarrow$ with respect to the preorder. This yields the free representation of this algebra: the equation $e = f$ is valid if and only if $\mathcal{G}(e)\downarrow = \mathcal{G}(f)\downarrow$.

To move from identity free Kleene lattices to reversible Kleene lattices, two steps are necessary: we need to add the converse, and to add the constant 1. The first step is somewhat straightforward, thanks to results by Ésik et al. [3]: they showed that the free representation of the algebra of languages with the regular operations together with converse is simply the set of regular languages over a duplicated alphabet, where we add for every letter a new letter representing its converse. This approach works well in our setting, by considering graphs labelled with the duplicated alphabet.

For the second step, we draw our inspiration from Lemma 3.4 in [1], that established that every term in $\mathcal{E}\langle X\rangle$ is equivalent to a finite sum of terms of the form $(1 \cap a \cap b \ldots) \cdot e$, where $a, b, \cdots \in X$ are letters, and 1 does not appear in e. For every interpretation $\sigma : X \to \mathcal{P}(\Sigma^\star)$, if there is some variable $x \in \{a, b, \ldots\}$ such that $\varepsilon \notin \sigma(x)$, then the interpretation of $1 \cap a \cap b \cap \ldots$ is $\emptyset$. Otherwise, if the empty word is in the interpretation of each of the $a, b, \ldots$, then the interpretation is $\{\varepsilon\}$. If we now look at the interpretation of the whole term, this means that:

$$\widehat{\sigma}((1 \cap a \cap b \cap \ldots) \cdot e) = \begin{cases} \widehat{\sigma}(e) & \text{if } \forall x \in \{a, b, \ldots\}, \varepsilon \in \sigma(x); \\ \emptyset & \text{otherwise.} \end{cases}$$

Consider now an inequation $f_1 \leq f_2$, where $f_i = (1 \cap a_{i,1} \cap \cdots \cap a_{i,n_i}) \cdot e_i$ for $i \in \{1, 2\}$. If there exists a variable $x \in \{a_{2,1}, \ldots, a_{2,n_2}\} \setminus \{a_{1,1}, \ldots, a_{1,n_1}\}$, we can build an interpretation σ such that (1) $\varepsilon \notin \sigma(x)$ and (2) $\widehat{\sigma}(f_1) \neq \emptyset$. The first condition ensures that the image of f_2 will be $\emptyset$, hence the inequation is not valid. Thus for the inequation to be valid, we need that $\{a_{2,1}, \ldots, a_{2,n_2}\} \subseteq \{a_{1,1}, \ldots, a_{1,n_1}\}$. Furthermore, for every σ such that there is an $a_{1,i}$ whose interpretation does not contain the empty word, the image of f_1 will be $\emptyset$, which is trivially contained in the image of the f_2. We reach the following equivalence: $f_1 \leq f_2$ is valid if and only if (1) $\{a_{2,1}, \ldots, a_{2,n_2}\} \subseteq \{a_{1,1}, \ldots, a_{1,n_1}\}$ and (2) for every interpretation σ such that the empty word is in the interpretation of every $a_{1,j}$, we have $\widehat{\sigma}(e_1) \subseteq \widehat{\sigma}(e_2)$. This means that we need to compare 1-free expressions under the assumption that certain variables contain the empty word.

This is the intuitions behind what we call weak graphs. Weak graphs are pairs of a graph and a set of test variables. They are equipped with a preorder relation $\blacktriangleleft$, which relates $\langle G, A\rangle$ and $\langle H, B\rangle$ if $B \subseteq A$ and there is a map φ from H to G such that every edge labelled outside of A is preserved, but edges labelled with tests in A are either preserved or contracted. Such a map is shown in Figure 3.

We then have theorems similar to those for identity free Kleene lattices and series parallel graphs, in the sense that for every pair of terms u, v over the syntax $\langle \cdot, \cap, 1, \_^\smile\rangle$, if we denote by $\mathcal{WG}(u), \mathcal{WG}(v)$ their associated weak graphs, $u \leq v$ is valid if and only if

$\mathcal{WG}(u) \blacktriangleleft \mathcal{WG}(v)$. Furthermore, if we associate to every expression e in $\mathcal{E}\langle X\rangle$ a downwards closed set of weak graphs ${}^{\blacktriangleleft}[\![e]\!]$, the equation $e = f$ is valid if and only if ${}^{\blacktriangleleft}[\![e]\!] = {}^{\blacktriangleleft}[\![f]\!]$.

2.2 Weak terms

We define the following two sets of terms over the alphabet X:
Ground terms: $u, v \in GT\langle X\rangle ::= 1 \mid a \mid a^{\smile} \mid u \cdot v \mid u \cap v$.
Simple ground terms: $u, v \in GT^{-}\langle X\rangle ::= a \mid a^{\smile} \mid u \cdot v \mid u \cap v$.

We call the variables of the term u, and write $\mathit{var}(u)$, the set of variables $a \in X$ such that a or $a^{\smile}$ appears in u. We call *weak terms* the elements of the set $(GT^{-}\langle X\rangle \cup \{1\}) \times \mathcal{P}(X)$, that is simple ground terms or 1 indexed with a set of test variables. The set of weak terms is written $WT\langle X\rangle$. This set is equipped with two products, denoted by $\bullet$ and $\|$, defined by:

$$1_A \bullet 1_B := 1_{A\cup B} \qquad 1_A \bullet u_B = u_A \bullet 1_B := u_{A\cup B} \qquad u_A \bullet v_B := (u \cdot v)_{A\cup B}$$

$$1_A \parallel 1_B := 1_{A\cup B} \qquad 1_A \parallel u_B = u_A \parallel 1_B := 1_{A\cup B\cup \mathit{var}(u)} \qquad u_A \parallel v_B := (u \cap v)_{A\cup B}.$$

Given an interpretation $\sigma : X \to \mathcal{P}(\Sigma^{\star})$, the interpretation $\tilde{\sigma}(u_A)$ of the weak term u_A is either $\emptyset$ if $\exists a \in A : \varepsilon \notin \sigma(a)$, or $\widehat{\sigma}(u)$ otherwise. We define a translation τ from ground terms to weak terms:

$$\tau(u \cdot v) := \tau(u) \bullet \tau(v) \qquad \tau(u \cap v) := \tau(u) \parallel \tau(v) \qquad \forall u \in \{1\} \cup \dot{X},\ \tau(u) := u_{\emptyset}.$$

This translation is faithful, in the sense that the following holds:

▶ **Lemma 1.** $\forall u \in GT\langle X\rangle, \forall \sigma : X \to \mathcal{P}(\Sigma^{\star}),\ \widehat{\sigma}(u) = \tilde{\sigma} \circ \tau(u)$.

Proof (Sketch). The proof relies on the fact that for every pair of weak terms x, y we have:

$$\tilde{\sigma}(x \bullet y) = \tilde{\sigma}(x) \cdot \tilde{\sigma}(y) \qquad \tilde{\sigma}(x \parallel y) = \tilde{\sigma}(x) \cap \tilde{\sigma}(y).$$

We then conclude by a simple induction on u. For concision, the full proof is omitted here. ◀

We can also define a converse translation $\kappa : WT\langle X\rangle \to GT\langle X\rangle$ which associate to a weak term $u_{\{a_1,\dots,a_n\}}$ the ground term $(1 \cap a_1 \cap \cdots \cap a_n) \cdot u$. It is immediate to check that for every term $x \in WT\langle X\rangle$ and every interpretation σ we have $\tilde{\sigma}(x) = \widehat{\sigma} \circ \kappa(x)$.

2.3 Weak graphs

A *graph* G in our setting is a tuple $\langle V_G, E_G, i_G, o_G\rangle$, where V_G is a finite set of vertices, $E_G \subseteq V_G \times \dot{X} \times V_G$ is a set of labelled and directed edges, and $i_G, o_G \in V_G$ are two vertices, called the input and output of the graph. *Term graphs* must further be series parallel[23], i_G must be the unique source vertex (*i.e.* with no incoming edge), and o_G the unique sink vertex (*i.e.* with no outgoing edge). We let G, H range over graphs. Term graphs can be sequentially composed, by identifying the output of the first graph with the input of the second one, or composed in parallel, by identifying the inputs of both graphs and identifying theirs outputs. These two compositions are respectively denoted by ; and |. The set $\ell(G)$ of labels of a graph G is defined as the set of letters $a \in X$ such that there is an edge in E_G labelled with either a or $a^{\smile}$.

The graph of a simple ground term u, written $\mathcal{G}(u)$, is a term graph defined inductively:

$\mathcal{G}(\alpha) :=$ 
$\qquad \mathcal{G}(u \cdot v) := \mathcal{G}(u) ; \mathcal{G}(v) \qquad \mathcal{G}(u \cap v) := \mathcal{G}(u) \mid \mathcal{G}(v).$

We define the graph $\not\Vdash$ as $\longrightarrow\!\!\circ\!\!\longrightarrow$. Notice that it is not a term graph, as it is not series parallel. We call *weak graph* a pair whose left part is either a term graph or $\not\Vdash$, and whose right part is a set of test variables. We denote the weak graph $\langle G, A\rangle$ by G_A. For every weak term x we associate a weak graph $\mathcal{WG}(x)$ as one would expect:

$$\mathcal{WG}(1_A) := \not\Vdash_A \qquad\qquad \mathcal{WG}(u_A) := \mathcal{G}(u)_A .$$

The weak graph G_A is smaller than H_B, written $G_A \blacktriangleleft H_B$, if $B \subseteq A$ and there exists a function $\varphi : V_H \to V_G$ such that $\varphi(i_H) = i_G$, $\varphi(o_H) = o_G$, and for every edge $\langle x, \alpha, y\rangle$ in E_H, either $\langle \varphi(x), \alpha, \varphi(y)\rangle \in E_G$ or $\alpha \in \dot{A}$ and $\varphi(x) = \varphi(y)$. The relation $\blacktriangleleft$ is a preorder. We will show in the next section that for any two ground terms u and v, the following holds:

$$\mathrm{Lang} \models u \leq v \Leftrightarrow \mathcal{WG}(\tau(u)) \blacktriangleleft \mathcal{WG}(\tau(v)) .$$

The first important lemma is the following. It generalises [1, Lemma 2.5] by including 1 and $\_^\smile$, thus moving from series parallel graphs to weak graphs.

▶ **Lemma 2.** *$\forall u \in WT\langle X\rangle$, there exists a word w_u and an interpretation σ_u such that for every $v \in WT\langle X\rangle$, $w_u \in \tilde{\sigma}_u(v) \Leftrightarrow \mathcal{WG}(u) \blacktriangleleft \mathcal{WG}(v)$.*

Proof. Let $\mathcal{WG}(u) = \langle\langle V_u, E_u, i_u, o_u\rangle, A\rangle$. Let $\mu : V_u \to \{1, \dots, |V_u|\}$ be a bijective map such that $\langle x, \alpha, y\rangle \in E_u \Rightarrow \mu(x) < \mu(y)$[1]. In particular, $\mu(i_u) = 1$ and $\mu(o_u) = |V_u|$. Let $n = 2 \times (|V_u| - 1)$, and Σ_u an alphabet composed of n distinct letters $x_1, \dots, x_n$.

We define $w_u = x_1 x_2 \dots x_n$, and $f : V_u \to \{0, \dots, n\}$ such that $f(x) = 2(\mu(x) - 1)$. Notice that $f(i_u) = 0$ and $f(o_u) = n$. We now define σ_u:

$$\sigma_u(a) := \begin{cases} \left\{w_u^f[x,y] \mid \langle x, a, y\rangle \in E_u\right\} \cup \left\{w_u^f[x,y]^\smile \;\middle|\; \langle x, a^\smile, y\rangle \in E_u\right\} \cup \{\varepsilon\} & \text{if } a \in A \\ \left\{w_u^f[x,y] \mid \langle x, a, y\rangle \in E_u\right\} \cup \left\{w_u^f[x,y]^\smile \;\middle|\; \langle x, a^\smile, y\rangle \in E_u\right\} & \text{if } a \notin A \end{cases}$$

Notice that for every $\alpha \in \dot{X}$, $\varepsilon \in \widehat{\sigma}_u(\alpha) \Leftrightarrow \alpha \in \dot{A}$, and that if $x \neq y$ then $w_u^f[x,y] \in \widehat{\sigma}_u(\alpha)$ if and only if $\langle x, \alpha, y\rangle \in E_u$.

Let $v = t_B \in WT\langle X\rangle$. First, suppose that $\exists a \in B \setminus A$. We know that $\varepsilon \notin \sigma_u(a)$, meaning that $\tilde{\sigma}_u(v) = \emptyset$. We also know by definition of $\blacktriangleleft$ that $\mathcal{WG}(u) \not\blacktriangleleft \mathcal{WG}(v)$. Thus the equivalence holds, as both sides are false. In the following, we thus assume that $B \subseteq A$.

If $t = 1$, then $\tilde{\sigma}_u(v) = \{\varepsilon\}$. This means that $w_u \in \tilde{\sigma}_u(v)$ if and only if $w_u = \varepsilon$. By definition, this is equivalent to $n = 0$, which is again equivalent to $|V_u| = 1$ thus to $u = 1_A$. We conclude this case by noticing that the only graph G such that $G_A \blacktriangleleft \not\Vdash_B$ is $\not\Vdash$ itself.

The other case is when t is a simple ground term. Then an induction much like in the proof of [1, Lemma 2.5] allows to conclude. We omit this part of the proof here. ◀

The other important lemma is a generalisation of [1, Lemma 2.3]. It will allow us to factor any interpretation of u through the weak graph $\mathcal{WG}(u)$.

▶ **Lemma 3.** *For every simple ground term u, every interpretation $\sigma : X \to \mathcal{P}(\Sigma^\star)$, and every word $w \in \Sigma^\star$ of length n:*

$$w \in \widehat{\sigma}(u) \Leftrightarrow \exists \varphi : V_u \to \{0, \dots, n\} : \begin{cases} \varphi(i_u) = 0 \wedge \varphi(o_u) = n \\ \langle x, \alpha, y\rangle \in E_u \Rightarrow w^\varphi[x,y] \in \widehat{\sigma}(\alpha) . \end{cases}$$

It can be proved by a simple induction on u; for concision, we omit this proof.

[1] Remember that both term graphs and $\not\Vdash$ are directed acyclic graphs.

2.4 Freeness results

We can now establish our first freeness result:

▶ **Theorem 4.** $\forall x, y \in GT\langle X\rangle$, $\mathcal{WG}(\tau(x)) \blacktriangleleft \mathcal{WG}(\tau(y)) \Leftrightarrow \mathrm{Lang} \models x \leq y$.

Proof. The statement of the theorem is equivalent to the following, thanks in part to Lemma 1: $\forall x, y \in WT\langle X\rangle, \mathcal{WG}(x) \blacktriangleleft \mathcal{WG}(y) \Leftrightarrow \forall \Sigma, \forall \sigma : X \to \mathcal{P}(\Sigma^\star), \tilde{\sigma}(x) \subseteq \tilde{\sigma}(y)$. We let $x = u_A$ and $y = v_B$, and proceed to prove both implications.

Suppose $\mathcal{WG}(x) \blacktriangleleft \mathcal{WG}(y)$, let σ be an interpretation, and w a word of length n. The case of 1 being trivial, we consider here the case where both u and v are simple ground terms. Assume $w \in \tilde{\sigma}(x)$, then we need to prove that $w \in \tilde{\sigma}(y)$. First notice that because $\tilde{\sigma}(x) \neq \emptyset$ it must be the case that $\forall a \in A, \varepsilon \in \sigma(a)$. By Lemma 3, we have a function $\varphi : V_u \to \{0, \ldots, n\}$ such that $\varphi(i_u) = 0$, $\varphi(o_u) = n$, and $\langle x, \alpha, y\rangle \in E_u \Rightarrow w^\varphi[x, y] \in \widehat{\sigma}(\alpha)$. By definition of $\blacktriangleleft$, we also have a function $\psi : V_v \to V_u$ such that $\psi(i_v) = i_u$, $\psi(o_v) = o_u$, and for every edge $\langle x, \alpha, y\rangle$ in E_v, either $\langle \psi(x), \alpha, \psi(y)\rangle \in E_u$ or $\alpha \in \dot{A}$ and $\psi(x) = \psi(y)$. We define $\Phi = \varphi \circ \psi$. Now we may check that $\Phi(i_v) = \varphi(i_u) = 0$; $\Phi(o_v) = \varphi(o_v) = n$; and if $\langle x, \alpha, y\rangle \in E_v$, then either

- $\langle \psi(x), \alpha, \psi(y)\rangle \in E_u$, which means $w^\Phi[x, y] = w^\varphi[\psi(x), \psi(y)] \in \widehat{\sigma}(\alpha)$;
- or $\alpha \in \dot{A}$ and $\psi(x) = \psi(y)$, which entails $w^\Phi[x, y] = \varepsilon \in \widehat{\sigma}(\alpha)$.

Using Lemma 3 again, we get that $w \in \widehat{\sigma}(v)$. Because $B \subseteq A$, we also have that $\tilde{\sigma}(y) = \widehat{\sigma}(v)$. Hence $\tilde{\sigma}(x) \subseteq \tilde{\sigma}(y)$.

For the converse, we now assume that $\mathcal{WG}(x) \not\blacktriangleleft \mathcal{WG}(y)$. Using Lemma 2, we know that $w_x \in \tilde{\sigma}_x(x)$ and that $w_x \notin \tilde{\sigma}_x(y)$. This proves that $\tilde{\sigma}_x(x) \not\subseteq \tilde{\sigma}_x(y)$. ◀

We define the set of weak terms $[\![e]\!]$ of an expression e by structural induction:

$$[\![0]\!] := \emptyset \qquad [\![1]\!] := \{1_\emptyset\} \qquad [\![\alpha]\!] := \{\alpha_\emptyset\} \qquad [\![e + f]\!] := [\![e]\!] \cup [\![f]\!]$$

$$[\![e \cdot f]\!] := \{u \bullet v \mid u \in [\![e]\!] \wedge v \in [\![f]\!]\} \qquad [\![e \cap f]\!] := \{u \parallel v \mid u \in [\![e]\!] \wedge v \in [\![f]\!]\}$$

$$[\![e^\star]\!] := \{u_1 \bullet \cdots \bullet u_n \mid n \geqslant 0 \wedge \forall 0 \leqslant i \leqslant n, u_i \in [\![e]\!]\}$$

The downward closure ${}^{\blacktriangleleft}S$ of a set of weak terms S is the set of weak terms x such that there exists a weak term $y \in S$ satisfying $\mathcal{WG}(x) \blacktriangleleft \mathcal{WG}(y)$. The function ${}^{\blacktriangleleft}$ is a closure operator. The set of downward closed sets of weak terms is the free representation of reversible Kleene lattices:

▶ **Theorem 5.** $\forall e, f \in \mathcal{E}\langle X\rangle$: ${}^{\blacktriangleleft}[\![e]\!] \subseteq {}^{\blacktriangleleft}[\![f]\!] \Leftrightarrow \mathrm{Lang} \models e \leq f$.

Proof. We use the fact that for every interpretation σ,

$$\widehat{\sigma}(e) = \bigcup_{u \in [\![e]\!]} \tilde{\sigma}(u) = \bigcup_{u \in {}^{\blacktriangleleft}[\![e]\!]} \tilde{\sigma}(u).$$

This can be proved using [1, Lemma 2.1], and Lemmas 1 and 2 and Theorem 4.

Suppose ${}^{\blacktriangleleft}[\![e]\!] \subseteq {}^{\blacktriangleleft}[\![f]\!]$, and let σ be an interpretation.

$$\widehat{\sigma}(e) = \bigcup_{u \in {}^{\blacktriangleleft}[\![e]\!]} \tilde{\sigma}(u) \subseteq \bigcup_{u \in {}^{\blacktriangleleft}[\![f]\!]} \tilde{\sigma}(u) = \widehat{\sigma}(f).$$

For the converse, suppose ${}^{\blacktriangleleft}[\![e]\!] \not\subseteq {}^{\blacktriangleleft}[\![f]\!]$. Because ${}^{\blacktriangleleft}$ is a closure operator, this means $[\![e]\!] \not\subseteq {}^{\blacktriangleleft}[\![f]\!]$. Let $u \in [\![e]\!] \setminus {}^{\blacktriangleleft}[\![f]\!]$. By Lemma 2, we have $w_u \in \tilde{\sigma}_u(u) \subseteq \widehat{\sigma}_u(e)$, but because $u \notin {}^{\blacktriangleleft}[\![f]\!]$, for every $v \in [\![f]\!]$, we have $\mathcal{WG}(u) \not\blacktriangleleft \mathcal{WG}(v)$ thus $w_u \notin \tilde{\sigma}_u(v)$. Hence w_u is not in the set $\bigcup_{v \in [\![f]\!]} \tilde{\sigma}_u(v) = \widehat{\sigma}_u(f)$. ◀

$A_R = \{a\}\,.$

Figure 6 Trace of R.

3 Decidability and complexity

To decide the equational theory of identity-free Kleene lattices, we used Petri automata[6]. This was a new style of automaton, which was designed to recognise sets of series parallel graphs. We modify this model slightly to recognise weak graphs, provide a construction to build automata out of expressions, and an algorithm to decide language containment (up-to closure by ◀) for these automata. This algorithm itself is inspired by the simulation algorithm for simple Petri automata. We conclude this section by showing that the problem is complete of the class ExpSpace.

3.1 Weak Petri automata

A weak Petri automaton is a Petri automaton [6, 4] whose transitions are labelled with sets of letters[2]. Formally, an *automaton* $\mathcal{A}$ over the finite alphabet X is a triple $\langle P, T, \iota\rangle$ where P is a finite set of *places*, $\iota \in P$ is the *initial place*, and $T \subseteq \mathcal{P}(P) \times \mathcal{P}(X) \times \mathcal{P}\left(\dot{X} \times P\right)$ is a set of *transitions*. Each transition $t \in T$ is composed of three parts: its *input* ${}^{\triangleright}t \subseteq P$, its *set of tests* $\widehat{t} \subseteq X$, and its *output* $t^{\triangleright} \subseteq \dot{X} \times P$. It will also be useful to write $\pi_2\left(t^{\triangleright}\right)$ for the *set of output places* of t, *i.e.* $\left\{p \in P \;\middle|\; \exists \alpha \in \dot{X} : \langle \alpha, p\rangle \in t^{\triangleright}\right\}$. The transition t is called *final* if $t^{\triangleright} = \emptyset$, and *initial* if ${}^{\triangleright}t = \{\iota\}$.

We will add a few constraints on this definition along the way, but we need more definitions to state them. An example of such an automaton is depicted in Figure 4. The graphical representation used here draws round vertices for places and rectangular vertices for transitions, with the incoming and outgoing arcs to and from the transition corresponding respectively to the inputs and outputs of said transition. The set of tests of a transition is written inside the rectangle. The initial place is denoted by an unmarked incoming arc.

Runs and reachable states

We define the operational semantics of weak Petri automata. Let us fix for the remainder of this section an automaton $\mathcal{A} = \langle P, T, \iota\rangle$. A *state* of this automaton is a set of places. In a given state $S \in \mathcal{P}(P)$, a transition t is *enabled* if ${}^{\triangleright}t \subseteq S$. In this case, we may

[2] In the following, we use the definitions from [4]. They differ slightly from those from [6], despite being overall equivalent.

fire t, leading to a new state $S' = (S \setminus {}^\triangleright t) \cup \pi_2(t^\triangleright)$. This will be denoted in the following by $S \xrightarrow{t}_{\mathcal{A}} S'$. We extend this notation to sequences of transitions in the natural way: if $S_0 \xrightarrow{t_1}_{\mathcal{A}} S_1$ and $S_1 \xrightarrow{t_2;\ldots;t_n}_{\mathcal{A}} S_n$ then we write $S_0 \xrightarrow{t_1;t_2;\ldots;t_n}_{\mathcal{A}} S_n$. In this case we say that $\langle S_0, t_1; t_2; \ldots; t_n, S_n\rangle$ is a *valid run*, or simply run, from S_0 to S_n. If $S_0 = \{\iota\}$ then the run is *initial* and if S_n is empty then it is *final*. A run which is both initial and final is called *accepting*. An accepting run of the automaton from Figure 4 is depicted in Figure 5. A state S is reachable in $\mathcal{A}$ if there is an initial run leading to S.

We may now state the first two constraints we impose on automata: if S is reachable in $\mathcal{A}$ and $S \xrightarrow{t}_{\mathcal{A}} S'$, then $(S \setminus {}^\triangleright t) \cap \pi_2(t^\triangleright) = \emptyset$, and for each transition $t \in T$, and every triple $\langle p, \alpha, \beta\rangle \in P \times \dot{X} \times \dot{X}$, we have: $\{\langle \alpha, p\rangle, \langle \beta, p\rangle\} \subseteq t^\triangleright \Rightarrow \alpha = \beta$. These constraints correspond to the classic Petri net property of safety, also called one-boundedness.

▶ Remark. These constraints are decidable: the set of transitions is finite, and because reachable states are subsets of a fixed finite set, there are only finitely many. Thus checking whether an automaton satisfies these two requirements only entails a finite number of tests.

We introduce some attributes of a run R: its *input* I_R, its *output* O_R, its *excess* E_R, its *tests* A_R, and its *internal labels* Λ_R. Let $R = S_0 \xrightarrow{t_1}_{\mathcal{A}} S_1 \ldots \xrightarrow{t_n}_{\mathcal{A}} S_n$ be a valid run in some automaton $\mathcal{A}$. I_R is the set of tokens (places) in S_0 which are consumed during the run; E_R is the rest of the tokens from S_0, those which are not moved; Λ_R is the set of labels appearing in some $t_i^\triangleright$ such that the associated token is consumed later on; A_R is the union of the sets of tests of R's transitions; and O_R is the set of outputs which are not consumed in the remainder of the run. Formally:

$$I_R := \{p \in S_0 \mid \exists i : p \in {}^\triangleright t_i\} \qquad O_R := \left\{\langle \alpha, p\rangle \;\middle|\; \exists i : \langle \alpha, p\rangle \in t_i^\triangleright \wedge \left(\forall j > i, p \notin {}^\triangleright t_j\right)\right\}$$

$$A_R := \bigcup_i \widehat{t_i} \qquad E_R := S_0 \setminus I_R \qquad \Lambda_R := \left\{\alpha \;\middle|\; \exists p, \exists i < j : \langle \alpha, p\rangle \in t_i^\triangleright \wedge p \in {}^\triangleright t_j\right\}.$$

In the example run of Figure 5, we have $I_R = \{1\}$, $E_R = \emptyset$, $O_R = \emptyset$, $A_R = \{a\}$, and $\Lambda_R = \{a, b, c\}$.

Traces

The trace language of an automaton can be obtained by extracting from every accepting run a weak graph, called its *trace*. Consider an accepting run $\langle \{\iota\}, t_0; \ldots; t_n, \emptyset\rangle$. The graph of its trace is constructed by creating a vertex k for each transition t_k of the run. We add an edge $\langle k, a, l\rangle$ whenever there is some place q such that $\langle a, q\rangle \in t_k^\triangleright$, and t_l is the first transition after t_k in the run with q among its inputs. The set of tests of the trace is A_R. The trace of the run in Figure 5 is presented in Figure 6. The definition we give below is a generalisation for arbitrary valid runs, which coincides with the informal presentation we just gave on accepting runs.

Let $R = \langle S, t_0; \ldots; t_n, S'\rangle$ be a run in $\mathcal{A}$. For every k and $p \in \pi_2(t_k^\triangleright) \setminus S'$, we define

$$\nu(k, p) = \min\{l \mid l > k \text{ and } p \in {}^\triangleright t_l\}.$$

The *trace* of R, denoted by $\mathcal{G}(R)$, is the pair $\langle G_R, A_R\rangle$, where G_R has vertices $V_R = \{0, \ldots, n\} \cup S'$ and edges defined by:

$$E_R = \{\langle k, a, l\rangle \mid \langle a, p\rangle \in t_k^\triangleright \text{ and } (l = p \wedge p \in S') \vee (l = \nu(k, p))\}.$$

The *language* $\mathcal{L}(\mathcal{A})$ *of an automaton* $\mathcal{A}$ is the set of traces of accepting runs of $\mathcal{A}$. In the following, we will only consider automata such that if $\langle G, A\rangle \in \mathcal{L}(\mathcal{A})$, then either G is either isomorphic to $\nVdash$ or is a term graph: that is, if G_A is a weak graph.

3.2 From expressions to automata

In this section, we show how to build inductively from an expression e an automaton $\mathcal{A}_e$ whose language is $\mathcal{L}(\mathcal{A}_e) = \mathcal{WG}([\![e]\!])$, following [4]. For $0, 1$ and atoms, we give a graphical description of the automata:

$\mathcal{A}_0 :=$  $\mathcal{A}_1 :=$  $\mathcal{A}_\alpha :=$ 
For the inductive cases, let $\mathcal{A}_e = \langle P_e, T_e, \iota_e \rangle$ and $\mathcal{A}_f = \langle P_f, T_f, \iota_f \rangle$, and suppose $P_e \cap P_f = \emptyset$.

Intuitively, the automaton for $e + f$ is the union of $\mathcal{A}_e$ and $\mathcal{A}_f$, where we copy the initial transitions of $\mathcal{A}_f$ so that they start from ι_e instead of ι_f. Formally:

$$\mathcal{A}_{e+f} = \langle P_e \cup P_f, T_e \cup T_f \cup T, \iota_e \rangle, \text{ where } T = \left\{ \left\langle \{\iota_e\}, \widehat{t}, t^{\triangleright} \right\rangle \;\middle|\; \left\langle \{\iota_f\}, \widehat{t}, t^{\triangleright} \right\rangle \in T_f \right\}.$$

For the product, we want an automaton $\mathcal{A}_{e \cdot f}$ such that $\mathcal{L}(\mathcal{A}_{e \cdot f}) = \mathcal{L}(\mathcal{A}_e) \bullet \mathcal{L}(\mathcal{A}_f)$. This property is satisfied by the automaton $\langle P_e \cup P_f, T_e^+ \cup T_f \cup T, \iota_e \rangle$ where T_e^+ is the set of non-final transitions in T_e, and $T = \{ \langle {}^{\triangleright}t, A \cup B, t^{\triangleright} \rangle \mid \langle {}^{\triangleright}t, A, \emptyset \rangle \in T_e \wedge \langle \{\iota_f\}, B, t^{\triangleright} \rangle \in T_f \}$.

Instead of defining directly an automaton for $e^\star$, we give an automaton for the non-zero iteration e^+, and then define $\mathcal{A}_{e^\star}$ to be $\mathcal{A}_{1 \cup e^+}$. Using the last two constructs, the automaton $\mathcal{A}_{e^+}$ is easy to define: $\mathcal{A}_{e^+} = \langle P_e, T_e \cup \{ \langle {}^{\triangleright}t, A \cup B, t^{\triangleright} \rangle \mid \langle {}^{\triangleright}t, A, \emptyset \rangle \in T_e \wedge \langle \{\iota_e\}, B, t^{\triangleright} \rangle \in T_e \}, \iota_e \rangle$.

Finally, we then define $\mathcal{A}_{e \cap f}$ to be the automaton $\langle P_e \cup P_f \cup \{\iota\}, T_1 \cup T_2 \cup T_3 \cup T_4, \iota \rangle$, where ι is a fresh place, and:

- T_1 is the set of non-initial, non-final transitions of T_e and T_f;
- T_2 is the set of triples $\left\langle \{\iota\}, \widehat{t_1} \cup \widehat{t_2}, t_1^{\triangleright} \cup t_2^{\triangleright} \right\rangle$ such that t_1 (resp. t_2) is initial but not final in T_e (resp. T_f);
- T_3 is the set of triples $\left\langle {}^{\triangleright}t_1 \cup {}^{\triangleright}t_2, \widehat{t_1} \cup \widehat{t_2}, \emptyset \right\rangle$ such that t_1 (resp. t_2) is final but not initial in T_e (resp. T_f);
- T_4 is the set of triples $\langle \{\iota\}, A, \emptyset \rangle$ such that $1_A \in [\![e \cap f]\!]$.

This definition is effective, as the set of $A \subseteq X$ such that $1_A \in [\![e]\!]$ can be computed in space $O\left(|e| \times 2^{|X|}\right)$. Using the proofs for Petri automata as a guideline, it is a simple exercise to check that the correctness of the construction, that is $\mathcal{L}(\mathcal{A}_e) = \mathcal{WG}([\![e]\!])$.

3.3 Comparing automata

The algorithm to compare weak Petri automata relies on the notion of simulation. Similarly to many finite transition systems, the language of an automaton $\mathcal{A}$ is included in that of the automaton $\mathcal{B}$ if $\mathcal{B}$ can simulate $\mathcal{A}$.

▶ **Definition 6** (Simulation). Let $\mathcal{A}_1 = \langle P_1, T_1, \iota_1 \rangle$ and $\mathcal{A}_2 = \langle P_2, T_2, \iota_2 \rangle$ be two automata, we say that $\mathcal{A}_2$ can simulate $\mathcal{A}_1$ if there exists a function $\preccurlyeq$ associating to every subset of X a set of triples from $\mathcal{P}(P_1) \times \mathcal{P}(X) \times \mathcal{P}(P_2 \rightharpoonup P_1)$, such that: *(We denote the fact that the triple $\langle S, B, E \rangle$ is contained in the image by $\preccurlyeq$ of the set A by $S \preccurlyeq_A^B E$.)*

(correspondence) if $S \preccurlyeq_A^B E$ and $\eta \in E$ then $range(\eta) \subseteq S$;

(initialisation) $\{\iota_1\} \preccurlyeq_A^\emptyset \{[\iota_2 \mapsto \iota_1]\}$;

(totality) if $\emptyset \preccurlyeq_A^A E$ then $\exists \eta \in E : dom(\eta) = \emptyset$;

(progress) if $S \preccurlyeq_A^B E$ and $S \xrightarrow{t}_{\mathcal{A}_1} S'$, then $S' \preccurlyeq_A^{B \cup \widehat{t}} E'$, where E' is the set of all η' such that there is a map η in E, and a run R in $\mathcal{A}_2$ from $dom(\eta)$ to $dom(\eta')$ s.t.:

$$I_R = \{p \mid \eta(p) \in {}^{\triangleright}t\} \qquad \Lambda_R \cup A_R \subseteq \dot{A} \qquad \forall \langle \alpha, p \rangle \in O_R,\ \langle \alpha, \eta'(p) \rangle \in t^{\triangleright}$$

$$\forall p \in E_R,\ \eta(p) = \eta'(p).$$

▶ **Lemma 7.** *$\mathcal{L}(\mathcal{A}_1) \subseteq {}^{\blacktriangleleft}\mathcal{L}(\mathcal{A}_2)$ if and only if $\mathcal{A}_2$ can simulate $\mathcal{A}_1$.*

Proof. We start by showing the right to left direction: suppose that $\mathcal{A}_2$ can simulate $\mathcal{A}_1$, as witnessed by the function $\preccurlyeq$, and consider an accepting run $R = \langle S_0, t_1; \dots; t_n; S_n\rangle$ in $\mathcal{A}_1$:

$$S_0 = \{\iota_1\} \qquad \forall 1 \leqslant i \leqslant n,\ S_{i-1} \xrightarrow{t_i}_{\mathcal{A}_1} S_i \qquad S_n = \emptyset.$$

We write $B_i = \bigcup_{j<i} \widehat{t_j}$. Using the relations $\preccurlyeq^{B_i}_{A_R}$, we can find a sequence of E_i (for $0 \leqslant i \leqslant n$) such that $S_i \preccurlyeq^{B_i}_{A_R} E_i$, $E_0 = \{[\iota_2 \mapsto \iota_1]\}$, and there is some $\eta_n \in E_n$ which has an empty domain. Backtracking from this η_n using the progress condition allows us to find a sequence of maps $(\eta_i)_{0\leqslant i\leqslant n}$, with domains $(T_i)_{0\leqslant i\leqslant n}$ such that there are valid runs R_i in $\mathcal{A}_2$ from T_{i-1} to T_i, and satisfying:

$$T_0 = \{\iota_2\} \qquad T_n = \emptyset \qquad I_{R_i} = \{p \mid \eta_{i-1}(p) \in {}^{\triangleright}t_i\} \qquad \Lambda_{R_i} \cup A_{R_i} \subseteq \dot{A}_R$$

$$\forall \langle \alpha, p\rangle \in O_{R_i},\ \langle \alpha, \eta_i(p)\rangle \in t_i^{\triangleright} \qquad \forall p \in E_{R_i},\ \eta_{i-1}(p) = \eta_i(p).$$

We now build the run R' by concatenating the R_is. We obtain an accepting run in $\mathcal{A}_2$, whose set of tests is $\bigcup_i A_{R_i} \subseteq A_R$. To any transition t'_j in R', the function φ associates the index i of the run R_i from which this transition was extracted. The function φ witnesses $\mathcal{G}(R) \blacktriangleleft \mathcal{G}(R')$.

For the converse direction, we prove an intermediary result. Let $R = \langle S_0, t_1; \dots; t_n, S_n\rangle$ be an accepting run in $\mathcal{A}_1$ and R' be an accepting run from $\mathcal{A}_2$ such that $\mathcal{G}(R) \blacktriangleleft \mathcal{G}(R')$, with φ as the witnessing function. Notice that if the transition t'_i is a cause of t'_{i+1} in R' (*i.e.* they cannot be exchanged without changing the trace), either $\varphi(i) = \varphi(i+1)$, or $t_{\varphi(i)}$ is a cause of $t_{\varphi(i+1)}$ in R, thus $\varphi(i) < \varphi(i+1)$. This means that we may permute transitions in R' without changing the trace, to obtain a run R'' such that $i < j \Rightarrow \varphi(i) \leqslant \varphi(j)$.

Now, the sets of transitions sharing the same value $\varphi(i)$ are contiguous, meaning that R'' can be split as the sequence of sub-runs $R_1; \dots; R_n$, such that φ maps every transitions in R_i to i. (It may be the case that some of these runs are empty.) As $\mathcal{G}(R) \blacktriangleleft \mathcal{G}(R'')$, we know that $A_{R''} \subseteq A_R$, which means that $\forall i, A_{R_i} \subseteq A_R$. Inside the run R_i, we know that the internal edges of the graph of R_i are labelled with letters from A_R, as both their extremities are mapped to i. This means $\Lambda_{R_i} \subseteq \dot{A}_R$.

We know define the η_i. First, we set $\eta_0(\iota_2) = \iota_1$, and $\forall p \in E_{R_i}, \eta_{i-1}(p) = \eta_i(p)$. If on the other hand $\langle \alpha, p\rangle \in O_{R_i}$, let k be the index in R'' corresponding to the output state of R_i, and $j = \nu_{R''}(p, k)$. As j cannot be in R_i, we know $\varphi(j) > \varphi(k)$. Thus, in the graph of R there is an edge $\langle \varphi(k), \alpha, \varphi(j)\rangle$. By definition of the graph of a run, there must be a pair $\langle \alpha, q\rangle \in t^{\triangleright}_{\varphi(k)}$ such that $\nu_R(q, \varphi(k)) = \varphi(j)$. Then this q is a suitable choice for $\eta_i(p)$.

It is then a simple matter of unfolding the definitions to check that:

$$I_{R_i} = \{p \mid \eta_{i-1}(p) \in {}^{\triangleright}t_i\} \qquad \forall \langle \alpha, p\rangle \in O_{R_i},\ \langle \alpha, \eta_i(p)\rangle \in t_i^{\triangleright} \qquad \forall p \in E_{R_i},\ \eta_{i-1}(p) = \eta_i(p).$$

This means that whenever we have R and R' accepting runs from respectively $\mathcal{A}_1$ and $\mathcal{A}_2$ s.t. $\mathcal{G}(R) \blacktriangleleft \mathcal{G}(R')$, we can find a sequence of η_i satisfying all four conditions of a simulation. Thus, if $\mathcal{L}(\mathcal{A}_1) \subseteq {}^{\blacktriangleleft}\mathcal{L}(\mathcal{A}_2)$, for every reachable state S of $\mathcal{A}_1$, we set $\preccurlyeq^B_A$ to relate S to the set of all maps η such that there is an index i, an accepting run R in $\mathcal{A}_1$, and an accepting run R' of $\mathcal{A}_2$ satisfying (1) $A_R = A$, (2) $\bigcup_{j<i} \widehat{t_j} = B$, (3) $S = S_i$, (4) $\mathcal{G}(R) \blacktriangleleft \mathcal{G}(R')$ and (5) the construction we just provided produces $\eta_i = \eta$. ◀

3.4 Complexity

▶ **Corollary 8.** *The theory of reversible Kleene lattices is* ExpSpace*-complete.*

Proof. The equational theory of identity-free Kleene lattices being already ExpSpace-complete [8, Proposition 10.2], we know the problem at hand to be ExpSpace-hard.

Let $e, f \in \mathcal{E}\langle X \rangle$, we ask whether Lang $\models e \leq f$. By Theorem 5, this reduces to testing if ${}^{\blacktriangleleft}[\![e]\!] \subseteq {}^{\blacktriangleleft}[\![f]\!]$, which is equivalent to $[\![e]\!] \subseteq {}^{\blacktriangleleft}[\![f]\!]$ by the properties of the closure operator. Using the construction in Section 3.2, this is amounts to checking if $\mathcal{L}(\mathcal{A}_e) \subseteq {}^{\blacktriangleleft}\mathcal{L}(\mathcal{A}_f)$. This later question can be decided by looking for a simulation function, thanks to Lemma 7.

We now inspect the space complexity of this method. Let n, m, x be respectively the size of e, the size of f and the size of the alphabet. By analysing each step in Section 3.2, we get that the number of places of $\mathcal{A}_e$ is less than $2 \times n$ (similarly for $\mathcal{A}_f$). The number of transitions is harder to work out from the construction, but because $T \subseteq \mathcal{P}(P) \times \mathcal{P}(X) \times \mathcal{P}\left(\dot{X} \times P\right)$, we know it is bounded by $2^{2n+x+2x\times 2n}$. Using Savitch's theorem [22], we only need to show that there is a non-deterministic semi-algorithm to refute the existence of a simulation, which uses only exponential space in n, m and x. Here is such a procedure:

1. choose $A \subseteq X$;
2. start with $S = \{\iota_1\}$, $B = \emptyset$ and $E = \{[\iota_2 \mapsto \iota_1]\}$;
3. if $\langle S, B\rangle = \langle \emptyset, A\rangle$ and E does not contain a map η whose domain is empty return `False`;
4. choose $t \in T_1$ such that ${}^{\triangleright}t \subseteq \pi_1(S)$, fire t from S, and update B as $\widehat{t} \cup B$;
5. update E according to the progress condition in Definition 6;
6. go to step 3.

All of these computations can be performed using exponential space. For instance, S, being a pair of a set of places in $\mathcal{A}_e$ and a set of letters, can be stored in space $2n\log(2n) \times x\log(x)$, and E only needs space $(2n+1)^{2m} \times 2m\log(2n+1)$. ◀

4 Conclusion

We showed that the free representation of reversible Kleene lattices consists of downward closed sets of weak terms, or equivalently of downward closed sets of weak graphs. By considering a suitable variation of Petri automata, and producing an algorithm to decide language containment of these automata, we showed that testing the validity of equations in reversible Kleene lattices is an ExpSpace-complete problem.

The results we obtained here could be naturally extended in a number of ways.

- We would like to add to our model some features of programming languages which have been studied independently, among which tests [16], and nominal structures [13, 18, 17, 7].
- Although Kleene algebra is known not to be finitely axiomatisable [20], several authors have proposed semi-axiomatisations [15, 9, 21]. A complete axiomatisation of Kleene algebra with converse, relative to an axiomatisation of KA, is also known [10]. As far as we know, no axiomatisation of reversible Kleene lattices exists. We believe the free representation we defined in Section 2 could help establishing such an axiomatisation.
- Since we provide here an algorithm, it would be interesting to implement it. Such a procedure could fit in very well in a proof assistant such as Coq.

Although the weak Petri automata introduced in this paper were just a means to an end, we are wondering whether this might be an interesting model of computation in itself. We are confident that we could reuse to technology of boxes introduced in [8, 4] to get a Kleene theorem for these automata. Their semantics could also be reformulated with transitions labelled with weights chosen from a finite lattice (instead of sets of letters from the alphabet).

Abstract

In this paper, we study the Connected $\mathcal{H}$-hitting Set and Dominating Set problems from the perspective of *approximate* kernelization, a framework recently introduced by Lokshtanov et al. [STOC 2017]. For the Connected $\mathcal{H}$-hitting set problem, we obtain an α-approximate kernel for every $\alpha > 1$ and complement it with a lower bound for the natural weighted version. We then perform a refined analysis of the tradeoff between the approximation factor and kernel size for the Dominating Set problem on d-degenerate graphs, and provide an interpolation of approximate kernels between the known d^2-approximate kernel of constant size and 1-approximate kernel of size $k^{\mathcal{O}(d^2)}$.

1 Introduction

Polynomial time preprocessing is one of the widely used methods to tackle NP-hardness in practice and the area of *kernelization* has been extremely successful in laying down a mathematical framework for the design and rigorous analysis of preprocessing algorithms for *decision problems*. We refer the reader to the survey articles by Kratsch [17] or Lokshtanov et al. [18] for recent developments, or the textbooks [6, 11] for an introduction to the field. The central notion in kernelization is that of a *kernel*, which is a preprocessing algorithm that runs in polynomial time and transforms a 'large' instance of a decision problem into a significantly smaller, but equivalent instance.

Unfortunately, the existing notion of kernels, having been built around decision problems, does not combine well with approximation algorithms and heuristics. In particular, in order for kernels to be useful, one is required to solve the preprocessed instance exactly. However, this may not always be possible and the existing theory of kernelization says nothing about being able to infer useful information from a good *approximate* solution for the preprocessed instance. Lokshtanov et al. [19] attempted to address this limitation by introducing the notion of *α-approximate kernels*. Informally speaking, an α-approximate kernel is a polynomial time algorithm that given an instance (I, k) outputs an instance (I', k') such that $|I'| + k' \leq g(k)$

* This work was partially supported by the Austrian Science Fund (FWF, projects P26696 and W1255-N23).

for some computable function g and any c-approximate solution to the instance (I', k') can be turned in polynomial time into a $(c \cdot \alpha)$-approximate solution to the original instance (I, k). The function g is ideally polynomially bounded, in which case we call this algorithm, an α-approximate polynomial kernel. We refer the reader to the section on Preliminaries for a formal definition of the terms involved.

In their work, Lokshtanov et al. considered several problems which are known to not admit a polynomial kernel and showed that they do have an α-approximate polynomial kernel for *every* fixed $\alpha > 1$. They also proposed a machinery for proving lower bounds and managed to rule out even α-approximate kernels for some basic problems such as Longest Path and Set Cover under standard complexity theoretic hypotheses.

One of the fundamental classes of problems known to exclude polynomial kernels is the class of 'subgraph hitting' problems *with a connectivity constraint*. It is well-known that placing connectivity constraints on certain subgraph hitting problems can have a dramatic effect on their amenability to preprocessing. A case in point is the classic Vertex Cover problem. This problem is known to admit a kernel with $\mathcal{O}(k)$ vertices [6]. However, the Connected Vertex Cover problem is among the earliest problems to be shown to exclude a polynomial kernel [10] and Lokshtanov et al. [19] showed that this problem admits an α-approximate polynomial kernel for every $\alpha > 1$. Their result motivates the need to obtain a finer understanding of the role played by connectivity constraints in relation to preprocessing for other subgraph hitting problems. Therefore, a systematic study of the approximate kernelization of subgraph hitting problems with connectivity constraints is a natural strategy towards achieving this goal.

Our Contributions. In this paper, we study the Connected $\mathcal{H}$-Hitting Set (Conn-$\mathcal{H}$-HS) problem where the input is a graph G and an integer k and the objective is to check whether there is a set S of at most k vertices such that $G[S]$ is connected and $G - S$ has no vertex-induced subgraph isomorphic to a graph in the fixed finite family of graphs, $\mathcal{H}$. It is easy to see that this problem generalizes Connected Vertex Cover (set $\mathcal{H} = \{K_2\}$) and hence it is unlikely to have a polynomial kernel. As a result, we consider the approximate kernelization complexity of the *optimization* version of this problem and provide two results; one positive and one negative. Our positive result generalizes the approximate kernel given by Lokshtanov et al. for the Connected Vertex Cover problem and shows that Conn-$\mathcal{H}$-HS also admits an α-approximate polynomial kernel for *every* constant $\alpha > 1$ and fixed $\mathcal{H}$.

▶ **Theorem 1.** *For every fixed $\epsilon > 0$, there is a $(1 + \epsilon)$-approximate polynomial kernel for* Connected $\mathcal{H}$-hitting set.

Our negative result shows that this ability to obtain approximate kernels vanishes in the presence of weights, even when the domain of the weight function is highly restricted. To be precise, we study the Weighted Conn-$\mathcal{H}$-HS problem where the input also includes a weight function on the vertices and the objective now is to minimize the total *weight* of a connected set of vertices hitting all vertex-induced subgraphs of G isomorphic to a graph in $\mathcal{H}$. We show that unless $\mathsf{NP} \subseteq \mathsf{coNP/Poly}$, this problem has no α-approximate polynomial kernel for *any* constant α even when the domain of the weight function is restricted to $\{0, 1\}$. The formal statement of this theorem requires certain terms which are as yet undefined and we refer the reader to Section 3.2 for the statement.

In the second part of the paper, we initiate the fine-grained analysis of the accuracy-size tradeoff encountered when designing approximate kernels for the Dominating Set problem on the class of d-degenerate graphs. The Dominating Set problem is one of the most

fundamental problems in algorithmic graph theory. In the decision version of this problem, the input is a graph G, an integer k and the objective is to decide whether G has a set S of at most k vertices which contains at least one neighbor of every vertex in $V(G) \setminus S$. It is well-known that Dominating Set is W[2]-hard [6], implying that it cannot have *any* kernel under standard complexity theoretic hypotheses. This fact motivated the study of preprocessing for this basic problem on restricted graph classes, leading to a long and rich literature [1, 2, 3, 7, 8, 12, 15, 20].

One of the more general graph classes on which Dominating Set is known to admit a polynomial kernel, is the class of d-degenerate graphs, which contains several well-studied graph classes such as planar graphs, graphs of bounded treewidth, graphs of bounded arboricity, and graphs excluding a fixed (topological) minor. Alon and Gutner [2] initiated the study of the parameterized complexity of Dominating Set on d-degenerate graphs and Philip et al. [20] obtained a kernel of size $k^{\mathcal{O}(d^2)}$, which was the first polynomial kernel for this problem on d-degenerate graphs. In fact, it follows from their proofs that this kernel is in fact a 1-approximate kernel. At the other extreme, it follows from [16] that there is a d^2-approximate kernel of *constant size*. These two results motivate the natural question: *What is the precise tradeoff between accuracy and kernel size for* Dominating Set *on d-degenerate graphs?* We give a sequence of approximate kernels for this problem which lie 'between' the two extremes and provide an interesting interpolation of kernels.

▶ **Theorem 2.** Dominating Set *on d-degenerate graphs has a $\lceil \frac{d}{\rho} \rceil$-approximate kernel of size $k^{\mathcal{O}(d\rho)}$, for any fixed integer $\rho \in \{1, \ldots, d\}$.*

All approximate kernels obtained thus far (including that in the first part of our paper) are focussed on problems which are known to not admit polynomial kernels. Our work on Dominating Set on d-degenerate graphs thus initiates and motivates the fine-grained study of approximate kernelization even for problems which have polynomial kernels. Therefore, we believe that our result opens up a new line of investigation in the topic of approximate kernelization.

2 Preliminaries

The notion of kernels is based on *parameterized problems* from the area of Parameterized Complexity [6, 11]. Inputs of a parameterized problem are of the form (I, k) where I is a bitstring encoding an instance and k is an integer called the *parameter*, and every input is either a yes instance or a no instance. A *kernel* is a polynomial time algorithm that given an instance (I, k) of a parameterized problem outputs an instance (I', k') of the same problem such that $|I'| + k' \leq g(k)$ for some computable function g and (I, k) is a yes instance if and only if (I', k') is a yes instance. We now recall the main definitions from [19] regarding *parameterized optimization problems and approximate kernels.*

▶ **Definition 3** ([19])**.** A parameterized optimization (minimization or maximization) problem Π is a computable function $\Pi : \Sigma^* \times \mathbb{N} \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}$.

The *instances* of a parameterized optimization problem Π are pairs $(I, k) \in \Sigma^* \times \mathbb{N}$, and a *solution* to (I, k) is simply a string $s \in \Sigma^*$, such that $|s| \leq |I| + k$. The *value* of the solution s is $\Pi(I, k, s)$. Since the problems we deal with in this paper are all minimization problems, we state some of the definitions only in terms of minimization problems when the definition for maximization problems is analogous.

▶ **Definition 4** ([19]). For a parameterized minimization problem Π, the *optimum value* of an instance $(I,k) \in \Sigma^* \times \mathbb{N}$ is $OPT_\Pi(I,k) = \min_{\substack{s\in\Sigma^* \\ |s|\leq |I|+k}} \Pi(I,k,s)$.

▶ **Definition 5** ([19]). Let $\alpha \geq 1$ be a real number and Π be a parameterized minimization problem. An *α-approximate polynomial time preprocessing algorithm* $\mathcal{A}$ for Π is a pair of polynomial time algorithms. The first one is called the *reduction algorithm*, and computes a map $\mathcal{R}_\mathcal{A} : \Sigma^* \times \mathbb{N} \to \Sigma^* \times \mathbb{N}$. Given as input an instance (I,k) of Π the reduction algorithm outputs another instance $(I',k') = \mathcal{R}_\mathcal{A}(I,k)$.

The second algorithm is called the *solution lifting algorithm*. This algorithm takes as input an instance $(I,k) \in \Sigma^* \times \mathbb{N}$ of Π, the output instance (I',k') of the reduction algorithm, and a solution s' to the instance (I',k'). The solution lifting algorithm works in time polynomial in $|I|$,k,$|I'|$,k' and s', and outputs a solution s to (I,k) such that the following holds.

$$\frac{\Pi(I,k,s)}{OPT(I,k)} \leq \alpha \cdot \frac{\Pi(I',k',s')}{OPT(I',k')}.$$

The *size* of a polynomial time preprocessing algorithm $\mathcal{A}$ is a function $\text{size}_\mathcal{A} : \mathbb{N} \to \mathbb{N}$ defined as follows.

$$\text{size}_\mathcal{A}(k) = \sup\{|I'| + k' : (I',k') = \mathcal{R}_\mathcal{A}(I,k), I \in \Sigma^*\}.$$

▶ **Definition 6** ([19]). An *α-approximate kernelization* (or *α-approximate kernel*) for a parameterized optimization problem Π, and real $\alpha \geq 1$, is an α-approximate polynomial time preprocessing algorithm $\mathcal{A}$ for Π such that $\text{size}_\mathcal{A}$ is upper bounded by a computable function $g : \mathbb{N} \to \mathbb{N}$. We say that $\mathcal{A}$ is an α-approximate polynomial kernelization if g is a polynomial function.

▶ **Definition 7** ([19]). Let $\alpha \geq 1$ be a real number, and Π be a parameterized minimization problem. An α-approximate polynomial time preprocessing algorithm for Π is said to be *strict* if, for every instance (I,k), reduced instance $(I',k') = \mathcal{R}_\mathcal{A}(I,k)$ and solution s' to (I',k'), the solution s to (I,k) output by the solution lifting algorithm when given s' as input satisfies the following.

$$\frac{\Pi(I,k,s)}{OPT(I,k)} \leq \max\left\{\frac{\Pi(I',k',s')}{OPT(I',k')}, \alpha\right\}$$

The notion of *strictness* in the above direction allows one to 'chain' multiple α-approximate preprocessing algorithms to obtain a single α-approximate preprocessing algorithm.

▶ **Definition 8.** A *reduction rule* is simply the reduction algorithm of a polynomial time preprocessing algorithm. The reduction rule *applies* if the output instance of the reduction algorithm is not the same as the input instance.

▶ **Definition 9** ([19]). A reduction rule is *α-safe for* Π if it is the reduction algorithm of a strict α-approximate polynomial time preprocessing algorithm for Π.

The notion of 1-safe reduction rules is crucial because numerous reduction rules used in the domain of (standard) kernelization can be either easily, or with very little effort, proved to be 1-safe. Therefore, when designing α-approximate kernels, it is a useful strategy to examine existing 1-safe reduction rules and either utilize them directly or design a 'relaxed' version which one can then prove to be α-safe for some $\alpha > 1$.

▶ **Definition 10** ([19]). Let $\alpha \geq 1$ be a real number. Let Π and Π' be two parameterized minimization problems. An *α-approximate polynomial parameter transformation* (α-appt for short) $\mathcal{A}$ from Π to Π' is a pair of polynomial time algorithms, called reduction algorithm $\mathcal{R}_{\mathcal{A}}$ and solution lifting algorithm. Given as input an instance (I,k) of Π the reduction algorithm outputs an instance (I',k') of Π' such that $k' = k^{\mathcal{O}(1)}$. The solution lifting algorithm takes as input an instance (I,k) of Π, the output instance $(I',k') = \mathcal{R}_{\mathcal{A}}(I,k)$ of Π', and a solution s' to the instance I' and outputs a solution s to (I,k) such that

$$\frac{\Pi(I,k,s)}{OPT_{\Pi}(I,k)} \leq \alpha \cdot \frac{\Pi'(I',k',s')}{OPT_{\Pi'}(I',k')}.$$

▶ **Definition 11** ([19]). Let $\alpha \geq 1$ be a real number. Let Π and Π' be two parameterized minimization problems. An *α-approximate compression* from Π to Π' is an α-appt $\mathcal{A}$ from Π to Π' such that $\text{size}_{\mathcal{A}}(k) = \sup\{|I'| + k' : (I',k') = \mathcal{R}_{\mathcal{A}}(I,k), I \in \Sigma^*\}$, is upper bounded by a computable function $g : \mathbb{N} \to \mathbb{N}$, where $\mathcal{R}_{\mathcal{A}}$ is the reduction algorithm in $\mathcal{A}$. We say that $\mathcal{A}$ is an α-approximate polynomial compression if g is a polynomial function. When we simply say that Π has an α-approximate compression, we mean that there is an α-approximate compression from Π to some language Π'.

▶ **Observation 12.** *Let $\alpha, \beta \geq 1$ be fixed real numbers and let Π and Π' be parameterized minimization problems. If there is an α-appt from Π to Π' and Π' has a β-approximate polynomial compression, then Π has an $(\alpha \cdot \beta)$-approximate polynomial compression.*

Steiner trees, set systems and degenerate graphs. Given a graph G, a set $R \subseteq V(G)$ whose vertices are called *terminals*, and a weight function $w : E(G) \to \mathbb{N}$, a *Steiner tree* is a subtree T of G such that $R \subseteq V(T)$, and the *cost* of a tree T is defined as $w(T) = \sum_{e \in E(T)} w(e)$. A *$k$-component* is a tree with at most k leaves which all coincide with a subset of terminals. A *k-restricted Steiner tree* $\mathcal{T}$ is a collection of k-components, such that the union of these components is a Steiner tree T. The cost of $\mathcal{T}$ is the sum of the costs of all the k-components in $\mathcal{T}$.

Let $\mathcal{F}$ be a set system over the universe $\mathcal{U}$. An element $e \in \mathcal{U}$ is said to *hit* a set $A \in \mathcal{F}$, if $e \in A$. Moreover, we say that a set $S \subseteq \mathcal{U}$ hits a set $A \in \mathcal{F}$ if $S \cap A \neq \emptyset$. A set $S \subseteq \mathcal{U}$ is a *hitting set* of $\mathcal{F}$ if it hits every set in $\mathcal{F}$. We say that $\mathcal{S} \subseteq \mathcal{F}$ is a *set cover* of $(\mathcal{F},\mathcal{U})$, if $\bigcup_{S \in \mathcal{S}} S = \mathcal{U}$. Note that if there exists a set cover of $(\mathcal{F},\mathcal{U})$, then there is one of size at most $|\mathcal{U}|$, as every vertex is in at least one set. Moreover, one can find a set cover of size at most $|\mathcal{U}|$ by greedily adding, in every step, a new set that covers an as yet uncovered vertex.

Let $\mathcal{H}$ be a fixed finite set of finite graphs. We denote by $d_{\mathcal{H}}$ the size of a largest graph in $\mathcal{H}$. For a graph G, we denote by $\mathcal{F}_{\mathcal{H}}(G)$ the following set system defined over the universe $V(G)$: $\mathcal{F}_{\mathcal{H}}(G) = \{S \subseteq V(G) \mid G[S] \text{ is isomorphic to some } H \in \mathcal{H}\}$. That is, $\mathcal{F}_{\mathcal{H}}(G)$ comprises precisely those subsets of $V(G)$ which induce a subgraph of G isomorphic to a graph in $\mathcal{H}$. Observe that for a fixed family $\mathcal{H}$ and a graph G, the set $\mathcal{F}_{\mathcal{H}}(G)$ can be computed in time $\mathcal{O}(|V(G)|^{d_{\mathcal{H}}})$. A set $S \subseteq V(G)$ is called a $\mathcal{H}$-hitting set of G if it is a hitting set for the family $\mathcal{F}_{\mathcal{H}}(G)$. A graph G is said to be d-degenerate if every subgraph of G has a vertex of degree at most d. It is well-known that a d-degenerate graph G has less than $d|V(G)|$ edges.

3 Approximate kernels for Connected $\mathcal{H}$-hitting set

In this section, we present our positive and negative results on the Connected $\mathcal{H}$-hitting set problem and its weighted variant. In what follows, we fix a family $\mathcal{H}$ and assume without loss of generality that for any distinct pair of graphs in $\mathcal{H}$, neither is a subgraph of the other.

3.1 The α-approximate kernel for Connected $\mathcal{H}$-hitting set

We begin by defining the parameterized optimization version of Conn-$\mathcal{H}$-HS. This is a minimization problem, where the optimization function is $\mathrm{CHS} : \Sigma^* \times \mathbb{N} \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}$ and defined as follows.

$$\mathrm{CHS}(G,k,S) = \begin{cases} \infty & \text{if } S \text{ is not a connected } \mathcal{H}\text{-hitting set in } G, \\ \min\{|S|, k+1\} & \text{otherwise.} \end{cases}$$

For the rest of Section 3.1, we define $\mathrm{OPT}(G,k) = \min_{S \subseteq V(G)} \mathrm{CHS}(G,k,S)$.

We split our approximate kernel for Conn-$\mathcal{H}$-HS into two steps. Let d denote the size of the largest graph in $\mathcal{H}$. First we compute a set D of size at most $k^{\mathcal{O}(d)}$ such that if a set S of size at most k is an $\mathcal{H}$-hitting set in $G[D]$, then S is an $\mathcal{H}$-hitting set in G. In the second step, we closely follow the idea of the approximate kernel for Steiner Tree (see [5, 19]) to bound the number of vertices outside D that we need to preserve to guarantee a 'good' connected set that hits all subgraphs in $G[D]$ isomorphic to a graph in $\mathcal{H}$.

Our starting point is the known kernel of size $k^{\mathcal{O}(d)}$ for the (not necessarily connected) $\mathcal{H}$-Hitting Set problem [6]. This kernel uses the *sunflower reduction rule* which is based on the classic sunflower lemma [14]. The sunflower reduction rule will also be a critical part of our approximate kernel and we begin by recalling the formal definition of sunflowers. Let $\mathcal{F}$ be a set system over the universe $\mathcal{U}$ and let $s \in \mathbb{N}$. A set $A_1, \ldots, A_s \in \mathcal{F}$ is called an *s-sunflower* if for every i, j such that $1 \leq i < j \leq s$, $A_i \cap A_j = \cap_{r=1}^{s} A_r$.

▶ **Proposition 13** ([14]). *Let $\mathcal{F}$ be a set system and d the size of a largest set in $\mathcal{F}$. If $|\mathcal{F}| > d!(k+1)^d$ $\mathcal{F}$, then $\mathcal{F}$ contains a $(k+2)$-sunflower. Moreover, it can be found in time polynomial in $|\mathcal{F}|$, k, and d.*

We now state and prove the following lemma, which is crucial for the correctness of the sunflower reduction rule. Although the following lemma is well-known, we state it in a way that is most convenient for our application.

▶ **Lemma 14.** *Let $\mathcal{U}$ be a universe of elements, $\mathcal{F}_1 \supset \mathcal{F}_2 \supset \cdots \supset \mathcal{F}_r$ be a family of set systems over $\mathcal{U}$ and $A_1, \ldots, A_{r-1} \subseteq \mathcal{U}$ such that for every $i \in \{1, \ldots, r-1\}$ the following holds: (a) $\mathcal{F}_{i+1} = \mathcal{F}_i \setminus A_i$ and (b) A_i is contained in a $(k+2)$-sunflower in $\mathcal{F}_i$. Then, if a set $S \subseteq \mathcal{U}$ of size at most k hits all sets in $\mathcal{F}_r$, then S also hits all sets in $\mathcal{F}_1$.*

We are now ready to formally describe the construction of the set D.

▶ **Lemma 15.** *Fix $\mathcal{H}$ and let $d = d_{\mathcal{H}}$. There exists a polynomial time algorithm that takes as input a graph G and integer k and outputs a set of vertices $D \subseteq V(G)$ of size at most $d \cdot d!(k+1)^d$ such that if a set S of size at most k is an $\mathcal{H}$-hitting set in $G[D]$, then S is an $\mathcal{H}$-hitting set in G.*

Due to this lemma, once we compute the set D, the *hitting* part of the Conn-$\mathcal{H}$-HS problem is taken care of and it is the *connectivity* which results in the hardness of standard kernelization. In other words, for every connected $\mathcal{H}$-hitting set S of a graph G of size at most k it follows from Lemma 15 that $D \cap S$ is also a $\mathcal{H}$-hitting set of G and the only role of vertices in $S - D$ is to connect the set of vertices in $D \cap S$. Such a situation could be handled relatively easily in the case of Connected Vertex Cover (see [19]) since the graph induced on $V(G) \setminus D$ is by definition an *independent set*. However, since we are dealing with an arbitrary family $\mathcal{H}$, we cannot rely on any structural consequences of a graph excluding $\mathcal{H}$; only the fact that the size of the largest graph in $\mathcal{H}$ is a fixed integer. A natural

approach to providing connectivity between vertices in a graph is to construct a Steiner tree over a particular set of terminals. Unfortunately, since we do not know the set $S \cap D$ apriori, one would have to try and compute an appropriate Steiner tree for every possible subset of D of size at most $k-1$, as the set of terminals. Since this would be too expensive for us, we will try to preserve all necessary *approximate* Steiner trees. We begin by recalling the following result of Borchers and Du [4].

▶ **Proposition 16** ([4]). *For every $t \geq 1$, graph G, terminal set R, cost function $w : E(G) \to \mathbb{N}$, and Steiner tree T, there is a t-restricted Steiner tree $\mathcal{T}$ of cost at most $(1 + \frac{1}{\lfloor \log_2 t \rfloor}) \cdot w(T)$.*

It follows from the proof of Borchers and Du [4] that if for every subset of R of size at most t, one were to preserve an *optimal* Steiner tree for this subset, then it is possible to construct a t-restricted Steiner tree of R of cost at most that of the tree $\mathcal{T}$ in Proposition 16 (see also [5, 19]). This fact will be used crucially in our algorithm.

▶ **Lemma 17.** *For every fixed $\epsilon > 0$, there exists a polynomial time algorithm that takes as an input a connected graph G and k and either correctly determines that G does not contain a connected $\mathcal{H}$-hitting set of size at most k or outputs an induced subgraph G' of G of size $\mathcal{O}(k^{d \cdot 2^{\frac{1}{\epsilon}}+1})$ such that:(1) if S is a connected $\mathcal{H}$-hitting set in G', then S is a connected $\mathcal{H}$-hitting set in G and (2) $\mathrm{OPT}(G', k) \leq (1+\epsilon) \cdot \mathrm{OPT}(G, k)$.*

Proof. The algorithm first executes the algorithm of Lemma 15 to obtain a set of vertices D of size at most $d \cdot d!(k+1)^d$ such that if a set S of size at most k is an $\mathcal{H}$-hitting set in $G[D]$, then S is an $\mathcal{H}$-hitting set in G. We fix a constant t such that $\frac{1}{\lfloor \log_2 t \rfloor} \leq \epsilon$. Now for every subset R of D of size at most t we fix a cost function assigning 1 to every edge and compute an *optimal* Steiner tree T_R for the set of terminals R using, for example, the Dreyfus-Wagner Algorithm [13]. It follows from [13] that this step takes time $\mathcal{O}(3^t|E(G)||V(G)|)$, which is polynomially bounded since ϵ is a fixed constant. If $|V(T_R)| \leq k$, then we *mark* the vertices of T_R. After we have computed T_R for every subset R (of size at most t) of D, we remove all unmarked vertices from G and denote the resulting graph by G'. We now claim that G' is the desired graph. It is easy to see that $|V(G')| \leq \sum_{i=1}^{t} \binom{|D|}{i} \cdot k = \mathcal{O}(k^{d \cdot t+1})$. Moreover, every connected $\mathcal{H}$-hitting set in G' is a $\mathcal{H}$-hitting set in $G[D]$ and hence it is also a connected $\mathcal{H}$-hitting set in G.

Note that if G' contains two different connected components A, B, then a shortest path with one endpoint in $A \cap D$ and the other in $B \cap D$ must have at least $k+1$ vertices. Otherwise, we would have marked such a path and A and B would not be distinct connected components of G'. Therefore, if both $A \cap D$ and $B \cap D$ contain a subgraph isomorphic to a graph in $\mathcal{H}$, then every connected $\mathcal{H}$-hitting set of G contains at least $k+1$ vertices and we may correctly return that G does not contain a connected $\mathcal{H}$-hitting set of size at most k.

Otherwise, for at most one component C of G', the graph $G[C \cap D]$ contains an induced subgraph isomorphic to a graph in $\mathcal{H}$. Since every $\mathcal{H}$-hitting set in $G[D]$ is a $\mathcal{H}$-hitting set in G, it follows that every *connected* $\mathcal{H}$-hitting set of $G[C]$ is also a connected $\mathcal{H}$-hitting set of G. Therefore, we assume in the following that G' is connected.

It remains for us to prove that $\mathrm{OPT}(G', k) \leq (1+\epsilon) \cdot \mathrm{OPT}(G, k)$. Observe that by the definition of the function OPT, it must be the case that $OPT(G, k), OPT(G', k) \leq k+1$. This is simply because $\mathrm{CHS}(G, k, V(G))$ and $\mathrm{CHS}(G', k, V(G'))$ are both bounded by $k+1$. Now, if it is the case that $\mathrm{OPT}(G, k) = k+1$, then $\mathrm{OPT}(G', k) \leq k+1 \leq (1+\epsilon) \cdot \mathrm{OPT}(G, k)$.

Therefore, we may assume that $\mathrm{OPT}(G, k) \leq k$. Let Q be an optimal connected $\mathcal{H}$-hitting set in G of size at most k. That is, $\mathrm{CHS}(G, k, Q) = OPT(G, k) = |Q|$. We denote $Q_D = Q \cap D$ and $Q_R = Q \setminus D$. Clearly, Q_D is a $\mathcal{H}$-hitting set in $G[D]$ and by our construction

of D, it follows that Q_D is a $\mathcal{H}$-hitting set in G. Hence, if we consider the Steiner tree instance obtained by assigning every edge in G weight 1 and choosing Q_D as the set of terminals, any spanning tree T of $G[Q]$ must in fact be an optimal Steiner tree in G for the aforementioned weight function and terminal set Q_D. We invoke Proposition 16 to infer that there is a t-restricted Steiner tree $\mathcal{T}$ of cost at most $(1+\frac{1}{\lfloor \log_2 t \rfloor})\cdot(|Q|-1)$. It remains to argue that we can reconstruct such a t-restricted Steiner tree $\mathcal{T}$ for Q_D using only the vertices in G'.

Consider a t-component C in $\mathcal{T}$ and let R be the set of terminals in C. Since $R \subseteq Q_D$, it implies that G' contains an optimal Steiner tree T_R for R. Moreover, C is a Steiner tree with R as the set terminals, hence $|T_R| \leq |C|$ and we can replace C by T_R in $\mathcal{T}$. Exhaustively repeating this argument we conclude that there is a t-restricted Steiner tree $\mathcal{T}'$ with set of terminals Q_D of cost no more than $(1+\frac{1}{\lfloor \log_2 t \rfloor})\cdot(|T|-1)$, such that all k-components in $\mathcal{T}'$ use only marked vertices. Furthermore, (see paragraph following Proposition 16), the union of all t-components in $\mathcal{T}'$, denoted by $\bigcup \mathcal{T}'$, is indeed a Steiner tree. In particular, $\bigcup \mathcal{T}'$ is connected and contains all vertices in Q_D. Therefore, $\bigcup \mathcal{T}'$ is a connected $\mathcal{H}$-hitting set in G of size at most $(1+\frac{1}{\lfloor \log_2 t \rfloor})\cdot(|Q|-1)+1 \leq (1+\epsilon)|Q|$. Since $|Q|$ is by definition the same as $\mathrm{OPT}(G,k)$, the lemma follows. ◀

▶ **Theorem 1.** *For every fixed $\epsilon > 0$, there is a $(1+\epsilon)$-approximate polynomial kernel for* Connected $\mathcal{H}$-hitting set.

Proof. We begin by describing the reduction algorithm. We first invoke the algorithm of Lemma 17. If this algorithm concludes that G does not contain a connected $\mathcal{H}$-hitting set of size at most k, then we return the instance $(H,0)$, where $H \in \mathcal{H}$. Otherwise, if this algorithm returns a graph G', then the reduction algorithm returns the instance (G',k). From Lemma 17 it follows that the size of the reduced instance is $\mathcal{O}(k^{d\cdot 2^{-\frac{1}{\epsilon}}})$.

We now describe the solution lifting algorithm as follows. Let S' be the given solution for (G',k). If S' is not a connected $\mathcal{H}$-hitting set in G', then the algorithm outputs $\emptyset$. If S' is a connected $\mathcal{H}$-hitting set in G', then the algorithm outputs S', if $|S'| \leq k$ and $V(G)$ otherwise. We denote by S the output of the solution lifting algorithm.

We now prove that this reduction algorithm and the solution lifting algorithm together constitute a $(1+\epsilon)$-approximate kernel. Note that if S' is not a connected $\mathcal{H}$-hitting set of G', then $\emptyset$ is also not a connected $\mathcal{H}$-hitting set of G and $\mathrm{CHS}(G',k',S') = \mathrm{CHS}(G,k,\emptyset) = \infty$. On the other hand, if $\mathrm{OPT}(G,k) = k+1$, then it follows from Lemma 17 and the definition of the reduction algorithm that $\mathrm{OPT}(G',k') = k'+1$. Therefore,

$$\frac{\mathrm{CHS}(G,k,V(G))}{\mathrm{OPT}(G,k)} = 1 \leq (1+\epsilon)\cdot\frac{\mathrm{CHS}(G',k',S)}{\mathrm{OPT}(G',k')} = (1+\epsilon)$$

Hence, we can assume that $\mathrm{OPT}(G,k) \leq k$ and the reduction algorithm returned the instance (G',k) such that G' is as in Lemma 17. Then either $|S'| \leq k$ and $S = S'$ or $|S'| \geq k+1$ and $S = V(G)$. However, in both cases it holds that $\mathrm{CHS}(G,k,S) = \mathrm{CHS}(G',k,S')$. Moreover, from Lemma 17 it follows that $\mathrm{OPT}(G',k) \leq (1+\epsilon)\cdot\mathrm{OPT}(G,k)$, implying the theorem. ◀

3.2 The lower bound for Weighted Connected $\mathcal{H}$-hitting set

In this section, we prove that in the presence of weights, the Connected $\mathcal{H}$-hitting set problem no longer admits an α-approximate kernel for *any* constant α. The parameterized optimization version of Weighted Connected $\mathcal{H}$-hitting set is formally defined via the function W-CHS : $\Sigma^* \times \mathbb{N} \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}$ as follows: $\text{W-CHS}((G,w),k,S) = \infty$

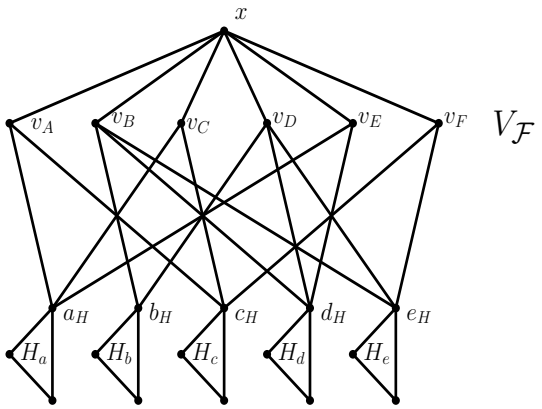

Figure 1 The graph output by our reduction algorithm starting from the SC/n instance $(\{A, B, C, D, E, F\}, \{a, b, c, d, e\})$ where the sets are defined as $A = \{a, c\}$, $B = \{b, d, e\}$, $C = \{a, c\}$, $D = \{b, d, e\}$, $E = \{a, d\}$, and $F = \{c, e\}$. Here, $\mathcal{H}$ contains only a triangle.

if S is not a connected $\mathcal{H}-$ hitting set of size at most k and W-CHS$((G, w), k, S) = w(s)$ otherwise.

We prove our lower bound by giving a polynomial time reduction from a parameterized optimization version of the classic Set Cover problem such that an α-approximate polynomial kernel for Weighted Connected $\mathcal{H}$-hitting set would imply one for Set Cover, which would contradict the lower bound in [19]. Note that since we are proving a lower bound, it is sufficient to demonstrate *one* family $\mathcal{H}$ for which Weighted Conn-$\mathcal{H}$-HS does not admit approximate kernels. However, in the interest of extracting the strongest possible consequence of our reduction, we introduce the following definition.

▶ **Definition 18.** Let $\mathcal{H}$ be a fixed finite family of finite graphs. We say that $\mathcal{H}$ is *rigid* if there is a connected graph H in $\mathcal{H}$ and a vertex $v \in V(H)$ such that no graph $H' \in \mathcal{H}$ is a subgraph of H and no graph $H' \in \mathcal{H}$ is the disjoint union of connected components each of which is isomorphic to $H - v$.

▶ **Theorem 19.** *Let $\mathcal{H}$ be a fixed rigid family of graphs. Then, there is no α-approximate polynomial compression for* Weighted Conn-$\mathcal{H}$-HS *for any constant α unless* NP $\subseteq$ coNP/Poly *even if the weight function is restricted to* $\{0, 1\}$.

Proof. We prove the theorem by giving a 1-approximate polynomial parameter transformation from SC/n to the Weighted Connected $\mathcal{H}$-hitting set problem. Recall that a polynomial parameter transformation consists of two algorithms, a reduction algorithm and a solution lifting algorithm. We describe a reduction algorithm that takes as input an instance $(\mathcal{F},\mathcal{U})$ of SC/n and outputs an instance (G, k, w) of Weighted Connected $\mathcal{H}$-hitting set such that $k = 2|\mathcal{U}| + 1$, $|G| \leq 1 + |\mathcal{F}| + d_{\mathcal{H}}|\mathcal{U}|$.

Reduction Algorithm. We construct G from $(\mathcal{F},\mathcal{U})$ as follows. The vertex set $V(G)$ is partitioned into sets $\{x\} \uplus V_{\mathcal{U}} \uplus V_{\mathcal{F}}$. Fix a graph $H \in \mathcal{H}$ which certifies the rigidity of $\mathcal{H}$. That is, there is a vertex $h^* \in V(H)$ such that no graph $H' \in \mathcal{H}$ is the disjoint union of connected components each of which is isomorphic to $H - h^*$. The set $V_{\mathcal{U}}$ induces in G, a disjoint copy H_u of H for every element $u \in \mathcal{U}$. We fix a special vertex $u_H \in H_u$ for every $u \in \mathcal{U}$. This vertex is the vertex of H_u corresponding to h^*. This is to ensure that after

deleting u_H from each H_u, we do not still have a graph from $\mathcal{H}$ contained in $G[V_\mathcal{U}]$. The set $V_\mathcal{F}$ contains a vertex v_S for every set $S \in \mathcal{F}$. Finally, x is a vertex disjoint from $V_\mathcal{U} \cup V_\mathcal{F}$. The edge set of G is defined as follows $E(G) = \{xv_S | v_S \in V_\mathcal{F}\} \cup \{v_S u_H | u \in S\} \cup_{u \in \mathcal{U}} E(H_u)$. In other words, $E(G)$ contains beside the edges for every copy of H, an edge between x and every vertex in $V_\mathcal{F}$ and then an edge between a vertex $v_S \in V_\mathcal{F}$ corresponding to the set S and the previously fixed special vertex u_H in the copy of H corresponding to an element u, if and only if $u \in S$ (see Figure 1). Finally, the weight function $w : V(G) \to \{0, 1\}$ is defined as follows. We let $w(v) = 0$ if $v \in \{x\} \cup V_\mathcal{U}$ and $w(v) = 1$ otherwise. The *weight* of a set $Q \subseteq V(G)$ is defined as $\Sigma_{q \in Q} w(q)$. This completes the description of the reduction algorithm.

Solution Lifting Algorithm. The solution lifting algorithm is straightforward. Given a solution string T for the instance (G, k, w), if T is not a connected $\mathcal{H}$-hitting set of size at most k, then we return a spurious solution string for the instance $(\mathcal{F},\mathcal{U})$. Otherwise, we return the sets in $\mathcal{F}$ which correspond to $V_\mathcal{F} \cap T$.

We are now ready to prove that this is a 1-approximate polynomial parameter transformation. Observe that in order to do so, it is sufficient to prove the following claim.

▶ **Claim 20.** *For every $p \in \mathbb{N}$ there is a set cover of $(\mathcal{F},\mathcal{U})$ of size p if and only if there is a connected $\mathcal{H}$-hitting set of G with at most k vertices and weight exactly p.*

Proof. Suppose that $\mathcal{S}$ is a set cover of $(\mathcal{F},\mathcal{U})$. We can assume without loss of generality that $|\mathcal{S}| \leq |\mathcal{U}|$. We claim that $T = \{x\} \cup \{v_S | S \in \mathcal{S}\} \cup \{u_H | u \in \mathcal{U}\}$ is a weighted connected $\mathcal{H}$-hitting set of G of weight $|\mathcal{S}|$. As all vertices in $V_\mathcal{F}$ have weight 1 and all other vertices have weight 0, the weight of T is $|\mathcal{S}|$. Moreover, all vertices in $V_\mathcal{F}$ are adjacent to x and since $\mathcal{S}$ is a set cover, every vertex u_H is adjacent to a vertex v_S for a set $S \in \mathcal{S}$ that contains u. Finally every connected component of $G - T$ is either a vertex or a graph isomorphic to $H - h^*$. Since $\mathcal{H}$ is rigid, we conclude that $G - T$ does not contain a graph in $\mathcal{H}$. Since $\mathcal{S}$ has size at most $|\mathcal{U}|$, the size of T is bounded by $2|\mathcal{U}| + 1$ which is precisely k.

In the converse direction suppose that T is a connected $\mathcal{H}$-hitting set of G of weight p. Since the only vertices with non-zero weights lie in $V_\mathcal{F}$ and they all have weight 1, we infer that $|V_\mathcal{F} \cap V(T)| = p$. We claim that $\mathcal{S} = \{S | v_S \in V(T) \cap V_\mathcal{F}\}$ is a set cover of $(\mathcal{F},\mathcal{U})$. Observe that since T is a $\mathcal{H}$-hitting set, it must be the case that for every $u \in \mathcal{U}$, T contains a vertex from H_u. Since T also contains at least one vertex of $V_\mathcal{F}$ (under the simple assumption that $|\mathcal{U}| > 1$), and only u_H is adjacent to a vertex outside H_u, it follows that $u_H \in V(T)$. Moreover, u_H is adjacent only to vertices in H_u or in $V_\mathcal{F}$. Therefore, u_H is adjacent to a vertex $v_S \in V_\mathcal{F} \cap V(T)$ for a set $S \in \mathcal{F}$. This implies that the element u is covered by the set $S \in \mathcal{S}$, completing the proof of the claim and the proof of the lemma. ◀

4 Interpolating kernels for Dominating Set on d-degenerate graphs

This section is devoted to Theorem 2, i.e., the approximate kernels interpolating between two known kernels with respect to their accuracy-size tradeoff.

▶ **Proposition 21.** [20] Dominating Set *has a kernel of size $\mathcal{O}((d+2)^{2(d+2)} k^{2(d+1)^2})$ on d-degenerate graphs.*

▶ **Definition 22.** The parameterized optimization version of Dominating Set is defined via the function $\mathrm{DS} : \Sigma^* \times \mathbb{N} \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}$ as follows:

$$\mathrm{DS}(G,k,S) = \begin{cases} \infty & \text{if } S \text{ is not a dominating set of } G, \\ \min\{|S|, k+1\} & \text{otherwise.} \end{cases}$$

For the rest of this section, we define $\mathrm{OPT}(G,k) = \min_{D \subseteq V(G)} \mathrm{DS}(G,k,D)$.

The kernelization algorithm of Philip et al. [20] can be seen to be a strict 1-approximate polynomial kernel and forms the starting point of our sequence of approximate kernels. We give here a slightly different description of this kernel (in particular of its analysis) so as to better serve our purposes. First of all, we will be working with a "colored" version of the problem where the vertices of the input graph are partitioned into two sets – the set of red vertices R and the set of blue vertices B – and the goal is to find a subset of at most k vertices of any color that dominates all red vertices. That is, a set $S \subseteq R \cup B$ with $|S| \leq k$ such that for every $v \in R$ we have $N[v] \cap S \neq \emptyset$. Clearly every instance of Dominating Set can be reduced to the colored variant by coloring all the vertices red. For presentation purposes, we will refer to the colored version as Dominating Set and instances of this problem are of the form (G,B,R,k) where B and R denote the set of blue and red vertices respectively. The functions $\mathrm{DS}(G,k,S)$ and $\mathrm{OPT}(G,k)$ are now represented as $\mathrm{DS}(G,B,R,k,S)$ and $\mathrm{OPT}(G,B,R,k)$ with the natural extended definitions. Furthermore, since edges between vertices in B are irrelevant with respect to the domination of R, we may assume without loss of generality that B is an independent set. Philip et al. [20] devised the following reduction rule and their proof of correctness of the rule also shows that it is in fact 1-safe.

Let (G,B,R,k) be the given instance of Dominating Set. For $i \in \{0,\ldots,d\}$: If there exists a set of $d+1-i$ vertices $X \subseteq R \cup B$ which have at least $k^i(d+1)$ common red neighbors $Y \subseteq R$, then remove the edges between X and Y, color all vertices in Y blue, and add $k+1$ new red vertices that are each connected to all vertices in X and no other vertex in G. The parameter remains k.

Henceforth, we assume that Reduction Rule 4 does not apply on the given instance of Dominating Set. Philip et al. [20] showed that if Reduction Rule 4 does not apply on the instance (G,B,R,k), then every vertex in G has at most $k^d(d+1)$ red neighbors, leading to the following observation.

▶ **Lemma 23.** *If Reduction Rule 4 does not apply on the instance (G,B,R,k), then either $|R| \leq k^{d+1}(d+1)$ or $\mathrm{OPT}(G,B,R,k) = k+1$.*

Due to Lemma 23, we may assume that $|R| \leq k^{d+1}(d+1)$. The following standard *twin reduction* rule can be easily seen to be 1-safe.

If $b_1, b_2 \in B$ are two non-adjacent vertices such that $N(b_1) = N(b_2)$, we remove b_1 from G.

In the following, for every $i \in \{0,\ldots,d\}$, we let B_i denote the set of blue vertices which have exactly i red neighbors and let $B_{>d}$ denote the set of blue vertices which have at least $d+1$ red neighbors. We now prove the following bound on the size of each of these sets.

▶ **Lemma 24.** *Let (G,B,R,k) be an instance of Dominating Set on which Reduction Rule 4 and Reduction Rule 4 do not apply. Then, $|B_{>d}| \leq d|R|$, and $|B_i| \leq |R|^i$ for each $i = 0,\ldots,d$.*

Observe that since we have only applied 1-safe reduction rules, the instance obtained after the exhaustive application of Reduction Rule 4 and Reduction Rule 4 is a strict 1-approximate

kernel and due to Lemma 24, the result is a strict 1-approximate kernel of size $k^{\mathcal{O}(d^2)}$. This is the kernel of Philip et al. [20] and henceforth we refer to instances of Dominating Set on which this preprocessing has been executed, as *reduced instances* and assume without loss of generality that the input has size bounded by $k^{\mathcal{O}(d^2)}$. We will now introduce a 'lossy reduction rule' to reduce the size of our kernel further at the cost of transforming it into a $\lceil \frac{d}{\rho} \rceil$-approximate kernel.

▶ **Lemma 25.** *Let $d, \rho \in \mathbb{N}$ be fixed integers such that $\rho < d$. There is an algorithm that, given a reduced instance (G, B, R, k) of* Dominating Set *runs in polynomial time and returns an instance (G', B', R', k) such that (a) $|V(G')| \leq k^{\mathcal{O}(\rho d)}$, (b) if S dominates R' in G', then S dominates R in G and (c) $\mathrm{OPT}(G', B', R', k) \leq \lceil \frac{d}{\rho} \rceil \cdot \mathrm{OPT}(G, B, R, k)$.*

Proof. Let B^* denote an auxiliary set of blue vertices which is initially empty. For each subset of ρ red vertices $R_0 \subseteq R$ we find a blue vertex $b \in B$ (if one exists) with $R_0 \subseteq N(b)$, and add it to our auxiliary set B^*. At the end of this procedure, we define the graph G' to be the subgraph of G induced by $R \cup B_0 \cup \cdots \cup B_\rho \cup B_{>d} \cup B^*$, $B' = B \cap V(G')$, and $R' = R$.

Recall that $|R| = \mathcal{O}(k^{d+1})$, and so there are $\binom{|R|}{\rho} = \mathcal{O}(k^{\rho(d+1)})$ subsets R_0. Thus, $|B^*| = \mathcal{O}(k^{\rho(d+1)})$. Moreover, $|B_0 \cup \cdots \cup B_\rho| = \mathcal{O}(k^{d\rho})$ according to Lemma 24. Therefore, $|V(G')|$ is bounded by $k^{\mathcal{O}(\rho d)}$ as required and the time required to compute G' is bounded polynomially in $|V(G)|$. We now proceed to the remaining two statements. Since $R' = R$ and G' is a subgraph of G, it follows that any set S which dominates all vertices of R' in G', also dominates all vertices of R in G. Hence, it only remains to prove the second statement.

Let S be an optimal solution for G. That is, $\mathrm{OPT}(G, B, R, k) = |S|$. We now construct a solution S' for G' as follows. We begin by setting $S' = S \cap V(G')$. Note that S' includes all vertices of $R \cap S$ since $R \subseteq V(G) \cap V(G')$. Consider now a blue vertex $b \in S \setminus V(G')$, and let $R(b)$ denote the set of red neighbors of b. Then $\rho + 1 \leq |R(b)| \leq d$ by the construction of G'. Moreover, for any subset of ρ vertices in $R(b)$, there is a vertex of B' in $V(G')$ which dominates these ρ vertices. Thus, we can replace b with at most $\lceil \frac{d}{\rho} \rceil$ vertices of B' in $V(G')$ and still dominate $R(b)$. Therefore, applying this switch for each $b \in S \setminus V(G')$, we obtain a solution S' for G' with $|S'| \leq \lceil \frac{d}{\rho} \rceil |S|$. This implies that $\mathrm{OPT}(G', B', R', k) \leq \lceil \frac{d}{\rho} \rceil \cdot \mathrm{OPT}(G, B, R, k)$, completing the proof of the lemma. ◀

From Lemma 25 it immediately follows that Dominating Set on d-degenerate graphs has $\lceil \frac{d}{\rho} \rceil$-approximate compression to the colored version of the problem. Theorem 2 then follows by gadgeteering similar to that used by Philip et al. [20]. Note that any graph that excludes K_h as a minor also excludes K_h as a topological minor (see [9] for a formal definition of minors and topological minors). Furthermore, it is known that any graph that does not contain K_h as a minor (topological minor) is d-degenerate where $d = \mathcal{O}(h^2)$ ($d = \mathcal{O}(h\sqrt{\log h})$ respectively) [2], giving us the following corollary.

▶ **Corollary 26.** *Let $\rho, h \in \mathbb{N}$. Then,* Dominating Set *on graphs excluding K_h as a minor (topological minor) has a $\mathcal{O}(\frac{h^2}{\rho})$-approximate kernel ($\mathcal{O}(\frac{h\sqrt{\log h}}{\rho})$-approximate kernel) of size $k^{\mathcal{O}(\rho h^2)}$ ($k^{\mathcal{O}(\rho h\sqrt{\log h})}$ respectively).*

5 Conclusions

Our work on the Connected $\mathcal{H}$-Hitting Set problem adds another interesting data point to the study of preprocessing for problems with connectivity constraints. We have also initiated the study of accuracy-size tradeoffs for problems which already have polynomial

kernels, via the design of a sequence of kernels capturing the gradient of the kernel-size with respect to the accuracy or approximation factor. Our results point to a few interesting questions for future research.

- Are there other connectivity-constrained problems which do not admit polynomial kernels but admit α-approximate kernels?
- Is it possible to obtain *meta-theorems* characterizing or providing at least a sufficiency condition for connectivity-constrained problems to admit α-approximate kernels?
- Is it possible to refine the interpolation (Theorem 2) by presenting a sequence of kernels between the d^2-approximate kernel of constant size and our d-approximate kernel of size $k^{\mathcal{O}(d)}$?

Undecidable Problems for Probabilistic Network Programming

David M. Kahn

Cornell University, Department of Computer Science, Ithaca NY, USA
dmk254@cornell.edu

Abstract

The software-defined networking language NetKAT is able to verify many useful properties of networks automatically via a PSPACE decision procedure for program equality. However, for its probabilistic extension ProbNetKAT, no such decision procedure is known. We show that several potentially useful properties of ProbNetKAT are in fact undecidable, including emptiness of support intersection and certain kinds of distribution bounds and program comparisons. We do so by embedding the Post Correspondence Problem in ProbNetKAT via direct product expressions, and by directly embedding probabilistic finite automata.

1 Introduction

The NetKAT family of programming languages aims to simplify network programming and its verification [1, 10]. The NetKAT languages do this is by centralizing network control in a scheme known as software-defined networking, and by exploiting the algebraic structure of Kleene algebra with tests. This leaves the language NetKAT sufficiently well-behaved so as to admit a relatively fast (PSPACE-complete) decision procedure for program equivalence [5]. Several important networking problems, such as waypointing and reachability, are reducible to program equivalence in NetKAT, so this decision procedure is quite useful for automated verification of NetKAT programs.

NetKAT, however, has limitations. NetKAT is deterministic and cannot express probabilistic concepts that often arise in networking, such as randomized routing algorithms and connection failure chance [4]. The language ProbNetKAT answers this by conservatively extending NetKAT with an operator for probabilistic choice. However, the addition of this new operator further distances the language from the well-behavedness of a pure Kleene algebra with tests. This opens up many new questions concerning decidability and deductive completeness. If the benefits of the NetKAT framework are to be applied to probabilistic networking, it is important to now determine what can or cannot be decided about ProbNetKAT. As of the time of this paper, few ProbNetKAT decidability results have been put forward.

This paper introduces several properties of ProbNetKAT programs that are not decidable, alongside some contexts in which they might arise. These undecideable properties include emptiness of support intersection, support size, and certain kinds of program distribution bounds and comparisons. We prove these problems undecidable through two different

embeddings. First, the Post Correspondence Problem is embedded in ProbNetKAT via direct product expressions, which are expressions in the direct product of regular expressions. And second, probabilistic finite automata are then directly embedded in ProbNetKAT, and their associated undecidable problems translated over.

2 Definition of ProbNetKAT

To understand ProbNetKAT, it is important to understand how NetKAT treats its *packets*, the information that is passed around a network. A given packet $\pi \in Pk$ is a collection of fields of information, such that $\pi(x)$ can be considered to be the value of field x. Each of these fields may be assigned value using the $\leftarrow$ operator, or *tested* using the $=$ operator. These tests act as filters, dropping all packets that do not satisfy them. Any such test can also be complemented using the $\neg$ operator.

For bookkeeping purposes, these packets are understood to be arranged in *histories*, $\pi_1 :: \pi_2 :: ... :: \pi_n$, which are sequences of snapshots of a given packet over time, from youngest to oldest. (Such a history is often shortened notationally to $\pi_1 :: \sigma$.) The operation which takes this snapshot is called *dup*, because it *duplicates* the latest packet, the head packet π_1, and appends it to the front of the sequence. Only the head packet ever actually exists in the network in execution, but tracking the history that a given program would generate for a packet allows for answering important questions about that packet, like where it has been.

In addition to these basic operations of test and assignment, NetKAT also employs the operators and constants of Kleene algebra. Kleene algebra's addition is given with & (parallel composition), its multiplication is given with ; (sequential composition), its asterate is given with * (iteration), its annihilator element 0 is given with *drop* (drops all packets), and its identity element 1 is given with *skip* (does nothing). Together, these form a Kleene algebra on the generating set of assignments and tests. This means, for instance, that & is commutative. Interestingly, in most contexts, we interpret Kleene algebras as treating & disjunctively, but in NetKAT, & is conjunctive. And, paired with the negation operator ($\neg$), these also can form a Boolean algebra on only tests ($=$). For a Boolean algebra, *drop* act as 0, *skip* acts as 1, & acts as disjunction, and ; acts as conjunction. This means, for instance, that both ; and & are commutative on the tests.

This Kleene algebra structure paired with Boolean algebra comprises the Kleene algebra with tests, or KAT, that NetKAT is named after. This algebra is sufficient to characterize a lot of programmatic structure, allowing for manipulation of such structure into different semantically equivalent forms. For instance, letting the term b below be such a Boolean term, and letting p and q be general expressions, we can represent the programming idioms of the while loop and if-then-else clause as below. The symbols used will be defined formally shortly.

$$\text{if } b \text{ then } p \text{ else } q = b;p\&\neg b;q \qquad \text{while } b \text{ do } p = (b;p)^*;\neg b$$

The relevant syntax of NetKAT can therefore be given just by KAT expressions of the above operators on an alphabet of tests, assignments, and *dup*s, where tests are the Boolean elements.

Before we provide the formal definition of the above pieces of NetKAT, it will be useful to mention the Haskell language's monad operators, *return* (η) and *bind* ($>>=$). Letting $T(A)$ be a type predicated on the type A (like a *list* of elements from A), the monad operators are of the types $>>=: T(A) \to (A \to T(B)) \to T(B)$ and $\eta : A \to T(A)$ for some types A and B.

These operators allow the functional language of Haskell to translate functions on A into $T(A)$ in a useful way, called *lifting*. Bind and return satisfy the following axioms, corresponding to something similar to left identity, right identity, and associativity, respectively.

$$\eta(x) >\!\!>\!= f = f(x) \quad t >\!\!>\!= \eta = t \quad t >\!\!>\!= (\lambda x.f(x) >\!\!>\!= g) = (t >\!\!>\!= f) >\!\!>\!= g$$

Formally, a NetKAT program p or q is usually interpreted as a function that maps a history in $\pi :: \sigma \in H$ to a set of histories $a \in 2^H$, with the semantics defined as follows [12]. These definitions will be presented alongside some monadic counterparts to better clarify their structure and emphasize the ability to lift the operators to act on sets of histories. The relevant monad for these operations is the powerset monad.

$$\eta(\pi :: \sigma) = \{\pi :: \sigma\} \quad a >\!\!>\!= [\![p]\!] = \bigcup_{h \in a} [\![p]\!](h)$$

$$\begin{array}{lcll}
[\![skip]\!](\pi :: \sigma) & = & \{\pi :: \sigma\} & = \quad \eta(\pi :: \sigma) \\
[\![drop]\!](\pi :: \sigma) & = & \emptyset & \\
[\![x \leftarrow n]\!](\pi :: \sigma) & = & \{\pi[n/x] :: \sigma\} & = \quad \eta(\pi[n/x] :: \sigma) \\
[\![x = n]\!](\pi :: \sigma) & = & \begin{cases} \{\pi :: \sigma\} & \pi(x) = n \\ \emptyset & otherwise \end{cases} & = \quad \begin{cases} \eta(\pi :: \sigma) & \pi(x) = n \\ \emptyset & otherwise \end{cases} \\
[\![dup]\!](\pi :: \sigma) & = & \{\pi :: \pi :: \sigma\} & = \quad \eta(\pi :: \pi :: \sigma) \\
[\![\neg b]\!](\pi :: \sigma) & = & \{\pi :: \sigma\} - [\![b]\!](\pi :: \sigma) & = \quad \begin{cases} \emptyset & [\![b]\!](\pi :: \sigma) = \eta(\pi :: \sigma) \\ \eta(\pi :: \sigma) & otherwise \end{cases} \\
[\![p \& q]\!](\pi :: \sigma) & = & [\![p]\!](\pi :: \sigma) \cup [\![q]\!](\pi :: \sigma) & = \quad [\![p]\!](\pi :: \sigma) \\
 & & & \quad >\!\!>\!= \lambda s.([\![q]\!](\pi :: \sigma) >\!\!>\!= \lambda t.\eta(s) \cup \eta(t))) \\
[\![p; q]\!](\pi :: \sigma) & = & \bigcup_{h \in [\![p]\!](\pi :: \sigma)} [\![q]\!](h) & = \quad [\![p]\!](\pi :: \sigma) >\!\!>\!= [\![q]\!] \\
[\![p^*]\!](\pi :: \sigma) & = & [\![skip \& p^*; p]\!](\pi :: \sigma) & = \quad [\![skip \& p; p^*]\!](\pi :: \sigma) \\
 & = & \bigcup_{n \in \mathbb{N}} [\![p^n]\!](\pi :: \sigma) &
\end{array}$$

To get ProbNetKAT, we start by lifting these operators with bind as $\lambda a.a >\!\!>\!= [\![p]\!]$ to get a new set of operators that allow us to interpret NetKAT programs as functions from *sets* of histories to sets of histories. Then we add in the probabilistic choice operator $\oplus$, which, with a given probability r, chooses to continue to the code on its left, and otherwise the code on its right. Syntactically it may be used with the same generality as & or ;, such that all take two ProbNetKAT programs and return one. The new operator's randomness introduces distributions on the output, so a ProbNetKAT program can be interpreted as a function that maps a set of histories $a \in 2^H$ to a distribution on sets of histories μ. The semantics for the this interpretation is defined below, where many of the definitions show the same structure as in NetKAT. These semantics use the Dirac delta function δ for probability measure (which yields a distribution that puts all weight on a single point) and the product measure $\times$. The relevant monad here is the Giry monad.

$$\delta_a(A) = \begin{cases} 1 & a \in A \\ 0 & else \end{cases} \quad \eta(a) = \delta_a \quad \mu >\!\!>\!= [\![p]\!] = \lambda A. \int_{a \in 2^H} [\![p]\!](a)(A) \cdot \mu(da)$$

$$
\begin{array}{lcll}
[\![skip]\!](a) & = & \delta_a & = \eta(a) \\
[\![drop]\!](a) & = & \delta_\emptyset & = \eta(\emptyset) \\
[\![x \leftarrow n]\!](a) & = & \delta_{\{\pi[n/x]::\sigma | \pi::\sigma \in a\}} & = \eta(\{\pi[n/x] :: \sigma | \pi :: \sigma \in a\}) \\
[\![x = n]\!](a) & = & \delta_{\{\pi::\sigma \in a | \pi(x)=n\}} & = \eta(\{\pi :: \sigma | \pi :: \sigma \in a \wedge \pi(x) = n\}) \\
[\![dup]\!](a) & = & \delta_{\{\pi::\pi::\sigma \ | \pi::\sigma \in a\}} & = \eta(\{\pi :: \pi :: \sigma \ | \pi :: \sigma \in a\}) \\
[\![\neg b]\!](a) & = & \delta_{\{\pi::\sigma \in a | \pi \not\vdash b\}} & = [\![b]\!](a) >\!\!>\!\!= \lambda s.\eta(a - s) \\
[\![p \& q]\!](a) & = & ([\![p]\!](a) \times [\![q]\!](a))(\{(s,t) | s \cup t \in a\}) & = [\![p]\!](\pi :: \sigma) \\
 & & & \quad >\!\!>\!\!= \lambda s.([\![q]\!](\pi :: \sigma) \\
 & & & \quad >\!\!>\!\!= \lambda t.\eta(s \cup t))) \\
[\![p; q]\!](a) & = & [\![q]\!]([\![p]\!](a)) & = [\![p]\!](\pi :: \sigma) >\!\!>\!\!= [\![q]\!] \\
[\![p \oplus_r q]\!](a) & = & r \cdot [\![p]\!](a) + (1 - r) \cdot [\![q]\!](a) & \\
[\![p^{(0)}]\!](a) & = & [\![skip]\!](a) & \\
[\![p^{(n+1)}]\!](a) & = & [\![skip \& p; p^{(n)}]\!](a) & \\
[\![p^*]\!](a) & = & \bigsqcup_{n \in \mathbb{N}} [\![p^{(n)}]\!](a) & = [\![skip \& p; p^*]\!](a)
\end{array}
$$

This maintains many, but not all, of the typical properties we expect a Kleene algebra with tests to have. For instance, & is still commutative (thanks to the Frobenius theorem) and so are the test operations, but $[\![skip \& p^*; p]\!](\pi :: \sigma)$ is no longer an identity of p^*.

It will next be useful to define an extended form of some operators to act as short-hand for writing them down multiple times. Let p_i be a program predicated on the variable i, and let I be a finite set of i values indexed 1 through n, and let r_i be a probability predicated on i.

$$\underset{i \in I}{;} p_i = p_{i_1}; p_{i_2}; ...; p_{i_n} \qquad \underset{i \in I}{\&} p_i = p_{i_1} \& p_{i_2} \& ... \& p_{i_n}$$

$$\underset{i \in I}{\oplus_{r_i}} p_i = p_{i_1} \oplus_{r_1} (p_{i_2} \oplus_{r_2/(1-r_1)} (...(p_{i_n} \oplus_{r_n/(1 - \sum_{1 \le i < n} r_i)} drop)...))$$

This definition of sequential composition across multiple terms is only well-defined where the p_i are commutative. We will only be using it in commutative contexts like with test terms, so it is sufficient for our purposes. The sequential composition of multiple choice is designed such that each term p_i is picked with the given probability r_i. This requires that the sum of the probabilities does not exceed 1.

It is also useful to replace the assignment operator $\leftarrow$ and test operator $=$ with a complete assignment operator ! and complete test operator ? defined below, where X is the set of all fields in a packet. The complete assignment operator assigns all fields of a packet to match those of another, turning the first packet into the second. The complete test operator tests all fields of a packet against those of another, dropping the first if it does not perfectly match the second.

$$[\![\pi?]\!](a) = [\![\underset{x \in X}{;} x = \pi(x)]\!](a) \quad [\![\pi!]\!](a) = [\![\underset{x \in X}{;} x \leftarrow \pi(x)]\!](a)$$

3 A Random Loop

Some of our results rely on a program structure that loops a random number of times before exiting the loop. The following ProbNetKAT code achieves that purpose. Π will be a set of packets where every packet has a boolean field x assigned to *true*. C will stand in for the body of the loop, written to only use packets of Π. Assigning $false$ to the Π packets' field x yields a new set of packets Ψ, in one-to-one correspondance. Because the following code

results in the execution of C a number of times that is a geometric random variable with parameter r, this code will be denoted $[\![C^{G_r}]\!]$.

$$[\![C^{G_r}]\!] = [\![(\text{while } x = true \text{ do } \{C \oplus_r x \leftarrow false\}); x \leftarrow true]\!]$$

Suppose this program is given a set of histories with head packets in Π, and consider dynamically each step the code takes. First it will enter a while loop conditioned on x being $true$, so that while the packets are in Π, the loop continues. Thus, being in Ψ at the end of the while loop acts as the marker to break the loop, and the loop will never execute its body on packets from Ψ. In each iteration of the while loop, the code makes a probabilistic choice. With probability r the code runs C, which, since C is designed to run only using packets from Π, will go through C's manipulations as expected, only extending the histories with packets from Π, and thus exiting its code block with all head packets in Π. Otherwise, with probability $1 - r$, the code maps the packets into Ψ, signalling the the end of the looping. After exiting the while loop, the code ends by re-mapping all head packets back into Π.

Thus, the while loop either exits with probability $1 - r$, or it runs C on the current head packets from Π and loops again. This is the structure of running Bernoulli trials until success, so the number of times C is run is geometrically distributed with respect to r. Specifically, the probability of running C n times is given by $(1 - r) * r^n$. This accomplishes the desired goal, as a geometric distribution assigns every natural number a positive probability, so C could be run for any number of iterations.

4 Main Results

4.1 A Post-Correspondance Embedding

Direct Product Expressions (DPEs) For the first undecidable problem that will be presented, it is best to lay out an intermediate undecidable problem involving a variation on regular expressions, which will be called DPEs as shorthand for "direct product expressions". DPEs, rather than describing sets of the usual words from Σ^* (the free monoid on a generating alphabet Σ), instead describe words from direct product of n copies of Σ^* in the category of monoids, denoted $(\Sigma^*)^n$. In this direct product, multiplication is defined component-wise, such that $(a_1, a_2, ..., a_n) \cdot (b_1, b_2..., b_n) = (a_1 \cdot b_1, a_2 \cdot b_2, ..., a_n \cdot b_n)$.

Consider the minimal generating set for $(\Sigma^*)^n$, elements of which are tuples made entirely of the identity element ϵ, except for one position in which sits an element of Σ. Call this set Γ. For brevity, refer to the element of Γ containing $a \in \Sigma$ in position i as $a_{(i)}$, and in general, the tuple containing only ϵ except for $w \in \Sigma^*$ at index i as $w_{(i)}$.

$$\Gamma = \{a_{(i)} | a \in \Sigma \wedge 1 \leq i \leq n\}$$

Now, Γ^*, being the free monoid generated by Γ, can be treated in the usual manner as the alphabet for a regular expression. And because $(\Sigma^*)^n$ is also a monoid generated by Γ, there exists a unique canonical epimorphism $h : \Gamma^* \to (\Sigma^*)^n$ that acts as an identity on elements of Γ. This h is the map that performs component-wise multiplication, introducing a sort of commutativity in its image such that, while $a_{(1)} \cdot a_{(2)} \neq a_{(2)} \cdot a_{(1)}$, it is the case that $h(a_{(1)} \cdot a_{(2)}) = (a, a) = h(a_{(2)} \cdot a_{(1)})$. It is in the image of this map h that we would like to consider DPEs, though the regular expressions yielding the DPEs will be easier to write out and work with here.

Addition on DPEs continues to remain a nondeterministic choice between terms, so that the set of words matching $(a, a) + (b, b)$ is just the set containing only (a, a) and (b, b). Note

that addition is therefore not componentwise and introduces a sort of choice dependence between the choices made at different indices; (a, b) matches $(a+b, a+b)$, but not $(a, a)+(b, b)$. Finally, the asterate is defined as per usual, with w^* being the supremum of across all n of w^n, satisfying $w^* = 1 + w \cdot w^*$, for w a word in the direct product and 1 the multiplicative identity. Informally, we can then see that a DPE looks like a set of regular expressions, each on their own separate track corresponding to index, which can behave dependently on one another. Expoitation of this dependency will yield the undecidability that we seek.

Certain properties of DPEs are decidable just as easily as regular expressions. Emptiness can be decided simply by checking if the expression is ϵ. Membership of some word w can be decided by considering each of the finite permutations of elements from Γ that map to w under h, and checking membership of any of those in any regular expression that maps to the DPE under h. The union of two DPEs x and y is also decidable, simply as $x + y$.

Unlike regular expressions, however, the intersection of DPEs is not decidable, as can be seen with an embedding of the Post-Correspondence Problem (PCP) below. It should be noted that similar undecidable results concerning Kleene algebras with commutativity conditions do already exist in the literature [8, 9]. However, the formulation of the proof below in terms of DPEs is more direct and intuitive for application to ProbNetKAT, as an indexed set of words looks quite similar to a set of histories marked by head packet. I conjecture that the related undecidable results for such commutative Kleene algebras can be embedded into ProbNetKAT similarly to the method shown.

▶ **Theorem 1.** *For arbitrary DPEs A and B, $A \cap B = \emptyset$ is undecidable.*

Proof. To show the undecideability of emptiness of intersection, we will start by defining notation for summing in an expression across multiple terms. Let I be a finite, indexed set of n with element m denoted i_m, and let e_{i_m} be an expression predicated on element i_m. Because addition of expressions is commutative and there are only finitely many terms, this is well-defined.

$$\sum_{i \in I} e_i = e_{i_1} + e_{i_2} + ... + e_{i_n}$$

Now take an arbitrary instance of the PCP. The PCP is the following decision problem: Given an indexed set of word pairs $\{(x_1, y_1), (x_2, y_2), ..., (x_n, y_n)\}$ on an alphabet (given here by Σ), does there exist a non-empty sequence of indices $i_1, i_2, ..., i_m$ such that $x_{i_1} \cdot x_{i_2} \cdot ... \cdot x_{i_m} = y_{i_1} \cdot y_{i_2} \cdot ... \cdot y_{i_m}$?

We then provide the two regular X and Y below with $n = 2$, involving the left and right sides of the PCP pairs. This uses the summation definition and $1 \leq k \leq n$ as shorthand for $k \in \{m \in \mathbb{N} | 1 \leq m \leq n\}$.

$$X = [\sum_{1 \leq k \leq n} (x_k)_{(1)} \cdot (y_k)_{(2)}] \cdot [\sum_{1 \leq k \leq n} (x_k)_{(1)} \cdot (y_k)_{(2)}]^*$$

$$Y = [\sum_{a \in \Sigma} a_{(1)} \cdot a_{(2)}] \cdot [\sum_{a \in \Sigma} a_{(1)} \cdot a_{(2)}]^*$$

X generates every possible non-empty ordering of the word pairs from the PCP with each side of the pairs at its own index, and Y generates every possible non-empty word in Σ^* copied at each index.

Mapping these sets under h now actually separates the words and indices into their designated positions, such that we are left with a pair of two words. For example, if (wo, w) and (rd, ord) were PCP pairs, then we would see $h((wo)_{(1)} \cdot w_{(2)} \cdot (rd)_{(1)} \cdot (ord)_{(2)}) = (word, word)$.

In that way, the mapping of X under h to get the DPE A gives us every pair of words generated by different sides of the PCP pairs with the same index sequence, and the mapping of Y to get the DPE B gives us every pair of matching words. Thus, if we could decide if there exists a word (s, t) in both A and B, we would know that the s and t are matching words made from the same index sequence, comprising an affirmative solution to the PCP problem. And if such a word did not exist, then there would be no solution, as every possible word from every possible sequence of indices is represented. This therefore decides the PCP. But, the PCP is undecidable, so the existence of any such word (s, t) in the intersection is also undecidable. ◀

ProbNetKAT DPEs. Suppose one has two ProbNetKAT programs p and q and wishes to decide if their support sets (where support is used in the discrete sense as the set given by $\mathsf{supp}(\mu)$ of points for which the distribution μ assigns positive mass). This could be used to determine if q successfully avoids every set of paths through waypoints that p routes through, regardless of the probability with which any permutation of waypoints is used. Perhaps some of p's route sets have been compromised, but exactly which ones are unknown. Or it could serve as a preliminary test for equality of the programs' distributions, as the decision procedure for equality might be difficult, and is in fact unknown at the time of this writing; certainly, if the supports are completely different, the distributions must also differ.

Or suppose that one wishes to check the size of the output set of a program on a given input. Perhaps this would be to ensure that packets never get too congested by using too few routes.

Unfortunately, the first of these problems is undecidable for fixed inputs with more than one distinct head packet. This can be shown in a discrete distribution case by showing that support intersection emptiness decides the emptiness of intersection of DPEs. The same example can further be used to show that the second problem, determining output size, is undecidable as well. These results do not reflect on the decidability of intersection or output size of non-random NetKAT programs, however. NetKAT programs can in fact be represented with regular sets of guarded strings [1] , so these two questions are easily decidable in NetKAT.

To show this, we will construct an embedding for DPEs in ProbNetKAT. This embedding will satisfy that $w = (w_1, w_2, ...w_n)$ is in a given DPE with alphabet Σ if and only if, given the set $\{\pi_1, \pi_2 ... \pi_n\}$ to start, the corresponding ProbNetKAT program puts out the history set $\{\pi_1 :: w_1, \pi_2 :: w_2, ...\pi_n :: w_n\}$ with positive probability, where the set of packets Pk is given by $\Sigma \cup \Pi \cup \Psi$, $\Pi = \{\pi_i | 1 \leq i \leq n\}$, and Ψ the appropriate packet set for the random loop from earlier. The embedding g is defined inductively below on regular expressions over $a_{(i)} \in \Gamma$, which yield the appropriate DPEs under h.

$$g(\epsilon) = [\![skip]\!]$$

$$g(a_{(i)}) = [\![\text{if } \pi_i? \text{ then } a!; dup; \pi_i! \text{ else } skip]\!]$$

$$g(x \cdot y) = g(y); g(x)$$

$$g(x + y) = g(x) \oplus g(y)$$

$$g(x^*) = [\![g(x)^{G_{0.5}}]\!]$$

▶ **Theorem 2.** *The function g yields a valid embedding of DPEs into ProbNetKAT, i.e., for a regular expression s on Γ, g satisfies that*

$$(w_1, ...w_n) \in h(s) \leftrightarrow g(s)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0.$$

Proof. This follows routinely by induction on the structure of regular expressions. See the appendix for the explicit proof. The trick is that each head packet acts as a label for its history, denoting the index or track of the regular expression to which that history matches in the DPE. ◀

▶ **Theorem 3.** *For arbitrary $a \in 2^H$ and ProbNetKAT programs p and q, whether or not $\mathsf{supp}([\![p]\!](a)) \cap \mathsf{supp}([\![q]\!](a)) = \emptyset$ is undecidable.*

Proof. Take the regular expressions X and Y from the section on DPEs. Because $h(X) \cap h(Y)$ is undecidable (as was proved in the above section on DPEs), we find that $\mathsf{supp}(g(X)(\{\pi_1, \pi_2\})) \cap \mathsf{supp}(g(Y)(\{\pi_1, \pi_2\})) = \emptyset$ is also undecidable. This is an example of the type of problem we wish to prove undecidable, so we are done. ◀

▶ **Theorem 4.** *For arbitrary $a \in 2^H$, $n \in \mathbb{N}$, and ProbNetKAT program p, whether or not $\exists b \in \mathsf{supp}([\![p]\!](a))$ such that $|b| = n$ is undecidable.*

Proof. Take the regular expressions X and Y from the section on DPEs. Consider the program given by $[\![g(X)\&g(Y)]\!]$.

Recognize that the program made by g always outputs a set of size 2 given $\{\pi_1, \pi_2\}$ as input. No base operation of g changes the number of elements in the set it is given, so this follows easily by induction. Then recall that the & operation essentially performs each of its two arguments' code independently, before taking the union of the results, respecting probability. The union of the results of $g(X)$ and $g(Y)$ on the input $\{\pi_1, \pi_2\}$ is thus of size 2 with positive probability iff there is some output made by both programs with positive probability, because the only way the union of two sets of the same finite size does not go up in size is if the two sets are the same. This means if we could decide if no output in the support was of size two, we could also decide the emptiness of support intersection. Emptiness of support intersection is undecidable, so we also cannot decide if the program $[\![g(X)\&g(Y)]\!]$ given $\{\pi_1, \pi_2\}$ has an output of size two in its support. ◀

▶ **Theorem 5.** *For arbitrary $a \in 2^H$, $n \in \mathbb{N}$, and ProbNetKAT program p, whether or not $\exists b \in \mathsf{supp}([\![p]\!](a))$ such that $|b| \leq n$ is undecidable.*

Proof. Consider the same set up as in theorem 4. Note again that the program made by g always outputs a set of size 2 given $\{\pi_1, \pi_2\}$ as input, and that the union of two sets is never less than the size of the either set. Thus, all sets in the support of $[\![g(X)\&g(Y)]\!]\{\pi_1, \pi_2\}$ are of size 2 or more. If there was a set b in that support of size at most 2, it would in fact be of size 2, and such a b of size 2 is of course size at most 2. Therefore, deciding if there is such b of size at most 2 is precisely the same as deciding if there is such a b of size 2 exactly. It is undecidable if there is such a set b of size 2, as proven in theorem 4, so it also undecideable if there is a set of size at most 2. ◀

4.2 A PFA embedding

PFAs Probabilistic finite automata (PFAs), are the probabilistic extension of DFAs. Rather than each transition deterministically moving from the current state to another state on a given symbol, each transition moves to one of several states with specific probability. The language, rather than being a set of strings, is a distribution on strings. This can be formally defined with the tuple $(Q, \Sigma, \Delta, q_0, F)$, where Q is a finite set of states, Σ is a finite set of symbols, Δ is a set of matrices, q_0 is the starting state, and F represents the set of final states. More specifically, Δ is a set of square stochastic matrices Δ_a indexed by states, such

that for each $a \in \Sigma$, $\Delta_a(x, y)$ is the probability that state x transitions to state y on input symbol a. It will be useful as well to let q_0 also stand in for the horizontal vector of zeroes save for a one at index q_0, and F stand in for the vertical vector of zeroes save for those indices that are in F.

Using the notation that $\Delta_{w \cdot w'} = \Delta_w \cdot \Delta_{w'}$ for $w, w' \in \Sigma^*$, we can then define the word distribution $D(M)$ for a PFA M as the function from $w \in \Sigma^*$ to $q_0 \cdot \Delta_w \cdot F$, which returns the probability that w will be accepted. This can then be used to define the language of M for a given threshold λ as follows.

$$L_\lambda(M) = \{w \in \Sigma^* | D(M)(w) \geq \lambda\}$$

There are a few undecidable problems associated with PFAs from previous work on the subject [6, 2], some of which are closely related. These include:

- The emptiness problem: $\exists w \in \Sigma^*.D(M)(w) \geq \lambda$
  (Is the language empty for a given cutpoint?)
- The strict emptiness problem: $\exists w \in \Sigma^*.D(M)(w) > \lambda$
  (Is the strict variant of the language empty for a given cutpoint?)
- The equality problem: $\exists w \in \Sigma^*.D(M)(w) = 0.5$
  (Is there any word accepted exactly half the time?)
- The isolation problem: $\exists \epsilon > 0. \forall w \in \Sigma^*.|D(M)(w) - \lambda| \geq \epsilon$
  (Are there words that are accepted with probability arbitrarily close to a given value?)
- The value 1 problem: $\exists \epsilon > 0. \forall w \in \Sigma^*.D(M)(w) \leq 1 - \epsilon$
  (Are there words that are accepted with arbitrarily high probability?)

Equivalence and certain kinds of approximations between PFAs, however, are decidable [3, 7, 13]. This means equivalence and those approximations of PFAs will not be as useful here for finding undecidable problems. Nor do they directly yield analagous decision procedures for general ProbNetKAT programs, as the provided embedding does not fully encompass the forms that ProbNetKAT programs can take.

ProbNetKAT PFAs. It is easy to create ProbNetKAT code that only does meaningful work on certain input sets, like code that begins by dropping everything with a certain head packet. This might arise in networking if some subset of the packets Pk are the only ones properly formatted as request packets for the network, so any other packet is discarded. It is also easy to create code that produces some output with some form of geometric distribution, as the random loop does. For this reason, it would be useful to be able to compare a ProbNetKAT program's distribution on specific sets to a geometric distribution, to see whether or not they are equal within a certain error, or whether one's probabilities dominate the other's.

One might also like to do the same sorts of comparisons between programs. Because these are probabilistic algorithms, approximation within a certain error is often just as good in application as actual equality. Determining whether one program's distribution on certain sets dominates another's could be useful in a context where one is trying to improve successful service probability. For such a case, suppose that one's current neworking program drops all packets (fails) with a positive probability, and that one wishes to improve it so that it fails less often, but doesn't lower the probability of any of its successful output. This would be solved by determining if a candidate replacement program dominated the original on non-empty outputs.

Unfortunately, because PFAs can be embedded in ProbNetKAT, these sorts of problems are often undecidable. These problems also do not have any clear analogues in non-random NetKAT, as they are intimately concerned with the properties of probability distributions.

The function g performs this embedding for a PFA $M = (Q, \Sigma, \Delta, q_0, F)$. Define $Pk = \Pi \cup \Psi \cup \Sigma$, where $\Pi = \{\pi_q | q \in Q\}$, Ψ as the image of Π under $x \leftarrow false$, $0 < r < 1$, and $0 < s \leq \frac{1}{|\Sigma|}$. Both Π and Ψ maintain their roles as given in section 3 for random looping. We can then give g with the following, which works as will be described in theorem 6.

$$g(M) = [\underset{q \in Q}{\&} \text{ if } \pi_q? \text{ then } \underset{a \in \Sigma}{\oplus_s} a!; dup; (\underset{t \in Q}{\oplus_{\Delta_a(q,t)}} \pi_t!) \text{ else } drop]^{G_r}; (\underset{f \in F}{\&} \pi_f?); \pi_{q_0}!$$

▶ **Theorem 6.** *The function g yields a valid embedding of PFAs into ProbNetKAT, i.e., for a PFA M, g satisfies that*

$$g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) = (rs)^{|w|} \cdot (1 - r) \cdot D(M)(w)$$

where $rev(x)$ is the function that reverses x.

Proof. This validity of this statement can be seen by considering traversal through the code dynamically. The head packet is used to record the state of the PFA, so it starts at the packet corresponding to the starting state of the PFA, q_0. The code then enters a random loop. Each iteration of this loop starts by determining which state the configuration is in by checking head packets, and picking a random letter/packet to add to the front of the history. By putting letters on the front each time, the sequence of letters chosen is recorded as the reverse of the packet history. If it randomly drops here instead of picking a letter, then every branch of parallel execution will have dropped, so the code will output the empty set. If a letter is picked and duped into the history, then, knowing which state the configuration is in and which letter it chose, the code chooses a new head packet with probability in accordance with Δ.

Thus each iteration of the loop corresponds to a transition in the PFA, and either maintains a singleton set or drops to the empty set. For each iteration of the random loop that doesn't drop to the empty set, not only is the probability multiplied by r to continue, but also by s to pick a letter, and further by the transition probability. If the sequence of letters chosen after $|w|$ iterations is the word w, then these transition probabilities multiply to $D(w)$ as in the PFA, for a total probability of $(rs)^{|w|}D(w)$ for having reached that iteration with those choices. When the random loop finally exits, it does so with a probability $1 - r$, for a total probability of $(rs)^{|w|}D(w) \cdot (1 - r)$.

After going through this loop some arbitrary number of times and finally exiting, the code checks to see if the state is now a final state. If not, it drops, but if so, it standardizes the head packet to that of the initial state. (Nothing here changes the probability.) Thus, any non-empty outputs from the input $\{\pi_{q_0}\}$ correspond to having reached a final state through PFA transitions, and the history of the output is the reverse of the word that led there. ◀

▶ **Theorem 7.** *For an aribtrary ProbNetKAT program p, a set of non-empty history sets B, an arbitrary $a \in 2^H$, arbitrary values u and v, and a function f taking a non-empty set of histories to a linear combination of the contained histories' lengths, whether or not $\exists b \in B.[\![p]\!](a)(b) \geq u \cdot v^{f(b)}$, i.e., whether the distribution on non-empty outputs of p on input a can be bounded by a geometric function of output history length, is undecidable.*

Proof. Take the emptiness problem for PFAs on alphabet Σ. Translate it into ProbNetKAT using g as follows, noting that the reverse of a word in $w \in \Sigma^*$ always exists and always is the same length as w.

$$\begin{aligned}
\exists w \in \Sigma^*.D(M)(w) \geq \lambda &\iff \exists w \in \Sigma^*.(rs)^{|w|} \cdot (1 - r) \cdot D(M)(w) \geq (rs)^{|w|} \cdot (1 - r) \cdot \lambda \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) \geq (rs)^{|w|} \cdot (1 - r) \cdot \lambda \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) \geq (rs)^{|w|} \cdot (1 - r) \cdot \lambda
\end{aligned}$$

Because the emptiness problem for PFAs is undecidable, so is the statement on the final line. Letting $g(M) = p$, $a = \{\pi_{q_0}\}$, $B = \{\pi_{q_0} :: w | w \in \Sigma^*\}$, $u = (1-r)\lambda$, $v = rs$, and $f(b) = \sum_{h \in b} |h|$, we find that said statement is an example of the type of problem we are trying to prove undecidable, so we are done. ◀

▶ **Theorem 8.** *For an arbitrary ProbNetKAT programs p and q, an arbitrary $a \in 2^H$, arbitrary values u and v, and a function f taking a non-empty set of histories to a linear combination of the contained histories' lengths, whether or not $\exists b \in B. |[\![p]\!](a)(b) - [\![q]\!](a)(b)| \geq u \cdot v^{f(b)}$, i.e., whether p's distribution approximates q's on non-empty outputs to within an error exponentially decaying with history length, is undecidable.*

Proof. Let q be the program $[\![drop]\!]$. This program's output distribution always assigns probability 0 to non-empty sets.

$$\begin{aligned} \exists b \in B. |[\![p]\!](a)(b) - [\![q]\!](a)(b)| \geq u \cdot v^{f(b)} &\iff \exists b \in B. |[\![p]\!](a)(b) - [\![drop]\!](a)(b)| \geq u \cdot v^{f(b)} \\ &\iff \exists b \in B. |[\![p]\!](a)(b) - 0| \geq u \cdot v^{f(b)} \\ &\iff \exists b \in B. [\![p]\!](a)(b) \geq u \cdot v^{f(b)} \end{aligned}$$

The statement in the final line was shown undecidable in thoerem 7, so our desired theorem is undecidable in the instance when $q = [\![drop]\!]$. It is therefore undecidable. ◀

▶ **Theorem 9.** *For an aribtrary ProbNetKAT program p, a set of non-empty history sets B, an arbitrary $a \in 2^H$, arbitrary values u and v, and a function f taking a non-empty set of histories to a linear combination of the contained histories' lengths, the following are undecidable.*

- $\exists b \in B. [\![p]\!](a)(b) > u \cdot v^{f(b)}$
  (Is p's distribution on non-empty outputs bounded from above by a given geometric function that changes with output history length?)
- $\exists b \in B. [\![p]\!](a)(b) = u \cdot v^{f(b)}$
  (Does p's distribution on non-empty outputs ever coincide with a given geometric function that changes with output history length?)
- $\exists \epsilon > 0. \forall b \in B. |[\![p]\!](a)(b) - u \cdot v^{f(b)}| \geq u \cdot v^{f(b)} \cdot \epsilon$
  (Does p's distribution on non-empty outputs get within an arbitrarily small scalar of a given geometric function that changes with output history length?)
- $\exists \epsilon > 0. \forall b \in B. [\![p]\!](a)(b) \leq u \cdot v^{f(b)} \cdot (1-\epsilon)$
  (Can p's distribution on non-empty outputs be bounded from above by a scalar<1 of a given geometric function that changes with output history length?)

Proof. Follow the same translation procedure as theorem 7. Starting from the strict emptiness problem, equality problem, isolation problem, and value 1 problem for PFAs, respectively. See the appendix for an explicit proof. ◀

▶ **Theorem 10.** *For arbitrary ProbNetKAT programs p and q, a set of non-empty history sets B, and arbitrary $a \in 2^H$, the following are undecidable.*

- $\exists b \in B. [\![p]\!](a)(b) \geq [\![q]\!](a)(b)$
  (Is p's distribution on non-empty outputs bounded strictly from above (strongly dominated) by q's?)
- $\exists b \in B. [\![p]\!](a)(b) > [\![q]\!](a)(b)$
  (Is p's distribution on non-empty outputs bounded from above (weakly dominated) by q's?)

- $\exists b \in B. [\![p]\!](a)(b) = [\![q]\!](a)(b)$
  (Does p's distribution on non-empty outputs ever coincide with q's?)
- $\exists \epsilon > 0. \forall b \in B. |[\![p]\!](a)(b) - [\![q]\!](a)(b)| \geq [\![q]\!](a)(b) \cdot \epsilon$
  (Does p's distribution on non-empty outputs get within an arbitrarily small scalar of q's?)
- $\exists \epsilon > 0. \forall b \in B. [\![p]\!](a)(b) \leq [\![q]\!](a)(b) \cdot (1 - \epsilon)$
  (Can p's distribution on non-empty outputs be bounded from above by a scalar<1 of q's?)

Proof. Consider the following program p

$$[\![p]\!] = [\![(\underset{a \in \Sigma}{\oplus_s} a!; dup)^{G_r}; \pi_{q_0}! \oplus_\lambda drop]\!]$$

This program's output distribution on input $\{\pi_{q_0}\}$ is given for non-empty output sets by

$$[\![p]\!](\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) = (rs)^{|w|} \cdot (1 - r) \cdot \lambda$$

This distribution is precisely the term that we showed was undecideably comparable to arbitrary programs in theorems 7 and 9. Substituting that term, not with $u \cdot v^{f(b)}$ as was done in theorems 7 and 9, but rather with $[\![q]\!](a)(b)$, yields instances of each of the above problems. As values were merely substituted for identical values, the statements are still undecidable. Thus, each of the problems named are not generally decidable. ◀

5 Conclusion

By encoding the Post Correspondence Problem and various undecidable problems of probabilistic finite automata, we have been able to show that various problems for ProbNetKAT are undecidable. These include emptiness of support intersection, size of the output set, dominance of distribution probabilities over other programs', the satisfaction of geometric distribution bounds, and more.

However, it is still open whether or not ProbNetKAT program equality is decidable. NetKAT's equality is decidable, and many useful networking problems like waypointing are reducible to program equality. There is hope that the same power could be achieved in ProbNetKAT. It is known that equality of ProbNetKAT programs is decidable if one removes random choice (since that is just NetKAT), if one removes *dup* (which can be shown with some linear algebra and Markov chains [11]), and if one removes the asterate (since distributions become finite). It still remains to be seen if ProbNetKAT program equality can be decided if all three are present. Unfortunately it may be the case that with all three features, program equality becomes undecidable. In such an event, embeddings like those shown here may be instrumental in proving undecidability.

Future work could also be done to determine if it is decidable whether one program approximates another to within a constant error bound. Being probabilistic, this is often as good as equality in application. We have shown here that it is undecidable on non-empty outputs where the error decays exponentially with history length (theorem 8).

A Appendix

A.1 Theorem 2 in Detail

Theorem 2 The function g yields a valid embedding of DPEs into ProbNetKAT, i.e., for a regular expression s on Γ, g satisfies that

$$w \in h(s) \leftrightarrow g(s)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0.$$

Proof. Define the predicate $P(s)$ for regular expression s to denote that g validly embeds s. We can then use induction on regular expressions to show that P holds for all expressions.

The base case expressions of our induction are the empty expression ϵ and each symbol in the alphabet Σ.

To get the case of ϵ, note that the only element in the support of $[\![skip]\!]\{\pi_1, ..., \pi_n\}$ is $\{\pi_1, ..., \pi_n\}$ itself, which has no histories beyond the head packets. Any words made from the histories must therefore be empty.

$$\begin{aligned}
&P(\epsilon): \\
w \in h(\epsilon) &\leftrightarrow \forall i, w_i = \epsilon \\
&\leftrightarrow \{\pi_1, ..., \pi_n\} = \{\pi_1 :: w_1, ..., \pi_n :: w_n\} \\
&\leftrightarrow [\![skip]\!](\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0 \\
&\leftrightarrow g(\epsilon)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0
\end{aligned}$$

To get the case of the single symbol, note that the code again only leaves a single element in the support:$\{\pi_1, ..., \pi_n\}$ with a single new packet added to the history of a single head packet. The only word made from such histories is thus that single symbol with the index of the head packet it is behind.

$$\begin{aligned}
&P(a_{(i)}): \\
w \in h(a_{(i)}) &\leftrightarrow w_i = a \wedge \forall j \neq i. w_j = \epsilon \\
&\leftrightarrow \pi_i :: w_i = \pi_i :: a \wedge \forall j \neq i. \pi_j :: w_j = \pi \\
&\leftrightarrow [\![\text{ if } \pi_i? \text{ then } a!; dup; \pi_i! \text{ else } skip]\!](\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0 \\
&\leftrightarrow g(a_{(i)})(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0
\end{aligned}$$

Now, assuming that the embedding is valid for smaller expressions x and y, we consider the inductive steps for each of the operators: multiplication, addition, and asterate.

Note that adding new elements to the history stores them in the reverse order of their addition, so we end up reversing the order of x and y terms. Further recall that the computation done on a packet at a given point is determined solely by the head packet, not the history, as no operation can read from the history. This allows us to prove the case of multiplication as follows.

$$\begin{aligned}
&P(x \cdot y): \\
w \in h(x \cdot y) &\leftrightarrow w \in h(x) \cdot h(y) \\
&\leftrightarrow \exists u, v \in (\Sigma^*)^n. u \in h(x) \wedge v \in h(y) \wedge u \cdot v = w \\
&\leftrightarrow \exists u, v \in (\Sigma^*)^n. g(x)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: u_1, ..., \pi_n :: u_n\}) > 0 \\
&\quad \wedge g(y)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: v_1, ..., \pi_n :: v_n\}) > 0 \wedge u \cdot v = w \\
&\leftrightarrow \exists u, v \in (\Sigma^*)^n. [\![g(y); g(x)]\!](\{\pi_1, ..., \pi_n\})(\{\pi_1 :: u_1 :: v_1, ..., \pi_n :: u_n :: v_n\}) > 0 \\
&\quad \wedge \forall i, u_i \cdot v_i = w_i \\
&\leftrightarrow [\![g(y); g(x)]\!](\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0 \\
&\leftrightarrow g(x \cdot y)(\{\pi_1, ..., \pi_n\})(\{\pi_1 :: w_1, ..., \pi_n :: w_n\}) > 0
\end{aligned}$$

The case of addition follows because scaling a probability by 0.5 does not change its positivity.

$$
\begin{aligned}
&P(x+y):\\
w \in h(x+y) &\leftrightarrow w \in h(x) \cup h(y)\\
&\leftrightarrow w \in h(x) \vee w \in h(y)\\
&\leftrightarrow g(x)(\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0\\
&\qquad \vee g(y)(\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0\\
&\leftrightarrow [\![g(x) \oplus_{0.5} g(y)]\!](\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0\\
&\leftrightarrow [\![g(x+y)]\!](\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0
\end{aligned}
$$

Finally, the asterate case follows from recalling that the random loop is capable stopping after any number of iterations, and always does so with a positive probability.

$$
\begin{aligned}
&P(x^*):\\
w \in h(x^*) &\leftrightarrow w \in \bigcup_{n\in\mathbb{N}} h(x)^n\\
&\leftrightarrow \exists n \in \mathbb{N}. w \in h(x)^n\\
&\leftrightarrow \exists n \in \mathbb{N}. [\![g(x)^n]\!](\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0\\
&\leftrightarrow [\![g(x)^{G_{0.5}}]\!](\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0\\
&\leftrightarrow [\![g(x^*)]\!](\{\pi_1,...,\pi_n\})(\{\pi_1 :: w_1,...,\pi_n :: w_n\}) > 0
\end{aligned}
$$

The validity of the embedding holds for all base elements and through all operations of regular expressions on Γ. Thus, by induction, the validity of the embedding holds for all regular expressions.

◀

A.2 Theorem 9 in Detail

Theorem 9 For an aribtrary ProbNetKAT program p, a set of non-empty history sets B, an arbitrary $a \in 2^H$, arbitrary values u and v, and a function f taking a non-empty set of histories to a linear combination of the contained histories' lengths, the following are undecidable.

- $\exists b \in B. [\![p]\!](a)(b) > u \cdot v^{f(b)}$
  (Is p's distribution on non-empty outputs bounded from above by a given geometric function that changes with output history length?)
- $\exists b \in B. [\![p]\!](a)(b) = u \cdot v^{f(b)}$
  (Does p's distribution on non-empty outputs ever coincide with a given geometric function that changes with output history length?)
- $\exists \epsilon > 0. \forall b \in B. |[\![p]\!](a)(b) - u \cdot v^{f(b)}| \geq u \cdot v^{f(b)} \cdot \epsilon$
  (Does p's distribution on non-empty outputs get within an arbitrarily small scalar of a given geometric function that changes with output history length?)
- $\exists \epsilon > 0. \forall b \in B. [\![p]\!](a)(b) \leq u \cdot v^{f(b)} \cdot (1-\epsilon)$
  (Can p's distribution on non-empty outputs be bounded from above by a scalar<1 of a given geometric function that changes with output history length?)

Proof. Take the strict emptiness problem for PFAs on alphabet Σ. Translate it into ProbNetKAT using g as follows, noting that the reverse of a word in $w \in \Sigma^*$ always exists and always is the same length as w.

$$\begin{aligned}
\exists w \in \Sigma^*.D(M)(w) > \lambda &\iff \exists w \in \Sigma^*.(rs)^{|w|} \cdot (1-r) \cdot D(M)(w) > (rs)^{|w|} \cdot (1-r) \cdot \lambda \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) > (rs)^{|w|} \cdot (1-r) \cdot \lambda \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) > (rs)^{|w|} \cdot (1-r) \cdot \lambda
\end{aligned}$$

Because the strict emptiness problem for PFAs is undecidable, so is the statement on the final line. Letting $g(M) = p$, $a = \{\pi_{q_0}\}$, $B = \{\pi_{q_0} :: w | w \in \Sigma^*\}$, $u = (1-r)\lambda$, $v = rs$, and $f(b) = \sum_{h \in b} |h|$, we find that said statement is an example of the first type of problem we are trying to prove undecidable, so we have proved that the first problem in the list is undecidable.

Take the equality problem for PFAs on alphabet Σ. Translate it into ProbNetKAT using g as follows.

$$\begin{aligned}
\exists w \in \Sigma^*.D(M)(w) = 0.5 &\iff \exists w \in \Sigma^*.(rs)^{|w|} \cdot (1-r) \cdot D(M)(w) = (rs)^{|w|} \cdot (1-r) \cdot 0.5 \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) = (rs)^{|w|} \cdot (1-r) \cdot 0.5 \\
&\iff \exists w \in \Sigma^*.g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) = (rs)^{|w|} \cdot (1-r) \cdot 0.5
\end{aligned}$$

Because the equality problem for PFAs is undecidable, so is the statement on the final line. Letting $g(M) = p$, $a = \{\pi_{q_0}\}$, $B = \{\pi_{q_0} :: w | w \in \Sigma^*\}$, $u = (1-r)/2$, $v = rs$, and $f(b) = \sum_{h \in b} |h|$, we find that said statement is an example of the second type of problem we are trying to prove undecidable, so we have proved that the second problem in the list is undecidable.

Take the isolation problem for PFAs on alphabet Σ. Pick an instance with a positive λ. Translate it into ProbNetKAT using g as follows.

$$\begin{aligned}
&\exists \epsilon > 0. \forall w \in \Sigma^*. |D(M)(w) - \lambda| \geq \epsilon \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. (rs)^{|w|} \cdot (1-r) \cdot |D(M)(w) - \lambda| \geq (rs)^{|w|} \cdot (1-r) \cdot \epsilon \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. |g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) - (rs)^{|w|} \cdot (1-r) \cdot \lambda| \geq (rs)^{|w|} \cdot (1-r) \cdot \epsilon \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. |g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) - (rs)^{|w|} \cdot (1-r) \cdot \lambda| \geq (rs)^{|w|} \cdot (1-r) \cdot \epsilon
\end{aligned}$$

At this point, let $u = (1-r)\lambda$ and $v = rs$. Continue by substituting these variables into the final line, and note that for every $\epsilon/\lambda > 0$ there exists $\epsilon' = \epsilon/\lambda > 0$.

$$\begin{aligned}
&\exists \epsilon > 0. \forall w \in \Sigma^*. |g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) - (rs)^{|w|} \cdot (1-r) \cdot \lambda| \geq (rs)^{|w|} \cdot (1-r) \cdot \epsilon \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. |g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) - u \cdot v^{|w|}| \geq u \cdot v^{|w|} \cdot \epsilon/\lambda \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. |g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) - u \cdot v^{|w|}| \geq u \cdot v^{|w|} \cdot \epsilon
\end{aligned}$$

Because the isolation problem for PFAs is undecidable, so is the statement on the final line. Letting $g(M) = p$, $a = \{\pi_{q_0}\}$, $B = \{\pi_{q_0} :: w | w \in \Sigma^*\}$, and $f(b) = \sum_{h \in b} |h|$, we find that said statement is an example of the third type of problem we are trying to prove undecidable, so we have proved that the third problem in the list is undecidable.

Take the value 1 problem for PFAs on alphabet Σ. Pick an instance with a positive λ. Translate it into ProbNetKAT using g as follows.

$$\begin{aligned}
&\exists \epsilon > 0. \forall w \in \Sigma^*. D(M)(w) \leq 1 - \epsilon \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. (rs)^{|w|} \cdot (1-r) \cdot D(M)(w) \leq (rs)^{|w|} \cdot (1-r) \cdot (1-\epsilon) \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: rev(w)\}) \leq (rs)^{|w|} \cdot (1-r) \cdot (1-\epsilon) \\
&\iff \exists \epsilon > 0. \forall w \in \Sigma^*. g(M)(\{\pi_{q_0}\})(\{\pi_{q_0} :: w\}) \leq (rs)^{|w|} \cdot (1-r) \cdot (1-\epsilon)
\end{aligned}$$

Because the value 1 problem for PFAs is undecidable, so is the statement on the final line. Letting $g(M) = p$, $a = \{\pi_{q_0}\}$, $B = \{\pi_{q_0} :: w | w \in \Sigma^*\}$, $u = (1-r)\lambda$, $v = rs$, and $f(b) = \sum_{h \in b} |h|$, we find that said statement is an example of the final type of problem we are trying to prove undecidable, so we are done. ◀

Computational Complexity of Graph Partition underVertex-Compaction to an Irreflexive Hexagon

Narayan Vikas

School of Computing Science, Simon Fraser University, Burnaby, BC, Canada
vikas@cs.sfu.ca

Abstract

In this paper, we solve a long-standing graph partition problem under vertex-compaction that has been of interest since about 1999. The graph partition problem that we consider in this paper is to decide whether or not it is possible to partition the vertices of a graph into six distinct non-empty sets A, B, C, D, E, and F, such that the vertices in each set are independent, i.e., there is no edge within any set, and an edge is possible but not necessary only between the pairs of sets A and B, B and C, C and D, D and E, E and F, and F and A, and there is no edge between any other pair of sets. We study the problem as the vertex-compaction problem for an irreflexive hexagon (6-cycle). Determining the computational complexity of this problem has been a long-standing problem of interest since about 1999, especially after the results of open problems obtained by the author on a related compaction problem appeared in 1999. We show in this paper that the vertex-compaction problem for an irreflexive hexagon is NP-complete. Our proof can be extended for larger even irreflexive cycles, showing that the vertex-compaction problem for an irreflexive even k-cycle is NP-complete, for all even $k \geq 6$.

1 Introduction

The vertex-compaction problem and the compaction problem are special graph colouring problems, and can also be viewed as graph partition problems. The colouring problem is a classic problem in graph theory. The graph homomorphism problem, also called the H-colouring problem, is a generalization of the colouring problem. The vertex-compaction problem is the graph homomorphism problem with additional constraints. The compaction problem is the vertex-compaction problem with additional constraints. We describe our motivation and results after introducing the following definitions and problems.

1.1 Definitions

The pair of vertices of an edge in a graph are called the *endpoints* of the edge. An edge with the same endpoints in a graph is called a *loop*. A vertex v of a graph is said to have a loop if vv is an edge of the graph. A *reflexive graph* is a graph in which every vertex has a loop. An *irreflexive graph* is a graph in which no vertex has a loop. Any graph, in general, is a *partially reflexive graph*, in which its vertices may or may not have loops. Thus reflexive and irreflexive graphs are special partially reflexive graphs. A *bipartite graph* G is a graph whose

vertex set can be partitioned into two distinct subsets G_A and G_B, such that each edge of G has one endpoint in G_A and the other endpoint in G_B; we say that (G_A, G_B) is a bipartition of G. Thus a bipartite graph is irreflexive by definition. If uv is an edge of a graph then vu is also an edge of the graph, i.e., we assume graphs to be undirected graphs. A cycle of length k is called a k-cycle, $k \geq 3$. A *hexagon* will be used as a synonym for a 6-cycle. We shall denote an irreflexive k-cycle by C_k.

Let G be a graph. We use $V(G)$ and $E(G)$ to denote the vertex set and the edge set of G respectively. Given an induced subgraph H of G, we denote by $G - H$, the subgraph obtained by deleting from G the vertices of H together with the edges incident with them; thus $G - H$ is a subgraph of G induced by $V(G) - V(H)$. The vertices in a set $I \subseteq V(G)$ are said to be *independent* if there is no edge in the subgraph of G induced by I. When a set S is an argument of a mapping f, we define $f(S) = \{f(s)|s \in S\}$. The *distance* between a pair of vertices u and v in G, denoted as $d_G(u, v)$ or $d_G(v, u)$, is the length of a shortest path from u to v in G, if u and v are connected in G; we define $d_G(u, v)$ (and $d_G(v, u)$) to be infinite, if u and v are disconnected in G. The *diameter* of G is the maximum distance between any two vertices in G. The distance between two sets X and Y of vertices in G, denoted as $d_G(X, Y)$ or $d_G(Y, X)$, is the minimum distance between any vertex of X and any vertex of Y in G, i.e., $d_G(X, Y) = min\{d_G(x, y)|x \in X, y \in Y\}$, where $min\ A$ gives the minimum element in a set A. If a set has only one vertex, we may just write the vertex instead of the set. In the following, let G and H be graphs.

A *homomorphism* $f : G \to H$, of G to H, is a mapping f of the vertices of G to the vertices of H, such that if g and g' are adjacent vertices of G then $f(g)$ and $f(g')$ are adjacent vertices of H. If there exists a homomorphism of G to H then G is said to be *homomorphic* to H. Note that if G is irreflexive then G is k-colourable if and only if G is homomorphic to the irreflexive complete graph K_k having k vertices. Thus the concept of a homomorphism generalises the concept of a k-colourability, and the *H-colouring* problem is to decide whether or not G is homomorphic to H. The *H-colouring* problem is trivial and easily seen to be polynomial time solvable if H is bipartite or H has a loop. For any fixed non-bipartite irreflexive graph H, it is shown in [Hell and Nesetril, 1990] that the *H-colouring* problem is NP-complete.

A *compaction* $c : G \to H$, of G to H, is a homomorphism of G to H, such that for every vertex x of H, there exists a vertex v of G with $c(v) = x$, and for every edge hh' of H, $h \neq h'$, there exists an edge gg' of G with $c(g) = h$ and $c(g') = h'$. Note that the first part of the definition for a compaction (the requirement for every vertex x of H) follows from the second part unless H has isolated vertices. If there exists a compaction of G to H then G is said to *compact* to H. Given a compaction $c : G \to H$, if for a vertex v of G, we have $c(v) = x$, where x is a vertex of H, then we say that the vertex v of G *covers the vertex* x of H under c; and if for an edge gg' of G, we have $c(\{g, g'\}) = \{h, h'\}$, where hh' is an edge of H, then we say that the edge gg' of G *covers the edge* hh' of H under c (note in the definition of compaction, it is not necessary that a loop of H be covered by any edge of G under c).

We notice that the notion of a *homomorphic image* described in [Harary, 1969] (also cf. [Hell & Miller, 1979]) coincides with the notion of a compaction in case of irreflexive graphs (i.e., when G and H are irreflexive in the above definition for compaction).

A *vertex-compaction* $c : G \to H$, of G to H, is a homomorphism of G to H, such that for every vertex x of H there exists a vertex v of G with $c(v) = x$. If there exists a vertex-compaction of G to H then G is said to *vertex-compact* to H. We define vertex and edge covering under a vertex-compaction c similarly as for a compaction. Note that every compaction is also a vertex-compaction.

A *retraction* $r : G \to H$, of G to H, with H as an induced subgraph of G, is a homomorphism of G to H, such that $r(h) = h$, for every vertex h of H. If there exists a retraction of G to H then G is said to *retract* to H. Note that every retraction $r : G \to H$ is necessarily also a compaction, and hence a vertex-compaction.

1.2 Vertex-Compaction, Compaction, and Retraction Problems

The problem of deciding the existence of a vertex-compaction to a fixed graph H, called the *vertex-compaction problem for* H, and denoted as *VCOMP-H*, asks whether or not an input graph G vertex-compacts to H.

Our graph partition problem is to decide whether or not it is possible to partition the vertices of a graph into six distinct non-empty sets A, B, C, D, E, and F, such that the vertices in each of these sets are independent, and an edge is possible but not necessary only between the pairs of sets A and B, B and C, C and D, D and E, E and F, and F and A, and there is no edge between any other pair of sets. We note that our graph partition problem is the problem *VCOMP-*C_6.

The problem of deciding the existence of a compaction to a fixed graph H, called the *compaction problem for* H, and denoted as *COMP-H*, asks whether or not an input graph G compacts to H. The compaction problem is a well studied problem over last several years, and includes some popular problems. Results on the compaction problem can be found in [Vikas, 1999, 2002, 2003, 2004a, 2004b, 2004c, 2005, 2011, 2013].

Note that unlike the *H-colouring* problem, the problems *VCOMP-H* and *COMP-H* are still interesting if H is bipartite or H has a loop. Some work on graph partition problems have also been studied in [Feder, Hell, Klein, and Motwani, 1999, 2003] and [Hell, 2014].

The problem of deciding the existence of a retraction to a fixed graph H, called the *retraction problem for* H, and denoted as *RET-H*, asks whether or not an input graph G, containing H as an induced subgraph, retracts to H. Retraction problems have been of continuing interest in graph theory for a long time and have been studied in various literature including [Hell, 1972], [Hell, 1974], [Nowakowski and Rival, 1979], [Pesch and Poguntke, 1985], [Bandelt, Dahlmann, and Schutte, 1987], [Hell and Rival, 1987], [Pesch, 1988], [Bandelt, Farber, and Hell, 1993], [Feder and Hell, 1998], [Feder and Vardi, 1993, 1998], [Feder, Hell, and Huang, 1999], [Vikas, 2004b, 2004c, 2005], etc.

1.3 Motivation and Results

It can be shown that for every fixed graph H, if the problem *COMP-H* is solvable in polynomial time then the problem *VCOMP-H* is also solvable in polynomial time (similarly as in [Vikas, 2004b]). Whether the converse is true is not known. The problem *COMP-*C_6 is shown to be NP-complete in [Vikas, 1999, 2004a]. It turns out that the unique smallest bipartite graph H for which *COMP-H* is NP-complete is C_6 [Vikas, 2004a]. Therefore, with respect to the preceding question on converse, we are motivated to specifically determine the computational complexity of our partition problem *VCOMP-*C_6, to see whether like *COMP-*C_6, it is also NP-complete in support of the converse. We show in this paper that *VCOMP-*C_6 is NP-complete. Determining the computational complexity of *VCOMP-*C_6 has been a long-standing problem of interest since about 1999, especially after results on the computational complexity of *COMP-*C_6 obtained by the author appeared in 1999 [Vikas, 1999]. Determining the computational complexity of *COMP-*C_6 was also a long-standing problem of interest since about 1988, solved by the author in [Vikas, 1999, 2004a]. Although

the problem *VCOMP-C_6* is only a little variation of the problem *COMP-C_6*, it turns out to be another difficult problem to determine its computational complexity.

Similarly, our motivation for the partition problem *COMP-C_6* was with respect to the retraction problem. It can be shown that for every fixed graph H, if the problem *RET-H* is polynomial time solvable then the problem *COMP-H* is also polynomial time solvable [Vikas, 2004b]. However, whether the converse is true is again not known. As discussed in [Vikas, 1999, 2003], the question on converse was also asked by Peter Winkler in 1988 in the context of reflexive graphs, and this was the general problem that motivated Winkler for asking the computational complexity of *COMP-H* when H is a reflexive square, as the unique smallest reflexive graph H for which *RET-H* is NP-complete is a reflexive square. It has been shown in [Vikas, 1999, 2003] that when H is a reflexive square, *COMP-H* is NP-complete. As discussed in [Vikas, 2004a], since the unique smallest bipartite graph H for which *RET-H* is NP-complete is C_6, we are therefore motivated, with respect to the above question on converse, to know whether the problem *COMP-C_6* is also NP-complete like the problem *RET-C_6* supporting the converse. As mentioned above, it is shown in [Vikas, 1999, 2004a] that *COMP-C_6* is NP-complete.

The problem *RET-C_6* is shown to be NP-complete in [Feder, Hell, and Huang, 1999], and also independently by G. MacGillivray in 1988. Since C_4 is a complete bipartite graph, it is easy to see that *RET-C_4*, and hence *COMP-C_4* and also *VCOMP-C_4*, are all polynomial time solvable. In fact, when H is a chordal bipartite graph (which includes C_4), the problem *RET-H* is polynomial time solvable [Bandelt, Dahlmann, and Schutte, 1987], and hence *COMP-H* and *VCOMP-H* are also polynomial time solvable. Thus it follows that the unique smallest bipartite graph H for which *RET-H*, *COMP-H*, and *VCOMP-H* are NP-complete is C_6.

It has been shown in [Hell and Nesetril, 1990] that the *H-colouring* problem is NP-complete for any fixed irreflexive non-bipartite graph H. It follows that *RET-H*, *COMP-H*, and *VCOMP-H* are also NP-complete for any non-bipartite irreflexive graph H, which includes an irreflexive odd k-cycle, for all $k \geq 3$.

As we mentioned earlier, the *H-colouring* problem is trivial and easily seen to be polynomial time solvable when H is a bipartite graph. The natural question for bipartite graphs H, which motivated Pavol Hell and Jaroslav Nesetril (personal communications) around 1988, was to ask for the computational complexity of the *H-colouring* problem with added constraints, namely the problem *COMP-H*, and in particular for the problem *COMP-C_6*.

It can also be shown that for every fixed graph H, if the problem *RET-H* is polynomial time solvable then the problem *VCOMP-H* is also polynomial time solvable (similarly as in [Vikas, 2004b]), but whether the converse is true is not known. Hence, once again, in relation to the converse and the problem *RET-C_6*, we are motivated to know whether the problem *VCOMP-C_6* is NP-complete.

The algorithms given in [Vikas, 2011, 2013] yield a polynomial time algorithm for *VCOMP-C_6* for any input graph of diameter more than four, and it is suggested in [Vikas, 2011, 2013] as a guidance that an input graph of diameter four could be a candidate for *VCOMP-C_6* to be possibly NP-complete. We are thus motivated to see whether *VCOMP-C_6* is indeed NP-complete for an input graph of diameter four, guided by the algorithmic aspects of the vertex-compaction problem studied in [Vikas, 2011, 2013]. The instance of the input graph for which we show *VCOMP-C_6* to be NP-complete in this paper is indeed of diameter four.

Our proof and technique of construction for C_6 can be extended for larger irreflexive even cycles to show that *VCOMP-C_k* is NP-complete, for all even $k \geq 6$. Our proof showing NP-completeness of *VCOMP-C_6* directly uses graphs that we construct just by adding vertices

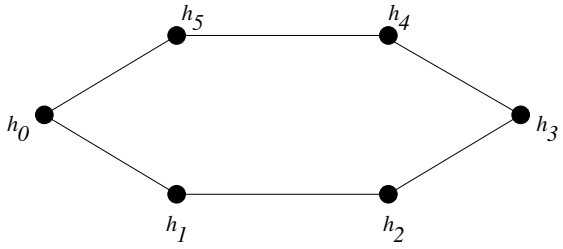

Figure 1 Irreflexive Hexagon H

and edges. Our graphs therefore lay down the foundation for construction of graphs for the case of a general irreflexive even k-cycle, by extending the paths constructed and adding edges appropriately, showing NP-completeness of *VCOMP-*C_k, for all even $k \geq 6$.

In Section 2, we present the proof showing NP-completeness of deciding the existence of a vertex-compaction to an irreflexive hexagon, i.e., the problem *VCOMP-*C_6. In Section 3, we address how our NP-completeness proof of *VCOMP-*C_6 can be extended for an irreflexive even k-cycle, showing NP-completeness of *VCOMP-*C_k, for all even $k \geq 6$.

2 Vertex-Compaction to an Irreflexive Hexagon

▶ **Theorem 2.1.** *The problem of deciding the existence of a vertex-compaction to an irreflexive hexagon is NP-complete.*

Proof. Let H be the irreflexive hexagon $h_0h_1h_2h_3h_4h_5h_0$ shown in Figure 1.

We shall prove that the problem of deciding the existence of a vertex-compaction to H, i.e., the problem *VCOMP-H*, is NP-complete. Clearly, the problem *VCOMP-H* is in NP. We give a polynomial transformation from the problem *RET-H* to *VCOMP-H*. As mentioned earlier, it is known that the problem *RET-H* is NP-complete. Since only a bipartite graph can be homomorphic to H, the problem *RET-H* remains to be NP-complete if the instance of *RET-H* is restricted to be only a bipartite graph.

Let a bipartite graph G, containing H as an induced subgraph, be an instance of *RET-H*. We construct in time polynomial in the size of G, a graph G', containing G as an induced subgraph, such that the following statements (i), (ii), and (iii) are equivalent:

(i) G retracts to H.
(ii) G' retracts to H.
(iii) G' vertex-compacts to H.

Since *RET-H*, with the instance restricted to be a bipartite graph, is NP-complete, this shows that *VCOMP-H* is also NP-complete. We prove that (i) is equivalent to (ii), and (ii) is equivalent to (iii), in two separate lemmas, Lemma 2.2 and Lemma 2.3, respectively.

One of the main challenges is to construct such a graph of diameter four. Let (G_A, G_B) be a bipartition of G, and (H_A, H_B) be a bipartition of H, with $H_A \subseteq G_A$, and $H_B \subseteq G_B$. We shall assume for convenience that $h_0 \in H_B$.

The construction of G' is as follows. For each vertex $a \in G_A - H_A$, we add a new vertex z_a adjacent to a and h_1. For every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$, we add a new vertex z_{ab} adjacent to z_a and b. Thus for each $a \in G_A - H_A$, we have paths $az_az_{ab}b$, $az_az_{ab'}b'$, for all $b, b' \in G_B - H_B$. See Figure 2. In the figure, we have taken three distinct vertices a, a', and a'' of $G_A - H_A$, and three distinct vertices b, b', and b'' of $G_B - H_B$. Also, in the figures in this section, we are not depicting any edge that may be present between a vertex of $G_A - H_A$ and a vertex of $G_B - H_B$.

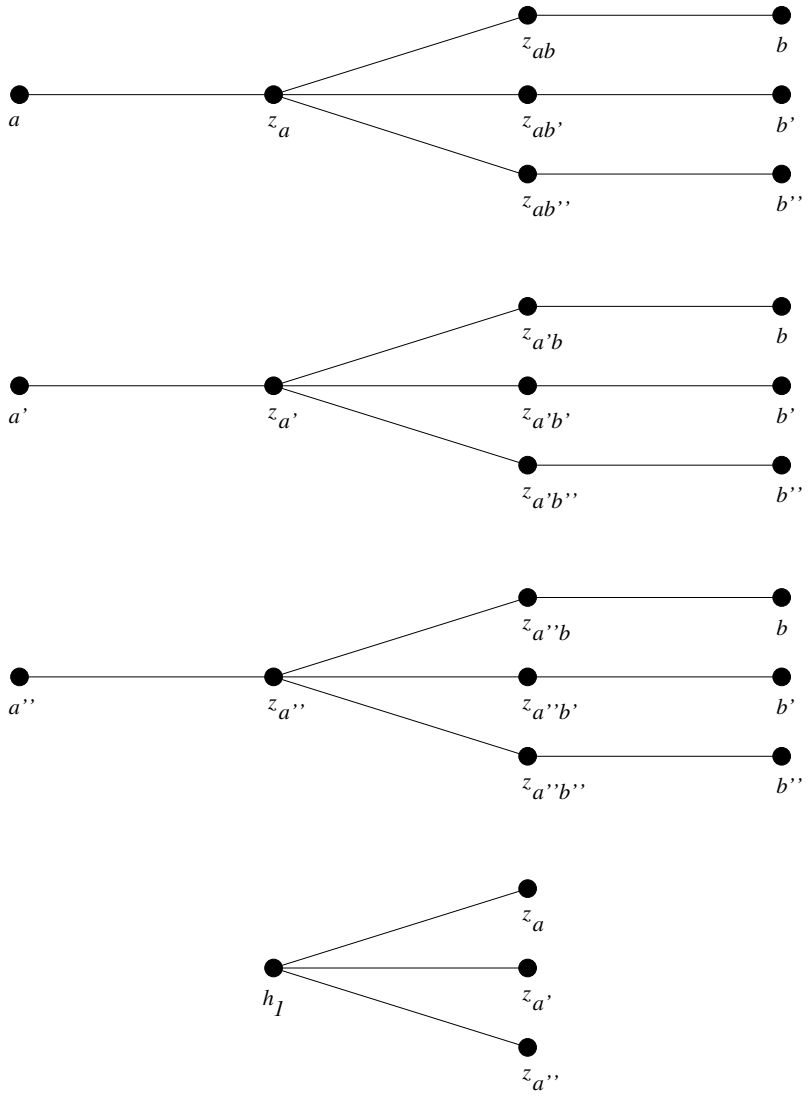

Figure 2 Construction of G', with z_a and z_{ab}, for every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$

In the graph G' constructed so far, the maximum distance between any pair of vertices in $V(G') - V(H)$ is already four, i.e., $d_{G'}(v, v') \leq 4$, with $v, v' \in V(G') - V(H)$. This can be observed due to the following paths and subpaths within those paths of length at most four : $az_az_{ab}bz_{a'b}$, $z_{ab}z_az_{ab'}b'z_{a'b'}$, $az_ah_1z_{a'}a'$, $bz_{ab}z_az_{ab'}b'$.

If we constructed the graph G' including the vertices of H also, i.e., if we constructed G' for every pair of vertices a and b, with $a \in G_A$, $b \in G_B$ then the diameter of G' would be four.

We continue further with the construction of G'. For each vertex $b \in G_B - H_B$, we add a new vertex x_b adjacent to z_{ab} and h_5, for all $a \in G_A - H_A$. For every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$, we add a new vertex x_{ba} adjacent to x_b and z_a. Thus for each $b \in G_B - H_B$, we have paths $z_{ab}x_bx_{ba}z_a$, $z_{a'b}x_bx_{ba'}z'_a$, for all $a, a' \in G_A - H_A$. See Figure 3.

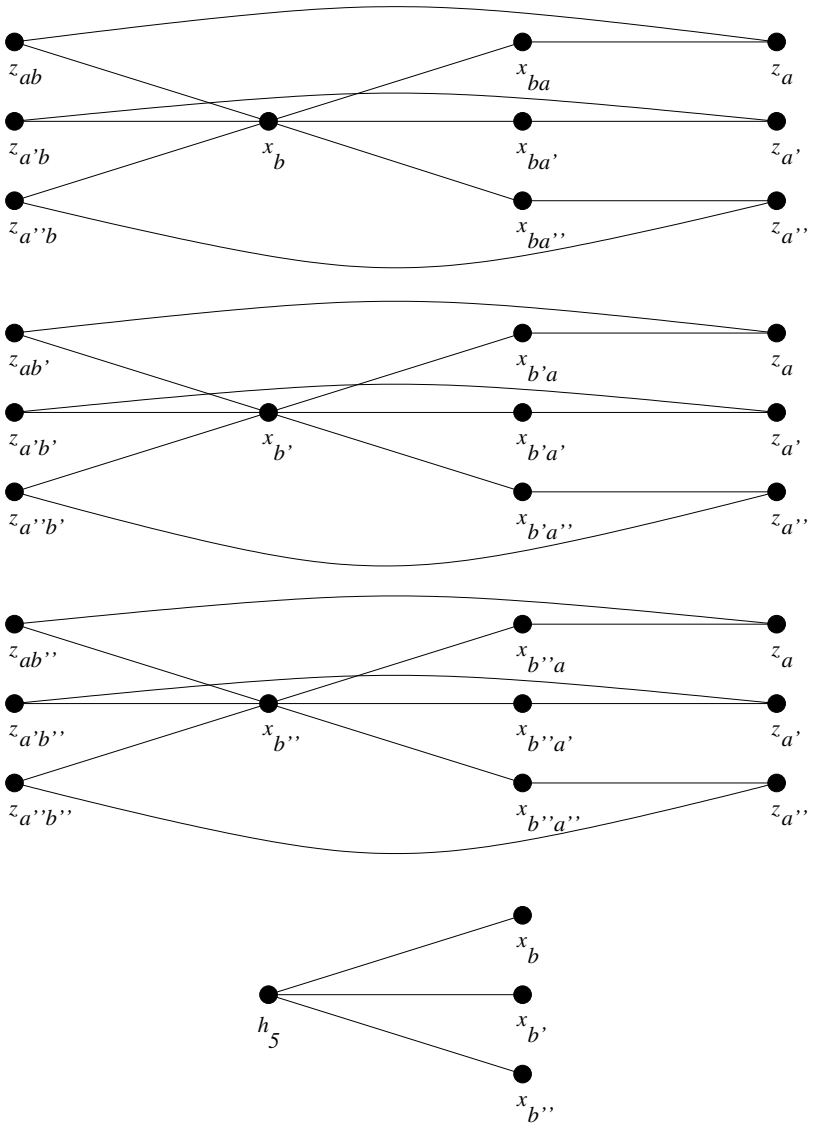

Figure 3 Construction of G', with x_b and x_{ba}, for every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$

The maximum distance between any pair of vertices in $V(G') - V(H)$ is still four. This can be observed due to the following paths and subpaths within those paths of length at most four : $x_{ba}x_bx_{ba'}z_{a'}x_{b'a'}$, $x_{ba}x_bx_{ba'}z_{a'}z_{a'b'}$, $x_{ba}x_bx_{ba'}z_{a'}a'$, $x_bx_{ba}z_az_{ab'}b'$.

For each vertex $a \in G_A - H_A$ (hence $d_G(h_0, a)$ is odd as we are assuming that $h_0 \in H_B \subseteq G_B$), we add to G new vertices u_1^a adjacent to h_0; u_2^a adjacent to u_1^a, a, and h_1; w_1^a adjacent to h_3, u_1^a, and a; y_1^a adjacent to h_1, u_1^a, and a; y_2^a adjacent to y_1^a, h_4, w_1^a, and u_2^a. See Figure 4. Note that there could be edges in G from a to some vertices of H but in Figure 4, we are not depicting these edges.

For each vertex $b \in G_B - H_B$ (hence $d_G(h_0, b)$ is even), we add to G new vertices u_1^b adjacent to h_0 and b; w_1^b adjacent to h_3 and u_1^b; w_2^b adjacent to w_1^b, b, and h_2; y_1^b adjacent to h_5, u_1^b, and w_2^b; y_2^b adjacent to y_1^b, h_2, w_1^b, and b. See Figure 5. There could be edges in G from b to some vertices of H but in Figure 5, we are not depicting these edges.

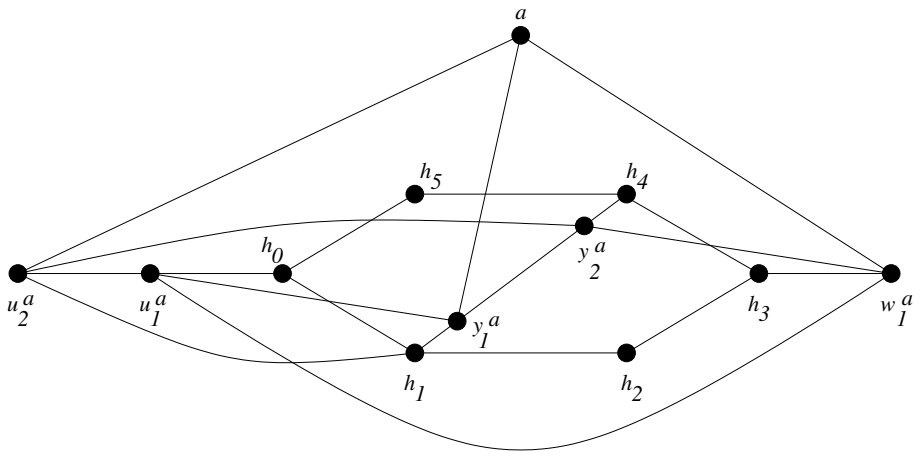

Figure 4 Construction of G' for a vertex a in $G_A - H_A$

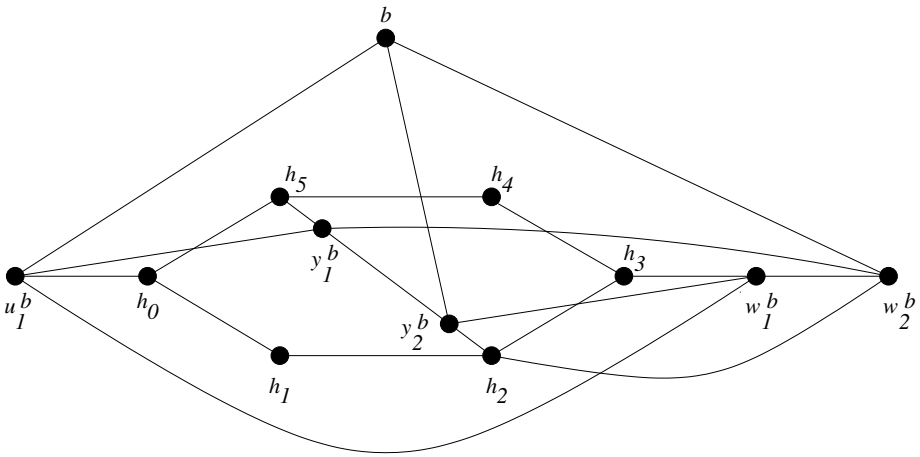

Figure 5 Construction of G' for a vertex b in $G_B - H_B$

For every vertex $a \in G_A - H_A$, we further make z_a adjacent to u_1^a and y_2^a. For every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$, we further also make z_{ab} adjacent to w_1^b and y_1^b.

For every vertex $b \in G_B - H_B$, we also further make x_b adjacent to u_1^b, y_2^b, and w_2^b. For every pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$, we further make x_{ba} adjacent to w_1^a, y_1^a, and u_2^a. See Figure 6.

This completes the construction of G'. The diameter of the graph G' is four. We now prove the following two lemmas in order to prove the theorem.

▶ **Lemma 2.2.** *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then it is clear that G also retracts to H, as G is a subgraph of G'. Now suppose that G retracts to H, and let $r : G \to H$ be a retraction. We define a retraction $r' : G' \to H$ as follows.

We define r' for the vertices v of G (that are also vertices of G') as
$r'(v) = r(v)$.
We define r' for the newly added vertices of G', with $a \in G_A - H_A$, as follows.

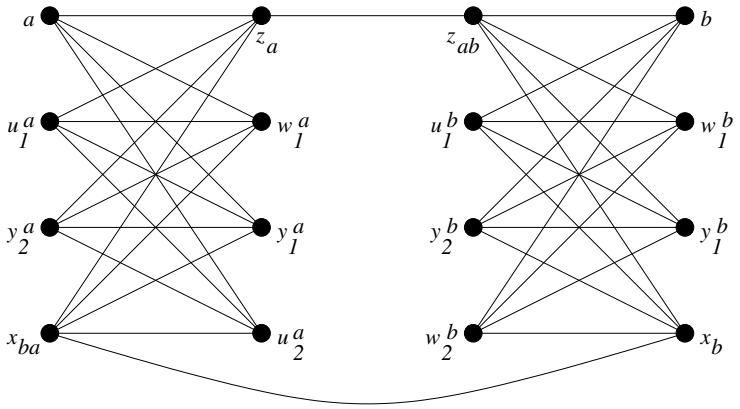

Figure 6 Construction of G' for a pair of vertices a and b, with $a \in G_A - H_A$, $b \in G_B - H_B$

If $r(a) = h_1$ or h_3, then we define
$r'(u_1^a) = h_1$, $r'(u_2^a) = h_2$,
$r'(w_1^a) = h_2$,
$r'(y_1^a) = h_2$, $r'(y_2^a) = h_3$,
$r'(z_a) = h_2$.
If $r(a) = h_5$, then we define
$r'(u_1^a) = h_5$, $r'(u_2^a) = h_0$,
$r'(w_1^a) = h_4$,
$r'(y_1^a) = h_0$, $r'(y_2^a) = h_5$,
$r'(z_a) = h_0$.
We define r' for the newly added vertices of G', with $b \in G_B - H_B$, as follows.
If $r(b) = h_0$ or h_2, then we define
$r'(u_1^b) = h_1$,
$r'(w_1^b) = h_2$, $r'(w_2^b) = h_1$,
$r'(y_1^b) = h_0$, $r'(y_2^b) = h_1$,
$r'(x_b) = h_0$.
If $r(b) = h_4$, then we define
$r'(u_1^b) = h_5$,
$r'(w_1^b) = h_4$, $r'(w_2^b) = h_3$,
$r'(y_1^b) = h_4$, $r'(y_2^b) = h_3$,
$r'(x_b) = h_4$.
We define r' for the vertices z_{ab} and x_{ba} of G', with $a \in G_A - H_A$, $b \in G_B - H_B$, as follows.
If $r(a) = h_1$ or h_3, and $r(b) = h_0$ or h_2, then we define
$r'(z_{ab}) = h_1$, $r'(x_{ba}) = h_1$.
If $r(a) = h_1$ or h_3, and $r(b) = h_4$, then we define
$r'(z_{ab}) = h_3$, $r'(x_{ba}) = h_3$.
If $r(a) = h_5$, and $r(b) = h_0$ or h_2, then we define
$r'(z_{ab}) = h_1$, $r'(x_{ba}) = h_5$.
If $r(a) = h_5$, and $r(b) = h_4$, then we define
$r'(z_{ab}) = h_5$, $r'(x_{ba}) = h_5$.

We now verify that $r' : G' \to H$ is indeed a homomorphism (and hence a retraction). We do this by considering all the edges ab of G', and proving that $r'(a)r'(b)$ is an edge of H. Before verifying, we point out that, as far as C_6 is concerned, we could use the vertices y_1^a

and y_1^b instead of the vertices z_a and x_b, respectively, but we have continued to keep z_a and x_b, as construction similar to them would be needed in the construction for larger cycles, with $a \in G_A - H_A$, $b \in G_B - H_B$.

Consider first an edge gg', with $gg' \in E(G)$. We have from our definition of r' that $r'(g) = r(g)$ and $r'(g') = r(g')$. Since $r : G \to H$ is a homomorphism, $r(g)r(g')$ must be an edge of H. Hence $r'(g)r'(g') = r(g)r(g')$ is an edge of H.

Now consider the edges $u_1^a h_0$, $u_2^a h_1$, $u_1^b h_0$, $w_1^a h_3$, $w_1^b h_3$, $w_2^b h_2$, $y_1^a h_1$, $y_2^a h_4$, $y_1^b h_5$, $y_2^b h_2$, $z_a h_1$, and $x_b h_5$, with $a \in G_A - H_A$, $b \in G_B - H_B$. From the definition of r', we have $r'(h_i) = r(h_i) = h_i$, for all $i = 0, 1, 2, 3, 4, 5$. Depending on the value of $r(a)$, we note from our definition of r' that $r'(u_1^a) = h_1$ or h_5, $r'(u_2^a) = h_2$ or h_0, $r'(w_1^a) = h_2$ or h_4, $r'(y_1^a) = h_2$ or h_0, $r'(y_2^a) = h_3$ or h_5, and $r'(z_a) = h_2$ or h_0. Hence $r'(u_1^a)r'(h_0)$, $r'(u_2^a)r'(h_1)$, $r'(w_1^a)r'(h_3)$, $r'(y_1^a)r'(h_1)$, $r'(y_2^a)r'(h_4)$, and $r'(z_a)r'(h_1)$ are always edges of H. Similarly, depending on the value of $r(b)$, from our definition of r', we have $r'(u_1^b) = h_1$ or h_5, $r'(w_1^b) = h_2$ or h_4, $r'(w_2^b) = h_1$ or h_3, $r'(y_1^b) = h_0$ or h_4, $r'(y_2^b) = h_1$ or h_3, and $r'(x_b) = h_0$ or h_4. Thus $r'(u_1^b)r'(h_0)$, $r'(w_1^b)r'(h_3)$, $r'(w_2^b)r'(h_2)$, $r'(y_1^b)r'(h_5)$, $r'(y_2^b)r'(h_2)$, and $r'(x_b)r'(h_5)$ are always edges of H.

The remaining edges of G' can also be verified. Since $r'(h) = r(h) = h$, for all $h \in V(H)$, the homomorphism $r' : G' \to H$ is a retraction. We have thus proved the lemma. ◀

▶ **Lemma 2.3.** *G' retracts to H if and only if G' vertex-compacts to H.*

Proof. If G' retracts to H then by definition G' vertex-compacts to H. Now suppose that G' vertex-compacts to H. We shall prove that G' also retracts to H. Let $c : G' \to H$ be a vertex-compaction. We let $U = \{u_1^v | v \in V(G - H)\} \cup \{h_1, h_0, h_5\}$ and $W = \{w_1^v | v \in V(G - H)\} \cup \{h_2, h_3, h_4\}$.

Since h_0 is adjacent to every other vertex in U, and G' is bipartite, the subgraph of G' induced by the vertices in U is of diameter two. Hence, the vertices of $c(U)$ induce a path of length one or two in H, as H is irreflexive. Thus $c(U)$ has either two or three vertices. Similarly, $c(W)$ has either two or three vertices. We shall prove that $c(U)$ and $c(W)$ both have three vertices.

Suppose that $c(U)$ has only two vertices. Then we know that the vertices in $c(U)$ are adjacent in H. Without loss of generality, let $c(U) = \{h_0, h_1\}$ and $c(h_0) = h_0$ (due to symmetry of vertices in H). Hence $c(U - \{h_0\}) = \{h_1\}$. We note that $d_{G'}(U - \{h_0\}, g) < 3$, for all $g \in V(G')$. Hence $d_{G'}(U - \{h_0\}, g) < d_H(c(U - \{h_0\}) = h_1, h_4) = 3$, for all $g \in V(G')$. This implies that $c(g) \neq h_4$, for all $g \in V(G')$, which is impossible, as $c : G' \to H$ is a vertex-compaction. Hence it must be that $c(U)$ has three vertices. We also note that $d_{G'}(W - \{h_3\}, g) < 3$, for all $g \in V(G')$, and hence, similarly, it must be that $c(W)$ also has three vertices.

Thus $c(U)$ and $c(W)$ both induce paths having three vertices in H. Without loss of generality, let $c(U) = \{h_1, h_0, h_5\}$ (due to symmetry). This implies that $c(h_0) = h_0$. We first prove that $c(h_3) = h_3$. We note that the diameter of G' is 4, and hence our vertex-compaction $c : G' \to H$ must also be a compaction, as otherwise the diameter of G' will be greater than 4. Let some edge gg' of G' cover the edge h_3h_4 or h_3h_2 of H under c, with $c(g) = h_3$ and $c(g') = h_4$ or h_2 (indeed there exists such an edge in G', as the vertex-compaction c is also a compaction). We note that h_3 is at distance 2 from $c(U)$ in H, as $d_H(c(U), h_3) = d_H(h_1, h_3) = 2$. Further, both h_4 and h_2 are at distance 1 from $c(U)$ in H, as $d_H(c(U), h_4) = d_H(h_5, h_4) = 1$, and $d_H(c(U), h_2) = d_H(h_1, h_2) = 1$. Thus it must be that $d_{G'}(U, g) \geq 2$ and $d_{G'}(U, g') \geq 1$. Since there is no vertex at distance more than 2 from U in G', we have $d_{G'}(U, g) = 2$ and $d_{G'}(U, g') = 1$ or 2. Further, since G' is bipartite, it must be that $d_{G'}(U, g) = 2$ and $d_{G'}(U, g') = 1$.

We note that the only vertices that could possibly be at distance 1 from U in G', as possible candidates for g', are : h_2, h_4, w_1^a, w_1^b, y_1^a, y_1^b, u_2^a, b, z_a, and x_b, with $a \in G_A - H_A$, $b \in G_B - H_B$. The only vertices that could possibly be at distance 2 from U in G', as possible candidates for g, are : h_3, y_2^a, y_2^b, w_2^b, a, z_{ab}, and x_{ba}, with $a \in G_A - H_A$, $b \in G_B - H_B$. Thus g and g' are among these vertices.

Since $c(h_0) = h_0$ and H is bipartite, $c(h_3) \neq h_4$ or h_2. Suppose that $c(h_3) \neq h_3$. Then no edge of G' with h_3 as an endpoint covers the edge h_3h_4 or h_3h_2 of H under c. Hence gg' must be an edge among $y_2^a w_1^a$, $y_2^b w_1^b$, $y_2^a y_1^a$, $y_2^b y_1^b$, $y_2^a z_a$, $y_2^a u_2^a$, $y_2^a h_4$, $y_2^b h_2$, $y_2^b b$, $y_2^b x_b$, $a y_1^a$, $a u_2^a$, $a w_1^a$, $a z_a$, $w_2^b w_1^b$, $w_2^b b$, $w_2^b x_b$, $w_2^b y_1^b$, $z_{ab} w_1^b$, $z_{ab} y_1^b$, $z_{ab} b$, $z_{ab} z_a$, $z_{ab} x_b$, $x_{ba} z_a$, $x_{ba} w_1^a$, $x_{ba} y_1^a$, $x_{ba} u_2^a$, $x_{ba} x_b$, and possibly ab, with $a \in G_A - H_A$, $b \in G_B - H_B$, where the first vertex in each of these edges stand for g and the second for g', and in order to meet the rquirements of the edge gg', the first vertex in each of these edges is assumed to achieve distance 2 from U in G' and hence may map to h_3 under c, and the second vertex in each of these edges is assumed to achieve distance 1 from U in G' and hence may map to h_4 or h_2 under c. We shall be always mentioning these edges in this order. Further, if ah_2 or ah_4 is an edge of G, for some vertex $a \in G_A - H_A$, then we need to include such an edge also for gg'. These edges for gg' are all the possible edges of G' that may cover the edge h_3h_4 or h_3h_2 of H under c assuming that $c(h_3) \neq h_3$. Since $c(h_3) \in H_A$ (as $c(h_0) = h_0 \in H_B$) and $c(h_3) \neq h_3$, we have $c(h_3) = h_1$ or h_5. The outline for proving that $c(h_3) \neq h_3$ is impossible is as follows. We suppose that $c(h_3) = h_1$, and consider each of the possible edges for gg' mentioned above, and show that they do not cover the edge h_3h_4 under c (i.e., $c(\{g, g'\}) \neq \{h_3, h_4\}$). Symmetrically, if $c(h_3) = h_5$ then it can be shown that none of the possible edges for gg' mentioned above can cover the edge h_3h_2 under c (i.e., $c(\{g, g'\}) \neq \{h_3, h_2\}$). Thus let $c(h_3) = h_1$.

Consider first the edges $y_2^a w_1^a$ and $y_2^b w_1^b$, with $a \in G_A - H_A$, $b \in G_B - H_B$. We consider them together as an edge $y_2^v w_1^v$, with $v \in V(G - H)$. Suppose that $y_2^v w_1^v$ covers the edge h_3h_4 under c. Then $c(y_2^v) = h_3$ and $c(w_1^v) = h_4$. By assumption, we have $c(h_3) = h_1$. Since w_1^v is adjacent to h_3, this implies that $c(w_1^v) = h_0$ or h_2. Thus $c(w_1^v) \neq h_4$, and we have a contradiction.

Next consider the edges aw_1^a, $w_2^b w_1^b$, and $z_{ab} w_1^b$, with $a \in G_A - H_A$, $b \in G_B - H_B$. Similar to the above, since $c(w_1^v)$ must be adjacent to $c(h_3) = h_1$, it is impossible that $c(w_1^v) = h_4$, with $v \in V(G - H)$, and hence the above edges cannot cover the edge h_3h_4 under c.

Now consider the edges $y_2^a y_1^a$ and $y_2^b y_1^b$, with $a \in G_A - H_A$, $b \in G_B - H_B$. We consider them together as an edge $y_2^v y_1^v$, with $v \in V(G - H)$. Suppose that $y_2^v y_1^v$ covers the edge h_3h_4 under c. Then $c(y_2^v) = h_3$ and $c(y_1^v) = h_4$. Since $c(u_1^v)$ must be adjacent to both $c(h_0) = h_0$ and $c(y_1^v) = h_4$, this implies that $c(u_1^v) = h_5$. Since $c(w_1^v)$ must be adjacent to both $c(u_1^v) = h_5$ and $c(y_2^v) = h_3$, it must be that $c(w_1^v) = h_4$. This implies that $y_2^v w_1^v$ covers the edge h_3h_4 under c, which we have already proved does not hold.

The remaining edges for gg' can be verified also. Symmetrically, if $c(h_3) = h_5$ then no possible edge for gg' can cover the edge h_3h_2 under c. We thus establish that $c(h_3) = h_3$, and hence $c(W) = \{h_2, h_3, h_4\}$.

We now prove that $c(h_1) \neq c(h_5)$. Suppose to the contrary that $c(h_1) = c(h_5)$. Since $c(h_0) = h_0$, we have $c(h_1), c(h_5) \in \{h_1, h_5\}$. Without loss of generality, let $c(h_1) = c(h_5) = h_1$ (due to symmetry). Since $c(U) = \{h_1, h_0, h_5\}$, it must be that $c(u_1^v) = h_5$ for some vertex v of $G - H$. Since $c(w_1^v)$, $c(h_2)$, and $c(h_4)$ must all be adjacent to $c(h_3) = h_3$, we have $c(w_1^v)$, $c(h_2)$, $c(h_4) \in \{h_2, h_4\}$. Since $c(w_1^v)$ must be adjacent to $c(u_1^v) = h_5$, it must be that $c(w_1^v) \neq h_2$, and hence $c(w_1^v) = h_4$. Since $c(h_2)$ must be adjacent to $c(h_1) = h_1$, it must be that $c(h_2) \neq h_4$, and hence $c(h_2) = h_2$. Since $c(h_4)$ must be adjacent to $c(h_5) = h_1$, it must be that $c(h_4) \neq h_4$, and hence $c(h_4) = h_2$. Now $c(y_2^a)$ must be adjacent to $c(h_4) = h_2$ and

$c(w_1^a) = h_4$, implying that $c(y_2^a) = h_3$, with $a \in G_A - H_A$. Also, $c(y_2^b)$ must be adjacent to $c(h_2) = h_2$ and $c(w_1^b) = h_4$, implying that $c(y_2^b) = h_3$ also, with $b \in G_B - H_B$. Thus we have, in general, $c(y_2^v) = h_3$. We also have that $c(y_1^a)$ must be adjacent to $c(h_1) = h_1$ and $c(u_1^a) = h_5$, implying that $c(y_1^a) = h_0$, with $a \in G_A - H_A$. Also, we have that $c(y_1^b)$ must be adjacent to $c(h_5) = h_1$ and $c(u_1^b) = h_5$, implying that $c(y_1^b) = h_0$ also, with $b \in G_B - H_B$. Thus we have, in general, $c(y_1^v) = h_0$. This is impossible as $c(y_1^v)$ must be adjacent to $c(y_2^v) = h_3$.

Thus $c(h_1) \neq c(h_5)$, i.e., $c(\{h_1, h_5\}) = \{h_1, h_5\}$. Without loss of generality, suppose that $c(h_1) = h_1$ and $c(h_5) = h_5$ (due to symmetry). Since $c(h_3) = h_3$, we have $c(h_2)$, $c(h_4) \in \{h_2, h_4\}$. Since $c(h_2)$ must be adjacent to $c(h_1) = h_1$, it must be that $c(h_2) \neq h_4$, and hence $c(h_2) = h_2$. Since $c(h_4)$ must be adjacent to $c(h_5) = h_5$, it must be that $c(h_4) \neq h_2$, and hence $c(h_4) = h_4$. We already have $c(h_0) = h_0$ and $c(h_3) = h_3$. Thus we have $c(h_i) = h_i$, for all $i = 0, 1, 2, 3, 4, 5$. Hence $c : G' \to H$ is a retraction, proving the lemma. ◀

We have thus proved Theorem 2.1. ◀

3 Vertex-Compaction to an Irreflexive k-Cycle

Our proof of Theorem 2.1 showing NP-completeness of *VCOMP-C_6* directly uses graphs that we construct simply by adding vertices and edges. Our technique of construction of graphs therefore lays down the foundation for construction of graphs for the case of a general irreflexive even k-cycle, by extending the paths constructed and adding edges appropriately, showing NP-completeness of *VCOMP-C_k*, for all even $k \geq 6$.

In [Vikas, 1999, 2004a], it is shown that the problem *COMP-C_k* is NP-complete, for all even $k \geq 6$. The problem *RET-C_k* is shown to be NP-complete, for all even $k \geq 6$, in [Feder, Hell, and Huang, 1999], and independently by G. Macgillivray in 1988. To prove NP-completeness of *VCOMP-C_k*, we give a transformation from *RET-C_k* to *VCOMP-C_k*, for all even $k \geq 6$. In our construction to prove NP-completeness of *VCOMP-C_k*, with even $k \geq 6$, we now have for example paths Z_{ab}, X_{ba}, U_a, U_b, W_a, W_b, Y_a, and Y_b of appropriate lengths instead of the vertices z_{ab}, x_{ba}, u_1^a, u_2^a, u_1^b, w_1^a, w_1^b, and w_2^b that we used in the construction in the proof of Theorem 2.1 for proving NP-completeness of *VCOMP-C_6*, and we add edges chosen appropriately.

Considering $k = 4$, it is easy to see that the problems *VCOMP-C_4*, *COMP-C_4*, and *RET-C_4* are polynomial time solvable, as C_4 is a complete bipartite graph. We now consider odd $k \geq 3$. Note that a graph G is homomorphic to a graph H if and only if the disjoint union $G \cup H$ vertex-compacts, compacts, and retracts to H. Thus we have a polynomial transformation from the *H-colouring* problem to the problems *VCOMP-H*, *COMP-H*, and *RET-H*. The *H-colouring* problem is shown to be NP-complete for any fixed non-bipartite irreflexive graph H in [Hell & Nesetril 1990]. Hence, it follows that the problems *VCOMP-H*, *COMP-H*, and *RET-H* are also NP-complete when H is any non-bipartite irreflexive graph. Thus, in particular, the problems *VCOMP-C_k*, *COMP-C_k*, and *RET-C_k* are NP-complete, for all odd $k \geq 3$.

Abstract

We continue research into a well-studied family of problems that ask if the vertices of a graph can be partitioned into sets A and B, where A is an independent set and B induces a graph from some specified graph class $\mathcal{G}$. We let $\mathcal{G}$ be the class of k-degenerate graphs. The problem is known to be polynomial-time solvable if $k = 0$ (bipartite graphs) and NP-complete if $k = 1$ (near-bipartite graphs) even for graphs of diameter 4, as shown by Yang and Yuan, who also proved polynomial-time solvability for graphs of diameter 2. We show that recognizing near-bipartite graphs of diameter 3 is NP-complete resolving their open problem. To answer another open problem, we consider graphs of maximum degree Δ on n vertices. We show how to find A and B in $O(n)$ time for $k = 1$ and $\Delta = 3$, and in $O(n^2)$ time for $k \geq 2$ and $\Delta \geq 4$. These results also provide an algorithmic version of a result of Catlin [1979] and enable us to complete the complexity classification of another problem: finding a path in the vertex colouring reconfiguration graph between two given k-colourings of a graph of bounded maximum degree.

1 Introduction

We consider the problem of partitioning the vertex set of a graph into two sets A and B where A is an independent set and B belongs to a specified graph class $\mathcal{G}$. The classes $\mathcal{G}$ we consider are those of k-degenerate graphs (a graph is k-degenerate if every induced subgraph has a vertex of degree at most k). A 0-degenerate graph has no edges, so in this case the problem is simply that of recognizing bipartite graphs. A graph is 1-degenerate if and only if it is a forest; we say that a graph is *near-bipartite* if it can be decomposed into an independent set and a forest. The problem of deciding whether or not a graph is near-bipartite is NP-complete (see [6]). We consider this problem when the input is restricted, but our main focus is the problem of *finding* the decomposition into an independent set and a

k-degenerate graph for graphs of bounded maximum degree. We also describe an application to a graph reconfiguration problem.

Related Work. As noted above, recognizing near-bipartite graphs is known to be an NP-complete problem. Yang and Yuan [29] proved that the problem remains NP-complete even for graphs of maximum degree 4 and for graphs of diameter 4. They also showed that it can be solved in polynomial time for graphs of maximum degree at most 3 and for graphs of diameter at most 2. They left open the problem of determining its computational complexity for graphs of diameter 3 (see also [4]). We note that the problem of recognizing near-bipartite graphs has also been studied from the perspective of parameterized complexity (in this setting the problem is known as Independent Feedback Vertex Set). With the size of A as the parameter, FPT algorithms have been found for general graphs [26]. The problem of finding a decomposition where the size of A is minimum has been shown to be NP-hard even for planar bipartite graphs of maximum degree 4, but linear-time solvable for graphs of bounded treewidth, chordal graphs and cographs [27] (it was already known that near-bipartite cographs can be recognized in linear time [4]). Recently, we extended the result of cographs to P_5-free graphs, and we also proved that recognizing near-bipartite line graphs of maximum degree 4 is NP-complete [2]. The variant where the maximum degree of the forest induced by B is bounded by some constant has also been studied, in particular from a structural point of view (see, for instance, [12]).

The Induced Forest 2-Partition problem is closely related to the problem of recognizing near-bipartite graphs. It asks whether the vertex set of a given graph can be decomposed into two disjoint sets A and B, where both A and B induce forests. Wu, Yuan and Zhao [28] proved that Induced Forest 2-Partition is NP-complete for graphs of maximum degree 5 and polynomial-time solvable for graphs of maximum degree at most 4. Brandstädt et al. [6] proved NP-completeness of another closely related problem, namely that of deciding whether the vertex set of a given graph can be decomposed into an independent set and a tree. Note that both this problem and that of recognizing near-bipartite graphs can be seen as restricted variants of the classical 3-Colouring problem,[1] which is well known to be NP-complete [20]. In fact, for a fixed graph class $\mathcal{G}$ (that is, $\mathcal{G}$ is not part of the input), Brandstädt et al. [6] considered the following more general problem:

Stable($\mathcal{G}$)	
Instance:	A graph $G = (V, E)$.
Question:	Can V be decomposed into two disjoint sets A and B, where A is an independent set and B induces a graph in $\mathcal{G}$?

Note that Stable($\mathcal{G}$) is equivalent to 3-Colouring if we choose $\mathcal{G}$ to be the class of bipartite graphs. For a positive integer k, we denote the class of k-degenerate graphs by $\mathcal{D}_k$. Then Stable($\mathcal{D}_1$) is the problem of finding near-bipartite graphs. If $\mathcal{G}$ is the class of complete graphs, Stable($\mathcal{G}$) is the problem of recognizing split graphs, which can be solved in polynomial time. Brandstädt et al. [6] proved that Stable($\mathcal{G}$) is NP-complete when $\mathcal{G}$ is the class of trees or the class of trivially perfect graphs, and polynomial-time solvable when $\mathcal{G}$ is the class of co-bipartite graphs, the class of split graphs, or the class of threshold graphs. Moreover, Stable($\mathcal{G}$) has also been shown to be NP-complete when $\mathcal{G}$ is

[1] For a fixed integer $k \geq 1$, the k-Colouring problem asks whether a given graph is *k-colourable*, that is, whether its vertices can be coloured with at most k colours such that no two adjacent vertices are coloured alike. As trees and forests are 2-colourable, the observation follows.

the class of triangle-free graphs [7], the class of cographs [17], the class of graphs of maximum degree 1 [22], or, more generally, the class of graphs that have any additive hereditary property not equal to or divisible by the property of being edgeless [19], whereas it is also polynomial-time solvable if $\mathcal{G}$ is the class of complete bipartite graphs [13] (see [5] for a faster algorithm). The Stable($\mathcal{G}$) problem has also been studied for hereditary graph classes $\mathcal{G}$ with subfactorial or factorial speed [11, 21] (the speed of a graph class is the function that given an integer n returns the number of labelled graphs on n vertices in the class).

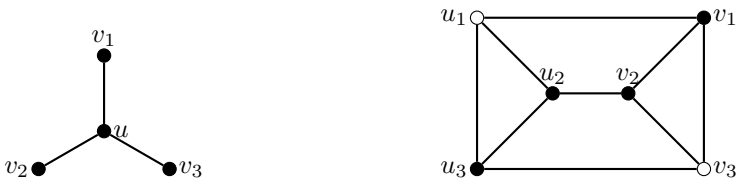
To obtain a more general problem than Stable($\mathcal{G}$), we can relax the condition on the set A being independent. This leads to the $(\mathcal{G}_1, \mathcal{G}_2)$-Recognition problem, which asks whether the vertex set of a graph can be decomposed into disjoint sets A and B, such that A induces a graph in $\mathcal{G}_1$ and B induces a graph in $\mathcal{G}_2$. For instance, if $\mathcal{G}_1$ is the class of cliques and $\mathcal{G}_2$ is the class of disjoint unions of cliques, the $(\mathcal{G}_1, \mathcal{G}_2$-Recognition problem is equivalent to recognizing unipolar graphs (see [24] for a quadratic algorithm). Generalizing Stable($\mathcal{G}$) also leads to a family of transversal problems, such as Feedback Vertex Set. However, such problems are beyond the scope of our paper.

As Stable($\mathcal{D}_k$) is NP-complete for every $k \geq 1$, its complexity has been determined for special graph classes. Recall the aforementioned hardness and tractability results of Yang and Yuan [29] on graph classes of bounded maximum degree and classes of bounded diameter when $k = 1$. Brandstädt, Brito, Klein, Nogueira and Protti [4] proved that Stable($\mathcal{D}_1$) is NP-complete on perfect graphs and, as stated earlier, that it is polynomial-time solvable for cographs. In particular, their hardness result for perfect graphs shows that the complexities of Stable($\mathcal{D}_1$) and 3-Colouring do not coincide, as k-Colouring is polynomial-time solvable for perfect graphs even when the number of colours k is part of the input [16].

Our Results. In Section 2, we consider the Stable($\mathcal{D}_1$) problem for graphs of bounded diameter. Recall that Yang and Yuan [29] left one missing case: they proved that recognizing near-bipartite graphs of diameter 4 is an NP-complete problem and that near-bipartite graphs of diameter 2 can be recognized in polynomial time. We show that Stable($\mathcal{D}_1$) is NP-complete for graphs of diameter 3, which resolves their open problem.

In Section 3, we consider near-bipartite decompositions of *subcubic* graphs (that is, graphs of maximum degree at most 3). By a result of Catlin and Lai [9], the only connected subcubic graph that is not near-bipartite is K_4 (see also Yang and Yuan [29]) and so near-bipartite subcubic graphs can be recognized in polynomial time. However, the proofs of [9, 29] do not lead to a linear-time algorithm for finding the desired partition (A, B); in particular, the result of [9] would require solving an NP-complete problem, namely Independent Set for cubic graphs [15]. We give a linear-time algorithm that finds such a partition.

We say a partition (A, B) of the vertex set of a graph is a *k-degenerate decomposition* if A is independent and B induces a $(k-2)$-degenerate graph (so Section 3 is concerned with 3-degenerate decompositions of graphs of maximum degree 3). In Section 4, we consider, more generally, Δ-degenerate decompositions of graphs of maximum degree at most Δ for any $\Delta \geq 3$. We give a quadratic-time algorithm to find such a decomposition in this general case (contrast with the linear-time algorithm for the special case of $\Delta = 3$). By a result of Matamala [23], the only connected graph with maximum degree at most Δ that does not have such a decomposition is $K_{\Delta+1}$. Matamala's result generalizes that of [9] and thus does not imply a polynomial-time algorithm for finding such a decomposition. We show that our algorithms for finding Δ-degenerate decompositions of graphs of maximum degree at most Δ also provide an algorithmic version of a result of Catlin [8]. In Section 5, we show how they can be applied to completely settle the complexity classification of a graph colouring reconfiguration problem considered in [14]. In Section 6 we give directions for future work.



(a) claw **(b)** triangular prism

Figure 1 The claw and the triangular prism. A near-bipartite decomposition of the triangular prism is indicated: the white vertices form an independent set and the black vertices induce a forest.

2 Graphs of Diameter 3

We present a hardness result (proof omitted) for the problem of deciding whether a graph of diameter at most 3 has a near-bipartite decomposition. In [25], Mertzios and Spirakis proved a remarkable result: 3-Colouring is NP-complete for graphs of diameter 3. The outline of their proof is straightforward: a reduction from 3-Sat that constructs, for any instance ϕ, a graph H_ϕ that is 3-colourable if and only if ϕ is satisfiable. It is possible to reduce 3-Sat to Stable($\mathcal{D}_1$) for graphs of diameter 3 using the same construction, thus showing that Stable($\mathcal{D}_1$) is also NP-complete on this class. That is H_ϕ is near-bipartite if and only if ϕ is satisfiable. So Theorem 1 below is an observation about the proof of Mertzios and Spirakis.

▶ **Theorem 1.** Stable($\mathcal{D}_1$) *is* NP*-complete for graphs of diameter at most* 3*.*

3 Subcubic Graphs

In this section we prove the following result.

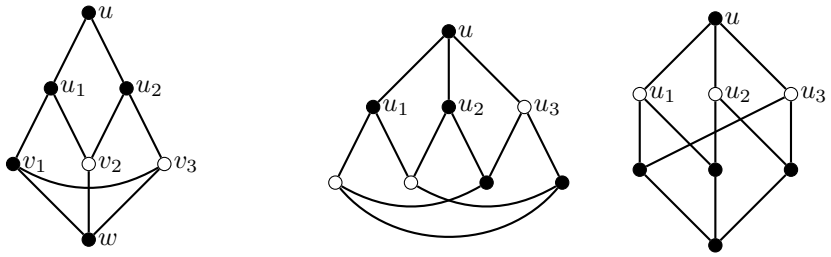
▶ **Theorem 2.** *Let G be a subcubic graph on n vertices, with no component isomorphic to K_4. Then a near-bipartite decomposition of G can be found in $O(n)$ time.*

Proof. We will repeatedly apply a set of *rules* to G. Each rule takes constant time to apply and after each application of a rule, the resulting graph contains fewer vertices. The rules are applied until the empty graph is obtained. We then reconstruct G from the empty graph by working through the rules applied in reverse order. As we rebuild G in this way, we find a near-bipartite decomposition of each obtained graph. We do this by describing how to extend, in constant time, a near-bipartite decomposition of a graph before some rule is undone to a near-bipartite decomposition of the resulting graph after that rule is undone. If we can do this then we say that the rule is *safe*. We conclude that the total running time of the algorithm is $O(n)$. It only remains to describe the rules, show that it takes constant time to do and undo each of them and prove that they are safe.

We need the following terminology. The *claw* is the graph with vertices u, v_1, v_2, v_3 and edges uv_1, uv_2, uv_3; the vertex u is the *centre* of the claw (see Figure 1). The *triangular prism* is the graph obtained from two triangles on vertices u_1, u_2, u_3 and v_1, v_2, v_3, respectively, by adding the edges u_iv_i for $i \in \{1, 2, 3\}$ (see Figure 1). Two vertices are *false twins* if they have the same neighbourhood (note that such vertices must be non-adjacent).

Let u be an arbitrary vertex of G. Our choice of u as an arbitrary vertex implies that u can be found in constant time. We then use the first of the following rules that is applicable.

Rule 1. If u has degree at most 2, then remove u.



(a) H_1 **(b)** H_2 **(c)** H_3

Figure 2 The graphs used in Rule 8. A near-bipartite decomposition of each is indicated: the white vertices form an independent set and the black vertices induce a forest.

Rule 2. If there is a vertex v of degree at most 2 that is at distance at most 3 from u, then remove v.

Rule 3. If G contains an induced diamond D whose vertices are at distance at most 3 from u, then remove the vertices of D.

Rule 4. If there is a pair of false twins u_1, u_2 each at distance at most 2 from u, then remove u_1, u_2 and their common neighbours (note that $u \in \{u_1, u_2\}$ is possible).

Rule 5. If u is in a connected component that is a triangular prism P, then remove the vertices of P.

Rule 6. If Rules 1–5 do not apply but u is in a triangle T, then the neighbours of the vertices in T that are outside T are pairwise distinct (since there is no induced diamond) and at least two them, which we denote by x', y', are non-adjacent (otherwise u belongs to a triangular prism). Remove the vertices of T and add an edge between x' and y'.

Rule 7. If u is the centre of an induced claw but has a neighbour v that belongs to a triangle, then apply one of the Rules 1–6 on v.

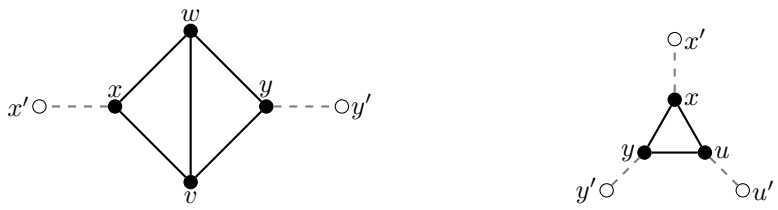
Rule 8. If the graph induced by the vertices at distance at most 3 from u contains the graph H_1, H_2 or H_3, depicted in Figure 2, with the vertex u in the position shown in the figure, then remove the vertices of this graph H_i.

Rule 9. If Rules 1–8 do not apply but u is the centre of an induced claw and its three neighbours u_1, u_2, u_3 are also centres of induced claws, then remove u, u_1, u_2, u_3 and for $i \in \{1, 2, 3\}$ add an edge joining the two neighbours of u_i distinct from u and denote it by e_i; we say that such an edge is *new* (note that such neighbours of two distinct u_i and u_j may overlap).

Let us show that at least one of the rules is always applicable. Suppose that, on the contrary, there is a vertex u of a subcubic graph for which no rule applies. Then u and its neighbours each have degree 3 (Rules 1 and 2) and so each either belongs to a triangle or is the centre of an induced claw. By Rule 6, u must be the centre of an induced claw and therefore, by Rule 7, the same is also true for each neighbour of u. This implies that Rule 9 applies, a contradiction.

Because G is subcubic, each of these rules takes constant time to verify and process. In particular, in some rules we need to detect some induced subgraph of constant size that contains u or replace u by some other vertex v. In all such cases we need to explore a set of vertices of distance at most 4 from u. As G is subcubic, this set has size at most $1 + 3 + 3^2 + 3^3 + 3^4 = 121$, so we can indeed do this in constant time.

It is clear that, as claimed, the application of a rule reduces the number of vertices and that if we repeatedly choose an arbitrary vertex u and apply a rule, we eventually obtain the empty



(a) diamond **(b)** triangle

Figure 3 The diamond and triangle (solid edges and vertices) together with their neighbourhoods in a cubic graph.

graph. We now consider undoing the applied rules in reverse order to rebuild G. As this is done, we will irrevocably *colour* vertices with colour 1 or 2 in such a way that the vertices coloured 1 will form an independent set and the vertices coloured 2 will induce a forest. Thus a rule is safe if this colouring can be extended whenever that rule is undone. When we reach G, the final colouring will correspond to the required near-bipartite decomposition.

We must prove each rule is safe. At each step of reconstructing G, we refer to the graph before a rule is undone as the *prior graph* and to the graph after that rule is undone as the *subsequent graph*. Note that the application of any of the Rules 1–9 again yields a subcubic graph. By the result of Yang and Yuan [29], every connected subcubic graph is near-bipartite, apart from K_4. So we need to ensure that an application of a rule does not create a K_4. This cannot happen when we remove vertices, but we will need to consider it for Rules 6 and 9.

▶ **Claim 3.** *Rules 1–5 are safe.*

In Rules 1–5 we only delete vertices. Rule 1 is safe since if both neighbours of u are coloured 2, then u can be coloured 1; otherwise u can be coloured 2. Similarly, we see that Rule 2 is safe. To see that Rule 3 is safe, let D be the diamond with vertex labels as illustrated in Figure 3, where u is one of v, w, x, y. If x' and y' are coloured 2, we colour x and y with 1 and v and w with 2. Otherwise we colour v with 1 and x, y and w with 2. We now show that Rule 4 is safe. Let u_1 and u_2 be false twins (at distance at most 2 from u). As G is subcubic, every vertex in $N(u_1)$ with a neighbour in $N(u_1)$ has no neighbours outside $N(u_1) \cup \{u_1, u_2\}$ and every vertex in $N(u_1)$ with no neighbour in $N(u_1)$ has at most one neighbour not equal to u_1 or u_2. Moreover, as G is subcubic, $N(u_1)$ contains no cycle. Hence we can always colour u_1, u_2 with 1 and the vertices of $N(u_1)$ with 2 regardless of the colours of vertices outside $N(u_1) \cup \{u_1, u_2\}$. Indeed, every vertex of $N(u_1)$ will have at most one neighbour that is not coloured 1, so cannot be in a cycle of vertices coloured 2 in the subsequent graph. Rule 5 is also safe since P is 3-regular and hence would be a component of our subsequent graph, so we can colour its vertices by assigning colour 1 to exactly one vertex from each of the two triangles and colour 2 to its other vertices (see Figure 1). This completes the proof of Claim 3.

▶ **Claim 4.** *Rules 6 and 7 are safe.*

First, let us demonstrate that Rule 6 is safe. If x' and y' are contained in a K_4 of the prior graph, then the subsequent graph contains a diamond whose vertices are at distance at most 3 from u. This contradicts Rule 3. Let T be the triangle with vertex labels as illustrated in Figure 3. Suppose x', y' and u' are coloured 2. Then we colour u with 1 and x and y with 2. The vertices in the subsequent graph with colour 2 still induce a forest, as we have replaced an edge in the forest by a path on four vertices. Suppose x' and y' are coloured 2 and u' is

coloured 1. Then we colour x with 1, and y and u with 2. Otherwise, since x' and y' are joined by an edge in the prior graph, we may assume that x' has colour 1 and y' has colour 2. In this case we can colour y with 1, and x and u with 2. This completes the proof that Rule 6 is safe. Since Rules 1–6 are safe, it follows that Rule 7 is also safe. This completes the proof of Claim 4.

▶ **Claim 5.** *Rule 8 is safe.*

We now show that Rule 8 is safe. Suppose u is contained in H_1. We use the vertex labels from Figure 2. As Rule 1 could not be applied, we find that u has a third neighbour u_3 distinct from u_1 and u_2. Regardless of whether u_3 is coloured 1 or 2, we colour u, u_1, u_2, v_1, w with 2 and v_2, v_3 with 1 to obtain a near-bipartite decomposition of G. We can also readily colour the vertices of H_2 or H_3 should u be contained in one of them (note that since H_2 and H_3 are 3-regular, these graphs can only appear as components in our subsequent graph). This completes the proof of Claim 5.

▶ **Claim 6.** *Rule 9 is safe.*

Suppose that the prior graph contains fewer than three new edges. Then we may assume without loss of generality that $e_1 = e_2$. Then u_1 and u_2 are false twins at distance 1 from u and we can apply Rule 4, a contradiction. So we may assume that the prior graph contains exactly three new edges.

We claim that the application of Rule 9 does not yield a K_4. For contradiction, suppose it does. Let K be the created K_4. Then at least one new edge is contained in K. If exactly one new edge e is contained in K, then $K - e$ is a diamond in the subsequent graph. Then we could have applied Rule 3, a contradiction. If all three new edges are in K, then they must induce either a path on four vertices or a triangle in the subsequent graph. In the first case the subsequent graph is H_2 and in the second case the subsequent graph is H_3. In both cases we would have applied Rule 8, a contradiction. Finally, suppose that K contains exactly two new edges, say e_1 and e_2. If e_1 and e_2 do not share a vertex, then they cover the vertices of K. Hence the end-vertices of e_1 are false twins (at distance 2 from u) in the subsequent graph, since they are both adjacent to u_1 and to each end-vertex of e_2. Then we could have applied Rule 4, a contradiction. If $e_1 = v_1v_2$ and $e_2 = v_3v_4$ share a vertex, say $v_2 = v_4$, then v_1 and v_3 are adjacent in the subsequent graph and the vertex $w \in K \setminus \{v_1, v_2, v_3\}$ is adjacent only to v_1, v_2 and v_3. Therefore Rule 8 could have been applied, a contradiction.

Thus an application of Rule 9 does not yield a K_4, and we may colour u_1, u_2, u_3 with 2 and u with 1. Indeed note that since if two end-vertices of a new edge are coloured 2, then in the subsequent graph the vertices coloured 2 will still induce a forest, in which such a new edge is replaced by a path of length 2. This completes the proof of Claim 6 and therefore completes the proof of Theorem 2. ◀

4 Graphs of Bounded Maximum Degree

Let $k \geq 3$ be an integer. Recall that a graph G has a k-degenerate decomposition if its vertex set can be decomposed into sets A and B where A is an independent set and B induces a $(k-2)$-degenerate graph. Note that 3-degenerate decompositions are near-bipartite decompositions. We give an $O(n^2)$ algorithm for finding a Δ-degenerate decomposition of a graph on n vertices of maximum degree at most Δ for every $\Delta \geq 3$ (note that for $\Delta = 3$ we can also use Theorem 2).

For $k \geq 1$, we say that an order $v_1, v_2, \ldots, v_n$ of the vertices of a graph G is *k-degenerate* if for all $i \geq 2$, the vertex v_i has at most k neighbours in $\{v_1, \ldots, v_{i-1}\}$. It is clear that a

graph is k-degenerate if and only if it has a k-degenerate order. If $\mathcal{O}$ is a k-degenerate order for G and W is a subset of the vertex set of G, then we let $\mathcal{O}|_W$ be the restriction of $\mathcal{O}$ to W, and let $G[W]$ be the subgraph of G induced by W. For a set of vertices C, we denote the *neighbourhood* of C by $N(C) = \bigcup\{N(u) \mid u \in C\} \setminus C$.

We need the following lemma, which is a refinement of Lemma 8 in [14] with the same proof.

▶ **Lemma 7.** *Let $k \geq 2$. Let G be a $(k-1)$-degenerate graph on n vertices. If a $(k-1)$-degenerate order $\mathcal{O}$ of G is given as input, a k-degenerate decomposition (A, B) of G can be found in $O(kn)$ time. In addition, we can ensure that $\mathcal{O}|_B$ is a $(k-2)$-degenerate order of $G[B]$, the set A is a maximal independent set and the first vertex in $\mathcal{O}$ belongs to A.*

A pair of non-adjacent vertices $\{u, v\}$ in a graph G is *strong* if u and v have a common neighbour in each component of the graph $G \setminus \{u, v\}$. In particular, note that if u and v have a common neighbour and $G \setminus \{u, v\}$ is connected, then $\{u, v\}$ is a strong pair. We need the following two lemmas (we omit the proof of the first one).

▶ **Lemma 8.** *Let $k \geq 3$. Let G be a connected k-regular graph on n vertices that contains a strong pair $\{u, v\}$. If $\{u, v\}$ is given as input, a k-degenerate decomposition of G can be found in $O(kn)$ time.*

▶ **Lemma 9.** *Let $k \geq 3$. Let G be a k-regular connected graph on n vertices, which contains a set C of $k+1$ vertices that induce a clique minus an edge uv. If C, u and v are given as input, then a k-degenerate decomposition of G can be found in $O(kn)$ time.*

Proof. Let x be a vertex in C distinct from u and v. Let G' be the graph obtained from G by deleting C. Each of u and v has exactly one neighbour that does not belong to C and all other vertices of C have no neighbours outside C. Let t be the neighbour of u not in C, and let w be the neighbour of v not in C. We may assume that t is distinct from w, otherwise we are done by Lemma 8. We can find a $(k-1)$-degenerate order $\mathcal{O}$ of G' in $O(kn)$ time by taking the vertices in the reverse of the order they are found in a breadth-first search from t, and then, if t and w do not belong to the same component of G', appending the vertices in the reverse of the order they are found in a breadth-first search from w. By Lemma 7, we can compute a k-degenerate decomposition (A, B) of G' in $O(kn)$ time such that $\mathcal{O}|_B$ is a $(k-2)$-degenerate order of B. If both t and w belong to B, let $A' = A \cup \{u, v\}$ and $B' = B \cup (C \setminus \{u, v\})$ and, since $(C \setminus \{u, v\})$ is a clique on $k-1$ vertices with no edge joining it to B, if follows that (A', B') is a k-degenerate decomposition of G. Assume now without loss of generality that $t \in A$ (we make no assumption about whether w is also in A). Then let $A' = A \cup \{x\}$ and $B' = B \cup (C \setminus \{x\})$. Then A' is an independent set. Recall that $\mathcal{O}|_B$ is a $(k-2)$-degenerate order of B. We show that we can append the vertices of $C \setminus \{x\}$ to obtain a $(k-2)$-degenerate order of B'. First add v, then the vertices of $C \setminus \{u, v, x\}$ and finally u. It is clear that no vertex has more than $k-2$ neighbours earlier in the order. ◀

▶ **Lemma 10.** *Let $k \geq 3$. Let G be a k-regular connected graph on n vertices containing a clique C on k vertices whose neighbourhood is of size 2. If C is given as input, a k-degenerate decomposition of G can be found in $O(kn)$ time.*

Proof. Let u and v be vertices not in C such that for each vertex in C, its unique neighbour not in C is either u or v. Neither u nor v can be adjacent to every vertex in C (as then the other would be adjacent to none, contradicting the premise that the neighbourhood has size 2). Since $k \geq 3$, one of u and v has at least two neighbours in C. Consider the

graph G' obtained from G by removing C and adding the edge uv (if it does not already exist). Note that u and v each have degree at most k in G' and at least one of them, say u, has degree less than k. Therefore, we can find a $(k-1)$-degenerate order $\mathcal{O}$ of G' in $O(kn)$ time by taking the vertices in the order they are found in a breadth-first search from u. Thus we can obtain a k-degenerate decomposition (A, B) of G' by Lemma 7, such that $\mathcal{O}|_B$ is a $(k-2)$-degenerate order of $G[B]$ and A is a maximal independent set. At least one of u and v must belong to B. Assume without loss of generality that either $v \in A$, $u \in B$ or both u and v belong to B, and, in the latter case, assume that u has at least two neighbours in C. Consider a neighbour t of u in C. We set $A' = A \cup \{t\}$ and $B' = B \cup (C \setminus \{t\})$, and claim that (A', B') is a k-degenerate decomposition of G. It is clear that A' is an independent set. Recall that $\mathcal{O}|_B$ is a $(k-2)$-degenerate order for $G[B]$. We must amend it to find a $(k-2)$-degenerate order for $G[B']$ that also includes the vertices of $C \setminus \{t\}$. We consider two cases.

First suppose $v \in A$. Then append to $\mathcal{O}|_B$ first the neighbours of u in $C \setminus \{t\}$ and then the neighbours of v. As the vertices of $C \setminus \{t\}$ are adjacent to t the only one that could have more than $k-2$ vertices before it in the order is the one that appears last, but this is also adjacent to v so we do indeed have a $(k-2)$-degenerate order.

Now suppose $v \in B$. Then u has a neighbour in G' that belongs to A (as A is a maximal independent set). Hence u has at most $k-2$ neighbours in B'. Append to $\mathcal{O}|_B$ the vertices of $C \setminus \{t\}$, ending with a neighbour of u (we know there is at least one), then move u to be the final vertex in the order. Again the only vertex of $C \setminus \{t\}$ that could have more than $k-2$ neighbours before it in the order is the one that appears last, and by choosing it to be a neighbour of u and putting u later in the order we ensure that a $(k-2)$-degenerate order is obtained. ◀

Given a graph G, five of its vertices t, u, v, w, x and a set of vertices C, we say that C induces a (u, v)-*lock with special vertices* $(t, \{w, x\})$ if $t, w, x \in C$ and $N(C) = \{u, v\}$, and both u and v are adjacent to t, each vertex in $\{w, x\}$ is adjacent to precisely one vertex in $\{u, v\}$, and $G[C]$ contains all possible edges except for wt and xt. We say that C is a *lock* if it is a (u, v)-*lock with special vertices* $(t, \{w, x\})$ for some choice of t, u, v, w, x.

▶ **Lemma 11.** *Let $k \geq 3$. Let G be a k-regular connected graph on n vertices containing a (u, v)-lock C with special vertices $(t, \{w, x\})$. If C and u, v, t, w, x are given as input, then a k-degenerate decomposition of G can be found in $O(kn)$ time.*

Proof. Since t has two neighbours outside C, it follows that $C \setminus \{t\}$ is a clique on k vertices. If w and x have the same neighbour in $\{u, v\}$, say u, then $N(C \setminus \{t\}) = \{t, u\}$ and so we are done by Lemma 10. We may therefore assume that w and x have distinct neighbours in $\{u, v\}$. Let G' be the graph obtained from G by deleting $C \setminus \{t\}$ and note that G' is connected since t is adjacent to both u and v. Note that both u and v have degree $k-1$ in G'. We can therefore find a $(k-1)$-degenerate order $\mathcal{O}$ of G' in $O(kn)$ time by taking the vertices in the reverse of the order they are found in a breadth-first search from u. Furthermore, since the only neighbours of t in G' are u and v, both of which have degree $k-1$, by moving t to the start of the order $\mathcal{O}$, we obtain a another $(k-1)$-degenerate order $\mathcal{O}'$. By Lemma 7, we can therefore find a k-degenerate decomposition (A, B) of G' such that $\mathcal{O}'|_B$ is a $(k-2)$-degenerate order on B and $t \in A$. Thus both u and v belong to B. We let $A' = A \cup \{w\}$ and $B' = B \cup (C \setminus \{w, t\})$, and claim that (A', B') is a k-degenerate decomposition of G. It is clear that A' is an independent set. We have the $(k-2)$-degenerate order $\mathcal{O}'|_B$ on B. We obtain a $(k-2)$-degenerate order on B' by appending to $\mathcal{O}'|_B$ the vertices of $C \setminus \{w, t\}$ beginning with x. Indeed, the only neighbour of x that is earlier in the

order is its single neighbour in $\{u, v\}$ (and note that $1 \leq k - 2$ since $k \geq 3$). Furthermore, since $w, t \in A'$, every vertex in $C \setminus \{w, t, x\}$ has only $k - 2$ neighbours in B'. ◀

A pair of non-adjacent vertices u, v in a graph is a *good* pair if u and v have a common neighbour. Note that if a good pair u, v is not strong, then $G \setminus \{u, v\}$ must be disconnected. We are now ready to state and prove the following result.

▶ **Theorem 12.** *Let $\Delta \geq 3$ and G be a graph on n vertices with maximum degree at most Δ. If no component of G is isomorphic to $K_{\Delta+1}$, then a Δ-degenerate decomposition of G can be found in $O(\Delta n^2)$ time.*

Proof. We may assume that G is connected, otherwise it can be considered componentwise. If G is not Δ-regular, then it has a vertex u of degree at most $\Delta - 1$, so we can find a $(\Delta - 1)$-degenerate order $\mathcal{O}$ of G in $O(kn)$ time by taking the vertices in the reverse of the order they are found in a breadth-first search from u. In this case, we are done by Lemma 7. For Δ-regular graphs, we use the procedure shown in Algorithm 1. (Whenever we apply one of the lemmas of this section, we set $k = \Delta$. We note in passing that if we could assume that G is biconnected, then we would immediately have, by [1, Lemma 3], that there is always a good pair u, v such that $G \setminus \{u, v\}$ is connected. As we cannot make this assumption however, we are not able to make use of this result.)

Let us make a few comments on this procedure. As G is regular, connected and not complete, we can initially choose any vertex as u and find another vertex v to form a good pair in $O(\Delta^2) = O(\Delta n)$ time. If we perform a breadth-first search (which takes $O(n+m) = O(\Delta n)$ time) from a neighbour of u that retreats from u or v whenever they are encountered, we discover a component of $G \setminus \{u, v\}$. If the component contains a common neighbour of u and v but is not equal to $G \setminus \{u, v\}$, we repeat starting from a neighbour of u or v that was not discovered. Thus we discover in $O(\Delta n)$ time that either u, v is a strong pair (if we find all components of $G \setminus \{u, v\}$ and they each contain a common neighbour of u and v), or that it is not. We set C to be one of the components of $G \setminus \{u, v\}$ arbitrarily. By Lemma 8, we therefore conclude that Lines 1 and 2 take $O(\Delta n)$ time. It is easy to check in $O(\Delta n)$ time whether we apply Lemmas 9–11 on Lines 3–5 and applying these lemmas takes $O(\Delta n)$

in each case. Now suppose that we do not apply any of these lemmas, in which case we reach Line 7. We will show that we can find u', v' and, if necessary, C' in $O(\Delta n)$ time. If we find u', v' such that $C' = G \setminus \{u', v'\}$ is connected, then u', v' is a strong pair, so after executing Line 9, the algorithm will stop on Line 2. In all other cases C' will be strictly smaller than C. This means that we apply Line 9 at most $O(n)$ times, implying that we execute Lines 2–9 at most $O(n)$ times. This will give an overall running time of $O(\Delta n^2)$. It remains to show that if execution reaches Line 7 then we can find the required good pair u', v' and the component C' in $O(\Delta n)$ time.

Let us first show that C contains good pairs — that is, that it is not a clique. If C is a clique, then it contains either $\Delta - 1$ or Δ vertices (as each vertex has degree Δ in G and the only other possible neighbours of vertices in C are u and v). If C has $\Delta - 1$ vertices, then each vertex of C must be adjacent to both u and v and we would have applied Lemma 9 on Line 3, a contradiction. If C has Δ vertices, then each vertex of C is adjacent to exactly one of u and v (and neither u nor v can be adjacent to every vertex in C, as this would form a $K_{\Delta+1}$, contradicting the fact that G is connected), in which case we would have applied Lemma 10 on Line 4, a contradiction. Therefore we may assume that C is not a clique.

We need describe how to choose a good pair u', v' in C. If we can show that u and v are in the same component of $G \setminus \{u', v'\}$ (which must necessarily contain all of $G \setminus C$), then we are done as either $G \setminus \{u', v'\}$ is connected or there is another component C' of $G \setminus \{u', v'\}$ which must be contained in C (and note that in this case C' can be found in $O(\Delta n)$ time using breadth-first search).

If u and v have a common neighbour outside C or at least three common neighbours in C, then any good pair in C can be chosen as u', v' (as u and v will then be in the same component of $G \setminus \{u', v'\}$). If u and v have exactly two common neighbours t_1, t_2 that both belong to C, then any good pair other than t_1, t_2 can be chosen as u', v'. If t_1, t_2 is the only good pair in C (so all other vertices in C are adjacent), then C is a clique minus an edge and must contain Δ vertices (t_1, t_2 and the $\Delta - 2$ neighbours of t_1 that are not in $\{u, v\}$). Considering degree, any vertex in C other than t_1 or t_2 must be adjacent to exactly one of u and v. If every vertex in $C \setminus \{t_1, t_2\}$ is adjacent to, say u, then $C \cup \{u\}$ is a clique on $\Delta + 1$ vertices minus an edge and we would have applied Lemma 9 on Line 3, a contradiction. We may therefore assume that at least one vertex in $C \setminus \{t_1, t_2\}$ is adjacent to u and at least one is adjacent to v, so there is a path from u to v avoiding t_1 and t_2, and $G \setminus \{t_1, t_2\}$ is connected, so we are done.

Finally, suppose that u and v have exactly one common neighbour t that belongs to C. Then any good pair not including t can be chosen as u', v', as then u and v will be in the same component of $G \setminus \{u', v'\}$. Suppose, for contradiction, that no such pair exists. Then $C \setminus \{t\}$ is a clique. The vertex t has $\Delta - 2$ neighbours in $C \setminus \{t\}$. Since $\Delta \geq 3$, let z be one of those neighbours. Since t is the only common neighbour of u and v, we have that z can only be adjacent to at most one of u and v. Therefore, t has a neighbour non-adjacent to z, so z must have a neighbour non-adjacent to t, which we denote w. As w is also adjacent to at most one of u and v, it also has a neighbour x that is a non-neighbour of t (and cannot be t itself). So $C \setminus \{t\}$ contains at least Δ vertices: the $\Delta - 2$ neighbours of t plus w and x. As $C \setminus \{t\}$ induces a clique, it must have exactly Δ vertices, since G cannot contain a $K_{\Delta+1}$. Thus the set C forms a lock, and so we would have applied Lemma 11 on Line 5. This contradiction completes the proof. ◀

We note that Theorems 2 and 12 concern decompositions (A, B) of the vertex set of a graph where A is independent and B induces a $(\Delta - 2)$-degenerate graph. As B therefore cannot be a clique on Δ vertices, we have the following corollary.

▶ **Corollary 13.** *Let $\Delta \geq 3$ and G be a graph on n vertices with maximum degree at most Δ. If the clique number of G is at most Δ, a decomposition of the vertices of G into sets A and B, where A is an independent set and B induces a graph that has clique number at most $\Delta - 1$, can be found in $O(n)$ time if $\Delta = 3$ and $O(\Delta n^2)$ time for all Δ.*

Catlin [8] proved that such decompositions exist, but his result did not imply the existence of a polynomial-time algorithm to find the decomposition. We note that his result contains the additional claim that A is maximum; we cannot hope for an algorithmic version, as this would solve the NP-hard problem of finding a maximum independent set in a cubic graph [15].

5 Reconfigurations of Vertex Colourings

Our interest in Stable($\mathcal{D}_k$) when $k \geq 2$ case stems from an open problem in the area of graph reconfigurations. For a graph G and integer $k \geq 1$, the k-colouring reconfiguration graph $R_k(G)$ has the vertex set consisting all possible k-colourings of G and two vertices of $R_k(G)$ are adjacent if and only if the corresponding k-colourings differ on exactly one vertex. A central problem in the area of reconfiguration is the Reachability problem. In the context of k-colourings, this is the problem of finding a path (if one exists) in $R_k(G)$ between two given k-colourings α and β of a graph G. The complexity of this problem has been studied for graphs G with maximum degree Δ and any positive integer k. This problem is PSPACE-hard for $k \geq 4$, $\Delta \geq k$ [3], solvable in $O(n + m)$ time on (general) graphs with n vertices and m edges for $k \leq 3$ [18] and solvable in $O(n^2)$ time for $k \geq 4$, $0 \leq \Delta \leq k - 2$ [10]. This leaves us with the case $k \geq 4$, $\Delta = k - 1$. In [14, Theorem 6], three of the authors of the current paper showed that this case can be solved in polynomial time as long as the input graph G is not Δ-regular, that is, if not all vertices in G have maximum degree Δ. The case where G is Δ-regular was left as an open problem, but using Theorem 12 we can now resolve it by giving an $O(n^2)$-time algorithm (assuming Δ is fixed and not part of the input).

▶ **Theorem 14.** *Fix $\Delta \geq 0$. Let G be a connected graph on n vertices with maximum degree Δ. The problem of finding a path (if one exists) between two k-colourings α and β in $R_k(G)$ is*

- *$O(n)$-time solvable if $1 \leq k \leq 3$;*
- *$O(n^2)$-time solvable if $k \geq 4$ and $0 \leq \Delta \leq k - 1$;*
- PSPACE*-hard if $k \geq 4$ and $\Delta \geq k$.*

6 Future Work

As well as showing that the problem of recognizing near-bipartite graphs of diameter 3 is NP-complete, we have proven that for every integer $\Delta \geq 3$, the Stable($\mathcal{D}_{\Delta-2}$) problem is polynomial-time solvable on graphs of maximum degree Δ. Is Stable($\mathcal{D}_{\Delta-2}$) NP-complete for graphs of maximum degree $\Delta + 1$? Recall that this is known to be the case for $\Delta = 3$, as proven by Yang and Yuan [29]. Their proof can easily be adapted to prove that Stable($\mathcal{D}_{\Delta-2}$) is NP-complete for graphs of maximum degree $2\Delta - 2$ for every $\Delta \geq 4$.

Abstract

In this paper, we study the NP-complete *colorful* variant of the classical Matching problem, namely, the Rainbow Matching problem. Given an edge-colored graph G and a positive integer k, this problem asks whether there exists a matching of size at least k such that all the edges in the matching have distinct colors. We first develop a deterministic algorithm that solves Rainbow Matching on paths in time $\mathcal{O}^\star(\left(\frac{1+\sqrt{5}}{2}\right)^k)$ and polynomial space. This algorithm is based on a curious combination of the method of bounded search trees and a "divide-and-conquer-like" approach, where the branching process is guided by the maintenance of an auxiliary bipartite graph where one side captures "divided-and-conquered" pieces of the path. Our second result is a randomized algorithm that solves Rainbow Matching on general graphs in time $\mathcal{O}^\star(2^k)$ and polynomial-space. Here, we show how a result by Björklund et al. [JCSS, 2017] can be invoked as a black box, wrapped by a probability-based analysis tailored to our problem. We also complement our two main results by designing kernels for Rainbow Matching on general and bounded-degree graphs.

1 Introduction

The classical notion of matching has been extensively studied for several decades in the area of Combinatorial Optimization [6, 14]. Given an undirected graph G, a set of edges is called a *matching* if the edges are pairwise non-adjacent. That is, no two edges share a common vertex. In the Maximum Matching problem, the objective is to find a matching of maximum size. The first polynomial time algorithm for Maximum Matching was given by Edmonds [6] in his classic paper *Paths, Trees and Flowers*. It is important to remark that this is the paper which underlined the importance of study of polynomial time algorithms for the first time. After a series of improvements, the current fastest algorithm for Maximum Matching was given by Micali and Vazirani and it runs in time $\mathcal{O}(m\sqrt{n})$ [15]. However, finding a matching that satisfies some additional constraints often immediately becomes NP-complete, where three notable examples are Minimum Maximal Matching [18], Induced

Matching [17] and Multiple Choice Matching [11]. In this paper, we study the NP-hard variant of Maximum Matching called Multiple Choice Matching from the viewpoint of parameterized complexity.

The Multiple Choice Matching problem, also called Rainbow Matching, is one of the NP-hard variant of Maximum Matching mentioned in the classical book by Garey and Johnson [9, Problem GT55]. In this work, we will stick to the name Rainbow Matching. This problem is formally defined as follows.

Rainbow Matching	**Parameter:** k
Input: An undirected graph G, a coloring function $\chi : E(G) \to \{1, \ldots, q\}$ and a positive integer k.	
Question: Does there exist a matching of size at least k such that all the edges in the matching have distinct colors?	

A matching where all the edges have distinct colors will be called *colorful matching*. Itai et al. [11] showed, already in 1978, that Rainbow Matching is NP-complete on (edge-colored) bipartite graphs. Close to three decades later, Le and Pfender [13] revisited the computational complexity of this problem. Specifically, they showed that the Rainbow Matching problem is NP-complete even on (edge-colored) paths, complete graphs, P_8-free trees in which every color is used at most twice, P_5-free linear forests in which every color is used at most twice, and P_4-free bipartite graphs in which every color is used at most twice. In this paper, we consider this problem from the parameterized rather than classical complexity perspective.

A *parameterization* of a problem is the association of an integer k with each input instance, which results in a *parameterized problem*. For our purposes, we need to recall three central notions that define the parameterized complexity of a parameterized problem. The first one is the notion of a *kernel*. Here, a parameterized problem is said to admit a *kernel* of size $f(k)$ for some function f that depends *only* on k if there exists a polynomial-time algorithm, called a *kernelization algorithm*, that translates any input instance into an equivalent instance of the same problem whose size is bounded by $f(k)$ and such that the value of the parameter does not increase. In case the function f is polynomial in k, the problem is said to admit a *polynomial kernel*. Hence, kernelization is a mathematical concept that aims to analyze the power of preprocessing procedures in a formal, rigorous manner. The second notion that we use is the one of *fixed-parameter tractability (FPT)*. Here, a parameterized problem Π is said to be FPT if there is an algorithm that solves it in time $f(k) \cdot |I|^{\mathcal{O}(1)}$, where $|I|$ is the size of the input and f is a function that depends only on k. Such an algorithm is called a *parameterized algorithm*. In other words, the notion of FPT signifies that it is not necessary for the combinatorial explosion in the running time of an algorithm for Π to depend on the input size, but it can be confined to the parameter k. Finally, we recall that Parameterized Complexity also provides tools to refute the existence of polynomial kernels and parameterized algorithms for certain problems (under plausible complexity-theoretic assumptions). We refer the reader to the books [3, 5] for more information on these notions in particular, and on Parameterized Complexity in general. The notation $\mathcal{O}^\star(\cdot)$ is used to hide factors polynomial in the input size.

1.1 Our Contribution

Our starting point is the FPT algorithm mentioned in the article of Le and Pfender [13]. This algorithm is based on the connection between Rainbow Matching and 3-Set Packing. In the 3-Set Packing problem, we are given a universe U, a set family $\mathcal{F}$ consisting of subsets

of U of size at most 3 and an integer k, and the objective is to check whether there exists a subfamily $\mathcal{F}' \subseteq \mathcal{F}$ containing at least k pairwise-disjoint sets. Observe that given an instance $I = (G, \chi, k)$ of Rainbow Matching, we can view I as an instance of 3-Set Packing by setting $U = V(G) \cup \{1, \ldots, q\}$, and letting $\mathcal{F}$ contain every set $\{u, v, \chi(e)\}$ corresponding to an edge $e = uv \in E(G)$. Now, observe that (G, χ, k) is a yes-instance of Rainbow Matching if and only if $(U, \mathcal{F}, k)$ is a yes-instance of 3-Set Packing. This immediately implies that known algorithms for 3-Set Packing can be employed to solve Rainbow Matching. In particular, using the known algorithms for 3-Set Packing, we obtain the following algorithms for Rainbow Matching: (1) a deterministic algorithm running in time $\mathcal{O}^\star(8.097^k)$ [19]; (2) a randomized algorithm running in time $\mathcal{O}^\star(1.4953^{3k}) = \mathcal{O}^\star(3.3434^k)$ [2].

Rainbow Matching on Paths. Our first contribution concerns the Rainbow Matching problem on paths. We obtain the following algorithm, which is faster than the one that we design later for general graphs.

▶ **Theorem 1.** *There exists a deterministic algorithm for* Rainbow Matching *on paths that runs in time* $\mathcal{O}^\star\left(\left(\frac{1+\sqrt{5}}{2}\right)^k\right)$ *and uses polynomial space.*

The proof of Theorem 1 is based on a combination of the classical method of bounded search trees [3, 5, 7, 8] together with a "divide-and-conquer-like" approach. The algorithm always maintains a family of vertex-disjoint paths $\mathcal{S}$, and the objective is to find a colorful matching of size k that uses exactly one edge from each path in $\mathcal{S}$ and $k - |\mathcal{S}|$ edges from P. We call this variant of Rainbow Matching the Disjoint Set Rainbow Matching problem. Observe that when $\mathcal{S} = \emptyset$, then Disjoint Set Rainbow Matching is precisely Rainbow Matching. To compactly represent potential partial solutions to our problem at every step of the recursion, that is, partial witnesses that there may indeed exist a colorful matching that uses exactly one edge from each path in $\mathcal{S}$, our algorithm works as follows. The algorithm uses an auxiliary bipartite graph where we maintain a partial solution to our problem, in terms of a matching in this bipartite graph. This has the additional benefit that the measure becomes very simple: we just measure the size left to cover, *i.e.* $k - t$, where $t = |\mathcal{S}|$ denotes the size of the partial solution. (We remark that we are able to construct a solution in the same time as it takes to solve the decision version of the Disjoint Set Rainbow Matching problem.)

Rainbow Matching on General Graphs. Our second contribution is an algorithm on general graphs that is better than the known algorithms for 3-Set Packing. In particular, we obtain the following result.

▶ **Theorem 2.** *There exists a randomized algorithm for* Rainbow Matching *with constant, one-sided error that runs in time* $\mathcal{O}^\star(2^k)$ *and uses polynomial space.*[1]

The proof of Theorem 2 is based on the general method described in [2] for solving various packing and matching problems. We tailor the analysis of Bjorklund et al. [2] to the Rainbow Matching problem. This gives us the desired saving over the algorithm for 3-Set Packing.

[1] Specifically, if the algorithm determines that an input instance is a yes-instance, then this answer is necessarily correct.

Kernelization. Finally, we turn to consider the question of kernelization. Here, we exploit the connection between our problem and 3-Set Packing to design a kernelization algorithm. We also design a smaller kernel for Rainbow Matching on paths, or more generally, for graphs of bounded degree.

▶ **Theorem 3.** Rainbow Matching *admits a kernel of size* $\mathcal{O}(k^3)$ *on general graphs. Moreover, it admits a kernel of size* $\mathcal{O}(dk^2)$ *on graphs of maximum degree* d*.*

1.2 Related Work

Le and Pfender [13] gave a factor $(\frac{2}{3} - \epsilon)$ approximation algorithm for Rainbow Matching on general graphs for every $\epsilon > 0$. They also designed a few polynomial time algorithms when the instances of Rainbow Matching are restricted to special graph classes. As stated before, Le and Pfender [13] also related this problem to 3-Set Packing, and showed that the problem is FPT. Moreover, they showed that the problem is FPT on P_5 free forests parameterized by the number of components. Colorful matchings have also been studied from graph theoretic and combinatorial perspectives. For example, they are related to Ryser's famous conjecture regarding Latin transversal [16]. In the language of colorful matchings, the conjecture says that every proper edge coloring of the complete bipartite graph $K_{2n+1,2n+1}$ with $2n + 1$ colors contains a rainbow matching with $2n + 1$ edges. Additional examples are studies of sufficient conditions for edge-colored graphs to guarantee the existence a colorful matching of a certain size. Moreover, previous studied also examined what is the size of the largest colorful matching in an edge-colored graph with additional restrictions. For more information on these topics, we refer to [13] and references therein. Finally, let us mention that colorful matchings belong to a family of problems called rainbow subgraph problems. A *rainbow subgraph* of an edge-colored graph is a subgraph whose edges have distinct colors. We refer to [12] for a survey containing results and questions regarding rainbow subgraps.

1.3 Preliminaries

Let $[n]$ denote the set $\{1, \ldots, n\}$. For a graph G, we let $V(G)$ and $E(G)$ denote its vertex set and its edge set, respectively. For two vertices $u, v \in V(G)$, we use uv to denote an edge between u and v.

Reduction Rule. To design our kernelization algorithm, we rely on the notion of a *reduction rule*. A reduction rule is a polynomial-time procedure that replaces an instance $(\mathcal{I}, k)$ of a parameterized problem Π (where k is the parameter) by a new instance $(\mathcal{I}', k')$ of Π. The rule is said to be *safe* if $(\mathcal{I}, k)$ is a yes-instance if and only if $(\mathcal{I}', k')$ is a yes-instance. As customary in the field we allow reduction rule to return the answer yes or the answer no (see [3, 5]).

2 Algorithm for Rainbow Matching on Paths

In this section we give a deterministic algorithm for Rainbow Matching on paths that is faster than the algorithm we will present for Rainbow Matching on general graphs in the next section. Towards that we will solve the following general problem, and from there solve Rainbow Matching in paths.

Disjoint Set Rainbow Matching	**Parameter:** k
Input: A path P with edge coloring $\chi : E(G) \to [q]$, a collection $\mathcal{S}$ of (vertex disjoint) paths (vertex disjoint from P) of arbitrary lengths, and a positive integer k.	
Question: Does there exist a colorful matching of size k that uses exactly one edge from each path in $\mathcal{S}$ and $k - \lvert\mathcal{S}\rvert$ edges from P?	

Note that Rainbow Matching is a special case of Disjoint Set Rainbow Matching, where P is the input graph (a path), $\mathcal{S} = \emptyset$ and k is the parameter. Thus, solving Disjoint Set Rainbow Matching will yield an algorithm for Rainbow Matching.

Overview. To solve Disjoint Set Rainbow Matching, whenever possible we apply reduction rules, or solve the instance in polynomial time. In the absence of either of these, the algorithm branches on an edge, based on whether it is part of the solution or not.

Measure. We associate the measure $\mu(P, \mathcal{S}, k) = k - |\mathcal{S}|$ to the instance $(P, \mathcal{S}, k)$. We will use this measure to bound the number of nodes in the search tree. When the instance is clear from the context, we will simply use μ.

Auxiliary bipartite graph. At every step of the search we maintain a bipartite graph $\mathcal{B}(\mathcal{S})$ on the vertex set $([q], \mathcal{S})$ and edge set containing pairs $cP' \in [q] \times \mathcal{S}$ such that color c appears on an edge in the path P' in (the collection) $\mathcal{S}$.

We first prove a lemma which allows us to solve the Disjoint Set Rainbow Matching problem when the measure is at most one.

▶ **Lemma 4.** *If $\mu(P, \mathcal{S}, k) \leq 1$, then we can test if $(P, \mathcal{S}, k)$ is a yes-instance in polynomial time.*

Proof. We divide the proof based on whether $\mu(P, \mathcal{S}, k) < 0$ or $\mu(P, \mathcal{S}, k) = 0$ or $\mu(P, \mathcal{S}, k) = 1$. If $\mu(P, \mathcal{S}, \mathcal{C}, k) < 0$, then $k < |\mathcal{S}|$ and so clearly no matching of size k can exist which chooses exactly one edge from each path in $\mathcal{S}$.

If $\mu(P, \mathcal{S}, k) = 0$, then $k = |\mathcal{S}|$. Let $Q_1, \ldots, Q_k$ denote the paths in $\mathcal{S}$. We will show that there exists a colorful matching of size k that uses exactly one edge from each path in $\mathcal{S}$ if and only if there is a matching in $\mathcal{B}(\mathcal{S})$ that saturates $\mathcal{S}$. Let $\mathcal{M}$ be a colorful matching of size k that uses exactly one edge from each path in $\mathcal{S}$. Furthermore, for each i $(1 \leq i \leq k)$ let $m_i \in \mathcal{M}$ be the edge that is part of path Q_i. Then $\{\chi(m_i)Q_i \mid i \in [k]\}$ forms a matching that saturates $\mathcal{S}$ in $\mathcal{B}(\mathcal{S})$. In the reverse direction given a matching $\mathcal{M}'$ in $\mathcal{B}(\mathcal{S})$ that saturates $\mathcal{S}$, we obtain a colorful matching $\mathcal{M}$ that uses exactly one edge from each path Q_i in $\mathcal{S}$, as follows. Since $\mathcal{M}'$ saturates $\mathcal{S}$ we have that for every path $Q_i \in \mathcal{S}$ there is an edge jQ_i for some $j \in [q]$. This implies that there is an edge, say m_i on Q_i such that $\chi(m_i) = j$, *i.e.* m_i has color j. Since, the paths in $\mathcal{S}$ are pairwise vertex disjoint, the set $\mathcal{M}^\star = \{m_i \mid i \in [k]\}$ forms a matching in the graph P. Recall that $\mathcal{M}'$ is a matching in $\mathcal{B}(\mathcal{S})$ in which one of the endpoints of the edges are from the set $[q]$, thus, it follows that $\mathcal{M}^\star$ is a colorful matching of size k that uses exactly one edge from each path in $\mathcal{S}$. Thus, implying that in this case we can check whether or not $(P, \mathcal{S}, k)$ is a yes-instance in polynomial time by checking if the bipartite graph $\mathcal{B}(\mathcal{S})$ has a matching that saturates $\mathcal{S}$ [10].

If $\mu(P, \mathcal{S}, k) = 1$, then $k = |\mathcal{S}| + 1$. In this case, we consider every edge $e = uv$ on P. Let us now consider a specific iteration concerning an edge $e = uv$ on P. Then, we construct $\mathcal{B}(\mathcal{S} \cup \{uv\})$. Similar to the case of $\mu(P, \mathcal{S} \cup \{uv\}), k) = 0$, we have now reduced the problem into checking whether or not, there is a matching in $\mathcal{B}(\mathcal{S} \cup \{uv\}))$ that saturates $\mathcal{S} \cup \{uv\}$.

This condition can be tested in polynomial time. If in at least one iteration, we found a saturating matching then we have a yes-instance, and otherwise we have no-instance. This completes the proof. ◀

Lemma 4 yields the following reduction rule.

▶ **Reduction Rule 5.** *If $\mu(P, \mathcal{S}, k) \leq 1$, then using Lemma 4 test whether or not $(P, \mathcal{S}, k)$ is a yes-instance. If Lemma 4 returns yes, then return that $(P, \mathcal{S}, k)$ is a yes-instance; else, return that $(P, \mathcal{S}, k)$ is a no-instance.*

The safeness of Reduction Rule 5 follows from Lemma 4. The next reduction rule allows us to identify a prefix of the path P such that there exists a colorful matching of size at least k that contains *exactly* one edge from the prefix.

▶ **Reduction Rule 6.** *In the instance $(P, \mathcal{S}, k)$, let $P = v_1, v_2, \ldots, v_{n-1}, v_n$. Suppose that for every index $i \in [n-1]$ the following property is true: when the subpaths $P_{i-1} = v_1, \ldots, v_{i-1}$ and $P' = v_i, v_{i+1}$ of P are added to $\mathcal{S}$, the size of a maximum matching in the new bipartite graph $\mathcal{B}(\mathcal{S} \cup \{P_{i-1}, P'\})$ (obtained after the addition of P_{i-1} and P' to $\mathcal{S}$, and suitable edges) is at most $|\mathcal{S}| + 1$. Then, return that $(P, \mathcal{S}, \mathcal{C}, k)$ is a no-instance.*

Next we show that the correctness of Reduction Rule 6.

▶ **Lemma 7.** *Reduction Rule 6 is safe.*

Proof. For the sake of contradiction, we assume that $(P, \mathcal{S}, k)$ is a yes-instance. In this case we will show that there exists an index $i \in [n-1]$ with the following property: when the subpaths $P_{i-1} = v_1, \ldots, v_{i-1}$ and $P' = v_i, v_{i+1}$ of P are added to $\mathcal{S}$, the size of a maximum matching in the new bipartite graph $\mathcal{B}(\mathcal{S} \cup \{P_{i-1}, P'\})$ is $|\mathcal{S}| + 2$. This will be contradiction, and thereby prove the lemma.

Since $(P, \mathcal{S}, k)$ is a yes-instance there exists a colorful matching of size k, denoted by $\mathcal{M}$, that uses k colors from $[q]$, exactly one edge from each path in $\mathcal{S}$, and $k - |\mathcal{S}|$ edges from P. Thus, there is a maximum matching in the bipartite graph on $\mathcal{B}(\mathcal{S})$ that saturates every vertex in the $\mathcal{S}$-side. It is obtained by taking edges that connect a vertex in the $\mathcal{S}$-side (*i.e.* a path in the collection $\mathcal{S}$) with the color that appears on the matching edge in $\mathcal{M}$ that is part of the same path. We use $\mathcal{M}'$ to denote this bipartite matching.

Let $\{e_{j_1}, e_{j_2}, \ldots, e_{j_{k-|\mathcal{S}|}}\}$ denote the matching edges in $\mathcal{M}$ as they appear left to right in P. For some $i \geq 3$, let $v_i v_{i+1}$ denote the edge e_{j_2} (the matching edge with the second smallest index in P). It follows that edge e_{j_1} appears in the subpath $P_{i-1} = v_1, \ldots, v_{i-1}$. Note that the vertex $\chi(e_{j_2}) \in [q]$ is not saturated by $\mathcal{M}'$ in $\mathcal{B}$ because e_{j_2} is part of the matching $\mathcal{M}$ while it is inside P. Similarly, the vertex $\chi(e_{j_1}) \in [q]$ is also not saturated by $\mathcal{M}'$ in $\mathcal{B}$. Hence, when paths P_{i-1} and P' are added to the bipartite graph, $\mathcal{M}'$ can be extended by exactly two more edges: edges between $\chi(e_{j_1})$ and P_{i-1} and $\chi(e_{j_2})$ and P'. Thus, the new bipartite graph has a matching of size $|\mathcal{S}| + 2$. ◀

The safeness of Reduction Rule 6, leads us to the following conclusion.

▶ **Lemma 8.** *If $(P, \mathcal{S}, k)$ is a yes-instance on which Reduction Rules 5 and 6 are not applicable, then there exists an index $i \in [n-1]$ such that there exists a colorful matching of size k that uses exactly one edge from the subpath $P_i = v_1, \ldots, v_i$ of P. Furthermore, such an index i can be found in polynomial time.*

Proof. Since Reduction Rules 5 and 6 are not applicable we have that $\mu(P, \mathcal{S}, k) \geq 2$. This implies that $k \geq |\mathcal{S}| + 2$. Let i denote the *smallest* integer in $[n-1]$ for which the following holds:

Property ($\star\star$) when the subpaths $P_{i-1} = v_1, \ldots, v_{i-1}$ and $P' = v_i, v_{i+1}$ of P are added to $\mathcal{M}$, the size of a maximum matching in the new bipartite graph $\mathcal{B}(\mathcal{S} \cup \{P_{i-1}, P'\})$ (obtained after the addition of P_{i-1} and P' to $\mathcal{S}$, and suitable edges) is $|\mathcal{S}| + 2$.

Observe that since $k \geq |\mathcal{S}| + 2 \geq 2$, such an integer i must exist.

Note that any colorful matching of size k uses at most *one* edge from P_i, else, it contradicts the fact that i is the smallest integer that satisfies Property ($\star\star$). Also note that since we have a colorful matching of size at least 2 in P_{i+1}, so $i \geq 3$. However, since there always exists a colorful matching of size k that uses one of the first two edges of the path P; hence, the matching must use one of the edges on P_i. This implies that there exists a colorful matching of size k that uses exactly one edge on P_i. Clearly, we can find the smallest integer described in the statement of the lemma in polynomial time. This concludes the proof. ◀

Lemma 8 yields a branching rule that can be described as follows. Let P_i be the subpath of P (given by Lemma 8) such that there exists a colorful matching of size k that uses exactly one edge from it. We recursively solve two subproblems one where we assume that edge v_iv_{i+1} is in the colorful matching of size k we are constructing, and the other where we assume that edge v_iv_{i+1} is not part of the solution we are constructing. Note that this rule is exhaustive because an edge (in particular, v_iv_{i+1}) can either belong to a matching, or it does not.

Algorithm. Now we can describe the branching rule in details along with the recursive call to a subproblem. Let $\mathcal{I} = (P = v_1, \ldots, v_n, \mathcal{S}, k)$ be the instance of Disjoint Set Rainbow Matching, where none of the Reduction Rules 5 or 6 are applicable. Let P_i be the subpath of P as described in Lemma 8.

Branch 1: (**The edge v_iv_{i+1} belongs to a colorful matching of size k.**)
We recursively solve the problem on the instance $(P \setminus \{v_1, \ldots, v_{i+1}\}, \mathcal{S} \cup \{P_{i-1}\} \cup \{[v_iv_{i+1}]\}, k)$. Since the size of $\mathcal{S}$ increases by 2, the measure μ decreases by 2. Observe that by Lemma 8 we know that there exists a colorful matching of size k that uses exactly one edge from the subpath P_i. However, since we have assumed that the edge v_iv_{i+1} belongs to the colorful matching of size k, thus, edge $v_{i-1}v_i$ cannot be part of the same matching, and so one of the edges in P_{i-1} must be part of the matching as well. Thus, in this case we know that two of the edges in our matching are due to the edge v_iv_{i+1} and the other is from P_{i-1}.

Branch 2: (**The edge v_iv_{i+1} does not belong to a colorful matching of size k.**)
In this case we recursively solve the problem on $(P \setminus \{v_1, \ldots, v_i\}, \mathcal{S} \cup \{P_i\}, k)$. Since the size of $\mathcal{S}$ increases by 1 and k remains the same, the measure μ decreases by 1. The correctness of this step follows from Lemma 8.

If either of the branches returns "yes", we return the same. Else, we return that the given instance is a no-instance.

The resulting branching vector for this algorithm is $(2, 1)$. Thus, solving the polynomial $x^2 \geq x + 1$ for a positive root yields $x \geq \frac{1}{2}(1 + \sqrt{5}) = 1.6181$. This upper bounds the running time of our algorithm. The correctness of the algorithm follows from Lemmas 4, 7 and 8.

Recall that as explained at the very onset of our discussion: Since Rainbow Matching is a special case of Disjoint Set Rainbow Matching, hence our algorithm can solve Rainbow Matching by using the algorithm for the latter on the instance $(G, \mathcal{S} = \emptyset, k)$. This completes the proof of Theorem 1.

3 FPT Algorithm for Rainbow Matching on General Graphs

This section is inspired by the proof of Theorem 4 in [2], which solves 3-Set Packing in time $\mathcal{O}^\star(3.3434^k)$. We show that by an analysis tailored to Rainbow Matching, we improve upon the time complexity $\mathcal{O}^\star(3.3434^k)$. More precisely, the objective of this section is to prove Theorem 2.

Towards the proof of Theorem 2, we need to consider a problem called 3-Set Prepacking, which was introduced in [2]. The input of this problem consists of an n-element universe U, an n_1-element subuniverse $U_1 \subseteq U$, a family $\mathcal{F}$ of 3-sets, a positive integer k, and three non-negative integers p_0, p_1 and p_2 whose sum is k. The task is to determine whether there exists a subfamily $\mathcal{F}' \subseteq \mathcal{F}$ of size k such that the 3-sets in $\mathcal{F}'$ are pairwise-disjoint, and for all $i \in \{0,1,2\}$, there exist exactly p_i sets S in $\mathcal{F}'$ such that $|S \cap U_1| = i$. We would need to rely on the following result.

▶ **Proposition 9.** *There exists a randomized algorithm for* 3-Set Prepacking *with constant, one-sided error that runs in time* $\mathcal{O}^\star(2^{3p_0+2p_1+p_2})$ *and uses polynomial space. Specifically, if the algorithm determines that an input instance is a yes-instance, then this answer is necessarily correct.*

Let us denote the algorithm given by Proposition 9 by PrepackAlg. We present a reduction from our problem to 3-Set Prepacking. For this purpose, we describe a procedure Reduce that given an instance $(G, \chi : V(G) \to [q], k)$ of Rainbow Matching, constructs an instance $\text{reduce}(G, \chi, k) = (U, U_1, \mathcal{F}, k, p_0, p_1, p_2)$ of 3-Set Prepacking with the same parameter k. Let us denote $n_1 = |V(G)| = n - q$, where n would denote $|U|$. First, Reduce sets $U = V(G) \cup [q]$, $\mathcal{F} = \{\{u, v, \chi(uv)\} : uv \in E(G)\}$, $p_0 = 0$, $p_1 = 0$ and $p_2 = k$. Second, Reduce sets $U_1 = V(G)$. Let us now argue that we obtain an equivalent instance.

▶ **Lemma 10.** *Let* $(G, \chi : V(G) \to [q], k)$ *be an instance of* Rainbow Matching*. Then,* $\text{reduce}(G, \chi, k) = (U, U_1, \mathcal{F}, k, p_0, p_1, p_2)$ *is a yes-instance of* 3-Set Prepacking *if and only if* $(G, \chi : V(G) \to [q], k)$ *is a yes-instance of* Rainbow Matching*.*

Proof. In the first direction suppose that $\text{reduce}(G, \chi, k) = (U, U_1, \mathcal{F}, k, p_0, p_1, p_2)$ is a yes-instance of 3-Set Prepacking. In particular, we then have that there exists a subfamily $\mathcal{F}' \subseteq \mathcal{F}$ of size k such that the 3-sets in $\mathcal{F}'$ are pairwise-disjoint. Let us denote $\mathcal{M} = \{uv \in E(G) : \exists S \in \mathcal{F}' \text{ s.t. } \{u, v\} \subseteq S\}$. Since $|\mathcal{F}'| = k$, we have that $|\mathcal{M}| = k$, and since the 3-sets in $\mathcal{F}'$ are pairwise-disjoint, we have that $\mathcal{M}$ is a colorful matching. Thus, $(G, \chi : V(G) \to [q], k)$ is a yes-instance of Rainbow Matching.

In the other direction suppose $(G, \chi : V(G) \to [q], k)$ is a yes-instance of Rainbow Matching. Then there exists a colorful matching $\mathcal{M}$ of size k. Let us denote $\mathcal{F}' = \{\{u, v, \chi(uv)\} | \ uv \in \mathcal{M}\}$. Since the size of $\mathcal{M}$ is k, we have that the size of $\mathcal{F}'$ is k and since $\mathcal{M}$ is a colorful matching we have that the sets in $\mathcal{F}'$ are pairwise disjoint. Notice that every set in $\mathcal{F}'$ exactly two elements from U_1. Therefore, for all $i \in \{0,1,2\}$, there exist exactly p_i sets S in $\mathcal{F}'$ such that $|S \cap U_1| = i$. Thus, $(U, U_1, \mathcal{F}, k, p_0, p_1, p_2)$ is a yes-instance of 3-Set Prepacking. ◀

Let us now prove Theorem 2.

Proof of Theorem 2. Given an instance $(G, \chi : V(G) \to [q], k)$ of Rainbow Matching, we construct the instance $\text{reduce}(G, \chi, k) = (U, U_1, \mathcal{F}, k, p_0, p_1, p_2)$ of 3-Set Prepacking. Then, we run the algorithm given by Proposition 9. We accept if and only if the algorithm from Proposition 9 accepted. The correctness follows from Proposition 9 and Lemma 10. Since, $p_0 = p_1 = 0$ and $p_2 = k$, by Proposition 9, the total running time is $\mathcal{O}^\star(2^k)$. ◀

4 Kernelization Algorithms

In this section we give a proof for Theorem 3. We first describe a kernel on general graphs. The kernelization algorithm on general graphs is actually a known kernel for 3-Set Packing given in [3, Theorem 12.20] (also see [1, 4]). The best known kernel for 3-Set Packing is given by Abu-Khzam [1] and it has $\mathcal{O}(k^2)$ elements and $\mathcal{O}(k^3)$ sets. However, as we explain now, we cannot use the kernel given by Abu-Khzam [1] directly for our purposes. This is in contrast to the fact that one can use the best known parameterized algorithms for 3-Set Packing to design parameterized algorithms for Rainbow Matching. Given an instance (G, χ, k) of Rainbow Matching, we can transform it to an instance $(U, \mathcal{F}, k)$ of 3-Set Packing as explained in the introduction. Now if we apply a kernelization algorithm for 3-Set Packing, then it will return an equivalent instance $(U', \mathcal{F}', k')$ of 3-Set Packing and *not of* Rainbow Matching. A priori, it is not clear how we can transform $(U', \mathcal{F}', k')$ to an instance of Rainbow Matching without increasing the size bounds on the kernel we obtain for Rainbow Matching. Thus, to design a kernelization algorithm for Rainbow Matching we give a kernelization algorithm for 3-Set Packing such that it is easy to transform an instance of the latter to an instance of Rainbow Matching. This kernel is given here mainly for *completeness*.

4.1 Kernelization for Rainbow Matching on general graphs

Now we give the kernelization algorithm alluded to in the first part of Theorem 3. Towards that we will use the sunflower lemma – a classical result of Erdős and Rado. We first define the terminology used in the statement of the lemma. A *sunflower* with k *petals* and a *core* Y is a collection of sets $S_1, \ldots, S_k$ such that $S_i \cap S_j = Y$ for all $i \neq j$; the sets $S_i \setminus Y$ are petals and we require *none of them to be empty*. Note that a family of pairwise disjoint sets is a sunflower (with an empty core).

▶ **Proposition 11.** [3, pg 38] (Sunflower lemma) *Let $\mathcal{A}$ be a family of sets (without duplicates) over a universe U, such that each set in $\mathcal{A}$ has cardinality exactly d. If $|\mathcal{A}| > d!(k-1)^d$, then $\mathcal{A}$ contains a sunflower with k petals and such a sunflower can be computed in time polynomial in $|\mathcal{A}|$, $|U|$, and k.*

Proof of first part of Theorem 3. Given an instance (G, χ, k) of Rainbow Matching, we view this as an instance $\mathcal{J}$ of 3-Set Packing as follows: $U = V(G) \cup \{1, \ldots, q\}$ and $\mathcal{F}$ consists of a set $\{u, v, \chi(uv)\}$ corresponding to every edge $e = uv \in E(G)$.

▶ **Reduction Rule 12.** *Let $(U, \mathcal{F}, k)$ be an instance of* 3-Set Packing *and suppose that $\mathcal{F}$ contains a sunflower $S = \{S_1, \ldots, S_{3(k-1)+2}\}$ of cardinality $3k-1$ with core Y. Then, return $(U', \mathcal{F}', k)$, where $U' = \bigcup_{X \in \mathcal{F}'} X$, and $\mathcal{F}' = (\mathcal{F} \setminus S_1)$ is obtained by deleting a set S_1 from $\mathcal{F}$.*

To show the correctness of Reduction Rule 12, we need to show the following lemma.

▶ **Lemma 13.** *Reduction Rule 12 is safe.*

Proof. We will prove that $(U, \mathcal{F}, k)$ is a yes-instance of 3-Set Packing if and only if $(U', \mathcal{F}', k)$ is a yes-instance of 3-Set Packing. It is clear that if $(U', \mathcal{F}', k)$ is a yes-instance of 3-Set Packing then so is $(U, \mathcal{F}, k)$; so the backward direction holds straightaway.

For the forward direction, we assume that we have a solution $\mathcal{S}$ to $(U, \mathcal{F}, k)$, *i.e.*, a set of k pairwise disjoint sets. If $\mathcal{S}$ does not contain S_1, then it is also a solution for $(U', \mathcal{F}', k)$. So let us assume that $S_1 \in \mathcal{S}$. Observe that the number of elements appearing in the sets in $\mathcal{S}$, apart from those present in S_1, is $3(k-1)$. Also, note that no set in $\mathcal{S} \setminus \{S_1\}$ intersects the

core Y. Thus, the number of sets in the sunflower S that intersects the elements present in the sets of $\mathcal{S}$ is upper bounded by $1 + 3(k-1)$ (the first one for S_1). This implies there exists a set $S^\star \in S$ that is pairwise disjoint with every set in $\mathcal{S} \setminus \{S_1\}$. Thus, $(\mathcal{S} \setminus \{S_1\}) \cup S^\star$ is a solution of size k for $(U', \mathcal{F}', k)$. This completes the proof. ◀

Now, we are ready to describe the kernelization algorithm. If the number of sets in $\mathcal{F}$ is more than $6(3k-2)^3$, then the kernelization algorithm applies the sunflower lemma to find a sunflower of size $3k-1$, and applies Reduction Rule 12 on this sunflower.

The algorithm applies this procedure exhaustively, and obtains a new family of sets $\mathcal{F}'$ of size at most $6(3k-2)^3$. This concludes the size bound on the family $(U', \mathcal{F}', k)$ of 3-Set Packing. Observe that throughout the process, we have never reduced the size of any set in the family and each set in the family still corresponds to an edge and its color. Thus, given $(U', \mathcal{F}', k)$, let W be the vertices present in U'. Then we return $(G[W], \chi', k)$, where edge coloring χ' is the restriction of χ to the edges present in $G[W]$. This concludes the description of the kernelization algorithm. ◀

4.2 A Kernel on graphs of bounded degree

In this section we design a small kernel for Rainbow Matching on graphs of bounded degree. Let (G, χ, k) be an instance of Rainbow Matching. Throughout this section we assume that the *maximum degree* of G is upper bounded by a fixed constant d.

For $i \in [q]$, let $E_i = \{e \in E(G) \mid \chi(e) = i\}$. We call the set of edges E_i as a *color class with color i*. Next we give reduction rule that bounds the size of each color class.

▶ **Reduction Rule 14.** *If there exists $i \in [q]$ such that $|E_i| \geq 2d(k-1)+1$ then delete E_i and reduce k by 1. That is, we obtain an instance $(G', \chi', k-1)$. Here, G' is obtained by deleting all the edges in E_i and edge coloring χ' is obtained by restricting χ to the edges in G'.*

▶ **Lemma 15.** *Reduction Rule 14 is safe.*

Proof. We will prove that G has a colorful matching of size k if and only if G' has a colorful matching of size $k-1$. We first prove the forward direction. If G has a colorful matching $\mathcal{M}$ of size k that contains an edge $uv \in E_i$, then $\mathcal{M} \setminus \{uv\}$ is a colorful matching of size $k-1$ in the graph G'. If $\mathcal{M}$ does not have an edge of color i, then $\mathcal{M}$ itself is a colorful matching of size at least $k-1$ for G'.

For the backward direction, let $\mathcal{M}'$ be a colorful matching of size $k-1$ of G'. Observe that $\mathcal{M}'$ has $2(k-1)$ distinct vertices and each vertex has degree at most d. If every edge in $\mathcal{M}'$ has an endpoint that is adjacent to an edge in E_i, then the vertices in $\mathcal{M}'$ can share at most $2d(k-1)$ vertices. That is, at most $2d(k-1)$ edges from E_i can share vertices with $\mathcal{M}'$. Since, $|E_i| \geq 2d(k-1)+1$, E_i has at least one edge that does not share a vertex with $\mathcal{M}'$. Let that edge be uv. Then, it follows that $\mathcal{M}' \cup \{uv\}$ is a k size colorful matching of G, and our proof is complete. ◀

We apply Reduction Rule 14 exhaustively. If the premise of the rule is not satisfied, then for each color i, we have that $|E_i| \leq 2d(k-1)$. Next we give a polynomial time procedure that either outputs a colorful matching of size at least k or bounds the number of colors.

▶ **Lemma 16.** *Let (G, χ, k) be an instance of* Rainbow Matching *for which Reduction Rule 14 is not applicable. Then, in polynomial time either we can conclude that (G, χ, k) is a yes-instance or the number of distinct colors in the instance is upper bounded by $2d(k-1)$.*

Proof. We iteratively try to build a colorful matching of size k. If we fail to do so, then it will enable us to bound the number of color classes. Let $\mathcal{M}$ be an empty set. We repeat the below procedure until the graph is empty.

1. Pick an edge uv of G arbitrarily, and add it to $\mathcal{M}$. Let the edges incident on u have colors $c_u^1, c_u^2, \ldots, c_u^\ell$ and the edges incident on v have colors $c_v^1, c_v^2, \ldots, c_v^p$.
2. Delete all the edges in $\bigcup_{i=1}^{\ell} E_{c_u^i}$ and $\bigcup_{i=1}^{p} E_{c_v^i}$. Let the resulting graph be also called G.

If we can continue the above process for k steps (*i.e.* $|\mathcal{M}| \geq k$) then $\mathcal{M}$ is a colorful matching of size at least k. In this case we output $\mathcal{M}$ as the desired colorful matching. To see its correctness, observe that in every iteration we deleted the edges incident on both the endpoints of the added to $\mathcal{M}$. So, the edges we added to $\mathcal{M}$ are indeed pairwise vertex disjoint. Also, note that we delete all the edges with colors that are used on the edges that are incident to the edges that were added to $\mathcal{M}$. Hence, the edges in $\mathcal{M}$ have distinct color.

Otherwise, our procedure ends within at most $k-1$ steps, and so $|\mathcal{M}| \leq k-1$. Now, let us count the number of color classes we delete in each iteration. In other words, we count the number of color classes that are deleted each time we add an edge to M. If all the edges incident on u have distinct colors then $\ell \leq d$ because degree of u is at most d. Similarly, we are argue that $p \leq d$. Together they imply that we delete at most $2d$ color classes in each iteration. Hence, in at most $k-1$ iterations we delete at most $2d(k-1)$ color classes. Following this we are left with an an empty graph. Thus, we have shown that in this case, we can have at most $2d(k-1)$ color classes. ◀

Lemmas 15 and 16 together prove second part of Theorem 3.

5 Conclusion, Discussion and Open Problems

In this paper, we considered Rainbow Matching from the viewpoint of parameterized complexity, and designed faster parameterized algorithms as well as kernels for this problem. Rainbow Matching is easily seen as a generalization of another well studied problem in parameterized algorithms, namely 3-Dimensional Matching, when we allow the input graph to be a multigraph. In this problem, we are given a set family $(U, \mathcal{F})$, together with a partition $U = \uplus_{i=1}^{3} U_i$ and a positive integer k. Here, every set $F \in \mathcal{F}$ has the property that for all $i \in [3]$, $|F \cap U_i| = 1$. The question is whether there exists a subfamily $\mathcal{F}' \subseteq \mathcal{F}$ containing k pairwise-disjoint sets. We first show that Rainbow Matching is indeed a generalization of 3-Dimensional Matching. Towards proving this, we give a polynomial time parameter-preserving reduction from 3−Dimensional Matching to Rainbow Matching. That is, we give the following ppt reduction, 3−Dimensional Matching $\leq_{\text{ppt}}$ Rainbow Matching. Here, let us only present a rough sketch of the proof. The idea of the construction is as follows. In the bipartite graph of the constructed instance of Rainbow Matching, one side represents the elements of U_1, and the other side represents the elements of U_2. Then, for every set $\{u_1, u_2, u_3\}$ in $\mathcal{F}$, where $u_i \in U_i$ for all $i \in [3]$, we add an edge between u_1 and u_2 whose color is u_3. It is easy to see that a solution for the original problem instance can be directly translated to a solution for the new problem instance, and vice versa. Moreover, the parameter k in both instances is set to be the same.

We also saw that there is a ppt reduction from Rainbow Matching to 3-Set Packing and thus we have the following chain of reductions.

3−Dimensional Matching $\leq_{\text{ppt}}$ Rainbow Matching $\leq_{\text{ppt}}$ 3−Set Packing.

It is known that 3-Dimensional Matching admits a randomized algorithm with running time $\mathcal{O}^\star(2^k)$ [2] and a deterministic algorithm with running time $\mathcal{O}^\star(2.5961^{2k}) = \mathcal{O}^\star(6.7398^k)$ [19]. We gave in the introduction a deterministic algorithm for Rainbow Matching that is the same as the one for 3-Set Packing. However, we remark that the algorithm for 3-Dimensional Matching given in [19] can actually be used to solve Rainbow Matching in $\mathcal{O}^\star(6.7398^k)$ time. Can we design a faster randomized or deterministic algorithm for Rainbow Matching or even 3-Dimensional Matching?

We gave an $\mathcal{O}(k^2)$ kernel on paths. Does there exist a linear kernel on paths? Could we get improved kernel for Rainbow Matching on simple family of graphs such as trees, graphs of constant treewidth or planar graphs. Could we show that $\mathcal{O}(k^3)$ size bound on the kernel for Rainbow Matching is optimal?

Finally, by a direct application of our randomized parameterized algorithm for Rainbow Matching running in time $\mathcal{O}^\star(2^k)$, we have that there exists a randomized algorithm for Rainbow Matching running in time $\mathcal{O}^\star(2^{n/2}) = \mathcal{O}^\star(1.4143^n)$. Here, n is the number of vertices in the input graph and the $n/2$ is an upper bound on the maximum size of a colorful matching in a graph. Using a simple dynamic programming algorithm, it is possible to design a $\mathcal{O}^\star(2^n)$ algorithm for Rainbow Matching. Designing a deterministic algorithm for Rainbow Matching running in time $(2-\epsilon)^n$ for some fixed $\epsilon > 0$ is another interesting open problem.

Abstract

We investigate the compositionality of both weak bisimilarity metric and weak similarity quasi-metric semantics with respect to a variety of standard operators, in the context of probabilistic process algebra. We show how compositionality with respect to nondeterministic and probabilistic choice requires to resort to rooted semantics. As a main application, we demonstrate how our results can be successfully used to conduct compositional reasonings to estimate the performances of group key update protocols in a multicast setting.

1 Introduction

Behavioural distances [35, 17, 14] allow us to compare the behaviour of probabilistic systems. Basically, they are the quantitative analog of the classical notions of *behavioural equivalence* and *preorder*. In the *weak semantic* approach, where *non-observable* actions are abstracted away, *weak bisimilarity metric* [18] and its asymmetric counterpart, *weak similarity quasi-metric* [30], have been proposed as the quantitative analog of *weak probabilistic bisimilarity* and *weak probabilistic similarity*, respectively [5, 4].

In order to specify and verify systems in a compositional manner, it is necessary to work with behavioural semantics which are preserved by all operators of the language. In this light, different forms of compositionality have been proposed for strong bisimilarity metrics by adopting different notions of *uniform continuity* [20]. Intuitively, a uniformly continuous operator ensures that a small variation in the behaviour of a system component leads to a smooth and bounded variation in the behaviour of the whole system (absence of chaotic behaviour when system components and parameters are modified in a controlled manner). More precisely, the uniform continuity of an n-ary process algebra operator f ensures that, once fixed the maximal tolerable distance ε between processes $f(s_1,\ldots,s_n)$ and $f(s'_1,\ldots,s'_n)$, there are values δ_i such that, whenever the distance between process arguments s_i and s'_i is below δ_i, for $1 \leq i \leq n$, then the distance between $f(s_1,\ldots,s_n)$ and $f(s'_1,\ldots,s'_n)$ is guaranteed to be below ε. The notions of uniform continuity considered in [20] are: (i) *non-extensiveness*, requiring $\varepsilon = \max(\delta_1,\ldots,\delta_n)$, (ii) *non-expansiveness*, with $\varepsilon = \delta_1+\ldots+\delta_n$, and (iii) *Lipschitz continuity*, where $\varepsilon = L\cdot(\delta_1+\ldots+\delta_n)$, for some $L \in \mathbb{R}_{\geq 1}$.

In this paper, we extend and generalise the work of [20] to *rooted* and *asymmetric* semantics. In particular, for all standard operators of probabilistic process algebras, such as

probabilistic CCS [24] and probabilistic CSP [24], we derive the notions of uniform continuity which are satisfied by *rooted* bisimilarity metric and/or *rooted* similarity quasimetric. It is well-known that weak probabilistic bisimilarity, unlike similarity, is not preserved by nondeterministic choice. Thus, with no surprise, the nondeterministic choice operator is not uniformly continuous with respect to weak bisimilarity metric, while it is uniformly continuous with respect to weak similarity quasimetric. In this paper, we show that probabilistic choice is uniformly continuous with respect to neither weak bisimilarity metric nor weak similarity quasimetric. Thus, in order to recover uniform continuity, we work with rooted (bi)similarities [36], where, in first step of the (bi)simulation game any *strong* transition must be matched by the same *strong* transition.

As main case study, we consider an abstract specification of the *group key update* protocol. In this protocol, whenever a principal joins or leaves the group, in order to guarantee *backward* and *forward confidentiality*, it is necessary to generate and distribute a new group key. However, this operation has a cost in terms of:

(i) the number of attacks aiming at compromising the group key,
(ii) the degradation of communication service,
(iii) battery consumption.

We show how our compositional theory can be used to estimate the distance between the ideal protocol, where groups cannot dynamically change, and some variations of the protocol obtained by playing with the following parameters:

(i) number of principals,
(ii) probability that principals leave the group,
(iii) probability that principals join the group.

The results of our analysis allow us to assert that the protocol under consideration has good efficiency in groups with low dynamicity, regardless of the size of the group.

Outline. Section 2 provides background on probabilistic semantics. Section 3 contains the main results on uniform continuity. Section 4 applies our theory to an abstract group key update protocol. Section 5 concludes and discusses related and future work.

2 Preliminaries

Nondeterministic probabilistic labelled transition systems (pLTSs) [33] represent a very general semantic model for probabilistic processes as they combine LTSs [26] and discrete time Markov chains [34, 23], to model reactive behaviour, nondeterminism and probability. The state space is given by a *signature* Σ consisting of both a set of *operators* and a *rank function* r, where $\mathsf{r}(f)$ returns the arity of the operator f. The set $\mathsf{T}(\Sigma)$ of *terms* over Σ, or *processes*, is the least set such that $f(t_1, \ldots, t_n) \in \mathsf{T}(\Sigma)$ whenever $f \in \Sigma$, $\mathsf{r}(f) = n$ and $t_1, \ldots, t_n \in \mathsf{T}(\Sigma)$. Notice that $\mathsf{T}(\Sigma) \neq \emptyset$ if and only if Σ contains *constants*, i.e., functions with arity 0. We write $\Delta(\mathsf{T}(\Sigma))$ to denote the set of all probability distributions with *finite support* over $\mathsf{T}(\Sigma)$, which are mappings $\pi \colon \mathsf{T}(\Sigma) \to [0, 1]$, with $\sum_{t \in \mathsf{T}(\Sigma)} \pi(t) = 1$.

▶ **Definition 1** (pLTS [33]). A *nondeterministic probabilistic labelled transition system* (*pLTS*) is given by a triple $P = (\mathsf{T}(\Sigma), \mathit{Act}, \to)$ where:

(i) Σ is a signature,
(ii) Act is a countable set of *actions*, and
(iii) $\to \subseteq \mathsf{T}(\Sigma) \times \mathit{Act} \times \Delta(\mathsf{T}(\Sigma))$ is a *transition relation*.

As usual, we write $t \xrightarrow{\alpha} \pi$ for $(t, \alpha, \pi) \in \rightarrow$. Let $der(t, \alpha) = \{\pi \in \Delta(\mathsf{T}(\Sigma)) \mid t \xrightarrow{\alpha} \pi\}$ be the set of the *derivatives* of t according to action α. We say that a pLTS P is *image finite* if $der(t, \alpha)$ is finite for all $t \in \mathsf{T}(\Sigma)$ and $\alpha \in Act$.

We consider a signature that contains many of the operators from probabilistic CCS and probabilistic CSP specified via the SOS rules in Table 1–3. The operators we consider are:

1. constants $\mathsf{0}$ (idle process) and ε (skip process);
2. a family of n-ary probabilistic prefix operators $\alpha.([p_1]\_ \oplus \ldots \oplus [p_n]\_)$ with $\alpha \in Act$, $n \geq 1$, $p_1, \ldots, p_n \in (0, 1]$ and $\sum_{i=1}^{n} p_i = 1$;
3. nondeterministic choice $\_ + \_$;
4. action restriction $(\nu\, \alpha)\_$ with $\alpha \in Act \setminus \{\tau, \surd\}$;
5. sequential composition $\_\,;\_$;
6. CSP-like parallel composition $\_ \parallel_B \_$, with $B \subseteq Act \setminus \{\tau, \surd\}$,
7. CCS-like parallel composition $\_ \mid \_$, which assumes a function $^-\colon Act \setminus \{\tau, \surd\} \rightarrow Act \setminus \{\tau, \surd\}$ with $\overline{\overline{a}} = a$,
8. probabilistic choice $\_ +_p \_$;
9. finite iteration $\_^n$,
10. finite replication $!^n\_$,
11. infinite iteration $\_^\omega$,
12. binary Kleene-star iteration $\_^*\_$,
13. infinite replication (bang) operator $!\_$, and
14. probabilistic bang operator $!_p\_$.

All rules in Table 1–3 obey to the *PGSOS format* [9, 10]. We assume a set of actions $Act = A \cup \{\tau, \surd\}$, with $\surd$ denoting the *successful* termination action, and τ denoting *non-observable* action. We let $\alpha, \beta, \ldots$ range over Act and $a, b, \ldots$ over $Act \setminus \{\tau\}$. The rules of Table 1–3 assume a set of *process variables*, ranged over by x, y and a set of *distribution variables*, ranged over by μ, ν, allowing us to generalise the notions of term and distribution to *open term* and *open distribution* in the standard way. The rules are then defined by using *open transitions*, such as $x \mid y \xrightarrow{a} \mu \mid \nu$, taking open terms to open distributions. The PGSOS rules rely on some notations and operations on distributions. For $t \in \mathsf{T}(\Sigma)$, $\delta(t)$ denotes the *Dirac distribution*, defined by $(\delta(t))(t) = 1$. The convex combination $\sum_{i\in I} p_i\pi_i$ of a finite set of distributions $\{\pi_i\}_{i\in I}$, with $p_i \in (0, 1]$ and $\sum_{i\in I} p_i = 1$, is defined by $(\sum_{i\in I} p_i\pi_i)(t) = \sum_{i\in I}(p_i\pi_i(t))$. We write $\pi \oplus_p \pi'$ for $p\pi + (1-p)\pi'$. For $f \in \Sigma$ and $\pi_i \in \Delta(\mathsf{T}(\Sigma))$, $f(\pi_1, \ldots, \pi_n)$ denotes the product distribution defined by $f(\pi_1, \ldots, \pi_n)(f(t_1, \ldots, t_n)) = \prod_{i=1}^{n} \pi_i(t_i)$. Notice that all distributions defined in this inductive way have *finite support*.

▶ **Definition 2** (PGSOS-TSS [6, 9]). A *PGSOS-transition system specification* (*PGSOS-TSS*) is a triple $T = (\Sigma, Act, R)$ where:

- **(i)** Σ is a signature,
- **(ii)** Act is a countable set of actions,
- **(iii)** R is a countable set of PGSOS rules,
- **(iv)** for each $f \in \Sigma$ and $\alpha \in Act$, the set of rules with conclusion of the form $f(x_1, \ldots, x_n) \xrightarrow{\alpha} \theta$ is finite.

We recall that *closed substitutions* map process variables to processes, and distribution variables to distributions. Closed substitutions allows us to derive the *supported model* of a TSS, namely a pLTS in which the transition relation $\rightarrow$ contains all and only those transitions inductively derived by the SOS rules [7, 6, 9]. Item (4) in Definition 2 ensures that the supported model of a TSS is always image finite.

▶ **Definition 3** (Disjoint extension [1]). Let $T_1 = (\Sigma_1, A, R_1)$ and $T_2 = (\Sigma_2, A, R_2)$ be two PGSOS-TSSs. We say that T_2 is a *disjoint extension* of T_1, written $T_1 \sqsubseteq T_2$, iff $\Sigma_1 \subseteq \Sigma_2$, $R_1 \subseteq R_2$ and R_2 introduces no new rule for any operator in Σ_1.

2.1 Weak behavioural distances

In this section, we give the formal definitions of the weak behavioural distances of [18, 30].

The definition of weak transitions $\stackrel{\alpha}{\Longrightarrow}$, which abstract away non-observable actions, is complicated by the fact that transitions take processes to distributions. Following [16], we need to generalise transitions, so that they take sub-distributions to sub-distributions. With an abuse of notation, we use π, π' to range also over sub-distributions, admitting $\sum_{t \in \mathsf{T}(\Sigma)} \pi(t) \leq 1$. For a term t and a distribution π, we write $t \xrightarrow{\hat{\tau}} \pi$ if $t \xrightarrow{\tau} \pi$ or $\pi = \delta(t)$. Then, for $a \in A$, we write $t \xrightarrow{\hat{a}} \pi$ if $t \xrightarrow{a} \pi$. Relation $\xrightarrow{\hat{\alpha}}$ is extended to model transitions from sub-distributions to sub-distributions. For a sub-distribution $\pi = \sum_{i \in I} p_i \delta(t_i)$, we write $\pi \xrightarrow{\hat{\alpha}} \pi'$ if there is a set $J \subseteq I$ with $t_j \xrightarrow{\hat{\alpha}} \pi_j$ for all $j \in J$, $t_i \not\xrightarrow{\hat{\alpha}}$, for all $i \in I \setminus J$, and $\pi' = \sum_{j \in J} p_j \pi_j$. If $\alpha \neq \tau$ then this definition entails that only some terms in the support of π have the $\xrightarrow{\hat{\alpha}}$ transition. Then, we define the weak transition relation $\stackrel{\hat{\tau}}{\Longrightarrow}$ as the transitive and reflexive closure of $\xrightarrow{\hat{\tau}}$, i.e. $\stackrel{\hat{\tau}}{\Longrightarrow} = (\xrightarrow{\hat{\tau}})^*$, while for $a \in A$ we let $\stackrel{\hat{a}}{\Longrightarrow}$ denote $\stackrel{\hat{\tau}}{\Longrightarrow}\xrightarrow{\hat{a}}\stackrel{\hat{\tau}}{\Longrightarrow}$.

Weak bisimilarity metric [18] (resp. weak similarity quasimetric [30]) is defined as a pseudometric (resp. pseudoquasimetric) measuring the tolerance of the probabilistic weak bisimilarity (resp. probabilistic weak similarity).

▶ **Definition 4** (Pseudoquasimetrics and pseudometrics). A function $d\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$ is said to be a *1-bounded pseudoquasimetric* when:
(i) $d(t,t) = 0$, for all $t \in \mathsf{T}(\Sigma)$, and
(ii) $d(t,t') \leq d(t,t'') + d(t'',t')$, for all $t, t', t'' \in \mathsf{T}(\Sigma)$.
If it is also symmetric, i.e. $d(t,t') = d(t',t)$, for all $t, t' \in \mathsf{T}(\Sigma)$, then it is said to be a *1-bounded pseudometric*.

We need to lift these two definitions to (sub)distributions. To this end, as in [30], we rely on the notions of *matching* [37] (also known as *coupling*) and *Kantorovich lifting* [25]. The original formulation in [18] is technically different, but equivalent [15].

▶ **Definition 5** (Matching). A *matching* for a pair of distributions (π, π') is a distribution ω in the product space $\mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma)$ with $\sum_{t' \in \mathsf{T}(\Sigma)} \omega(t,t') = \pi(t)$, for $t \in \mathsf{T}(\Sigma)$, and $\sum_{t \in \mathsf{T}(\Sigma)} \omega(t,t') = \pi'(t')$, for $t' \in \mathsf{T}(\Sigma)$. Let $\Omega(\pi, \pi')$ be the set of all matchings for (π, π').

▶ **Definition 6** (Kantorovich lifting). Let $d\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$ be a pseudo(quasi)metric. The *Kantorovich lifting* of d is the function $\mathbf{K}(d)\colon \Delta(\mathsf{T}(\Sigma)) \times \Delta(\mathsf{T}(\Sigma)) \to [0,1]$ defined as:

$$\mathbf{K}(d)(\pi, \pi') \;=\; \min_{\omega \in \Omega(\pi,\pi')} \sum_{t,t' \in \mathsf{T}(\Sigma)} \omega(t,t') \cdot d(t,t').$$

Note that since we are considering only distributions with finite support, the minimum over the set of matchings $\Omega(\pi, \pi')$ is well defined.

Now, we are ready to define our behavioural distances. They are parametric on a *discount factor* $\lambda \in (0,1]$ which mitigates the (bi)simulation tolerance on future activities [12, 17].

▶ **Definition 7** (Weak behavioural distances). Let $|\pi|$ be an abbreviation for $\sum_{t \in \mathsf{T}(\Sigma)} \pi(t)$. We say that a pseudoquasimetric $d\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$ is a *weak simulation quasimetric* if for all $s, t \in \mathsf{T}(\Sigma)$, with $d(s,t) < 1$, whenever $s \xrightarrow{\alpha} \pi_s$ there is a sub-distribution π_t such that $t \stackrel{\hat{\alpha}}{\Longrightarrow} \pi_t$ and $\lambda \cdot \mathbf{K}(d)(\pi_s, \pi_t + (1 - |\pi_t|)\mathsf{0}) \leq d(s,t)$. Moreover, if d is a pseudometric, then d is a *weak bisimulation metric*.

In the previous definition, if $|\pi_t| < 1$ then, with probability $1 - |\pi_t|$, there is no way to simulate the behaviour of any process different from $\mathsf{0}$ in the support of π_s. We remark that the kernel of a weak bisimulation pseudometric is a weak probabilistic bisimulation [18] and the kernel of a weak simulation pseudoquasimetric is a weak probabilistic simulation [30].

Crucial results are the existence of both the minimal weak bisimulation metric [18], called *weak bisimilarity metric*, and denoted with $\mathbf{d}^{\mathsf{m}}$, and the minimal weak simulation quasimetric [30], called *weak similarity quasimetric*, and denoted with $\mathbf{d}^{\mathsf{q}}$.

3 Uniform continuity for rooted (quasi)metric semantics

In this section, we show that the operators in Table 1–3 allow for compositional reasoning with respect to a *rooted* variant of our weak behavioural distances. We start by recalling the notion of uniform continuity, whose intuitive meaning was discussed in the Introduction.

▶ **Definition 8** (Modulus of continuity)**.** Let $T = (\Sigma, Act, R)$ be a TSS, $f \in \Sigma$ an n-ary operator, and $d\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$ a function. A mapping $\omega_f\colon [0,1]^n \to [0,1]$ is a *modulus of continuity* for f with respect to d when:

- $d(f(s_1,\ldots,s_n), f(t_1,\ldots,t_n)) \leq \omega_f(d(s_1,t_1),\ldots,d(s_n,t_n))$, for all processes $s_i, t_i \in \mathsf{T}(\Sigma)$;
- ω_f is continuous at $(0,\ldots,0)$, i.e. $\lim_{(\epsilon_1,\ldots,\epsilon_n)\to(0,\ldots,0)} \omega(\epsilon_1,\ldots,\epsilon_n) = \omega(0,\ldots,0)$;
- $\omega_f(0,\ldots,0) = 0$.

▶ **Definition 9** (Uniformly continuous operator [20])**.** Let $T = (\Sigma, A, R)$ be a TSS and $d\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$. We say that an operator $f \in \Sigma$ is:

- *uniformly continuous with respect to d* if f admits some modulus of continuity wrt. d;
- *L-Lipschitz continuous with respect to d*, for $L \in \mathbb{R}_{\geq 1}$, if $\omega_f(\epsilon_1,\ldots,\epsilon_n) = L \cdot \sum_{i=1}^{n} \epsilon_i$ is a modulus of continuity for f with respect to d;
- *non-expansive with respect to d* if f is 1-Lipschitz continuous with respect to d;
- *non-extensive with respect to d* if $\omega_f(\epsilon_1,\ldots,\epsilon_n) = \max_{i=1}^{n} \epsilon_i$ is a modulus of continuity for f with respect to d.

As expected, since τ-transitions may solve nondeterminism, $\mathbf{d}^{\mathsf{m}}$ is not uniformly continuous with respect to $+$, thus requiring to introduce a rooted version for $\mathbf{d}^{\mathsf{m}}$. For instance, $\mathbf{d}^{\mathsf{m}}(\tau.a.\mathsf{0}, a.\mathsf{0}) = 0$ but $\mathbf{d}^{\mathsf{m}}(\tau.a.\mathsf{0} + b.\mathsf{0}, a.\mathsf{0} + b.\mathsf{0}) = \lambda$, thus implying that no modulus of continuity for operator $+$ with respect to $\mathbf{d}^{\mathsf{m}}$ can be defined. Interestingly, in the metric context also the asymmetric simulation-like approach requires rootedness. Indeed, $\mathbf{d}^{\mathsf{q}}$ is not continuous with respect to $+_p$. For instance, $\mathbf{d}^{\mathsf{q}}(\tau.a.b.\mathsf{0}, a.b.\mathsf{0}) = 0$, but $\mathbf{d}^{\mathsf{q}}(\tau.a.b.\mathsf{0} +_p a.\mathsf{0}, a.b.\mathsf{0} +_p a.\mathsf{0}) = \lambda^2(1-p)$, thus implying that no modulus of continuity for $+_p$ wrt. $\mathbf{d}^{\mathsf{q}}$ can be defined. In fact, transition $\tau.a.b.\mathsf{0} +_p a.\mathsf{0} \xrightarrow{\tau} \delta(a.b.\mathsf{0})$ can be simulated only by $a.b.\mathsf{0} +_p a.\mathsf{0} \stackrel{\tau}{\Longrightarrow} \delta(a.b.\mathsf{0} +_p a.\mathsf{0})$, then $\lambda\,\mathbf{K}(\mathbf{d}^{\mathsf{q}})(\delta(a.b.\mathsf{0}), \delta(a.b.\mathsf{0} +_p a.\mathsf{0})) = \lambda \mathbf{d}^{\mathsf{q}}(a.b.\mathsf{0}, a.b.\mathsf{0} +_p a.\mathsf{0}) = \lambda^2(1-p)$. Notice that we also have that $\mathbf{d}^{\mathsf{m}}(\tau.a.b.\mathsf{0}, a.b.\mathsf{0}) = 0$ and $\mathbf{d}^{\mathsf{m}}(\tau.a.b.\mathsf{0} +_p a.\mathsf{0}, a.b.\mathsf{0} +_p a.\mathsf{0}) \geq \lambda^2(1-p)$. This implies that $\mathbf{d}^{\mathsf{m}}$, like $\mathbf{d}^{\mathsf{q}}$, is not uniformly continuous with respect to $+_p$.

▶ **Definition 10** (Rooted behavioural distances)**.** We say that a pseudoquasimetric $r\colon \mathsf{T}(\Sigma) \times \mathsf{T}(\Sigma) \to [0,1]$ is a *rooted simulation quasimetric* if there exists a weak simulation quasimetric d such that for all $s, t \in \mathsf{T}(\Sigma)$, with $r(s,t) < 1$, whenever $s \xrightarrow{\alpha} \pi_s$ there is a distribution π_t such that $t \xrightarrow{\alpha} \pi_t$ and $\lambda \cdot \mathbf{K}(d)(\pi_s, \pi_t) \leq r(s,t)$. Moreover, if both r and d are pseudometrics, then r is a *rooted bisimulation metric*.

Table 1 Non-extensive operators

$$\frac{}{\varepsilon \xrightarrow{\checkmark} \delta(\mathsf{0})} \qquad \frac{}{\alpha.\bigoplus_{i=1}^{n}[p_i]x_i \xrightarrow{\alpha} \sum_{i=1}^{n} p_i\delta(x_i)} \qquad \frac{x \xrightarrow{\alpha} \mu}{x+y \xrightarrow{\alpha} \mu} \qquad \frac{y \xrightarrow{\alpha} \nu}{x+y \xrightarrow{\alpha} \nu}$$

$$\frac{x \xrightarrow{\alpha} \mu \quad y \not\xrightarrow{\alpha}}{x +_p y \xrightarrow{\alpha} \mu} \qquad \frac{x \not\xrightarrow{\alpha} \quad y \xrightarrow{\alpha} \nu}{x +_p y \xrightarrow{\alpha} \nu} \qquad \frac{x \xrightarrow{\alpha} \mu \quad y \xrightarrow{\alpha} \nu}{x +_p y \xrightarrow{\alpha} \mu \oplus_p \nu} \qquad \frac{x \xrightarrow{\alpha} \mu \text{ and } \alpha \notin \{\beta, \overline{\beta}\}}{(\nu\,\beta)\,x \xrightarrow{\alpha} \mu}$$

▶ **Theorem 11.** *There exists a rooted simulation quasimetric* $\mathbf{r}^{\mathsf{q}}$ *(resp. rooted bisimulation metric* $\mathbf{r}^{\mathsf{m}}$*) such that* $\mathbf{r}^{\mathsf{q}}(s,t) \leq r(s,t)$ *(resp.* $\mathbf{r}^{\mathsf{m}}(s,t) \leq r(s,t)$*) for all rooted simulation quasimetrics (resp. rooted bisimulation metrics)* r *and all processes* $s,t \in \mathcal{T}(\Sigma)$*.*

We call $\mathbf{r}^{\mathsf{q}}$ *rooted similarity quasimetric*, and $\mathbf{r}^{\mathsf{m}}$ *rooted bisimilarity metric.*

In the following, for each operator, we compute a suitable upper bound on the rooted simulation and bisimulation tolerance between processes composed by that operator, then we use this bound to infer its compositionality property. Basically, our goal is to express a bound on the rooted (bi)simulation tolerance between composed processes $f(s_1,\ldots,s_n)$ and $f(t_1,\ldots,t_n)$ in terms of the tolerance between the components s_i and t_i.

Non-extensive operators. Consider the TSS $T_{\mathrm{NExt}} = (\Sigma_{\mathrm{NExt}}, Act, R_{\mathrm{NExt}})$ given by the rules R_{NExt} in Table 1. We show that all operators in Table 1 are non-extensive.

▶ **Proposition 12.** *Assume any TSS* $T = (\Sigma, A, R)$ *with* $T_{NExt} \sqsubseteq T$ *and* $s_i, t_i \in \mathcal{T}(\Sigma)$*. For* $\mathsf{j} \in \{\mathsf{q},\mathsf{m}\}$*, let us define* $r^{\mathsf{j}}_{(s,t,t')} = \min(\mathbf{r}^{\mathsf{j}}(s,t), \mathbf{r}^{\mathsf{j}}(s,t'))$ *and* $r^{\mathsf{j}}_{(q,s,t,t')} = \min(\mathbf{r}^{\mathsf{j}}(s,t), q(\mathbf{r}^{\mathsf{j}}(s,t)) + (1-q)\mathbf{r}^{\mathsf{j}}(s,t'))$*. Then, we have:*

(a) $\mathbf{r}^{\mathsf{j}}(\alpha.\bigoplus_{i=1}^{n}[p_i]s_i, \alpha.\bigoplus_{i=1}^{n}[p_i]t_i) \leq \lambda \cdot \sum_{i=1}^{n} p_i \mathbf{r}^{\mathsf{j}}(s_i,t_i)$ *with* $\mathsf{j} \in \{\mathsf{q},\mathsf{m}\}$*;*
(b) $\mathbf{r}^{\mathsf{q}}(s_1+s_2, t_1+t_2) \leq \max(r^{\mathsf{q}}_{(s_1,t_1,t_2)}, r^{\mathsf{q}}_{(s_2,t_1,t_2)})$*;*
(c) $\mathbf{r}^{\mathsf{m}}(s_1+s_2, t_1+t_2) \leq \max(r^{\mathsf{m}}_{(s_1,t_1,t_2)}, r^{\mathsf{m}}_{(s_2,t_1,t_2)}, r^{\mathsf{m}}_{(t_1,s_1,s_2)}, r^{\mathsf{m}}_{(t_2,s_1,s_2)})$*;*
(d) $\mathbf{r}^{\mathsf{q}}(s_1 +_p s_2, t_1 +_p t_2) \leq \max(r^{\mathsf{q}}_{(p,s_1,t_1,t_2)}, r^{\mathsf{q}}_{((1-p),s_2,t_2,t_1)})$*;*
(e) $\mathbf{r}^{\mathsf{m}}(s_1 +_p s_2, t_1 +_p t_2) \leq \max(r^{\mathsf{m}}_{(p,s_1,t_1,t_2)}, r^{\mathsf{m}}_{((1-p),s_2,t_2,t_1)}), r^{\mathsf{m}}_{(p,t_1,s_1,s_2)}, r^{\mathsf{m}}_{((1-p),t_2,s_2,s_1)})$*;*
(f) $\mathbf{r}^{\mathsf{j}}((\nu\,\alpha)\,s, (\nu\,\alpha)\,t) \leq \mathbf{r}^{\mathsf{j}}(s,t)$ *with* $\mathsf{j} \in \{\mathsf{q},\mathsf{m}\}$*.*

As expected, the asymmetry leads to have upper bounds for $\mathbf{r}^{\mathsf{q}}$ below those for $\mathbf{r}^{\mathsf{m}}$. For instance, by Proposition 12.2 we get $\mathbf{r}^{\mathsf{q}}(a.\mathsf{0}+a.\mathsf{0}, a.\mathsf{0}+b.\mathsf{0}) \leq \max(\min(0,1),\min(0,1)) = 0$, while by Proposition 12.3 $\mathbf{r}^{\mathsf{m}}(a.\mathsf{0}+a.\mathsf{0}, a.\mathsf{0}+b.\mathsf{0}) \leq \max(\min(0,1),\min(0,1),\min(0,0),\min(1,1)) = 1$.

Note that in Proposition 12 we have $T_{\mathrm{NExt}} \sqsubseteq T$ (Definition 3), namely processes s_i and t_i are obtained by using arbitrary operators, not necessarily only operators in Σ_{NExt}. Thus, these bounds hold independently from T. The following result follows from Proposition 12.

▶ **Theorem 13.** *The operators in Table 1 are non-extensive with respect to* $\mathbf{r}^{\mathsf{q}}$ *and* $\mathbf{r}^{\mathsf{m}}$*.*

Non-expansive operators. We proceed to show that all operators in Table 2 are non-expansive. Consider the TSS $T_{\mathrm{NExp}} = (\Sigma_{\mathrm{NExp}}, Act, R_{\mathrm{NExp}})$ with $T_{\mathrm{NExt}} \sqsubseteq T_{\mathrm{NExp}}$ and R_{NExp} containing the rules in Table 2, besides those in Table 1.

Table 2 Non-expansive operators, where the operator $|$ assumes a function $^- : Act \setminus \{\tau, \surd\} \to Act \setminus \{\tau, \surd\}$ with $\overline{\overline{a}} = a$, and the operator $||_B$ is defined for $B \subseteq Act \setminus \{\tau, \surd\}$

$$\frac{x \xrightarrow{\alpha} \mu}{x \mid y \xrightarrow{\alpha} \mu \mid \delta(y)} \qquad \frac{y \xrightarrow{\alpha} \nu}{x \mid y \xrightarrow{\alpha} \delta(x) \mid \nu} \qquad \frac{x \xrightarrow{a} \mu \quad y \xrightarrow{\overline{a}} \nu \quad a \in Act \setminus \{\tau, \surd\}}{x \mid y \xrightarrow{\tau} \mu \mid \nu}$$

$$\frac{x \xrightarrow{\surd} \mu \quad y \xrightarrow{\surd} \nu}{x \mid y \xrightarrow{\surd} \delta(0)} \qquad \frac{x \xrightarrow{\alpha} \mu \quad a \neq \surd}{x; y \xrightarrow{\alpha} \mu; \delta(y)} \qquad \frac{x \xrightarrow{\surd} \mu \quad y \xrightarrow{\alpha} \nu}{x; y \xrightarrow{\alpha} \nu} \qquad \frac{x \xrightarrow{\surd} \mu \quad y \xrightarrow{\surd} \nu}{x \mid\mid_B y \xrightarrow{\surd} \delta(0)}$$

$$\frac{x \xrightarrow{a} \mu \quad y \xrightarrow{a} \nu \quad a \in B}{x \mid\mid_B y \xrightarrow{a} \mu \mid\mid_B \nu} \qquad \frac{x \xrightarrow{\alpha} \mu \quad \alpha \notin (B \cup \{\surd\})}{x \mid\mid_B y \xrightarrow{\alpha} \mu \mid\mid_B \delta(y)} \qquad \frac{y \xrightarrow{\alpha} \nu \quad \alpha \notin (B \cup \{\surd\})}{x \mid\mid_B y \xrightarrow{\alpha} \delta(x) \mid\mid_B \nu}$$

▶ **Proposition 14.** *Assume any TSS $T = (\Sigma, A, R)$ with $T_{NExp} \sqsubseteq T$ and $s_i, t_i \in \mathcal{T}(\Sigma)$. For $\mathsf{j} \in \{\mathsf{q}, \mathsf{m}\}$ we have:*

(a) $\mathbf{r}^{\mathsf{j}}(s_1; s_2, t_1; t_2) \leq \begin{cases} 1 & \text{if } \mathbf{r}^{\mathsf{j}}(s_1, t_1)=1 \\ \max\{\mathbf{r}^{\mathsf{j}}(s_1, t_1)+\lambda(1-\frac{\mathbf{r}^{\mathsf{j}}(s_1,t_1)}{\lambda})\mathbf{r}^{\mathsf{j}}(s_2, t_2)\,,\ \mathbf{r}^{\mathsf{j}}(s_2, t_2)\} & \text{if } \mathbf{r}^{\mathsf{j}}(s_1, t_1)\in[0, 1) \end{cases}$

(b) $\mathbf{r}^{\mathsf{j}}(s_1 \mid s_2, t_1 \mid t_2) \leq r^{\mathsf{j}}_{\mathsf{synch}}$

(c) $\mathbf{r}^{\mathsf{j}}(s_1 \parallel_B s_2, t_1 \parallel_B t_2) \leq \begin{cases} r^{\mathsf{j}}_{\mathsf{synch}} & \text{if } B \neq \emptyset \\ r^{\mathsf{j}}_{\mathsf{asynch}} & \text{otherwise} \end{cases}$

with

$$r^{\mathsf{j}}_{\mathsf{synch}} = \begin{cases} 1 & \text{if } \mathbf{r}^{\mathsf{j}}(s_1, t_1) = 1 \vee \mathbf{r}^{\mathsf{j}}(s_2, t_2) = 1 \\ \mathbf{r}^{\mathsf{j}}(s_1, t_1) + \mathbf{r}^{\mathsf{j}}(s_2, t_2) - \frac{\mathbf{r}^{\mathsf{j}}(s_1,t_1)\mathbf{r}^{\mathsf{j}}(s_2,t_2)}{\lambda} & \text{otherwise} \end{cases}$$

$$r^{\mathsf{j}}_{\mathsf{asynch}} = \begin{cases} 1 & \text{if } \mathbf{r}^{\mathsf{j}}(s_1, t_1)=1 \vee \mathbf{r}^{\mathsf{j}}(s_2, t_2)=1 \\ \max\{\mathbf{r}^{\mathsf{j}}(s_1, t_1) + \lambda^2\mathbf{r}^{\mathsf{j}}(s_2, t_2) - \lambda\mathbf{r}^{\mathsf{j}}(s_1, t_1)\mathbf{r}^{\mathsf{j}}(s_2, t_2), & \\ \quad \mathbf{r}^{\mathsf{j}}(s_2, t_2) + \lambda^2\mathbf{r}^{\mathsf{j}}(s_1, t_1) - \lambda\mathbf{r}^{\mathsf{j}}(s_1, t_1)\mathbf{r}^{\mathsf{j}}(s_2, t_2)\} & \text{otherwise.} \end{cases}$$

Let us explain first Proposition 14.1. If $\mathbf{r}^{\mathsf{j}}(s_1, t_1) = 1$ then the maximal distance between s_1 and t_1 extends to $s_1; s_2$ and $t_1; t_2$. If $\mathbf{r}^{\mathsf{j}}(s_1, t_1) < 1$ then $\mathbf{r}^{\mathsf{j}}(s_1; s_2\,,\ t_1; t_2)$ is the maximum between the values given by the two different scenarios:

(i) the first one is that s_1 and t_1 evolve followed by s_2 and t_2, thus implying that we observe the distance $\mathbf{r}^{\mathsf{j}}(s_1, t_1)$ between s_1 and t_1 plus the distance $\mathbf{r}^{\mathsf{j}}(s_2, t_2)$ between s_2 and t_2, weighted by the likelihood that s_1 and t_1 exhibit the same behaviour, which is at most $(1 - \mathbf{r}^{\mathsf{j}}(s_1, t_1)/\lambda)$, and discounted by λ, since s_2 and t_2 are delayed by at least one step;

(ii) the second scenario is that s_1 and t_1 terminate immediately, so that we can observe only the distance $\mathbf{r}^{\mathsf{j}}(s_2, t_2)$ between s_2 and t_2, with no discount.

Consider now Proposition 14.2. If $\mathbf{r}^{\mathsf{j}}(s_1, t_1) = 1$ or $\mathbf{r}^{\mathsf{j}}(s_2, t_2) = 1$ then the upper bound is immediate. Otherwise, we obtain $\mathbf{r}^{\mathsf{j}}(s_1 \mid s_2, t_1 \mid t_2)$ by summing the distances $\mathbf{r}^{\mathsf{j}}(s_1, t_1)$ and $\mathbf{r}^{\mathsf{j}}(s_2, t_2)$ and, then, by subtracting $\frac{\mathbf{r}^{\mathsf{j}}(s_1,t_1)\mathbf{r}^{\mathsf{j}}(s_2,t_2)}{\lambda}$, which allows us to weight one of the two distances, say $\mathbf{r}^{\mathsf{j}}(s_2, t_2)$ by the likelihood that the other two processes exhibit the same behaviour, namely $(1 - \frac{\mathbf{r}^{\mathsf{j}}(s_1,t_1)}{\lambda})$. Finally, consider Proposition 14.3. If processes can synchronise, then the upper bound is the same as Proposition 14.2. Otherwise, either s_1 and t_1 evolve and s_2 and t_2 are delayed, or, symmetrically, s_2 and t_2 evolve and s_1 and t_1 are delayed. The distance between the delayed processes is therefore discounted and we get a bound slightly below that of Proposition 14.2.

Table 3 Lipschitz continuous operators

$$\frac{x \xrightarrow{a} \mu \quad a \neq \surd}{x^{n+1} \xrightarrow{a} \mu;\delta(x^n)} \qquad \frac{x \xrightarrow{\surd} \mu}{x^{n+1} \xrightarrow{\surd} \mu} \qquad \frac{}{x^0 \xrightarrow{\surd} \delta(0)} \qquad \frac{x \xrightarrow{\surd} \mu \quad x \xrightarrow{a} \nu \quad a \neq \surd \quad n > m}{x^n \xrightarrow{a} \nu;\delta(x^m)}$$

$$\frac{x \xrightarrow{a} \mu \quad a \neq \surd}{!^{n+1}x \xrightarrow{a} \mu \,||_\emptyset\, \delta(!^n x)} \qquad \frac{x \xrightarrow{\surd} \mu}{!^{n+1}x \xrightarrow{\surd} \mu} \qquad \frac{}{!^0 x \xrightarrow{\surd} \delta(0)} \qquad \frac{x \xrightarrow{a} \mu \quad a \neq \surd}{x^\omega \xrightarrow{a} \mu;\delta(x^\omega)}$$

$$\frac{x \xrightarrow{a} \mu \quad a \neq \surd}{x^* y \xrightarrow{a} \mu;\delta(x^* y)} \qquad \frac{y \xrightarrow{a} \nu}{x^* y \xrightarrow{a} \nu} \qquad \frac{x \xrightarrow{a} \mu \quad a \neq \surd}{!x \xrightarrow{a} \mu \,|||\, \delta(!x)} \qquad \frac{x \xrightarrow{a} \mu \quad a \neq \surd}{!_p x \xrightarrow{a} \mu \oplus_p (\mu \,|||\, \delta(!_p x))}$$

Notice that also the processes s_i and t_i in Proposition 14 are obtained by using arbitrary operators, not necessarily in Σ_{NExp}. The following result follows from Proposition 14.

▶ **Theorem 15.** *The operators in Table 2 are non-expansive with respect to* $\mathbf{r}^{\mathsf{q}}$ *and* $\mathbf{r}^{\mathsf{m}}$.

Clearly, the results in Proposition 14 can be generalised to more complex terms. For instance, we give two generalizations of Proposition 14.2 that will be used in the case study presented in the next section.

▶ **Proposition 16.** *Assume processes* $s_1, t_1, \ldots, s_n, t_n$, *with* $n \geq 2$. *We have:*

$$\mathbf{r}^{\mathsf{m}}(s_1|\ldots|s_n, t_1|\ldots|t_n) \;\leq \sum_{\emptyset \subset I \subseteq \{1,\ldots,n\}} (-1)^{|I|+1} \prod_{i \in I} \mathbf{r}^{\mathsf{m}}(s_i, t_i) \;\; .$$

▶ **Proposition 17.** *Assume processes* $s_1, t_1, \ldots, s_n, t_n$, *with* $n \geq 2$. *If* $\mathbf{r}^{\mathsf{m}}(s_i, t_i) = r$ *for all* $i = 1, \ldots n$, *then we have:*

$$\mathbf{r}^{\mathsf{m}}(s_1|\ldots|s_n, t_1|\ldots|t_n) \;\leq\; -\sum_{i=1}^{n} \binom{n}{i} (-r)^i \;\; .$$

Lipschitz continuous operators. Now we show that all operators in Table 3 are Lipschitz continuous. Consider the TSS $T_{\mathrm{LC}} = (\Sigma_{\mathrm{LC}}, Act, R_{\mathrm{LC}})$ with $T_{\mathrm{NExp}} \sqsubseteq T_{\mathrm{LC}}$ and R_{LC} containing the rules in Table 3, besides those in Table 1–2.

▶ **Proposition 18.** *Assume any TSS* $T = (\Sigma, A, R)$ *with* $T_{LC} \sqsubseteq T$ *and* $s, s_i, t, t_i \in \mathcal{T}(\Sigma)$. *For* $\mathsf{j} \in \{\mathsf{q}, \mathsf{m}\}$ *we have:*

(a) $\mathbf{r}^{\mathsf{j}}(s^n, t^n) \leq \begin{cases} \mathbf{r}^{\mathsf{j}}(s,t)\frac{1-(\lambda-\mathbf{r}^{\mathsf{j}}(s,t))^n}{1-(\lambda-\mathbf{r}^{\mathsf{j}}(s,t))} & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in (0,1) \\ \mathbf{r}^{\mathsf{j}}(s,t) & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in \{0,1\} \end{cases}$

(b) $\mathbf{r}^{\mathsf{j}}(!^n s, !^n t) \leq \begin{cases} \mathbf{r}^{\mathsf{j}}(s,t)\frac{1-(\lambda^2-\lambda\mathbf{r}^{\mathsf{j}}(s,t))^n}{1-(\lambda^2-\lambda\mathbf{r}^{\mathsf{j}}(s,t))} & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in (0,1) \\ \mathbf{r}^{\mathsf{j}}(s,t) & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in \{0,1\} \end{cases}$

(c) $\mathbf{r}^{\mathsf{j}}(s^\omega, t^\omega) \leq \begin{cases} \mathbf{r}^{\mathsf{j}}(s,t)\frac{1}{1-(\lambda-\mathbf{r}^{\mathsf{j}}(s,t))} & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in (0,1) \\ \mathbf{r}^{\mathsf{j}}(s,t) & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in \{0,1\} \end{cases}$

(d) $\mathbf{r}^{\mathsf{j}}(!s, !t) \leq \begin{cases} \mathbf{r}^{\mathsf{j}}(s,t)\frac{1}{1-(\lambda^2-\lambda\mathbf{r}^{\mathsf{j}}(s,t))} & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in (0,1) \\ \mathbf{r}^{\mathsf{j}}(s,t) & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in \{0,1\} \end{cases}$

(e) $\mathbf{r}^{\mathsf{j}}(s_1{}^* s_2, t_1{}^* t_2) \leq \max(\mathbf{r}^{\mathsf{j}}(s_1{}^\omega, t_1{}^\omega), \mathbf{r}^{\mathsf{j}}(s_2, t_2))$

(f) $\mathbf{r}^{\mathsf{j}}(!_p s, !_p t) \leq \begin{cases} \mathbf{r}^{\mathsf{j}}(s,t)\frac{1}{1-(1-p)(\lambda^2-\lambda\mathbf{r}^{\mathsf{j}}(s,t))} & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in (0,1) \\ \mathbf{r}^{\mathsf{j}}(s,t) & \text{if } \mathbf{r}^{\mathsf{j}}(s,t) \in \{0,1\}. \end{cases}$

The bound in Proposition 18.1 is obtained by applying $n-1$ times the bound in Proposition 14 for operator $\_\,;\_$, the rationale being that the pLTS associated to s^n is isomorphic to that of process $s;\ldots;s$ with n occurrences of s. Similarly, the bound in Proposition 18.2 is obtained by applying $n-1$ times the bound in Proposition 14 for operator $\_\,||_\emptyset\,\_$, the rationale being that $!^n s$ denotes a pLTS isomorphic to that of process $s\,||_\emptyset \ldots ||_\emptyset\, s$ with n occurrences of s. The bounds in Proposition 18.3 and Proposition 18.4 are obtained by taking the limits for the bounds in Proposition 18.1 and Proposition 18.2, respectively. Proposition 18.5 is obtained by observing that the (bi)simulation tolerance between processes ${s_1}^* s_2$ and ${t_1}^* t_2$ is less than or equal to the maximum of the tolerance bound $\mathbf{r}^{\mathsf{j}}({s_1}^\omega, {t_1}^\omega)$ (infinite iteration of s_1 and t_1 such that s_2 and t_2 never evolve), and the tolerance bound $\mathbf{r}^{\mathsf{j}}(s_2,t_2)$ (s_2 and t_2 evolve immediately). The case where s_1 and t_1 iterate n-times and then s_2 and t_2 evolve leads always to a tolerance bound $\mathbf{r}^{\mathsf{j}}({s_1}^n,{t_1}^n) + (\lambda - \mathbf{r}^{\mathsf{j}}(s_1,t_1))^n \mathbf{r}^{\mathsf{j}}(s_2,t_2) \leq \max(\mathbf{r}^{\mathsf{j}}({s_1}^\omega,{t_1}^\omega), \mathbf{r}^{\mathsf{j}}(s_2,t_2))$. Finally, Proposition 18.6 can be understood by observing that $!_p s$ behaves as $!^{n+1}s$ with probability $p(1-p)^n$. Hence, by Proposition 18.2 we get $\mathbf{r}^{\mathsf{j}}(!_p s, !_p t) \leq \sum_{n=0}^{\infty} p(1-p)^n \mathbf{r}^{\mathsf{j}}(!^{n+1}s, !^{n+1}t) \leq \sum_{n=0}^{\infty} p(1-p)^n r^{\mathsf{j}}_{!^{n+1}} = \mathbf{r}^{\mathsf{j}}(s,t)/(1-(1-p)(\lambda^2 - \lambda \mathbf{r}^{\mathsf{j}}(s,t)))$.

Notice also that the processes s, t, s_i, t_i in Proposition 18 are obtained by using arbitrary operators, not necessarily in Σ_{LC}. The following result follows from Proposition 18.

▶ **Theorem 19.** *The operators*

(i) *finite iteration* $\_^n$
(ii) *finite replication* $!^n\_$
(iii) *probabilistic replication* $!_p\_$

are Lipschitz continuous with respect to $\mathbf{r}^{\mathsf{q}}$ *and* $\mathbf{r}^{\mathsf{m}}$ *for any* $\lambda \in (0,1]$. *The operators*

(i) *infinite iteration* $\_^\omega$
(ii) *nondeterministic Kleene-star iteration* $\_^*\_$
(iii) *infinite replication* $!\_$

are Lipschitz continuous with respect to $\mathbf{r}^{\mathsf{q}}$ *and* $\mathbf{r}^{\mathsf{m}}$ *for any* $\lambda \in (0,1)$.

Notice that discounting the distance observed at step n by λ^n is necessary to have compositionality of the operators $\_^\omega$, $\_^*\_$, and $!\_$.

4 A case study: Group Key Update

A *group key* is a secret key shared by a group of principals to secure their *multicast communications*. Group key update protocols were originally adopted to secure LANs [32]. Nowadays they are widely used in different contexts, such as: audio and video conferencing in Computer Supported Co-operative Work (CSCW), Virtual Private Networks (VPN), distributed databases, instant messaging applications, etc.

A crucial problem when dealing with key-secured communications is *rekeying*, i.e. the process of distributing new keys to the principals. Rekeying is necessary when a member joins the group, to prevent it to access the information exchanged in the past (*backward confidentiality*), and when a member leaves the group, to prevent it to access future data (*forward confidentiality*). Rekeying is managed either by a third trusted party or by a member acting as *group owner*. In our example, we abstract from these two solutions by assuming a unique *key manager entity* which takes care of rekeying.

We assume a set $\mathcal{N}$ of member IDs. For each members $i \in \mathcal{N}$, the probabilities of leaving and joining the group are $l(i)$ and $j(i)$, respectively. Furthermore, each member can leave/join the group at most n times. Notice that high values of n, $l(i)$ or $j(i)$ cause frequent rekeying, with obvious consequences on:

Table 4 An abstract group key update protocol.

$$
\begin{array}{lcl}
\mathit{Group}(l,j) & = & (\nu\,(\mathit{Act} \setminus \mathsf{newK}))\,\big(\mathit{Manager} \mid \prod_{i\in\mathcal{N}} \mathit{Member}(i,l(i),j(i))\big) \\
\mathit{Manager} & = & \mathit{Connected} \mid \big(\sum_{I\subseteq\mathcal{N}} \mathsf{act}_I; \mathit{Mng}(I)\big)^{\omega} \\
\mathit{Connected} & = & \overline{\mathsf{act}}_{\mathcal{N}}; \Big(\sum_{I\subseteq\mathcal{N}} \mathsf{sync}_I; \overline{\mathsf{act}}_I; \varepsilon\Big)^{\omega} \\
\mathit{Mng}(I) & = & \big(\sum_{i\in I} \mathsf{leave}_i; \overline{\mathsf{newK}}; \mathit{SendNewKey}(I\setminus i); \overline{\mathsf{sync}}_{I\setminus i}; \varepsilon\big) + \\
 & & \big(\sum_{i\in(\mathcal{N}\setminus I)} \mathsf{join}_i; \overline{\mathsf{newK}}; \mathit{SendNewKey}(I\cup i); \overline{\mathsf{sync}}_{I\cup i}; \varepsilon\big) \\
\mathit{SendNewKey}(\{i_1,\ldots,i_k\}) & = & \overline{(\mathsf{i}_1,\mathsf{Key})}; \ldots; \overline{(\mathsf{i}_k,\mathsf{Key})}; \varepsilon \\
\mathit{Member}(i,p,q) & = & \mathit{State}(i) \mid \big(\mathit{MembIn}(i,p) + \mathit{MembOut}(i,q)\big)^{n} \\
\mathit{State}(i) & = & \overline{\mathsf{in}}_i; \big(\overline{\mathsf{in}}_i{}^{*}; \mathsf{change}_i; \overline{\mathsf{out}}_i{}^{*}; \mathsf{change}_i; \varepsilon\big)^{*} \\
\mathit{MembIn}(i,p) & = & \mathsf{in}_i; \big((\mathsf{i},\mathsf{Key}) + \tau; \big((\overline{\mathsf{leave}}_i; \overline{\mathsf{change}}_i; \varepsilon) \oplus_p \varepsilon\big)\big) \\
\mathit{MembOut}(i,q) & = & \mathsf{out}_i; \tau; \big((\overline{\mathsf{join}}_i; \overline{\mathsf{change}}_i; (\mathsf{i},\mathsf{Key}); \varepsilon) \oplus_q \varepsilon\big)
\end{array}
$$

(a) the number of attacks aiming at compromising the group key,
(b) degradation of communication service,
(c) battery consumption.

Thus, in the following, a group key protocol in which members never leave/join the group (i.e. $l(i) = j(i) = 0$, for any $i \in \mathcal{N}$) will be called *ideal*.

Our goal is to show that the theory developed in the previous section represents an effective instrument to estimate the distance between the ideal protocol and possible variations of the protocol obtained by playing with the parameters n, $l(i)$ and $j(i)$, for $i \in \mathcal{N}$.

Table 4 reports an abstract representation of the rekeying process in terms of our general process algebra. Since cryptographic details are not relevant for our purposes, we protect communications via the restriction operator $(\nu\,\alpha)\,\_$. We observe only the signal newK denoting the rekeying event. For simplicity, in the protocol, we will write $I \setminus i$ instead of $I \setminus \{i\}$, and $I \cup i$ instead of $I \cup \{i\}$.

The process $\mathit{Group}(l,j)$ represents a group, in its initial configuration, containing all members in $\mathcal{N}$, each of which can leave/enter the group at most n times. This process consists of the parallel composition of the process *Manager* together with a process for each member in $\mathcal{N}$. The process *Manager* has two parallel components: (a) the process *Connected*, which determines those members which are currently part of the group, and (b) a process that upon reception of a signal act_I, with $I \subseteq \mathcal{N}$, it behaves as $\mathit{Mng}(I)$, i.e. the process managing the group with members in the set I. Initially, all members join the group. Thus, *Connected* starts by activating the process $\mathit{Mng}(\mathcal{N})$. Then, whenever *Connected* receives a signal sync_I (from some $\mathit{Mng}(J)$) it activates $\mathit{Mng}(I)$ by sending the signal act_I. Notice that, in this case, there is a member i such that either $I = J \setminus \{i\}$, because i has left the group, or $I = J \cup \{i\}$, because i has joined the group.

The process $\mathit{Mng}(I)$ behaves as follows. Whenever it senses a signal leave_i (resp. join_i) denoting that a connected member $i \in I$ (resp. an unconnected member $i \in \mathcal{N} \setminus I$) is leaving (resp. joining) the group, it performs the following actions:

(i) it signals the generation of a new key,
(ii) it broadcasts the new key to all members in $J = I \setminus i$ (resp. $J = I \cup i$), namely the members of the new group,
(iii) it communicates to *Connected* the new set of current members in the group via a signal sync_J.

The process $Member(i,p,q)$ consists of the parallel composition of the process $State(i)$, which stores the state of member i, together with either the process $MembIn(i,p)$, which describes the behaviour of i when it is in the group, or the process $MembOut(i,q)$, which describes the behaviour of i when it is out of the group. The signal in_i (resp. out_i) is used by $State(i)$ to activate $MembIn(i,p)$ (resp. $MembOut(i,q)$). Via process $MembIn(i,p)$, the member i may either receive the new key from the manager or leave the group with a probability p. Similarly, via process $MembOut(i,q)$, the member i may decide to join the group with probability q. If i succeeds in joining the group then a new group key is sent to i and all current members of the group. This completes the explanation of the protocol.

Now, let $\mathbf{p}$ denote the constant function $\mathbf{p}\colon \mathcal{N} \to [0,1]$, with $\mathbf{p}(i) = p$ for all $i \in \mathcal{N}$. Similarly, we define $\mathbf{q}$. Thus, $Group(\mathbf{p},\mathbf{q})$ denotes the instance of the protocol where all members have the same leave/join probability, whereas $Group(\mathbf{0},\mathbf{0})$ denotes the *ideal* group, where rekeying never occurs as the no principal leaves or join the group.

We start our analysis by providing an upper bound of the distance between the behaviours of an arbitrary member $i \in \mathcal{N}$, when varying leave/join probabilities. For that we need a technical lemma to estimate the distance between two occurrences of probabilistic prefix dealing with the same processes, but different probabilities.

▶ **Lemma 20.** *For all $s,t \in \mathcal{T}(\Sigma)$ we have $\mathbf{r}^{\mathsf{m}}(a.(s \oplus_p t), a.(s \oplus_q t)) \leq |p-q|$.*

▶ **Proposition 21.** *Let $p,q,p',q' \in [0,1]$, then*

$$\mathbf{r}^{\mathsf{m}}(Member(i,p,q), Member(i,p',q')) \;\leq\; \max(|p-p'|,|q-q'|)\frac{1-(1-r)^n}{1+r}.$$

Proof. By Lemma 20 and compositionality results in Proposition 12.1 and Prop. 12.2 we get $\mathbf{r}^{\mathsf{m}}(MembIn(i,p), MembIn(i,p')) \leq |p-p'|$ and $\mathbf{r}^{\mathsf{m}}(MembOut(i,q), MembOut(i,q')) \leq |q-q'|$. Then, the thesis follows by applying the compositionality results in Proposition 12.3, Proposition 14.2, Proposition 18.1 ◀

We can generalise this result by taking into account all members in $\mathcal{N}$.

▶ **Proposition 22.** *Given arbitrary functions $l,j,l',j'\colon \mathcal{N} \to [0,1]$, we have:*

$$\mathbf{r}^{\mathsf{m}}(Group(l,j), Group(l',j')) \leq \sum_{I\subseteq\mathcal{N}, I\neq\emptyset} (-1)^{|I|+1} \prod_{i\in I} r(i)\frac{1-(1-r(i))^n}{1+r(i)}$$

with $r(i) = \max(|l(i)-l'(i)|, |j(i)-j'(i)|)$.

Proof. By Proposition 21, Proposition 16 and the compositionality results of Proposition 14.2 and Proposition 12.6. ◀

Proposition 22 estimates the distance between an arbitrary group and the ideal one.

▶ **Corollary 23.** *For any $l,j,r\colon \mathcal{N} \to [0,1]$ such that $r(i) = \max(l(i),j(i))$, we have:*

$$\mathbf{r}^{\mathsf{m}}(Group(\mathbf{0},\mathbf{0}), Group(l,j)) \;\leq\; \sum_{I\subseteq\mathcal{N}, I\neq\emptyset} (-1)^{|I|+1} \prod_{i\in I} r(i)\frac{1-(1-r(i))^n}{1+r(i)} \quad .$$

We can also compare two instances of the protocol when assuming homogeneous probabilities (i.e. all members leaves/join the group with the same probabilities.)

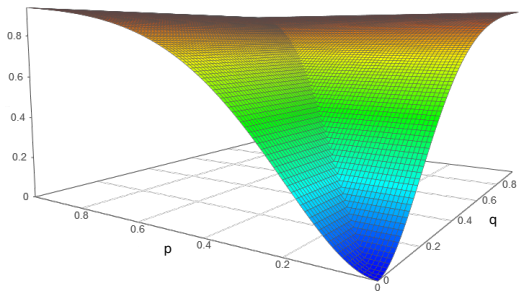

Figure 1 Upper bound to $\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{q}))$

▶ **Proposition 24.** *For arbitrary probabilities $p, p', q, q' \in [0,1]$ we have:*

$$\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{p},\mathbf{q}), \mathit{Group}(\mathbf{p}',\mathbf{q}')) \leq -\sum_{i=1}^{|\mathcal{N}|} \binom{|\mathcal{N}|}{i} \left(-r\frac{1-(1-r)^n}{1+r}\right)^i$$

with $r = \max(|p-p'|, |q-q'|)$.

Proof. By Proposition 21, Proposition 17 and the compositionality results of Proposition 12.6 and Proposition 14.2. ◀

This allows us to compare a group with homogeneous probabilities with the ideal group.

▶ **Corollary 25.** *For arbitrary probabilities $p, q \in [0,1]$ we have:*

$$\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{q})) \leq -\sum_{i=1}^{|\mathcal{N}|} \binom{|\mathcal{N}|}{i} \left(-(\max(p,q)\frac{1-(1-(\max(p,q))^n}{1+(\max(p,q)}\right)^i.$$

For instance, assume an instance of the protocol with $\mathcal{N} = \{1,\ldots,4\}$ and $n = 3$. Then we have $\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{q})) \leq 4r - 6r^2 + 4r^3 - r^4$, with $r = \max(p,q)\frac{1-(1-\max(p,q))^3}{1+\max(p,q)}$. The upper bound is reported in Fig. 1. Notice that the surface is symmetric, meaning that the upper bounds for $p \geq q$ and $q \geq p$ coincide (because they depend on $\max(p,q)$).

Figures 2 and 3 describe the evolution of the upper bound of $\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{p}))$, i.e. when leave and join probability are the same ($p = q$). In Figure 2 we fix 4 members and we vary n in the set $\{3,5,7,9,11\}$. We can observe that $\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{p}))$ grows with n, in particular for group with low values of p and q. In Figure 3, we fix n equals to 3 and vary the number of members in the set $\{4,5,6,7,8\}$. We can observe that $\mathbf{r}^{\mathsf{m}}(\mathit{Group}(\mathbf{0},\mathbf{0}), \mathit{Group}(\mathbf{p},\mathbf{p}))$ grows with the size of the group, in particular in group with high values of p (and q).

Summarising, we can assert that the protocol under analysis has good efficiency in groups with low dynamicity, regardless of the size of the group.

5 Conclusions, related and future work

We showed that uniform continuity is an effective property to achieve compositional reasoning with respect to rooted (quasi)metric semantics. We considered all standard operators of

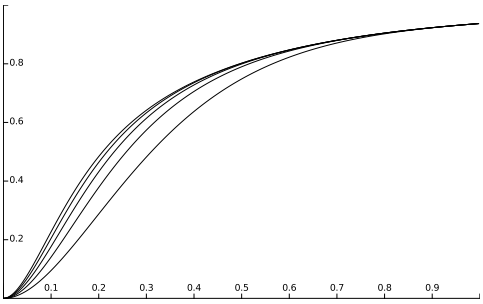

Figure 2 4 members and $n \in \{3, 5, 7, 9, 11\}$.

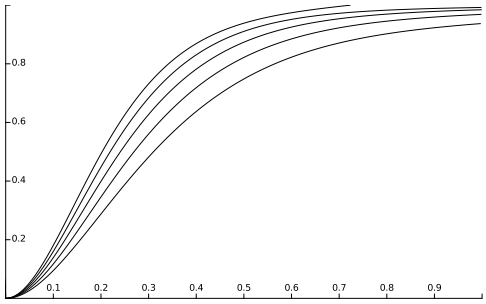

Figure 3 $n = 3$ and $4 \leq$ members ≤ 8.

probabilistic process algebra and provided suitable upper bounds on the distance between processes composed by these operators. This allows us to infer their uniform continuity with respect to both rooted bisimilarity metric and rooted similarity quasimetric. Interestingly, the rootedness condition, introduced to deal with nondeterministic and probabilistic choice, is crucial when dealing with similarity quasimetric. We exemplified how these semantic theories can be used to pursue compositional reasoning over a non-trivial protocol.

The current paper is the ideal continuation of [20]. In that paper, the authors show that uniform continuity captures the essential intuition of compositional reasoning when dealing with probabilistic processes. The proposal of [20] generalises and extends earlier proposals in [17, 2] to capture recursive operators. The focus of all these papers is on strong bisimulation metrics. We remark that, following [35, 17, 14], we have considered (bi)simulation-inspired (quasi)metric for the pLTS model. However, the literature offers also different approaches to estimate the distance between processes. In [19] a spectrum of distances between processes is obtained by applying the theory of quantitative Ehrenfeucht-Fraïssé games to transition systems. This theory allows to generate different notions of distance by means of different generalisations of a suitable distance over traces. Paper [11] studies distances between processes in the semantic model of Metric Transition Systems. In [3, 8] trace metrics for the model of Markov Chains are defined as total variation distances on the cones generated by the execution traces. In [29] the distance between systems is defined by means of a probabilistic approximated bisimulation. This paper provides a technique to compute upper bounds based on compositional algebraic laws.

As *future work*, we will extend the analysis of concrete process algebra operators to general SOS rule and specification formats. A SOS rule and specification format ensuring uniform continuity of operators with respect to strong bisimilarity metric has been proposed in [21, 22], the idea being that process arguments of operators are copied only finitely many times along their evolution. In order to achieve the same result in the weak case, it is necessary to strengthen the format of [21] by preventing that process replication can arise by τ-transitions. After that, we intend to extend our approach to the weak versions of other notions of distance, such as convex bisimulation metric [13], trace metric [19], and total-variation distance based metrics [31]. Finally, another possible research direction is develop a timed-variant of our technique to deal with timed aspects of systems as in [27, 28].

Abstract

Clique-width is an important graph parameter due to its algorithmic and structural properties. A graph class is hereditary if it can be characterized by a (not necessarily finite) set $\mathcal{H}$ of forbidden induced subgraphs. We initiate a systematic study into the boundedness of clique-width of hereditary graph classes closed under complementation. First, we extend the known classification for the $|\mathcal{H}| = 1$ case by classifying the boundedness of clique-width for every set $\mathcal{H}$ of self-complementary graphs. We then completely settle the $|\mathcal{H}| = 2$ case. In particular, we determine one new class of $(H, \overline{H})$-free graphs of bounded clique-width (as a side effect, this leaves only six classes of (H_1, H_2)-free graphs, for which it is not known whether their clique-width is bounded). Once we have obtained the classification of the $|\mathcal{H}| = 2$ case, we research the effect of forbidding self-complementary graphs on the boundedness of clique-width. Surprisingly, we show that for a set $\mathcal{F}$ of self-complementary graphs on at least five vertices, the classification of the boundedness of clique-width for $(\{H, \overline{H}\} \cup \mathcal{F})$-free graphs coincides with the one for the $|\mathcal{H}| = 2$ case if and only if $\mathcal{F}$ does not include the bull (the only non-empty self-complementary graphs on fewer than five vertices are P_1 and P_4, and P_4-free graphs have clique-width at most 2). Finally, we discuss the consequences of our results for Colouring.

1 Introduction

Many graph-theoretic problems that are computationally hard for general graphs may still be solvable in polynomial time if the input graph can be decomposed into large parts of "similarly

behaving" vertices. Such decompositions may lead to an algorithmic speed up and are often defined via some type of graph construction. One particular type is to use vertex labels and to allow certain graph operations, which ensure that vertices labelled alike will always keep the same label and thus behave identically. The clique-width $\mathrm{cw}(G)$ of a graph G is the minimum number of different labels needed to construct G using four such operations (see Section 2 for details). Clique-width has been studied extensively both in algorithmic and structural graph theory. The main reason for its popularity is that, indeed, many well-known NP-hard problems [14, 25, 35, 40], such as Colouring and Hamilton Cycle, become polynomial-time solvable on any graph class $\mathcal{G}$ of *bounded* clique-width, that is, for which there exists a constant c, such that every graph in $\mathcal{G}$ has clique-width at most c. Graph Isomorphism is also polynomial-time solvable on such graph classes [30]. Having bounded clique-width is equivalent to having bounded rank-width [39] and having bounded NLC-width [33], two other well-known width-parameters. However, despite these close relationships, clique-width is a notoriously difficult graph parameter, and our understanding of it is still very limited. For instance, no polynomial-time algorithms are known for computing the clique-width of very restricted graph classes, such as unit interval graphs, or for deciding whether a graph has clique-width at most 4.[1] In order to get a better understanding of clique-width and to identify new "islands of tractability" for central NP-hard problems, many graph classes of bounded and unbounded clique-width have been identified; see, for instance, the Information System on Graph Classes and their Inclusions [24], which keeps a record of such graph classes. In this paper we study the following research question:

What kinds of properties of a graph class ensure that its clique-width is bounded?

We refer to the surveys [31, 34] for examples of such properties. Here, we consider graph complements. The *complement* $\overline{G}$ of a graph G is the graph with vertex set V_G and edge set $\{uv \mid uv \notin E(G)\}$ and has clique-width $\mathrm{cw}(\overline{G}) \leq 2\,\mathrm{cw}(G)$ [15]. This result implies that a graph class $\mathcal{G}$ has bounded clique-width if and only if the class consisting of all complements of graphs in $\mathcal{G}$ has bounded clique-width. Due to this, we initiate a *systematic* study of the boundedness of clique-width for graph classes $\mathcal{G}$ *closed under complementation*, that is, for every graph $G \in \mathcal{G}$, its complement $\overline{G}$ also belongs to $\mathcal{G}$.

To get a handle on graph classes closed under complementation, we restrict ourselves to graph classes that are not only closed under complementation but also under vertex deletion. This is a natural assumption, as deleting a vertex does not increase the clique-width of a graph. A graph class closed under vertex deletion is said to be *hereditary* and can be characterized by a (not necessarily finite) set $\mathcal{H}$ of forbidden induced subgraphs. Over the years many results on the (un)boundedness of clique-width of hereditary graph classes have appeared. We briefly survey some of these results below.

A hereditary graph class of graphs is monogenic or H-free if it can be characterized by one forbidden induced subgraph H, and bigenic or (H_1, H_2)-free if it can be characterized by two forbidden induced subgraphs H_1 and H_2. It is well known (see [23]) that a class of H-free graphs has bounded clique-width if and only if H is an induced subgraph of P_4.[2] By combining known results [3, 5, 7, 8, 9, 10, 11, 17, 18, 21, 38] with new results for bigenic graph classes, Dabrowski and Paulusma [23] classified the (un)boundedness of clique-width of (H_1, H_2)-free graphs for all but 13 pairs (H_1, H_2) (up to an equivalence relation). Afterwards,

[1] It is known that computing clique-width is NP-hard in general [27] and that deciding whether a graph has clique-width at most 3 is polynomial-time solvable [13].

[2] We refer to Section 2 for all the notation used in this section.

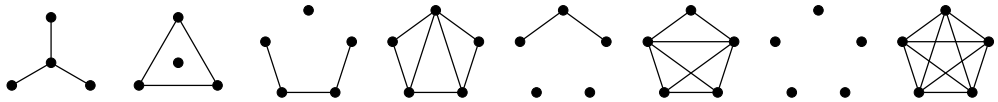

Figure 1 Graphs H for which the clique-width of $(H, \overline{H})$-free graphs is bounded ($s = 5$ is shown).

five new classes of (H_1, H_2)-free graphs were identified by Dross et al. [16] and recently, another one was identified by Dabrowski et al. [19]. This means that only seven cases (H_1, H_2) remained open. Other systematic studies were performed for H-free weakly chordal graphs [5], H-free chordal graphs [5] (two open cases), H-free triangle-free graphs [19] (two open cases), H-free bipartite graphs [22], H-free split graphs [4] (two open cases), and $\mathcal{H}$-free graphs where $\mathcal{H}$ is any set of 1-vertex extensions of the P_4 [6] or any set of graphs on at most four vertices [7]. Clique-width results or techniques for these graph classes impacted upon each other and could also be used for obtaining new results for bigenic graph classes.

Our Contribution. Recall that we investigate the clique-width of hereditary graph classes closed under complementation. A graph that contains no induced subgraph isomorphic to a graph in a set $\mathcal{H}$ is said to be *$\mathcal{H}$-free*. We first consider the $|\mathcal{H}| = 1$ case. The class of H-free graphs is closed under complementation if and only if H is a self-complementary graph, that is, $H = \overline{H}$. Self-complementary graphs have been extensively studied; see [26] for a survey. From the aforementioned result for P_4-free graphs, we find that the only self-complementary graphs H for which the class of H-free graphs has bounded clique-width are $H = P_1$ and $H = P_4$. In Section 3 we prove the following generalization of this result.

▶ **Theorem 1.** *Let $\mathcal{H}$ be a set of non-empty self-complementary graphs. Then the class of $\mathcal{H}$-free graphs has bounded clique-width if and only if either $P_1 \in \mathcal{H}$ or $P_4 \in \mathcal{H}$.*

We now consider the $|\mathcal{H}| = 2$ case. Let $\mathcal{H} = \{H_1, H_2\}$. Due to Theorem 1 we may assume $H_2 = \overline{H_1}$ and H_1 is not self-complementary. The class of $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs was one of the seven remaining bigenic graph classes, and the only bigenic graph class closed under complementation, for which boundedness of clique-width was open. We settle this case by proving in Section 4 that the clique-width of this class is bounded. In the same section we combine this new result with known results to prove the following theorem, which, together with Theorem 1, shows to what extent the property of being closed under complementation helps with bounding the clique-width for bigenic graph classes (see also Figure 1).

▶ **Theorem 2.** *For a graph H, the class of $(H, \overline{H})$-free graphs has bounded clique-width if and only if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$ or sP_1 for some $s \geq 1$.*

For the $|\mathcal{H}| = 3$ case, where $\{H_1, H_2, H_3\} = \mathcal{H}$, we observe that a class of (H_1, H_2, H_3)-free graphs is closed under complementation if and only if either every H_i is self-complementary, or one H_i is self-complementary and the other two graphs H_j and H_k are complements of each other. By Theorem 1, we only need to consider $(H_1, \overline{H_1}, H_2)$-free graphs, where H_1 is not self-complementary, H_2 is self-complementary, and neither H_1 nor H_2 is an induced subgraph of P_4. The next two smallest self-complementary graphs H_2 are the C_5 and the bull (see also Figure 2). Observe that any self-complementary graph on n vertices must contain $\frac{1}{2}\binom{n}{2}$ edges and this number must be an integer, so $n = 4q$ or $n = 4q + 1$ for some integer $q \geq 0$. There are exactly ten non-isomorphic self-complementary graphs on eight vertices [41] and we depict these in Figure 3.

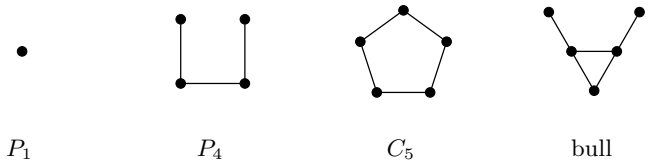

Figure 2 The four non-empty self-complementary graphs on less than eight vertices [41].

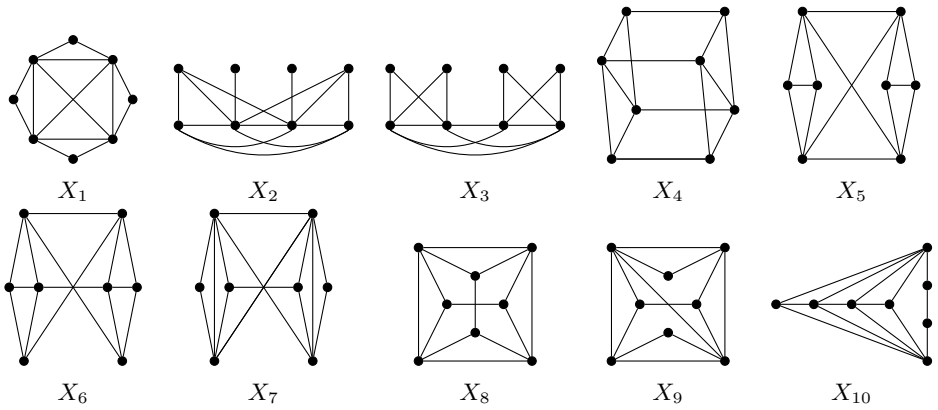

Figure 3 The ten self-complementary graphs on eight vertices [41].

It is known that split graphs, or equivalently, $(2P_2, \overline{2P_2}, C_5)$-free graphs have unbounded clique-width [38]. In Section 5 we determine three new hereditary graph classes of unbounded clique-width, which imply that the class of $(H, \overline{H}, C_5)$-free graphs has unbounded clique-width if $H \in \{K_{1,3}+P_1, 2P_2, 3P_1+P_2, S_{1,1,2}\}$. By combining this with known results, we discovered that the classification of boundedness of clique-width for $(H, \overline{H}, C_5)$-free graphs coincides with the one of Theorem 2. This raised the question of whether the same is true for other sets of self-complementary graphs $\mathcal{F} \neq \{C_5\}$. If $\mathcal{F}$ contains the bull, then the answer is negative: by Theorem 2, the class of $(S_{1,1,2}, \overline{S_{1,1,2}})$-free graphs and the class of $(2P_2, C_4)$-free graphs both have unbounded clique-width, but both the class of $(S_{1,1,2}, \overline{S_{1,1,2}}, \text{bull})$-free graphs and even the class of $(P_5, \overline{P_5}, \text{bull})$-free graphs have bounded clique-width [6]. However, also in Section 5, we prove that the bull is the *only* exception (apart from the trivial cases when $H' \in \{P_1, P_4\}$ which yield bounded clique-width of $(H, \overline{H}, H')$-free graphs for any graph H).

▶ **Theorem 3.** *Let $\mathcal{F}$ be a set of self-complementary graphs on at least five vertices not equal to the bull. For a graph H, the class of $(\{H, \overline{H}\} \cup \mathcal{F})$-free graphs has bounded clique-width if and only if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, P_1+P_4, $2P_1+P_3$ or sP_1 for some $s \geq 1$.*

Consequences. Due to our result for $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs, we can update the summary of [19] for the clique-width of bigenic graph classes and reduce the number of open cases from seven to six.

▶ **Open Problem 4.** *Have (H_1, H_2)-free graphs bounded or unbounded clique-width when:*

(i) $H_1 = 3P_1$ *and* $\overline{H_2} \in \{P_1 + S_{1,1,3}, S_{1,2,3}\}$;
(ii) $H_1 = 2P_1 + P_2$ *and* $\overline{H_2} \in \{P_1 + P_2 + P_3, P_1 + P_5\}$;
(iii) $H_1 = P_1 + P_4$ *and* $\overline{H_2} \in \{P_1 + 2P_2, P_2 + P_3\}$.

Another consequence of our result for $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs is that Colouring is polynomial-time solvable for this graph class. This result was used by Blanché et al. [2]:

▶ **Theorem 5** ([2]). *Let $H, \overline{H} \notin \{(s+1)P_1 + P_3, sP_1 + P_4 \mid s \geq 2\}$. Then* Colouring *is polynomial-time solvable for $(H, \overline{H})$-free graphs if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$, $P_2 + P_3$, P_5, or $sP_1 + P_2$ for some $s \geq 0$ and it is* NP*-complete otherwise.*

Comparing Theorems 2 and 5 shows that there are graph classes of unbounded clique-width closed under complementation for which Colouring is polynomial-time solvable. Nevertheless, on many graph classes, polynomial-time solvability of NP-hard problems stems from the underlying property of having bounded clique-width. The present paper illustrates this for the Colouring problem, since Theorem 28 implies that Colouring is solvable in polynomial time on $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs. By updating the summary of [16] (see also [29]), we find that there are twelve classes of (H_1, H_2)-free graphs, for which Colouring could still potentially be solved in polynomial time by showing that their clique-width is bounded.

Future Work. Apart from settling the classification of boundedness of clique-width for (H_1, H_2)-free graphs by addressing Open Problem 4, we aim to continue our study of boundedness of clique-width for graph classes closed under complementation. In particular, to complete the classification for $\mathcal{H}$-free graphs when $|\mathcal{H}| = 3$, we still need to determine those graphs H for which $(H, \overline{H}, \text{bull})$-free graphs have bounded clique-width (there are several cases left).

2 Preliminaries

The *disjoint union* $(V(G) \cup V(H), E(G) \cup E(H))$ of two vertex-disjoint graphs G and H is denoted by $G + H$ and the disjoint union of r copies of a graph G is denoted by rG. For a subset $S \subseteq V(G)$, we let $G[S]$ denote the subgraph of G induced by S. If $S = \{s_1, \ldots, s_r\}$ then, to simplify notation, we may also write $G[s_1, \ldots, s_r]$ instead of $G[\{s_1, \ldots, s_r\}]$. We write $G \setminus S = G[V(G) \setminus S]$; if $S = \{v\}$, we may write $G \setminus v$ instead. We write $G' \subseteq_i G$ to indicate that G' is an induced subgraph of G. The graphs C_r, K_r, $K_{1,r-1}$ and P_r denote the cycle, complete graph, star and path on r vertices, respectively. The graphs K_3 and $K_{1,3}$ are also called the *triangle* and *claw*. The graph $S_{h,i,j}$, for $1 \leq h \leq i \leq j$, denotes the *subdivided claw*, that is, the tree with only one vertex x of degree 3 and exactly three leaves, which are of distance h, i and j from x, respectively. Observe $S_{1,1,1} = K_{1,3}$. We let $\mathcal{S}$ be the class of graphs each connected component of which is either a subdivided claw or a path.

For a set of graphs $\mathcal{H}$, a graph G is *$\mathcal{H}$-free* (or $(\mathcal{H})$-free) if it has no induced subgraph isomorphic to a graph in $\mathcal{H}$. If $\mathcal{H} = \{H_1, \ldots, H_p\}$ for some integer p, then we may write $(H_1, \ldots, H_p)$-free instead of $(\{H_1, \ldots, H_p\})$-free, or, if $p = 1$, we may simply write H_1-free. For a graph $G = (V, E)$, the set $N(u) = \{v \in V \mid uv \in E\}$ denotes the *neighbourhood* of $u \in V$. A graph is *bipartite* if its vertex set can be partitioned into two (possibly empty) independent sets. A graph is *split* if its vertex set can be partitioned into a (possibly empty) independent set and a (possibly empty) clique. Split graphs have been characterized as follows.

▶ **Lemma 6** ([28]). *A graph G is split if and only if it is $(2P_2, C_4, C_5)$-free.*

Let X be a set of vertices in a graph $G = (V, E)$. A vertex $y \in V \setminus X$ is *complete* to X if it is adjacent to every vertex of X and *anti-complete* to X if it is non-adjacent to every

vertex of X. Similarly, a set of vertices $Y \subseteq V \setminus X$ is *complete* (resp. *anti-complete*) to X if every vertex in Y is complete (resp. anti-complete) to X. We say that the edges between two disjoint sets of vertices X and Y form a *matching* (resp. *co-matching*) if each vertex in X has at most one neighbour (resp. non-neighbour) in Y and vice versa (if each vertex has exactly one such neighbour, we say that the matching is *perfect*). A vertex $y \in V \setminus X$ *distinguishes* X if y has both a neighbour and a non-neighbour in X. The set X is a *module* of G if no vertex in $V \setminus X$ distinguishes X. A module X is *non-trivial* if $1 < |X| < |V|$, otherwise it is *trivial*. A graph is *prime* if it has only trivial modules.

To help reduce the amount of case analysis needed to prove Theorems 2 and 3, we will use the following lemma (proof omitted).

▶ **Lemma 7.** *Let $H \in \mathcal{S}$. Then H is $(K_{1,3} + P_1, 2P_2, 3P_1 + P_2, S_{1,1,2})$-free if and only if H is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$ or sP_1 for some $s \geq 1$.*

The *clique-width* $\mathrm{cw}(G)$ of a graph G is the minimum number of labels needed to construct G by using the following four operations:

1. creating a new graph consisting of a single vertex v with label i;
2. taking the disjoint union of two labelled graphs G_1 and G_2;
3. joining each vertex with label i to each vertex with label j ($i \neq j$);
4. renaming label i to j.

For an induced subgraph G' (or vertex set $X \subseteq V(G)$) of a graph G, the *subgraph complementation* operation replaces every edge present in G' (resp. $G[X]$) by a non-edge, and vice versa. For two disjoint vertex subsets S and T in G, the *bipartite complementation* operation replaces every edge with one end-vertex in S and the other one in T by a non-edge and vice versa. Let $k \geq 0$ be a constant and let γ be some graph operation. A class $\mathcal{G}'$ is (k, γ)-*obtained* from a class $\mathcal{G}$ if:

1. every graph in $\mathcal{G}'$ is obtained from a graph in $\mathcal{G}$ by performing γ at most k times, and
2. for every $G \in \mathcal{G}$ there exists at least one graph in $\mathcal{G}'$ that is obtained from G by performing γ at most k times.

We say that γ *preserves* boundedness of clique-width if for any finite constant k and any graph class $\mathcal{G}$, any graph class $\mathcal{G}'$ that is (k, γ)-obtained from $\mathcal{G}$ has bounded clique-width if and only if $\mathcal{G}$ has bounded clique-width.

Fact 1. Vertex deletion preserves boundedness of clique-width [36].

Fact 2. Subgraph complementation preserves boundedness of clique-width [34].

Fact 3. Bipartite complementation preserves boundedness of clique-width [34].

We need the following lemmas on clique-width, the first one of which is easy to show.

▶ **Lemma 8.** *The clique-width of a graph of maximum degree at most 2 is at most 4.*

▶ **Lemma 9** ([23])**.** *Let H be a graph. The class of H-free graphs has bounded clique-width if and only if $H \subseteq_i P_4$.*

▶ **Lemma 10** ([37])**.** *Let $\{H_1, \ldots, H_p\}$ be a finite set of graphs. If $H_i \notin \mathcal{S}$ for all $i \in \{1, \ldots, p\}$ then the class of $(H_1, \ldots, H_p)$-free graphs has unbounded clique-width.*

▶ **Lemma 11** ([15])**.** *Let G be a graph and let $\mathcal{P}$ be the set of all induced subgraphs of G that are prime. Then $\mathrm{cw}(G) = \max_{H \in \mathcal{P}} \mathrm{cw}(H)$.*

3 The Proof of Theorem 1

We use the following lemma (proof omitted), which we also need for Theorem 3.

▶ **Lemma 12.** *If G is a (C_4, C_5, K_4)-free self-complementary graph, then $G \subseteq_i$ bull.*

We are now ready to prove Theorem 1. Note that this theorem also holds if $\mathcal{H}$ is infinite.

▶ **Theorem 1** (restated)**.** Let $\mathcal{H}$ be a set of non-empty self-complementary graphs. Then the class of $\mathcal{H}$-free graphs has bounded clique-width if and only if either $P_1 \in \mathcal{H}$ or $P_4 \in \mathcal{H}$.

Proof. Suppose there is a graph $H \in \mathcal{H} \cap \{P_1, P_4\}$. Then the class of $\mathcal{H}$-free graphs is a subclass of the class of P_4-free graphs, which have bounded clique-width by Lemma 9. Now suppose that $\mathcal{H} \cap \{P_1, P_4\} = \emptyset$. The only non-empty self-complementary graphs on at most five vertices that are not equal to P_1 and P_4 are the bull and the C_5 (see Figure 2). By Lemma 12, it follows that every graph in $\mathcal{H}$ contains an induced subgraph isomorphic to the bull, C_4, C_5 or K_4. Therefore the class of $\mathcal{H}$-free graphs contains the class of (bull, C_4, C_5, K_4)-free graphs, which has unbounded clique-width by Lemma 10. ◀

4 The Proof of Theorem 2

In this section we prove Theorem 2 by combining known results with the new result that $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs have bounded clique-width. We prove this result in the following way. We first prove two useful structural lemmas, namely Lemmas 13 and 14, which we will use repeatedly throughout the proof. Next, we prove Lemmas 15 and 16, which state that if a $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graph G contains an induced C_5 or C_6, respectively, then G has bounded clique-width. We do this by partitioning the vertices outside this cycle into sets, depending on their neighbourhood in the cycle. We then analyse the edges within these sets and between pairs of such sets. After a lengthy case analysis, we find that G has bounded clique-width in both these cases. By Fact 2 it only remains to analyse $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs that are also $(C_5, C_6, \overline{C_6})$-free. Next, in Lemma 17, we show that if such graphs are prime, then they are either K_7-free or $\overline{K_7}$-free. In Lemma 27 we use the fact that $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs are χ-bounded to deal with the case where a graph in the class is K_7-free. Finally, we combine all these results together to obtain the new result (Theorem 28). We omit the proofs of Lemmas 13–16.

▶ **Lemma 13.** *Let G be a $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graph whose vertex set can be partitioned into two sets X and Y, each of which is a clique or an independent set. Then by deleting at most one vertex from each of X and Y, it is possible to obtain subsets such that the edges between them form a matching or a co-matching.*

▶ **Lemma 14.** *Let G be a $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graph whose vertex set can be partitioned into a clique X and an independent set Y. Then by deleting at most three vertices from each of X and Y, it is possible to obtain subsets that are either complete or anti-complete to each other.*

▶ **Lemma 15.** *The class of $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs containing an induced C_5 has bounded clique-width.*

▶ **Lemma 16.** *The class of $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs containing an induced C_6 has bounded clique-width.*

▶ **Lemma 17.** *Every prime $(2P_1 + P_3, \overline{2P_1 + P_3}, C_6, \overline{C_6})$-free graph is K_7-free or $\overline{K_7}$-free.*

Proof. Let G be a prime $(2P_1 + P_3, \overline{2P_1 + P_3}, C_6, \overline{C_6})$-free graph. Suppose, for contradiction, that G contains an induced K_7 and an induced $\overline{K_7}$. We will show that in this case the graph G is not prime. Note that any induced K_7 and induced $\overline{K_7}$ in G can share at most one vertex. We may therefore assume that G contains a clique C on at least six vertices and a vertex-disjoint independent set I on at least six vertices. Furthermore, we may assume that C is a maximum clique in $G \setminus I$ and I is a maximum independent set in $G \setminus C$ (if not, then replace C or I with a bigger clique or independent set, respectively).

By Lemma 14, there exist sets $R_1 \subset C$ and $R_2 \subset I$ each of size at most 3 such that $C' = C \setminus R_1$ is either complete or anti-complete to $I' = I \setminus R_2$. Without loss of generality, we may assume that R_1 and R_2 are minimal, in the sense that the above property does not hold if we remove any vertex from R_1 or R_2. Note that the class of prime $(2P_1+P_3, \overline{2P_1 + P_3}, C_6, \overline{C_6})$-free graphs containing an induced K_7 and an induced $\overline{K_7}$ is closed under complementation. Therefore, complementing G if necessary (in which case the sets I and C will be swapped, and the sets R_1 and R_2 will be swapped), we may assume that C' is anti-complete to I'.

▶ **Claim 18.** $|R_1| \leq 1$ and $|R_2| \leq 1$.

By construction, R_1 and R_2 each contain at most three vertices and I' and C' each contain at least three vertices. Since R_1 (resp. R_2) is minimal, every vertex of R_1 (resp. R_2) has at least one neighbour in I' (resp. C').

Choose $i_1, i_2 \in I'$ arbitrarily and suppose, for contradiction, that $y \in R_2$ is not complete to C'. Then y must have a neighbour $c_1 \in C'$ and a non-neighbour $c_2 \in C'$, so $G[i_1, i_2, y, c_1, c_2]$ is a $2P_1 + P_3$, a contradiction. Therefore R_2 is complete to C'. If $y, y' \in R_2$ then for arbitrary $c_1 \in C'$, the graph $G[i_1, i_2, y, c_1, y']$ is a $2P_1 + P_3$, a contradiction. It follows that $|R_2| \leq 1$.

Choose $c_1, c_2 \in C'$ arbitrarily. Suppose, for contradiction, that $x \in R_1$ has two non-neighbours $i_1, i_2 \in I'$. Recall that x must have a neighbour $i_3 \in I'$, so $G[i_1, i_2, i_3, x, c_1]$ is a $2P_1 + P_3$, a contradiction. Therefore every vertex of R_1 has at most one non-neighbour in I'. Suppose, for contradiction, that $x, x' \in R_1$. Since I' contains at least three vertices, there must be a vertex $i_1 \in I'$ that is a common neighbour of x and x'. Now $G[x, x', c_1, i_1, c_2]$ is a $\overline{2P_1 + P_3}$, a contradiction. It follows that $|R_1| \leq 1$. This completes the proof of Claim 18.

Note that Claim 18 implies that $|C'| \geq 5$ and $|I'| \geq 5$. Let A be the set of vertices in $V \setminus (C \cup I)$ that are complete to C'. If $x \in A$ is adjacent to $y \in R_1$ then by Claim 18 $C \cup \{x\}$ is a bigger clique than C, contradicting the maximality of C. It follows that A is anti-complete to R_1. If $x, y \in A$ are adjacent then by Claim 18, $(C \cup \{x, y\}) \setminus R_1$ is a bigger clique than C, contradicting the maximality of C. It follows that A is an independent set. Furthermore, by the maximality of I and the definition of A, every vertex in $V \setminus (C \cup I \cup A)$ has a neighbour in I and non-neighbour in C'.

▶ **Claim 19.** Let x be a vertex in $V \setminus (C \cup I \cup A)$. Then either x is complete to I', or x has exactly one neighbour in I.

Suppose, for contradiction, that x has a non-neighbour z in I', and two neighbours $y, y' \in I$. Now x cannot have another non-neighbour $z' \in I \setminus \{z\}$, otherwise $G[z, z', y, x, y']$ would be a $2P_1 + P_3$. Therefore x must be complete to $I \setminus \{z\}$. In particular, since $|I'| \geq 5$, this means that x has two neighbours in I', say y_1 and y_2 (not necessarily distinct from y and y'). Recall that x must have a non-neighbour $c_1 \in C'$. Now $G[c_1, z, y_1, x, y_2]$ is a $2P_1+P_3$. This contradiction completes the proof of Claim 19.

By Claim 19 we can partition the vertex set $V \setminus (C \cup I \cup A)$ into subsets $V_{I'}$ and V_x for every $x \in I$, where $V_{I'}$ is the set of vertices that are complete to I', and V_x is the set of vertices whose unique neighbour in I is x. Let $U_x = V_x \cup \{x\}$.

▶ **Claim 20.** For all $x \in I'$, U_x is anti-complete to C'.

Suppose $x \in I'$. Clearly x is anti-complete to C'. Suppose, for contradiction, that $y \in U_x \setminus \{x\} = V_x$ has a neighbour $z \in C'$ and choose $u, v \in I' \setminus \{x\}$. Then $G[u, v, x, y, z]$ is a $2P_1 + P_3$. This contradiction completes the proof of Claim 20.

▶ **Claim 21.** For every $x \in I$, the set U_x is a clique.

Note that $x \in I$ is adjacent to all other vertices of U_x, by definition. If $y, z \in V_x$ are non-adjacent then $(I \setminus \{x\}) \cup \{y, z\}$ would be a bigger independent set than I, a contradiction.

▶ **Claim 22.** If $x, y \in I$ are distinct, then U_x is anti-complete to U_y.

Clearly x is anti-complete to U_y and y is anti-complete to U_x. Suppose, for contradiction, that $x' \in U_x \setminus \{x\}$ is adjacent to $y' \in U_y \setminus \{y\}$. Choose $u, v \in I \setminus \{x, y\}$. Then $G[u, v, x, x', y']$ is a $2P_1 + P_3$. This contradiction completes the proof of Claim 22.

▶ **Claim 23.** For every $x \in I'$, the set U_x is complete to $V_{I'}$.

By definition, x is complete to $V_{I'}$. Suppose, for contradiction that $x' \in U_x \setminus \{x\}$ is non-adjacent to $y \in V_{I'}$. As $y \notin A$, the vertex y must have a non-neighbour $c_1 \in C'$ and note that x' is non-adjacent to c_1 by Claim 20. Choose $u, v \in I' \setminus \{x\}$. Then $G[c_1, x', u, y, v]$ is a $2P_1 + P_3$. This contradiction proves Claim 23.

Suppose $x \in I'$. Claim 21 implies that U_x is a clique, Claim 20 that U_x is anti-complete to C' and Claim 23 that U_x is complete to $V_{I'}$. Furthermore for all $y \in I \setminus \{x\}$, Claim 22 implies that U_x is anti-complete to U_y. We conclude that given any two vertices $x, y \in I'$, no vertex in $V \setminus (A \cup R_1 \cup U_x \cup U_y)$ can distinguish the set $U_x \cup U_y$. In the remainder of the proof, we will show there exist $x, y \in I'$ such that no vertex of $A \cup R_1$ distinguishes the set $U_x \cup U_y$, meaning that $U_x \cup U_y$ is a non-trivial module, contradicting the assumption that G is prime.

▶ **Claim 24.** If $u \in A \cup R_1$ then either u is anti-complete to U_x for all $x \in I'$ or else u is complete to U_x for all but at most one $x \in I'$.

Suppose, for contradiction, that the claim does not hold for a vertex $u \in A \cup R_1$. Then u must have a neighbour $x' \in U_x$ for some $x \in I'$ and must have non-neighbours $y' \in U_y$ and $z' \in U_z$ for some $y, z \in I'$ with $y \neq z$. Since $|I'| \geq 5$, we may also assume that $x \notin \{y, z\}$. Choose $c_1 \in C'$ arbitrarily. By Claim 20, c_1 is non-adjacent to x', y' and z'. It follows that $G[y', z', c_1, u, x']$ is a $2P_1 + P_3$. This contradiction completes the proof of Claim 24.

Let A^* denote the set of vertices in $A \cup R_1$ that have a neighbour in U_x for some $x \in I'$.

▶ **Claim 25.** The set A^* is complete to all, except possibly two, sets $U_x, x \in I'$.

Suppose, for contradiction, that there are three different vertices $x, y, z \in I'$ such that A^* is complete to none of the sets U_x, U_y, and U_z. By Claim 24 and the definition of A^*, every vertex in A^* is complete to at least two of the sets U_x, U_y, U_z. Therefore there exist three vertices $u, v, w \in A^*$ such that:

- u is not adjacent to some vertex $x' \in U_x$, but is complete to U_y and U_z;
- v is not adjacent to some vertex $y' \in U_y$, but is complete to U_x and U_z;
- w is not adjacent to some vertex $z' \in U_z$, but is complete to U_x and U_y.

Therefore $G[u, y', w, x', v, z']$ is a C_6. This contradiction completes the proof of Claim 25.

Now, as $|I'| \geq 5$, Claims 24 and 25 imply there exist two distinct vertices $x, y \in I'$ such that every vertex of $A \cup R_1$ is either complete or anti-complete to $U_x \cup U_y$. Hence $U_x \cup U_y$ is a non-trivial module in G, contradicting the fact that G is prime. This completes the proof. ◀

The *chromatic number* $\chi(G)$ of a graph G is the minimum positive integer k such that G is k-colourable. The *clique number* $\omega(G)$ of G is the size of a largest clique in G. A class $\mathcal{C}$ of graphs is *χ-bounded* if there is a function f such that $\chi(G) \leq f(\omega(G))$ for all $G \in \mathcal{C}$.

▶ **Lemma 26** ([32]). *For every natural number k the class of P_k-free graphs is χ-bounded.*

▶ **Lemma 27.** *For $k \geq 1$, $(K_k, 2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs have bounded clique-width.*

Proof. Fix a constant $k \geq 1$ and let G be a $(K_k, 2P_1 + P_3, \overline{2P_1 + P_3})$-free graph. By Lemma 16, we may assume that G is C_6-free. Since G is $(2P_1 + P_3)$-free, it is P_7-free, so by Lemma 26 it has chromatic number at most ℓ for some constant ℓ. This means that we can partition the vertices of G into ℓ independent sets $V_1, \ldots, V_\ell$ (some of which may be empty). By Lemma 13, deleting finitely many vertices (which we may do by Fact 2), we may assume that for all distinct $i, j \in \{1, \ldots, \ell\}$, the edges between V_i and V_j form a matching or a co-matching. Since G is C_6-free, if the vertices between V_i and V_j form co-matching, this co-matching can contain at most two non-edges. Therefore, by deleting finitely many vertices (which we may do by Fact 2), we may assume that the edges between V_i and V_j form a matching or V_i and V_j are complete to each other. By deleting finitely many vertices (which we may do by Fact 2), we may assume that each set V_i is either empty or contains at least five vertices.

Suppose the edges from V_i to V_j and the edges from V_i to V_k form a matching and that there is a vertex $x \in V_i$ that has a neighbour $y \in V_j$ and a neighbour $z \in V_k$. Then y must be adjacent to z, otherwise for $x', x'' \in V_i \setminus \{x\}$ the graph $G[x', x'', y, x, z]$ would be a $2P_1 + P_3$, a contradiction. If V_j is complete to V_k then for $y', y'' \in V_j$, $z' \in V_k$ and $x', x'' \in V_i \setminus (N(y') \cup N(y'') \cup N(z'))$ (such vertices exist since each of y', y'' and z' have at most one neighbour in V_i and V_i contains at least five vertices) we have $G[x', x'', y', z', y'']$ is a $2P_1 + P_3$, a contradiction. Therefore the edges between V_j and V_k form a matching.

Now for each $i, j \in \{1, \ldots, \ell\}$ with $i < j$, if V_i is complete to V_j, then by Fact 2 we may apply a bipartite complementation between V_i and V_j. Let G' be the resulting graph. The previous paragraph implies if x has two neighbours y and z in G' then y is adjacent to z in G, so G' is P_3-free. So G' is a disjoint union of cliques, and thus has clique-width at most 2. ◀

We are now ready to prove our main result.

▶ **Theorem 28.** *The class of $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graphs has bounded clique-width.*

Proof. Let G be a $(2P_1 + P_3, \overline{2P_1 + P_3})$-free graph. By Lemma 11, we may assume that G is prime. If G contains an induced C_6 then we are done by Lemma 16. If G contains an induced $\overline{C_6}$ then we are done by Lemma 16 and Fact 2. We may therefore assume that G is also $(C_6, \overline{C_6})$-free. By Lemma 17, we may assume that G is either K_7-free or $\overline{K_7}$-free. By Fact 2, we may assume that G is K_7-free. Lemma 27 completes the proof. ◀

Combining Theorem 28 with the current state-of-the-art for classifying the boundedness of clique-width for (H_1, H_2)-free graphs (see [20]) yields Theorem 2 (proof omitted).

▶ **Theorem 2** (restated). For a graph H, the class of $(H, \overline{H})$-free graphs has bounded clique-width if and only if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$ or sP_1 for some $s \geq 1$.

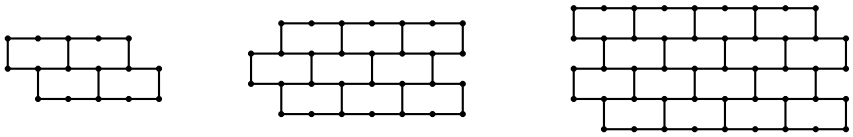

Figure 4 Walls of height 2, 3 and 4, respectively.

5 New Classes of Unbounded Clique-Width and Proof of Theorem 3

In this section we first identify three new graph classes of unbounded clique-width. To do so, we need the notion of a *wall*. Figure 4 shows three walls of different height (see e.g. [12] for a formal definition). The class of walls is well known to have unbounded clique-width; see for example [34]. A *k-subdivided wall* is the graph obtained from a wall after subdividing each edge exactly k times for some constant $k \geq 0$. The following lemma is well known.

▶ **Lemma 29** ([37]). *Let $k \geq 0$. The class of k-subdivided walls has unbounded clique-width.*

Dabrowski et al. [17] showed that $(4P_1, \overline{3P_1 + P_2})$-free graphs have unbounded clique-width. However, their construction was not C_5-free. We give an alternative construction that neither contains an induced C_5 nor an induced copy of any larger self-complementary graph. Namely, we first consider a graph H' that is a 1-subdivided wall. By Lemma 29, such graphs have unbounded clique-width. Let V_1 be the set of vertices in H' that are also present in H. Let V_2 be the set of vertices obtained from subdividing vertical edges in H, and let V_3 be the set of vertices obtained from subdividing horizontal edges. Note that V_1, V_2 and V_3 are independent sets. Furthermore, every vertex in V_1 has at most one neighbour in V_2 and at most two neighbours in V_3, while every vertex in $V_2 \cup V_3$ has at most two neighbours, each of which is in V_1. Let H'' be the graph obtained from H' by applying complementations on V_1, V_2 and V_3. By Fact 2, such graphs have unbounded clique-width. We claim that H'' is $(\{4P_1, \overline{3P_1 + P_2}\} \cup \mathcal{F})$-free, where $\mathcal{F}$ is the set of all self-complementary graphs on at least five vertices that are not equal to the bull (proof omitted). This leads to the following theorem.

▶ **Theorem 30.** *Let $\mathcal{F}$ be the set of all self-complementary graphs on at least five vertices that are not equal to the bull. The class of $(\{4P_1, \overline{3P_1 + P_2}\} \cup \mathcal{F})$-free graphs has unbounded clique-width.*

By Lemma 12, any self-complementary graph on at least five vertices not equal to the bull has an induced subgraph isomorphic to C_4, C_5 or K_4, so such graphs are automatically excluded from the class specified in our next theorem. Its proof, which we omitted, is based on observing that the construction of Brandstädt et al. [7] for proving that $(C_4, K_{1,3}, K_4, \overline{2P_1 + P_2})$-free graphs have unbounded clique-width is, in fact, also C_5-free.

▶ **Theorem 31.** *$(C_4, C_5, K_{1,3}, K_4, \overline{2P_1 + P_2})$-free graphs have unbounded clique-width.*

For our third result we need two lemmas. Given natural numbers k, ℓ, let $Rb(k, \ell)$ denote the smallest number such that if every edge of a $K_{Rb(k,\ell),Rb(k,\ell)}$ is coloured red or blue then it will contain a monochromatic $K_{k,\ell}$. It is known that $Rb(k, \ell)$ always exists [1].

▶ **Lemma 32** ([1]). *$Rb(2, 2) = 5$.*

Let $G = (V, E)$ be a split graph. By definition, G has a *split partition*, that is, a partition of V into two (possibly empty) sets C and I, where C is a clique and I is an independent set. A split graph G may have multiple split partitions. For self-complementary split graphs we can show the following (proof omitted).

▶ **Lemma 33.** *Let G be a self-complementary split graph on n vertices. If n is even, then G has a unique split partition and in this partition the clique and independent set are of equal size. If n is odd, then there exists a vertex v such that $G \setminus v$ is also a self-complementary split graph.*

▶ **Theorem 34.** *Let $\mathcal{F}$ be the set of all self-complementary graphs on at least five vertices that are not equal to the bull. The class of $(\{C_4, 2P_2\} \cup \mathcal{F})$-free graphs has unbounded clique-width.*

Proof. First note that the only self-complementary graph on five vertices apart from the bull is the C_5. Since $C_5 \in \mathcal{F}$, by Lemma 6, we may remove all graphs that are not split from $\mathcal{F}$, apart from C_5; in particular, this means that we remove $X_4, \ldots, X_{10}$ from $\mathcal{F}$ (see also Figure 3). By Lemma 33, if $G \in \mathcal{F}$ has an odd number of vertices, but is not equal to C_5, then $G \setminus v \in \mathcal{F}$ for some vertex $v \in V(G)$. Let $\mathcal{F}'$ be the set of self-complementary split graphs on at least eight vertices that have an even number of vertices. It follows that the class of $\mathcal{F}'$-free split graphs is equal to the class of $(\{C_4, 2P_2\} \cup \mathcal{F})$-free graphs.

Consider a 2-subdivided wall H and note that it is (C_4, C_8)-free; recall that 2-subdivided walls have unbounded clique-width by Lemma 29. Note that H is a bipartite graph, and fix a bipartition (A, B) of H. Let H' be the graph obtained from H by applying a complementation to A and note that H' is a split graph. In H', every vertex in B has a non-neighbour in A and every vertex in A has a neighbour in B, so (A, B) is the unique split partition of H'. By Fact 2, the family of graphs H' produced in this way also has unbounded clique-width. It remains to show that H' is $\mathcal{F}'$-free.

First note that X_1 (see also Figure 3) is the graph obtained from the bipartite graph C_8 by complementing one of the independent sets in the bipartition. Since H is C_8-free and X_1 has a unique split partition (by Lemma 33), it follows that H' is X_1-free. Note that H is C_4-free and so H' does not contain two vertices x, x' in the clique A and two vertices y, y' in the independent set B such that $\{x, x'\}$ is complete to $\{y, y'\}$. Now suppose $G \in \mathcal{F}' \setminus \{X_1\}$. Recall that by Lemma 33, G has a unique split partition (C, I), and this partition has the property that $|C| = |I|$. Therefore, if we can show that G contains two vertices $x, x' \in C$ and two vertices $y, y' \in I$ with $\{x, x'\}$ complete to $\{y, y'\}$ then H' must be G-free and the proof is complete. It is easy to verify that this is the case if $G \in \{X_2, X_3\}$ (see also Figure 3 and recall that $X_4, \ldots, X_{10} \notin \mathcal{F}'$). Otherwise, G has at least ten vertices so $|C|, |I| \geq 5$. By Lemma 32, there must be two vertices $x, x' \in C$ and two vertices $y, y' \in I$ with $\{x, x'\}$ either complete or anti-complete to $\{y, y'\}$. In the first case we are done. In the second case we note that complementing G will swap the sets C and I and make $\{x, x'\}$ complete to $\{y, y'\}$, returning us to the previous case. We conclude that H' is indeed $\mathcal{F}'$-free. ◀

We are now ready to prove Theorem 3. Note that this theorem holds even if $\mathcal{F}$ is infinite.

▶ **Theorem 3** (restated)**.** Let $\mathcal{F}$ be a set of self-complementary graphs on at least five vertices not equal to the bull. For a graph H, the class of $(\{H, \overline{H}\} \cup \mathcal{F})$-free graphs has bounded clique-width if and only if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$ or sP_1 for some $s \geq 1$.

Proof. Let H be a graph. By Theorem 2, if H or $\overline{H}$ is an induced subgraph of $K_{1,3}$, $P_1 + P_4$, $2P_1 + P_3$ or sP_1 for some $s \geq 1$, then the class of $(\{H, \overline{H}\} \cup \mathcal{F})$-free graphs has bounded clique-width. Consider a graph $F \in \mathcal{F}$. Since F contains at least five vertices and is not isomorphic to the bull, Lemma 12 implies that F contains an induced subgraph isomorphic to C_4, C_5 or K_4, and so $F \notin \mathcal{S}$. Therefore the class of $(\{H, \overline{H}\} \cup \mathcal{F})$-free graphs contains the class of $(H, \overline{H}, C_4, C_5, K_4)$-free graphs. If $H \notin \mathcal{S}$ and $\overline{H} \notin \mathcal{S}$, then the class of $(H, \overline{H}, C_4, C_5, K_4)$-free graphs has unbounded clique-width by Lemma 10. By Fact 2, we

may therefore assume that $H \in \mathcal{S}$. By Lemma 7, we may assume H contains $K_{1,3}+P_1$, $2P_2$, $3P_1+P_2$ or $S_{1,1,2}$ as an induced subgraph, otherwise we are done. In this case, the class of $(\{H,\overline{H}\}\cup\mathcal{F})$-free graphs contains the class of $(K_{1,3},K_4,C_4,C_5)$-free, $(\{2P_2,C_4\}\cup\mathcal{F})$-free, $(\{4P_1,\overline{3P_1+P_2}\}\cup\mathcal{F})$-free or $(K_{1,3},\overline{2P_1+P_2},C_4,C_5,K_4)$-free graphs, respectively. These classes have unbounded clique-width by Theorems 31, 34, 30 and 31, respectively. This completes the proof. ◀

Abstract

We study computation by formulas over $(\min, +)$. We consider the computation of $\max\{x_1, \ldots, x_n\}$ over $\mathbb{N}$ as a difference of $(\min, +)$ formulas, and show that size $n + n \log n$ is sufficient and necessary. Our proof also shows that any $(\min, +)$ formula computing the minimum of all sums of $n - 1$ out of n variables must have $n \log n$ leaves; this too is tight. Our proofs use a complexity measure for $(\min, +)$ functions based on minterm-like behaviour and on the entropy of an associated graph.

1 Introduction

A $(\min, +)$ formula is a formula (tree) in which the leaves are labeled by variables or constants. The internal nodes are gates labeled by either min or +. A min gate computes the minimum value among its inputs while a + gate simply adds the values computed by its inputs. Such formulas can compute any function expressible as the minimum over several linear polynomials with non-negative integer coefficients.

In this work, we consider the following problem: Suppose we are given n input variables $x_1, x_2, \ldots, x_n$ and we want to find a formula which computes the maximum value taken by these variables, $\max(x_1, x_2, \ldots, x_n)$. If variables are restricted to take non-negative integer values, t is easy to show that no $(\min, +)$ formula can compute max. Suppose now we strengthen this model by allowing minus gates as well. Now we have a very small linear sized formula: $\max(x_1, x_2, \ldots, x_n) = 0 - \min(0 - x_1, 0 - x_2, \ldots, 0 - x_n)$. It is clear that minus gates add significant power to the model of $(\min, +)$ formulas. But how many minuses do we actually need? It turns out that only one minus gate, at the top, is sufficient. Here is one such formula: (Sum of all variables) - $\min_i$ (Sum of all variables except x_i). The second expression above can be computed by a $(\min, +)$ formula of size $n \log n$ using recursion. So, we can compute max using min, + and one minus gate at the top, at the cost of a slightly super-linear size. Can we do any better? We show that this simple difference formula is indeed the best we can achieve for this model.

The main motivation behind studying this question is the following question asked in [8]: Does there exist a naturally occuring function f for which $(\min, +)$ circuits are super-polynomially weaker than $(\max, +)$ circuits? There are two possibilities:

1. Show that max can be implemented using a small $(\min, +)$ circuit.
2. Come up with an explicit function f which has *small* $(\max, +)$ circuits but requires *large* $(\min, +)$ circuits.

Since we show that no $(\min, +)$ formula (or circuit) can compute max, option 1 is ruled out. In the weaker model of formulas instead of circuits, we show that any difference of $(\min, +)$ formulas computing max should have size at least $n \log n$. This yields us a separation between $(\max, +)$ formulas and difference of $(\min, +)$ formulas.

Background

Many dynamic programming algorithms correspond to $(\min, +)$ circuits over an appropriate semiring. Notable examples include the Bellman-Ford-Moore (BFM) algorithm for the single-source-shortest-path problem (SSSP) [2, 5, 14], the Floyd-Warshall (FW) algorithm for the All-Pairs-Shortest-Path (APSP) problem [4, 18], and the Held-Karp (HK) algorithm for the Travelling Salesman Problem (TSP) [6]. All these algorithms are just recursively constructed $(\min, +)$ circuits. For example, both the BFM and the FW algorithms give $O(n^3)$ sized $(\min, +)$ circuits while the HK algorithm gives a $O(n^2 \cdot 2^n)$ sized $(\min, +)$ circuit. Matching lower bounds were proved for TSP in [7], for APSP in [8], and for SSSP in [10]. So, proving tight lower bounds for circuits over $(\min, +)$ can help us understand the power and limitations of dynamic programming. We refer the reader to [8, 9] for more results on $(\min, +)$ circuit lower bounds.

Note that algorithms for problems like computing the diameter of a graph are naturally expressed using $(\min, \max, +)$ circuits. This makes the cost of converting a max gate to a $(\min, +)$ circuit or formula an interesting measure.

A related question arises in the setting of counting classes defined by arithmetic circuits and formulas. Circuits over $\mathbb{N}$, with specific resource bounds, count accepting computation paths or proof-trees in a related resource-bounded Turing machine model defining a class $\mathcal{C}$. The counting function class is denoted $\#\mathcal{C}$. The difference of two such functions in a class $\#\mathcal{C}$ is a function in the class Diff$\mathcal{C}$. On the other hand, circuits with the same resource bounds, but over $\mathbb{Z}$, or equivalently, with subtraction gates, describe the function class Gap$\mathcal{C}$. For most complexity classes $\mathcal{C}$, a straightforward argument shows that that Diff$\mathcal{C}$ and Gap$\mathcal{C}$ coincide. See [1] for further discussion on this. In this framework, we restrict attention to computation over $\mathbb{N}$ and see that as a member of a Gap class over $(\min, +)$, max has linear-size formulas, whereas as a member of a Diff class, it requires $\Omega(n \log n)$ size.

Our results and techniques

We now formally state our results and briefly comment on the techniques used to prove them.

1. For $n \geq 2$, no $(\min, +)$ formula over $\mathbb{N}$ can compute $\max(x_1, x_2, \ldots, x_n)$. (Theorem 10)
   The proof is simple: apply a carefully chosen restriction to the variables and show that the $(\min, +)$ formula does not output the correct value of max on this restriction.
2. $\max(x_1, x_2, \ldots, x_n)$ can be computed by a difference of two $(\min, +)$ formulas with total size $n + n\lceil \log n \rceil$. More generally, the function computing the sum of the topmost k values amongst the n variables can be computed by a difference of two $(\min, +)$ formulas with total size $n + n(\lceil \log n \rceil)^{\min\{k, n-k\}}$. (Theorem 11)
   Note that the sum of the topmost k values can be computed by the following formula: (Sum of all variables) - $\min_S$ (Sum of all variables except those in S). Here S ranges over all possible subsets of $\{x_1, x_2, \ldots, x_n\}$ of cardinality $n - k$. Using recursion, we obtain the claimed size bound.

3. Let F_1, F_2 be $(\min, +)$ formulas over $\mathbb{N}$ such that $F_1 - F_2 = \max(x_1, x_2, \ldots, x_n)$. Then F_1 must have at least n leaves and F_2 at least $n \log n$ leaves. (Theorem 13)
   A major ingredient in our proof is the definition of a measure for functions computable by constant-free $(\min, +)$ formulas, and relating this measure to formula size. The measure involves terms analogous to minterms of a monotone Boolean function, and uses the entropy of an associated graph under the uniform distribution on its vertices. In the setting of monotone Boolean functions, this technique was used in in [15] to give formula size lower bounds. We adapt that technique to the $(\min, +)$ setting.
   The same technique also yields the following lower bound: Also, any $(\min, +)$ formula computing the minimum over the sums of $n-1$ variables must have at least $n \log n$ leaves. This is tight. (Lemma 12 and Corollary 18)

2 Preliminaries

2.1 Notation

Let X denote the set of variables $\{x_1, \ldots, x_n\}$. We use $\tilde{x}$ to denote $(x_1, x_2, \ldots, x_n, 1)$.

We use e_i to denote the $(n+1)$-dimensional vector with a 1 in the ith coordinate and zeroes elsewhere. For $i \in [n]$, we also use e_i to denote an assignment to the variables $x_1, x_2, \ldots, x_n$ where x_i is set to 1 and all other variables are set to 0.

▶ **Definition 1.** For $0 \leq r \leq n$, the n-variate functions Sum_n, MinSum_n^r and MaxSum_n^r are as defined below.

$$\begin{aligned}
\mathsf{Sum}_n &= \sum_{i=1}^{n} x_i \\
\mathsf{MinSum}_n^r &= \min\left\{\sum_{i\in S} x_i \mid S \subseteq n, |S| = r\right\} \\
\mathsf{MaxSum}_n^r &= \max\left\{\sum_{i\in S} x_i \mid S \subseteq n, |S| = r\right\}
\end{aligned}$$

Note that MinSum_n^0 and MaxSum_n^0 are the constant function 0, and MinSum_n^1 and MaxSum_n^1 are just the min and max respectively.

▶ **Observation 2.** *For* $1 \leq r < n$, $\mathsf{MinSum}_n^n = \mathsf{MaxSum}_n^n = \mathsf{Sum}_n = \mathsf{MinSum}_n^r + \mathsf{MaxSum}_n^{n-r}$.

2.2 Formulas

A $(\min, +)$ formula is a directed tree. Each leaf of a formula has a label from $X \cup \mathbb{N}$; that is, it is labeled by a variable x_i or a constant $\alpha \in \mathbb{N}$. Each internal node has exactly two children and is labeled by one of the two operations min or $+$. The output node of the formula computes a function of the input variables in the natural way. The input nodes of a formula are also referred to as gates.

If all leaves of a formula are labeled from X, we say that the formula is constant-free.

A $(\min, +, -)$ formula is similarly defined; the operation at an internal node may also be $-$, in which case the children are ordered and the node computes the difference of their values.

We define the size of a formula as the number of leaves in the formula. For a formula F, we denote by $L(F)$ its size, the number of leaves in it. For a function f, we denote by $L(f)$ the smallest size of a formula computing f. By $L_{cf}(f)$ we denote the smallest size of a constant-free formula computing f.

2.3 Graph Entropy

The notion of the entropy of a graph or hypergraph, with respect to a probability distribution on its vertices, was first defined by Körner in [11]. In that and subsequent works (e.g. [12, 13, 3, 15]), equivalent characterizations of graph entropy were established and are often used now as the definition itself, see for instance [16, 17]. In this paper, we use graph entropy only with respect to the uniform distribution, and simply call it graph entropy. We use the following definition, which is exactly the definition from [17] specialised to the uniform distribution.

▶ **Definition 3.** Let G be a graph with vertex set $V(G) = \{1, \ldots, n\}$.

The *vertex packing polytope* $VP(G)$ of the graph G is the convex hull of the characteristic vectors of independent sets of G.

The entropy of G is defined as

$$H(G) = \min_{\vec{a} \in VP(G)} \sum_{i=1}^{n} \frac{1}{n} \log \frac{1}{a_i} \quad .$$

It can easily be seen that $H(G)$ is a non-negative real number, and moreover, $H(G) = 0$ if and only if G has no edges. We list non-trivial properties of graph entropy that we use.

▶ **Lemma 4** ([12, 13]). *Let $F = (V, E(F))$ and $G = (V, E(G))$ be two graphs on the same vertex set. The following hold:*

1. ***Monotonocity.*** *If $E(F) \subseteq E(G)$, then $H(F) \leq H(G)$*
2. ***Subadditivity.*** *Let Q be the graph with vertex set V and edge set $E(F) \cup E(G)$. Then $H(Q) \leq H(F) + H(G)$.*

▶ **Lemma 5** (see for instance [16, 17]). *The following hold:*

1. *Let K_n be the complete graph on n vertices. Then $H(K_n) = \log n$.*
2. *Let G be a graph on n vertices, whose edges induce a bipartite graph on m (out of n) vertices. Then $H(G) \leq \frac{m}{n}$.*

3 Transformations and Easy bounds

We consider the computation of $\max\{x_1, \ldots, x_n\}$ over $\mathbb{N}$ using $(\min, +)$ formulas.

To start with, we describe some properties of $(\min, +)$ formulas that we use repeatedly. The first property, Proposition 7 below, is expressing the function computed by a formula as a depth-2 polynomial where $+$ plays the role of multiplication and min plays the role of addition. The next properties, Proposition 8 and 9 below, deal with removing redundant sub-expressions created by the constant zero or moving common parts aside.

▶ **Definition 6.** Let F be a $(\min, +)$ formula with leaves labeled from $X \cup \mathbb{N}$. For each gate $v \in F$, we construct a set $S_v \subseteq \mathbb{N}^{n+1}$ as described below.

We construct the sets inductively based on the depth of v.

1. Case 1. v is a leaf labeled α for some $\alpha \in \mathbb{N}$. Then $S_v = \{\alpha \cdot e_{n+1}\}$. (Recall, e_i is the unit vector with 1 at the ith coordinate and zero elsewhere).
2. Case 2: v is a leaf labeled x_i for some $i \in [n]$. Then $S_v = \{e_i\}$.
3. Case 3: $v = \min\{u, w\}$. Then $S_v = S_u \cup S_w$.
4. Case 4: $v = u + w$. Then $S_v = \{\tilde{a} + \tilde{b} \mid \tilde{a} \in S_u,\ \tilde{b} \in S_w\}$ (coordinate-wise addition).

Let r be the output gate of F. We denote by $S(F)$ the set S_r so constructed.

It is straightforward to see that if F has no constants (so Case 1 is never invoked), then a_{n+1} remains 0 throughout the construction of the sets S_v. Hence if F is constant-free, then for each $\tilde{a} \in S(F)$, $a_{n+1} = 0$.

By construction, the set $S(F)$ describes the function computed by F. Thus we have the following:

▶ **Proposition 7.** *Let F be a formula with* min *and* $+$ *gates, with leaves labeled by elements of $\{x_1, \ldots, x_n\} \cup \mathbb{N}$. For each gate $v \in F$, let f_v denote the function computed at v.*

Then $f_v = \min\{\langle \tilde{a} \cdot \tilde{x} \rangle \mid \tilde{a} \in S_v\}$.

The following proposition is an easy consequence of the construction in Definition 6.

▶ **Proposition 8.** *Let F be a $(\min, +)$ formula over $\mathbb{N}$. Let G be the formula obtained from F by replacing all constants by the constant 0. Let H be the constant-free formula obtained from G by eliminating 0s from G through repeated replacements of $0 + A$ by A, $\min\{0, A\}$ by 0. Then*

1. *$L(H) \leq L(G) = L(F)$,*
2. *$S(G) = \{\tilde{b} \mid b_{n+1} = 0, \exists \tilde{a} \in S(F), \forall i \in [n], a_i = b_i\}$, and*
3. *G and H compute the same function $\min\{\langle \tilde{b} \cdot \tilde{x} \rangle \mid \tilde{b} \in S(G)\}$.*

(Note: It is not the claim that $S(G) = S(H)$. Indeed, this may not be the case. eg. let $F = x + \min\{1, x + y\}$. Then $S(F) = \{101, 210\}$, $S(G) = \{100, 210\}$, $S(H) = \{100\}$, However, the functions computed are the same.)

The next proposition shows how to remove "common" contributors to $S(F)$ without increasing the formula size.

▶ **Proposition 9.** *Let F be a $(\min, +)$ formula computing a function f.*

If, for some $i \in [n]$, $a_i > 0$ for every $\tilde{a} \in S(F)$, then $f - x_i$ can be computed by a $(\min, +)$ formula F' of size at most size(F).

If $a_{n+1} > 0$ for every $\tilde{a} \in S(F)$, then $f - 1$ can be computed by a $(\min, +)$ formula F' of size at most size(F).

In both cases, $S(F') = \{\tilde{b} \mid \exists \tilde{a} \in S(F), \tilde{b} = \tilde{a} - e_i\}$.

Proof. First consider $i \in [n]$. Let X be the subset of nodes in F defined as follows:

$$X = \{v \in F \mid \forall \tilde{a} \in S_v : a_i > 0\}$$

Clearly, the output gate r of F belongs to X. By the construction of the sets S_v, whenever a min node v belongs to X, both its children belong to X, and whenever a $+$ node belongs to X, at least one of its children belongs to X. We pick a set $T \subseteq X$ as follows. Include r in T. For each min node in T, include both its children in T. For each $+$ node in T, include in T one child that belongs to X (if both children are in X, choose any one arbitrarily). This gives a sub-formula of F where all leaves are labeled x_i. Replace these occurrences of x_i in F by 0 to get formula F'. It is easy to see that $S(F') = \{\tilde{a} - e_i \mid \tilde{a} \in S\}$. Hence F' computes $f - x_i$.

For $i = a_{n+1}$, the same process as above yields a subformula where each leaf is labeled by a positive constant. Subtracting 1 from the constant at each leaf in T gives the formula computing $f - 1$. ◀

It is intuitively clear that no $(\min, +)$ formula can compute max. A formal proof using Proposition 7 appears below.

▶ **Theorem 10.** *For $n \geq 2$, no $(min, +)$ formula over $\mathbb{N}$ can compute $\max\{x_1, \ldots, x_n\}$.*

Proof. Suppose, to the contrary, some formula C computes max. Then its restriction D to $x_1 = X$, $x_2 = Y$, $x_3 = x_4 = \ldots = x_n = 0$, correctly computes $\max\{X, Y\}$. Since all leaves of D are labeled from $\{x_1, x_2\} \cup \mathbb{N}$, the set $S(D)$ is a set of triples. Let $S \subseteq \mathbb{N}^3$ be this set. For all $X, Y \in \mathbb{N}$, $\max\{X, Y\}$ equals $E(X, Y) = \min\{AX + BY + C \mid (A, B, C) \in S\}$.

Let K denote the maximum value taken by C in any triple in S. If for some $B, C \in \mathbb{N}$, the triple $(0, B, C)$ belongs to S, then $E(K + 1, 0) \leq C \leq K < K + 1 = \max\{0, K + 1\}$. So for all $(A, B, C) \in S$, $A \neq 0$, so $A \geq 1$. Similarly, for all $(A, B, C) \in S$, $B \geq 1$. Hence for all $(A, B, C) \in S$, $A + B \geq 2$.

Now $E(1, 1) = \min\{A + B + C \mid (A, B, C) \in S\} \geq 2 > 1 = \max\{1, 1\}$. So $E(X, Y)$ does not compute $\max(X, Y)$ correctly. ◀

However, if we also allow the subtraction operation at internal nodes, it is very easy to compute the maximum in linear size; $\max(x_1, \ldots, x_n) = -\min\{-x_1, -x_2, \ldots, -x_n\}$. Here $-a$ is implemented as $0 - a$, and if we allow only variables, not constants, at leaves, we can compute $-a$ as $(x_1 - x_1) - a$.

Thus the subtraction operation adds significant power. How much? Can we compute the maximum with very few subtraction gates? It turns out that the max function can be computed as the difference of two $(\min, +)$ formulas. Equivalently, there is a $(\min, +, -)$ formula with a single $-$ gate at the root, that computes the max function. This formula is not linear in size, but it is not too big either; we show that it has size $O(n \log n)$. A simple generalisation allows us to compute the sum of the largest k values.

▶ **Theorem 11.** *For each $n \geq 1$, and each $0 \leq k \leq n$, the function MaxSum_n^k can be computed by a difference of two $(\min, +)$ formulas with total size $n + n(\lceil \log n \rceil)^{\min\{k, n-k\}}$.*

In particular, the function $\max\{x_1, \ldots, x_n\}$ can be computed by a difference of two $(min, +)$ formulas with total size $n + n\lceil \log n \rceil$.

Proof. Note that $\mathsf{MaxSum}_n^k = \mathsf{Sum}_n - \mathsf{MinSum}_n^{n-k}$. Lemma 12 below shows that MinSum_n^{n-k} can be computed by a formula of size $n(\lceil \log n \rceil)^{\min\{k, n-k\}}$ for $0 \leq k \leq n$. Since Sum_n can be computed by a formula of size n, the claimed upper bound for MaxSum_n^k follows. ◀

▶ **Lemma 12.** *For all n, k such that $n \geq 1$ and $0 \leq k < n$, the functions MinSum_n^k, MinSum_n^{n-k} can be computed by a $(\min, +)$ formula of size $n(\lceil \log n \rceil)^k$.*

Hence the functions MinSum_n^k, MinSum_n^{n-k} can be computed by $(\min, +)$ formulas of size $n(\lceil \log n \rceil)^{\min\{k, n-k\}}$.

Proof. We prove the upper bound for MinSum_n^{n-k}. The bound for MinSum_n^k follows from an essentially identical argument.

We prove this by induction on k.

- Base Case: $k = 0$. For every $n \geq 1$, $\mathsf{MinSum}_n^{n-k} = \mathsf{Sum}_n$ and can be computed with size n.
- Inductive Hypothesis: For all $k' < k$, and all $n > k'$, $\mathsf{MinSum}_n^{n-k'}$ can computed in size $n(\lceil \log n \rceil)^{k'}$.
- Inductive Step: We want to prove the claim for k, where $k \geq 1$, and for all $n > k$. We proceed by induction on n.
  - Base Case: $n = k + 1$. $\mathsf{MinSum}_n^{n-k} = \mathsf{MinSum}_n^1$ is the minimum of the n variables, and can be computed in size n.
  - Inductive Hypothesis: For all $k < m < n$, MinSum_m^{m-k} can be computed in size $m(\lceil \log m \rceil)^k$.

- Inductive Step: Let $m' = \lfloor n/2 \rfloor$, $m'' = \lceil n/2 \rceil$, Let X, X_l, X_r denote the sets of variables $\{x_1, \ldots, x_n\}$, $\{x_1, \ldots, x_{m'}\}$, $\{x_{m'+1}, \ldots, x_n\}$. Note that $|X_l| = m'$, $|X_r| = m''$, $m' + m'' = n$. Let p denote $\lceil \log n \rceil$. Note that $\lceil \log m' \rceil = \lceil \log m'' \rceil = p - 1$.
To compute MinSum_n^{n-k} on X, we first compute, for various values of t, $\mathsf{MinSum}_{m'}^{m'-t}$ on X_l, $\mathsf{MinSum}_{m''}^{m''-(k-t)}$ on X_r, and add them up. We then take the minimum of these sums. Note that if $m' = t$ or $m'' = k - t$, then that summand is simply 0 and we only compute the other summand. Now $\mathsf{MinSum}_n^{n-k}(X)$ can be computed as

$$\min \left\{ \mathsf{MinSum}_{m'}^{m'-t}(X_l) + \mathsf{MinSum}_{m''}^{m''-(k-t)}(X_r) \mid \max\{0, k - m''\} \leq t \leq \min\{m', k\} \right\}$$

For all the sub-expressions appearing in the above construction, we can use inductively constructed formulas. Using the inductive hypotheses (both for $t < k$ and for $t = k$, $m'' < n$), we see that the number of leaves in the resulting formula is given by

$$\begin{aligned}
& \sum_{t=\max\{0,k-m''\}}^{\min\{m',k\}} \left[m'(p-1)^t + m''(p-1)^{k-t} \right] \\
\leq\ & \sum_{t=0}^{k} \left[m'(p-1)^t + m''(p-1)^{k-t} \right] \\
=\ & \left[\sum_{t=0}^{k} m'(p-1)^t \right] + \left[\sum_{t=0}^{k} m''(p-1)^t \right] \\
=\ & (m' + m'') \left[\sum_{t=0}^{k} (p-1)^t \right] \\
\leq\ & n \left[(p-1) + 1 \right]^k = np^k
\end{aligned}$$

◀

In the rest of this paper, our goal is to prove a matching lower bound for the max function. Note that the constructions in Theorem 11 and Lemma 12 yield formulas that do not use constants at any leaves. Intuitively, it is clear that if a formula computes the maximum correctly for all natural numbers, then constants cannot help. So the lower bound should hold even in the presence of constants, and indeed our lower bound does hold even if constants are allowed.

4 The main lower bound

In this section, we prove the following theorem:

▶ **Theorem 13.** *Let F_1, F_2 be $(min, +)$ formulas over $\mathbb{N}$ such that $F_1 - F_2 = \max(x_1, \ldots, x_n)$. Then $L(F_1) \geq n$, and $L(F_2) \geq n \log n$.*

The proof proceeds as follows: we first transform F_1 and F_2 over a series of steps to formulas G_1 and G_2 no larger than F_1 and F_2, such that $G_1 - G_2$ equals $F_1 - F_2$ and hence still computes max, and G_1 and G_2 have some nice properties. These properties immediately imply that $L(F_1) \geq L(G_1) \geq n$. We further transform G_2 to a constant-free formula H no larger than G_2. We then define a measure for functions computable by constant-free $(\min, +)$ formulas, relate this measure to formula size, and use the properties of G_2 and H to show that the function h computed by H has large measure and large formula size.

Transformation 1. For $b \in \{1,2\}$, let S_b denote the set $S(F_b)$. For $i \in [n+1]$, let A_i be the minimum value appearing in the ith coordinate in any tuple in $S_1 \cup S_2$. Let $\tilde{A}$ denote the tuple $(A_1, \ldots, A_n, A_{n+1})$. By repeatedly invoking Proposition 9, we obtain formulas G_b computing $F_b - \langle \tilde{A} \cdot \tilde{x} \rangle$, with $L(G_b) \leq L(F_b)$. For $b \in \{1,2\}$, let T_b denote the set $S(G_b)$.

We now establish the following properties of G_1 and G_2.

▶ **Lemma 14.** *Let F_1, F_2 be $(\min,+)$ formulas such that $F_1 - F_2$ computes* max. *Let G_1, G_2 be obtained as described above. Then*

1. $L(G_1) \leq L(F_1)$, $L(G_2) \leq L(F_2)$,
2. $\max(X) = F_1 - F_2 = G_1 - G_2$,
3. *For every $i \in [n]$, for every $\tilde{a} \in T_1$, $a_i > 0$. Hence $L(G_1) \geq n$.*
4. *For every $i \in [n]$, there exists $\tilde{a} \in T_2$, $a_i = 0$.*
5. *There exist $\tilde{a} \in T_1$, $\tilde{b} \in T_2$, $a_{n+1} = b_{n+1} = 0$.*
6. *For every $i, j \in [n]$ with $i \neq j$, for every $\tilde{a} \in T_2$, $a_i + a_j > 0$.*

Proof. 1. This follows from proposition 9.

2. Obvious.
3. Suppose for some $\tilde{a} \in T_1$ and for some $i \in [n]$, $a_i = 0$. Consider the input assignment $\tilde{d}$ where $d_i = 1 + a_{n+1}$ and $d_j = 0$ for $j \in [n] \setminus \{i\}$. Then $\max\{d_1, \ldots, d_n\} = 1 + a_{n+1}$. However, $\langle \tilde{a} \cdot \tilde{d} \rangle = a_{n+1}$. Therefore on input $\tilde{d}$, $G_1(\tilde{d}) \leq a_{n+1}$. Since $G_2 \geq 0$ on all assignments, we get $G_1(\tilde{d}) - G_2(\tilde{d}) \leq a_{n+1} < \max(\tilde{d})$, contradicting the assumption that $G_1 - G_2$ computes max.
4. This follows from the previous point and the choice of A_i for each i.
5. From the choice of A_{n+1}, we know that there is an $\tilde{a}$ in $T_1 \cup T_2$ with $a_{n+1} = 0$. Suppose there is such a tuple in exactly one of the sets T_1, T_2. Then exactly one of $G_1(\tilde{0})$, $G_2(\tilde{0})$ equals 0, and so $G_1 - G_2$ does not compute $\max(\tilde{0})$.
6. Suppose to the contrary, some $\tilde{a} \in T_2$ has $a_i = a_j = 0$. Consider the input assignment $\tilde{d}$ where $d_i = d_j = 1 + a_{n+1}$ and $d_k = 0$ for $k \in [n] \setminus \{i, j\}$. Then $\max\{d_1, \ldots, d_n\} = 1 + a_{n+1}$. Since every x_k figures in every tuple of T_1, $G_1(\tilde{d}) \geq d_i + d_j = 2a_{n+1} + 2$. But $G_2(\tilde{d}) \leq a_{n+1}$. Hence $G_1(\tilde{d}) - G_2(\tilde{d})$ does not compute $\max(\tilde{d})$.

◀

We have already shown above that $L(F_1) \geq L(G_1) \geq n$. Now the more tricky part: we need to lower bound $L(G_2)$.

Transformation 2. Let H' be the formula obtained by simply replacing every constant in G_2 by 0. Let H be the constant-free formula obtained from H' by eliminating the zeroes, repeatedly replacing $0 + A$ by A, $\min\{0, A\}$ by 0. Let h be the function computed by H. Then, $L_{cf}(h) \leq L(H) \leq L(H') = L(G_2) \leq L(F_2)$. It thus suffices to show that $L_{cf}(h) \geq n \log n$. To this end, we define a complexity measure μ, relate it to constant-free formula size, and show that it is large for the function h.

▶ **Definition 15.** For an n-variate function f computable by a constant-free $(\min,+)$ formula, we define

$$(f)_1 = \{i \mid f(e_i) \geq 1, f(0) = 0\}.$$
$$(f)_2 = \{(i,j) \mid f(e_i + e_j) \geq 1, f(e_i) = 0, f(e_j) = 0\}.$$

We define $G(f)$ to be the graph whose vertex set is $[n]$ and edge set is $(f)_2$.

The measure μ for function f is defined as follows:

$$\mu = \frac{|(f)_1|}{n} + H(G(f))$$

The following lemma relates $\mu(f)$ with $L(f)$. This relation has been used before, see for instance [15] for applications to monotone Boolean circuits. Since we have not seen an application in the setting of $(\min, +)$ formulas, we (re-)prove this in detail here; however, it is really the same proof.

▶ **Lemma 16.** *Let f be an n-variate function computable by a constant-free $(\min, +)$ formula. Then $L_{cf}(f) \geq n \cdot \mu(f)$.*

Proof. The proof is by induction on the depth of a witnessing formula F that computes f and has $L_{cf}(F) = L_{cf}(f)$.

Base case F is an input variable, say x_i. Then $(f)_1 = \{x_i\}$, and $G(f)$ is the empty graph, so $\mu(f) = \frac{1}{n}$. Hence $1 = L_{cf}(f) = n\mu(f)$.

Inductive step F is either $F' + F''$ or $\min\{F', F''\}$ for some formulas F', F'' computing functions f', f'' respectively. Since F is an optimal-size formula for f, F' and F'' are optimal-size formulas for f' and f'' as well. So $L_{cf}(f) = L(F) = L(F') + L(F'') = L_{cf}(f') + L_{cf}(f'')$.

Case a. $F = F' + F''$. Then $(f)_1 = (f')_1 \cup (f'')_1$ and $G(f) \subseteq G(f') \cup G(f'')$. Hence,

$$\begin{aligned}
\mu(f) &\leq \frac{|(f')_1 \cup (f'')_1|}{n} + H(G(f') \cup G(f'')) && \text{(Lemma 4)} \\
&\leq \frac{|(f')_1|}{n} + \frac{|(f'')_1|}{n} + H(G(f')) + H(G(f'')) && \text{(Lemma 4)} \\
&= \mu(f') + \mu(f'') \\
&\leq \frac{1}{n} \cdot L_{cf}(f') + \frac{1}{n} \cdot L_{cf}(f'') && \text{(Induction)} \\
&= \frac{1}{n} \cdot L_{cf}(f) && (L_{cf}(f) = L_{cf}(f') + L_{cf}(f''))
\end{aligned}$$

Case b. $F = \min(F', F'')$. Let $(f')_1 = A$ and $(f'')_1 = B$. Then $(f)_1 = A \cap B$ and $G(f) \subseteq G(f') \cup G(f'') \cup G(A \setminus B, B \setminus A)$. Here, $G(P, Q)$ denotes the bipartite graph G with parts P and Q. Hence,

$$\begin{aligned}
\mu(f) &\leq \frac{1}{n}(|A \cap B|) + H(G(f') \cup G(f'') \cup G(A \setminus B, B \setminus A)) && \text{(Lemma 4)} \\
&\leq \frac{1}{n}(|A \cap B|) + H(G(f')) + H(G(f'')) + H(G(A \setminus B, B \setminus A)) && \text{(Lemma 4)} \\
&\leq \frac{1}{n}(|A \cap B|) + H(G(f')) + H(G(f'')) + \frac{1}{n}(|A \setminus B| + |B \setminus A|) && \text{(Lemma 5)} \\
&\leq \frac{1}{n}(|A| + |B|) + H(G(f')) + H(G(f'')) \\
&= \mu(f') + \mu(f'') \\
&\leq \frac{1}{n} \cdot L_{cf}(f') + \frac{1}{n} \cdot L_{cf}(f'') && \text{(Induction)} \\
&= \frac{1}{n} \cdot L_{cf}(f) && (L_{cf}(f) = L_{cf}(f') + L_{cf}(f''))
\end{aligned}$$

Hence, $\mu(f) \leq \frac{1}{n} \cdot L_{cf}(f)$. ◀

Using this measure, we can now show the required lower bound.

▶ **Lemma 17.** *For the function h obtained after Transformation 2, $\mu(h) \geq \log n$.*

Proof. Recall that we replaced constants in G_2 by 0 to get H', then eliminated the 0s to get constant-free H computing h. By Proposition 8, we know that $S(H') = \{\tilde{b} \mid b_{n+1} = 0, \exists \tilde{a} \in T_2, a_i = b_i \forall i \in [n]\}$ and that $h = \min\{\tilde{x} \cdot \tilde{b} \mid \tilde{b} \in S(H')\}$.

From item 4 in Lemma 14, it follows that $(h)_1 = \emptyset$. (For every i, there is a $\tilde{b} \in S(H')$ with $b_i = 0$. So $h(e_i) \leq \langle e_i \cdot \tilde{b} \rangle = 0$.)

Since $(h)_1$ is empty, $(i,j) \in G(h)$ exactly when $h(e_i + e_j) \geq 1$. From item 6 in Lemma 14, it follows that every pair (i,j) is in $G(h)$. Thus $G(h)$ is the complete graph K_n.

From Lemma 5 we conclude that $\mu(h) = \log n$. ◀

Lemmas 16 and 17 imply that $L_{cf}(h) \geq n \log n$. Since $L_{cf}(h) \leq L(H) \leq L(H') = L(G_2) \leq L(F_2)$, we conclude that $L(F_2) \geq n \log n$.

This completes the proof of Theorem 13.

A major ingredient in this proof is using the measure μ. This yields lower bounds for constant-free formulas. For functions computable in a constant-free manner, it is hard to see how constants can help. However, to transfer a lower bound on $L_{cf}(f)$ to a lower bound on $L(f)$, this idea of "constants cannot help" needs to be formalized. The transformations described before we define μ do precisely this.

For the MinSum_n^{n-1} function, applying the measure technique immediately yields the lower bound $L_{cf}(\mathsf{MinSum}_n^{n-1}) \geq n \log n$. Transferring this lower bound to formulas with constants is a corollary of our main result, and with it we see that the upper bound from Lemma 12 is tight for MinSum_n^{n-1}.

▶ **Corollary 18.** *Any* $(\min, +)$ *formula computing* MinSum_n^{n-1} *must have size at least* $n \log n$.

Proof. Let F be any formula computing MinSum_n^{n-1}. Applying Theorem 13 to $F_1 = x_1 + \ldots + x_n$ and $F_2 = F$, we obtain $L(F) \geq n \log n$. ◀

5 Discussion

Our results hold when variables take values from $\mathbb{N}$. In the standard $(\min, +)$ semi-ring, the value ∞ is also allowed, since it serves as the identity for the min operation. The proof of our main result Theorem 13 does not carry over to this setting. The main stumbling block is the removal of the "common" part of $S(F)$. However, if we allow ∞ as a value that a variable can take, but not as a constant appearing at a leaf, then the lower bound proof still seems to work. However, the upper bound no longer works; while taking a difference, what is $\infty - \infty$?

Apart from the many natural settings where the tropical semiring $(\min, +, \mathbb{N} \cup \{\infty\}, 0, \infty)$ crops up, it is also interesting because it can simulate the Boolean semiring for monotone computation. The mapping is straightforward: $0, 1, \vee, \wedge$ in the Boolean semiring are replaced by $\infty, 0, \min, +$ respectively in the tropical semiring. Proving lower bounds for $(\min, +)$ formulas could be easier than for monotone Boolean formulas because the $(\min, +)$ formula has to compute a function correctly at all values, not just at $0, \infty$. Hence it would be interesting to extend our lower bound to this setting with ∞ as well.

Our transformations crucially use the fact that there is a minimum element, 0. Thus, we do not see how to extend these results to computations over integers. It appears that we will need to include $-\infty$, and since we are currently unable to handle even $+\infty$, there is already a barrier.

The lower bound method uses graph entropy which is always bounded above by $\log n$. Thus this method cannot give a lower bound larger than $n \log n$. It would be interesting to obtain a modified technique that can show that all the upper bounds in Theorem 11 and

Lemma 12 are tight. It would also be interesting to find a direct combinatorial proof of our lower bound result, without using graph entropy.

Abstract

The Independent Cascade Model (ICM) is a widely studied model that aims to capture the dynamics of the information diffusion in social networks and in general complex networks. In this model, we can distinguish between active nodes which spread the information and inactive ones. The process starts from a set of initially active nodes called seeds. Recursively, currently active nodes can activate their neighbours according to a probability distribution on the set of edges. After a certain number of these recursive cycles, a large number of nodes might become active. The process terminates when no further node gets activated.

Starting from the work of Domingos and Richardson [10, 26], several studies have been conducted with the aim of shaping a given diffusion process so as to maximize the number of activated nodes at the end of the process. One of the most studied problems has been formalized by Kempe et al. and consists in finding a set of initial seeds that maximizes the expected number of active nodes under a budget constraint [14]. In this paper we study a generalization of the problem of Kempe et al. in which we are allowed to spend part of the budget to create new edges incident to the seeds. That is, the budget can be spent to buy seeds or edges according to a cost function. The problem does not admin a PTAS, unless $P = NP$. We propose two approximation algorithms: the former one gives an approximation ratio that depends on the edge costs and increases when these costs are high; the latter algorithm gives a constant approximation guarantee which is greater than that of the first algorithm when the edge costs can be small.

1 Introduction

When a new idea or innovation arises in a network of individuals, it can either quickly propagate to a large part of the network and be adopted by many individuals or immediately expire. Understanding the dynamics that regulate these behaviours has been one of the main goals in the field of complex network analysis and has been studied under the name of *influence spreading* or *information diffusion* analysis problem [10, 14]. The motivating application span several fields: from marketing with the aim of evaluating the success of a new product or maximizing its adoption [3, 4, 11, 21, 26], to epidemiology in order to limit the diffusion of a virus or disease [22, 23], the study of adoption of innovations [5, 27, 30],

the analysis of social networks to find influential users and to study how information flows through the network [2], and the analysis of cascading failures in power networks [1].

Different models of information diffusion have been introduced in the literature. Two widely studied models are the *Linear Threshold Model* (LTM) [13, 15, 28] and the *Independent Cascade Model* (ICM) [11, 12, 14, 15]. In both models, we can distinguish between *active*, or *affected*, nodes which spread the information and inactive ones. At the beginning of the process a small percentage of nodes of the graph is set to active in order to let the information diffusion process start. These nodes are called *seeds*. Recursively, currently affected nodes can infect their neighbours with some probability. After a certain number of these cascading cycles, a large number of nodes might become affected in the network. In LTM the idea is that a node becomes active as more of its neighbours become active. Formally, each node u has a threshold t_u chosen uniformly at random in the interval $[0, 1]$. The threshold represents the weighted fraction of neighbours of u that must become active in order for u to become active. During the process, a node u becomes active if the total weight of its active neighbours is greater than t_u. In ICM, instead, an active node u tries to influence one of its inactive neighbours but the success of node u in activating the node v only depends on the propagation probability of the edge from u to v (each edge has its own value). Regardless of its success, the same node will never get another chance to activate the same inactive neighbour. The process terminates when no further node gets activated.

An interesting question, in the analysis of the information diffusion through a network, is how to shape a given diffusion process so as to maximize or minimize the number of activated nodes at the end of the process by taking intervention actions. Many intervention actions have been studied in the literature, the most important one has been proposed by Domingos and Richardson in the field of viral marketing and asks to find a small set of "influential" seeds in a network in order to activate a large part of the network [10, 26]. The problem has been formalized by Kempe et al. [15] as follows: if we are allowed to choose at most k seeds, which ones should be selected so as to maximize the number of active nodes resulting from the diffusion process [15]. This problem admits a $(1 - \frac{1}{e})$-approximation algorithm and this factor cannot be improved, unless $P = NP$ [15]. Besides seeds selection, other intervention actions may be used to facilitate the diffusion processes, such as inserting or deleting edges and adding or deleting nodes in the network. Since in social networks and in other complex networks users can add edges incident to themselves, in this paper we consider the possibility to create a limited number of new edges incident to the initial seed nodes. In detail, we study the following generalization of the problem of Kempe et al.: we are given a cost for each possible edge that can be created in a network and a budget k, and we want to find a set of seed nodes A and a set of edges S incident to the nodes in A such that the expected number of active nodes at the end of the diffusion process is maximized and the overall cost of A and S does not exceed k, assuming that all the seeds have the same cost.

Related work. The problem of choosing initially active nodes to maximize the information diffusion in a network has been widely studied, we refer the interested reader to [15] and references therein for more detail, while the budgeted version of the problem was proposed in [24]. In the following we focus on the problem of modifying a graph in order to maximize or minimize the spread of information in a network under LTM and ICM models.

To the best of our knowledge, under LTM, the problems that have been studied are those outlined in what follows. Khalil et al. [16] consider two types of actions, adding edges to or deleting edges from the existing network to minimize the information diffusion and they show that this network structure modification problem has a supermodular objective and therefore

can be solved by algorithms with provable approximation guarantees. Zhang et al. [32] consider arbitrarily specified sets of nodes, and interventions that involve both edge and node removal from the sets. They develop algorithms with rigorous performance guarantees and good empirical performance. Kimura et al. [18] use a greedy approach to delete edges under the LTM but do not provide any rigorous approximation guarantees. Kuhlman et al. [20] propose heuristic algorithms for edge removal under a simpler deterministic variant of LTM which is not only hard, but also has no approximation guarantee. Papagelis [25] and Crescenzi et al. [6] study the problem of augmenting the graph in order to increase the connectivity or the centrality of a node, respectively and experimentally show that this increases the average number of eventual active nodes.

Under ICM, Wu et al. [31] consider intervention actions other than edge addition, edge deletion and seed selection, such as increasing the probability that a node infects its neighbours. They proved that optimizing the selection of these actions with a limited budget is NP-hard and is neither submodular nor supermodular. Sheldon et al. [29] study the problem of node addition to maximize the spread of information, and provide a counterexample showing that the objective function is not submodular. Kimura et al. [19] propose methods for efficiently finding good approximate solutions on the basis of a greedy strategy for the edge deletion problem under the ICM, but do not provide any approximation guarantees. D'Angelo et al. [7, 8] focus on the case in which the initial set of seeds is given and provide a constant approximation algorithm.

Our results. In this paper, we focus on the independent cascade model and investigate the problem of selecting a set of initial seeds and adding a small number of edges incident to the seeds, without exceeding a given budget k, in order to maximize the spread of information in terms of the expected number of nodes that eventually become active. The problem we analyse differs from above mentioned ones since we make the reasonable restriction that the edges to be added can only be incident to the seed nodes. To our knowledge, similar problems have never been studied for the independent cascade model. We refer to this problem as the *Budgeted Influence Maximization with Augmentation problem* (BIMA).

We observe that the BIMA problem is a generalization of the problem in [15] and therefore cannot be approximated within a factor greater than $1 - \frac{1}{e}$, unless $P = NP$.

We then focus on approximation algorithms. We first assume that the edge costs are all greater that a given constant c_{min} and, in Section 3, we propose two approximation algorithms that guarantee approximation factors of $1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}$ and $\left(1 - \frac{1}{e}\right) c_{\min}$, respectively. Note that these factors increase with $c_{\min}$ and the second algorithm achieves the optimal approximation of $1 - \frac{1}{e}$ when all the edge costs are equal to 1. It is somewhat expected that when the all costs are high the approximation factor gets closer to the lower bound of $1 - \frac{1}{e}$. Indeed, when the cost of buying an edge approaches the cost of buying the node at the tail of this edge, we can buy the node instead of the edge with small increase in the cost. This allows us to exploit the $1 - \frac{1}{e}$ approximation algorithm for the seed selection problem proposed in [15]. However, the challenge of our problem consists in finding a good approximation even when the cost function includes small values. In Section 4, we focus on the general case and propose an algorithm that guarantees a constant approximation ratio of about 0.0878. This algorithm outperforms the other two algorithms when the cost is allowed to be small. See Figure 1 for a summary of the approximation ratio of our algorithms.

Some of the proofs are omitted due to space constraints and can be found in the full version of the paper [9].

2 Preliminaries

A social network is represented by a weighted directed graph $G = (V, E, p, c)$, where V represents the set of nodes, E represents the set of relationships, $p : V \times V \to [0, 1]$ is the propagation probability of an edge, that is the probability that the information is propagated from u to v if $(u, v) \in E$, and $c : V \times V \to [0, 1]$ is the cost of adding an edge to E. In ICM, each node can be either *active* or *inactive*. If a node is active (or adopter of the innovation), then it is already influenced by the information under diffusion. If a node is inactive, then it is unaware of the information or not influenced. The process runs in discrete steps. At the beginning of the ICM process, few nodes are given the information, they are known as *seed nodes*. Upon receiving the information these nodes become active. In each discrete step, an active node tries to influence its inactive neighbours. The success of node u in activating the node v depends on the propagation probability of the edge (u, v), independently of the history so far. Regardless of its success, the same node will never get another chance to activate the same inactive neighbour. The process terminates when no further nodes become activated from inactive state.

We define the influence of a set $A \subseteq V$ in the graph G, denoted $\sigma(A)$, to be the expected number of active nodes in G at the end of the process, given that A is the set of seeds. Given a set S of edges not in E, we denote by $G(S)$ the graph augmented by adding the edges in S to G, i.e. $G(S) = (V, E \cup S)$. We denote by $\sigma(A, S)$ the influence of A in $G(S)$.

In this paper we look for a set of seeds A and a set of edges S, to be added to G, incident to these seeds that maximize $\sigma(A, S)$. W.l.o.g. we assume that each seed node can be selected with cost 1, while each edge $e \in (V \times V) \setminus E$ can be selected with cost $c_e \in [0, 1]$. In detail, the BIMA problem is defined as follows: given a graph $G = (V, E)$ and a budget k, find a set A of seeds and a set S of edges such that $S \subseteq (A \times V) \setminus E$, $c(A, S) \leq k$, and $\sigma(A, S)$ is maximum, where $c(A, S) = |A| + \sum_{e \in S} c_e$.

A *live-edge graph* $X = (V, E_X)$ of G is a directed graph where the set of nodes is the same set V and the set of edges E_X is a subset of E given by an edge selection process in which each edge in E belongs to E_X or not according to its propagation probability. In detail, we can assume that for each edge $e = (u, v)$ in the graph, we flip a coin of bias p_e and only the edges for which the coin indicated an activation belong to E_X. It is easy to show that the information diffusion process is equivalent to a reachability problem in live-edge graphs: given any seed set A, the distribution of active node sets after the diffusion process ends is the same as the distribution of node sets reachable from A in live-edge graphs. We denote by χ the probability space in which each sample point specifies one possible set of outcomes for all the coin flips on the edges, that is the set of all possible live-edge graphs of G. For a set of edges $S \subseteq (V \times V) \setminus E$, the set of all possible live-edge graphs of $G(S)$ is denoted by $\chi(S)$. Given two set of edges S, T, such that $S \subseteq T$, for each live-edge graph X in $\chi(S)$ we denote by $\chi(T, X)$ the set of live-edge graphs in $\chi(T)$ that have X as a subgraphs and possibly contain other edges in $T \setminus S$. In other words, a live-edge graphs in $\chi(T, X)$ has been generated with the same outcomes as X on the coin flips in the edges of $E \cup S$ and it has other outcomes for edges in $T \setminus S$. The following holds: $|\chi(T, X)| = 2^{|T \setminus S|}$, for each $Y \in \chi(T, X)$ $\mathbb{P}[Y] = \mathbb{P}[Y|X]\mathbb{P}[X]$, $\mathbb{P}[X] = \sum_{Y \in \chi(T,X)} \mathbb{P}[Y]$, and $\sum_{Y \in \chi(T,X)} \mathbb{P}[Y|X] = 1$. For a node $a \in V$ and a live-edge graph X in $\chi(S)$, let $R(a, X)$ be the set of all nodes that can be reached from a in graph X, that is for each node $u \in R(a, X)$, there exists a path from a to u consisting entirely of live edges with respect to the outcome of the coin flips that generates X. Let $R(A, X) = \bigcup_{a \in A} R(a, X)$, then $\sigma(A, S)$ can be computed as $\sigma(A, S) = \sum_{X \in \chi(S)} \mathbb{P}[X] \cdot |R(A, X)|$.

Computing $\sigma(A)$ is $\#P$-complete [4], however it has been proven by using the Chernoff bound that it can be approximated within an arbitrarily good factor by simulating the random process a polynomial number of times [15]. Therefore, in the rest of the paper we can assume that we can compute $\sigma(A)$ (and $\sigma(A, S)$) within an arbitrary bound. This reflects to an additional factor $1 + \epsilon$, for any $\epsilon > 0$, to all algorithms presented in this paper. For the sake of clarity, we omit this factor from the approximation factor of our algorithms.

Given a set of edges S, for each graph $X \in \chi(S)$ and subset of edges $T \subseteq S$, we denote by X^T the graph obtained by removing edges in T from X. Given two feasible solutions (A_1, S_1) and (A_2, S_2), such that $A_2 \subseteq A_1$ and $S_2 \subseteq S_1$, we denote with $\delta(A_1, S_1, A_2, S_2)$ the expected number of nodes affected by (A_1, S_1) and not affected by (A_2, S_2), formally: $\delta(A_1, S_1, A_2, S_2) = \sum_{X \in \chi(S_1)} \mathbb{P}[X] \cdot \left(|R(A_1, X)| - |R(A_2, X^T)|\right)$, where $T = S_1 \setminus S_2$.

▶ **Proposition 1.** *For each $A_2 \subseteq A_1 \subseteq V$ and $S_2 \subseteq S_1 \subseteq V \times V$, such that the edges in S_1 and S_2 are outgoing A_1 and A_2, respectivey, then $\delta(A_1, S_1, A_2, S_2) = \sigma(A_1, S_1) - \sigma(A_2, S_2)$.*

We observe that our problem is a generalization of the influence maximization problem in [15], indeed it is enough to set $c_e = 1$ for each $e \in (V \times V) \setminus E$. It follows that BIMA cannot be approximated within a factor greater than $1 - \frac{1}{e}$, unless $P = NP$.

3 Lower-bounded edge costs

In this section we consider the case in which the edge costs are at least a given value $c_{\min}$, that is for each $e \in V \times V, c_e \geq c_{\min}$. It can be easily shown that in this case selecting a set A of k seed nodes that maximizes $\sigma(A, \emptyset)$ guarantees an approximation factor of $c_{\min}$. Since this problem can be optimally approximated within $1 - \frac{1}{e}$ [15], we can obtain an overall $\left(1 - \frac{1}{e}\right) c_{\min}$ approximation. In what follows we give an approximation algorithm that improves over this bound for small values of $c_{\min}$. The following analysis serves also as a warm-up for the analysis of the algorithm proposed in the next section.

Our algorithm, whose pseudocode is reported in Algorithm 1, finds two candidate solutions: the first solution is obtained by a greedy algorithm at lines 2–25, the second solution is found at line 26 and is made of a single node a_M and a single edge (a_M, v_M) for which $\sigma(\{a_M\}, \{(a_M, v_M)\})$ is maximized. Then, the algorithm outputs one of the candidate solutions that maximizes the expected number of affected nodes (line 27).

The greedy phase, at each iteration, selects a solution (A, S) that adds at most one node and one edge to the current solution (A', S') and that maximizes the ratio between $\delta(A, S, A', S')$ and the marginal cost of (A, S), that is the cost of the added node or edge. In particular, it considers three possible ways of obtaining (A, S) from (A', S'):

line 3: select a seed node a that maximizes $r_1 = \delta(A' \cup \{a\}, S', A', S')$, $(A, S) = (A' \cup \{a\}, S')$;

line 4: select an edge (a, v) incident to a seed a in A' that maximizes $r_2 = \frac{\delta(A', S' \cup \{(a,v)\}, A', S')}{c_{(a,v)}}$, $(A, S) = (A', S' \cup \{(a, v)\})$;

line 5: select a seed node a not in A' and edge (a, v) incident to a that maximize $r_3 = \frac{\delta(A' \cup \{a\}, S' \cup \{(a,v)\}, A', S')}{1 + c_{(a,v)}}$, $(A, S) = (A' \cup \{a\}, S' \cup \{(a, v)\})$.

The greedy phase of the algorithm selects a solution (A, S) that maximizes the three above ratios. If (A, S) does not violate the budget, i.e. cost $c(A, S)$ is at most k, then it is chosen as new solution.

We denote by (A^*, S^*) an optimal solution to the BIMA problem. Let us consider the iterations executed by the greedy algorithm in which an element is added to (A, S). For $i \geq 1$, let us denote by j_i the index of these iterations, $j_i < j_{i+1}$, and let j_{l+1} be the index of the first iteration in which an element in (A^*, S^*) is considered (i.e. it maximizes the

Algorithm 1:
Input : A directed graph $G = (V, E)$ and an integer $k \in \mathbb{N}$
Output : A set of nodes A and a of edges $S \subseteq (A \times V) \setminus E$ such that $c(A, S) \leq k$

$A := \emptyset$; $S := \emptyset$; $U := V$; $T := (V \times V) \setminus E$;
while $T \neq \emptyset$ *or* $U \neq \emptyset$ **do**
  $r_1 = \max_{a \in U} \{\delta(A \cup \{a\}, S, A, S)\}$;
  $r_2 = \max_{(a,v) \in (A \times V) \cap T} \left\{\delta(A, S \cup \{(a, v)\}, A, S)/c_{(a,v)}\right\}$;
  $r_3 = \max_{a \in U, (a,v) \in (\{a\} \times V) \cap T} \left\{\delta(A \cup \{a\}, S \cup \{(a, v)\}, A, S)/(1 + c_{(a,v)})\right\}$;
  if $\max\{r_1, r_2, r_3\} = r_1$ **then**
    $\hat{a} = \arg\max_{a \in U} \{\delta(A \cup \{a\}, S, A, S)\}$;
    if $k - 1 \geq 0$ **then**
      $A := A \cup \{\hat{a}\}$;
      $k := k - 1$;
    $U := U \setminus \{\hat{a}\}$;
  else
    if $\max\{r_1, r_2, r_3\} = r_2$ **then**
      $(\hat{a}, \hat{v}) := \arg\max_{(a,v) \in A \times V \cap T} \left\{\delta(A, S \cup \{(a, v)\}, A, S)/c_{(a,v)}\right\}$;
      if $k - c_{(\hat{a},\hat{v})} \geq 0$ **then**
        $S := S \cup \{(\hat{a}, \hat{v})\}$;
        $k := k - c_{(\hat{a},\hat{v})}$;
      $T := T \setminus \{(\hat{a}, \hat{v})\}$;
    else
      $(\hat{a}, (\hat{a}, \hat{v})) := \arg\max_{a \in U, (a,v) \in \{a\} \times V \cap T} \left\{\delta(A \cup \{a\}, S \cup \{(a, v)\}, A, S)/(1 + c_{(a,v)})\right\}$;
      if $k - c_{(\hat{a},\hat{v})} - 1 \geq 0$ **then**
        $(A, S) := (A \cup \{\hat{a}\}, S \cup \{(\hat{a}, \hat{v})\})$;
        $U := U \setminus \{\hat{a}\}$;
        $k := k - 1 - c_{(\hat{a},\hat{v})}$;
      $T := T \setminus \{(\hat{a}, \hat{v})\}$;
$(a_M, (a_M, v_M)) := \arg\max_{a \in V, (a,v) \in (\{a\} \times V) \setminus E} \{\sigma(A \cup \{a\}, S \cup \{(a, v)\})\}$;
return $\arg\max\{\sigma(A, S), \sigma(\{a_M\}, \{(a_M, v_M)\})\}$;

above ratios) but not added to (A, S) because it violates the budget constraint. We denote by (A_i, S_i) the solution at the end of iteration j_i and by $\bar{c}_i$ the marginal cost of (A_i, S_i) as computed in the above three ratios,

$$\bar{c}_i = \begin{cases} 1 & \text{if } A_i \setminus A_{i-1} = \{a\} \text{ and } S_i = S_{i-1} \quad (\text{i.e. } \max\{r_1, r_2, r_3\} = r_1) \\ c_e & \text{if } A_i = A_{i-1} \text{ and } S_i \setminus S_{i-1} = \{(a, v)\} \quad (\text{i.e. } \max\{r_1, r_2, r_3\} = r_2) \\ 1 + c_e & \text{if } A \setminus A_{i-1} = \{a\} \text{ and } S_i \setminus S_{i-1} = \{(a, v)\} \quad (\text{i.e. } \max\{r_1, r_2, r_3\} = r_3). \end{cases}$$

The next two lemmas are the core of our analysis [17].

▶ **Lemma 2.** *After each iteration* j_i, $i = 1, 2, \ldots, l + 1$, $\sigma(A_i, S_i) - \sigma(A_{i-1}, S_{i-1}) \geq \frac{\bar{c}_i}{k} \frac{c_{\min}}{1+c_{\min}} (\sigma(A^*, S^*) - \sigma(A_{i-1}, S_{i-1}))$.

Proof. We denote by δ_i the expected number of nodes affected by solution (A_i, S_i) and not affected by solution (A_{i-1}, S_{i-1}), $\delta_i = \delta(A_i, S_i, A_{i-1}, S_{i-1})$. We first show that the value $\sigma(A^*, S^*) - \sigma(A_{i-1}, S_{i-1})$ is at most the sum, for each element in (A^*, S^*) and not in (A_{i-1}, S_{i-1}), of the expected number of nodes affected by this element and not affected by solution (A_{i-1}, S_{i-1}), that is the following inequality holds:

$$\sigma(A^*, S^*) - \sigma(A_{i-1}, S_{i-1}) \leq \sum_{a \in A_1^*} \delta(A_{i-1} \cup \{a\}, S_{i-1}, A_{i-1}, S_{i-1}) + \tag{1}$$

$$\sum_{\substack{e=(a,v) \in S^* \setminus S_{i-1} \\ \text{s.t. } a \in A_{i-1}}} \delta(A_{i-1}, S_{i-1} \cup \{e\}, A_{i-1}, S_{i-1}) + \sum_{\substack{a \in A_2^* \\ e=(a,v) \in S^* \setminus S_{i-1}}} \delta(A_{i-1} \cup \{a\}, S_{i-1} \cup \{e\}, A_{i-1}, S_{i-1}),$$

where we divided the set $A^* \setminus A_{i-1}$ into two subsets: A_1^* is the subset of $A^* \setminus A_{i-1}$ that contains the seeds a with no incident edges in S^* (i.e. $\nexists (a,v) \in S^*$), and $A_2^* = A^* \setminus (A_{i-1} \cup A_1^*)$.

The difference $\sigma(A^*, S^*) - \sigma(A_{i-1}, S_{i-1})$ is at most $\sigma(A^* \cup A_{i-1}, S^* \cup S_{i-1}) - \sigma(A_{i-1}, S_{i-1})$ and therefore upper-bounded by:

$$\begin{aligned}
&\sum_{X \in \chi(S^* \cup S_{i-1})} \mathbb{P}[X] |R(A^* \cup A_{i-1}, X)| - \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] |R(A_{i-1}, X)| \\
&= \sum_{X \in \chi(S_{i-1})} \sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y] |R(A^* \cup A_{i-1}, Y)| - \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] |R(A_{i-1}, X)| \\
&= \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] \sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] |R(A^* \cup A_{i-1}, Y)| - \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] |R(A_{i-1}, X)| \\
&= \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] \left[\sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] |R(A^* \cup A_{i-1}, Y)| - |R(A_{i-1}, X)| \right] \\
&= \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] \left[\sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] |R(A^* \cup A_{i-1}, Y)| - \sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] |R(A_{i-1}, X)| \right] \\
&= \sum_{X \in \chi(S_{i-1})} \mathbb{P}[X] \sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] \left(|R(A^* \cup A_{i-1}, Y)| - |R(A_{i-1}, X)| \right) \qquad (2)
\end{aligned}$$

For each $X \in \chi(S_{i-1})$ and $Y \in \chi(S^* \cup S_{i-1}, X)$, the difference $|R(A^* \cup A_{i-1}, Y)| - |R(A_{i-1}, X)|$ between the nodes reachable from $A^* \cup A_{i-1}$ in Y and those reachable from A_{i-1} in X can be bounded as follows:

$$|R(A^* \cup A_{i-1}, Y)| - |R(A_{i-1}, X)| \leq \sum_{a \in A_1^*} \left(|R(A_{i-1} \cup \{a\}, X)| - |R(A_{i-1}, X)| \right) + \qquad (3)$$

$$\sum_{\substack{e=(a,v) \in Y \setminus X \\ \text{s.t. } a \in A_{i-1}}} \left(|R(A_{i-1}, X \cup \{e\})| - |R(A_{i-1}, X)| \right) + \sum_{\substack{a \in A_2^* \\ e=(a,v) \in Y \setminus X}} \left(|R(A_{i-1} \cup \{a\}, X \cup \{e\})| - |R(A_{i-1}, X)| \right).$$

Combining (2) and the first term of (3), we obtain the first term of (1). To show the second and third term of (1), observe that for a function $f : V \times V \to \mathbb{N}$ and for each $X \in \chi(S_{i-1})$,

$$\sum_{Y \in \chi(S^* \cup S_{i-1}, X)} \mathbb{P}[Y|X] \sum_{e \in Y \setminus X} f(e) \leq \sum_{e \in S^* \setminus S_{i-1}} p_e \sum_{Y \in \chi(S^* \cup S_{i-1} \setminus \{e\}, X)} \mathbb{P}[Y|X \cup \{e\}] f(e) = \sum_{e \in S^* \setminus S_{i-1}} p_e f(e).$$

This shows inequality (1).

Since the greedy phase of the algorithm selects a solution that that maximizes the ratio between the marginal increment in the objective function and the cost, the following holds:

- For each $a \in A_1^*$, $\delta(A_{i-1} \cup \{a\}, S_{i-1}, A_{i-1}, S_{i-1}) \leq \frac{\delta_i}{\bar{c}_i}$;
- For each $e = (a,v) \in S^* \setminus S_{i-1}$ such that $a \in A_{i-1}$, $\frac{\delta(A_{i-1}, S_{i-1} \cup \{e\}, A_{i-1}, S_{i-1})}{c_e} \leq \frac{\delta_i}{\bar{c}_i}$;
- For each $a \in A_2^*$ and $e = (a,v) \in S^* \setminus S_{i-1}$, $\frac{\delta(A_{i-1} \cup \{a\}, S_{i-1} \cup \{e\}, A_{i-1}, S_{i-1})}{1 + c_e} \leq \frac{\delta_i}{\bar{c}_i}$.

Since the edge costs are at least $c_{\min}$, then the number of edges in $S^* \setminus S_{i-1}$ incident to each $a \in A_2^*$ is at most $\left\lfloor \frac{k}{c_{\min}} \right\rfloor \leq \frac{k}{c_{\min}}$. Therefore, the right hand side of (1) is at most:

$$\begin{aligned}
&\sum_{a \in A_1^*} \frac{\delta_i}{\bar{c}_i} + \sum_{\substack{e=(a,v) \in S^* \setminus S_{i-1} \\ \text{s.t. } a \in A_{i-1}}} \frac{\delta_i}{\bar{c}_i} c_e + \sum_{\substack{a \in A_2^* \\ e=(a,v) \in S^* \setminus S_{i-1}}} \frac{\delta_i}{\bar{c}_i} (1 + c_e) \\
&\leq \frac{\delta_i}{\bar{c}_i} \left(|A_1^*| + \sum_{\substack{e=(a,v) \in S^* \setminus S_{i-1} \\ \text{s.t. } a \in A_{i-1}}} c_e + \frac{k}{c_{\min}} + \sum_{\substack{a \in A_2^* \\ e=(a,v) \in S^* \setminus S_{i-1}}} c_e \right) \leq \left(1 + \frac{1}{c_{\min}} \right) k \frac{\delta_i}{\bar{c}_i}.
\end{aligned}$$

Where the last inequality is due to $|A_1^*| + \sum_{\substack{e=(a,v)\in S^*\setminus S_{i-1} \\ \text{s.t. } a\in A_{i-1}}} c_e + \sum_{\substack{a\in A_2^* \\ e=(a,v)\in S^*\setminus S_{i-1}}} c_e \leq k$.

To conclude the proof, $\delta_i = \sigma(A_i, S_i) - \sigma(A_{i-1}, S_{i-1})$ follows from Proposition 1. ◀

The next lemma can be proven by induction on iterations j_i and by using Lemma 2.

▶ **Lemma 3.** *After each iteration j_i, $i = 1, 2, \ldots, l+1$,*

$$\sigma(A_i, S_i) \geq \left[1 - \prod_{\ell=1}^{i} \left(1 - \frac{\bar{c}_\ell}{k} \frac{c_{\min}}{(1 + c_{\min})}\right)\right] \sigma(A^*, S^*).$$

▶ **Theorem 4.** *Algorithm 1 achieves an approximation factor of $\frac{1}{2}\left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right)\sigma(A^*, S^*)$.*

Proof. We observe that since (A_{l+1}, S_{l+1}) violates the budget, then $c(A_{l+1}, S_{l+1}) > k$. Moreover, for a sequence of numbers $a_1, a_2, \ldots, a_n$ such that $\sum_{\ell=1}^{n} a_\ell = B$, the function $\left[1 - \prod_{i=1}^{n}\left(1 - \frac{a_i}{B\cdot\beta}\right)\right]$ achieves its minimum when $a_i = \frac{B}{n}$ and that $\left[1 - \prod_{i=1}^{n}\left(1 - \frac{a_i}{B\cdot\beta}\right)\right] \geq 1 - \left(1 - \frac{1}{n\cdot\beta}\right)^n \geq 1 - e^{-\frac{1}{\beta}}$. Therefore, by applying Lemma 3 for $i = l+1$ and observing that $\sum_{\ell=1}^{l+1} \bar{c}_\ell = c(A_{l+1}, S_{l+1})$, we obtain:

$$\begin{aligned}
\sigma(A_{l+1}, S_{l+1}) &\geq \left[1 - \prod_{\ell=1}^{l+1}\left(1 - \frac{\bar{c}_\ell}{k\left(\frac{1+c_{\min}}{c_{\min}}\right)}\right)\right]\sigma(A^*, S^*) \\
&\geq \left[1 - \prod_{\ell=1}^{l+1}\left(1 - \frac{\bar{c}_\ell}{c(A_{l+1}, S_{l+1})\left(\frac{1+c_{\min}}{c_{\min}}\right)}\right)\right]\sigma(A^*, S^*) \\
&\geq \left[1 - \left(1 - \frac{1}{(l+1)\frac{1+c_{\min}}{c_{\min}}}\right)^{l+1}\right]\sigma(A^*, S^*) \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right)\sigma(A^*, S^*).
\end{aligned}$$

By Proposition 1, follows that:

$$\sigma(A_{l+1}, S_{l+1}) = \sigma(A_l, S_l) + \delta_{l+1} \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right)\sigma(A^*, S^*). \tag{4}$$

Since $\delta_{l+1} \leq \sigma(\{a_M\}, \{(a_M, v_M)\})$, we get

$$\sigma(A_l, S_l) + \sigma(\{a_M\}, \{(a_M, v_M)\}) \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right)\sigma(A^*, S^*).$$

Hence, $\max\{\sigma(A_l, S_l), \sigma(\{a_M\}, \{(a_M, v_M)\})\} \geq \frac{1}{2}\left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right)\sigma(A^*, S^*)$. ◀

We now propose an algorithm which improves the performance guarantee of Algorithm 1. Let M a fixed integer, we consider all the solutions (A, S) with cardinality M (i.e. $|A| + |S| = M$) and cost at most k ($c(A, S) \leq k$), and we complete all these solutions by using the greedy algorithm. The pseudocode is reported in Algorithm 2.

▶ **Theorem 5.** *For $M \geq 4$ Algorithm 2 achieves an approximation factor of $1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}$.*

Algorithm 2:
Input : A directed graph $G = (V, E)$, integer $M \in \mathbb{N}$ and an integer $k \in \mathbb{N}$
Output : A set of nodes A and a of edges $S \subseteq (A \times V) \setminus E$ such that $c(A, S) \leq k$
$(A_1, S_1) := \arg\max\{\sigma(A, S) : |A| + |S| < M, c(A, S) \leq k\}$;
$A_2 := \emptyset$; $S_2 := \emptyset$; $U := V$; $T := (V \times V) \setminus E$;
foreach $A \subseteq U, S \subseteq (A \times V) \setminus E$ such that $|A| + |S| = M$ and $c(A, S) \leq k$ **do**
  $U := U \setminus A$; $T := T \setminus S$;
  Complete (A, S) by using Algorithm 1 with U and T as possible nodes and edges;
  if $\sigma(A, S) > \sigma(A_2, S_2)$ **then**
    $A_2 := A$;
    $S_2 := S$;
return $\arg\max\{\sigma(A_1, S_1), \sigma(A_2, S_2)\}$;

Proof. We assume that $|A^*| + |S^*| > M$ since otherwise Algorithm 2 finds an optimal solution. We sort the elements in (A^*, S^*) by selecting at each step the element, which can be either a seed or an edge, that maximizes the marginal increment in the number of influenced nodes. Let $Z = (A_Z, S_Z)$ be the first M elements in this order. We now consider the iteration of Algorithm 2 in which element Z is considered. We define $(A_{Z'}, S_{Z'})$ as the elements added by the algorithm to (A_Z, S_Z) and $(A, S) = (A_Z \cup A_{Z'}, S_Z \cup S_{Z'})$. By Proposition 1 follows that $\sigma(A, S) = \sigma(A_Z, S_Z) + \delta(A_Z \cup A_{Z'}, S_Z \cup S_{Z'}, A_Z, S_Z)$.

The completion of (A_Z, S_Z) to (A, S) is an application of the greedy algorithm and therefore, we can use the result from the previous theorems. Let us consider the iterations executed by the greedy algorithm during the completion of (A_Z, S_Z) to (A, S). For $i \geq 1$, let us denote by j_i the index of these iterations, $j_i < j_{i+1}$, and let j_{l+1} be the index of the first iteration in which an element in $(A^* \setminus A_Z, S^* \setminus S_Z)$ is considered but not added to $(A_{Z'}, S_{Z'})$ because it violates the budget constraint. Applying inequality (4) to the instance of the problem obtained removing the nodes covered by solution Z we get: $\delta(A_Z \cup A_{Z'}, S_Z \cup S_{Z'}, A_Z, S_Z) + \delta_{l+1} \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^* \setminus A_Z, S^* \setminus S_Z)$.

Moreover, since we ordered the elements in (A^*, S^*) and in iteration j_{l+1} and most 2 elements are selected, then $\delta_{l+1} \leq \frac{2\sigma(A_Z, S_Z)}{M}$ and

$$\begin{aligned}
\sigma(A, S) &= \sigma(A_Z, S_Z) + \delta(A_Z \cup A_{Z'}, S_Z \cup S_{Z'}, A_Z, S_Z) \\
&\geq \sigma(A_Z, S_Z) + \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^* \setminus A_Z, S^* \setminus S_Z) - \delta_{l+1} \\
&\geq \sigma(A_Z, S_Z) + \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^* \setminus A_Z, S^* \setminus S_Z) - \frac{2\sigma(A_Z, S_Z)}{M} \\
&\geq \left(1 - \frac{2}{M}\right) \sigma(A_Z, S_Z) + \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^* \setminus A_Z, S^* \setminus S_Z)
\end{aligned}$$

But, $\sigma(A_Z, S_Z) + \sigma(A^* \setminus A_Z, S^* \setminus S_Z) \geq \sigma(A^*, S^*)$, and we get:

$$\sigma(A, S) \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^*, S^*) + \left(\frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}} - \frac{2}{M}\right) \sigma(A_Z, S_Z) \geq \left(1 - \frac{1}{e^{\frac{c_{\min}}{1+c_{\min}}}}\right) \sigma(A^*, S^*),$$

for $M \geq 2e^{\frac{c_{\min}}{1+c_{\min}}}$. Since $2e^{\frac{c_{\min}}{1+c_{\min}}} < 4$ for $c_{\min} \in [0, 1]$, the theorem follows. ◀

4 General case

In this section we introduce an approximation algorithm for the BIMA problem that guarantees a constant approximation ratio, i.e. it does not depend on the edge costs.

The algorithm is similar to Algorithm 1, that is it chooses the best between two candidate solutions: one solution is made of a single node a_M and a single edge (a_M, v_M) that maximizes $\sigma(\{a_M\}, \{(a_M, v_M)\})$, the other solution is found by means of a greedy algorithm that at each step maximizes the ratio between the marginal increment in the objective function of a candidate solution and its marginal cost. The main difference consists in the way in which the greedy algorithm computes a candidate solution. In fact, the algorithm presented here might select more than one edge at one time. In particular, at each iteration the greedy algorithm computes four candidate solutions starting from the current solution (A', S'). The first two solutions correspond to cases r_1 and r_2 of Algorithm 1, and differ from (A', S') by a single seed node or a single edge incident to a seed in A', respectively. To compute the two further candidate solutions, the algorithm divides the edges into two sets: those whose cost is at least b and those whose cost is smaller than b, for some given constant b, and proceeds as follows.

- Select a seed node a not in A' and an edge (a, v), which cost is $c_{(a,v)} \geq b$, incident to a that maximize $\frac{\delta(A' \cup \{a\}, S' \cup \{(a,v)\}, A', S')}{1+c_{(a,v)}}$;
- Select a seed node a not in A' and a set S of edges incident to a, whose overall cost is smaller than b (i.e. $\sum_{(a,v)\in S} c_{(a,v)} < b$), that maximize $\frac{\delta(A' \cup \{a\}, S' \cup S, A', S')}{1+\sum_{(a,v)\in S} c_{(a,v)}}$.

The greedy phase of the algorithm selects the candidate solution that gives the maximum ratio among the above four possibilities.

To compute the fourth candidate solution we need to solve an optimization problem, which we call RBIMA (where R stands for ratio). In the following, we assume that we can exploit an α-approximation algorithm for this sub-problem. At the end of this section we will introduce a suitable algorithm for RBIMA.

The analysis of the algorithm is similar to that in the previous section. In particular, the next lemma is the core of the analysis and corresponds to Lemma 2. We denote by j_i an iteration of the greedy algorithm in which an element is added to the solution, by j_{l+1} the first iteration in which an element of the optimum is not added to the solution and by $\bar{c}_i$ the marginal cost of the solution (A_i, S_i) computed at the iteration j_i.

▶ **Lemma 6.** *After each iteration j_i, $i = 1, 2, \ldots, l+1$,*

$$\sigma(A_i, S_i) - \sigma(A_{i-1}, S_{i-1}) \geq \frac{\bar{c}_i}{k} \frac{b\alpha}{b\alpha + b + \alpha + 2} (\sigma(A^*, S^*) - \sigma(A_{i-1}, S_{i-1})).$$

Proof. We denote by δ_i the expected number of nodes affected by (A_i, S_i) and not affected by (A_{i-1}, S_{i-1}), $\delta_i = \delta(A_i, S_i, A_{i-1}, S_{i-1})$. We divide the set $A^* \setminus A_{i-1}$ into two subsets: A_1^* is the subset that contains the seeds a with no incident edges in S^*, and $A_2^* = A^* \setminus (A_{i-1} \cup A_1^*)$. For each $a \in A_2^*$ let us consider the subset of S^* containing edges incident to a such that $c_e < b$. We partition this set into sets of edges whose overall cost is smaller than b in such a way that the number of sets in the partition is minimized. We denote this a partition by $\mathcal{S}_a$ and observe that the overall number of sets in $\mathcal{S}_a$, for all $a \in A_2^*$, is at most $2\frac{k}{b}$ as it is equivalent to the minimum number of bins of size b needed to pack a set of items of overall size k. By using similar arguments as in Lemma 2, we can show that

$$\sigma(A^*,S^*)-\sigma(A_{i-1},S_{i-1}) \leq \sum_{a\in A_1^*}\delta(A_{i-1}\cup\{a\},S_{i-1},A_{i-1},S_{i-1})$$
$$+\sum_{\substack{e=(a,v)\in S^*\setminus S_{i-1}\\ \text{s.t. } a\in A_{i-1}}}\delta(A_{i-1},S_{i-1}\cup\{e\},A_{i-1},S_{i-1})+ \tag{5}$$
$$\sum_{\substack{a\in A_2^*\\ e=(a,v)\in S^*\setminus S_{i-1}\\ c_e\geq b}}\delta(A_{i-1}\cup\{a\},S_{i-1}\cup\{e\},A_{i-1},S_{i-1})+\sum_{\substack{a\in A_2^*\\ S\in\mathcal{S}_a}}\delta(A_{i-1}\cup\{a\},S_{i-1}\cup S,A_{i-1},S_{i-1}).$$

Indeed, $\sigma(A^*,S^*)-\sigma(A_{i-1},S_{i-1}) \leq \sum_{X\in\chi(S_{i-1})}\mathbb{P}[X]\sum_{Y\in\chi(S^*\cup S_{i-1},X)}\mathbb{P}[Y|X](|R(A^*\cup A_{i-1},Y)|-|R(A_{i-1},X)|)$ and for each $X\in\chi(S_{i-1})$ and $Y\in\chi(S^*\cup S_{i-1},X)$,

$$\begin{aligned}|R(A^*\cup A_{i-1},Y)|-|R(A_{i-1},X)| \leq &\sum_{a\in A_1^*}(|R(A_{i-1}\cup\{a\},X)|-|R(A_{i-1},X)|)\\ &+\sum_{\substack{e=(a,v)\in Y\setminus X\\ \text{s.t. } a\in A_{i-1}}}(|R(A_{i-1},X\cup\{e\})|-|R(A_{i-1},X)|)\\ &+\sum_{\substack{a\in A_2^*\\ e=(a,v)\in Y\setminus X\\ c_e\geq b}}(|R(A_{i-1}\cup\{a\},X\cup\{e\})|-|R(A_{i-1},X)|)\\ &+\sum_{\substack{a\in A_2^*\\ S\in\mathcal{S}_a}}(|R(A_{i-1}\cup\{a\},X\cup(S\cap Y))|-|R(A_{i-1},X)|)\,.\end{aligned}$$

The following holds since the greedy phase of the algorithm selects a solution that maximizes the ratio between the marginal increment in the objective function and the cost:

- For each $a\in A_1^*$, $\delta(A_{i-1}\cup\{a\},S_{i-1},A_{i-1},S_{i-1})\leq\frac{\delta_i}{\bar{c}_i}$;
- For each $e=(a,v)\in S^*\setminus S_{i-1}$ such that $a\in A_{i-1}$, $\frac{\delta(A_{i-1},S_{i-1}\cup\{e\},A_{i-1},S_{i-1})}{c_e}\leq\frac{\delta_i}{\bar{c}_i}$;
- For each $a\in A_2^*$ and $e=(a,v)\in S^*\setminus S_{i-1}$ s.t. $c_e\geq b$, $\frac{\delta(A_{i-1}\cup\{a\},S_{i-1}\cup\{e\},A_{i-1},S_{i-1})}{1+c_e}\leq\frac{\delta_i}{\bar{c}_i}$;
- For each $a\in A_2^*$ and $S\in\mathcal{S}_a$, $\frac{\delta(A_{i-1}\cup\{a\},S_{i-1}\cup S,A_{i-1},S_{i-1})}{1+\sum_{e\in S}c_e}\leq\frac{\delta_i}{\bar{c}_i}\cdot\frac{1}{\alpha}$,

where the term $\frac{1}{\alpha}$ in the last inequality is due to the use of an α-approximation algorithm in the computation of the fourth candidate solution of the greedy phase. The number of edges incident to each $a\in A_2^*$ with cost at least b is at most $\frac{k}{b}$. Therefore, the right hand side of (5) is at most:

$$\sum_{a\in A_1^*}\frac{\delta_i}{\bar{c}_i}+\sum_{\substack{e=(a,v)\in S^*\setminus S_{i-1}\\ \text{s.t. } a\in A_{i-1}}}\frac{\delta_i}{\bar{c}_i}c_e+\sum_{\substack{a\in A_2^*\\ e=(a,v)\in S^*\setminus S_{i-1}\\ c_e\geq b}}\frac{\delta_i}{\bar{c}_i}(1+c_e)+\sum_{\substack{a\in A_2^*\\ S\in\mathcal{S}_a}}\frac{1}{\alpha}\frac{\delta_i}{\bar{c}_i}\left(1+\sum_{e\in S}c_e\right)$$
$$=\frac{\delta_i}{\bar{c}_i}\left(|A_1^*|+\sum_{\substack{e=(a,v)\in S^*\setminus S_{i-1}\\ \text{s.t. } a\in A_{i-1}}}c_e+\frac{k}{b}+\sum_{\substack{a\in A_2^*\\ e=(a,v)\in S^*\setminus S_{i-1}\\ c_e\geq b}}c_e+\frac{1}{\alpha}\frac{2k}{b}+\frac{1}{\alpha}\sum_{\substack{a\in A_2^*\\ S\in\mathcal{S}_a}}\sum_{e\in S}c_e\right)$$
$$\leq\left(1+\frac{1}{b}+\frac{2}{b\alpha}+\frac{1}{\alpha}\right)k\frac{\delta_i}{\bar{c}_i}=\left(\frac{b\alpha+\alpha+2+b}{b\alpha}\right)k\frac{\delta_i}{\bar{c}_i}.$$

To conclude, we observe that by Proposition 1 follows that $\delta_i=\sigma(A_i,S_i)-\sigma(A_{i-1},S_{i-1})$. ◀

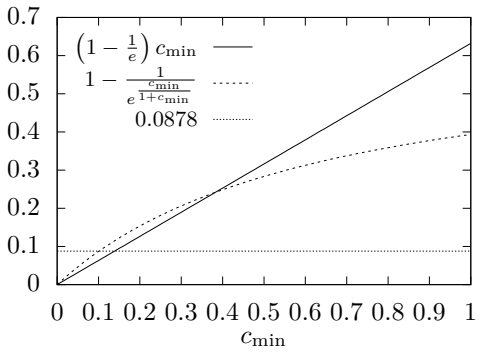

Figure 1 Approximation ratio of the three algorithm presented as a function of $c_{\min}$. Intersection points are at $c_{\min} \approx 0.1011$ and $c_{\min} \approx 0.3821$.

The statements of Lemmas 2 and 6 differ only for the coefficients $\frac{c_{\min}}{1+c_{\min}}$ and $\frac{b\alpha}{b\alpha+b+\alpha+2}$. Then, equipped with Lemma 6, we prove the next theorem, which corresponds to Theorem 4.

▶ **Theorem 7.** *The greedy algorithm achieves an approximation factor of* $1-\frac{1}{e^{\frac{b\alpha}{b\alpha+b+\alpha+2}}}$.

It remains to give an α-approximation algorithm for the RBIMA problem which consists in selecting a seed node a not in the current solution (A', S') and a set S of edges incident to a, which overall cost is smaller than b (i.e. $\sum_{(a,v)\in S} c_{(a,v)} < b$), that maximize $\frac{\delta(A'\cup\{a\}, S'\cup S, A', S')}{1+\sum_{(a,v)\in S} c_{(a,v)}}$. To this aim we define the CostIMA [8] problem as follows. Given a directed graph $G = (V, E, p, c)$, an integer $k \in \mathbb{N}$ and a seed set A, find a set of edges $S \subseteq A \times V \setminus E$ such that $c(S) \leq k$ and $\sigma(A, S)$ is maximized.

Let us consider the instances of the CostIMA problem where $A = \{a\}$ and let m^* be the maximum, over all $a \in V \setminus A'$, among the optima of these instances. It is easy to show that m^* is at least $b+1$ times the optimum of RCostIMA. It has been shown that the CostIMA problem can be approximated within a factor of $1-\frac{1}{e}$ by using a greedy algorithm [8]. Therefore we obtain an overall approximation of $\alpha = \left(1-\frac{1}{e}\right)\frac{1}{b+1}$. The next corollary follows by applying Theorem 7 with $\alpha = \left(1-\frac{1}{e}\right)\frac{1}{b+1}$ and optimizing over b.

▶ **Corollary 8.** *There exists an algorithm that achieves an approximation factor* > 0.0878 *for the* BIMA *problem.*

5 Conclusions

In Figure 1 we summarize our approximation ratios as a function of $c_{\min}$. As expected, when all the edge costs are high, it is not worth to buy them. Indeed the algorithm that selects only seeds outperforms the other algorithms and it reaches the optimal approximation of $1-\frac{1}{e}$ when all the costs are equal to 1. However, the challenge of our problem consists in finding a good approximation even when the cost function includes small values. In the general case and when the minimum edge cost can be very small ($c_{\min} < 0.1011$) the best algorithm is the constant factor algorithm given in Section 4, while when the minimum cost is in $(0.1011, 0.3821)$ the best algorithm is the one presented in Section 3.

The main open problem is the gap between the lower bound on approximation of $1-\frac{1}{e} \approx 0.6321$ and the constant approximation of 0.0878. To close this gap, we aim at improving the algorithm in Section 4 by devising a better approximation algorithm for

RCostIMA problem, which directly implies a better approximation for the BIMA problem. Other research directions that deserve further investigation include the study of the BIMA problem on different information diffusion models such as LTM or the Triggering Model [15]. Moreover, we plan to design efficient heuristics in order to assess the performance of our greedy algorithm from the experimental point of view.

Abstract

Graphs of treewidth at most two are the ones excluding the clique with four vertices as a minor. Equivalently, they are the graphs whose biconnected components are series-parallel.

We turn those graphs into a free algebra, answering positively a question by Courcelle and Engelfriet, in the case of treewidth two. First we propose a syntax for denoting them: in addition to series and parallel compositions, it suffices to consider the neutral elements of those operations and a unary transpose operation. Then we give a finite equational presentation and we prove it complete: two terms from the syntax are congruent if and only if they denote the same graph.

1 Introduction

The notion of treewidth is a cornerstone in (algorithmic) graph theory [16]. It measures how close a graph is to a forest, and classes of graphs of bounded treewidth often enjoy good computational properties. For instance, graph homomorphism (and thus k-colouring) becomes polynomial-time [19, 7, 21], so does model-checking of Monadic Second Order (MSO) formulae, and satisfiability of MSO formulae becomes decidable, even linear [9]. (See the monograph of Courcelle and Engelfriet about monadic second order logic on graphs [13].)

Here we focus on graphs of treewidth at most two. They coincide with the *partial* 2*-trees*, with the K_4*-free* graphs (those that exclude the clique with four vertices (K_4) as a *minor*), and with the graphs whose biconnected components are *series-parallel* [18, 5].

We consider the set Gph of directed graphs with edges labelled with letters $a, b, \ldots$ in some alphabet Σ, and with two distinguished vertices, called the *input* and the *output*. We represent such graphs as usual, using an unlabelled ingoing (resp. outgoing) arrow to denote the input (resp. output). Such graphs can be composed:

- in *parallel* by putting them side by side, merging their inputs, and merging their outputs;
- in *series* by putting them one after the other and merging the output of the first one with the input of the second one.

Every letter of the alphabet gives rise to a graph consisting of two vertices (the input and the output), and a single edge from the input to the output, labelled with that letter.

If we allow only those operations, we obtain the series-parallel graphs, and it is easy to see that these form the free algebra over the signature $\langle \parallel, \cdot \rangle$, where $\parallel$ is an associative-commutative binary operation (parallel composition), and $\cdot$ is an associative binary operation

* An extended version of this abstract, including proofs, is available on HAL [8]. This work was supported by the European Research Council (ERC) under the Horizon 2020 programme (CoVeCe, grant agreement No 678157) and the LABEX MILYON (ANR-10-LABX-0070) of Université de Lyon, within the program "Investissements d'Avenir" (ANR-11-IDEX-0007)

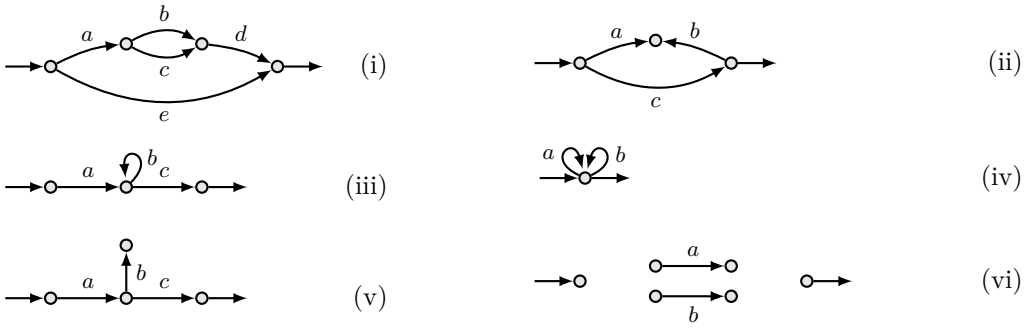

Figure 1 Some graphs of treewidth at most two

(series composition). For instance, the terms $((a{\cdot}(b \parallel c)){\cdot}d) \parallel e$ and $e \parallel (a{\cdot}((c \parallel b){\cdot}d))$ both denote the graph (i) in Figure 1; they are equal up to associativity of $\cdot$ and commutativity of $\parallel$. Parallel composition is not idempotent: $(a{\cdot}b) \parallel (a{\cdot}b)$ and $a{\cdot}b$ denote distinct graphs.

However, we cannot denote all graphs of treewidth at most two in such a way.

First the notion of treewidth does not depend on the orientation of the edges. For instance, the graph (ii) has treewidth two, yet it is not the image of a term in the previous syntax. To this end, we add a unary operation $\cdot^\circ$ to our signature, which we interpret in graphs as the exchange of input and output. Doing so, the terms $(a{\cdot}b^\circ) \parallel c$ and $(b{\cdot}a^\circ)^\circ \parallel c$ denote the graph (ii), and series-parallel graphs with converse become a free algebra when we ask that $\cdot^\circ$ is an involution that distributes over $\parallel$ and satisfies $(a{\cdot}b)^\circ = b^\circ{\cdot}a^\circ$.

Second, the treewidth of a graph does not depend on self-loops, so that the graph (iii) actually has treewidth one (it is a tree once we remove the self-loop). There it suffices to add a constant, 1, interpreted as the graph with a single vertex (both input and output), and no edge. Doing so, the graph (iii) is denoted by $a{\cdot}(1 \parallel b){\cdot}c$. While the constant 1 is clearly a neutral element for series composition $(\cdot)$, axiomatising its interactions with parallel composition is much harder, and is actually one of the key contributions of the present work. For instance, the equation $(1 \parallel a){\cdot}(1 \parallel b) = 1 \parallel a \parallel b$ belongs to the theory as both sides denote the graph (iv).

Up-to this point, we have recovered the syntax of *allegories* [20], and the graphs associated to the terms are precisely the ones Freyd and Scedrov use to obtain that the theory of representable allegories is decidable, yet not finitely presentable [20, p. 210].

But we still miss some graphs, like (v). One can also remark that we only obtain connected graphs using the above operations. Instead, treewidth allows disconnected graphs: a graph has a given treedwidth if and only if all of its connected components do. Surprisingly, it suffices to add a second constant, $\top$, interpreted as the disconnected graph with no edges and two distinct vertices (the input and the output). This allows us to obtain disconnected graphs, but also to get a term for the connected graph (v), namely, $a{\cdot}((b{\cdot}\top) \parallel c)$. Again while it is clear that this constant is a neutral element for parallel composition ($\parallel$), capturing its interactions with the other operations is non-trivial. For instance, $\top{\cdot}a{\cdot}\top{\cdot}b{\cdot}\top$ and $\top{\cdot}b{\cdot}\top{\cdot}a{\cdot}\top$ both denote the graph (vi), and should thus be equated.

To sum up, the set Gph of graphs forms an algebra for the signature $\langle \cdot_2, \parallel_2, \cdot^\circ_1, 1_0, \top_0 \rangle$; the various operations of this algebra are depicted in Figure 2.

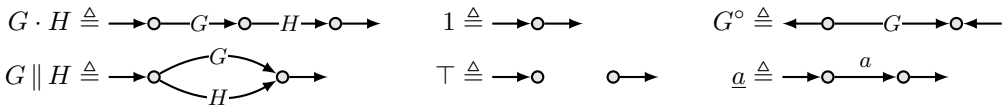

Figure 2 The 2p-algebra of graphs and the graph of a letter

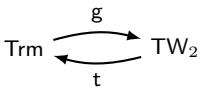
Write Trm for the set of terms over the alphabet Σ and TW_2 for the set of graphs of treewidth at most two when an extra edge is added between input and output[1]. One easily proves that the latter set actually forms a subalgebra of the algebra of graphs. Therefore, the function interpreting each term as a graph actually gives a function $\mathsf{g} : \mathsf{Trm} \to \mathsf{TW}_2$.

We first prove that this function has a right-inverse: we define a function $\mathsf{t} : \mathsf{TW}_2 \to \mathsf{Trm}$ such that for all graph $G \in \mathsf{TW}_2$, $\mathsf{g}(\mathsf{t}(G))$ is isomorphic to G:



$$\mathsf{g}(\mathsf{t}(G)) \simeq G \tag{1}$$

By doing so, we get that the graphs of treewidth at most two are exactly the ones that can be expressed using the syntax.

Our key contribution then consists in giving a finite equational axiomatisation of graph isomorphism over this syntax. This answers positively the question asked by Courcelle and Engelfriet in their book, for treewidth two [13, p. 118].

Note that the choice of the syntax is important. Various finite syntaxes have already been proposed [15, 16, 13] to capture graphs of treewidth at most k, for a given k. However, some choices prevent finite presentations. For instance, while the *converse* operation we use could be eliminated by pushing it to the leaves, doing so would turn some of our axioms into infinite equational schemes. (See also Remark 27.)

As explained above, a few laws are rather natural like associativity of the two compositions, commutativity of $\parallel$, or the facts that 1 and $\top$ are neutral elements and that $\cdot^\circ$ is an involution. Those are the first eight laws in Figure 3. Surprisingly, the four subsequent axioms suffice to obtain a complete axiomatisation: for all terms u, v, u and v are provably equal using the axioms from Figure 3 if and only if $\mathsf{g}(u)$ and $\mathsf{g}(v)$ are isomorphic:

$$u \equiv v \quad \Leftrightarrow \quad \mathsf{g}(u) \simeq \mathsf{g}(v) \tag{2}$$

In other words, calling a *2p-algebra* an algebra satisfying the axioms from Figure 3, TW_2 is the free 2p-algebra.

All axioms but (A3) are independent; (A3) follows from (A9) and (A12). Correctness, i.e., the left-to-right implication in (2), is easy to establish. Indeed, it suffices to compute and compare the graphs of each equation, and to prove that valid equations are stable under graph substitution. The converse implication, completeness, is much harder. This is because there is no canonical way of extracting a term out of a graph. In particular, the function t we define to this end has to make choices based on the concrete representation of the input graph, so that isomorphic graphs do not always map to syntactically equal terms.

[1] This additional condition is natural when considering pointed graphs [11]; this is not a restriction for unpointed graphs as one can always set input and output to the same arbitrary node.

$$u \parallel (v \parallel w) \equiv (u \parallel v) \parallel w \quad \text{(A1)} \qquad u{\cdot}(v{\cdot}w) \equiv (u{\cdot}v){\cdot}w \quad \text{(A4)}$$

$$u \parallel v \equiv v \parallel u \quad \text{(A2)} \qquad u{\cdot}1 \equiv u \quad \text{(A5)}$$

$$u \parallel \top \equiv u \quad \text{(A3)}$$

$$1 \parallel 1 \equiv 1 \quad \text{(A9)}$$

$$u^{\circ\circ} \equiv u \quad \text{(A6)} \qquad 1 \parallel u{\cdot}v \equiv 1 \parallel (u \parallel v^{\circ}){\cdot}\top \quad \text{(A10)}$$

$$(u \parallel v)^{\circ} \equiv u^{\circ} \parallel v^{\circ} \quad \text{(A7)} \qquad u{\cdot}\top \equiv (1 \parallel u{\cdot}\top){\cdot}\top \quad \text{(A11)}$$

$$(u{\cdot}v)^{\circ} \equiv v^{\circ}{\cdot}u^{\circ} \quad \text{(A8)} \qquad (1 \parallel u){\cdot}v \equiv (1 \parallel u){\cdot}\top \parallel v \quad \text{(A12)}$$

Figure 3 Twelve axioms for 2p-algebras, all independent except for (A3)

We proceed in the following way to obtain completeness. First we prove that the function t maps isomorphic graphs to congruent terms:

$$G \simeq H \qquad \Rightarrow \qquad \mathsf{t}(G) \equiv \mathsf{t}(H) \tag{3}$$

Then we prove that this function is a homomorphism (up to the axioms), which allows us to deduce that for all terms u, $\mathsf{t}(\mathsf{g}(u))$ is provably equal to u:

$$\mathsf{t}(\mathsf{g}(u)) \equiv u \tag{4}$$

In a sense, by interpreting a term u into a graph and then reading it back, we obtain a term $\mathsf{t}(\mathsf{g}(u))$ which plays the role of a normal form even if it is not canonical (which would typically be the case in rewriting theory, or in normalisation by evaluation [4]).

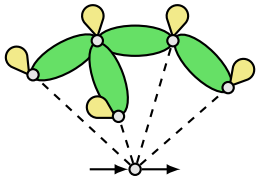
Defining a function t satisfying (1) could be done rather easily by relying on the notion of tree decomposition. However, doing so makes it extremely difficult to obtain properties (3) and (4): the notion of tree decomposition, despite its inductive nature, does not provide enough structure. Instead, we use the fact that treewidth at most two graphs are K_4-free, and we exhibit stronger graph invariants that allow us to extract terms from graphs in a much more structured way.

For instance, when the graph is connected and when its input and output are distinct, one can compute its *checkpoints*: those vertices which all paths from the input to the output must visit. Those checkpoints are linearly ordered so that the graph has the following shape

(5)

If there is at least one checkpoint then the graph should be interpreted as a series composition. Otherwise, by the absence of K_4 as a minor, one can show that the graph necessarily is a non-trivial parallel composition.

The aforementioned step is already there in the standard result that the biconnected components of a K_4-free graph are series-parallel. More challenging is the case when the input and output coincide. In this case, we consider the checkpoints of all pairs of neighbours of the input, and we show that they form a tree which is a minor of the starting graph.



This tree is a key invariant of the isomorphism class of the graph and we show that one can extract a term for each choice of a node in this tree. This is where our function $\mathtt{t}$ has to rely on the concrete representation of the graph: although all choices of a node in the tree result in provably equal terms, they do not yield syntactically equal terms. A similar situation happens with components which are disconnected from the input and the output: we handle those recursively by taking any vertex as a new choice of input and output.

2 Related work

Except for the presence of $\top$, the algebra of graphs we work with has been proposed independently by Freyd and Scedrov [20, p. 207], and by Andréka and Bredikhin [1]. They used it to characterise the equational theory of binary relations over the considered signature. Indeed the set of binary relations over a fixed set forms an algebra for the signature we consider in this paper: $\cdot$ is relational composition, $\parallel$ is set-theoretic intersection (thus it is written $\cap$ in [20, 1]), $\cdot^\circ$ is transposition, 1 is the identity relation and $\top$ is the full relation. Writing $\mathrm{Rel} \vDash u \leq v$ for the containments that hold in all such algebras of relations, and $G \blacktriangleleft H$ if there exists a graph homomorphism from H to G, we have the following equivalence.

$$\mathrm{Rel} \vDash u \leq v \qquad \Leftrightarrow \qquad \mathsf{g}(u) \blacktriangleleft \mathsf{g}(v)$$

This characterisation immediately gives decidability: existence of a graph homomorphism is an NP-complete problem. Thanks to the present observation that graphs of terms have bounded treewidth, the complexity is actually polynomial [21].

Freyd and Scedrov also use this characterisation to prove that this theory is not finitely presentable [20]: every complete equational axiomatisation must contain axioms corresponding to homomorphisms equating arbitrarily many vertices at a time, and thus must be infinite. Andréka and Bredikhin go even further and show that it is not even a variety [1].

In this work we focus on isomorphism rather than on homomorphism, and this is why we do obtain a finite equational axiomatisation. Although all algebras of relations validate our axioms, these algebras cannot be free models. For instance, their parallel composition (intersection) is always idempotent. Freyd and Scedrov remark that certain graphs cannot be the image of a term [20, p. 207], and Andréka and Bredikhin use a weak form of the K_4 exclusion property [1, Lemma 7]. They cannot obtain a characterisation result since they do not consider $\top$, which is necessary to reach all graphs of treewidth at most two.

Our work is also really close to that of Dougherty and Gutiérrez [17], who proposed an axiomatisation of graph isomorphism for a slightly different syntax: instead of the constant $\top$, they use a unary operation $\mathrm{dom}(\cdot)$, called *domain*. This operation can be defined in our setting: we have $\mathrm{dom}(u) = 1 \parallel (u \cdot \top)$; at the graphical level, it consists in relocating the output of a graph on its input. In contrast, $\top$ cannot be defined in terms of $\mathrm{dom}(\cdot)$ and the other operations. Choosing this domain operation has the advantage of keeping connected graphs, and the disadvantage of being less general: disconnected graphs cannot be expressed. More importantly, the operation $\top$ being more primitive than $\mathrm{dom}(\cdot)$, we can obtain a shorter axiomatisation: while we share with [17] the nine natural axioms from Figure 3 that do not mention $\top$, the four remaining ones in this figure have to be replaced by nine axioms when using $\mathrm{dom}(\cdot)$: three about 1 and $\parallel$, and six about $\mathrm{dom}(\cdot)$. To prove completeness, Dougherty and Gutiérrez compute normal forms for terms using rewriting techniques. Like in the present work, their normal forms are not canonical and some additional work is needed. In a second part of the paper, they characterise graphs of terms using a minor exclusion theorem which corresponds precisely to what we obtain in

the connected case (see Remark 27). There are however several typos or gaps in their paper which we were not able to fix—see [8] for more details.

Bauderon and Courcelle gave a syntax and a complete axiomatisation for arbitrary graphs [3]. While the overall statement is similar to ours, their syntax can hardly be related to the present one (it is infinitary, for instance), and the present results are not corollaries of their work. The structural invariants we exhibit here are reminiscent of the general decomposition results of Tutte [27], which Courcelle later studied in the context of MSO [12].

3 2p-algebra

We consider the signature $\langle \cdot_2, \parallel_2, \cdot^\circ_1, 1_0, \top_0 \rangle$ and we let u, v, w range over *terms* over a set Σ of variables. We usually omit the $\cdot$ symbol and we assign priorities so that the term $(a \cdot (b^\circ)) \parallel c$ can be written just as $ab^\circ \parallel c$. A *2p-algebra* is an algebra over this signature satisfying the axioms from Figure 3. We write $u \equiv v$ when two terms u and v are congruent modulo those axioms, or equivalently, when the equation holds in all 2p-algebras.

Following notations from Kleene algebra with tests (KAT) [22], we let α, β range over *tests*, those terms that are congruent to some term of the shape $1 \parallel u$. (By axiom A9, u is a test iff $u \equiv 1 \parallel u$.) Graphs of tests are those whose input and output coincide.

We shall use the derived operation mentioned in Section 2, *domain*, as well as its dual, *codomain*: $\mathrm{dom}(u) \triangleq 1 \parallel u\top$ and $\mathrm{cod}(u) \triangleq 1 \parallel \top u$. Those are tests by definition.

As is standard for involutive monoids, the first eight axioms from Figure 3 entail $1^\circ \equiv 1$, $\top^\circ \equiv \top$, and $1u \equiv u$. We use such laws freely in the sequel. We recall the four remaining axioms below, using the above notations.

$$1 \parallel 1 \equiv 1 \qquad \text{(A9)} \qquad\qquad u\top \equiv \mathrm{dom}(u)\top \qquad \text{(A11)}$$

$$1 \parallel uv \equiv \mathrm{dom}(u \parallel v^\circ) \qquad \text{(A10)} \qquad\qquad \alpha v \equiv \alpha\top \parallel v \qquad \text{(A12)}$$

Thanks to converse being an involution, there is a notion of duality in 2p-algebras: one obtains a valid law when swapping the arguments of all products and exchanging domains with codomains in a valid law. (We have $\mathrm{cod}(u) \equiv \mathrm{dom}(u^\circ)$.)

▶ **Proposition 1.** *The following equations hold in all 2p-algebras.*

$$\alpha^\circ \equiv \alpha \qquad (6)$$

$$\alpha\beta \equiv \alpha \parallel \beta \qquad (7)$$

$$\alpha(v \parallel w) \equiv \alpha v \parallel w \qquad (8)$$

$$(v \parallel w)\alpha \equiv v\alpha \parallel w \qquad (9)$$

$$\mathrm{dom}(uv \parallel w) \equiv \mathrm{dom}(u \parallel wv^\circ) \qquad (10)$$

$$\top u^\circ \top \equiv \top u \top \qquad (11)$$

$$u\top w \equiv u\top \parallel \top w \qquad (12)$$

$$u\top v\top w \equiv u\top w \parallel \top v\top \qquad (13)$$

$$(u \parallel \top v\top)w \equiv uw \parallel \top v\top \qquad (14)$$

4 Graphs

As explained in the introduction, we consider labelled directed graphs with two designated vertices. We just call them graphs in the sequel. Note that we allow multiple edges between two vertices, as well as self-loops.

▶ **Definition 2.** A *graph* is a tuple $G = \langle V, E, s, t, l, \iota, o \rangle$, where V is a finite set of *vertices*, E is a finite set of *edges*, $s, t : E \to V$ are maps indicating the *source* and *target* of each edge, $l : E \to \Sigma$ is map indicating the *label* of each edge, and $\iota, o \in V$ are the designated vertices, respectively called *input* and *output*.

We write $G[x;y]$ for the graph G with input set to x and output set to y; we abbreviate $G[x;x]$ to $G[x]$.

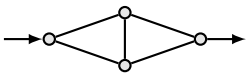
▶ **Definition 3.** An *homomorphism* from $G = \langle V, E, s, t, l, \iota, o\rangle$ to $G' = \langle V', E', s', t', l', \iota', o'\rangle$ is a pair $h = \langle f, g\rangle$ of functions $f : V \to V'$ and $g : E \to E'$ that respect the various components: $s' \circ g = f \circ s$, $t' \circ g = f \circ t$, $l' = g \circ l$, $\iota' = f(\iota)$, and $o' = f(o)$.

A *(graph) isomorphism* is a homomorphism whose two components are bijective functions. We write $G \simeq G'$ when there exists an isomorphism between graphs G and G'.

▶ **Proposition 4.** *Graphs up to isomorphism form a 2p-algebra.*

▶ **Definition 5.** Let $G = \langle V, E, s, t, l, \iota, o\rangle$ be a graph. A *tree decomposition* of G is a tree T where each node t is labelled with a set $V_t \subseteq V$ of vertices, such that:
(T1) for every vertex $x \in V$, the set of nodes t such that $x \in V_t$ forms a sub-tree of T;
(T2) for every edge $e \in E$, there exists a node t such that $\{s(e), t(e)\} \subseteq V_t$;
(T3) there exists a node t such that $\{\iota, o\} \subseteq V_t$.
The *width* of a tree decomposition is the size of the largest set V_t minus one; the *treewidth* of a graph is the minimal width of a tree decomposition for this graph. We write TW_2 for the set of graphs of treewidth at most two.

The first two conditions in the definition of tree decomposition are standard; the third one is related to the presence of distinguished nodes: it requires them to lie together in some node of the tree. This condition ensures that the following graph is excluded from TW_2 whatever the orientation and labelling of its edges.



(M_3)

Indeed, such a graph cannot be represented in the syntax we consider. (Something already observed by Freyd and Scedrov [20]—the addition of $\top$ to the syntax does not help.)

▶ **Proposition 6.** *Graphs of treewidth at most two form a subalgebra of the algebra of graphs.*

The graphs we associate to each letter (Figure 2) also belong to this subalgebra, so that we obtain a homomorphism $\mathsf{g} : \mathsf{Trm} \to \mathsf{TW}_2$ associating a graph of treewidth at most two to each syntactic term. When taking quotients under term congruence and graph isomorphism, this function becomes a 2p-algebra homomorphism $\mathsf{g}' : \mathsf{Trm}_{/\equiv} \to \mathsf{TW}_{2/\simeq}$. Our key result is that g' actually is an isomorphism of 2p-algebras (Corollary 33).

5 K_4-freeness

In this section we establish preliminary technical results about unlabelled undirected graphs with at most one edge between two vertices and without self-loops; we call those *simple graphs*. We use standard notation and terminology from graph theory [16]. In particular, we denote by xy a potential edge between two vertices x and y; an xy-path is a (possibly trivial) path whose ends are x and y; $G + xy$ is the simple graph obtained from G by adding the edge xy if x and y were not already adjacent; $G \backslash x$ is the simple graph obtained from G by removing the vertex x and its incident edges.

▶ **Definition 7.** A *minor* of a simple graph G is a simple graph obtained by performing a sequence of the following operations on G: delete an edge or a vertex, contract an edge.

A cornerstone result of graph theory, Robertson and Seymour's graph minor theorem [26], states that (simple) graphs are well-quasi-ordered by the minor relation. As a consequence, the classes of graphs of bounded treewidth, which are closed under taking minors, can be characterised by finite sets of excluded minors. Two simple and standard instances are the following ones: the graphs of treewidth at most one (the forests) are precisely those excluding the cycle with three vertices (C_3); those of treewidth at most two are those excluding the complete graph with four vertices (K_4) [18]. We eventually reprove the latter one here.

 (C_3)  (K_4)

We fix a connected simple graph G in the remainder of this section.

▶ **Definition 8.** The *checkpoints* between two vertices x, y are the vertices which any xy-path must visit: $\mathsf{CP}(x, y) \triangleq \{z \mid \text{every } xy\text{-path crosses } z\}$.

For all vertices x, y, we have $\mathsf{CP}(x, x) = \{x\}$ and $\{x, y\} \subseteq \mathsf{CP}(x, y) = \mathsf{CP}(y, x)$. Two vertices x, y are *linked*, written $x \Diamond y$, when $x \neq y$ and $\mathsf{CP}(x, y) = \{x, y\}$, i.e., when there are no proper checkpoints between x and y. The *link graph* of G is the graph of linked vertices. Note that G is a subgraph of its link graph: if xy is an edge in G then $x \Diamond y$. We also have the following properties.

▶ **Lemma 9.** *Any cycle in the link graph is actually a clique.*

▶ **Lemma 10.** *If xyz is a triangle in the link graph and ι is a vertex not in G, then the graph $G + \iota x + \iota y + \iota z$ admits K_4 as a minor.*

Now fix a set U of vertices; we extend the notion of checkpoints as follows.

▶ **Definition 11.** The *checkpoints* of U, $\mathsf{CP}(U)$, is the set of vertices which are checkpoints of some pair in U: $\mathsf{CP}(U) \triangleq \bigcup_{x,y \in U} \mathsf{CP}(x, y)$. The *checkpoint graph* of U is the subgraph of the link graph induced by this set. We also denote this graph by $\mathsf{CP}(U)$.

▶ **Lemma 12.** CP *is a closure operator on the set of vertices. In particular, for all checkpoints $x, y \in \mathsf{CP}(U)$, $\mathsf{CP}(x, y) \subseteq \mathsf{CP}(U)$.*

▶ **Lemma 13.** *For every path in G between two checkpoints $x, y \in \mathsf{CP}(U)$, the sequence obtained by keeping only the elements in $\mathsf{CP}(U)$ is an xy-path in $\mathsf{CP}(U)$.*

Since G is assumed to be connected, it follows that so is $\mathsf{CP}(U)$. A key instance of a checkpoint graph is when U only contains two vertices, presumably the input and output of some graph: the checkpoint graph is a line in this case, as in (5), and it allows us to decompose the considered graph into a sequence of series compositions.

▶ **Lemma 14.** *If $U = \{x, y\}$, then $\mathsf{CP}(U)$ is a line graph whose ends are x and y.*

The following two lemmas are helpful in Proposition 20 below, to prove that the checkpoint graph is a tree under certain circumstances.

▶ **Lemma 15.** *If xy is an edge in $\mathsf{CP}(U)$, then there exists $x', y' \in U$ such that x and y belong to $\mathsf{CP}(x', y')$.*

▶ **Lemma 16.** *If xyz is a triangle in $\mathsf{CP}(U)$, then there exists $x', y', z' \in U$ such that x and y (resp. x and z, y and z) belong to $\mathsf{CP}(x', y')$ (resp. $\mathsf{CP}(x', z')$, $\mathsf{CP}(y', z')$).*

As explained above we use the checkpoint graphs to decompose graphs. The following notions of intervals and bags are the basic blocks of those decompositions.

▶ **Definition 17.** Let x, y be two vertices. The *strict interval* $]\!]x;y[\!]$ is the following set of vertices.

$$]\!]x;y[\!] \triangleq \{p \mid \text{there is an } xp\text{-path avoiding } y \text{ and a } py\text{-path avoiding } x\}$$

The *interval* $[\![x;y]\!]$ is obtained by adding x and y to that set. We abuse notation and write $[\![x;y]\!]$ for the subgraph of G induced by the set $[\![x;y]\!]$.

Note that while the intervals do not depend on the set U, we mostly use them under the assumption that xy is an edge in a checkpoint graph.

▶ **Definition 18.** The *bag* of a checkpoint $x \in \mathsf{CP}(U)$ is the set of vertices that need to cross x in order to reach the other checkpoints.

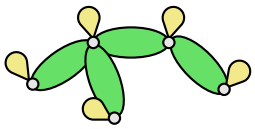
$$[\![x]\!]_U \triangleq \{p \mid \forall y \in \mathsf{CP}(U),\ \text{any } py\text{-path crosses } x\}\,.$$

As before, we also write $[\![x]\!]_U$ for the induced subgraph of G.

Note that $[\![x]\!]_U$ depends on U and differs from $[\![x;x]\!]$ (which is always the singleton $\{x\}$).

▶ **Proposition 19.** *If $\mathsf{CP}(U)$ is a tree, then the following set $\mathcal{V}$ is a partition of the vertices of G such that any edge of G appears in exactly one graph of the set $\mathcal{E}$.*

$$\mathcal{V} \triangleq \{[\![x]\!]_U \mid x \in \mathsf{CP}(U)\} \cup \{]\!]x;y[\!] \mid xy \text{ edge in } \mathsf{CP}(U)\}$$
$$\mathcal{E} \triangleq \{[\![x]\!]_U \mid x \in \mathsf{CP}(U)\} \cup \{[\![x;y]\!] \mid xy \text{ edge in } \mathsf{CP}(U)\}$$



Graphically, this means G can be decomposed as in the picture above; only the vertices of $\mathsf{CP}(U)$ are depicted, the green blocks correspond to edges in $\mathsf{CP}(U)$, the yellow blocks correspond to the graphs $[\![x]\!]_U$. The leaves of $\mathsf{CP}(U)$ are elements of U (but not always conversely). As a consequence, when $\mathsf{CP}(U)$ is a tree, it is a minor of G: contract all subgraphs of the form $[\![x]\!]_U$ into vertex x and all subgraphs of the form $[\![x;y]\!]$ into edge xy.

The following proposition is a key element in the developments to come. It makes it possible to extract a term out of a graph whose input and output coincide, by providing ways to chose an element where to relocate the output and resort to the easier case when input and output differ. (Note that G is still assumed to be connected.)

▶ **Proposition 20.** *Assume $G = H\backslash\iota$, for some K_4-free simple graph H and some vertex ι. Further assume that U is the set of neighbours of ι in H and that this set is not empty.*

(i) *$\mathsf{CP}(U)$ is a tree,*
(ii) *for every edge xy in $\mathsf{CP}(U)$, the graph $[\![x;y]\!] + xy$ is K_4-free,*
(iii) *for every vertex x in $\mathsf{CP}(U)$, the graph $H + \iota x$ is K_4-free.*

As a consequence of the above proposition, we have the following one, which makes it possible to decompose graphs with distinct input and output into a parallel composition when they cannot be a series composition.

▶ **Proposition 21.** *Let ι, o be two distinct vertices such that $G + \iota o$ is K_4-free. We have that:*

(i) *if ι and o are not adjacent in G and $\iota \Diamond o$, then the graph induced by $[\![\iota; o]\!]$ has at least two connected components.*

(ii) *for every edge xy in $\mathsf{CP}(\{\iota, o\})$, the graph $[\![x; y]\!] + xy$ is K_4-free,*

6 Extracting terms

Now we have enough preliminary material and we can look for a right inverse to the function $\mathsf{g} : \mathsf{Trm} \to \mathsf{TW}_2$. As explained in the Introduction, we use K_4-freeness to extract terms from graphs in a more structured way than using tree decompositions directly.

▶ **Definition 22.** The *skeleton* of a graph G is the simple graph S obtained from G by forgetting input, output, labelling, edge directions, edge multiplicities, and self-loops. The *strong skeleton* of G is $S + \iota o$ if $\iota \neq o$, and S otherwise.

As an example, the strong skeleton of any instance of the graph (M_3) from Section 4 is K_4. More generally, a graph belongs to TW_2 if and only if its strong skeleton has treewidth at most two in the standard sense.

▶ **Proposition 23.** *The strong skeleton of every graph in TW_2 is K_4-free.*

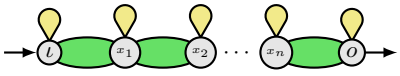
Given a graph G and two vertices x, y, we write $G[\![x; y]\!]$ for the subgraph of G induced by the set $[\![x; y]\!]$ (computed in the skeleton of G), with input and output respectively set to x and y, and with self-loops on x and y removed. The strong skeleton of $G[\![x; y]\!]$ is $[\![x; y]\!] + xy$.

Similarly, given a graph G, a set U of vertices and vertex x, we write $G[\![x]\!]_U$ for the subgraph of G induced by the set $[\![x]\!]_U$ (computed in the skeleton of G), with both input and output set to x. Doing so, the skeleton and strong skeleton of $G[\![x]\!]_U$ are both $[\![x]\!]_U$. We shall omit the subscript when it is clear from the context.

▶ **Definition 24.** The term $\mathsf{t}(G)$ of a graph G whose strong skeleton is K_4-free is defined by induction on the number of edges in G[2]. When G is connected there are two main cases depending on whether the input and output coincide *(a)* or not *(b)*. We deal with the general case *(c)* by decomposing the graph into connected components.

(a) Connected, distinct input and output

Consider the line graph (Lemma 14) obtained by taking the checkpoint graph of $U = \{\iota, o\}$ in the skeleton of G. Write it as $x_0 \dots x_{n+1}$ with $\iota = x_0$ and $o = x_{n+1}$. According to Proposition 19, G looks as follows.



We set $\mathsf{t}(G) \triangleq \mathsf{t}(G[\![x_0]\!]) \cdot \mathsf{t}(G[\![x_0; x_1]\!]) \cdot \mathsf{t}(G[\![x_1]\!]) \cdot \ldots \cdot \mathsf{t}(G[\![x_n]\!]) \cdot \mathsf{t}(G[\![x_n; x_{n+1}]\!]) \cdot \mathsf{t}(G[\![x_{n+1}]\!])$

The (strong) skeleton of each graph $G[\![x_i]\!]$ is just $[\![x_i]\!]$, which is necessarily K_4-free, as a subgraph of that of G. Proposition 21(2) moreover ensures that so are the strong skeletons of all graphs $G[\![x_i; x_{i+1}]\!]$. The above recursive calls occur on smaller graphs unless $n = 0$ and the graphs $G[\![\iota]\!]$ and $G[\![o]\!]$ are reduced to the trivial graph with one vertex and no edge (i.e., the graph 1). In such a situation,

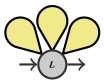
[2] More precisely, on the lexicographic product of the number of edges and the textual precedence of the three considered cases.

- either ι and o are adjacent in G. Then let G' be the graph obtained by removing from G all edges between ι and o and let $u = a_1 \parallel \ldots \parallel a_i \parallel b_1^\circ \parallel \ldots b_j^\circ$ be a term corresponding to those edges. Accordingly, we set $\mathsf{t}(G) \triangleq \mathsf{t}(G') \parallel u$.
- Or they are not, and Proposition 21(2) applies so that we can decompose G into parallel components: $G = G_1 \parallel \ldots \parallel G_m$ with $m \geq 2$. We set $\mathsf{t}(G) \triangleq \mathsf{t}(G_1) \parallel \ldots \parallel \mathsf{t}(G_m)$.

(b) Connected, input equals output

If there are self-loops on ι, let $u = a_1 \parallel \ldots \parallel a_n$ be a term corresponding to those edges, let G' be the graph obtained by removing them, and recursively set $\mathsf{t}(G) \triangleq \mathsf{t}(G') \parallel u$.

Otherwise let H be the skeleton of G. Decompose $H\backslash\iota$ into connected components $H_1\backslash\iota, \ldots, H_m\backslash\iota$ such that $H \simeq H_1 \cup \cdots \cup H_m$. The graph looks as follows.



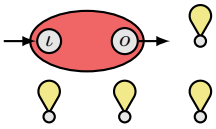
If $m = 0$, then set $\mathsf{t}(G) = 1$. If $m > 1$, set $\mathsf{t}(G) \triangleq \|_{i \leq m} \mathsf{t}(G_i)$, where G_i is the subgraph of G induced by H_i. It remains to cover the case where $m = 1$. Let U be the set of neighbours of the input and compute the checkpoint graph $\mathsf{CP}(U)$ in $H\backslash\iota$. Pick an arbitrary node $x \in \mathsf{CP}(U)$. By Proposition 20(3), the strong skeleton of $G[\iota; x]$ is K_4-free. Set $\mathsf{t}(G) \triangleq \mathrm{dom}(\mathsf{t}(G[\iota; x]))$. (Remember that $\mathrm{dom}(\cdot)$ relocates the output to the input.)

(c) General case

Decompose the graph G into connected components $G_1, \ldots, G_n$. For all $i \leq n$, pick an arbitrary vertex x_i in the component G_i. There are two cases:

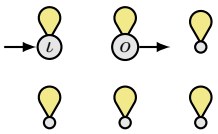
- either input and output belong to the same component, say G_j; then set

$$\mathsf{t}(G) \triangleq \mathsf{t}(G_j) \parallel \Big\|_{i \neq j} \top \cdot \mathsf{t}(G_i[x_i]) \cdot \top$$



- or they belong to two distinct components, say ι in G_j and o in G_k, in which case we set

$$\mathsf{t}(G) \triangleq \mathsf{t}(G_j[\iota]) \cdot \top \cdot \mathsf{t}(G_k[o]) \parallel \Big\|_{i \neq j,k} \top \cdot \mathsf{t}(G_i[x_i]) \cdot \top$$



In both cases, it is easy to check that the recursive calls occur on graphs whose (strong) skeletons are subgraphs of the strong skeleton of G, and thus K_4-free.

The definition of the extraction function t ends here. This function is defined on "concrete" graphs: we need to choose some vertices in cases *(b)* and *(c)*, and we can only do so by relying on the concrete identity of those vertices (e.g., choosing the smallest one, assuming they are numbers). We shall see in the following section that all those potential choices, nevertheless, always lead to congruent terms (Theorem 30). By construction, we obtain:

▶ **Theorem 25.** *For every graph $G \in \mathsf{TW}_2$, $\mathsf{g}(\mathsf{t}(G)) \simeq G$.*

▶ **Corollary 26.** *The following are equivalent for all graphs G:*

(i) *G has treewidth at most two;*
(ii) *the strong skeleton of G is K_4-free;*
(iii) *G is (isomorphic to) the graph of a term.*

▶ Remark 27. When G is connected, $\mathsf{t}(G)$ does not contain occurrences of $\top$ other than those that are implicit in our uses of $\mathrm{dom}(\cdot)$ in case *(b)*. Thus we obtain an alternative proof of Dougherty and Gutiérrez' characterisation [17, Section 4, Theorem 31] (their minor exclusion property is easily proved equivalent to ours—they do not mention treewidth).

Also note that we can easily avoid using 1 (but not $\mathrm{dom}(\cdot)$) when the graph does not contain self-loops and is not reduced to the trivial graph 1. When the graph does not contain self-loops and has distinct input and output, the construction can be modifed to produce terms without both 1 and $\mathrm{dom}(\cdot)$; the resulting construction becomes, however, less local, and we do not know how to use it to axiomatise the 1-free reduct of 2p-algebra.

7 Completeness of the axioms

We can finally prove that the axioms of 2p-algebras are complete w.r.t. graphs: they suffice to equate all terms denoting the same graph up to isomorphism. For lack of space, we present only the main steps. Proofs for this last part consist in detailed analyses of the term extraction function (t) through inductive arguments following its recursive definition, and using the laws from Proposition 1 to relate the extracted terms. All details are in [8].

We first prove that t maps isomorphic graphs to congruent terms. We need for that the following propositions.

▶ **Proposition 28.** *Let $G \in \mathsf{TW}_2$ be a graph with $\iota = o$, without self-loops on ι. Let S be its skeleton, and assume that $S\backslash\iota$ is connected. Let U be the neighbours of ι in G and consider the checkpoint graph of U in the skeleton of $S\backslash\iota$. For all checkpoints x, y, we have* $\mathrm{dom}(\mathsf{t}(G[\iota, x])) \equiv \mathrm{dom}(\mathsf{t}(G[\iota, y]))$.

▶ **Proposition 29.** *Let $G \in \mathsf{TW}_2$ be a connected graph. For all vertices x, y, we have* $\top\mathsf{t}(G[x])\top \equiv \top\mathsf{t}(G[y])\top$.

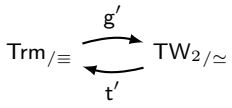
▶ **Theorem 30.** *Let $G, H \in \mathsf{TW}_2$ be two graphs. If $G \simeq H$ then* $\mathsf{t}(G) \equiv \mathsf{t}(H)$.

In other words, the extraction function t yields a function $\mathsf{t}' : \mathsf{TW}_{2/\simeq} \to \mathsf{Trm}_{/\equiv}$ between 2p-algebras. We finally prove that t' is a homomorphism, and, in fact, an isomorphism.

▶ **Proposition 31.** *The function $\mathsf{t}' : \mathsf{TW}_{2/\simeq} \to \mathsf{Trm}_{/\equiv}$ is an homomorphism of 2p-algebras.*

▶ **Theorem 32.** *For every term u, we have* $\mathsf{t}(\mathsf{g}(u)) \equiv u$.

▶ **Corollary 33.** *For all terms u and v, we have $u \equiv v$ if and only if $\mathsf{g}(u) \simeq \mathsf{g}(v)$. Graphs of treewidth at most two form the free 2p-algebra, as witnessed by the diagram on the right.*



8 Future work

What is the free idempotent 2p-algebra? (Where parallel composition is idempotent.) One could be tempted to switch to simple directed graphs, where there is at most one edge with a given label from one vertex to another. This is however not an option: the graphs of $ab \parallel ab$ and ab are not isomorphic. One could also consider equivalences on graphs that are weaker than isomorphism. The notion of (two-way) bisimilarity [25, 24] that come to mind does not work either: such an equivalence relation on graphs certainly validates idempotency of

parallel composition, but it also introduces new laws, e.g., $\top(1 \parallel aa)\top = \top(1 \parallel a)\top$, which are not even true in algebras of binary relations.

Courcelle used the algebraic theory he defined with Bauderon for arbitrary graphs [3] to propose a notion of graph recognisability [9], based on the generic framework by Mezei and Wright [23]. He proved that sets of graphs definable in MSO are recognisable. The converse does not hold in general. He later proved it for graphs of treewidth at most two [10] with a *counting* variant of MSO, conjecturing that it would be so for classes of graphs of bounded treewidth. This conjecture was proved only last year, by Bojańczyk and Pilipczuk [6].

The present work makes it possible to propose an alternative notion of recognisability for treewidth at most two, *2p-recognisability*: recognisability by a finite 2p-algebra. We conjecture that this notion coincides with recognisability. That recognisability entails 2p-recognisability is easy. The converse is harder; it amounts to proving that any finite congruence with respect to substitutions in treewidth at most two graphs can be refined into a finite congruence with respect to substitutions in arbitrary graphs. We see two ways of attaining this implication:

1. prove that 2p-recognisability entails MSO-definability, which could possibly be done along the lines of [10], by showing that our term extraction procedure is MSO-definable.
2. or use a slight generalisation of the result by Courcelle and Lagergren [14], relating recognisability to *k-recognisability* for graphs of treewidth at most k. Indeed, 2*p*-recognisability is really close to 2-recognisability. Unfortunately, Courcelle and Lagergren's result is established only for unlabelled, undirected graphs, without sources, while we need labelled directed graphs with two sources.

One can easily extend our syntax to cover graphs of treewidth at most k, with k sources, for a given k (see, e.g., [15, 2]). However, we do not know how to generate finite axiomatisations in a systematic way, for every such k. Moreover, our proof strategy heavily depends on the fact that when $k = 2$, K_4 is the only excluded minor. We would need another strategy to deal with the general case since the excluded minors are not known for $k \geq 4$.

Abstract

We study an extension of MTL in pointwise time with regular expression guarded modality $\mathsf{Rat}_I(\mathsf{re})$ where re is a rational expression over subformulae. We study the decidability and expressiveness of this extension (MTL+ URat+Rat), called RatMTL, as well as its fragment SfrMTL where only star-free rational expressions are allowed. Using the technique of temporal projections, we show that RatMTL has decidable satisfiability by giving an equisatisfiable reduction to MTL. We also identify a subclass MITL + URat of RatMTL for which our equisatisfiable reduction gives rise to formulae of MITL, yielding elementary decidability. As our second main result, we show a tight automaton-logic connection between SfrMTL and partially ordered (or very weak) 1-clock alternating timed automata.

1 Introduction

Temporal logics provide constructs to specify qualitative ordering between events in time. Real time logics are quantitative extensions of temporal logics with the ability to specify real time constraints amongst events. Logics MTL and TPTL are amongst the prominent real time logics [2]. Two notions of MTL semantics have been studied in the literature : continuous and pointwise [5]. The expressiveness and decidability results vary considerably with the semantics used : while the satisfiability checking of MTL is undecidable in the continuous semantics even for finite timed words [1], it is decidable in pointwise semantics with non-primitive recursive complexity over finite timed words [15]. The satisfiability checking over infinite timed words is undecidable for both the semantics. Due to the hardness of analysis, quest for a decidable subclass and extension was started.

Related Work. Due to limited expressive power of MTL, several additional modalities have been proposed : the threshold counting modality [16] $\mathsf{C}_I^{\geq n}\phi$ states that in time interval I relative to current point, ϕ occurs at least n times. Note that we represent the set of modalities C_I is represented by C. The Pnueli modality [16] $\mathsf{Pn}_I(\phi_1, \ldots, \phi_n)$ states that there

* Please refer url <http://arxiv.org/abs/1705.01501> for full version

is a subsequence of n time points inside interval I where at i^{th} point the formula ϕ_i holds. In a recent result, Hunter [10] showed that, in continuous time semantics, MTL enriched with C modality (denoted MTL + C) is as expressive as FO[<, +1], which is as expressive as TPTL. Unfortunately, satisfiability and model checking of all these logics are undecidable. This has led us to focus on the pointwise case with only the until modality, i.e. logic MTL[U_I], which we abbreviate as MTL in rest of the paper.Also, MTL + *op* means MTL with modalities U_I as well as *op*.

In pointwise semantics, it can be shown that MTL+C is strictly more expressive than MTL and remains decidable for finite words (see [12]). In this paper, we propose a generalization of threshold counting and Pnueli modalities by a rational expression modality $\mathsf{Rat}_I\mathsf{re}(\phi_1, \ldots, \phi_k)$, which specifies that the truth of the subformulae, $\phi_1, \ldots, \phi_k$, at the set of points within interval I is in accordance with the regular expression $\mathsf{re}(\phi_1, \ldots, \phi_k)$. The resulting logic is called RatMTL and is the subject of this paper. The inability to specify rational expression constraints has been an important lacuna of LTL and its practically useful extensions such as PSL sugar [7], [6] (based on Dynamic Logic [8]) which extend LTL with both counting and rational expressions were studied. This indicates that our logic RatMTL is a natural and useful logic for specifying properties. Adding timing constraints to regular expressions was first given by Asarin, Caspi and Maler in [3] and was called as Timed Regular Expressions. They also show that these expressions exactly characterize the expressive power of Timed Automata. But this equivalence relies indispensably on the addition of renaming operation within there syntax [9] and are not closed under negations. In fact the validity checking for this extension was undecidable. Thus we propose a boolean closed decidable logic which can express regular expressions along with timing constraints. To our knowledge, impact of rational expression constraints on metric temporal modalities have not been studied before. The expressive power of logic RatMTL raises several points of interest.

As our first main result, we show that satisfiability of RatMTL is decidable by giving an equisatisfiable reduction to MTL. The reduction makes use of the technique of *oversampled temporal projections* which was previously proposed [11], [12] and used for proving the decidability of MTL + C. The reduction given here has several novel features such as an MTL encoding of the run tree of an alternating automaton which restarts the DFA of a given rational expression at each time point (section 3.1). We identify two syntactic subsets of RatMTL, the first denoted as MITL + URat with 2EXPSPACE easy satisfiability, and its further subset MITL+UM with EXPSPACE-complete satisfiability. As our second main result, we show that the star-free fragment SfrMTL of RatMTL characterizes exactly the class of partially ordered 1-clock alternating timed automata, thereby giving a tight logic automaton connection. The most non-trivial part of this proof is the construction of SfrMTL formula equivalent to a given partially ordered 1-clock alternating timed automaton $\mathcal{A}$ (Lemma 11).

2 Timed Temporal Logics

This section describes the syntax and semantics of the timed temporal logics needed in this paper : MTL and TPTL. Let Σ be a finite set of propositions. A finite timed word over Σ is a tuple $\rho = (\sigma, \tau)$. σ and τ are sequences $\sigma_1\sigma_2 \ldots \sigma_n$ and $\tau_1\tau_2 \ldots \tau_n$ respectively, with $\sigma_i \in \mathcal{P}(\Sigma) - \emptyset$, and $\tau_i \in \mathbb{R}_{\geq 0}$ for $1 \leq i \leq n$ and $\forall i \in dom(\rho)$, $\tau_i \leq \tau_{i+1}$, where $dom(\rho)$ is the set of positions $\{1, 2, \ldots, n\}$ in the timed word. For convenience, we assume $\tau_1 = 0$. The σ_i's can be thought of as labelling positions i in $dom(\rho)$. For example, given $\Sigma = \{a, b, c\}$, $\rho = (\{a, c\}, 0)(\{a\}, 0.7)(\{b\}, 1.1)$ is a timed word. ρ is strictly monotonic iff $\tau_i < \tau_{i+1}$ for all $i, i + 1 \in dom(\rho)$. Otherwise, it is weakly monotonic. The set of finite timed words

over Σ is denoted $T\Sigma^*$. Given $\rho = (\sigma, \tau)$ with $\sigma = \sigma_1 \dots \sigma_n$, σ^{single} denotes the set of words $\{w_1 w_2 \dots w_n \mid w_i \in \sigma_i\}$. For ρ as above, σ^{single} consists of $(\{a\}, 0)(\{a\}, 0.7)(\{b\}, 1.1)$ and $(\{c\}, 0)(\{a\}, 0.7)(\{b\}, 1.1)$. Let $I\nu$ be a set of open, half-open or closed time intervals. The end points of these intervals are in $\mathbb{N} \cup \{0, \infty\}$. For example, $[1, 3), [2, \infty)$. For $\tau \in \mathbb{R}_{\geq 0}$ and interval $\langle a, b\rangle$, with $<\in \{(, [\}$ and $>\in \{],)\}$, $\tau + \langle a, b\rangle$ stands for the interval $\langle \tau + a, \tau + b\rangle$.

Metric Temporal Logic (MTL). Given a finite alphabet Σ, the formulae of MTL are built from Σ using boolean connectives and time constrained version of the modality U as follows: $\varphi ::= a(\in \Sigma) \mid true \mid \varphi \wedge \varphi \mid \neg\varphi \mid \varphi\, \mathsf{U}_I \varphi$, where $I \in I\nu$. For a timed word $\rho = (\sigma, \tau) \in T\Sigma^*$, a position $i \in dom(\rho)$, and an MTL formula φ, the satisfaction of φ at a position i of ρ is denoted $(\rho, i) \models \varphi$, and is defined as follows: (i) $\rho, i \models a \leftrightarrow a \in \sigma_i$, (ii) $\rho, i \models \neg\varphi \leftrightarrow \rho, i \not\models \varphi$, (iii) $\rho, i \models \varphi_1 \wedge \varphi_2 \leftrightarrow \rho, i \models \varphi_1$ and $\rho, i \models \varphi_2$, (iv) $\rho, i \models \varphi_1\, \mathsf{U}_I \varphi_2 \leftrightarrow \exists j > i$, $\rho, j \models \varphi_2, \tau_j - \tau_i \in I$, and $\rho, k \models \varphi_1\ \forall\ i < k < j$.

The language of a MTL formula φ is $L(\varphi) = \{\rho \mid \rho, 1 \models \varphi\}$. Two formulae φ and ϕ are said to be equivalent denoted as $\varphi \equiv \phi$ iff $L(\varphi) = L(\phi)$. Additional temporal connectives are defined in the standard way: we have the constrained future eventuality operator $\Diamond_I a \equiv true\, \mathsf{U}_I a$ and its dual $\Box_I a \equiv \neg\Diamond_I \neg a$. We also define the next operator as $\mathsf{O}_I \phi \equiv \bot\, \mathsf{U}_I \phi$. Non-strict versions of operators are defined as $\Diamond_I^{\mathsf{ns}} a = a \vee \Diamond_I a, \Box_I^{\mathsf{ns}} a \equiv a \wedge \Box_I a$, $a\, \mathsf{U}_I^{\mathsf{ns}} b \equiv b \vee [a \wedge (a\, \mathsf{U}_I b)]$ if $0 \in I$, and $[a \wedge (a\, \mathsf{U}_I b)]$ if $0 \notin I$. Also, $a\, \mathsf{W} b$ is a shorthand for $\Box a \vee (a\, \mathsf{U} b)$. The subclass of MTL obtained by restricting the intervals I in the until modality to non-punctual intervals is denoted MITL.

Timed Propositional Temporal Logic (TPTL). TPTL is a prominent real time extension of LTL, where timing constraints are specified with the help of freeze clocks. The set of TPTL formulas are defined inductively as $\varphi ::= a(\in \Sigma) \mid true \mid \varphi \wedge \varphi \mid \neg\varphi \mid \varphi\, \mathsf{U} \varphi \mid y.\varphi \mid y \in I$. $\mathcal{C}$ is a set of clock variables progressing at the same rate, $y \in \mathcal{C}$, and I is an interval as above. For a timed word $\rho = (\sigma_1, \tau_1) \dots (\sigma_n, \tau_n)$, we define the satisfiability relation, $\rho, i, \nu \models \phi$ saying that the formula ϕ is true at position i of the timed word ρ with valuation ν of all the clock variables as follows: (1) $\rho, i, \nu \models a \leftrightarrow a \in \sigma_i$, (2) $\rho, i, \nu \models \neg\varphi \leftrightarrow \rho, i, \nu \not\models \varphi$, (3) $\rho, i, \nu \models \varphi_1 \wedge \varphi_2 \leftrightarrow \rho, i, \nu \models \varphi_1$ and $\rho, i, \nu \models \varphi_2$, (4) $\rho, i, \nu \models x.\varphi \leftrightarrow \rho, i, \nu[x \leftarrow \tau_i] \models \varphi$, (5) $\rho, i, \nu \models x \in I \leftrightarrow \tau_i - \nu(x) \in I$, (6) $\rho, i, \nu \models \varphi_1\, \mathsf{U} \varphi_2 \leftrightarrow \exists j > i$, $\rho, j, \nu \models \varphi_2$, and $\rho, k, \nu \models \varphi_1\ \forall\ i < k < j$. ρ satisfies ϕ denoted $\rho \models \phi$ iff $\rho, 1, \bar{0} \models \phi$. Here $\bar{0}$ is the valuation obtained by setting all clock variables to 0. We denote by $k-$TPTL the fragment of TPTL using at most k clock variables.

▶ **Theorem 1** ([15]). MTL *satisfiability is decidable over finite timed words and is non-primitive recursive.*

MTL with Rational Expressions (RatMTL)

We propose an extension of MTL with rational expressions, that forms the core of the paper. These modalities can assert the truth of a rational expression (over subformulae) within a particular time interval with respect to the present point. For example, $\mathsf{Rat}_{(0,1)}(\varphi_1.\varphi_2)^+$ when evaluated at a point i, asserts the existence of $2k$ points $\tau_i < \tau_{i+1} < \tau_{i+2} < \dots < \tau_{i+2k} < \tau_i + 1$, $k > 0$, such that φ_1 evaluates to true at τ_{i+2j+1}, and φ_2 evaluates to true at τ_{i+2j+2}, for all $0 \leq j < k$.

RatMTL Syntax Formulae of RatMTL are built from Σ (atomic propositions) as follows: $\varphi ::= a(\in \Sigma) \mid true \mid \varphi \wedge \varphi \mid \neg\varphi \mid \mathsf{Rat}_I \mathsf{re}(\mathsf{S}) \mid \varphi \mathsf{U} \mathsf{Rat}_{I,\mathsf{re}(\mathsf{S})} \varphi$, where $I \in I\nu$ and S is a finite set of formulae of interest generated by this grammar, and $\mathsf{re}(\mathsf{S})$ is defined as a

rational expression over S. $\mathsf{re(S)} ::= \varphi(\in \mathsf{S}) \mid \mathsf{re(S).re(S)} \mid \mathsf{re(S)} + \mathsf{re(S)} \mid [\mathsf{re(S)}]^*$. Thus, RatMTL is MTL + URat + Rat. An *atomic* rational expression re is any well-formed formula $\varphi \in \mathsf{RatMTL}$.

RatMTL Semantics For a timed word $\rho = (\sigma, \tau) \in T\Sigma^*$, a position $i \in dom(\rho)$, and a RatMTL formula φ, a finite set S of formulae, we define the satisfaction of φ at a position i as follows. For positions $i < j \in dom(\rho)$, let $\mathsf{Seg}(\rho, \mathsf{S}, i, j)$ denote the untimed word over $\mathcal{P}(\mathsf{S})$ obtained by marking the positions $k \in \{i+1, \ldots, j-1\}$ of ρ with $\psi \in \mathsf{S}$ iff $\rho, k \models \psi$. For a position $i \in dom(\rho)$ and an interval I, let $\mathsf{TSeg}(\rho, S, I, i)$ denote the untimed word over $\mathcal{P}(\mathsf{S})$ obtained by marking all the positions k such that $\tau_k - \tau_i \in I$ of ρ with $\psi \in \mathsf{S}$ iff $\rho, k \models \psi$.

1. $\rho, i \models \varphi_1 \mathsf{URat}_{I,\mathsf{re(S)}} \varphi_2 \leftrightarrow \exists j > i,\ \rho, j \models \varphi_2, \tau_j - \tau_i \in I,\ \rho, k \models \varphi_1\ \forall i < k < j$ and, $[\mathsf{Seg}(\rho, \mathsf{S}, i, j)]^{\mathsf{single}} \cap L(\mathsf{re}(S)) \neq \emptyset$, where $L(\mathsf{re(S)})$ is the language of the rational expression re formed over the set S. The subclass of RatMTL using only the URat modality is denoted RatMTL[URat] or MTL + URat and if only non-punctual intervals are used, then it is denoted RatMITL[URat] or MITL + URat.
2. $\rho, i \models \mathsf{Rat}_I \mathsf{re} \leftrightarrow [\mathsf{TSeg}(\rho, S, I, i)]^{\mathsf{single}} \cap L(\mathsf{re}(S)) \neq \emptyset$.

The language accepted by a RatMTL formula φ is given by $L(\varphi) = \{\rho \mid \rho, 0 \models \varphi\}$.

▶ **Example 2.** Consider the formula $\varphi = a\mathsf{URat}_{(0,1),ab^*} b$. Then $\mathsf{re} = ab^*$, and the subformulae of interest are a, b. For $\rho = (\{a\}, 0)(\{a, b\}, 0.3)(\{a, b\}, 0.99)$, $\rho, 1 \models \varphi$, since $a \in \sigma_2, b \in \sigma_3$, $\tau_3 - \tau_1 \in (0, 1)$ and $a \in [\mathsf{Seg}(\rho, \{a, b\}, 1, 3)]^{\mathsf{single}} \cap L(ab^*)$. On the other hand, for the word $\rho = (\{a\}, 0)(\{a\}, 0.3)(\{a\}, 0.5)(\{a\}, 0.9)(\{b\}, 0.99)$, we know that $\rho, 1 \not\models \varphi$, since even though $b \in \sigma_5, a \in \sigma_i$ for $i < 5$, $[\mathsf{Seg}(\rho, \{a, b\}, 1, 5)]^{\mathsf{single}} = aaa$ and $aaa \notin L(ab^*)$.

▶ **Example 3.** Consider the formula $\varphi = \mathsf{Rat}_{(0,1)}[\mathsf{Rat}_{(0,1)} a]^*$.
For $\rho = (\{a, b\}, 0)(\{a, b\}, 0.7)(\{b\}, 0.98)(\{a, b\}, 1.4)$, we have $\rho, 1 \not\models \mathsf{Rat}_{(0,1)}[\mathsf{Rat}_{(0,1)} a]^*$, since point 2 is not marked $\mathsf{Rat}_{(0,1)} a$, even though point 3 is.

Generalizing Counting, Pnueli & Mod Counting Modalities. The following reductions show that RatMTL subsumes most of the extensions of MTL studied in the literature.

(1) Threshold Counting constraints [16], [13], [12] specify the number of times a property holds within some time region is at least (or at most) n. These can be expressed in RatMTL: (i) $\mathsf{C}_I^{\geq n} \varphi \equiv \mathsf{Rat}_I(\mathsf{re}_{th})$, (ii) $\phi_1 \mathsf{UT}_{I,\varphi \geq n} \phi_2 \equiv \phi_1 \mathsf{URat}_{I,\mathsf{re}_{th}} \phi_2$, where $\mathsf{re}_{th} = true^* \underbrace{\varphi.true^*. \ldots .\varphi.true^*}_{n \text{ times}}$.

(2) Pnueli Modalities[1] [16], which enhance the expressiveness of MITL in continuous semantics preserving the complexity, can be written in RatMTL: $\mathsf{Pn}_I(\phi_1, \phi_2, \ldots, \phi_k)$ can be written as $\mathsf{Rat}_I(true^*.\phi_1.true^*\phi_2. \ldots .true^*.\phi_k.true^*)$.

(3) Modulo Counting constraints [4], [14] specify the number of times a property holds modulo $n \in \mathbb{N}$, in some region. We extend these to the timed setting by proposing two modalities $\mathsf{MC}_I^{k\%n}$ and $\mathsf{UM}_{I,\varphi=k\%n}$. $\mathsf{MC}_I^{k\%n} \varphi$ checks if the number of times φ is true in interval I is $M(n) + k$, where $M(n)$ denotes a non-negative integer multiple of n, and $0 \leq k \leq n-1$, while $\varphi_1 \mathsf{UM}_{I,\#\psi=k\%n} \varphi_2$ when asserted at a point i, checks

[1] The version of the modality only specified sequences for the next unit interval. We talk about a more general version of this operator which is appended by timing interval.

the existence of $j > i$ such that $\tau_j - \tau_i \in I$, φ_2 is true at j, φ_1 holds between i, j, and the number of times ψ is true between i, j is $M(n) + k$, $0 \leq k \leq n-1$. As an example, $\psi = true\mathsf{UM}_{(0,1),\#b=1\%2}(a \vee b)$, when asserted at a point i, checks the existence of a point $j > i$ such that a or $b \in \sigma_j$, $\tau_j - \tau_i \in (0,1)$, and the number of points between i, j where b is true is odd. Both these modalities can be rewritten equivalently in RatMTL as follows: $\mathsf{MC}_I^{k\%n}\varphi \equiv \mathsf{Rat}_I(\mathsf{re}_{mod})$ and $\phi_1\mathsf{UM}_{I,\varphi=k\%n}\phi_2 \equiv \phi_1\mathsf{URat}_{I,\mathsf{re}_{mod}}\phi_2$ where $\mathsf{re}_{mod} = ([\underbrace{(\neg\varphi)^*.\varphi.\ldots.(\neg\varphi)^*.\varphi}_{n \text{ times}}]^*.[\underbrace{(\neg\varphi)^*.\varphi.\ldots.(\neg\varphi)^*.\varphi}_{k \text{ times}}]$. The extension of MTL (MITL) with only UM is denoted MTL + UM (MITL + UM) while MTL + MC (MITL + MC) denotes the extension using MC.

3 Satisfiability of RatMTL and Complexity

The main results of this section are as follows.

▶ **Theorem 4.** *(1) Satisfiability of* RatMTL *is decidable over finite timed words. (2) Satisfiability of* MITL + UM *is* EXPSPACE*-complete. (3) Satisfiability of* MITL + URat *is within* 2EXPSPACE*. (4) Satisfiability of* MITL + MC *is* $\mathbf{F}_{\omega^\omega}$*-hard.*

Details of 4.2, 4.3, 4.4 are in appendices E.2,E.3 and E.4 of the full version, respectively.

▶ **Theorem 5.** MTL + URat $\subseteq$ MTL + Rat, MTL + UM $\subseteq$ MTL + MC.

Theorem 5 shows that the Rat modality can capture URat (and likewise, MC captures UM). Thus, RatMTL $\equiv$ MTL + Rat. Observe that any re can be decomposed into finitely many factors, i.e. $\mathsf{re} = \sum_{i=1}^{n} R_1^i.R_2^i$. Given $true\mathsf{URat}_{[l,u),\mathsf{re}}\phi_2$, we assert R_1^i within interval $(0,l]$ and R_2^i in the prefix of the latter part within $[l,u)$, followed by ϕ_2. $true\mathsf{URat}_{[l,u),\mathsf{re}}\phi_2 \equiv \bigvee_{i\in\{1,2\ldots,n\}} \mathsf{Rat}_{(0,l)}R_1^i \wedge \mathsf{Rat}_{[l,u)}R_2^i.\phi_2.\Sigma^*$. The proofs are in appendix G of the full version.

3.1 Proof of Theorem 4.1

Equisatisfiability. We will use the technique of equisatisfiability modulo oversampling [11] in the proof of Theorem 4. Using this technique, formulae φ in one logic (say RatMTL) can be transformed into formulae ψ over a simpler logic (say MTL) such that whenever $\rho \models \varphi$ for a timed word ρ over alphabet Σ, one can construct a timed word ρ' over an extended set of positions and an extended alphabet Σ' such that $\rho' \models \psi$ and vice-versa [11], [12]. In *oversampling*, (i) $dom(\rho')$ is extended by adding some extra positions between the first and last point of ρ, (ii) the labeling of a position $i \in dom(\rho)$ is over the extended alphabet $\Sigma' \supset \Sigma$ and can be a superset of the previous labeling over Σ, while the new positions are labeled using only the new symbols $\Sigma' - \Sigma$. We can recover ρ from ρ' by erasing the new points and the new symbols. A restricted use of oversampling, when one only extends the alphabet and not the set of positions of a timed word ρ is called *simple extension*. In this case, if ρ' is a simple extension of ρ, then $dom(\rho) = dom(\rho')$, and by erasing the new symbols from ρ', we obtain ρ. See Figure 1 for an illustration. The formula ψ over the larger alphabet $\Sigma' \supset \Sigma$ such that $\rho' \models \psi$ iff $\rho \models \varphi$ is said to be equisatisfiable modulo temporal projections to φ. In particular, ψ is equisatisfiable to φ modulo simple extensions or modulo oversampling, depending on how the word ρ' is constructed from the word ρ.

The oversampling technique is used in the proofs of parts 4.1, 4.3 and 4.4.

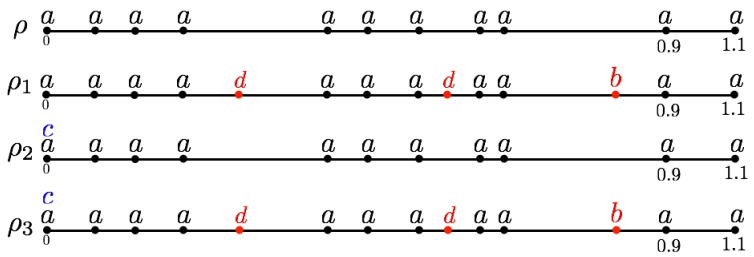

Figure 1 ρ is over $\Sigma = \{a\}$ and satisfies $\varphi = \Box_{(0,1)}a$. ρ_1 is an oversampling of ρ over an extended alphabet $\Sigma_1 = \Sigma \cup \{b, d\}$ and satisfies $\psi_1 = \Box(b \leftrightarrow \neg a) \wedge (\neg b \,\mathsf{U}_{(0,1)} b)$. The red points in ρ_1 are the oversampling points. ρ_2 is a simple extension of ρ over an extended alphabet $\Sigma_2 = \Sigma \cup \{c\}$ and satisfies $\psi_2 = \Box(c \leftrightarrow \Box_{(0,1)}a) \wedge c$. It can be seen that ψ_1 is equivalent to φ modulo oversampling, and ψ_2 is equivalent to φ modulo simple extensions using the (respectively oversampling, simple) extensions ρ_1, ρ_2 of ρ. However, ρ_3 above, obtained by merging ρ_1, ρ_2, eventhough an oversampling of ρ, is not a good model for the formula $\psi_1 \wedge \psi_2$ over $\Sigma_1 \cup \Sigma_2$. However, we can relativize ψ_1 and ψ_2 with respect to Σ as $\Box(act_1 \rightarrow (b \leftrightarrow \neg a)) \wedge [(act_1 \rightarrow \neg b) \,\mathsf{U}_{(0,1)} (b \wedge act_1)]$, and $\Box(act_2 \rightarrow (c \leftrightarrow \Box_{[0,1)}(act_2 \rightarrow a))) \wedge (act_2 \wedge c)$ where $act_1 = \bigvee \Sigma_1, act_2 = \bigvee \Sigma_2$. The relativized formula $\kappa = Rel(\psi_1, \Sigma) \wedge Rel(\psi_2, \Sigma)$ is then equisatisfiable to φ modulo oversampling, and ρ_3 is indeed an oversampling of ρ satisfying κ. This shows that while combining formulae ψ_1, ψ_2 which are equivalent to formulae φ_1, φ_2 modulo oversampling, we need to relativize ψ_1, ψ_2 to obtain a conjunction which will be equisatisfiable to $\varphi_1 \wedge \varphi_2$ modulo oversampling. See [11] for details.

Equisatisfiable Reduction : RatMTL to MTL

Let φ be a RatMTL formula. To obtain equisatisfiable MTL formula ψ, we do the following.

1. We "flatten" the rational(Rat & URat) modalities to simplify the formulae, eliminating nested rational modalities by allotting witness variable for each rational subformulae . Thus the resulting formulae will be of the form $\mathsf{prop} \wedge \Box^{\mathsf{ns}}[w_1 \leftrightarrow \mathsf{Rat}_I, \mathsf{URat}] \cdots \wedge \Box^{\mathsf{ns}}[w_k \leftrightarrow \mathsf{Rat}_I, \mathsf{URat}]$ where prop refers to some boolean formulae over atoms and $\mathsf{Rat}_I, \mathsf{URat}$ denotes formulae of the form $\mathsf{Rat}_I \mathsf{re{-}atom}$, $\mathsf{propURat}_{I,\mathsf{re-atom}}\mathsf{prop}$, respectively. Each conjunct of the form $\Box^{\mathsf{ns}}[w_1 \leftrightarrow \mathsf{Rat}_I, \mathsf{URat}]$ is called as *temporal definition*.
2. The elimination of rational modalities is achieved by obtaining equisatisfiable MTL formulae ψ_i over X_i, possibly a larger set of propositions than $\Sigma \cup W_i$ corresponding to each temporal definition T_i of φ_{flat}. Relativizing these MTL formulae and conjuncting them, we obtain an MTL formula $\bigwedge_i Rel(\psi_i, \Sigma)$ that is equisatisfiable to φ (see Figure 1 for relativization).

The above steps are routine [11], [12]. What remains is to handle the temporal definitions.

Embedding the Runs of the DFA

For any given ρ over $\Sigma \cup W$, where W is the set of witness propositions used in the temporal definitions T of the forms $\Box^{\mathsf{ns}}[w \leftrightarrow \mathsf{Rat}_I \mathsf{re{-}atom}]$ or $\Box^{\mathsf{ns}}[w \leftrightarrow x\mathsf{URat}_{I',\mathsf{re-atom}}y]$, the rational expression re−atom has a corresponding minimal DFA recognizing it. We define an LTL formula $\mathsf{GOODRUN}(\phi_e)$ which takes a formula ϕ_e as a parameter with the following behaviour. $\rho, i \models \mathsf{GOODRUN}(\phi_e)$ iff for all $k > i$, $(\rho, k \models \phi_e) \rightarrow (\rho[i, k] \in L(\mathsf{re{-}atom}))$. To achieve this, we use two new sets of symbols Threads and Merge for this information. This results in the extended alphabet $\Sigma \cup W \cup \mathsf{Threads} \cup \mathsf{Merge}$ for the simple extension ρ' of ρ. The behaviour of Threads and Merge are explained below.

Consider $\mathsf{re{-}atom} = \mathsf{re}(\mathsf{S})$. Let $\mathcal{A}_{\mathsf{re-atom}} = (Q, 2^{\mathsf{S}}, \delta, q_1, Q_F)$ be the minimal DFA for re−atom and let $Q = \{q_1, q_2, \ldots, q_m\}$. Let $\mathsf{In} = \{1, 2, \ldots, m\}$ be the indices of the states.

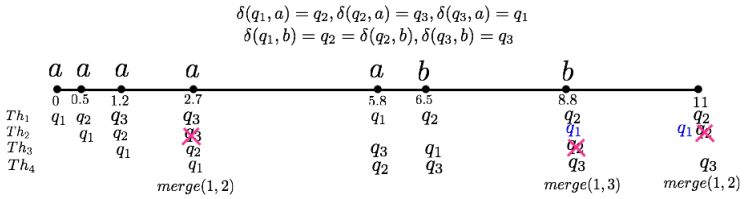

Figure 2 Depiction of threads and merging. At time point 2.7, thread 2 is merged with 1, since they both had the same state information. This thread remains inactive till time point 8.8, where it becomes active, by starting a new run in state q_1. At time point 8.8, thread 3 merges with thread 1, while at time point 11, thread 2 merges with 1, but is reactivated in state q_1.

Conceptually, we consider multiple runs of $\mathcal{A}_{\mathsf{re-atom}}$ with a new run (new thread) started at each point in ρ. Threads records the state of each previously started run. At each step, each thread is updated from it previous value according to the transition function δ of $\mathcal{A}_{\mathsf{re-atom}}$ and also augmented with a new run in initial state. Potentially, the number of threads would grow unboundedly in size but notice that once two runs are the same state at position i they remain identical in future. Hence they can be merged into single thread (see Figure2). As a result, m threads suffice. We record whether threads are merged in the current state using variables Merge. An LTL formula records the evolution of Threads and Merge over any behaviour ρ. We can define formula $\mathsf{GOODRUN}(\phi_e)$ in LTL over Threads and Merge.

1. At each position, let $\mathsf{Th}_i(q_x)$ be a proposition that denotes that the ith thread is active and is in state q_x, while $\mathsf{Th}_i(\bot)$ be a proposition that denotes that the ith thread is not active. The set Threads consists of propositions $\mathsf{Th}_i(q_x), \mathsf{Th}_i(\bot)$ for $1 \leq i, x \leq m$.
2. If at a position e, we have $\mathsf{Th}_i(q_x)$ and $\mathsf{Th}_j(q_y)$ for $i < j$, and if $\delta(q_x, \sigma_e) = \delta(q_y, \sigma_e)$, then we can merge the threads i, j at position $e+1$. Let $\mathsf{merge}(i,j)$ be a proposition that signifies that threads i, j have been merged. In this case, $\mathsf{merge}(i,j)$ is true at position $e+1$. Let Merge be the set of all propositions $\mathsf{merge}(i,j)$ for $1 \leq i < j \leq m$.

We now describe the conditions to be checked in ρ'.

- **Initial condition**(φ_{init})- At the first point of the word, we start the first thread and initialize all other threads as $\bot$: $\varphi_{init} = ((\mathsf{Th}_1(q_1)) \wedge \bigwedge_{1<i\leq m} \mathsf{Th}_i(\bot))$.
- **Initiating runs at all points**(φ_{start})- To check the rational expression within an arbitrary interval, we need to start a new run from every point. $\varphi_{start} = \Box^{\mathsf{ns}}(\bigvee_{i\leq m} \mathsf{Th}_i(q_1))$
- **Disallowing Redundancy**(φ_{no-red})- At any point of the word, if $i < j$ and $\mathsf{Th}_i(q_x)$ and $\mathsf{Th}_j(q_x)$ are both true, $q_x \neq q_y$. $\varphi_{no-red} = \bigwedge_{x\in\mathsf{In}} \Box^{\mathsf{ns}}[\neg \bigvee_{1\leq i<j\leq m} (\mathsf{Th}_i(q_x) \wedge \mathsf{Th}_j(q_x))]$
- **Merging Runs**$(\varphi_{\mathsf{merge}})$- If two different threads $\mathsf{Th}_i, \mathsf{Th}_j (i < j)$ reach the same state q_x on reading the input at the present point, then we merge thread Th_j with Th_i. We remember the merge with the proposition $\mathsf{merge}(i,j)$. We define a macro $\mathsf{Nxt}(\mathsf{Th}_i(q_x))$ which is true at a point e if and only if $\mathsf{Th}_i(q_y)$ is true at e and $\delta(q_y, \sigma_e) = q_x$, where $\sigma_e \subseteq AP$ is the maximal set of propositions true at e: $\bigvee_{\{(q_y,prop)\in(Q,2^{AP})|\delta(q_y,prop)=q_x\}} [prop \wedge \mathsf{Th}_i(q_y)]$.
  Let $\psi(i,j,k,q_x)$ be a formula that says that at the next position, $\mathsf{Th}_i(q_x)$ and $\mathsf{Th}_k(q_x)$ are true for $k > i$, but for all $j < i$, $\mathsf{Th}_j(q_x)$ is not. $\psi(i,j,k,q_x)$ is given by $\mathsf{Nxt}(\mathsf{Th}_i(q_x)) \wedge \bigwedge_{j<i} \neg\mathsf{Nxt}(\mathsf{Th}_j(q_x)) \wedge \mathsf{Nxt}(\mathsf{Th}_k(q_x))$. In this case, we merge threads $\mathsf{Th}_i, \mathsf{Th}_k$, and either restart Th_k in the initial state, or deactivate the kth thread at the next position. This is given by the formula $\mathsf{NextMerge(i,k)} = \mathsf{O}[\mathsf{merge}(i,k) \wedge (\mathsf{Th}_k(\bot) \vee \mathsf{Th}_k(q_1)) \wedge \mathsf{Th}_i(q_x)]$.
  $\varphi_{\mathsf{merge}} = \bigwedge_{x,i,k\in\mathsf{In}\wedge k>i} \Box^{\mathsf{ns}}[\psi(i,j,k,q_x) \rightarrow \mathsf{NextMerge(i,k)}]$.

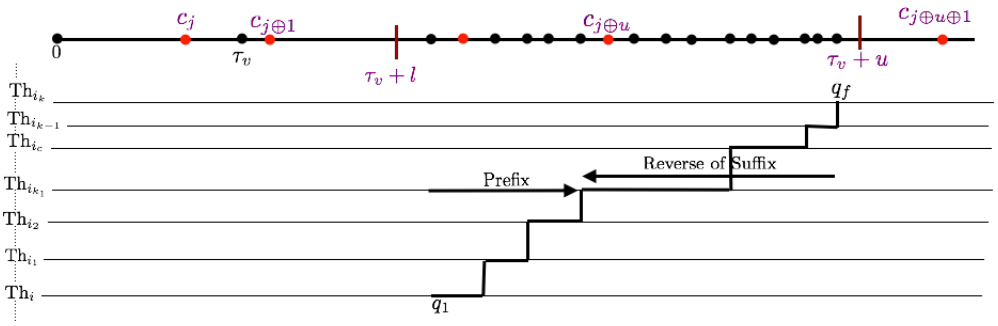

Figure 3 The linking thread at $c_{j\oplus u}$. The points in red are the oversampling integer points, and so are $\tau_v + l$ and $\tau_v + u$.

- **Propagating runs**$(\varphi_{pro}, \varphi_{NO-pro})$- If $\mathsf{Nxt}(\mathsf{Th}_i(q_x))$ is true at a point, and if for all $j < i$, $\neg\mathsf{Nxt}(\mathsf{Th}_j(q_x))$ is true, then at the next point, we have $\mathsf{Th}_i(q_x)$. Let $\mathsf{NextTh}(i, j, q_x)$ denote the formula $\mathsf{Nxt}(\mathsf{Th}_i(q_x)) \wedge \neg\mathsf{Nxt}(\mathsf{Th}_j(q_x))$. The formula φ_{pro} is given by $\bigwedge_{i,j\in\mathsf{In}\wedge i<j} \Box^{\mathsf{ns}}[\mathsf{NextTh}(i, j, q_x) \rightarrow \mathsf{O}[\mathsf{Th}_i(q_x) \wedge \neg\mathsf{merge}(i, j)]]$. If $\mathsf{Th}_i(\bot)$ is true at the current point, then at the next point, either $\mathsf{Th}_i(\bot)$ or $\mathsf{Th}_i(q_1)$. The latter condition corresponds to starting a new run on thread Th_i. $\varphi_{NO-pro} = \bigwedge_{i\in\mathsf{In}} \Box^{\mathsf{ns}}\{\mathsf{Th}_i(\bot) \rightarrow \mathsf{O}(\mathsf{Th}_i(\bot) \vee \mathsf{Th}_i(q_1))\}$

Let Run be the formula obtained by conjuncting all formulae explained above. Once we construct the simple extension ρ', checking whether the rational expression $\mathsf{re{-}atom}$ holds in some interval I in the timed word ρ, is equivalent to checking that if u is the first action point within I, and if $\mathsf{Th}_i(q_1)$ holds at u, then after a series of merges of the form $\mathsf{merge}(i_1, i)$,$\mathsf{merge}(i_2, i_1)$, $\ldots$ $\mathsf{merge}(j, i_n)$, at the last point v in the interval I, $\mathsf{Th}_j(q_f)$ is true, for some final state q_f. This is encoded as $\mathsf{GOODRUN}(q_f)$. It can be seen that the number of possible sequences of merges are bounded. Figure 2 illustrates the threads and merging. To write an MTL formula that checks the truth of $\mathsf{Rat}_{[l,u)}\mathsf{re{-}atom}$ at a point v, we need to oversample ρ' as shown below.

▶ **Lemma 6.** *Let $T = \Box^{\mathsf{ns}}[w \leftrightarrow \mathsf{Rat}_I\mathsf{re{-}atom}]$ be a temporal definition built from $\Sigma \cup W$. Then we synthesize a formula $\psi \in \mathsf{MTL}$ over $\Sigma \cup W \cup X$ such that T is equivalent to ψ modulo oversampling.*

Proof. Lets first consider the case when the interval I is bounded of the form $[l, u)$. Consider a point in ρ' with time stamp τ_v. To assert w at τ_v, we look at the first action point after time point $\tau_v + l$, and check that $\mathsf{GOODRUN}(last(q_f))$ holds, where $last(q_f)$ identifies the last action point just before $\tau_v + u$. The first difficulty is the possible absence of time points $\tau_v + l$ and $\tau_v + u$. To overcome this difficulty, we oversample ρ' by introducing points at times $t + l, t + u$, whenever t is a time point in ρ'. These new points are labelled with a new proposition ovs. Sadly, $last(q_f)$ cannot be written in MTL.

To address this, we introduce new time points at every integer point of ρ'. The starting point 0 is labelled c_0. Consecutive integer time points are marked $c_i, c_{i\oplus 1}$, where $\oplus$ is addition modulo the maximum constant used in the time interval in the RatMTL formula. This helps in measuring the time elapse since the first action point after $\tau_v + l$, till the last action point before $\tau_v + u$ as follows: if $\tau_v + l$ lies between points marked $c_j, c_{j\oplus 1}$, then the last integer point before $\tau_v + u$ is **uniquely** marked $c_{j\oplus u}$.

- Anchoring at τ_v, we assert the following at distance l: no action points are seen until the first action point where $\mathsf{Th}_i(q_1)$ is true for some thread Th_i. Consider the next point

where $c_{j\oplus u}$ is seen. Let $\mathsf{Th}_{i_{k_1}}$ be the thread to which Th_i has merged at the last action point just before $c_{j\oplus u}$. Let us call $\mathsf{Th}_{i_{k_1}}$ the "last merged thread" before $c_{j\oplus u}$. The sequence of merges from Th_i till $\mathsf{Th}_{i_{k_1}}$ asserts a prefix of the run that we are looking for between $\tau_v + l$ and $\tau_v + u$. To complete the run we mention the sequence of merges from $\mathsf{Th}_{i_{k_1}}$ which culminates in some $\mathsf{Th}_{i_k}(q_f)$ at the last action point before $\tau_v + u$.

- Anchoring at τ_v, we assert the following at distance u: we see no action points since $\mathsf{Th}_{i_k}(q_f)$ at the action point before $\tau_v + u$ for some thread Th_{i_k}, and there is a path linking thread $\mathsf{Th}_{i_{k_1}}$ to Th_{i_k} since the point $c_{j\oplus u}$. We assert that the "last merged thread", $\mathsf{Th}_{i_{k_1}}$ is active at $c_{j\oplus u}$: this is the linking thread which is last merged into before $c_{j\oplus u}$, and which is the first thread which merges into another thread after $c_{j\oplus u}$.

These two formulae thus "stitch" the actual run observed between points $\tau_v + l$ and $\tau_v + u$. The formal technical details can be seen in Appendix D in the full version. If I was an unbounded interval of the form $[l, \infty)$, then we will go all the way till the end of the word, and assert $\mathsf{Th}_{i_k}(q_f)$ at the last action point of the word. Thus, for unbounded intervals, we do not need any oversampling at integer points. ◀

In a similar manner, we can eliminate the URat modality, the proof of which can be found in Appendix E in the full version. If we choose to work on logic MITL + URat, we obtain a 2EXPSPACE upper bound for satisfiability checking, since elimination of URat results in an equisatisfiable MITL formula. This is an interesting consequence of the oversampling technique; without oversampling, we can eliminate URat obtaining 1-TPTL (Appendix C, full version). However, 1-TPTL does not enjoy the benefits of non-punctuality, and is non-primitive recursive (Appendix F, full version).

4 Automaton-Metric Temporal Logic-Freeze Logic Equivalences

The focus of this section is to obtain equivalences between automata, temporal and freeze logics. First of all, we identify a fragment of RatMTL denoted SfrMTL, where the rational expressions in the formulae are all star-free. We then show the equivalence between po-1-clock ATA, 1−TPTL, and SfrMTL (po-1-clock ATA $\subseteq$ SfrMTL $\subseteq$ 1−TPTL $\equiv$ po-1-clock ATA). The main result of this section gives a tight automaton-logic connection in Theorem 7, and is proved using Lemmas 9, 10 and 11.

▶ **Theorem 7.** *1−TPTL, SfrMTL and po-1-clock ATA are all equivalent.*

We first show that partially ordered 1-clock alternating timed automata (po-1-clock ATA) capture exactly the same class of languages as 1−TPTL. We also show that 1−TPTL is equivalent to the subclass SfrMTL of RatMTL where the rational expressions re involved in the formulae are such that $L(\mathsf{re})$ is star-free.

A 1-clock ATA [15] is a tuple $\mathcal{A} = (\Sigma, S, s_0, F, \delta)$, where Σ is a finite alphabet, S is a finite set of locations, $s_0 \in S$ is the initial location and $F \subseteq S$ is the set of final locations. Let x denote the clock variable in the 1-clock ATA, and $x \bowtie c$ denote a clock constraint where $c \in \mathbb{N}$ and $\bowtie \in \{<, \leq, >, \geq\}$. Let X denote a finite set of clock constraints of the form $x \bowtie c$. The transition function is defined as $\delta : S \times \Sigma \to \Phi(S \cup \Sigma \cup X)$ where $\Phi(S \cup \Sigma \cup X)$ is a set of formulae defined by the grammar $\varphi ::= \top | \bot | \varphi_1 \wedge \varphi_2 | \varphi_1 \vee \varphi_2 | s | x \bowtie c | x.\varphi$ where $s \in S$, and $x.\varphi$ is a binding construct corresponding to resetting the clock x to 0.

The notation $\Phi(S \cup \Sigma \cup X)$ thus allows boolean combinations as defined above of locations, symbols of Σ, clock constraints and $\top, \bot$, with or without the binding construct $(x.)$. A configuration of a 1-clock ATA is a set consisting of locations along with their clock valuation. Given a configuration C, we denote by $\delta(C, a)$ the configuration D obtained by applying

$\delta(s,a)$ to each location s such that $(s,\nu) \in C$. A run of the 1-clock ATA starts from the initial configuration $\{(s_0,0)\}$, and proceeds with alternating time elapse transitions and discrete transitions obtained on reading a symbol from Σ. A configuration is accepting iff it is either empty, or is of the form $\{(s,\nu) \mid s \in F\}$. The language accepted by a 1-clock ATA $\mathcal{A}$, denoted $L(\mathcal{A})$ is the set of all timed words ρ such that starting from $\{(s_0,0)\}$, reading ρ leads to an accepting configuration. A po-1-clock ATA is one in which (i) there is a partial order denoted $\prec$ on the locations, such that whenever s_j appears in $\Phi(s_i)$, $s_j \prec s_i$, or $s_j = s_i$. Let $\downarrow s_i = \{s_j \mid s_j \prec s_i\}$, (ii) $x.s$ does not appear in $\delta(s,a)$ for all $s \in S, a \in \Sigma$.

▶ **Example 8.** Consider the po-1-clock ATA $\mathcal{A} = (\{a,b\}, \{s_0, s_a, s_\ell\}, s_0, \{s_0, s_\ell\}, \delta)$ with transitions $\delta(s_0,b) = s_0, \delta(s_0,a) = (s_0 \wedge x.s_a) \vee s_\ell$, $\delta(s_a,a) = (s_a \wedge x < 1) \vee (x > 1) = \delta(s_a,b)$, and $\delta(s_\ell,b) = s_\ell, \delta(s_\ell,a) = \bot$. The automaton accepts all strings where every non-last a has no symbols at distance 1 from it, and has some symbol at distance > 1 from it.

▶ **Lemma 9.** po-*1-clock ATA and* $1-$TPTL *are equivalent in expressive power.*

The translation from $1-$TPTL to po-1-clock ATA is easy, as in the translation from MTL to po-1-clock ATA. For the reverse direction, we start from the lowest location (say s) in the partial order, and replace the transitions of s by a 1-TPTL formula that models timed words which are accepted, when started in s. The accepting behaviours of each location s, denoted $\mathsf{Beh}(s)$ is computed bottom up. The 1-TPTL formula that we are looking for is $\mathsf{Beh}(s_0)$ where s_0 is the initial location. In example 8, $\mathsf{Beh}(s_\ell) = \Box^{\mathsf{ns}} b$, $\mathsf{Beh}(s_a) = (x < 1)\ \mathsf{U}^{\mathsf{ns}}(x > 1)$, $\mathsf{Beh}(s_0) = [(a \wedge x.\mathsf{OBeh}(s_a)) \vee b]\ \mathsf{W}(a \wedge \mathsf{OBeh}(s_\ell)) = ((a \wedge (x.\mathsf{O}[(x < 1)\ \mathsf{U}^{\mathsf{ns}} x > 1])) \vee b)\ \mathsf{W}(a \wedge \mathsf{O}\Box^{\mathsf{ns}} b)$. Step by step details for Lemma 9 can be seen in Appendix H of the full version.

▶ **Lemma 10.** $\mathsf{SfrMTL} \subseteq 1 - \mathsf{TPTL}$.

The proof of Lemma 10 can be found in Appendix I of the full version. The intuition is to freeze a clock x at the current point, and write an LTL formula equivalent to the star-free expression over an interval I which can be constrained checking $x \in I$ in the LTL formula.

▶ **Lemma 11.** *(*po-*1-clock ATA to* SfrMTL*) Given a* po-*1-clock ATA* $\mathcal{A}$*, we can construct a* SfrMTL *formula* φ *such that* $L(\mathcal{A}) = L(\varphi)$.

Proof. (Sketch) We give a proof sketch here, a detailed proof can be found in Appendix J of the full version. Let $\mathcal{A}$ be a po-1-clock ATA with locations $S = \{s_0, s_1, \ldots, s_n\}$. Let K be the maximal constant used in the guards $x \sim c$ occurring in the transitions. Let $R_{2i} = [i,i], R_{2i+1} = (i, i+1), 0 \le i < K$ and $R_K^+ = (K, \infty)$ be the regions $\mathcal{R}$ of x. Let $R_h \prec R_k$ denote that region R_h precedes region R_k. For each location s,$\mathsf{Beh}(s)$ as computed in Lemma 9 is a 1-TPTL formula that gives the timed behaviour starting at s, using constraints $x \sim c$ since the point where x was frozen. In example 8, $\mathsf{Beh}(s_a) = (x < 1)\ \mathsf{U}^{\mathsf{ns}}(x > 1)$, allows symbols a, b as long as $x < 1$ keeping the control in s_a, has no behaviour at $x = 1$, and allows control to leave s_a when $x > 1$. For any s, we "distribute" $\mathsf{Beh}(s)$ across regions by untiming it. In example 8, $\mathsf{Beh}(s_a)$ is $\Box^{\mathsf{ns}}(a \vee b)$ for regions R_0, R_1, it is $\bot$ for R_2 and is $(a \vee b)$ for R_1^+. Given any $\mathsf{Beh}(s)$, and a pair of regions $R_j \preceq R_k$, such that s has a non-empty behaviour in region R_j, and control leaves s in R_k, the untimed behaviour of s between regions $R_j, \ldots, R_k$ is written as LTL formulae $\varphi_j, \ldots, \varphi_k$. This results in a "behaviour description" (or BD for short) denoted $\mathsf{BD}(s, R_j, R_k) = \{\mathsf{BD}_1, \mathsf{BD}_2, \ldots, \mathsf{BD}_w\}$[2] where each BD_i is a $2K+1$

[2] Note that if s is one of the lowest locations in the partial order, this is a singleton set. We will denote the elements of $\mathsf{BD}(s, R_j, R_k)$ as $BD_{no.}$.

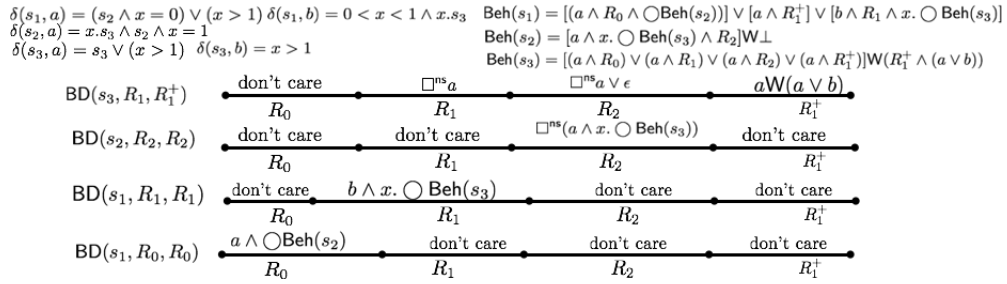

Figure 4 A po-1-clock ATA with initial location s_1 and s_2, s_3 are accepting.

tuples with $\mathsf{BD}_i[R_l] = \varphi_l$ for $j \leq l \leq k$, and $\mathsf{BD}[R] = \top$ denoting "dont care" for the other regions. Let $\mathsf{BDSet}(s)$ denote the union of all BDs for a location s. For the initial location s_0, consider all $\mathsf{BD}_i \in \mathsf{BD}(s_0, R_j, R_k)$ that have a behaviour starting in R_j, and ends in an accepting configuration in R_k. Each LTL formula $\mathsf{BD}_i[R_i]$ is replaced with a star-free rational expression denoted $\mathsf{re}(\mathsf{BD}(s_0, R_j, R_k)[R_i])$. Then $\mathsf{BD}(s_0, R_j, R_k)$ is transformed into a SfrMTL formula $\varphi(s_0, R_j, R_k) = \bigvee_{BD_i \in \mathsf{BD}(s_0,R_j,R_k)} \bigwedge_{j \leq g \leq k} \mathsf{Rat}_{R_g}\mathsf{re}(\mathsf{BD}_i[R_g])$. The language accepted by the po-1-clock ATA $\mathcal{A}$ is then given by $\bigvee_{0 \leq j \leq k \leq 2K} \varphi(s_0, R_j, R_k)$.

Computing $\mathsf{BD}(s, R_i, R_j)$ for a location s and pair of regions $R_i \preceq R_j$. We first compute $\mathsf{BD}(s, R_i, R_j)$ for locations s which are lowest in the partial order, followed by computing $\mathsf{BD}(s', R_i, R_j)$ for locations s' which are higher in the order. For any location s, $\mathsf{Beh}(s)$ has the form φ or $\varphi_1 \mathsf{W}\varphi_2$ or $\varphi_1 \mathsf{U}^{ns}\varphi_2$, where $\varphi, \varphi_1, \varphi_2$ are disjunctions of conjunctions over $\Phi(S \cup \Sigma \cup X)$, where S is the set of locations with or without the binding construct $x.$, and X is a set of clock constraints of the form $x \sim c$. Each conjunct has the form $\psi \wedge x \in R$ where $\psi \in \Phi(\Sigma \cup S)$ and $R \in \mathcal{R}$. Let $\varphi_1 = \bigvee(P_i \wedge C_i), \varphi_2 = \bigvee(Q_j \wedge E_j)$ where $P_i, Q_j \in \Phi(\Sigma \cup S)$ and $C_i, E_j \in \mathcal{R}$. Let $\mathcal{C}$ and $\mathcal{E}$ be shorthands for any C_k, E_l.

If $\mathsf{Beh}(s)$ is an expression without U, W (the case of φ above), then $\mathsf{BD}(s, R_i, R_i)$ is defined for a region R_i if $\varphi = \bigvee(Q_j \wedge E_j)$ and there is some E_l with $x \in R_i$. It is a $2K + 1$ tuple with $\mathsf{BD}(s, R_i, R_i)[R_i] = Q_l$[3]we know that , and the rest of the entries are $\top$ (for dont care). If $\mathsf{Beh}(s)$ has the form $\varphi_1 \mathsf{W}\varphi_2$ or $\varphi_1 \mathsf{U}^{ns}\varphi_2$, then for $R_i \preceq R_j$, and a location s, $\mathsf{BD}(s, R_i, R_j) = \{BD_1\}$ where BD_1 is a $2K + 1$ tuple with (i) formula $\top$ in regions $R_0, \ldots, R_{i-1}, R_{j+1}, \ldots, R_K^+$, (ii) If $C_k = E_l = (x \in R_j)$ for some C_k, E_l, then the LTL formula in region R_j is $P_k \mathsf{U}Q_l$ if s is not accepting, and is $P_k \mathsf{W}Q_l$ if s is accepting, (iii) If no C_k is equal to any E_l, and if $E_l = (x \in R_j)$ for some l, then the formula in region R_j is Q_l. If $C_m = (x \in R_i)$ for some m, then the formula for region R_i is $\Box^{ns}P_m$. If there is some $C_h = (x \in R_w)$ for $i < w < j$, then the formula in region R_w is $\Box^{ns}P_h \vee \epsilon$, where ϵ signifies that there may be no points in regions R_w. If there are no C_m's such that $C_m = (x \in R_w)$ for $R_i \prec R_w \prec R_j$, then the formula in region R_w is ϵ. ϵ is used as a *special symbol* in LTL whenever there is no behaviour in a region.

$\mathsf{BD}(s, R_i, R_j)$ for location s lowest in po. Let s be a location that is lowest in the partial order. In general, if s is the lowest in the partial order, then $\mathsf{Beh}(s)$ has the form $\varphi_1 \mathsf{W}\varphi_2$ or $\varphi_1 \mathsf{U}^{ns}\varphi_2$ or φ where $\varphi, \varphi_1, \varphi_2$ are disjunctions of conjunctions over $\Phi(\Sigma \cup X)$. Each conjunct has the form $\psi \wedge x \in R$ where $\psi \in \Phi(\Sigma)$ and $R \in \mathcal{R}$. See Figure 4, with regions

[3] We abuse the notation by indexing the $\mathsf{BD}(s, R_i, R_i)[R_i]$ instead of BD when it is a singleton set.

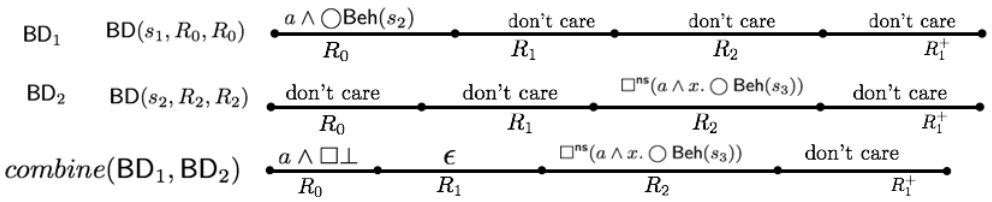

Figure 5 Combining BDs

R_0, R_1, R_2, R_1^+, and some example BDs. In Figure 4, using the BDs of the lowest location s_3, we write the SfrMTL formula for $\mathsf{Beh}(s_3)$: $\psi(s_3) = \varphi_{R_0}(s_3) \wedge \varphi_{R_1}(s_3) \wedge \varphi_{R_2}(s_3) \wedge \varphi_{R_1^+}(s_3)$, where each φ_R describes the behaviour of s_3 starting from region R. For a fixed region R_i, $\varphi_{R_i}(s_3)$ is $\bigwedge_{R_g \prec R_i} \mathsf{Rat}_{R_g}\epsilon \wedge \mathsf{Rat}_{R_i}\Sigma^+ \rightarrow \{\bigvee_{R_i \prec R_j} \varphi(s_3, R_i, R_j)\}$, where $\varphi(s_3, R_i, R_j)$ is described above. $\mathsf{Rat}_{R_g}\epsilon$ means that there is no behaviour in R_g. $\varphi_{R_0}(s_3)$ is given by $\mathsf{Rat}_{R_0}\Sigma^+ \rightarrow \{(\mathsf{Rat}_{R_0}a^* \wedge \mathsf{Rat}_{R_1}[a^* + \epsilon] \wedge \mathsf{Rat}_{R_2}[a^* + \epsilon] \wedge \mathsf{Rat}_{R_1^+}[a^* + a^*b])\}$.

$\mathsf{BD}(s, R_i, R_j)$ for a location s which is higher up . If s is not the lowest in the partial order, then $\mathsf{Beh}(s)$ can have locations $s' \in\downarrow s$. s' occurs as $\mathsf{O}(s')$ or $x.\mathsf{O}(s')$ in $\mathsf{Beh}(s)$. For $x.\mathsf{OBeh}(s_3)$ in $\mathsf{BD}(s, R_i, R_j)$, since the clock is frozen, we plug-in the SfrMTL formula $\psi(s_3)$ computed above for $x.\mathsf{OBeh}(s_3)$ in $\mathsf{BD}(s_1, R_i, R_j)$. For instance, in figure 4, $x.\mathsf{OBeh}(s_3)$ appears in $\mathsf{BD}(s_2, R_2, R_2)[R_2]$. We simply plug in the SfrMTL formula $\psi(s_3)$ in its place. Likewise, for locations s, t, if $\mathsf{OBeh}(t)$ occurs in $\mathsf{BD}(s, R_i, R_j)[R_k]$, we look up $\mathsf{BD}(t, R_k, R_l) \in \mathsf{BDSet}(t)$ for all $R_k \preceq R_l$ and *combine* $\mathsf{BD}(s, R_i, R_j), \mathsf{BD}(t, R_k, R_l)$ in a manner described below. This is done to detect if the "next point" for t has a behaviour in R_k or later.

(a) If the next point for t is in R_k itself, then we *combine* all $\mathsf{BD}_1 \in \mathsf{BD}(s, R_i, R_j)$ with every $\mathsf{BD}_2 \in \bigcup_{R_k \preceq R_l} \mathsf{BD}(t, R_k, R_l) \subseteq \mathsf{BDSet}(t)$ as follows[4]. $\mathsf{combine}(\mathsf{BD}_1, \mathsf{BD}_2)$ results in BD_3 such that $\mathsf{BD}_3[R]$=$\mathsf{BD}_1[R]$ for $R \prec R_k$, $\mathsf{BD}_3[R]$=$\mathsf{BD}_1[R] \wedge \mathsf{BD}_2[R]$ for $R_k \prec R$, where $\wedge$ denotes component wise conjunction. $\mathsf{BD}_3[R_k]$ is obtained by replacing $\mathsf{OBeh}(s_2)$ in $\mathsf{BD}_1[R_k]$ with $\mathsf{BD}_2[R_k]$. Doing so enables the next point in R_k, emulating the behaviour of t in R_k.

(b) Assume the next point for t lies in R_b, $R_k \prec R_b$. The difference with case (a) is that we combine $\mathsf{BD}_1 \in \mathsf{BD}(s, R_i, R_j)$ with $\mathsf{BD}_2 \in \bigcup_{R_k \preceq R_l} \mathsf{BD}(t, R_k, R_l) \subseteq \mathsf{BDSet}(t)$. Then $\mathsf{combine}(\mathsf{BD}_1, \mathsf{BD}_2)$ results in a BD, say BD_3 such that $\mathsf{BD}_3[R] = \mathsf{BD}_1[R]$ for $R \prec R_k$, $\mathsf{BD}_3[R] = \mathsf{BD}_1[R] \wedge \mathsf{BD}_2[R]$ for all $R_b \preceq R$, and $\mathsf{BD}_3[R] = \epsilon$ for $R_k \prec R \prec R_b$. The $\mathsf{OBeh}(t)$ in $\mathsf{BD}_1[R_k]$ is replaced with $\Box\bot$ to signify that the next point is not enabled for t. See Figure 5 where $R_b = R_2$. The conjunction with $\Box\bot$ in R_0 signifies that the next point for s_2 is not in R_0; the ϵ in R_1 signifies that there are no points in R_1 for s_2. Conjuncting $\Box\bot$ in a region signifies that the next point does not lie in this region.

We look at the "accepting" BDs in $\mathsf{BDSet}(s_0)$, viz., all $\mathsf{BD}(s_0, R_j, R_k)$, such that acceptance happens in R_k, and s_0 has a behaviour starting in R_j. The LTL formulae $\mathsf{BD}_i[R]$ [where $\mathsf{BD}_i \in \mathsf{BDSet}(s_0)$] is replaced with star-free expression $\mathsf{re}(\mathsf{BD}_i[R])$. $\mathsf{BDSet}(s_0)$ gives an SfrMTL formula φ= $\bigvee_{\mathsf{BD}_i \in \mathsf{BDSet}(s_0)} \bigwedge_{R_j \preceq R \preceq R_k} \mathsf{Rat}_R\mathsf{re}(\mathsf{BD}_i[R])$ whose language is $L(\varphi)$=$L(\mathcal{A})$. ◀

[4] Take cross product of two sets and then applying combine operation

5 Discussion

We propose RatMTL which significantly increases the expressive power of MTL and yet retains decidability over pointwise finite words. The Rat operator added to MTL syntactically subsumes several other modalities in literature including threshold counting, modulo counting and the Pnueli modality. The reduction of RatMTL to equisatisfiable MTL has elementary complexity and allows us to identify two fragments of RatMTL with 2EXPSPACE and EXPSPACE satisfiability. In [11], oversampled temporal projections were used to reduce MTL with punctual future and non-punctual past to MTL. Our reduction can be combined with the one in [11] to obtain decidability of RatMTL and elementary decidability of MITL + URat + non-punctual past. These are amongst the most expressive decidable extensions of MTL known so far. The exact complexity class for satisfiability of MITL + URat is an interesting open question. We also show an exact logic-automaton correspondence between the fragment SfrMTL and po-1-clock ATA. It is not difficult to see that full RatMTL can be reduced to equivalent 1 clock ATA. This provides an alternative proof of decidability of RatMTL but the proof will not extend to decidability of RatMTL+ non-punctual past, nor prove elementary decidability of MITL + URat+non-punctual past. Hence, we believe that our proof technique has some advantages. An interesting related formalism of timed regular expressions was defined by Asarin, Maler, Caspi, and shown to be expressively equivalent to timed automata. Our RatMTL has orthogonal expressive power, and it is boolean closed (thus the decidability of universality checking comes for free). The exact expressive power of RatMTL which is between 1-clock ATA and po-1-clock ATA is open.

Abstract

Given a linear recurrence sequence (LRS), the Skolem problem, asks whether it ever becomes zero. The decidability of this problem has been open for several decades. Currently decidability is known only for LRS of order upto 4. For arbitrary orders (i.e., number of terms the n^{th} depends on), the only known complexity result is NP-hardness by a result of Blondel and Portier from 2002.

In this paper, we give a different proof of this hardness result, which is arguably simpler and pinpoints the source of hardness. To demonstrate this, we identify a subclass of LRS for which the Skolem problem is in fact NP-complete. We show the generic nature of our lower-bound technique by adapting it to show stronger lower bounds of a related problem that encompasses many known decision problems on linear recurrent sequences.

1 Introduction

While linear dynamical systems have been studied for a long time, several interesting and computationally relevant decision problems remain unsolved. The *Skolem problem* is a long-standing open problem in mathematics which asks whether zero ever occurs in the infinite sequence generated by a given linear recurrence sequence (LRS) with specific initial conditions. The *positivity problem* asks if the values of an LRS are always positive. Both these problems have received consider attention from mathematicians and computer scientists over the years. The positivity problem is related to program termination for initialized linear loop programs [23, 8, 16], while the Skolem and its variants have been considered in probabilistic verification [1, 2, 3] among other applications. However, despite decades of active research, the problems in their full generality have remained open.

While a result of Blondel and Portier [7] showed NP-hardness for the Skolem problem, the only known positive results are for very restricted class of recurrences, with restrictions

* Supported by DFG grant TH 472/4. Part of this work was done when the author was a Postdoctoral fellow at IIT Bombay.

on either the order of the recurrence (i.e., number of terms defining the sequence) or on the roots of the characteristic polynomial associated with the recurrence. On one hand, the Skolem problem is known to be decidable for order 4 [17, 25] and positivity for degree 6 [19]. On the other hand, by restricting LRS to only considering those with distinct roots (these are called simple LRS), Ouaknine and Worrell show decidability of positivity for order 9 LRS [18] and decidability of a related variant, *ultimate positivity* (is there a point after which the LRS is always positive) [20]. Further, in [18] they show that the decidability of the the positivity problem for order 6 LRS would entail solutions to longstanding open problems on Diophantine approximations. While it is well-known and probably a folklore result ([25]) that if the roots of characteristic polynomial are real (in fact, more generally, if the LRS has a single dominant root) then Skolem and positivity are decidable, the exact complexity of these problems have not been mapped out. Indeed, it is customary for papers in the area to study LRS that are *non-degenerate* (which is when there are no two characteristic roots such that their ratio is a root of unity), since it is known that the general case reduces to this case as far as decidability is concerned.

In this paper, we focus on linear recurrence sequences, whose characteristic polynomial has roots of some special form. Our contributions are the following: we give a new NP-hardness proof for the Skolem problem by a reduction from the classic Subset Sum problem. This gives an alternate proof of NP-hardness of Skolem (as well as coNP-hardness for positivity), which matches the best lower bound known for the Skolem problem, due to Blondel and Portier [7]. A closer inspection of our proof shows that the LRS that is output by our reduction is a special subclass of LRS whose characteristic polynomial has roots that are complex roots of unity (i.e., complex numbers α such that $\alpha^n = 1$ for some integer n). We investigate this natural class of LRS and match our lower bound by showing that the Skolem problem for this class can be solved in NP. Thus, we obtain a natural subclass of LRS of arbitrary order with an NP-complete Skolem problem, which to the best of our knowledge has not been observed before. Finally, we show that both the lower bound and upper bound techniques can be lifted to other problems.

We now explain the significance of all these three results and place them in the context of existing results. We start with the hardness result, where as mentioned earlier, Blondel and Portier [7] already proved NP-Hardness of Skolem. However, our proof is of independent interest for the following reasons:

- Our proof is a direct reduction from the classical subset sum problem and is arguably simpler/shorter than the proof in [7], which goes via automata theory, by showing a reduction from universality of unary NFA.
- The proof in [7] shows NP-hardness by considering LRS whose characteristic polynomials have 0/1-coefficients. While this is indeed a simple subclass of LRS, the characteristic polynomial of such LRS could still have complex roots with phase/angle that is an irrational multiple of π. Current techniques seem inadequate to solve the Skolem and positivity problem for LRS of this kind and hence do not give effective upper bounds. In contrast, for the subclass of LRS arising from our hardness proof, the Skolem problem admits an NP algorithm. [1]
- Our NP-hardness proof can be extended to show hardness for other problems as shown in Section 4.

Next, we turn to the NP upper bound. We first note that we are able to achieve this result for LRS of arbitrary orders. All upper bounds currently known for restricted variants of the

[1] In fact, a closer inspection of Blondel and Portier's proof, reveals that their hard instances actually fall into a stricter subclass, which can be shown to be NP-complete using our techniques.

Skolem (and related problems) problem, restrict the order to a fixed constant [18] or assume that the recurrence with arbitrary order is simple [20]. Our upper bound techniques rely on basic linear algebra and complexity theory and do not need the development or application of advanced techniques from algebraic number theory and Diophantine approximation as in the other results in [18, 20]. This indeed makes our proofs more elementary, but allows for easy generalization to other problems as we show next.

Our third and final contribution is to show that our lower bound proof and the upper bound techniques can be extended. To illustrate this, we consider a related variant of the Skolem and positivity problem which we call the *polytope containment problem*. We will define this problem in the matrix form rather than in terms of LRS, while noting that we can use Cayley-Hamilton theorem and basic linear algebra to see their equivalence (see [25] for details). Recall that a *(convex) polytope* is an intersection of finitely many half-spaces and it is said to be *bounded* if the region enclosed in it is bounded. Given a bounded polytope V_1 and a (possibly unbounded) polytope V_2 over $\mathbb{Z}^d$ and a $d * d$ matrix M with integer entries, the *Integer Polytope Containment Problem* asks if for all $v \in V_1$ does there exist a positive integer n such that $vM^n \in V_2$.

There are two main motivations to look at this problem. First, it generalizes the Skolem problem, higher-order orbit problem [10] and polyhedron hitting problem [9] over integers. For the former, we set V_1 to be the initial vector and V_2 the space orthogonal to the target vector (defined as the intersection of halfspaces $\{x \mid x \cdot w \leq 0 \wedge x \cdot w \geq 0\}$). The higher-order orbit problem is obtained by fixing V_1 as the initial vector and no restrictions on V_2.

The second main motivation is that the negation of this problem is closely related to program termination of linear loops. Program termination is a classical undecidable problem, but the special case of the problem over linear loops has received considerable attention ([21] surveys these results as well as their link to linear recurrence sequences). There are two main variants of this problem. First, the initialized termination problem asks: starting from a initial vector v, is it the case that for all $n \in \mathbb{N}$, $vM^n > 0$? Next the uninitialized termination problem asks: does there exist an initial vector v such that for all $n \in \mathbb{N}$, we have $vM^n > 0$? In [23, 8], Tiwari and Braverman showed that the uninitialized problem is decidable in polynomial time for reals and integers respectively. The initialized problem, often called the positivity problem, however is still open in its fully generality though some results in restricted cases have been proved recently [18, 20, 19].

We observe that the negation of the above defined polytope containment problem is: given a bounded polytope V_1 and a polytope V_2, does there exist $v \in V_1$ such that for all $n \in \mathbb{N}$, $vM^n \notin V_2$. By fixing V_2 to be the halfspace $\{x \in \mathbb{Z}^d \mid c^T x \leq 0\}$, we obtain (i) the initialized termination problem over integers by fixing V_1 to be the singleton initial vector and (ii) the uninitialized termination problem over integers by fixing V_1 to be the entire space $\mathbb{Z}^d$. Thus, this problem generalizes both initialized and uninitialized linear program termination problems. For e.g., the following is an instance of this problem.

Given M, V_1 (a bounded polytope), c, does the following loop terminate for all $x \in V_1$

```
while c^T x > 0 do
    x ← Mx
```

Showing decidability of this problem in general would imply the decidability of the many of these longstanding open problems, including Skolem and Positivity. Nevertheless, one may ask whether looking at this general problem allows us to prove better lower bounds or/and upper bounds in restricted cases. We remark here that if we generalize V_1 to allow

unbounded polytopes, it turns out that we can encode Petri net reachability and hence this problem is EXPSPACE-hard [6]. However, this hardness result crucially depends on the unboundedness of V_1 and does not seem to work for a bounded initial space over integers.

As before, we restrict ourselves to the subclass whose characteristic roots are all complex roots of unity (or zero). We are able to then show that for this restricted class, the problem is Π_2^P-complete, building upon our lower-bound and upper-bound techniques.

2 Preliminaries

For a complex number $z = x + iy$, the absolute value and phase of the complex number are respectively denoted by $|z| = \sqrt{x^2 + y^2}$ and $arg(z) = \tan^{-1}(\frac{y}{x})$. We denote by e_i the k-dimensional standard basis vector that has 1 at the i-th position and 0 elsewhere.

2.1 Linear Recurrence Sequences

We recall some definitions and basic properties of linear recurrence sequences that will be useful in the rest of the paper. For a detailed treatment, we refer the reader to the excellent text of Everest et al. [12].

▶ **Definition 1** (Linear Recurrence Sequence)**.** A sequence $\langle u \rangle = \langle u_n \rangle_{n=0}^{\infty}$ is called a *linear recurrence sequence* (LRS) of *order* k if k is the smallest positive integer such that the n^{th} term of the sequence can be expressed as $u_n = a_{k-1}u_{n-1} + \ldots + a_1 u_{n-k-1} + a_0 u_{n-k}$, for every $n \geq k$, where $a_j \in \mathbb{Z}$ for $j \in \{0, 1, \ldots, k-1\}$ and $a_0 \neq 0$. Such a sequence is uniquely determined by the *initial conditions* $u_0, u_1, \ldots, u_{k-1}$.

An LRS $\langle u \rangle = \{u_n\}_{n=0}^{\infty}$ is said to be *periodic* with period p if $u_n = u_{n+p}$ for every $n \geq 0$. For a linear recurrence sequence $\langle u \rangle$ of order k, we denote by $||u||$, the size of the bit representation of the coefficients of $\langle u \rangle$, namely $a_0, a_1, \ldots, a_{k-1}$ and the initial conditions $u_0, u_1, \ldots, u_{k-1}$.

To every such recurrence sequence $\langle u \rangle$ above, one can associate a univariate polynomial $\chi_u(x) = x^k - a_{k-1}x^{k-1} - a_{k-2}x^{k-2} - \ldots - a_1 x - a_0$ of degree at most k. $\chi_u(x)$ is called the *characteristic polynomial* of the recurrence $\langle u \rangle$. The roots of the characteristic polynomial are called the *characteristic roots* and they yield useful information about the asymptotic behavior of the recurrence. More formally, let $\{\lambda_1, \lambda_2, \ldots, \lambda_d\}$ be the roots of $\chi_u(x)$ with multiplicity $\rho_1, \rho_2, \ldots, \rho_d$ respectively. Then the n^{th} term of such an LRS $\langle u \rangle$, denoted u_n can be expressed as

$$u_n = \sum_{j=1}^{d} q_j(n)\lambda_j^n \tag{1}$$

where $q_j(x) \in \mathbb{C}[x]$ are univariate polynomials with complex coefficients of degree at most $\rho_j - 1$ such that $\sum_{j=1}^{d} \rho_j = k$. We say an LRS is *simple* when for every j, $\rho_j = 1$. Equivalently, for a simple LRS for every j, $q_j \in \mathbb{C}$ is a constant.

Given an LRS $\langle u \rangle$ of order k with characteristic polynomial $\chi_u(x) = x^k - a_{k-1}x^{k-1} - a_{k-2}x^{k-2} - \ldots - a_1 x - a_0$, one can associate a $k \times k$ matrix M_u called the *companion matrix* of the recurrence as shown in the following figure.

$$M_u^T = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ a_0 & a_1 & a_2 & \cdots & a_{k-1} \end{bmatrix}$$

Given a vector v of dimension $k \times 1$ containing the k initial conditions of the recurrence, one can easily observe that $u_1 = e_1 M_u^T v$ and $e_1 (M_u^T)^n v$ gives u_n. Further, the eigenvalues of this matrix are exactly the roots of the characteristic polynomial of the LRS. In what follows, we sometimes abuse notation and call them as eigenvalues of the LRS. It is often useful to rewrite each λ_j in polar coordinates as $r_j e^{i\theta_j}$. In this representation, the n^{th}-term of the sequence is given by

$$u_n = \sum_{j=1}^{d} q_j(n) r_j^n e^{in\theta_j} \tag{2}$$

The following folklore lemma says that the sum and product of two LRS is an LRS (see for example, Theorem 4.1[12]). It is also known that the resulting LRS is constructible in P.

▶ **Lemma 2.** *Let $\langle u_1 \rangle, \ldots, \langle u_\ell \rangle$ be LRS of order $k_1, \ldots k_\ell$ respectively and let $\chi_{u_1}(x), \ldots, \chi_{u_\ell}(x)$ be their respective characteristic polynomials. Then the following properties hold:*

1. *$\langle u \rangle = \sum_{i=1}^{\ell} \langle u_i \rangle$ is also an LRS of order at most $\sum_{i=1}^{\ell} k_i$. Moreover, $\chi_u(x)$ is a factor of $\prod_{i=1}^{\ell} \chi_{u_i}(x)$.*
2. *$\langle u \rangle = \langle u_1 \rangle \langle u_2 \rangle$ is also an LRS of order (and $\chi_u(x)$ is of degree) at most $k_1 k_2$.*

It is an easy observation via Lemma 2, that the complement of the Skolem problem reduces to the Positivity problem (since $u_n \neq 0$ if and only if $u_n^2 > 0$ for all n).

2.2 Algebraic Numbers

We will extensively use algebraic numbers and their properties throughout the paper. We refer the reader to the excellent text by Cohen [11] for a extensive treatment of the computational aspects of algebraic number theory. Here we collect below some useful definitions and facts that are used throughout the rest of the paper.

A complex number α is called *algebraic* if there is a unique univariate polynomial $p_\alpha(x)$ with integer coefficients of minimum degree that vanishes at α. p_α is said to be the *defining polynomial* or the *minimal polynomial* of the algebraic number α. The *degree* and *height* of α are then the degree and height of p_α (Height of a polynomial is the maximum value of its coefficients). The roots of p_α are called the *Galois conjugates* of α.

▶ **Definition 3** (Roots of unity)**.** A complex number r is an n-th root of unity if $r^n = 1$ and a *primitive* n-th root of unity if in addition, n is the smallest $k \in \{1, \ldots, n\}$ for which $r^k = 1$.

▶ **Definition 4** (Cyclotomic polynomial)**.** The n-th Cyclotomic polynomial, denoted $\Phi_n(x)$ is the unique monic irreducible (over $\mathbb{Q}$) polynomial with integer coefficients that is a divisor of $x^n - 1$ and is not a divisor of $x^k - 1$ for any $k < n$. Its roots are all the n-th primitive roots of unity. Formally, $\Phi_n(x) = \prod_{\substack{1 \leq k \leq n \\ gcd(k,n)=1}} \left(x - e^{\frac{i2\pi k}{n}}\right)$.

An important relation involving Cyclotomic polynomials (See for example [5]) and primitive n-th roots of unity is that

$$x^n - 1 = \prod_{1 \le k \le n} \left(x - e^{\frac{i2\pi k}{n}}\right) = \prod_{d|n} \prod_{\substack{1 \le k \le n \\ gcd(k,n)=1}} \left(x - e^{\frac{i2\pi k}{n}}\right) = \prod_{d|n} \Phi_{n/d}(x) = \prod_{d|n} \Phi_d(x)$$

The degree of $\Phi_n(x)$ (which is also precisely the number of n-th roots of unity) is $\phi(n)$ where ϕ is Euler's totient function, $\phi(n) = |\{k \mid k \le n, \gcd(k,n) = 1\}$. An expression for $\phi(n)$ is given by $\phi(n) = n\prod_{p|n}(1 - \frac{1}{p})$. For $n \ge 2$, $\phi(n) \ge \sqrt{\frac{n}{2}}$.

2.3 Problem statements

We now formally define three problems of interest on LRS. We will define a fourth all-encompassing problem in Section 4.

▶ **Definition 5** (Skolem, Positivity, Ultimate Positivity)**.** Given a LRS $\langle u \rangle$,

- *Skolem Problem*: Decide if there exists an $n \in \mathbb{N}$ such that $u_n = 0$.
- *Positivity problem*: Decide if $u_n > 0$ for all $n \in \mathbb{N}$.
- *Ultimate Positivity problem*: Decide if there exists $n_0 \in \mathbb{N}$ s.t., $u_n > 0$ for all $n > n_0$.

As mentioned in the introduction, we consider restriction of these problems to linear recurrent sequences with special properties, namely, the roots of their characteristic polynomial (also called characteristic roots henceforth) are complex roots of unity. We denote by Skolem_ω Pos_ω UPos_ω the Skolem, Positivity and Ultimate Positivity questions respectively for linear recurrence sequences whose characteristic roots are roots of unity.

3 LRS with roots of unity – an NP-complete subclass

In this section, we consider the special subclass of linear recurrence sequences, whose characteristic roots are exactly roots of unity, and show that the Skolem problem restricted to this subclass is NP-complete.

First, we show that Skolem_ω is NP-hard, UPos_ω and Pos_ω are coNP-hard for this class. This immediately shows NP-hardness (respectively coNP-hardness) for the Skolem problem (respectively Positivity and Ultimate Positivity) for LRS of unbounded order.

▶ **Theorem 6.** Skolem_ω *is* NP*-hard and* Pos_ω *and* UPos_ω *are* coNP*-hard.*

Proof. We show a reduction from Subset Sum to Skolem_ω. Denote by $\mathsf{SUBSETSUM}(A, T)$ the following instance of the Subset Sum problem: We have a set $A = \{a_1, a_2, \ldots, a_m\}$ where $a_i \in \mathbb{N}$ and a target $T \in \mathbb{N}$. Now, $\mathsf{SUBSETSUM}(A, T) = 1$ if there exists a subset S of A whose sum is equal to T. The *Subset Sum problem*, i.e., given A, T deciding whether $\mathsf{SUBSETSUM}(A, T) = 1$, is a classic NP-complete problem [15]. We will now construct a linear recurrence sequence $\langle u_{A,T} \rangle$ over integers which has a zero i.e., there exists r such that $u_r = 0$, iff there is a set $S \subseteq T$ such that $\sum_{s \in S} a_s = T$.

We construct the LRS as follows: For every $i \in \{1, \ldots, m\}$, let p_i be the i-th-prime. Then, for each i, we have a LRS $\langle u^i \rangle$, whose n-th term is defined as

$$u^i_n = \begin{cases} 0 & \text{if } 1 \le n < p_i \\ a_i & \text{if } n = p_i \\ u^i_{n-p_i} & \text{otherwise} \end{cases}$$

This is a periodic LRS of period p_i, where the first p_i terms are $(0, 0, \ldots, a_i)$. Note that the order (and hence the degree of the characteristic polynomial) of this LRS is p_i.

We are now ready to define LRS $\langle u_{A,T} \rangle$: the n^{th} term of $\langle u_{A,T} \rangle$ is given by $\langle u_{A,T} \rangle_n = \sum_{i=1}^{m} u_n^i - T$. Since the sum of LRS is also an LRS (by Lemma 2), $u_{A,T}$ is also an LRS. Now, by the prime number theorem (see [13] for instance), it follows that the number of primes less than $n \in \mathbb{N}$ asymptotically grows as $\frac{n}{\log(n)}$, which implies that the n^{th} prime number is of magnitude $\mathcal{O}(n \log n)$. Thus, from this and Lemma 2, it follows that the order (and hence also the degree of the characteristic polynomial) of $u_{A,T}$ is at most $(\sum_{i=1}^{m} p_i) + 1 = \mathcal{O}(m^2 \log m)$ and $u_{A,T}$ can be constructed from a given instance of $\mathsf{SUBSETSUM}(A, T)$ in polynomial time. We have the following

▶ **Claim 7.** *$\langle u_{A,T} \rangle$ is zero if and only if there exists a subset $S \subseteq [m]$ such that $\sum_{s \in S} a_s = T$.*

Proof. Suppose there exists r such that $u_r = 0$. Then $\sum_{i=1}^{m} u_r^i = S$. As u_n^i can either be a_i or 0, this implies that there exists a subset $S \subseteq [m]$ such that $\sum_{s \in S} a_s = T$. This proves the forward direction of the claim. For the other direction, let us suppose there exists a subset $S \subseteq [m]$ such that $\sum_{s \in S} a_s = T$. Consider $N = \prod_{s \in S} p_s$. Then it is easy to see that u_N is precisely $\sum_{s \in S} a_s - T = 0$. ◀

This completes the NP-hardness of Skolem problem. The coNP-hardness of Positivity follows from noting that the square of a linear recurrence is also a linear recurrence. The complement of the Skolem problem reduces to the Positivity problem because $u_n \neq 0$ if and only if $u_n^2 > 0$ for all n. A closer observation of the proof of hardness yields the following important property of $u_{A,T}$: *the roots of $\chi_{u_{A,T}}$ are roots of unity.* This follows by observing that the characteristic polynomial of $\langle u^i \rangle$ is precisely $x^{p_i} - 1 = 0$. Hence all its roots are the p_i-th roots of unity. Now by Lemma 2, $\chi_{u_{A,T}}$ is a factor of the product $(x-1)\prod_{i=1}^{m}(x^{p_i} - 1)$ (here the term $x - 1$ is contributed by the integer $-T$ in the subset sum instance). The LRS $u_{A,T}$ is hence an instance[2] of Skolem_ω.

For the positivity problem, we have to square $u_{A,T}$ and since the characteristic roots of $(u_{A,T}^2)_n = \left(\beta_0 + \sum_{j=1}^{m} \beta_j e^{i\theta_j}\right)^2 = \sum_{j,\ell \in [m]} \beta_j \beta_\ell e^{i\theta_j} e^{i\theta_\ell}$, the characteristic roots of $u_{A,T}^2$ are also roots of unity. Hence the positivity problem for the LRS derived from the subset sum is actually an instance of Pos_ω. It is easy to see that for periodic LRS, the questions of positivity and ultimate positivity are equivalent. Since $u_{A,T}$ constructed in our proof is periodic, the coNP-hardness of Pos_ω also entails the same hardness for UPos_ω. ◀

To complement the hardness result from Theorem 6, we now prove that Skolem_ω(respectively Pos_ω and UPos_ω) is decidable in NP(respectively coNP). It is worthwhile to contrast this with the case of arbitrary recurrences for which decidability is open. We have the following

▶ **Theorem 8.** *Skolem_ω is in NP, Pos_ω and UPos_ω are in coNP.*

The rest of this section will prove the above theorem. We start with some basic properties. Consider the general form of the n^{th} term of an LRS as given in Equation 2. When the eigenvalues are roots of unity, this simplifies to

$$u_n = \sum_{j=1}^{d} q_j(n) e^{in\theta_j} \tag{3}$$

[2] In fact, it is easy to transform our recurrence $u_{A,T}$ in to another recurrence $u'_{A,T}$, while maintaining the property YES and NO instances of subset sum are mapped to YES and NO instance of Skolem_ω for $u'_{A,T}$, such that $u'_{A,T}$ is also a simple LRS.

where q_j are polynomials of degree at most $k-1$ and $\sum_{j=1}^{d}(\deg(q_j)+1) = k$ and $\theta_j = \frac{a_j 2\pi}{b_j}$ as roots of characteristic equation are roots of unity. In order to prove an NP upper bound, it suffices to show that there exists an $N \leq 2^{\mathsf{poly}(||u||)}$ such that if u is zero at all, then $u_N = 0$ and this can verified in P. Recall that $||u||$ denotes the size of the bit representation of the coefficients of u_n, namely $a_0, a_1, \ldots, a_{k-1}$ and the initial conditions $u_0, u_1, \ldots, u_{k-1}$. We first note a few easy observations about the characteristic roots:

▶ **Proposition 9.** *If $e^{i\theta_j}$ is a characteristic root of multiplicity ρ_j of an LRS of order k, with $\theta_j = \frac{2\pi a_j}{b_j}$, $gcd(a_j, b_j) = 1$ then*

- *For any $1 \leq a < b_j$ such that $gcd(a, b_j) = 1$, and $\theta = \frac{2\pi a}{b_j}$, $e^{i\theta}$ is also a root with multiplicity ρ_j.*
- *$\rho_j b_j \leq k^3$*

This implies that the characteristic roots can be partitioned into multisets $\vartheta_j = \{e^{\frac{i2\pi a}{b_j}} \mid gcd(a, b_j) = 1\}$ and $|\vartheta_j| = \rho_j \phi(b_j)$, where ϕ is Euler's totient function.

Proof. The elements in multiset ϑ_j are exactly $e^{i\theta_j}$ and their Galois conjugates hence they must all occur, with same multiplicity. The cardinality of such numbers is exactly $\phi(b_j) \geq \sqrt{\frac{b_j}{2}}$ (where ϕ is Euler's totient function). Since the number of roots is k and each element in ϑ_j occurs ρ_j times, we obtain that each $\rho_j \phi(b_j) \leq k$. As $\phi(b_j) \geq \sqrt{\frac{b_j}{2}}$ we get $\rho_j b_j \leq k^3$. ◀

The solution set of Skolem_ω instances are very structured given the fact that the characteristic roots are roots of unity. Consider for each $m \in \mathbb{N}$, a polynomial $P_m = \sum_{j=1}^{d} q_j(x) e^{im\theta_j}$ and let P denote the set of polynomials $\{P_m \mid m \in \mathbb{N}\}$. We have the following

▶ **Lemma 10.** *The set P is finite i.e., $P = \{P_m \mid m \in [0, k^{3k}]\}$ where $k^{3k} < 2^{\mathsf{poly}(||u||)}$.*

Proof. When characteristic roots are roots of unity, each θ_j is of the form $\frac{2\pi a_j}{b_j}$ for some (positive) integers $a_j \leq b_j$. Now $b_j \leq k^3$ by Proposition 9. Each $e^{im\theta_j} = e^{i(m+b_j)\theta_j}$ for all m, i.e., they repeat after b_j steps. Hence $P_m = P_{m+t}$ for $t = \mathrm{lcm}\{b_1, \ldots b_d\}$. Therefore $|P| \leq t = \mathrm{lcm}\{b_1, \ldots, b_d\} \leq b_1 \cdots b_d \leq k^{3k} \leq 2^{k^4}$. Since $k < \mathsf{poly}(||u||)$, the result follows. ◀

Note that even though q_j could be polynomials with complex coefficients, the coefficients of polynomials in P are rational. This is because, all the polynomials P_m evaluate to integer values at infinitely many integers via Equation 3, since the recurrence always evaluates to integer values). By interpolation, these coefficients have to be rational.

Hence deciding Skolem_ω essentially boils down to finding the union of zero sets of all the polynomials in P. This naturally leads us to the problem of bounding the coefficients of polynomials in P since this immediately yields a bound on the roots. A natural way to proceed here would be to use interpolation to bound the coefficients (see e.g., [14]). The problem with this approach is that this yields an expression for the coefficients q_{kj} of the polynomials q_j in terms of linear combinations of λ_j, which are algebraic numbers. Standard techniques (see for example, the work of Tiwari on the sign problem [24]) however, do not yield a lower bound which is exponential in d, the degree of the roots. Thus, while this suffices to obtain an NP upper bound for LRS of fixed order (where d becomes constant), for the case of unbounded order LRS, it does not yield an NP upper bound. In the next two lemmas, we show how to sidestep this issue, by crucially exploiting the fact that our characteristic roots are roots of unity.

First, note that χ_u can be written as

$$\chi_u(x) = \prod_{j=1}^{d}(x - e^{2\pi i \frac{a_j}{b_j}})^{\rho_j} = \prod_{j=1}^{D} \prod_{\substack{1\leq a\leq b_j \\ gcd(a,b_j)=1}} (x - e^{2\pi i \frac{a}{b_j}})^{\rho_j} \tag{4}$$

where D is the number of distinct values of b_j. We know from Lemma 2 that the sum of LRS is again a LRS. We obtain here a partial converse of part 1 of Lemma 2.

▶ **Lemma 11.** *Let $\langle u\rangle$ be a LRS with characteristic polynomial $\chi_u(x) = p_1(x)p_2(x)$ where p_1 and p_2 do not share a common root. Then we can find LRS $\langle u^1\rangle$ and $\langle u^2\rangle$ with characteristic polynomials p_1 and p_2 such that $\langle u\rangle = \langle u^1\rangle + \langle u^2\rangle$.*

Proof. We know that $u_n = \sum_{j=1}^{d} q_j(n)\lambda_j^n$. Let $R(p)$ denote the set of roots of polynomial $\chi_u(x)$. Since p_1 and p_2 do not share a common root i.e. $R(p_1) \cap R(p_2)$ is empty and $R(p_1) \cup R(p_2) = R(p)$, we can rewrite the exponential polynomial solution from Equation 1 as $u_n = \sum_{\lambda_j \in\ R(p_1)} q_j(n)\lambda_j^n + \sum_{\lambda_j \in\ R(p_2)} q_j(n)\lambda_j^n$.

Let us consider the set of LRS defined by the characteristic polynomial p_1 (by fixing all possible initial conditions). This is a vector space and one can see that the set $\{n^i\lambda_j^n : \lambda_j \in\ R(p_1), 0 \leq i \leq$ multiplicity of λ_j in $p_1\}$ describes a basis for this vector space. As $\sum_{\lambda_j \in\ R(p_1)} q_j(n)\lambda_j^n$ is just a linear combination of such terms, it is also a possible LRS with characteristic polynomial p_1, let us call this u_n^1. Similarly $\sum_{\lambda_j \in\ R(p_2)} q_j(n)\lambda_j^n$ defines an LRS u_n^2. Hence u_n can be written as $u_n^1 + u_n^2$. ◀

As none of the inner products in Equation 4 share a root by Lemma 11 we can break the linear recurrence as a sum of linear recurrences. Let $\langle u\rangle = \langle u^1\rangle + \ldots + \langle u^D\rangle$ where the characteristic polynomial of $\langle u^j\rangle$ is exactly $\prod_{\substack{1\leq a\leq b_j \\ gcd(a,b_j)=1}} (x - e^{2\pi i \frac{a}{b_j}})^{\rho_j}$. This is exactly the b_j^{th} cyclotomic polynomial raised to ρ_j. Note that this is a integral polynomial with coefficients bounded by poly($||u||$)-many bits. Now, we have the following:

▶ **Lemma 12.** *The first k^3 values of all u^j are* poly($||u||$)*-bit bounded rationals and can be calculated in* P*.*

Proof. The linear recurrence for u^j has degree $\phi(b_j)\rho_j$. We think of the first $\phi(b_j)\rho_j$ initial values as variables. Fixing them fixes u^j. We can express first k^3 values of u^j as integral combinations of first $\phi(b_j)\rho_j$ values. In this integral combination the weights are poly($||u||$)-bit bounded as weight $<$ (sum of coefficients of $u^j)^{k^3}$. Next we argue that these k^3 initial values of the u^j are poly($||u||$)-bit bounded rationals. We remember that sum of all u^k is u and we have k initial values of u. We know that $\sum_{j=1}^{D} \phi(b_j)\rho_j = k$ as both LHS and RHS represent number of roots of χ_u. The initial values for these D sequences can be found by setting up a system of k linear equations in k variables and solving them where each the n^{th} equation says that $\sum_{j=1}^{D} u_n^k = u_n$. Note that for u^j only first $\phi(b_j)\rho_j$ values are variables not all k, but all of them can be represented as integral combination of first $\phi(b_j)\rho_j$ values with poly($||u||$)-bit bounded weights. Note that since the initial values of $\langle u\rangle$ are given as integers as a part of the input hence they are representable in poly($||u||$)-bit. Hence for the linear equations all coefficients are poly($||u||$)-bit bounded. Hence the initial values of the D linear recurrences are also obtainable as rationals of bit length at most polynomial in $||u||$. As any of the first k^3 values is expressible as integral combinations of first $\phi(b_j)\rho_j$ values with poly($||u||$)-bit bounded weights, hence all of first k^3 values are poly($||u||$)-bit bounded. ◀

Now as we had defined P for original linear recurrence u we can define P^j for u^j. Note that $|P^j| \leq b_j < k^3$ and hence polynomially bounded in k unlike $|P|$ for which we could only give an exponential bound. Similar to P coefficients of P^j are also rationals. The degree of any polynomial is P^j is at most the multiplicity which is ρ_j.

▶ **Lemma 13.** *Coefficients of any polynomial in P^j are* $\mathsf{poly}(||u||)$*-bit bounded rationals and can be calculated in* P.

Proof. By the definition of P^j, $u_n^k = P_q^j(n)$ when n is of the form $n = bp + q$ and $0 \leq q < b$. Now we can interpolate to get coefficients of this polynomial. We need ρ_j values to interpolate where one value occurs every b_j terms. By Proposition 9 $b_j\rho_j < k^3$ and by Lemma 12 we know that first k^3 values are $\mathsf{poly}(||u||)$-bit bounded rationals. The other coefficients in the interpolation are of the form n^i where $n < k^3$ and $i < k$ hence they are also bounded by k^{3k} ($\mathsf{poly}(||u||)$-bit). So the interpolated coefficients will also be $\mathsf{poly}(||u||)$-bit bounded rationals. ◀

We are now ready to prove Theorem 8:

Proof. (of Theorem 8) First, notice that any n such that $u_n = 0$, n is a root of one of the polynomials in P. For any of these polynomials the coefficient is the sum of corresponding coefficients in P^j's, which are $\mathsf{poly}(||u||)$-bit bounded rationals by Lemma 13. Hence their sum i.e. coefficient of any polynomial in P is also $\mathsf{poly}(||u||)$-bit bounded and can be calculated P. Note that as mentioned above, this property also does not hold for arbitrary algebraic numbers. Now as the coefficients of all the polynomials in P can be represented by rational numbers in $\mathsf{poly}(||u||)$ bits hence their roots are bounded in magnitude by $2^{\mathsf{poly}(||u||)}$ (unless one of the polynomials is identically 0). As we are only interested in integer roots, this implies that any integer root n of a non-zero polynomial in P can be written in $\mathsf{poly}(||u||)$ bits. For a zero polynomial $P_m \in P$, at $n = m$ $u_n = P_m(m) = 0$ hence $n = m$ is a zero and can be written in $\mathsf{poly}(||u||)$ bits by Lemma 10. In both cases n is therefore a short ($\mathsf{poly}(||u||)$-bit bounded) certificate for the Skolem problem, guessed by an NP machine.

Now observe that for such a n, $u_n = P_m(n)$. As both the coefficients of P_m and n are $\mathsf{poly}(||u||)$-bit bounded hence u_n is also $\mathsf{poly}(||u||)$-bit bounded. Hence the guessed n can be verified in P by observing that $u_n = e_1(M_u^T)^n v$, where M_u^T is the corresponding companion matrix. $e_1(M_u^T)^n v$ can be calculated in P via repeated squaring : Since the companion matrix M also satisfies the characteristic polynomial of the recurrence by Cayley-Hamilton theorem, its entries satisfy the recurrence u_n. Hence the preceding argument that u_n is $\mathsf{poly}(||u||)$-bit bounded, also works for each of these entries of the $(M_u^T)^n$. This proves that $\mathsf{Skolem}_\omega$is in NP. To see that $\mathsf{Pos}_\omega$is in coNP note that we need the following 2 conditions to ensure positivity:

- Since the zeros of all the polynomials in the set P (which is also exponentially bounded in size) lie in the range $[0, 2^{\mathsf{poly}(||u||)}]$, it suffices to check that for all the polynomials evaluated at all the points in this range evaluate to a positive value
- All polynomials in set P are ultimately positive.

For condition 1 we need to ensure $u_n \neq 0$ for all $n \in [1, 2^{\mathsf{poly}(||u||)}]$. As u_n can be calculated in P for such an n, this can be implemented in coNP. We can ensure condition 2 for a P_m by making sure that the first non-zero coefficient in positive. By Lemma 10 we just need to ensure this for $m \in [1, 2^{\mathsf{poly}(||u||)}]$ but as coefficients for any m can be calculated in P we can implement this check also in coNP. Hence Pos_ω is in coNP. UPos_ω requires us to just check condition 2, hence it is also in coNP. ◀

Combining the above theorem with Theorem 6, we obtain our completeness results as stated, i.e., if all characteristic roots of an LRS are roots of unity, then Skolem (resp. Positivity, Ultimate Positivity) for such recurrences is NP-complete (resp. coNP-complete).

4 Integer Polytope Containment Problem

In this section, we consider a new problem on dynamical systems. We start by fixing some notation. A *(convex) polytope* is an intersection of finitely many half-spaces. A polytope is said to be *bounded* if the region enclosed in it is bounded.

▶ **Definition 14** (Integer Polytope Containment Problem)**.** Given a bounded polytope $V_1 \subset \mathbb{Z}^d$ and a (possibly unbounded) polytope $V_2 \subseteq \mathbb{Z}^d$ and a $d * d$ matrix M with integer entries, the Polytope Containment Problem asks if for all $v \in V_1$ (for $v \in \mathbb{Z}^d$), does there exist a positive integer n such that $vM^n \in V_2$.

As before, we restrict ourselves to a subclass of this problem, where the eigenvalues are all complex roots of unity.

▶ **Definition 15** ($\mathsf{Contain}_\omega$)**.** $\mathsf{Contain}_\omega$ is the subclass of Polyhedron Containment Problem when the corresponding matrix M has roots of unity and 0 as eigenvalues.

▶ **Theorem 16.** $\mathsf{Contain}_\omega$ *is* Π_2^P*-hard.*

For definitions of coNP, $\Pi_2^P$and other standard complexity classes, we refer the reader to the excellent text due to Arora and Barak [4]. Interestingly, our proof can be seen as an application or generalization of our earlier technique to obtain the reduction of the Skolem problem from the Subset Sum problem. Indeed, since we use our NP-hard instance of the Skolem for this reduction, it is not clear how we can do a similar lift from the earlier NP-hardness proof of Blondel-Portier [7], or indeed any other existing approach.

The rest of this section forms the proof of the above theorem. We start by considering the following generalized form of the subset sum (GSS) problem, which is known to be Π_2^P-complete [22]. Given two vectors $b = (b_1, \ldots b_\ell)$ and $a = (a_1, \ldots a_m)$ and $\alpha \in \mathbb{Z}$, for all $x \in \{0,1\}^\ell$, does there exist $y \in \{0,1\}^m$ such that $x \cdot b + y \cdot a = \alpha$?[3] We will also use the set notation $B = \{b_1, \ldots b_\ell\}$ and $A = \{a_1, \ldots, a_m\}$ when convenient.

Our goal is to reduce this above problem to $\mathsf{Contain}_\omega$. In order to do so, we will use the Subset-sum to Skolem_ω reduction from Section 3. Consider the LRS u_A whose n^{th} term is $\sum_{i=1}^{m} u_n^i$, where u_n^i is the LRS constructed in Section 3. We can observe the following properties about this LRS:

(F1) Each entry of u_A gives a sum of a subset of elements from A, i.e., $y \cdot a$ for some $y \in \{0,1\}^m$.

(F2) Every subset of sum of elements of A occurs as some entry of u_A.

(F3) The LRS u_A is periodic, i.e., the elements repeat after a certain period (product of the first m-primes to be precise). Thus the bound that they repeat after or the period is exponentially bounded.

(F4) The LRS u_A can be written in matrix form as a matrix M_A such that for all $n \geq 0$, $\langle u_A \rangle_{n+1} = vM^n w$ where v is the first m entries of the LRS and $w = (1, 0, \ldots 0, 0)$. Further, the roots of the characteristic polynomial of u_A (which were noted earlier to be roots of unity) are the eigenvalues of M_A. The proof of these facts follows by simple linear algebra and can be found for instance in [25]. Further, we may also observe that

[3] In fact, to be precise, [22] defines the complement of this problem.

the entries in the matrix are exponentially bounded in the input-size of the subset-sum instance and can be computed in poly-time. It follows that the sequence of numbers vM^nw for all $n \geq 0$ satisfy the three properties (F1–F3) listed above.

Given an instance of GSS problem, we will build an instance of $\mathsf{Contain}_\omega$as follows. Define a square matrix G of dimension $\ell+m+2$, as shown below. Note that the eigenvalues of G are all roots of unity and 0. This follows from the fact that G is a block upper triangular matrix hence $det(G - \lambda I) = det(I_{(\ell+1)\times(\ell+1)} - \lambda I_{(\ell+1)\times(\ell+1)})det(M_{m\times m} - \lambda I_{m\times m})det(-\lambda)$, which implies that the eigenvalues are 1, eigenvalues of M and 0. We fix V_1 to be the set of all vectors $\{(x_1, \ldots x_\ell, 1, v, 0) \mid x_i \in \{0,1\}, \text{ for all } 1 \leq i \leq \ell\}$. Note that this is a polytope, i.e., an intersection of half spaces. Next, we fix V_2 to be the polytope $\{y \in \mathbb{Z}^{\ell+m+2} \mid y \cdot e_{\ell+m+2} = 0\}$, where $e_{\ell+m+2}$ is the $\ell + m + 2$-dimension vector $(0, \ldots 0, 1)$.

$$G = \left[\begin{array}{c|c|c} I_{(\ell+1)\times(\ell+1)} & 0 & \begin{matrix} b_1 \\ b_2 \\ \vdots \\ b_\ell \\ -\alpha \end{matrix} \\ \hline 0 & M_{m\times m} & w \\ \hline 0 & 0 & 0 \end{array}\right]$$

Let $z = (x, 1, v, 0) \in V_1$ for some $x \in \{0,1\}^\ell$. By induction, we obtain that for all $n \geq 1$, $z \cdot G^n = (x, 1, v \cdot M_A^n, x \cdot b - \alpha + v \cdot M_A^{n-1} \cdot w)$. Now GSS has a solution iff for all $x \in \{0,1\}^\ell$, there exists $y \in \{0,1\}^m$ such that $x \cdot b + y \cdot a = \alpha$. From facts above, it follows that for each such $y \in \{0,1\}^m$, there exists $n \geq 0$ such that $y \cdot a = vM^nw$. In other words, GSS has a solution iff for all $x \in \{0,1\}^\ell$, there exists $n \geq 0$ such that $x \cdot b + vM^nw = \alpha$. That is, GSS has a solution iff for all $z \in V_1$, there exists $n \geq 0$ such that $z \cdot G^{n+1} \cdot e_{\ell+m+2} = 0$ iff for all $z \in V_1$, there exists $n' \geq 1$ such that $z \cdot G^{n'} \in V_2$. This gives the solution for our instance of the $\mathsf{Contain}_\omega$problem and completes the proof of correctness of the reduction.

From this we immediately obtain, that the Integer Polytope Containment Problem is Π_2^P hard. Finally, we will show that:

▶ **Theorem 17.** $\mathsf{Contain}_\omega$ *is* Π_2^P*-complete.*

Proof. We have already shown hardness for $\mathsf{Contain}_\omega$ in Theorem 16 so now we only need to show inclusion in Π_2^P. Description size of any integer value $x \in V_1$ i.e. $||x||$ is $\mathsf{poly}(||V_1||)$ where V_1 is a bounded polytope and is specified as intersection of hyperplanes. This because the corner points are solutions of linear equations which is bounded by $\mathsf{poly}(||V_1||)$-bits. Hence all integral points inside are also bounded by $\mathsf{poly}(||V_1||)$-bits. As checking if a particular $x \in V_1$ can be done P we can go over all $x \in V_1$ in coNP. After fixing x, this the problem reduces to Skolem_ω which, by Theorem 8, is in NP. Hence $\mathsf{Contain}_\omega$ is in $\mathsf{coNP}^{\mathsf{NP}} = \Pi_2^P$. ◀

While our hardness results lift to the non-integer case, our containment proofs do not extend immediately to the non-integer case. However, we conjecture that using techniques from [8], we can obtain similar decidability results, for this subclass for rational/real cases.

5 Conclusion

In this paper, we investigate linear recurrence sequences whose characteristic roots which are complex roots of unity. We show that the Skolem problem (resp. positivity, ultimate positivity) restricted to this subclass of LRS is NP-complete (resp. coNP-complete). The lower bound is via a novel reduction from subset sum, which we are also able to extend to show Π_2^P-hardness for a more general yet interesting problem on LRS. Note that this lower bound (as well as the one in [7]), requires LRS to be of arbitrary or unbounded orders. One interesting open question is whether one could show any non-trivial lower bound (e.g., NP-hardness) for LRS of a fixed order.

Our approach for upper-bounds can be extended further to tackle LRS whose characteristic roots are complex roots of any real number, i.e., complex numbers whose phases are rational multiples of π. However, we get more relaxed upper-bounds, without matching lower-bounds. While disappointing, this is not surprising since any improvement in the lower-bound would be a highly remarkable result as commented in the conclusion of [21].

Abstract

We study the computational complexity of identifying dense substructures, namely *r/2-shallow topological minors* and *r-subdivisions*. Of particular interest is the case $r = 1$, when these substructures correspond to very localized relaxations of subgraphs. Since Densest Subgraph can be solved in polynomial time, we ask whether these slight relaxations also admit efficient algorithms.

In the following, we provide a negative answer: Dense r/2-Shallow Topological Minor and Dense r-Subdivision are already NP-hard for $r = 1$ in very sparse graphs. Further, they do not admit algorithms with running time $2^{o(\mathbf{tw}^2)}n^{O(1)}$ when parameterized by the treewidth of the input graph for $r \geqslant 2$ unless ETH fails.

1 Introduction

Many structural graph theory results stem from the principle that excluding certain (dense) substructures affords algorithmic tractability [7, 8, 12, 13, 11, 16, 9, 20]. It is therefore natural to ask for each of these substructures whether computing its densest occurrence is efficiently possible. In this paper, we characterize the complexity of this problem for substructures formed by contracting short disjoint paths.

There has been significant recent work on a slightly more general substructure, r-shallow minors, which are formed by contracting disjoint connected *subgraphs* of radius at most r. Shallow minors form a gradient between the locality of subgraphs (0-shallow minors) and the global nature of (∞-shallow) minor containment. Because finding r-shallow minors of density/degeneracy at least d is polynomial time solveable at $r = 0$ [15, 14] but NP-complete at $r = \infty$ [3], one might expect the problem to be fixed-parameter tractable with respect to r. However, Dvořák proved that for any fixed $r > 0$ both variations are NP-complete already in graphs of maximum degree four and $d \geqslant 4$ ($d \geqslant 2$ if degeneracy is the measure) [10]. Accordingly, a parameterization by d also cannot possibly yield an fpt-algorithm—a sharp

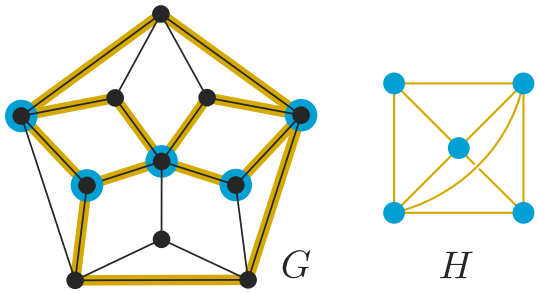

Figure 1 The graph H is a 1-shallow topological minor of G, as witnessed by the model marked with blue nails and golden paths.

contrast to unrestricted minors [3]. Dvořák further showed that the problem is in FPT if parameterized by the treewidth **tw** of the input graph and designed an $O(4^{\mathbf{tw}^2}n)$ dynamic programming algorithm.

We consider whether more conservative relaxations of subgraph containment remain efficiently solvable, specifically $r/2$-shallow *topological* minors and *r-subdivisions*. A graph H is an $r/2$-shallow topological minor of a graph G if a $(\leqslant r)$-subdivision of H is isomorphic to some subgraph of G. The case of $r = 1$ is of particular interest because it generalizes subgraphs to a proper subset of 1-shallow minors.

We show that Dense $r/2$-Shallow Topological Minor (Dense $r/2$-STM) and Dense r-Subdivision (Dense r-SD) are NP-complete already in subcubic apex-graphs[1] for $r \geqslant 1$ via a reduction from Positive 1-in-3SAT. Accordingly, a parameterization by the target density d does not make these problems fixed-parameter tractable. The same reduction also implies that neither problem can be solved in time $O(2^{o(n)})$ unless the ETH fails. In other words, finding dense substructures which are just slightly 'less local' than subgraphs seems to be intrinsically difficult. Following Dvořák's results, we then consider a parameterization by treewidth and ask whether an algorithm with running time better than $O(2^{\mathbf{tw}^2}n)$ is possible. Surprisingly, we can rule out such an algorithm already for Dense 1-Shallow Topological Minor: unless the ETH fails, no algorithm with running time $O(2^{o(\mathbf{tw}^2)}n)$ can exist.

2 Preliminaries

For a graph G we use $|G|$ to denote the number of vertices and $\|G\|$ to denote the number of edges in G. A graph H appears as an *r-subdivision* in a graph G if the graph obtained from H by subdividing every edge r times is isomorphic to some subgraph of G. Similarly, H is a *$r/2$-shallow topological minor*[2] of G if a graph obtained from H by subdividing every edge *up to* r times is isomorphic to a subgraph of G. In both cases, the subgraph witnessing the minor is the *model* and we call those vertices in it that correspond to (subdivided) edges *subdivision vertices* and all other vertices *nails*. If S_{uv} is the set of subdivision vertices on a subdivided uv edge, we say S_{uv} is *smoothed* into the uv edge.

The following two problems are the focus of this paper:

[1] That is, a graph in which the removal of a single vertex results in a subcubic planar graph.
[2] The somewhat cumbersome convention of letting an r-shallow topological minor contract paths of length $2r + 1$ is convenient in the broader context of sparse graph classes (*cf.* [18]).

Dense $r/2$-Shallow Topological Minor (Dense $r/2$-STM)

Input: A graph G and a rational number d.
Question: Is there an $r/2$-shallow topological minor H of G with density $\|H\|/|H| \geqslant d$?

Dense r-Subdivision (Dense r-SD)

Input: A graph G and a rational number d.
Question: Is there a graph H that is contained in G as an r-subdivision with density $\|H\|/|H| \geqslant d$?

The following variant, which we prove to be NP-complete in Section 4.1, might be of independent interest:

Dense Bipartite Subdivision

Input: A bipartite graph (X, Y, E) and a rational number d.
Question: Are there subsets $X' \subseteq X, Y' \subseteq Y$ such that all vertices in X' can be smoothed into unique edges in Y' and $|X'|/|Y'| \geqslant d$?

Our main tool will be linear reductions from the following SAT-variant:

Positive 1-in-3SAT

Input: A CNF boolean formula ψ with only positive literals.
Question: Does ϕ have a satisfying assignment such that each clause contains exactly one true variable?

Mulzer and Rote showed [17] that Positive 1-in-3SAT remains NP-hard when restricted to *planar* formulas. A formula ϕ is planar if the graph obtained from ϕ by creating one vertex for each clause and variable and connecting a variable-vertex to a clause-vertex if the clause contains said variable is planar.

Schaefer [21] provided a linear reduction from 3SAT to 1-in-3SAT. We can further easily transform a formula ϕ with negative literals into one with only positive literals as follows: for each variable x, introduce the variables x^+, x^-, a_x, b_x, c_x. Replace every occurrence of x with x^+ and every occurrence of $\bar{x}$ with x^- and add the clauses

$$\{x^+, x^-, a_x\}, \{x^+, x^-, b_x\}, \{a_x, b_c, c_x\},$$

to the formula. It is easy to verify that exactly one of x^+, x^- must be true in a 1-in-3 satisfying assignment and that the resulting formula ϕ' has size linear in $|\phi|$. In conclusion, there exists a linear reduction from 3SAT to Positive 1-in-3SAT which implies that under ETH, Positive 1-in-3SAT cannot be solved in time $2^{o(n)}(n+m)^{O(1)}$, where n is the number of variables and m is the number of clauses. Using sparsification one can further show that the ETH excludes algorithms for 3SAT with running time $2^{o(m)}(n+m)^{O(1)}$ (see *e.g.* the survey by Cygan *et al.* [5]). The above reduction implies the following lower bound:

▶ Proposition 1. Unless the ETH is false, Positive 1-in-3SAT cannot be solved in time $2^{o(m)}(n+m)^{O(1)}$.

3 Algorithmic considerations

We start with a basic observation about the problems in question with the smallest sensible depths of $r = 1$:

▶ **Lemma 1.** *The densest ½-shallow minor or* 1*-subdivision on a given set of nails can be computed in polynomial time.*

Proof. Assume we are to find the densest 1-subdivision with nail set X in a graph G. We construct an auxilliary bipartite graph $\hat{G}$ with vertex set $V(G) \setminus X$ and $\binom{X}{2}$ where the vertex $v \in V(G) \setminus X$ is connected to $xy \in \binom{X}{2}$ iff $\{x, y\} \subseteq N(v)$ in G, that is, if v can be contracted into the edges x, y. Now simply note that a matching of cardinality ℓ in $\hat{G}$ corresponds to a 1-subdivision in G with ℓ subdivisions. Finding a maximal matching in $\hat{G}$ therefore provides us with the densest 1-subdivision in G with nail set X. The same proof works for ½-shallow minors if we subdivide all edges existing inside X and then construct $\hat{G}$. ◀

Consequently, Dense 1-SD and Dense ½-STM both admit a simple $2^n n^{O(1)}$-algorithm: we guess the nail set X and apply the matching construction from Lemma 1. For the same reasons, both problems are in XP when parameterized by the number of nails. We cannot hope for much better since for $r = 0$ and $d \sim k^2$ we simply recover the problem of finding a k-clique. Besides being W[1]-hard and thus probably not in FPT, k-Clique further does not admit algorithms with running time $f(k)n^{o(k)}$ unless the ETH fails [4].

The approach of guessing the nail sets also fails for larger depths: knowing the nails of a, say, 1-shallow minors leaves us with the problem of contracting paths of length two into X, which cannot be represented as a simple matching problem. The reduction presented in Section 4.2 proves as a corollary that Dense 1-STM remains NP-hard when the nail set of the densest minor is known.

Finally, as we will see in Section 4.1, both problems are already NP-complete for very small densities d, making them paraNP-complete under this parameterization. Therefore none of the input variables will work well as a parameterization, and it is sensible to consider *structural* parameters, meaning parameters derived from the input graph. A good contender for such parameters are *width measures* like tree-, path-, or cliquewidth. Indeed, we can express the problem of finding a dense shallow minor or a dense subdivision in MSO_2 and apply variants of Courcelle's theorem to obtain the following:

▶ Proposition 2. Dense $r/2$-STM and Dense r-SD are in FPT when parameterized by the treewidth of the input graph.

Proof. We can express a model for an r-shallow minor in MSO_2 as follows: it consists of a vertex-set W and an edge set F, where F induces a set of paths. We can further easily express that the paths formed by F are a) of length at most r, b) disjoint, and c) have endpoints in W. Lastly, we demand that for every pair $x, y \in W$ there exists at most one path in F that has x and y as endpoints.

From an optimization perspective, we can therefore express the *feasible* solutions to Dense $r/2$-STM (and Dense r-SD with small modifications). In order to express our optimization goal, let us introduce one more set of vertices C with the property that every path induced by F contains at most one vertex from C—for example, we can express in MSO_2 that vertices of C are not pairwise reachable via the graph induced by F. With this auxilliary set, the density of the resulting minor is at least $|C|/|W|$ and exactly the density if C is maximial with respect to our choice of F. Accordingly, we find that there exists an r-shallow topological minor of density at least d if $|C| - d|W| \geqslant 0$. This constraint and the aforementioned MSO_2-description of a minor fall within the expressive power of the EMSO-framework introduced by Arnborg, Lagergren, and Seese [1] and we conclude that both Dense $r/2$-STM and Dense r-SD are fpt when parameterized by treewidth. ◀

Furthermore, it is not difficult (albeit tedious) to design a dynamic programming algorithm that solves Dense $r/2$-STM and Dense r-SD in time $2^{O(\mathbf{tw}^2)}n$. The quadratic dependence on the treewidth stems from the fact that we have to keep track of which edges we have contracted so far and there is no obvious way to circumvent this. The important question was whether any of the known techniques to reduce the complexity of connectivity-problems [6, 2, 19] could be applied here. The answer is, to our surprise, negative as we will discuss in Section 4.2.

4 Hardness results

4.1 NP-hardness and ETH lower bounds

This section will be dedicated to the proof the following theorems which both follow directly via a linear reduction from Positive 1-in-3SAT.

▶ **Theorem 2.** Dense $r/2$-STM *and* Dense r-SD *are* NP*-hard for* $r \geqslant 1$*, even when restricted to graphs that can be turned into subcubic planar graphs by deleting a single vertex.*

▶ **Theorem 3.** Dense $r/2$-STM *and* Dense r-SD *cannot be solved in time* $2^{o(n)}n^{O(1)}$ *on bipartite graphs unless the ETH fails.*

A special case of our result might be of independent interest:

▶ **Theorem 4.** Dense Bipartite Subdivision *is* NP*-hard even on instances* $\big((X, Y, E), d\big)$ *where vertices in* X *have degree at most* 3 *and* $d \geqslant 3$*.*

In the following, we present two reduction from Positive 1-in-3SAT that depend on the parity of r. We describe the reduction for $r \in \{1, 2\}$ and then argue how to modify the construction for arbitrary values of r. Note that the resulting instances are such that the densest graph H that appears as a $r/2$-shallow topological minor appears, in fact, as an r-subdivision and thus the reductions work for both problems.

Reduction for r odd

Let ψ be a Positive 1-in-3SAT instance with clauses $C_1, \dots C_m$ and variables $x_1, \dots x_p$. We assume that every variable in ψ appears in at least 3 clauses; if not, we can duplicate clauses to achieve this without changing the satisfiability of ψ. We construct a graph G from ψ in the following manner (*cf.* Figure 2):

1. For each variable x_i, create a cycle D_i with as many vertices as the frequency of x_i in ψ.
2. Create an apex-vertex a that is connected to every vertex of the cycles $D_1, \dots, D_p$.
3. For each clause $\{x_i, x_j, x_k\}$, add a vertex u_{ijk} to the graph and connect it to one vertex in D_i, D_j, D_k each that has not yet been connected to any clause-vertex.
4. Subdivide every edge appearing in the cycles $D_1, \dots, D_p$ and all edges incident to the apex a.

For easier presentation, let us color the vertices of G as follows: the vertices introduced in the first step are *white*, the vertices introduced in the third step *gray*, and the subdivision vertices created in the last step *black* (the apex vertex a remains uncolored). Note that the graph G is bipartite, where one side of the partition contains exactly the white vertices and a.

Note that if the input formula ψ is planar, then the constructed graph is planar and subcubic after removing the apex vertex a.

▶ **Lemma 5.** *If* ψ *is satisfiable then* G *has a topological minor at depth* $1/2$ *of density* $\frac{5m}{2m+1}$*.*

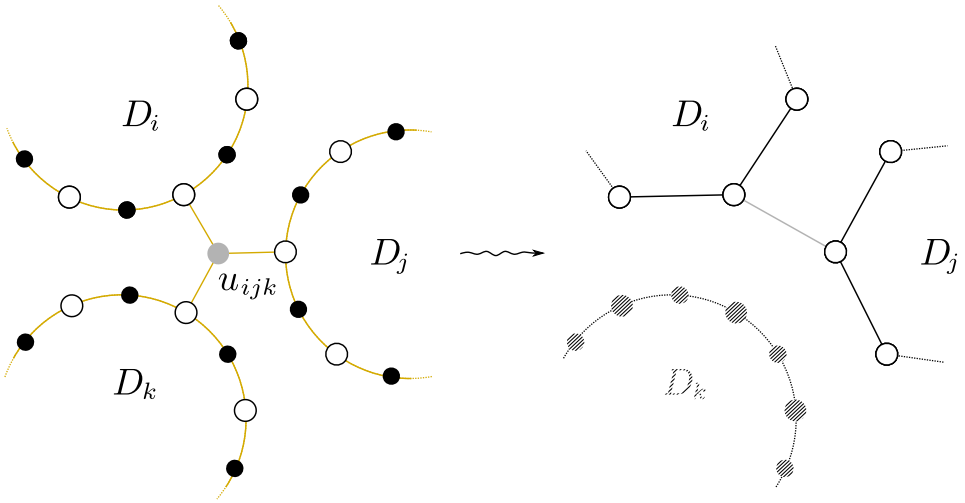

Figure 2 Three variable gadgets D_i, D_j, D_j connected by the gray clause vertex u_{ijk}. Setting variable x_k to true and x_i, x_j to false corresponds to the contractions on the right-hand side. The apex vertex a is not shown.

Proof. We construct the minor H by first smoothing each black vertex. Then, for each variable set to true, we delete the corresponding cycle D_i. Since ψ is satisfiable and each clause has exactly one variable set to true, this step deletes exactly one neighbor from each gray vertex. We complete the construction of H by smoothing out each gray vertex.

$V(H)$ consists of exactly two vertices corresponding to each clause plus the apex a, for a total of $2m+1$ vertices. Since all vertices of H were colored white in G, a has degree $2m$. Aside from the edges incident to a, there are m edges from smoothing gray vertices and $2m$ edges from smoothing black vertices, which yield a total of $5m$ edges. Thus, we have found a minor at depth $1/2$ of density $\frac{5m}{2m+1}$. ◀

▶ **Lemma 6.** *If G has a topological minor at depth $1/2$ of density at least $\frac{5m}{2m+1}$, then the formula ψ is satisfiable.*

Proof. Let H be the densest shallow topological minor at depth $1/2$ and fix some model of H in G. We first argue that the nails of H consist only of white vertex and potentially the apex vertex a.

▶ Claim. The nails of H consist of the apex vertex a and some subset of white vertices.

First, since the density of H is greater than two, its minimum degree is at least three (the removal of a degree-two vertex would increase the density). Since black vertices have degree two in G, the nails of the model forming H therefore cannot be black. Accordingly, every black vertex either does not participate in the formation of H or it is smoothed into an edge.

Let us define G_b to be the graph obtained from G by smoothing all black vertices. Since black vertices have degree exactly two, this operation is uniquely defined. By the previous observation, H can be obtained from G_b by only smoothing gray vertices and taking a subgraph. This of course implies that the nails of H are all either gray, white, or the apex vertex a. Let us now exclude the first of these three cases: assume y is a gray nail of H in G_b. Again, the degree of y in H must be at least three to ensure maximal density of H, and since y has degree three in G it must also have degree exactly three in H. Note that the three neighbors of y are necessarily white and independent in G_b, thus we can smooth y into an (arbitrary) edge between two of its neighbors. The newly obtained graph H' is again a

half-shallow topological minor of G and it contains one vertex and two edges less than H. Since the density of H is greater than two, this implies that the density of H' is greater than that of H, a contradiction. We conclude that the nails of H cannot be gray and therefore only consist of white vertices and, potentially, the apex vertex a. To see that a must be contained in H, simply note that otherwise the maximum degree of H would be three and as thus Hs density would lie strictly below the assumed $\frac{5m}{2m+1}$. In summary: H's nails consist of the apex vertex a and some subset of white vertices of G, proving the claim.

Since the white vertices in G are independent, the above claim further implies that the construction of H can be accomplished without smoothing white vertices. We can therefore divide said construction into two steps: first we smooth all gray and black vertices to construct a graph G_{gb} from G and then we take the subgraph $H \subseteq G_{gb}$. In the following, we will refer to edges in G_{gb} or H as *gray* if they originated from smoothing a gray vertex and *black* if they originated from smoothing a black vertex. Note that the set of black and gray edges partition $E(G_{gb})$ and hence also $E(H)$.

We now denote by v_4 the number of degree-four vertices in H and by v_3 the number of degree-three vertices (as observed above, no vertex with degree lower than three can exist in H and a is the only vertex of degree greater than four). Since the number of gray edges is at most m and a degree-four vertex must be incident to a gray edge, we have that $v_4 \leqslant 2m$. Let $w = v_3 + v_4$ be the number of white vertices in H and $\alpha = v_4/w$ the ratio of degree-four vertices among them. Using these quantities, we can express H's density as

$$\frac{2v_3 + {}^5\!/_2 v_4}{v_3 + v_4 + 1} = 2\frac{w}{w+1} + \frac{\alpha}{2}\frac{w}{w+1} = \Big(2 + \frac{\alpha}{2}\Big)\frac{w}{w+1}$$

which we combine with the density-requirement on H to obtain

$$\Big(2 + \frac{\alpha}{2}\Big)\frac{w}{w+1} \geqslant \frac{5m}{2m+1} \iff \alpha \geqslant 2\Big(\frac{5m}{2m+1}\frac{w+1}{w}\Big) - 4.$$

Note that the right-hand side is equal to one for $w = 2m$, smaller than one for $w > 2m$, and larger than one for $w < 2m$. This last regime would imply the impossible $\alpha > 1$ and we conclude $2m \leqslant w \leqslant 3m$, where the upper bound $3m$ is simply the total number of white vertices in G. Rewriting w as βm for $2 \leqslant \beta \leqslant 3$, we revisit the density-constraint on H:

$$\begin{aligned}\Big(2 + \frac{\alpha}{2}\Big)\frac{\beta m}{\beta m + 1} \geqslant \frac{5m}{2m+1} &\iff \Big(2\beta + \frac{\alpha\beta}{2}\Big)(2m+1) \geqslant 5(\beta m + 1) \\ &\implies (\alpha - 1)m + \frac{5}{2} \geqslant \frac{5}{\beta}. \qquad (\star)\end{aligned}$$

We will now show that α, the fraction of degree-four vertices among all w white vertices, needs to be one in order for $(\star)$ to hold. To that end, we distinguish the following two cases:

Case 1: $\beta = 2$. Assuming $\alpha \neq 1$, the largest possible value for α is achieved when $v_4 = 2m - 2$ (the case of exactly one gray edge missing from H), resulting in $\alpha = (2m-2)/2m = 1 - \frac{1}{m}$. Plugging this value of α and $\beta = 2$ into $(\star)$, we obtain that

$$(1 - 1/m - 1)m + \frac{5}{2} = -1 + \frac{5}{2} \geqslant \frac{5}{2},$$

a contradiction. Smaller values of α lead to the same contradiction, and we conclude that necessarily $\alpha = 1$.

Case 2: $2 < \beta \leqslant 3$. Assuming $\alpha \neq 1$, the largest possible value for α is achieved when $v_4 = 2m$, resulting in $\alpha = 2m/\beta m = \frac{2}{\beta}$. Now $(\star)$ becomes

$$\Big(\frac{2}{\beta} - 1\Big)m + \frac{5}{2} \geqslant \frac{5}{\beta} \iff m \leqslant \frac{10 - 5\beta}{2\beta} \cdot \frac{\beta}{2-\beta} = \frac{5}{2}.$$

Thus for formulas ψ with at least three clauses, we arrive at a contradiction and conclude that $\alpha = 1$.

We have now shown that a) H contains *only* vertices of degree four and b) that $|H| \geqslant 2m$. Since there cannot be more than $2m$ vertices of degree four, we conclude that H has exactly $2m$ vertices. Note that therefore H must consist of a collection of black-edge cycles with a total of $2m$ vertices, each of which is incident to exactly one of the m gray edges. Note that each black cycle B_i in H corresponds to a cycle D_i (associated with variable x_i) in G, where B_i was constructed from D_i by smoothing black vertices. Thus we can associate every black cycle B_i in H with a variable x_i in ψ. We claim that setting all such variables x_i that have a black cycle C_i in H to false and all other variables to true is a 1-in-3 satisfying assignment of ψ.

Consider any clause $\{x_i, x_j, x_k\}$ in ψ. The corresponding gray vertex u_{ijk} in G was smoothed into a gray edge e_{ijk} in H, since all m gray are present in H. Accordingly, exactly two of the three black cycles B_i, B_j, B_k are contained in H. Thus the assignment constructed above will set exactly two of the variables x_i, x_j, x_k to false and one variable to true. This argument holds for every clause in ψ and we conclude that the constructed assignment is 1-in-3 satisfying, proving the lemma. ◀

This concludes the reduction from Positive 1-in-3SAT. Note that an optimal solution in the reduction necessarily does not use any edges from the original graph, but only edges resulting from contractions. Therefore the reduction works for both Dense ½-STM and Dense ½-SD. As noted above, for $r = 1$ the constructed graph is bipartite. Since the latter set has degree at most three, Theorem 4 follows.

In order for the reduction to work for arbitrary odd r, we need to modify the construction in two places: first, we subdivide every edge in the clause gadget $(r-1)/2$ times. Second, instead of subdividing all edges appearing in the cycles $D_1, \ldots, D_p$ and edges incident to the apex a once, we subdivide them r times. The correctness of this reduction follows from easy modifications to Lemma 5 and 6, concluding our proof of Theorem 2 for odd values of r. Finally, to see that the above reduction also proofs Theorem 3 for odd r, simply note that the reduction results in a graph of size $\Theta(m)$ and the ETH lower bound follows from Proposition 1.

Reduction for r even

Let ψ be a Positive 1-in-3SAT instance as described above. Construct graph G in the following manner. We once again create a cycle D_i for each variable x_i, connect an apex vertex a to each vertex on the cycles, and color these vertices white. For this construction, however, we subdivide all edges between white vertices twice i.e. each white-white edge is replaced by a three-edge path. As with our previous construction, the subdivision vertices are all colored black. For each clause $C_i = \{x_j, x_k, x_\ell\}$, we add a triangle u_{ij}, u_{ij}, u_{ik} and connect it to the vertices from D_j, D_k, and D_ℓ corresponding to C_i such that u_{ij} is incident to the vertex from D_j etc. We color each of these vertices gray.

▶ **Lemma 7.** *If ψ is satisfiable then G has a topological minor at depth 1 of density $\frac{5m}{2m+1}$.*

Proof. We construct the minor H by first smoothing each black vertex. Then, for each variable set to true, we delete the corresponding cycle D_i. Since ψ is satisfiable and each clause has exactly one variable set to true, each gray triangle has two vertices of degree three and one of degree two. The degree two gray vertices are deleted, leaving the remaining gray

vertices to lie on three-edge paths between white vertices. These paths are subsequently smoothed to create white-white edges.

$V(H)$ consists of exactly two vertices corresponding to each clause plus a, for a total of $2m+1$ vertices. Since all vertices of H were colored white in G, a has degree $2m$. Aside from the edges incident to a, there are m edges from smoothing gray vertices and $2m$ edges from smoothing black vertices, which yield a total of $5m$ edges. Thus, we have found a minor at depth 1 of density $\frac{5m}{2m+1}$. ◀

▶ **Lemma 8.** *If G has a topological minor at depth 1 of density $\frac{5m}{2m+1}$ then ψ is satisfiable.*

Proof. Let H' be the densest topological minor at depth 1. For the same reasons presented in Lemma 6, H' has no black nails, and thus we can smooth all black vertices into white-white edges. This lack of black nails also implies that no white vertices can be smoothed to form a new edge incident to a gray vertex.

If H' contains all the gray and white vertices, it has $3m$ degree 4 white vertices, $3m$ degree 3 gray vertices, and a with degree $3m$ for a total of $12m$ edges and $6m+1$ vertices. This implies a density below $\frac{5m}{2m+1}$, and thus not all white and gray vertices are nails.

Since the gray vertices induce triangles, there is no way to smooth gray vertices to create a new gray-gray edge. Consider one such triangle T_i. If we smooth two vertices in T_i to create a single gray-white edge, the gray nail has degree 2 and should be deleted instead to increase the density. On the other hand, smoothing exactly one gray vertex to create a gray-white edge cause the remaining gray vertex to have degree two. Thus, any gray nail in H' is adjacent to three white vertices. Note that instead of having a gray nail, we could delete one gray vertex and smooth the other two into a white-white edge. The proof in Lemma 6 already demonstrated that forming the white-white edges is necessary to yield a density of $\frac{5m}{2m+1}$, and thus H' has no gray nails.

Since the gray vertices must be smoothed and deleted to create two degree 4 vertices and one degree 3 vertex per clause, the arguments in Lemma 6 imply that for H' to have density $\frac{5m}{2m+1}$, ψ must be satisfiable. ◀

In order for the reduction to work for arbitrary even r, we again modify the construction in two places: first, we subdivide every edge of the triangle making up the clause gadget $r/2-1$ times. Second, instead of subdividing all edges appearing in the cycles $D_1, \ldots, D_p$ and edges incident to the apex a twice, we subdivide them r times. With both cases of r even or odd covered, we conclude that Theorem 2 and Theorem 3 hold true.

4.2 Excluding a $2^{o(\mathrm{tw}^2)}n^{O(1)}$-algorithm

We show in this section that the ETH implies that we cannot get a single-exponential algorithm parameterized by treewidth for Dense $r/2$-STM for $r \geqslant 2$.

▶ **Theorem 9.** *Unless the ETH fails, there is no algorithm that decides* Dense 1-Shallow Topological Minor *on a graph with treewidth t in time $2^{o(t^2)}n^{O(1)}$.*

Our proof proceeds via a reduction from CNF-SAT. Assume that the CNF formula Φ with variables $x_1, \ldots, x_n$ and clauses $C_1, \ldots, C_m$ is such that $\sqrt{n}$ is an even integer; if not, we pad Φ with dummy variables that appear in no clauses, which does not affect the answer to Φ. Figure 3 contains a sketch of the construction outlined in the following.

Decision gadget: The reduction will use sequences of vertices connected by decision gadgets. The decision gadget is a path of three vertices d_L, d_C, d_R which we will always connect to

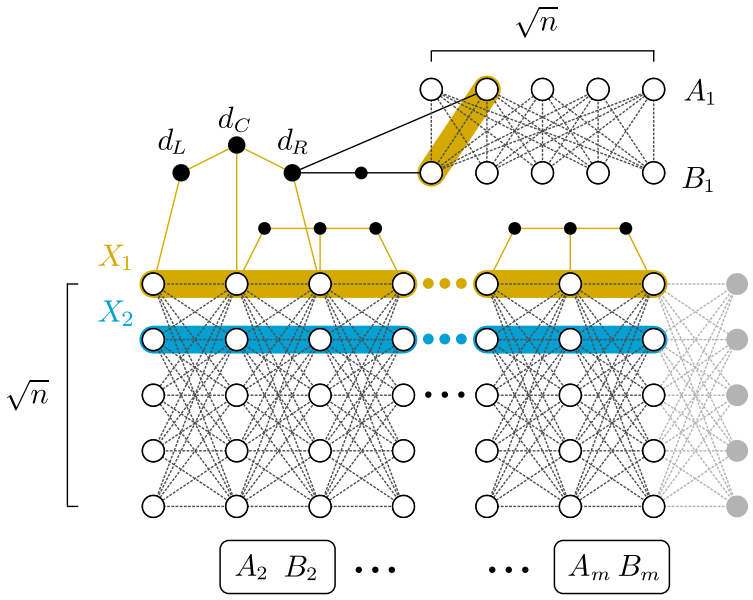

Figure 3 A sketch of the construction for Theorem 9, with an exemplary connection of the variable-path X_1 to the first clause gadget (here, x_1 appears negatively in C_1). Dashed edges denote parts that are actually connected via decision gadgets. 3-paths between the grid R and the clause gadgets (A_i, B_i) are not drawn.

a sequence of three vertices. For a sequence of vertices v_1, v_2, v_3, connecting the decision gadget to the sequence involves adding the edges $\{d_L, v_1\}$, $\{d_C, v_2\}$, and $\{d_R, v_3\}$.

Variable gadgets: We construct a grid of vertices R with $\sqrt{n}$ rows and m columns, denoting with $R[i, j]$ the vertex in the ith row and jth column. Each variable x_i will be represented by a sequence of m vertices X_i, one from each column. We will denote with $X_i[j]$ the jth vertex in the sequence X_i for any $1 \leqslant j \leqslant m$. In order to represent each of the n variables with m vertices using a $\sqrt{n} \times m$ grid, the sequences X_i must overlap and each vertex in R is part of the representation of $\sqrt{n}$ varibles. Specifically, let $X_i[j] = R[(i + j\lfloor i/\sqrt{n} \rfloor) \bmod \sqrt{n}, j]$. In other words, two vertices in successive columns will be in the same row in sequences $X_1, \ldots, X_{\sqrt{n}}$; they will be one row apart ("wrapping around" to the top from the bottom) in sequences $X_{1+\sqrt{n}}, \ldots, X_{2\sqrt{n}}$, two rows apart in $X_{1+2\sqrt{n}}, \ldots, X_{3\sqrt{n}}$, and so on.

For each sequence X_i, we connect $X_i[j-1]$, $X_i[j]$, and $X_i[j+1]$ to a decision gadget. Denote such a decision gadget as $D_{i,j}$. We also "wrap around" X_i by connecting $X_i[m-1], X_i[m], X_i[1]$ and $X_i[m], X_i[1], X_i[2]$ to their own decision gadgets.

Clause gadgets: Each clause C_i will be represented by a bipartition of vertices A_i, B_i where $|A_i| = |B_i| = \sqrt{n}$. Let $A_i[j]$ be the jth vertex in A_i and $B_i[j]$ likewise. Let σ be an ordering of the vertices in $A_i \cup B_i$ corresponding to an Eulerian tour of a biclique with bipartition A_i, B_i. Assume without loss of generality that $\sigma_i = A_i[\sqrt{n}], B_i[1], \ldots, B_i[\sqrt{n}], A_i[\sqrt{n}]$ and note that every pair of vertices $a \in A_i$ and $b \in B_i$ appears consecutively exactly once in σ. For each consecutive triple of vertices in σ_i, attach a decision gadget (but do not "wrap around").

Connecting variables and clauses: For each pair of vertices $(A_i[j], B_i[k])$ for $1 \leqslant j, k \leqslant \sqrt{n}$ assign the pair with a unique variable x_ℓ. Connect $X_\ell[i]$ to $A_i[j]$ and $B_i[k]$ via 3-edge paths. If x_ℓ appears in clause C_i positively, connect d_L of the decision gadget $D_{i,\ell}$ to $B_i[k]$ via an edge and to $A_i[j]$ via a 2-edge path. If it appears negatively, add the same connections to d_R of $D_{i,\ell}$ instead.

With the description of the reduction completed, let us now proof its correctness, *i.e.* We prove that G has a 1-STM of density $\rho = \frac{4\sqrt{n}}{3}$ if and only if Φ is satisfiable.

Forward direction: To prove the forward direction, we show how the satisfying assignment yields a topological minor of the desired density. We note that a cyclical sequence of vertices joined by decision gadgets can form a cycle in one of two ways: by smoothing each d_C and d_L or each d_C and d_R. Let the former be know as the *left configuration* of those sequenced gadgets and the latter the *right configuration*. Create a cycle on the vertices in X_i by choosing the right configuration if x_i is true and the left configuration if x_i is false.

For each clause, pick an arbitrary variable x_ℓ that satisfies it and let a and b be the pair of vertices from A_i and B_i assigned to that variable. If $a <_\sigma b$, set all decision gadgets preceding a in σ to the left configuration and all the decision gadgets succeeding b to the right configuration; do the reverse if $b <_\sigma a$. Thus A_i and B_i form a biclique missing the ab edge. Since there is a 3-edge path from a to b in G through a vertex in $D_{i,\ell}$ that has not been smoothed, we can use that path to form the ab edge. Smooth the remaining 3-edge induced paths in G and delete the vertices from the decision gadgets that were not contracted.

The nails of the resulting minor are exactly $\mathcal{A} \cup \mathcal{B} \cup R$. There are $m\sqrt{n}$ vertices in R and each one participates in $\sqrt{n}$ variable gadgets. Since each variable gadget becomes a cycle there are mn edges within R. The m clause gadgets become bicliques on $2\sqrt{n}$ vertices each and thus contain mn edges in total. Each variable gadget ends up with two edges into each clause gadget, for a total of $2mn$ edges connecting them. In total, this makes $4mn$ edges and $3m\sqrt{n}$ vertices, exactly ρ.

Reverse direction: We now prove the reverse direction by assuming Φ is unsatisfiable. Let H' be a 1-STM with density ρ. Since ρ is $\Theta(\sqrt{n})$ and the vertices in the induced paths and decision gadgets have degree at most 4, we can assume that none of those vertices appears as a nail in H'. Thus, the nail set of H' is a subset of $\mathcal{A} \cup \mathcal{B} \cup R$. The only paths between these nail candidates that use at most three edges do not contain nail candidates as interior vertices, meaning nail candidates are never smoothed. Let $H(\Phi)$ be the minor constructed by the process described in the forward direction proof for an arbitrary satisfying assignment of Φ. Observe that for fixed n and m, the minor $H(\psi)$ is identical for every satisfiable formula ψ; let $\mathcal{H}(n, m)$ be that minor. Moreover, every pair of nail candidates that has a 3-edge path between them in G is adjacent in $\mathcal{H}(n, m)$, meaning that H' is a either a subgraph of or identical to $\mathcal{H}(n, m)$.

We now show that no proper induced subgraph of $\mathcal{H}(n, m)$ has density ρ. If a graph is d-regular and connected, it has edge density $d/2$; deleting part of a degree regular graph leaves vertices with degree less than d, so no proper subgraph reaches that density. Therefore R and each $A_i \cup B_i$ achieve their maximum densities of $\sqrt{n}$ and $\sqrt{n}/2$ only when including the entire subgraph, implying a dense subgraph must contain portions of both vertex and clause gadgets. The only vehicle for increasing density is to use edges between vertex and clause gadgets, which means we should only include a vertex in R in a subgraph if it also contains its neighbors from $\mathcal{A}$ and $\mathcal{B}$. Let G' be the subgraph of G induced on an $i \times j$ subgrid of R and all of its neighbors in $\mathcal{A} \cup \mathcal{B}$. The density within the subset of $\mathcal{A} \cup \mathcal{B}$ is greatest when those vertices induce $j \times j$ bicliques, so we assume they do. Under this assumption, the density of G' is $\frac{4i}{3}$ if $j = m$ and $\frac{(4j-1)i}{3j}$ if $j < m$ since the edges that wrap around R cannot be realized. In either case, the density is strictly less than ρ unless $j = m$ and $i = \sqrt{n}$ i.e. exactly $\mathcal{H}(n, m)$.

A decision gadget connected to sequential vertices v_1, v_2, v_3 can only create the edge v_1, v_2 or the edge v_2, v_3, since d_C needs to be smoothed to construct either edge. Consequently, choosing to set some decision gadgets in the same variable gadget to opposite configurations

(or neither configuration) creates at least one fewer edge than if they were all set to the same decision. Thus, the configurations of the variable gadgets correspond to some truth assignment to Φ in the way intended in $H(\Phi)$. This indicates that there is a clause gadget that has no neighbors in a variable gadget that can be used to be smoothed into an edge in the clause gadget. However, because there is one fewer decision gadget than the number of biclique edges in the clause gadgets of $\mathcal{H}(n, m)$, H' cannot realize all possible edges in the biclique and thus there is no 1-STM of density ρ.

It stands to prove that the above reduction has the proper implications for a parameterization by treewidth. Using cops and robbers, we can show that G has treewidth $O(\sqrt{n})$ as follows: We permanently station $\sqrt{n}$ cops on the first column of R. We use $2\sqrt{n}$ cops to walk through the columns of R sequentially; when a column is completely covered with cops we can explore its corresponding clause gadget with a separate unit of $2\sqrt{n}$ cops. In total, this requires $O(\sqrt{n})$ cops. Although the formula Φ may have been padded with additional variables, it would only have been enough to increase $\sqrt{n}$ by 2. This means the number of variables in the unpadded instance is still $\Theta(n)$. Thus, if an algorithm parameterized by treewidth t could find a dense 1-STM in time $2^{o(t^2)}n^{O(1)}$, then we could use our reduction to solve CNF-SAT in time $2^{o(n)}n^{O(1)}$, violating ETH. This concludes the proof of Theorem 9.

An immediate consequence is that, unlike Dense ½-STM, Dense 1-STM is still NP-hard when the exact nail set is known.

5 Conclusion

We showed that finding dense substructures that are just slightly less local than subgraphs is computationally hard, and even a parameterization by treewidth cannot provide very efficient algorithms. While our first reduction excludes a subexponential exact algorithm assuming the ETH, we could not exclude an algorithm with a running time of $(2-\varepsilon)^n n^{O(1)}$. Is such an algorithm possible for $r = 1$, or can one find a tighter reduction that provides a corresponding SETH lower bound? Our second reduction rules out a $2^{o(\mathbf{tw}^2)}n^{O(1)}$-algorithm for $r = 2$. Is a faster algorithm for $r = 1$ possible?

Finally, we ask whether there is a sensible notion of substructures that fit in between ½-shallow topological minors and subgraphs for which we can find the densest occurrence in polynomial time.

Abstract

Multi-unit auctions are a paradigmatic model, where a seller brings multiple units of a good, while several buyers bring monetary endowments. It is well known that Walrasian equilibria do not always exist in this model, however compelling relaxations such as Walrasian envy-free pricing do. In this paper we design an optimal envy-free mechanism for multi-unit auctions with budgets. When the market is even mildly competitive, the approximation ratios of this mechanism are small constants for both the revenue and welfare objectives, and in fact for welfare the approximation converges to 1 as the market becomes fully competitive. We also give an impossibility theorem, showing that truthfulness requires discarding resources, and in particular, is incompatible with (Pareto) efficiency.

1 Introduction

Auctions are procedures for allocating goods that have been studied in economics in the 20th century, and which are even more relevant now due to the emergence of online platforms. Major companies such as Google and Facebook make most of their revenue through auctions, while an increasing number of governments around the world use spectrum auctions to allocate licenses for electromagnetic spectrum to companies. These transactions involve hundreds or thousands of participants with complex preferences, reason for which auctions require more careful design and their study has resurfaced in the computer science literature.

In this paper we study a paradigmatic model known as multi-unit auctions with budgets, in which a seller brings multiple units of a good (e.g. apples), while the buyers bring money and have interests in consuming the goods. Multi-unit auctions have been studied in a large body of literature due to the importance of the model, which already illustrates complex phenomena [16, 6, 18, 17, 19].

The main requirements from a good auction mechanism are usually computational efficiency, revenue maximization for the seller, and simplicity of use for the participants, the latter of which is captured through the notion of truthfulness. An important property that is often missing from auction design is fairness, and in fact for the purpose of maximizing revenue it is useful to impose higher payments to the buyers that are more interested in the goods. However, there are studies showing that customers are unhappy with such discriminatory prices (see, e.g., [1]), which has lead to a body of literature focused on achieving fair pricing [25, 22, 14, 23, 38].

A remarkable solution concept that has been used for achieving fairness in auctions comes from free markets, which are economic systems where the prices and allocations are not designed by a central authority. Instead, the prices emerge through a process of adjusting demand and supply such that everyone faces the same prices and the buyers freely purchase the bundles they are most interested in. When the goods are divisible, an outcome where supply and demand are perfectly balanced – known as competitive (or Walrasian) equilibrium [39] – always exists under mild assumptions on the utilities and has the property that the participants face the same prices and can freely acquire their favorite bundle at those prices. The competitive equilibrium models outcomes of large economies, where the goods are divisible and the participants so small (infinitesimal) that they have no influence on the market beyond purchasing their most preferred bundle at the current prices. Unfortunately, when the goods are indivisible, the competitive equilibrium does not necessarily exist (except for small classes of valuations see, e.g., [30, 24]) and the induced mechanism – the Walrasian mechanism [3, 13] – is generally manipulable.

A solution for recovering the attractive properties of the Walrasian equilibrium in the multi-unit model is to relax the clearing requirement of the market equilibrium, by allowing the seller to not sell all of the units. This solution is known as (Walrasian) envy-free pricing [25], and it ensures that all the participants of the market face the same prices[1], and each one purchases their favorite bundle of goods. An envy-free pricing trivially exists by pricing the goods infinitely high, so the challenge is finding one with good guarantees, such as high revenue for the seller or high welfare for the participants.

We would like to obtain envy-free pricing mechanisms that work well with strategic participants, who may alter their inputs to the mechanism to get better outcomes. To this end, we design an optimal truthful and envy-free mechanism for multi-unit auctions with budgets, with high revenue and welfare in competitive environments. Our work can be viewed as part of a general research agenda of *simplicity in mechanism design* [27], which recently proposed item pricing [4, 23] as a way of designing simpler auctions while at the same time avoiding the ill effects of discriminatory pricing [22, 1]. Item pricing is used in practice all over the world to sell goods in supermarkets or online platforms such as Amazon, which provides a strong motivation for understanding it theoretically. Other recent notions of simplicity in mechanism design include the menu-size complexity [26], the competition complexity [20], and verifiability of mechanisms (e.g. that the participants can easily convince themselves that the mechanism has a property, such as being truthful [9, 31]).

[1] The term envy-free pricing has also been used when the pricing is per-bundle, not per-item. We adopt the original definition of [25] which applies to unit-pricing, due to its attractive fairness properties [22].

1.1 Our Results

Our model is a multi-unit auction with budgets, in which a seller owns m identical units of an item. Each buyer i has a budget B_i and a value v_i per unit. The utilities of the buyers are quasi-linear up to the budget cap, while any allocation that exceeds that cap is unfeasible.

We deal with the problem of designing envy-free pricing schemes for the strongest concept of incentive compatibility, namely dominant strategy truthfulness. The truthful mechanisms are in the *prior-free* setting, i.e. they do not require any prior distribution assumptions. We evaluate the efficiency of mechanisms using the notion of *market share*, s^*, which captures the maximum buying power of any individual buyer in the market. A market share of at most 50% roughly means that no buyer can purchase more than half of the resources when competition is maximal, i.e. at the minimum envy-free price. Our main theorem can be summarized as follows.

▶ **Theorem 1** (Main Theorem (informal)). *For linear multi-unit auctions with known monetary endowments:*

- *There exists no (Walrasian) envy-free mechanism that is both truthful and non-wasteful.*
- *There exists a truthful (Walrasian) envy-free auction, which attains a fraction of at least* $\max\left\{2, \frac{1}{1-s^*}\right\}$ *of the optimal revenue and at least* $1 - s^*$ *of the optimal welfare on any market, where* $0 < s^* < 1$ *is the market share. This mechanism is optimal for both the revenue and welfare objectives when the market is even mildly competitive (i.e. with market share* $s^* \leq 50\%$*), and its approximation for welfare converges to* 1 *as the market becomes fully competitive.*

In the statement above, optimal means that there is no other truthful envy-free auction mechanism with a better approximation ratio. A mechanism is non-wasteful if it allocates as many units as possible at a given price. The impossibility theorem implies in particular that truthfulness is incompatible with Pareto efficiency. Our positive results are for *known* budgets, similarly to [16]. In the economics literature budgets are viewed as hard information (quantitative), as opposed to the valuations, which represent soft information and are more difficult to verify (see, e.g., [37]).

1.2 Related Work

The multi-unit setting has been studied in a large body of literature on auctions ([16, 6, 18, 17, 19]), where the focus has been on designing truthful auctions with good approximations to some desired objective, such as the social welfare or the revenue. Quite relevant to ours is the paper by [16], in which the authors study multi-unit auctions with budgets, however with no restriction to envy-free pricing or even item-pricing. They design a truthful auction (that uses discriminatory pricing) for *known budgets*, that achieves near-optimal revenue guarantees when the influence of each buyer in the auction is bounded, using a notion of buyer *dominance*, which is conceptually close to the market share notion that we employ. Their mechanism is based on the concept of clinching auctions [2].

Attempts at good prior-free truthful mechanisms for multi-unit auctions are seemingly impaired by their general impossibility result which states that truthfulness and efficiency are essentially incompatible when the budgets are *private*. Our general impossibility result is very similar in nature, but it is not implied by the results in [16] for the following two reasons: (a) our impossibility holds for *known* budgets and (b) our notion of efficiency is weaker, as it is naturally defined with respect to envy-free allocations only. This also means that our impossibility theorem is not implied by their uniqueness result, even for two buyers.

Multi-unit auctions with budgets have also been considered in [17] and [6], and without budgets ([19, 5, 18]); all of the aforementioned papers do not consider the envy-freeness constraint.

The effects of strategizing in markets have been studied extensively over the past few years ([7, 8, 12, 33, 34]). For more general envy-free auctions, besides the multi-unit case, there has been some work on truthful mechanisms in the literature of envy-free auctions ([25]) and ([28]) for *pair envy-freeness*, a different notion which dictates that no buyer would want to swap its allocation with that of any other buyer [32]. It is worth noticing that there is a body of literature that considers envy-free pricing as a purely optimization problem (with no regard to incentives) and provides approximation algorithms and hardness results for maximizing revenue and welfare in different auction settings [22, 15].

It is worth mentioning that the good approximations achieved by our truthful mechanism are a *prior-free setting* ([29]), i.e. we don't require any assumptions on prior distributions from which the input valuations are drawn. Good prior-free approximations are usually much harder to achieve and a large part of the literature is concerned with auctions under distributional assumptions, under the umbrella of *Bayesian mechanism design* ([10, 11, 29, 35]).

2 Preliminaries

In a linear multi-unit auction with budgets there is a set of buyers, denoted by $N = \{1, \dots, n\}$, and a single seller with m indivisible units of a good for sale. Each buyer i has a valuation $v_i > 0$ and a budget $B_i > 0$, both drawn from a discrete domain $\mathbb{V}$ of rational numbers: $v_i, B_i \in \mathbb{V}$. The valuation v_i indicates the value of the buyer for one unit of the good.

An *allocation* is an assignment of units to the buyers denoted by a vector $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{Z}_+^n$, where x_i is the number of units received by buyer i. We are interested in feasible allocations, for which: $\sum_{i=1}^{n} x_i \leq m$.

The seller will set a price p per unit, such that the price of purchasing ℓ units is $p \cdot \ell$ for any buyer. The interests of the buyers at a given price are captured by the demand function.

▶ **Definition 2** (Demand)**.** The *demand* of buyer i at a price p is a set consisting of all the possible bundle sizes (number of units) that the buyer would like to purchase at this price:

$$D_i(p) = \begin{cases} \min\{\lfloor \frac{B_i}{p} \rfloor, m\}, & \text{if } p < v_i \\ 0, \dots, \min\{\lfloor \frac{B_i}{p} \rfloor, m\}, & \text{if } p = v_i \\ 0, & \text{otherwise.} \end{cases}$$

If a buyer is indifferent between buying and not buying at a price, then its demand is a set of all the possible bundles that it can afford, based on its budget constraint.

▶ **Definition 3** (Utility)**.** The *utility* of buyer i given a price p and an allocation $\mathbf{x}$ is

$$u_i(p, x_i) = \begin{cases} v_i \cdot x_i - p \cdot x_i, & \text{if } p \cdot x_i \leq B_i \\ -\infty, & \text{otherwise} \end{cases}$$

(Walrasian) Envy-free Pricing. An allocation and price $(\mathbf{x}, p)$ represent a (Walrasian) *envy-free pricing* if each buyer is allocated a number of units in its demand set at price p, i.e. $x_i \in D_i(p)$ for all $i \in N$. A price p is an *envy-free price* if there exists an allocation $\mathbf{x}$ such that $(\mathbf{x}, p)$ is an envy-free pricing.

While an envy-free pricing always exists (just set $p = \infty$), it is not always possible to sell *all* the units in an envy-free way. We illustrate this through an example.

▶ **Example 4** (Non-existence of envy-free clearing prices)**.** Let $N = \{1, 2\}$, $m = 3$, valuations $v_1 = v_2 = 1.1$, and $B_1 = B_2 = 1$. At any price $p > 0.5$, no more than 2 units can be sold in total because of budget constraints. At $p \leq 0.5$, both buyers are interested and demand at least 2 units each, but there are only 3 units in total.

Objectives. We are interested in maximizing the *social welfare* and *revenue* objectives attained at envy-free pricing. The *social welfare* at an envy-free pricing $(\mathbf{x}, p)$ is the total value of the buyers for the goods allocated, while the *revenue* is the total payment received by the seller, i.e. $\mathcal{SW}(\mathbf{x}, p) = \sum_{i=1}^{n} v_i \cdot x_i$ and $\mathcal{REV}(\mathbf{x}, p) = \sum_{i=1}^{n} x_i \cdot p$.

Mechanisms. The goal of the seller will be to obtain money in exchange for the goods, however, it can only do that if the buyers are interested in purchasing them. The problem of the seller will be to obtain accurate information about the preferences of the buyers that would allow optimizing the pricing. Since the inputs (valuations) of the buyers are private, we will aim to design auction mechanisms that incentivize the buyers to reveal their true preferences [36].

An auction *mechanism* is a function $M : \mathbb{V}^n \to \mathbb{O} \times \mathbb{Z}_+^n$ that maps the valuations reported by the buyers to a price $p \in \mathbb{O}$, where $\mathbb{O}$ is the space from which the prices are drawn[2], and an allocation vector $\mathbf{x} \in \mathbb{Z}_+^n$.

▶ **Definition 5** (Truthful Mechanism)**.** A mechanism M is *truthful* if it incentivizes the buyers to reveal their true inputs, i.e. $u_i(M(\mathbf{v})) \geq u_i(M(v_i', v_{-i}))$, for all $i \in N$, any alternative report $v_i' \in \mathbb{V}$ of buyer i and any vector of reports v_{-i} of all the other buyers.

Requiring incentive compatibility from a mechanism can lead to worse revenue, so our goal will be to design mechanisms that achieve revenue close to that attained in the pure optimization problem (of finding a revenue optimal envy-free pricing without incentive constraints).

Types of Buyers. The next definitions will be used extensively in the paper. Buyer i is said to be *hungry* at price p if $v_i > p$ and *semi-hungry* if $v_i = p$. Given an allocation $\mathbf{x}$ and a price p buyer i is *essentially hungry* if it is either semi-hungry with $x_i = \min\{\lfloor B_i/p \rfloor, m\}$ or hungry. In other words, a buyer is essentially hungry if its value per unit is at least as high as the price per unit and, moreover, the buyer receives the largest non-zero element in its demand set.

3 An optimal envy-free and truthful mechanism

In this section, we present our main contribution, an envy-free and truthful mechanism, which is optimal among all truthful mechanisms and achieves small constant approximations to the optimal welfare and revenue. The approximation guarantees are with respect to the *market-share* s^*, which intuitively captures the maximum purchasing power of any individual buyer in the auction. The formal definition is postponed to the corresponding subsection.

[2] In principle the spaces $\mathbb{V}$ and $\mathbb{O}$ can be the same but for the purpose of getting good revenue and welfare, it is useful to have the price to be drawn from a slightly larger domain; see Section 3.

▶ **Theorem 6.** *There exists a truthful (Walrasian) envy-free auction, which attains a fraction of at least*

- $\max\left\{2, \frac{1}{1-s^*}\right\}$ *of the optimal revenue, and*
- $1 - s^*$ *of the optimal welfare*

on any market. This mechanism is optimal for both the revenue and welfare objectives when the market is even mildly competitive (i.e. with market share $s^* \leq 50\%$), and its approximation for welfare converges to 1 *as the auction becomes fully competitive.*

Consider the following mechanism.

All-or-Nothing:

Given as input the valuations of the buyers, let p be the minimum envy-free price and $\mathbf{x}$ the allocation obtained as follows:

- For every hungry buyer i, set x_i to its demand.
- For every buyer i with $v_i < p$, set $x_i = 0$.
- For every semi-hungry buyer i, set $x_i = \lfloor B_i/p \rfloor$ if possible, otherwise set $x_i = 0$ taking the semi-hungry buyers in lexicographic order.

In other words, the mechanism always outputs the minimum envy-free price but if there are semi-hungry buyers at that price, they get either all the units they can afford at this price or 0, even if there are still available units, after satisfying the demands of the hungry buyers.

▶ **Lemma 7.** *The minimum envy-free price does not exist when the price domain is* $\mathbb{R}$.

Proof. If the price can be any real number, consider an auction with $n = 2$ buyers, $m = 2$ units, valuations $v_1 = v_2 = 3$ and budgets $B_1 = B_2 = 2$. At any price $p \leq 1$, there is overdemand since each buyer is hungry and demands at least 2 units, while there are only 2 units in total. At any price $p \in (1, 2]$, each buyer demands at most one unit due to budget constraints, and so all the prices in the range $(1, 2]$ are envy-free. This is an open set, and so there is no minimum envy-free price. Note however, that by making the output domain discrete, e.g. with 0.1 increments starting from zero, then the minimum envy-free price output is 1.01. At this price each buyer purchases 1 unit. ◀

Given the example above, we will consider the discrete domain $\mathbb{V}$ as an infinite grid with entries of the form $k \cdot \epsilon$, for $k \in \mathbb{N}$ and some sufficiently small[3] ϵ. For the output of the mechanism, we will assume a slightly finer grid, e.g. with entries $k \cdot \delta = k(\epsilon/2)$, for $k \in \mathbb{N}$. The minimum envy-free price can be found in time which is polynomial in the input and $\log(1/\epsilon)$, using binary search[4] and the mechanism is optimal with respect to discrete domain that we operate on. Operating on a grid is actually without loss of generality in terms of the objectives; even if we compare to the optimal on the continuous domain, if our discretization is fine enough, we don't lose any revenue or welfare. This is established by the following theorem; the proof is omitted due to lack of space (see full version).

[3] For most of our results, any discrete domain is sufficient for the results to hold; for some results we will need to a number of grid points that polynomial in the size of the input grid.

[4] In the full version, we describe a faster procedure that finds the minimum envy-free without requiring to do binary search over the grid.

▶ **Theorem 8.** *When the valuation and budget of each buyer are drawn from a discrete grid with entries $k \cdot \epsilon$, and the price is is drawn from a finer grid with entries $k \cdot \epsilon/2$, for $k \in \mathbb{N}$, then the welfare and revenue loss of the* All-or-Nothing *mechanism due to the discretization of the output domain is zero. The mechanism always runs in time polynomial in the input and* $\log(1/\epsilon)$.

Truthfulness of the All-or-Nothing Mechanism

The following theorem establishes the truthfulness of All-or-Nothing.

▶ **Theorem 9.** *The* All-or-Nothing *mechanism is truthful.*

Proof. First, we will prove the following statement. If p is any envy-free price and p' is an envy-free price such that $p \leq p'$ then the utility of any essentially hungry buyer i at price p is at least as large as its utility at price p'. The case when $p' = p$ is trivial, since the price (and the allocation) do not change. Consider the case when $p < p'$. Since p is an envy-free price, buyer i receives the maximum number of items in its demand. For a higher price p', its demand will be at most as large as its demand at price p and hence its utility at p' will be at most as large as its utility at p.

Assume now for contradiction that Mechanism All-or-Nothing is not truthful and let i be a deviating buyer who benefits by misreporting its valuation v_i as v_i' at some valuation profile $\mathbf{v} = (v_1, \ldots, v_n)$, for which the minimum envy-free price is p. Let p' be the new minimum envy free price and let $\mathbf{x}$ and $\mathbf{x}'$ be the corresponding allocations at p and p' respectively, according to All-or-Nothing. Let $\mathbf{v}' = (v_i', v_{-i})$ be the valuation profile after the deviation.

We start by arguing that the deviating buyer i is essentially hungry. First, assume for contradiction that i is neither hungry nor semi-hungry, which means that $v_i < p$. Clearly, if $p' \geq p$, then buyer i does not receive any units at p' and there is no incentive for manipulation; thus we must have that $p' < p$. This implies that every buyer j such that $x_j > 0$ at price p is hungry at price p' and hence $x_j' \geq x_j$. Since the demand of all players does not decrease at p', this implies that p' is also an envy-free price on instance $\mathbf{v}$, contradicting minimality of p.

Next, assume that buyer i is semi-hungry but not essentially hungry, which means that $v_i = p$ and $x_i = 0$, by the allocation of the mechanism. Again, in order for the buyer to benefit, it has to hold that $p' < p$ and $x_i' > 0$ which implies that $x_i' = \lfloor B_i/p' \rfloor$, i.e. buyer i receives the largest element in its demand set at price p'. But then, since $p' < p$ and p' is an envy-free price, buyer i could receive $\lfloor B_i/p \rfloor$ units at price p without violating the envy-freeness of p, in contradiction with each buyer i being essentially hungry at p.

From the previous two paragraphs, the deviating buyer must be essentially hungry. This means that $x_i > 0$ and $v_i \geq p$. By the discussion in the first paragraph of the proof, we have $p' < p$. Since $x_i > 0$, the buyer does not benefit from reporting v_i' such that $v_i' < p'$. Thus it suffices to consider the case when $v_i' \geq p'$. We have two subcases:

- $v_i' > p$: Buyer i is essentially hungry at price p according to v_i and hungry at price p' according to v_i'. The reports of the other buyers are fixed and B_i is known; similarly to above, price p' is an envy-free price on instance $\mathbf{v}$, contradicting the minimality of p.

- $v_i' = p'$: Intuitively, an essentially hungry buyer at price p is misreporting its valuation as being lower trying to achieve an envy-free price p' equal to the reported valuation. Since $v_i' = p'$, Mechanism All-or-Nothing gives the buyer either as many units as it can afford at this price or zero units. In the first case, since p' is envy-free and B_i is known,

buyer i at price p' receives the largest element in its demand set and since the valuations of all other buyers are fixed, p' is also an envy-free price on input $\mathbf{v}$, contradicting the minimality of p. In the second case, the buyer does not receive any units and hence it does not benefit from misreporting.

Thus there are no improving deviations, which concludes the proof of the theorem. ◀

Performance of the All-or-Nothing Mechanism

Next, we show that the mechanism has a good performance for both objectives. We measure the performance of a truthful mechanism by the standard notion of approximation ratio, i.e.

$$\text{ratio(M)} = \sup_{\mathbf{v}\in\mathbb{R}^{\mathbf{n}}} \frac{\max_{\mathbf{x},p} \mathcal{OBJ}(\mathbf{v})}{\mathcal{OBJ}(M(\mathbf{v}))},$$

where $\mathcal{OBJ} \in \{\mathcal{SW}, \mathcal{REV}\}$ is either the social welfare or the revenue objective. Obviously, a mechanism that outputs a pair that maximizes the objectives has approximation ratio 1. The goal is to construct truthful mechanisms with approximation ratio as close to 1 as possible.

We remark here that for the approximation ratios, we only need to consider valuation profiles that are not "trivial", i.e. input profiles for which at any envy-free price, no hungry or semi-hungry buyers can afford a single unit and hence the envy-free price can be anything; on trivial profiles, both the optimal price and allocation and the price and allocation output by Mechanism All-or-Nothing obtain zero social welfare or zero revenue.

Market Share. A well-known notion for measuring the competitiveness of a market is the *market share*, understood as the percentage of the market accounted for by a specific entity (see, e.g., [21], Chapter 2).

In our model, the maximum purchasing power (i.e. number of units) of any buyer in the auction occurs at the minimum envy-free price, p_{min}. By the definition of the demand, there are many ways of allocating the semi-hungry buyers, so when measuring the purchasing power of an individual buyer we consider the maximum number of units that buyer can receive, taken over the set of all feasible maximal allocations at p_{min}. Let this set be $\mathcal{X}$. Then the market share of buyer i can be defined as:

$$s_i = \max_{\mathbf{x}\in\mathcal{X}} \left(\frac{x_i}{\sum_{k=1}^{n} x_k} \right).$$

Then, the *market share* is defined as $s^* = \max_{i=1}^{n} s_i$. Roughly speaking, a market share $s^* \leq 1/2$ means that a buyer can never purchase more than half of the resources.

▶ **Theorem 10.** *The* All-or-Nothing *mechanism approximates the optimal revenue within a factor of* 2 *whenever the market share,* s^**, is at most* 50%*.*

Proof. Let OPT be the optimal revenue, attained at some price p^* and allocation $\mathbf{x}$, and $\mathcal{REV}(AON)$ the revenue attained by the All-or-Nothing mechanism. By definition, mechanism All-or-Nothing outputs the minimum envy-free price p_{min}, together with an allocation $\mathbf{z}$. For ease of exposition, let $\alpha_i = B_i/p_{min}$ and $\alpha_i^* = B_i/p^*$, $\forall i \in N$. There are two cases, depending on whether the optimal envy-free price, p^*, is equal to the minimum envy-free price, p_{min}:

Case 1: $p^* > p_{min}$. Denote by L the set of buyers with valuations at least p^* that can afford at least one unit at the optimal price. Note that the set of buyers that get allocated

at p_{min} is a superset of L. Moreover, the optimal revenue is bounded by the revenue attained at the (possibly infeasible) allocation where all the buyers in L get the maximum number of units in their demand. These observations give the next inequalities:

$$\mathcal{REV}(AON) \geq \sum_{i \in L} \lfloor \alpha_i \rfloor \cdot p_{min} \quad \text{and} \quad OPT \leq \sum_{i \in L} \lfloor \alpha_i^* \rfloor \cdot p^*.$$

Then the revenue is bounded by:

$$\begin{aligned} \frac{\mathcal{REV}(AON)}{OPT} &\geq \frac{\sum_{i \in L} \lfloor \alpha_i \rfloor \cdot p_{min}}{\sum_{i \in L} \lfloor \alpha_i^* \rfloor \cdot p^*} \geq \frac{\sum_{i \in L} \lfloor \alpha_i \rfloor \cdot p_{min}}{\sum_{i \in L} \alpha_i^* \cdot p^*} = \frac{\sum_{i \in L} \lfloor \alpha_i \rfloor \cdot p_{min}}{\sum_{i \in L} B_i} \\ &= \frac{\sum_{i \in L} \lfloor \alpha_i \rfloor}{\sum_{i \in L} \alpha_i} \geq \frac{\sum_{i \in L} \lfloor \alpha_i \rfloor}{\sum_{i \in L} 2 \lfloor \alpha_i \rfloor} = \frac{1}{2}, \end{aligned}$$

where we used that the auction is non-trivial, i.e. for any buyer $i \in L$, $\lfloor \alpha_i \rfloor \geq 1$, and so $\alpha_i \leq \lfloor \alpha_i \rfloor + 1 \leq 2 \lfloor \alpha_i \rfloor$.

Case 2: $p^* = p_{min}$. The hungry buyers at p_{min}, as well as the buyers with valuations below p_{min}, receive identical allocations under All-or-Nothing and the optimal allocation, $\mathbf{x}$. However there are multiple ways of assigning the semi-hungry buyers to achieve an optimal allocation. Recall that $\mathbf{z}$ is the allocation made by All-or-Nothing. Without loss of generality, we can assume that $\mathbf{x}$ is an optimal allocation with the property that $\mathbf{x}$ is a superset of $\mathbf{z}$ and the following condition holds:

- *the number of buyers not allocated under* $\mathbf{z}$*, but that are allocated under* $\mathbf{x}$*, is minimized.*

We argue that $\mathbf{x}$ allocates at most one buyer more compared to $\mathbf{z}$. Assume by contradiction that there are at least two semi-hungry buyers i and j, such that $0 < x_i < \lfloor \alpha_i \rfloor$ and $0 < x_j < \lfloor \alpha_j \rfloor$. Then we can progressively take units from buyer j and transfer them to buyer i, until either buyer i receives $x_i' = \lfloor \alpha_i \rfloor$, or buyer j receives $x_j' = 0$. Hence we can assume that the set of semi-hungry buyers that receive non-zero, non-maximal allocations in the optimal solution $\mathbf{x}$ is either empty or a singleton. If the set is empty, then All-or-Nothing is optimal. Otherwise, let the singleton be ℓ; denote by $\tilde{x}_\ell$ the maximum number of units that ℓ can receive in any envy-free allocation at p_{min}. Since the number of units allocated by any maximal envy-free allocation at p_{min} is equal to $\sum_{i=1}^n x_i$, but $x_\ell \leq \tilde{x}_\ell$, we get:

$$\frac{x_\ell}{\sum_{i=1}^n x_i} \leq \frac{\tilde{x}_\ell}{\sum_{i=1}^n x_i} = s_i^*.$$

Thus

$$\begin{aligned} \frac{\mathcal{REV}(AON)}{OPT} &= \frac{OPT - x_\ell \cdot p_{min}}{OPT} \geq \frac{OPT - \tilde{x}_\ell \cdot p_{min}}{OPT} = 1 - \frac{\tilde{x}_\ell \cdot p_{min}}{\sum_{i=1}^n x_i \cdot p_{min}} \\ &= 1 - \frac{\tilde{x}_\ell}{\sum_{i=1}^n x_i} = 1 - s_i^* \geq 1 - s^* \end{aligned}$$

Combining the two cases, the bound follows. This completes the proof. ◀

▶ **Corollary 11.** *The performance of the* All-or-Nothing *mechanism is* $\max\{2, 1/(1-s^*)\}$ *on any market (i.e. with market share* $0 < s^* < 1$*).*

Proof. From the proof of Theorem 10, since the arguments of Case 1 do not use the market share s^*, it follows that the ratio of All-Or-Nothing for the revenue objective can alternatively be stated as $\max\{2, 1/(1-s^*)\}$ and therefore it degrades gracefully with the increase in the market share. ◀

The next theorem establishes that the approximation ratio for welfare is also constant.

▶ **Theorem 12.** *The approximation ratio of Mechanism* All-or-Nothing *with respect to the social welfare is at most* $1/(1-s^*)$*, where the market share* $s^* \in (0,1)$*. The approximation ratio goes to* 1 *as the market becomes fully competitive.*

Proof. For social welfare we have, similarly to Theorem 10, that

$$\frac{\mathcal{SW}(AON)}{OPT} = \frac{OPT - x_\ell \cdot v_\ell}{OPT} \geq \frac{OPT - \tilde{x}_\ell \cdot v_\ell}{OPT} = 1 - \frac{\tilde{x}_\ell \cdot v_\ell}{\sum_{i=1}^n x_i \cdot v_i} \geq 1 - \frac{\tilde{x}_\ell \cdot v_\ell}{\sum_{i=1}^n x_i \cdot v_\ell}$$
$$= 1 - \frac{\tilde{x}_\ell}{\sum_{i=1}^n x_i} = 1 - s_i^* \geq 1 - s^*,$$

where OPT is now the optimal welfare, $\mathbf{x}$ the corresponding allocation at OPT, and we used the fact that $v_\ell \leq v_i$ for all $i \in L$. ◀

Finally, All-or-Nothing is optimal among all truthful mechanisms for both objectives whenever the market share s^* is at most $1/2$.

▶ **Theorem 13.** *Let* M *be any truthful mechanism that always outputs an envy-free pricing scheme. Then the approximation ratio of* M *for the revenue and the welfare objective is at least* $2 - \frac{4}{m+2}$.

Proof. Consider an auction with equal budgets, B, and valuation profile $\mathbf{v}$. Assume that buyer 1 has the highest valuation, v_1, buyer 2 the second highest valuation v_2, with the property that $v_1 > v_2 + \epsilon$, where ϵ is set later. Let $v_i < v_2$ for all buyers $i = 3, 4, \ldots, n$. Set B such that $\lfloor \frac{B}{v_2} \rfloor = \frac{m}{2} + 1$ and ϵ such that $\lfloor \frac{B}{v_2+\epsilon} \rfloor = \frac{m}{2}$. Informally, the buyers can afford $\frac{m}{2} + 1$ units at prices v_2 and $v_2 + \epsilon$. Note that on this profile, Mechanism All-or-Nothing outputs price v_2 and allocates $\frac{m}{2} + 1$ units to buyer 1. For a concrete example of such an auction, take $m = 12$, $v_1 = 1.12$, $v_2 = 1.11$ (i.e. $\epsilon = 0.01$) and $B = 8$ (the example can be extended to any number of units with appropriate scaling of the parameters).

Let M be any truthful mechanism, p_M its price on this instance, and p^* the optimal price (with respect to the objective in question). The high level idea of the proof, for both objectives, is the following. We start from the profile $\mathbf{v}$ above, where $p_{min} = v_2$ is the minimum envy-free price, and argue that if $p^* \neq v_2$, then the bound follows. Otherwise, $p^* = v_2$, case in which we construct a series of profiles $\mathbf{v}, \mathbf{v}^{(1)}, \mathbf{v}^{(2)}, \ldots, \mathbf{v}^{(k)}$ that only differ from the previous profile in the sequence by the reported valuation $v_2^{(j)}$ of buyer 2. We argue that in each such profile, either the mechanism allocates units to buyer 1 only, case in which the bound is immediate, or buyer 2 is semi-hungry. In the latter case, truthfulness and the constraints on the number of units will imply that any truthful mechanism must allocate to buyer 2 zero items, yielding again the required bound.

First, consider the social welfare objective. Observe that for the optimal price p^* on profile $\mathbf{v}$, it holds that $p^* = v_2$. We have a few subcases:

Case 1: $p_M < v_2$. Then M is not an envy-free mechanism, since in this case there would be over-demand for units.

Case 2: $p_M > v_2$: Then M allocates units only to buyer 1, achieving a social welfare of at most $(\frac{m}{2} + 1)v_2$. The maximum social welfare is $m \cdot v_2$, so the approximation ratio of M is at least $\frac{m}{(m/2)+1} = 2 - \frac{4}{m+2}$.

Case 3: $p_M = v_2$: Let x_2 be the number of units allocated to buyer 2 at price v_2; note that since buyer 2 is semi-hungry at v_2, any number of units up to $\frac{m}{2} - 1$ is a valid allocation. If $x_2 = 0$, then M allocates units only to buyer 1 at price v_2 and for the same reason as in Case 2, the ratio is greater than or equal to $2 - \frac{4}{m+2}$; so we can assume $x_2 \geq 1$.

Next, consider valuation profile $\mathbf{v}^{(1)}$ where for each buyer $i \neq 2$, we have $v_i^{(1)} = v_i$, while for buyer 2, $v_2 < v_2^{(1)} < v_2 + \epsilon$. By definition of B, the minimum envy-free price on $\mathbf{v}^{(1)}$ is $v_2^{(1)}$. Let $p_M^{(1)}$ be the price output by M on valuation profile $\mathbf{v}^{(1)}$ and take a few subcases:

(a) $p_M^{(1)} > v_2^{(1)}$: Then using the same argument as in Case 2, the approximation is at least $2 - \frac{4}{m+2}$.

(b) $p_M^{(1)} < v_2^{(1)}$: This cannot happen because by definition of the budgets, $v_2^{(1)}$ is the minimum envy-free price.

(c) $p_M^{(1)} = v_2^{(1)}$: Let $x_2^{(1)}$ be the number of units allocated to buyer 2 at profile $\mathbf{v^{(1)}}$; we claim that $x_2^{(1)} \geq 2$. Otherwise, if $x_2^{(1)} \leq 1$, then on profile $\mathbf{v}^{(1)}$ buyer 2 would have an incentive to report v_2, which would move the price to v_2, giving buyer 2 at least as many units (at a lower price), contradicting truthfulness.

Consider now a valuation profile $\mathbf{v}^{(2)}$, where for each buyer $i \neq 2$, it holds that $v_i^{(2)} = v_i^{(1)} = v_i$ and for buyer 2 it holds that $v_2^{(1)} < v_2^{(2)} < v_2 + \epsilon$. For the same reasons as in Cases a-c, the behavior of M must be such that:

- the price output on input $\mathbf{v}^{(2)}$ is $v_2^{(2)}$ (otherwise M only allocates to buyer 1, and the bound is immediate), and
- the number of units $x_2^{(2)}$ allocated to buyer 2 is at least 3 (otherwise truthfulness would be violated).

By iterating through all the profiles in the sequence constructed in this manner, we arrive at a valuation profile $\mathbf{v}^{(k)}$ (similarly constructed), where the price is $v_2^{(k)}$ and buyer 2 receives at least $m/2$ units. However, buyer 1 is still hungry at price $v_2^{(k)}$ and should receive at least $\frac{m}{2} + 1$ units, which violates the unit supply constraint. This implies that in the first profile, $\mathbf{v}$, M must allocate 0 units to buyer 2 (by setting the price to v_2 or to something higher where buyer 2 does not want any units). This implies that the approximation ratio is at least $2 - \frac{4}{m+2}$.

For the revenue objective, the argument is exactly the same, but we need to establish that at any profile $\mathbf{v}$ or $\mathbf{v^{(i)}}$, $i = 1, \ldots, k$ that we construct, the optimal envy-free price is equal to the second highest reported valuation, i.e. v_2 or $v_2^{(i)}$, $i = 1, \ldots, k$ respectively. To do that, choose v_1 such that $v_1 = v_2 + \delta$, where $\delta > \epsilon$, but small enough such that $\lfloor \frac{B}{v_2+\delta} \rfloor = \lfloor \frac{B}{v_2} \rfloor$, i.e. any hungry buyer at price $v_2 + \delta$ buys the same number of units as it would buy at price v_2. Furthermore, ϵ and δ can be chosen small enough such that $(\frac{m}{2} + 1)(v_2 + \delta) < m \cdot v_2$, i.e. the revenue obtained by selling $\frac{m}{2} + 1$ units to buyer 1 at price $v_2 + \delta$ is smaller than the revenue obtained by selling $\frac{m}{2} + 1$ units to buyer 1 and $\frac{m}{2} - \epsilon$ units to buyer 2 at price v_2. This establishes the optimal envy-free price is the same as before, for every profile in the sequence and all arguments go through.

Given that we are working over a discrete domain, for the proof to go through, it suffices to assume that there are m points of the domain between v_1 and v_2, which is easily the case if the domain is not too sparse. Specifically, for the concrete example presented at the first paragraph of the proof, assuming that the domain contains all the decimal floating point numbers with up to two decimal places suffices. ◀

4 Impossibility Results

In this section, we state our impossibility results, which imply that truthfulness can only be guaranteed when there is some kind of wastefulness; a similar observation was made in [6] for a different setting.

▶ **Theorem 14.** *There is no Pareto efficient, truthful mechanism that always outputs an envy-free pricing, even when the budgets are known.*

The proof of the theorem is left for the full version. The next theorem provides a stronger impossibility result. First, we provide the necessary definitions. A buyer i on profile input v is called *irrelevant* if at the minimum envy-free price p on v, the buyer can not buy even a single unit. A mechanism is called *in-range* if it always outputs an envy-free price in the interval $[0, v_j]$ where v_j is the highest valuation among all buyers that are not irrelevant. Finally, a mechanism is *non-wasteful* if at a given price p, the mechanism allocates as many items as possible to the buyers. Note that Pareto efficiency implies in-range and non-wastefulness, but not the other way around. In a sense, while Pareto efficiency also determines the price chosen by the mechanism, non-wastefulness only concerns the allocation given a price, whereas in-range only restricts prices to a "reasonable" interval.

▶ **Theorem 15.** *There is no in-range, non-wasteful and truthful mechanism that always outputs an envy-free pricing scheme, even when the budgets are known.*

We leave the proof for the full version. To prove the impossibility, we first obtain a necessary condition; any mechanism in this class must essentially output the minimum envy-free price (or the next highest price on the output grid). Then we can use this result to construct and example where the mechanism must leave some items unallocated in order to satisfy truthfulness.

5 Discussion

Our results show that it is possible to achieve good approximate truthful mechanisms, under reasonable assumptions on the competitiveness of the auctions which retain some of the attractive properties of the Walrasian equilibrium solutions. The same agenda could be applied to more general auctions, beyond the case of linear valuations or even beyond multi-unit auctions. It would be interesting to obtain a complete characterization of truthfulness in the case of private or known budgets; for the case of private budgets, we can show that a class of order statistic mechanisms are truthful, but the welfare or revenue guarantees for this case may be poor. Finally, in the full version, we present an interesting special case, that of *monotone auctions*, in which Mechanism All-Or-Nothing is optimal among all truthful mechanisms for both objectives, regardless of the market share.

Abstract

Distributed/concurrent strategies have been introduced as special maps of event structures. As such they factor through their "rigid images", themselves strategies. By concentrating on such "rigid image" strategies we are able to give an elementary account of distributed strategies and their composition, resulting in a category of games and strategies. This is in contrast to the usual development where composition involves the pullback of event structures explicitly and results in a bicategory. It is shown how, in this simpler setting, to extend strategies to probabilistic strategies; and indicated how through probability we can track nondeterministic branching behaviour, that one might otherwise think lost irrevocably in restricting attention to "rigid image" strategies.

1 Introduction

Traditionally in understanding and analysing a large system, whether it be in computer science, physics, biology or economics, the system's behaviour is thought of as going through a sequence of actions as time progresses. This is bound up with our experience of the world as individuals; in our conscious understanding of the world we experience and narrate our individual history as a sequence, or total order, of events, one after the other. However, a complex system is often much more than an individual agent. It is better thought of as several or many agents interacting together and distributed over various locations. In which case it can be fruitful to abandon the view of its behaviour as caught by a total order of events and instead think of the events of the systems system as comprising a partial order. The partial order expresses the causal dependency between events, how an event depends on possibly several previous events. The view that causal dependency should be paramount over an often incidental temporal order has been discovered and rediscovered in many disciplines: in physics in the understanding of the causal structure of space time; in biology and chemistry in the description of biochemical pathways; in computer science, originally in the work of Petri on Petri nets, and later in the often more mathematically amenable event structures.

Interacting systems are often represented mathematically via games. A system operates in an unknown environment, so often a prescription for its intended behaviour can be expressed as a strategy in which the system is Player against (an unpredictable) Opponent, standing for the environment. Games and their strategies are ubiquitous. They appear in logic (proof theory, set theory, ...), computer science (semantics, algorithmics, ...), biology, economics, *etc.*. They codify the mathematics of interacting systems. But they almost always follow the traditional line of representing the history of a play of the game as a sequence of moves, most often alternating between Player and Opponent. Until recently there was no mathematical

theory of games based on partial orders of causal dependency between move occurrences. This handicapped their use in modelling and analysing a system of distributed agents.

What was lacking was a mathematical theory of distributed games in which Player and Opponent are more accurately thought of as teams of players, distributed over different locations, able to move and communicate with each other. Although there are glimpses of such a mathematical theory of distributed games in earlier work of Abramsky, Mellies and Mimram [1, 13], Faggian and Piccolo [8], and others, a breakthrough occurred with the systematic use of event structures to formalise distributed games and strategies [14]. This meant that we could harness the mathematical techniques developed around event structures in an early mathematical foundation for work on synchronising processes [18]; the move from total to partial orders brings in its wake a lot of technical difficulty and potential for undue complexity unless it's done artfully.

But here we meet an obstacle for many people. Distributed/concurrent strategies have been based on maps of event structures and composition on pullback, which in the case of event structures has to be defined rather indirectly. Then, one obtains not a category but a bicategory of games and strategies. At what seems like an increasingly slight cost, a more elementary treatment can be given. Its presentation is the purpose of this article. The maps and pullbacks are still there of course, but pushed into the background.

The realisation that a more elementary presentation will often suffice has been a gradual one. It is based on the fact that a strategy, presented as a map of event structures, has a "rigid image" in the game and that in many cases this image can stand as a proxy for the original strategy [25]. True some branching behaviour is lost, just as it, and possible deadlock and divergence, can be lost in the composition of strategies. But extra structure on strategies generally remedies this. For example, the introduction of probability to strategies allows the detection of divergence in composition, or hidden branching, through leaks of probability. One can go far with rigid images of strategies. They permit the elementary development presented here.

In their CONCUR'16 paper [2] Castellan and Clairambault used the simple presentation of "rigid image" strategies here. Meanwhile rigid images of strategies had come to play an increasing role in Winskel's ECSYM notes [25]. Before this, Nathan Bowler recognised essentially the same subcategory of games and "rigid image" strategies, within the bicategory of concurrent games and strategies. (At the time, Winskel thought that too much of the nondeterministic branching behaviour would be lost irrecoverably to be very enthusiastic.)

Finally, an apology: we obtained the results here by specialising more general results on strategies to their rigid-images [25]; elementary proofs of the results would be desirable for a fully self-contained presentation, and should be written up shortly.

2 Event structures

An *event structure* comprises $(E, \leq, \mathrm{Con})$, consisting of a set E of *events* which are partially ordered by $\leq$, the *causal dependency relation*, and a nonempty *consistency* relation Con consisting of finite subsets of E. The relation $e' \leq e$ expresses that event e causally depends on the previous occurrence of event e'. That a finite subset of events is consistent conveys that its events can occur together by some stage in the evolution of the process. Together

the relations satisfy several axioms:

$[e] =_{\text{def}} \{e' \mid e' \leq e\}$ is finite for all $e \in E$,

$\{e\} \in \text{Con}$ for all $e \in E$,

$Y \subseteq X \in \text{Con}$ implies $Y \in \text{Con}$, and

$X \in \text{Con}$ & $e \leq e' \in X$ implies $X \cup \{e\} \in \text{Con}$.

There is an accompanying notion of state, or history, those events that may occur up to some stage in the behaviour of the process described. A *configuration* is a, possibly infinite, set of events $x \subseteq E$ which is: *consistent,* $X \subseteq x$ and X is finite implies $X \in \text{Con}$; and *down-closed,* $e' \leq e \in x$ implies $e' \in x$.

Two events e, e' are considered to be causally independent, and called *concurrent* if the set $\{e, e'\}$ is in Con and neither event is causally dependent on the other; then we write $e \mathrel{co} e'$. In games the relation of *immediate* dependency $e \rightarrowtriangle e'$, meaning e and e' are distinct with $e \leq e'$ and no event in between, plays a very important role. We write $[X]$ for the down-closure of a subset of events X. Write $\mathcal{C}^\infty(E)$ for the configurations of E and $\mathcal{C}(E)$ for its finite configurations. (Sometimes we shall need to distinguish the precise event structure to which a relation is associated and write, for instance, $\leq_E$, $\rightarrowtriangle_E$ or co_E.)

We can describe a computation path by an *elementary* event structure, which is a partial order $p = (|p|, \leq_p)$ for which the set $\{e' \in |p| \mid e' \leq_p e\}$ is finite for all $e \in |p|$. We can regard an elementary event structure as an event structure in which the consistency relation consists of all finite subsets of events. There is a useful subpath order of rigid inclusion of one elementary event structure in another. Let $p = (|p|, \leq_p)$ and $q = (|q|, \leq_q)$ be elementary event structures. Write

$$p \hookrightarrow q \text{ iff } |p| \subseteq |q| \;\&\; \forall e \in |p|, e' \in |q|.\ e' \leq_p e \iff e' \leq_q e\,.$$

We shall often view a configuration x of E as an elementary event structure, *viz.* a partial order with underlying set x and partial order the causal dependency of E restricted to x.

In an interactive context a configuration x may be subject to causal dependencies beyond those of E. It will become an elementary event structure $p = (|p|, \leq_p)$ comprising an underlying set $|p| = x$ with a partial order $\leq_p$ which augments that from E:

$$\forall e \in |p|, e' \in E.\ e' \leq_E e \implies e' \leq_p e\,.$$

Write $\text{Aug}(E)$ for the set of such *augmentations* associated with E. The order of rigid inclusion of one augmentation in another expresses when one augmentation is a sub-behaviour of another.

It will be useful to combine augmentations, in effect subjecting a configuration simultaneously to the causal dependencies of the two augmentations – provided this does not lead to causal loops. Define a key partial operation

$$\wedge : \text{Aug}(E) \times \text{Aug}(E) \rightharpoonup \text{Aug}(E)$$

by taking

$$p \wedge q = \begin{cases} (|p|, (\leq_p \cup \leq_q)^*) & \text{if } |p| = |q| \;\&\; (\leq_p \cup \leq_q)^* \text{ is antisymmetric,} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

▶ **Lemma 1.** *Letting $p, q \in \text{Aug}(E)$ for which $p \wedge q$ is defined, $e' \rightarrowtriangle_{p\wedge q} e$ implies*

$$[e' \rightarrowtriangle_p e \;\&\; (e' \rightarrowtriangle_q e \text{ or } e' \mathrel{co}_q e)] \text{ or } [e' \rightarrowtriangle_q e \;\&\; (e' \rightarrowtriangle_p e \text{ or } e' \mathrel{co}_p e)]\,.$$

In fact we can see $\mathrm{Aug}(E)$ as an event structure in its own right. Its events are those augmentations with a top event, their causal dependency and consistency induced given by rigid inclusion [20]. The remark is an instance of a general fact:

▶ **Proposition 2.** *A* rigid family $\mathcal{R}$ *comprises a non-empty subset of finite elementary event structures which is down-closed w.r.t. rigid inclusion, i.e.* $p \hookrightarrow q \in \mathcal{R}$ *implies* $p \in \mathcal{R}$*. A rigid family determines an event structure* $\Pr(\mathcal{R})$ *whose order of finite configurations is isomorphic to* $(\mathcal{R}, \hookrightarrow)$*. The event structure* $\Pr(\mathcal{R})$ *has events those elements of* $\mathcal{R}$ *with a top event; its causal dependency is given by rigid inclusion; and its consistency by compatibilty w.r.t. rigid inclusion. The order isomorphism* $\theta_{\mathcal{R}} : \mathcal{C}(\Pr(\mathcal{R})) \cong \mathcal{R}$ *is given by* $\theta_{\mathcal{R}}(x) = \bigcup x$*, the union of (the consistent) augmentations in* $x \in \mathcal{C}(\Pr(\mathcal{R}))$*.*

3 Event structures with polarity

An event structure with polarity comprises (A, pol) where A is an event structure with a polarity function $pol_A : A \to \{+, -, 0\}$ ascribing a polarity + (Player), − (Opponent) or 0 (neutral) to its events. The events correspond to (occurrences of) moves. It will be technically useful to allow events of neutral polarity; they arise, for example, in a play between a strategy and a counterstrategy. A *game* shall be represented by an event structure with polarity in which no moves are neutral.

▶ **Notation 3.** *In an event structure with polarity* (A, pol)*, with configurations* x *and* y*, write* $x \subseteq^- y$ *to mean inclusion in which all the intervening events are moves of Opponent. Write* $x \subseteq^+ y$ *for inclusion in which the intervening events are neutral or moves of Player.*

3.1 Operations

We introduce two fundamental operations on event structures with polarity. We shall adopt the same operations for elementary event structures, and also for configurations, regarding a configuration as an elementary event structure with the order of the ambient event structure.

3.1.1 Dual

The *dual*, $A^\perp$, of A, an event structure with polarity, comprises the same underlying event structure A but with a reversal of polarities, events of neutral polarity remaining neutral.

We shall implicitly adopt the view of Player and understand a strategy in a game A as strategy for Player. A counterstrategy in a game A is a strategy for Opponent in the game A, *i.e.* a strategy (for Player) in the game $A^\perp$.

3.1.2 Simple parallel composition

This operation simply juxtaposes two event structures with polarity. Let $(A, \leq_A, \mathrm{Con}_A, pol_A)$ and $(B, \leq_B, \mathrm{Con}_B, pol_B)$ be event structures with polarity. The events of $A \| B$ are $(\{1\} \times A) \cup (\{2\} \times B)$, their polarities unchanged, with the only relations of causal dependency given by $(1, a) \leq (1, a')$ iff $a \leq_A a'$ and $(2, b) \leq (2, b')$ iff $b \leq_B b'$; a subset of events C is consistent in $A \| B$ iff $\{a \mid (1, a) \in C\} \in \mathrm{Con}_A$ and $\{b \mid (2, b) \in C\} \in \mathrm{Con}_B$. The empty event structure with polarity, written $\varnothing$, is the unit w.r.t. $\|$.

4 Strategies

A strategy in a game will be a (special) subset of plays in the game.

▶ **Definition 4.** A *play* in A, an event structure with polarity, comprises an augmentation, a finite elementary event structure $p = (|p|, \leq_p)$ with underlying set $|p| \in \mathcal{C}(A)$, which may augment with extra causal dependencies provided it does so *courteously*:

$$\forall a, a' \in |p|.\ a' \rightarrowtriangle_p a \ \&\ pol_A(a') = + \text{ or } pol_A(a) = - \implies a' \rightarrowtriangle_A a\,.$$

Note A, and so p, may involve neutral moves.

If A is a game, so with no neutral moves, the only augmentations allowed of a play p to the immediate causal dependency of A are those of the form $\ominus \rightarrowtriangle \oplus$.

The order of rigid inclusion between plays, $p \hookrightarrow q$, expresses that p is a subplay of q. We shall write

$$p \hookrightarrow^+ q \text{ iff } p \hookrightarrow q \ \&\ |p| \subseteq^+ |q|\,,$$

so when the extension only involves neutral or Player moves, and similarly $p \hookrightarrow^- q$ when only Opponent moves are involved.

▶ **Definition 5.** A *bare strategy* in A, an event structure with polarity, is a rigid family of plays, so a nonempty subset $\sigma \subseteq \mathrm{Plays}(A)$ satisfying $p \hookrightarrow q \in \sigma \implies p \in \sigma$, which is also

- receptive, $p \in \sigma \ \&\ |p| \subseteq^- x \in \mathcal{C}(A) \implies \exists q \in \sigma.\ p \hookrightarrow q \in \sigma \ \&\ |q| = x\,.$
  (Note that q is unique by courtesy.)

Write $\sigma : A$ when σ is a bare strategy of A. When A is a game, so an event structure with polarity without neutral moves, we say σ is a *strategy*.

One simple example of a strategy $\sigma : A$ in a game A is got by taking σ to consist of all the finite configurations of A regarded as elementary event structures in which their order of causal dependency is inherited from A. (Bare strategies, with neutral events, have been called "partial strategies" in [25] and an "uncovered strategies" in [16].)

We shall regard a strategy in the compound game $A^\perp \| B$, where A and B are games as a strategy *from* the game A *to* the game B [7, 12].

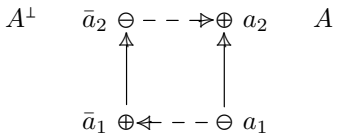
4.1 Copycat

We shall shortly define the composition of strategies. Identities w.r.t. composition are given by copycat strategies. Let A be a game. The copycat strategy $\mathfrak{cc}_A : A^\perp \| A$ is an instance of a strategy. We obtain copycat from the finite configurations of an event structure $\mathfrak{CC}_A$ based on the idea that Player moves, of +ve polarity, in one component of the game $A^\perp \| A$ always copy previous corresponding moves of Opponent, of −ve polarity in the other component.

For $c \in A^\perp \| A$ we use $\bar{c}$ to mean the corresponding copy of c, of opposite polarity, in the alternative component, *i.e.* $\overline{(1,a)} = (2,a)$ and $\overline{(2,a)} = (1,a)$. Define $\mathfrak{CC}_A$ to comprise the event structure with polarity $A^\perp \| A$ together with extra causal dependencies $\bar{c} \leq_{\mathfrak{CC}_A} c$ for all events c with $pol_{A^\perp \| A}(c) = +$. Take a finite subset to be consistent in $\mathfrak{CC}_A$ iff its down-closure w.r.t. the relation $\leq_{\mathfrak{CC}_A}$ is consistent in $A^\perp \| A$.

▶ **Example 6.** We illustrate the construction of $\mathfrak{CC}_A$ for the event structure A comprising the single immediate dependency $a_1 \rightarrowtriangle a_2$ from an Opponent move a_1 to a Player move

a_2. The event structure $!A$ is obtained from $A^\perp \| A$ by adjoining the additional immediate dependencies shown:



▶ **Lemma 7.** *Let A be an event structure with polarity. Then, $!A$ is an event structure with polarity. Moreover,*

$$x \in \mathcal{C}(!A) \text{ iff } x \in \mathcal{C}(A^\perp \| A) \;\&\; \forall c \in x.\ pol_{A^\perp \| A}(c) = + \implies \bar{c} \in x\,.$$

The *copycat* strategy $\mathrm{cc}_A : A^\perp \| A$ is defined by taking

$$\mathrm{cc}_A = \{(x, \leq_{!A} \upharpoonright x) \mid x \in \mathcal{C}(!A)\}\,.$$

In other words, cc_A consists of all the finite configurations of $!A$, each understood as a finite partial order through inheriting the causal dependency of $!A$.

5 Composition of strategies

A play of a strategy σ in a game $A^\perp \| B$ and a play of a strategy τ in a game $B^\perp \| C$ can interact at the common game B, where the two strategies adopt complementary views, in which one sees a move of Player the other sees a move of Opponent, and *vice versa*. In effect, the two plays synchronise at common moves in B, one strategy being receptive to the Player moves of the other. Together they produce a play in the event structure with polarity $A^\perp \| B^0 \| C$ – the event structure with polarity B^0 has the same underlying event structure as B but where all events now carry neutral polarity. This is because the interaction over the game B produces moves which are no longer open to Player or Opponent.

We can express this interaction through a partial operation

$$\circledast : \mathrm{Plays}(B^\perp \| C) \times \mathrm{Plays}(A^\perp \| B) \rightharpoonup \mathrm{Plays}(A^\perp \| B^0 \| C)$$

defined as follows. Let $p \in \mathrm{Plays}(A^\perp \| B)$, $q \in \mathrm{Plays}(A^\perp \| B)$ with $|p| = x_{A^\perp} \| x_B$ and $|q| = y_{B^\perp} \| y_C$. Take

$$q \circledast p =_{\mathrm{def}} (p \| y_C) \wedge (x_{A^\perp} \| q)\,,$$

where we understand the configurations y_C and $x_{A^\perp}$ to inherit the partial order of their ambient event structures. Notice that $q \circledast p$ is defined only if $x_B = y_{B^\perp}$, and then only if no causal loops are introduced.

▶ **Lemma 8.** *Let $p \in \mathrm{Plays}(A^\perp \| B)$ and $q \in \mathrm{Plays}(B^\perp \| C)$. Then, if defined, $q \circledast p \in \mathrm{Plays}(A^\perp \| B^0 \| C)$.*

Define the *projection*

$$(\_)\downarrow : \mathrm{Plays}(A^\perp \| B^0 \| C) \to \mathrm{Plays}(A^\perp \| C)\,,$$

of a play p in $A^\perp \| B^0 \| C$,with $|p| = x_{A^\perp} \| x_B \| x_C$, to a play $p\downarrow$ in $A^\perp \| C$, to be the restriction of the order on p to the set $x_{A^\perp} \| x_C$.

Define a partial operation

$$\odot : \mathrm{Plays}(B^\perp \| C) \times \mathrm{Plays}(A^\perp \| B) \rightharpoonup \mathrm{Plays}(A^\perp \| C)$$

by

$$q \odot p = (q \circledast p)\downarrow$$

for $p \in \mathrm{Plays}(A^\perp \| B)$ and $q \in \mathrm{Plays}(B^\perp \| C)$.

▶ **Lemma 9.** *Let $p \in \mathrm{Plays}(A^\perp \| B)$ and $q \in \mathrm{Plays}(B^\perp \| C)$. Then, if defined, $q \odot p \in \mathrm{Plays}(A^\perp \| C)$.*

Let $\sigma : A^\perp \| B$ and $\tau : B^\perp \| C$ be strategies. Define their composition

$$\tau \odot \sigma = \{q \odot p \mid p \in \sigma \ \&\ q \in \tau \ \&\ q \odot p \text{ is defined}\}\,.$$

It is sometimes useful to consider their composition *without hiding*, the *interaction*

$$\tau \circledast \sigma = \{q \circledast p \mid p \in \sigma \ \&\ q \in \tau \ \&\ q \circledast p \text{ is defined}\}\,,$$

which is like the strategy $\tau \odot \sigma$, but before hiding the neutral moves over the game B.

▶ **Lemma 10.** *The interaction of strategies $\sigma : A^\perp \| B$ and $\tau : B^\perp \| C$ yields a bare strategy $\tau \circledast \sigma : A^\perp \| B^0 \| C$.*

▶ **Theorem 11.** *The composition of strategies $\sigma : A^\perp \| B$ and $\tau : B^\perp \| C$ yields a strategy $\tau \odot \sigma : A^\perp \| C$. Taking objects to be games and arrows from a game A to a game B to be strategies in the game $A^\perp \| B$, with composition as above, yields a category in which copycat is identity. (This is in contrast to the* bicategory *of [14].)*

5.1 Deterministic strategies

Let A be an event structure with polarity. A bare strategy $\sigma : A$ is *deterministic* iff

$$p \hookrightarrow^+ q \ \&\ p \hookrightarrow r \text{ in } \sigma \implies \exists s \in \sigma.\ q \hookrightarrow s \ \&\ r \hookrightarrow s\,.$$

The interaction of deterministic bare strategies is deterministic. Similarly, the composition of deterministic strategies is deterministic. However, for general games A, the copycat strategy need not be deterministic. It will be deterministic iff A is *race-free*, *i.e.*,

$$x \subseteq^+ y \ \&\ x \subseteq^- z \implies y \cup z \in \mathcal{C}(A)\,.$$

Restricting to race-free games as objects and deterministic strategies as arrows we obtain a category. Deterministic strategies coincide with the *receptive* ingenuous strategies of Melliès and Mimram [13] and are closely related to the strategies of Faggian and Piccolo [8], and Abramsky and Melliès' strategies as closure operators [1].

The subcategory of deterministic strategies on games which countable and purely positive, *i.e.* for which there are no Opponent moves, is isomorphic to that of Berry's dI-domains and stable functions. If we restrict the subcategory further to objects in which causal dependency is simply the identity relation we obtain Girard's qualitative domains with linear maps and if yet further insist that consistency Con is determined in a binary fashion, *i.e.*

$$X \in \mathrm{Con} \iff \forall a_1, a_2 \in X.\ \{a_1, a_2\} \in Con\,,$$

his coherence spaces. In this sense we can see strategies as extending the world of stable domain theory. The relationship with the broader world of traditional domain theory, following in the footsteps of Scott, is more subtle. In [23], it is shown how a strategy determines a presheaf and a strategy between games a profunctor, giving a relationship with a form of generalised domain theory [10, 4].

6 Strategies as maps of event structures

A strategy σ in a game A is a rigid family and so, by Proposition 2, determines an event structure S whose events are those plays in σ which have a top element. Each top element is an event of the game A so there is a function from the events of S to those of A; this function is a total map of event structures and indeed a *concurrent strategy* in the sense of [14]. Not all the concurrent strategies of [14] are obtained this way. But any concurrent strategy of [14] has a rigid image [25] which corresponds to a strategy as presented here. Though not essential to the rest of the paper, we now explain this summary of the relation with the concurrent strategies of [14] in more detail.

Recall a *(total) map* of event structures $f : E \to E'$ is a function f from E to E' such that the image of a configuration x is a configuration fx and any event of fx arises as the image of a unique event of x. Maps compose as functions. Write $\mathcal{E}$ for the ensuing category.

A map $f : E \to E'$ reflects causal dependency locally, in the sense that if e, e' are events in a configuration x of E for which $f(e') \leq f(e)$ in E', then $e' \leq e$ also in E; the event structure E inherits causal dependencies from the event structure E' via the map f. Consequently, a map $f : E \to E'$ preserves concurrency: if two events are concurrent, $e_1 \mathrel{co_E} e_2$, then their images are also concurrent, $f(e_1) \mathrel{co_{E'}} f(e_2)$. In general a map of event structures need not preserve causal dependency; when it does we say it is *rigid*. Write $\mathcal{E}_r$ for the subcategory of rigid maps.

The inclusion functor $\mathcal{E}_r \hookrightarrow \mathcal{E}$ has a right adjoint ([20], Proposition 2.3): There is an obvious map of event structures $\epsilon_B : \Pr(\mathrm{Aug}(B)) \to B$ taking an event of $\Pr(\mathrm{Aug}(B))$ to its top element. Post-composition by ϵ_B yields a bijection

$$\epsilon_B \circ \_ : \mathcal{E}_r(A, \Pr(\mathrm{Aug}(B))) \cong \mathcal{E}(A, B)\,,$$

furnishing the data required for an adjunction. Hence $\Pr(\mathrm{Aug}(\_))$ extends to a right adjoint to the inclusion $\mathcal{E}_r \hookrightarrow \mathcal{E}$. From the bijection of the adjunction, we have a correspondence between maps $f : A \to B$ and rigid maps $\bar{f} : A \to \Pr(\mathrm{Aug}(B))$. The adjunction is unchanged by the addition of polarity to event structures; maps are assumed to preserve polarity.

A strategy determines a map and indeed a "concurrent strategy"as in [14]:

▶ **Proposition 12.** *Let $\sigma : A$ be a strategy in a game A. The function $f_\sigma : \Pr(\sigma) \to A$, taking an event of $\Pr(\sigma)$ to its top element, is a map of event structures with polarity. It is a concurrent strategy in the sense of [14], viz. a map which is*

- courteous, *$s' \rightarrowtriangle s$ and $pol(s') = +$ or $pol(s) = -$ in $\Pr(\sigma)$ implies $f_\sigma(s') \rightarrowtriangle_A f_\sigma(s)$ in A, (called* "innocent" *in [14]), and*
- receptive, *$f_\sigma x \sqsubseteq^- y$ in $\mathcal{C}(A)$, for $x \in \mathcal{C}(\Pr(\sigma))$, implies there is a unique $x' \in \mathcal{C}(\Pr(\sigma))$ such that $f_\sigma x' = y$.*

Not all the concurrent strategies of [14] are obtained in the manner of Proposition 12. However, from any concurrent strategy $f : S \to A$ in a game A there is $\sigma : A$ obtained as the image

$$\sigma =_{\mathrm{def}} \{\theta(\bar{f}x) \in \mathrm{Aug}(A) \mid x \in \mathcal{C}(S)\}$$

of the finite configurations of S as augmentations of A; recall from Proposition 2, the order isomorphism $\theta : \mathcal{C}(\Pr(\mathrm{Aug}(A))) \cong \mathrm{Aug}(A)$. From the definition of σ, the rigid map $\bar{f} : S \to \Pr(\mathrm{Aug}(A))$ cuts down to a rigid map $\bar{f} : S \to \Pr(\sigma)$. The concurrent strategy f factors through its "rigid image" $f_\sigma : \Pr(\sigma) \to A$ in that

$$f : S \xrightarrow{\bar{f}} \Pr(\sigma) \xrightarrow{f_\sigma} A\,,$$

where the rigid image f_σ is itself a concurrent strategy. The simple strategies of this article correspond to such rigid image strategies.

The determination of a strategy, call it σ_f, from a concurrent strategy f is functorial: identity, copycat, strategies are preserved and if concurrent strategies f and g are composable then $\sigma_{g \odot f} = \sigma_g \odot \sigma_f$. Often extra structure on a concurrent strategy f can be pushed forward along the rigid map $\bar{f}$ from to its rigid image, so to a simple strategy of this article. For example, probabilistic structure (in the form of a valuation – see the next section) making a concurrent strategy probabilistic can be pushed forward along the rigid map $\bar{f}$ from S to $\Pr(\sigma_f)$, and so to σ_f [25]. As a consequence, in the next section, we are able to develop probabilistic strategies in the simpler framework of this paper.

A major result of [14] is that receptivity and courtesy (called innocence there) are necessary and sufficient conditions in order for copycat to behave as identity w.r.t. composition; this motivated the definition of concurrent strategy there. That article directly spawned work on games with winning conditions and payoff [5, 6], imperfect information [21], probabilistic strategies [24], "stopping configurations" [3] and "essential events" [16] – the latter two concerned with capturing the liveness behaviour of concurrent strategies viewed as processes. (Concurrent strategies are currently being extended to cope with quantum computation of the kind addressed in the quantum lambda calculus [15].) As an indication of how much of the work ensuing from [14] could be reformulated in terms of the simple strategies on which this article concentrates we next address the issue of how to make strategies probabilistic. Probabilistic strategies developed in this simpler framework, instead of that of concurrent strategies [14], do not suffer from any loss of information *e.g.* with regard to expected payoff.

7 Probabilistic strategies

As a first step we describe how to make event structures probabilistic, in itself an issue, as event structures lie outside the models of probabilistic processes most commonly considered.

7.1 Probabilistic event structures

A probabilistic event structure essentially comprises an event structure together with a continuous valuation on the Scott-open sets of its domain of configurations.[1] The continuous valuation assigns a probability to each open set and can then be extended to a probability measure on the Borel sets [11]. However open sets are several levels removed from the events of an event structure, and an equivalent but more workable definition is obtained by considering the probabilities of sub-basic open sets, generated by single finite configurations; for each finite configuration x this specifies $\mathrm{Prob}(x)$ the probability of obtaining events x, so as result a configuration which extends the finite configuration x. Such valuations on configuration determine the continuous valuations from which they arise, and can be characterised through the device of "drop functions" which measure the drop in probability across certain generalised intervals. The characterisation yields a workable general definition of probabilistic event structure as event structures with *configuration-valuations*, *viz.* functions

[1] A *Scott-open* subset of configurations is upwards-closed w.r.t. inclusion and such that if it contains the union of a directed subset S of configurations then it contains an element of S. A *continuous valuation* is a function w from the Scott-open subsets of $\mathcal{C}^\infty(E)$ to $[0,1]$ which is *((normalized)* $w(\mathcal{C}^\infty(E)) = 1$; *(strict)* $w(\varnothing) = 0$; *(monotone)* $U \subseteq V \implies w(U) \leq w(V)$; *(modular)* $w(U \cup V) + w(U \cap V) = w(U) + w(V)$; and *(continuous)* $w(\bigcup_{i \in I} U_i) = \sup_{i \in I} w(U_i)$, for *directed* unions.

from finite configurations to the unit interval for which the drop functions are always nonnegative [22].

In detail, a *probabilistic event structure* comprises an event structure E with a *configuration-valuation*, a function v from the finite configurations of E to the unit interval which is

- *(normalized)* $v(\varnothing) = 1$ and satisfies the
- *(drop condition)* $d_v[y; x_1, \cdots, x_n] \geq 0$ when $y \subseteq x_1, \cdots, x_n$ for finite configurations $y, x_1, \cdots, x_n$;

where the "drop" across the generalized interval starting at y and ending at one of the $x_1, \cdots, x_n$ is given by

$$d_v[y; x_1, \cdots, x_n] =_{\text{def}} v(y) - \sum_I (-1)^{|I|+1} v(\bigcup_{i \in I} x_i)$$

– the index I ranges over nonempty $I \subseteq \{1, \cdots, n\}$ such that the union $\bigcup_{i \in I} x_i$ is a configuration. The "drop" $d_v[y; x_1, \cdots, x_n]$ gives the probability of the result being a configuration which includes the configuration y and does not include any of the configurations $x_1, \cdots, x_n$.

If $x \subseteq y$ in $\mathcal{C}(E)$, then, provided $v(x) \neq 0$, the conditional probability $\text{Prob}(y \mid x)$ is $v(y)/v(x)$; this is the probability that the resulting configuration includes the events y conditional on it including the events x.

7.2 Probability with an Opponent

This prepares the ground for a definition of probabilistic distributed strategies. Firstly though, we should restrict to race-free games, in particular because without copycat being deterministic there would be no probabilistic identity strategies. A probabilistic strategy in a game A, is a strategy $\sigma : A$ in which we endow σ with probability, while taking account of the fact that in the strategy Player can't be aware of the probabilities assigned by Opponent. To this end we notice that σ, being a rigid family, has the form of a family of configurations. We can't just regard σ as a probabilistic event structure however. This is because Player is oblivious to the probabilities of Opponent moves beyond those determined by causal dependencies of σ. An appropriate *valuation* for σ needs to take account of Opponent moves. It turns out to be useful to extend the concept of valuation to *bare* strategies, which may also have neutral moves.

Let $\sigma : A$ be a bare strategy in A, an event structure with polarity; so both A and σ may involve neutral moves. A *valuation* on σ is a function v, from σ to the unit interval, which is

- *(normalized)* $v(\varnothing) = 1$,
- *(oblivious)* $v(p) = v(q)$ when $p \hookrightarrow^- q$ for $p, q \in \sigma$, and satisfies the
- *(drop condition)* $d_v[q; p_1, \cdots, p_n] \geq 0$ when $q \hookrightarrow^+ p_1, \cdots, p_n$ for elements of σ.

When $p \hookrightarrow^+ q$ in σ, we can still express $\text{Prob}(q \mid p)$, the conditional probability of the additional neutral or Player moves making the play q given p, as $v(q)/v(p)$, provided $v(p) \neq 0$. The game being race-free and the valuation being oblivious ensure the probabilistic independence of Player or neutral moves and Opponent moves with which are concurrent.

For a race-free game A, the copycat strategy is deterministic and we obtain a valuation on cc_A by taking v_{cc_A} to be the function which is constantly 1.

7.3 Composing probabilistic strategies

Let A, B and C be race-free games. Assume $\sigma : A^\perp \| B$, with valuation v_σ, and $\tau : B^\perp \| C$, with valuation v_τ, are probabilistic strategies. To define their interaction and composition we must define the valuations $v_\tau \circledast v_\sigma$ on $\tau \circledast \sigma$ and $v_\tau \odot v_\sigma$ on $\tau \odot \sigma$, respectively.

▶ **Lemma 13.** *For $r \in \tau \circledast \sigma$, defining*

$$(v_\tau \circledast v_\sigma)(r) =_{\text{def}} \sum \{v_\tau(q).v_\sigma(p) \mid q \circledast p = r\},$$

yields a valuation on $\tau \circledast \sigma$.

▶ **Lemma 14.** *For $r \in \tau \odot \sigma$, defining*

$$(v_\tau \odot v_\sigma)(r) =_{\text{def}} \sum \{v_\tau(q).v_\sigma(p) \mid q \odot p = r\},$$

yields a valuation on $\tau \odot \sigma$.

▶ **Theorem 15.** *For race-free games A, B and C, we define the composition of probabilistic strategies σ from A to B, with valuation v_σ, and τ from B to C, with valuation v_τ, to be $\tau \odot \sigma$, with valuation $v_\tau \odot v_\sigma$. Taking objects to be games and arrows from a game A to a game B to be probabilistic strategies in the game $A^\perp \| B$, with composition as above, yields a category in which copycat, with the constantly-1 valuation, is identity.*

The next example illustrates how through probability leaks we can track deadlocks, or divergences, that can arise in the composition of strategies. (Such branching behaviour might otherwise be lost in the composition of strategies and through concentrating on rigid images.)

▶ **Example 16.** Let B be the game consisting of two concurrent Player events b_1 and b_2, and C the game with a single Player event c. We illustrate the composition of two probabilistic strategies σ from the empty game $\varnothing$ to B and τ from B to C. The strategy $\sigma : \varnothing^\perp \| B$ plays b_1 with probability 2/3 and b_2 with probability 1/3 (and plays both with probability 0). The strategy $\tau : B^\perp \| C$ does nothing if just b_1 is played and plays the single Player event c of C with certainty, probabilty 1, if b_2 is played. Their composition yields the strategy $\tau \odot \sigma : \varnothing^\perp \| C$ which plays c with probability 1/3, so has a 2/3 chance of doing nothing.

One way in which the probabilistic interaction of strategies is important is in calculating the expected outcome of the competition between a probabilistic strategy and a counterstrategy, the subject of the following example.

▶ **Example 17.** Given a probabilistic strategy $\sigma : A$, with valuation v_σ, and a counterstrategy $\tau : A^\perp$, with valuation v_τ, we obtain a valuation $v_\tau \circledast v_\sigma$ on their interaction $\tau \circledast \sigma : A^0$, where now all the events of the interaction are neutral. Via the order isomorphism $\theta : \mathcal{C}(\Pr(\tau \circledast \sigma)) \cong \tau \circledast \sigma$ we obtain a configuration-valuation $(v_\tau \circledast v_\sigma) \circ \theta$, making $\Pr(\tau \circledast \sigma)$ a probabilistic event structure. As such we get a probability measure $\mu_{\sigma,\tau}$ on the Borel sets of its configurations. Assuming a *payoff* given as a Borel measurable function X from $\mathcal{C}^\infty(A)$ to the real numbers, the *expected payoff* is obtained as the Lebesgue integral

$$\mathbf{E}_{\sigma,\tau}(X) =_{\text{def}} \int_{x \in \mathcal{C}^\infty(\Pr(\tau \circledast \sigma))} X(|x|)\, d\mu_{\sigma,\tau}(x),$$

where $|x| \in \mathcal{C}^\infty(A)$ is the configuration of A over which $x \in \mathcal{C}^\infty(\Pr(\tau \circledast \sigma))$ lies.

8 Conclusion

We have provided an elementary account of a form of distributed strategies by choosing only to represent the rigid images of concurrent strategies. Is anything irredeemably lost through this simplification? (In the sense that it can't be regained through adding extra structure, in the way that probabilistic structure recovers hidden branching.) Not obviously. Though, for

instance, we couldn't exactly reproduce the result of [3], establishing a bijection between events of a strategy and derivations in an operational semantics. Though an elementary account is more accessible, a more abstract, categorical account can be helpful too. As often, there are pros and cons. To some extent, one pays for the elementary treatment in not seeing the abstract picture, the wood for the trees.

On another tack, the account of strategies here reveals an alternative way to develop strategies while capturing noneteristic branching explicitly, *viz.* as (pre)sheaves over plays rather than subsets, in the form of rigid families. For instance, we can recover the concurrent strategies of [14] as certain separated presheaves in the manner of [19]; this brings us close to the developments of Hirschowitz and Pous [9] and Ong and Tsukada [17].

Acknowledgments. Thanks to Nathan Bowler, Jonathan Hayman and Martin Hyland for advice and encouragement, and to the ERC for the Advanced Grant "Events, Causality and Symmetry" (ECSYM).

1 Overview of the talk

The foundational observation of the field of automata and logic is that on many well-behaved classes of structures the notion of *recognizability* of a structure's property by a finite-state automaton is equivalent to *definability* of this property in *monadic second-order logic* (MSO). This equivalence holds for properties of words and trees, both finite and infinite, and provides means for the algorithmic treatment of MSO-definable properties in these classes of structures.

It is natural to ask what aspects of a class of structures imply that the notions of MSO-definability and recognizability by (appropriately defined) finite automata coincide on this class. In early 90s, Courcelle [2] proved that on any class of structures of bounded treewidth, that is, where structures roughly look like trees with trunks of width bounded by a constant, one implication holds: MSO-definability implies recognizability. This fundamental result already provides most of the desired algorithmic corollaries, most notably that MSO-definable properties of structures of bounded treewidth can be decided in linear fixed-parameter time, where treewidth is the parameter. However, the reverse implication became known as the *Courcelle's conjecture* and remained open until very recently, despite multiple attempts and some incomplete proofs [3, 4]. Finally, last year together with Bojańczyk we resolved the conjecture in affirmative [1].

The main obstacle when approaching the Courcelle's conjecture is that the constructed MSO formula expressing the recognizable property in question has to work only on the structure, and not on its tree decomposition certifying the constant upper bound on the treewidth. More precisely, if we were given such a tree decomposition, then we could just existentially quantify an accepting run of the automaton recognizing the property. However, while graphs of treewidth 1, that is, forests, can be perfectly understood, for structures of larger treewidth computing an optimum-width tree decomposition is a highly nontrivial combinatorial task, and an appropriate tree decomposition cannot be immediately defined from the structure. Therefore, the main technical contribution of [1] is a proof that an approximate tree decomposition of a structure can be constructed by means of a *nondeterministic MSO transduction*, which is a formalism that captures MSO-definable

transformations of relational structures. The crucial ingredient of this proof is an application of Simon's factorization forest theorem [5].

During the talk, we will discuss the relation between MSO-definability and recognizability on various classes of structures, in particular on classes of bounded treewidth. We will also give a sketch of the proof of the Courcelle's conjecture, focusing on the role played by Simon's factorization forest theorem.

Hardness and Approximation of High-Dimensional Search Problems

Rasmus Pagh*

IT University of Copenhagen, Denmark
pagh@itu.dk

Abstract

The need to perform search in a collection of high-dimensional vectors arises in many areas of computer science including databases, image analysis, information retrieval, and machine learning. In contrast to lower-dimensional settings, we do not know of worst-case efficient data structures for such search problems. In fact, if we make no assumptions on the input there is no known way of doing significantly better than brute force. In this talk I survey recent developments in the theoretical study of high dimensional search problems, including:

- Conditional hardness results linking search problems to well-known computationally hard problems such as k-SAT.
- Upper bounds for *approximate* high-dimensional search using locality-sensitive maps and filters, and work towards derandomizing these algorithms.
- Surprising upper bounds in *batched* settings where there are many simultaneous searches.

The talk ends by sketching directions for future research, connecting to other areas of theoretical computer science but also attempting to obtain better theoretical models that explain the performance of search algorithms that are used in practice.

1 Overview of the talk

Temporal logics have been widely used in model checking over the last 40 years, as a formalism for reasoning about executions of computer systems. They are sufficiently powerful to specify most properties one may want to check of reactive systems, while enjoying reasonably-efficient verification algorithms [21, 11, 22, 12, 7, 6]. Temporal logics and model checking have had a major impact in computer science (as witnessed by two Turing awards won by Pnueli in 1996, and by Clarke, Emerson and Sifakis in 2007), and have been applied in numerous industrial cases.

Several attempts have been made to extend temporal logics to multi-agent systems, where several components interact: while the *Computation-Tree Logic* (CTL) can only express the existence (or absence) of executions of the global system having certain properties, the aim here is to quantify over the possible behaviours of the individual components interacting in the system (be it in a collaborative or adversarial way).

In 1997, CTL has been extended into the *Alternating-time Temporal Logic* (ATL), with the introduction of *strategy quantifiers* [3, 4]. In ATL, strategy quantifiers express the existence (or absence) of a behaviour of one of the agents (or of a coalition) so that any resulting execution in the global system satisfies a given property (notice in particular that such an existential quantification over strategies involves an implicit universal quantification over the resulting executions). The semantics of ATL formulas as defined in [4] is *bottom-up*: when evaluating a formula with nested strategy quantifiers, the innermost quantifiers are evaluated first. While this allows for efficient model-checking algorithms, this prevents strategic interactions: the innermost quantifier being evaluated first, it can be replaced with a fresh atomic proposition labelling those states where the subformula holds true.

During the 2000's, several adaptations of ATL have been proposed in order to introduce strategy interactions [23, 24, 1, 20], until the development of a *top-down semantics*, storing selected strategies in a context for later interaction with other strategies [5, 2, 9, 13]. This

* Supported by ERC grant EQualIS (308087).

† This abstract is based on joint works with Patricia Bouyer, Patrick Gardy, and François Laroussinie.

results in a much richer framework, suitable for expressing classical game-theoretic properties (such as the existence of Nash equilibria) and many extra properties mixing collaborative and adversarial interactions (such as the interactions between a server and several clients competing for accessing some shared resource). Such an expressiveness has a cost, and checking if a formula in ATL with strategy contexts holds in a given model is in k-EXPTIME, where k is the number of nested strategy quantifiers in the formula.

Simultaneously, an orthogonal approach has been defined and explored: it allows to manipulate strategies explicitly, quantifying over them and assigning them to agents [10, 19, 17]. The resulting logic, called *Strategy Logic* (SL), has similar algorithmic properties as ATL with strategy contexts [17, 16, 15], but allows for even more expressive power (e.g., strategies can be revoked and applied again later, or two players can follow the same strategy). However, recent works have shown that slight natural variations in the semantics of SL may have significant impact both on the algorithmics and on the expressiveness of the logic [18, 8, 14].

During this talk, we survey these results, giving a uniform presentation of the verification and expressiveness results for those logics and their semantic variants.

Ideal-Based Algorithms for the Symbolic Verification of Well-Structured Systems

Philippe Schnoebelen

LSV, CNRS & ENS Paris Saclay, Cachan, France
phs@lsv.fr

Abstract

We explain how the downward-closed subsets of a well-quasi-ordering $(X, \leq)$ can be represented via the ideals of X and how this leads to simple and efficient algorithms for the verification of well-structured systems.

1998 ACM Subject Classification F.1.1 Models of Computation, F.3.1 Specifying and Verifying and Reasoning about Programs

Keywords and phrases Well-structured systems and verification, Order theory

Category Invited Talk

1 Summary of the talk

Well-structured systems, also known under the acronym "WSTSs", are a family of infinite-state models for which generic verification algorithms exist [1, 2, 13, 18, 23]. With WSTSs, the main ingredient for decidability is the existence of an ordering on configurations that enjoys two properties:

- it is a well-quasi-ordering (a WQO): every infinite sequence $c_0, c_1, c_2, \ldots$ of configurations contains an increasing pair $c_i \leq c_j$ with $i < j$;
- transitions are monotonic: if the system can perform a step $c \to c'$ then from any configuration $d \geq c$, a "similar" step is possible, i.e., there is some $d \to d'$ with $d' \geq c'$.

The most well-known instances of WSTSs are some families of counter machines or vector addition systems [8, 12]. For simplicity, we shall assume that the WQO set of configurations for these systems is $\mathit{Conf} = (\mathbb{N}^d, \leq_\times)$ for some dimension $d \in \mathbb{N}$, where the *component-wise ordering* $\leq_\times$ is given by $\boldsymbol{u} = (u_1, \ldots, u_d) \leq_\times \boldsymbol{v} = (v_1, \ldots, v_d) \stackrel{\text{def}}{\Leftrightarrow} u_1 \leq v_1 \wedge \cdots \wedge u_d \leq v_d$.

Another well-known instance are the lossy channel systems [4, 7], where for simplicity we assume that the set of configurations is $(\Sigma^*, \leq_*)$ for some finite alphabet $\Sigma = \{\mathtt{a}, \mathtt{b}, \ldots\}$ of messages, and where $\leq_*$ is the *subword ordering* [1] given by

$$u \leq v \stackrel{\text{def}}{\Leftrightarrow} \exists \mathtt{a}_1, \ldots, \mathtt{a}_\ell \in \Sigma : \exists v_0, \ldots, v_\ell \in \Sigma^* : u = \mathtt{a}_1\mathtt{a}_2 \cdots \mathtt{a}_\ell \wedge v = v_0\mathtt{a}_1 v_1 \mathtt{a}_2 \cdots \mathtt{a}_\ell v_\ell \,.$$

Algorithms for the verification of safety properties of WSTSs usually involve reasoning and computing with *upward-closed* and/or *downward-closed* sets of configurations. A set $U \subseteq \mathit{Conf}$ is upward-closed $\stackrel{\text{def}}{\Leftrightarrow} c \in U \wedge c \leq c' \implies c' \in U$, and there is a similar definition

[1] That $(\Sigma^*, \leq_*)$ is a WQO is known as Higman's Lemma.

for downward-closed subsets. These sets are usually infinite (like *Conf* itself) and symbolic representations or data structures are needed in algorithms handling them.

For upward-closed subsets, a well-known representation relies on the existence of *minimal bases*, i.e., the fact that the set of minimal elements of any subset is finite and unique (modulo equivalence). This representation is generic: it works for any WQO. Furthermore, it enjoys several nice algorithmic properties, e.g., testing inclusion between upward-closed subsets reduces to a quadratic number of comparisons between individual configurations, and the union of upward-closed sets is very easy to compute. In the case of $(\mathbb{N}^d, \leq_\times)$ or $(\Sigma^*, \leq_*)$, algorithms for computing intersections reduce to easy computations of least upper bounds between elements.

For downward-closed subsets, one cannot rely on a mirror notion of maximal elements and this makes symbolic computations harder to envision. The question of finding a generic approach for computing with downward-closed sets was first raised in [14].

In the case of $(\mathbb{N}^d, \leq_\times)$, a symbolic technique was popularized by Karp and Miller with their classic algorithm for coverability in VAS [19]. They define $\mathbb{N}_\omega = \mathbb{N} \cup \{\omega\}$ —where the set of natural numbers is completed with a new infinite element ω that is larger than any finite number— and consider d-tuples over $\mathbb{N}_\omega$. It turns out that this is exactly what we need to represent downward-closed subsets of $\mathbb{N}^d$. For $\sigma = (s_1, \ldots, s_d) \in \mathbb{N}_\omega^d$, we let $\downarrow\sigma = \{c \in \mathbb{N}^d \mid c \leq_\times \sigma\}$ denote the downward-closed subset of $\mathbb{N}^d$ generated by σ and call it an *ideal* of $(\mathbb{N}^d, \leq_\times)$. Then downward-closed subsets of $\mathbb{N}^d$ can be denoted in a unique way by finite unions of incomparable ideals. Computing unions and intersections with such representations, and deciding inclusion between them, use simple algorithms that are uncannily similar to what happened with the finite-basis representation for upward-closed subsets.

If we now consider $(\Sigma^*, \leq_*)$, a very elegant representation for downward-closed subsets was proposed by Abdulla et al. in [3]. They show that any downward-closed $D \subseteq \Sigma^*$ can be represented by a *simple regular expression* (a SRE), obtained as a union of concatenations of *atoms* of the form Γ^* for a subalphabet $\Gamma \subseteq \Sigma$, or of the form $\mathtt{a} + \epsilon$ for some letter $\mathtt{a} \in \Sigma$. Furthermore, these SREs support simple and efficient algorithms for unions, intersections, comparisons, and more.

It turns out that concatenations of atoms denote exactly the ideals of $(\Sigma^*, \leq_*)$. Formally, an ideal of a WQO $(X, \leq)$ is a nonempty downward-closed directed subset $D \subseteq X$. Being directed means that for all $x, y \in D$ there is some $z \in D$ with $x \leq z \wedge y \leq z$. Given any WQO $(X, \leq)$, the downward-closed subsets of X can be written as unions of finitely many pairwise incomparable ideals, and this decomposition is unique. This property explains the nice algorithmic properties we observed with $\mathbb{N}_\omega^d$ and the SREs over Σ, and it generalizes to any WQO where we can provide effective characterizations for the ideals.

In the second part of the talk, we show how such effective characterizations exist for most of the WQOs one encounters in practice. This is done by considering the most common ways of constructing new WQOs from previous ones (sequence extension, powerset, but also substructures and quotients) and characterizing the ideals of the new WQOs in terms of the ideals of the earlier ones.

We illustrate these constructions with lesser known WSTSs like priority channel systems and higher-order channel systems [17], or data nets [20] and timed-arc Petri nets [5].

Acknowledgments. This talk is based on joint work with J. Goubault-Larrecq, S. Halfon, P. Karandikar, K. Narayan Kumar, S. Schmitz, and it has further profited from many discussions with A. Finkel, J. Leroux and G. Sutre. Most of the presented definitions and

results can be found in recent works like [6, 9, 10, 11, 16, 21, 22]. A full version of these notes is in preparation [15].
